Kyphoscoliosis may be a manifestation of an isolated vertebral defect or may be associated with **myelomeningocele** or with complex syndromes, such as **VACTERL, limb–body wall complex, neurofibromatosis, arthrogryposis, diastrophic dysplasia,** and other skeletal dysplasias.

HAND AND FOOT MALFORMATIONS

A complete digit evaluation can be performed by 12 to 13 weeks' gestation.[105] The fetus typically maintains open hands with digit extension in the first half of gestation, whereas in the second half of gestation the fetus may maintain hand closure for relatively prolonged periods, up to 30 minutes, limiting detailed evaluation. The incidence of finger abnormalities is approximately 1 in 1000 fetuses, of which 60% will have either an associated malformation sequence or karyotypic malformation. The optimal time for evaluation of the hands and feet is during the second trimester.[14,106-108]

Transient findings represent a potential pitfall in the analysis of the distal extremities. During the second half of gestation, the fetus may appear to have **pseudosyndactyly** by maintaining a closed hand for prolonged periods. The diagnosis of an isolated clubfoot can be risky because the fetus can hold the foot in a position to suggest the diagnosis in the absence of a structural defect. An apparent clubfoot may be secondary to positioning against the maternal uterine wall or in the setting of oligohydramnios, which subsequently resolves with a change in fetal position or amniotic fluid volume.

Aneuploidy is associated with an increased risk of hand and foot anomalies, including persistent **clenched hand, overlapping digits, clinodactyly, polydactyly, syndactyly, simian creases, talipes equinovarus, rocker-bottom foot,** and **sandal toes** (Fig. 40.36).

Persistent clenched hand with overlapping of digits occurs in more than 50% of trisomy 18 fetuses and is generally bilateral. This characteristic hand appearance is highly suggestive of trisomy 18 but can also occur in other conditions, such as **fetal akinesia syndrome** and **triploidy.**

Clinodactyly is the permanent incurvature of a finger. Clinodactyly, caused by asymmetrical hypoplasia of the middle phalanx (medial shorter than lateral aspect), most often involves the fifth finger and is associated with trisomies 13, 15, 18, and 21 (Fig. 40.36G). Clinodactyly occurs in 60% of fetuses with trisomy 21; however, up to 18% of normal fetuses may have a

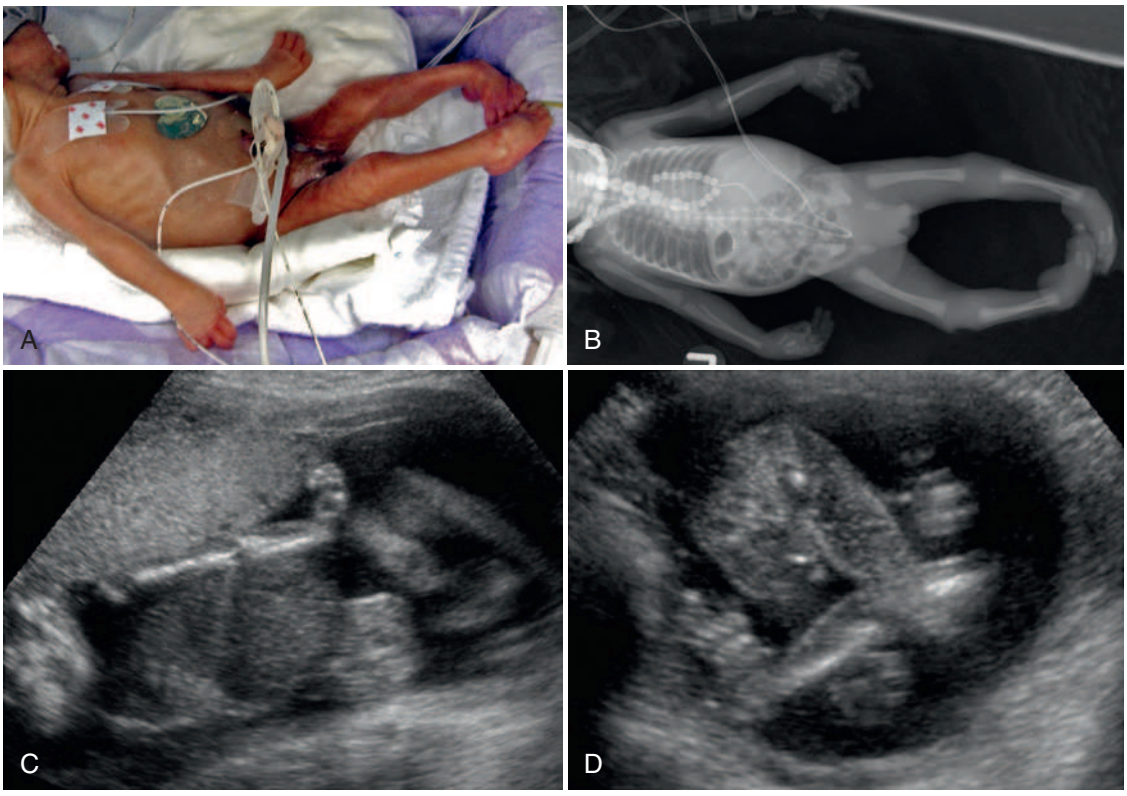

FIG. 40.34 Arthrogryposis Multiplex Congenita. Decreased muscle bulk is replaced by a mixture of fat and adipose tissue, resulting in multiple congenital joint contractures, including fixed internal rotation of shoulders, hyperextension of elbows, flexion of wrists, and talipes equinovarus (clubfoot). Note that severity of deformity increases distally. The knees and hips at birth were demonstrated to be nonrigid contractures amenable to conservative postural therapy. **(A)** Photograph demonstrates fixed contractures of the elbows, wrists, digits, and ankles. **(B)** Radiograph demonstrates similar contractures. **(C)** Ultrasound of upper extremity demonstrates fixed extension of the elbow and fixed flexion of the wrist and digits with talipomanus. **(D)** "Buddha position" with flexed hips, knees, and ankles and clubfoot distally.

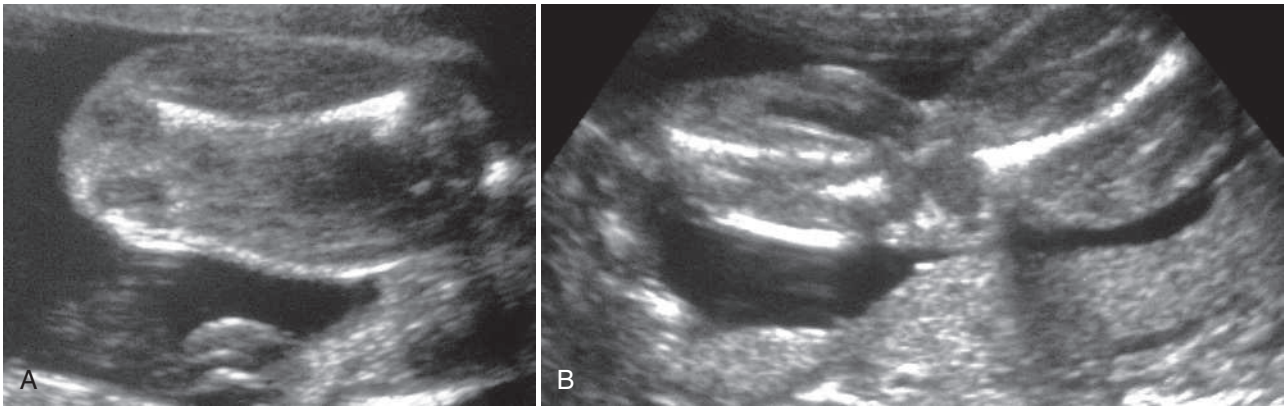

FIG. 40.35 Hereditary Lymphedema at 21 Weeks. (A) Femur surrounded by marked thickening of the subcutaneous tissues. **(B)** Lower extremity with marked thickening of subcutaneous tissues.

mild degree of clinodactyly.[106] **Camptodactyly** is the permanent flexion of a finger caused by flexion contracture of an interphalangeal joint.

Polydactyly is the presence of extra digits on the foot or hand. Most cases are isolated, but extra digits can be associated with syndromes and chromosomal abnormalities. Polydactyly may be diagnosed toward the end of the first trimester. The extra digit may consist of a small, soft tissue projection or a complete digit. **Postaxial polydactyly** (ulnar or fibular) is more common and is found in conditions such as **Ellis–van Creveld syndrome, asphyxiating thoracic dystrophy, short-rib polydactyly syndrome,** and **trisomy 13.**

Polydactyly may be an isolated finding and can be hereditary and familial. Because this form is associated with a good prognosis, it is important to review the pertinent family history. **Preaxial** (radial or tibial) **polydactyly** is found in familial conditions,

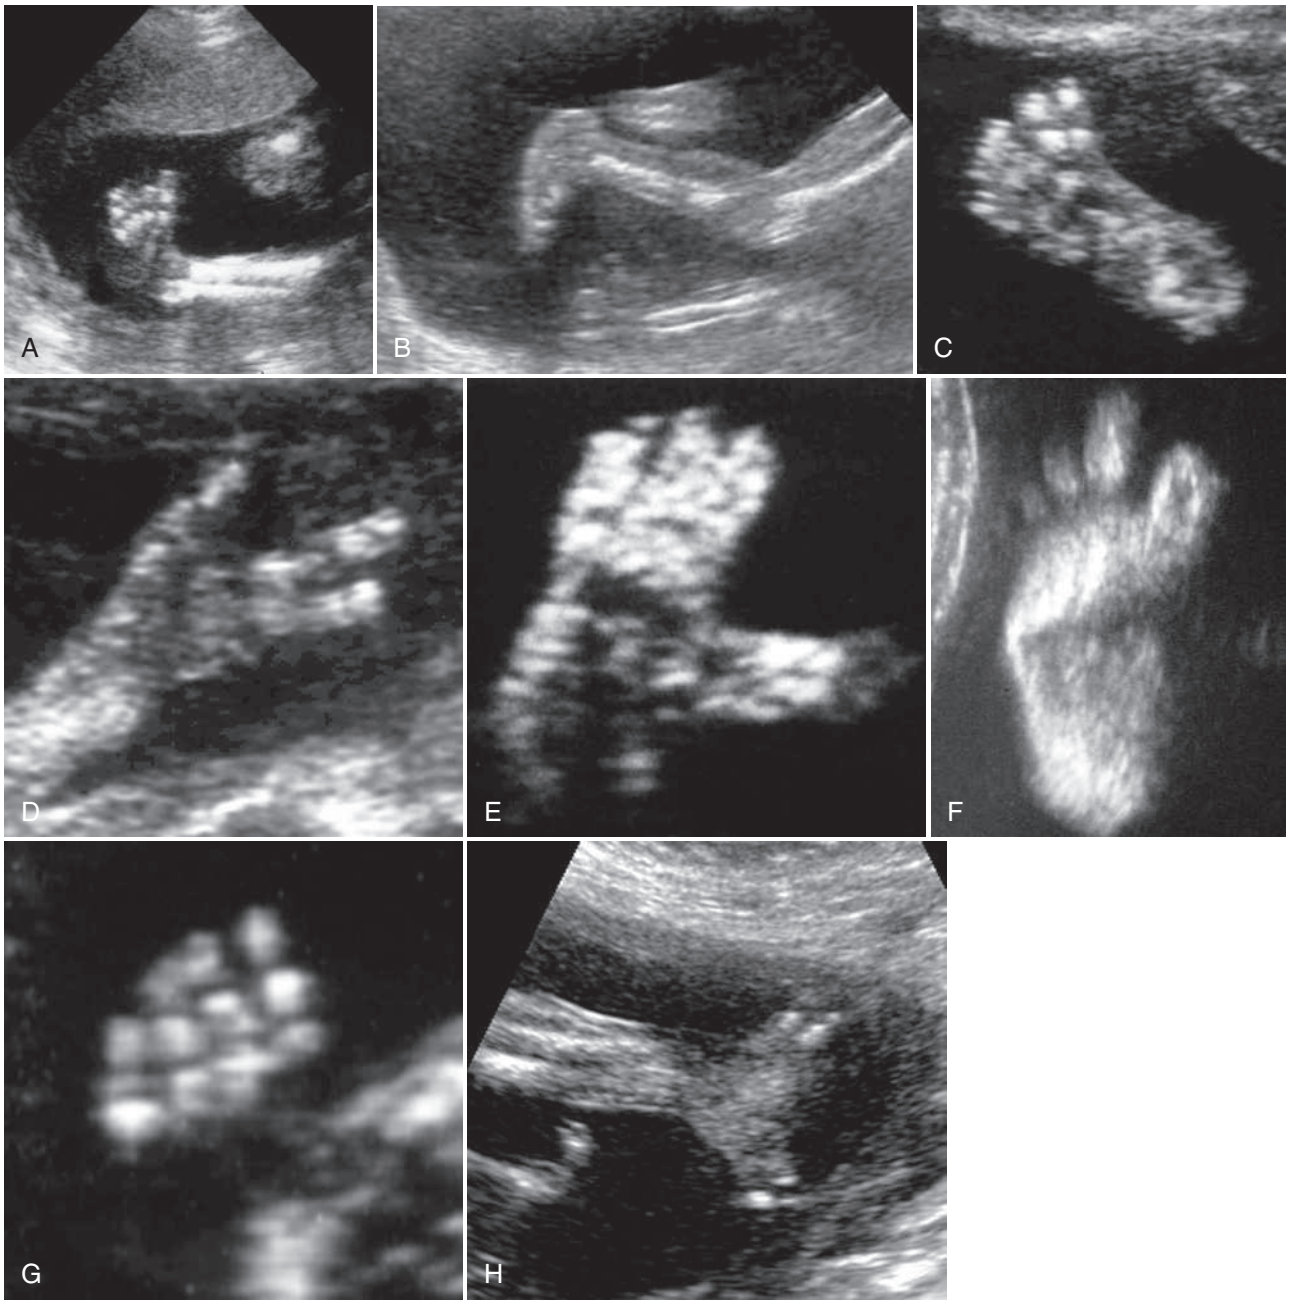

FIG. 40.36 Collage of Hand and Foot Anomalies. (A) Talipes equinovarus (clubfoot). Inverted plantar flexion with medial deviation of the foot results in visualization of the long axis of the foot (metatarsals) and lower leg in the same plane. Note the rounded angle between the foot and lower leg. **(B) Rocker-bottom foot.** Convex sole contour and rounded soft tissue protrusion posterior to the calf soft tissues. **(C) Toe polydactyly,** six digits. **(D) Oligodactyly,** three digits. **(E) Syndactyly.** Soft tissue fusion of the first and second digits. **(F) Sandal toes** in a 37-week fetus with Nager syndrome demonstrates an exaggerated gap between the first and second toes and a plantar skin furrow. **(G) Clinodactyly.** Hypoplastic middle phalanx of fifth digit. **(H) Ectrodactyly,** or split hand or foot deformity. (**C** and **E** courtesy of Ants Toi, MD, University of Toronto; **D** and **H** courtesy of Shia Salem, MD, University of Toronto.)

such as **Fanconi syndrome, Holt-Oram syndrome, acrocephalosyndactyly,** and conditions associated with **triphalangeal thumb.**[73] Central polydactyly can also occur.

Syndactyly refers to soft tissue and/or osseous fusion of digits (Fig. 40.36E). Syndactyly of the third and fourth fingers in association with IUGR in the second trimester suggests the diagnosis of **triploidy.**

An abducted, low-set thumb, or **hitchhiker thumb** (see Fig. 40.25), is associated with **diastrophic dwarfism.** An adducted thumb may be associated with **aqueductal stenosis.**

Ectrodactyly, or the split hand or foot **"lobster claw"** deformity, is a deficiency of the central digits resulting in a cleft. It can occur as an isolated abnormality or in association with other findings, such as **cleft lip and/or palate,** as in

ectrodactyly–ectodermal dysplasia clefting syndrome, Cornelia de Lange syndrome, and **limb-mammary syndrome**[109] (Fig. 40.36H). Many isolated cases are the result of a new dominant mutation or are inherited from parents with minimal manifestations. Thus a careful examination of the parents is needed before counseling low recurrence risk.[109,110]

Talipomanus, or **clubhand,** can be radial or ulnar. Radial clubhand is more common and is generally associated with the syndromes or karyotype abnormalities previously described with radial ray variants. Trisomies 18 and 21, long arm deletion of chromosome 13, and ring formation of chromosome 4 can be associated with radial clubhand. Other conditions associated with talipomanus include the **VACTERL association, Goldenhar syndrome,** and **Klippel-Feil** syndrome. Another abnormality includes a sporadic group of syndromes associated with craniofacial abnormalities, most often cleft lip and palate. Ulnar clubhand, associated with ulnar ray defects, is uncommon and may be an isolated finding.

Talipes equinovarus, or **clubfoot,** occurs in 0.1% to 0.2% of the population. The recurrence risk after the birth of one child with isolated clubfoot is 2% to 3%, and if one of the parents is affected, the recurrence risk is 3% to 4%. It is more common in males than females, and the prenatal diagnosis is based on the recognition of an inverted and plantar-flexed foot in which the metatarsal long axis is in the same plane as the tibia and fibula, in association with a rounded angle of junction between the foot and the lower leg (Fig. 40.37, Video 40.2). The majority are isolated malformations; however, MRI and fetal karyotyping should be considered when clubfoot is found in association with other structural abnormalities.[111-116] The outcome of antenatally detected talipes is primarily dependent on whether it is isolated or associated with other anomalies. Early amniocentesis (<14 weeks) is associated with an increased risk of clubfoot.[117] Hindfoot equinus (plantar flexion), hindfoot varus (inward rotation), forefoot adduction, and variable forefoot cavus (plantar flexion) can also occur.

Congenital talipes equinovarus represents a spectrum ranging from "postural" talipes or nonrigid deformity requiring little active management, to a severe, rigid deformity requiring extensive surgery. The foot is fixed in adduction, supination, and varus position, thus appearing to be turned inward. Tillett et al.[115] found that up to 26% of cases of clubfoot required no active postnatal management, presumably in the postural group. It is difficult to determine if this group is positional or a false-positive diagnosis. False-positive results are most often found in the group with an isolated diagnosis of talipes equinovarus made in late pregnancy, although they can occur at the 18- to 22-week evaluation, at a reported rate of 2.3%.[118] The normal foot may achieve extreme dorsiflexion or plantar flexion, and caution is advised when making the initial diagnosis of isolated clubfoot in the third trimester.[114,116] In the setting of isolated clubfoot (unilateral or bilateral), the likelihood of requiring surgery is approximately 40%.[118]

Rocker-bottom foot is the result of a vertical position of the talus and equinus or vertical position of the calcaneus secondary to a short Achilles tendon (Fig. 40.37B). The tarsal bones are dislocated dorsally, so there is a convex plantar surface with posterior bulging of the calcaneus. It carries a high risk for fetal chromosomal abnormalities such as **trisomies 18 and 13** when associated with other abnormalities, as well as for other syndromes such as **fetal akinesia sequence.**

Brachydactyly is the abnormal shortening of the digits. There is relative sparing of foot length in many skeletal dysplasias, but the hands may be affected. **Achondroplasia** has a characteristic configuration with the digits ending at the same level and unable to approximate the second, third, or fourth digits, leading to the appearance of the "trident hand" (Fig. 40.38).

Sandal toes, or an exaggerated gap between the first and second digits, is often visualized in the normal fetus but has a higher prevalence in trisomy 21 fetuses[14] (see Fig. 40.36F). An elevated first digit or toe may cause a false or transient abnormality that mimics sandal toes.

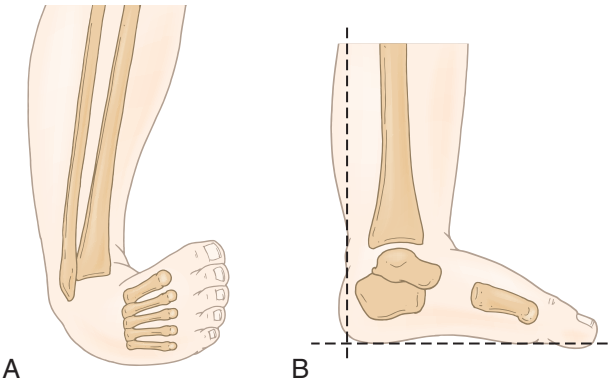

FIG. 40.37 Clubfoot. (A) Inverted, plantar-flexed, and medially deviated foot results in visualization of the long axis of the foot and tibia/fibula in the same plane. Note the rounded angle of junction between the lower leg and foot. **(B) Normal foot.** Note the normal relationship of tibia and fibula to the metatarsals and the normal squared angle of the lower leg to the foot. (With permission from Jeanty P, Romero R, d'Alton M, et al. In utero sonographic detection of hand and foot deformities. J Ultrasound Med. 1985;4[11]:595-601.[108])

SKELETAL FINDINGS ASSOCIATED WITH ANEUPLOIDY

When an abnormality in the musculoskeletal system is detected during routine ultrasound examination, a systematic search is performed to detect other defects that may lead to the diagnosis of a specific genetic or chromosomal defect.[119,120] During the second trimester, an expected-to-measured FL ratio below 0.9, based on BPD, should prompt a detailed examination to assess for other possible features of aneuploidy. However, in the third trimester, a mildly shortened femur is generally associated with asymmetrical IUGR or a constitutional small fetus rather than with aneuploidy. A femur-to-foot ratio greater than 0.9 suggests IUGR rather than a bone dysplasia, whereas a femur-to-foot ratio of less than 0.9 suggests a skeletal dysplasia.[14,121] In general, chromosomal anomalies are associated with a symmetrical form of IUGR versus asymmetrical IUGR often associated with

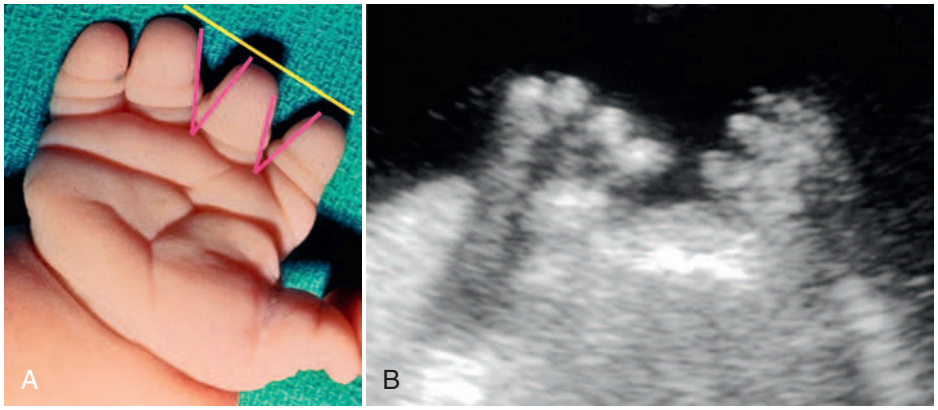

FIG. 40.38 Achondroplasia and the "Trident Hand" Configuration. (A) Homozygous achondroplasia with trident configuration with the digits ending at the same level *(yellow line),* with inability to approximate the second, third, and fourth digits *(pink lines).* **(B)** Homozygous achondroplasia with ultrasound appearance of severe brachydactyly with trident configuration.

uteroplacental insufficiency. Triploidy is an exception, occurring with a severe asymmetrical form of IUGR.

Trisomy 21 (Down syndrome) is the most common chromosome abnormality in newborns, with an incidence of 1 in 600 to 1 in 800. About 95% of such cases result from an additional chromosome 21, 3% result from translocation, and 2% are mosaic. Most cases are sporadic and there is an association with advanced maternal age. Characteristic skeletal findings include mild shortening of the femur and humerus, clinodactyly of the fifth finger, sandal gap toes, flat nasal bridge, frontal bossing, and brachycephaly.

Trisomy 21: Musculoskeletal Features

Mild shortening of femur and humerus
Clinodactyly of fifth finger
Sandal toes
Flat nasal bridge
Frontal bossing
Brachycephaly

Trisomy 18 (Edwards syndrome) is a sporadic condition, in most cases associated with advanced maternal age and with an incidence of 1 in 5000 live births. The classic appearance is a persistently clenched hand with overlapping of the second and third digits and the fourth and fifth digits, often in association with clinodactyly of the fifth digit. The findings are usually bilateral and occur in more than 50% of trisomy 18 cases. Other musculoskeletal findings include radial ray defect in 10% to 50%, syndactyly of the second and third toes, single palmar creases, clubfoot or rocker-bottom foot, incomplete clavicle ossification, and vertebral and rib anomalies. The prognosis is poor; 90% of neonates succumb in the first year of life, and all survivors have profound mental retardation.

Trisomy 18: Musculoskeletal Features

Persistent clenched hand with overlapping digits
Radial ray aplasia variants
Syndactyly
Talipes equinovarus (clubfoot)
Rocker-bottom foot
Vertebral and rib anomalies

Trisomy 13 (Patau syndrome) is in most cases a sporadic disorder with an incidence of 1 in 10,000 live births. The musculoskeletal anomalies include postaxial polydactyly of hands and feet, possible clenched hand (with or without overlapping digits), clinodactyly, and possibly associated hypoplastic ribs and pelvic bones.

Trisomy 13: Musculoskeletal Features

Polydactyly
Persistent clenched hand with or without overlapping digits
Clinodactyly
Hypoplastic ribs and pelvic bones
Microcephaly
Hypotelorism
Facial clefts

Triploidy (69,XXX, 69,XXY, or 69,XXY) occurs in 18% of all early miscarriages, but the incidence is only 1 in 2500 births. In 60% of cases, triploidy results from dispermy, and in 40%, from diploid sperm or diploid egg. Early severe asymmetrical IUGR and oligohydramnios suggest the diagnosis. The placenta may be either small or enlarged and hydropic. Associated musculoskeletal findings include **syndactyly** of the third and fourth fingers, **simian crease, talipes equinovarus,** and **hitchhiker toe** deformity.

Other findings may include **micrognathia, ventriculomegaly, myelomeningocele,** and cardiac abnormalities.

SUMMARY

The finding of a skeletal dysplasia and the subsequent communication of the findings are challenging tasks requiring empathy and support. In some cases, it may not be possible to establish a specific diagnosis and counseling will have to be based on prognosis estimated from ultrasound findings. The implications should be discussed in simple terms permitting the parents to make an informed decision about the management of the pregnancy, the delivery, and postnatal care. This discussion typically involves a multidisciplinary team who provide the most up-to-date information to the parents about options, possible outcomes, and implications for a future pregnancy. The team will usually involve an imaging specialist, maternal-fetal medicine experts, medical geneticists, and the neonatology team. Additional consultation with orthopedic surgeons, palliative treatment groups, social workers, and supportive organizations may be helpful for the family. The mode of delivery should be discussed in advance, especially in conditions associated with fetal macrocrania, in which vaginal delivery at term may not be possible. After delivery or pregnancy termination, the diagnosis should be confirmed by radiographic, photographic, and histomorphic analysis. Cell culture and DNA should be banked and used for further molecular investigation. The parents should be seen at a later time to discuss the results and the implications these results may have on their future reproductive plans.

Acknowledgments

Special thanks to all the staff at Medical Imaging and Maternal Fetal Medicine Departments at Sunnybrook Health Science Center and the Mount Sinai Hospital in Toronto who have provided many wonderful images and generously shared their knowledge and work.

CHAPTER 41

Fetal Hydrops

Deborah Levine

SUMMARY OF KEY POINTS

- Hydrops is defined as an abnormal accumulation of interstitial fluid in at least two body cavities (pleural, peritoneal, or pericardial) or one body cavity in association with anasarca (generalized massive edema). Placentomegaly and polyhydramnios are common findings in cases of hydrops but are not needed for the diagnosis.
- Hydrops represents a terminal stage for many conditions, the vast majority of which are fetal in origin.
- The onset of hydrops signifies fetal decompensation.
- Immune causes can be successfully treated in utero, as can an increasing number of nonimmune causes.
- Middle cerebral artery Doppler ultrasound can be used to assess fetuses at risk for anemia.
- A team approach using obstetric imagers, maternal fetal medicine specialists, neonatologists, and geneticists can help to decide which cases are suitable for therapeutic intervention.

CONCLUSION

Hydrops fetalis is an end-stage process for a number of different diseases. It is defined as an abnormal accumulation of interstitial fluid in at least two body cavities (pleural, peritoneal, or pericardial) or one body cavity in association with anasarca (generalized massive edema). Placentomegaly and polyhydramnios are common findings in cases of hydrops but are not needed for the diagnosis.

Lymphangiectasia, which is abnormal dilatation of the lymphatic vessels, should not be mistaken for hydrops. In the first trimester, general body wall lymphangiectasia can have a "space suit" appearance (Fig. 41.1) due to the fluid in the skin and/or subcutaneous tissues. The finding has a poor prognosis, with 26 in 30 prospectively identified cases in the first trimester having abnormal karyotype.[1] However, because there is not typically fluid in other body cavities, this is not hydrops.

Hydrops is the late stage of many processes that lead to redistribution of body fluids among the intravascular and interstitial compartments. This imbalance of fluid can have many causes (Table 41.1). There are at more than 150 different causes of fetal hydrops. Many of the causes and associations with hydrops overlap. The basic etiology of hydrops is an imbalance of interstitial fluid, which may be caused by myocardial failure, high-output cardiac failure, decreased colloid oncotic plasma pressure (anemia), increased capillary permeability, and/or obstruction of venous and lymphatic flow.

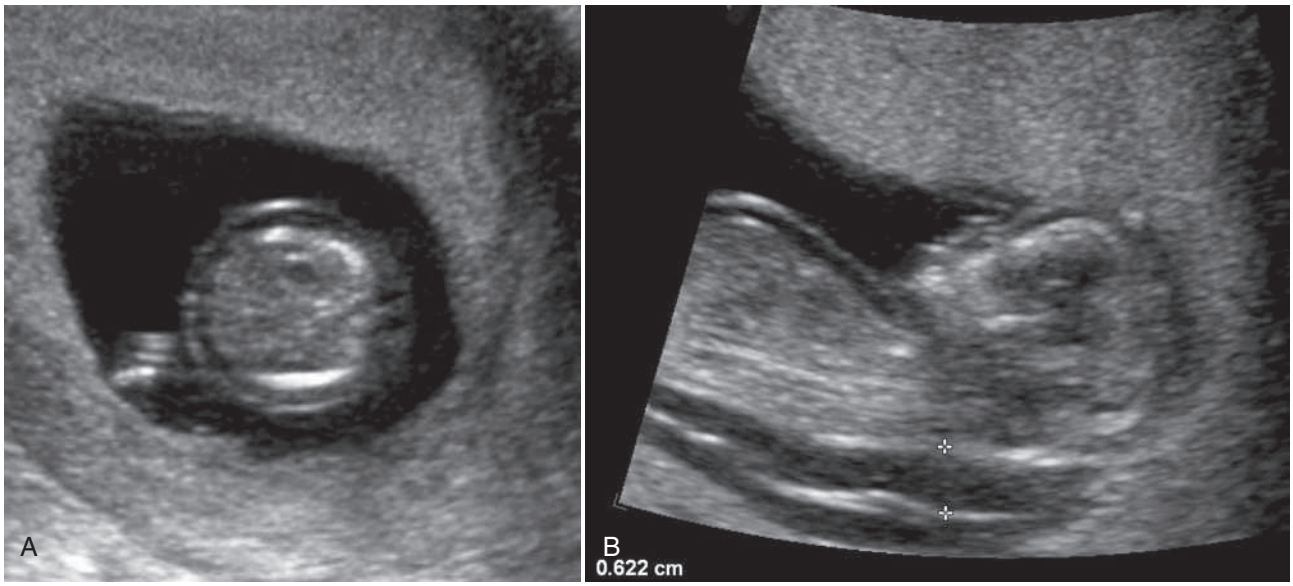

FIG. 41.1 Lymphangiectasia in Fetus With Abnormal Nuchal Translucency. (A) Transverse abdomen shows edema of the skin, but no ascites. **(B)** Sagittal image shows abnormal nuchal translucency of 6 mm *(calipers)* and skin thickening that extends anteriorly around the torso and fetal skull, a "space suit" appearance.

Hydrops can be **immune** or **nonimmune** in origin. Immune hydrops is defined by a circulating antibody against red blood cells (RBCs) in the mother, whereas in nonimmune hydrops no such antibody is found. Before the widespread introduction of rhesus (Rh) anti-D immune globulin in the 1970s, most cases of hydrops were immune,[2,3] whereas currently, about 85% are nonimmune.[4] This chapter reviews the findings of fluid in different body cavities and the causes, diagnosis, and treatment of hydrops. Recent series have reported fetal hydrops mortality rates ranging from 58% to 61%.[4-7] This improved survival compared to older series is thought to be due to fetal medical and interventional techniques that allow for reversal of hydrops in nonaneuploid cases.[4,5] Although hydrops is a relatively common indication for tertiary-level fetal evaluation, because of the many causes, each specific etiology is relatively rare.

SONOGRAPHIC FEATURES

It is important for clinicians to understand the sonographic appearance of fluid in the different interstitial compartments of the fetus. These fluid collections can occur in isolation, as in isolated **ascites** or isolated **pleural** or **pericardial** effusion. When one collection is seen, it is important to assess for a second collection to make the diagnosis of hydrops; the fluid collection must be in at least two body cavities to qualify as hydrops. Other findings in hydrops can include **subcutaneous edema, polyhydramnios,** and **placentomegaly.**

Ascites

Fetal ascites is diagnosed when fluid is seen between **bowel loops,** along the abdominal flanks, around the liver, and outlining the umbilical vessels (Fig. 41.2). In normal fetuses, a small hypoechoic band (<2 mm in thickness) extending along the anterior and lateral fetal abdomen may be present. This "pseudoascites" represents normal abdominal wall muscles or abdominal wall fat and should not be mistaken for an abnormal fluid collection[8] (Fig. 41.3). The distinction between the pseudoascites appearance and true ascites can be made when the transducer angle is changed and the appearance resolves. Pseudoascites does not surround the liver but rather stops at the insertion of the ribs. Note that true ascites will extend around bowel loops (Fig. 41.4, Video 41.1), whereas pseudoascites is always a subcutaneous finding.

Isolated ascites can be an early sign of hydrops. If truly isolated, it can be caused by a urinary or gastrointestinal obstruction. Isolated fetal ascites has a more favorable prognosis than hydrops but requires follow-up to ensure that hydrops does not ensue.

Small collections of ascitic fluid may outline abdominal viscera, including bowel loops or bladder, and may cause an apparent increase in their echogenicity. Larger accumulations outline the liver and spleen (see Fig. 41.2A and D). The umbilical vessels will be seen as parallel echogenic lines traversing the fluid space (see Fig. 41.2C). Bowel loops may be free floating or, when meconium peritonitis is present, may appear as a matted, echogenic posterior mass. In male fetuses, ascitic fluid may track through the patent processus vaginalis into the scrotum, leading to **hydroceles** (Fig. 41.5). Chronic chest compression from massive ascites may result in **pulmonary hypoplasia.**

Pleural Effusions

Pleural effusions typically occur later in hydrops than does ascites. If isolated and small, pleural effusions tend to have a benign course (Fig. 41.6A, Video 41.2). A small effusion is seen as a thin, echolucent rim surrounding lung tissue and may also outline mediastinal structures. Small pleural effusions do not shift the mediastinum. Pleural effusions associated with hydrops may be **unilateral** or **bilateral,** often beginning as unilateral collections that progress to bilateral involvement (Fig. 41.6D). If mediastinal shift is visualized in association with a small pleural effusion, a

TABLE 41.1 Nonimmune Hydrops: Common Causes and Associations[a]

Cause (Percentage of Nonimmune Hydrops)	Mechanism	Examples
Cardiovascular (20%)	Increased central venous pressure	Structural heart disease (hypoplastic left or right heart syndrome, atrioventricular canal) Myocardial or pericardial tumors (rhabdomyoma in tuberous sclerosis) Tachyarrhythmia Bradyarrhythmia (congenital heart block [anti-Rho] or other maternal autoimmune disease)
Monochorionic twins (4%)	Anemia and/or high-output cardiac failure	Twin-to-twin transfusion syndrome (usually the recipient but can occur in the donor), twin anemia polycythemia sequence Acardiac twin (donor)
Lymphatic dysplasia (15%)	Abnormal lymphatic drainage	Congenital lymphatic dysplasia
Neck/chest (2%)	Vena caval obstruction or increased intrathoracic pressure with impaired venous return	Cystic hygroma Congenital high airway obstruction Pleural effusion (chylothorax) Chest mass (congenital pulmonary airway malformation, sequestration, congenital diaphragmatic hernia)
Gastrointestinal (1%)	Obstruction of venous return, gastrointestinal obstruction and infarction with protein loss and decreased colloid osmotic pressure	Portal vein thrombosis Volvulus Obstruction Meconium peritonitis
Urinary tract (1%)	Urinary ascites; nephrotic syndrome with hypoproteinemia	Finnish nephrosis, urinary tract obstruction
Aneuploidy (13%)	Cardiac anomalies, lymphatic dysplasia, anemia, abnormal myelopoiesis	45,XO, trisomy 21, trisomy 18, triploidy
Hematologic (9%[b])	Anemia, high-output cardiac failure; hypoxia (α-thalassemia)	α-Thalassemia (homozygous) Fetomaternal transfusion
Infection (7%)	Anemia, anoxia, endothelial cell damage, increased capillary permeability, myocarditis	Parvovirus, cytomegalovirus, adenovirus, syphilis, toxoplasmosis
Inborn errors of metabolism (1%)	Anemia Hemolysis	Lysosomal storage disease, mucopolysaccharidoses, Gaucher disease, Niemann-Pick disease G6PD deficiency
Other syndromes (5.5%)	Visceromegaly, obstruction of venous return, decreased erythropoiesis, anemia, hypoproteinemia	Noonan syndrome Skeletal dysplasias such as achondroplasia, osteogenesis imperfecta, thanatophoric dysplasia arthrogryposis, congenital myotonic dystrophy
Extrathoracic tumors (1%)	Anemia, high-output cardiac failure, hypoproteinemia	Vascular/lymphatic tumors Teratoma, neuroblastoma, arteriovenous malformation
Maternal		Severe diabetes mellitus, severe anemia, severe hypoproteinemia, thyrotoxicosis Indomethacin use (premature closure of ductus arteriosus)
Placental/cord		Placental or umbilical vein thrombosis, cord knot, chorioangioma
Idiopathic 20%		

[a]Adapted from references 4, 23, 36, 43, 226, and 230-237.
[b]Much higher percentage of hydrops in regions with α-thalassemia, such as Southeast Asia.

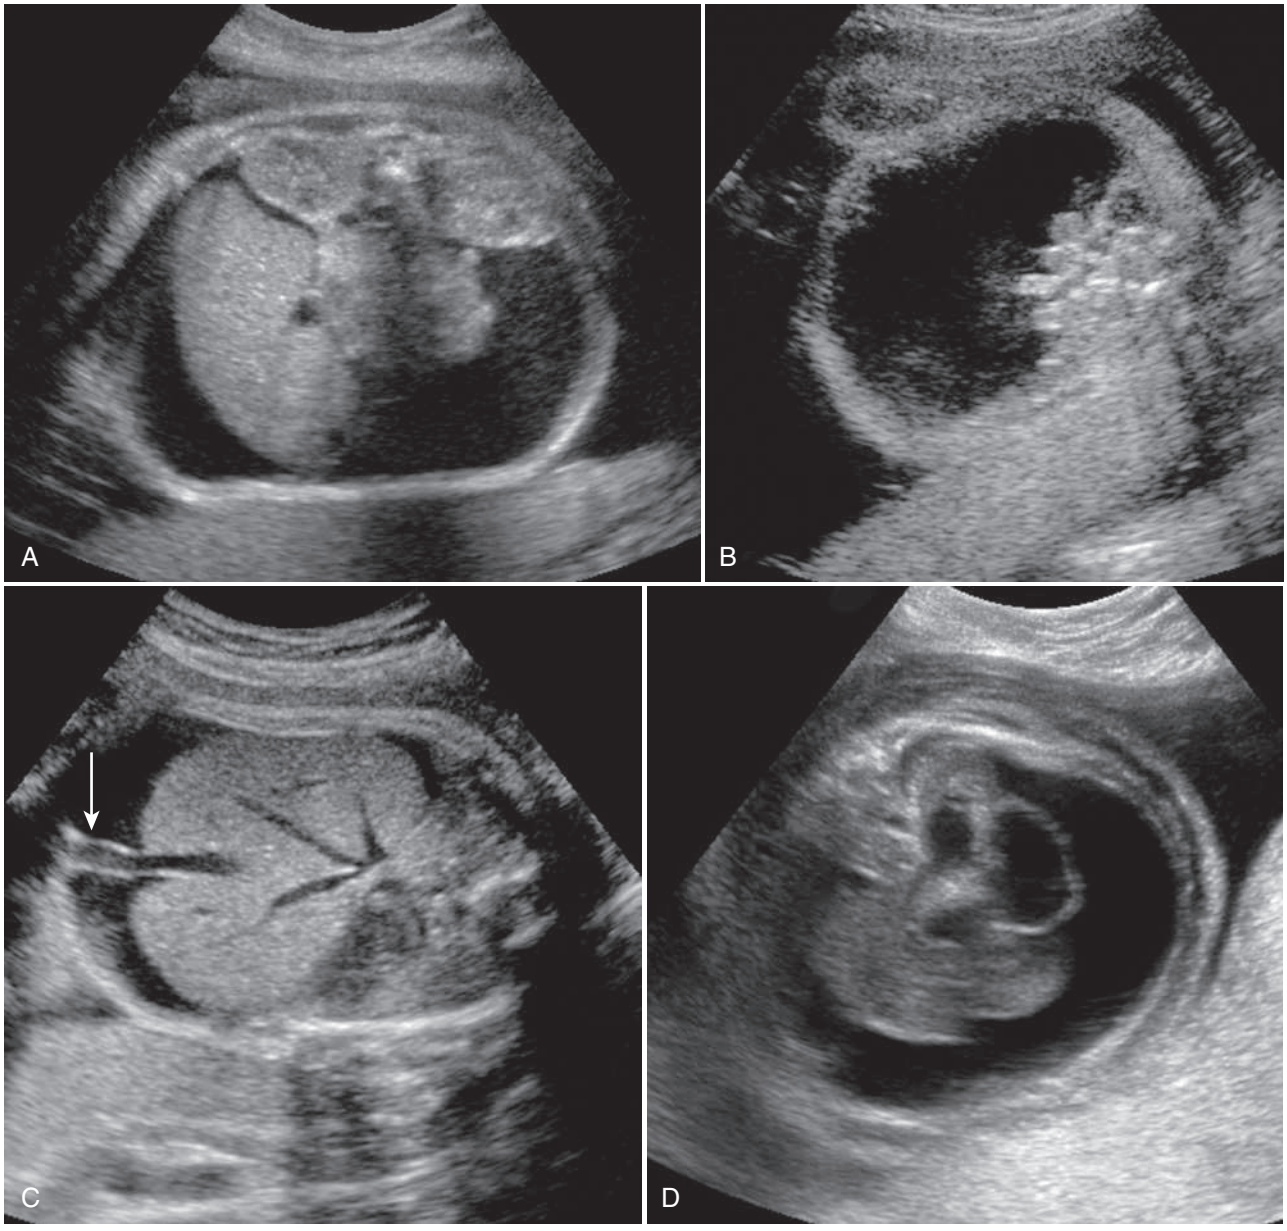

FIG. 41.2 Ascites. (A) Fluid outlines the liver. **(B)** Fluid outlines the bowel, compressing it posteriorly. **(C)** Ascites outlines the umbilical vein *(arrow)*. **(D)** Fluid outlines the liver and stomach. Note associated skin thickening.

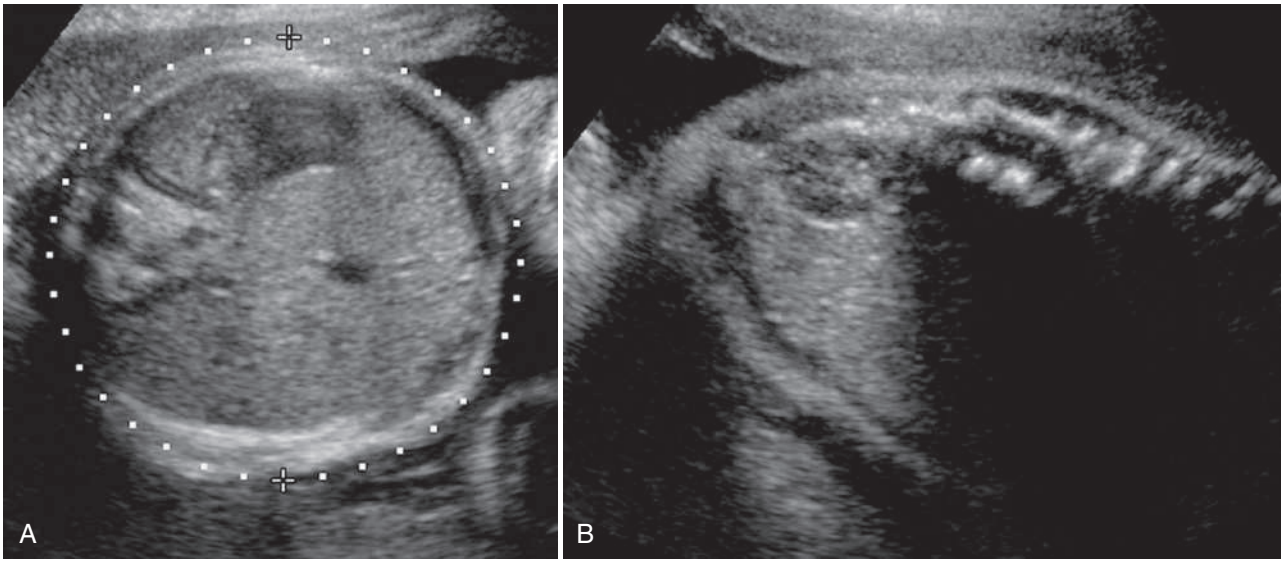

FIG. 41.3 Pseudoascites. (A) Transverse and **(B)** parasagittal ultrasound views show hypoechoic abdominal musculature and fat mimicking ascites. Note that this appearance will change with transducer angle, and the hypoechoic material will always be visualized in the subcutaneous regions, not surrounding bowel.

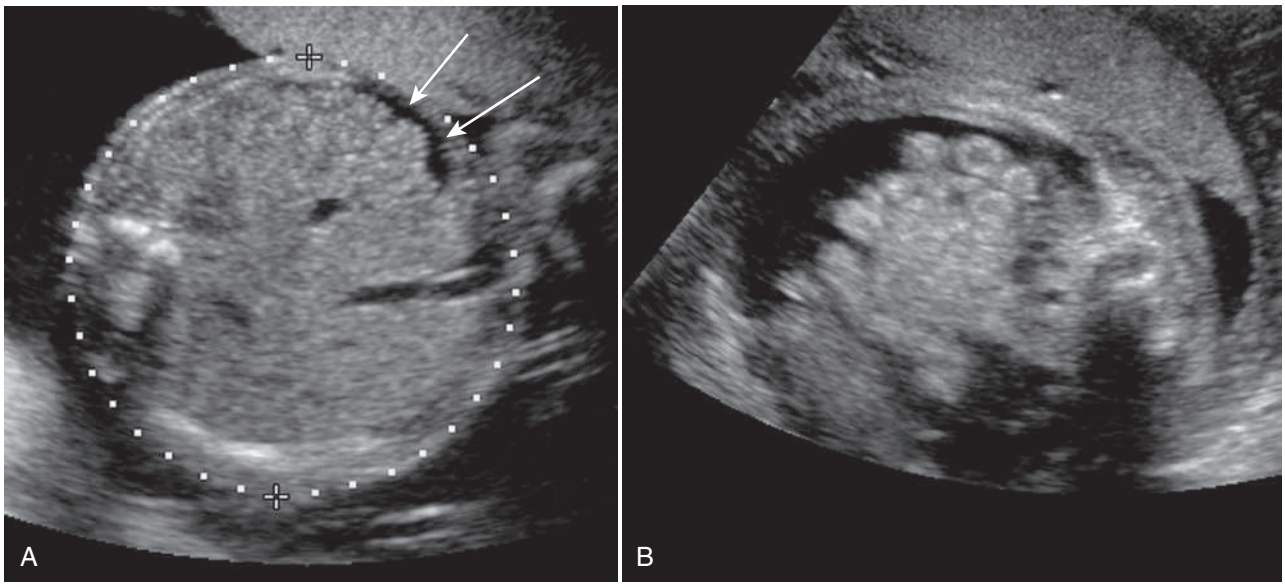

FIG. 41.4 Ascites. (A) Small amount of ascites *(arrows)*. **(B)** Moderate amount of ascites. Note how the ascites surrounds loops of bowel. The bowel can appear echogenic because of through transmission from the fluid. See also Video 41.1.

FIG. 41.5 Hydrocele. Ultrasound of male fetus with hydrops with fluid extending into the scrotum.

chest mass such as a hernia or congenital pulmonary airway malformation (CPAM) should be sought (Fig. 41.7). Larger effusions will lead to flattening and eversion of the hemidiaphragms (Video 41.3) and, when sufficiently large, mediastinal shift. A large, unilateral effusion suggests a local cause, such as **chylothorax.** Although chylothorax begins as a unilateral effusion, it can progress to cause mediastinal shift, obstructing venous return and leading to hydrops. In large, bilateral pleural effusions the lungs appear as free-floating "bat wings" beside the heart (see Fig. 41.6D). When chronic, large effusions can lead to pulmonary hypoplasia. As pleural effusions enlarge, compression or kinking of mediastinal vascular structures causes upper body edema and functional esophageal obstruction, leading to secondary polyhydramnios.

Chylothorax is the most common cause of pleural effusion leading to respiratory distress in the newborn. This is an important diagnosis to suggest when associated with hydrops because drainage can be curative. Drainage of the effusion can lead to reversal of hydrops and can prevent pulmonary hypoplasia. Drainage immediately before delivery can assist in peripartum care. When drained, the fluid has a large number of lymphocytes in clear, yellow fluid. The fluid will not be "milky" until after the infant feeds.

In a recent review of 31 fetuses with primary hydrothorax, 24 had hydrops. Hydropic fetuses were more likely to present with bilateral effusions. Of all fetuses with primary hydrothorax, 21 had fetal interventions. Survival without hydrops was 7/7 (100%), whereas survival with hydrops depended on whether or not the patient had fetal intervention: 12/19 (63%) with intervention and 1/5 (20%) without intervention. Premature delivery was common (44%) among those who had fetal intervention.[9]

Pericardial Effusions

In contrast to pleural effusions that surround the lungs and compress the tissue medially, pericardial effusions are anteromedial fluid collections. Fluid collections of up to 2 mm in thickness are common, and a small amount of pericardial fluid (up to 7 mm, in isolation) can be a normal finding[10] (Fig. 41.8, Video 41.4). A large pericardial effusion compresses the lungs against the posterior chest wall (Fig. 41.9). The heart is visualized as "floating" within the anterior thoracic fluid collection.

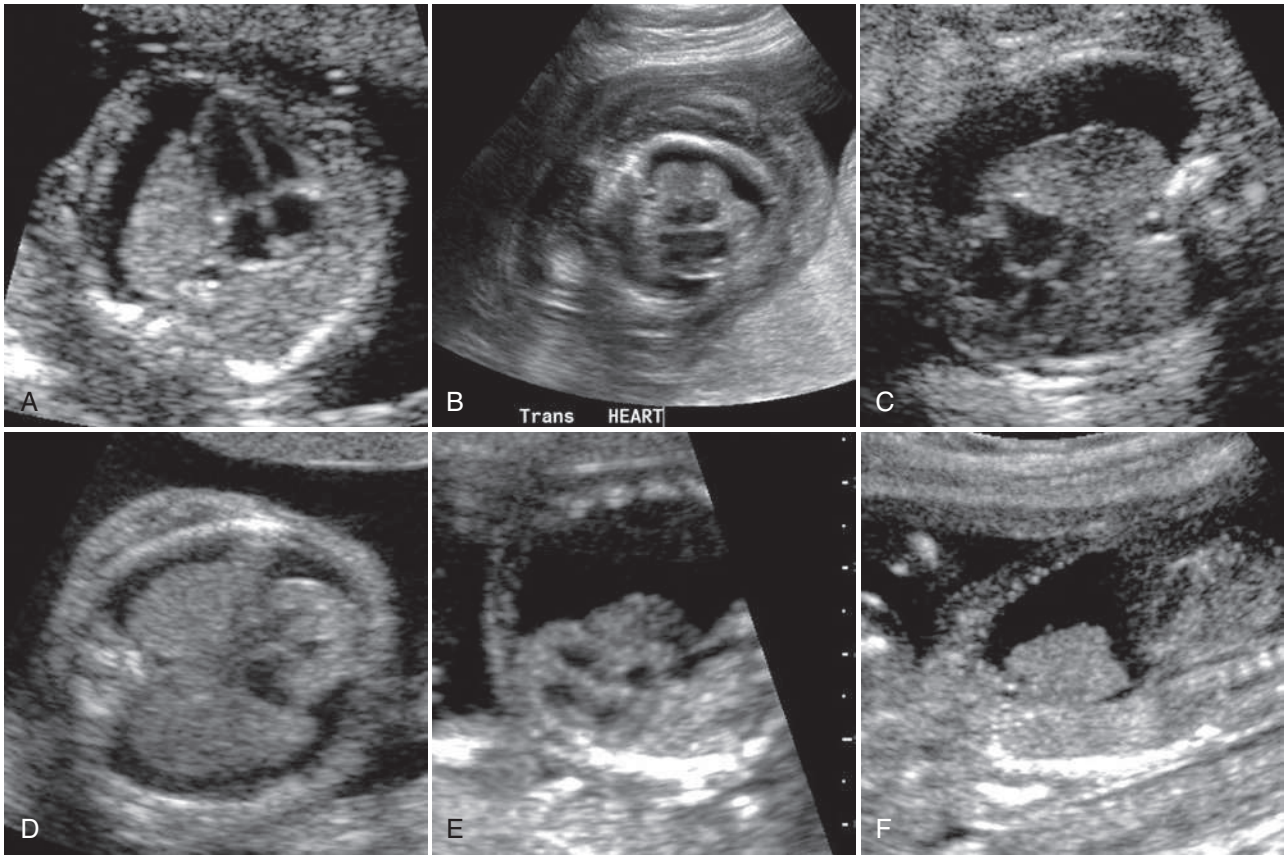

FIG. 41.6 Fetal Pleural Effusions. (A) Unilateral small right pleural effusions. **(B)** Bilateral pleural effusions in fetus with abnormal heart and severe skin thickening. **(C)** Moderate right effusion. Note moderate mediastinal shift to the left. **(D)** Bilateral moderate effusions. Note how the partially compressed lungs appear as free-floating "bat wings." **(E)** Axial and **(F)** oblique coronal views of large right pleural effusion. Note the severe mediastinal shift in **E.** See also Video 41.2.

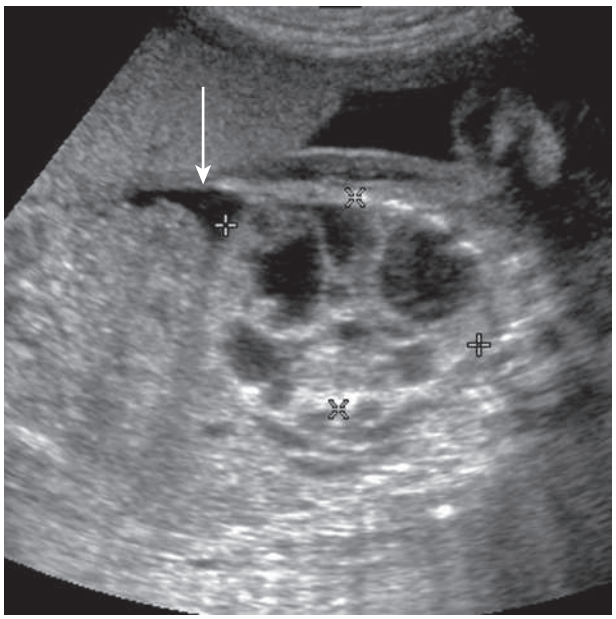

FIG. 41.7 Small Pleural Effusion in Association With Congenital Pulmonary Airway Malformation. Note the large cystic mass *(calipers)* and small pleural effusion *(arrow)*.

Subcutaneous Edema

Subcutaneous edema may be localized or generalized (Fig. 41.10), depending on the cause. A thickness of 5 mm has been suggested as the cutoff value.[11] Edema is most easily seen over the fetal scalp or face, where thickening of skin overlying bone is visualized (Figs. 41.10A and 41.11A). It is important to realize that the **biparietal diameter** and **head circumference** measurements are taken around the skull bone, excluding the skin. Subcutaneous edema may also be seen over the limbs and abdominal wall. Care should be taken not to mistake prominent fat in a macrosomic fetus as anasarca in a hydropic fetus. Subcutaneous edema will increase the abdominal circumference measurement, beyond that which is expected for gestational age (Fig. 41.11B). It is important when measuring the fetus to include the entirety of the skin in the abdominal circumference measurement, because this affects the weight calculation of the fetus. Thus, when biometric assessment of the hydropic fetus is performed, the abdominal circumference measurement is included in the weight calculation, but it should be excluded from the gestational age assessment so that the thickened skin does not falsely elevate estimated fetal age. When generalized subcutaneous edema is present, the appearances may be referred to as "anasarca" (Fig. 41.12, Video 41.5).

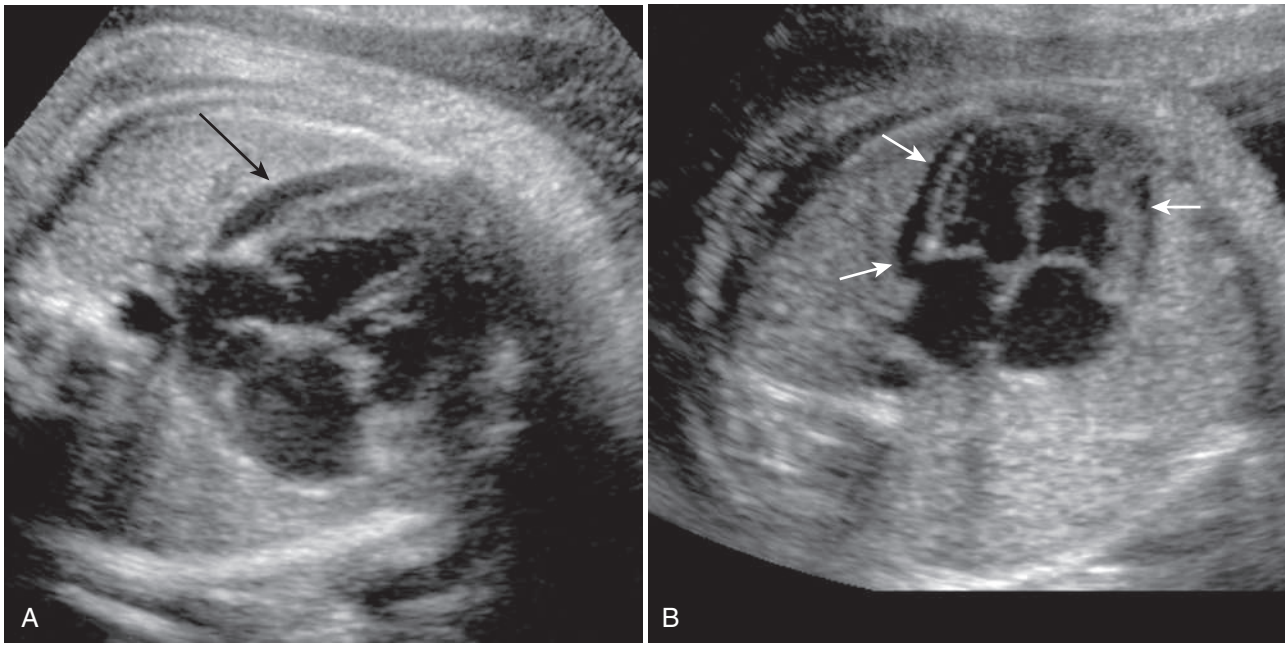

FIG. 41.8 Normal Finding of Small Amount of Pericardial Fluid. (A) and **(B)** Note the small rim of anechoic fluid *(arrows)* in two different fetuses. See also Video 41.4.

FIG. 41.9 Large Pericardial Effusion. Lungs are compressed posteriorly, and the heart appears to be "floating" in the fluid.

Placentomegaly

Placental edema is a variable and usually late sign in hydrops (Fig. 41.13). The sonographic texture of the placenta may be altered, and its appearance may be described as **thickened, echogenic, spongy,** or **ground glass.** Placental dimensions, especially thickness, are increased above the normal of 4 cm thickness in the second trimester and 6 cm in the third trimester.[11-15] When placental edema is secondary to a fetal abnormality, the entire placenta is usually affected. This finding may be used to exclude the very rare primary placental causes of hydrops (e.g., chorioangioma).

Polyhydramnios

The assessment of amniotic fluid is described in Chapters 39 and 42. Polyhydramnios occurs frequently in conjunction with hydrops (Fig. 41.14, see Video 41.1). A single amniotic fluid pocket of 8 cm or more, regardless of gestational age, is a useful threshold for polyhydramnios. Polyhydramnios increases the risk of prematurity, which adds to the morbidity associated with hydrops.

ETIOLOGY

Before the availability of Rho (D) immune globulin (RhoGAM), immune hydrops represented more than 80% of all cases of hydrops. Now, **nonimmune hydrops** represents more than 85% of cases. The **distribution, timing,** and **size** of fluid collections and edema as detected by ultrasound provide clues as to the etiology of hydrops. For example, in **immune hydrops,** ascites appears first, with subcutaneous edema appearing only with more advanced anemia. Intrathoracic collections generally do not occur or occur late in the process.

Generally, pleural and pericardial effusions appear earlier and more prominently with thoracic pathologies, whereas ascites appears earlier and predominates with anemia and primary abdominal pathologies. Massive ascites with associated bowel hyperechogenicity is typical of either **parvovirus** infection (when the ascites is very tense) or a bowel perforation that may be secondary to **meconium peritonitis** (Fig. 41.15). Localized fluid collections may progress to hydrops because of pressure or

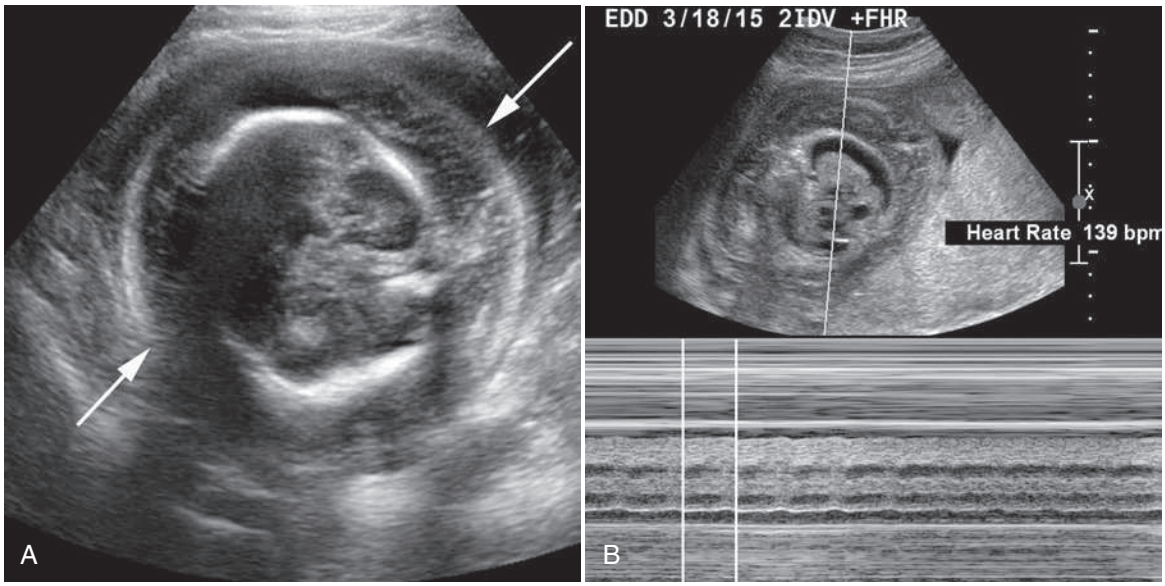

FIG. 41.10 Skin Thickening in Fetus With Hydrops. (A) Transverse view of skull shows marked edematous appearance of the skin *(arrows).* **(B)** In the same fetus, transverse M-mode image of fetal thorax shows normal cardiac rhythm, bilateral pleural effusions, and marked skin thickening.

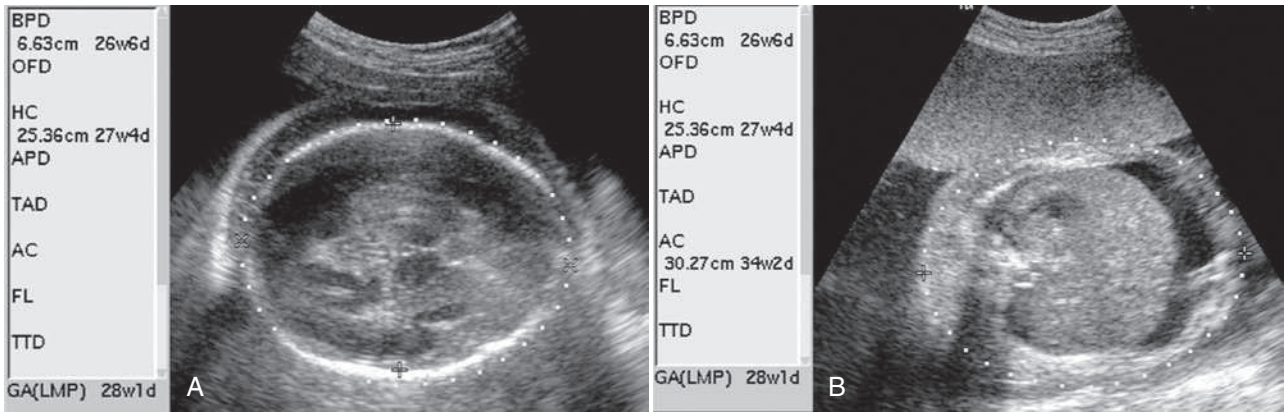

FIG. 41.11 Scalp and Body Wall Edema Are Measured Differently. (A) Fetal scalp edema. Head measurements *(cursors)* are obtained around the bone, not the skin. **(B) Abdominal wall thickening.** Abdominal wall measurements are obtained around the abdomen, including the skin thickening. Note that gestational age is 27 weeks by head circumference *(HC)* but 34 weeks if only abdominal circumference *(AC)* is used. *BPD,* Biparietal diameter.

metabolic effects, and thus the pattern of hydrops may evolve over time.

IMMUNE HYDROPS

Immune hydrops, or **erythroblastosis fetalis,** occurs when a sensitized mother develops antibodies to fetal RBCs that lead to hemolysis. Circulating maternal immunoglobulin G (IgG) antibodies cross the placenta and attack antigen-positive fetal RBCs. The majority of cases still occur in the presence of Rh(D) antibodies. Other antibodies such as Kell, Rh(C), and Rh(E) develop in 1% to 2% of individuals after blood transfusion and cause 2% of hemolytic disease of the fetus. The result is anemia, extramedullary erythropoiesis, hepatosplenomegaly, hypoalbuminemia, and congestive heart failure. Hydrops develops when the **fetal hemoglobin** (HbF) **deficit** exceeds 7 g/dL,[16] probably because of reduced oncotic pressure secondary to hypoalbuminemia, combined with high-output cardiac failure. Eventually, the fetus develops both metabolic and lactic acidosis,[17,18] and once this decompensation occurs, progression of hydrops is rapid, leading to fetal demise within 48 hours.

Causes of maternal sensitivity include fetal maternal hemorrhage and transplacental hemorrhage. In women with incompatible blood types with respect to the fetus (Rh alloimmunization or other RBC antigen), antibodies can be made. This typically occurs after delivery of the first pregnancy and therefore will affect the second pregnancy. Other times of blood sharing include miscarriage, therapeutic abortion, amniocentesis, placental

abruption, incompatible blood transfusions, and transplacental hemorrhage. An additional blood incompatibility issue is fetal **alloimmune thrombocytopenia.**

To avoid maternal sensitization, 300 mg of RhoGAM is given at 28 weeks' gestation in sensitized individuals. This protects against 30 mL of fetal blood. If a greater degree of fetomaternal hemorrhage is suspected, a **Kleihauer-Betke test** can be done to quantify fetal blood in maternal circulation to determine the necessary dose. As a prophylactic measure, RhoGAM is given to Rh-negative women within 48 hours after invasive fetal procedures such as amniocentesis and chorionic villus sampling.

Noninvasive Assessment of Alloimmunization

Fetuses are screened for risk of alloimmunization by determining the Rh status of the parents. If the pregnant woman is Rh negative, the father is screened. If the father of the baby is also Rh negative, no further screening is needed. If the mother is Rh negative and the father is Rh positive, maternal antibody titers are monitored. If they rise above 1:8, further testing is warranted. In the past, this was done with amniocentesis assessing for optical density (OD_{50}) of amniotic fluid (hemolysis increases OD of amniotic fluid), and serial percutaneous umbilical cord blood sampling (PUBS) procedures were performed as indicated to determine hematocrit (Hct). Currently, Hct is indirectly inferred from middle cerebral artery (MCA) Doppler studies, in which **peak systolic velocity** (PSV) is elevated in cases of anemia.

In response to severe anemia, the **fetal circulation becomes hyperdynamic** with increased blood flow velocities, which are thought to result from increased cardiac output and decreased viscosity of fetal blood. In addition, blood flow in the MCA may be increased further because the brain circulation responds quickly to hypoxemia.[19] Although flow velocities in all fetal vessels will be increased, the MCA is particularly suitable for assessment because of its easy visualization with color Doppler imaging (Video 41.6) as it courses directly above the greater wing of the sphenoid bone, carrying more than 80% of cerebral blood flow. The MCA has a high-impedance circulation with continuous forward flow. The method for MCA Doppler includes finding the circle of Willis, measuring a pulsed Doppler waveform of the proximal MCA at the base of the brain soon after its origin from the internal carotid artery (ICA) and obtaining a PSV measurement with the angle of insonation close to 0 degrees (Fig. 41.16B). Intraobserver and interobserver variability is low. Technique is important for obtaining accurate results. In most cases the examination can be performed in less than 5 minutes.

Measurement of Middle Cerebral Artery (MCA) Peak Systolic Velocity (PSV)

1. Obtain an axial section of the head at the level of the sphenoid bones during a period of fetal rest.
2. Use color Doppler ultrasound to identify circle of Willis with MCA at angle close to 0 degrees.
3. Enlarge image of MCA such that it occupies more than 50% of the image.
4. Interrogate MCA soon after its origin from the ICA at angle close to 0 degrees using a 1- to 2-mm sample volume. (If an angle close to 0 degrees cannot be obtained, then angle correction can be utilized.)[20]
5. Measure PSV.
6. Repeat the collection of MCA Doppler ultrasound three times.
7. Repeated waveforms should be similar.

The measured PSV is compared to median measures with respect to gestational age. A measurement of 1.5 multiples of the median (MoM) suggests severe anemia (Table 41.2). In a study of 111 fetuses at risk for anemia and 265 nonanemic fetuses, Mari et al. reported a sensitivity of a single value of MCA-PSV of nearly 100% for moderate or severe anemia with a false-positive rate of 12%.[19]

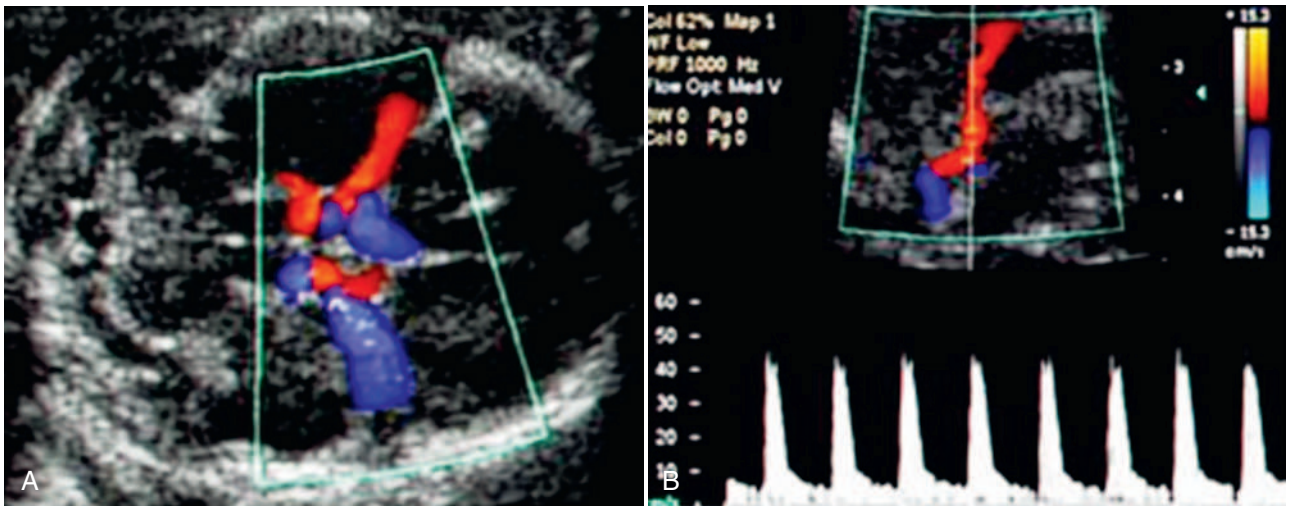

FIG. 41.16 Middle Cerebral Artery (MCA) on Color Doppler Ultrasound. (A) Circle of Willis. **(B)** Spectral Doppler tracing. Note how Doppler gate is on the MCA just after the origin from the internal carotid artery. Note that the MCA is studied with an angle close to 0 degrees; therefore, the velocity is close to the real velocity of the blood flow. See also Video 41.6. With permission from Mari G, Deter RL, Carpenter RL, et al. Noninvasive diagnosis by Doppler ultrasonography of fetal anemia due to maternal red-cell alloimmunization. N Engl J Med. 2000;342(1):9-14.[19]

In 2009, Pretlove et al.[21] published a meta-analysis (that included pooled data from nine studies) on the diagnostic value of MCA Doppler flow studies for fetal anemia. Severe anemia was detected with sensitivity and specificity of 75% and 91%, respectively. The use of the MCA-PSV trends (as opposed to a single measurement) may decrease the false-positive rate to less than 5%.[22]

The timing of MCA-PSV examination surveillance depends on prior history, gestational age, and measured MCA-PSV MoM level. Surveillance should begin when the pregnancy is advanced enough such that a fetal blood sampling procedure or intrauterine transfusion can technically be completed, typically after 18 weeks of gestation. After 24 weeks of gestation, routine testing is usually done on a weekly basis but may be done more frequently with higher MoM levels or other abnormal ultrasound findings that are suggestive of developing anemia.[23]

The **middle cerebral artery peak systolic velocity** (MCA-PSV) **is increased in intrauterine growth-restricted fetuses,** and therefore not all fetuses with elevated MCA-PSV will have anemia. A variable sign of anemia in the fetus is that of **hepatosplenomegaly.** The fetal liver and spleen increase in size because of their increased production of RBCs. However, the fetus may be able to compensate for the breakdown of RBCs and, in such cases, may have a large liver and spleen but would not necessarily be severely anemic. Conversely, more rapid breakdown of RBCs may prevent the fetus from adapting to hemolysis. Therefore, anemia may develop without hepatosplenomegaly.[24,25]

MCA Doppler ultrasound can help time a second fetal transfusion procedure,[26] but need for subsequent transfusions are better predicted by estimating the decrease in fetal hematocrit over time.[27]

Immune hydrops is an indication for urgent **fetal blood sampling** and transfusion. Use of MCA-PSV data allows for PUBS procedures to be timed to the need for in utero transfusions.[19,28,29] In a study of 80 fetuses with hydrops secondary to anemia, when hydrops was mild before treatment (only a thin rim of ascites, with or without pericardial effusion), hydrops was reversed in 88%; when hydrops was severe before treatment, hydrops reversed in only 65%. This stresses the importance of early treatment in cases of suspected anemia. After reversal of hydrops, survival rate was 98%.[30]

It should be recognized that immune hydrops, even untreated, is not uniformly lethal, and can spontaneous reverse, particularly if hydrops is mild, and an infection, such as parvovirus, is self-limited. Complications of transfusion for fetal anemia are detailed

later in this chapter and include in utero demise, preterm delivery, intracranial hemorrhage, and postnatal developmental delays.

NONIMMUNE HYDROPS

Nonimmune hydrops occurs in 1 in 1500 to 1 in 4000 pregnancies. It is a common pathologic finding in first- and second-trimester spontaneous abortions. The cause varies geographically and with gestational age. In North America and Europe, most cases are cardiovascular (20%), hematologic (9%), infective (7%), or chromosomal (13%; usually Turner syndrome; trisomy 21 and 18) in origin (see Table 41.1).[4] In Southeast Asia, however, homozygous **α-thalassemia** is a common cause[31]; in this region, carrier status for α-thalassemia occurs in 5% to 15% of the population. Nonimmune hydrops in homozygous α-thalassemia accounts for 25% of perinatal deaths in Southeast Asia.

Pathophysiology

Nonimmune hydrops represents the terminal stage for many conditions and is frequently multifactorial. Pathophysiology of hydrops may involve increased hydrostatic pressure, high-output cardiac failure, decreased plasma oncotic pressure, increased capillary permeability, obstruction of lymph flow, or a combination of these factors (Fig. 41.17). Fluid collections result from redistribution of fetal body fluids among the intravascular, intracellular, and interstitial compartments, secondary to an imbalance in capillary ultrafiltration and interstitial fluid return.[32] Hypoxia and circulatory failure may result in capillary damage that leads to plasma protein and fluid loss from the intravascular compartment.

Several factors predispose to edema in the fetus versus after birth. Both total body and extracellular fluid compartments are proportionately greater in the fetus, particularly at earlier gestational ages. Colloid osmotic pressure is lower because of lower albumin concentrations. High compliance of the interstitial space facilitates the accumulation of large volumes of fluid. Many causes of hydrops, especially those with a cardiac component, result from an increase in systemic venous pressure, to which the fetus is particularly sensitive. In the fetus, there is a net movement of fluid from the intravascular to the extravascular space. Fivefold larger volumes of fluid are removed by the lymphatics in fetal models than in adult animal models. Thus small elevations in systemic venous pressure (2-3 mm Hg) in the fetus can substantially reduce lymphatic flow and can drive large amounts of fluid into the extracellular space. This process is further enhanced by the relatively greater permeability of fetal capillaries to protein. The fetus is therefore particularly susceptible to small elevations in venous pressure from a number of causes, all of which can result in hydrops.[16,17,33]

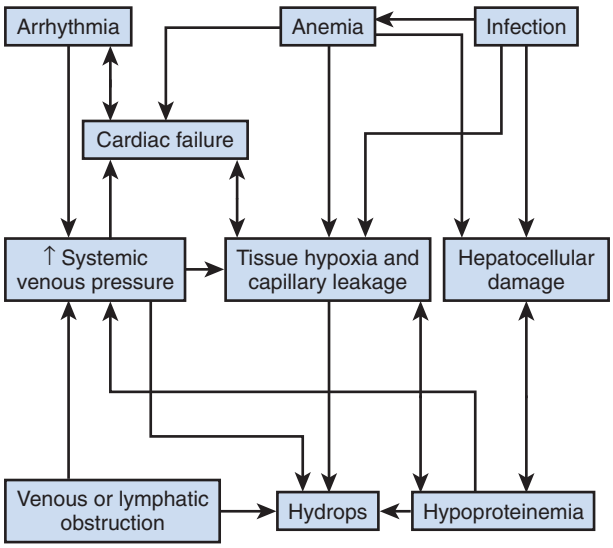

FIG. 41.17 Pathogenesis of Hydrops.

Causes and Associations

Nonimmune hydrops most commonly has a **fetal** etiology but also may be caused by maternal or placental factors. **Maternal** causes (such as poorly controlled diabetes mellitus) are rare and should be differentiated from maternal complications, which are secondary to fetal hydrops (termed **mirror syndrome** because edema develops in the mother of an hydropic fetus, "mirroring" the condition in the fetus).[34,35] Maternal thyrotoxicosis can cause fetal hyperthyroidism and fetal hydrops, with potential for resolution of hydrops after treatment with antithyroid drugs.[36] **Placental** causes, such as **chorioangioma** and other vascular shunts, are relatively rare and are usually associated with high-output failure states and, in some cases, fetal anemia.[37,38] Chorioangiomas need to be large (>4-5 cm) before they lead to hemodynamic compromise. They can be treated by laser, radiofrequency ablation, and/or surgical clip application.[39] Fetal metabolic causes are rare but important, because diagnosis can lead to appropriate neonatal treatment and appropriate counseling of the patients regarding recurrence risks.

A classification scheme for fetal causes is shown in Table 41.1 and has some overlap in the groupings, some of which represent associations rather than causations.

Cardiovascular Abnormalities

Structural cardiovascular abnormalities (Fig. 41.18) are the cause of hydrops in about 20% of cases.[4] However, hydrops is a rare complication of *isolated* cardiac abnormality because the fetus has a parallel flow circulation. In chromosomal abnormalities, for example, other factors with or without cardiac abnormality lead to hydrops.

Right-sided lesions, whether obstructive, such as **pulmonary or tricuspid atresia,** or structural lesions that result in right atrial volume or pressure overload, such as **mitral regurgitation,** can result in congestive heart failure and hydrops.[40,41] Left-sided obstructive lesions, such as **aortic stenosis, mitral stenosis,** and **coarctation of the aorta,** can result in a hypoplastic left heart, causing increased blood flow through the fetal right ventricle, which may result in hydrops.[42] The prognosis of nonimmune hydrops fetalis caused by cardiac structural abnormalities is poor, with a combined fetal and infant mortality rate of 92%, largely because of the severity of the heart defects that cause in utero congestive heart failure.[43] Some fetuses with structural cardiac anomalies also have rhythm disturbances, which contribute to the poor prognosis. In a series of 301 fetuses with atrioventricular

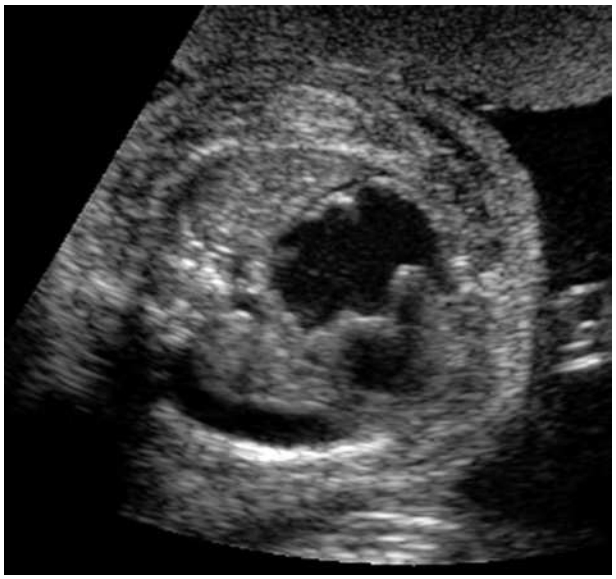

FIG. 41.18 Hydrops Secondary to Structural Cardiac Abnormality. Note the enlarged abnormal heart, pleural effusions, and skin thickening.

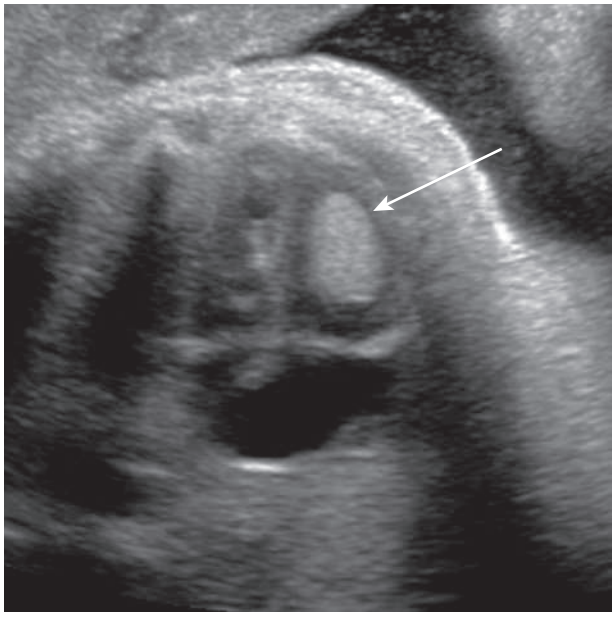

FIG. 41.19 Cardiac Rhabdomyoma. Note the echogenic lesion *(arrow)* adjacent to the myocardium.

(AV) septal defects, the presence of fetal hydrops, together with **bradycardia** from sinus node dysfunction or **complete heart block,** was associated with a poor outcome.[44]

Cardiac Tumors. Cardiac tumors are a rare cause of hydrops.[45-50] Hydrops in the context of cardiac tumors may be caused by several mechanisms, depending on the tumor location, size, and number. Cardiac lesions may cause obstruction to blood flow and alteration of AV valve function and may lead to arrhythmia, cardiac tamponade, pericardial effusion, and hydrops.[47-49]

Rhabdomyomas are the most common fetal cardiac tumor and are seen in association with **tuberous sclerosis** in more than 80% of cases.[50] Rhabdomyomas are also the most common cardiac tumors to cause hydrops. Usually, these tumors are multiple, well-circumscribed, hyperechoic, and homogeneous and mainly involve the ventricular myocardium[48] (Fig. 41.19). Rhabdomyomas tend to grow during the second half of pregnancy,[51] so most are diagnosed during the second and third trimesters.

Intrapericardial teratomas are rare, usually appearing as cystic and solid masses outside the cardiac cavities, arising from the pericardium. Teratomas may be larger than the heart, and rapid growth of the tumor within the small, confined space can result in pericardial effusion and hydrops as a result of cardiac compression.[52,53] Drainage of pericardial fluid associated with an intrapericardial teratoma has been reported, with resolution of associated hydrops.[54,55] Frequently, more than one drainage procedure is necessary.[56] At times, a shunt is placed if fluid rapidly reaccumulates after drainage.[57] Drainage of pericardial effusion secondary to intrapericardial teratoma usually results in a live birth after 32 weeks' gestational age.

Arrhythmias. Arrhythmias associated with hydrops are most often **tachyarrhythmias** (≥200 beats/min) and, less frequently, bradyarrhythmias. The diagnosis is important because treatment can reverse the hydrops. It is important to avoid premature delivery; treatment of a hydropic preterm fetus is difficult. Fetal tachyarrhythmias are most often **supraventricular tachycardia** (SVT, which includes **atrial fibrillation/flutter**)[58] (Fig. 41.20). The prognosis for a fetus with an isolated arrhythmia is favorable, with a 95% likelihood of survival.[59] However, when hydrops is present (41% in this series) with an otherwise isolated arrhythmia, the survival decreases to 73%.[58] When studying neonates who had fetal SVT, most cases are the result of reentry circuits.[60] If the SVT is of limited duration, there are typically no fetal consequences. However, with sustained SVT, hydrops may develop. The presence of hydrops in these cases is associated with more difficult prenatal antiarrhythmic control of the tachycardia and higher mortality. Prenatal control of the tachycardia was achieved in 83% of treated nonhydropic fetuses, compared with 66% of the treated hydropic fetuses.[58]

Tachyarrhythmia treatment is almost always given transplacentally; the pregnant woman is given an antiarrhythmic drug, which crosses the placenta and enters the fetal circulation. Rarely is direct fetal administration required.[31] At present, there is no consensus on first-line treatment of SVT. In one report flecainide and digoxin were slightly more effective than sotalol.[61] Combination therapies (amiodarone/digoxin, amiodarone/flecainide, sotalol/digoxin, and sotalol/flecainide) have been reported to be effective when single agents have failed.[62] Treatment for SVT has been described as early as 13 weeks' gestational age.[63] Prognosis in the setting of fetal tachyarrhythmia depends on a number of factors, including type and duration of arrhythmia, presence of structural cardiac anomalies, gestational age, and response to intrauterine therapy.[64]

In rare cases of SVT and hydrops, preterm delivery (if at sufficient gestational age) may be the best option, allowing for direct treatment of the tachyarrhythmia. Again, however, treatment of a hydropic preterm infant is difficult, and therefore preterm delivery is usually not indicated.

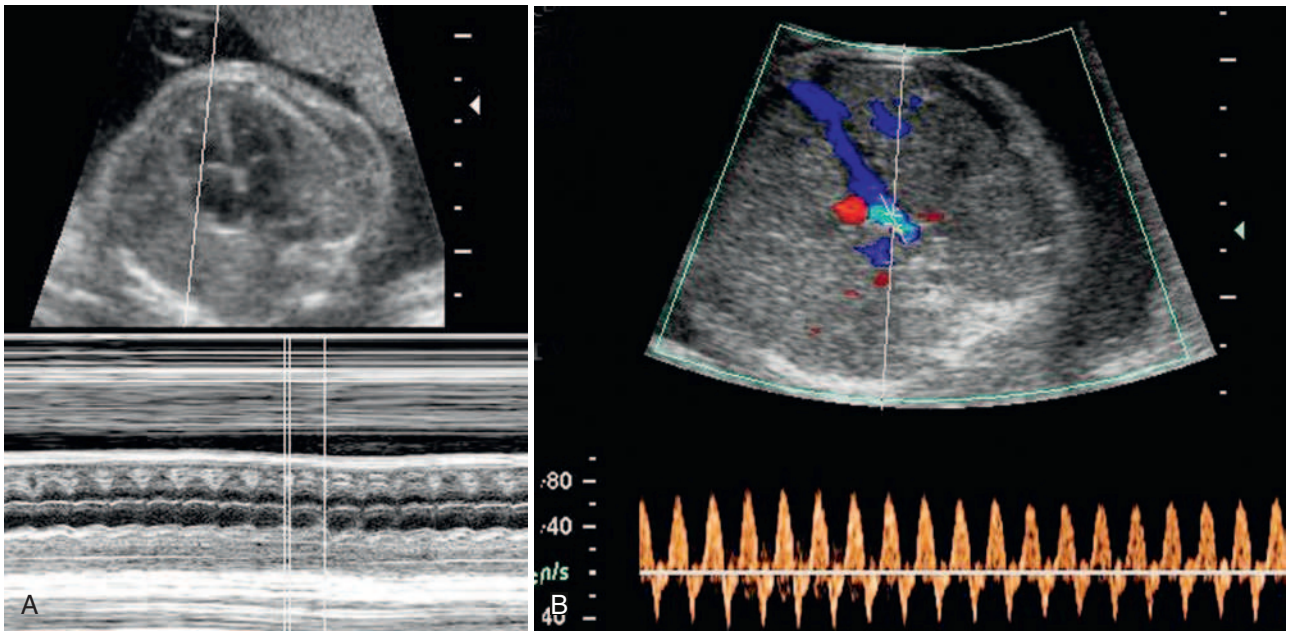

FIG. 41.20 Supraventricular Tachycardia (SVT). (A) Atrial rate of 250 beats/min. **(B)** Color Doppler ultrasound shows ductus venosus waveform with SVT.

Heart Block. Congenital heart block (CHB) is a rare cardiac conduction defect, occurring in 1 in 15,000 to 1 in 20,000 live births. In fetuses with CHB, hydrops results from a combination of low cardiac output, a slow heart rate, and a structural lesion, if present. The increased venous pressure in association with low colloid oncotic pressure leads to edema. Because approximately one-third of fetuses with CHB have associated structural heart defects, a detailed fetal echocardiographic assessment is always warranted.

In isolated heart block, maternal rheumatologic disease is common. Maternal serologic testing for anti-Ro/La antibodies is warranted because transplacental passage of maternal anti-Ro and anti-La autoantibodies is seen in 95% of cases of fetal CHB.[65] These antibodies cross the placenta from as early as 16 weeks' gestational age and initiate inflammatory damage to the fetal conduction system and myocardium.[66,67] Hydrops develops with ventricular rates less than 60 beats/min (about 40% of cases with isolated heart block)[68,69] and has a mortality rate of 25% to 100%.[68,70] Treatment can be given with steroids and plasmapheresis,[71-75] but the efficacy of these is not well established. Epicardial pacemaker can be placed at birth.[76] Although 95% of mothers tested positive for anti-Ro/La antibodies, fewer than 5% of these pregnant patients had signs and symptoms of connective tissue disease at diagnosis of fetal AV block.[65]

When structural abnormalities accompany heart block, hydropic fetuses have a combined fetal and neonatal mortality rate of 83% to 100%.[65,69] Jaeggi et al.[65] reported 29 cases of prenatally diagnosed isolated congenital AV block; six fetuses presented with hydrops: two died antenatally, and four died in the neonatal period.[65] In these cases, corticosteroid use during pregnancy did not reverse hydrops or reduce the severity of AV block. In addition to hydrops, other poor prognostic factors include **endocardial fibroelastosis** with ventricular dysfunction and coexistent structural heart disease.[68]

Decreased Myocardial Function. Cardiomyopathies can be classified as primary or secondary or by an echocardiographic evaluation as **dilated** or **hypertrophic. Primary** fetal cardiomyopathies may have intrinsic causes (e.g., single-gene disorders, mitochondrial disorders, chromosomal abnormalities, α-thalassemia) or extrinsic causes such as infection, maternal disease (autoantibodies or insulin-dependent diabetes), and twin-twin transfusion syndrome. **Secondary** fetal cardiomyopathies are associated with structural or functional cardiac disorders (Video 41.7) and high-output states.[77]

Neck Abnormalities

Neck masses, such as **teratomas** and **lymphangiomas,** cause fetal hydrops from compression or high-output cardiac failure (Fig. 41.21). A **cystic hygroma** (fluid in posterior neck) may indicate a chromosomal (e.g., 45,XO) or other abnormality. Of 42 fetuses with first-trimester cystic hygroma, 14 developed hydrops later in pregnancy. Each of these had a **nuchal translucency** measurement of 3 mm or more at diagnosis of cystic hygroma.[78] For fetuses presenting with hydrops in the first trimester, all have increased nuchal translucency.[79]

Thoracic Anomalies

Hydrops can result from obstruction of venous or lymphatic return due to maldevelopment, compression, kinking, or cardiac tamponade. **Mediastinal masses, pleural effusions,** and **diaphragmatic hernias** may cause nonimmune hydrops by similar mechanisms.[80]

The incidence of **fetal hydrothorax** is estimated at 1 in 15,000 pregnancies. Isolated hydrothorax is most often caused

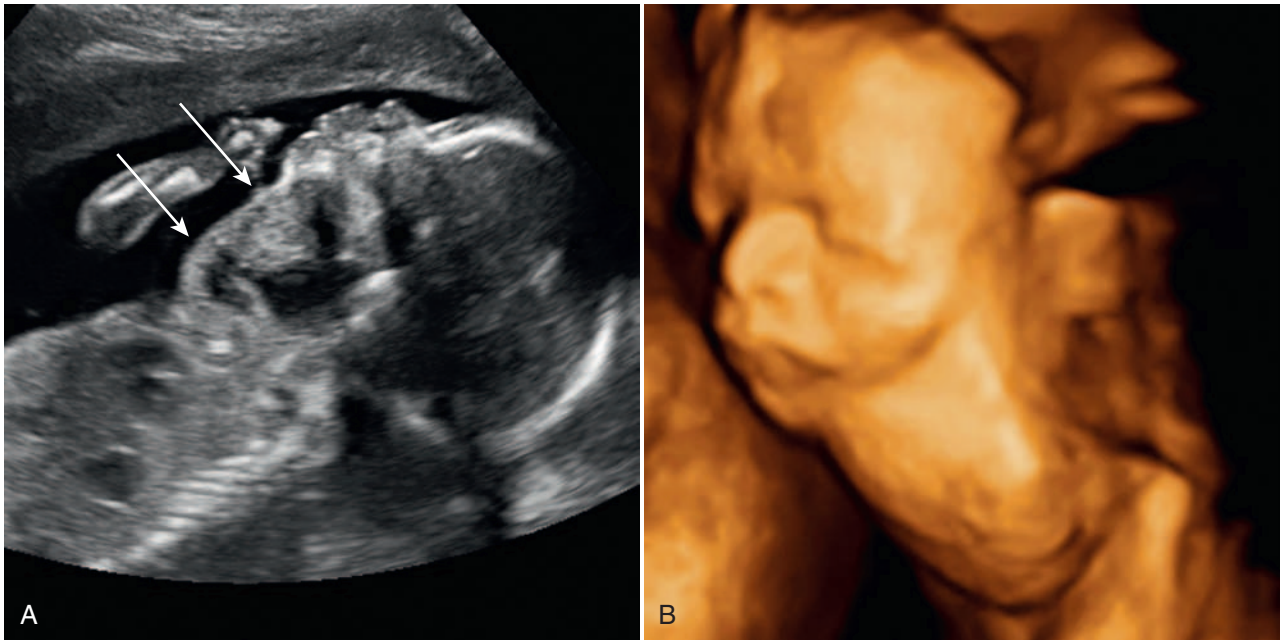

FIG. 41.21 Neck Teratoma. (A) Sagittal ultrasound with face up; mass *(arrows)* elevates chin. **(B)** Three-dimensional ultrasound shows the relation of the mass with the face.

by **congenital chylothorax,** a primary lymphatic abnormality. Accumulation of fluid in the pleural space may lead to pulmonary hypoplasia, compression of the heart, and obstruction of venous return, with subsequent development of hydrops and compression of the esophagus leading to polyhydramnios. Untreated, the perinatal mortality is 22% to 53%.[81-85] Associated malformations (≈25% of cases) and aneuploidy (≈7%) worsen the outcome.[84-87]

In the absence of hydrops, fetuses with isolated hydrothorax have such a good prognosis that invasive prenatal treatment is not indicated.[82,88] However, when hydrops develops, the outcome without intervention is very poor. In a large review, perinatal mortality in the hydropic group was 69% despite prenatal interventions in a number of cases.[84]

An echogenic lung mass is usually a **congenital pulmonary airway malformation** (CPAM), including the previously termed "congenital cystic adenomatoid malformation"; a **bronchopulmonary sequestration** (BPS); congenital lobar emphysema; or, in rare cases, **congenital high airway obstruction syndrome.** Most cases of CPAM, regardless of their size, regress spontaneously at least partially during the third trimester, and only a minority of fetuses become hydropic. Focal lung masses can lead to ipsilateral pleural effusion (Fig. 41.22; see also Fig. 41.7), mediastinal shift, and, ultimately, hydrops. However, the hydrops may not be caused only by the mediastinal shift but also by high-output cardiac failure because of shunting that may occur in an anomalous systemic artery and venous drainage through pulmonary or systemic veins.[89]

In a report of 67 cases of lung masses, only 7% developed hydrops.[90] Of 134 fetuses with CPAM referred to two fetal surgical centers in the United States, 101 were followed expectantly, and all 25 hydropic fetuses died, whereas all 76 nonhydropic fetuses survived,[91] suggesting that fetal surgery might be considered for hydropic cases. In the absence of hydrops, and provided there are no other anomalies, survival in these cases is virtually 100%.[92,93]

When a fetus with CPAM develops hydrops, the prognosis is poor, and antenatal intervention is often advisable. Intervention may be in the form of decompression by cyst aspiration (see Fig. 41.22), shunt, or open fetal surgery. A 2006 meta-analysis showed that shunting of CPAMs improved survival in fetuses with hydrops, as opposed to no effect on survival in fetuses with chest masses without hydrops.[94] Antenatal predictors of progression to hydrops include a combination of microcystic and macrocystic components and a large volume ratio of the mass to the normal lung (>1.6).[95] For fetuses with no dominant cyst and CPAM volume ratio less than 1.6, 97% did not progress to hydrops, whereas in the group with volume ratio greater than 1.6, 75% progressed to hydrops.[95] The success with open fetal surgery in cases of CPAM is variable, 29% to 62%. Antenatal aspiration of a macrocystic CCAM at times may be an effective treatment,[95] but frequently it is ineffective because of rapid reaccumulation of the cyst fluid. In cases with rapid reaccumulation of fluid, thoracoamniotic shunting may be a better approach.[96] Survival after shunting is correlated to gestational age at birth, percent reduction in lesion size, and resolution of hydrops.[97] Maternal administration of steroids also may be helpful.[98]

Although nonimmune hydrops fetalis rarely occurs in BPS cases, it is associated with a high rate of perinatal mortality and severe respiratory insufficiency in the neonate.[99,100] However, neonates with BPS and hydrops can survive.[101] Different strategies of in utero treatment have been proposed, such as thoracoamniotic shunting of pleural effusion,[102-105] thoracentesis and intravascular furosemide and digoxin,[106] alcohol ablation of the vascular pedicle with placement of a shunt,[107] ablation of the abnormal systemic artery from the aorta,[108,109] and open fetal surgery.[99]

In CHAOS the mechanism of hydrops is secondary to cardiac and great vessel compression by the enlarged fetal lungs.[110]

Chest Drainage Procedures. Aneuploidy is present in about 6% of cases of chylothorax and should be excluded.[111] Isolated

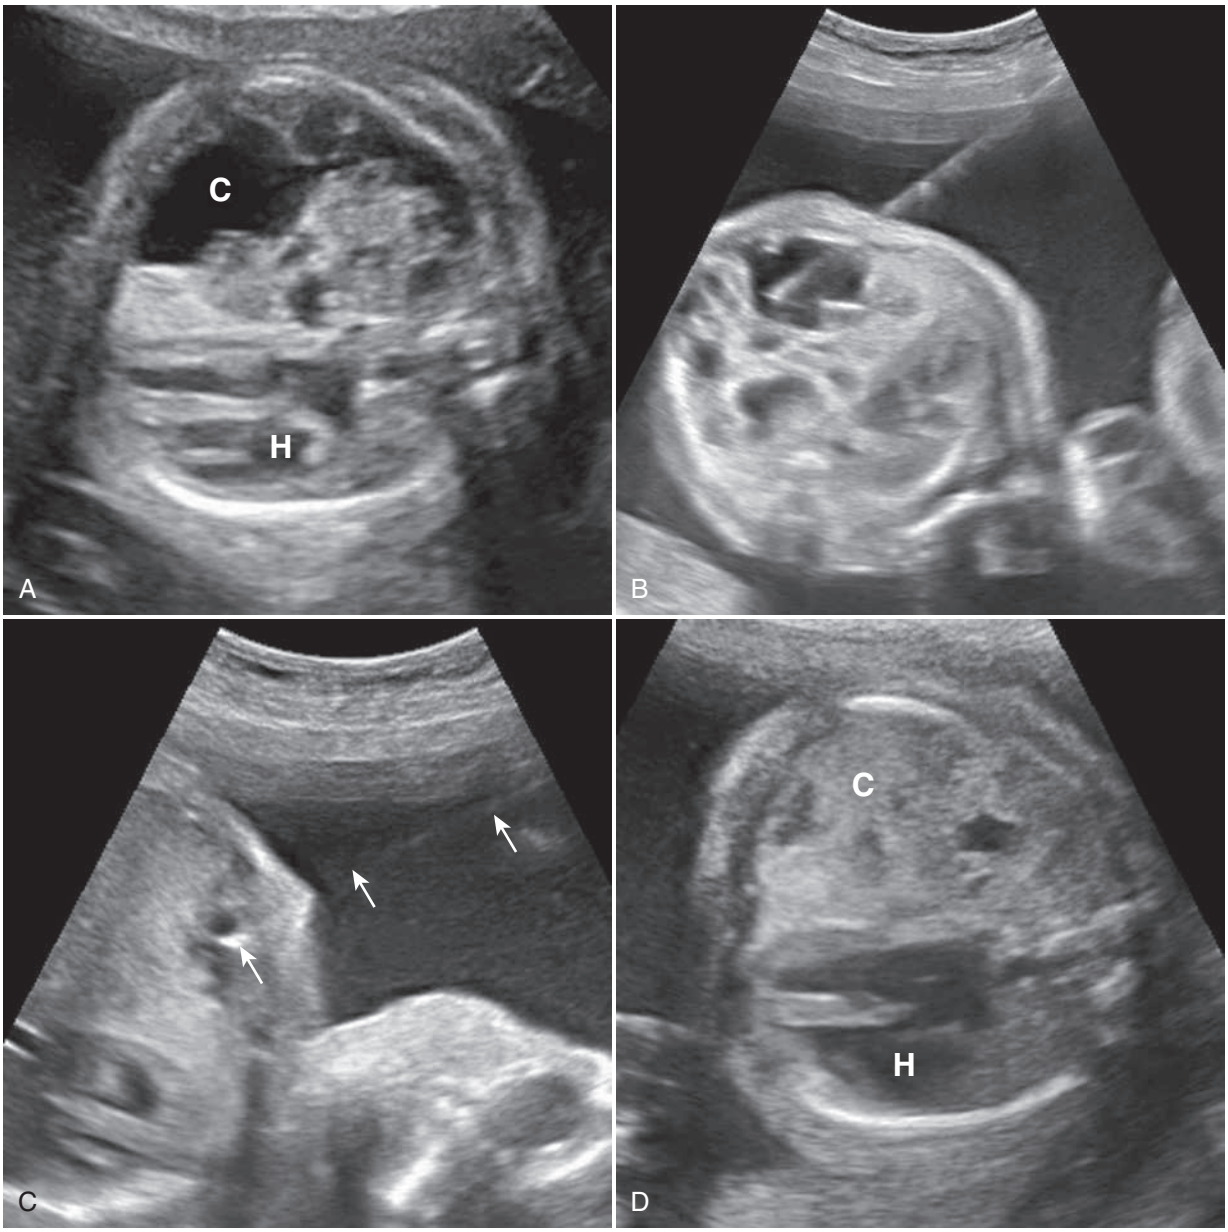

FIG. 41.22 Drainaging of macrocystic congenital pulmonary airway malformation with mediastinal shift and incipient hydrops. **(A)** shows a cyst in the cyst *(c)* with mediastinal shift of the heart *(H)*. **(B)** shows needle in the largest cyst. **(C)** shows decreased size of the cyst. Needle can be seen *(arrows)*. **(D)** At the completion of the procedure, the heart *(H)* is less compressed, and the echogenic chest mass *(c)* can still be seen, but the large cyst is no longer present.

large effusions may be drained initially using a fine needle and the fluid sent for lymphocyte count (>80% lymphocytes in the absence of infection is diagnostic of chylothorax),[112] rapid karyotyping, protein, inclusion bodies, and infection studies. This maneuver also evaluates the ability of the lungs to reexpand and may occasionally be therapeutic. Effusions that recollect rapidly can have multiple drainage procedures or may have shunt placement.[82,113] With treatment, survival is greater than 60%.[114] For large effusions occurring late in pregnancy, therapeutic drainage immediately before delivery facilitates neonatal resuscitation.[115] In a 2015 retrospective review of fetuses with congenital lung lesion or pleural effusion who underwent shunt placement, 97 shunts were placed in 75 fetuses. Average gestational age at shunt placement and birth was 25 and 35 weeks, respectively. Shunt placement resulted in a 55% ± 21% decrease in macrocystic lung lesion volume and complete or partial drainage of the pleural effusion in 29% and 71% of fetuses. Sixty-nine percent of fetuses presented with hydrops, which resolved following shunt placement in 83%. Survival was 68%, which correlated with gestational age at birth, percent reduction in lesion size, unilateral pleural effusions, and hydrops resolution.[97]

Gastrointestinal Anomalies

Anomalies of the gastrointestinal tract typically cause isolated ascites rather than hydrops. If there is local obstruction of lymphatic and venous drainage, as from intestinal obstruction, volvulus, or omphalocele, hydrops may result in rare cases. Abdominal masses presumably act by compression of venous

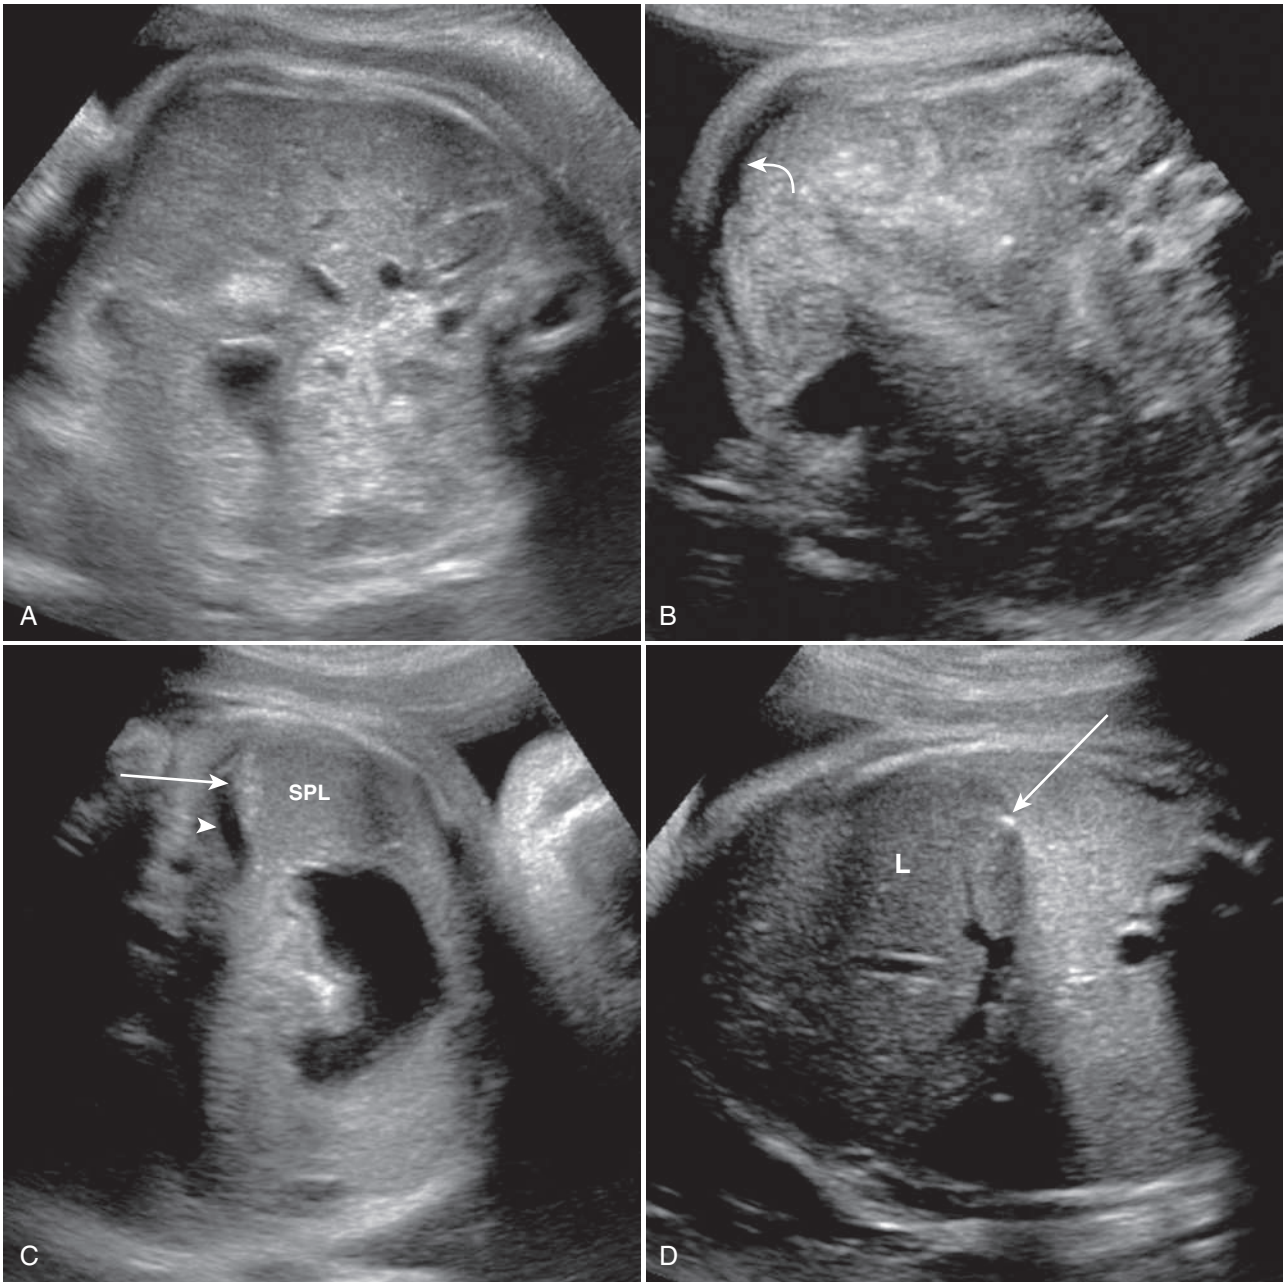

FIG. 41.23 Meconium Peritonitis. (A)-(D) Transverse views of the fetal abdomen demonstrate echogenic bowel and punctate echogenicities *(arrows)* around the spleen *(SPL)* and liver *(L)*. Note associated ascites (*curved arrow* in **B**) and pleural effusion (*arrowhead* in **C**).

return, although hypoproteinemia and/or AV shunting can also play a role.

Meconium peritonitis is associated with fetal **cystic fibrosis** in 70% of cases. Bowel rupture results in a sterile chemical peritonitis, often with ascites[116] (Fig. 41.23; see also Fig. 41.15). The ascites may be clear or particulate on ultrasound, and its appearance may change over time. The bowel will usually have a bunched or matted appearance, and areas of calcification may be visible. If this diagnosis is suspected, the parents should be offered carrier testing for the common cystic fibrosis mutations.

Urinary Tract Anomalies

Urinary tract anomalies are rare causes of hydrops. Congenital nephrosis can lead to severe proteinuria and hypoalbuminemia as the cause of hydrops.[117] Bladder rupture can lead to urinary ascites but rarely hydrops (Fig. 41.24).

Lymphatic Dysplasia

Congenital lymphatic dysplasia may be the source of many cases of hydrops that do not have an obvious cause. Bellini et al.[118] found that six newborns presenting at birth with hydrops of unidentified cause all had lymphatic dysplasia.

Monochorionic Twins

Twins have an increased incidence of hydrops secondary to a higher incidence of congenital anomalies and secondary to complications associated with the monochorionic placenta: **twin-twin transfusion syndrome** (TTTS) and **acardiac twinning.** These are described in detail in Chapter 32. The Quintero classification of TTTS has, as stage IV, hydrops of one or both twins.[119] The **recipient twin** experiences an elevation in cardiac output and blood pressure as a result of shunting of blood through the AV anastomoses. Initially, the increase in right ventricular workload is compensated for by ventricular hypertrophy, with minimal hemodynamic dysfunction. With ongoing volume and pressure overload, the right ventricle stretches and the tricuspid regurgitation begins, probably associated with increase in right ventricular end-diastolic pressure, reflected in the end-diastolic pressure of the right atrium. Atrial contractions against an elevated pressure produce retrograde flow during atrial systole in the ductus venosus, hepatic veins, and inferior vena cava. Eventually, metabolic acidosis and congestive heart failure develop.[120]

Conservative management of early-onset severe TTTS is associated with a survival rate of less than 10%.[121] Death is caused by extreme prematurity, in association with growth restriction in the donor and cardiac failure and hydrops in the recipient (Fig. 41.25). Current series suggest improved survival and decreased neurologic sequelae if severe TTTS before 26 weeks is treated with endoscopic selective laser ablation of the placental vascular anastomoses.[122-124]

For this procedure, a laser is introduced endoscopically into the uterus and used to ablate surface placental vessel anastomoses under ultrasound guidance.

In acardiac twins (**twin reversed arterial perfusion** [TRAP] **sequence**) a monochorionic pair has a pump twin and an acardiac twin. The **pump twin** perfuses the acardiac twin and develops high-output cardiac failure (particularly if the weight of the acardiac twin is >70% of the donor twin) and polyhydramnios.[125] The **acardiac twin** has anasarca but not true hydrops. Treatment involves interruption of the blood flow to the acardiac twin, typically by radiofrequency ablation, laser ablation, or cord ligation.[126-132] Radiofrequency ablation can result in survival of 80%.[133]

FIG. 41.24 Lower Urinary Tract Obstruction. Urinary ascites in obstructive uropathy with bladder rupture. Note the thickened bladder wall.

Chromosomal Anomalies

The incidence of aneuploidy is higher in hydrops cases presenting before 24 weeks than those later in pregnancy. Before 24 weeks, the incidence of aneuploidy in cases of hydrops ranges from 33% to 78%.[134-136] After 24 weeks the incidence of aneuploidy in hydrops is as low as 2%.[135]

Turner syndrome (45,XO) is classically associated with a cystic hygroma in the first and early second trimesters (Fig. 41.26; see also Fig. 41.12). Many of these disorders result in early spontaneous abortion. **Trisomies 21, 18, and 13** and **triploidy** have been associated with nonimmune hydrops, although it is

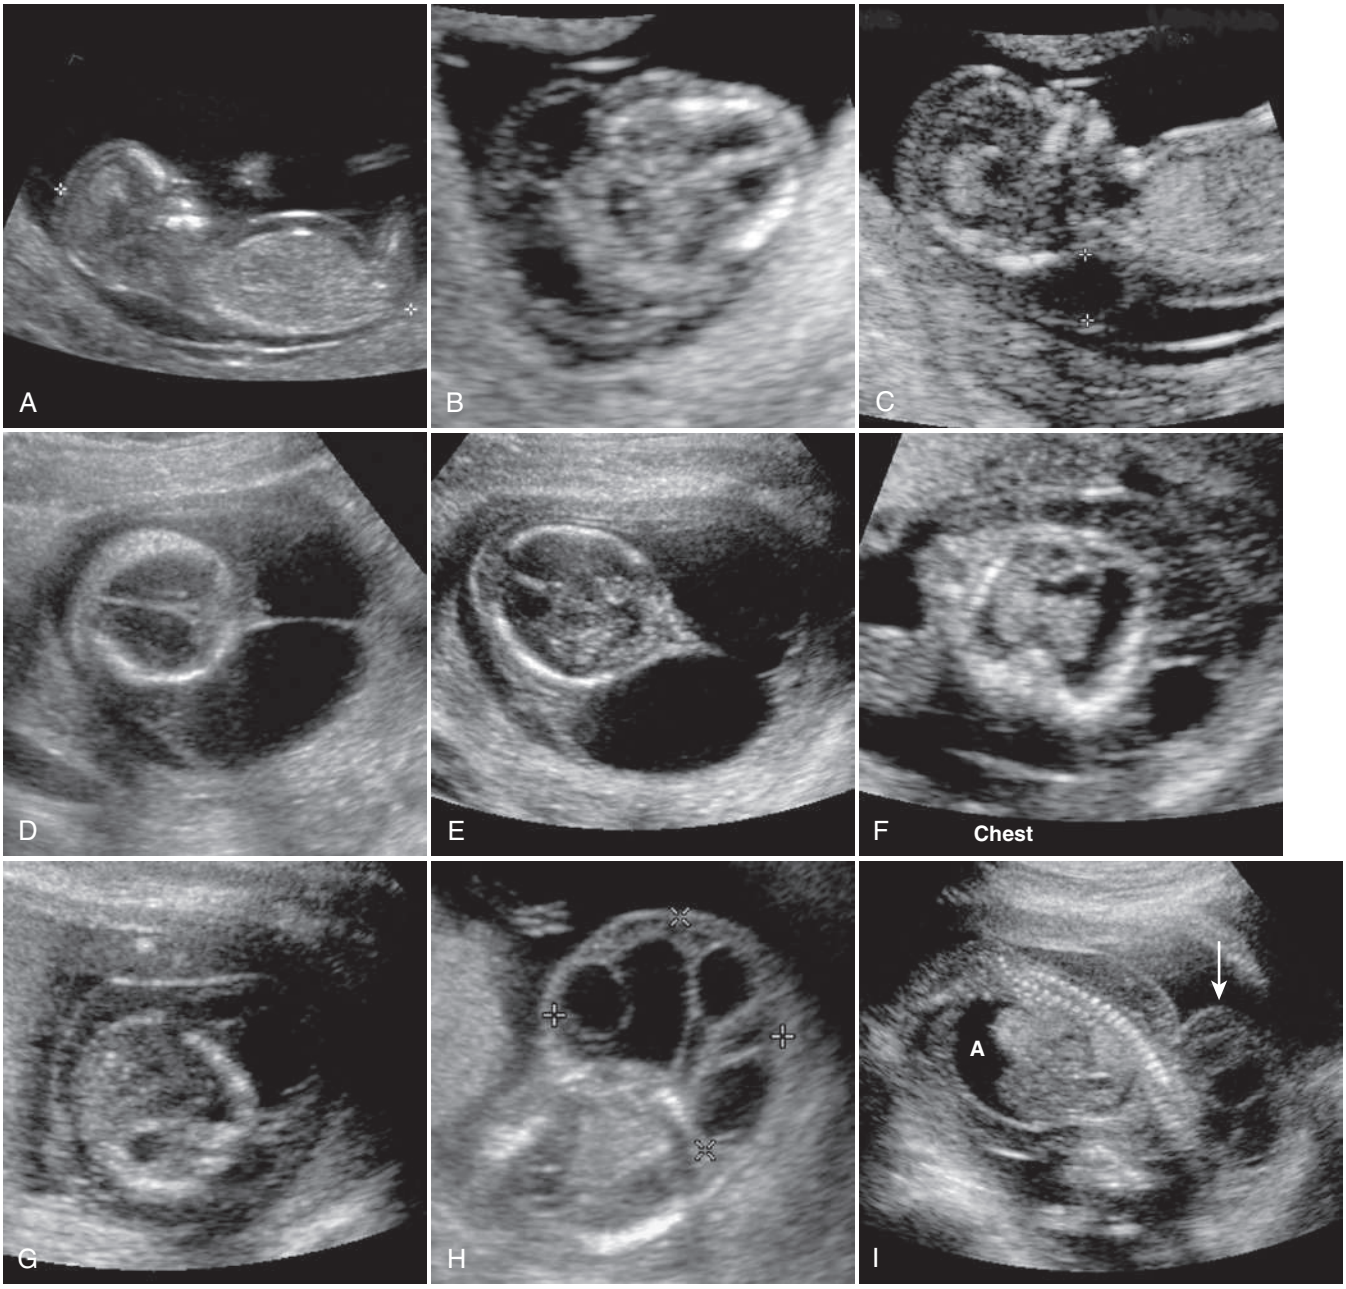

FIG. 41.26 Turner Syndrome in First and Second Trimesters. (A) Fetus at 12 weeks with diffuse skin thickening and lymphangiectasia. **(B)** and **(C)** Fetus at 13 weeks with nuchal thickening and diffuse body wall edema. **(D)-(G)** Fetus at 18 weeks with cystic hygroma and pleural effusion and diffuse body wall edema. **(H)** and **(I)** Fetus at 19 weeks with cystic hygroma *(arrow)* and ascites *(A)*.

often unclear why hydrops develops. There are a few reports of transient abnormal myelopoiesis with trisomy 21 as a cause of hepatomegaly and nonimmune hydrops.[137,138] In these cases, PUBS demonstrates fetal anemia and hypoalbuminemia. A hydropic fetus with multiple structural anomalies, prominent cystic hygromas, or increased nuchal translucency likely has a chromosomal abnormality. The physiologic basis for increased nuchal translucency is incompletely understood, but it may be caused by delayed lymphatic development and/or related to cardiovascular malformations,[139] especially in cases with aneuploidy.[140]

Tumors

Arteriovenous malformations and arteriovenous shunting in large tumors with a high proportion of solid tissue lead to hydrops by causing high-output cardiac failure and leading to **Kasabach-Merritt sequence** (consumptive coagulopathy). Selected fetuses with tumors, such as large **sacrococcygeal teratoma** associated with hydrops, have undergone in utero procedures, including cyst aspiration and open fetal surgical resection. However, these procedures are complicated by preterm delivery and other obstetric complications.[141] More recent reports suggest improved outcomes with laser ablation or alcohol sclerosis targeting the

feeding vessel(s) of the tumor.[142] In utero treatment for sacrococcygeal teratoma has a survival rate of 30% to 55%.[143]

Anemia

Fetal anemia is caused by decreased RBC production, increased hemolysis, or hemorrhage. If the process is gradual, the fetus mounts a compensatory erythropoietic response, and nonimmune hydrops develops only when the anemia exceeds its ability to keep pace, which is typically when the hemoglobin concentration deficit is 7 g/dL or greater.[17] Hydrops results from a combination of high-output cardiac failure and hypoxic capillary damage, causing protein leakage, as well as infiltration of the liver by erythropoietic tissue, leading to portal hypertension.[17]

Decreased Red Blood Cell Production. Homozygotes with **α-thalassemia** cannot manufacture HbF in utero or hemoglobin A (HbA) after birth.[144] Instead, Hb Bart is formed in utero, which has such a high affinity for oxygen that tissue hypoxia results, leading to capillary damage, protein leakage, cardiac failure, and hydrops. Other causes of decreased RBC production in utero include generalized marrow aplasia, as found in parvovirus infection[32,145] and fetal leukemia.[138]

Hemolysis. Glucose-6-phosphate dehydrogenase (G6PD) deficiency has been reported as a rare cause of nonimmune hydrops resulting from increased hemolysis.[146] Hemolysis may also contribute to anemia caused by in utero infection.

Hemorrhage. Blood loss may occur either into another fetus in TTTS, into the fetus itself (e.g., intracranial), into a tumor (e.g., sacrococcygeal teratoma), or transplacental.

Infection

Intrauterine infections account for up to 16% of cases of nonimmune hydrops.[147] An autopsy series of fetuses with in utero demise and nonimmune hydrops showed that 33% had infection.[148] Hydrops may result from effects on the bone marrow (**parvovirus, cytomegalovirus** [CMV], **toxoplasmosis**), myocardium (**adenovirus, coxsackievirus, CMV,** leading to congestive heart failure), vascular endothelium (hypoxic capillary damage causing protein leakage), or overwhelming sepsis with hepatitis and decreased protein production **(syphilis).**[149-154] In addition to hydrops, signs of infection include calcifications in the pericardium or brain, as well as ventriculomegaly.

Parvovirus B19. Parvovirus B19 is responsible for up to 27% of cases of nonimmune hydrops.[155] Myocarditis and fetal anemia secondary to bone marrow aplasia are thought to be the mechanisms of hydrops (Fig. 41.27). The marrow is particularly sensitive to parvovirus infection from 16 to 24 weeks' gestation.[149] The impact on RBC aplasia is further pronounced by the shortened life span of RBCs (45-70 days).[156]

Fetal infection occurs in up to 10% of pregnancies with maternal infection. This leads to an excess fetal loss rate of 9% of fetuses infected between 9 and 20 weeks' gestation.[157] In the first trimester, fetal infection can cause miscarriage, whereas in the second trimester, the fetus is at risk for hydrops. In contrast to most other congenital infections, adverse long-term sequelae are rarely associated with parvovirus.[152] Although hydrops associated with parvovirus B19 can spontaneously resolve without transfusion,[158-161] most cases benefit from intrauterine transfusion. Parvovirus infection is suspected when maternal blood shows positive immunoglobulin M (IgM, indicating a recent infection) and high or increasing IgG. Cordocentesis will show aplastic anemia with few reticulocytes, although at times the hydrops is caused by myocarditis.[158] Fetal parvovirus infection is diagnosed by polymerase chain reaction (PCR) testing of amniotic fluid or fetal blood.[162] PCR results can be available within a few hours.

When maternal parvovirus infection is discovered, serial monitoring of the pregnancy is indicated, with weekly sonograms

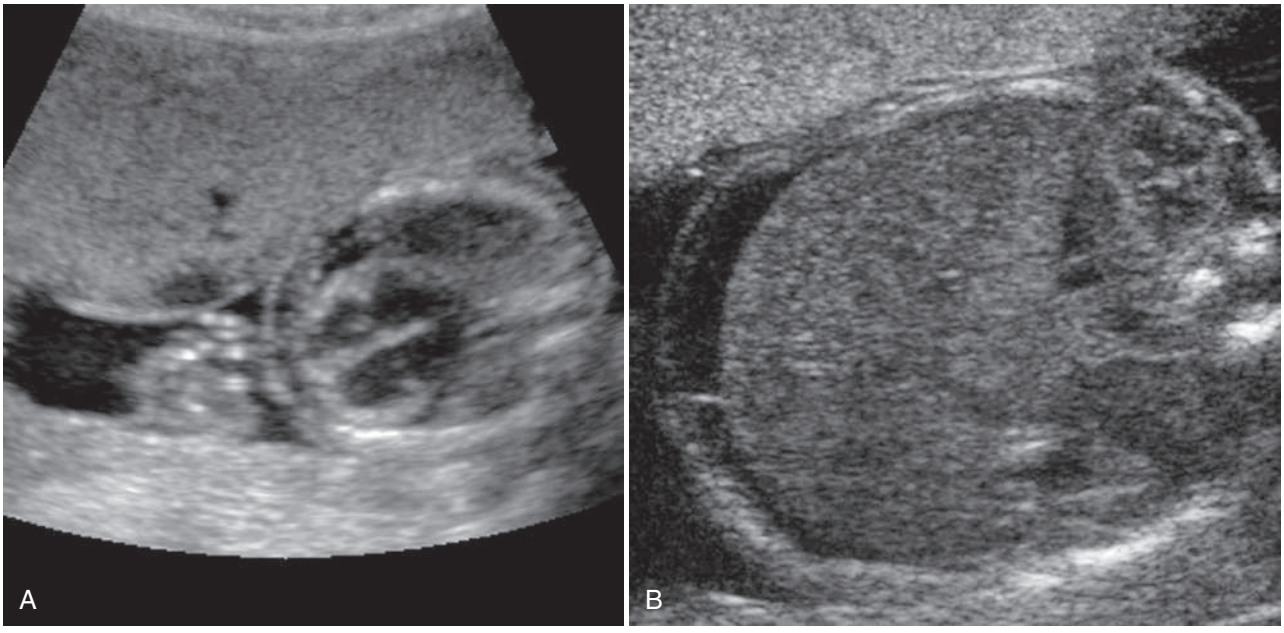

FIG. 41.27 Hydrops in Fetus With Parvovirus Infection and Anemia at 19 Weeks. (A) Transverse view of the fetal thorax shows a slightly enlarged heart with echogenic myocardium and small pericardial effusion. **(B)** Transverse view of abdomen shows ascites. Middle cerebral artery Doppler studies (not shown) showed peak systolic velocity of 55 cm/sec, indicating severe anemia.

for 8 to 12 weeks after maternal infection. Sonograms are performed to assess for signs of hydrops and include Doppler analysis to assess for elevated MCA velocity, as an indication of fetal anemia.

In cases of infection with parvovirus treated with intrauterine transfusion, survival is 43% to 84%.[157,163-165] However, there are also reports of abnormal developmental outcome in up to 31% of cases.[163]

Toxoplasmosis. Congenital infection with *Toxoplasma gondii* can cause anemia, intracerebral or intrahepatic calcifications, ventriculomegaly, and chorioretinitis and can present with hydrops, particularly ascites.[166-168] Most pregnant women with congenital toxoplasmosis are asymptomatic or only mildly symptomatic during pregnancy. The rate of fetal infection varies according to the gestational age at the time of vertical transmission, ranging from 26% to 40%.[166] Prenatal diagnosis of toxoplasmosis can be difficult and depends on the demonstration of maternal seroconversion and/or the parasite in amniotic fluid by PCR or isolation techniques.[166] Diagnosis is important because infected mothers are treated with spiramycin throughout pregnancy; if fetal infection was demonstrated, pyrimethamine and sulfadoxine or sulfadiazine are added to the regimen.[167]

Other Infections. Congenital **CMV** infection is responsible for 1% to 2% of cases of nonimmune hydrops and can occur even with recurrent maternal infection.[169] Fetal treatment can be attempted with umbilical vein injection of ganciclovir[170] or intraperitoneal injection of hyperimmunoglobulin.[171] **Rubella, syphilis,** and **varicella** are less common causes of nonimmune hydrops.[172,173] Diagnosis is important; in cases of syphilis, if the fetus is in the third trimester and the lungs are mature, delivery and treatment with penicillin can lead to resolution of the hydrops. Rare infectious causes of nonimmune hydrops include **herpes simplex virus,**[174,175] **adenovirus,**[176] and acute maternal **hepatitis B** infection.[177]

Genetic Disorders

Multiple nonchromosomal genetic conditions can cause nonimmune hydrops[178] (see Table 41.1). The mechanisms are poorly understood and are multifactorial. In storage diseases, the most likely mechanism is hepatic infiltration resulting in hypoproteinemia or vascular obstruction.

Metabolic Disorders

Inborn errors of metabolism are rare, and these are a rare cause of hydrops. However, diagnosis is important because early treatment of some disorders can lead to improved outcome. Diagnosis is also important for genetic counseling regarding recurrence risk. Lysosomal disorders associated with hydrops fetalis include GM1 gangliosidosis, galactosialidosis, infantile free–sialic acid storage disease, mucopolysaccharidosis types IV and VII, mucolipidosis types I and II, Gaucher disease type II, Farber disease, Niemann-Pick disease, Wolman disease, and multiple sulfatase deficiency.[179] Hydrops fetalis has been associated with deficiencies of G6PD[146] or pyruvate kinase,[180,181] Pearson syndrome[182] and other mitochondrial disorders,[182,183] congenital defects of N-glycosylation,[184] glycogen storage disease type IV,[185] and neonatal hemochromatosis.[186]

Skeletal Disorders

Skeletal dysplasia is a rare cause of hydrops.[178] Examples include achondroplasia, achondrogenesis, osteogenesis imperfecta, hypophosphatasia, and arthrogryposis.

Endocrine Disorders

Fetal endocrine disorders are rare causes of nonimmune hydrops. Fetal hypothyroidism and hyperthyroidism can cause hydrops.[182,187] Hydrops can develop from maternal antibodies crossing the placenta, even if the pregnant patient has already been treated for Graves disease.[188]

Drugs

In utero exposure to **indomethacin** can result in ductus arteriosus constriction and, rarely, hydrops. Because of this, ultrasound evaluation of the ductus arteriosus should be performed within 48 hours of starting indomethacin therapy.[189]

Idiopathic Disorders

The number of idiopathic cases of nonimmune hydrops (for which we still cannot identify a cause) is about 10%[31,147] and will continue to decrease as our investigative abilities improve.

DIAGNOSTIC APPROACH TO HYDROPS

Systematic prenatal evaluation can establish a cause for nonimmune hydrops in up to 90% of cases.[147] This is important not only for the management of the current pregnancy but also for future genetic counseling.[148] A summary of the workup of hydrops is given in Table 41.3.

History

A detailed history may provide the first clues to the cause and may suggest appropriate investigations. For example, a maternal history of systemic lupus erythematosus or diabetes may be relevant, and homozygous α-thalassemia is particularly prevalent in patients of Southeast Asian origin. Blood type can supply a clue to isoimmunization. Maternal diseases with anemia or infection are important. Previous pregnancy losses may be related to one of the inborn errors of metabolism or chromosome rearrangements, and the family history or presence of consanguinity may suggest other genetic conditions. Parvovirus infection is more likely to occur in teachers or day-care workers.[190] Medication use can at times establish a cause.

Complete Obstetric Ultrasound

A comprehensive sonographic evaluation should be the initial step. However, no cause is found through use of sonography in 15% to 30% of cases. **Polyhydramnios** is a common association. A common indication for ultrasound is the clinical suspicion of being large for gestational dates. Collections of fluid in the pleural, peritoneal, and pericardial spaces are diagnostic, and their relative distribution and the timing of their development may give a clue to the cause.[191] Ultrasound markers of aneuploidy suggest

TABLE 41.3 Workup of Hydrops After Fetal Echocardiogram, Maternal History Including Family History, Medications, Exposures

Anatomic Survey		Maternal Tests	Additional Fetal Tests	Invasive Tests/ Treatment	Tests of Amniotic Fluid/ Fetal Blood
Structurally normal		Blood type Rh(D) antigen status Indirect Coombs test (antibody screen) Kleihauer-Betke test Parvovirus serology (other infections to consider: syphilis, CMV, toxoplasmosis)	MCA Doppler		
	Cardiac arrhythmia	Check Ro/La if bradyarrhythmia		Treat if tachyarrhythmia	
	No arrhythmia, MCA Doppler normal			Amniocentesis	Karyotype and/or chromosomal microarray; PCR for CMV and toxo AFAFP Lysosomal enzyme testing
	Anemia (MCA-PSV > 1.5 MoM)	MCV of parents to check for thalassemia (<80 suggests carrier status)		Amnio (at time of PUBS), transfuse if needed	Karyotype and/or chromosomal microarray PCR for CMV and toxo and parvovirus Consider G6PD, pyruvate kinase deficiency, lysosomal enzyme testing if no other cause
Structurally abnormal				Amniocentesis	Karyotype and/or chromosomal microarray, ± PCR for CMV, toxo, DNA testing for specific anomalies as indicated

a chromosomal cause. The degree of polyhydramnios should be assessed because this may pose an imminent threat of premature rupture of the membranes or preterm labor, and the cervix should be imaged to ensure there is no funneling or shortening.

A systematic detailed survey of fetal anatomy should be performed, searching for other clues to the cause of the hydrops. The fetal bladder should be visualized to exclude urinary ascites caused by bladder rupture. Bone length, curvature, density, and presence or absence of fractures should be evaluated to exclude skeletal dysplasias. Stigmata of congenital infection should be assessed, such as microcephaly or calcifications within the fetal brain or liver. A dedicated fetal echocardiographic structural and functional assessment is warranted to evaluate fetal heart structure, rhythm, and function in hydrops.

Maternal Investigations

Maternal blood type, indirect Coombs test (antiglobulin titer), and presence or absence of RBC antibodies should be checked to exclude immune hydrops. Other baseline tests include a complete blood count (CBC) and indices, Kleihauer-Betke test, infection screen (TORCH, parvovirus IgM/IgG), and glucose.

Fetal Investigations

Amniocentesis for fetal karyotype (if at an appropriate gestational age), antigen tests by PCR, and culture for syphilis, CMV, and toxoplasmosis are often indicated. MCA Doppler should be performed, with PUBS when the Doppler indicates anemia. Fluid aspirated from one of the fetal body cavities can also be used for fetal testing. The most appropriate choice depends on gestational age, accessibility, and urgency of results. A rapid karyotype can be obtained successfully from most collections of fetal body fluid.[192] **Fluorescent in situ hybridization** (FISH) can be used to identify common **aneuploidies** (trisomies 13, 18, and 21; monosomy X or Turner syndrome) and other specific deletions and chromosome rearrangements. This technique can provide a result from amniotic fluid in 24 to 48 hours.[193] In practice, the

confirmation or exclusion of the most common aneuploidies is often adequate to guide pregnancy management. Amniotic fluid is preferable for both viral culture and PCR for toxoplasmosis[167] and CMV, and it can be used to assess fetal lung maturity at later gestations. Chorionic villous sampling is an alternative at any gestation for obtaining a rapid karyotype or DNA testing.

Fetal blood sampling is a key investigation in many cases when the chromosomes do not provide a diagnosis. Basic fetal blood work should include a direct Coombs test, CBC and indices, karyotype, protein, albumin, and viral-specific IgM. Other tests are done selectively,[194,195] and samples can be stored for subsequent evaluation. With this approach, the cause of hydrops can be determined in most cases.

Performing PUBS

Cordocentesis has a 1% to 1.6% risk of fetal loss.[196-200] The fetal risks need to be interpreted knowing that these fetuses are at particularly high background risk for fetal loss and adverse outcomes. Ghidini et al.[200] performed a meta-analysis that excluded cases with pathologic fetal conditions and determined that the loss rate in a "low-risk" population undergoing fetal blood sampling was approximately 1.4%. A more recent study found that procedure-related complications of 3.1% and procedure-related loss rates of 1.6%.[196] Other complications of cordocentesis include fetal bradycardia (4%-12%), bleeding at puncture site (20%-40%), hematomas (17%), infection (1%), abruption (rare), fetomaternal hemorrhage (40%), and preterm contractions (7%).[196,198,200,201] Complications are more common with arterial than venous puncture.[199] In a recent report from Belgium, summarizing 14 years' experience,[202] 135 intrauterine transfusions were performed in 56 fetuses. There were no fetal or neonatal deaths. Mild adverse events were noted in 10% and severe events in 1.5%. Hydrops and transfusion in a free loop were associated with an increased risk of adverse events whereas gestational age at transfusion after 34 weeks was not. Besides phototherapy, 65% required additional neonatal treatment for alloimmune anemia. Nonhematologic complications occurred in 24% and were mainly related to preterm birth.

PUBS is recommended when the fetus is at substantial risk for severe fetal anemia (MCA-PSV > 1.5 MoM or hydropic), unless the pregnancy is at a gestational age when risks associated with delivery are considered to be less than those associated with the procedure.[203]

If it is anticipated that the fetus may require transfusion (e.g., parvovirus infection with elevated MCA Doppler velocity), it is prudent to have crossmatched blood and platelets ready to avoid the risks with a second procedure.

PUBS is usually performed in a setting that allows maternal sedation and intervention for fetal distress after 24 weeks, most often an operating room for labor and delivery. The patient is prepped and sterilely draped and the uterus displaced slightly to the left with appropriate maternal wedging. The ultrasound transducer is draped with a sterile sheath to allow guidance on the sterile field. The patient is often given conscious sedation for comfort and to minimize maternal movement during the procedure. Local anesthetic with lidocaine may be used for patient comfort. Ultrasound guidance may be provided by a second provider or by the operator using a freehand technique. A 20- to 22-gauge needle is typically used, and most often the umbilical vein is targeted at the **placental cord insertion** (Fig. 41.28). Other approaches include the **umbilical vein at the fetal cord insertion** or a **free loop of cord.** The needle position is confirmed by obtaining a blood specimen, ultrasound observation of the needle in the vein, and sonographic streaming within the umbilical vein after injection of saline. Heparinized syringes are used for fetal blood sampling, and values for hemoglobin/hematocrit, platelets, and mean corpuscular volume (MCV) are obtained. The fetal MCV (which should be >100 μm^3) is higher than the maternal value and can help confirm fetal origin of the blood sample.

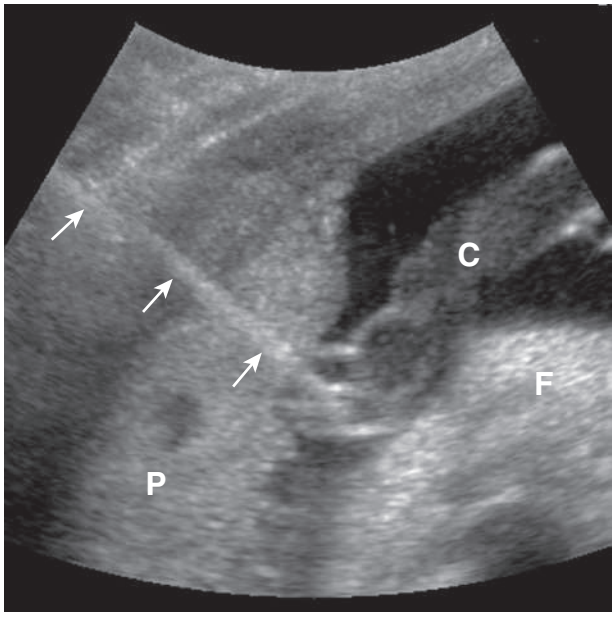

FIG. 41.28 Cordocentesis. Transverse ultrasound image shows needle *(arrows)* traversing placenta *(P)* and entering placental cord insertion. Note loop of umbilical cord *(C)* and fetus *(F)*.

Depending on the insertion site and indication for cordocentesis, fetal paralysis can be considered with vecuronium (0.1 mg/kg estimated fetal weight)[204] or atracurium besylate (0.4 mg/kg estimated fetal weight).[205] Fetal cardiac activity is documented throughout the procedure.

The fetal hematocrit is checked to determine the amount of transfusion needed (Hct < 30% is 2.5th centile >20 weeks). To limit the amount of fluid being transfused into the relatively small circulatory capacity of the fetus, packed RBCs (type O negative; Hct > 90%) are given. The goal is to transfuse to Hct of 40 mL/dL. Successful treatment of anemia with intravascular blood transfusion has been reported as early as 13 weeks' gestation.[145] When performing PUBS it is important to have a team involved that includes genetic counselors (regarding the underlying cause of anemia), laboratory medicine professionals (to check the MCV and have packed RBCs available), and maternal fetal medicine specialists as well as individuals familiar with guidance for procedures with ultrasound.

When PUBS is not possible, particularly at early gestational age when the umbilical cord is small and difficult to safely

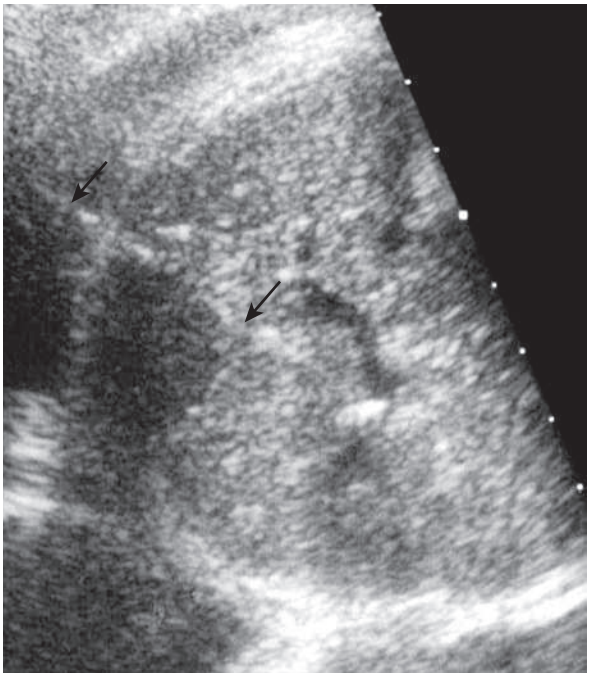

FIG. 41.29 Fetal Blood Sampling in Intrahepatic Portion of Umbilical Vein. Arrows point to the position of the 20-gauge needle in the intrahepatic portion of the umbilical vein.

instrument, intraperitoneal, intrahepatic (Fig. 41.29), or intracardiac transfusion can be performed.[206]

Fetal Transfusion

If fetal transfusion is required, T-connector tubing is often employed for ease of transfusion. The volume to be transfused can be calculated by using the following formula[207]:

$$\text{Volume}_{\text{transfused}}\ (\text{mL}) = \text{Volume}_{\text{fetoplacental unit}}\ (\text{mL}) \times \left[\frac{\text{Hematocrit}_{\text{final}} - \text{Hematocrit}_{\text{initial}}}{\text{Hematocrit}_{\text{transfused blood}}}\right]$$

The fetoplacental volume can be estimated as 1.046 + fetal weight in grams × 0.14.[207] Either maternal cells or donated O-negative, washed, leukocyte-reduced blood is used for transfusion. Maternal cells may be consumed less rapidly than anonymous donation, but timing and pregnancy-associated anemia limit its use.[208] A posttransfusion sample is obtained to evaluate the effects of the procedure. Future transfusions are scheduled based on fetal Doppler assessment[26] or by estimating a 0.7% decrease in the hematocrit per day and scheduling transfusion for estimated hematocrits of 20 to 22 mL/dL.[209]

If the cordocentesis or transfusion is being performed for reasons other than Rh(D) isoimmunization, in a Rh(D)-negative mother, RhoGAM should be administered after the procedure.

Cavity Aspiration

The clinician can usually advance the needle easily into the fetal chest, abdomen, or amniotic fluid at the time of fetal blood sampling or amniocentesis (Fig. 41.30). This can be both diagnostic (e.g., lymphocyte count in chylothorax or for rapid karyotype) and occasionally therapeutic. Simultaneous sampling does not increase the overall procedure risk.

Postnatal Investigations

After birth, the **placenta** should be sent for pathologic analysis, and a **skeletal survey** may be helpful. A geneticist may see the neonate to provide additional input. In cases of death, detailed **autopsy** and placental examination, correlated with antenatal findings, is the best way to determine the cause of nonimmune hydrops.[210,211] Further investigations may be prompted by additional physical findings at autopsy.[212] If a metabolic condition is suspected as the cause of hydrops, inclusion bodies can be sought on microscopy. In some series the cause of hydrops was identified in only 40% to 50% of patients without autopsy,[135] versus 80% to 90% after postmortem examination.[210,213]

FETAL WELFARE ASSESSMENT IN NONIMMUNE HYDROPS

Noninvasive ultrasound techniques for fetal well-being assessment in pregnancies complicated by nonimmune hydrops include biophysical assessment, pulsed Doppler velocimetry of umbilical and regional fetal vessels, and functional cardiac assessment. Fetal Doppler evaluation may give some indication of anemia, cardiac failure, and well-being.[25] Umbilical vein and intrahepatic vein pulsations, or ductus venosus *a*-wave reversal, represent cardiac diastolic dysfunction and have been correlated with poor perinatal outcomes.[214]

OBSTETRIC PROGNOSIS

The overall **mortality** rate among fetuses with nonimmune hydrops is approximately 70%,[31] with mortality in cases of structural abnormalities not amenable to therapy as high as 100%. In a series of 100 cases of nonimmune hydrops, 74 were thought to have a nontreatable cause, and none of these resulted in a live birth; of 26 with a treatable cause, 18 resulted in a live birth and were alive at 1 year of age.[31] Gestational age at diagnosis of hydrops has been used to predict outcome. A 10-year review of 82 cases presenting after 20 weeks[135] reported an overall mortality rate of 87%, and those diagnosed after 24 weeks were more likely to be idiopathic or related to cardiothoracic abnormalities. Spontaneous resolution of hydrops has been reported in fetuses with normal chromosomes diagnosed before 24 weeks.

Although the overall prognosis for fetal hydrops has improved in recent years, most series are small with a mixture of causes and thus are difficult to compare. Some improvement in outcome over earlier reports is attributable to the growing number of cases that are amenable to in utero therapy. Unfortunately, many cases still represent a terminal process. Earlier identification and referral, thorough evaluation, and fetal therapy in appropriate cases are the cornerstone to further improvements in prognosis. Obtaining the best diagnosis is helpful in counseling about recurrence risks.

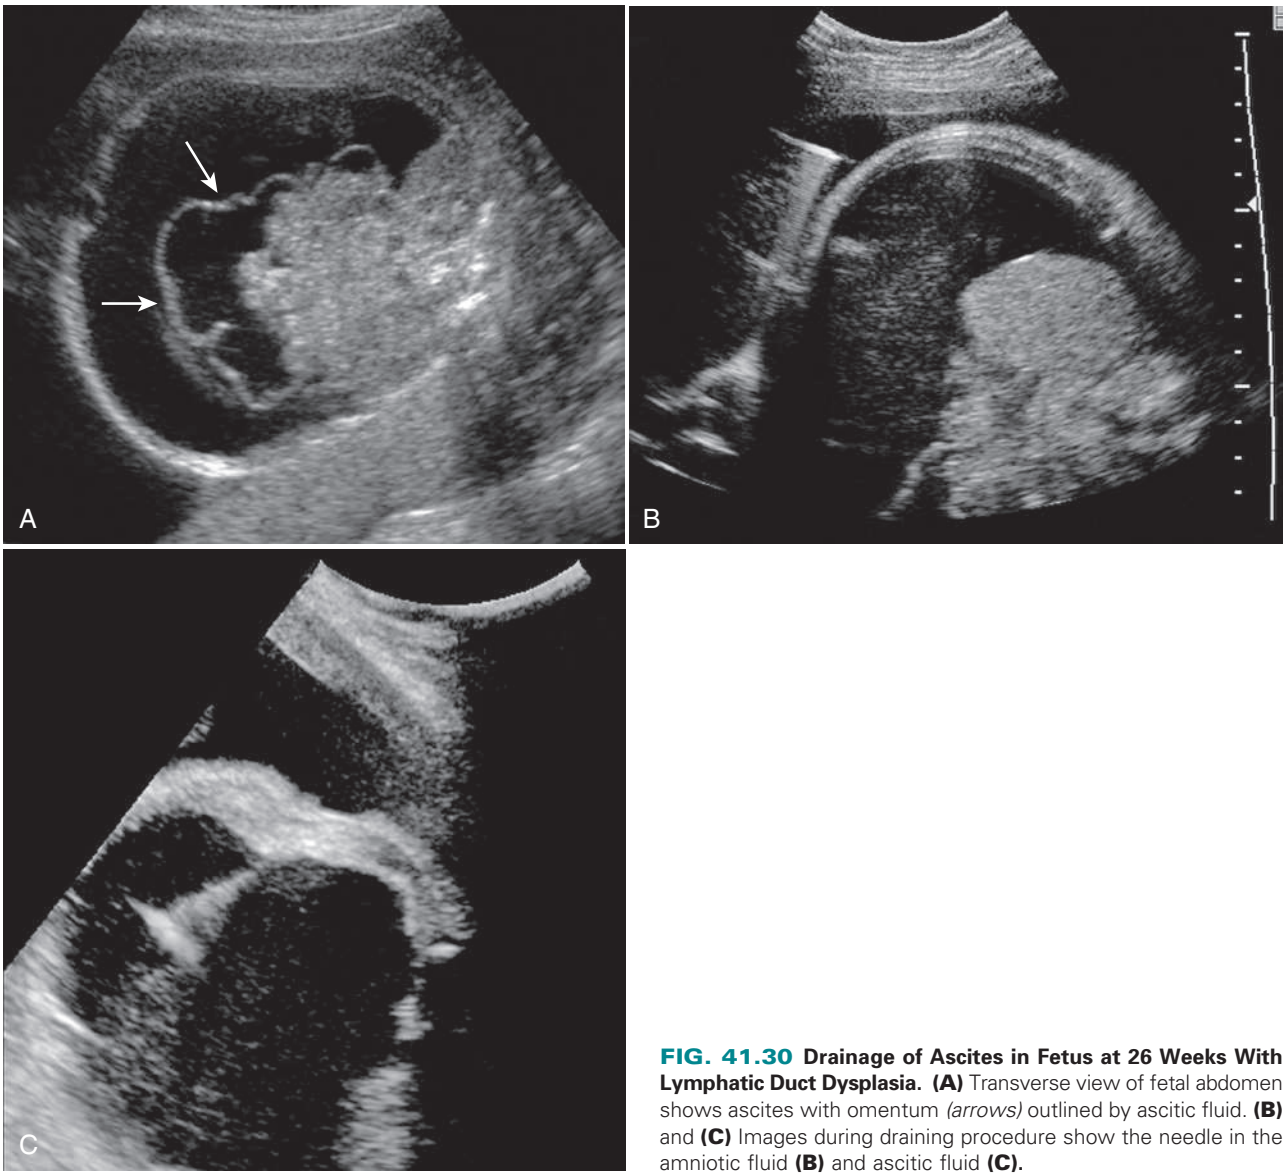

FIG. 41.30 Drainage of Ascites in Fetus at 26 Weeks With Lymphatic Duct Dysplasia. (A) Transverse view of fetal abdomen shows ascites with omentum *(arrows)* outlined by ascitic fluid. **(B)** and **(C)** Images during draining procedure show the needle in the amniotic fluid **(B)** and ascitic fluid **(C)**.

Maternal Complications (Mirror Syndrome)

Maternal complications may occur in association with fetal hydrops. Hypoproteinemia, edema, weight gain, hypertension, oliguria, and **preeclampsia** may develop.[215] This association has been termed **mirror syndrome** because edema in the pregnant patient mirrors that of the hydropic fetus.[34,216,217] The syndrome has been described in conjunction with hydrops of various causes.[215,218,219] Perinatal mortality and morbidity rates are high. Maternal outcome can be improved by delivery of the fetus and placenta or by fetal intervention to treat the cause of the hydrops.[217,220-222] If hydrops cannot be cured, delivery may limit the risk of maternal complications.[35,222]

Espinoza et al.[223] recently suggested the high plasma concentrations of soluble vascular endothelial growth factor receptor 1 (sVEGFR-1) is implicated in the pathophysiology of mirror syndrome. Hypoxia of the villous trophoblast in cases of villous edema leads to increased production and release of sVEGFR-1 and other antiangiogenic factors into the maternal circulation. Excessive concentrations of these products may be responsible for maternal edema in mirror syndrome.

Delivery

Mode and location of delivery are based on obstetric factors, taking into account the underlying prognosis.[224] Uterine overdistention in severe polyhydramnios carries the risks of **placental abruption** and **cord prolapse** after membrane rupture and **postpartum hemorrhage** from uterine atony. Prematurity secondary to polyhydramnios is a major contributing factor to the poor outcome of some neonates. **Therapeutic amniocentesis** before induction of labor may be considered in cases with massive polyhydramnios to decrease the risk of malpresentation or cord prolapse. **Indomethacin** has also been used to decrease the amniotic fluid volume.[225] This drug should be used with caution after 32 weeks' gestation because of the potential for ductal constriction.

Predelivery Aspiration Procedures

Fetal fluid collections may be drained under ultrasound guidance just before delivery to assist with **neonatal resuscitation.** This is particularly relevant if large fetal pleural effusions are present.[115] Massive ascites may also be drained to prevent abdominal dystocia (when vaginal birth is planned) and aid in fetal breathing when ascites has caused elevation of the diaphragms.

Postnatal Outcome

Because of the high incidence of in utero demise, the cause of hydrops in utero is different from that with a live neonate. In a review of 30 cases of hydrops diagnosed between 10 and 14 weeks of pregnancy, all pregnancies with nonimmune hydrops resulted in abortion, intrauterine fetal death, or pregnancy termination.[136] A 2007 national database review of live-born neonates with hydrops found heart problems (13.7%), abnormalities in heart rate (10.4%), TTTS (9%), congenital anomalies (8.7%), chromosomal abnormalities (7.5%), congenital viral infections (6.7%), isoimmunization (4.5%), and congenital chylothorax (3.2%).[226] Mortality rates were highest among neonates with congenital anomalies (57.7%) and lowest among those with congenital chylothorax (5.9%), and a cause could not be determined in 26%. Factors associated independently with death were younger gestational age, low 5-minute Apgar score, and high levels of support needed the first day after birth.[226] This study reported a 36% death rate before discharge or transfer to another hospital. The severity of hydrops and birth gestational age of the infant are the key determinants for survival. This is important because delivering a fetus early to treat worsening hydrops may not improve survival.

Data are limited regarding long-term outcome of children surviving after hydrops. In one series, 13 in 19 (68%) children surviving beyond 1 year of age were normal; two had mild developmental delay at 1 year of age; one 8-year-old child was mentally retarded; and three (16%) had severe psychomotor impairment with marked growth failure.[227] Haverkamp et al.[228] found that 86% of patients had normal psychomotor development, 86% showed normal neurologic status, 7% had minor neurologic dysfunction, and 4% had spastic cerebral paresis.

CONCLUSION

Hydrops represents a terminal stage for many conditions, the vast majority of which are fetal in origin. The onset of hydrops signifies fetal decompensation. Immune causes can be successfully treated in utero, as can an increasing number of nonimmune causes. Whereas in the past, nonimmune hydrops carried virtually 100% mortality, this is no longer the case. A team approach using obstetric imagers, maternal fetal medicine specialists, neonatologists, and geneticists can help to decide which cases are suitable for therapeutic intervention. A comprehensive approach must be taken to the investigation of hydrops, both for the management of the index case and for future counseling. Cornerstones of this investigation are detailed ultrasound, including echocardiography, fetal karyotyping, and other diagnostic interventions as appropriate, and pathologic examination of the fetus and placenta.

CHAPTER 42

Fetal Measurements: Normal and Abnormal Fetal Growth and Assessment of Fetal Well-Being

Carol B. Benson and Peter M. Doubilet

SUMMARY OF KEY POINTS

- Accurate assignment of gestational age to a pregnancy is important for several reasons, including timing of screening tests for aneuploidy, monitoring fetal growth and diagnosing growth disturbances, and scheduling of delivery by elective induction or cesarean.
- If a woman has more than one sonogram during her pregnancy, the pregnancy should not be redated after the first scan; instead, the gestational age at the time of subsequent scans is the age at initial scan plus the time elapsed since that scan.
- In the first trimester, dating by sonographic findings or mean sac diameter prior to 6.0 weeks' gestation has an accuracy of ±0.5 weeks, while dating by crown-rump length at 6.0 weeks or later has an accuracy of ±0.7 weeks.
- Sonographic dating in the second and third trimesters has an accuracy of ±1.2 weeks at 14 to 20 weeks, ±1.9 weeks at 20 to 26 weeks, ±3.1 to 3.4 weeks at 26 to 32 weeks, and ±3.5 to 3.8 after 32 weeks.
- Fetal weight is estimated using a formula that incorporates measurements of the fetal head, abdomen, and femur and has an accuracy (95% confidence range) of ±15% to 18%.
- Estimated fetal weight should be assessed in relation to gestational age to determine whether the fetus is appropriate in size for gestational age.
- If a fetus is diagnosed as small-for-gestational-age, with an estimated fetal weight less than 10th percentile for gestational age, an attempt should be made to determine the cause through evaluation of both mother and fetus.
- When a fetus is suspected of being growth restricted, antenatal surveillance with biophysical profiles and fetal Doppler can guide management and improve outcome.

Summary of Fetal Doppler

Sonographic measurements of the fetus provide information about fetal age and growth. These data are used to assign gestational age, estimate fetal weight, and diagnose growth disturbances. As discussed in other chapters, fetal measurements are also used in the diagnosis of a number of fetal anomalies, such as skeletal dysplasias[1] and microcephaly.[2] Each of these abnormalities can be diagnosed or suspected on the basis of measurements that deviate from the "normal for dates."

It is important to begin by defining the various terms used in the evaluation of the age of a pregnancy. The true measure of a pregnancy's age is the number of days since conception, termed **conceptual age.** Historically, however, pregnancies were dated by the number of days since the first day of the last menstrual period (LMP), termed **menstrual age,** because for most of human history it was unknown when conception occurred. In women with regular 28-day cycles, menstrual age

is 2 weeks more than conceptual age, because conception occurs approximately 2 weeks after the LMP in such women. Currently, the term most often used to date pregnancies is **gestational age,** which is similar to menstrual age and is defined as follows:

$$\text{Gestational age} = \text{Conceptual age} + 2 \text{ weeks}$$

In women with 28-day cycles, gestational age and menstrual age are equal. In women with longer cycles, gestational age is less than menstrual age; the opposite holds in women with shorter cycles.

Accurate knowledge of gestational age is important for a number of reasons. The timing of screening tests in the first trimester, such as nuchal translucency measurement and maternal cell free fetal DNA analysis,[3,4] genetic amniocentesis in the second trimester, and elective induction or cesarean delivery in the third trimester are all based on the gestational age. The differentiation between term and preterm labor and the characterization of a fetus as "postdates" depend on gestational age. Knowledge of the gestational age can be critical in distinguishing normal from pathologic fetal development. Midgut herniation, for example, is normal up to 11 to 12 weeks of gestation[5] but signifies omphalocele thereafter. The normal size of a variety of fetal body parts depends on gestational age, as do levels of maternal serum alpha-fetoprotein,[6] human chorionic gonadotropin,[7] and estriol.[8] When a fetal anomaly is detected prenatally, the maternal choices and obstetric management are significantly influenced by gestational age.

Estimation of the fetal weight, on its own and in relation to the gestational age, can influence obstetric management decisions concerning the timing and route of delivery. A fetus growing poorly may benefit from close monitoring of fetal well-being to determine if early delivery is indicated. Such a fetus may be inadequately supplied by its placenta with oxygen and nutrients and, therefore, may do better in the care of a neonatologist than in utero. When a fetus is large, cesarean may be the preferred route of delivery, particularly in pregnancies complicated by maternal diabetes. In view of these considerations, fetal measurements should be a component of every complete obstetric sonogram.[9]

The well-being of the fetus at risk for perinatal morbidity and mortality, such as a growth-restricted fetus, can be monitored by ultrasound using the biophysical profile and Doppler. Abnormalities and changes in any of these surveillance tests may guide decisions about timing of delivery.[10,11]

GESTATIONAL AGE DETERMINATION

Clinical dating of a pregnancy is usually based on the patient's recollection of the first day of her LMP and on physical examination of uterine size. Unfortunately, both of these methods are imprecise, leading to inaccuracies in gestational age assignment. Dating by LMP (menstrual age) may be inaccurate because of variability in length of menstrual cycles, faulty memory,[12,13] recent exposure to oral contraceptives, or bleeding during early pregnancy.[14] Determining gestational age from the palpated dimension of the uterus may be affected by uterine fibroids, multiple pregnancy, and maternal body habitus.

Clinical dating is accurate only if either of the following two conditions apply: (1) the patient is a good historian with regular menstrual cycles, and the uterine size correlates closely with LMP; or (2) information is available specifying the time of conception, such as a basal body temperature chart or pregnancy achieved via assisted reproductive technologies in women treated for infertility.

Ultrasound provides an alternative and, in many cases, superior approach to gestational age estimation. Sonographic age estimation is based on sonographic findings or measurements taken during the ultrasound examination. Because biologic variability in the size of fetuses increases as pregnancy progresses, the accuracy of sonographic age estimates declines as pregnancy proceeds.[15-28] Thus, if a woman has more than one sonogram during a pregnancy, the pregnancy should never be redated after the first scan.

The decision as to whether to use clinical dating or sonographic dating at the time of the first scan is not well established for all pregnancies. In some cases, though, the decision is clear-cut: pregnancies achieved via *in vitro* fertilization should be dated based on the embryo transfer dates, and naturally conceived pregnancies in women with irregular menstrual cycles or with poor recollection of their LMP should be dated based on sonographic criteria. In other situations, however, particularly for pregnancies conceived naturally in women with regular cycles and good recollection of LMP, there are two reasonable alternatives. The first approach is to date the pregnancy based on LMP whenever the ages based on LMP and sonography are close to one another: within 5 days up to 8.9 weeks; within 7 days from 9.0 weeks to 15.9 weeks; within 10 days from 16.0 weeks to 21.9 weeks; within 14 days from 22.0 weeks to 27.9 weeks; and within 21 days from 28.0 weeks onward.[16] An alternative approach is to use sonographic dating routinely up to 24 weeks and the LMP thereafter, if the LMP is clearly recalled and within 21 days of sonographic dating.[15]

Whichever approach is used, it is important to know what sonographic criteria are available for gestational age estimation and which are the most accurate at each stage of pregnancy.

First Trimester

Sonographic findings and measurements allow highly accurate dating from 5 weeks' gestation until the end of the first trimester. The earliest sign of an intrauterine pregnancy is identification of a **gestational sac** in the uterine cavity. This appears as a round or oval fluid collection within the uterine cavity first seen on transvaginal sonography at approximately 5 weeks' gestation.[29] In some cases, the early gestational sac is surrounded by one or two echogenic rings, formed by the proliferating chorionic villi and the deeper layer of the decidua vera.[30,31] These rings are not consistently present, however, and any round or oval fluid collection in the mid uterus of a woman with a positive pregnancy test is highly likely to be a gestational sac[32] (Fig. 42.1).

From 5 to 6 weeks' gestation, two methods can be used to assign gestational age by ultrasound: (1) measurement of **mean sac diameter** (MSD) or (2) sonographic identification of gestational sac contents. The MSD is calculated as the average of the anteroposterior diameter, the transverse diameter, and the longitudinal diameter. It increases from 2 mm at 5 weeks to

FIG. 42.1 Gestational Sac. At 5.0 weeks' gestation, gestational sac *(arrow)* appears as a small, intrauterine fluid collection.

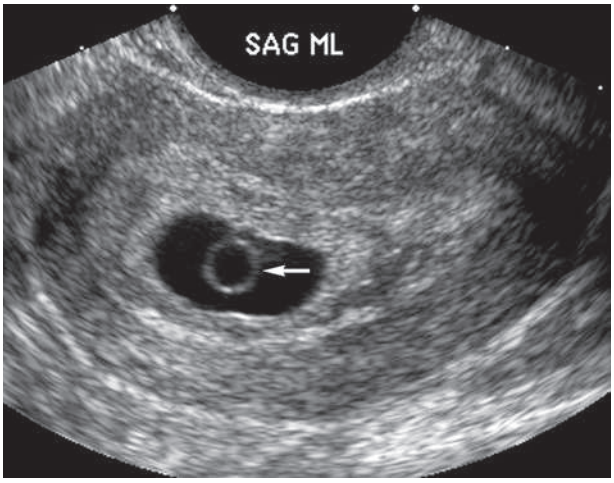

FIG. 42.2 Yolk Sac. Gestational sac contains yolk sac *(arrow)* on transvaginal sonogram at 5.5 weeks' gestation. No embryo is seen. *SAG ML,* Sagittal midline.

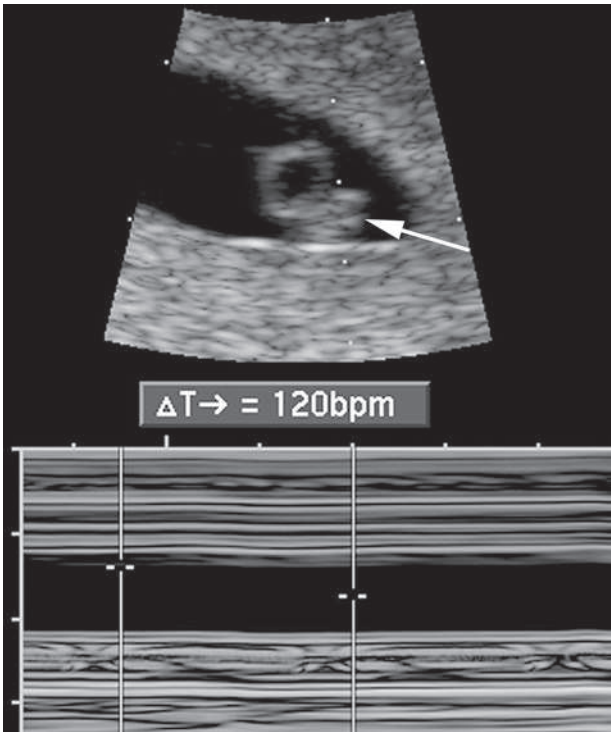

FIG. 42.3 Embryonic Heartbeat. Transvaginal sonogram and M-mode at 6 weeks demonstrate cardiac activity originating from tiny embryo *(arrow)* adjacent to the yolk sac. See also Video 42.1.

10 mm at 6 weeks,[33] a growth pattern that can be used to assign gestational age during this period (Table 42.1).

The second method, based on the sonographic findings within the gestational sac, is best done by transvaginal sonography and relies on the observation that, on average, the gestational sac is first identifiable at 5.0 weeks, the **yolk sac** at 5.5 weeks (Fig. 42.2), and the embryo and **embryonic heartbeat** at 6.0 weeks[34] (Fig. 42.3, Video 42.1). The timing of these milestones is subject to minimal variability, with a 95% confidence range of approximately 0.5 weeks.[31] Gestational age can be assigned based on these milestones (Table 42.2).

From 6 weeks until the end of the first trimester, gestational age correlates closely with the **crown-rump length** (CRL) of the embryo or fetus.[35,36] The term **embryo** is commonly used up to 10 weeks' gestation, and the term **fetus** applies thereafter.[37] The CRL is the length of the embryo or fetus from the top of its head to the bottom of its torso. It is measured as the longest dimension of the embryo, excluding the yolk sac and extremities. From 9 or 10 weeks onward, the CRL measurements are most accurate if taken with the fetus in neutral position[38] (Fig. 42.4). The CRL can be used to assign gestational age accurately up to 14 weeks because there is little biologic variability in fetal length up until that age[39] (Table 42.3). After that point, the CRL of the longer, more developed fetus becomes less reliable. At this later stage, the CRL is affected by the fetal position, measuring shorter in a fetus whose spine is flexed and longer in a fetus whose spine is extended.

TABLE 42.2 Gestational Dating by Ultrasound in the First Trimester

Sonographic Finding	Gestational Age (Weeks)
Gestational sac, no yolk sac, embryo, or heartbeat	5
Gestational sac with yolk sac, no embryo or heartbeat	5.5
Gestational sac with heartbeat and embryo <5 mm in length	6
Embryo/fetus ≥5 mm in length	Age based on crown-rump length (see Table 42.3)

FIG. 42.4 Crown-Rump Length Measurement. Cursors delineate the length of the fetus from the top of its head to the bottom of its torso.

Second and Third Trimesters

Many sonographic parameters have been proposed for estimating gestational age in the second and third trimesters. These include several fetal measurements: **biparietal diameter** (BPD),[40,41] **head circumference** (HC),[42] **abdominal circumference** (AC),[43] **femur length** (FL),[25,44-46] as well as combinations of two or more fetal measurements: the **corrected-BPD**[41] and **composite age formulas.**[43,47] Measurements of structurally abnormal fetal body parts should not be used in the assignment of gestational age.

Fetal Head Measurements

Three measurements or parameters involve the fetal head: BPD, **occipitofrontal diameter** (OFD), and HC. All three measurements are taken from transaxial sonograms of the fetal head at the level of the paired thalami and cavum septi pellucidi[48] (Fig. 42.5). These head measurements are most accurate if the image is a true axial plane demonstrating the head as oval with symmetry of the thalami and cerebral hemispheres and without visualization of the posterior fossa.[49] The BPD is measured from the outer edge of the cranium nearest the transducer to the inner edge of the cranium farthest from the transducer ("leading edge to leading edge") (Fig. 42.5). The OFD is obtained from the same transaxial image as the BPD and is measured from mid-skull to mid-skull along the long axis of the fetal head (Fig. 42.5). This latter measurement is used in conjunction with the BPD to calculate the corrected-BPD using the following formula[41]:

$$\text{Corrected-BPD} = \sqrt{(\text{BPD} \times \text{OFD})/1.265}$$

Note how the calipers for the BPD are placed from the outer aspect of the skull to the inner aspect of the skull, "leading edge to leading edge."

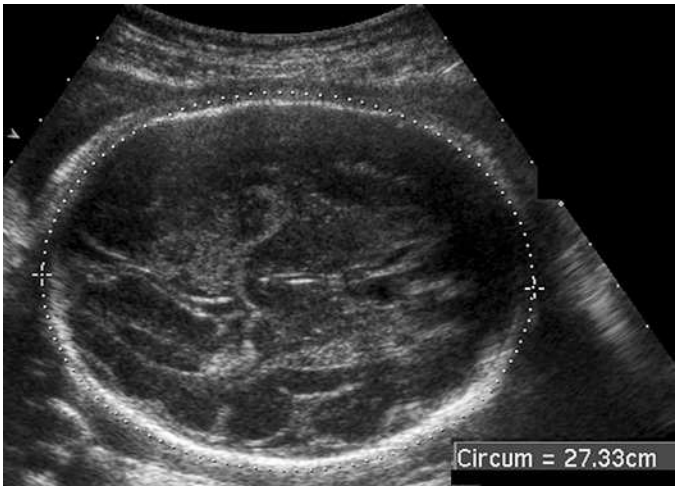

FIG. 42.6 Head Circumference (HC) Measurement. HC measurement (*calipers* and *tracing dots*) on transaxial sonogram of the fetal head at the same level as for the biparietal diameter measurement. Note how the HC measurement is obtained by tracing around the bone.

The rationale for the corrected-BPD is that it represents the BPD of the standard-shaped head (one with an OFD/BPD ratio of 1.265) of the same cross-sectional area.[41] The same tables or formulas used to determine gestational age from the BPD are used to determine gestational age from the corrected-BPD (Table 42.4).

The HC is the length of the outer perimeter of the cranium, made on the same transaxial image of the fetal head. It can be measured by using an electronic ellipse[50] (Fig. 42.6, Table 42.5) or calculated from the outer-edge-to-outer-edge analogs of the BPD and OFD:

$$HC = 1.57 \times [(\text{Outer-to-outer BPD}) + (\text{Outer-to-outer OFD})]$$

BPDc, Corrected-BPD.
Values from Doubilet PM, Benson CB. Improved prediction of gestational age in the late third trimester. J Ultrasound Med. 1993;12(11):647-653.[44]

Although the BPD is simpler to measure than the corrected-BPD or HC, it has the disadvantage of being the only one of the three measurements that disregards head shape. This means that two heads of equal widths but different lengths will have the same BPD, but the longer head will have a greater corrected-BPD and HC than the shorter head (Fig. 42.7). The fetus with the longer head will therefore be assigned a greater gestational age based on the corrected-BPD or HC; however, both fetuses will

be assigned the same gestational age if the BPD is used as the basis for age assignment.

Femur Length

The length of the ossified diaphysis of the fetal femur is often used for gestational age estimation.[25,41,45] Careful measurement technique is necessary to obtain an accurate estimate of gestational age by FL (Fig. 42.8, Table 42.6). The transducer must be aligned to the long axis of the diaphysis, perpendicular to the beam, with both ends of the ossified diaphysis appearing squared off. The cursors should be positioned at the junction of the echogenic bone with the hypoechoic cartilage, and the thin, bright reflection of the cartilaginous epiphysis should not be included in the measurement.[49,51]

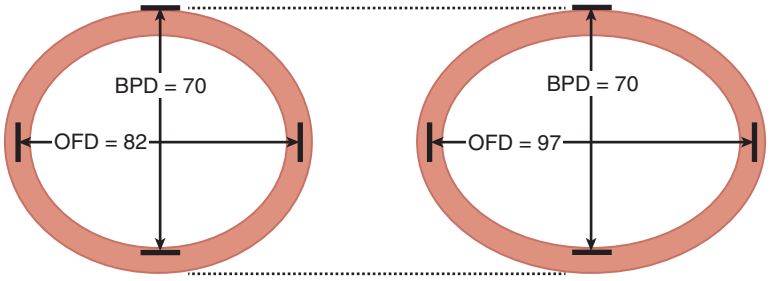
Abdominal Circumference

The fetal AC is the length of the outer perimeter of the fetal abdomen, measured on transverse view at the level of the intrahepatic portion of the umbilical vein. Ideally the stomach will also be visible (Fig. 42.9). Ideally, the abdomen should appear round. The level chosen should demonstrate only a short segment of the umbilical vein in the anterior third of the liver. Measurement of the AC involves placing the ellipse along the outer skin surface[49] (Fig. 42.9A). Alternatively, the AC may be calculated from two orthogonal **abdominal diameters** (AD_1, AD_2), one anteroposterior and the other transverse (Fig. 42.9B), measured on the same image, as follows[50,52]:

$$AC = 1.57 \times (AD_1 + AD_2)$$

Composite Formulas

Gestational age can be estimated from measurements of the head, abdomen, or femur by means of tables or formulas that present the mean value of each measurement for a given gestational age (Tables 42.4 to 42.6). Composite age formulas that combine several fetal measurements can also be used to estimate gestational age.[25,47]



A Corrected BPD = 67 HC = 250

B Corrected BPD = 73 HC = 274

FIG. 42.7 Effect of Head Shape on Corrected-BPD and HC. Heads **A** and **B** have equal biparietal diameters *(BPD),* but **A** has a smaller occipitofrontal diameter *(OFD)* than **B.** Therefore the corrected-BPD and head circumference *(HC)* are smaller for **A** than **B.** Based on BPD, fetuses **A** and **B** would be assigned the same gestational age. Based on corrected-BPD or HC, however, fetus **A** would be assigned a lower gestational age than fetus **B.**

FIG. 42.8 Femur Length Measurement. Electronic calipers measure the ossified diaphysis of the femur. Note how the bone is imaged parallel to the transducer.

Because composite age formulas use a combination of two or more measurements in conjunction to estimate gestational age, a potential disadvantage of using such formulas is that an abnormal measurement or anomaly might be obscured. For example, in a fetus with a skeletal dysplasia manifested by shortened long bones and a normal head size, the gestational age based on the composite formula will be an underestimation, falling between that predicted by the HC and that predicted by the short FL. As a result, the FL might not appear to be abnormally small when compared to this improperly calculated gestational age.

Gestational Age Estimation by Ultrasound: Most Accurate Approach at Each Stage of Pregnancy

When sonographic, as opposed to clinical, dating is used to assign gestational age, it is important to use the most accurate method or measurement available (Table 42.7). This is most relevant at the time of the initial scan in a woman's pregnancy, since, as noted previously, it is inappropriate to reassign gestational age at the time of the second or subsequent scan during the pregnancy.

If the initial scan is performed in the early first trimester, when ultrasound demonstrates no embryo or an embryo less than 5 mm in length, two approaches to gestational age assignment are equal in accuracy, both with 95% confidence ranges of ±0.5 weeks: date the pregnancy based on MSD (see Table 42.1) or on sac contents (see Table 42.2). For the rest of the first trimester, when the CRL measures 5 to 80 mm, dating based on CRL (see Table 42.3) is very accurate, with a 95% confidence range of ±0.7 weeks.[53]

In the second and third trimesters, there are several options for sonographic dating, including measurements of the head, femur, or abdomen, as well as composite formulas based on measurements of two or more of these. When both the width and length of the head (BPD and OFD) are visible, the optimal approach to sonographic age assignment in the second trimester is to use either the corrected-BPD or the HC, and, in the third trimester, use the corrected-BPD, the HC, or the FL. When either the anterior or posterior aspects of the cranium are not well seen on ultrasound, so that the OFD and HC cannot be measured accurately, it is best to date based on the BPD or FL in the second trimester and on the FL in the third trimester.[44,54,55] These approaches are the most accurate single-body-part sonographic dating methods and are preferable to composite age formulas for reasons presented earlier.

TABLE 42.6 Gestational Age Estimation by Femur Length (FL)

Sonographic prediction of gestational age: accuracy of second- and third-trimester fetal measurements. AJR Am J Roentgenol. 1991;157(6):1275-1277.[54]

WEIGHT ESTIMATION AND ASSESSMENT

Before the availability of ultrasound, manual examination of the maternal abdomen was the approach used to estimate fetal size. The physical examination, however, provides only a general approximation of fetal weight because the palpated dimensions of the uterus are affected by several factors other than fetal size, including amniotic fluid volume, presence of fibroids, and maternal obesity.

Sonographic measurements of fetal body parts provide a direct way of assessing fetal weight and are used mainly in the third trimester. The approach to fetal weight estimation and assessment involves a number of steps: (1) estimate the fetal weight based on fetal measurements; (2) estimate the gestational age using the approach described earlier; (3) determine the weight percentile for gestational age using a formula or chart of weight norms as a function of gestational age; (4) if the fetus is above the 90th percentile or above 4000 g estimated weight, consider options for route of delivery; (5) if the weight is at or below the 10th

percentile, attempt to determine whether the fetus is constitutionally small or small because of a pathologic etiology, then manage the pregnancy accordingly.

Estimation of Fetal Weight

Numerous formulas have been published for estimating fetal weight based on sonographic measurements, most of which use one or more of these fetal body parts: head (BPD or HC), abdomen (AD or AC), and femur (FL).[19-24,26-28,56] Other measurements, such as thigh circumference, have been used as well.[28] Formulas that estimate fetal weight using three-dimensional (3D) sonography[57-59] and 3D magnetic resonance imaging (MRI) have also been published.[60,61]

The accuracy of a weight prediction formula is determined by assessing how well the formula works in a group of fetuses scanned close to delivery. An important measure of a formula's performance is its 95% confidence range. If the 95% confidence range is ±18%, for example, the estimated weight will fall within 18% of the actual weight in 95% of cases, and the error will be greater than 18% in only 5% of cases. The narrower the confidence range is, the more reliable is the formula.

Many published studies provide information on this measure of a formula's accuracy[62-65] (Table 42.8). The following points are noteworthy:

TABLE 42.8 Accuracy of Fetal Weight Prediction Formulas

Head, abdomen, femur, and thigh	Vintzileos et al.[28]	±15.6-17.8[28]

[a]Computed as two standard deviations (2 SD) of the relative error, as reported in the study(ies) referenced, unless otherwise indicated.
[b]Based on the fraction of cases in which the estimated weight falls within 10% of the actual weight.

- The accuracy of weight prediction formulas improves as the number of measured body parts increases up to three, achieving greatest accuracy when measurements of the head, abdomen, and femur are used. There is no apparent improvement by adding the thigh circumference as a fourth measurement[66] and no proven benefit from using 3D sonography or MRI.
- Even when based on measurements of the head, abdomen, and femur, sonographic weight prediction has a rather wide 95% confidence range of at least ±15%. Based on the abdomen and either the head or femur, the range is at least ±16% to 18%. Precision is considerably worse when only the abdomen is used.
- A number of factors have been studied to determine their effect on accuracy of weight prediction. Accuracy appears to be worse in fetuses that weigh less than 1000 g than in larger fetuses.[63] Over the rest of the birth weight range, however, accuracy is fairly constant.[26,56,62,67] Weight prediction is less accurate in diabetic than in nondiabetic mothers: in diabetic mothers, formulas that use measurements of the head, abdomen, and femur have a 95% confidence range of ±24%,[68] wider than the range of ±15% in the general population.[26,56] The presence of oligohydramnios or polyhydramnios has no impact on accuracy.[23,63,69] Scan quality may have an effect on accuracy. Studies have shown a trend toward greater accuracy in scans that were rated "good" compared with those rated "poor" based on ability to visualize anatomic landmarks.[63,70]

Recommended Approach

An attempt should be made to image all three key fetal anatomic regions—head, abdomen, and femur—at the appropriate anatomic levels (Table 42.9). If measurements of all three structures can be obtained, Formula 1 in Table 42.9 should be used to estimate fetal weight. This formula should be used with the corrected-BPD when the OFD is available, and with the BPD itself if not. An alternative approach, equally accurate but more cumbersome, would be to use Formula 1 when the OFD is unavailable, and a formula based on HC, AC, and FL when the OFD is available. If the abdomen and only one of the head or the femur can be appropriately imaged, Formula 2 or 3 should be used. If the abdomen cannot be measured, or both the head and femur cannot be measured, then a weight estimate should not be calculated. Using the approach outlined in Table 42.9, an accuracy of ±15% to 18% can be achieved for weight estimation.

Weight Assessment in Relation to Gestational Age

When an ultrasound is performed in the third trimester, best estimates of gestational age and fetal weight should be established. The gestational age may be based on a prior ultrasound, clinical dating criteria, or current measurements; fetal weight is always calculated from current measurements. The two values should be assessed in relation to one another to determine whether the fetus is appropriate in size for dates. This can be accomplished by using a table that provides norms for fetal weight as a function

of gestational age (Table 42.10), several of which appear in the literature.[71-76]

There is some debate about a number of aspects of fetal weight assessment in relation to gestational age. Should a weight table or chart based on neonatal weights or on estimated fetal weights be used? Should the table or chart be derived solely from pregnancies of low-risk mothers? Should "population norms" or "customized norms" be used?

Most weight norms (tables or charts) are derived from large data sets of neonatal birth weights from babies born at a known gestational age.[71-76] At least one chart, on the other hand, was produced using estimated fetal weights instead of neonatal birth weights.[77,78] A rationale for the latter is that several studies have shown that fetuses that deliver preterm are smaller, on average, than those of the same gestational age that remain in utero.[79-83] Babies born preterm thus represent an abnormal group with a negatively skewed weight distribution. This supports the argument that fetuses should be compared to fetuses, not to babies.[84]

A large international study, INTERGROWTH-21st, used another approach to produce weight norms derived from a healthy population.[85,86] Although it is based on birth weights rather than fetal weights, the study population used to generate these norms consists of babies born at or beyond 33 weeks to mothers with no known pregnancy-related risk factors. The INTERGROWTH-21st norms, however, are of limited use for assessing fetal weight in relation to gestational age, because they do not cover the period prior to 33 weeks' gestation.

Perhaps the biggest controversy in weight assessment is whether the estimated weight of a fetus should be compared to norms from the overall population or to customized norms[87-91] derived from a subgroup of fetuses similar to that fetus. For example, if an African-American fetus has an estimated weight of 1200 g at 30 weeks' gestation, should the weight percentile be determined from overall population norms or from African-American norms? In that example, the population-based percentile would be lower than the customized percentile, because African-American fetuses and neonates are smaller, on average, than those in the general population.[92] Although there are proponents of customized norms,[93-95] a major concern with this approach is that it can do harm by inadvertently normalizing the weight of a fetus who is small on a pathologic basis.[96,97] This viewpoint is supported by the fact that at least some population groups with small babies have elevated rates of postnatal complications[98] and by the INTERGROWTH-21st finding that neonates of healthy mothers do not differ in size based on ethnic background.[99]

Overall, our recommended approach is to use population norms. Although it would theoretically be preferable to use norms

derived from estimated fetal weights,[77,78] norms derived from birth weights are better established and are based on larger study populations.[71-76]

The weight gain between two ultrasound examinations can be estimated as the difference between the two estimated weights. Adequacy of weight gain can be assessed by comparing this difference to established normal fetal growth rate as a function of gestational age. INTERGROWTH-21st data indicate that median fetal weight gain per week decreases progressively from 33 weeks of gestation onward, with a maximum rate of 270 g per week at 33 weeks, down to 100 g per week at 41 weeks.[86] Other older growth tables suggest that weight gain may increase until 36 weeks, then decline steadily thereafter.[71,72] The longer the time is between scans, the more accurate the sonographic estimate of interval weight gain will be. When two scans are performed within 1 week of each other, weight gain cannot be determined reliably, because weight prediction is too imprecise to detect small changes in growth. Furthermore, estimating weight too close to the time of the prior scan could raise unnecessary concern by a spurious finding that the fetus has grown subnormally or even lost weight. Thus there is little or no value in computing an estimated weight at the time of the second scan 1 week after the first. Instead, it is recommended that fetal weight gain only be assessed after an interval of at least 2 weeks' duration.[10,11]

When several examinations have been performed, fetal growth can be depicted graphically by means of a trend plot or growth curve. One form of growth curve plots the **estimated fetal weight versus gestational age,** with the curve for the fetus being examined superimposed on lines depicting the 1st, 10th, 50th, 90th, and 99th percentiles (Fig. 42.10A). An alternative mode of display plots the **estimated fetal weight percentile versus gestational age** (Fig. 42.10B). In this latter format, the graph for a normally growing fetus will be a horizontal line, indicating maintenance of a particular weight percentile throughout gestation. A down sloping line suggests subnormal growth rate.

Calculation of weight percentiles and plotting of growth curves are most easily accomplished by computer, using an obstetric ultrasound software package that performs these tasks.[100-102] Alternatively, similar results can be achieved by means of a calculator and manual plotting of data.

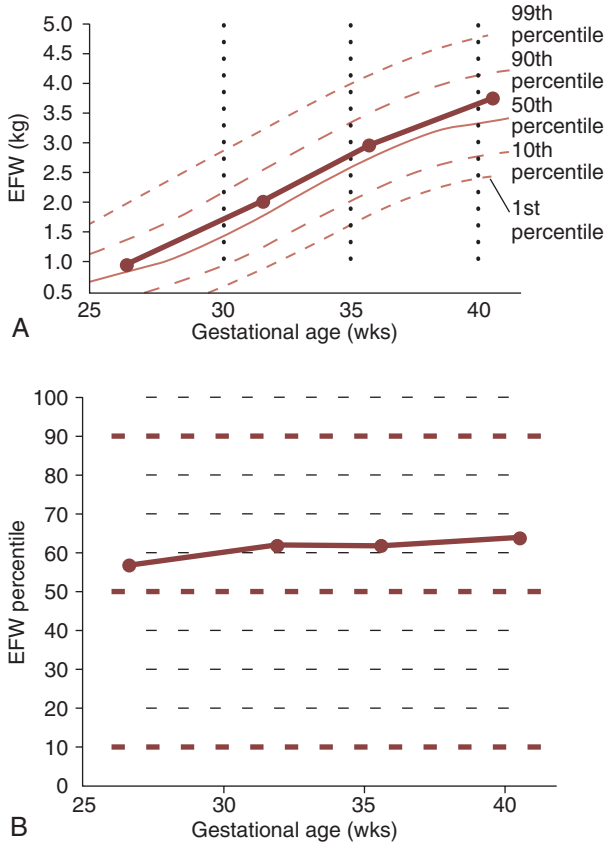

FIG. 42.10 Fetal Growth Curves. (A) Estimated fetal weight plotted against gestational age, superimposed on 1st, 10th, 50th, 90th, and 99th percentile curves. The fetus depicted here has a normal growth pattern, with estimated fetal weights between the 50th and 90th percentile over four sonograms. **(B)** Estimated fetal weight *(EFW)* percentile against gestational age.

FETAL GROWTH ABNORMALITIES

The Large Fetus

The **large-for-gestational-age** (LGA) neonate (or fetus) is defined as one whose weight is above the 90th percentile for gestational age.[71,103-105] **Macrosomia,** a related entity, is most often defined on the basis of a weight above 4000 g; other weight cutoffs (4100 g, 4500 g) are sometimes used.[74,76-80,106] These growth disturbances occur with different frequencies and are associated with different morbidities and mortalities in diabetic mothers as compared to the general population. Therefore these two patient populations are considered separately.

General Population

About 10% of all infants have birth weights above the 90th percentile for gestational age and are considered LGA infants. Of all newborns, 8% to 10% have birth weights over 4000 g and thus are classified as "macrosomic," and 2% weigh over 4500 g.[104,106-109] These rates, however, vary considerably among different patient subgroups, depending on presence or absence of risk factors. Risk factors for LGA and macrosomia include maternal obesity, history of a previous LGA infant, prolonged pregnancy (>40 weeks), excess pregnancy weight gain, multiparity, and advanced maternal age.[103,104,107,110-112]

Large fetuses have an increased incidence of perinatal morbidity and mortality, in large part because of obstetric complications. Shoulder dystocia, fractures, and facial and brachial plexus palsies occur more frequently as a result of traumatic delivery.[106,110,113,114] The incidence of perinatal asphyxia, meconium aspiration, neonatal hypoglycemia, and other metabolic complications is significantly increased in these pregnancies.[103,106,107,110]

The most straightforward approach to diagnosing fetal LGA and macrosomia is to use the estimated fetal weight computed from sonographic measurements. An estimated weight above the 90th percentile for gestational age suggests LGA, and a weight estimate above 4000 g suggests macrosomia. Although weight estimation is somewhat less accurate in large than in average-sized fetuses,[62,115] this approach has been demonstrated to be moderately good for diagnosing LGA and macrosomia. It has a **positive**

predictive value (PPV) of up to 51% for LGA and 67% for macrosomia. Other proposed sonographic parameters have lower sensitivity or lower PPV than the estimated fetal weight[62,103,106,116-124] (Table 42.11).

Diabetic Mothers

Fetuses of insulin-dependent and gestational diabetic mothers are exposed to high levels of glucose throughout pregnancy and, as a result, produce excess insulin. This leads to overgrowth of the fetal trunk and abdominal organs, while the head and brain grow at a normal rate.[104,105] Therefore these fetuses tend to have different body proportions than fetuses of nondiabetic mothers. Sonographic measurements of fetuses of diabetic mothers demonstrate accelerated growth of the fetal thorax and abdomen beginning between 28 and 32 weeks' gestation.[104,105,125]

An LGA weight occurs in 25% to 42% and macrosomia in 10% to 50% of infants of diabetic mothers.[104,105,126] As many as 12% of infants of mothers with diabetes weigh more than 4500 g at birth. Perinatal complications are more frequent in macrosomic fetuses of diabetic mothers than in those of nondiabetic mothers.[109,113,114,127,128] Shoulder dystocia, for example, occurs in 31% of macrosomic fetuses of diabetic mothers and only 3% to 10% of macrosomic fetuses of nondiabetic mothers.[110,113]

Many sonographic parameters, involving a variety of measurements, formulas, and ratios, have been proposed for diagnosing LGA and macrosomia in the fetus of the diabetic mother[117,129-131] (Table 42.12). As a group, these have higher sensitivities and PPVs than sonographic criteria in the general population, in part because of the higher prevalence of large fetuses in diabetic mothers.

As in the general population, the most straightforward approach to diagnosing LGA and macrosomia in the fetuses of diabetic mothers is by means of the sonographically estimated fetal weight.[68,117,129,132,133] A fetus whose estimated weight falls above the 90th percentile for gestational age has a 74% likelihood of being LGA, versus 19% if the estimated weight lies below the 90th percentile.[129] A weight estimate above 4000 g is associated with a 77% chance of macrosomia, and one above 4500 g with an 86% chance. The chance of macrosomia is only 16% when the weight estimate is less than 4000 g.[68] Thus, if vaginal delivery is believed to be contraindicated for the macrosomic fetuses of diabetic mothers, the estimated fetal weight should be considered when selecting the route of delivery.

The Small-for-Gestational-Age Fetus and Fetal Growth Restriction

Fetuses are termed *small for gestational age* (SGA) if their estimated weights are below the 10th percentile for gestational age. SGA fetuses are a heterogeneous group and can be subdivided into constitutionally small fetuses (e.g., those with small parents) and fetuses whose small size is due to a pathologic process.

As a group, SGA fetuses have a poor prognosis, with increased perinatal morbidity and mortality rates. Their mortality rate is four to eight times that of non-SGA fetuses.[134-136] Half of surviving SGA fetuses have serious short- or long-term morbidity, including meconium aspiration, pneumonia, and metabolic disorders.[134,137-139] The risk, however, is dependent on the cause of the small size. Constitutionally small fetuses carry no elevated risk, unlike those who are small because of a pathologic condition. Furthermore, the potential to improve outcome by appropriate management of pathologically small fetuses varies depending on causation. For example, when the small size is caused by placental insufficiency, early delivery may improve outcome, but this intervention is unlikely to affect outcome in chromosomally abnormal fetuses.

The term *fetal growth restriction* (FGR), also called *intrauterine growth restriction,* is used differently by different authors. Some use FGR and SGA synonymously, considering all fetuses below the 10th percentile for gestational age to be growth restricted. Others use FGR to refer to pathologically small fetuses.

Terminology aside, determination of the cause(s) of small fetal size is often difficult, so that all SGA fetuses should be classified as suspected FGR.[140] The approach to SGA or FGR involves three steps: (1) diagnosis: identify small fetuses; (2) classification: attempt to determine the cause of the small size; (3) management: institute monitoring and decide on timing of delivery.

The most direct approach to identifying SGA fetuses is to diagnose SGA if the estimated fetal weight falls below the 10th percentile for the best estimate of gestational age. Several other criteria for diagnosing SGA or FGR have been proposed, including sonographic measurements and ratios,[141] as well as a multiparameter scoring system.[142,143] None of the individual parameters has a high PPV,[141] and the performance characteristics of the scoring system[143] are not good enough to make up for its complexity and cumbersome nature. Thus the straightforward approach of using the estimated fetal weight percentile is the preferred method for diagnosing SGA fetuses.

Once SGA has been diagnosed, an attempt should be made to determine its cause through evaluation of both the mother and the fetus. Maternal assessment should include physical examination and blood tests, directed toward diagnosis of **hypertension, renal disease,** and other maternal conditions that can cause FGR. Fetal assessment begins with a careful sonographic examination, looking especially for findings suggestive of a **chromosomal** or **viral** cause (e.g., holoprosencephaly, clenched hands, rocker-bottom feet, intracranial calcifications). If such a finding is present, amniocentesis or umbilical blood sampling can confirm the diagnosis of a chromosomal abnormality. A viral cause of FGR may also be diagnosed by these procedures, in some cases.[144]

Growth-restricted fetuses, other than those with a lethal condition, such as **trisomy 13 or 18,** should be carefully monitored for the remainder of the pregnancy. The monitoring is typically performed at weekly or semiweekly intervals. Sonographic features to be followed include **amniotic fluid volume, biophysical profile score, estimated fetal weight percentile,** and **fetal Doppler.** A worsening trend in one or more of these features should prompt consideration of early delivery.

ASSESSMENT OF FETAL WELL-BEING

It has been shown that when a fetus is suspected of being growth restricted or having another condition that could affect the

oxygenation or nutrition to the fetus, antenatal surveillance can improve the outcome for these fetuses. Surveillance of such a fetus includes serial ultrasounds to monitor fetal growth, perform biophysical profiles (BPPs), and measure Doppler parameters. Nonstress tests (NSTs) are also used to monitor fetal well-being. The nature and frequency of monitoring tests depends on the apparent severity of fetal compromise.[10,11]

Biophysical Profile

The BPP, introduced in the 1980s, is a noninvasive test of fetal well-being based on four ultrasound parameters and the NST. The four ultrasound parameters are (1) fetal movement, (2) fetal tone, (3) fetal breathing movements, and (4) amniotic fluid volume (Table 42.13, Fig. 42.11, Videos 42.2 and 42.3). Each parameter receives 2 points if the fetus meets criteria and 0 points if it does not. Thus a perfect score for the ultrasound portion of the BPP is 8 out of 8, with 2 points given for each of the four parameters.[145,146] The parameters were chosen to assess both the acute and the chronic state of the fetus, with acute parameters being fetal tone, movement, and breathing movements, and amniotic fluid volume being a chronic marker of fetal well-being.[145] Studies have shown that the BPP is reliable and reproducible, and that scores of 8 out of 8 are associated with a low rate of stillbirths and low rate of fetal asphyxia within 1 week of testing.[11,145,147-150] Lower scores, those below 6 out of 8, are associated with increased risk for fetal asphyxia, low cord pH, cerebral palsy, and stillbirth. The lower the score is, the higher the risk of perinatal compromise will be.[11,145,148]

The BPP exam is performed within 30 minutes. If a fetus does not meet criteria for a parameter within the 30-minute time period, that parameter is given a score of 0. The BPP score

TABLE 42.13 Biophysical Profile Parameters for 30-Minute Ultrasound Examination

Parameter	2 Points Given	0 Points Given
Fetal movement	At least 3 discrete body or limb movements	Less than 3 discrete body or limb movements
Fetal tone	At least 1 episode of extension and flexion of extremity or spine	No episode of extension and flexion of extremity or spine
Fetal breathing movement	At least 30 seconds of continuous, rhythmic breathing movements	No episode of continuous breathing movement for 30 seconds
Amniotic fluid volume	Single pocket at least 1 cm across and 2 cm in vertical	No pocket 1 cm across and 2 cm in vertical

With permission from Manning FA, Platt LD, Sipos L. Antepartum fetal evaluation: development of a fetal biophysical profile. Am J Obstet Gynecol. 1980;136(6):787-795.[146]

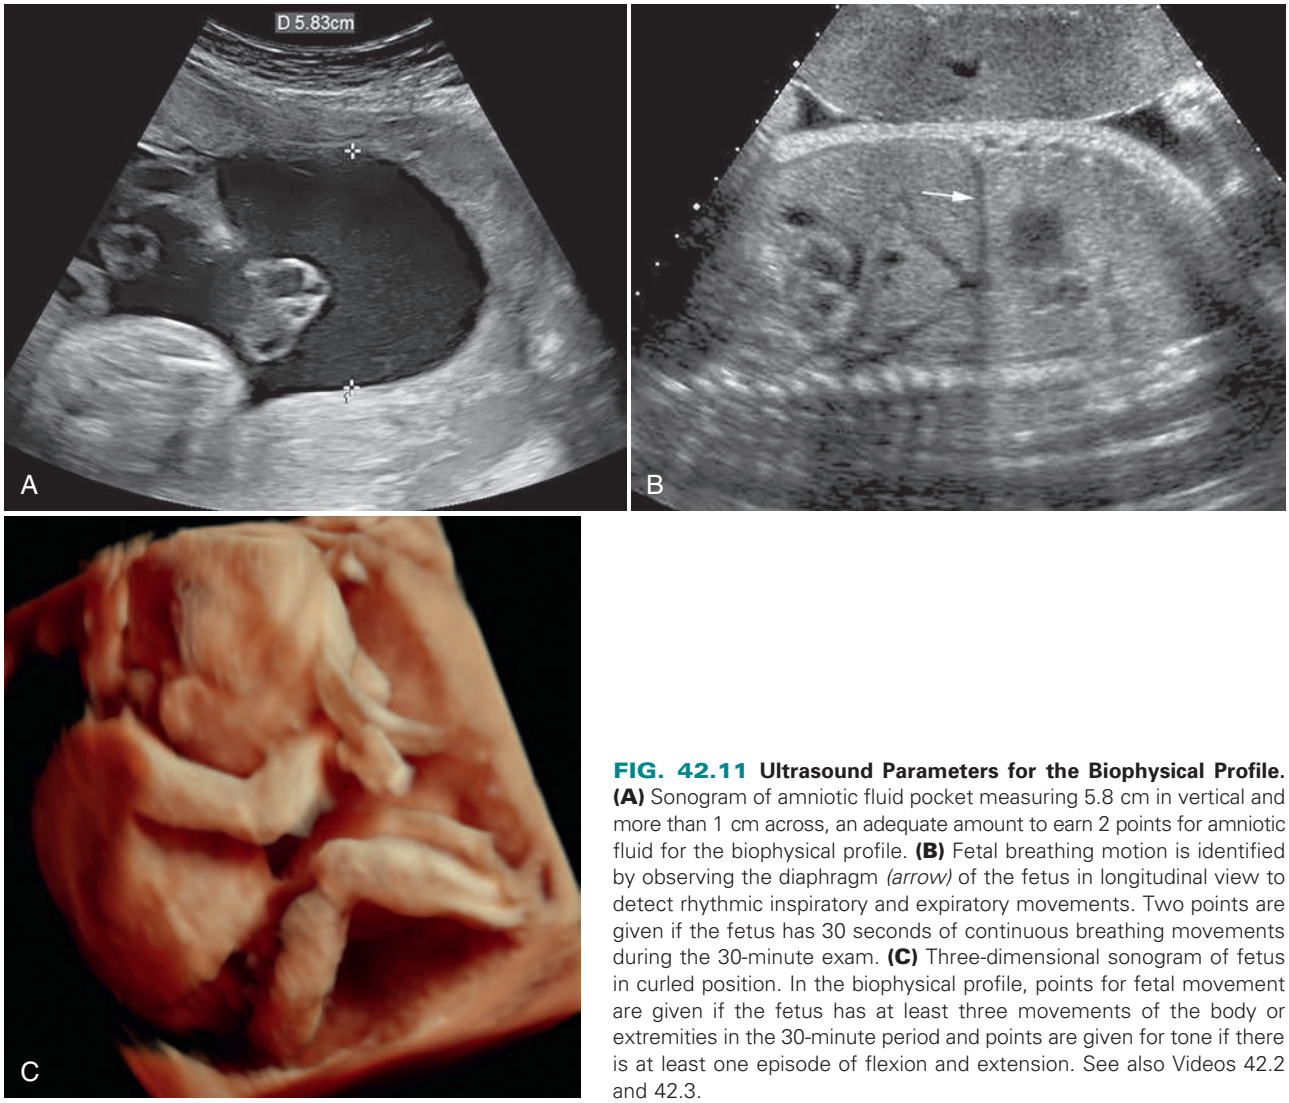

FIG. 42.11 Ultrasound Parameters for the Biophysical Profile. **(A)** Sonogram of amniotic fluid pocket measuring 5.8 cm in vertical and more than 1 cm across, an adequate amount to earn 2 points for amniotic fluid for the biophysical profile. **(B)** Fetal breathing motion is identified by observing the diaphragm *(arrow)* of the fetus in longitudinal view to detect rhythmic inspiratory and expiratory movements. Two points are given if the fetus has 30 seconds of continuous breathing movements during the 30-minute exam. **(C)** Three-dimensional sonogram of fetus in curled position. In the biophysical profile, points for fetal movement are given if the fetus has at least three movements of the body or extremities in the 30-minute period and points are given for tone if there is at least one episode of flexion and extension. See also Videos 42.2 and 42.3.

is reported as the number of points earned over the total for the study, which is 8 for an ultrasound BPP without NST. When a score of less than 8 out of 8 is given, the parameter or parameters for which no points were given should also be reported. For example, if a fetus has normal amniotic fluid volume with a pocket of fluid more than 2 cm vertical and 1 cm wide, demonstrates adequate fetal movement and tone to obtain 2 points for each, but does not demonstrate fetal breathing movement during the 30-minute exam, that BPP would be reported as 6 out of 8 with 2 points deducted for lack of fetal breathing movement. In

most cases, the BPP does not require a full 30 minutes of sonographic evaluation, because, given the short sleep cycles of the fetus, it typically meets criteria in less than that time, sometimes as short as 5 minutes.[145]

The BPP as a test of fetal well-being has several limitations. First, the test is less reliable in the severely premature fetus because of lack of brain maturity and should not be administered before 24 weeks' gestation.[145] Second, the biophysical state of the fetus is affected by administration of corticosteroids, which may cause depression of fetal breathing and movement for a few days after treatment.[151-155] This latter limitation must be kept in mind when using the BPP to guide management decisions shortly after steroid treatment.[145]

Fetal Doppler

Doppler parameters of a number of vessels, including the umbilical artery, umbilical vein, ductus venosus, middle cerebral artery, aortic isthmus, and uterine artery in the mother, have been studied to determine if Doppler parameters can be used to predict outcome and direct management.[140,156-160] Among vessels studied, umbilical artery Doppler has been shown to be the most useful for monitoring fetuses at risk for compromise, particularly those with suspected FGR.[11,140,148,156,160,161] When umbilical artery Doppler is incorporated into surveillance of fetuses with suspected growth restriction, overall outcome is improved, with fewer unnecessary interventions, inductions of labor, cesarean deliveries, and perinatal deaths.[10,148,160-162] Although umbilical artery Doppler has been shown to improve outcome in fetuses with suspected growth restriction and in mothers with preeclampsia or hypertension, routine screening with umbilical artery Doppler in low-risk pregnancies is not recommended, because it has not resulted in improved outcome in this patient population.[140,161]

Although some advocate adding middle cerebral artery and/or ductus venosus Doppler to the evaluation of fetuses with suspected growth restriction and abnormal umbilical artery Doppler,[161,163-165] studies have not yet shown improved outcomes when these additional Doppler studies are performed.[10,11,140,148,160]

Umbilical Artery Doppler

Umbilical artery Doppler is used to assess fetal well-being after 24 weeks' gestation for those fetuses with suspected growth restriction or in mothers with preeclampsia or hypertension.[140,148,156,160,161] To obtain a waveform, the Doppler gate is placed on a free loop of umbilical cord, away from the placental and fetal cord insertions and in the absence of fetal breathing movements. The ratio of peak systolic to end-diastolic velocity is calculated (S/D ratio). Flow in the umbilical artery is normally low resistance, with an S/D ratio of less than 3.5 up to 28 weeks' gestation and less than 3.0 thereafter[166] (Fig. 42.12A). With significant placental dysfunction, resistance in the placenta increases and flow in the umbilical artery demonstrates diminished diastolic flow, with an S/D ratio above the normal range (Fig. 42.12B). In such cases, the risk of fetal compromise and perinatal mortality is increased. The risk of fetal compromise is increased further when end-diastolic flow in the umbilical artery is absent (Fig. 42.12C), and is highest when end-diastolic flow is reversed (Fig. 42.12D). In particular, the risk of perinatal mortality within 1 week of diagnosing reversed end-diastolic flow in the umbilical artery of a growth-restricted fetus is so high, close to 50%, that delivery is generally recommended, regardless of the gestational age.[10,11,140,156,167-170]

Ductus Venosus Doppler

The ductus venosus is the short vessel connecting the umbilical vein near its junction with the left portal vein directly to the inferior vena cava. This allows shunting of umbilical venous blood directly to the heart, bypassing the liver. Normal flow in the ductus venosus is antegrade, toward the heart, throughout the cardiac cycle (Fig. 42.13A). Studies have shown that absent or reversed flow (Fig. 42.13B) in the ductus venosus at any time during the cardiac cycle is a sign of cardiovascular instability and is associated with increased morbidity and mortality rates in growth-restricted fetuses.[10,11,140,148,150,160] However, these same studies demonstrate poor sensitivities and specificities, and, therefore, the value of ductus venosus Doppler for directing the management of growth-restricted fetuses has not been established.[11,140,148,160]

Middle Cerebral Artery Doppler

Doppler of the middle cerebral artery (MCA) provides information about flow resistance in the fetal brain. For optimal interrogation of the MCA, the Doppler gate should be placed on the middle cerebral artery in the proximal third of the vessel, close to its origin from the circle of Willis. If peak systolic velocity is being measured, the Doppler angle must be zero or angle correction must be used. Normally, flow in the MCA is high resistance, with low diastolic flow (Fig. 42.14A). In the compromised fetus, vessels in the brain vasodilate, a response called "brain sparing," leading to decreased resistance to blood flow and increased diastolic flow in the MCA. This "brain-sparing" effect can be measured by calculating the resistive index (RI) of the MCA waveform. The RI is considered abnormal when it is less than the fifth percentile for gestational age[148,159,160] (Fig. 42.14B). An abnormal RI in the MCA is associated with perinatal mortality and morbidity, including acidosis at birth, low 5-minute Apgars, and neonatal intracranial hemorrhage.[148,159] However, the published studies are inconsistent, and an abnormal MCA Doppler is a poor predictor of adverse outcome in preterm infants. There is no convincing evidence that the use of MCA Doppler for guiding management of growth-restricted fetuses improves outcome.[10,148,160,171]

Some have advocated using the MCA Doppler in conjunction with umbilical artery Doppler to improve the identification of fetuses at risk for poor outcome. In particular, some have recommended comparing the RI or pulsatility index (PI) in the MCA to the corresponding RI or PI in the umbilical artery in a ratio called the "cerebroplacental ratio" (Fig. 42.15):

$$\text{Cerebroplacental ratio} = \frac{\text{Middle cerebral artery pulsatility index}}{\text{Umbilical artery pulsatility index}}$$

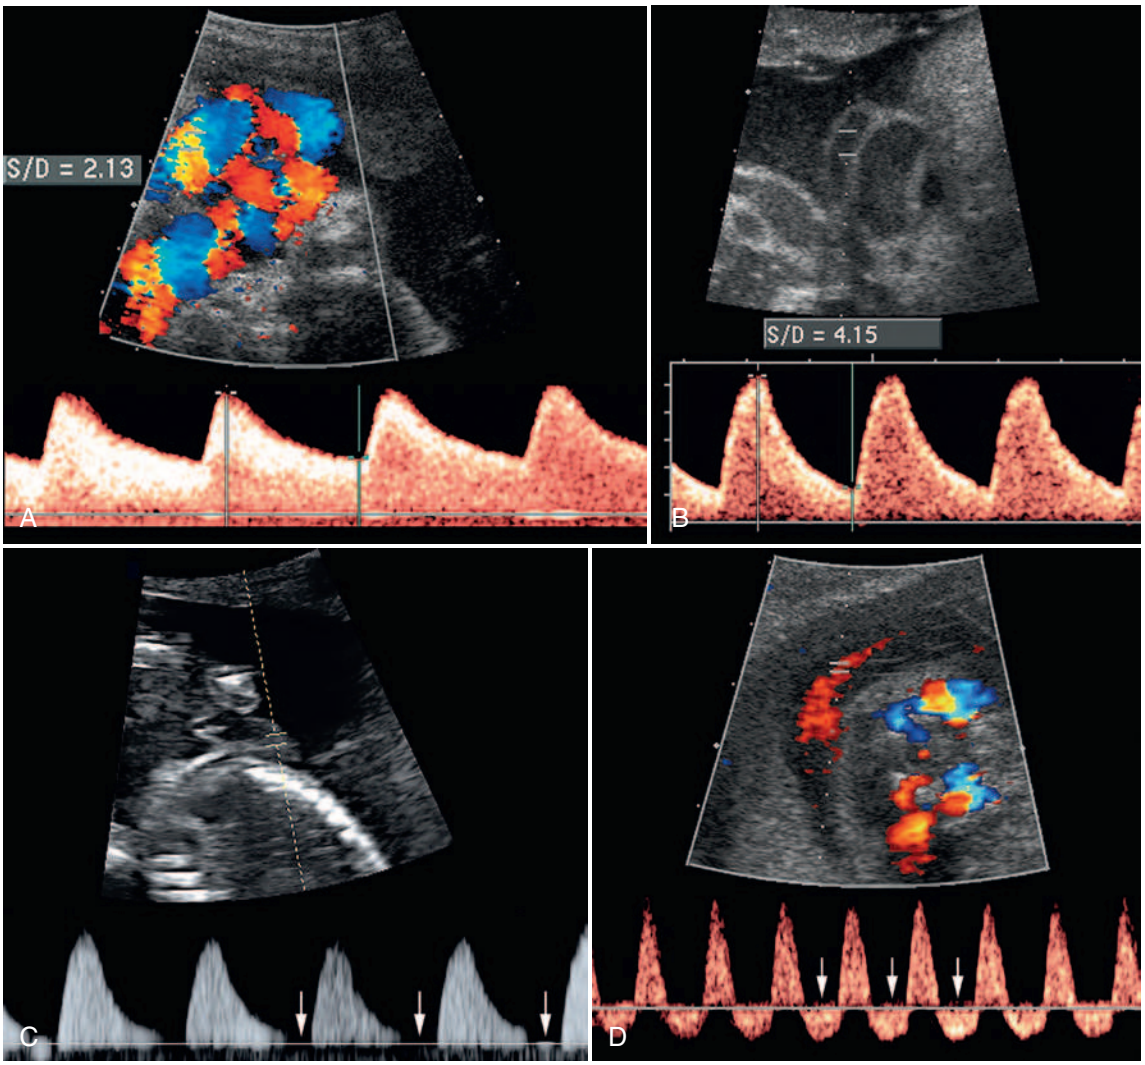

FIG. 42.12 Umbilical Artery Doppler. (A) Color and spectral Doppler of umbilical artery demonstrating normal flow with systolic to diastolic ratio *(S/D)* normal at 2.13. **(B)** Sonogram of term fetus showing Doppler gate on umbilical artery and spectral waveform with elevated S/D of 4.15 due to diminished diastolic flow. **(C)** Sonogram showing Doppler gate on umbilical artery and spectral waveform below demonstrating absent end-diastolic flow *(arrows)*. **(D)** Color and spectral Doppler demonstrating reversed end-diastolic flow *(arrows)*.

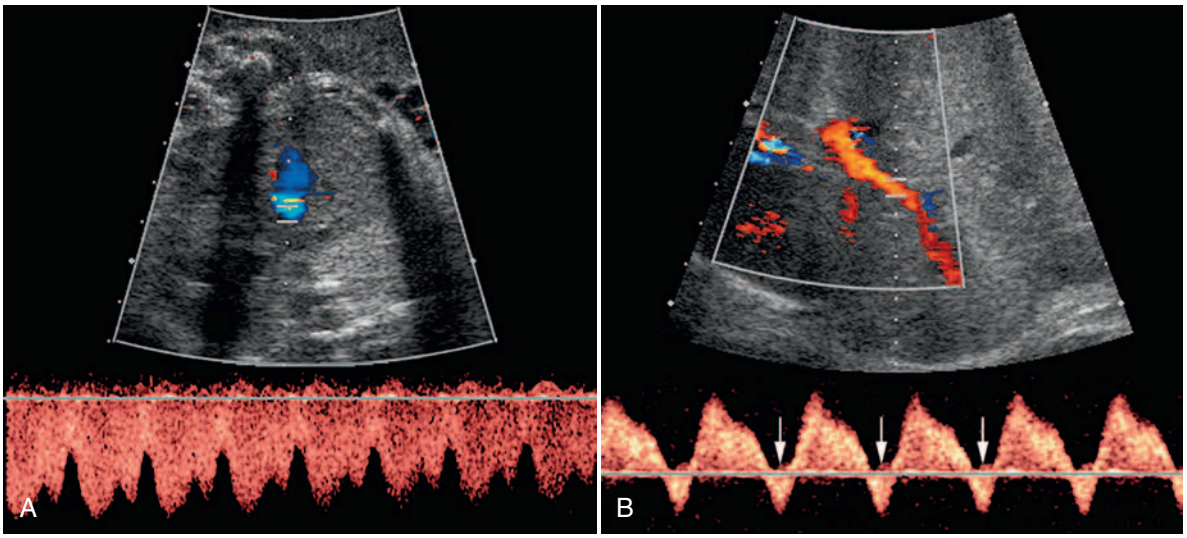

FIG. 42.13 Ductus Venosus Doppler. (A) Color and spectral Doppler of the ductus venosus demonstrating normal flow, toward the heart throughout the cardiac cycle. **(B)** Color and spectral Doppler of the ductus venosus demonstrating reversed flow *(arrows)* during part of the cardiac cycle, an abnormal finding.

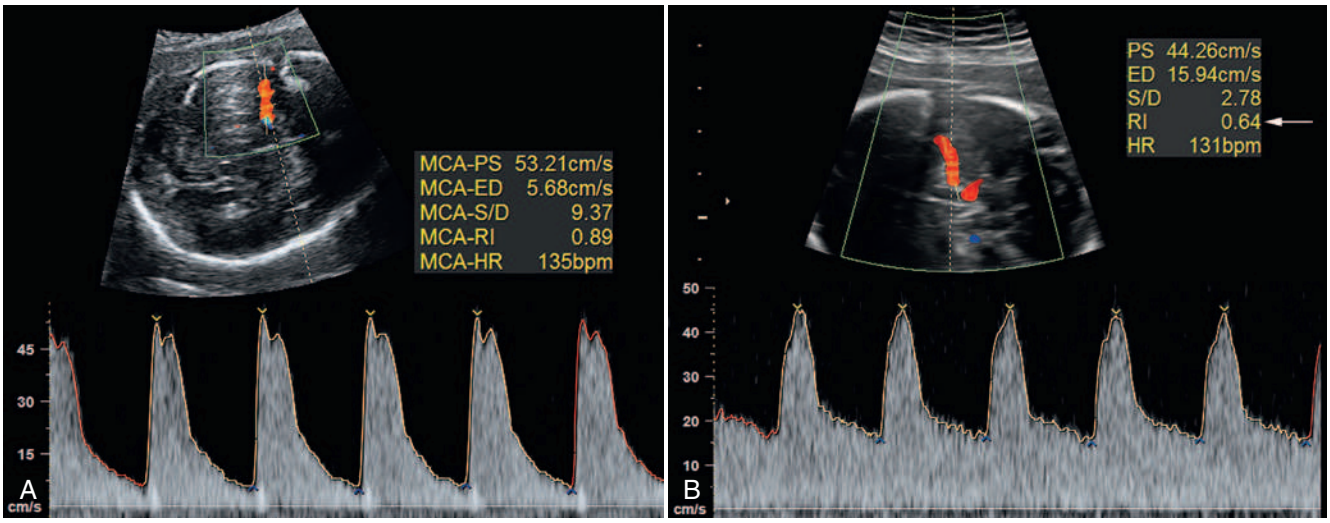

FIG. 42.14 Middle Cerebral Artery Doppler. (A) Color and spectral Doppler of normal fetal middle cerebral artery with normal resistive index *(RI)* of 0.89. **(B)** Color and spectral Doppler of abnormal fetal middle cerebral artery demonstrating abnormally low resistive index *(RI)* of 0.64 *(arrow)* as a result of elevated diastolic flow.

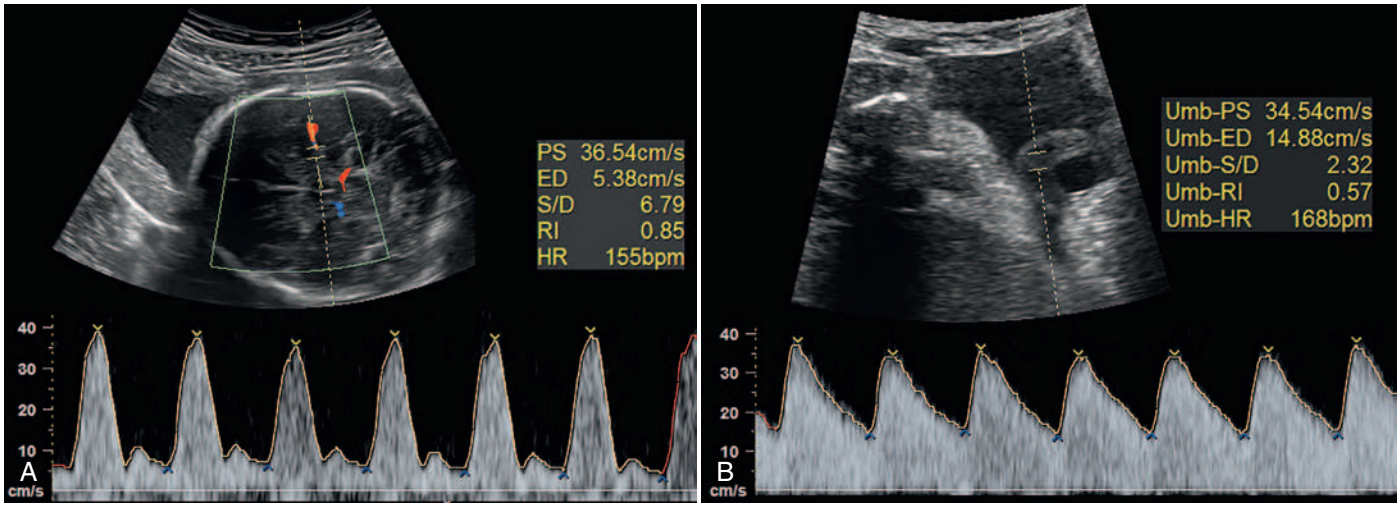

FIG. 42.15 Cerebroplacental Ratio. Normal cerebroplacental ratio of 1.49, calculated by taking the ratio of **A,** the resistive index in the middle cerebral artery (0.85) to **B,** the resistive index in the umbilical artery (0.57).

The cerebroplacental ratio is abnormal if it is less than 1.0.[161,163] This ratio takes into account the decreased MCA resistance with "brain sparing" and vasodilation and increased umbilical artery resistance from increased placental resistance associated with placental dysfunction. An abnormal cerebroplacental ratio is associated with increased fetal distress in labor, low cord pH, and high neonatal intensive care admissions.[10,140,159,160,163,172] However, the utility of this ratio in the surveillance of the growth-restricted fetus has not been well established.

Summary of Fetal Doppler

To date, the only Doppler surveillance study that has been shown to improve outcome in growth-restricted fetuses is umbilical artery Doppler. Although ductus venosus and MCA Doppler have been shown to demonstrate changes with fetal compromise, their use in guiding management of high-risk pregnancies with FGR has not been proven.

CHAPTER 43

Sonographic Evaluation of the Placenta

Thomas D. Shipp

SUMMARY OF KEY POINTS

- The placenta undergoes tremendous development within the first half of pregnancy yet continues to mature and develop during the gestation.
- A placenta that lies near or over the internal cervical os is common early in gestation, yet most of these will resolve by the end of pregnancy. Ultrasound, especially transvaginal sonography, is instrumental to determine placental position.
- Placenta accreta is increasingly common and ultrasound is vital for its identification, especially in patients at high risk for its development. Sonographic findings most important for identifying placenta accreta are placental lacunae, loss of the placental-myometrial hypoechoic space, abnormalities of the uterine-bladder interface, and color Doppler abnormalities.
- Placental infarctions are commonly identified within the placenta, especially in patients at high risk for their development (e.g., those who have preeclampsia, maternal vascular disease, or thrombophilia).
- Abnormalities of placental shape are common, as are differences in location of the placental umbilical cord insertion.
- The presence of a vasa previa is associated with increased perinatal morbidity and mortality rates. Vasa previa should be evaluated for all gravidas, especially for those with an increased risk of its development.
- Those parturients with abnormal postpartum bleeding should be evaluated for the presence of retained products of conception. Echogenic endometrial masses in these patients strongly suggest the presence of retained products of conception.

CONCLUSION

The use of ultrasound to evaluate the placenta is routine among the majority of pregnant American women because they have at least one ultrasound examination during pregnancy. A wide range of pregnancy complications result from abnormal placental development, including preeclampsia, intrauterine growth restriction (IUGR), and abruption. Other placental and umbilical cord abnormalities, such as placenta previa, placenta accreta/increta/percreta, or vasa previa, may cause major maternal and fetal complications, especially if not recognized antenatally. Timely recognition of these abnormalities can lead to improved management of pregnancy and delivery. Thus careful examination of the placenta by ultrasound can contribute directly to enhanced patient care and improved outcomes.

PLACENTAL DEVELOPMENT

The early developing embryo is surrounded by amnion and chorion. Villi cover the entire surface of the chorion up to about 8 weeks of gestation (Fig. 43.1). The villi, which are the basic structures of the placenta, initially form by 4 or 5 weeks' gestation. The villi next to the **decidua capsularis** degenerate, forming the **chorion laeve.** The villi contiguous with the **decidua basalis**

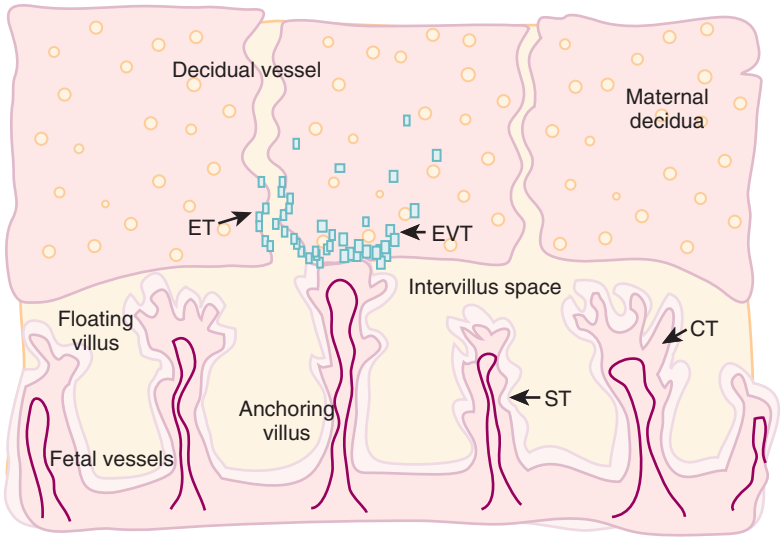

FIG. 43.1 Human Placenta Microarchitecture. Fetal derivatives in the placenta consist of fetal vessels and placental cotyledons (villi). Villi consist of fetal vessels surrounded by **cytotrophoblast** cells *(CT).* Covering the cytotrophoblast cells is a multinucleated cellular layer called the **syncytiotrophoblast** *(ST).* Anchoring villi are in direct contact with the maternal uterine lining, called the **decidua.** The decidua is traversed by maternal vasculature. Blood from these vessels empties into the intervillous space and bathes the placental villi. Note that maternal and fetal blood vessels are separated by trophoblast, villous stroma, and fetal vascular endothelium. Cytotrophoblast cells from anchoring villi can change into an invasive phenotype called extravillous cytotrophoblast cells *(EVT).* EVT invade deeply into the maternal decidua. Some EVT, called endovascular trophoblast cells *(ET),* embed within the walls of the maternal vasculature. (With permission from Comiskey M, Warner CM, Schust DJ. MHC molecules of the preimplantation embryo and trophoblast. In: Mor G, editor. Immunology of pregnancy. Austin/New York: Landes Bioscience, 2006.)

become the **chorion frondosum** and later the placenta. The fetal side of the placenta consists of the **chorionic plate** and **chorionic villi.** The maternal side consists of the decidua basalis, which opens up into large cisterns, the **intervillous spaces.** The fetal villi are immersed in maternal blood located in the intervillous spaces. Anchoring villi develop from the chorionic plate.[1] These attach to the decidua basalis, holding the placenta in place.[2,3] By the end of pregnancy, the villi have a surface area of 12 to 14 square meters.[4] This type of placentation, seen in humans and some rodents, is termed *hemochorial placentation.*

Placental Appearance

Sonographically, the placenta in the first and second trimesters is slightly more echogenic than the surrounding myometrium (Fig. 43.2A). The attachment site, or base of the placenta, should be clearly delineated from the underlying myometrium. The edges of the placenta usually have a small sinus, the **marginal sinus of the placenta** (Fig. 43.2B), where intervillous blood drains into the maternal venous circulation. This area should not be confused with a placental separation.

Placental lakes (venous lakes, at least 2 × 2 cm) occur in up to 5% of pregnancies[5-10] (Fig. 43.2C, Video 43.1). They represent areas of intervillous spaces devoid of placental villous trees and are seen as hypoechoic structures within the placenta. Moving blood flow can be seen in these areas. They may have irregular shapes or a narrow, cleftlike appearance and may change in appearance over the gestation. Large placental lakes (>5 cm in largest dimension) have been associated with IUGR.[10]

As the placenta matures, areas of echogenicity within the placenta are visualized (Fig. 43.2D and E). In cases of **placental infarction,** there may be hypoechoic lesions with echogenic borders.

Placental Size

The placenta typically has a round shape with a central umbilical cord insertion, but variability in the shape of the placenta is quite common.[11] Placental length is approximately six times its maximal width at 18 to 20 weeks' gestation. The mean thickness of the placenta in millimeters in the first half of pregnancy closely approximates the gestational age in weeks.[12] If the placenta thickness is greater than 4 cm (40 mm) before 24 weeks, an abnormality should be suspected. These abnormalities include **ischemic-thrombotic damage, intraplacental hemorrhage, chorioangioma,** and **fetal hydrops**[13] (Fig. 43.3, Video 43.2).

Given the variable shape of the placenta, calculating a placental volume from two-dimensional (2D) imaging can be complicated. Multiplanar volume calculation involves sequential sections of the placenta at intervals such as 1.0 mm. The margins are manually traced, and a volume is calculated.[14] Most current studies appraising the use of three-dimensional (3D) sonography have used the VOCAL (Virtual Organ Computer-aided AnaLysis) method,[14] in which the 3D volume in question is rotated and the area of interest traced at its margin, after which a volume is calculated (Fig. 43.4).

Placental volume approximation in the first trimester holds promise as an important part of early pregnancy evaluation. Uterine artery Doppler analysis provides limited information regarding IUGR and the effects of maternal hypertension, but it is insufficient as a sole indicator of trophoblast invasion, in part because it is typically performed late in the second trimester. Small placental volumes in the first trimester presage abnormal uterine artery perfusion.[15] Uterine artery Doppler ultrasound combined with assessment of placental volume may identify pregnant women at risk for hypertension, abruption, or IUGR.[16,17] First-trimester placental volumes correlate with both placental

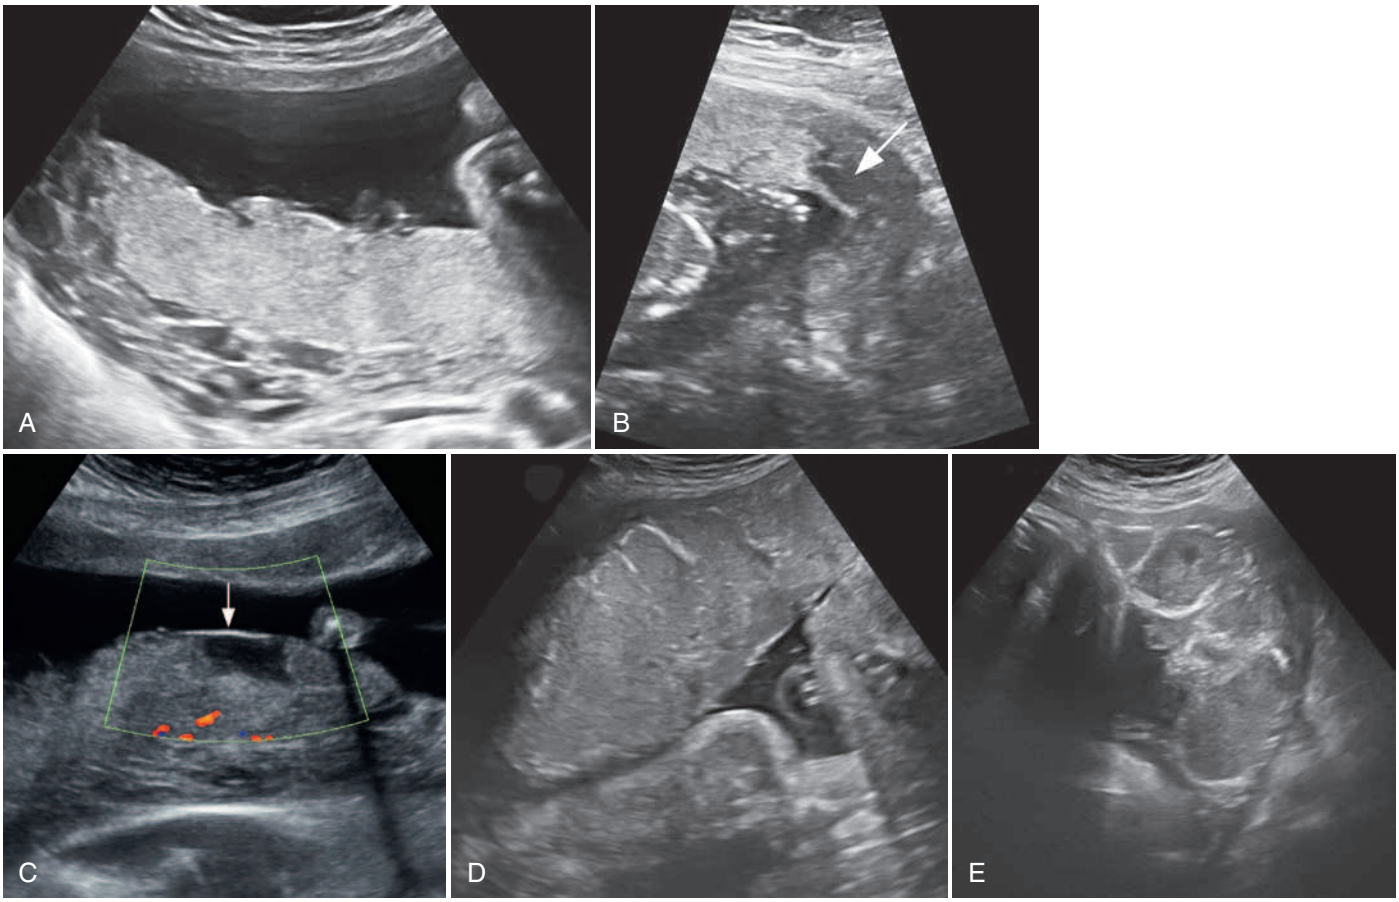

FIG. 43.2 Normal Appearance of Placenta. (A) At 18 weeks, note the uniformly echogenic appearance of the placenta. **(B)** Note **marginal sinus of placenta** *(arrow),* a circumferential venous drainage point into the maternal uterine veins that should not be mistaken for placental separation. **(C) Placental lake** *(arrow)* at 20 weeks. See also Video 43.1. **(D)** Placenta at 32 weeks' gestation. Note the diffuse placental calcifications. **(E)** Placenta at 39 weeks' gestation with defined linear calcifications outlining the placental cotyledons. Note the increasing echogenicity in the placenta as it matures.

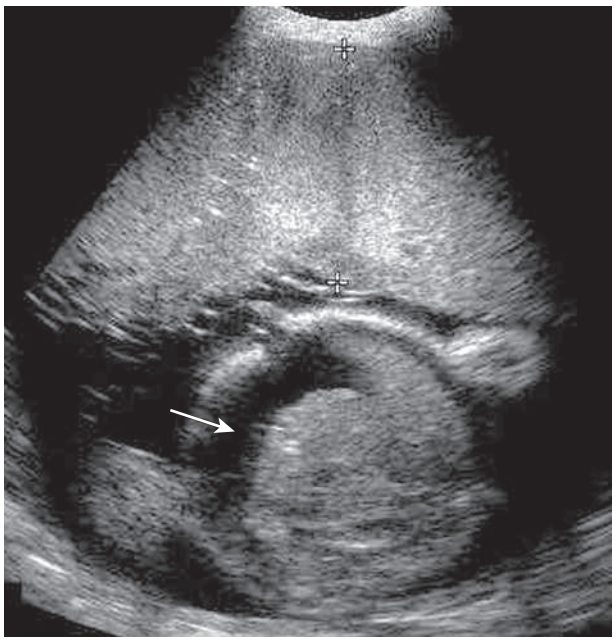

FIG. 43.3 Thick Placenta in Fetal Hydrops. The calipers indicate how one would measure the thickness of the placenta. Note the ascites *(arrow).* See also Video 43.2 for thick placenta in fetus with **villitis.**

weight and birth weight, but they have not been shown to predict the development of preeclampsia.[18,19] The first-trimester **placental volume quotient** (placental volume/crown-rump length) is low for aneuploid fetuses, with 53% having a quotient less than 10th percentile.[20] For twins, the placental volume is 83%, and for triplets 76%, that of singletons, for a given gestational age.[21]

The placenta dramatically increases in size until approximately 15 to 17 weeks' gestation. From this point, there is a fourfold increase in placental size until delivery, whereas over this same time period the fetus has a 50-fold increase in size.[22] Midtrimester placental volume is associated with maternal nutritional status, birth weight, and pregnancy outcome.[23-27]

Placental Vascularity and Doppler Ultrasound

The human placenta is a discoidal, villous, hemochorial structure. Nutrients are exchanged over many villi. Surrounding the villi are the **intervillous spaces,** which are bathed in maternal blood. The villi are sproutlike projections from the chorionic plate into the intervillous space. The villi are directly connected to the fetal vascular system, whereas the maternal blood emanates from the developing spiral arteries to the intervillous spaces to contact

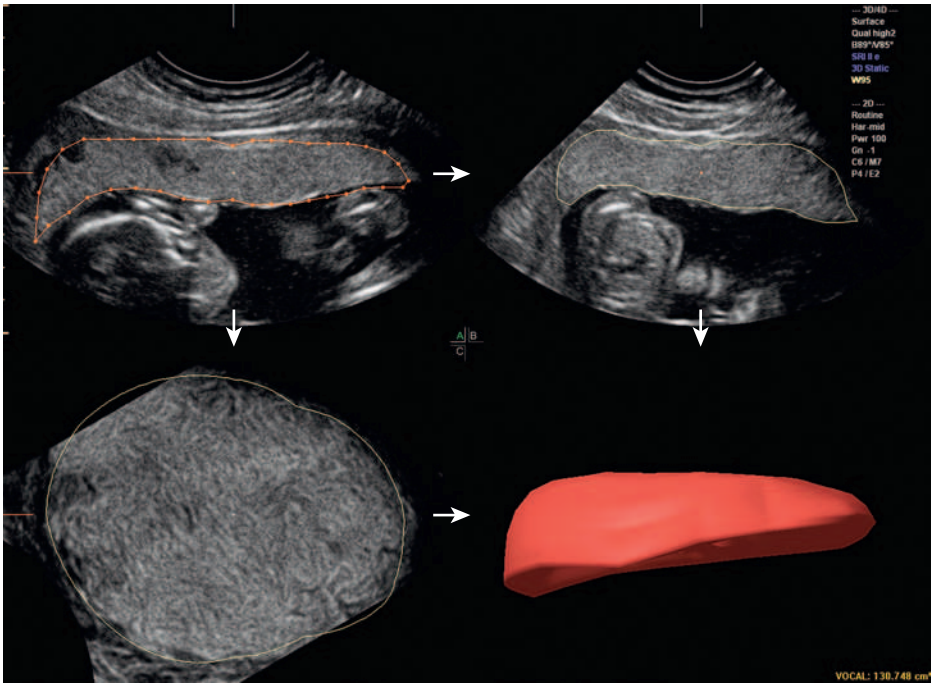

FIG. 43.4 **Three-Dimensional Assessment of Placental Volume in Second Trimester.**

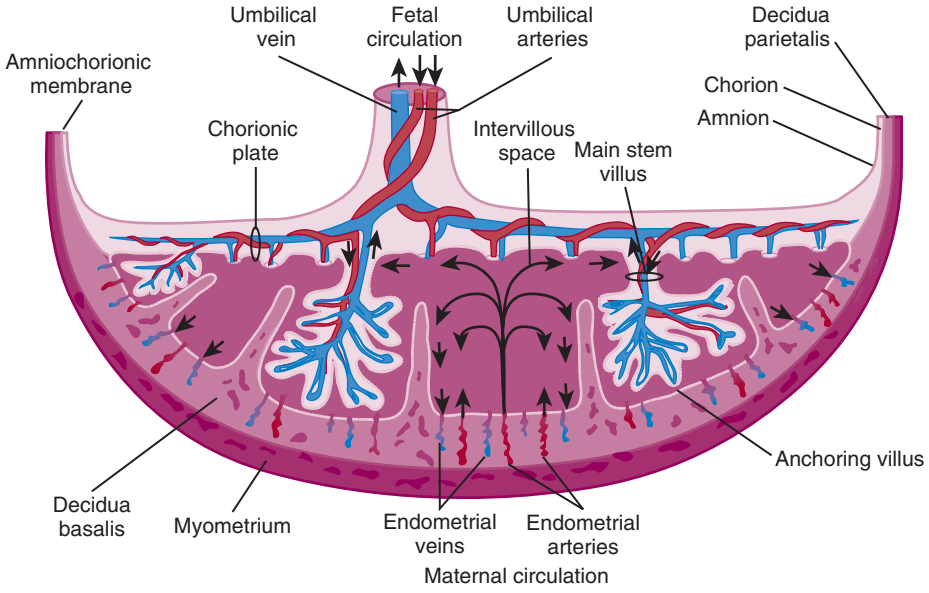

FIG. 43.5 **Schematic Drawing of Placental Vasculature.**

directly the trophoblasts of the villi[28] (Fig. 43.5). Maternal blood flow of the intervillous space depends on flow from the spiral arteries. Maternal vascular disease (e.g., hypertension) can directly affect the pregnancy by limiting this blood flow.[29]

Intervillous blood flow begins early in the first trimester.[30-32] Color Doppler ultrasound has been used to detect this intervillous and spiral artery flow by 12 weeks' gestation, but the flow, if any, that occurs before this time is not well understood.[33] Before 12 weeks, the presence of intervillous blood flow by gray-scale imaging may indicate failed pregnancy.[34]

Color and power Doppler sonography have been used to identify blood flow in intraplacental villous arteries.[35] A decrease in the number of detectable intraplacental villous arteries is associated with IUGR.[36] Three-dimensional power Doppler ultrasound provides a better appreciation of placental vascularity and pathophysiology by assessing placental flow and documenting the amount of flow in a given area. Because of its low variability between sampling sites in varied parts of the placenta, 3D imaging may have a future role in assessing flow in high-risk pregnancies (e.g., hypertension, IUGR).[37] Recent work by multiple researchers has shown that 3D placental vascularization indices are lower for those with preeclampsia,[19] are not aided by the inclusion of pregnancy-associated plasma protein A (PAPP-A) and uterine artery Doppler indices,[38] and may be improved with the addition

of 3D placental volume and computer analysis of placental calcification.[39] How well these indices can be used for the prediction of preeclampsia requires further investigation. First-trimester 3D power Doppler placental indices are unable to differentiate between those destined to have growth restriction as compared to normally grown fetuses.[40] Recent work in an animal model, however, demonstrating discrimination of maternal and fetal blood flow in the microvasculature of the placenta may allow further insights into placental blood flow and its effects on placental function.[41]

Amnion-Chorion Separation

The amnion normally "fuses" with the chorion early in the second trimester. Failure of the amnion and chorion to fuse after 17 weeks is a rare complication of pregnancy, associated with multiple abnormalities. Previous amniocentesis is a risk factor for amnion-chorion separation.[42] Associated factors may include IUGR, preterm delivery, oligohydramnios, placental abruption, and Down syndrome[43] (Fig. 43.6).

Elastography

A preliminary report has attempted to differentiate subchorionic hematoma from placenta previa using elastography.[44] More rigorous evaluations have shown that the use of both shear wave and strain elastography of the placenta was different between normal pregnancies and those that developed preeclampsia.[45,46] This exciting novel area of placental research offers much promise for the future.

PLACENTA PREVIA

The term *placenta previa* refers to a placenta that is "previous" to the fetus in the birth canal. The incidence at delivery is approximately 0.5% of all pregnancies.[47] **Bleeding** in the second and third trimesters is the hallmark of placenta previa. This bleeding can be life threatening to the mother and fetus. With antenatal detection, expectant management and cesarean delivery, both maternal and perinatal mortality rates have decreased over the past 40 years.[48,49] Accurate diagnosis of placenta previa is vital to improve the outcome for mother and neonate.

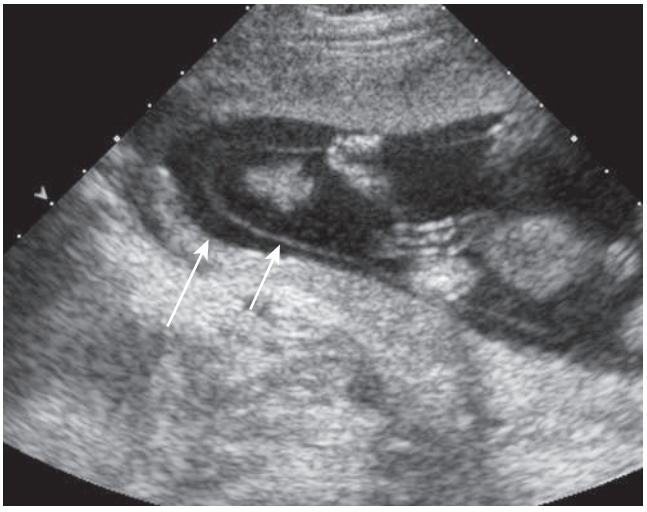

FIG. 43.6 Chorioamniotic Separation in Second Trimester. Amnion *(short arrow)* is separated from the chorion *(long arrow)*.

The differentiation of placental position has historically been performed by digital assessment of the lower uterine segment and placenta through the cervix. Using this potentially hazardous method of evaluation, placental position was classified as complete placenta previa, partial placenta previa, incomplete placenta previa, marginal placenta previa, low-lying placenta, and placenta distant from the internal cervical os. These classifications do not directly apply to the ultrasound examination of placental position relative to the cervix. The use of ultrasound to evaluate the position of the placenta in the uterus has both improved knowledge of the placenta within the uterus and simplified terminology with respect to placental position (Fig. 43.7). **Complete placenta previa** describes the situation in which the internal cervical os is totally covered by the placenta. Some differentiate those placentas that have a portion of placental substance that extends over the internal cervical os from those that are centrally placed over the cervix, a so-called central placenta previa. **Marginal placenta previa** denotes placental tissue at the edge of, or encroaching on, the internal cervical os. A **low placenta** is one in which the placental edge is within 2 cm, but not covering any portion, of the internal cervical os. The terms *incomplete placenta previa* and *partial placenta previa* have no place in the current sonographic assessment of placental position and should be used only by a clinician performing a digital examination when a "double setup" is necessary to determine where the leading edge of the placenta lies.

Transabdominal scanning can be used to visualize the internal cervical os and to determine the relation of the placenta to the cervix in most cases. Factors that can adversely affect the visualization of the cervix include prior abdominal surgery, obesity, deep or low position of the fetal head or presenting part, overfilled or underfilled maternal bladder, or uterine contractions. Transvaginal sonography (TVS) is safe[50] and accurate in depicting the internal cervical os. The proximity of the cervix to the vaginal probe allows higher-frequency probes to be used, with better resolution and thus better visualization of the internal cervical os. With improved resolution, clinicians can accurately determine the position of the leading placental edge to the internal cervical os. The use of TVS has been shown to change the assessment of the placental location in 25% of cases when the placenta is within 2 cm of the internal cervical os, as identified with transabdominal sonography.[51] A leading placental edge greater than 2 cm from the internal cervical os is associated with vaginal delivery, and distances less than 2 cm are associated with bleeding, potentially leading to cesarean delivery.[52,53]

Although placenta previa can occur in nulliparas, risk factors include number of prior cesarean deliveries (odds ratio: 4.5 for one; 44.9 for four[54]), increasing parity independent of number of prior cesarean deliveries,[55] and increasing maternal age.[56]

Early in the second trimester, the placenta occupies a relatively large portion of the uterine cavity and often is positioned near the cervix. As the uterus grows, a lesser proportion of placentas are located near the internal cervical os. This relative change in placental position is best understood by the placental migration

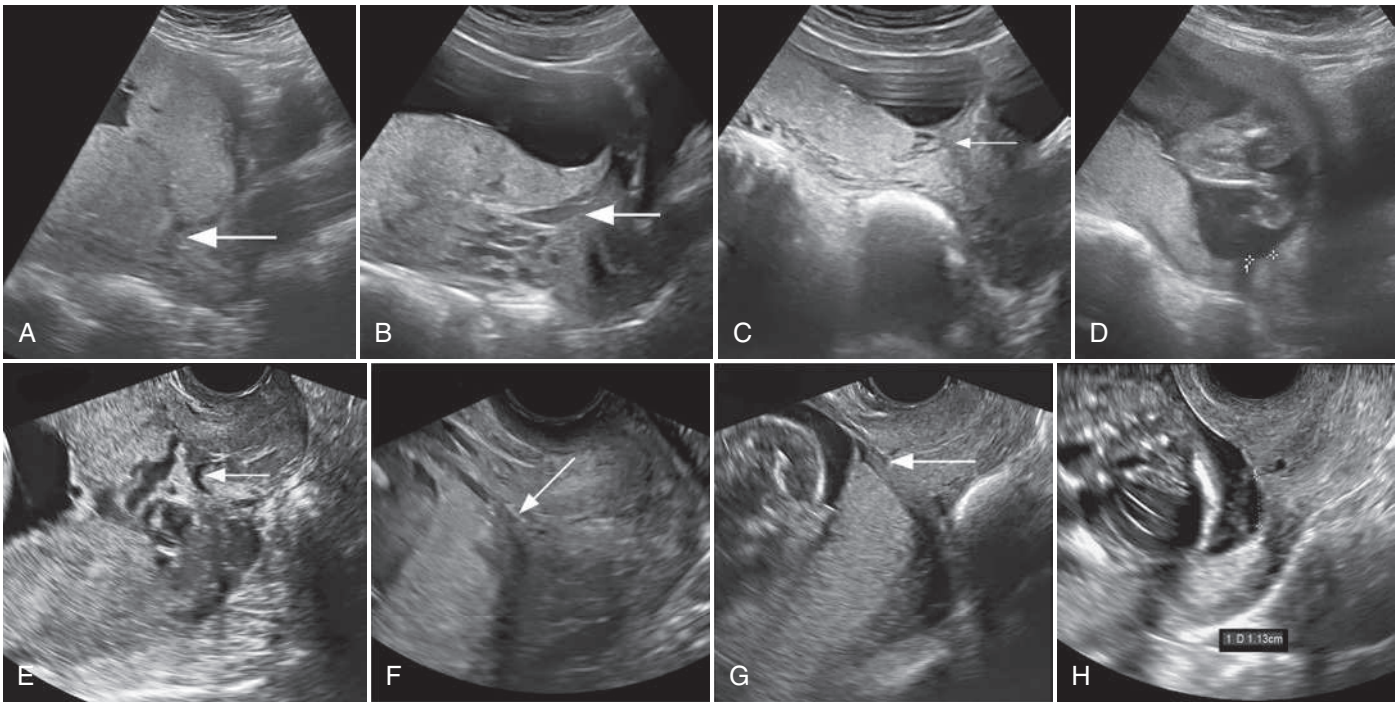

FIG. 43.7 Placental Position. (A)-(D) Transabdominal sonography (TAS) and **(E)-(H)** transvaginal sonography (TVS) can be used to determine placental position with respect to the internal os *(arrows)*. If the position is unclear with TAS, TVS should be used. **(A)** and **(E)** Complete central placenta previa. **(B)** and **(F)** Complete posterior placenta previa. **(C)** and **(G)** Marginal placenta previa. **(D)** and **(H)** Low placenta. The calipers show the distance from the internal cervical os to the leading placental edge.

theory.[57] This theory of "dynamic placentation" suggests that as the uterus develops, the placenta is "drawn away" from the internal cervical os. It is unclear whether the primary mechanism is disproportionate development of the lower uterine segment so that the placenta, although it does not detach from the uterine wall, comes to lie more distant from the internal cervical os. This theory would also be consistent with complete central placenta previas that do not resolve at a rate approaching that of other low-lying placentas, because the expansion of the lower uterine segment would not lead to the resolution of this type of placenta previa.

If the placenta overlaps the cervix by less than 2 cm at the end of the second trimester, more than 88% of patients deliver vaginally.[58] A rate of migration (in the second and third trimesters) away from the internal os of 3.0 to 5.4 mm per week is also associated with vaginal delivery, whereas a placental-internal os distance of less than 2 cm or a pattern of migration of 0.3 to 0.6 mm weekly are associated with interventional cesarean delivery and a higher rate of peripartum complications.[58,59]

The prediction of a placenta previa at delivery is best when the placenta overlaps the internal cervical os by 1.4 cm at 10 to 16 weeks' gestation,[60] or 2 cm at 20 to 23 weeks' gestation.[61] Mustafa et al.[62] demonstrated that if the placenta overlaps by 2.3 cm at 11 to 14 weeks, the probability of a placenta previa at term is 8%, with a sensitivity of 83% and a specificity of 86%.[62] Aside from a complete central placenta previa, given the current data, it is still difficult to predict precisely which patients will have resolution of their low placenta; therefore further ultrasound examinations are required to assess placental position if a low placenta is identified early in gestation. In a large retrospective study, if the placenta was low (<2 cm from the internal cervical os) at 16 to 24 weeks' gestation, 1.6% had a persistent low placenta or placenta previa at or near term.[63]

For women with a low placenta, the description of the leading edge of the placenta in the early third trimester as "thin" (≤1 cm in thickness and/or angle of placental edge <45 degrees) or "thick" (any other type of placenta) is predictive of delivery complications. Antepartum hemorrhage is more common with thick-edged placentas, as is the rate of cesarean delivery, placenta accreta, low birth weight, and earlier gestational age at delivery.[64] Interestingly, a more recent study performed in the first and second trimesters suggested that a thin-edged placenta with a smaller angle was more predictive of placenta previa.[65] Although not ready for clinical implementation, this parameter may help identify patients who can be reassured early in pregnancy that they will not have a placenta previa at delivery.

PLACENTA ACCRETA

The normal placenta attaches to but does not invade the myometrium. At delivery, the placenta separates at the decidual plane, with an abrupt cessation of intraplacental flow as the myometrium contracts.[66] A placenta that is abnormally adherent to the uterine wall after delivery is termed **placenta accreta. Placenta increta** occurs if the placenta invades the myometrium more deeply, and **placenta percreta** refers to a placenta that at least in part protrudes through the uterine serosa. Placenta accreta, increta, and percreta (hereafter referred to as "placenta accreta" unless

otherwise indicated) are serious complications of pregnancy associated with maternal blood loss, need for hysterectomy, and retained products of conception. With ultrasound, placenta accreta can be identified antenatally so that delivery plans can be made prospectively, improving the outcome for mother and child.

Although placenta accreta (or increta or percreta) can occur in any pregnancy, important risk factors include prior uterine surgery (with risk increasing with increasing number of prior cesarean deliveries), placenta previa, unexplained elevated maternal serum alpha-fetoprotein (MS-AFP), increased maternal cell-free placental lactogen, and advancing maternal age.[67-70] A woman with no placenta previa and no prior history of cesarean section has a baseline risk of 0.26% for placenta accreta. This increases almost linearly with number of prior cesarean sections, to 10% in patients with four or more.[71] Women with a placenta previa and an unscarred uterus have a 5% risk of clinical placenta accreta. With a placenta previa and one previous cesarean section, the risk of placenta accreta is 24%; this risk increases to 67% with a placenta previa and four or more cesarean deliveries.[71]

Several sonographic signs are associated with placenta accreta. The presence of a coexisting **placenta previa** in the majority of cases makes it particularly likely that the adherent portion of the placenta will be low in the uterus, in the region of a prior cesarean scar. This simple fact makes the evaluation of these placentas much more straightforward with TVS. Sonographic findings of placenta accreta include loss of the normal hypoechoic retroplacental-myometrial interface, thinning or disruption of the hyperechoic subvesicular uterine myometrium/serosa, presence of focal exophytic masses, and numerous placental lakes[72-75] (Fig. 43.8, Video 43.3).

The color Doppler ultrasound findings suggestive of placenta previa accreta include diffuse lacunar blood flow throughout the placenta, dilated vascular channels between the placenta and bladder or cervix, absence of the normal subplacental venous flow, and the demonstration of vessels crossing the placental-myometrial disruption site.[76,77] Three-dimensional sonography may also be helpful for evaluation of vascular anatomy in the setting of a placenta accreta.[78,79] The gray-scale and color Doppler sonographic findings described for placenta accreta are also present, but more exaggerated, in placenta increta and placenta percreta (Figs. 43.8 and 43.9; Videos 43.4 and 43.5). Three-dimensional color and power Doppler ultrasound are helpful to demonstrate the extensive torturous vascularity seen with such placentas. Greatly increased vascular lacunae with turbulent or "tornado" blood flow increases the likelihood of placenta increta or placenta percreta.[80]

Many recent studies have documented the use of ultrasound findings to identify women with placenta accreta. A recent meta-analysis documented that incorporation of sonographic abnormalities (placental lacunae, loss of the placental-myometrial hypoechoic space, abnormalities of the uterine-bladder interface, and color Doppler) led to a sensitivity of 91% and specificity of 97% for the detection of placenta accreta.[81] A "Placenta Accreta Index" was reported that included number of prior cesarean deliveries, placental location, presence and grade of lacunae, smallest myometrial thickness, and presence of bridging vessels, and constructed a receiver operating characteristic curve whereby the area under the curve was 0.87 (95% confidence interval [CI], 0.8, 0.95). A score of 0 to 9 had a range of probability of placenta accreta from 2% to 96%, respectively.[82] Further work is necessary to determine the historical and sonographic parameters needed to optimize prenatal diagnosis.

As in many aspects of obstetric sonography, early diagnosis is preferable. In women with a history of cesarean delivery, a gestational sac in the lower half of the uterus, at or before 10 weeks' gestation, is associated with placenta accreta,[83] as are first-trimester placental lacunae, an irregular placental-myometrial interface and placenta previa[84-86] (Fig. 43.10). Cesarean scar ectopic pregnancies appear to be precursors of placenta accreta.[87] When the diagnosis is unclear or nonspecific findings are present, magnetic resonance imaging (MRI) may be helpful,[88-93] particularly when the placenta is posterior over an area of prior uterine scar, such as from myomectomy (Fig. 43.11).

Information about placenta accreta and its variants is indispensable for delivery management. Accurate prenatal diagnosis allows uterine conservation and avoidance of massive blood loss at delivery. Strategies include preoperative placement of internal iliac artery balloon catheters and ultrasound-guided fundal classical cesarean incisions to deliver the fetus above the upper margin of the placenta.

PLACENTAL ABRUPTION

Placental abruption is one of the worrisome causes of vaginal bleeding in the latter part of pregnancy because it contributes to perinatal mortality. Patients typically present with third-trimester vaginal bleeding associated with abdominal or uterine pain and labor. The incidence is approximately 0.5% of pregnancies. History of prior abruption, hypertension, prolonged rupture of membranes, IUGR, chorioamnionitis, polyhydramnios, maternal thrombophilias, maternal substance use (tobacco, alcohol, cocaine), maternal trauma, and advanced maternal age are all risk factors for placental abruption.[94-96] The diagnosis of placental abruption is typically made based on clinical findings; the retroplacental clot is frequently isoechoic to the placenta or myometrium and cannot always be identified sonographically.

A **subplacental hematoma** between the placenta and uterine wall is a placental abruption (Fig. 43.12, Videos 43.6 and 43.7). This should be differentiated from a **subchorionic hematoma,** in which the hematoma is located beneath the chorion, not the placenta. Although a subchorionic hematoma can occur anytime during pregnancy, it is more common in the first half of pregnancy, and its appearance will change as the hematoma organizes (Fig. 43.13A). A **preplacental hematoma** is a rare condition likely caused by bleeding from fetal vessels and located on the fetal surface of the placenta under the chorion (Fig. 43.14, Videos 43.8 and 43.9). Because preplacental hematomas likely result from the accumulation of fetal blood, prognosis may be poorer.[97] When massive, these hematomas are sometimes termed **Breus mole.** Preplacental hematomas are associated with maternal hypertension.[98]

An acute hematoma has an echogenicity similar to that of the placenta, making sonographic visualization difficult. As the hematoma organizes, it becomes more hypoechoic (Fig. 43.13B)

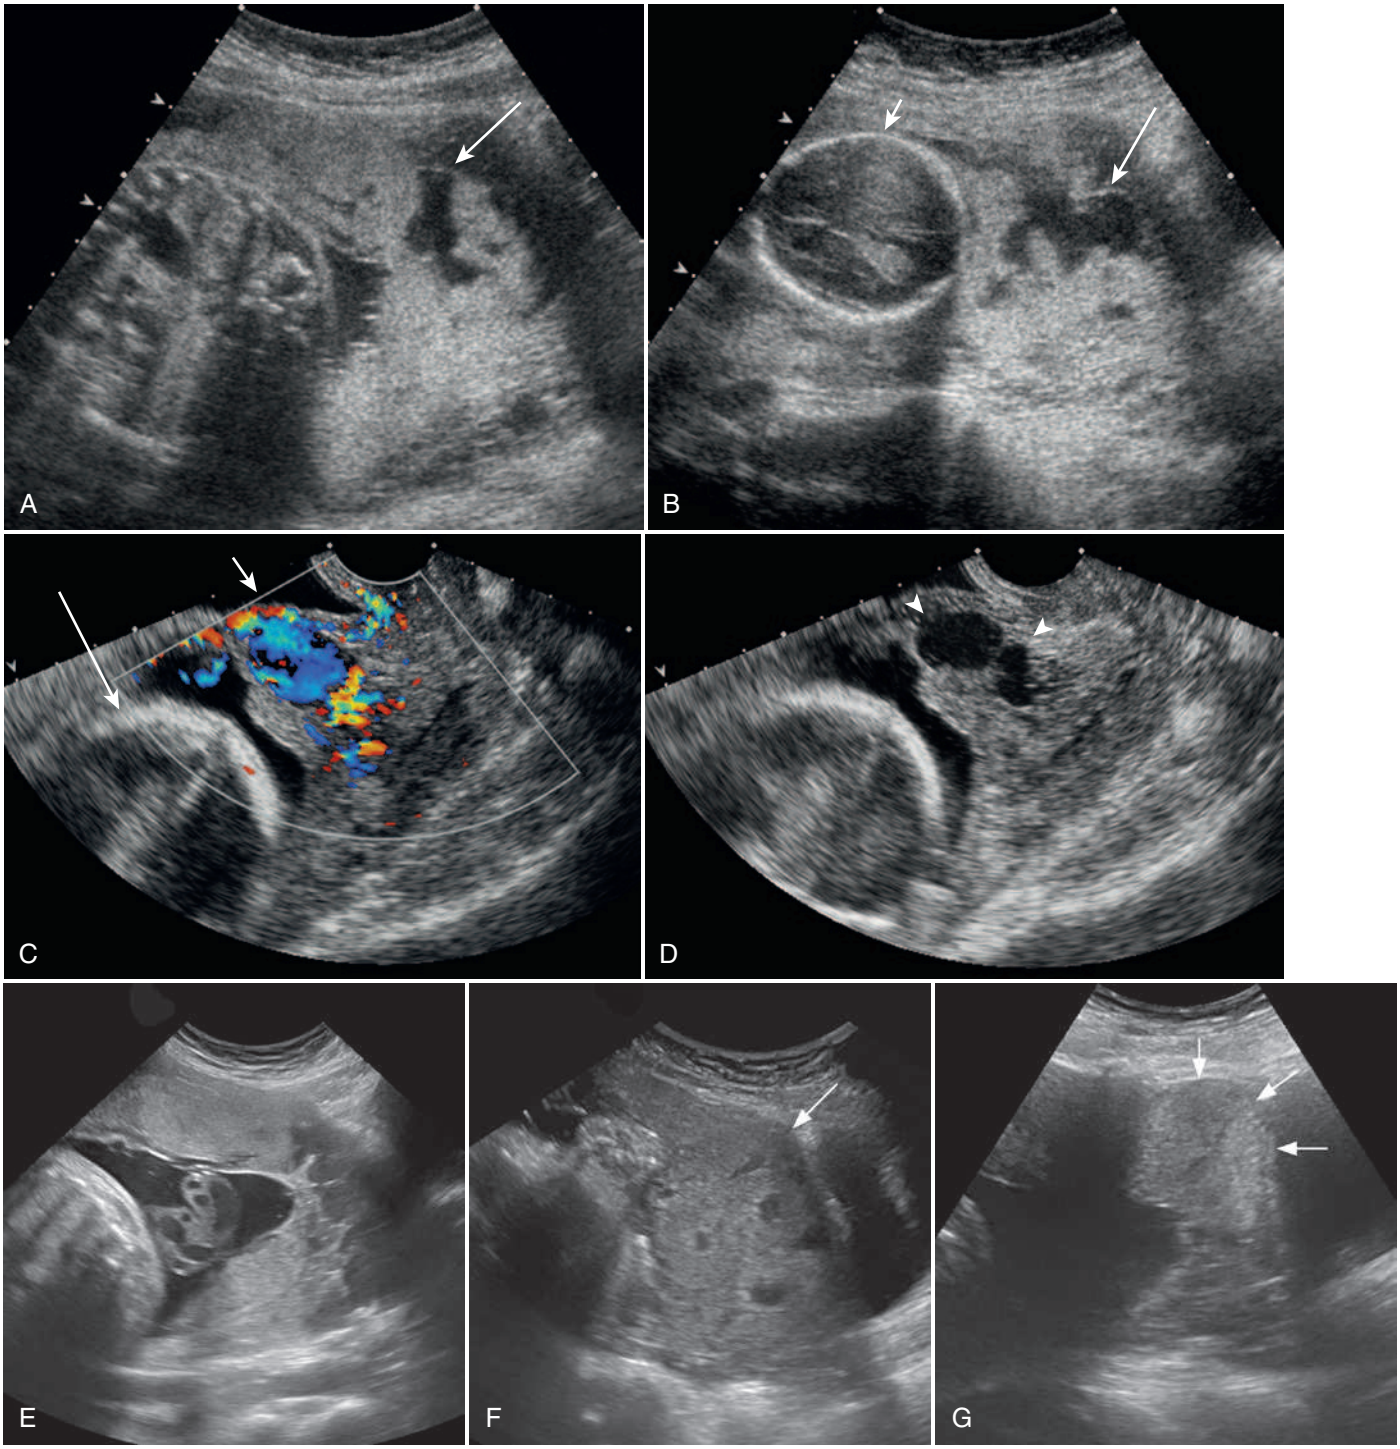

FIG. 43.8 Placenta Accreta With Placental Lakes. **(A)** Transabdominal sonogram of a third-trimester placenta shows a placental (venous) lake *(arrow).* **(B)** In a different patient, transabdominal sonogram of second-trimester placenta shows multiple placental lakes *(long arrow); short arrow,* fetal head. **(C)** In another patient, transvaginal sonogram of second-trimester placenta shows intense color flow within and below the placenta; *long arrow,* fetal head; *short arrow,* maternal bladder. **(D)** In the same patient as **C,** multiple placental lakes are visualized *(arrowheads).* **(E)** Placenta accreta. Note the multiple placental lakes in the lower uterine segment in the area of scar from a prior cesarean. **(F)** Placenta increta. Note the placental lakes and the loss of the hypoechoic zone between the placenta and myometrium *(arrow).* **(G)** Placenta percreta. Note the bulging of the placenta in the lower uterine segment including into the posterior wall of the bladder *(arrows).* See also Video 43.3 (accreta), Video 43.4 (increta), and Video 43.5 (percreta).

and can approach the echogenicity of the myometrium. An indirect sign of the presence of an acute hematoma is apparent thickening of the placenta, which is associated with worse outcome.[99,100]

Even though placental abruption remains a clinical diagnosis, ultrasound can play an important role. Larger hematomas are expected to be seen (Fig. 43.15), and these are more likely to be clinically important. Glantz and Purnell[101] reported that the identification of placental abruption by ultrasound had a sensitivity, specificity, positive predictive value, and negative predictive value of 24%, 96%, 88%, and 53%, respectively. They determined that if a hematoma was identified by sonography, there was an increased risk of preterm delivery, low birth weight, and neonatal intensive care unit admission. Increased size of the hematoma and percentage of placental involvement are associated with increased fetal mortality.[102]

PLACENTAL INFARCTION

Placental infarctions can occur focally or throughout the placenta and are thought to have a vascular etiology. **Maternal floor infarction** is a diffuse entity overtaking the villi with a fibrinoid deposition at the maternal surface and basal plate, reaching into the placental substance. The presence of this fibrin surrounding the villi obstructs nutrient exchange from mother to fetus. Both

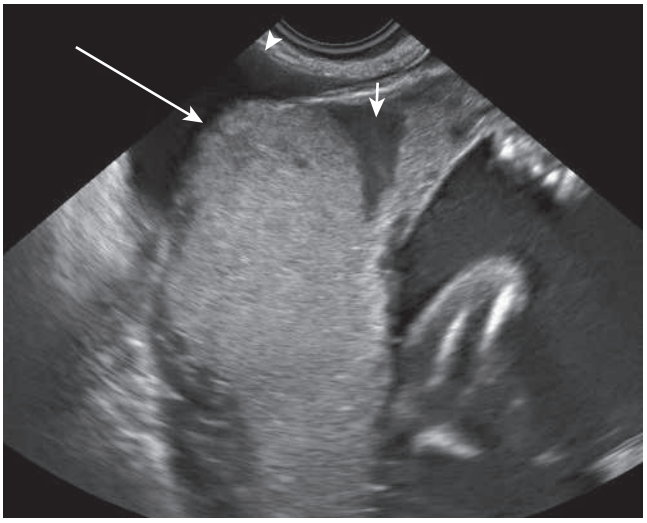

FIG. 43.9 Placenta Percreta. Transvaginal sonogram of a third-trimester placenta shows loss of the hypoechoic border between the placenta and the myometrium, with protrusion of the placenta *(long arrow)* into the maternal bladder *(arrowhead); short arrow,* placental lake.

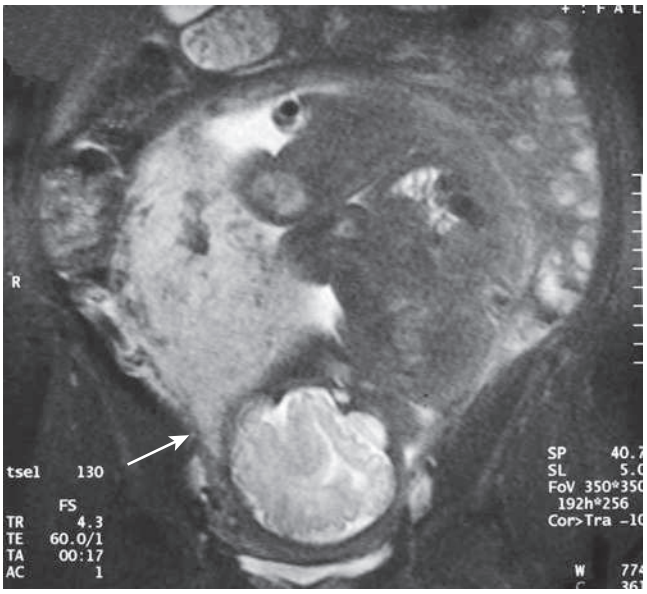

FIG. 43.11 Placenta Accreta. Coronal T2-weighted MR image shows an absent myometrial-placental interface in a posterolateral location *(arrow)* surrounded by normal myometrial-placental interface in a patient with previous posterior myomectomy. This region was not well evaluated with ultrasound. (With permission from Levine D. Placenta accreta: evaluation with color Doppler, power Doppler and fast MRI. Radiology. 1997;205:773-776.[89])

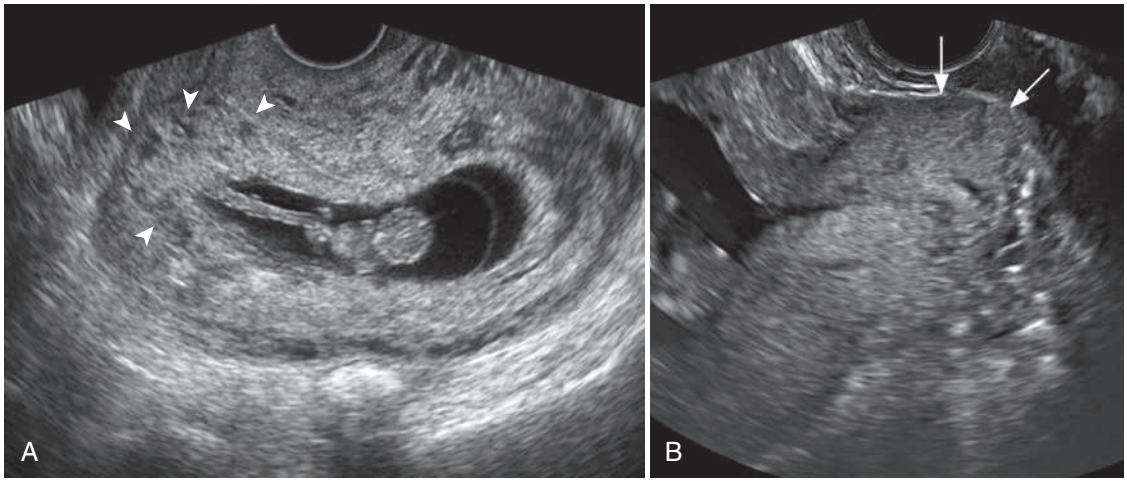

FIG. 43.10 First-Trimester Placenta Accreta. (A) The umbilical cord insertion is low in the uterus; arrowheads indicate multiple small placental lakes. This patient had a prior cesarean delivery and subsequently was shown to have a placental previa accreta. **(B)** A different patient with two prior cesarean deliveries. Note bulging of the placental tissue in the scar from a prior cesarean into the posterior wall of the bladder *(arrows).*

abnormalities are associated with oligohydramnios, umbilical artery Doppler abnormalities, IUGR, central nervous system injury, and fetal demise. Maternal floor infarction tends to recur in subsequent pregnancies.[28,103-105] Although peripheral infarctions are common at term, infarctions larger than 3 cm or involving more than 5% of the placenta are associated with increased perinatal morbidity. Both maternal and fetal thrombophilias can lead to placental infarctions.[106]

The sonographic findings of maternal floor infarction include a hyperechoic placental mass (Fig. 43.16A) or placental thickening. Hyperechoic areas of the placenta are especially prominent along the maternal surface of the placenta and can stretch into the placental substance itself. These can be a normal finding, especially with mature placentas. Hyperechoic placental masses may be associated with central hypoechoic spaces as they organize. **Subchorionic cysts** are also commonly present with maternal floor infarction (Fig. 43.16B). On this continuum are placental basal plate calcifications, which at times, can be quite prominent (Fig. 43.16C). The hyperechoic mass seen with maternal floor infarction resembles that seen with placental chorioangiomas.[107]

Placental infarctions caused by maternal vascular disease often result in uteroplacental ischemia and infarction of the villi. These appear as echogenic, rimmed cystic lesions within the placenta, not necessarily at the maternal side of the placenta or basal plate (Fig. 43.17, Videos 43.10 and 43.11). When identified early in gestation, anticoagulation with heparin may improve outcome; however, further investigation is necessary before establishing treatment guidelines.[108,109]

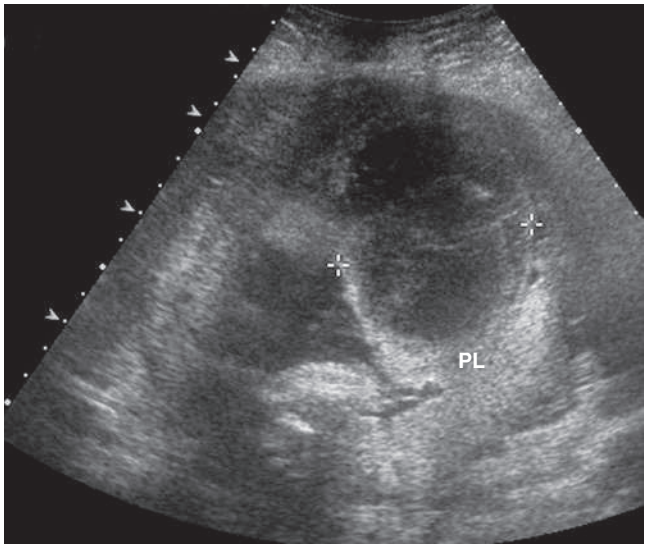

FIG. 43.12 Placental Abruption. Transabdominal sonogram of the placenta *(PL)* with a hematoma *(calipers)* lifting the placenta away from the uterine wall. See also Videos 43.6 and 43.7.

PLACENTAL MASSES

Solid-appearing placental masses include **chorioangioma, subamniotic hematoma, subchorionic hematoma,** and **placental hemorrhage.** These masses should be differentiated from fluid-filled placental regions of placental cysts and venous lakes. As previously discussed, placental infarctions may also have a masslike appearance.

Subchorionic placental cysts on the fetal surface of the placenta are predominantly innocuous findings on prenatal sonography, similar to cysts in the substance of the placenta (Fig. 43.18). Most fetuses whose placentas contain these cysts have normal outcomes. Larger cysts (>4.5 cm) are associated with IUGR. Maternal floor infarction may also be associated with placental cysts.[110,111]

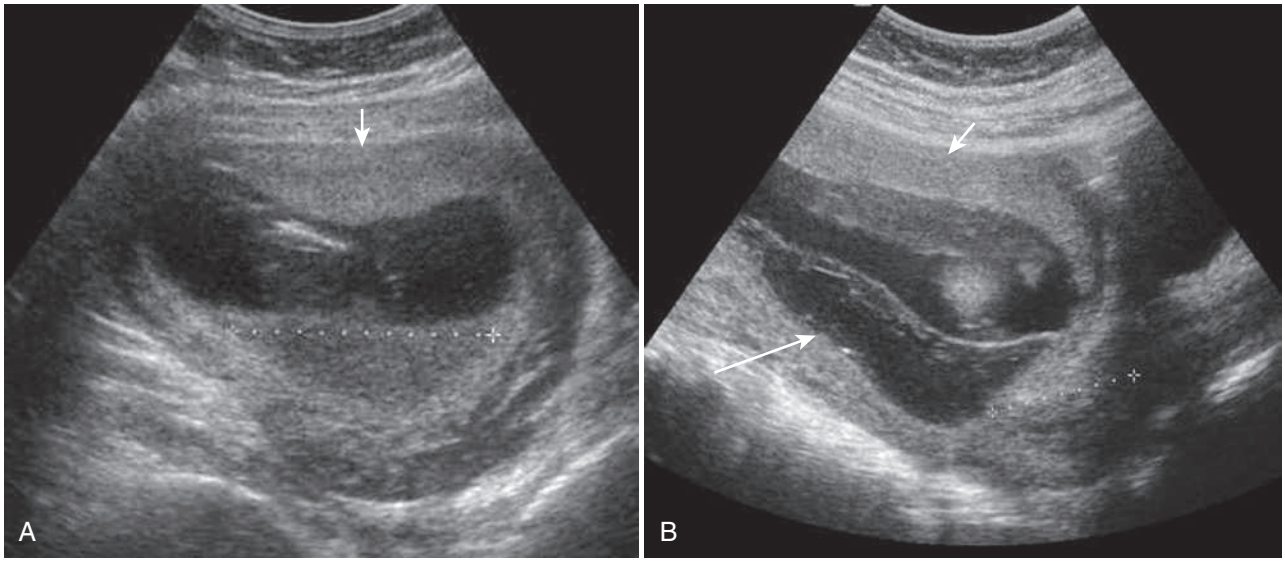

FIG. 43.13 Subchorionic Hematoma. (A) Transabdominal transverse view of the uterus in the second trimester shows acute subchorionic hematoma *(calipers).* The anterior placenta is shown by the short arrow. **(B)** Transabdominal midsagittal view of the same patient later in pregnancy demonstrates the subchorionic hematoma *(long arrow)* more hypoechoic and located overlying the cervix *(calipers); short arrow,* placenta.

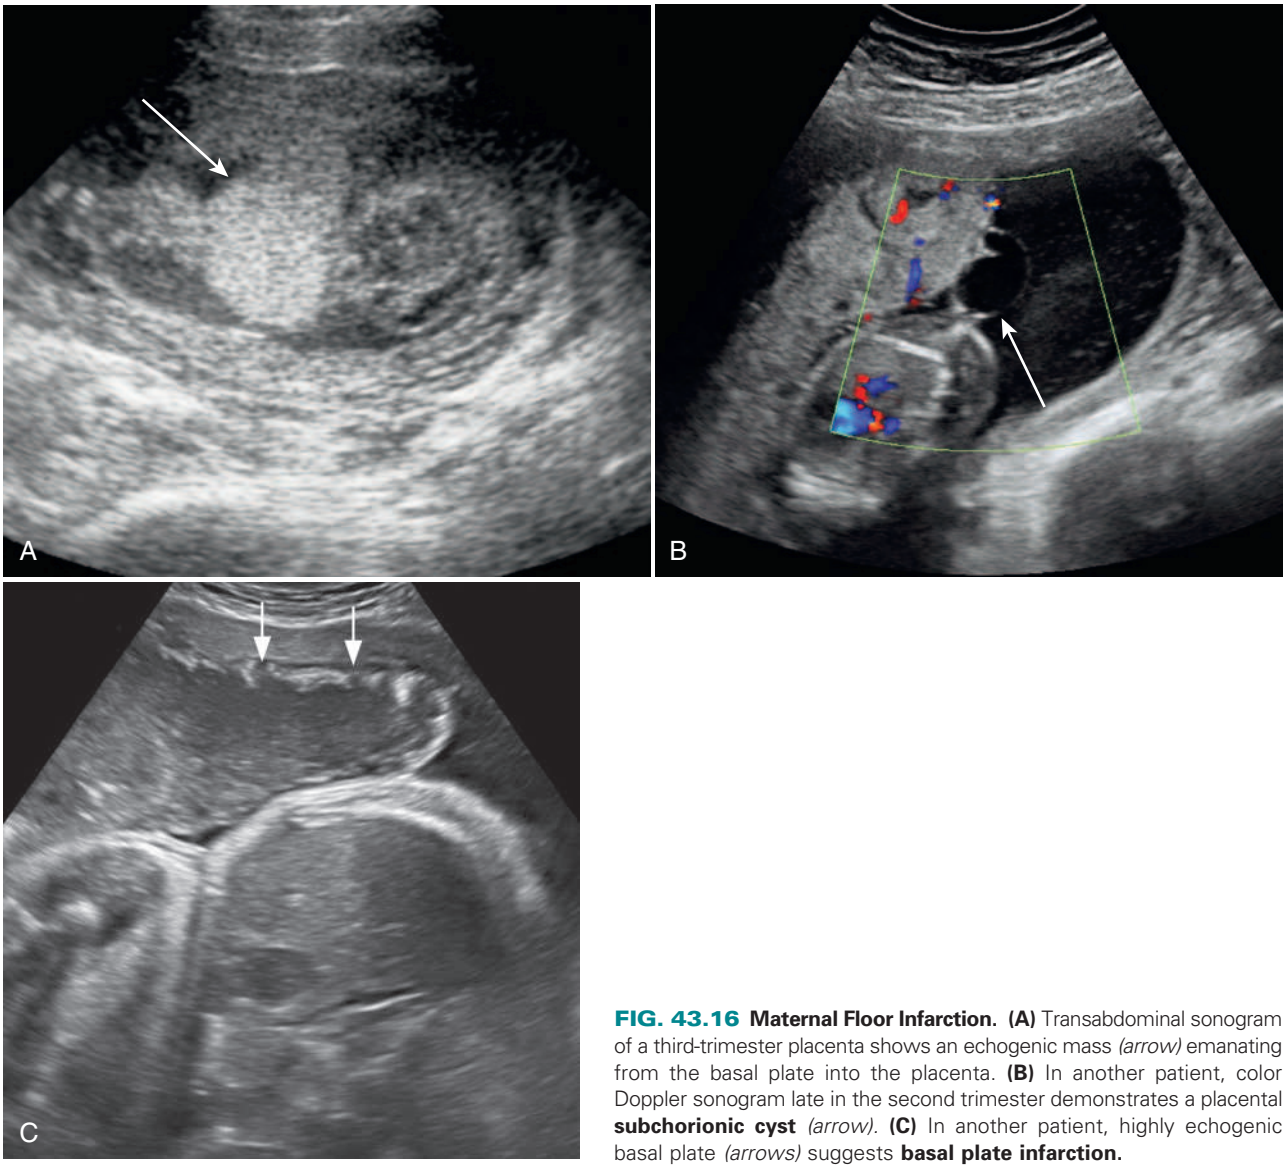

FIG. 43.16 Maternal Floor Infarction. (A) Transabdominal sonogram of a third-trimester placenta shows an echogenic mass *(arrow)* emanating from the basal plate into the placenta. **(B)** In another patient, color Doppler sonogram late in the second trimester demonstrates a placental **subchorionic cyst** *(arrow)*. **(C)** In another patient, highly echogenic basal plate *(arrows)* suggests **basal plate infarction.**

The most common benign tumor of the placenta is the **chorioangioma,** occurring in approximately 1% of pregnancies (Fig. 43.19). Although most are asymptomatic, large chorioangiomas can lead to high-output fetal cardiac failure, anemia, hydrops, and death.[112] Chorioangiomas appear as well-circumscribed solid tumors in the placenta. They can range from hypoechoic to hyperechoic compared to the echogenicity of the placenta. A threshold of 5 cm in diameter typically portends a high risk for adverse outcome.[113,114] Use of color or power Doppler ultrasound is helpful to identify increased blood flow within the solid mass, thereby distinguishing the mass as a chorioangioma.[115,116] Blood flow is not consistently demonstrable, especially with smaller chorioangiomas; those with low flow tend to have a better outcome, whereas chorioangiomas with extremely elevated flow usually are associated with adverse perinatal outcome, commonly through high-output heart failure. These pregnancies require close follow-up and surveillance for polyhydramnios and other signs of fetal hydrops.[117,118] Decreasing blood flow, as documented by color or power Doppler ultrasound, signals an improved prognosis.[118] Three-dimensional power Doppler can assist with the diagnosis of chorioangioma and can be used to quantitate blood flow to the tumor.[113]

In cases where the fetus is at risk for **hydrops,** in utero intervention improves perinatal outcomes. Interventions have included injection of thrombogenic material,[119] microcoil embolization,[120] and endoscopic laser devascularization,[121] in utero transfusion, amnioreduction (for those with polyhydramnios), and alcohol injection.[122]

Maternal **malignancies** rarely metastasize to the placenta. Malignant melanoma and adenocarcinoma of the breast, pancreas, and colon are most common.[123,124] These deposits are typically microscopic and do not interfere with placental function.

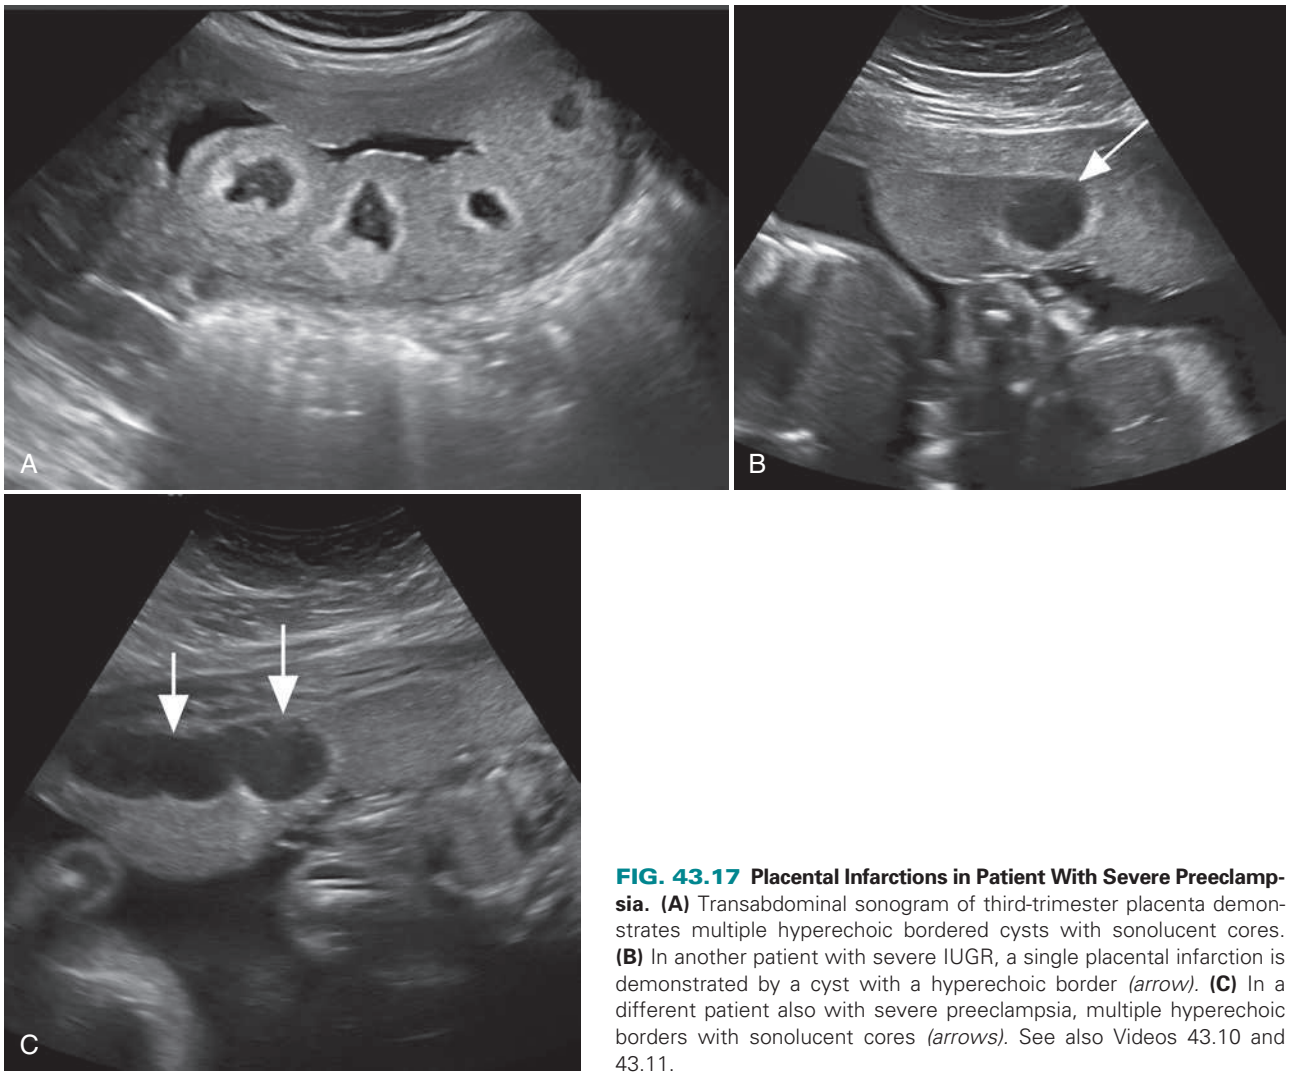

FIG. 43.17 Placental Infarctions in Patient With Severe Preeclampsia. (A) Transabdominal sonogram of third-trimester placenta demonstrates multiple hyperechoic bordered cysts with sonolucent cores. **(B)** In another patient with severe IUGR, a single placental infarction is demonstrated by a cyst with a hyperechoic border *(arrow)*. **(C)** In a different patient also with severe preeclampsia, multiple hyperechoic borders with sonolucent cores *(arrows)*. FIG. 43.19, cont'd **(H)** and **(I)** Placental chorioangioma *(arrow)* in another patient (**I** taken 4 weeks after **H**). The chorioangioma is relatively homogeneous and similar in echogenicity to the placenta.

MESENCHYMAL DYSPLASIA OF THE PLACENTA

Mesenchymal dysplasia of the placenta resembles a partial hydatidiform mole both grossly and microscopically, with a thickened placenta and small cystic lesions. The appearance of the placenta has been described as having a "stained-glass" appearance when color Doppler sonography is used, due to the flow noted in the multiple placental cysts.[125] In contrast to partial moles, mesenchymal dysplasia of the placenta may be associated with a normal fetus, although IUGR is common. There is also an association with **Beckwith-Wiedemann syndrome**[126] (Fig. 43.20). The villi in these cases are cystic with dilated vasculature. The karyotype is usually normal.[127]

FIG. 43.20 Mesenchymal Dysplasia of Placenta. Associated with Beckwith-Weidemann syndrome at 20 weeks' gestation. Note the enlarged placenta (8 cm, *calipers*) with multiple cystic spaces.

MOLAR GESTATIONS

Gestational trophoblastic disease consists of **complete mole** (Fig. 43.21) and **partial mole** and **choriocarcinoma.** These placental abnormalities are discussed in detail in Chapter 30.

MORPHOLOGIC PLACENTAL ABNORMALITIES

There are a number of placental shape abnormalities, some quite common, and some quite rare. New evidence suggests that the development of placental shape abnormalities originates from placental vascular abnormalities in the first trimester, also leading to umbilical cord insertion abnormalities.[11]

Circumvallate Placenta

In circumvallate placenta the membranes of the chorion laeve, instead of inserting at the margin of the placental disc, insert more toward the center of the disc. The pathologist can identify fibrin at the margin along with evidence of bleeding. With a complete circumvallate placenta, a ring may constrict the chorion frondosum.[28] Because of this placement, there is disproportionate folding of the placenta and fetal membranes. This results in the chorionic plate being smaller than the basal plate. Within the membrane fold, hyalinized villi may be seen after being incorporated into the fold.

Circumvallate placenta has the sonographic appearance of a rolled edge of membranes at the placental edge inserting toward the center of the placental chorionic disc (Fig. 43.22, Videos 43.12 and 43.13). Termed a **placental shelf,** this rolled edge of membranes can be thick and most often occupies only a small

portion of the placenta. Circumvallate placentas can also be confused with **uterine synechiae** (Fig. 43.23A), **uterine septum** (Fig. 43.23B), and **amniotic bands.** Carefully identifying the insertion of the membranes and determination of the echogenicity of the rolled edge of placenta, which should be similar to that of the placenta, should provide the correct diagnosis.

If a circumvallate placenta is identified, even if it seems to occupy only a small portion of the placenta, the rest of the placenta must be evaluated to determine whether the rolled edge of membranes involves the entire placenta. Three-dimensional sonography has been suggested as helpful for diagnosing a complete circumvallate placenta with the appearance of a "tire mounted on a wheel" or the "tire sign."[128] Complete circumvallate placentae are associated with adverse neonatal outcomes, including placental abruption, preterm delivery, oligohydramnios, IUGR, emergency cesarean delivery, Apgar scores less than 7, and perinatal death.[129,130] Fortunately, complete circumvallate placenta is rare, whereas partial circumvallate placentas are quite common and should be regarded as normal variants.

Evaluating second-trimester placental shelves to determine whether the sonographic finding persisted into the third trimester, Shen et al.[129] found an incidence of 11% for the identification of these shelves at the 13- to 16-week scan. Of note, none of the placental shelves occupied more than 25% of the placenta. Also, none of the partial circumvallate placentas could be sonographically appreciated in the third trimester. All neonates had a normal outcome. A recent large study of postdelivery placenta inspection yielded a complete circumvallate placenta incidence of 1.8%, none of which was detected antenatally.

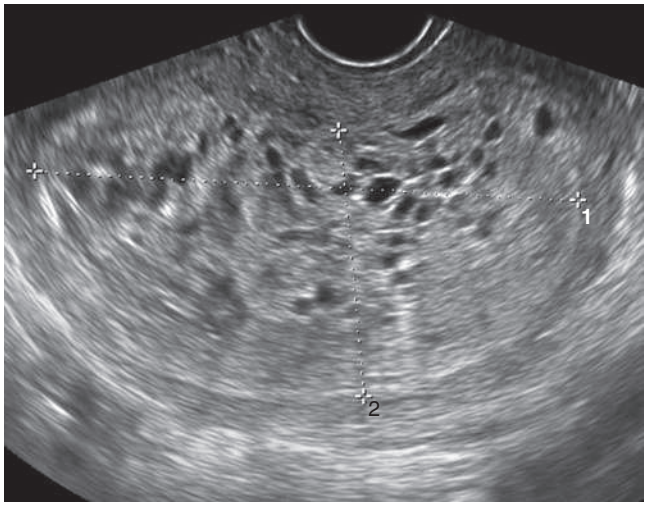

FIG. 43.21 Molar Pregnancy. Transvaginal sonogram in the late first trimester demonstrates a moderate amount of gestational tissue with multiple cystic spaces.

Succenturiate Lobe

Succenturiate lobes, or **accessory lobes,** of the placenta can be a single lobe or multiple lobes in addition to the main placental lobe (Fig. 43.24). Their incidence is as high as 6%.[28] Given that placental tissue is present in the accessory lobe, there must be arterial and venous connections to the main portion of the placenta. One concern involves a retained placental accessory lobe after delivery, if not expected from the antenatal sonogram. Succenturiate lobes can also lie over the cervix as a variant of **placenta previa.**[126] Even more important is the concern over the location of the vascular connection between the main placenta and the succenturiate lobe. If the vessels lie in proximity to the cervix, a **vasa previa** may be present.

When a succenturiate lobe of the placenta is identified, it is imperative that the vascular connection between the succenturiate lobe and placenta be identified. This can be difficult at times because of poor visualization, especially later in pregnancy, and because the closest distance between succenturiate lobe and placenta is not always the route taken by the vessels. At a

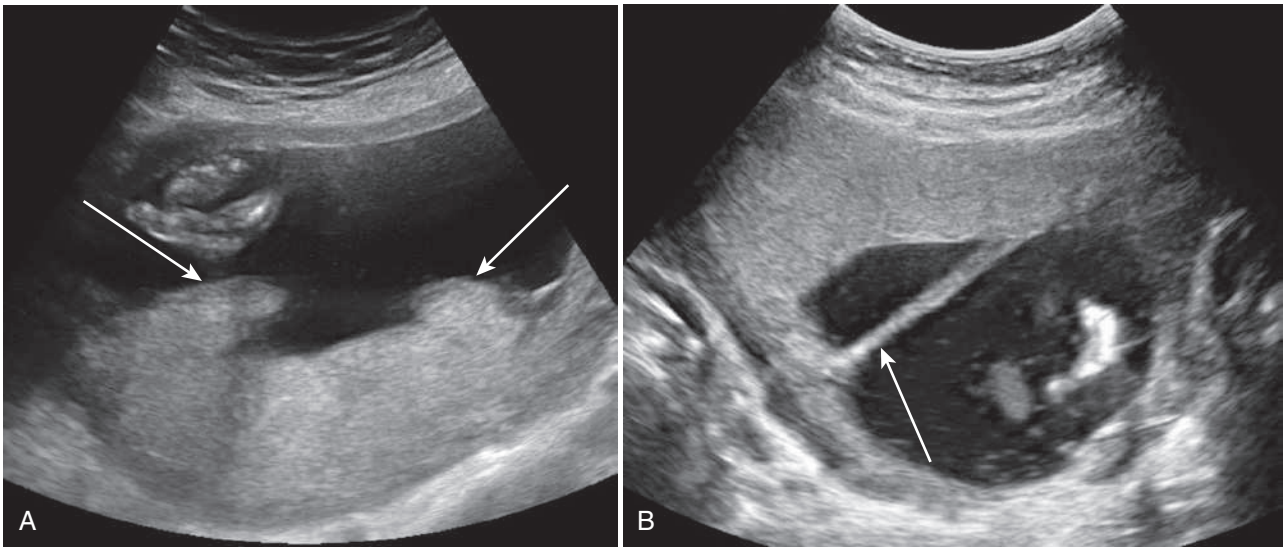

FIG. 43.22 Circumvallate Placenta. (A) Transabdominal sonogram in the early third trimester shows rolled edges of the placenta *(arrows).* **(B)** Transabdominal sonogram in the second trimester shows a placental shelf *(arrow),* which has echogenicity similar to the remainder of the placenta. minimum, the internal cervical os should be evaluated to assess for the presence of fetal vessels.

Bilobed Placenta

Bilobed placentas consist of two similarly sized placental lobes separated by intervening membranes (Fig. 43.25, Video 43.14). There must be some vascular connection between the lobes, and the umbilical cord may insert in the membranes between the lobes. Although rare, a bilobed placenta can be regarded similar to succenturiate lobes, with similar risks. Bilobed placentas may have more unprotected vessels, however, reinforcing the need for careful evaluation of the placental vasculature in such cases.

UMBILICAL CORD

Size and Appearance

Umbilical cord length varies, and a normal length has not been established. However, extremes of cord length are associated with abnormal outcome. **Short umbilical cords** are associated with conditions that impair fetal movement early in gestation, such as akinesia syndromes, aneuploidy, and extreme IUGR. **Excessive cord length** is associated with asphyxia or death resulting from a variety of situations that compromise cord flow, including excessive coiling, true knots, multiple loops of nuchal cord, and cord prolapse.

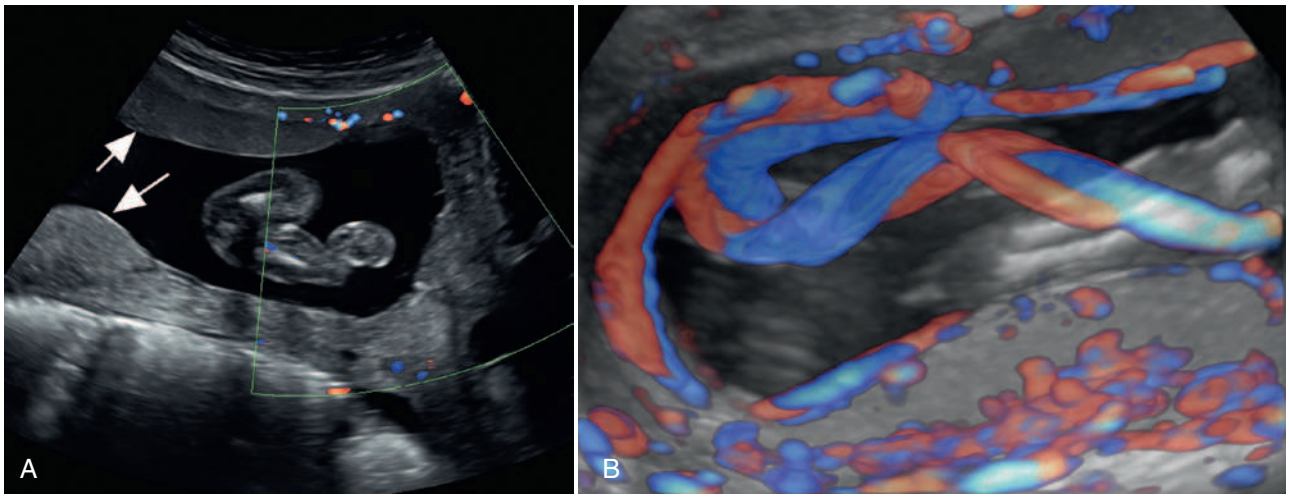

FIG. 43.25 Bilobed Placenta. (A) Transabdominal sonogram of a third-trimester bilobed placenta. Both placental discs are of comparable size *(arrows)*. **(B)** Three-dimensional color Doppler ultrasound demonstrates the umbilical cord inserting into the upper lobe and the fetal vascular connection between the lobes. See also Video 43.14.

The potential importance of the **diameter** of the umbilical cord is unclear. In the first trimester, fetal size correlates with cord diameter, and small diameter may be a marker for pregnancy loss.[131] Also, data from multiple centers suggest that cord diameter may be a marker for chromosomal abnormalities when larger[132] or smaller than expected.[133] In the second and third trimesters, the largest contributor to the size of the umbilical cord is **Wharton jelly,** the supportive substance surrounding the umbilical vessels. A nomogram has been developed for the area of Wharton jelly that correlates with fetal biometry up to 32 weeks' gestation.[134,135] In the second trimester, a larger-than-expected umbilical cord is associated with aneuploidy.[136] IUGR has been associated with thin cords; diabetes, fetal macrosomia, placental abruption, and rhesus isoimmunization have been associated with thicker cords.[137] The associations between fetal umbilical cord size and fetal growth overlap too greatly to be useful screening tools for these entities.[138]

Information on the umbilical cord and its manner of **twisting** comes from the pathology literature. Left twists occur in 83%, right twists in 12%, and absent twists in 5% of umbilical cords in live-born singletons. For the umbilical cords that have a twist, ascertainment of the degree of twist has been reported antenatally. The **umbilical coiling index** is calculated by dividing the number of helices by the cord length in centimeters (Fig. 43.26). The mean umbilical coiling index is 0.44 ± 0.11 antenatally and 0.28 ± 0.08 after delivery.[139] Umbilical coiling does not vary with respect to the amount of Wharton jelly present.[140] Assessment of the degree of coiling in the second trimester does not correlate well with the umbilical coiling index at term.[141]

Absent umbilical cord twists are associated with single umbilical arteries, multiple gestations, fetal demise, preterm delivery, aneuploidy, and both marginal and velamentous umbilical cord insertions[142-144] (Fig. 43.27). Lower degrees of coiling are associated with lesser degrees of fetal growth.[145]

True knots of the umbilical cord occur in 1% to 2% of pregnancies. Although some are normal variants,[146] these knots may also be associated with increased fetal mortality. Sonographic

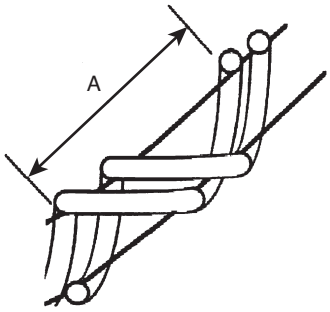

FIG. 43.26 Umbilical Coiling Index. Defined as the distance *(A)* between the same umbilical artery making one turn around the umbilical vein. FIG. 43.27 Uncoiled Cord in Second Trimester.

features such as the "hanging noose sign" have been proposed to make this diagnosis antenatally, with 2D imaging as well as 3D and 4D sonography.[147,148] Although 3D sonography may be helpful for suggesting the presence of a true knot of the umbilical cord, multiple loops of cord lying next to each other can mimic the presence of a knot.[149,150]

Cysts of the umbilical cord can be seen throughout pregnancy, occurring most frequently on the portion closest to the fetus (Fig. 43.28). Many cysts develop from the allantois and omphalomesenteric duct, or **pseudocysts** may develop through liquefaction of Wharton jelly, giving the umbilical cord a hydropic appearance[151,152] (Fig. 43.29). All cord cysts are associated with both structural and chromosomal defects, so a detailed structural survey is required whenever a cyst is encountered.[153] However, cord cysts seen in the first trimester often resolve, without sequelae.[154] **Trisomies 13 and 18** are the most common chromosomal abnormalities associated with umbilical cord cysts,[152,155] and genitourinary and gastrointestinal anomalies are the most common structural defects.[156-159]

Vascular anomalies of the umbilical cord are associated with adverse fetal outcomes. **Umbilical artery aneurysms** are associated with vascular abnormalities, trisomy 18, and fetal demise.[152,160-162] **Spontaneous rupture** of the umbilical artery with a resultant umbilical cord hematoma has also been reported.[162]

Umbilical cord tumors are exceedingly rare. The most common is the umbilical cord **hemangioma,** which appears as a heterogeneous mass surrounded by multiple peripheral cystic areas. Cord hematomas are associated with an increased risk of fetal demise.[163,164]

Nuchal cord (cord around neck of the fetus) is often seen in the second and third trimesters and is a common finding at delivery. Multiple tight loops of nuchal cord indenting the skin late in the third trimester may prompt further evaluation

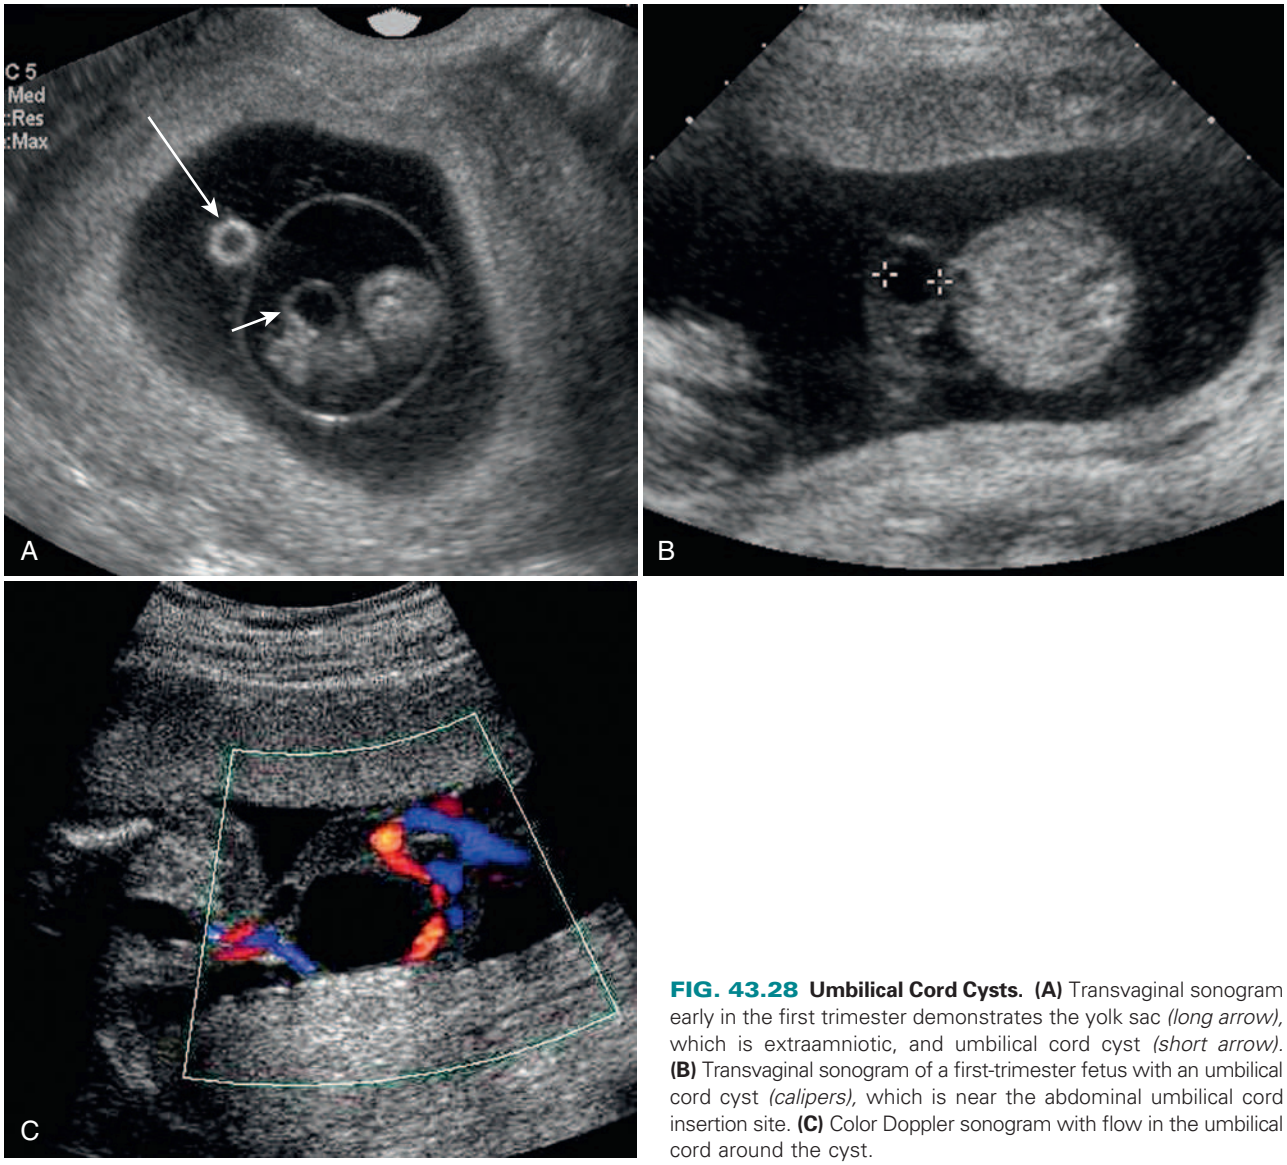

FIG. 43.28 Umbilical Cord Cysts. (A) Transvaginal sonogram early in the first trimester demonstrates the yolk sac *(long arrow),* which is extraamniotic, and umbilical cord cyst *(short arrow).* **(B)** Transvaginal sonogram of a first-trimester fetus with an umbilical cord cyst *(calipers),* which is near the abdominal umbilical cord insertion site. **(C)** Color Doppler sonogram with flow in the umbilical cord around the cyst.

but management is unclear, especially because documenting circumferential looping of the umbilical cord around the fetal neck is difficult because of the shadowing present late in gestation.

The normal umbilical cord has three vessels; one vein carries oxygenated blood to the fetus, and two arteries carry deoxygenated blood from the fetus. In 1% to 2% of pregnancies, however, there is only a **single umbilical artery** (Fig. 43.30, Video 43.15). The diagnosis is made either by examining a free loop of cord in the amniotic fluid or by assessing the umbilical arteries around the fetal bladder. Although associated with aneuploidy as well as many anomalies, especially renal and cardiac abnormalities, in isolation a single umbilical artery has no functional importance.

FIG. 43.29 Edematous Cord. Transabdominal sonogram of a third-trimester fetus shows an edematous area *(arrow)* of cord near the abdominal umbilical cord insertion.

Insertion Into the Placenta

The normal umbilical cord normally inserts into the central portion of the placenta. Identifying the placental umbilical cord insertion is important to recognize abnormalities of the umbilical cord vessels, as with gray-scale imaging and color or power Doppler sonography[165] (Fig. 43.31, Video 43.16).

Velamentous and Marginal Cord Insertions

A **velamentous umbilical cord insertion** refers to the situation where the umbilical cord inserts into the membranes and not the placental disc (Fig. 43.32, Video 43.15). A **marginal cord insertion** (Fig. 43.33), also known as a **battledore placenta,** occurs when the umbilical cord inserts into the very margin of the placenta. Velamentous umbilical cord insertions occur in approximately 1% of singleton pregnancies; marginal cord insertions occur in approximately 7% of singletons. Both of these cord insertions are more common in multiple gestations and are also associated with single umbilical arteries[28] and are associated with the smaller twins in monochorionic twin pregnancies with discordant growth.[166]

Velamentous umbilical cord insertions are sonographically identified throughout the second and third trimesters of pregnancy with great reliability. Sepulveda et al.[167] identified the placental cord insertion in more than 99% of pregnancies, correctly identifying all velamentous cord insertions using both gray-scale and color Doppler sonography.[167] A velamentous cord insertion has been identified as early as 10 weeks' gestation[168] and can be routinely identified on the 11- to 14-week first-trimester scan.[169] Velamentous cord insertions are associated with IUGR, preterm delivery, congenital anomalies, low Apgar scores, fetal and

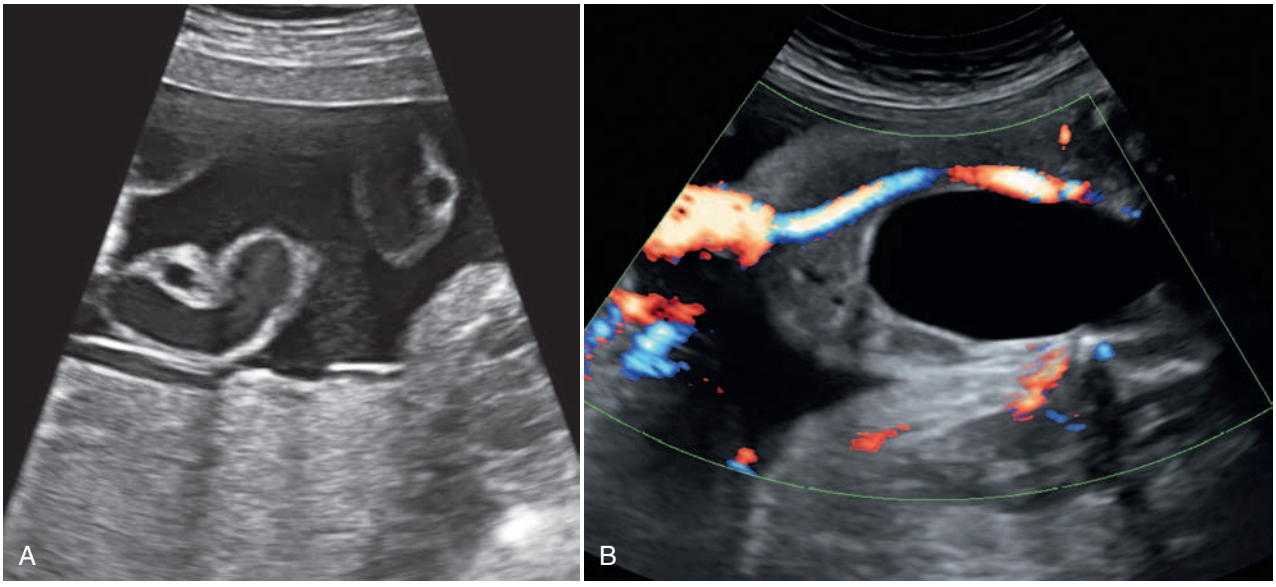

FIG. 43.30 Single Umbilical Artery. (A) Gray-scale sonogram shows a single artery and a single vein. **(B)** Color Doppler ultrasound adjacent to the fetal bladder shows a single umbilical artery. See also Video 43.15.

neonatal death, retained placenta after delivery, and postpartum hemorrhage.[167,170,171] Marginal umbilical cord insertions are not associated with IUGR or preterm delivery[172] but are associated with vasa previa.

The insertion of the umbilical cord into the membranes leads to the unsupported coursing of the umbilical vessels to the placental disc and many complications. Wharton jelly supports and protects the umbilical vessels in the umbilical cord. With the vessels in the membranes, no Wharton jelly is present, leading to increased risk of compression or even rupture of these vessels. Intrapartum fetal heart rate patterns show more variable decelerations and no accelerations with velamentous cord insertions during the first and second stages of labor compared to controls.[170] Increasing length of the unsupported membrane vessels is associated with increasing rates of abnormal heart rate patterns, as is the umbilical cord insertion being in the lower portion rather than the middle or upper portion of the uterus.[170] Nonreassuring fetal heart rate patterns and emergency cesarean deliveries are more frequent with velamentous cord insertions in the lower third than in the middle or upper third of the uterus.[170] Because velamentous cord insertions are typically located low in the uterus, TVS can be critical to making this diagnosis.

A rare abnormality of umbilical cord insertion that overlaps with velamentous umbilical cord insertions is furcate umbilical cord insertion. This occurs when the umbilical cord vessels prematurely divide and insert into the membranes with vessels coursing to the placental substance (Fig. 43.34). The mangrove sign, so called because of the roots of a mangrove tree having a similar appearance, has been coined to denote furcate umbilical cord insertions.[173] A recent case report documents the association of a furcate umbilical cord insertion with retained placenta and a fetal syndrome.[174] Further research is necessary to better understand this rare entity.

Vasa Previa

Vasa previa is the situation where the umbilical cord vessels overlie the internal cervical os (Fig. 43.35, Video 43.17). The incidence is approximately 0.6 in 1000 pregnancies,[175] but approximately 25% that are diagnosed in the second trimester resolve.[176] Because these are fetal vessels, even a small amount of blood loss from rupture of these vessels can lead to fetal death. High-risk situations that require specific exclusion of vasa previa include velamentous umbilical cord insertions in which the membranous fetal umbilical vessels can traverse the internal cervical os somewhere along their length. Marginal umbilical cord insertions, especially those with aberrant vessels within the membranes, also are associated with vasa previa.[177] Presence of bilobed placentas[178] or the more common succenturiate lobes[179] requires that a vasa previa be excluded, given the potential for a poor neonatal outcome. Prior low placenta, placenta previa, multiple gestations, pregnancies resulting from *in vitro* fertilization, and pregnancies with umbilical cord insertions occurring in the lower third of the uterus in the first trimester are all associated with vasa previa.[175,177,179,180]

Once a vasa previa is diagnosed, obstetric management is critical to optimize outcome. Current recommendations are for antenatal corticosteroids between 28 and 32 weeks' gestation, consideration of hospitalization between 30 and 34 weeks' gestation, and delivery at 34 to 37 weeks' gestation, which is recommended to obviate the risks of vessel rupture that can occur with labor or rupture of the membranes.[181] If the patient has preterm labor, ruptured membranes, or bleeding before 35 weeks, delivery at the earlier gestational age should be considered.[180,182]

Vasa previa is diagnosed when a fetal vessel is identified overlying the internal cervical os. Although gray-scale ultrasound

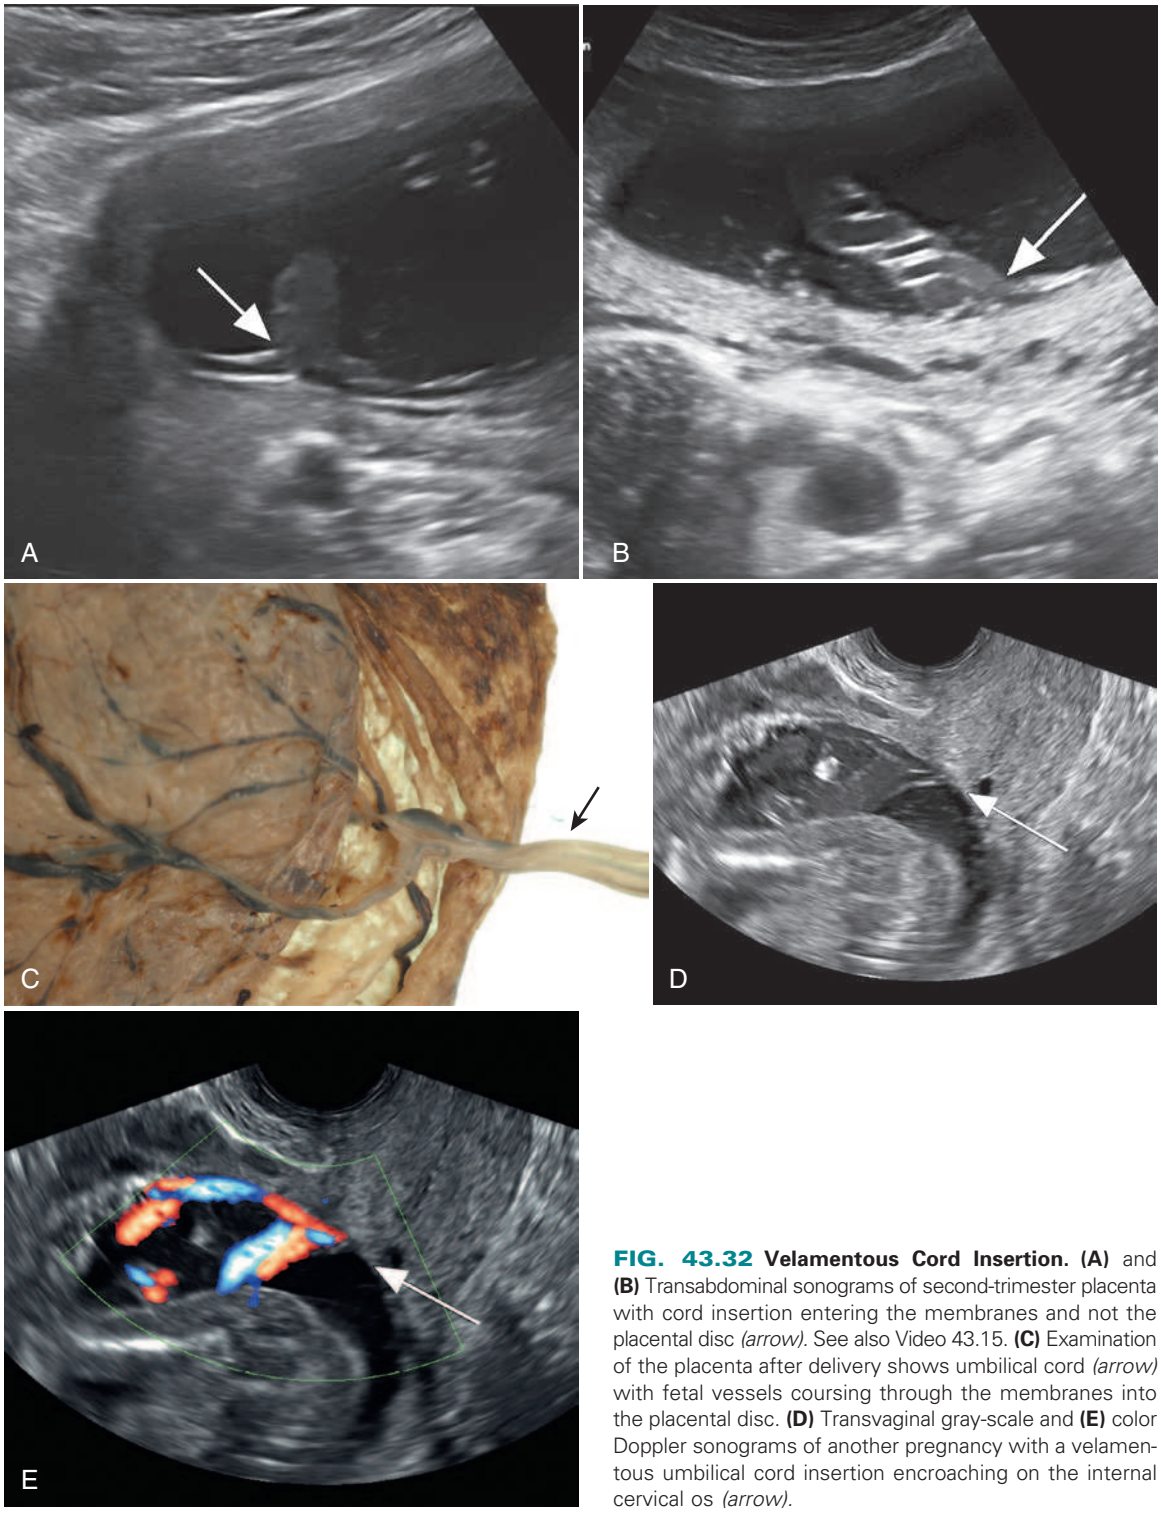

FIG. 43.32 Velamentous Cord Insertion. (A) and **(B)** Transabdominal sonograms of second-trimester placenta with cord insertion entering the membranes and not the placental disc *(arrow)*. See also Video 43.15. **(C)** Examination of the placenta after delivery shows umbilical cord *(arrow)* with fetal vessels coursing through the membranes into the placental disc. **(D)** Transvaginal gray-scale and **(E)** color Doppler sonograms of another pregnancy with a velamentous umbilical cord insertion encroaching on the internal cervical os *(arrow)*.

can identify the vessel, color or power Doppler sonography can assist with visualizing the vessel. Pulsed wave Doppler ultrasound should confirm a fetal artery, by demonstrating the heart rate of the fetus rather than that of the pregnant woman. Three-dimensional sonography may assist with making the diagnosis of a vasa previa,[177,183] especially using 3D power Doppler sonography to map out the aberrant vessels.[184] The clinician must be careful, however, especially when using color or power Doppler ultrasound, not to equate identification of the umbilical cord in the lower uterine segment or overlying the cervix with a vasa previa (Fig. 43.36). The cord could be free floating in this area, termed a **funic presentation,** and not a vasa previa (Fig. 43.37). Careful attention to detail, using movement of the probe or follow-up sonography, may be necessary to reach the correct diagnosis.[185]

FIG. 43.33 Marginal Cord Insertion. Gray-scale sonogram shows the umbilical cord inserting into the edge of the placenta *(arrows).*

PLACENTA DURING LABOR AND POSTPARTUM

Third Stage of Labor

Ultrasound may have some role during the third stage of labor, the time from delivery of the neonate to delivery of the placenta. A prolonged third stage, with the placenta retained, has various causes. If the placenta does not separate, a placenta accreta could be present.[66] A prolonged third stage may also be caused by retention of a detached placenta from poor contractility or atony of the uterus, sometimes from infection. These abnormalities are treated differently, and ultrasound may help differentiate the various causes of a prolonged third stage of labor and lead to improved patient care.[186]

The mechanism of placental separation has been reported using gray-scale sonography.[187] Color Doppler ultrasound provides information on the phases of placental separation during the third stage of labor by specifically assessing blood flow between the myometrium and the placenta.[188] The manner in which the placenta separates varies, based on prior cesarean delivery and a prolonged second stage of labor.[189]

Retained Products of Conception

Women with suspected retained products of conception (RPOC) typically present with abnormal bleeding. RPOC are most common after second-trimester spontaneous abortion, extreme preterm birth, medical termination of pregnancy, and unsuspected placenta accreta. RPOC are suggested when an echogenic endometrial mass is visualized within the uterine cavity (Fig. 43.38). This mass may extend into the myometrium[190] and can be differentiated from blood clot when blood flow is

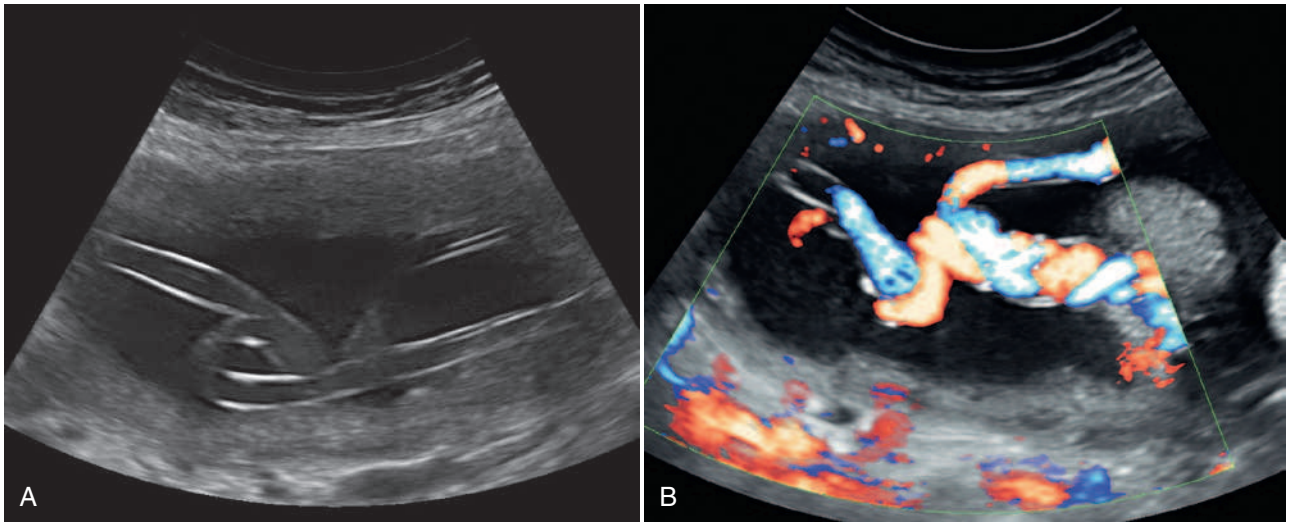

FIG. 43.34 Furcate Cord Insertion. (A) Gray-scale and **(B)** color Doppler sonograms of a patient with a furcate insertion of the umbilical cord. Note the separation of the vessels within the membranes.

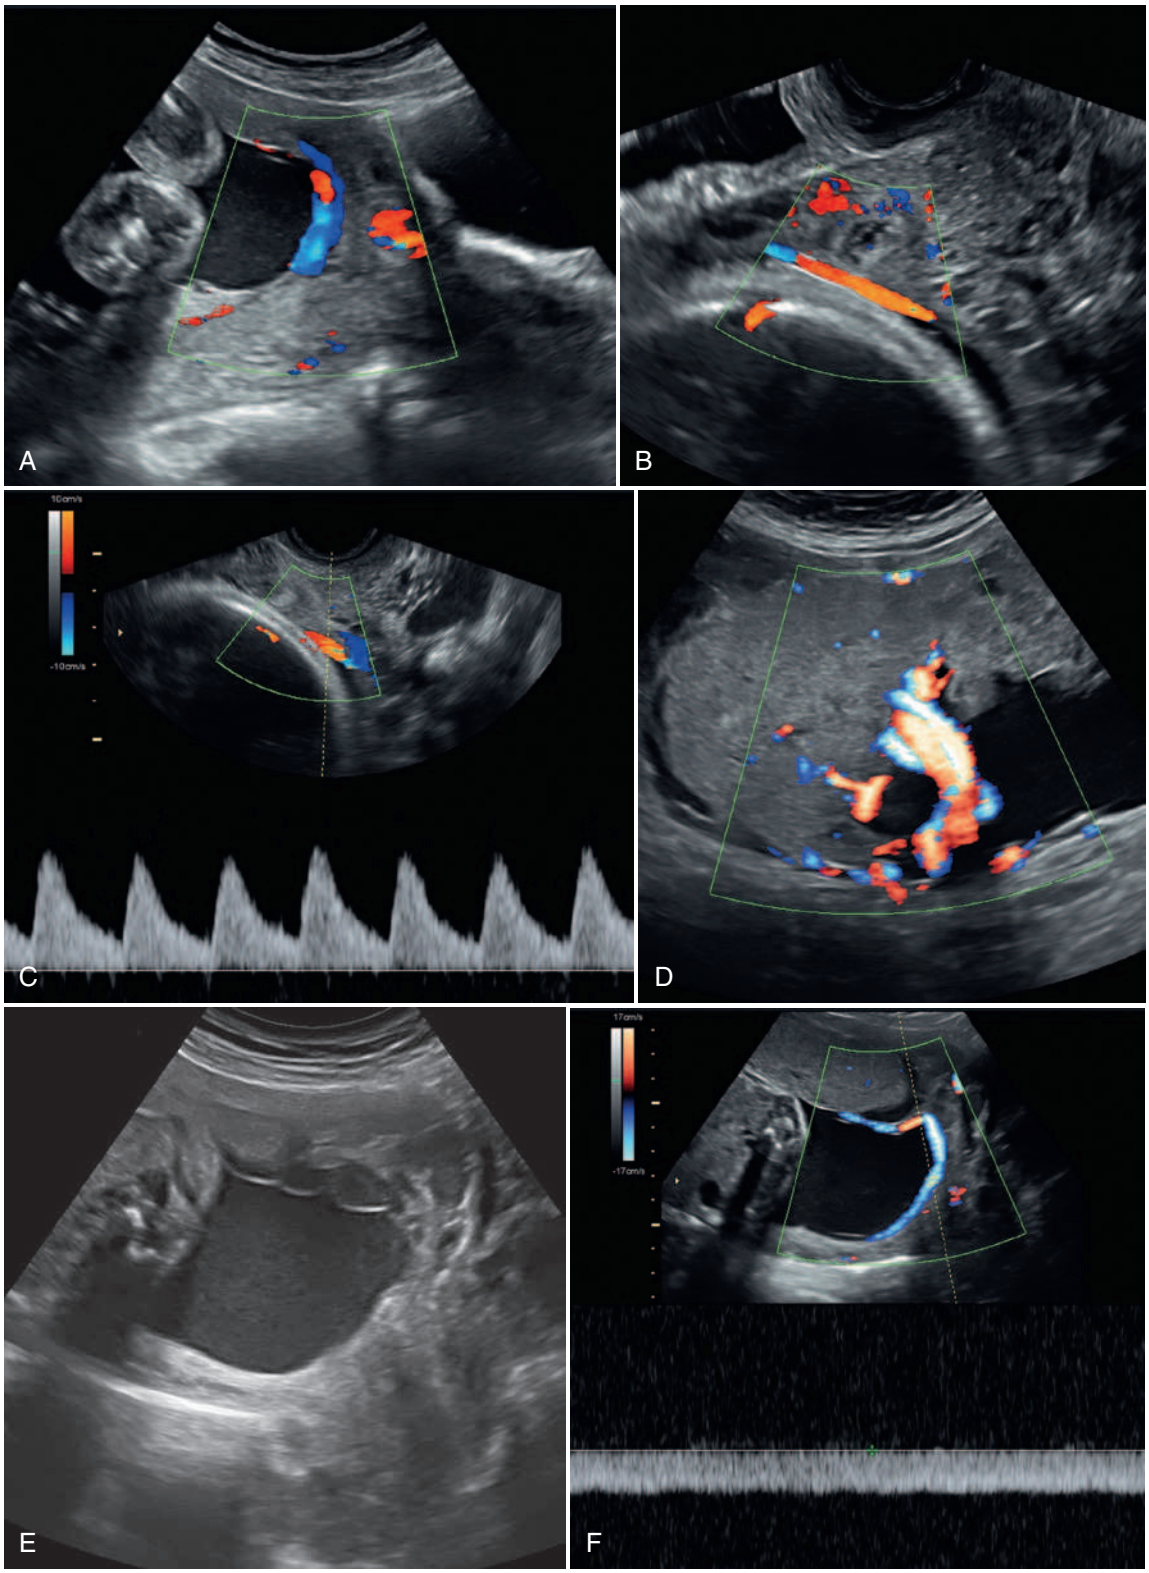

FIG. 43.35 Vasa Previa. (A) Transabdominal color Doppler demonstrating vessels overlying the internal cervical os. **(B)** Transvaginal color Doppler demonstrating a vessel overlying the internal cervical os. The fetal cranium is shown in the lower portion of the image. **(C)** Color and pulsed Doppler demonstrating a fetal artery overlying the internal cervical os consistent with a vasa previa. **(D)** Color Doppler sonogram demonstrating a normal placental umbilical cord insertion. **(E)** Gray-scale sonogram of the same patient in **D** demonstrating an apparently normal image of the internal cervical os. **(F)** Color and pulsed Doppler demonstrating a placental vessel overlying the internal cervical os consistent with a vasa previa. Placental vessels can emanate from the placental disc even in those with normal umbilical cord insertions. See also Video 43.17.

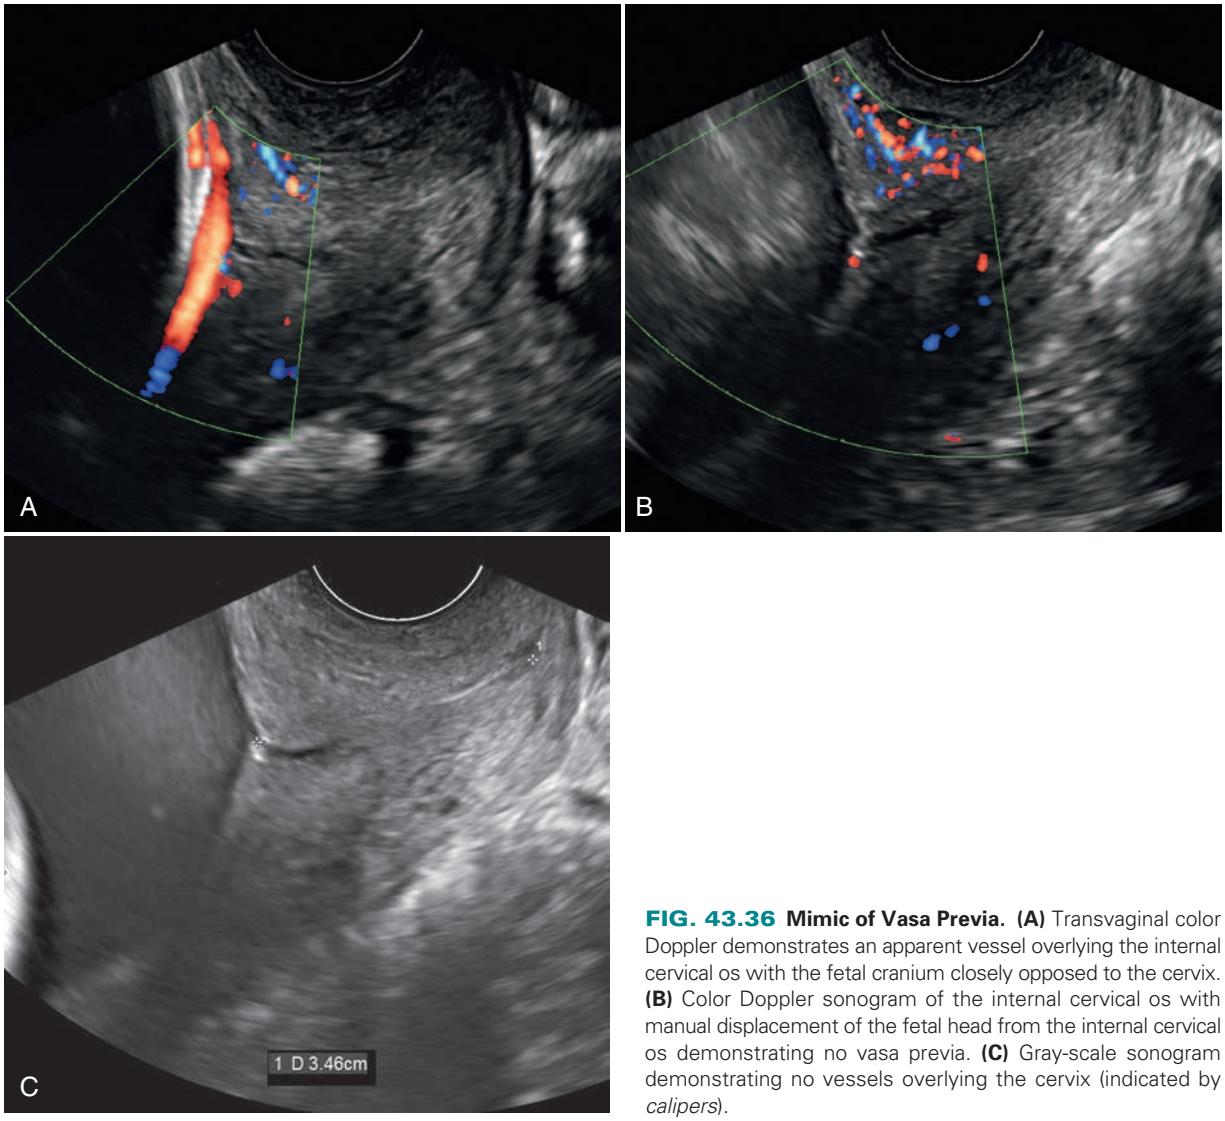

FIG. 43.36 Mimic of Vasa Previa. (A) Transvaginal color Doppler demonstrates an apparent vessel overlying the internal cervical os with the fetal cranium closely opposed to the cervix. **(B)** Color Doppler sonogram of the internal cervical os with manual displacement of the fetal head from the internal cervical os demonstrating no vasa previa. **(C)** Gray-scale sonogram demonstrating no vessels overlying the cervix (indicated by *calipers*).

FIG. 43.37 Funic Presentation. Transvaginal ultrasound of a single loop of normal umbilical cord, free floating and overlying the internal cervical os. The cervix is indicated by the calipers. The three vessels of the umbilical cord are seen in cross section.

demonstrated. However, lack of flow does not exclude RPOC. Care should be taken not to mistake vascularized RPOC for a uterine arteriovenous malformation, because prominent flow can be seen in RPOC.[190] In fact, the association of an endometrial mass with prominent blood flow strongly suggests RPOC.[191,192] Endometrial measurements less than 10 mm suggest the absence of RPOC, especially in the absence of blood flow, with high negative predictive values.[193] Calcifications in the endometrial mass are highly suggestive of RPOC. These calcifications represent normal placental maturation that occurred during pregnancy.

CONCLUSION

Multiple abnormalities associated with placental development and function can be identified by prenatal sonography. Sonographers and sonologists need to understand the basic anatomy and physiology of the placenta so that abnormal findings on prenatal sonography can be acknowledged, to achieve the best possible outcome for mother and neonate.

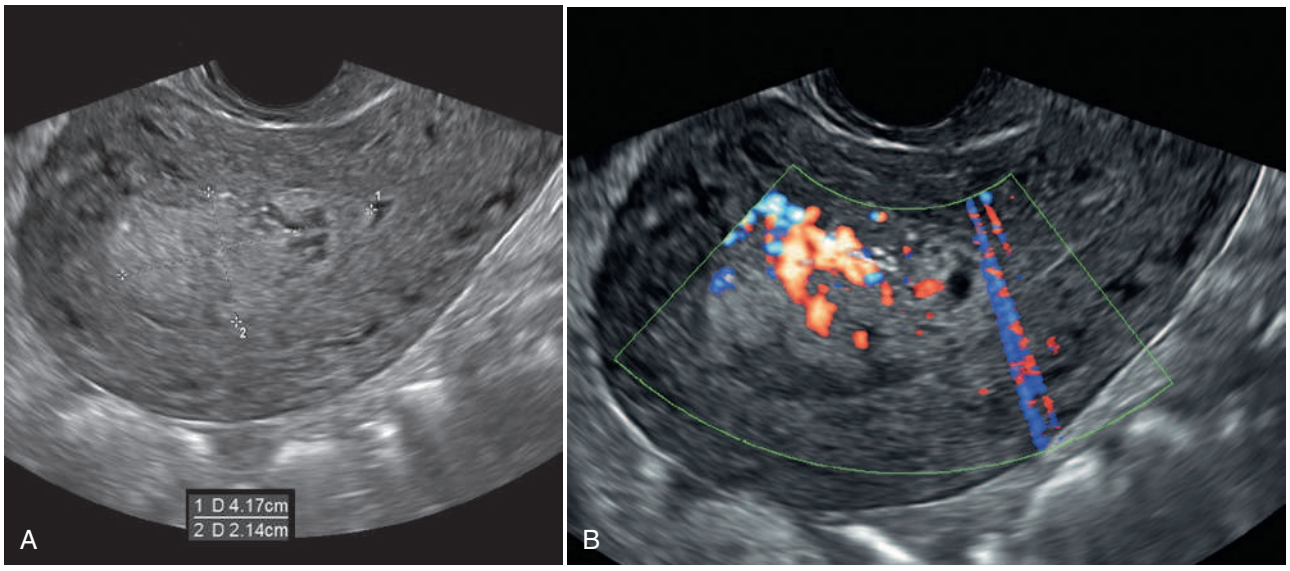

FIG. 43.38 Retained Products of Conception. (A) Transvaginal gray-scale sonogram shows a heterogeneous area of echogenic tissue in the endometrial cavity. **(B)** Transvaginal color Doppler sonogram in the same patient shows vascularization of an endometrial mass, consistent with retained products of conception.

CHAPTER

44 Cervical Ultrasound and Preterm Birth

Hournaz Ghandehari and Phyllis Glanc

SUMMARY OF KEY POINTS

- There is a significant association between cervix length and the risk of preterm birth.
- A cervical length of more than 3 cm has a high negative predictive value for delivery at less than 34 weeks' gestation.
- The most reliable method of documenting cervical length is transvaginal ultrasound.
- The single most reliable parameter for cervical assessment is a short cervical length.
- The earlier in gestation, the shorter the cervix, the greater is the risk of spontaneous preterm birth before 34 weeks, with the best predictive value when cervical length measures less than 25 mm.
- Rate of cervical change may be a better predictor than cervical length.

CHAPTER OUTLINE

PRETERM BIRTH

Preterm birth (PTB), defined as delivery before 37 weeks of gestation, occurs in 5% to 11% of all pregnancies, ranging from as low as 5% in some European countries to 15% in the United States and to as high as 18% in some African countries, attributable to geographic, socioeconomic, and racial disparities.[1-3] PTB is the leading cause of neonatal morbidity and mortality not attributable to congenital anomalies or aneuploidy. If an infant is born preterm, the risk of death in the first year of life is 40-fold greater compared with an infant born at term.[2]

Immediate consequences of PTB include respiratory distress, intraventricular hemorrhage, sepsis, and retinopathy of prematurity.[2] In the long term, infants born preterm represent one-half the children with cerebral palsy, one-third of those with abnormal vision, one-quarter of those with chronic lung disease, and one-fifth of children with mental retardation.[2,4,5] The morbidity of prematurity persists to adulthood, with an increased incidence of behavioral problems, lower levels of educational achievement, reduced rates of reproductive success (with incidence of both conception and live birth adversely affected), and an increased incidence of second-generation PTB.[6-8]

The risk of prematurity persists in subsequent pregnancies, with a twofold increased risk in the next pregnancy and up to 50% risk of PTB if the woman has experienced two or more prior PTBs.[2] Given the substantial and far-reaching impact of PTB, it is important to recognize patients at increased risk of **spontaneous preterm birth** (SPTB), such that therapeutic interventions can be implemented to improve neonatal outcome.

About 85% of preterm deliveries occur spontaneously and are traditionally classified as one of three discrete events: **preterm labor** (uterine activity with coordinated cervical effacement and dilation), **preterm premature ruptured membranes** (ruptured

fetal membranes in the absence of uterine activity and cervical change), or **cervical incompetence** (cervical dilation in the absence of uterine activity).[2,9,10] Cervical incompetence can be further defined as either a **mechanical failure** of the cervix to remain closed against the increasing intrauterine expansion or as a **functional failure,** with premature activation of the events of cervical ripening (dilation and effacement) that normally occur at term.[9] Although categorized in this manner, spontaneous premature delivery is best described along a continuum of biologic events leading to early delivery, given that the biochemical mediators that effect uterine contractions, fetal membrane disruption, and cervical ripening are similar: prostaglandins, the metallomatrix proteases and their inhibitors, and the families of proinflammatory and antiinflammatory cytokines.[2,10] As such, the events of prematurity often overlap; in particular, cervical change can precede fetal membrane rupture and uterine contractions, although the cervix may not be functionally or mechanically incompetent.

Evaluation of the cervix has been used as a tool to predict SPTB based on the concept that the cervix acts as an anatomic marker of the underlying pathologic processes leading to a premature delivery. Digital examination of the cervix measures only the length from the external cervical os to the cervical-vaginal junction, not the intrapelvic cervical-isthmus portion of the cervix. Therefore digital examination underestimates cervical length by a mean difference of 12 mm in more than 80% of women in the second and third trimesters compared with sonography.[11] Moreover, dilation of the cervix starts proximally so the distal portion may still appear normal on digital exam, even when the cervix has started to shorten and/or dilate. The current approach to evaluation of the cervix is by ultrasound, preferably via the transvaginal route. This chapter reviews the techniques of uterine cervix sonography and its relationship with PTB prediction.

SONOGRAPHY OF THE UTERINE CERVIX

There are three approaches to scanning the cervix: transabdominal sonography (TAS), transvaginal sonography (TVS) and transperineal (translabial) sonography. Each approach has advantages and limitations for different clinical scenarios. The closed length of the cervix is the single most important parameter to report, as it is most closely linked to the risk of PTB. Additional comments include any evidence of funneling.

Transabdominal Approach

TAS of the cervix is typically performed during the standard second- and third-trimester obstetric ultrasound examinations and is used as a routine screening tool for measurement of closed cervical length.

Longitudinal scanning is initiated in the midline of the lower abdomen, just above the symphysis pubis, using a transducer with a frequency of 3 MHz or higher.[12,13] Landmarks include the internal cervical os, the external cervical os, the outline of the cervical canal, and the outline of the cervical corpus[14] (Fig. 44.1).

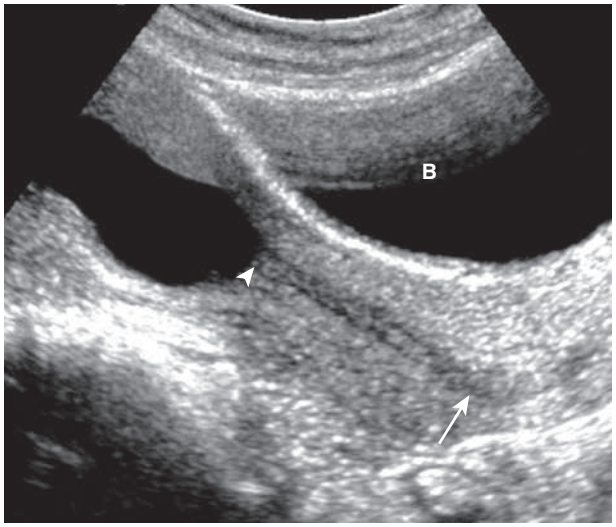

FIG. 44.1 Normal Cervix. TAS full-bladder technique. Longitudinal midline image of the cervix. The cervical canal is seen from the internal os *(arrowhead)* to the external os *(arrow). B,* Bladder.

FIG. 44.2 Normal Cervix. TAS empty-bladder technique. Longitudinal midline image of the cervix obtained by scanning through the amniotic fluid. The cervical canal is indicated by calipers.

Measurement of cervical length is affected by overdistention of the urinary bladder. Increased bladder pressure can compress the lower uterine segment and falsely elongate the cervix or mask cervical dilation.[12] Cervices less than 2 cm in length cannot be easily visualized against the vaginal and bladder tissue.[12]

In the second trimester, if the urinary bladder is empty, amniotic fluid can be used as an acoustic window to scan the cervix. Longitudinal scans are obtained with the transducer angled downward from just below the umbilicus. The cervix may assume a more vertical orientation and appear bulkier (Fig. 44.2) when the bladder is empty. Difficulty in identifying the external os can contribute to error in cervical length measurement.

Visualization of the cervix can be difficult because of large maternal habitus or an engaged position of the fetal head.[12,13,15] Regardless of the gestational age, there is relatively poor

reproducibility of TAS measurement of the cervix. Research has demonstrated conflicting results regarding the usefulness of TAS screens in that the cutoff in TAS to identify a cervix length of 25 mm or less is variable. This suggests that higher TAS cutoffs are required to achieve high sensitivity.[14,16] The challenge is that in a low-risk group, the prevalence of short cervix due to cervical incompetence is low and a large sample size is required to achieve meaningful statistics.

Transperineal/Translabial Approach

Transperineal sonography is reserved for patients for whom the cervix cannot be adequately visualized by TAS, and in whom TVS is unacceptable for personal or discomfort-related concerns. Scanning is performed with an empty urinary bladder. An abdominal transducer with a frequency of 3 MHz or higher can be used.[17-19] To minimize the risk of transmission of infection, the transducer is covered with plastic wrap. With the patient supine and hips abducted, the transducer is placed between the labia minora at the vaginal introitus. The ultrasound beam is oriented in a sagittal plane along the direction of the vagina. The vagina is seen in a vertical plane between the bladder and the rectum (Fig. 44.3).[15,20,21] The cervix is oriented horizontally, at a right angle with the vagina. The full length of the cervical canal can be visualized in 86% to 96% of patients with this technique[17,18]; however, in some cases the region of the external os can be obscured by rectal gas or the symphysis pubis. Although some reports have suggested that the reproducibility of the measurements is poor,[21-24] others have demonstrated improved reproducibility and accuracy in the hands of an experienced examiner.[15,22,25] This enhanced requirement for experience limits the utility of this study. This examination has a greater learning curve in order to perform reliably and reproducibly than TVS studies. Cicero et al.[25] showed that 50% of transperineal studies were inadequate because of shadowing in the learning phase of the first 200 patients. Subsequently in the second phase reliable images were obtained in 78% of cases. Because transperineal scanning of the cervix is more dependent on gestational age and the experience of the investigator, it should be reserved as an alternative study in patients for whom a TVS is deemed unacceptable for psychological, cultural, or medical reasons.

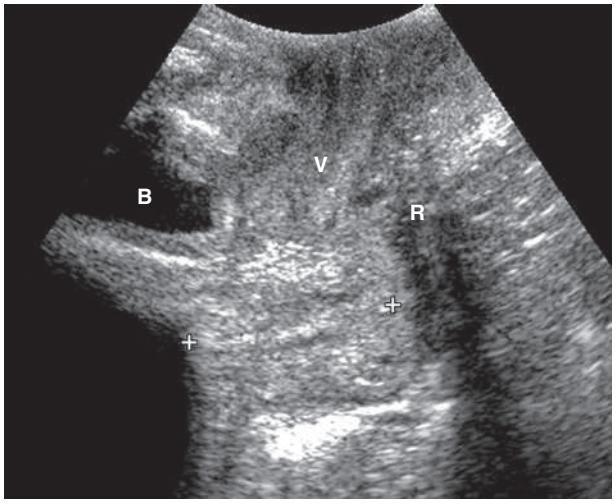

FIG. 44.3 Transperineal Scan of Normal Cervix. The cervix *(calipers)* is oriented horizontally, approximately perpendicular to the ultrasound beam. The vagina *(V)* is oriented in a nearly vertical plane. *B,* Bladder; *R,* rectum.

Transvaginal Sonography

TVS is the reference-standard technique for accurate determination of the dimensions and characteristics of the cervix.[26] The examination is performed with an empty urinary bladder. A gynecologic table fitted with stirrups is preferred, although the examination can be carried out with the patient's hips elevated on a thick cushion or wedge. With the patient in a dorsal lithotomy position, supine and hips abducted, an endovaginal transducer (5-MHz or higher frequency) covered with plastic wrap is placed in the vagina and oriented in a longitudinal plane. The probe is inserted under real-time visualization until the cervix comes into view. Usually, the transducer is inserted only 3 to 4 cm into the vagina so that the images of the cervix are within the effective focal range of the transducer (Fig. 44.4). Depending on the position of the cervix in the vagina, the probe may need to be moved anteriorly, posteriorly, and/or laterally.[27] There is a standardized method for obtaining reproducible cervical measurements (see box).

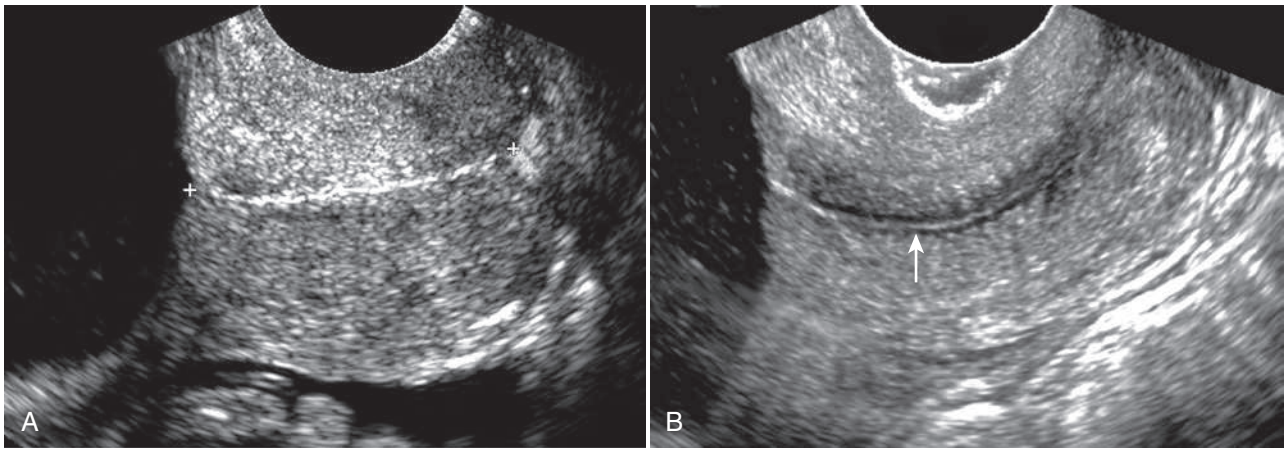

FIG. 44.4 TVS of Normal Cervix. (A) Suggested placement of cursors for measuring cervical length. **(B)** Normal cervical glandular area. The cervical canal is seen as an echogenic line *(arrow)* surrounded by a hypoechoic zone resulting from endocervical glands.

Standard Technique for Cervical Measurement

1. Place the probe in the anterior fornix of the vagina.
2. Obtain a sagittal view of the cervix, with the long-axis view of echogenic endocervical mucosa along the length of the canal.
3. Withdraw the probe until the image is blurred, and reapply just enough pressure to restore the image (to avoid excessive pressure on the cervix, which can elongate it).
4. Enlarge the image so that the cervix occupies at least two-thirds of the image and external and internal os are well seen.
5. Measure the cervical length from the internal to the external os along the endocervical canal.
6. Obtain at least three measurements, and record the shortest best measurement in millimeters.

With permission from Berghella V, Bega G, Tolosa JE, Berghella M. Ultrasound assessment of the cervix. Clin Obstet Gynecol. 2003; 46(4):947-962.[21]

A symmetrical image of the external os should be obtained, and the distance from the surface of the anterior lip to the cervical canal should be equal to the distance from the surface of the posterior lip to the cervical canal. If the anterior lip appears thinner than the posterior lip, there may be undue pressure placed on the cervix by the transvaginal probe. An additional sign of excessive pressure is increased echogenicity of the cervix[21] (Fig. 44.5).

When the cervix appears curved (deviation of the central canal of >5 mm from a straight line connecting the external and internal os), the cervical length can be either traced or the sum of two straight lines that follow the curve can be used.[21,28] Using these standard criteria, the interobserver coefficient of variation can be improved to 3.3%.[27]

TVS is superior to the TAS technique. Higher-frequency transducers and closer proximity to the structures studied allow for better resolution. Potential complications of TVS include an increased risk of bleeding in the presence of placenta previa, induction of uterine activity in women with cervical shortening caused by cervical stimulation, and chorioamnionitis in the presence of ruptured membranes. However, increased risk of chorioamnionitis or neonatal sepsis with TVS after preterm premature rupture of membranes (PPROM) has not been demonstrated.[29,30] TVS has also been deemed safe to use in patients with placenta previa with no increased risk for bleeding; however, caution is advised to ensure that the probe is always carefully inserted under real-time visualization.[31]

To date, TVS assessment of cervical length by three-dimensional sonography has been limited to the development of a normal distribution curve of cervical length through gestation. Overall, mean cervical length appears to be longer than the measurement by traditional two-dimensional scanning. However, there is to be high intra/interobserver variability.[32] Currently, there are no reported studies of the relationship between three-dimensional TVS and SPTB prediction.

Technical Limitations and Pitfalls

As mentioned previously, one limitation of TAS, especially in advanced gestation, is that the cervix may be obscured by the presenting part, in particular with a cephalic presentation. In addition, a short cervix or empty bladder may reduce the quality of the measurement obtained, whereas a full bladder may artificially elongate the cervix.

There are a number of technical limitations and pitfalls associated with TVS of the cervix. Large maternal body habitus can limit visualization. Bowel gas can obscure visualization.

A lower uterine segment myometrial contraction, immediately superior to the cervix, may result in a pseudoelongation of the cervix (Fig. 44.6). The classic tips to recognize this appearance is the artificially elongated length of the cervix (>5 cm), the thicker diameter of the "cervix" at the proximal extent, which actually incorporates the lower uterine muscle so that it appears thicker than at the external os. The thickness of the internal and external cervical os should be similar. Lower uterine segment contractions are transient and rarely persist beyond 15 minutes.

A second pitfall associated with the lower uterine segment contraction has been termed "pseudodilation" of the cervix. It

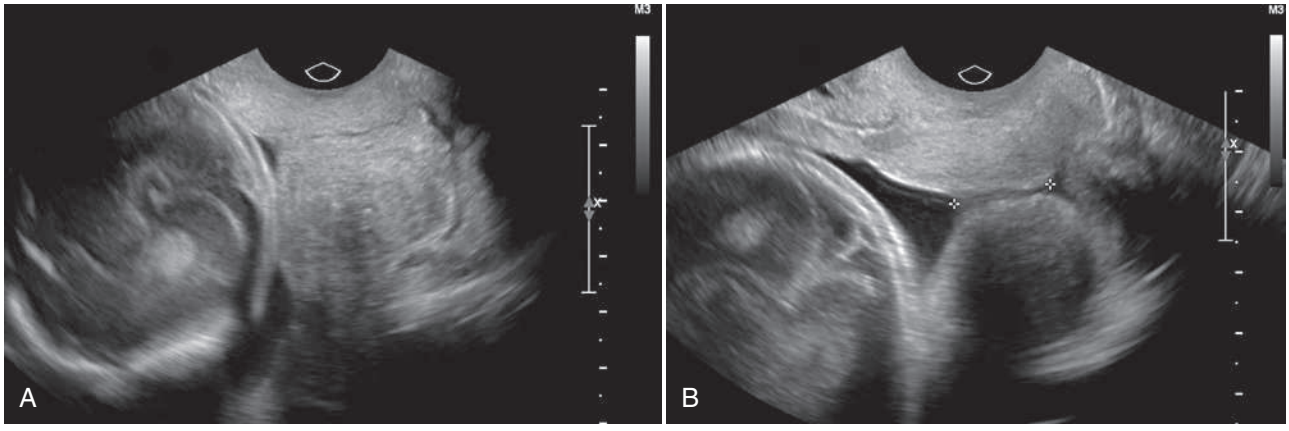

FIG. 44.5 Example of Poor Technique During TVS of Cervix. Calipers measure appropriate cervical length.

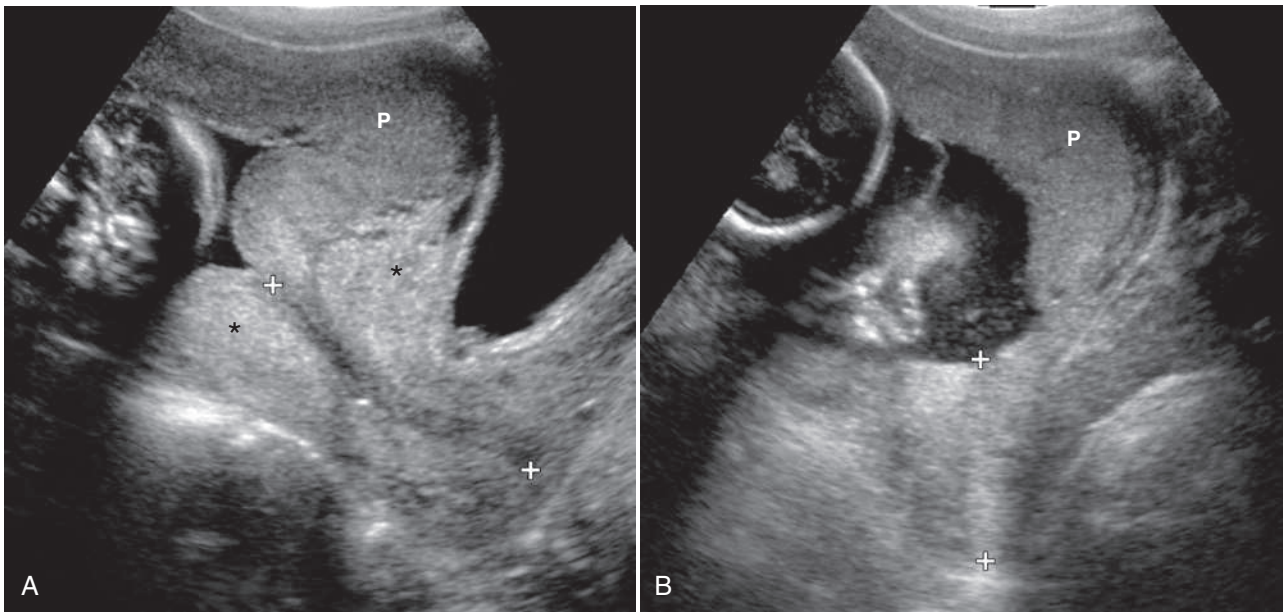

FIG. 44.6 Uterine Contractions. (A) TAS longitudinal image shows contraction (*) leading to a falsely elongated cervical canal *(calipers),* which measures 7.4 cm. **(B)** After relaxation of the contraction, the cervix *(calipers)* measures 4.2 cm. *P,* Placenta.

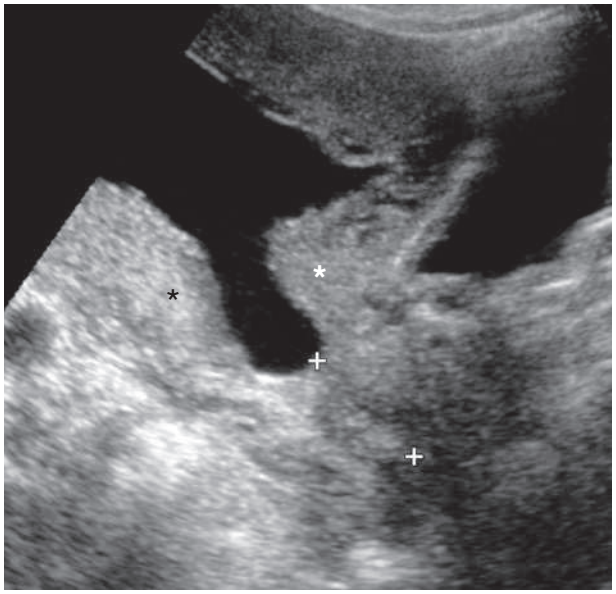

FIG. 44.7 Pseudodilation Caused by Uterine Contractions. Transabdominal longitudinal scan shows a lower uterine segment contraction (*) leading to a false appearance of dilated cervical canal. The closed cervix *(calipers)* measures 3.5 cm.

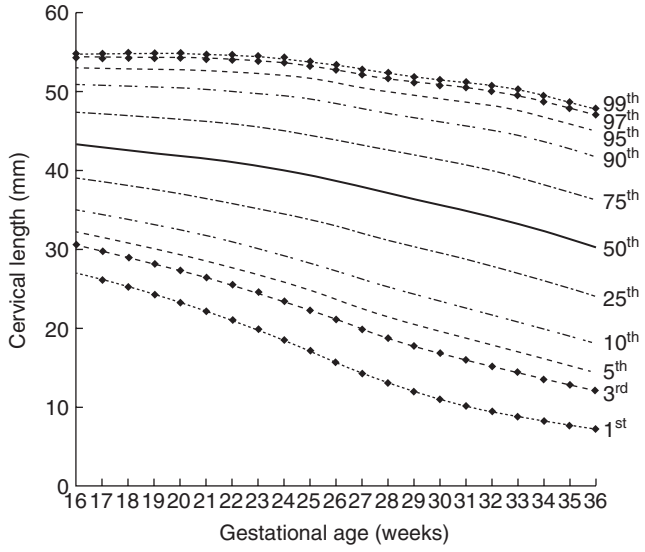

FIG. 44.8 Reference Ranges for Cervical Length Across Gestation. First to 99th percentiles are indicated. (With permission from Salomon LJ, Diaz-Garcia C, Bernard JP, Ville Y. Reference range for cervical length throughout pregnancy: non-parametric LMS-based model applied to a large sample. Ultrasound Obstet Gynecol. 2009;33[4]: 459-464.[33])

is caused by a lower uterine segment contraction with partial (Fig. 44.7) or complete approximation of the anterior and posterior myometrium with the resultant false appearance of a "funnel" above the closed cervix. The classic tips to recognize this appearance is the artificially elongated length of the cervix (>5 cm), the normal cervix lying caudal with respect to the pseudodilation, and the transient nature of this appearance.

Normal Cervix

Sonographically, the cervix appears as a distinct, soft tissue structure containing midrange echoes. The **endocervical canal** often appears as an echogenic line surrounded by a hypoechoic zone attributed to the endocervical glands (see Fig. 44.4B). Occasionally, the endocervical canal may appear hypoechoic and minimally dilated along its entire length. Benign **nabothian cysts** can be seen within the cervical soft tissues.

Numerous studies have evaluated **cervical length** in normal pregnancy. The typical cervix increases its length in the first trimester because of elaboration of the glandular content of the cervix.[27] Salomon et al.[33] published a reference curve of cervical length through gestation using TVS based on a large sample (Fig. 44.8). Based on this study, at about 20 weeks' gestation,

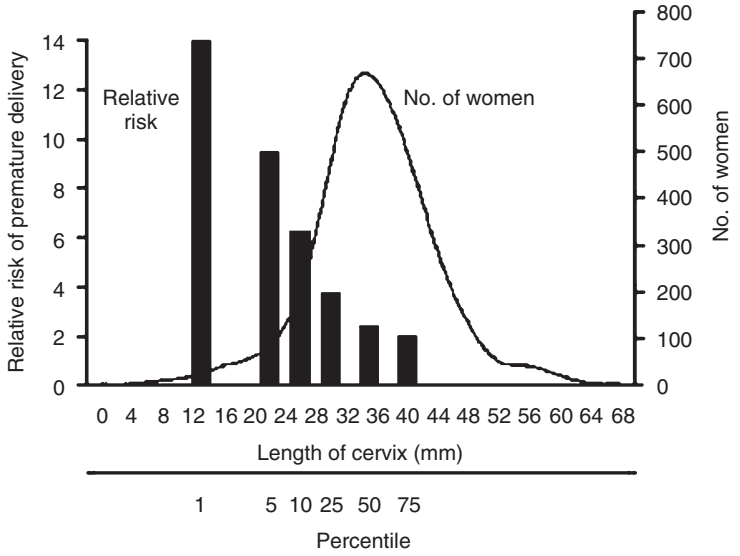

FIG. 44.9 Cervical Length and Risk of Preterm Delivery Percentile Ranking. Transvaginal ultrasound cervical length percentile rank, at 24 weeks' gestation, and relative risk of preterm delivery before 35 weeks. (With permission from Iams JD, Goldenberg RL, Meis PJ, et al. The length of the cervix and the risk of spontaneous premature delivery. National Institute of Child Health and Human Development Maternal Fetal Medicine Unit Network. N Engl J Med. 1996;334[9]:567-572.[34])

the 10th, 50th, and 90th percentiles of cervical length are 32.3, 41.9, and 50.5 mm, respectively.[33] A progressive linear reduction in cervical length occurs over the 10th to 40th week of gestation.

"Short" Cervix

With the goal of understanding the relationship between cervical length and SPTB (delivery before 35 weeks' gestation), in 1996, Iams et al.[34] published a prospective, multicenter study in which an unselected general population of women with singleton pregnancies underwent TVS at 24 and 28 weeks' gestation. Cervical length at both examinations was comparable and normally distributed, with a mean ±SD of 35.2 ± 8.3 mm at 24 weeks and 33.7 ± 8.5 mm at 28 weeks. A correlation between cervical length and the rate of SPTB was determined (Fig. 44.9); if the cervix was less than 26 mm (10th percentile) or less than 13 mm (1st percentile), risk of SPTB was increased by 6.49-fold and 13.99-fold, respectively, compared with the rate of SPTB if the cervix was at the 75th percentile length (40 mm) or greater.[34] Based on this landmark study, the definition of a **"short cervix" as less than 25 mm** (or <10th percentile length at 24-28 weeks) was accepted (Fig. 44.10).

Since then, more than 50 studies of TVS evaluation of the cervix and the risk of SPTB have been published. In 2003, Honest et al.[35] conducted a meta-analysis of 46 studies (including more than 31,000 asymptomatic singleton patients) and concluded that the utility of TVS assessment of cervical length for the prediction of SPTB varies with the gestational age at assessment and the definition of SPTB (birth before gestational age <32 weeks, <34 weeks, or <37 weeks). To summarize, the earlier in gestation, the shorter the cervix, the greater is the risk of SPTB, with the best predictive value when cervical length measures less than 25 mm and SPTB is defined as delivery earlier than 34 weeks' gestation (Table 44.1).

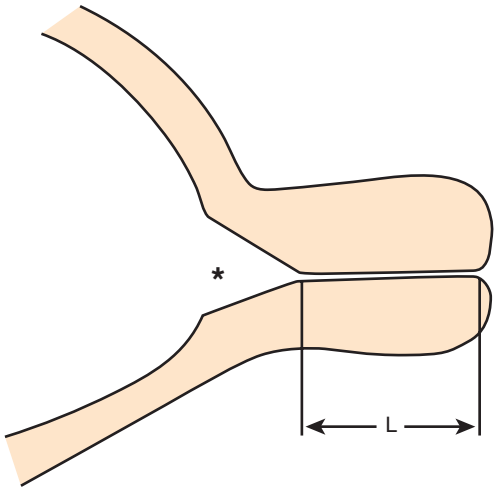

FIG. 44.10 Schematic of Abnormal Cervix. Length of the closed cervical canal *(L)* and the presence or absence of funneling (*) should be reported.

However, it should be recognized that the previous studies assessed cervical length at or before 28 weeks' gestation. Several reports have demonstrated no predictive value of TVS measurement of the cervix beyond 30 weeks of gestation for any definition of SPTB, likely because the cervix undergoes a gradual shortening process beyond this gestational age regardless of the timing of delivery.

The controversial aspect of TVS assessment of cervical length and the prediction of SPTB is that not all patients with a defined "short" cervix at any gestational age will deliver preterm. TVS is a reasonable tool for identifying patients who will deliver at or close to term with good negative predictive value. However, more than 50% of patients with a cervical length less than 25 mm measured at 20 weeks will deliver beyond 34 weeks' gestation.[34,35]

TABLE 44.1 Prediction of Spontaneous Preterm Birth Based on Gestational Age (GA) at Cervical Length Measurement (<25 mm)[a]

GA at Delivery	<20 Weeks	20-24 Weeks	24-28 Weeks
<32 weeks	4.1 (1.6-10.1)	4.19 (2.6-6.7)	No data
<34 weeks	6.2 (3.2-12.0)	4.40 (3.5-5.4)	4.0 (3.1-5.2)
<37 weeks	8.7 (3.8-19.9)	25.6 (8.5-76.7)	3.1 (1.1-8.9)

[a]Data presented as odds ratio ±95th percentile confidence intervals. Modified from Honest H, Bachmann LM, Coomarasamy A, et al. Accuracy of cervical transvaginal sonography in predicting preterm birth: a systematic review. Ultrasound Obstet Gynecol. 2003;22(3):305-322.[35]

Several studies have attempted to improve the predictive value of TVS by combining with other factors, including obstetric history and the concentration of fetal fibronectin in cervicovaginal secretions, to create a risk assessment formula.

PREDICTION OF SPONTANEOUS PRETERM BIRTH

Obstetric Factors

Celik et al.[36] presented a model to evaluate the ability of combinations of maternal demographics (age, race, weight, height, smoking status, history of cervical surgery, obstetric history) and cervical length between 20 and 24 weeks' gestation for prediction of SPTB in about 59,000 women with singleton pregnancies. The best prediction for SPTB was provided by cervical length alone, which was improved by adding obstetric history but not maternal characteristics. The estimated detection rates for extreme (<28 weeks), early (28-30 weeks), moderate (31-33 weeks), and mild (34-36 weeks) PTB by combining obstetric history and cervical length were 80.6%, 58.5%, 53.0%, and 28.6%, respectively, with a 10% false-positive rate. These data suggest that the combined screening model has better predictive value than either factor alone; similar findings in smaller-scale studies have been reported.[37]

Fetal fibronectin (FFN) is a glycoprotein that binds the amniochorion to the decidua and is released into cervicovaginal fluid in response to inflammation or separation of amniochorion from the decidua. Recent studies suggest that the combined use of cervical length and FFN improves the diagnostic performance of each test.[38,39] However, it has been shown that positive or negative FFN is relevant only when the sonographic cervical length is less than 30 mm.[40] Risk of SPTB remains low in women with cervical length of 30 mm or more and in those with cervical length of between 15 and 30 mm and negative FFN.[38,39,41]

Cervical Funneling

Much controversy surrounds the utility of measuring the **cervical "funnel,"** which is defined as the dilation of the internal os and the herniation of the fetal membranes into the cervical canal by more than 5 mm[42] (Figs. 44.11 and 44.12, Video 44.1). To et al.[43] reported that **funneling** of the internal os was present in 4% of all pregnancies; the shorter the cervix was, the greater was the likelihood of funneling, with 98% prevalence if the length was less than 15 mm and only 1% if greater than 30 mm. The rate of SPTB was increased in pregnancies demonstrating cervical funneling. However, funneling did not provide any significant contribution to the prediction of SPTB when combined with cervical length.[44,45] As an isolated finding compared with cervical length, the residual closed length measurements have a better predictive value than funneling. In addition, the shape or size of the funnel was not correlated to SPTB. As such, funneling is best reported as a categorical variable (present or absent) and best interpreted in the context of overall cervical length and obstetrical history.

Rate of Cervical Change

In their meta-analysis, Honest et al.[35] correlated a single measurement of cervical length at a single time point in gestation with the risk of SPTB. However, the events of prematurity occur along a continuum and likely develop over an as-yet undefined and variable period. Therefore **progressive shortening of the cervix** may be more important than a single abnormal cervical length measurement. A "short and shortening" cervical length may be a more effective tool for SPTB prediction than a "short but stable" cervical length. In a cohort of unselected patients, Naim et al.[46] demonstrated that if cervical length decreased on serial scans, the odds ratio for SPTB increased 6.8-fold per unit of change (one unit = decline of 10 mm per month). In women at increased risk of PTB, Owen at el.[28] reported that serial measurements up to 24 weeks' gestation significantly improved the prediction of SPTB compared with a single cervical measurement at 16 to 18 weeks. Similarly, in women at increased risk of SPTB (based on obstetric history), if cervical length remained stable from 12 to 20 weeks and greater than 25 mm, all patients delivered at term.[47] Patients in whom cervical length became serially shorter (ultimately <15 mm) and the decrease in length occurred before 20 weeks were offered and accepted a cervical cerclage, and all delivered after 30 weeks' gestation. Groom et al.[48] and Szychowski et al[49] reported similar results. These studies suggest three important points:

1. Serial cervical assessment is important to predict SPTB.
2. Progressive cervical shortening in patients at increased risk may begin before the typical timing of routine cervical assessment at the second-trimester fetal anatomic scan, advocating for initiation of serial cervical assessment early in the second trimester.
3. Serial cervical shortening in the second trimester may identify patients with true mechanical failure of the cervix, who may benefit from the placement of a cerclage to prevent SPTB.

Dynamic Cervical Change

A **dynamic cervix** is defined as having spontaneous shortening, lengthening, or funneling observed during real-time TVS[50] (Fig. 44.13). However, the value of a dynamic cervix for the prediction of SPTB is less clearly defined than that of a short cervix. Owen et al.[28] demonstrated that dynamic cervical length shortening in

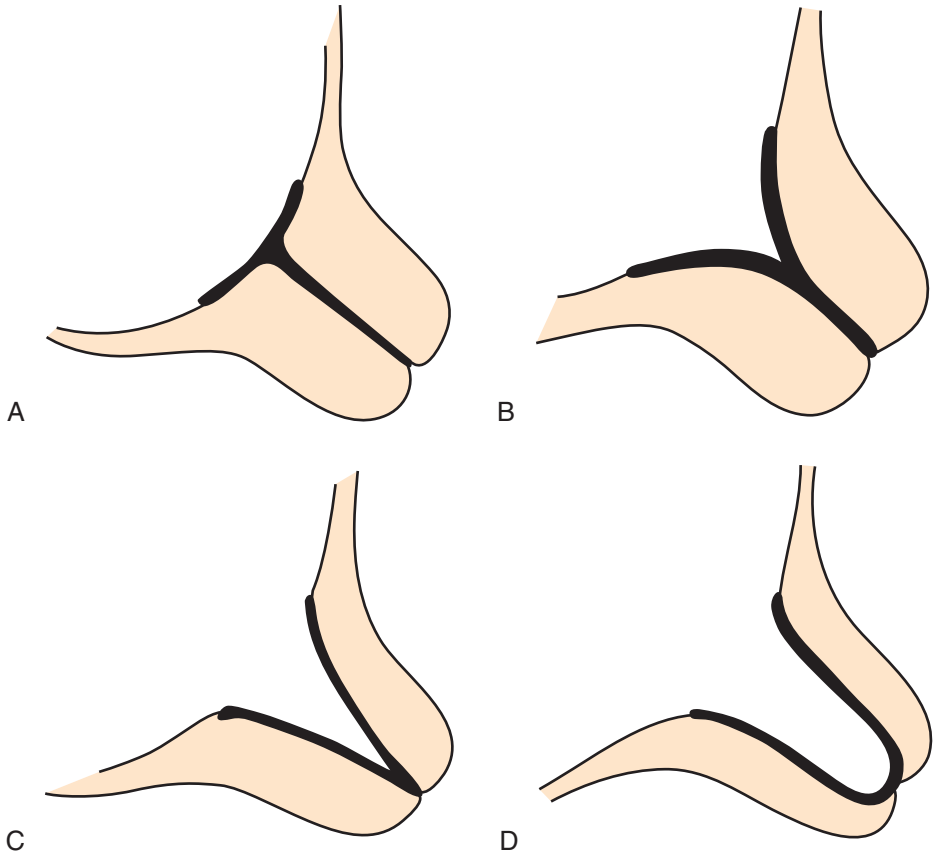

FIG. 44.11 Schematic of Normal Cervix and Cervical Funnel Shapes. (A) The normal closed internal os and the cervical canal appear T shaped. **(B)-(D)** Different stages of funneling resemble the letters Y, V, and U.

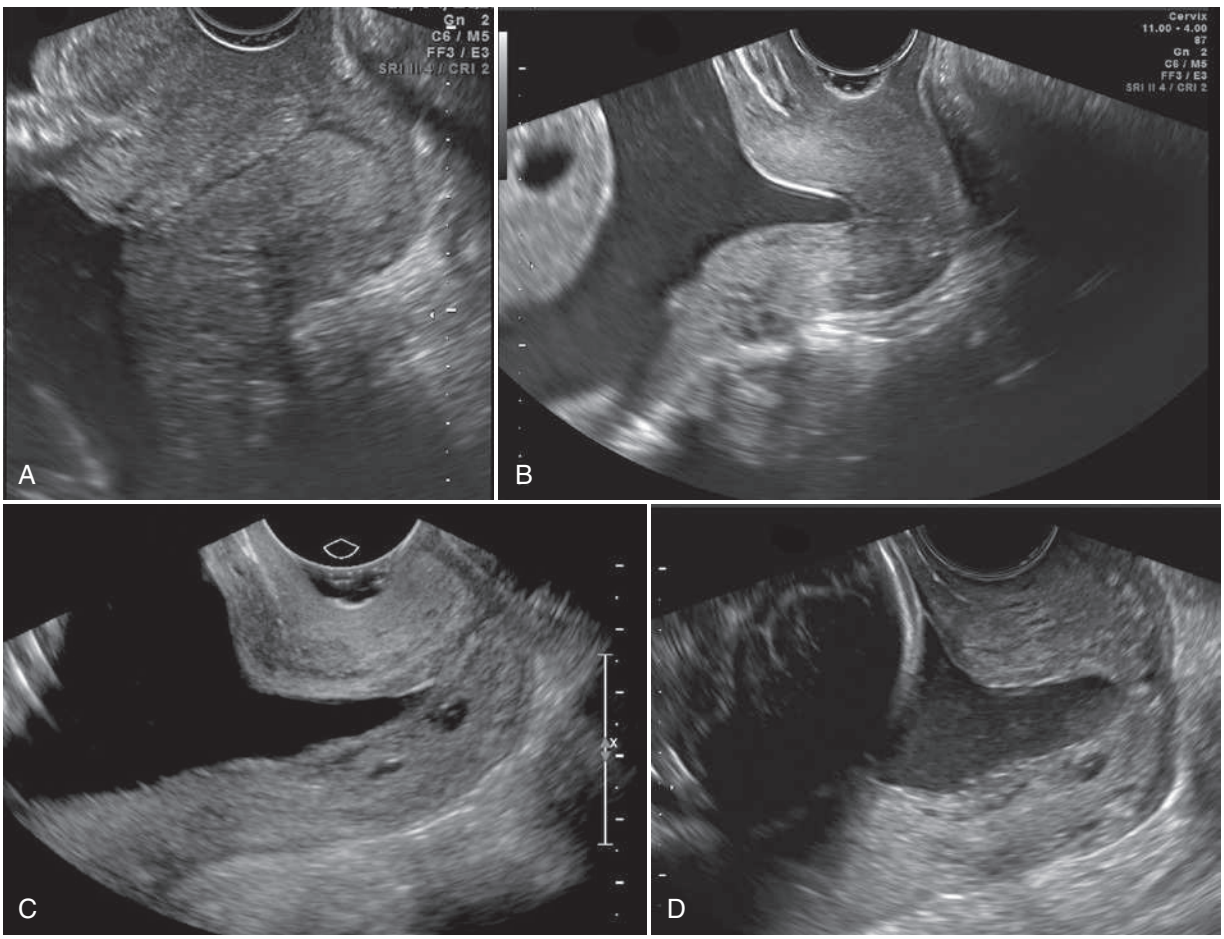

FIG. 44.12 Normal Cervix and Cervical Funneling. (A) Transvaginal scan of normal cervix, showing a T-shaped closed internal os. **(B)-(D)** Transvaginal scan shows different types of herniation of membranes, which respectively resemble the letters Y, V, and U. In **D,** with the U configuration, in this case the "U" is so deep there is no residual measurable closed cervical length.

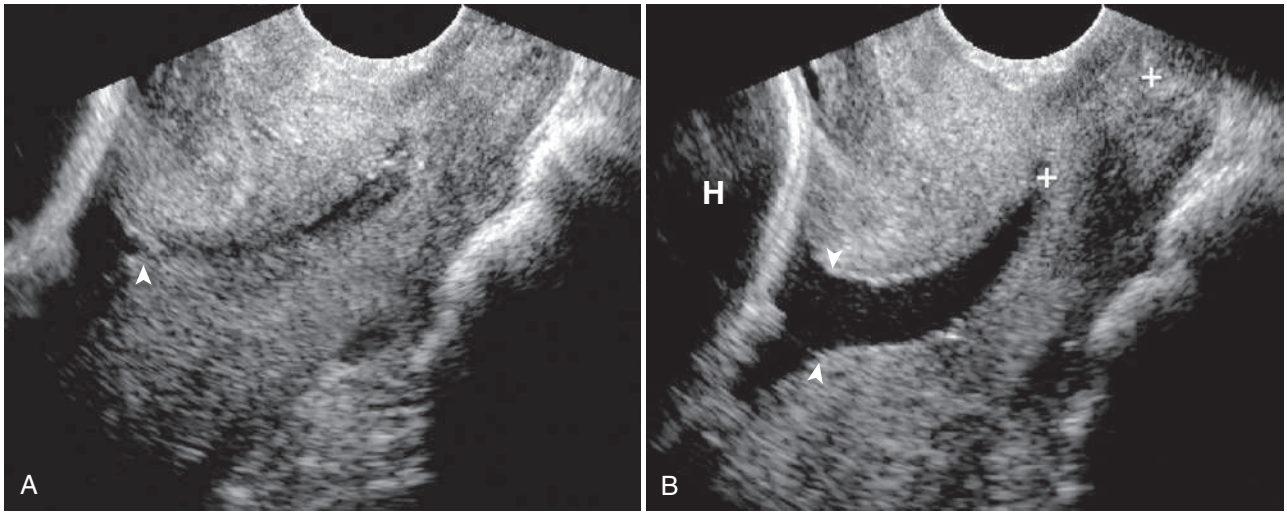

FIG. 44.13 Dynamic Dilation of the Cervix, Transvaginal Ultrasound. (A) Initially, the internal os appears closed *(arrowhead).* **(B)** Image obtained 30 seconds later shows funneling of the internal os *(arrowheads).* The residual closed cervix *(calipers)* measures 12 mm. *H,* Fetal head.

asymptomatic high-risk women during serial evaluations significantly improved the prediction of PTB. Patients with uterine contractions also had a greater incidence of dynamic cervical change than asymptomatic patients.[51] In both clinical scenarios, the minimal closed cervical length, not the "dynamic change," was the better predictor of SPTB. Several noninvasive stress techniques have been suggested to elicit cervical change and improve the ability of TVS to predict cervical incompetence. These stressors include **transfundal pressure** (pressure applied at the fundus for 15 seconds that elicits >5 mm in cervical length shortening), standing, and coughing. Several small studies found that transfundal pressure was the most effective tool in cervical assessment and the most sensitive tool to predict progressive cervical shortening.[52,53]

Other Sonographic Features

Several sonographic features other than cervical length have been studied to predict SPTB, including canal dilation, absence of the glandular area along the length of the canal, and amniotic fluid debris. Each feature is associated with an increased risk of PTB independent of cervical length. **Cervical canal dilation** of 2 to 4 mm was associated with a 5.5-fold increased risk of SPTB.[54] The **cervical glandular area** is a hypoechoic zone that runs along the length of the cervical canal (see Fig. 44.4B). In 388 unselected women, an absent cervical glandular area at 21 to 24 weeks' gestation predicted SPTB before 35 weeks (odds ratio of 129), suggesting a strong association.[55]

Cervix: Abnormal Findings on TVS[a]

Shortest closed cervical length <25 mm
Presence of funneling
Presence of positive response to fundal pressure
Presence of amniotic fluid debris ("sludge")
Shortening of 8-10 mm since previous TVS

[a]Gestational age less than 30 weeks.

"Sludge" or **debris** can be observed at ultrasound examination as free-floating echogenic material in close proximity to the cervix (Fig. 44.14, Videos 44.2 and 44.3). Samples of the sludge in patients with impending preterm delivery have been aspirated under ultrasound guidance, and the microbiologic examination reveals clusters of inflammatory cells and bacteria. Presence of sludge is an independent risk factor for **SPTB,**[56] PPROM, increased concentration of microbes within the amniotic fluid, and histologic chorioamnionitis in asymptomatic patients at high risk for spontaneous preterm delivery. Furthermore, the combination of "sludge" and a short cervix conferred a greater risk for SPTB than a short cervix alone.[57]

CERVICAL ASSESSMENT IN SPECIFIC CLINICAL SCENARIOS

Asymptomatic Patients

General Obstetric Population Screening

The prevention of PTB is a major health care priority. Only about 10% of spontaneous early PTBs occur in women with a prior history.[58] This leaves approximately 90% of PTBs occurring in women with no prior history of PTB, that is, the "low-risk" population.

It has been shown that over 95% of women without a prior PTB and with a singleton gestation have additional risk factors that would place them at increased risk for PTB, regardless of cervical length.[59] Therefore perhaps the term "low risk" needs to be redefined. Two large randomized clinical trials have demonstrated that in women with no prior history of PTB, a combined approach in which mid-trimester TVS screening for cervical length is used to identify patients at risk for preterm delivery (cervical length of <20 mm), followed by the administration of vaginal progesterone gel from the mid-trimester pregnancy until term reduces the rate of PTB before 33 weeks of gestation up to 45%.[60,61]

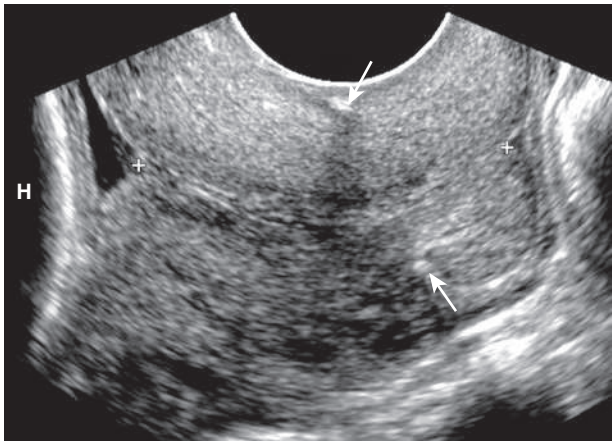

FIG. 44.14 Cervical Cerclage. Transvaginal scan demonstrates a closed cervix that measures 28 mm *(calipers)*. The cerclage sutures *(arrows)* appear hyperechoic. *H,* Fetal head.

Moreover, this protocol resulted in decreased rates of respiratory distress syndrome (the most common complication of preterm neonates), significant reduction in proportion of infants with any mortality or morbidity event, decreased rates of low birth weight (<1500 g), and improved neonatal outcomes.[60] An individual patient data meta-analysis of five large randomized controlled trial studies, including the two studies mentioned earlier, indicates that vaginal progesterone is effective in women with or without a history of PTB and a short cervix and therefore recommends that universal transvaginal sonographic measurement of cervical length be performed at 19 to 24 weeks of gestation.[62] Cost-effectiveness of this approach has been demonstrated in two separate studies, one of which demonstrated that 19 million dollars can be saved for every 100,000 women screened.[63,64]

Thus there is level I evidence for prevention of PTB and neonatal benefits based on treating with vaginal progesterone of low-risk singleton gestations identified with TVS screening to have a short cervical length. Cervical length TVS of singleton gestations fulfills many criteria for an effective screening test. However, the issue of universal screening of singleton gestations without prior PTB for the prevention of PTB remains a topic of debate because of insufficient data.[65]

During TAS for fetal anatomy or other indications, if the closed cervical length is less than 25 mm any time before 28 weeks of gestation, or suspicion of findings such as a dilated cervical canal, a ballooned fluid-filled lower segment with no visible cervix, or a cord or fetal part in the canal are noted, then further evaluation of the cervix by TVS is indicated.

As will be further discussed in subsequent sections, randomized controlled studies of cerclage placement in low-risk women identified with a "short cervix" have not demonstrated benefit of the cerclage for the prolongation of pregnancy.[66] Antibiotic therapy and bed rest have not been demonstrated to be effective at reducing the rate of SPTB in women with a "short cervix."[2]

High-Risk Obstetric Population Screening

Prior Preterm Birth. Once a patient has experienced an SPTB, the risk of recurrence is increased twofold based on history alone. TVS assessment of cervical length has been suggested as a tool of surveillance to evaluate the risk of SPTB specific to the individual patient and to identify those at greatest risk. Iams et al.[34] reported that cervical length was more predictive of PTB when other risk factors were also present. For a cervical length less than 25 mm at 22 to 24 weeks of gestation in a woman with a previous PTB, the relative risk was approximately 10-fold greater than that of women in the unselected population. Berghella et al.[45] demonstrated that the risk of recurrent SPTB varies with the gestational age at the time of measurement and the total length of cervix, but is not affected by the number of previous PTBs or the gestational age at delivery of the previous PTB. The risk of SPTB was decreased by 5.5% per week of gestation gained and by 6.0% per mm increase in cervical length. Crane and Hutchens[67] performed a systematic review of 14 studies involving 2258 asymptomatic high-risk women. In women with previous SPTB, for cervical length less than 25 mm, the likelihood ratios for SPTB were 4.3 and 2.8 when gestational age at assessment was less than 20 weeks and 20 to 24 weeks, respectively. Following that review, Seaward et al.[68] found limited utility of cervical length after 24 weeks' gestation in 75 high-risk patients; cervical length less than 25 mm or less than 15 mm measured at 24 to 30 weeks did not predict SPTB (defined as either <32 or <35 weeks' gestation) or adverse perinatal outcome. As discussed previously, the rate of cervical change may be a better predictive tool to identify those at greatest (and conversely lower) risk.

Multiple Gestations. Twin and higher-order multiple gestations are at increased risk of SPTB; 50% of twin gestations deliver before 35 weeks of gestation, and the mean gestational age for a triplet gestation is 32 weeks. Several studies have attempted to define individual patient risk by using TVS assessment of the cervix. For the twin gestation, when measured at 20 to 22 weeks, both length less than 25 mm and presence of funneling were predictive of SPTB, but at 27 weeks, only length less than 25 mm predicted SPTB.[69-72] The likelihood ratio of SPTB for cervical length less than 25 mm was 5.4-fold, but if the cervix

TAS Findings That Indicate TVS Follow-Up

- Closed cervical length less than 25 mm (any time <28 weeks)
- Dilated cervical canal
- Ballooned, fluid-filled lower segment with no visible cervix
- Suspicion of cord or fetal parts prolapse into the cervical canal

Risk Factors for Preterm Birth

- Short cervical length
- Prior preterm birth
- Uterocervical anomalies (such as müllerian duct abnormalities)
- Prior cervical surgery such as LEEP
- Multiple gestations
- Polyhydramnios

LEEP, Loop electrosurgical excision procedure.

measured greater than 30 mm, rate of SPTB was as low as 4%. For the triplet gestation, using the same cutoff length of less than 25 mm, a positive predictive value of 83% for SPTB was reported when the cervix was measured at 14 to 20 weeks' gestation.[69-72]

Uterocervical Anomalies and Cervical Surgery. Previous cervical surgery (cone biopsy or laser excisional therapy) and a known uterine or cervical congenital anomaly (uterine didelphys, bicornuate uterus, or diethylstilbestrol [DES] exposure in utero) are factors that significantly increase the risk of SPTB. Several researchers have sought to determine if the cutoff cervical length value of less than 25 mm provides the best predictive for SPTB for women with known congenital uterine anomalies. As expected, women with a unicornuate uterus had the shortest mean cervical length and the highest rate of SPTB, compared with women with a bicornuate or septate uterus. However, the mean gestational age at delivery was typically longer than 30 weeks' gestation. Using a cervical length cutoff of 30 mm when measured after 20 weeks, rate of SPTB was increased by 13-fold; at 14 to 23 weeks, if the cervix was less than 25 mm, rate of SPTB was as high as 50%.[73] After cervical amputation by cone biopsy or laser excisional surgery (loop electrosurgical excision procedure [LEEP]), the mean cervical length is shorter.[74] LEEP and cone biopsy therapy are associated with increased risk of SPTB by 3.45-fold, presumably from effects on cervical length and function. Again, a longer cervical cutoff of greater than 30 mm gave the best predictive value for identifying patients not at risk of SPTB, with a negative predictive value of 97%.

Preterm Premature Rupture of Membranes. Although the odds ratio for prediction of PPROM by TVS cervical assessment increases in relation to serial decreases in cervical length less than 20 mm, the positive and negative predictive values are low compared with the prediction of SPTB in general. TVS after PPROM can be performed without increased risk of chorioamnionitis or neonatal sepsis.[29] A cervical length less than 20 mm was associated with a latency period of less than 48 hours following PPROM.[29]

Polyhydramnios. Given that polyhydramnios is a risk factor for SPTB, presumably related to uterine distention triggering of uterine activity or mechanical cervical incompetence, one small study examined the relationship among the severity of polyhydramnios, cervical length, and SPTB.[75] A gradual shortening of cervical length was associated with advancing gestational age but not the severity of the polyhydramnios. Cervical length less than 15 mm was associated with an earlier gestational age at delivery.

Fetal Therapy. Based on the assumption that cervical length is an anatomic marker of underlying pathologic processes that lead to SPTB, clinicians have sought to use the cervical length measurement to quantify risk in patients undergoing a fetal therapeutic intervention that in itself increases the risk of SPTB. A cervical length less than 30 mm at multipregnancy reduction from triplet to twin gestation (at <14 weeks) has a positive predictive value of 67% for delivery less than 33 weeks after the procedure.[76-78] Similarly, a cervical length less than 30 mm before laser treatment of twin-twin transfusion syndrome was associated with SPTB, independent of parity, intrauterine death of one fetus, disease severity, or volume of the amniotic fluid reduction as part of the procedure.[76-78]

Symptomatic Patients

A patient presenting with symptoms consistent with preterm labor (uterine contractility, vaginal discharge or bleeding) is considered at increased risk of SPTB, although two-thirds of women admitted with the diagnosis of threatened PTB deliver at term.[2] Honest et al.[35] summarized the risk of SPTB before 34 weeks' gestation as follows: if the cervix measured less than 30 mm, risk increased by 2.0-fold if measured before 20 weeks and increased by 2.3-fold after 20 weeks. The presence of funneling, regardless of gestational age, increased the likelihood ratio to 4.7-fold. Alternatively, a TVS cervical length of longer than 30 mm makes the diagnosis of preterm labor extremely unlikely, with a negative predictive value of 98% to 99%. Multiple studies have shown the importance of sonographic assessment of cervical length in distinguishing between true and false labor in patients presenting with symptoms of preterm labor.[79]

As previously stated, assessment of FFN in the cervical-vaginal secretions improves the prediction of delivery provided by cervical length evaluation in patients with a cervical length of less than 30 mm.[38,40,41]

Cervical Incompetence and Cervical Cerclage

Cervical incompetence is defined as the inability to support a full-term pregnancy because of a functional or mechanical defect of the cervix.[80] It is characterized clinically by acute painless dilation of the cervix usually in the mid-trimester, culminating in prolapse and/or PPROM with resultant preterm delivery. This occurs in 0.5% to 1.0% of all pregnancies, with a recurrence risk of 30%.[2,9] **Functional failure** of the cervix is premature cervical ripening (shortening and dilation normally occurring at the end of gestation) and most often is related to urogenital or intrauterine infection or inflammation and thus has a low risk of recurrence. **Mechanical failure** of the cervix, defined as a defect in the structural integrity of the cervix, may result from traumatic injury to the cervix, including cervical laceration, amputation, conization, excessive cervical dilation before diagnostic curettage, or therapeutic abortion.[2] It may also be associated with DES in utero or uterine malformations. Serial cervical shortening in the second trimester and a positive response to fundal pressure may be used to unmask specific cervical mechanical incompetence during pregnancy.[48,49,53]

Certain nonsurgical approaches, including activity restriction, bed rest, and pelvic rest have not been proved to be effective for the treatment of cervical insufficiency.[81,82] These patients may benefit from the placement of a **cervical cerclage,** a suture used to reinforce the structural integrity of the cervical canal.

Indications for cerclage include[83]:

- History indicated (prophylactic) cerclage: in patients with unexplained second-trimester delivery in the absence of labor or abruptio placentae. Three randomized controlled trials have reported on the efficacy of this approach; two found no significant improvement in outcomes[84,85] and one found fewer preterm deliveries before 33 weeks in the cerclage group.[86]

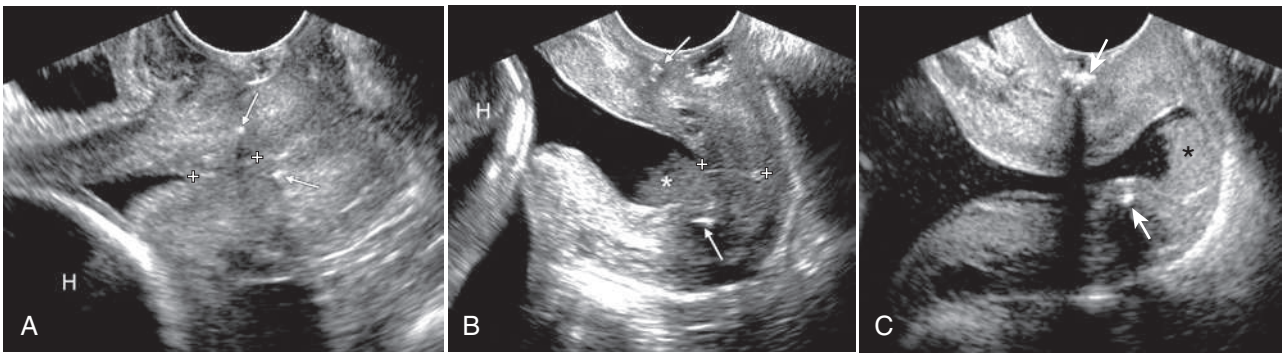

FIG. 44.15 Funneling After Cervical Cerclage. (A) Transvaginal scan demonstrates mild protrusion of the membranes. There remains 10-mm closed cervix length *(calipers)* above the sutures *(arrows)*. **(B)** Transvaginal scan demonstrates protrusion of the membranes to the level of the sutures *(arrows)*. The residual closed cervix length below the cerclage sutures measures 10 mm *(calipers)*. **(C)** Transvaginal scan demonstrates protrusion of the membranes beyond the sutures *(arrows)*. *H,* Fetal head; * indicates amniotic fluid sludge.

- Physical examination indicated ("rescue") cerclage: in patients presenting with advanced cervical dilation in the absence of labor or abruptio placentae. Limited data from one small randomized trial and retrospective studies have suggested the possibility of benefit from cerclage placement in these women.[83]
- Sonographic finding of a short cervix (<25 mm) before 24 weeks of gestation in patient with singleton pregnancy and prior history of PTB less than 34 weeks of gestation.

Numerous studies have compared perinatal outcome in cerclage patients treated with history-indicated cerclage versus those monitored with serial TVS examinations that have been treated with an ultrasound-indicated cerclage as needed. Two recent summaries of the results of these multiple studies have drawn the following conclusions, which are limited to singleton pregnancies:

1. Most patients at risk of cervical insufficiency can be safely monitored with serial TVS examinations in the second trimester.[87,88]
2. History-indicated cerclage procedures can be avoided in more than one-half of the patients who undergo serial TVS cervical length monitoring.[87,89]
3. Duration of surveillance should begin at 16 weeks and end at 24 weeks of gestation.[87]
4. Although women with a current singleton pregnancy, prior SPTB at less than 34 weeks of gestation, and short cervical length (<25 mm) before 24 weeks of gestation do not meet the diagnostic criteria for cervical insufficiency, available evidence suggests that cerclage placement may be effective in this setting[90,91] Cerclage is associated with significant decreases in PTB outcomes, as well as improvements in composite neonatal morbidity and mortality.

Sonography has been used in the operating room to guide the placement of cervical cerclage, especially when the cervix is short, to ensure that the suture material is placed within the cervical tissue and does not encroach on bladder mucosa or rectum. Once in place, the cervical cerclage will appear as one or more echodense "dots" along the length of the cervical canal

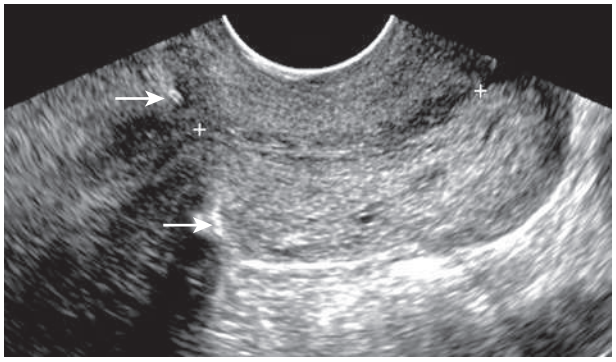

FIG. 44.16 Abdominal Cervical Cerclage. Transvaginal longitudinal scan demonstrates hyperechoic sutures *(arrows)* at the internal os in this woman with a history of incompetent cervix. The cervix is closed and long, measuring 4.5 cm *(calipers)*.

(Fig. 44.14). Postcerclage evaluation includes location of the sutures in relation to both the internal and the external cervical os and measurement of the length of the closed cervical canal both above and below the level of the suture line. Once the cerclage has been placed, cervical length assessment continues to have value in the prediction of SPTB. Several studies reported that if the residual total closed cervical length after cerclage placement was less than 15 mm, or if "funneling to stitch" (open canal to level of suture line) was present (Fig. 44.15), the patient was at significantly increased risk of delivery before 32 weeks' gestation, regardless of the indication for stitch placement.[68,92,93] Beyond 30 weeks, there was no predictive value of cervical assessment in women with a cerclage.

When the vaginal portion of the cervical tissue is absent or damaged (trachelectomy, cone biopsy, birth trauma), the placement of a cerclage in the vaginal component of the cervix is not possible. Alternatively, a cerclage can be placed at the level of the cervicouterine isthmus either by laparoscopy or laparotomy. On TVS assessment, the echodense dots of this "abdominal" cerclage will be visualized close to the bladder and adjacent to the lower uterine segment (Fig. 44.16).

Who Should Not Get a Cerclage? Incidentally detected short cervical length in the second trimester in the absence of a prior singleton PTB is not diagnostic of cervical insufficiency,

and cerclage is not clearly indicated in this setting.[94] Cerclage may increase the risk of PTB in women with a twin pregnancy and an ultrasonographically detected cervical length less than 25 mm and thus is not recommended.[88,95] In addition, evidence is lacking for the benefit of cerclage solely for the following indications: prior LEEP, cone biopsy, or müllerian anomaly.

Cervical Incompetence and Vaginal Pessary

Cervical pessary is a silicone device that has been used in the past 50 years to prevent PTB. Two randomized controlled studies have assessed the effectiveness of this treatment option in women with singleton gestations and a mid-trimester short cervical length detected by TVS and with no prior history of PTB, one of which is in favor (PECEP trial)[62] and the other one from China, which did not show significant benefit to using this device.[96]

A Cochrane review in 2010 (before these two trials were published)[97] did not identify any well-designed randomized clinical trial in order to confirm or refute the benefit of cervical pessary in singleton gestations. However, it was noted that there is evidence from nonrandomized trials that showed some benefit of cervical pessary in preventing PTB. At this time, evidence remains controversial.

Vaginal Progesterone and 17-Alpha Hydroxyprogesterone Caproate

It is important to note that progesterone and 17-alpha hydroxyprogesterone caproate (17α-OHPC) have different chemical structures, pharmacologic effects, clinical indications, and safety profiles.[98] Progesterone is a natural progestogen, whereas 17α-OHPC is a synthetic progestogen. Vaginal progesterone is recommended for the prevention of PTB in women with a short cervix (with or without a history of PTB). 17α-OHPC is currently recommended for the prevention of PTB in women with a singleton gestation and a history of PTB. Currently, there is a safety warning for 17α-OHPC based on a nonsignificant increased rate of stillbirth and miscarriages in women who received 17α-OHPC,[99] whereas no such issues have been reported with vaginal progesterone.

MANAGEMENT PROTOCOLS FOR THE ABNORMAL CERVIX

Because of improved test characteristics in women at increased risk of SPTB, and because interventions such as cerclage and progesterone therapy may have a potential benefit in the high-risk patient, cervical length measurement is currently used as a screening test in high-risk pregnancies and perhaps in the future, universally for all pregnancies. What remains to be determined is the frequency of evaluation, the gestational age of first evaluation, and the utility of the measurements after 30 weeks of gestation. Based on the previous discussions, specific management protocols are suggested (Figs. 44.17 and 44.18).

CONCLUSION

TVS is the reference-standard approach for cervical assessment in pregnancy. Cervical length is used most often to predict SPTB. Cervical length should be taken in the context of maternal risk factors for SPTB (obstetric history, uterine contractions), gestational age, funneling, response to fundal pressure, previous measurement, presence of cervical glandular area, and amniotic fluid debris. The cervical length cutoff of 25 mm at mid-trimester provides the best predictive values for SPTB before 34 weeks. A "short" (<25 mm) cervical length is not a diagnosis of impending SPTB, but rather a tool to quantify the increased risk of such an event.

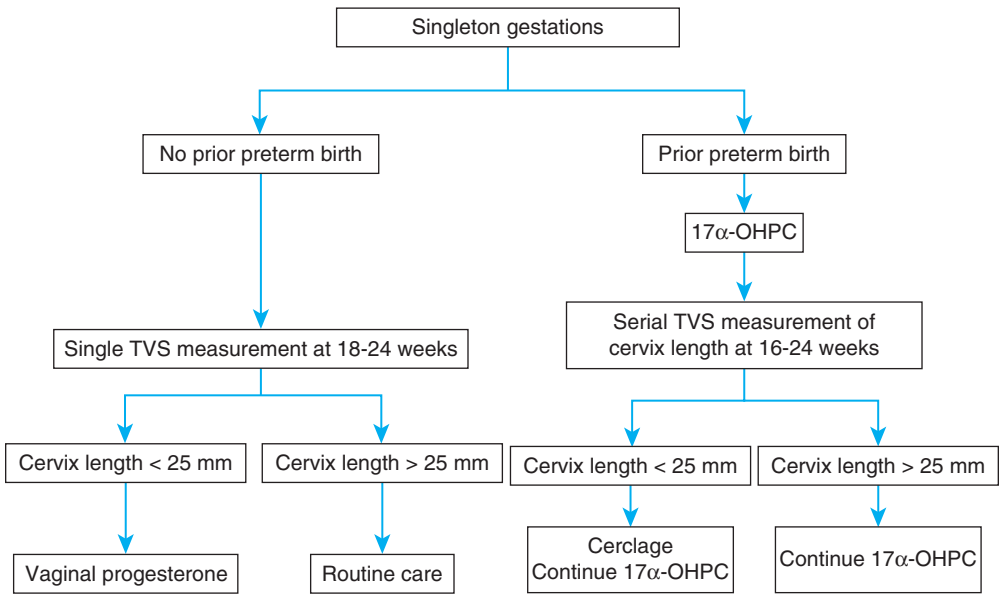

FIG. 44.17 Management Protocol: General Obstetric Population. Proposed algorithm to guide response to cervical length measurements at transvaginal sonography (at 18-24 weeks' gestation). *17α-OHPC,* 17-alpha Hydroxyprogesterone caproate. *TVS,* transvaginal sonography.

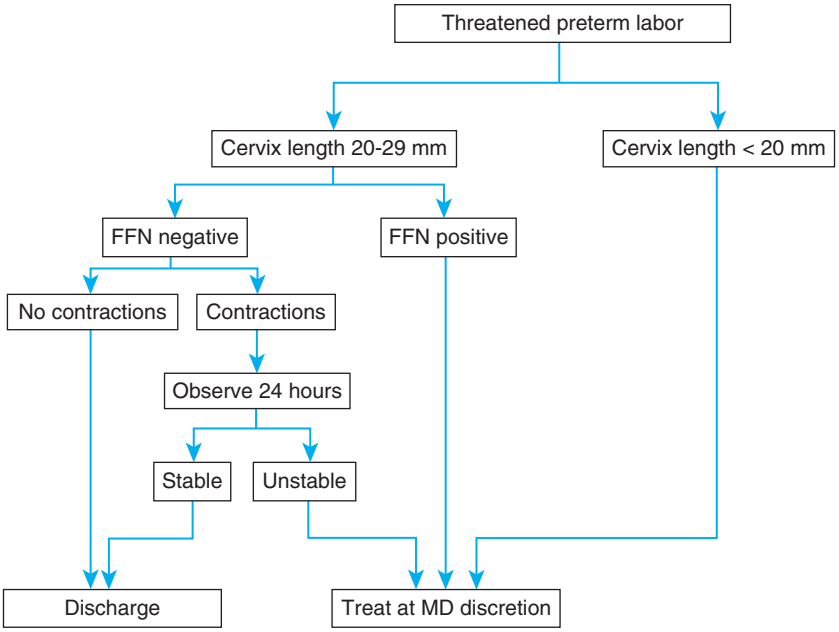

FIG. 44.18 Management Protocol: High-Risk Obstetric Population. Algorithm to guide management in threatened preterm labor. *FFN,* Fetal fibronectin.

CHAPTER 45

Neonatal and Infant Brain Imaging

Carol M. Rumack and Amanda K. Auckland

SUMMARY OF KEY POINTS

- Brain ultrasound of premature infants is best performed for germinal matrix hemorrhage and hydrocephalus at 10 to 14 days of life and for cystic periventricular leukomalacia at 30 days of life.
- The best time to assess for white matter injury of prematurity is at term-equivalent age.
- Cerebellar hemorrhage is missed if mastoid views of the posterior fossa are not obtained.
- High-resolution images are needed to fully study the brain parenchyma for white matter injury.
- Multiple acoustic windows are essential for accurate detailed ultrasound imaging of the brain.
- Doppler evaluation is key for any cystic lesion to exclude vascular malformations.
- Computed tomography of the newborn brain is not indicated except in the case of a traumatic birth.
- Congenital anomalies are well evaluated with ultrasound and, if further information is needed, are an indication for magnetic resonance imaging.

Neonatal sonography of the brain is an essential part of newborn care, particularly in high-risk and unstable premature infants.[1,2] Current ultrasound technology allows for rapid evaluation of infants in the intensive care nursery with virtually no risk. The advantages of sonography over computed tomography (CT) or magnetic resonance imaging (MRI) include portability, lower cost, speed, no ionizing radiation, no sedation, and real-time visualization with video clips saved for later review. Screening of premature infants for intracranial hemorrhage has proven highly sensitive and specific. Daneman and colleagues have reported that optimal imaging of the neonatal brain requires delineation of structures in both the near and far fields. Thus magnification of selected areas with focal zone and higher resolution megahertz adjustments are essential for these detailed regional assessments.[3,4] Real-time assessment is essential to detect subtle changes in echogenicity of the brain parenchyma, especially common in white matter injury of prematurity (WMIP). MRI is very sensitive and specific with regard to identification of brain injuries but, because of the cost and need for transfer of very unstable premature infants, is typically performed at term-equivalent age if concerns regarding neurodevelopmental outcomes are present.

Ultrasound is essential to the neonatal evaluation and follow-up of hydrocephalus and periventricular leukomalacia (PVL). Prenatal ultrasound and MRI diagnosis[5] of central nervous system (CNS) malformations, infection, or masses is now followed up by ultrasound in the neonatal period. When major anomalies are present, associated anomalies may need evaluation by neonatal MRI. CT is not indicated in premature infants because of the lack of good gray versus white matter differentiation from the high water content in the newborn brain.[6] For the same reason, CT is rarely used for term infants unless there is a history of birth trauma.

Ultrasound can be useful for the follow-up of ventricular shunt therapy or possible complications. Color and spectral Doppler ultrasound of cranial blood flow may prove valuable, particularly for cystic lesions when the differential diagnosis includes a vascular lesion, or for possible subdural hematomas, and to separate normal vascular structures from clot. Doppler ultrasound is also useful in infants receiving extracorporeal membrane oxygenation (ECMO) or when decreased blood flow is a risk for infarction (see Chapter 46).

EQUIPMENT

In the premature infant, a 7.5-MHz or higher transducer is recommended to obtain the highest resolution possible. A 5-MHz transducer may be necessary to allow for adequate sound penetration of a larger infant head.[7] Electronic phased array transducers with a 120-degree sector angle and multifocal zone capabilities are generally used for imaging through the anterior fontanelle. **Small-footprint, linear array, high-frequency transducers** (up to 12 MHz) can provide high-quality images for scanning of near-field pathology through the anterior fontanelle. These transducers are best for subdural hematomas, meningitis, superior sagittal sinus thrombosis, and cerebral edema, and in some cases, migrational abnormalities,[8] or for scanning over the mastoid fontanelle, posterior fontanelle, and foramen magnum. The squamosal portion of the temporal bone is thin but may require a 5-MHz transducer if not imaged through the mastoid fontanelle. The multifocal zone capability provides excellent resolution throughout the field of view, but requires a cooperative patient because the frame rate is slowed significantly. **Compound imaging,** allowing for multiple angles of insonation, is also useful when imaging through small spaces such as the fontanelles. Video clip capabilities are invaluable in an uncooperative infant or when documenting motion, such as blood flow.

It has become routine to save video clips for later review, to prevent repeating an examination if there is a questionable finding and to be certain that each view has been completely evaluated. Clips can greatly improve the understanding of the pathology. Areas of increased or decreased echogenicity may be extremely subtle on single images, but they become much more apparent when integrated with cine or video that captures real-time ultrasound findings and the relationship to normal structures.

SONOGRAPHIC TECHNIQUE

Currently, most brain sonographic examinations are performed through the **anterior fontanelle** in both the coronal and the sagittal planes. It has become clear that the neonatal brain is not fully examined unless the posterior fossa is evaluated through the **posterior and mastoid fontanelles.** In fact, cerebellar hemorrhage has been proven by MRI correlation to be missed without the mastoid views of the posterior fossa.[9] Posterior fossa malformations may not be well understood without these highly detailed views of the cerebellum, fourth ventricle, and cisterna magna.[10-12] Thus the posterior fossa views from the mastoid fontanelle are extremely important in the evaluation of cerebellar hemorrhage or posterior fossa anomalies, which are quite common. Good skin-to-transducer coupling can be achieved by an acoustic coupling gel. Occasionally, a standoff pad can be useful to evaluate superficial abnormalities such as subdural hemorrhage, but a higher resolution transducer is a better option to evaluate the near field in detail.

It is very important to use color Doppler ultrasound imaging to evaluate **fluid collections** because some cystic areas are actually vessels. If extracerebral fluid collections are expected, they are better evaluated with CT or MRI. Axial ultrasound scanning has been used extensively in utero, particularly for accurate measurements of fetal ventricular dimensions. In the newborn, axial scanning is used in evaluation of the posterior fossa through the mastoid fontanelle and to evaluate the circle of Willis with color Doppler ultrasound.[7,13-15] Doppler evaluation of the major cerebral arteries may be indicated with particular attention to the resistive index changes that can indicate cerebral blood flow abnormalities. Color and spectral Doppler may show hyperemia, and they can be used to depict patency and flow in the major dural sinuses (see Chapter 46). The posterior scanning techniques are the best approach to evaluate the occipital horns for ventricular clot. The foramen magnum approach may be useful when evaluating the upper spinal canal, as in patients with a Chiari malformation.

The anterior fontanelle remains open until approximately 2 years of age but is suitable for scanning only until about 12 to 14 months. The smaller the fontanelle, the smaller is the acoustic window and the more difficult the examination will be.[7,13]

Every effort should be made to maintain normal body temperature in premature infants when performing ultrasound. Their small size results in a high surface-to-volume ratio and rapid heat loss when they are exposed. Overhead warming lamps, blankets, and warmed coupling gel should be routinely used. If the infant is in an Isolette, heat loss may be minimized by using access side holes as an entry site for the transducer.

Handwashing and cleansing of the transducer between patients are of paramount importance to avoid the spread of infection in the intensive care nursery. Simple cleansing of the transducer head with a manufacturer-approved disinfectant should be adequate. When absolute sterility is required, such as during operative sonography, the transducer can be placed inside a sterile surgical glove or sterile transducer cover with coupling gel. Sterile aqueous gel or saline solution can be used as a coupler outside the sterile cover.

Standard brain scanning includes sagittal and coronal planes through the anterior fontanelle and should also routinely include at least two axial views: through the posterior fontanelle and the mastoid fontanelle. Coronal images acquired through the posterior fontanelle may be useful as well, to compare ventricular size. Magnified views with high-frequency transducers are essential to study near-field pathology such as extraaxial fluid for hemorrhage or infection and dural venous sinuses. Whenever possible, the transducer should be held firmly between the thumb and index finger, and the lateral aspect of the hand should rest on the infant's head for stability. Video clips should be obtained routinely for any abnormality to improve ultrasound diagnosis, avoid repeating a scan on an unstable newborn, and allow review of complex images and prompt diagnosis without delaying the patient workflow. Real-time imaging enables the appreciation of subtle changes in echogenicity more easily than static images. Lesions that affect gray-white matter differentiation as well as focal nonhemorrhagic infarcts may cause mild changes in echogenicity.[3]

Coronal Imaging

Coronal images are obtained by placing the scan head of the transducer transversely across the anterior fontanelle (Fig. 45.1, Video 45.1). The plane of the ultrasound beam should then sweep in an anterior-to-posterior direction, completely through the brain. Care must be taken to maintain symmetrical imaging of the brain and skull. An initial sweep of the brain to obtain parallel alignment of the thick glomus of the choroid plexus in each trigone is a good method to obtain symmetry. At least six standard coronal images should be obtained during this anterior-to-posterior sweep.[13]

The most anterior image is acquired just **anterior to the frontal horns** of the lateral ventricles[16] (Fig. 45.2A). Visualization of the anterior cranial fossa is obtained, including the frontal lobes of the cerebral cortex with the orbits deep to the floor of the skull base.

Moving posteriorly, the **frontal horns of the lateral ventricles** appear as symmetrical, anechoic, comma-shaped structures with the hypoechoic caudate heads within the concave lateral border (see Fig. 45.2B). Structures visualized from superior to inferior in the midline include the interhemispheric fissure, cingulate sulcus, genu and anterior body of the corpus callosum, and septum pellucidum between the ventricles. Moving laterally from the midline, the caudate nucleus is separated from the putamen by the internal capsule. Lateral to the putamen, the sylvian fissure is echogenic because it contains the **middle cerebral artery** (MCA). The sylvian fissure separates the frontal from the temporal lobe. Inferiorly, the internal carotid arteries bifurcate to form the echogenic anterior cerebral artery and MCA.

Progressing farther posteriorly to the level above the midbrain, the **body of the lateral ventricles** is visible on either side of the cavum septi pellucidi (see Fig. 45.2C). Below this, the thalami lie on either side of the third ventricle, which is usually too thin to visualize in normal infants. Deep to the thalami, the brainstem begins to be visualized. Lateral to the midline, the **thalami** are separated from the lentiform nuclei **(caudate and putamen)** by the **internal capsule.** Lateral to the lentiform nuclei is the deep white matter region of brain called the **centrum semiovale.** Again, the sylvian fissures are visible.

A slightly more posterior transducer angulation results in a plane that includes the **cerebellum.** The body of the lateral ventricles becomes somewhat more rounded as the size of the caudate nucleus decreases once posterior to the foramen of Monro (see Fig. 45.2D). At this level in the midline, the body of the corpus callosum is deep to the cingulate sulcus, and the third ventricle is located between the anterior portions of the thalami. Echogenic material visualized in the floor of the lateral ventricles is the **choroid plexus.** Echogenic choroid plexus is also seen in the roof of the third ventricle, resulting in three echogenic foci of choroid. The thalami are now more prominent on either side of the third ventricle. Midline structures are unchanged, except that deep to the thalami, the tentorium covering the cerebellum can be visualized. Below this, in the posterior fossa, the **vermis** is the echogenic structure in the midline surrounded by the more hypoechoic cerebellar hemispheres. When the septum pellucidum is cystic posteriorly, it is called the **cavum vergae.** Because the cystic center of the septum pellucidum closes from posterior to anterior as the brain matures, late-gestation neonates often have only the more anterior cavum septi pellucidi. The

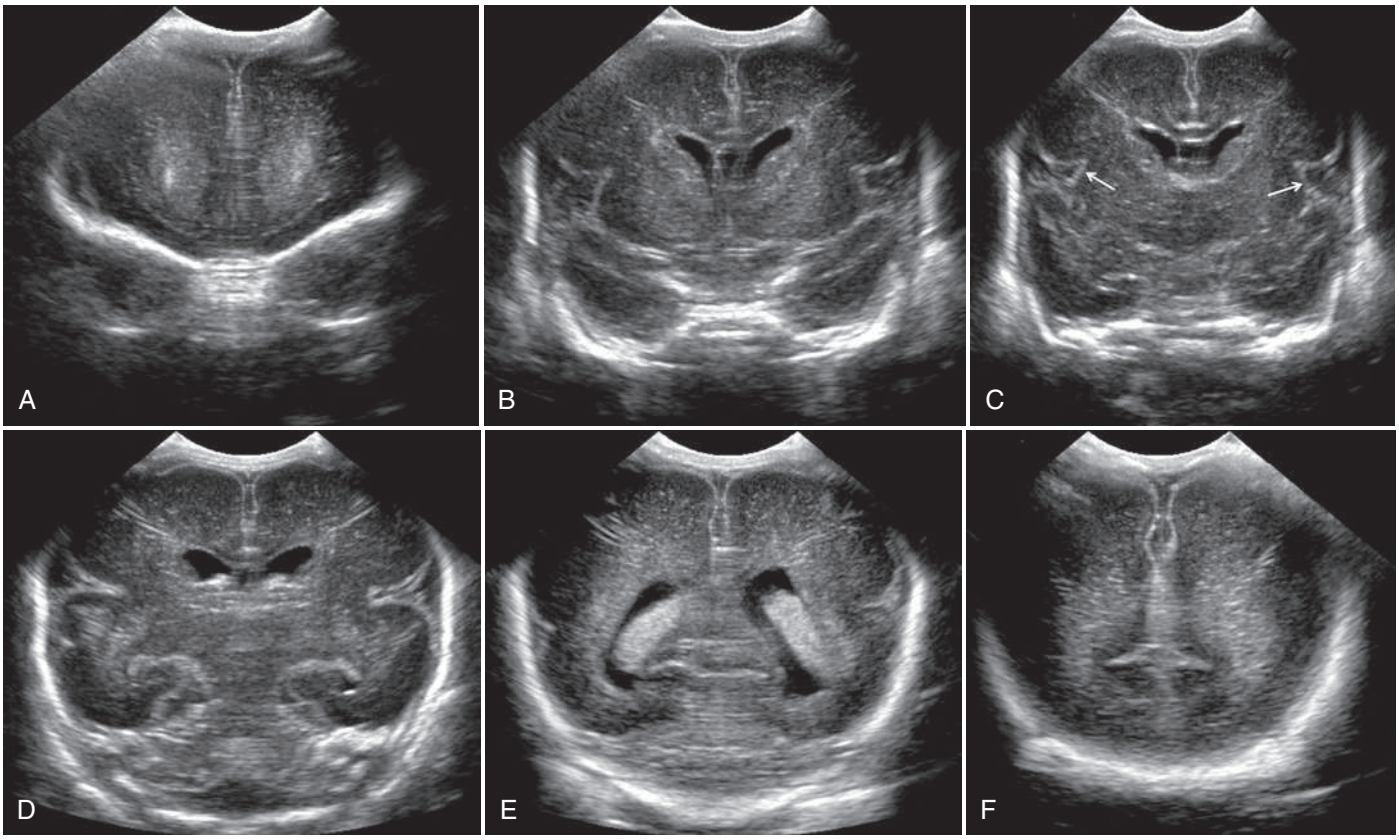

FIG. 45.3 Normal Coronal Brain Images: Premature Newborn Infant. (A)-(F) Coronal images in very premature infant; ventricles can be larger with extreme prematurity. **(C)** Sylvian fissures *(arrows)* appear boxlike.

lentiform nuclei may no longer be seen at this level. The **temporal horns** of the lateral ventricles may be seen lateral and inferior to the thalami, but are usually not seen unless there is hydrocephalus.

Further posteriorly, the **trigone** or **atrium of the lateral ventricles** and **occipital horns** are visualized (see Fig. 45.2E). The extensive echogenic glomus of the choroid plexus nearly obscures the lumen of the cerebrospinal fluid (CSF)–filled ventricle at the trigone. In the midline—the visualized portion of the corpus callosum deep to the cingulate sulcus—is the splenium. Inferiorly, the cerebellum is separated from the occipital cortex by the tentorium cerebelli.

The most posterior section visualizes predominantly **occipital lobe cortex** and the most posterior aspect of the occipital horns of the lateral ventricles that do not contain choroid plexus (see Fig. 45.2F). This section is angled posterior to the cerebellum.

Normal premature brain ultrasound images in the same planes are shown in Fig. 45.3. The lateral ventricles are slightly larger; the cavum septi pellucidi extends back to become the cavum vergae between the lateral ventricle bodies and occipital horns. There are only a few sulci, and the sylvian fissures are wider and typically appear boxlike rather than as thin fissures. The basal ganglia in premature infants are normally diffusely homogeneously echogenic, an appearance that is more prominent than in the thalami and typically more echogenic than the cerebral cortex. Basal ganglia and thalami do not show increased echogenicity at term-equivalent age.[17]

Sagittal Imaging

The sagittal images are obtained by placing the transducer longitudinally across the anterior fontanelle and angling it to each side (Fig. 45.4, Video 45.2). The **midline** is first identified through the interhemispheric fissure by recognition of the curving line of the corpus callosum above the cystic cavum septi pellucidi and cavum vergae. Below the cavum lies the choroid plexus in the roof of the third ventricle. If there is third ventricular enlargement, the massa intermedia will be outlined by CSF and the **aqueduct of Sylvius** may be visualized. The **fourth ventricle** is identified as a notch in the anterior surface of the highly echogenic **cerebellar vermis**[18] (Fig. 45.5).

The **cingulate sulcus** lies parallel to and above the corpus callosum. The highly echogenic falx can be difficult to scan directly through and obtain a clear midline sagittal image; therefore a very slight movement to either side of the falx may be necessary to adequately visualize midline brain structures. In this view, the size of the cerebellar vermis has been used to assess gestational age.[19] However, the degree of sulcal development is the most reliable method for gestational age based on established pathologic standards.[20] Shallow angulation to each side of about 10 degrees will show the normally small **lateral ventricles** (Fig. 45.6A-B). The ventricles are not located in a perfectly straight plane anterior to posterior. The transducer must be angled so that the anterior portion of the sector is directed more medially and the posterior portion more laterally, to include the entire lateral ventricle in a single image.[13]

Above the lateral ventricle is the cerebral cortex, and below it is the cerebellar hemisphere. The **caudate nucleus** and the **thalamus** surround the third ventricle and are within the arms of the ventricle (see Fig. 45.6B). The **caudothalamic groove** at the junction of these two structures is an important area to

recognize, because this is the most common site of germinal matrix hemorrhage (GMH) in the subependymal region of the ventricle.

More pronounced lateral angulation will demonstrate the peripheral aspect of the ventricles and the more lateral **cerebral hemisphere,** including the temporal lobes (see Fig. 45.6C) where the MCA branches extend toward the ventricle.

Sagittal sonography almost always reveals a normal hyperechoic **peritrigonal blush**[21] in the parietal lobe just posterior and superior to the ventricular trigones on parasagittal views (see Fig. 45.6B). It is caused by the interface of numerous parallel fibers that are perpendicular to the longitudinal angle of the ultrasound beam passing through the anterior fontanelle. This is an **anisotropic effect** artifact that occurs when the beam is perpendicular to the fibers through the anterior fontanelle. A similar area of increased echogenicity is not seen on sonograms obtained through the posterior fontanelle, because with that angulation, the long axis of the ultrasound beam and the fiber tracts are almost parallel.

Posterior Fontanelle Imaging

Posterior fontanelle imaging is very useful to evaluate the occipital horns for the diagnosis of intraventricular hemorrhage (IVH). The posterior fontanelle lies in the midline at the junction of the lambdoid and sagittal sutures; it is open only until about 3 months of age[22] (Fig. 45.7). The transducer should be angled slightly off midline with the anterior portion of the probe directed slightly medially, to demonstrate the lateral ventricular trigone with its occipital horn in the near field (Fig. 45.8). The choroid glomus will be seen with extensions into the ventricular body and temporal horn. The **occipital horn** does not contain choroid plexus and should be completely anechoic. Angling the transducer into the left and right parasagittal planes will display each occipital horn. These planes are extremely useful for detecting dependently layering clot and clot attached to the choroid plexus.

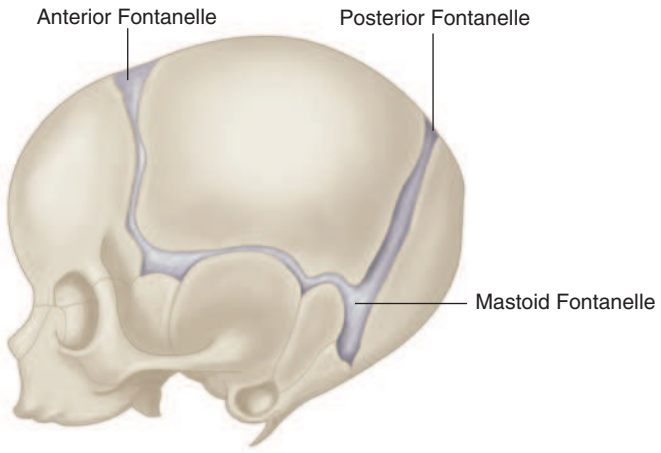

FIG. 45.7 Acoustic Windows: Anterior, Posterior, and Mastoid Fontanelles.

Mastoid Fontanelle Imaging

The mastoid fontanelle allows assessment of the brainstem and posterior fossa, which are not well demonstrated in the standard planes through the anterior fontanelle. The ultrasound transducer is placed about 1 cm behind the helix of the ear and 1 cm above the tragus. The mastoid fontanelle is located at the junction of the squamosal, lambdoidal, and occipital sutures (see Fig. 45.7, Video 45.3). Posterior fossa axial images, with the anterior portion of the transducer angled slightly cephalad, will demonstrate the **fourth ventricle, posterior cerebellar vermis, cerebellar hemispheres,** and the **cisterna magna.** These axial images should be displayed with the top of the head to the left (Fig. 45.9). The radiating folia of the cerebellar hemispheres contain relatively hypoechoic neural tissue and are surrounded by echogenic leptomeninges in the multiple cerebellar fissures.[23] In the roof of the fourth ventricle lies the normal echogenic **fourth ventricular choroid plexus.**[24] Behind the fourth ventricle is the

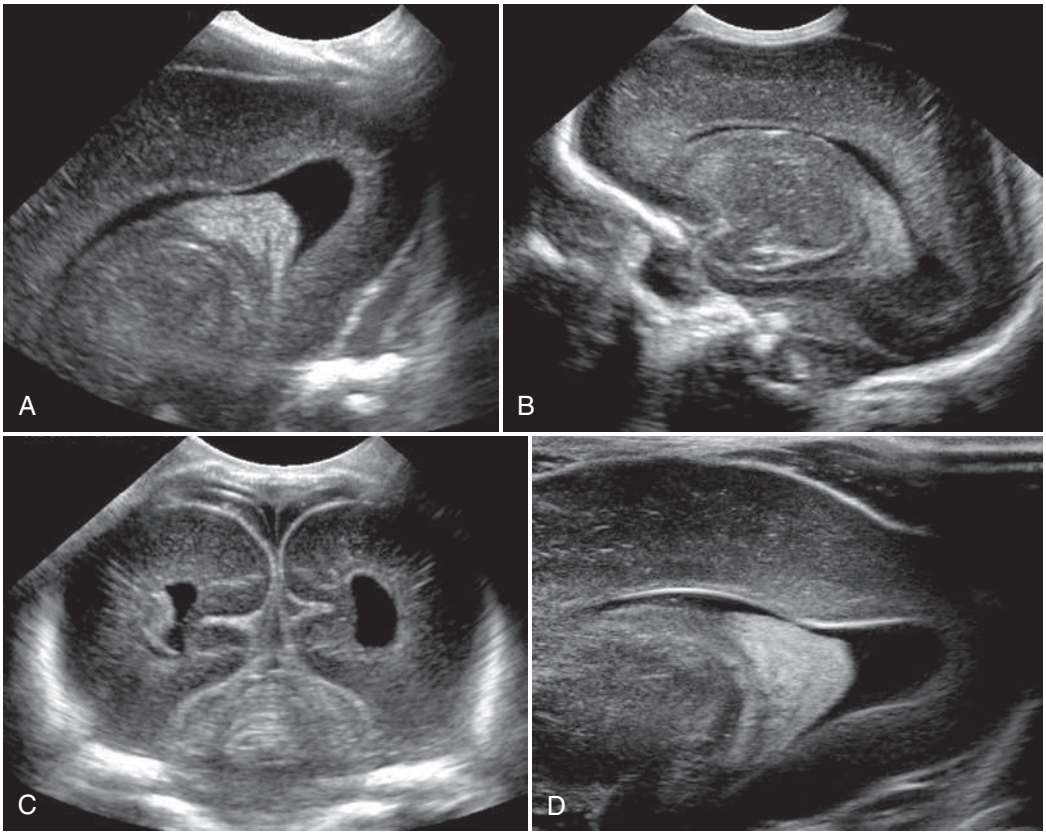

FIG. 45.8 Occipital Horn. (A) Sagittal occipital horn from the posterior fontanelle. **(B)** Same sagittal occipital horn from the anterior fontanelle. **(C)** Coronal occipital horns from the posterior fontanelle; echogenic clot visible in right occipital horn. **(D)** Same occipital horn; linear transducer shows increased resolution.

echogenic midline vermis, which appears less echogenic in the axial view compared with midline sagittal scans. When angled axial images are obtained through the lower parts of the cerebellum below the fourth ventricle, the (normally thin) **vallecula** may be seen in the midline as a space between the cerebellar hemispheres (see Fig. 45.9C), particularly in the presence of hydrocephalus. In steeply angled axial scans, the **foramen of Magendie** can be seen in the midline as a thin sonolucent line between the cerebellar hemispheres extending from the fourth ventricle to the cisterna magna. It should not be mistaken for a Dandy-Walker variant.[25] The presence of an intact vermis on higher images and the marked caudal angulation required to see the vallecula allow differentiation of this normal variant.[11,12,14] Color Doppler ultrasound in this view allows evaluation of flow in the transverse and straight sinuses to exclude venous thrombosis.

A slightly higher axial scan should include the thalami, midbrain, third ventricle, aqueduct of Sylvius, and quadrigeminal plate cistern, with the transducer angled from the standard axial plane and placed cephalad to the external auricle (Fig. 45.10). At this level, the **thalami** are hypoechoic, inverted, heart-shaped structures. The midbrain, including the **cerebral peduncles** and **corpora quadrigemina,** consists of paired hypoechoic lenticular structures just caudal to the thalami. The third ventricle is usually a thin cleft, barely visible between the thalami. The aqueduct is usually a thin echogenic line but may occasionally be a thin slit in the midbrain. The **quadrigeminal cistern** is echogenic and surrounds the midbrain.

Three-Dimensional Ultrasound

Three-dimensional (3-D) ultrasound may be a useful adjunct to standard two-dimensional (2-D) imaging of the neonatal brain.[26] A volume of brain can be acquired in a few seconds, and then reconstructed displays of three octagonal slices at any angle can be viewed, in addition to coronal, sagittal, and axial planes. Brain lesions can be tracked in three views at once, which can better identify the position in the brain and the most likely diagnosis. Some authors recommend 3-D volume measurement of the ventricles[27,28]; the standard method is still a qualitative assessment based on typical normal ventricles of different age groups.

STANDARDIZED REPORTS

Standardized Views for Display

Brain anatomy images should be displayed in a consistent manner so that comparisons can be easily made. At our institution, routine sagittal images are always shown with the infant's face to the left. Labels on sagittal scans should be "left" or "right." Video clips are more difficult to label and might be best done separately on the left and right, in addition to a full sweep through the entire brain from side to side.

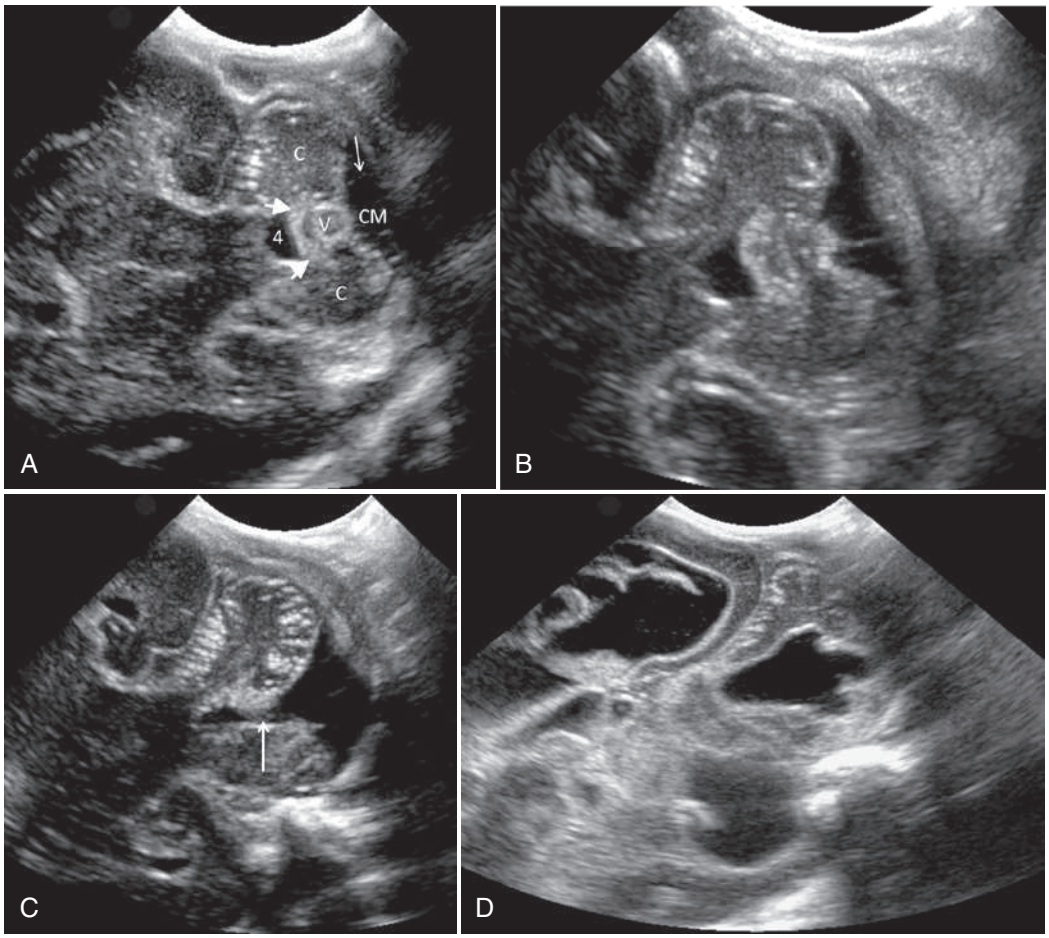

FIG. 45.9 Mastoid Fontanelle Images at Fourth Ventricle Level in Posterior Fossa. (A) Mild posthemorrhagic hydrocephalus, axial plane at the level of the atria of the lateral ventricle *(A),* frontal horns *(f),* thalami *(T),* and third ventricle *(arrow).* **(B)** Axial plane in an infant with moderate posthemorrhagic hydrocephalus, third ventricle *(arrow).*

With use of the American College of Radiology (ACR) and American Institute of Ultrasound Medicine (AIUM) practice parameters for the performance of neurosonography in neonates and infants,[29] there are specific questions to answer. Developing a template for reports is a useful task to ensure complete reporting.

DEVELOPMENTAL ANATOMY

Brain Sulcal Development and Subarachnoid Spaces

In the very premature infant, the brain sulci are not fully developed and the brain appears quite smooth[20,30] (Figs. 45.11 and 45.12).

Ultrasound of the Brain: Standard Report Template

The ventricular size and configuration are <normal>.
The corpus callosum is <present> <above the cavum septum pellucidi and/or cavum vergae>.
There is <no hemorrhage in the caudothalamic groove or in the ventricular system>.
The cerebellar vermis, fourth ventricle, and cerebellar hemispheres <appear normal>.
Sulcal development is <normal> for gestational age.

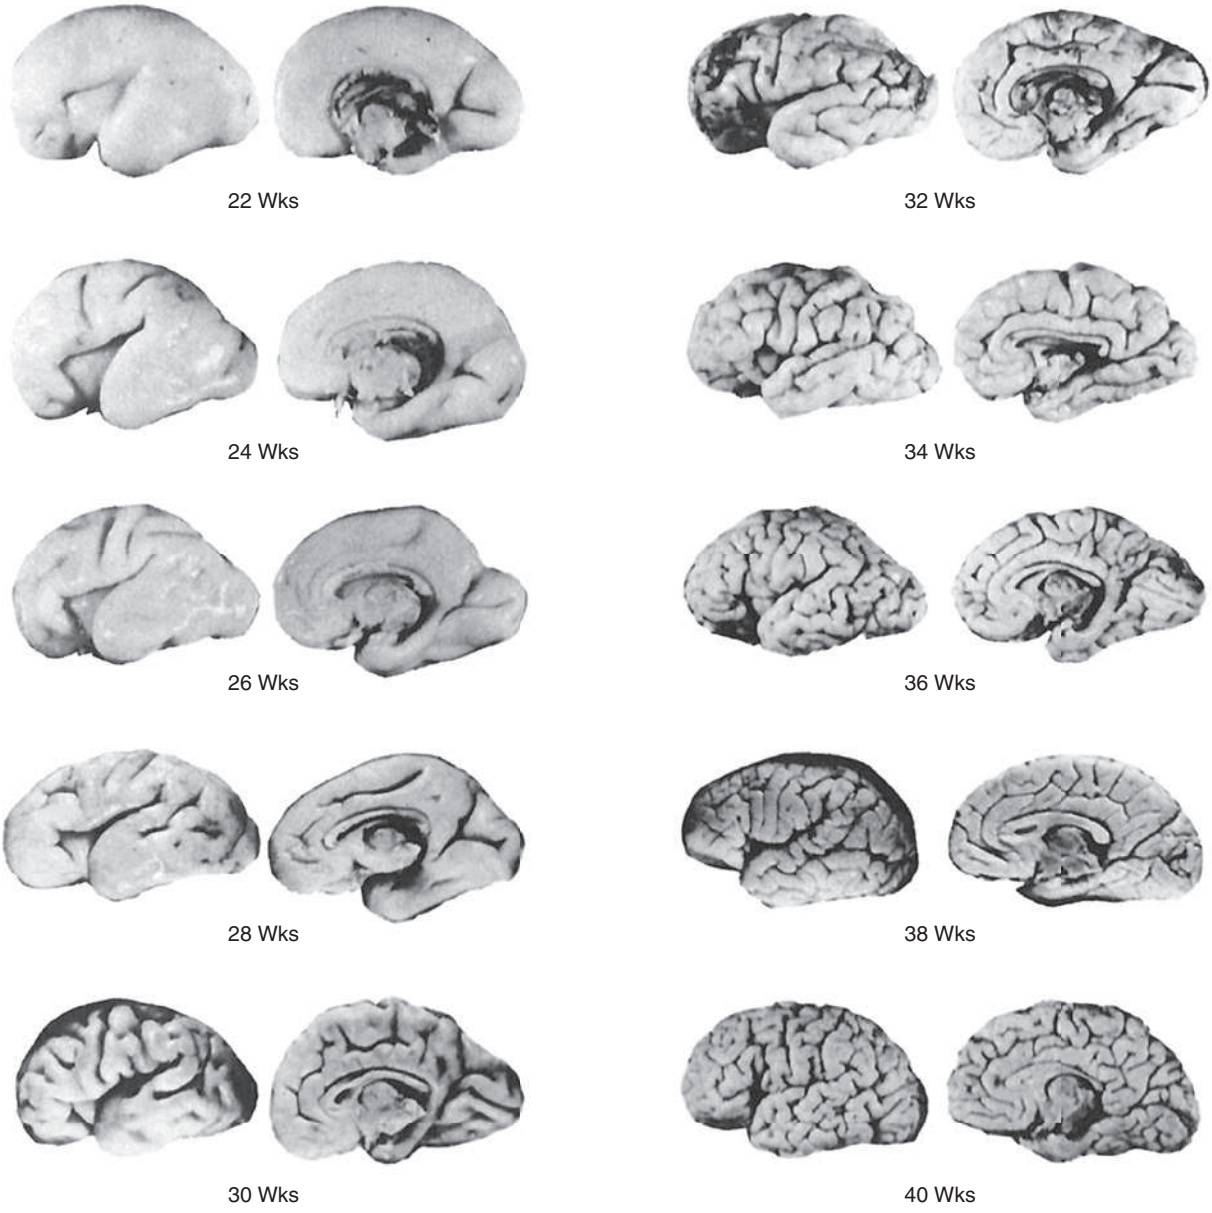

FIG. 45.11 Normal Sulcal Pattern Development. At 22 to 40 weeks' gestation. (With permission from Dorovini-Zis K, Dolman CL. Gestational development of brain. Arch Pathol Lab Med. 1977;101[4]:192-195.[20])

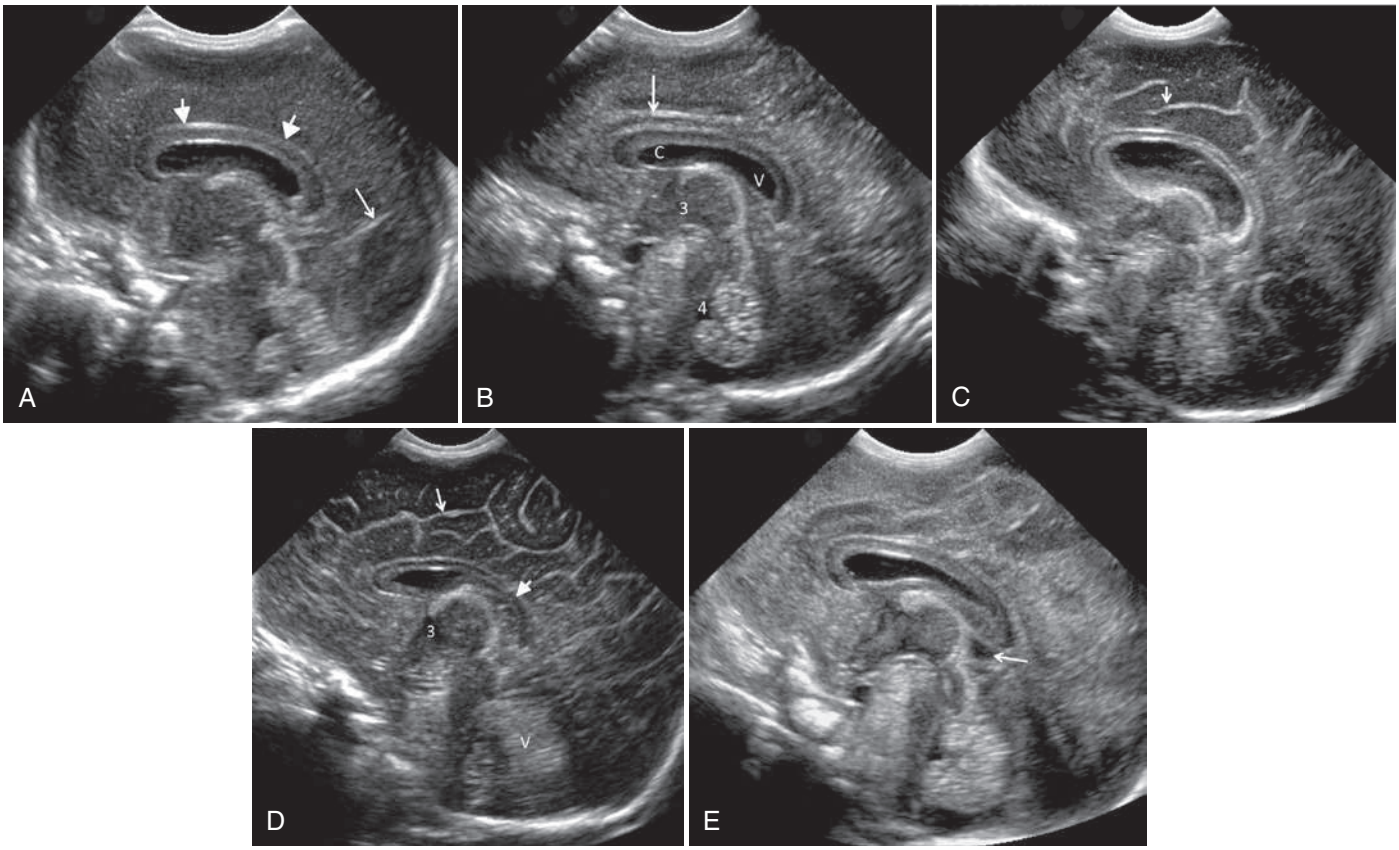

FIG. 45.12 Development of Sulci in a Premature Infant Brain. (A) At 24 weeks. No sulci; occipitoparietal fissure *(arrow)* can be seen; corpus callosum *(short arrows)* lies above the cavum septi pellucidi and cavum vergae. **(B)** At 27 weeks. Cingulate sulcus *(arrow)* is visible. Cavum septi pellucidi *(C),* cavum vergae *(V),* third ventricle *(3),* and fourth ventricle *(4)* are shown in this midline sagittal image. **(C)** At 33 weeks. Cingulate sulcus *(arrow)* now has a few branches. **(D)** At 39 weeks. Cingulate sulcus *(medium arrow)* has many branches. Cavum vergae *(short arrow)* is closed; third ventricle *(3)* and cerebellar vermis *(V)* are shown. **(E)** Cavum veli interpositum *(arrow).*

The first sulcus to form is the primitive, almost square, **sylvian fissure,** best seen on coronal images[31] (see Fig. 45.3C). Later, after infolding of the insula (opercularization), the sylvian fissure becomes a narrow, echogenic fissure filled with MCA branches.[30,32] Sulcal development, best evaluated on midline sagittal images, then extends to the **calcarine fissure** as a simple straight line in the fifth gestational month (20 weeks).[33] By 24 to 25 weeks' gestation, the **occipitoparietal fissure** is present, but no actual sulci. By 28 weeks, the **callosomarginal sulcus** over the corpus callosum and a simple linear **cingulate sulcus** superior and parallel to the corpus callosum are seen (see Fig. 45.12B). By 30 weeks, the cingulate sulcus is branched. Between 33 and 40 weeks' gestation, sulci bend, branch, and anastomose so that a full-term infant has many peripheral branches over the brain surface (see Fig. 45.12D).

Although not used routinely, measurement of the subarachnoid space on a magnified view of the brain can be done from the triangular sagittal sinus to the surface of the cortex. Armstrong and colleagues[34] have reported that the subarachnoid space is normally less than 3.5 mm in 95% of preterm infants before 36 weeks' gestation. Closer to term, the values tended to be at the higher end of the range, increasing slightly on a weekly basis, which suggests that premature infants have reduced brain growth during extrauterine life.

Cavum Septi Pellucidi and Cavum Vergae

There is one continuous cystic midline structure in the septum pellucidum during fetal life. The septum contains the cavum septi pellucidi anterior to the foramen of Monro (see Fig. 45.12) and the cavum vergae posteriorly. Both parts are normally present early in gestation, but they close from back to front, starting at approximately 6 months' gestation (Fig. 45.13). By full term, closure has occurred posteriorly in 97% of infants so that there is only a cavum septi pellucidi at birth. By 3 to 6 months after birth, this septum is completely closed in 85% of infants, although in some the septum remains open into adulthood.[35] In fetal brain imaging, Callen and colleagues[36] reported that the columns of the **fornix** can be mistaken for the cavum septi pellucidi. On axial views below the frontal horns, the fornix appears as a cystic structure with a central linear echo. Absence of the corpus callosum may not be identified because the fornices are present and simulate the cavum between the two frontal horns. Careful evaluation of the inferior position of the fornices below the frontal horns will avoid this error.

Cavum Veli Interpositi

The cavum of the velum interpositum represents a potential space above the choroid in the roof of the third ventricle and

below the columns of the fornices.[2,37] It may appear as an anechoic, inverted, helmetlike space just inferior and posterior to the splenium in the pineal region (see Fig. 45.12E). Blasi and colleagues[38] have described the prenatal diagnosis of the cavum veli interpositi on 2-D and 3-D ultrasound with color flow Doppler. Careful study of the anatomic location of the cystic structure, its size, and changes over time is required to be certain this is a normal variant, not an arachnoid cyst with mass effect or associated anomaly of the corpus callosum. Chen and colleagues[37] reported that 21% of neonates have a cavum veli interpositi on sonography. By 2 years of age, this cystic area is an uncommon finding and thus is thought to be a normal stage of brain development. Rarely, a cyst is found in this area that causes compression of other structures.

Frontal Horn Variants

A few newborns have cysts exactly parallel (not above or below) and adjacent to the frontal horns (Fig. 45.14). These cysts are typically bilateral and have septations between the cyst and the frontal horns. **Frontal horn cysts,** also called **coarctation of the frontal horn**[39] and **connatal cysts,**[40] are caused by folding of the frontal horn on itself, resulting in kinking (seen as a septation). Typical normal frontal horns are directly lateral to the cavum septi pellucidi on coronal images, below the corpus callosum. The frontal horns are relatively thin compared with the occipital horns.

Choroid Plexus and Variants

The choroid plexus is the site of CSF production in the ventricles (Fig. 45.15). The largest portion of the choroid plexus is the **glomus,** a highly echogenic structure attached to the trigone of each lateral ventricle. The choroid tapers as it extends anteriorly to the foramen of Monro and continues from each lateral ventricle into and along the roof of the third ventricle. The choroid plexus tapers laterally as it extends into the temporal horn of the lateral ventricle. The choroid plexus does not extend into the frontal

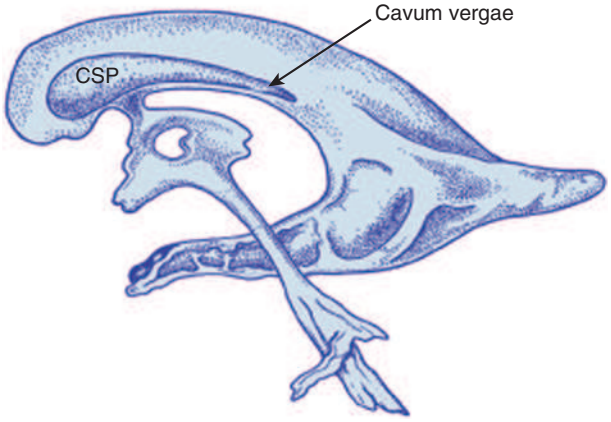

FIG. 45.13 Cavum Septi Pellucidi *(CSP).* Arrow indicates **cavum vergae** projecting on the medial surface of the lateral ventricles. (With permission from Rumack CM, Manco-Johnson ML. Perinatal and infant brain imaging: role of ultrasound and computed tomography. St Louis: Mosby; 1984.[7])

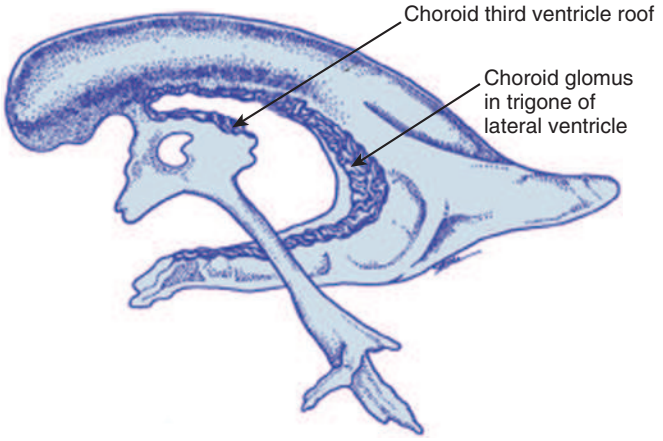

FIG. 45.15 Choroid Plexus. Drawing shows choroid plexus as it courses through the third and lateral ventricles *(arrows).* (With permission from Rumack CM, Manco-Johnson ML. Perinatal and infant brain imaging: role of ultrasound and computed tomography. St Louis: Mosby; 1984.[7])

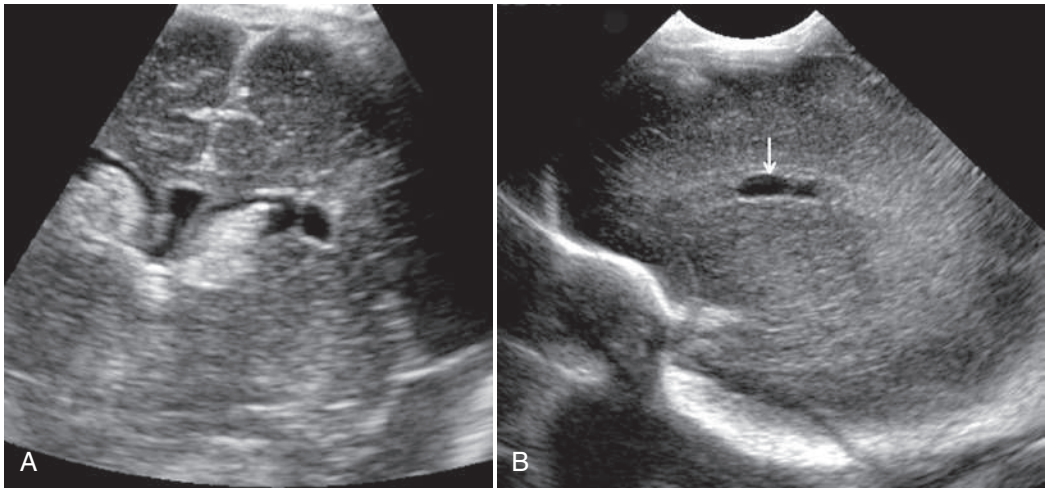

FIG. 45.14 Frontal Horn Cysts. (A) and **(B)** Coronal and sagittal sonograms show the uncommon normal variant, also called "coarctation of the frontal horn" or "connatal cysts," which are immediately lateral *(arrow)* to the ventricle. They are thought to be caused by folding of the frontal horn on itself. (There is also bilateral **subependymal and intraventricular hemorrhage** in both frontal horns.)

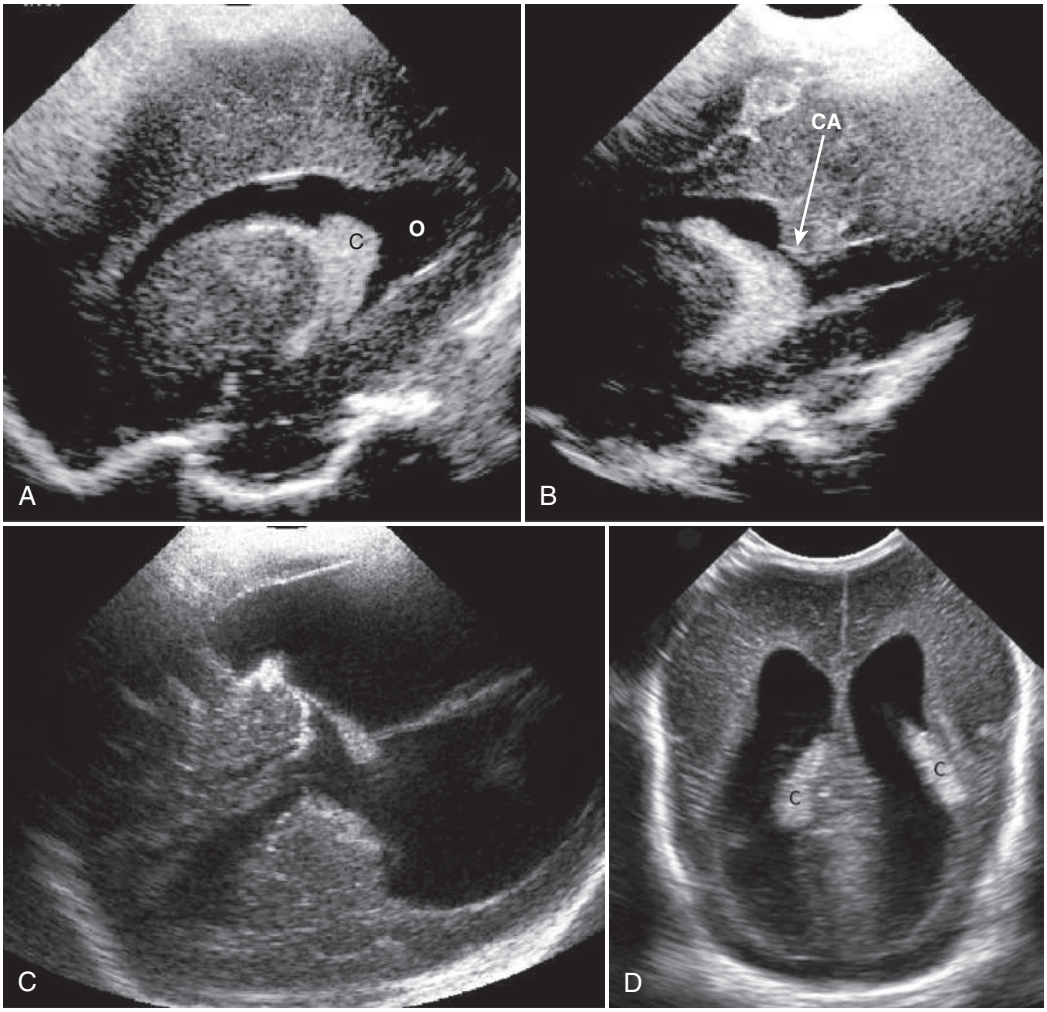

FIG. 45.16 Choroid Plexus and Calcar Avis. (A) and **(B)** Posterior fontanelle views of lateral ventricle. **(A)** Normal choroid plexus glomus *(c)* does not extend into the occipital horn *(O)*. **(B)** Calcar avis *(CA)* can be seen projecting into the occipital horn and imitates hemorrhage. Continuity with the adjacent brain identifies this structure. **(C)** Axial view of the lateral ventricles shows "dangling" choroid plexus in a newborn with hydrocephalus from **aqueductal stenosis. (D)** Coronal view of the lateral ventricles shows dependent choroid plexus.

or occipital horn. The choroid plexus is also present in the roof of the fourth ventricle.[24] (see 45.9A) Small cysts in the choroid plexus are common, but at times areas that appear to be cysts are in fact small vessels.

The glomus of the choroid plexus is often doubled and thus appears **lobulated** (Fig. 45.16). Some authors have termed this appearance a **"split" choroid plexus.**[41] It may be mistaken for clot adhering to the choroid plexus. Color Doppler ultrasound will differentiate the normal highly vascular choroid from similarly echogenic, but avascular, clot (see Fig. 45.8C). Coronal views may also show a flattened or truncated choroid plexus at the level of the thickest portion at the trigone, probably related to the angle of the transducer to the choroid.[41] If there is a large ventricle, the choroid will normally "dangle," or hang down toward the dependent ventricle, when the infants are lying on their side (see Fig. 45.16D).

Pitfalls in Neurosonography

Peritrigonal blush on sagittal view (anisotrophic effect)
Choroid plexus shapes affected by position
- Normal choroid plexus: split, lobulated, or truncated
- Dangling choroid (in hydrocephalus)
- Normal choroidal vessels vs. choroid plexus cyst
- Normal choroid plexus vs. hemorrhage around the choroid

Asymmetrical normal-sized ventricles
Dandy-Walker malformation false-positive diagnosis due to angled view through the lower cerebellum

Germinal Matrix

The germinal matrix develops deep to the ependyma and consists of loosely organized, proliferating cells that give rise to the neurons and glia of the cerebral cortex and basal ganglia (Fig. 45.17). Its vascular bed is the most richly perfused region of the developing brain. Vessels in this region form an immature vascular rete of fine capillaries, extremely thin-walled veins, and larger irregular vessels.[42] The capillary network is best developed on the periphery of the germinal matrix and becomes less well developed toward the central glioblastic mass. Although the germinal matrix is not visualized on sonography, it is important as the typical anatomic site over the caudate nucleus where GMH occurs in premature infants.

Early in gestation, the germinal matrix forms the entire wall of the ventricular system. After the third month of gestation, the germinal matrix regresses, first around the third ventricle, then around the temporal and occipital horns and trigone. By 24 weeks' gestation, the germinal matrix persists only over the head of the caudate nucleus and to a lesser extent over the body of the caudate. By 32 weeks' gestation, it is unusual to see GMH because these cells migrate out to the cerebral cortex. This regression continues until 40 weeks' gestation, when the germinal matrix ceases to exist as a discrete structure, and the immature vascular rete has been remodeled to form adult vascular patterns.

Calcar Avis

On posterior fontanelle views, a normal gyrus, the calcar avis, frequently protrudes into the medial aspect of the lateral ventricle at the junction of the trigone and occipital horn (see Fig. 45.16B). Although this normal brain gyrus may mimic intraventricular clot, slightly turning the transducer will show its continuity with the brain. It can be recognized because of a central echogenic sulcus **(calcarine fissure),** its continuity with the adjacent brain, and normal vascularity on color Doppler ultrasound.[41]

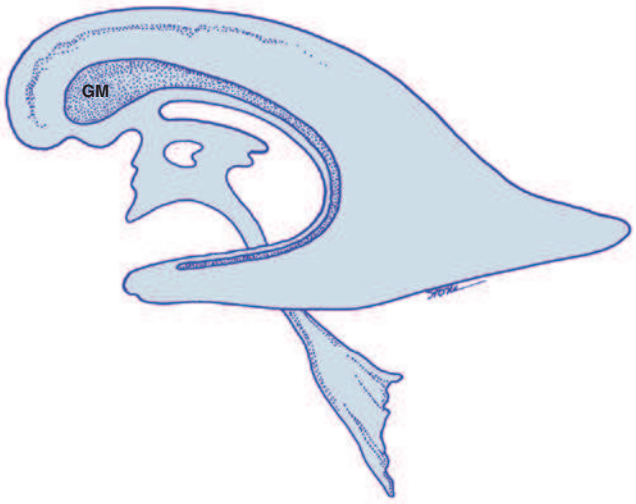

FIG. 45.17 Germinal Matrix. Drawing shows germinal matrix *(GM)* at 30 to 32 weeks' gestation, with largest amount near the caudate nucleus. (With permission from Rumack CM, Manco-Johnson ML. Perinatal and infant brain imaging: role of ultrasound and computed tomography. St Louis: Mosby; 1984.[7])

Cerebellar Vermis

Because the cerebellum develops late in gestation, a mistaken fetal diagnosis of cerebellar vermian hypoplasia is occasionally made. If axial scans are done below the normal level of the fourth ventricle, the vallecula between the cerebellar hemispheres may be mistaken for a Dandy-Walker variant. Pseudoabsence of the inferior vermis[41] or pseudo–vermian hypoplasia can be appreciated on axial views through the posterior fossa. There may appear to be a small or absent cerebellar vermis and a wide communication between the fourth ventricle and cisterna magna. Slightly more superior axial views will show the normal cerebellar vermis. The appearance of a missing or hypoplastic vermis can be evaluated carefully by moving the transducer superiorly to depict the normal vermis, and by obtaining sagittal midline views. The cerebellar vallecula is a variably sized subarachnoid space below and not continuous with the fourth ventricle. The foramen of Magendie is thinner than the vermian cleft in a Dandy-Walker variant[14] (see Fig. 45.9C).

Cisterna Magna

Cisterna magna septa are typically seen inferior and posterior to the cerebellar vermis, usually straight and parallel (see Fig. 45.9). These septa arise at the cerebellovermian angle and continue to the occipital bone. Robinson and Goldstein[43] proposed that these septa are a remnant of Blake pouch cysts and thus a marker of normal cerebellar development.[44,45]

CONGENITAL BRAIN MALFORMATIONS

Congenital brain malformations are the most common anomalies in humans.[42,46,47] Malformations can be classified based on brain development and the types of anomalies that result when development is altered. Brain development can be divided into three stages.[46] **Cytogenesis** involves the formation of cells from molecules. **Histogenesis** is the formation of cells into tissues and involves neuronal proliferation and differentiation. **Organogenesis** is the formation of tissues into organs.

Organogenesis can be subdivided into further stages[48] (Fig. 45.18). The first stage, **neural tube formation and closure,** occurs at 3 to 4 weeks' gestation. The neural plate folds in on itself, fusing dorsally and giving rise to the earliest recognizable brain and spinal cord. In the next stage, **segmentation and diverticulation** of the forebrain occur at 5 to 6 weeks. The single central fetal ventricle separates into two lateral ventricles, and the brain divides into two cerebral hemispheres. Anterior diverticulation results in the formation of the olfactory bulbs and optic vesicles and the induction of facial development. The pituitary and pineal gland also develop by diverticulation from the ventricle at this stage.

Neuronal proliferation and migration occur at 8 to 24 weeks' gestation. Tremendous cellular proliferation is necessary to provide

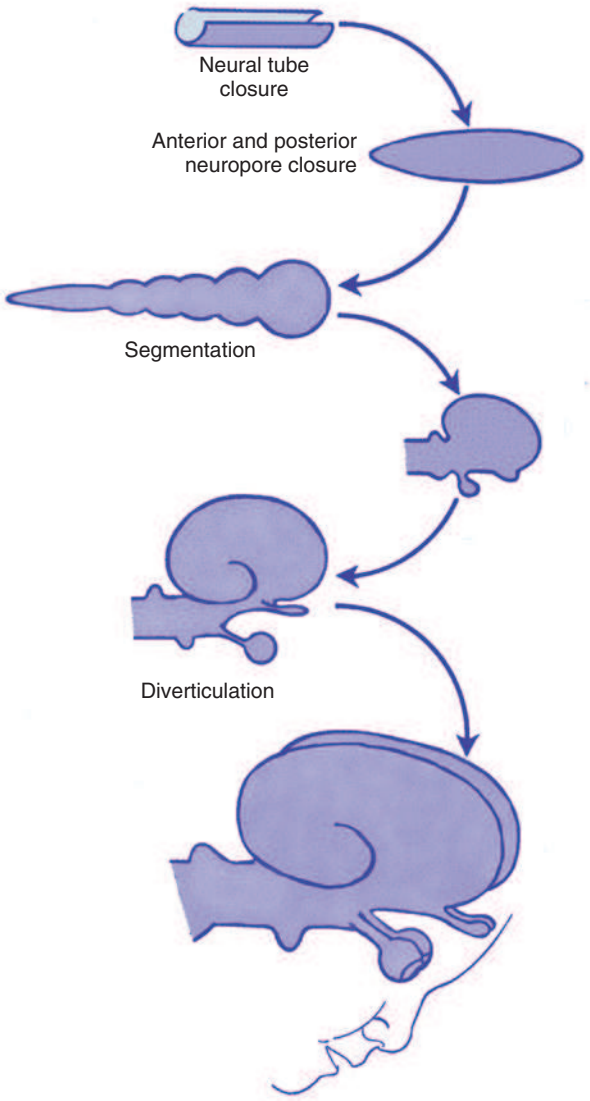

FIG. 45.18 Stages of Organogenesis. The neural tube closure at 3 to 4 weeks' gestation, including closure of the anterior and posterior neuropores. At 5 to 6 weeks, the brain segments and five types of diverticula form. First, the paired olfactory tracts, optic tracts, and cerebral ventricles develop, then the unpaired pineal and pituitary. Neural proliferation, migration, organization, and myelination occur after these stages. (With permission from DeMyer W. Classification of cerebral malformations. Birth Defects Orig Artic Ser. 1971;7[1]:78-93.[48])

Congenital Brain Malformations

DISORDERS OF ORGANOGENESIS
Disorders of Neural Tube Closure
Chiari malformation
Agenesis of the corpus callosum
Lipoma of the corpus callosum
Dandy-Walker malformation or variant
Posterior fossa arachnoid cyst
Teratoma

Disorders of Diverticulation and Cleavage
Septo-optic dysplasia
Holoprosencephaly (alobar, semilobar, lobar)

Disorders of Sulcation/Cellular Migration
Lissencephaly
Schizencephaly
Heterotopias
Pachymicrogyria or polymicrogyria

DISORDERS OF SIZE
DISORDERS OF MYELINATION
DESTRUCTIVE LESIONS
DISORDERS OF HISTOGENESIS

Neurocutaneous Syndromes (Phakomatoses)
Tuberous sclerosis
Neurofibromatosis
Congenital Vascular Malformations

DISORDERS OF CYTOGENESIS
Congenital neoplasms

Modified from DeMeyer classification of anomalies.[21,22,48]

Stages of Brain Development

Cytogenesis: development of molecules into cells
Histogenesis: development of cells into tissues
Organogenesis: development of tissues into organs
- Neural tube closure (dorsal induction: 3-4 weeks' gestation)
- Diverticulation (ventral induction: 5-6 weeks' gestation)
- Neuronal proliferation (8-16 weeks' gestation)
- Neuronal migration (24 weeks' gestation to years)
- Organization (6 months' gestation to years after birth)
- Myelination (birth to years after birth)

[a]Stages overlap in time but may be individually abnormal.
Modified from Volpe JJ. Brain injury in premature infants: a complex amalgam of destructive and developmental disturbances. Lancet Neurol. 2009;8(1):110-124.[46]

a growing brain with the necessary building blocks to form properly. Finally, millions of cells must migrate into the organized functional structure that is recognized as a normal brain. The germinal matrix is a source of many of the migrating cells and eventually disappears as they migrate out. **Myelination** occurs from the second trimester to adulthood but is most active from directly after birth until 2 years of age.[46,47] Migration and myelination defects are best evaluated with MRI and have been well described by Barkovich.[31] MRI has greatly increased our understanding of brain development, and many genetic and environmental factors may interfere with normal development.

Destructive lesions can occur at any point in brain development. Congenital malformations of the brain are often diagnosed in utero, and neonatal sonographic imaging may be needed to confirm or further evaluate the prenatal diagnosis. In most cases, MRI may be required to clarify the ultrasound findings. In general, MRI is preferred over CT because it best demonstrates sulcal patterns, migrational anomalies, and abnormal myelination. Disorders of cerebellar growth and development are now better

understood with major advances in fetal magnetic resonance neuroimaging and with major advances in genetics. Examples of reviews of cerebellar development and malformations are those by Limperopoulos and du Plessis[49] and Patel and Barkovich.[50]

DISORDERS OF NEURAL TUBE CLOSURE

Chiari Malformations

There are three classic Chiari malformations. **Chiari I** malformation is simply the downward displacement of the cerebellar tonsils, without displacement of the fourth ventricle or medulla. **Chiari II** malformation is the most common and of greatest clinical importance because of its almost universal association with myelomeningocele. **Chiari III** malformation is a high cervical encephalomeningocele in which the medulla, fourth ventricle, and virtually the entire cerebellum reside.

Classic sonographic findings of the Chiari II malformation involve the entire brain. Present theories propose that a failure in neural tube closure results in a small posterior fossa.[31,50] In early brain development, abnormal neural tube closure may result in a spinal defect such as a myelomeningocele. This decompresses the ventricles and leads to underdevelopment of the posterior fossa bony structures. The intracranial findings are the result of the small posterior fossa. The tentorial attachment is low, and the combined effect causes compression of the upper cerebellum by the tentorium. The inferior cerebellum is compressed and displaced into the foramen magnum. The cerebellar tonsils and vermis herniate into the spinal canal through an enlarged foramen magnum. The pons and medulla are inferiorly displaced, as is the elongated fourth ventricle (Figs. 45.19 and 45.20; Video 45.4 and Video 45.5).

Chiari II Malformation: Sonographic Findings

- Anterior and inferior pointed frontal horns
  - Batwing configuration
- Enlarged lateral ventricles
  - (colpocephaly if associated corpus callosum agenesis or dysgenesis)
- Enlarged massa intermedia fills third ventricle
- Elongation and caudal displacement of fourth ventricle, pons, medulla, and vermis
- Nonvisualization of fourth ventricle due to compression

There is usually marked **enlargement of the massa intermedia** on the coronal and midline sagittal ultrasound images. Although the third ventricle is often enlarged and the aqueduct is kinked, the enlarged massa intermedia often fills the third ventricle, causing it to appear only slightly larger than normal. The fourth ventricle is often not visualized because it is thin, elongated, compressed, and displaced into the upper spinal canal. The frontal horns are typically small and pointed. The corpus callosum is frequently either dysgenetic or absent. When callosal abnormalities are present, the posterior horns of the lateral ventricles often are disproportionately large, called "colpocephaly." The **anterior and inferior pointing of the frontal horns** has often been referred to as a **"bat wing" configuration** see (Figs. 45.19 and 45.20, Video 45.6). The septum pellucidum may be completely or partially absent. The interhemispheric fissure usually appears to be widened on coronal images, particularly after shunting. There may also be **gyral interdigitation** when the corpus callosum is absent (see Fig. 45.20). The posterior fossa is usually small, and the tentorium appears relatively low and hypoplastic. Hydrocephalus resulting from the Chiari II malformation is frequently mild in utero but may be progressive over time and associated with a tethered spinal cord (Video 45.7). When CSF circulation can no longer decompress into the myelomeningocele after the repair, hydrocephalus typically worsens. Neonatal screening for hydrocephalus will be best done routinely about 2 days after the myelomeningocele repair, as the ventricles may appear undilated before this. Ultrasound diagnosis of **craniolacunia** (lacuna skull, lückenschädel) is possible. Lacunar skull is a dysplasia that is often present at birth in the Chiari II malformation. The lacunar skull has a wavy, irregular appearance of the inner calvaria.[51] Craniolacunia will disappear over the first year of life even without shunting.

Routine prenatal screening for maternal serum alpha-fetoprotein (MS-AFP), which is elevated with neural tube defects, and the widespread use of sonography in pregnancy allow for the prenatal diagnosis of most Chiari malformations.[52] Because of its classic appearance, the Chiari II brain malformation is often recognized in utero and alerts the sonographer to look closely for a myelomeningocele. In less than 2% of myelomeningoceles, the neural tube defect is covered by skin, so there is no elevation of MS-AFP and there may be no Chiari II malformation (Fig. 45.21). Sonography or CT is reliable for follow-up of shunting procedures. MRI may be necessary to evaluate infants with symptoms suggesting brainstem compression because this may require decompression of the foramen magnum. Fetal myelomeningocele repair in selected patients may decrease the severity of the Chiari II malformation after birth.[53]

Agenesis of Corpus Callosum

The corpus callosum forms broad bands of connecting fibers between the cerebral hemispheres. Development of the corpus callosum occurs between 8 and 20 weeks of gestation. Magnetic resonance images from early fetuses show that the genu and anterior body develop first, and development proceeds both anteriorly to the rostrum and posteriorly to develop the splenium.[31,54] Therefore, depending on the timing of the intrauterine insult, development may be partially arrested, or complete agenesis may occur. If development is partial, the genu is usually present and the dorsal splenium or the anterior rostrum is absent. Because insults causing anomalies of the corpus callosum occur early (8-20 weeks) in development, other CNS anomalies occur in up to 80% of cases.[28,54] These associated anomalies include **Chiari II** and **Dandy-Walker** malformation, **holoprosencephaly, encephalocele, lipoma, arachnoid cyst, migrational abnormalities,** and **Aicardi syndrome** (female infants with agenesis of the corpus callosum, ocular abnormalities, and infantile spasms). If the corpus callosum is absent, MRI will be valuable either in

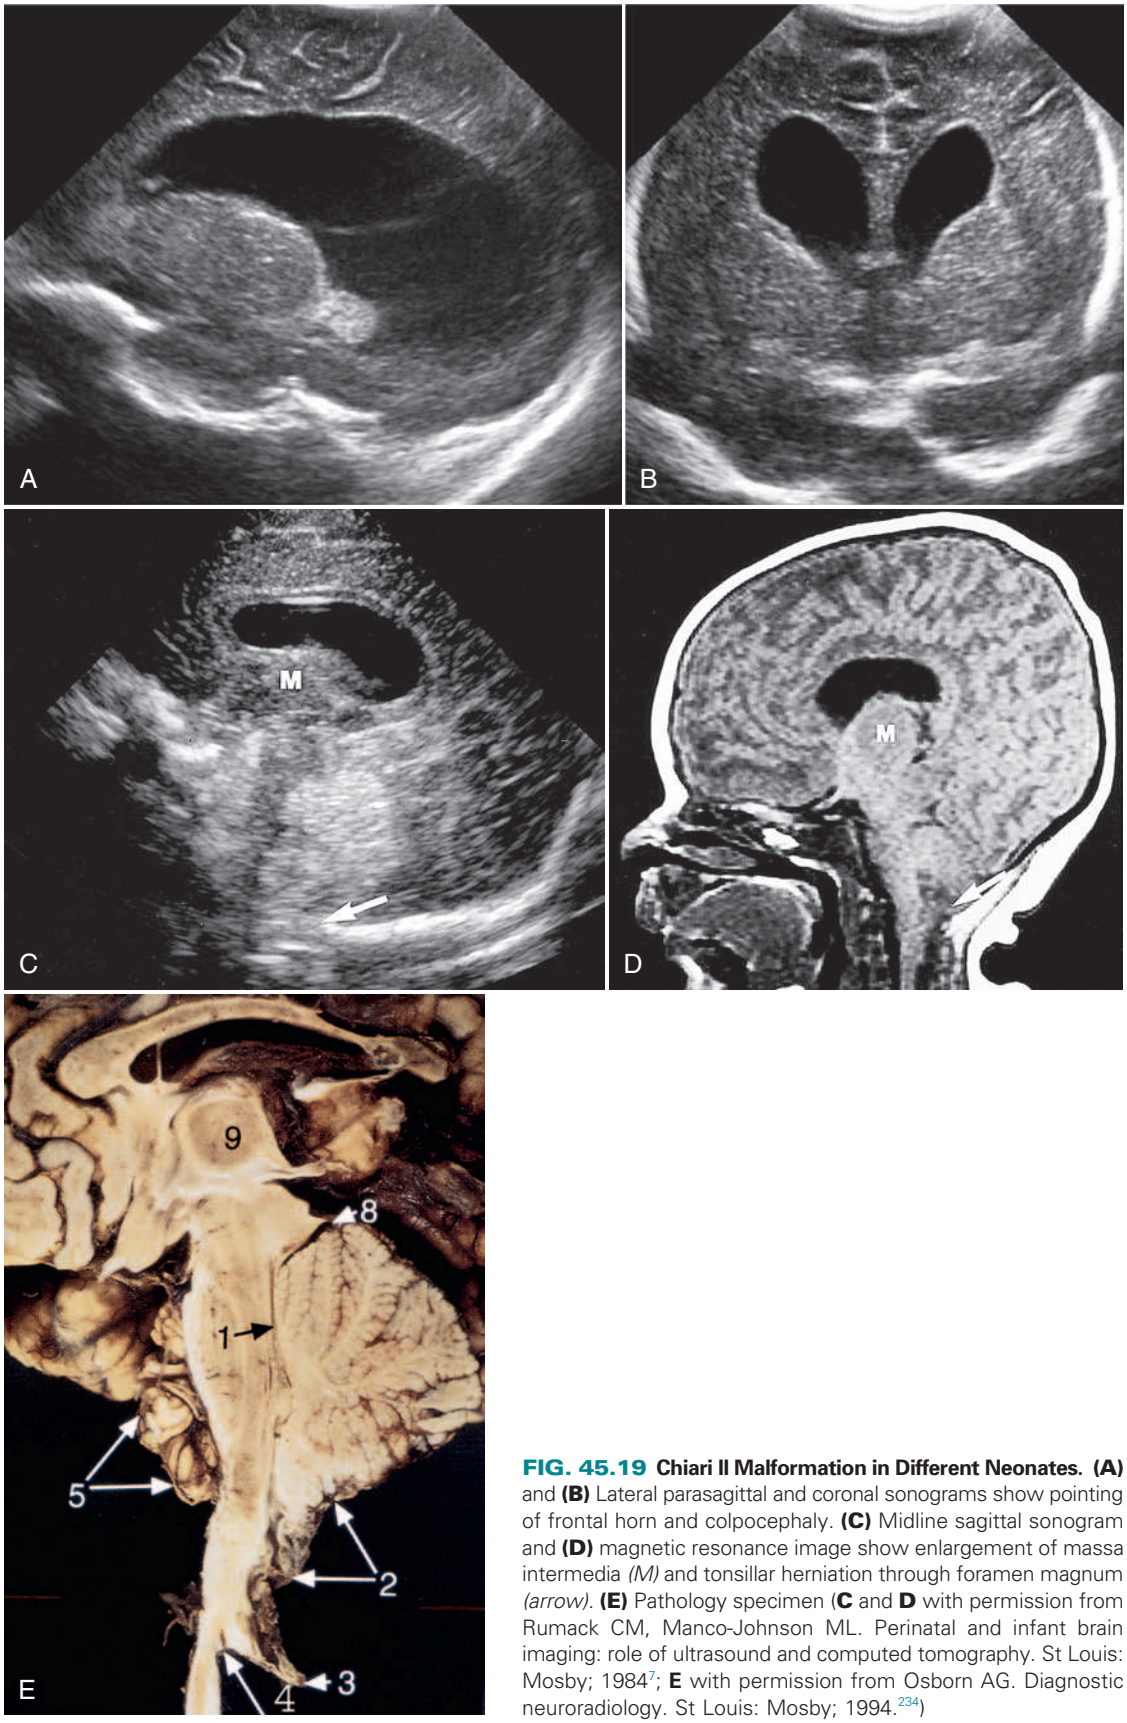

FIG. 45.19 Chiari II Malformation in Different Neonates. (A) and **(B)** Lateral parasagittal and coronal sonograms show pointing of frontal horn and colpocephaly. **(C)** Midline sagittal sonogram and **(D)** magnetic resonance image show enlargement of massa intermedia *(M)* and tonsillar herniation through foramen magnum *(arrow)*. **(E)** Pathology specimen (**C** and **D** with permission from Rumack CM, Manco-Johnson ML. Perinatal and infant brain imaging: role of ultrasound and computed tomography. St Louis: Mosby; 1984[7]; **E** with permission from Osborn AG. Diagnostic neuroradiology. St Louis: Mosby; 1994.[234])

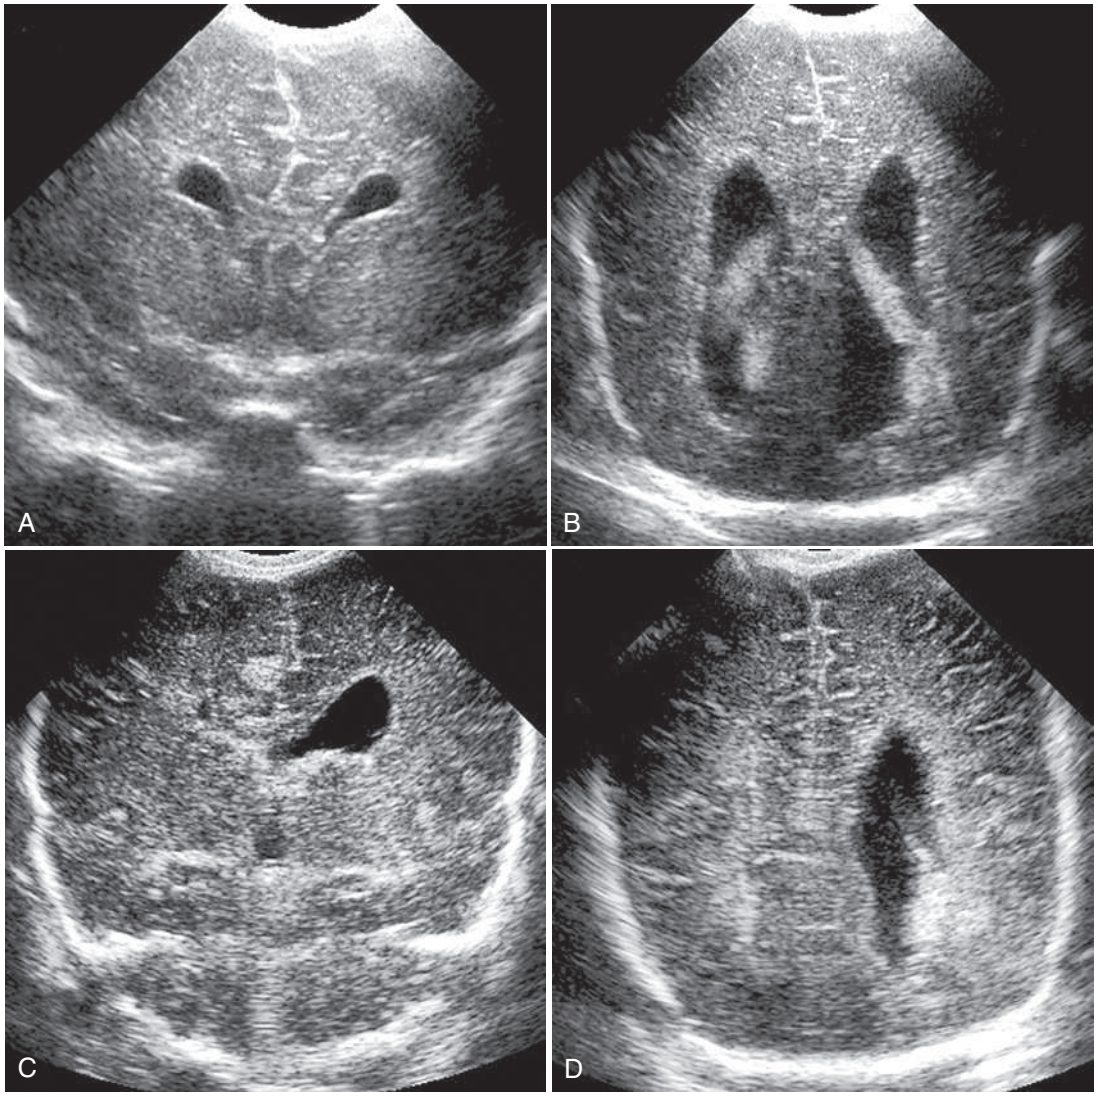

FIG. 45.20 Chiari II and Absent Corpus Callosum. (A) Anterior coronal image shows widely separated frontal horns. **(B)** Posterior coronal view shows the parallel orientation of the ventricles. Gyral interdigitation is best seen before shunting in this patient. **(C)** and **(D)** Anterior and posterior coronal ultrasound scans show Chiari II malformation after ventriculoperitoneal shunting for hydrocephalus. The right lateral ventricle is much smaller, typical of the side with the shunt. See also Video 45.4, Video 45.5, and Video 45.6.

utero or at birth to delineate associated findings that may cause a poor prognosis and change patient management.[31,55] Isolated agenesis of the corpus callosum may have a normal prognosis. However, Barkovich[31] has reported that symptomatic patients with absence of the corpus callosum typically have seizures, microcephaly, delayed development, mental retardation, or hypothalamic dysfunction.

The key diagnostic clues to agenesis of the corpus callosum on sonography are the widely spaced, parallel-oriented lateral ventricles that have extremely narrow, often slitlike frontal horns[56] (Fig. 45.22). Coronally, the frontal horns and ventricular bodies have sharply angled, lateral peaks. There may be relative enlargement of the occipital horns (colpocephaly) and often, enlarged temporal horns. **Probst bundles,** longitudinal callosal fibers that failed to decussate or cross to the other cerebral hemisphere, bulge into the ventricles along the superomedial aspect of the lateral ventricles. These are best seen on coronal images as the concave medial border to the lateral ventricles. There is no septum pellucidum. The third ventricle is often dilated and elevated; its roof extends superiorly between the lateral ventricles and into the interhemispheric fissure and may be associated with a dorsal midline cyst (Fig. 45.23). The medial cerebral sulci are typically radially arranged, perpendicular to the expected course of the corpus callosum, causing a **"sunburst" sign** on sagittal midline images (Fig. 45.24). The pericallosal sulcus is missing, and the cingulate sulcus is absent or present only as unconnected segments. Because agenesis of the corpus callosum has additional brain anomalies in more than 75% of patients, further evaluation with postnatal MRI is indicated. **Cerebellar hypoplasia, gyral anomalies,** and **heterotopia** are seen most often on MRI.[28]

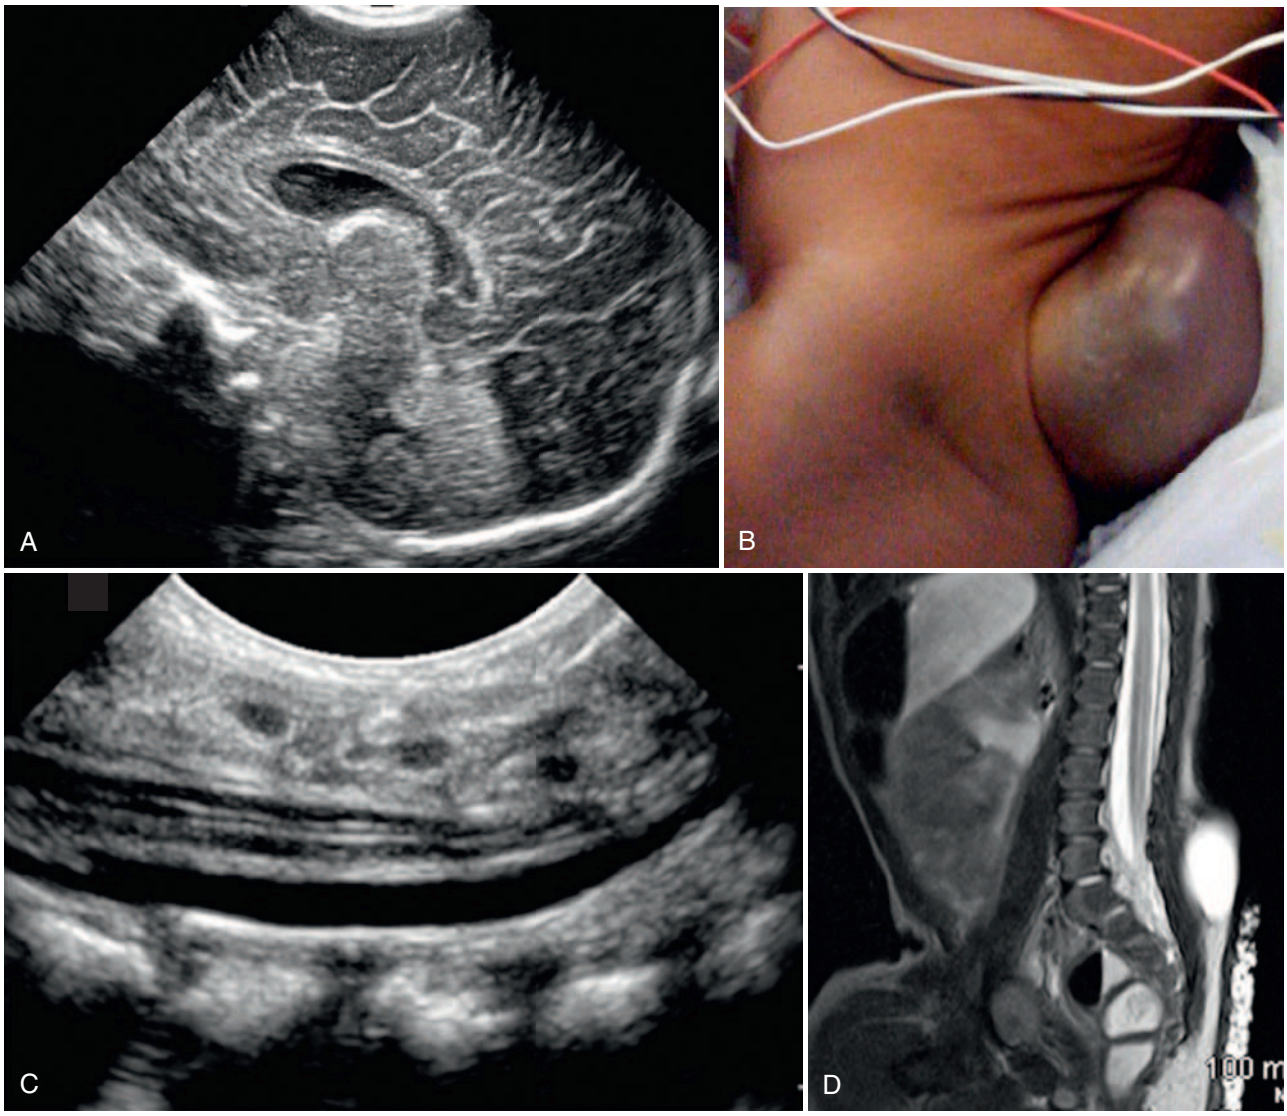

FIG. 45.21 Myelomeningocele, Skin Covered, With No Chiari II Malformation. (A) Midline sagittal brain ultrasound and **(B)** photograph of myelomeningocele. **(C)** Sagittal spine ultrasound and **(D)** T2-weighted magnetic resonance imaging show tethered cord extending almost to the sacrum. See also Video 45.7.

Agenesis of Corpus Callosum: Sonographic Findings

Absent corpus callosum
Absent cingulate gyrus and sulcus
Radial arrangement of medial sulci above third ventricle ("sunburst" sign)
Widely spaced, parallel lateral ventricles
Extremely narrow frontal horns (slitlike)
Concave or straight medial borders secondary to Probst bundles
Colpocephaly (dilated atria and occipital horns)
Elevated third ventricle extending between lateral ventricles, continuous with interhemispheric fissure, with or without dorsal cyst
Absent septum pellucidum

Corpus Callosum Lipoma

Maldevelopment of embryonic neural crest tissues may result in lipomas of the interhemispheric fissure. These lipomas have no mass effect and thus do not require surgery. Corpus callosum lipomas account for 30% to 50% of intracranial lipomas and are associated with dysgenesis of the corpus callosum[31] (Fig. 45.25).

Dandy-Walker Spectrum

Dandy-Walker malformation appears as a dilated fourth ventricle in direct communication with the cisterna magna (Fig. 45.26). The posterior fossa is enlarged, with elevation of the tentorium cerebelli, straight sinus, and torcular Herophili at the venous sinus confluence. The vermis of the cerebellum is hypoplastic to absent, and the cerebellar hemispheres are variably hypoplastic and displaced laterally by the enlarged fourth ventricle. The brainstem may be compressed anteriorly or hypoplastic.

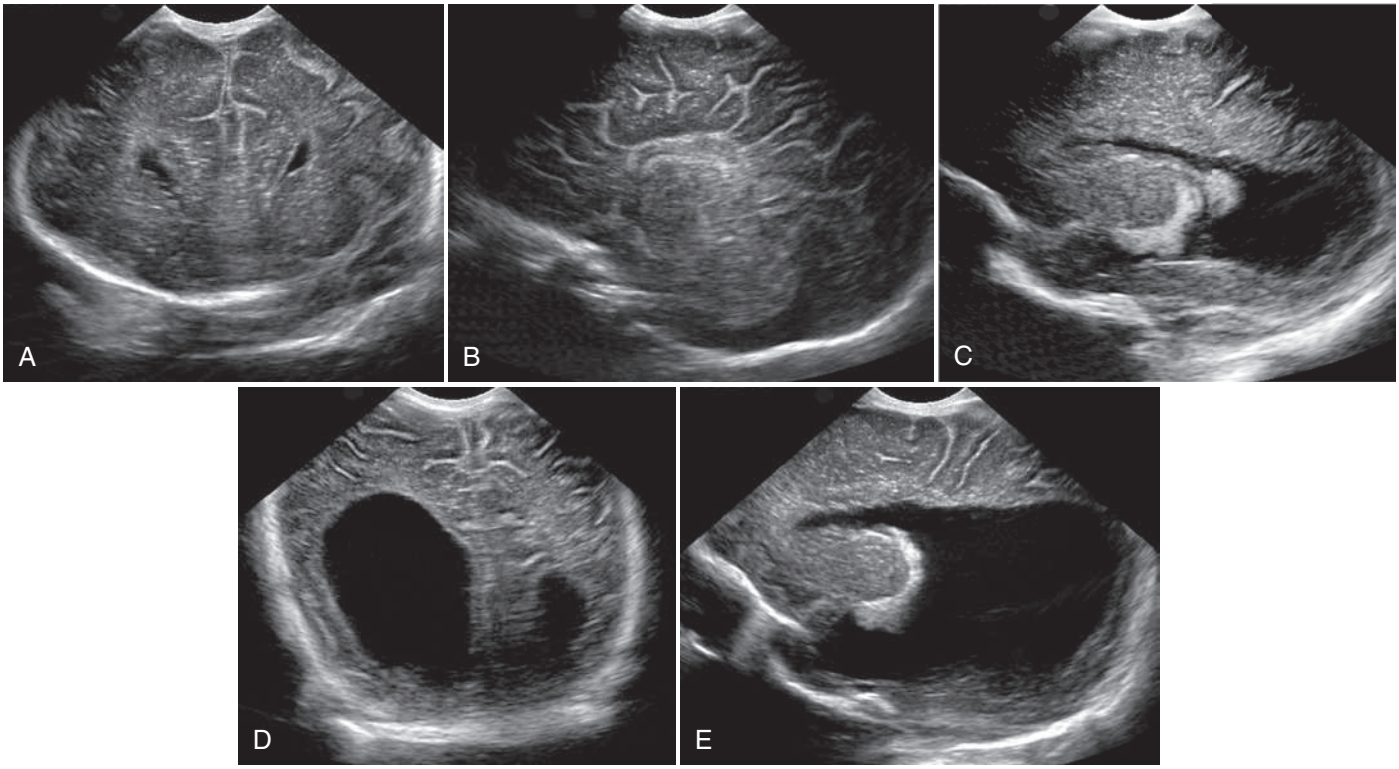

FIG. 45.22 Agenesis of the Corpus Callosum, Isolated Anomaly in Two Neonates. *Neonate 1:* **(A)** Small frontal horns are widely separated. **(B)** Sulci radiate in sunburst pattern in parasagittal just off midline view. **(C)** Colpocephaly seen in parasagittal view of lateral ventricle. *Neonate 2:* **(D)** Coronal view of the occipital horns shows enlarged right occipital horn. **(E) Colpocephaly** seen in parasagittal view of right lateral ventricle.

Generalized obstructive hydrocephalus occurs in up to 80% of cases. If there is also agenesis of the corpus callosum, colpocephaly is typically present.[7,57]

Dandy-Walker Malformation: Sonographic Findings

- Enlarged fourth ventricle connects to Dandy-Walker cyst posteriorly
- Large posterior fossa
- Hypoplastic cerebellar vermis
- Hypoplastic cerebellar hemispheres displaced laterally by fourth ventricle
- Small brainstem
- Hydrocephalus (80%)
- Obstruction above and below fourth ventricle
- Absent or dysgenetic corpus callosum (up to 70%)

The etiology of Dandy-Walker malformation is not definitively known. Theories include agenesis of the foramina of Luschka and Magendie in the first trimester, malformation of the roof of the fourth ventricle, and delayed opening of the foramen of Magendie.[31] The prenatal diagnosis of Dandy-Walker malformation, with differentiation from Dandy-Walker variant, a posterior fossa arachnoid cyst, and mega–cisterna magna, is usually possible. Some severe cases may be diagnosed early, but typically Dandy-Walker malformation is diagnosed after 17 weeks' gestation, when the inferior vermis has normally completely formed.[40,58]

The Dandy-Walker malformation is associated with other CNS anomalies in up to 70% of cases. These include partial or complete agenesis of the corpus callosum, encephalocele, holoprosencephaly, microcephaly, gray matter heterotopia, and gyral malformations. Chromosomal abnormalities are described in up to 20% to 50% of cases and include trisomy 13, 18, and 21. Other associated anomalies include gastrointestinal, genitourinary, cardiac, musculoskeletal, and pulmonary malformations, including congenital diaphragmatic hernia and cystic hygroma.[57,59,60]

Therapy for the Dandy-Walker malformation includes ventriculoperitoneal shunting, which will decompress the lateral ventricles but may not decompress the posterior fossa cyst. The cyst may require a separate shunt for decompression. Sonography can be used to follow these procedures until the infant is approximately 18 months of age, but this method is rarely used after the first few months of life.

In the **Dandy-Walker Spectrum,** there is variable hypoplasia of the posterior inferior vermis and communication between the fourth ventricle and cisterna magna. The fourth ventricle may be slightly to moderately enlarged. In the mildest form, the posterior fossa is normal in size, and although the vermis is small, the cerebellar hemispheres are normal. There is no associated hydrocephalus. Mastoid fontanelle views should be taken in this setting through the fourth ventricle so that the normal

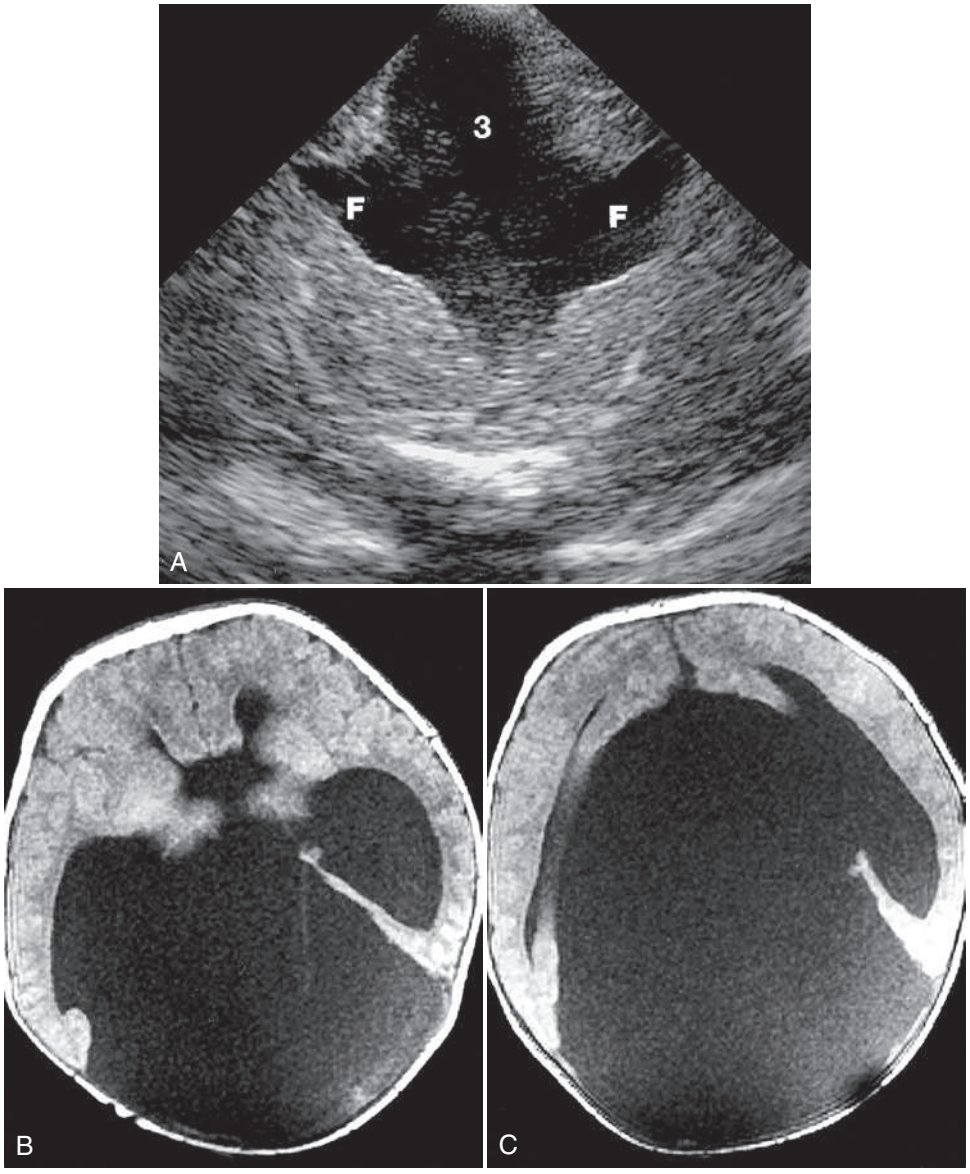

FIG. 45.23 Agenesis of Corpus Callosum (ACC) With Elevation of Third Ventricle and Continuation Into a Large Dorsal Cyst. (A) Coronal sonogram and **(B)** and **(C)** computed tomography scans show widely separated frontal horns *(F)*, a large third ventricle that extends superiorly as a dorsal cyst *(3)* between the lateral ventricles in a newborn who also had Dandy-Walker malformation.

foramen of Magendie and vallecula, which may be enlarged with hydrocephalus, are not mistaken for a Dandy-Walker anomaly[25] (see Fig. 45.9C). The Dandy-Walker spectrum varies greatly with vermian hypoplasia, an enlarged fourth ventricle, a large aqueduct, and a large third ventricle.[14] Chromosomal abnormalities occur in up to 30% of these infants. Associated CNS or extra-CNS anomalies may affect the outcome of the infant more than the Dandy-Walker spectrum.[31,57]

Two differential diagnoses of posterior fossa cystic lesions mimic Dandy-Walker syndrome. A **mega–cisterna magna** is described as the mildest form of this spectrum and includes no mass effect, no hydrocephalus, and a normal cerebellar vermis, fourth ventricle, and cerebellar hemisphere (Fig. 45.27). A **posterior fossa subarachnoid cyst** can be differentiated from Dandy-Walker malformation or spectrum by the lack of communication of the cyst with the fourth ventricle. The normal fourth ventricle, vermis, and cerebellum are displaced by the arachnoid cyst.[58,59]

New York: Springer-Verlag; 1975.[42])

Complete agenesis of the cerebellar vermis without hydrocephalus occurs in **Joubert syndrome,** with associated symptoms including episodic hyperpnea, ataxia, abnormal eye movements, and mental retardation.[31] This anomaly is thought to be caused by the inability of the posterior fossa axons to cross the midline. There is a Meckel-like syndrome with Dandy-Walker malformation, polycystic kidneys, hepatic fibrosis, and hand and genital anomalies. True **Meckel-Gruber syndrome** includes an encephalocele, renal cystic dysplasia, short limbs, and polydactyly.[60]

DISORDERS OF DIVERTICULATION AND CLEAVAGE: HOLOPROSENCEPHALY

Holoprosencephaly results from a failure of diverticulation when the primitive prosencephalon does not divide into the telencephalon and the diencephalon between the fourth and eighth weeks of gestation. The telencephalon normally develops into the cerebral hemispheres, ventricles, putamen, and caudate nuclei. The diencephalon becomes the third ventricle, thalami, hypothalamus, and lateral globus pallidus. Holoprosencephaly represents a spectrum of malformations that form a continuum from most severe, with no separation of the telencephalon into hemispheres (**alobar** holoprosencephaly), to least severe, with partial separation of the dorsal aspects of the brain (**lobar** holoprosencephaly). The septum pellucidum is absent in all forms of holoprosencephaly (Fig. 45.28).

Septo-Optic Dysplasia

Some consider the mildest form of lobar holoprosencephaly to be **septo-optic dysplasia,** with absence of the septum pellucidum and optic nerve hypoplasia (Fig. 45.29, Video 45.8). About two-thirds of these infants have hypothalamic-pituitary dysfunction. They may have visual symptoms and growth restriction. In

(A) and **(B)** Coronal and sagittal sonograms show highly echogenic fat surrounded by calcification; both are causing major acoustic shadowing. **(C)** Computed tomography scan shows black central fat surrounded by white flecks of calcium. **(D)** Sagittal magnetic resonance scan shows fat (bright white on T1-weighted image) extending over the corpus callosum.

FIG. 45.26 Dandy-Walker Complex Compared With Normal Posterior Fossa. (A) and **(B)** Axial posterior fossa sonograms in two infants with Dandy-Walker complex show a wide continuity between the fourth ventricle and the cisterna magna. **(C)** Normal axial sonogram of the fourth ventricle and slightly echogenic cerebellar vermis.

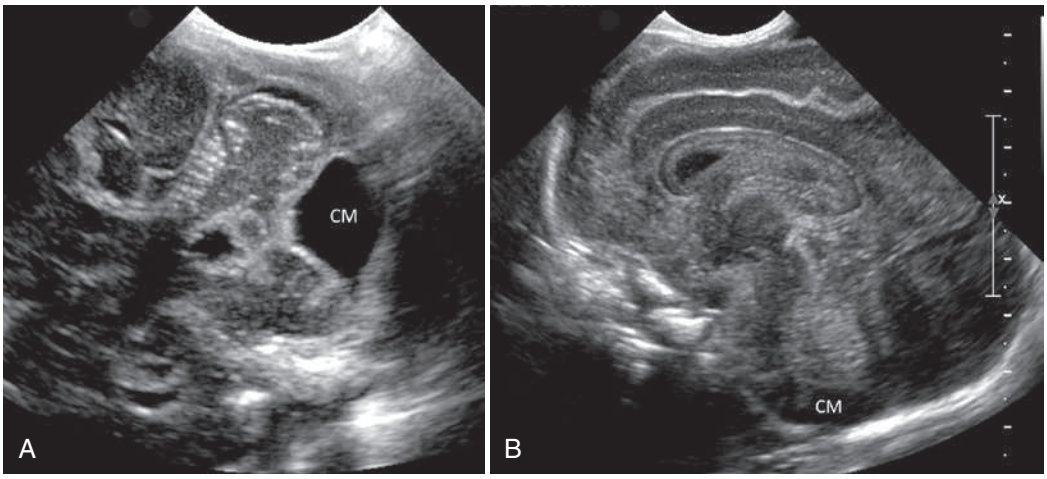

FIG. 45.27 Mega–Cisterna Magna. (A) and **(B)** Axial and sagittal sonograms show an enlarged cisterna magna *(CM)* with no connection to the fourth ventricle and no ventriculomegaly.

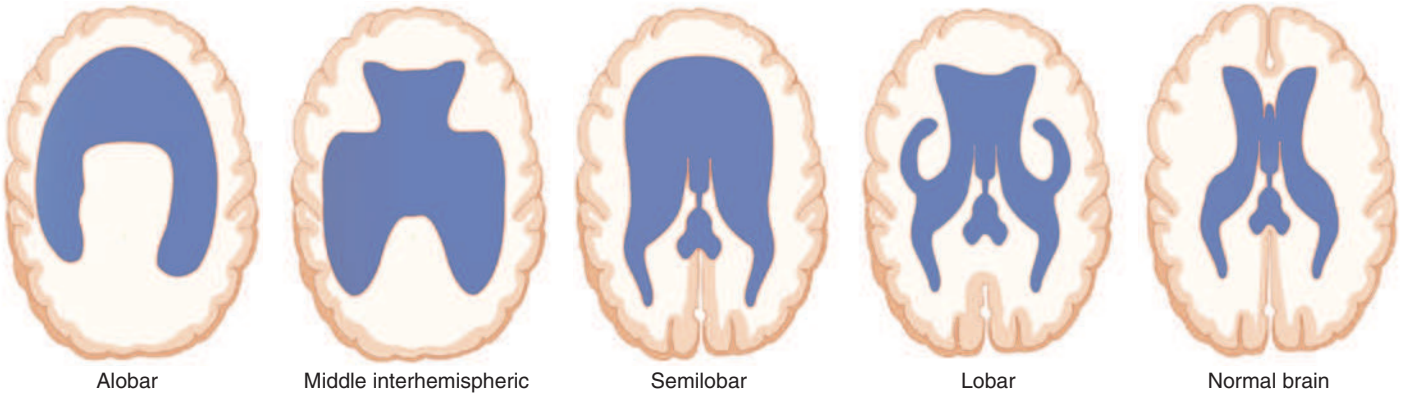

FIG. 45.28 Holoprosencephaly Classification. Holoprosencephaly classification. Normal versus four types—alobar (most severe), middle interhemispheric, semilobar, and lobar.

addition to occurrence with holoprosencephaly, callosal agenesis, and Chiari II malformations, other associations suggest that septo-optic dysplasia may occur from destructive processes that cause schizencephaly and chronic severe hydrocephalus.[31] Intermediate in severity between alobar and lobar is **semilobar** holoprosencephaly, with fusion of the cortex and ventricle anteriorly but variable separation posteriorly; facial anomalies are mild or absent. Anomalies of the face and calvaria accompany and help predict the severity of the brain malformation, because the face develops at the same time as the brain during diverticulation. Cases of holoprosencephaly are usually suspected as a result of the accompanying facial anomalies, with more severe facial anomalies predicting more severe intracranial anomalies. Holoprosencephaly is most frequently seen in **trisomy 13 and 18 syndromes** and can also be caused by **teratogens,** the most common mechanism in **infants of diabetic mothers.**[31,60-62]

Alobar Holoprosencephaly

Alobar holoprosencephaly is the most severe form of this disorder. Infants with this defect usually die within the first months of life or are stillborn. Facial features may include **cebocephaly** (hypotelorism and malformed nose; Fig. 45.30D), **cyclopia,** and **ethmocephaly** (cyclopia or hypotelorism with a midline proboscis above the eyes). The brain surrounds a single midline horseshoe- or crescent-shaped ventricle with a surrounding thin, primitive cerebral cortex[59] (Fig. 45.30). The hemispheres are fused as a pancakelike mass of tissue in the most anterior portion of the calvaria. Only in holoprosencephaly will the splenium of the corpus callosum be the only segment present.[31] The thalami are fused, and there is no falx, corpus callosum, or interhemispheric

Alobar Holoprosencephaly: Sonographic Findings

Single midline crescent-shaped ventricle
Thin layer of cerebral cortex
No falx
No interhemispheric fissure
No corpus callosum
Fused thalami and basal ganglia
Fused echogenic choroid plexus
Absent third ventricle
Large dorsal cyst

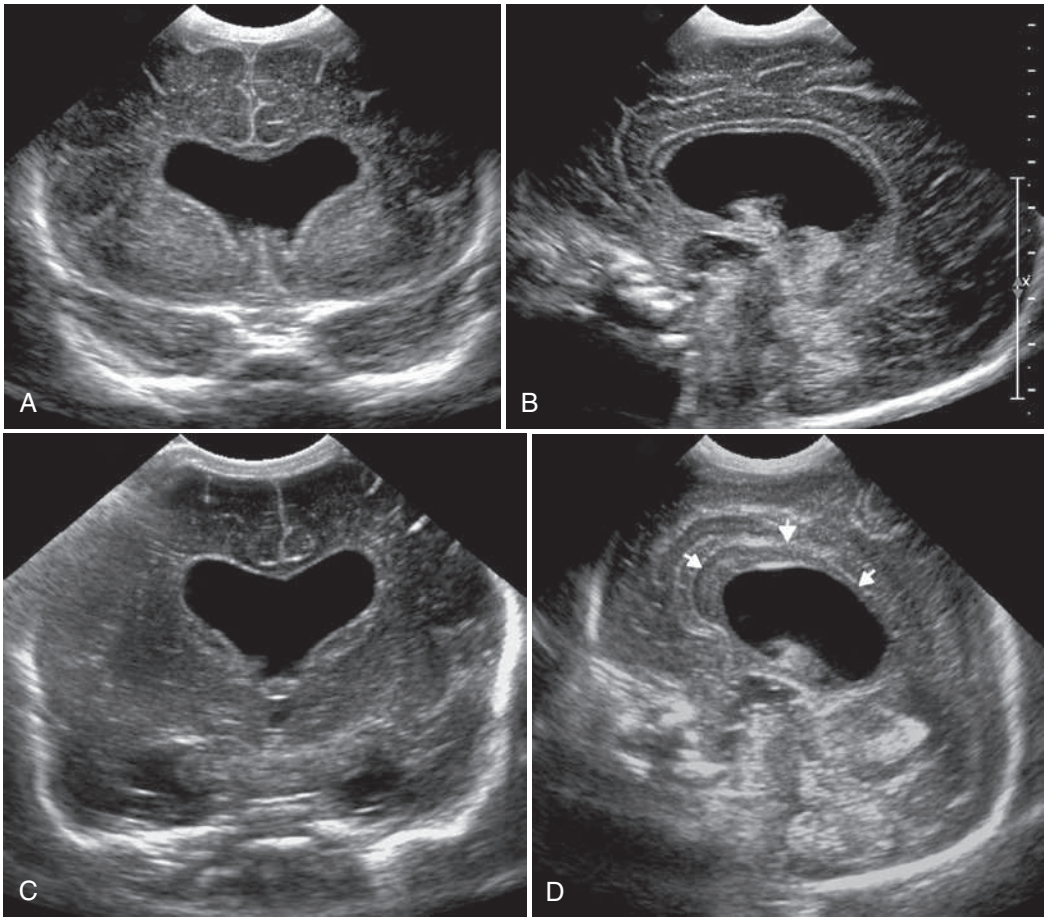

FIG. 45.29 Septo-Optic Dysplasia in Two Infants. (A) and **(B)** Coronal and sagittal sonograms. Although the cavum septum pellucidum is absent, the corpus callosum is present and complete. **(C)** Coronal sonogram shows continuity between frontal horns resulting from absence of the septum pellucidum. **(D)** Sagittal midline sonogram shows the corpus callosum *(arrows),* which is thinned posteriorly. See also Video 45.8.

fissure. Midline, moderately echogenic, fused thalami are seen anterior to the fused, hyperechogenic choroid plexus. The third ventricle is usually absent, so the large, single, central holoventricle communicates inferiorly with the aqueduct and may also connect posteriorly with a dorsal cyst. Pachygyria may be seen. Posterior fossa structures may be normal.

Semilobar Holoprosencephaly

In semilobar holoprosencephaly, more brain parenchyma is present, but the single ventricle persists. There may be separate occipital and temporal horns. A small portion of the falx and interhemispheric fissure develops in the occipital cortex posteriorly. The splenium and genu of the corpus callosum are often formed and may be seen on midline sagittal sections. The thalami are partially separated, and the third ventricle is rudimentary. Facial anomalies are less severe than in alobar holoprosencephaly, usually with only mild hypotelorism and median or lateral cleft lip.

Lobar Holoprosencephaly

Lobar holoprosencephaly is the least severe form of this disorder. There is almost complete separation of hemispheres, with development of a falx and interhemispheric fissure, but these may be shallow anteriorly, and the frontal lobes are fused. The septum pellucidum is absent. The anterior horns of the lateral ventricles are fused and square, but the occipital horns are separated. Temporal horns may be present. The third ventricle is usually present, separating the thalami. The splenium and body of the corpus callosum are often present, with absence of the genu and rostrum. Facial anomalies are mild and similar to the semilobar form or absent.

Middle Interhemispheric Form of Holoprosencephaly

A fourth variant of holoprosencephaly, the **middle interhemispheric form** of holoprosencephaly, also called **syntelencephaly,** occurs in less than 5% of cases. This has a separation of the anterior and posterior parts of the hemispheres, but fusion is present in the central region of the brain between parietal hemispheres, and the face is generally normal. Cases typically show mild ventriculomegaly, absence of parts of the septi pellucidi, abnormality of the midpart of the corpus callosum, and dorsal cysts. The middle interhemispheric form can resemble mild ventriculomegaly with septal fenestration. Coronal scanning may show fusion of the central parts of the hemisphere. MRI helps

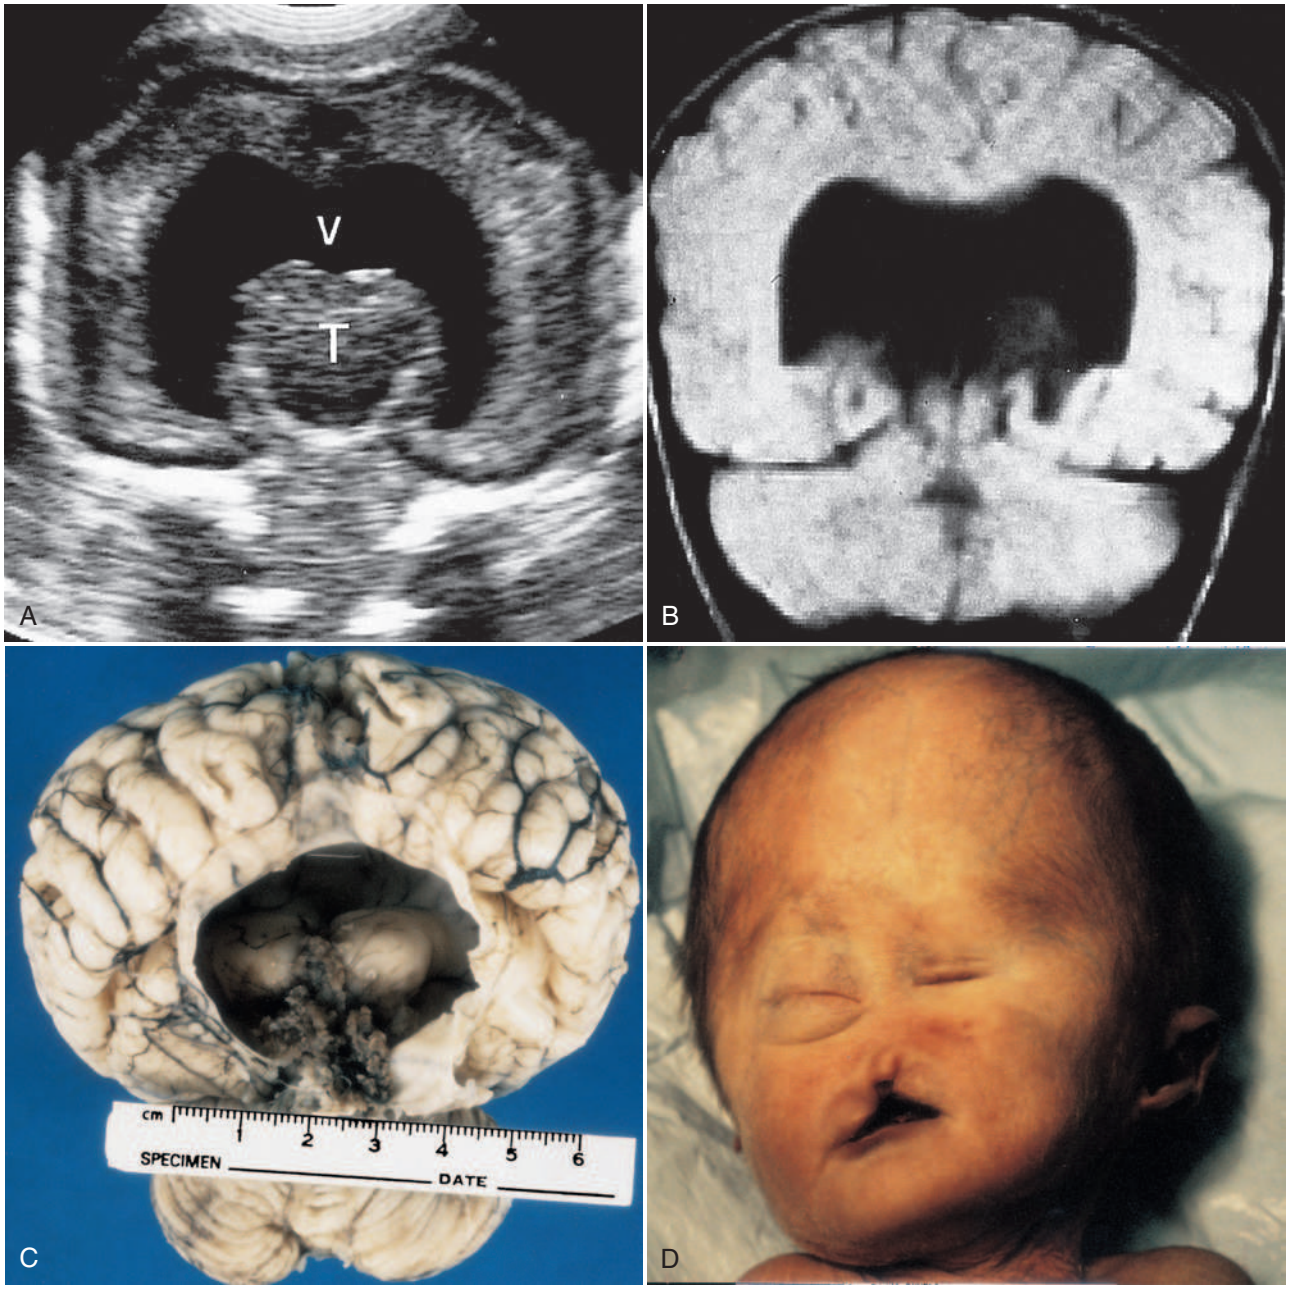

FIG. 45.30 Alobar Holoprosencephaly. (A) Coronal sonogram shows single central ventricle *(V)* and fused thalami *(T)*. No falx or interhemispheric fissure is present. **(B)** Magnetic resonance image and **(C)** pathology specimen show single central ventricle and fused thalami. **(D)** Autopsy specimen shows **cebocephaly** (severe hypotelorism and malformed nose).

confirm this appearance and typically shows sylvian fissures connecting abnormally across the midline.[63-66]

DISORDERS OF SULCATION AND CELLULAR MIGRATION

Schizencephaly

Believed to be caused by a primary neuronal migration malformation in utero, schizencephaly has been reported in familial cases and in early prenatal injury from drug abuse and abdominal trauma, vascular insult, or toxin.[67] It causes gray matter–lined clefts that extend through the entire hemisphere, from the ependymal lining of the lateral ventricles to the pial covering of the cortex. The clefts may be bilateral or unilateral (Fig. 45.31). There may be wide openings of the clefts **(open-lip schizencephaly).** In some cases the cleft is closed **(closed-lip schizencephaly)** and may require MRI for diagnosis, because gray matter–white matter differentiation is not well demonstrated on sonography. Most of these patients develop seizures, hemiparesis, and variable developmental delay. The severity is related to the amount of brain involved. Some patients with schizencephaly

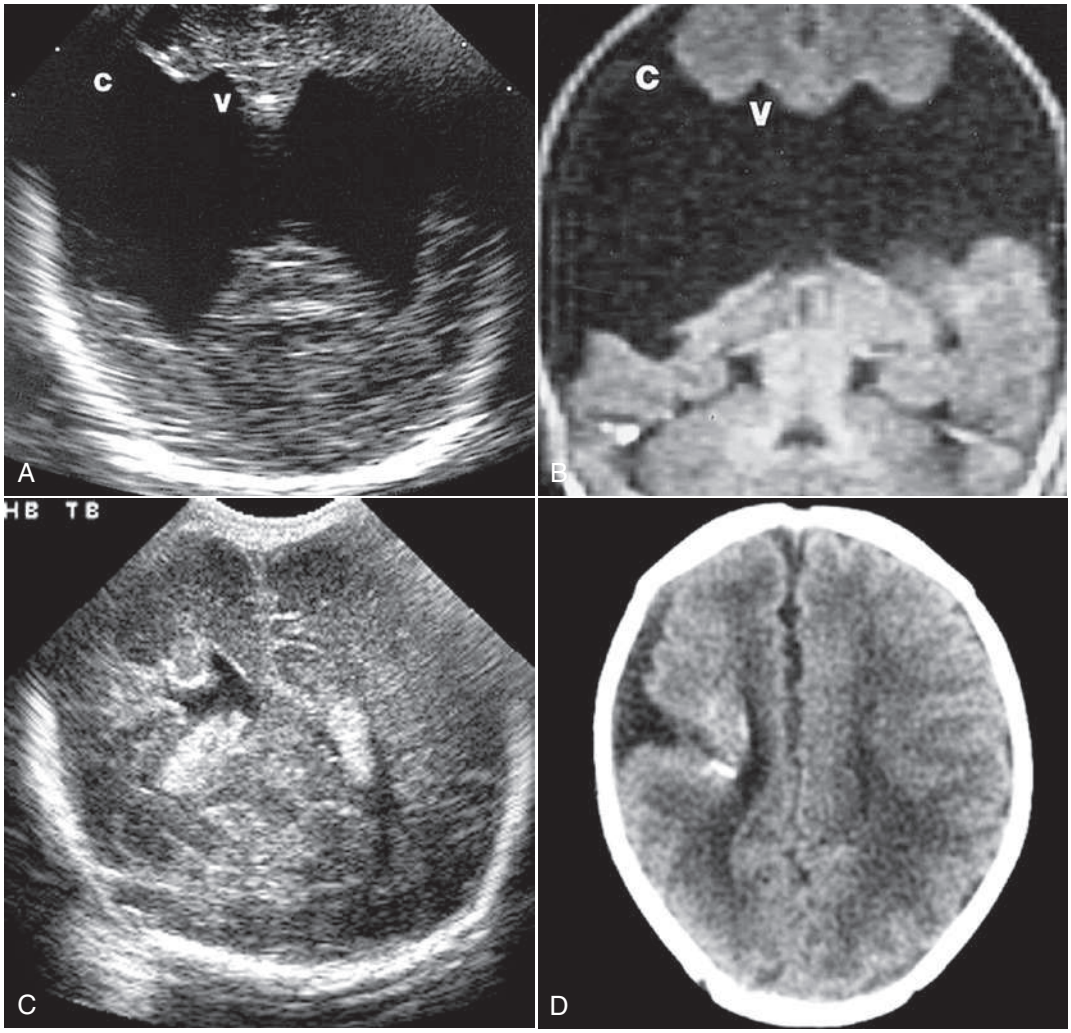

FIG. 45.31 Schizencephaly. (A) Coronal sonogram and **(B)** coronal magnetic resonance image of open-lip schizencephaly show bilateral clefts *(c)* with wide openings to the ventricular *(v)* system. **(C)** Sonogram and **(D)** computed tomography image show closed-lip schizencephaly with calcification from in utero infection.

have blindness, thought to be related to absence of the septum pellucidum and associated optic nerve hypoplasia. This is thought to be an acquired septo-optic dysplasia. There are genetic cases from the *EMX2* homeobox gene[31] and other patients with possible in utero injury during the second trimester. **Cytomegalovirus** (CMV) has been reported to cause schizencephaly as would be expected for those maternal infections that occur in the first trimester at the time of initial brain development.[68,69] In patients with unilateral involvement, recent reports show reorganization of the motor area so that the unaffected hemisphere takes over function.[70]

Lissencephaly

Complete lack of sulcal formation caused by lissencephaly can be recognized on ultrasound when the sulcal pattern does not match that expected for gestational age. Hourglass or "figure 8" has been described as typical of the cortical surface. The sylvian fissures are often open owing to failure of the opercularization process.[30-33] The arrested myelination results in only four layers of cortex and a smooth brain. Because these patients typically have microcephaly, it is important to study these patients very carefully. Although lissencephaly is associated with many genetic syndromes, CMV and other infections have also been reported to cause lissencephaly.

DESTRUCTIVE LESIONS

Porencephalic Cyst

Before 26 weeks' gestation, focal brain destruction will typically heal with dysplastic gray matter and result in schizencephaly, usually associated with migrational defects.[42] After 26 weeks' gestation, a porencephalic cyst will develop in an area of normally developed brain that has been damaged and heals with scarring because of a lining of gliotic white matter. By definition, porencephalic cysts always connect with the ventricular system but do not extend to the surface cortex. They usually occur after birth, secondary to intraparenchymal hemorrhage (IPH), infection (focal vasculitis, abscess), or trauma.

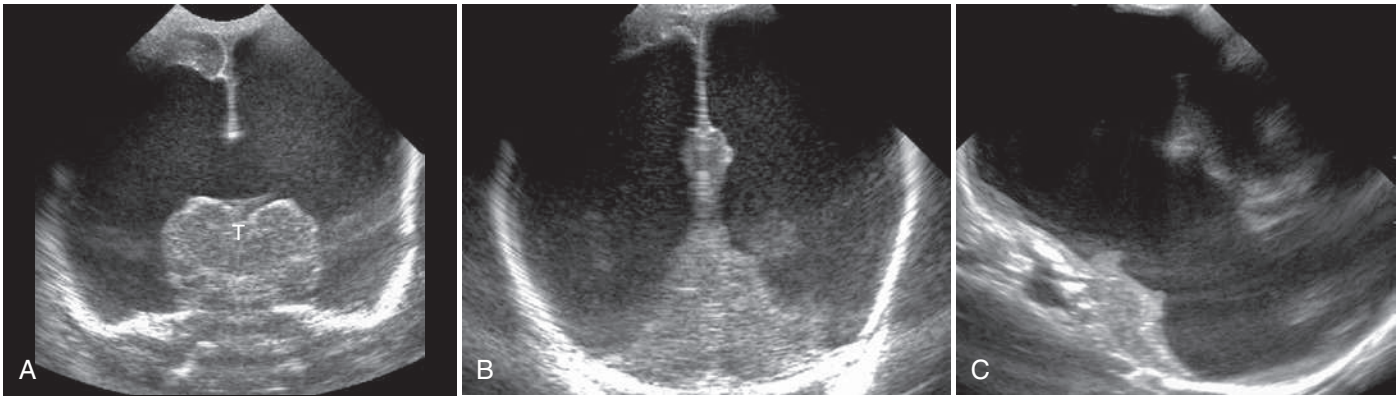

FIG. 45.32 Hydranencephaly Versus Severe Ventriculomegaly. (A) and **(B)** Coronal anterior. **(C)** Midline sagittal. Note that only cerebrospinal fluid is seen above thalamus *(T),* except for a small amount of tissue in the right high parietal region. This at first looks like holoprosencephaly, but an echogenic falx is seen in the midline.

Hydranencephaly

Classically, hydranencephaly is believed to be caused by bilateral occlusion of the internal carotid arteries during fetal development, but it may result from any of several intracranial destructive processes[71] (Fig. 45.32). Hydranencephaly is the severest form of porencephaly in that there is almost total destruction of the cerebral cortex.[72] These infants may appear surprisingly normal at birth but are developmentally delayed from an early age and frequently die within the first year of life.

The sonographic findings include a calvaria filled with CSF, but little else. Structures that receive their blood supply from the posterior cerebral artery and vertebral artery, such as the thalamus, cerebellum, brainstem, and posterior choroid plexus, are spared and are usually identifiable. Blood flow will not be appreciated by color or spectral Doppler in the carotid arteries. An incomplete or complete falx may be identifiable. The presence of the falx helps differentiate this lesion from alobar holoprosencephaly, in which the falx does not form. It can be difficult to differentiate hydranencephaly from severe hydrocephalus, but a thin rim of cortex should be visualized by sonography in hydrocephalus.[72] If there is an enlarging head circumference, ventriculoperitoneal shunting may be indicated, regardless of the actual diagnosis, to control CSF accumulation and severe skull enlargement.

Cystic Encephalomalacia

Encephalomalacia is an area of focal brain damage that pathologically has astrocytic proliferation and glial septations. In diffuse brain damage, there may be large areas of cystic encephalomalacia (Fig. 45.33). The location of the damage depends on the type of insult. Typically, there is no connection to the ventricular system. In neonates, infection or anoxia can cause widespread damage, whereas a thrombus may cause focal damage.

Metabolic Disorders

A wide range of abnormalities are seen on neonatal brain ultrasound in metabolic disorders,[73] including cysts, calcifications, structural brain abnormalities, and white matter echogenicity. Significant hypoglycemia can manifest in the first 3 days of life with seizures. Hyperechoic areas of the brain are seen in the posterior parietal regions bilaterally—not in the typical watershed areas.[53]

HYDROCEPHALUS

Hydrocephalus results from an imbalance between CSF production and its drainage by the arachnoid villi. Hydrocephalus can result from **intraventricular obstruction,** when CSF flow is obstructed within the ventricular system, or from **extraventricular obstruction** to CSF circulation, which occurs within the subarachnoid spaces and cisterns or is secondary to decreased CSF absorption at the arachnoid villi in the sagittal sinus. **Overproduction** of CSF from a choroid plexus papilloma is an unusual cause. Other causes include venous obstruction or vascular malformations; vein of Galen malformation often obstructs. The most common causes of **intraventricular obstructive hydrocephalus** (IVOH) include infection or hemorrhage (causing obstruction to the exiting foramina of the third or fourth ventricle), congenital anomalies (e.g., aqueductal stenosis [Fig. 45.34], Dandy-Walker malformation), and tumors. Aqueductal stenosis occurs in males from an X-linked gene *(L1-CAM)* and may be diagnosed by about 18 weeks of gestation with hydrocephalus and adducted thumbs.[74] The most common causes of **extraventricular obstructive hydrocephalus** (EVOH) are hemorrhage and infection with fibrosis at the basal cisterns, incisura, convexity cisterns, or parasagittal region.

Cerebrospinal Fluid Production and Circulation

CSF provides a chemically controlled protective environment that continually bathes and circulates around the CNS. Although mainly produced by the choroid plexus, CSF is also produced by the ventricular ependyma, the intracranial subarachnoid lining, and the spinal subarachnoid lining. CSF normally flows from the lateral ventricles, through the foramina of Monro, third ventricle, aqueduct of Sylvius, fourth ventricle, lateral foramina of Luschka or medial foramen of Magendie, and into the basal cisterns. From there, a small quantity circulates down into the

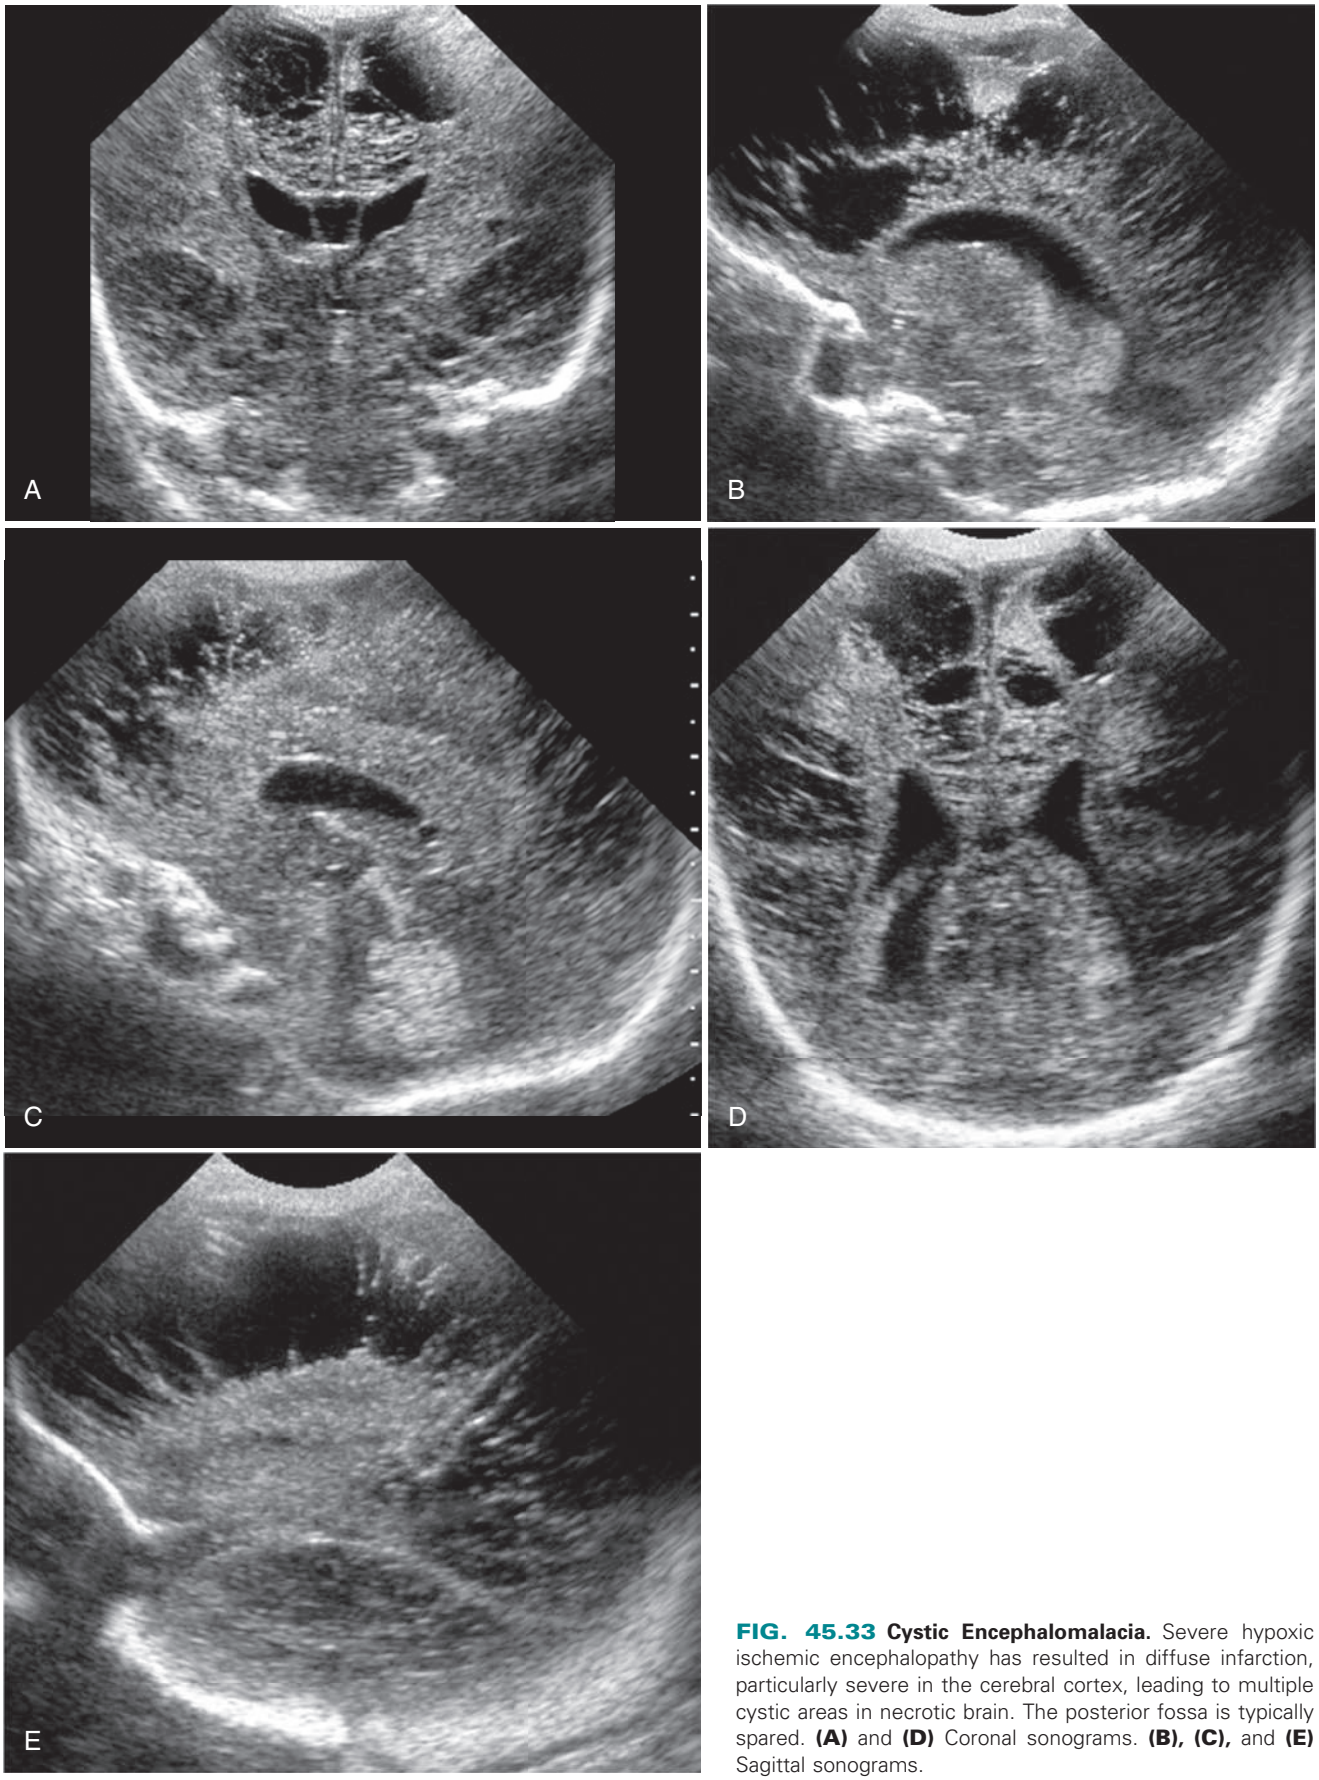

FIG. 45.33 Cystic Encephalomalacia. Severe hypoxic ischemic encephalopathy has resulted in diffuse infarction, particularly severe in the cerebral cortex, leading to multiple cystic areas in necrotic brain. The posterior fossa is typically spared. **(A)** and **(D)** Coronal sonograms. **(B), (C),** and **(E)** Sagittal sonograms.

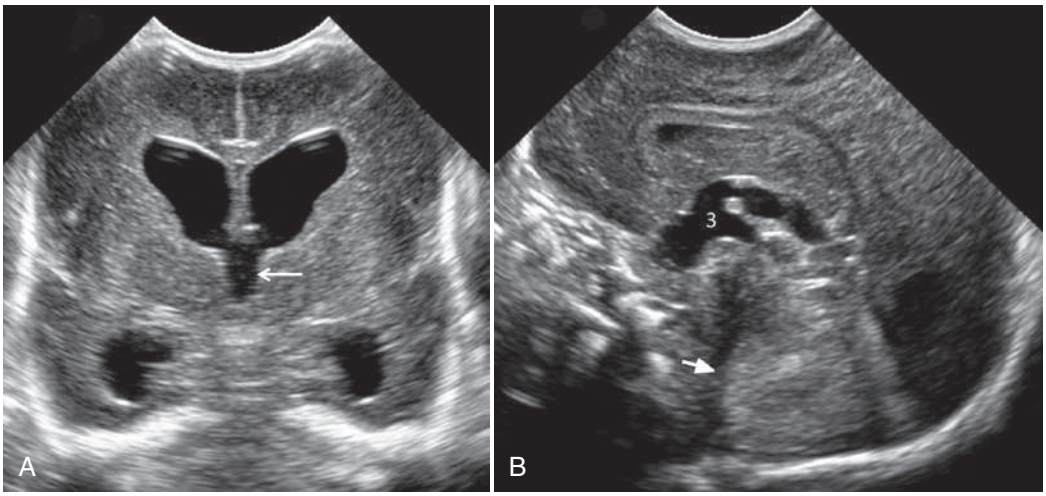

FIG. 45.34 Aqueductal Stenosis. (A) Coronal sonogram shows dilation of lateral ventricles and third ventricle *(arrow).* **(B)** Sagittal midline sonogram shows marked third ventricle *(3)* dilation and normal fourth ventricle *(short arrow).*

spinal subarachnoid space. CSF flows upward around the brain anteriorly and posteriorly to reach the vertex, where it is resorbed by the arachnoid granulations into the superior sagittal sinus.

Hydrocephalus often can be diagnosed in utero by 15 weeks' gestation.[75-77] The size of the atrium of the ventricle and the glomus of the choroid plexus remains constant in the second and third trimesters in the transaxial plane. In utero an upper limit of 10 mm for the ventricular atrium has been established and well reviewed.[78,79] However, ventricles can be enlarged (ventriculomegaly) owing to a dysgenetic process involving the white and/or gray matter rather than a fluid imbalance. Once hydrocephalus is recognized, close inspection for spinal dysraphism and other CNS or extra-CNS anomalies is warranted. Chromosome evaluation is often recommended if other anomalies are recognized. Signs of the Chiari II malformation should be especially sought because this is associated with a myelomeningocele in almost 100% of cases.

Neonatal hydrocephalus is easily recognized by routine coronal and sagittal imaging.[78,79] Ventricular size is slightly larger in premature newborns than in term infants. Progression of hydrocephalus can best be estimated by comparison with previous studies. Sonography is also helpful in following ventricular decompression in patients shunted for hydrocephalus. In following ventricular size in cases of hydrocephalus, care must be taken so that changes in ultrasound sector depth do not result in apparent enlargement or decompression of the ventricles related to magnification differences when different depth scales are used.

Level of Obstruction

Asymmetry of the lateral ventricles can cause a ventricle to be slightly larger as a normal variant. The entire ventricular system should be evaluated to identify the level at which a transition occurs from a large to a small ventricle.[80] Dilation of the lateral and third ventricles indicates an aqueduct of Sylvius obstruction, often an X-linked recessive trait, and at times caused by IVH. The rare case of isolated dilation of the fourth ventricle also requires ventricular system evaluation. Dilation of all ventricles suggests an extraventricular source.

Causes of Hydrocephalus

INTRAVENTRICULAR OBSTRUCTION
Posthemorrhagic
Aqueductal obstruction
Fourth ventricle obstruction
Posterior fossa subdural hematoma
Chiari II malformation
Dandy-Walker malformation
Aqueductal stenosis
Postinfectious scarring
Vein of Galen malformation
Tumor or cyst

EXTRAVENTRICULAR OBSTRUCTION
Posthemorrhagic scarring
Postinfectious scarring
Achondroplasia
Absence or hypoplasia of arachnoid granulations
Venous obstruction

OVERPRODUCTION OF CEREBROSPINAL FLUID
Choroid plexus papilloma

Ventricular enlargement does not always mean obstruction. Severe cases of **hypoxic-ischemic injury** result in large ventricles due to brain atrophy 2 to 4 weeks after the insult rather than obstructive hydrocephalus. One rare cause of ventricular enlargement is **glutaric aciduria type 1.**[81] These patients actually have macrocephaly at birth or within the first few weeks of life. Cystlike bilateral widening of the sylvian fissures may be the first sign, followed by progressive frontotemporal subarachnoid and ventricular enlargement, thought to be caused by atrophy. If glutaric aciduria is diagnosed in early infancy, rigorous dietary control may allow normal neurologic development. Some believe that the cystic changes represent focal areas of edema causing the macrocephaly and later atrophy as the head size becomes

smaller, apparently from brain destruction. It is essential to recognize this pattern and test for glutaric aciduria.

HYPOXIC-ISCHEMIC EVENTS

Hypoxic-ischemic events in the neonate can be divided into maternal causes and causes attributable to the neonate. **Maternal causes** include chronic cardiac or pulmonary lung disease, placental insufficiency, shock, placental abruption, and cardiorespiratory arrest, all of which can cause severe birth asphyxia. An uncommon cause is maternal cocaine use.[82] Some **therapeutic maneuvers** in these extremely sick, hypoxic neonates have also been associated with an increased risk for GMH secondary to increased venous obstruction.[83] Increased venous pressure has been demonstrated in infants breathing out of sequence with a mechanical ventilator, during endotracheal tube suctioning, and with high peak inspiratory pressure.[84] Tension pneumothorax, exchange transfusions, rapid infusions of colloid, and myocardial injury caused by asphyxia are other factors that may greatly affect hemodynamics and venous pressure.[84-86]

Arterial Watershed Determines Regional Pattern of Brain Damage

The sonographic findings are varied depending on the cause and the age of the neonate when the hypoxic-ischemic event occurs, because the watershed areas of the brain change in location during the last trimester[46,87] (Table 45.1). In premature infants the watershed is in the immediate periventricular region, and thus **GMH** and **PVL** are common pathologic findings. With the advantage of MRI examinations, noncystic forms of white matter injury have been increasingly diagnosed in premature infants that extend beyond the periventricular space to affect the diffuse cerebral white matter, thalamus, basal ganglia, brainstem, and cerebellum.[46] In full-term infants, damage tends to occur more in the cortical or subcortical regions, because the watershed moves to these areas more toward the brain surface, resulting in **parasagittal infarction** regions in term infants.[88] How to study hypoxic-ischemic encephalopathy (HIE) depends on the brain maturity and stability of the newborn infant. Findings at MRI complement ultrasound and may more often predict noncystic white matter lesions.[89-93]

Lack of autoregulation of cerebral blood pressure, which typically occurs in premature infants and less often in asphyxiated full-term infants, will cause cerebral perfusion to be directly affected by hypertensive or hypotensive episodes. This pressure-passive system can result in sudden focal hemorrhage or, with hypotension, diffuse or focal infarction.

The neurologic manifestations of brain injury in the premature infant range from the less severe motility and cognitive deficits to major spastic motor deficits, including spastic diplegia and spastic quadriplegia with more profound intellectual deficits. In the full-term infant the hypoxic-ischemic events may manifest as seizures, movement disorders including arching and fisting, altered tone, absent suck, and, depending on the severity, intellectual deficits.

TABLE 45.1 Patterns of Hypoxic-Ischemic Injury in Newborns

Hypotension	Premature Infant	Term Infant
Mild to moderate	GMH or periventricular hemorrhagic infarction White matter injury of prematurity (WMIP a.k.a. PVL)	Parasagittal cortical or subcortical injury
Severe	Deep gray matter Brainstem and cerebellar infarct	Lateral thalamus Posterior putamen hippocampus Corticospinal and sensorimotor tracts

WMIP formerly periventricular leukomalacia (PVL) has more extensive injury into cerebral white matter and cortex, thalamus, basal ganglia, brainstem, and cerebellum.
GMH, Germinal matrix hemorrhage.
Modified from Volpe JJ. Brain injury in premature infants: a complex amalgam of destructive and developmental disturbances. Lancet Neurol. 2009;8(1):110-124.[46]

Germinal Matrix Hemorrhage

GMH may lead to **IVH, hydrocephalus,** and **porencephaly.** GMH is a common event that occurs primarily in premature infants less than 32 weeks' gestational age. Although the incidence once was as high as 55%, most nurseries have experienced a significant drop in GMH, such that the range is now 10% to 25% in very-low-birth-weight infants (<1000 g) in most neonatal intensive care units.[94,95] Infants at greatest risk are those at gestational ages of less than 30 weeks, with birth weight less than 1500 g, or both.[96] Severe grades of hemorrhage with hydrocephalus (grade III) and IPH (grade IV) have stabilized at about 11%, according to a large outcome study of very-low-birth-weight infants (<1500 g) by the National Institute of Child Health and Human Development (NICHD).[97]

Multiple factors are associated with GMH, including prematurity with complications caused by altered cerebral blood flow such as hypoxia, hypertension, hypercarbia, hypernatremia, rapid volume increase, and pneumothorax.[84-86] Other causes include increases in cerebral venous pressure at delivery, congestive heart failure, increased ventilator pressures, and coagulopathies.[53] Factors associated with decreased incidence of GMH include increased use of antenatal steroids[98,99] and improved neonatal respiratory care, such as the effective use of high-frequency ventilators, oscillators, and surfactant, which decrease pressure to the lung.

GMH originates below the subependymal layer and may be contained by the ependyma or may rupture into the ventricular system or less often into the adjacent parenchyma and thus can

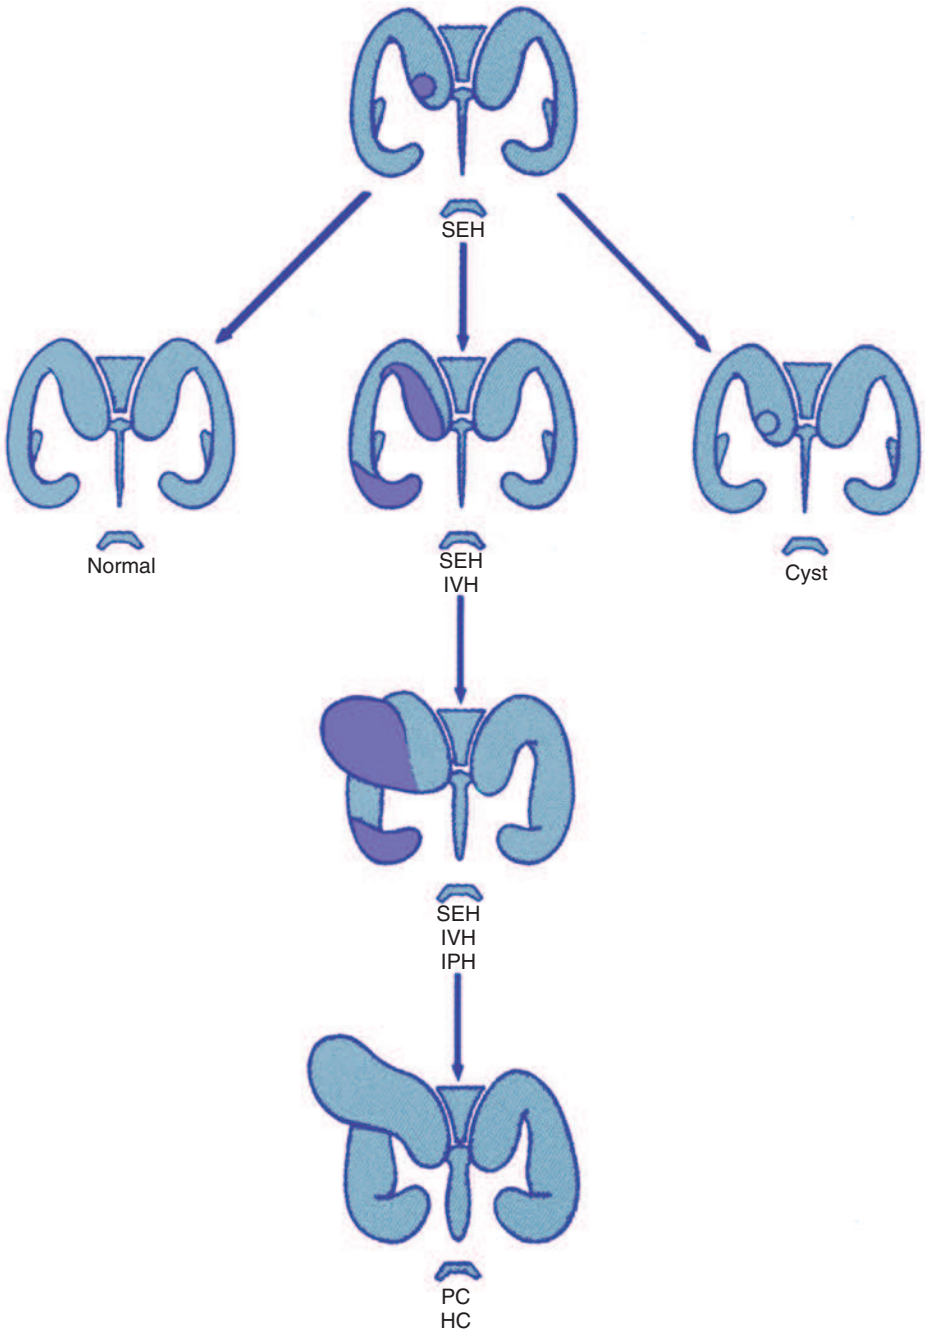

FIG. 45.35 Sequelae of Subependymal Hemorrhage *(SEH).* SEH may resolve, leaving a normal scan; may resolve, leaving a small subependymal cyst; or may progress, rupturing into the ventricle, causing intraventricular hemorrhage *(IVH),* or extending into the parenchyma, causing intraparenchymal hemorrhage *(IPH).* Hydrocephalus *(HC)* and porencephaly *(PC)* are common sequelae of SEH. (With permission from Rumack CM, Manco-Johnson ML. Perinatal and infant brain imaging: role of ultrasound and computed tomography. St Louis: Mosby; 1984.[7])

manifest as subependymal hemorrhage (SEH), IVH, or IPH[100] (Fig. 45.35). The **germinal matrix** is a fine network of blood vessels and primitive neural tissue that lines the ventricular system in the subependymal layer during fetal life. As the fetus matures, the germinal matrix regresses toward the foramen of Monro so that, by full term, only a small amount of germinal matrix is present in the caudothalamic groove between the thalamus and the caudate nucleus. This fine network of blood vessels is highly susceptible to pressure and metabolic changes, which can lead to rupture of the vessels. The germinal matrix is rarely a site of hemorrhage after 32 weeks' gestation because it has almost disappeared. Thus full-term infants rarely experience this type of hemorrhage.

The classification of GMH most widely used was proposed by Burstein and colleagues.[100] Other systems are used as well, but the **anatomic description** of exactly where the brain damage

occurs is more important than the classification. The key causes of poor neurologic outcome relate to hydrocephalus and parenchymal extension into the descending white matter tracts (Table 45.2).

Sonography is the most effective method for detecting this hemorrhage in the newborn period and for follow-up in the subsequent weeks. Most hemorrhage (90%) occurs in the first 7 days of life, but only one-third of these occur in the first 24 hours.[101] The optimal cost-effective timing to screen premature infants is at 10-14 days of life, to identify patients with significant hemorrhage as well as those developing hydrocephalus.[102] Small SEHs (grade I) might be missed when screening late if they resolve quickly, but these have not proven clinically important. A late screen for PVL should performed at 1 month to search for the cystic changes of PVL,[103,104] because the clinical course or first brain ultrasound will not predict the later development of hydrocephalus or PVL. An examination should be performed earlier if required by the patient's condition. Term-equivalent age studies with MRI are now frequently done to determine the extent of damage. Careful recent studies with ultrasound done at term-equivalent age by Daneman and colleagues[3] have demonstrated that many of the noncystic findings can be identified with high-resolution transducers focused on the brain parenchyma in areas that are not periventricular where the noncystic WMIP occurs.

TABLE 45.2 Grades of Germinal Matrix Hemorrhage

Grade	Type and Description
I	Subependymal hemorrhage
II	Intraventricular extension without hydrocephalus
III	Intraventricular hemorrhage with hydrocephalus
IV	Intraparenchymal hemorrhage with or without hydrocephalus

Optimal Brain Ultrasound Screening in Premature Infants (Less Than 30 Weeks' Gestation or Less Than 1500 g)

FIRST SCAN: 10 TO 14 DAYS
Germinal matrix hemorrhage
Posthemorrhagic hydrocephalus

SECOND SCAN: 4 WEEKS OF AGE
Cystic PVL
Cystic PVL lesions coalesce, leaving only thin white matter after 4 weeks
Ventricular enlargement

THIRD SCAN: TERM-EQUIVALENT AGE
White matter injury of prematurity (beyond only PVL)
Best seen by ultrasound or magnetic resonance imaging

PVL, Periventricular leukomalacia.

Complications of SHE and IVH are IVOH, usually at the foramina of Monro or the sylvian aqueduct, and EVOH, at the arachnoid granulations. Complications of IPH are permanent areas of damaged brain that can become necrotic, leading to porencephalic cysts.

Subependymal Hemorrhage (Grade I Hemorrhage)

On sonographic examination, acute SEH appears as a homogeneous, moderately to highly echogenic mass (Fig. 45.36). The echogenic clot often causes focal hemorrhage in the caudothalamic groove. The choroid plexus is normally quite thick at the trigone of the lateral ventricle and tapers progressively anteriorly, descending between the head of the caudate and the thalamus just above the foramen of Monro. SEH may appear as a bulge in the choroid plexus (Fig. 45.37, Video 45.9 and Video 45.10). As the hematoma ages, the clot becomes less echogenic, with its center becoming sonolucent. Over time the clot retracts, and necrosis

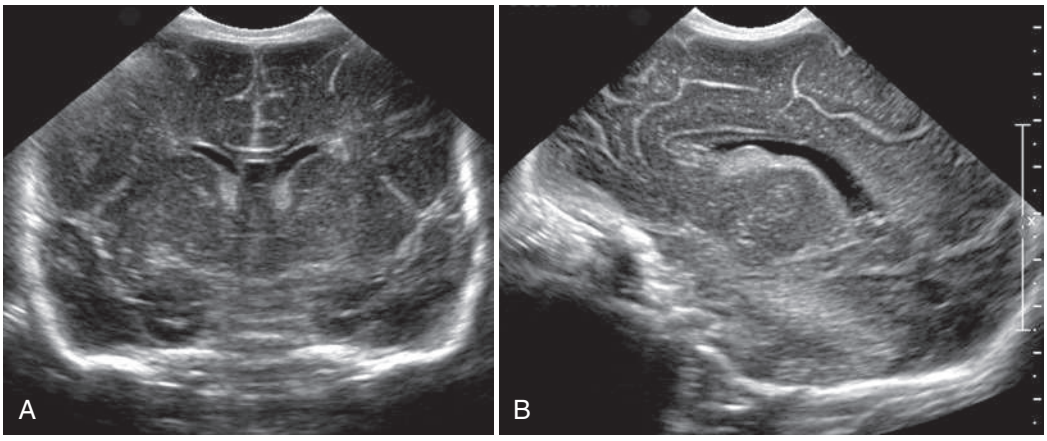

FIG. 45.36 Subependymal Hemorrhage (SEH), Bilateral. (A) Coronal sonogram shows echogenic SEH bilaterally. **(B)** Parasagittal sonogram shows the hemorrhage located in the caudothalamic notch. See also Video 45.9 and Video 45.10.

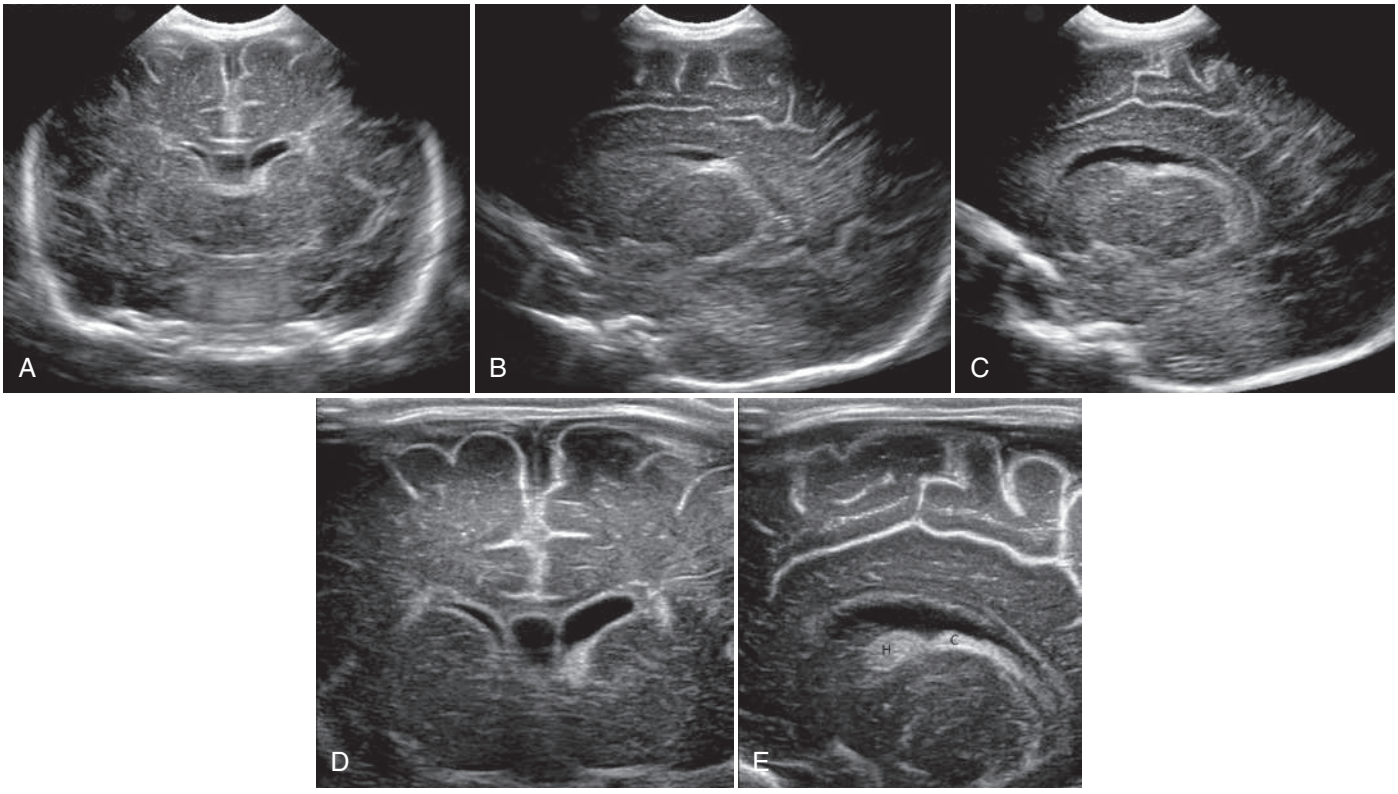

FIG. 45.37 Subependymal Hemorrhage (SEH), Unilateral. (A) Coronal sonogram showing a subtle unilateral SEH. **(B)** Parasagittal sonogram of normal caudothalamic notch. **(C)** Parasagittal sonogram of SEH. **(D)** Coronal sonogram obtained with a higher frequency linear transducer clarifies the SEH. **(E)** Parasagittal sonogram obtained with linear transducer shows the SEH *(H)* clearly separate from the choroid plexus *(C)*.

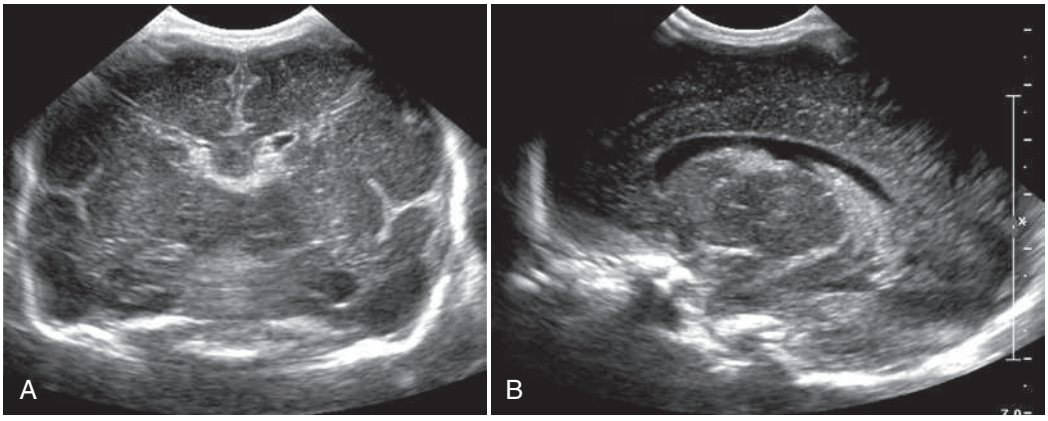

FIG. 45.38 Intraventricular Hemorrhage. (A) and **(B)** Coronal and sagittal sonograms show intraventricular hemorrhage from bilateral SEH breaking into the lateral ventricles.

occurs with complete resolution of hemorrhage or occasionally development of a **subependymal cyst.** SEH may persist as a linear echo adjacent to the ependyma. Hemorrhage is still evident for months on MRI but becomes isodense on CT at about 10 days so that these comparison studies may suggest different findings.

Intraventricular Hemorrhage (Grade II Hemorrhage)

When SEH bursts into the lateral ventricle, IVH appears as hyperechoic clot that fills a portion of the ventricular system or all of a ventricle when the clot forms a cast of the ventricle (Fig. 45.38). The clot itself may obscure the ventricle owing to complete filling of the lumen. The normally thick, echogenic choroid plexus may appear asymmetrically thick and may be difficult to define within the ventricle separate from the densely echogenic hemorrhage (Fig. 45.39). As the clot matures, it becomes echolucent centrally and more well defined and separable from the more echogenic choroid plexus. Low-level echoes from debris floating in a ventricle may occur as the clot breaks apart. Use of the posterior fontanelle or mastoid fontanelle axial views will increase the detection of IVH in normal-sized ventricles, because at times there are only small clots or **CSF-blood fluid levels** in the occipital horn (Fig. 45.39D-E).

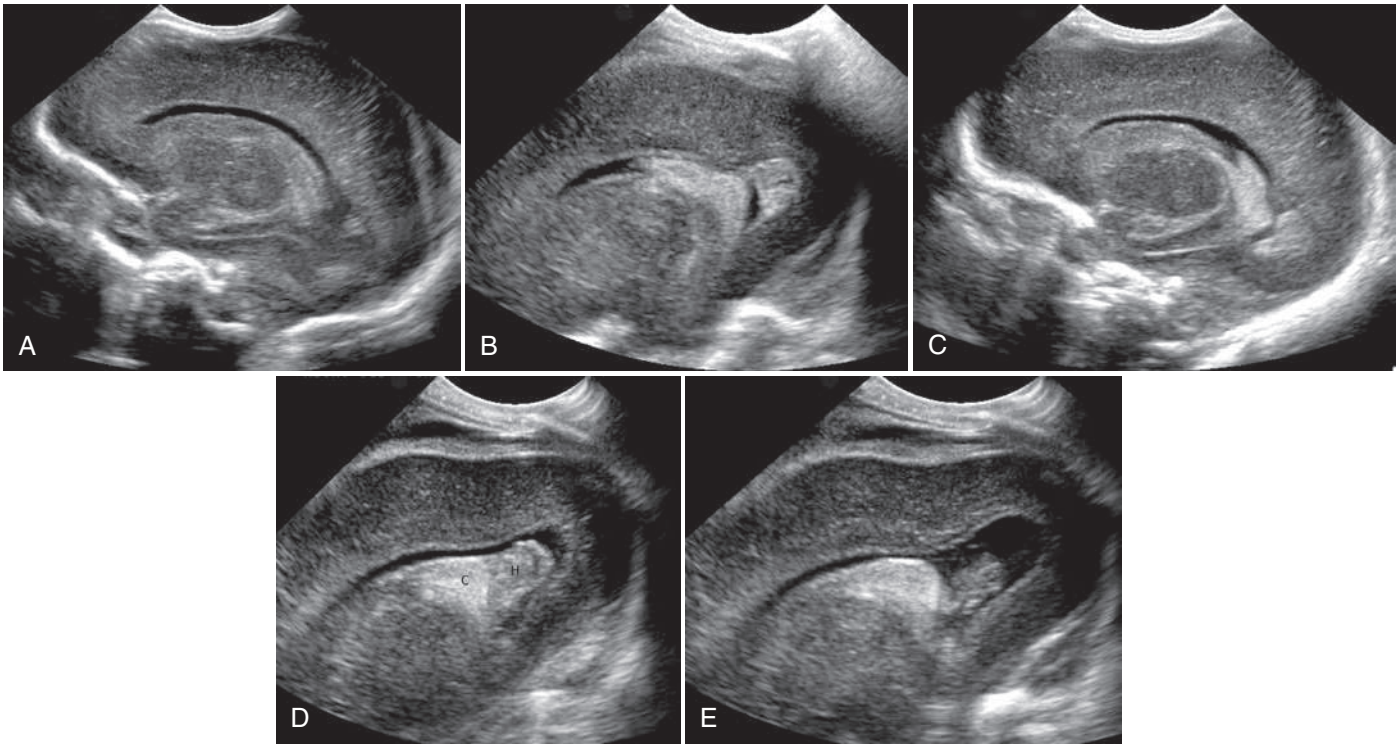

FIG. 45.39 Intraventricular Hemorrhage: Anterior and Posterior Fontanelle in Two Neonates. *Neonate 1:* **(A)** Sagittal sonogram through the anterior fontanelle shows intraventricular hemorrhage within the occipital horn. **(B)** Occipital horn hemorrhage better visualized through the posterior fontanelle. *Neonate 2:* **(C)** Sagittal sonogram through the anterior fontanelle vaguely shows clot in occipital horn. **(D)** Sagittal sonogram through the posterior fontanelle clearly shows hemorrhage *(H)* and choroid plexus *(C)* better than the previous image. **(E)** Hemorrhage seen separate from the choroid plexus. Note how the echogenicity of the clot is lower than that of the choroid plexus in neonate 2, suggesting older hemorrhage than that seen in neonate 1.

Signs of Intraventricular Hemorrhage

Hyperechoic material fills portion of ventricular system
Clot forms a cast of the ventricle
  May obscure ventricle because lumen completely filled
Thick, echogenic choroid plexus
Echolucent centrally later, as clot matures
Low-level echoes floating in a ventricle
Cerebrospinal fluid–blood fluid levels

Blood in the third or fourth ventricle may be missed and is much more clearly identified on posterior fossa ultrasound with mastoid views. If the blood extends into the subarachnoid space and cisterna magna, there is an increased risk for posthemorrhagic hydrocephalus[105,106] (Fig. 45.40, Video 45.11 and Video 45.12). **Cisterna magna clot** is a better predictor of posthemorrhagic hydrocephalus than initial hydrocephalus. Early-onset IVH, in the first 6 hours of life, is uncommon and is associated with a higher risk for both cognitive and motor impairment, including cerebral palsy.[107] Neurodevelopmental outcomes in extremely premature infants have shown increased rates of neurosensory impairment, developmental delay, cerebral palsy, blindness, and deafness at 2 to 3 years corrected age in an Australian cohort study,[108] even when the original injury was grade 1 or II IVH.

Intraventricular Hemorrhage With Hydrocephalus (Grade III Hemorrhage)

The ventricular enlargement that occurs after IVH allows for clear visualization of clot, which often assumes a dependent location but may be adherent to ventricular walls and/or choroid plexus (Figs. 45.41 and 45.42, Video 45.13, Video 45.14, Video 45.15). Change in position may lead to change in location of mobile clot. Posterior fontanel le images may show IVH in the occipital horn in subtler cases. As with SEH, in time the echogenic clot will become more echolucent centrally and may eventually resolve. A **chemical ventriculitis** as a response to blood in the CSF typically causes thickening and increased echogenicity of the subependymal lining of the ventricle. Posthemorrhagic hydrocephalus may require shunting if it is progressive. Follow-up scans should be obtained weekly unless the head grows rapidly or another crisis intervenes. Typically, the most severe degree of hydrocephalus occurs after several weeks. As the blood clears from the ventricles, particularly with a block at the aqueduct, the ventricular size may return to normal. In one series, posthemorrhagic ventricular dilation required surgical treatment with a ventriculoperitoneal reservoir or shunt in only 34% of very-low-birth-weight infants with hydrocephalus.[109] Another series reported a marked decrease in both temporary and permanent shunts in extremely low-gestational-age newborns, such that only 16% of these infants required a permanent shunt after

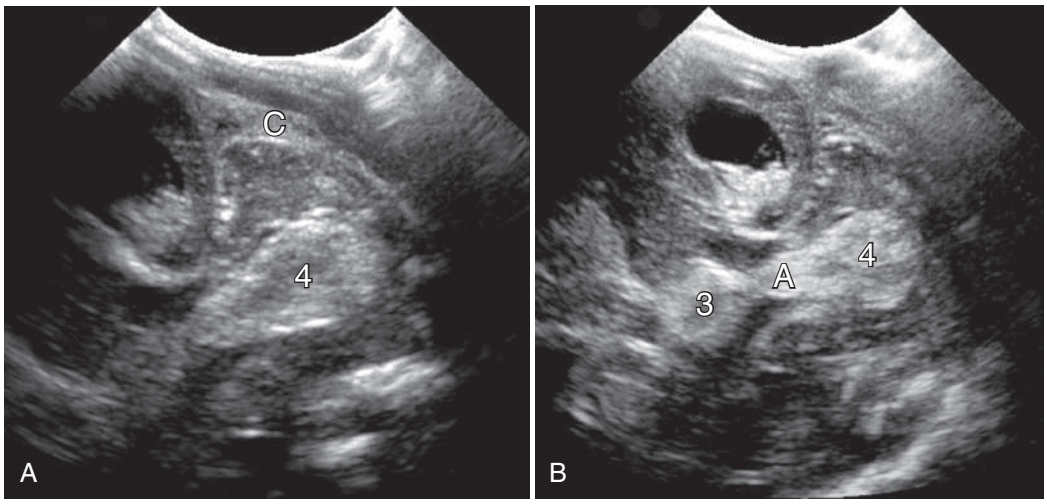

FIG. 45.40 Cisterna Magna and Fourth Ventricle Clot. (A) Axial sonogram shows echogenic clot within the cisterna magna *(C)* and fourth ventricle *(4)*. **(B)** Expansive clot within the aqueduct of Sylvius *(A)* between the third *(3)* and fourth *(4)* ventricles.

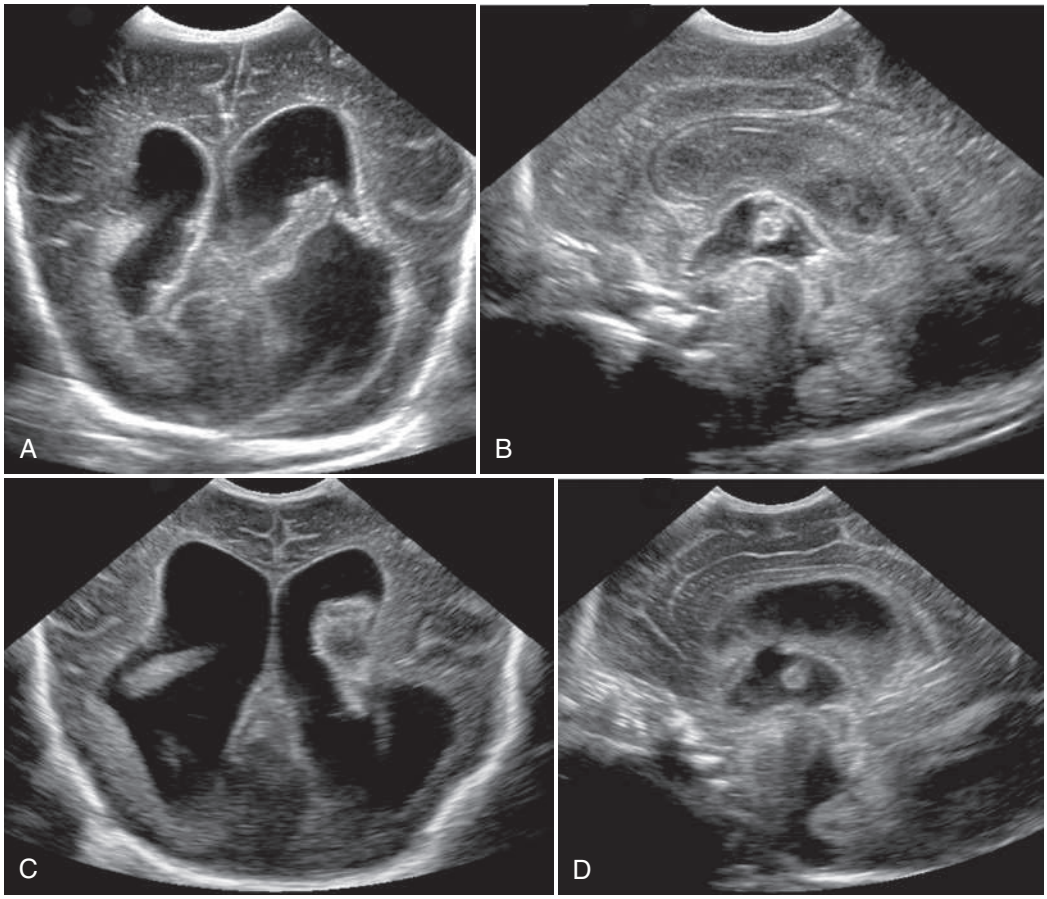

FIG. 45.41 Intraventricular Hemorrhage and Hydrocephalus. (A) and **(B)** Coronal and sagittal sonograms show enlarged lateral ventricles and third ventricle; clot is causing intraventricular obstructive hydrocephalus. Note the echogenic lining of the lateral ventricles due to ventriculitis associated with the hemorrhage. **(C)** and **(D)** Coronal and sagittal sonograms shows extraventricular obstructive hydrocephalus; the lateral ventricles, third ventricle, and fourth ventricle are all enlarged.

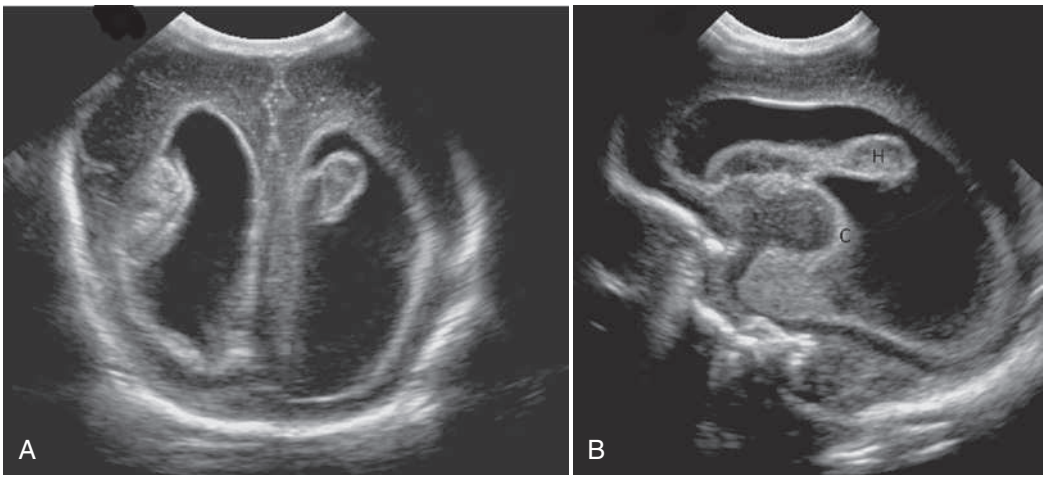

FIG. 45.42 Intraventricular Hemorrhage: Dependent Clot. (A) Coronal sonogram shows dependent clot in an infant with the right side of the head down. **(B)** Sagittal sonogram of the left lateral ventricle shows dependent clot *(H)* separate from the choroid plexus *(C)*. Note also the extensive echogenicity lining the ventricles, likely due to ventriculitis and blood clot.

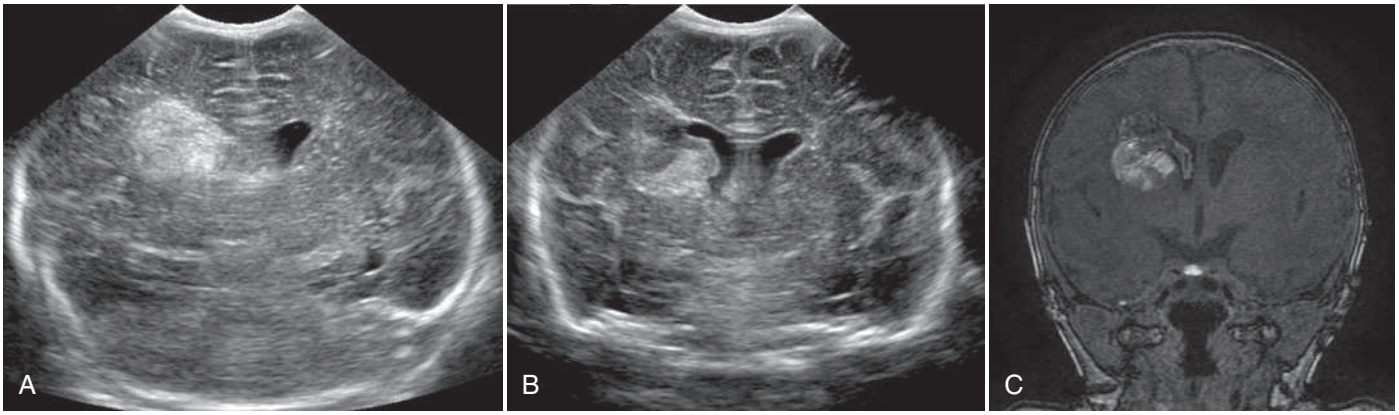

FIG. 45.43 Intraparenchymal Hemorrhage. (A) and **(B)** Coronal sonograms show acute intraparenchymal hemorrhage in the right parietal lobe and follow-up 8 days later. Note the change in echogenicity of the clot over time, with some areas that are still echogenic but other areas that are now more isoechoic to brain parenchyma. **(C)** Coronal magnetic resonance image shows the clot. See also Video 45.11 and Video 45.12.

severe posthemorrhagic hydrocephalus.[110] Occasionally, a **trapped fourth ventricle** may be caused by obstruction of both the aqueduct and the outlets of the fourth ventricle. In these cases a ventriculoperitoneal shunt will decompress only the lateral and third ventricles. Shunting can have long-term side effects, especially if there is a multiloculated hydrocephalus after shunt infection.[111]

Intraparenchymal Hemorrhage (Grade IV Hemorrhage)

IPH is usually in the cerebral cortex and located in the frontal or parietal lobes, because it often extends from the subependymal layer over the **caudothalamic groove** (Fig. 45.43). Studies suggest that IPH is caused by hemorrhagic venous infarction.[84,85] **Periventricular hemorrhagic infarction** (PVI) is believed to be venous infarction secondary to a large SEH compressing subependymal veins. These focal periventricular white matter infarcts are typically frontal to parieto-occipital and are asymmetrical, usually unilateral, and if bilateral, asymmetrical in size. PVI in the temporal lobe is associated with a greater risk of cognitive, behavioral, and visual problems.[112] Infants with IPH associated with GMH typically develop hemiparesis, and if there is periventricular hyperintensity, they may develop cerebral palsy.[113-118] It is thought that this hyperintensity may relate to pressure from hydrocephalus. This is in contrast to infants with periventricular echogenicity and minimal or no IVH, who are at much higher risk for PVL. These infarcts typically cause spastic hemiparesis.[31,113]

Acutely, IPH appears as an echogenic homogeneous mass extending into the brain parenchyma. As the clot retracts, the edges form an echogenic rim around the center, which becomes sonolucent. The clot may move to a dependent position, and by 2 to 3 months after the injury, an area of **porencephaly** (if there is communication with the ventricle) or encephalomalacia develops (Figs. 45.44 and 45.45).

Unusual types and sites of IPH, acute cystic changes, midline shift, and downward extension of hemorrhage into the thalamus may result from hemorrhage into PVL, secondary to infarction or thromboembolism, from a bleeding diathesis (e.g., vitamin

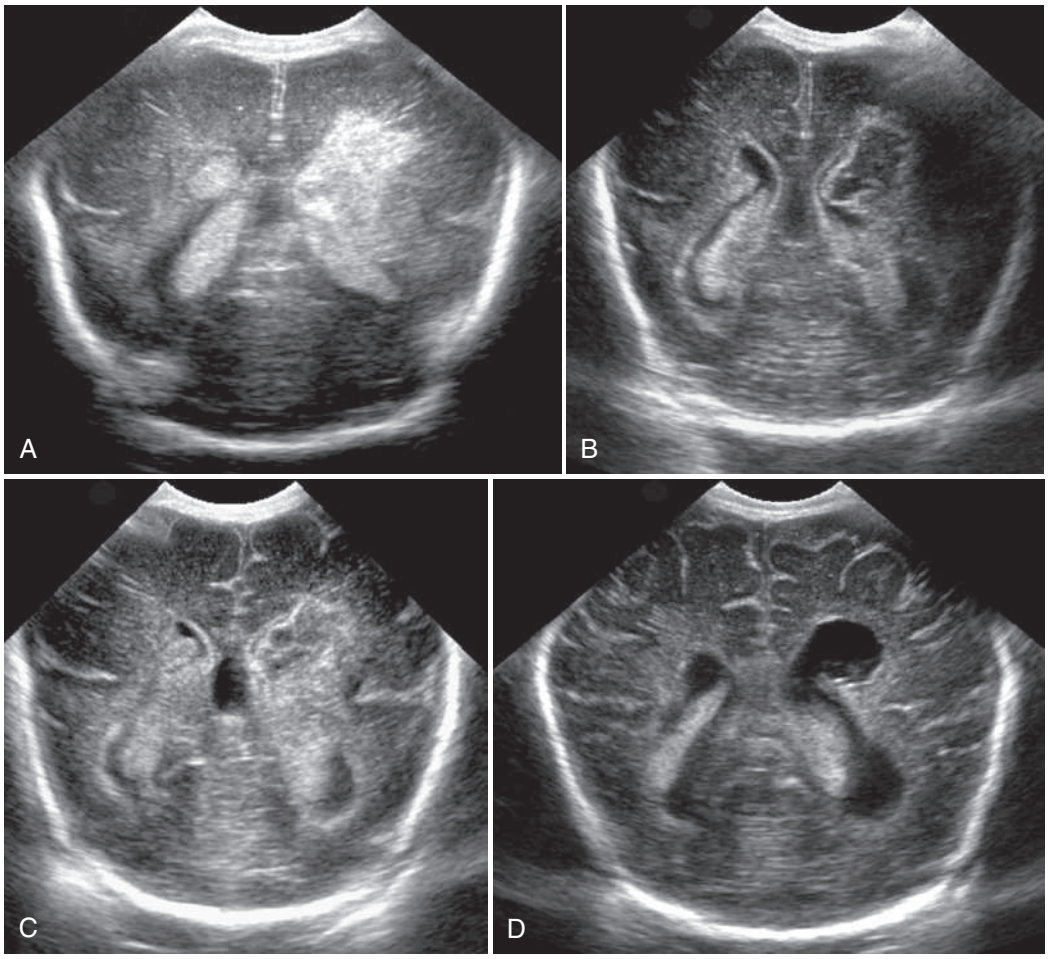

FIG. 45.44 Intraparenchymal Hemorrhage: Development of Porencephaly. (A) Coronal sonogram of 2-day-old infant shows intraparenchymal hemorrhage in the left parietal lobe. **(B)** At 17 days old. **(C)** At 29 days old. **(D)** At 2 months old.

K deficiency), hemophilia, alloimmune thrombocytopenia or Rh immune incompatibility, and hypernatremia.[119,120] Hemophilia has been associated with intracranial hemorrhage. A review of 102 newborns with hemorrhage in 33 publications found 65% intracranial and 35% extracranial.[121] Spontaneous IPH has been reported in term infants but was associated with signs of trauma or venous compression. If a unilateral thalamic hemorrhage appears in a newborn, **cerebral sinovenous thrombosis** should be strongly considered.[122,123]

Extracorporeal membrane oxygenation (ECMO) complications include IPH secondary to infarction, ischemia, and thromboembolism. GMH or IVH is less common after ECMO because premature infants are at high risk for these types of hemorrhage and thus this procedure is typically not done in premature infants.[124] These complications may be from the hypoxic brain damage secondary to the underlying lung disease, even before initiation of ECMO therapy. The complications from ECMO are also caused by heparinization and transient hypertension.[125]

Ultrasound is used for daily evaluation of the newborn receiving ECMO. The portability and ease of use in the critically ill infant without the need for transport are the main advantages. A 20-year study in Netherlands demonstrated 17% brain abnormalities with 8% hemorrhage and 5% stroke, particularly on the left. Sonography can alert the clinician to intracranial hemorrhage and the option to stop ECMO therapy.

Cerebellar Hemorrhage

Cerebellar hemorrhage has been diagnosed more frequently with special sonographic views through the mastoid fontanelle and from MRI evaluation of disrupted cerebellar development.[126-131] **Posterior fossa hemorrhage** is a reported complication of a traumatic delivery in full-term infants, in ECMO therapy, or with a coagulopathy. However, cerebellar hemorrhage can occur in premature infants because there is germinal matrix in the fourth ventricle (Fig. 45.46). The periphery of the cerebellar hemisphere is also a typical site of cerebellar hemorrhage. Mastoid fontanelle imaging is now routinely used to visualize the cerebellum in the optimum focal zone to allow cerebellar hemorrhage to be seen and the posterior fossa fully evaluated. Resolution of cerebellar hemorrhage into a cyst in the posterior fossa may allow easier diagnosis; the normal echogenic cerebellum may obscure hemorrhage when acute but is more clearly visualized with an "optimized examination" to look for subtle

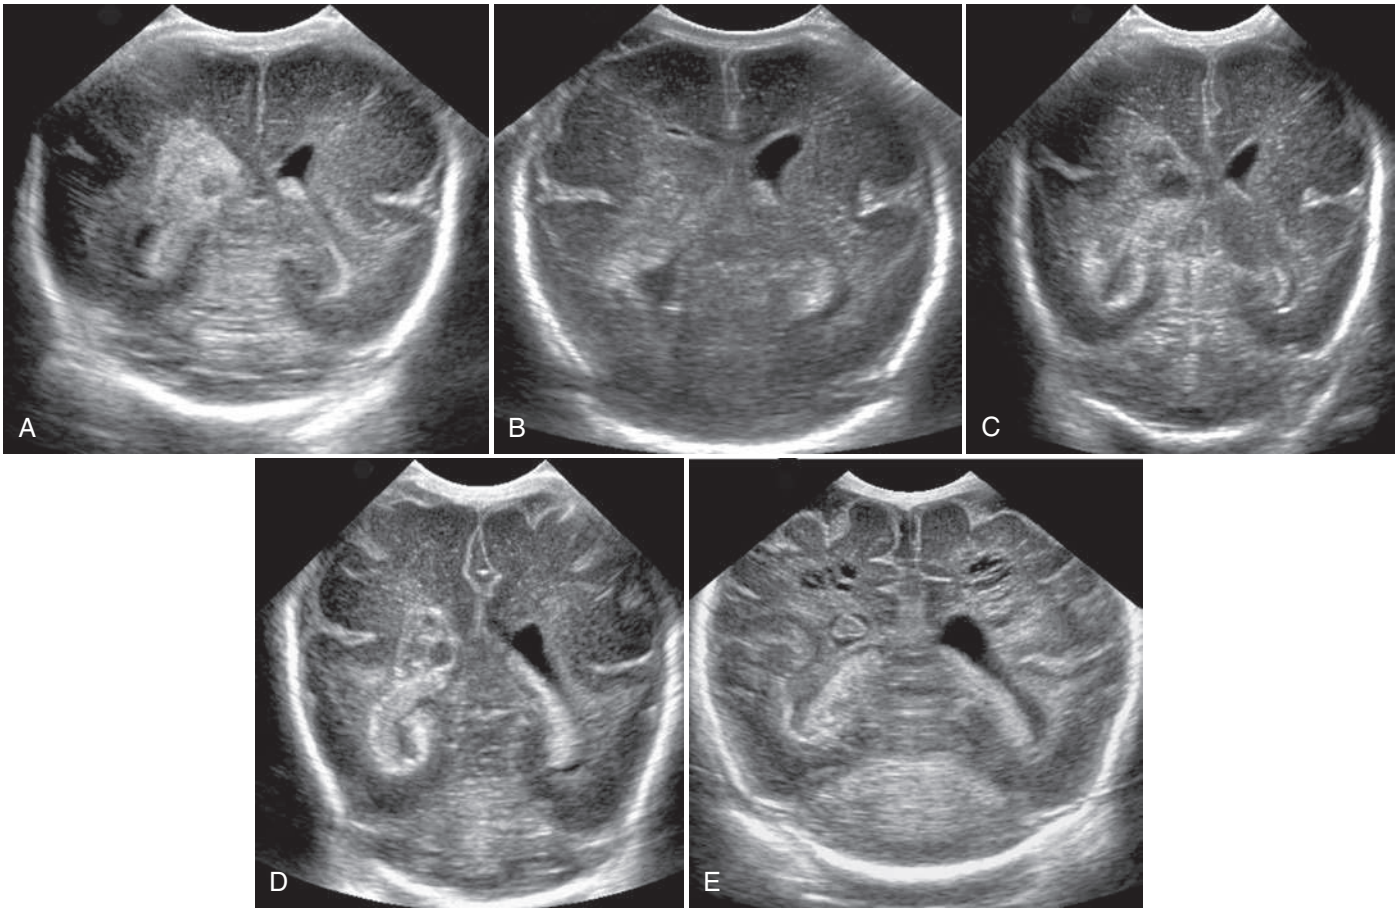

FIG. 45.45 Intraparenchymal Hemorrhage (IPH): Periventricular Hemorrhagic Infarction (PVI) and Later Periventricular Leukomalacia (PVL). (A) Coronal sonogram of 3-day-old infant shows IPH in the right parietal lobe. **(B)** At 12 days old. IPH is becoming sonolucent centrally. **(C)** At 19 days old. IPH has echogenic rind around lucent center. **(D)** At 1 month old. **(E)** At 2 months old, extensive PVL white matter damage is visible bilaterally.

parenchymal hemorrhage or injury as described by Daneman[3] and others.[132]

Merrill and colleagues[133] reported 13 cerebellar hemorrhages in 525 infants under 1500 g. Each of these occurred in the first week of life in unstable neonates with acidosis or hypotension requiring intensive resuscitation, but not always associated with supratentorial hemorrhage. On follow-up to 2 years, four infants had cognitive deficits and developmental delay without signs of motor abnormalities. Cerebellar hemorrhage has been followed to term with MRI in some studies, and cerebellar volume loss has been reported that has been more extensive than the initial hemorrhage. The exact mechanism is not known, but Volpe has postulated that it may be due to selective neuronal necrosis.[134] Three cases of prenatally diagnosed posterior fossa cysts were found to result from hemorrhage. These were initially thought to be congenital posterior fossa arachnoid cysts but were recognized because of debris in the cysts and hemosiderin on MRI.[135] In neonates, cerebellar hemorrhage has rarely required surgical intervention, although older children may require emergency drainage.

Subarachnoid Hemorrhage

The presence of enlarged interhemispheric and sylvian fissures with thickened sulci and increased echogenicity can suggest the diagnosis of subarachnoid hemorrhage (SAH). SAH may occur in neonates who have experienced asphyxia, trauma, or disseminated intravascular coagulation and may be the only hemorrhage in full-term infants who are not at risk for GMH. Cisternal SAH has been found after IVH but can be a difficult diagnosis on ultrasound. Posterior fossa views can aid in making the diagnosis (Fig. 45.47). Spread of blood from the ventricular system into the spinal subarachnoid space after GMH is common and can be seen within 24 hours of the initial, severe IVH in premature infants.[107]

Cerebral Edema and Infarction

White Matter Injury of Prematurity or Periventricular Leukomalacia

WMIP, previously known as "periventricular leukomalacia," the principal ischemic lesion of the premature infant, is infarction and necrosis of the periventricular white matter. In MRI studies[136] the use of diffusion-weighted imaging (which shows hyperintense areas of restricted diffusion) have demonstrated that white matter damage to premature infants often extends beyond the periventricular areas into the cerebral white matter and cortex, the thalamus, basal ganglia, brainstem, and cerebellum. This premature pattern has been termed "white matter injury of prematurity."[31,46,54] In some cases, there is a history of cardiorespiratory compromise, resulting in hypotension and severe hypoxia and ischemia. The pathogenesis of PVL has been found to relate to three major factors: (1) the immature vasculature in the periventricular watershed; (2) the absence of vascular autoregulation in premature infants, particularly in the cerebral white matter; and (3) the maturation-dependent vulnerability of the oligodendroglial precursor cell. These cells are extremely vulnerable to attack by free radicals generated in the ischemia-reperfusion sequence.[46,97]

The prevalence of PVL in the very-low-birth-weight infant (<1000 g) was previously reported as 25% to 40%.[87] Later, Ment and colleagues[94] reported that PVL incidence decreased to 7%. However, with both ultrasound and MRI comparison, cystic and noncystic white matter damage has been shown in 50% of preterm infants.[31] Because more infants are surviving with WMIP/PVL (and thus are at risk for cerebral palsy) than in the past, it becomes even more important to diagnose these lesion. WMIP consists of cystic changes of PVL, which are more often visualized on ultrasound, and noncystic white matter damage, which is better seen on MRI[137] (Fig. 45.48).

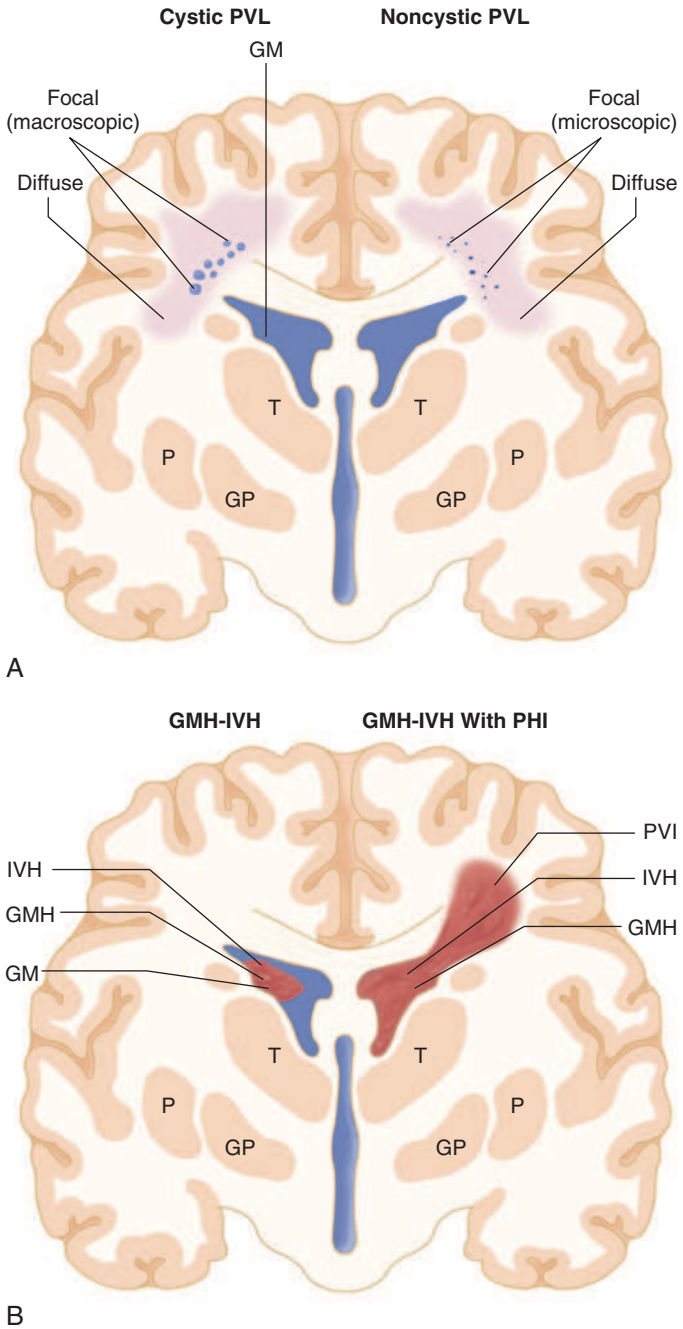

FIG. 45.48 Cystic and Noncystic Periventricular Leukomalacia *(PVL)* and Germinal Matrix Hemorrhage–Intraventricular Hemorrhage *(GMH-IVH)* and Periventricular Hemorrhagic Infarction *(PVI).* Diagram illustrates coronal sections from the brain of a 28-week-old premature infant. The dorsal cerebral subventricular zone, the ventral germinative epithelium of the germinal matrix *(GM),* thalamus *(T),* and putamen *(P)* and globus pallidus *(GP)* are shown. **(A)** The focal necrotic lesions in cystic PVL are macroscopic in size and evolve to cysts. The focal necrotic lesions in noncystic PVL are microscopic in size and evolve to glial scars. The diffuse component of both cystic and noncystic PVL *(pink)* is characterized by the cellular changes. **(B)** Hemorrhage *(red)* into the GM results in GMH, which could burst through the ependyma to cause an IVH *(left).* When the GHM-IVH is large, PHI might result *(right).* (Adapted from Volpe JJ. Brain injury in premature infants: a complex amalgam of destructive and developmental disturbances. Lancet Neurol. 2009;8[1]:110-124.[46])

In the cystic pattern of PVL, the white matter most affected is in the arterial border zones at the level of the optic radiations adjacent to the trigones of the lateral ventricles and the frontal cerebral white matter near the foramina of Monro. This cystic pattern can involve the white matter diffusely as well. The prevalence of PVL has been noted to increase with the duration of survival in premature infants, raising the possibility of cumulative postnatal insults, including circulatory compromise, patent ductus arteriosus, apneic spells, and sepsis.[101,138,139]

In the noncystic pattern of WMIP/PVL, there may be diffuse cerebral cortex white matter damage, microscopic focal white matter damage, and basal ganglia, thalamic,[140] and cerebellar damage that evolves to glial scars. Typically, the white matter is thinned with irregular ventricular walls. There may also be corpus callosum injury. Epelman and colleagues[141] have shown that careful ultrasound evaluation may show increased callosal echogenicity, which reflects corpus callosum damage and can be used as a specific marker for this injury early when MRI is less often used. Near-term ultrasound and MRI at term-equivalent age have been shown to predict neurodevelopmental outcomes in extremely premature infants.[142]

Maternal chorioamnionitis has been associated with WMIP/PVL, possibly the result of vasoactive proteins being released into the fetal circulation, causing fluctuations in cerebral blood flow. Inflammatory responses to infection in the fetus or the neonate that activate astrocytes and microglia may cause PVL,[143,144] or these may represent a pathologic response to repair the tissue injury in PVL.[145] Proinflammatory cytokines found after chorioamnionitis correlate with PVL development.[146] Prevention of PVL may depend on treatment with maternal antibiotics (in the case of chorioamnionitis before delivery) or anticytokine agents and therapy with free-radical scavengers.

Cystic PVL can been anticipated to follow a severe hemodynamic event in 56% of premature infants with PVL. Unexpected PVL (without a specific clinical neonatal event) has been reported in as many as 44% of cases.[147] This series of PVL patients had been treated for preterm delivery and often had maternal chorioamnionitis. It is proposed that the maternal infection predisposes to preterm delivery and PVL. Antenatal steroids have been shown to decrease the incidence of PVL and the incidence of IPH from GMH.[148-151]

Later neurologic problems from cystic PVL/WMIP include developmental delay and spastic diplegia involving both legs, often noticeable by 6 months of age. Spastic diplegia occurs because the pyramidal tracts from the motor cortex that innervate the legs pass through the internal capsule and travel close to the lateral ventricular wall. Severe cases of PVL will also affect the arms, resulting in spastic quadriplegia, and also cause vision and intellectual deficits.[152-155] The prevalence of cerebral palsy was evaluated in the French EPIPAGE cohort study of 2364 children born at 22 to 32 weeks' gestation; 1954 (83%) were studied at 2 years of age. Twenty percent had cerebral palsy if born at 24 to 26 weeks' gestation, whereas only 4% had cerebral palsy if born at 32 weeks. For those with neonatal head ultrasound and follow-up, 17% of children with neonatal IVH (grade III) and 25% with neonatal white matter damage had cerebral palsy, compared with 4% with normal ultrasound scans.[156]

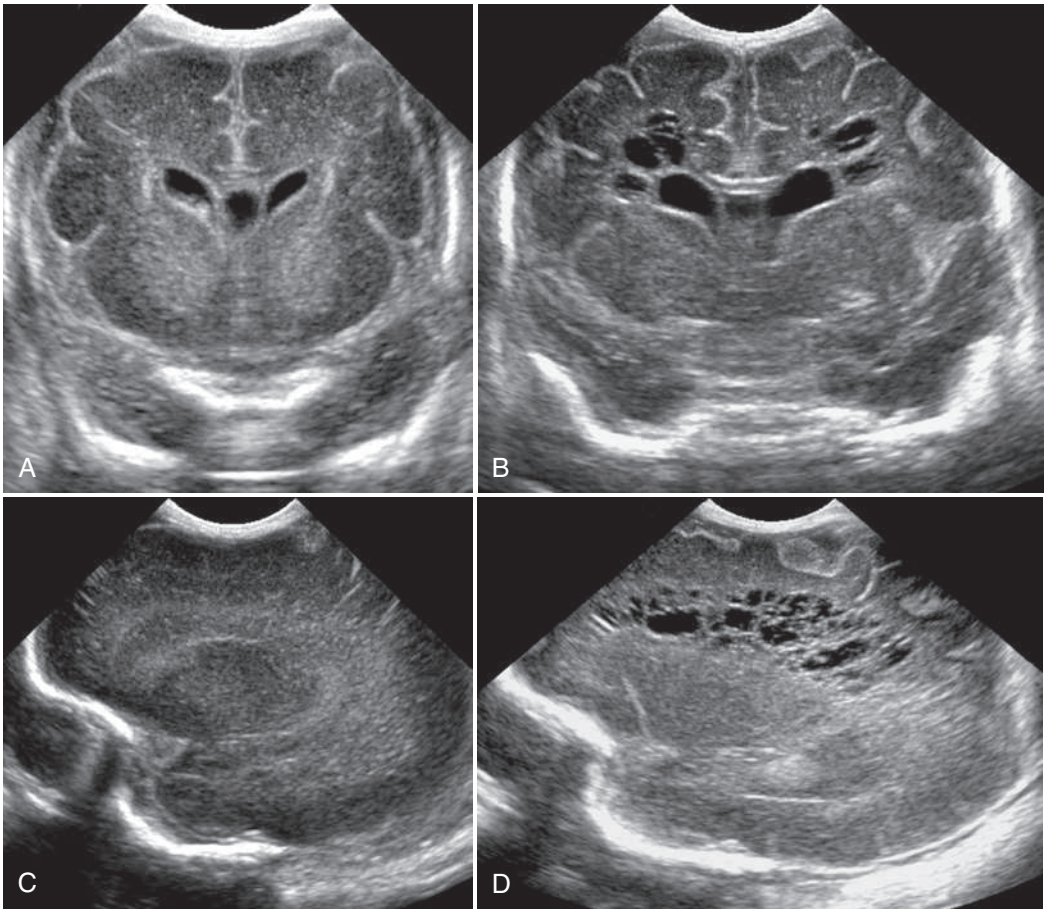

FIG. 45.49 Periventricular Leukomalacia (PVL): Echogenic to Cystic. (A) Coronal sonogram shows acute increased areas of echogenicity. **(B)** Development of cystic PVL 1 month later. **(C)** and **(D)** Sagittal sonograms. See also Video 45.16.

Pathologically, the periventricular white matter undergoes coagulation necrosis, followed by phagocytosis of the necrotic tissue. This necrosis usually occurs in the white matter adjacent to the external angles of the lateral ventricles. This results in decreased myelination in these areas and focal dilated lateral ventricles. In more severe cases of PVL, cystic cavities develop.[40,152,154] Petechial hemorrhages can complicate PVL. In fact, hemorrhagic PVL has been shown to be much more common (64%) than thought when there is MRI-ultrasound correlation.[157]

The initial sonographic examination findings in infants who ultimately develop cystic PVL may be normal. Within 2 weeks of the initial insult, however, the periventricular white matter increases in echogenicity until it is greater than the adjacent choroid plexus. This increased echogenicity is usually caused by edema from infarction and may also result from hemorrhage[158] (Fig. 45.49A). Two to 4 weeks after the insult, cystic changes may develop in the area of abnormal echogenic parenchyma (Fig. 45.49B-D; Video 45.16). The cysts can be single or multiple and are parallel to the ventricular border in the deep white matter and often lateral and/or superior to the top of the ventricles. These cysts measure from millimeters to 2 cm in diameter. The cystic changes are usually bilateral and often symmetrical. Cystic changes in the corpus callosum can progress to later thinning.[139,159]

Pathologic studies suggest that sonography actually underestimates the incidence of PVL.[158,160] In 51 cases of postmortem-proven PVL, Adcock and colleagues[160] found that in 44% the neurosonogram failed to make the diagnosis for two main reasons: (1) most often the ultrasound examinations were performed before 1 month of age and missed the cystic stage of PVL, and (2) the lesions were microcystic and not large enough to find on ultrasound.

On subsequent sonograms, the cystic lesions may enlarge or resolve.[154] Therefore normal-appearing white matter on sonograms obtained several weeks to months after the insult does not exclude the occurrence of PVL. MRI becomes more sensitive than either CT or ultrasound for long-term follow-up of parenchymal injury, because when myelination progresses, **glial scarring** from damaged white matter can be diagnosed (Fig. 45.50), typically with thinning of the white matter adjacent to an enlarged ventricle where the cysts have coalesced and are no longer visible. Because the initial ultrasound examination findings are often normal in infants who have sustained a significant hypoxic-ischemic event, late sonograms should be obtained at about 4 weeks after birth to exclude evolving PVL. The characteristic distribution of cystic lesions that are clearly separate from the ventricle in PVL should distinguish them from the parenchymal hemorrhage that occurs in grade IV GMH. However, PVL and GMH can occur

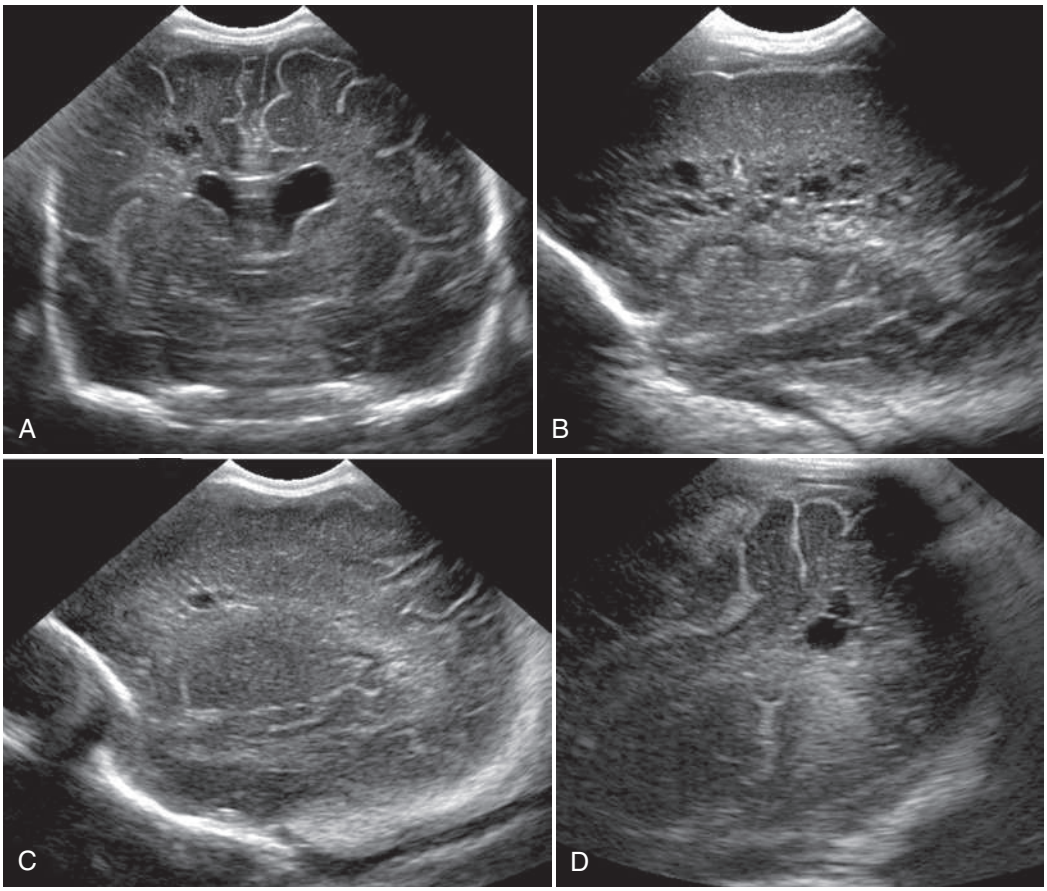

FIG. 45.50 Periventricular Leukomalacia (PVL). (A) Coronal sonogram of cystic PVL. **(B)** and **(C)** Sagittal sonograms show large and small affected areas of PVL. **(D)** Sagittal sonogram shows cystic PVL in the occipital lobe.

simultaneously.[161] Periventricular white matter damage can be studied with cranial ultrasound if technical factors include careful attention to focal areas of hyperechogenicity. Leijser and colleagues[162] divided white matter into **grade 0,** less echogenicity than choroid plexus; **grade 1,** same echogenicity as choroid plexus; and **grade 2,** brighter than choroid plexus. Only severe grade (grade 2) predicted a poor neurologic outcome.

MRI has proven to be the best method for WMIP/PVL diagnosis when done at term-equivalent age in the very-low-birth-weight infants most at risk for PVL.[163,164] The increasing use of MRI has been controversial as a standard of care but clearly adds to the prognostic value in predicting neurodevelopmental outcomes of very premature infants.[165,166] The addition of diffusion-weighted imaging[167] and diffusion tensor imaging[168] have also been shown to add value in predicting more extensive white matter injury. Delayed myelination, ventricular enlargement, and width of extracerebral spaces were not found to be good predictors of cerebral palsy.

Term Infants With Hypoxic Ischemic Injury

Diffuse cerebral edema with or without SAH is a common result of hypoxic-ischemic events in full-term infants. In some cases, acute very focal areas of edema may cause increased gray matter–white matter differentiation. However, it is common that when brain edema can be diagnosed on ultrasound, there are typically slitlike ventricles in a diffusely echogenic brain with poorly defined sulci. This echogenicity may cause **effacement of the sulci** so that the sulci seem to disappear (Fig. 45.51).[4] The brain parenchyma appears echogenic in the distribution of the injury, and the sulci are difficult to appreciate because of surrounding echogenic edematous brain. The mechanism of the increased echogenicity of the brain parenchyma from cerebral edema is not understood completely. One possibility is that the increased intracellular fluid causes more interfaces.

Color Doppler ultrasound evaluation of severely asphyxiated infants has demonstrated earlier and at times more focal abnormalities than gray-scale evaluation alone (see Chapter 46). Investigators have used Doppler sonography to classify brain edema and to predict outcome. Outcome of children with significantly abnormal cerebral blood flow was noted in 47 patients, from newborns to 4 years of age. However, loss or reversal of diastolic flow did not necessarily imply a lethal outcome. Survival was associated with prompt and effective treatment.[169] A few studies have shown MRI changes early in neonatal life from asphyxia, but most neonatologists resist moving a very unstable newborn for magnetic resonance scanning. If the ischemic event was severe enough to lead to infarction, diffuse brain volume loss occurs within 2 weeks, with ventricular enlargement

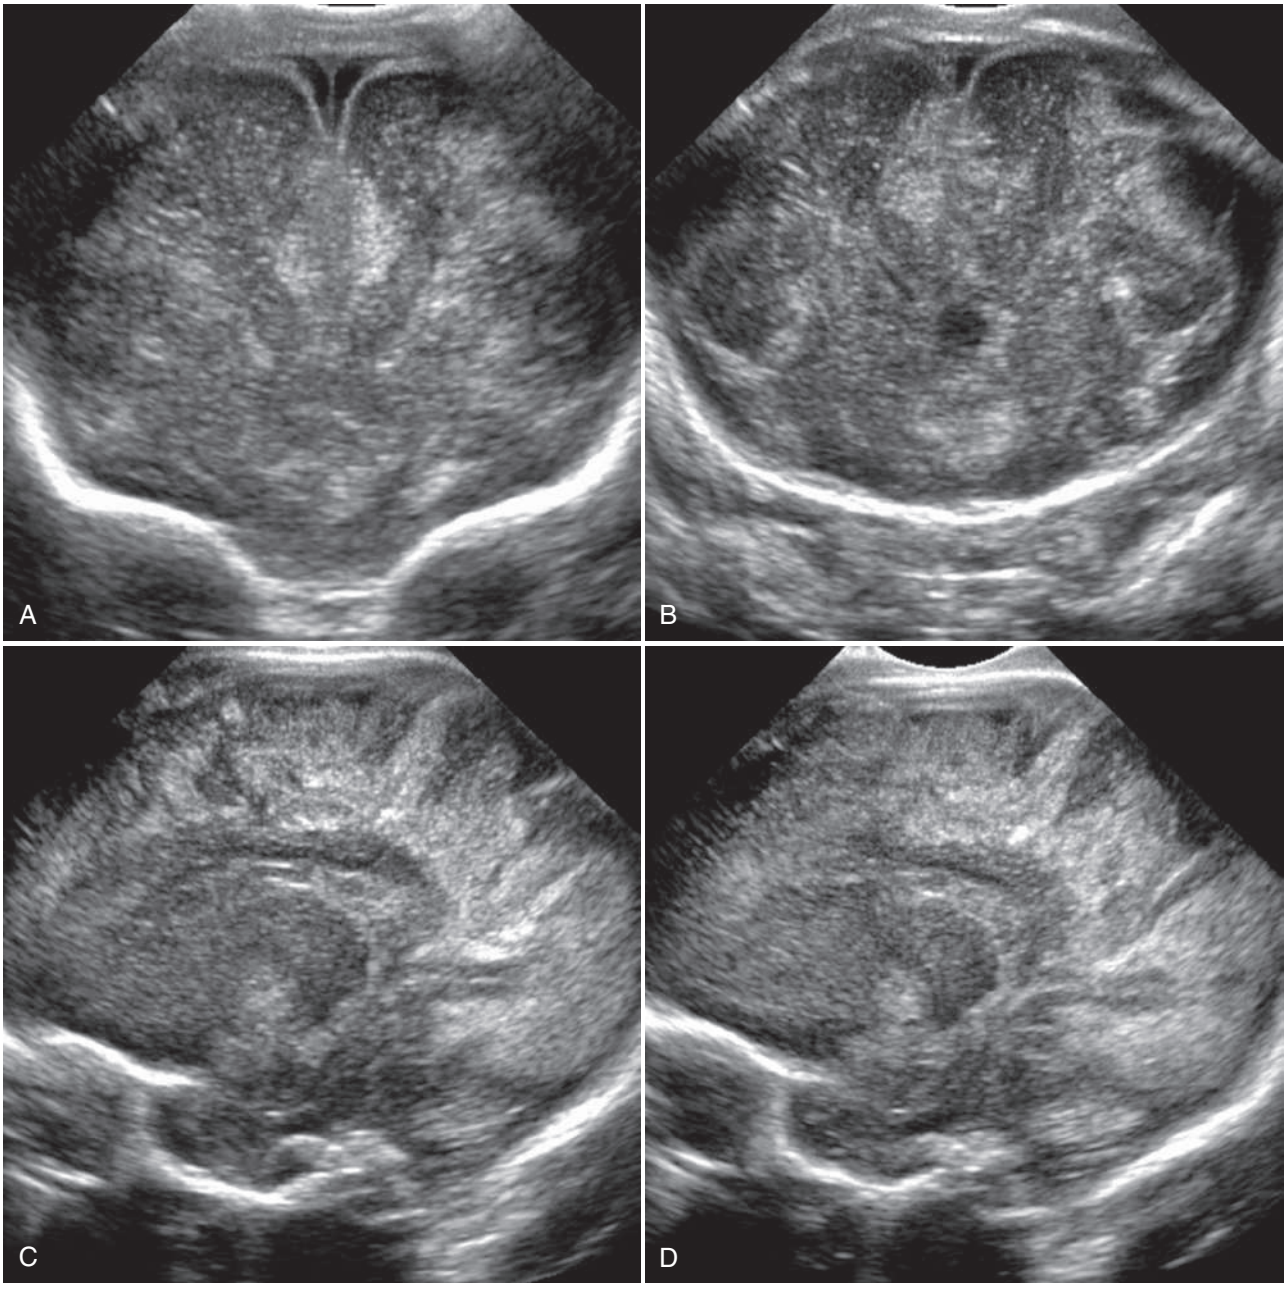

FIG. 45.51 Cerebral Edema. (A) and **(B)** Coronal sonograms; **(C)** and **(D)** sagittal sonograms. Severe cerebral edema has caused effacement and silhouetting of the sulci from acute, near-total intrauterine asphyxia after placental abruption. Diffuse increased echogenicity from edema obscures sulci. Ventricles are slitlike because of the severe edema.

secondary to atrophy.[31] Enlarged extraaxial fluid spaces also develop as a consequence of the atrophic changes. The head circumference is very helpful to distinguish diffuse atrophy from hydrocephalus, because the head circumference is normal to small in patients who have undergone diffuse brain atrophy. Depending on the type of insult, generalized brain atrophy or focal areas of porencephaly or encephalomalacia may occur. With **acute near-total intrauterine asphyxia** in the newborn, an unusual pattern of basal ganglia damage with sparing of the cerebral cortex and white matter has been reported. This may be difficult to diagnose with ultrasound if it is not hemorrhagic until late changes of atrophy develop[31] (Fig. 45.52).

Sonography can detect these complications of hypoxic-ischemic events, but MRI is more sensitive to the full extent of the insult near the cortical surface.[31,170] To optimize ultrasound imaging of the term neonatal brain, Daneman and colleagues[171] used higher frequencies (8-17 MHz) with multiple focal planes in near-field, midfield, and far-field magnified views with spectral and color Doppler ultrasound, searching for abnormal resistive indices on spectral Doppler ultrasound. They also emphasized the need to perform the ultrasound examination within 2 hours of MRI for an accurate comparison. Special features to be evaluated on every ultrasound study in neonates with hypoxic-ischemic insult should include gray matter–white matter differentiation

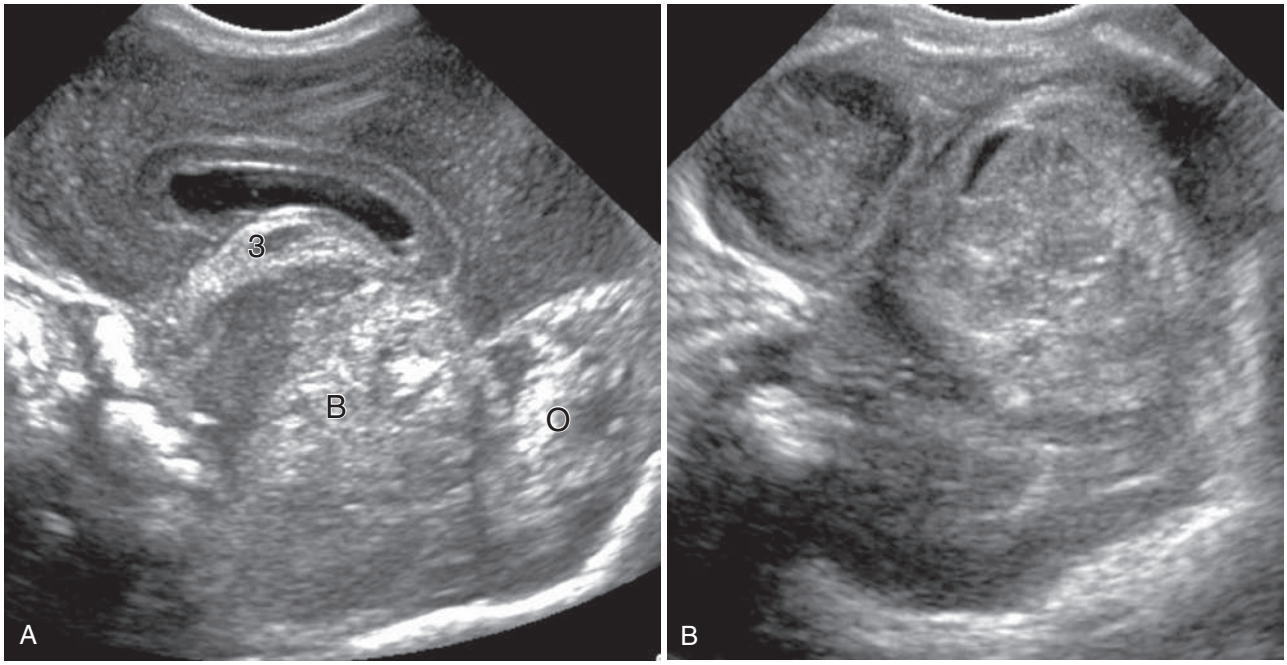

FIG. 45.52 Brainstem and Cerebellar Hemorrhage. (A) and **(B)** Sagittal and axial sonograms show highly echogenic hemorrhage in the brainstem *(B),* cerebellar vermis, and hemispheres, and posteriorly in the occipital cortex *(O),* after acute, near-total intrauterine asphyxia. Clot is also seen in the third ventricle *(3)* just below the cavum septi pellucidi.

and focal abnormal echogenicity in cerebral cortex and deeper structures. Doppler ultrasound to look for flow fluctuations in resistive indices and flow in the dural sinuses is valuable.

In term infants treated with **hypothermia for hypoxic ischemic encephalopathy,** there have been rare reports of IVH.[166,172,173] However, outcomes after hypothermia for HIE from the NICHD Neonatal Research Network studies show that there is a decrease in deaths and that hypothermia does not increase rates of severe disability among survivors.

Neonatal HIE is best evaluated with ultrasound in the first few days of life. MRI is the most sensitive and specific imaging technique, and is useful in stable term infants. Some authors suggest that MRI late in the first week of life may be useful but term-equivalent age is best for prognosis. However, the brain may appear normal or near normal at 5 to 7 days after the event. For severe hypotensive episodes, thalami, brainstem, and cerebellum are most sensitive owing to their high metabolic activity. In premature infants, HIE injury appears as increased echogenicity on ultrasound, hypoattenuation on CT (may be missed because of high neonatal brain water content), and hyperintensity from restricted diffusion on diffusion-weighted imaging. In term infants, the lateral thalami, posterior putamen, hippocampus, brainstem, corticospinal tracts, and sensorimotor cortex are most affected.[88,89,174]

Focal Infarction

Cerebral infarction in the neonate, aside from PVL or periventricular hemorrhagic venous infarction, is uncommon. Risk factors are prematurity, severe birth asphyxia, congenital heart disease (resulting in a left-to-right shunt), meningitis, emboli (from the placenta or systemic circulation), polycythemia, hypernatremia, and trauma.[120,175,176] Symptoms vary, ranging from asymptomatic to seizures with lethargy and coma. The MCA distribution is the most frequent site, although the anterior and posterior circulations have also been affected.[46] Single areas of infarction are more frequently seen in full-term infants, whereas premature infants often demonstrate multiple sites of injury. Cerebral blood flow evaluation with color and or power Doppler sonography are used in unstable neonates, and diffusion-weighted MRI is used in stable infants to identify the earliest signs of stroke.[177-182]

Cerebellar infarction is much less common than cerebral infarction. However, six cases were reported in 3 years at Hammersmith Hospital in London, diagnosed by MRI in patients at several years of age who were born prematurely.[183] All these patients also had IVH, and thus cerebellar damage was likely a result of diffuse ischemic injury. Only one of the six patients was diagnosed on sonography as having cerebellar damage. Because the vermis is so echogenic, edema or hemorrhage can be a difficult diagnosis in this region. Cerebellar infarction was also diagnosed with MRI in 13 patients with severe cerebral palsy who had cerebellar hemispheric and vermian damage.[184] Now that we are routinely evaluating the posterior fossa in detail, we are more aware of cerebellar infarction at the time of the injury in premature infants.[185]

On sonography, the infarcted brain parenchyma demonstrates specific findings within the first 2 weeks (see Fig. 45.52; Fig. 45.53). These include echogenic parenchyma, lack of arterial pulsation, lack of blood flow appreciated by pulsed or color Doppler sonography, mass effect from edema, arterial territorial distribution of injury, and decreased sulcal definition. After 2 weeks, the echogenic lesions begin to show cystic changes, and

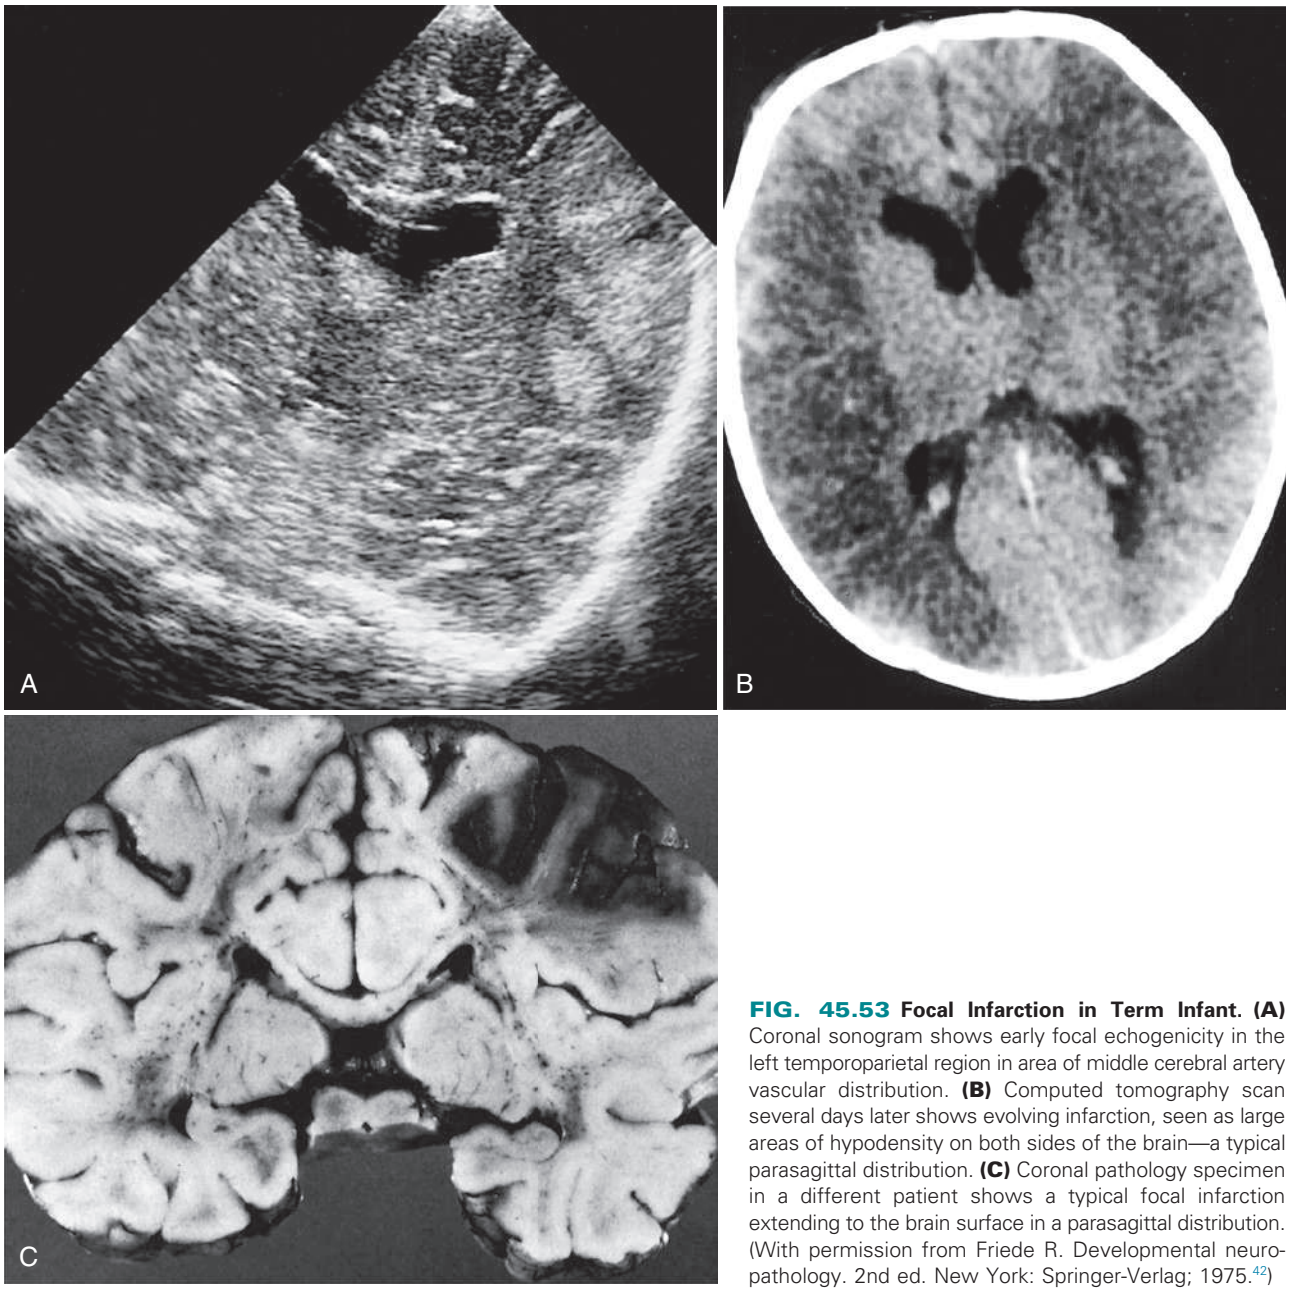

FIG. 45.53 Focal Infarction in Term Infant. (A) Coronal sonogram shows early focal echogenicity in the left temporoparietal region in area of middle cerebral artery vascular distribution. **(B)** Computed tomography scan several days later shows evolving infarction, seen as large areas of hypodensity on both sides of the brain—a typical parasagittal distribution. **(C)** Coronal pathology specimen in a different patient shows a typical focal infarction extending to the brain surface in a parasagittal distribution. Cerebral Infarction: Sonographic Signs

Echogenic parenchyma
Lack of flow on color Doppler and pulsed Doppler
Mass effect from edema
Arterial territorial distribution of injury
Decreased sulcal definition
Increased pulsation in periphery of infarcted section
Early collateral arterial vessels within hours of insult

ipsilateral ventricular enlargement from evolving atrophy (hydrocephalus ex vacuo), as well as a gradual return of arterial pulsations in the major branches from proximal to peripheral distribution. Cerebellar lesions are typically peripheral and thus do not lead to local ventricular enlargement. Using color Doppler imaging, **luxury perfusion** has been identified within hours of a focal vascular insult, both experimentally and in newborn infants. Power Doppler may be more sensitive than color Doppler in detecting the increase in the size and number of vessels seen with luxury perfusion.

Lenticulostriate Vasculopathy

Linear branching echogenicity in the lenticulostriate arteries of the thalamus and basal ganglia is uncommon but has been described in intrauterine viral infections (CMV, rubella, syphilis) (Video 45.17 and Video 45.18), neonatal asphyxia, nonimmune hydrops, fetal alcohol syndrome, and trisomies 13 and 21. Coley and colleagues[186] reported that hypoxic-ischemic conditions accounted for 30 of 63 cases. In a study by Amir, of 92 infants

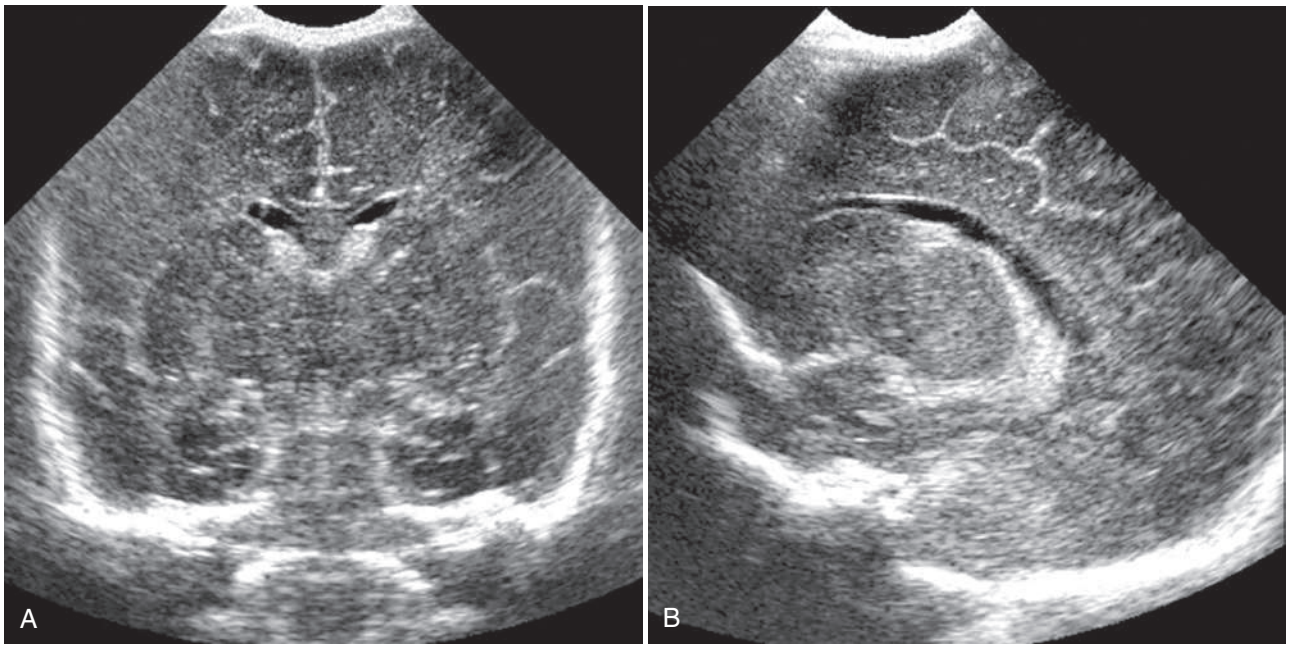

FIG. 45.54 Hyperechoic Caudate Nucleus (Bilateral). (A) and **(B)** Coronal and sagittal sonograms show echogenic caudate nuclei that did not appear abnormal until the premature infant was about 1 month of age (postulated to be remote ischemic damage).

with congenital CMV, half had lenticulostriate vasculopathy on an initial head ultrasound, and this was a marker for sensorineural hearing loss.[187] In a study by Chamnanvanakij and colleagues, of 10 preterm infants who ultimately developed linear hyperechogenicity in the basal ganglia and thalamus, the mean age of diagnosis was 1 month and it was a marker for more diffuse brain injury and for poor neurologic outcome.[188]

Hyperechoic Caudate Nuclei

Bilateral hyperechoic foci in the caudate nuclei develop in the characteristic location of GMH but are atypical in that they are sharply marginated, teardrop shaped, bilateral, and symmetrical (Fig. 45.54). Schlesinger and colleagues[189] reported that five of nine infants had ischemia and two were normal in this area, based on MRI and histopathologic review. Hyperechoic caudate nuclei seem to occur late, usually after the first week of life, when most GMH occurs.

POSTTRAUMATIC INJURY

Subdural and Epidural Hematomas

Subdural and epidural hemorrhage can be a difficult diagnosis on sonography compared with CT or MRI.[7] On sonographic examination, these hematomas appear as unilateral or bilateral hypoechoic fluid collections surrounding the brain parenchyma (Fig. 45.55). Subdural hematomas are uncommon in newborns and not necessarily indicative of birth trauma—13 of 26 affected infants diagnosed on CT had a history of trauma.[190] Fortunately, surgery is rarely required. Small amounts of fluid may be difficult to detect secondary to the near-field artifact inherent in every transducer. However, this is less of a problem if a high-frequency transducer (10-12 MHz) is used. With a lower-frequency transducer, interposing an acoustic gel pad between the transducer and the fontanelle can assist in eliminating the near-field artifact. Magnified coronal sections with high-frequency linear transducers (at least 10-12 MHz) are best for appreciating the epidural and subdural collections in the supratentorial space. Imaging through the foramen magnum or posterior fontanelle can assist in diagnosing infratentorial extraaxial fluid collections.

Color Doppler sonography has been shown to distinguish subarachnoid and subdural fluid and hemorrhage based on displacement of vessels on the brain surface (see Fig. 45.55; see Chapter 46). Doppler ultrasound may be useful in determining which patients may be simply observed and which require MRI for a more specific diagnosis of hemorrhage.

After the neonatal period, when birth trauma may cause hemorrhage, the presence of new subdural fluid collections should suggest preexisting meningitis (most often from *Haemophilus influenzae*) or nonaccidental trauma. If an infant's head circumference increases abnormally quickly after the first 2 weeks of life, a CT examination is usually performed to search for extraaxial fluid, because the most common cause is subdural hemorrhage, not hydrocephalus. If a sonographic examination is performed, the clinician should carefully search the near field with magnified views for extracerebral fluid and cerebral tears, as well as membranes seen in chronic subdural fluid collections.

INFECTION

Congenital Infections

Congenital infections can have serious consequences for the developing fetus. Death of the fetus, congenital malformations,

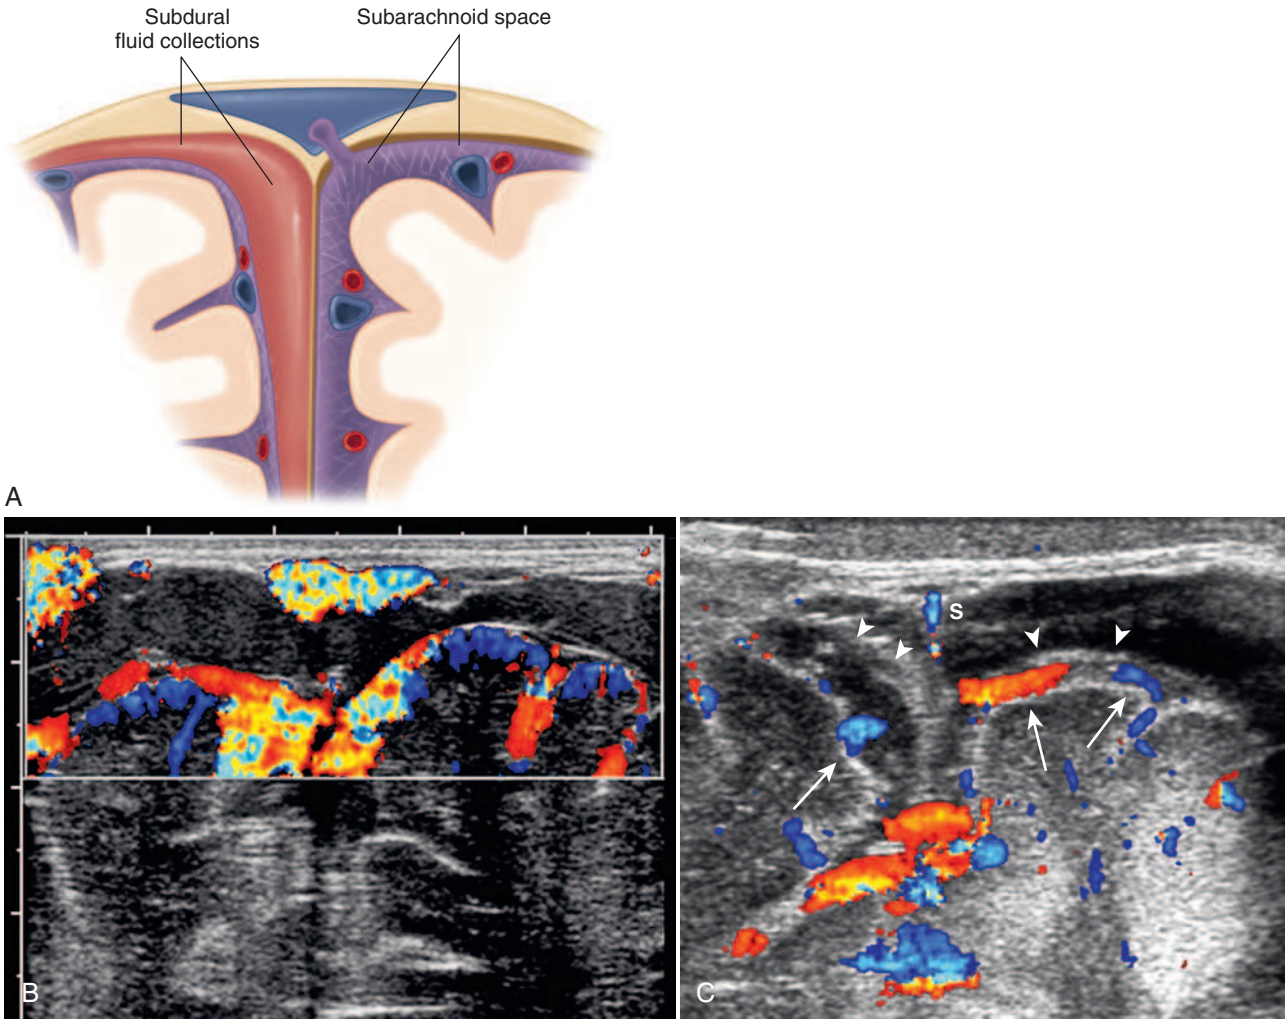

FIG. 45.55 Subdural and Subarachnoid Fluid Collections. (A) Drawing shows vessels are compressed onto the surface of the brain in subdural fluid collections and vessels cross the fluid in subarachnoid space. **(B)** Magnified coronal color Doppler image of interhemispheric fissure in a 2-week-old infant. Large bilateral echogenic subdural effusions from **meningitis** compress the superficial cortical vessels onto the cortical surface. **(C)** Coronal color Doppler image of interhemispheric fissure in a 1-month-old infant. Large left and small right hypoechoic chronic subdural hematomas *(S)* from **nonaccidental trauma** lie above the echogenic subarachnoid fluid. The cortical surface is compressed by the echogenic subarachnoid fluid, which surrounds superficial cortical vessels *(arrows)* separated from the relatively lucent subdural fluid by echogenic and thickened pia-arachnoid *(arrowheads).* Note the echogenic subcortical white matter and superior sagittal sinus.

mental retardation or developmental delay, and spasticity or seizures may result from infection at critical times during gestation. Ultrasound plays an important role in identifying and following both antenatal and neonatal complications from congenital infections, with MRI showing additional findings in many cases.[191,192]

The most frequent congenital infections are commonly referred to by the acronym TORCH. This refers to the infections *Toxoplasma gondii,* rubella, CMV, and herpes simplex virus type 2 (HSV-2). The O stands for "other," such as syphilis. Syphilis causes acute meningitis, infrequently resulting in parenchymal lesions in the newborn.[193]

Of the TORCH group, congenital infection by CMV is the most common, occurring in approximately 1% of all births.[194] CMV may be acquired at or after birth with little or no consequence, but prenatal infections may result in serious damage to the developing brain.[195,196] Maternal infection is usually subclinical. Maternal immunity to CMV reduces the risk of CMV in utero, and vaccines are being considered.[197] Toxoplasmosis is the second common congenital infection and is caused by the unicellular parasite *T. gondii.*[198,199]

The severity of the infection with either CMV or toxoplasmosis depends on the timing of the infection during gestation. Earlier infection, before 20 to 24 weeks, results in more devastating outcomes: microcephaly, lissencephaly with abnormal myelination, a hypoplastic cerebellum, polymicrogyria and cortical dysplasias, porencephaly, and multicystic encephalomalacia.[200] CMV has been reported to cause schizencephaly in some patients[69,70] (Fig. 45.56). Ventriculomegaly may result from brain volume loss. Later infection, after 24 weeks, will result in less severe neurologic damage.

To differentiate CMV from toxoplasmosis, serum titers for antibodies against these organisms are useful. Other differentiating criteria include the petechial skin lesions and hepatomegaly

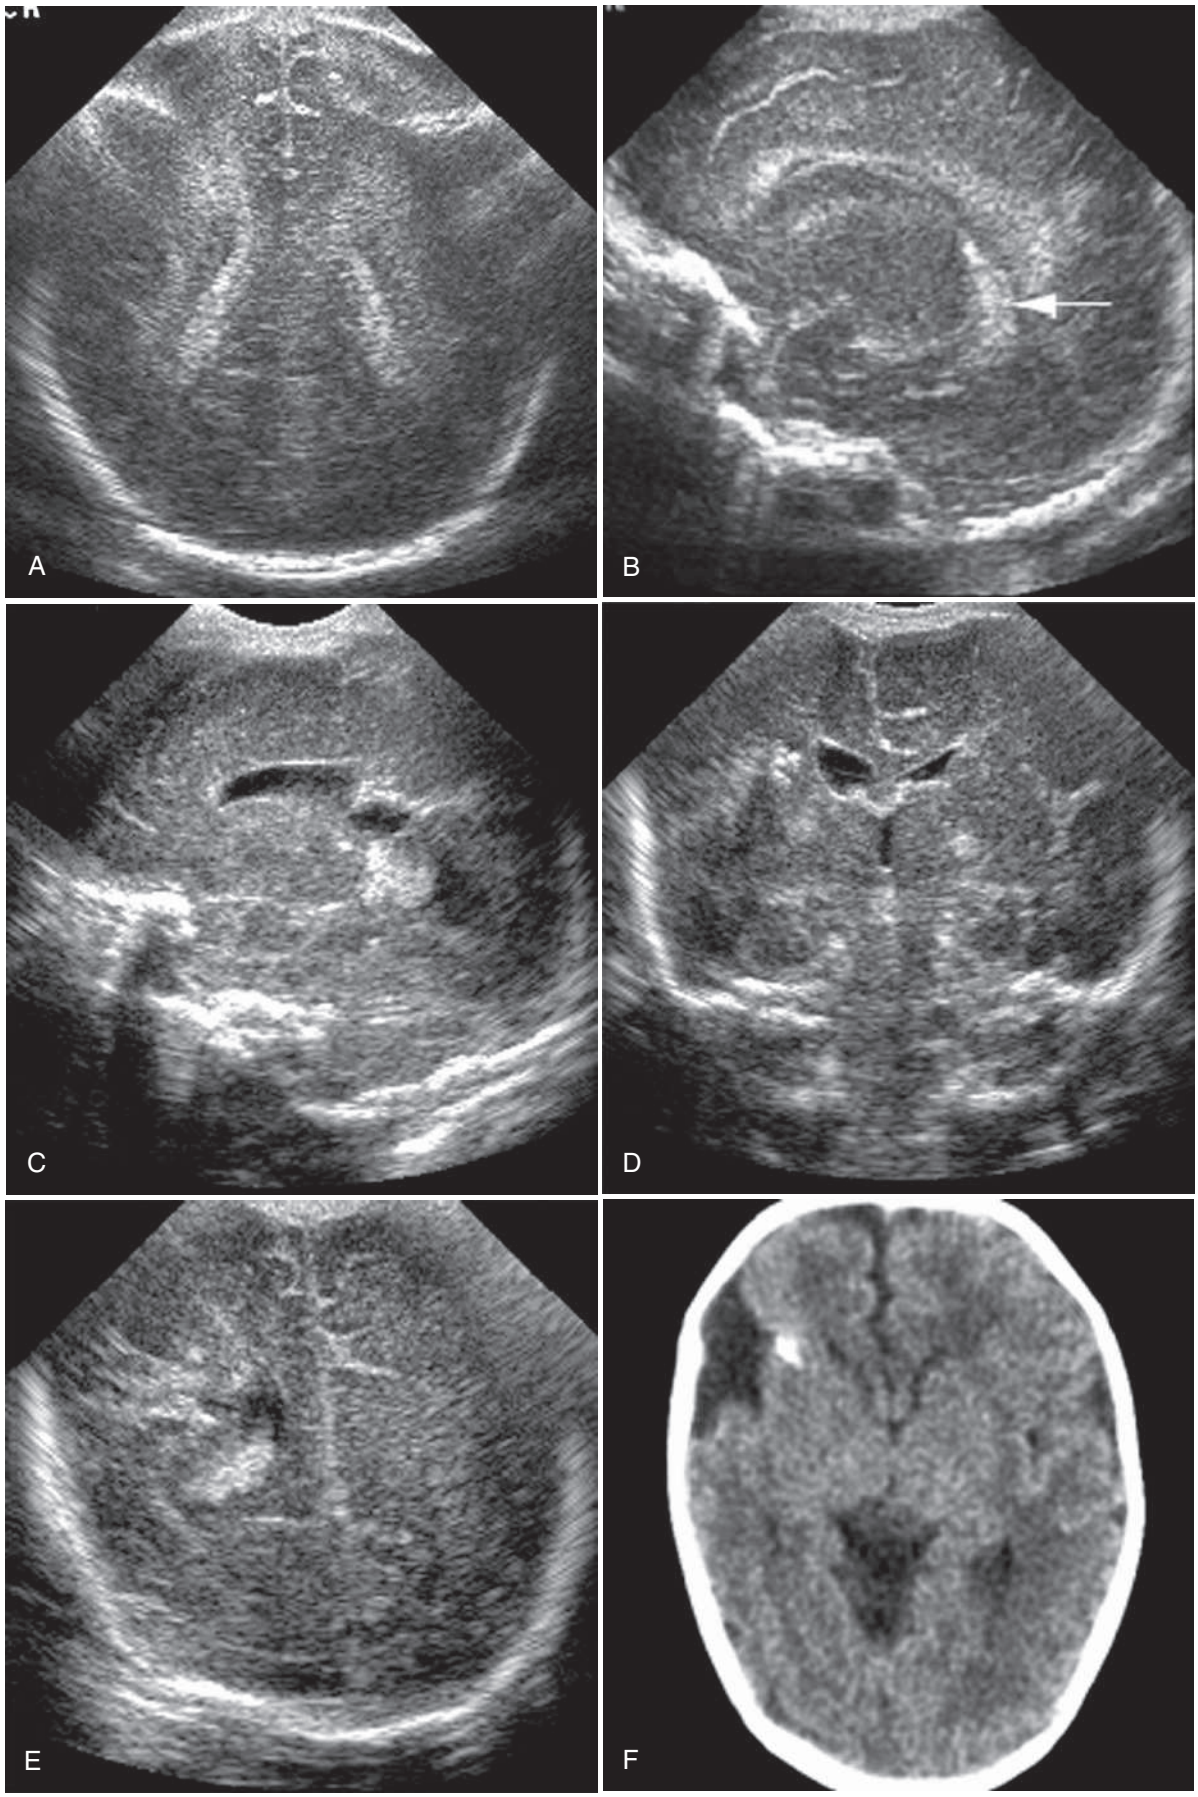

FIG. 45.56 Cytomegalovirus Encephalitis. (A) and **(B)** Periventricular echogenicity and focal calcification *(arrow)* with little acoustic shadowing. **(C)-(E)** In another patient, focal calcifications on ultrasound. **(F)** Computed tomography scan. See also Video 45.17, Video 45.18, and Video 45.19.

associated with CMV and chorioretinitis associated with toxoplasmosis. Intracranial calcifications have been described in both infections. CMV classically causes periventricular calcifications (see Fig. 45.56, Videos 45.17 and 45.18). Ventricular septations have also been described (Video 45.19). Toxoplasmosis causes more scattered calcifications with a predilection for the basal ganglia. However, both patterns have been seen in both infections.[201] Resolution of intracranial calcification has been reported after treatment of congenital toxoplasmosis, consistent with improved neurologic outcome.[202]

Sonography can demonstrate the periventricular or scattered cerebral calcifications as echogenic foci with or without acoustic shadowing. In eight proven cases of CMV, Malinger and colleagues[200] reported periventricular hyperintensity in all cases, as well as calcification, ventriculomegaly, hypoplastic vermis, periventricular cysts, intraventricular adhesions, and echogenic vasculature in the basal ganglia. Cerebellar calcification was seen in one patient.[200] The brain parenchyma may appear disorganized, with poorly defined sulci and corpus callosum. CT demonstrates the calcifications to a better extent, but MRI shows abnormal myelination or cortical dysplasias most reliably.

Recently, maternal **Zika virus infection** has been described in Brazil and many other countries and is associated with fetal microcephaly and severe cerebral damage.[203] Sonographic findings are similar to severe forms of CMV with microcephaly, ventriculomegaly, corpus callosum abnormalities, gray and white matter loss, and cerebral calcifications.[204-213]

HSV-1 or HSV-2 may cause disease of the CNS, although HSV-2 is more common in the neonate, and HSV-1 occurs primarily in older children and adults. HSV-2 may be acquired transplacentally or by vaginal exposure to herpetic genital lesions during birth. The resulting encephalitis is typically diffuse, resulting in loss of gray matter–white matter differentiation. (This differs from the temporal lobe disease seen in older children and adults with HSV-1.) Cystic encephalomalacia of periventricular white matter and hemorrhagic infarction with scattered parenchymal calcifications frequently result.[214] Relative sparing of the lower neural axis, including the basal ganglia, thalamus, cerebellum, and brainstem, is typical. Infections acquired in utero may lead to microcephaly, intracranial calcifications, and retinal dysplasias.[215]

Since the widespread availability of rubella vaccine after 1967, congenital rubella has fortunately become extremely uncommon in the Western world. Unfortunately, it remains a significant problem in many other parts of the world. Subependymal cysts, microcephaly, and vasculopathy have been described.[216]

Neonatal Acquired Infections

Meningitis and Ventriculitis

Despite the development of antibiotics to treat bacterial infections, there are now cases of methicillin-resistant infections,[217] and bacterial meningitis remains a serious concern for infants and children. Neonatal sepsis has a major impact on neurodevelopmental outcome of extremely premature infants independent of other risk factors.[218] Schlapbach and colleagues[218] found three times the risk for cerebral palsy after sepsis; proposed mechanisms included direct brain damage from infection and secondary arterial hypotension from septic shock.

During the first month of an infant's life, the two most common infections result from *Escherichia coli* and group B streptococci. Between 4 and 12 weeks, *E. coli* and *Streptococcus pneumoniae* are the most common, and from 3 months to 3 years, *H. influenzae* is most frequent. Enteroviruses have been reported to cause encephalitis as well.[219] Meningitis is usually a clinical diagnosis; imaging is needed only to evaluate for complications or when the patient's clinical situation deteriorates.[31,216]

Complications of meningitis include subdural empyemas or fluid collections (Figs. 45.57 and 45.58), cerebritis, abscess formation, and venous sinus thrombosis. Infarctions can occur from either arterial vasculitis or venous obstruction, as a result of venous sinus thrombosis. Sonography can identify these complications but is not specific. Areas of increased or decreased echogenicity of brain parenchyma or sulci may represent edema, cerebritis, or evolving infarction (Fig. 45.59).

Ventriculitis, another complication of meningitis seen in 60% to 95% of cases, is suggested by the sonographic findings of hydrocephalus, echogenic debris within the ventricles, increased echogenicity, or a shaggy ependymal lining or fibrous septa within the ventricles (Fig. 45.60). Ultrasound is best for identifying intraventricular septa formation compared with CT or MRI. These septations can result in shunt failure or allow bacteria to escape antibiotic exposure. MRI and CT with enhancement are more sensitive for localizing the complications of infection, such as infarcts, venous sinus thrombosis, and extraaxial fluid collections.

INTRACRANIAL MASSES

Brain Tumors

In only 11% of children are brain neoplasms seen before 2 years of age. Tumors that do occur before the age of 2 years are usually congenital and may appear on prenatal ultrasound as polyhydramnios.[220] Tumors can be difficult to diagnosis in the neonate. If the neoplasm causes hydrocephalus, signs and symptoms of increased intracranial pressure, such as enlarging head size, vomiting, or behavioral alteration, it may be recognized. More specific signs and symptoms depend on the location of the tumor, such as cranial nerve findings or pituitary gland and hypothalamic dysfunctions. In general, MRI is the imaging modality of choice in these infants. However, with nonspecific signs and symptoms, including an enlarging head from hydrocephalus, ultrasound may be the first imaging procedure performed. Sonography can delineate the tumor site and size and evaluate cystic and solid components.

Tumors may manifest initially because of hemorrhage into the tumor. In fact, because hemorrhage is so much more common than tumor in newborns, it may be extremely difficult to differentiate a simple hematoma from a tumor; both can be quite echogenic. Any hemorrhage present in unusual circumstances or in an unusual location should be investigated by contrast-enhanced CT or MRI, searching for an occult tumor.[7] For unusual hemorrhage, follow-up scans are also helpful because clotting

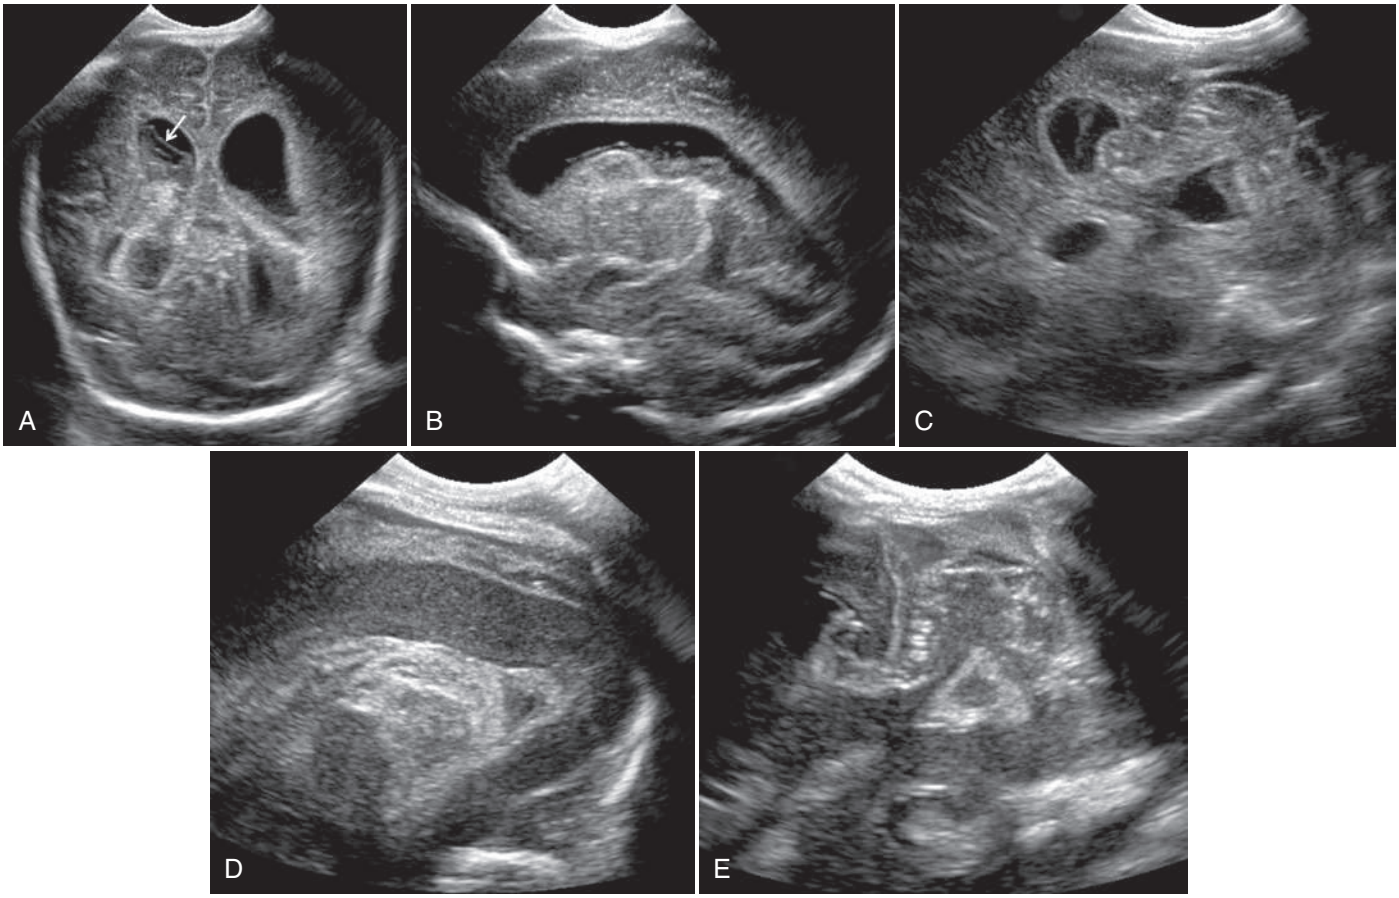

FIG. 45.57 Ventriculitis: *Escherichia Coli* Meningitis and *Chlamydia* Chorioamnionitis. (A)-(C) *E. coli* meningitis–affected infant with echogenic ventricular walls and intraventricular septations *(arrow).* **(D)** and **(E)** Thick, echogenic walls of the lateral ventricle and fourth ventricle in an infant of a mother with chlamydia, causing severe chorioamnionitis; at the time of cesarean section the uterus contained copious amounts of purulent fluid. Note echogenic material in the extraaxial space as well.

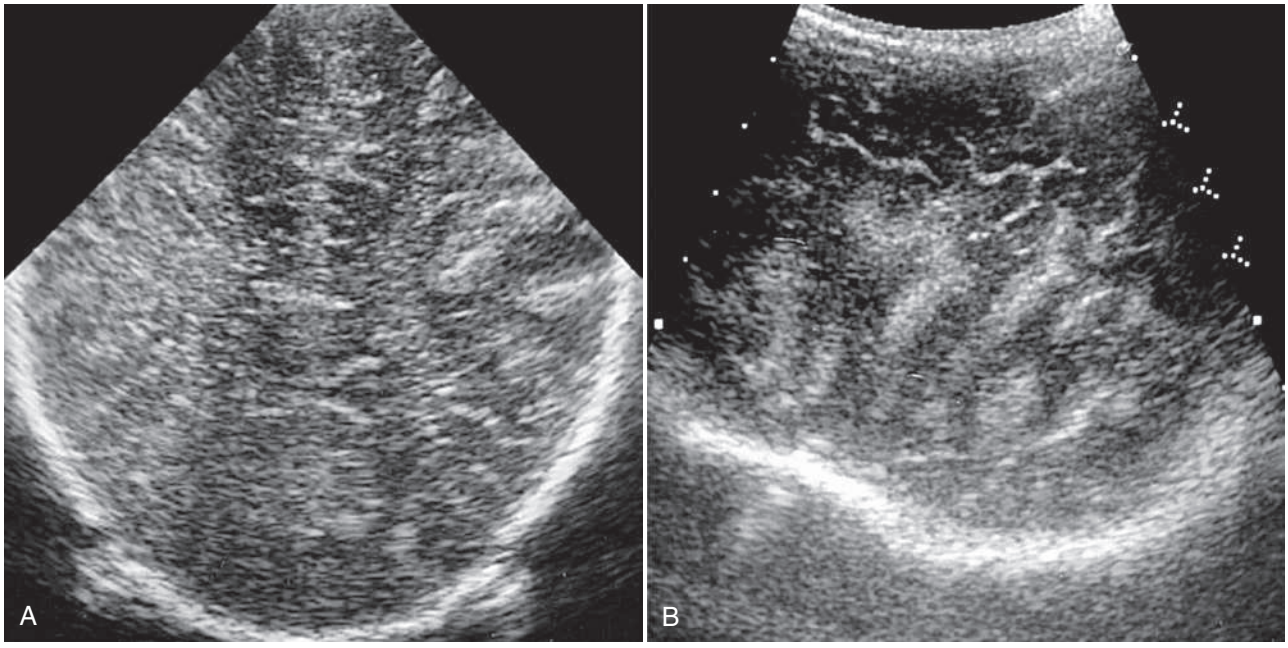

FIG. 45.58 Group B Streptococcal Meningitis. (A) and **(B)** Coronal and sagittal sonograms show diffusely echogenic sulci that appear thicker than normal.

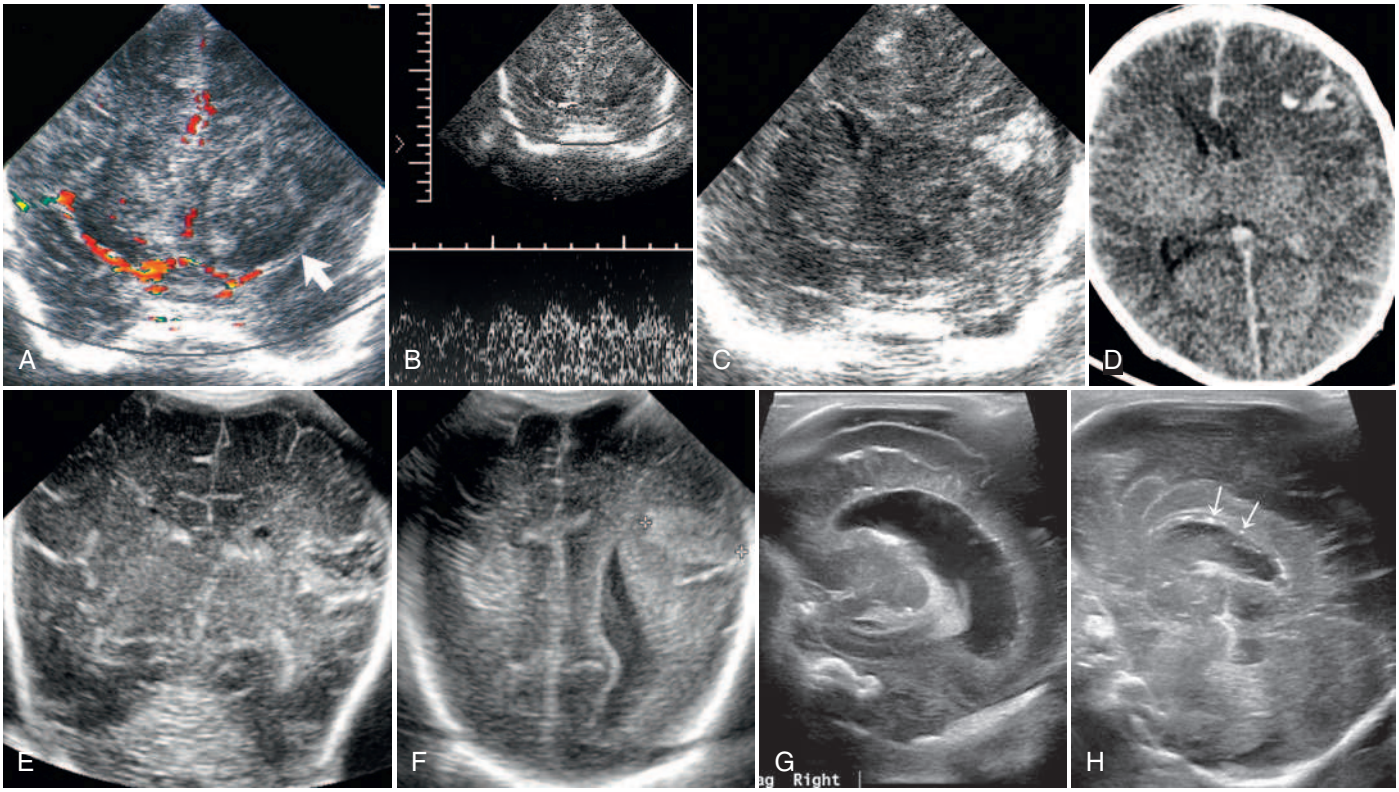

FIG. 45.59 Infections. (A)-(D) Group B streptococcal meningitis with focal infarction. (A) Coronal sonogram with color Doppler shows lack of flow in the left middle cerebral artery (MCA; *arrow*); gray-scale imaging alone showed symmetrical, increased echogenicity. **(B)** Pulsed Doppler image in the right MCA (opposite side) shows greatly increased diastolic flow. **(C)** Coronal sonogram and **(D)** computed tomography scan later show hemorrhage into an infarction with midline shift from left to right. **(E)** and **(F)** Coronal anterior and posterior sonograms show left MCA focal echogenic infarct *(calipers)*, cause unknown, in another premature infant at 2 weeks after birth. **(G)** and **(H)** Sagittal sonogram in fetus with unknown infection, but the pattern of calcification at gray-white junction suggests Zika. Note also the calcifications in the corpus callosum *(arrows)*. (**G** and **H** courtesy of I. Castro-Aragon, MD, Boston.)

from the hemorrhage will resolve over time, allowing the tumor to be visualized.

Spectral and color Doppler imaging can identify vascular components of the tumor. Follow-up with MRI is then performed to evaluate the full extent of the neoplasm, assist with differential diagnosis, and evaluate for therapeutic approaches. Differentiating the histologic type of the neoplasm is not possible, but localizing the tumor usually allows a differential diagnosis.

Tumor location in infants younger than 1 year differs from that in older children and differs by series.[31,221-223] **Supratentorial neoplasms** are more common than infratentorial tumors by approximately 2.5:1. **Teratomas** are the most frequent neoplasms reported in the first year of life. **Astrocytomas** (astrocytic gliomas) are second in most series, usually arising from the optic chiasm and nerves or the hypothalamus (Figs. 45.61 and 45.62). Other neoplasms include **atypical teratomas or rhabdoid tumors** (rather than medulloblastomas), **primitive neuroectodermal tumors** (PNETs), **ependymomas,**[224] and **choroid plexus papillomas** (Fig. 45.63). Sporadic cases of oligodendroglioma, hemangioblastoma, hemangioma, dermoid cyst, lipoma, primary neuroblastoma, teratoma, and meningioma have been reported.[224] A few cases of diffuse neonatal hemangiomatosis have been reported, with numerous hemangiomas of the brain, skin, spinal cord, liver, and heart. Although these may cause congestive heart failure, the greatest risk is bleeding into the lesions and possible disseminated intravascular coagulopathy. These infants do not usually live long enough for steroid therapy to cause involution of the lesions, which typically helps in neonatal hemangiomas.[225]

Common Brain Tumors in First Year of Life

Teratoma
Suprasellar astrocytoma (hypothalamic)
Teratoma or rhabdoid tumor
Ependymoma
Choroid plexus tumor

Cystic Intracranial Lesions

Cystic intracranial lesions are quite common, and ultrasound is the best method for evaluating such lesions (short of surgical proof). Fortunately, most cystic masses of the brain are

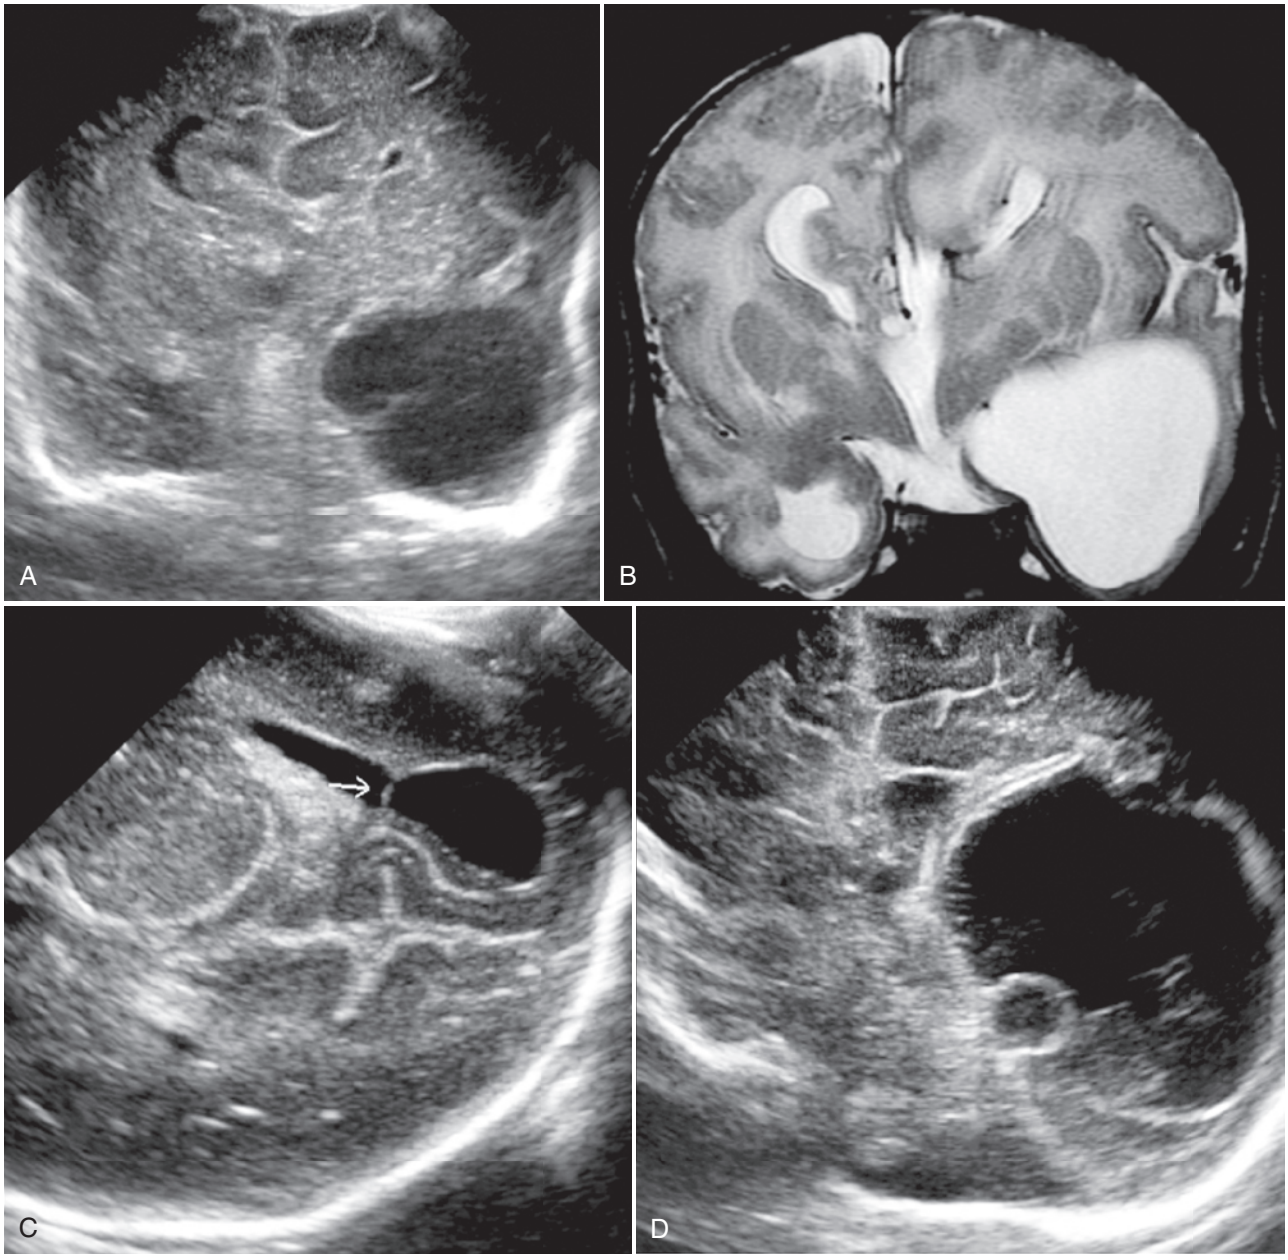

FIG. 45.60 Antenatal Infection: Ventriculitis. (A-D) Term infant with diffusely echogenic cerebral cortex and hydrocephalus. **(C)** Septations *(arrow)* have isolated the left temporal horn into a cystic mass, in addition to absence of the corpus callosum and vermian hypoplasia.

benign.[31,39,40,226,227] First, it is important to recognize the **normal cystic structures** and the variants discussed earlier under Developmental Anatomy, including the cavum septi pellucidi and vergae, cavum veli interpositi, frontal horn cysts, and cisterna magna (Table 45.3). Second, a normal variant, a large cisterna magna or **mega–cisterna magna,** is not a true cyst (see Fig. 45.27).

Arachnoid Cysts

Arachnoid cysts are the most common true cysts of the brain but make up only 1% of all space-occupying lesions in children.[31] Arachnoid cysts are CSF-containing spaces between two layers of arachnoid membrane. Primary and secondary cysts are believed to develop by different mechanisms. Primary cysts are believed to result from abnormal splitting of the arachnoid and from CSF collecting between the two layers. Secondary arachnoid cysts may develop when CSF is trapped between arachnoid adhesions. Arachnoid cysts, particularly those in the midline, may grow and cause obstruction of the ventricular system.[31] These midline arachnoid cysts most often manifest with hydrocephalus in infancy. The ultrasound appearance of an arachnoid cyst is an anechoic area with discrete walls. Midline arachnoid cysts are

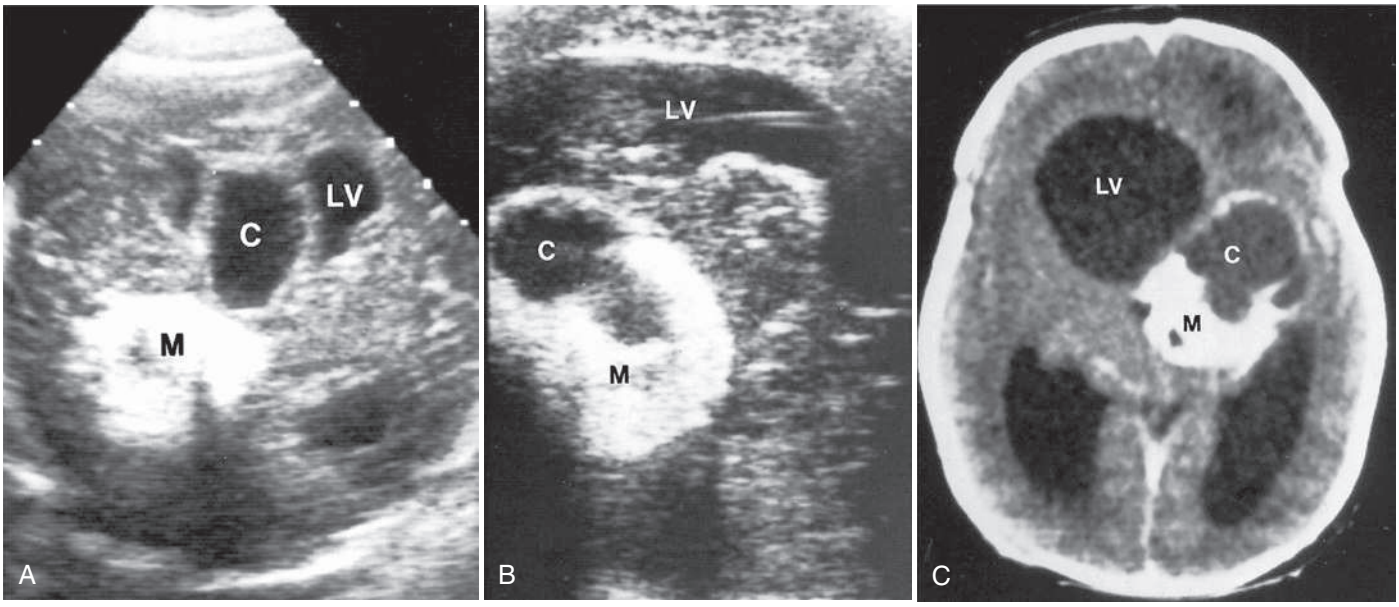

FIG. 45.61 Astrocytic Glioma (Astrocytoma). (A) and **(B)** Coronal and sagittal scans show echogenic mass *(M)* with cystic component *(C)* extending superiorly between lateral ventricles *(LV)*. **(C)** Axial enhanced computed tomography scan. (Courtesy of T. Stoeker, MD, Roanoke, VA.)

TABLE 45.3 Cystic Brain Lesions

Category	Specific Lesions
Normal variants	Frontal horn cysts (connatal cysts, coarctation of the lateral ventricle)
	Choroid plexus cysts
Congenital	Primary arachnoid cyst
	Dandy-Walker malformation
	Hydranencephaly
	Holoprosencephaly
Periventricular	Periventricular leukomalacia
	Subependymal cyst
	Porencephalic cyst
Neoplastic	Cerebellar astrocytoma (cystic type)
	Craniopharyngioma
	Teratoma
Inflammatory	Abscess
	Subdural empyema
Other	Secondary arachnoid cysts
	Vein of Galen malformation

Sites of Arachnoid Cysts

Anterior portions of middle cranial fossa
Suprasellar region
Posterior fossa
Quadrigeminal region
Cerebral convexities
Interhemispheric fissure

[a]In decreasing order of frequency.

frequently associated with other brain anomalies. With agenesis of the corpus callosum, midline cysts are frequently continuous with an elevated third ventricle. In alobar holoprosencephaly, a dorsal cyst may be continuous with the single central ventricle.

Porencephalic Cysts

Porencephalic cysts are a result of brain necrosis and cavitation, which is continuous with the ventricular system (see Fig. 45.44). These lesions are usually caused by brain parenchymal hemorrhage, infection, or surgery.[7]

Choroid Plexus Cysts

Choroid plexus cysts are common and usually asymptomatic. Choroid cysts occur in all age groups and are found in 34% of fetuses and infants at autopsy. However, prenatal and neonatal ultrasound reports have identified choroid cysts in only approximately 1% of the populations studied. Choroid plexus cysts tend to be single and occur as an isolated finding. However, large (>10 mm) and multiple choroid cysts are occasionally associated with chromosomal anomalies, particularly trisomy 18,[2] trisomy 21, and Aicardi syndrome.[228] Many other anomalies are typically present in these newborns.

A choroid plexus cyst appears as a cyst with well-defined walls within the choroid plexus (Fig. 45.64). Choroid cysts vary in size from less than 4 mm to over 1 cm and are usually unilateral, left greater than right, and situated in the dorsal aspect of the choroid plexus. Rare cases of symptomatic choroid cysts causing obstructive hydrocephalus have been reported but are probably related to some specific cause rather than a normal variant.[228] Occasional choroid cysts develop after choroid plexus hemorrhage into the ventricle. Color Doppler is helpful to distinguish vessels in the choroid from cysts.

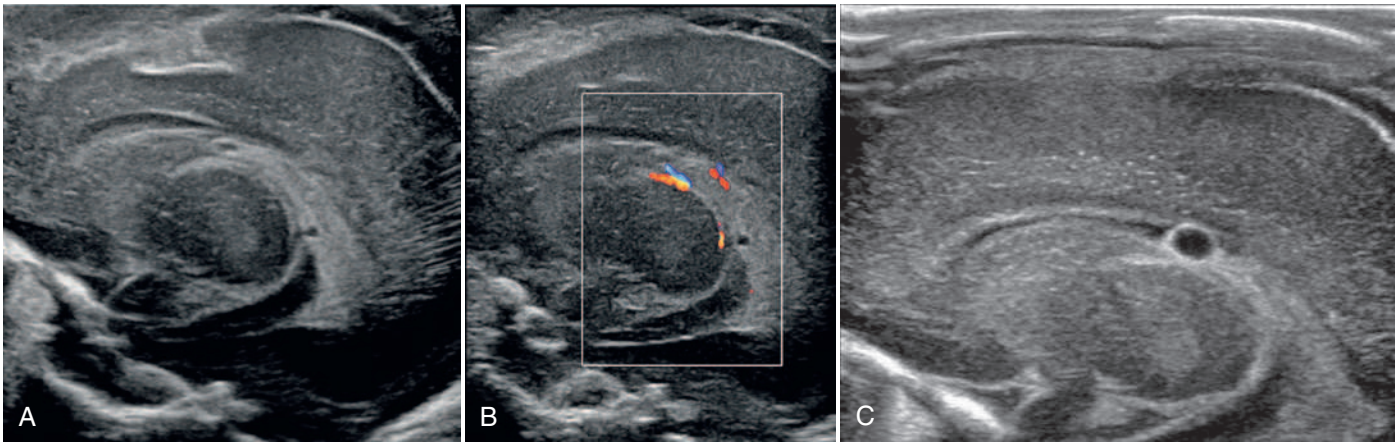

FIG. 45.64 Choroid Plexus Cysts. (A)-(C) Sagittal sonograms show varying sizes of cysts. Normal vascularity of the choroid plexus and avascularity of the cyst are demonstrated.

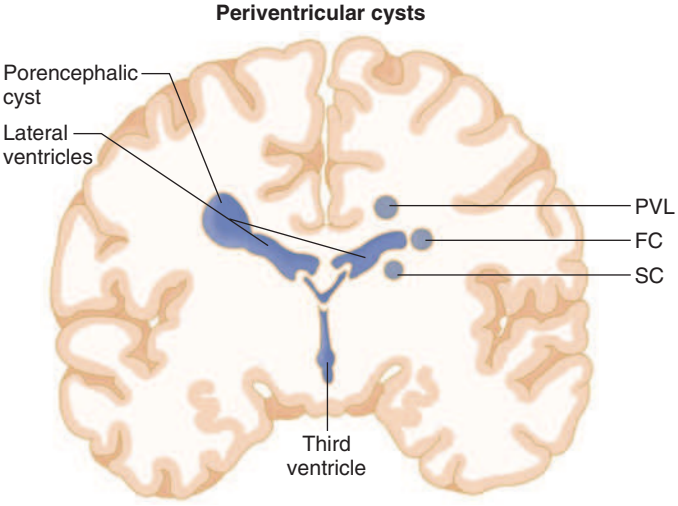

FIG. 45.65 Periventricular Cysts. These cysts include the normal-variant frontal horn cyst *(FC),* the subependymal cyst *(SC),* cystic periventricular leukomalacia *(PVL),* and porencephalic cysts that communicate directly with the ventricle, caused by intraparenchymal hemorrhage or infection (cerebritis).

Supratentorial Periventricular Cystic Lesions

Many periventricular cysts are found in and around the normal ventricles (Fig. 45.65).

Frontal Horn Cysts

The frontal horn cysts that are attached directly lateral to the frontal horn have also been called **coarctation of the lateral ventricles** and **connatal cysts**[40] (see Fig. 45.14A). Although these frontal horn cysts were previously thought to be postischemic, it is now believed that they form as a normal variant anterior to the foramen of Monro. The ventricle seems to have folded on itself, causing the wall to lie against the frontal horn.

Subependymal Cysts

Subependymal cysts are discrete cysts in the lining of the ventricles (Fig. 45.66). These cysts most often result from the sequelae of GMH in premature infants.[229] Other causes include infection, including CMV and rubella, and the rare **cerebrohepatorenal (Zellweger) syndrome.**[61,84] Subependymal cysts can also be an isolated finding with no apparent predisposing event. Cocaine exposure has been reported to increase the incidence of subependymal cysts in premature infants.[230]

Periventricular Leukomalacia

Periventricular cysts also result from PVL (see Fig. 45.50). These cysts develop lateral to and above the entire lateral ventricle, typically above the frontal horn and body of the ventricle.

Galenic Venous Malformations

Galenic venous malformations are frequently referred to as "vein of Galen aneurysms," but this is a misnomer because these are not true aneurysms. These abnormalities actually represent dilation of the vein of Galen caused by a vascular malformation that is fed by large arteries off the anterior or posterior cerebral artery circulation.[231] Infants with large shunts usually are presented in the first month of life with **congestive heart failure.** In later childhood, smaller shunts manifest with seizure, cranial bruit, hydrocephalus, and cardiomegaly.

Sonographically, a galenic venous malformation appears as an anechoic cystic mass between the lateral ventricles (Fig. 45.67). It lies posterior to the foramen of Monro, superior to the third ventricle, and primarily in the midline. These malformations are differentiated from other cystic masses by identification of a large feeding vessel. Spectral or color Doppler sonography can be used to identify blood flow filling the mass, thus confirming the diagnosis. Hydrocephalus may or may not be present. Calcification may occur, especially if there is thrombosis in the malformation.[232] MRI and magnetic resonance angiography may be valuable in planning treatment.[233,234]

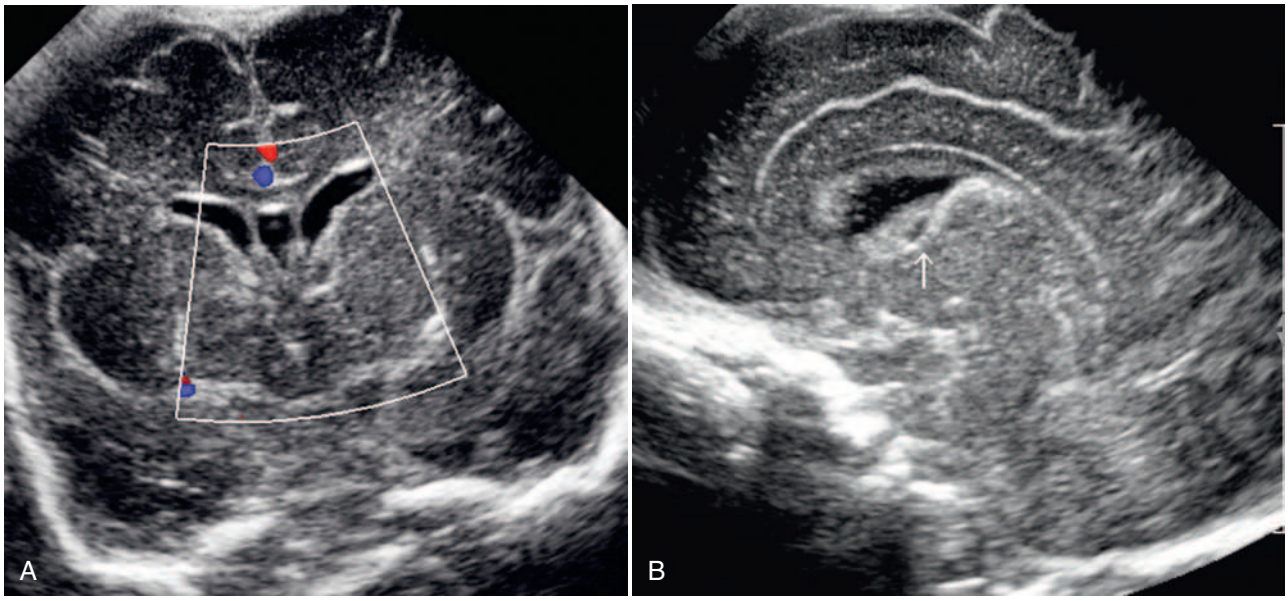

FIG. 45.66 Subependymal Cyst. (A) and **(B)** Coronal and midline sagittal sonograms show cyst *(arrow),* which formed after cytomegalovirus antenatal infection in the region of the caudothalamic notch, where we typically expect to see germinal matrix hemorrhage. The cyst was present at birth.

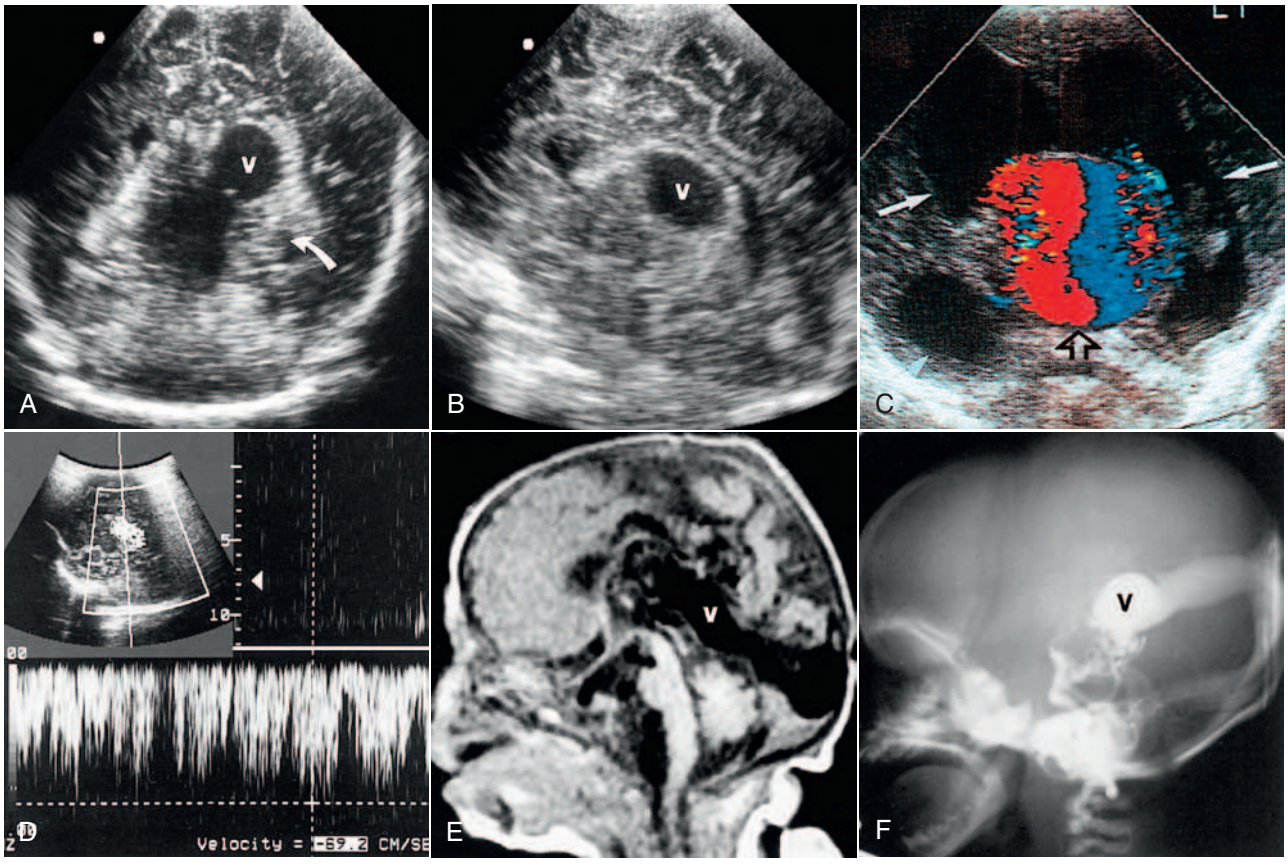

FIG. 45.67 Vein of Galen Malformation. (A) and **(B)** Coronal and sagittal sonograms show enlarged vein of Galen *(V)* and straight sinus. Echogenic arterial feeding vessels below and anterior to dilated vein of Galen *(curved arrow).* **(C)** and **(D)** Color Doppler and duplex Doppler ultrasound scans show turbulent flow, which clearly defines this cystic-appearing mass as vascular. **(E)** Sagittal magnetic resonance scan and **(F)** angiogram, in a different patient, show that the echogenic region is a tortuous tangle of abnormal feeding vessels; cystic mass is dilated vein of Galen *(V).*

CHAPTER

46 Duplex Sonography of the Neonatal and Infant Brain

Thierry A.G.M. Huisman and Andrea Poretti

SUMMARY OF KEY POINTS

- Duplex sonography is a valuable, functional addition to anatomic sonography of the pediatric brain.
- Various quantitative metrics can be extracted from the flow curves, including peak systolic, end-diastolic flow velocity, time average maximum mean blood flow velocity, and resistive index.
- The quantitative markers may be influenced or altered by mechanical ventilation, patent ductus arteriosus, extracorporeal membrane oxygenation (ECMO), arteriovenous shunting, and pathologies that are affected by cerebral hemodynamic autoregulation.
- In hypoxic ischemic injury and general brain edema, the resistive index values typically drop to low values.
- Duplex sonography may help to identify and explore arterial and venous malformations such as the vein of Galen aneurysmal malformation.

Dural Venous Sinus Thrombosis
UNCOMMON VASCULAR APPLICATIONS
PITFALLS OF DUPLEX SONOGRAPHY

Continuous and pulsed echo technique, or **duplex sonography** in which gray-scale tissue imaging is combined with blood flow sampling, has been in use for the past decades in the evaluation of normal and abnormal neonatal intracranial hemodynamics.[1-3] In addition, **color Doppler sonography** renders valuable information about the direction of the blood flow in relation to the transducer. This technique allows better understanding of altered intracranial flow or exploring the complex angioarchitecture of vascular malformations. Continuing improvements in transducer design and sensitivity allow routine imaging of the intracranial vasculature in newborns and young infants, including the identification of flow in submillimeter arteries (e.g., lenticulostriate arteries) and patency of dural venous sinuses (e.g., superior and inferior sagittal sinus) of the brain.[4] The wide dynamic range and high sensitivity of **power Doppler sonography,** in which blood flow is represented as various shades of a single color (amplitude-coded color or color flow Doppler energy), is especially helpful to depict low-velocity and low-amplitude blood flow. Power Doppler sonography, however, lacks information about flow direction. Furthermore, analysis of the sampled **flow spectra/curves** and postprocessing software programs offer extraction of objective semiquantitative data (e.g., **peak systolic velocity** [PSV], **end-diastolic flow velocity** [EDV], **resistive index** [RI], and **time-averaged mean blood flow velocity** [TAV]). These semiquantitative data can be collected serially, giving valuable real-time information about progression of disease or recovery. Analysis of the shape of the spectral pattern with delayed systolic flow acceleration, flattened systolic upstroke, slow diastolic deceleration, or reversal of flow during diastole may provide important information about the cerebral hemodynamics. This chapter describes how brain ultrasonography combining multiplanar, multiapproach anatomic and functional/hemodynamic

data has become an invaluable noninvasive bedside imaging modality supporting diagnosis, monitoring, guidance of treatment options, and estimation of prognosis for neonates with a wide variety of neurologic diseases.

SONOGRAPHIC TECHNIQUE

Approaches

Three different scanning approaches to the neonatal brain have worked well, each with its own advantages and limitations.[5-9] The **anterior fontanelle approach** is the most common and easiest to use. The basilar, internal carotid, and anterior cerebral arteries, as well as the internal cerebral veins, vein of Galen, and superior sagittal, inferior, and straight sinus, can be routinely sampled on **midsagittal scans** (Fig. 46.1A-B). The smaller thalamostriate arteries and opercular branches of the middle cerebral artery (MCA) may be seen on angled parasagittal images.

On **coronal scans** through the anterior fontanelle, the supraclinoid internal carotid arteries, M1 segments of the MCAs, thalamostriate arteries, A1 segments of the anterior cerebral arteries, and the cavernous sinus can almost always be visualized on anteriorly angled scans (see Fig. 46.1C). Paired terminal, caudothalamic/thalamostriate, and internal cerebral veins, the basilar artery, straight sinus, and transverse sinuses can be seen on more posteriorly angled scans. A major drawback of the coronal plane is the near perpendicular angle between the MCA and the ultrasound beam, such that measured frequency shifts from flowing red blood cells approach zero, making the MCA appear to have no flow.

The **temporal bone approach** is best for the MCA. The transducer is placed in axial orientation approximately 1 cm anterior and superior to the helix of the ear. Using the thin temporal bone as an acoustic window, adequate penetration for imaging and Doppler studies can be achieved in most full-term neonates. This approach allows visualization of the major branches of the circle of Willis (see Fig. 46.1D). In most premature infants, both MCAs can be easily insonated from one side of the head.

The **mastoid fontanelle approach** is an angled axial scan. This acoustic window is located approximately 1 cm behind and superior to the helix of the ear at the junction of the posterior parietal, temporal, and occipital bones. It is the preferred approach for imaging flow in the transverse dural sinuses, and the torcular Herophili in selected patients (see Fig. 46.1E).

Dedicated images of the posterior fossa circulation may be obtained using the **foramen magnum approach or suboccipital approach** (see Fig. 46.1F). The neonate is placed in lateral recumbent position with the head gently flexed. The transducer is placed in the midline, just inferior to the occipital protuberance, and angled cephalad in either sagittal or axial orientation. Alternatively, the **posterior fontanelle** (see Fig. 46.1G) at the junction between the lambdoid and sagittal suture can be used as an acoustic window. The posterior fossa arterial and venous vasculature can be depicted in most children.

Finally, a **transorbital approach** (see Fig. 46.1H) may be selected to evaluate the ophthalmic artery and the internal carotid siphon. Typically, the transducer is positioned over the closed eyelid and angled slightly medially and upward toward the region of the orbital apex/optic nerve canal.

Doppler Optimization

- Acoustic window should match sampled vessel.
- Electronically magnify image.
- Restrict color region of interest to enhance color sensitivity and frame rate.
- Adjust color gain to maximize vascular signal and minimize aliasing and tissue artifact.
- Use lowest bandpass filter to maximize low-flow sensitivity and evaluate venous structures.
- Use 7- to 15-MHz linear transducer for superior sagittal sinus.
- Use power-mode Doppler for smallest vessels when flow direction is not needed.
- Insonication angle for spectral data collection should be less than 60 degrees.
- Sample volume box should be centered to vessel lumen, avoiding sharp curves of vessel.

Doppler Optimization

For the best visualization of the intracranial vascular system, the image should be electronically magnified and the color region of interest restricted to enhance color sensitivity and frame rate. Color gain should be carefully adjusted and balanced to maximize vascular signal, limit flow aliasing, and minimize tissue motion artifacts, and the lowest bandpass filter should be used to maximize low-flow sensitivity necessary for evaluating venous structures. A 7- to 15-MHz linear transducer is recommended for examining the superficially located superior sagittal sinus. Visualization of the smaller arterial branches of the middle and anterior cerebral arteries can also be accomplished in the majority of normal premature and full-term infants but often requires a higher frequency (7 or 10 MHz) vector or sector transducers capable of detecting lower velocity and amplitude signal. The use of power Doppler sonography is recommended when directional information is of secondary importance and detection of flow is primary.

For specific vessel evaluation, spectral Doppler imaging can be performed using 3.5- to 15-MHz probes, depending on the depth and location of the target vessel. To ensure reliable and reproducible quantitative hemodynamic metrics, care should be given to maintain an angle of insonication of less than 60 degrees while sampling the intravascular flow. Furthermore, comparison of serial data requires a standardized, uniform angle of insonication of the same vessel during subsequent studies. In addition, factors that may alter the diameter of the sampled vessels should be taken into account, such as acute changes in systemic blood pressure, $Paco_2$, Pao_2, and hematocrit.

Safety Considerations

During pulsed wave and color flow Doppler examinations, signal is obtained by imparting energy into tissues. Although intracranial Doppler ultrasound is safe, biologic effects may be identified in

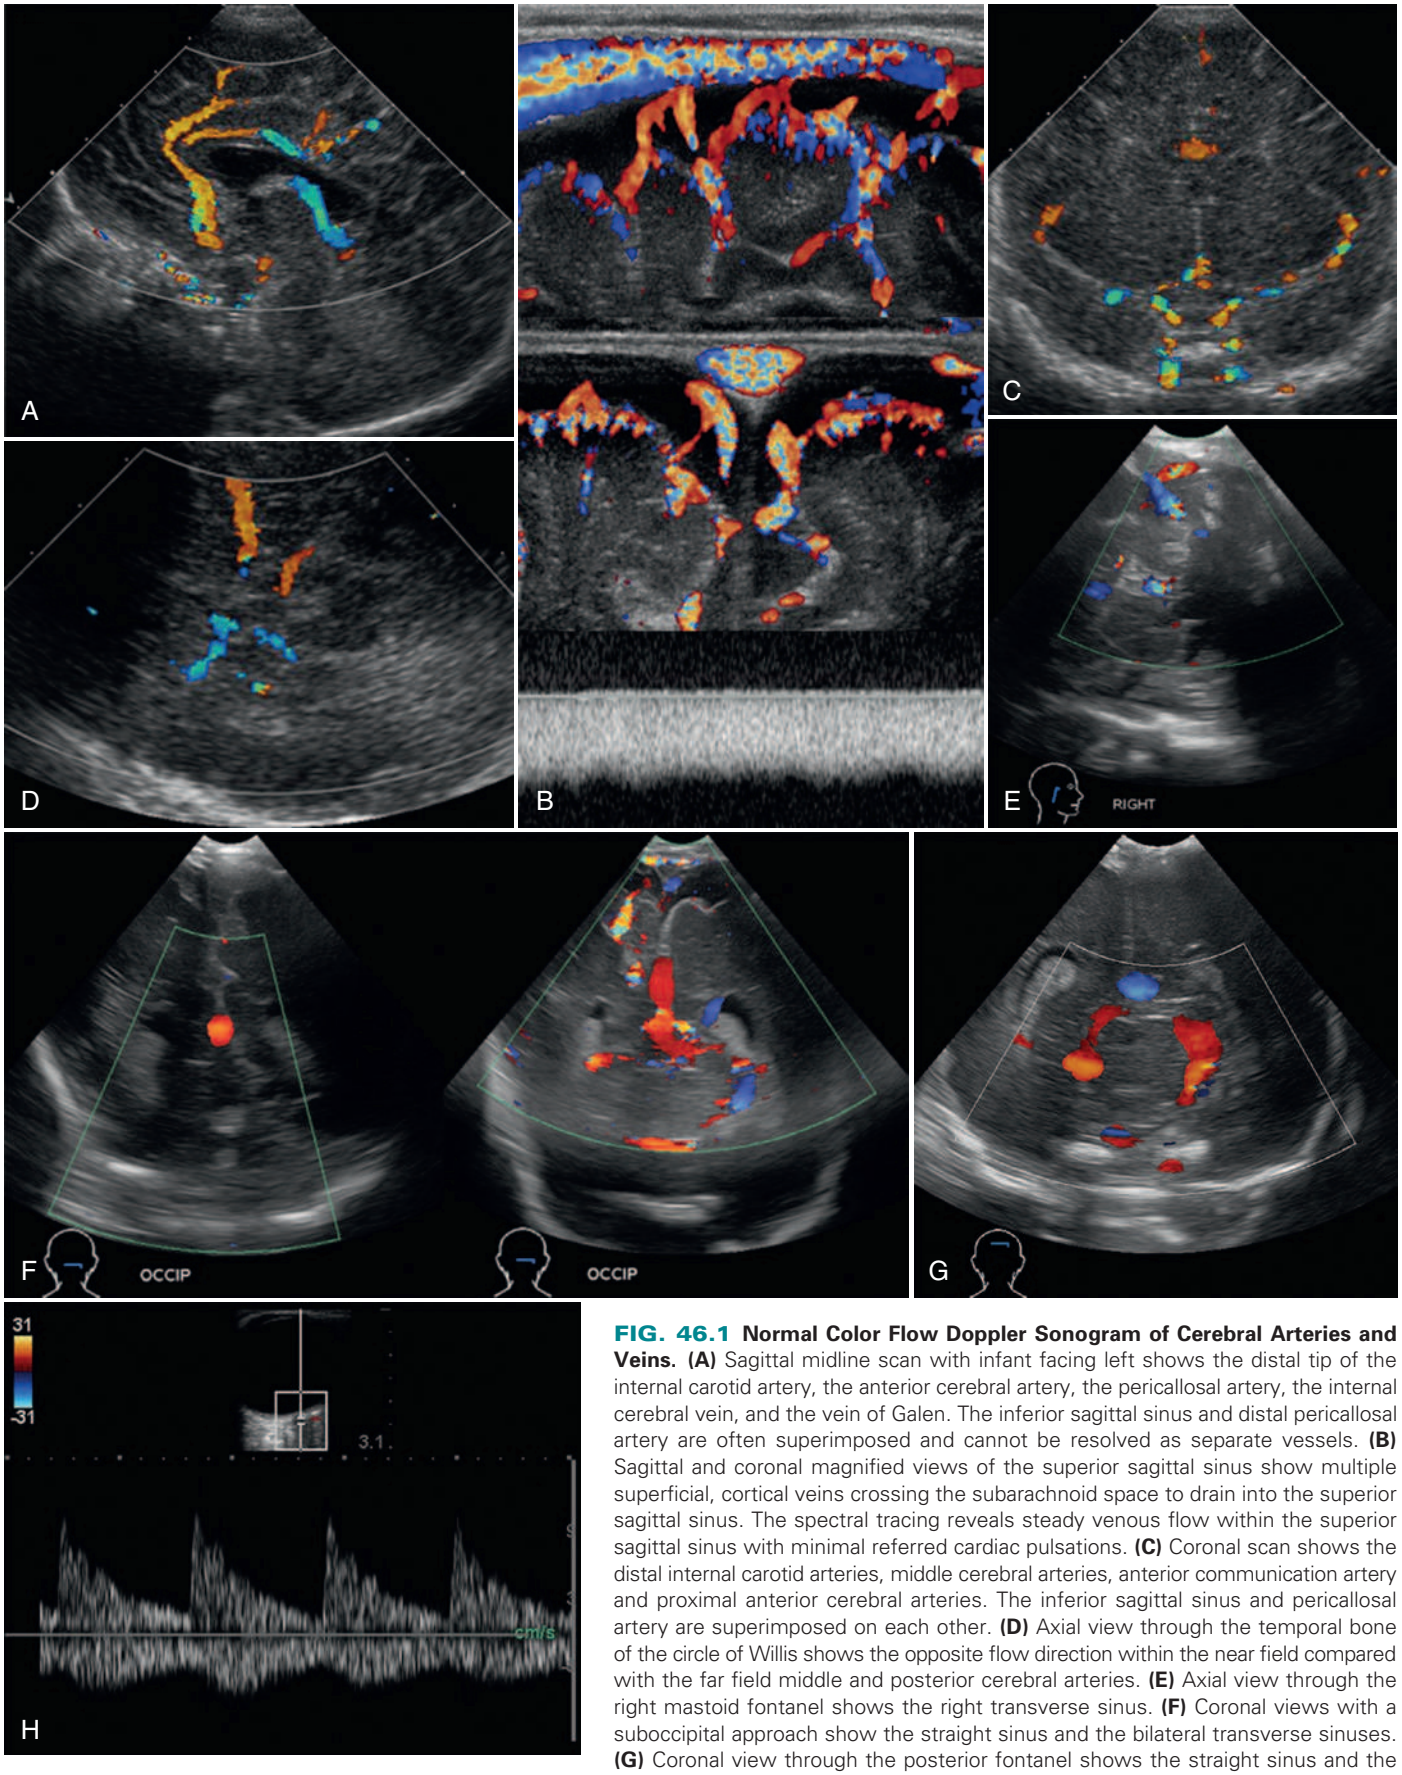

FIG. 46.1 Normal Color Flow Doppler Sonogram of Cerebral Arteries and Veins. **(A)** Sagittal midline scan with infant facing left shows the distal tip of the internal carotid artery, the anterior cerebral artery, the pericallosal artery, the internal cerebral vein, and the vein of Galen. The inferior sagittal sinus and distal pericallosal artery are often superimposed and cannot be resolved as separate vessels. **(B)** Sagittal and coronal magnified views of the superior sagittal sinus show multiple superficial, cortical veins crossing the subarachnoid space to drain into the superior sagittal sinus. The spectral tracing reveals steady venous flow within the superior sagittal sinus with minimal referred cardiac pulsations. **(C)** Coronal scan shows the distal internal carotid arteries, middle cerebral arteries, anterior communication artery and proximal anterior cerebral arteries. The inferior sagittal sinus and pericallosal artery are superimposed on each other. **(D)** Axial view through the temporal bone of the circle of Willis shows the opposite flow direction within the near field compared with the far field middle and posterior cerebral arteries. **(E)** Axial view through the right mastoid fontanel shows the right transverse sinus. **(F)** Coronal views with a suboccipital approach show the straight sinus and the bilateral transverse sinuses. **(G)** Coronal view through the posterior fontanel shows the straight sinus and the bilateral transverse sinuses. **(H)** Normal Doppler waveform produced by the central retinal artery and the central retinal vein (**H** courtesy of Dr. Rebecca Riggs, The Johns Hopkins Hospital, Baltimore, MD).

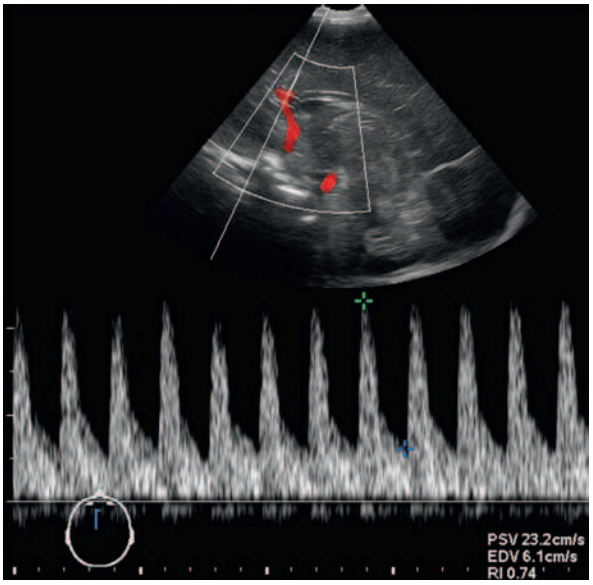

FIG. 46.2 Determination of Peak Systolic Flow Velocity (PSV), End-Diastolic Flow Velocity (EDV) and Resistive Index (RI) Within an Arterial Branch of the Anterior Arterial Circulation. The RI can be derived by placing the Doppler cursor at PSV *(green cross),* and at EDV, or minimum velocity *(blue cross).* The RI is calculated as (PSV – EDV)/PSV.

the future. Thus Doppler exposure should be time limited, and the signal intensity should be maximized by increasing gain and not transducer power output settings. The ALARA principle (as low as reasonably achievable) should be followed to limit energy exposure to tissues.

Doppler Measurements and Factors That Change Resistive Index

The **peak systolic velocity, end-diastolic flow velocity, resistive index,** and **time-averaged mean flow velocity** (TAV) are the most commonly used semiquantitative spectral Doppler measures for monitoring intracranial hemodynamics (Fig. 46.2).

One should, however, be aware of the various factors that may modify the measured or calculated RI values, which include both technical causes and patient comorbidities outside of the brain[10-12] (Fig. 46.3, Table 46.1).

With **increasing filter settings,** lower velocities are not depicted, resulting in a falsely elevated RI. **Transducer pressure** on the anterior fontanelle may transiently increase intracranial pressure (ICP), which in turn preferentially reduces flow during diastole and increases RI, especially in neonates with impaired cerebral autoregulation (e.g., secondary to hypoxic ischemic injury [HII]). In infants with symptomatic **patent ductus arteriosus,** resistance to flow in the cerebrovascular bed is higher than pulmonary vascular resistance. This results in shunting of blood away from the brain during diastole and an elevated intracranial RI. During **tachycardia,** the arterial pressure wave has less time to dissipate before another systolic ejection occurs. Intracranial RI is artificially lower because diastolic velocities are measured at middiastole, when velocities are higher, rather than during end diastole. **Left ventricular dysfunction** (decreased cardiac output) results in a decreased systolic pressure wave, lowered systolic velocities, and a reduced RI.

TABLE 46.1 Factors That Change Resistive Index (RI)

Factor	Effect on RI
High-pass filter settings	Increased
Transducer scanning pressure	Increased
Patent ductus arteriosus	Increased
Elevated heart rate	Decreased
Decreased cardiac output	Decreased

The RI is only a weak predictor of cerebrovascular resistance under most physiologic conditions. Mean blood flow velocity measures are the most informative indices of **cerebral blood flow** (CBF). Although accurate placement of the sample volume and angle of insonation are required, a strong correlation has been demonstrated between mean blood flow velocity and changes in global CBF under a variety of clinical and experimental conditions.[13-16]

NORMAL HEMODYNAMICS

Normal Arterial Blood Flow Patterns

Arterial hemodynamics in the cerebral circulation are affected by normal maturational events in the healthy newborn. The RI in the **anterior cerebral artery** decreases from a mean of 0.78 (range, 0.5-1.0) in **preterm infants** to a mean of 0.71 (range, 0.6-0.8) in full-term newborns.[2,3,17-19] This trend is associated with increasing diastolic flow velocities and may be related to peripheral changes in cerebrovascular resistance or to changes proximal to the site of recording, such as a closing ductus arteriosus and a diminishing left-to-right shunt. In **full-term infants,** RI may also change over the first few days of life.[2] In a study of 476 normal newborns weighing over 2500 g at birth, anterior cerebral artery RI decreased from a mean of 70.6 ± 7 (range, 51-87) to 68.3 ± 6 (range, 51-83) within the first 24 hours.[20]

Table 46.2 provides the range of published peak systolic and end diastolic velocities and RI values in several intracranial arteries. Although the range of normal values is broad, no great variability should be seen in the individual patient. Changes of more than 50% from baseline values should be considered abnormal. There are no consistent differences in instantaneous blood flow velocity among the major branches of the circle of Willis or between right-sided and left-sided structures. The measured blood flow velocities may, however, vary with pressure applied to the anterior fontanel. In healthy preterm and term neonates a tendency toward higher RI values can be observed with anterior fontanel compression, and a statistically significant increase in RI values may be observed in children with presumed impaired autoregulation of brain perfusion caused by hydrocephalus or brain edema related to HII.[11,21]

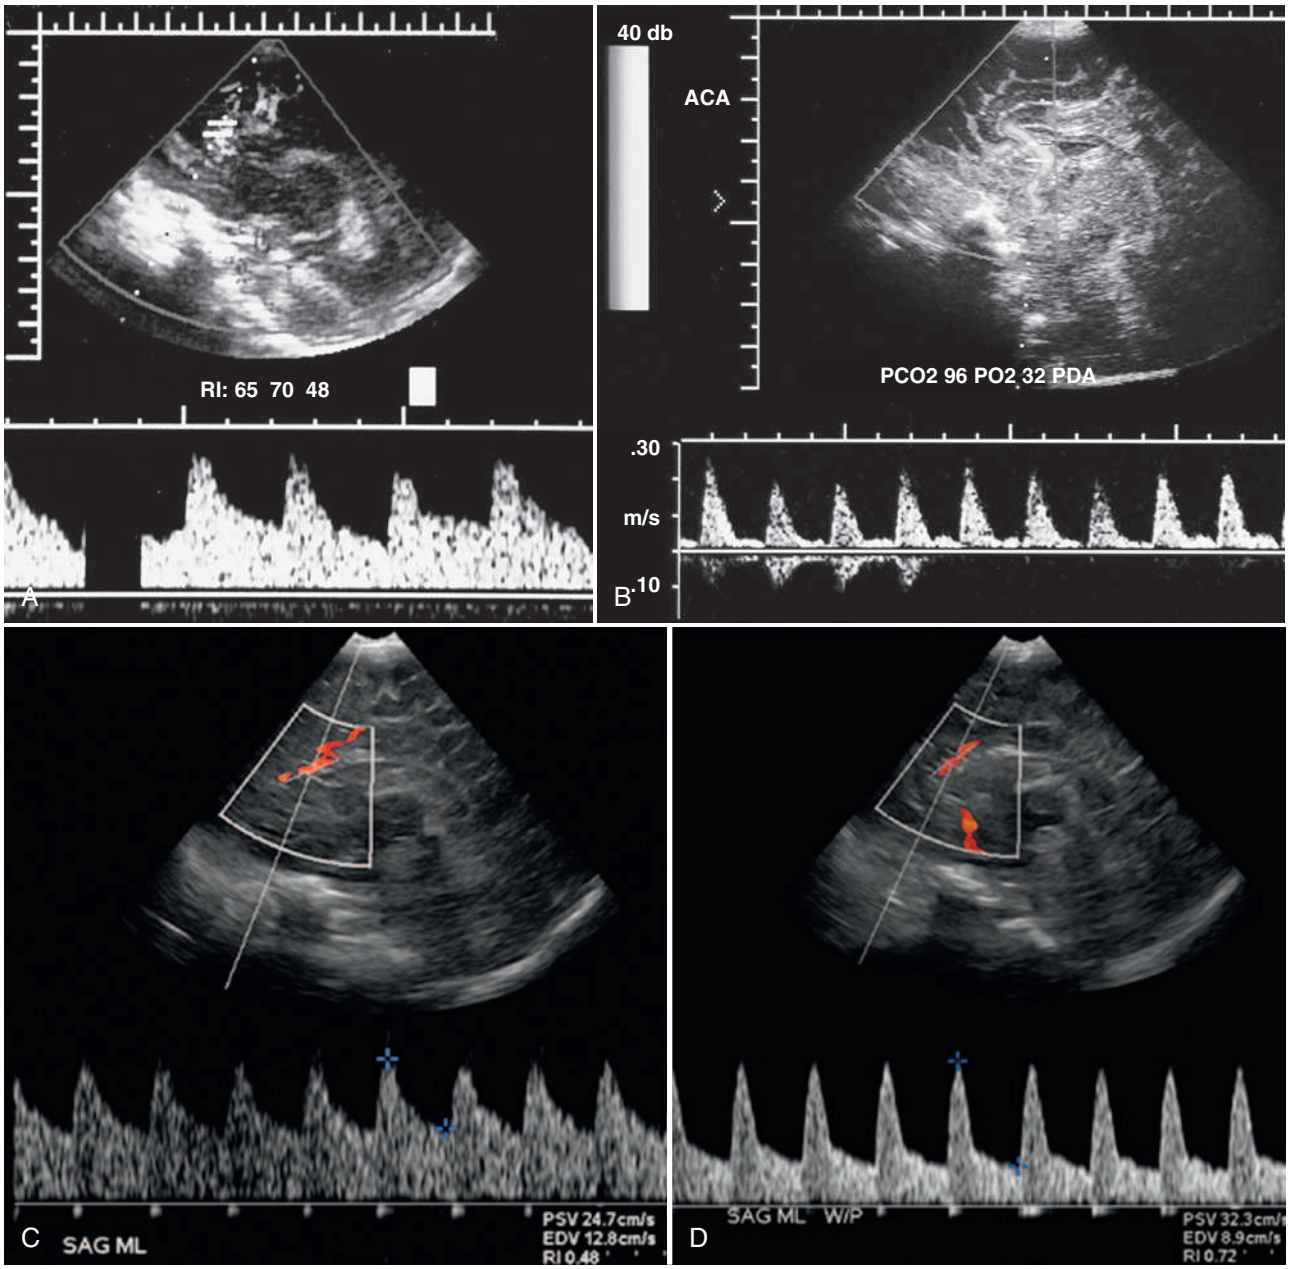

FIG. 46.3 Factors Affecting Intracranial Resistive Index (RI). (A) High variability in pulsatility of flow related to left ventricular dysfunction in an infant with congenital heart disease. **(B)** Absent diastolic flow in an infant with symptomatic patent ductus arteriosus. **(C)** and **(D)** High variability in spectral Doppler flow measurements and RI values occur in neonatal hypoxic ischemic injury as a result of impaired hemodynamic autoregulation; RI values increase significantly when sampled without (**[C]** RI = 0.48) and with (**[D]** RI = 0.72) gentle pressure to the anterior fontanelle.

TABLE 46.2 Range of Arterial Blood Flow Velocities in Full-Term Infants[a]

Artery	Peak Systolic Velocity (cm/sec)	End-Diastolic Velocity (cm/sec)	Resistive Index
Internal carotid	12-80	3-20	0.5-0.8
Basilar	30-80	5-20	0.6-0.8
Middle cerebral	20-70	8-20	0.6-0.8
Anterior cerebral	12-35	6-20	0.6-0.8

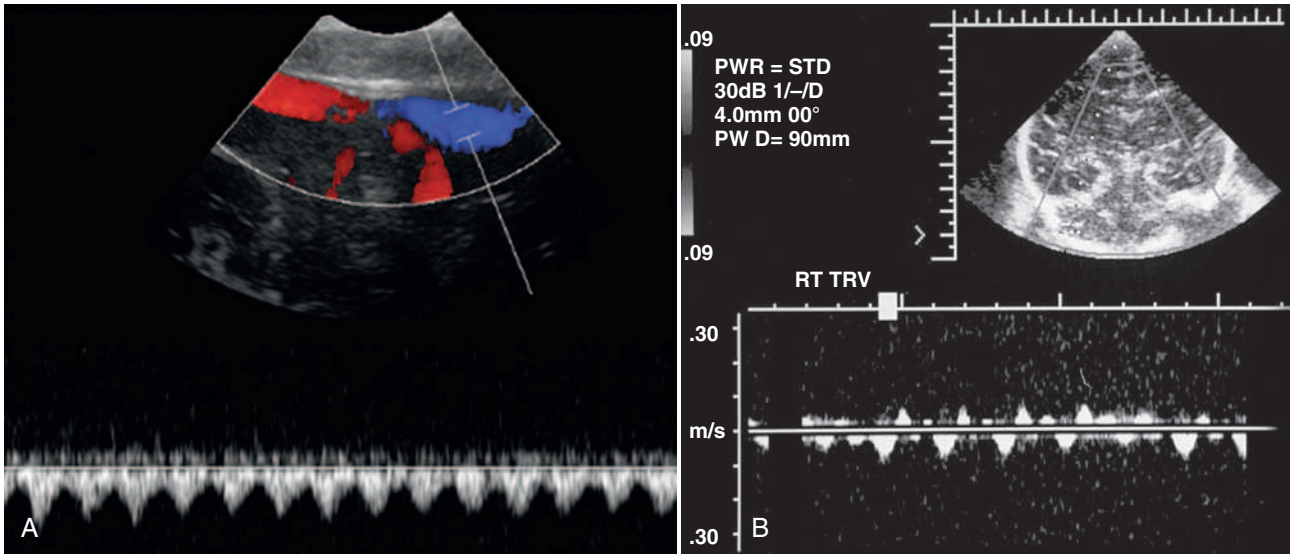

FIG. 46.4 Referred Cardiac Pulsations in Veins. **(A)** Doppler tracing from the superior sagittal sinus in a full-term newborn shows low-amplitude pulsatility. **(B)** Exaggerated venous pulsations from tricuspid regurgitation.

Normal Venous Blood Flow Patterns

Venous blood flow is continuous in the intracerebral veins and dural sinuses.[22] Cardiac pulsations of variable amplitude may occasionally be propagated into the larger venous structures, such as the vein of Galen and the sagittal and transverse sinuses (Fig. 46.4). High-amplitude or sawtooth patterns of pulsatility are not normal and may be seen in infants with **elevated right-sided heart pressures** or **tricuspid regurgitation.** Although respiratory changes are not usually observed during normal quiet respiration, marked changes in velocity can occur during **forceful crying** or are seen secondary to high-frequency ventilation settings.[8,22,23] Table 46.3 provides ranges for mean blood flow velocities in several intracranial veins and sinuses.

TABLE 46.3 Mean Venous Blood Flow Velocities in Full-Term Newborns

Vessel	Mean TAV[a] (cm/sec)
Terminal veins	3.0 ± 0.3
Internal cerebral veins	3.3 ± 0.3
Vein of Galen	4.3 ± 0.7
Straight sinus	5.9 ± 1.0
Superior sagittal sinus	9.2 ± 1.1
Inferior sagittal sinus	3.5 ± 0.3

[a]Time-averaged mean blood flow velocity (± standard error of the mean). Values modified from Taylor GA. Intracranial venous system in the newborn: evaluation of normal anatomy and flow characteristics with color Doppler US. Radiology. 1992;183(2):449-452.[8]

INTENSIVE CARE THERAPIES AND CEREBRAL HEMODYNAMICS

Mechanical Ventilation

Cerebral hemodynamics can be greatly affected by mechanical ventilation. Changes in venous return to the heart caused by **breathing out of synchrony** with the ventilator may result in significant beat-to-beat variability in arterial waveforms.[24]

Similarly, **high peak inspiratory pressures** can impede venous return to the heart and result in reversal of flow in the intracranial veins. Treatment with **high-frequency ventilation** exerts its effects on both arterial and venous hemodynamics in the form of short-amplitude oscillations (Fig. 46.5).[9,25] **Endotracheal suctioning** has been associated with marked increases in mean arterial blood pressure and arterial blood flow velocities in premature infants and has been attributed to the relative pressure-passive cerebral circulation (lack of autoregulation) in these patients.[26] Treatment with **inhaled nitric oxide** has also been reported to decrease CBF velocities in newborns with pulmonary hypertension. These infants experience an acute improvement in pulmonary hemodynamics and gas exchange at the onset of nitric oxide therapy.[27]

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) may be used for the treatment of infants with severe, refractory respiratory and/or cardiac failure who have not responded to maximal conventional treatment. ECMO is also used for postoperative support in children with cardiopulmonary failure after surgical repair of congenital heart disease or congenital diaphragmatic hernia. During venoarterial ECMO **(VA-ECMO),** infants typically undergo cannulation and ligation of the right common carotid artery and jugular vein for vascular access and are placed on **nonpulsatile partial cardiopulmonary bypass.** This results in significant alterations in intracranial hemodynamics[28,29] (Fig. 46.6A). As the amount of flow through the ECMO bypass circuit increases, arterial pulsatility decreases proportionately and may

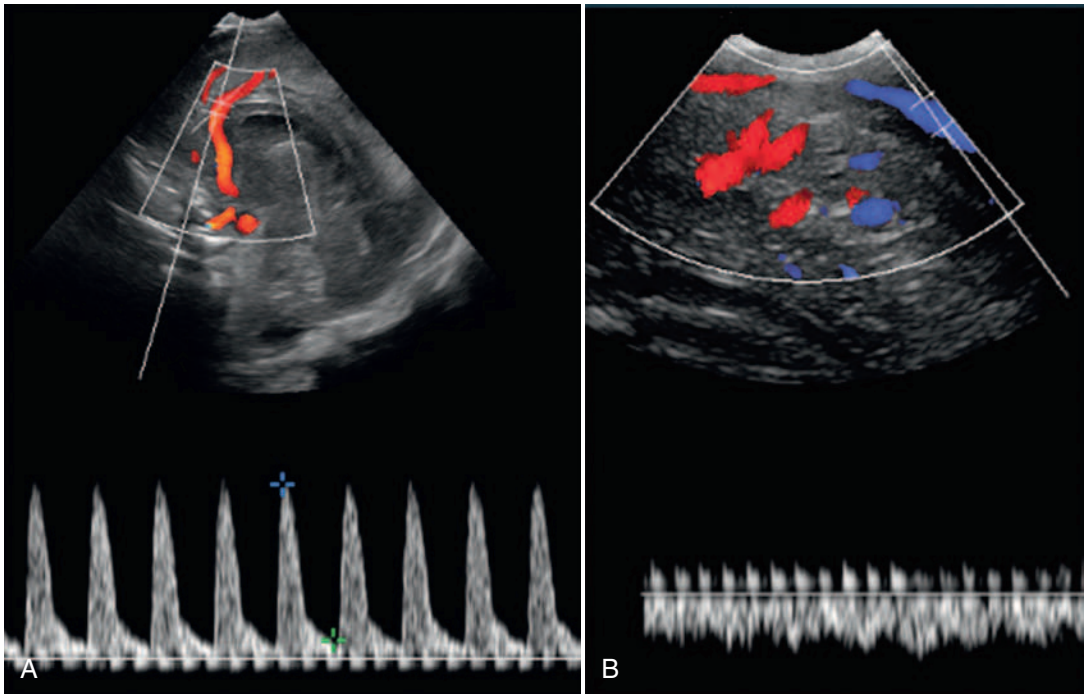

FIG. 46.5 High-Frequency Ventilation of Premature Infants. Pulsed wave Doppler tracing shows ventilation-related oscillations next to the arterial flow **(A)** and venous flow **(B).**

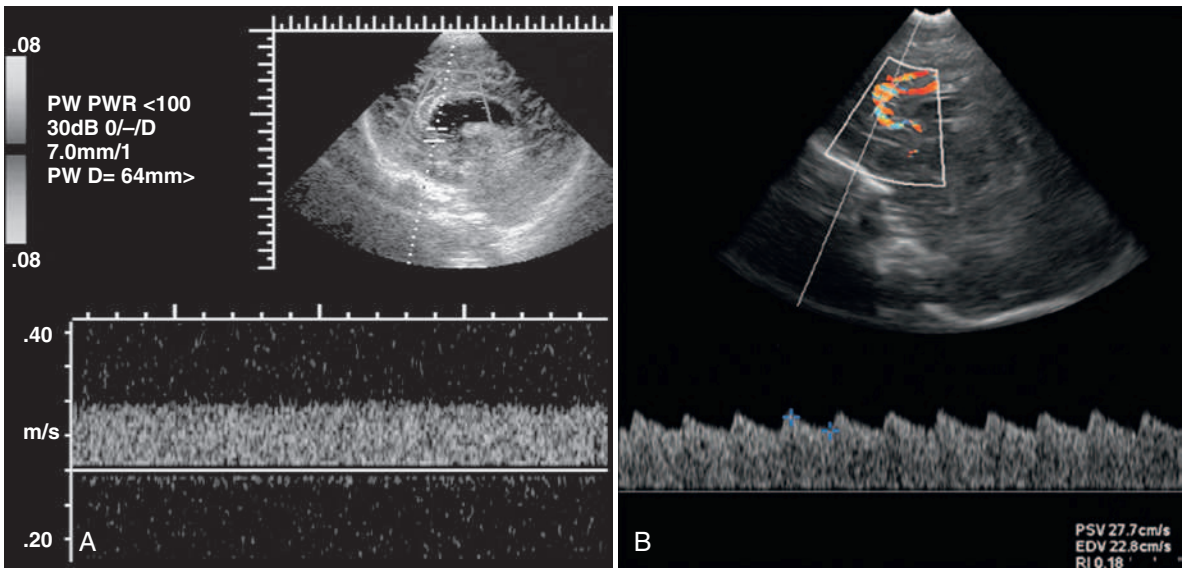

FIG. 46.6 Doppler Changes During Extracorporeal Membrane Oxygenation (ECMO). (A) Continuous nonpulsatile flow on pulsed wave Doppler tracing from the anterior cerebral artery in an infant with congenital heart disease and severe cardiac dysfunction during venoatrial ECMO shows absent arterial pulsatility. **(B)** In a different infant, residual pulsatile flow on pulsed wave Doppler tracing from the anterior cerebral artery in an infant with congenital heart disease and moderate cardiac dysfunction during venovenous ECMO shows minimal arterial pulsatility.

disappear altogether, especially in association with severe cardiac dysfunction.[30] Venous drainage and flow are typically also affected, partially as a result of the jugular vein ligation.[27,31]

More recently, double-lumen venous cannulas have allowed the use of venovenous circuits (venovenous extracorporeal membrane oxygenation [**VV-ECMO**]) in which the functionally intact left side of the heart pumps the oxygenated blood (delivered to the right side of the heart by the VV-ECMO circuit) into the systemic circulation. Major differences between the VV-ECMO circuit and the VA-ECMO circuit are the maintenance of pulsatile blood flow (see Fig. 46.6B), avoidance of ligation of the carotid artery, and perfusion of the pulmonary and coronary circulation by well-oxygenated blood.[32] VV-ECMO is used when there is only pulmonary dysfunction.

Duplex sonography may serve as a bedside monitoring modality for brain injury in a patient on ECMO. Studies have shown that in neonates without apparent neurologic injury, cerebral blood flow velocity (CBFV) was significantly lower than normal while on ECMO support and that CBFV increased after decannulation. Children who developed cerebral hemorrhage had higher CBFV for days before clinical recognition of a cerebral hemorrhage.[33]

Therapeutic Hypothermia and Brain Cooling

Brain temperature has been shown to be tightly linked to brain perfusion. Few data are available on the impact of brain cooling on the neonatal cerebral hemodynamics. Previous studies have primarily focused on patients who received cooling for cardiac surgery or treatment of traumatic brain injury. Hypothermia was noted to decrease CBFV, whereas increased temperatures increased CBFV.[34]

DIFFUSE NEURONAL INJURY

Hypoxic Ischemic Injury and Asphyxia

The cerebral hemodynamic changes associated with HII or asphyxia depend on many complex interacting factors including the severity, time, and duration of the insult; ongoing hypercapnia and hypoxemia; and maturity of the brain. In the setting of severe or prolonged asphyxia, brain tissue HII results in the excessive release of excitatory amino acids, such as glutamate and aspartate. The subsequent complex cascade of neurometabolic events results in cerebral vasodilation with subsequent cerebral edema.[35] In addition to the conventional gray-scale imaging findings of increased echogenicity of the hemispheric white matter, increased corticomedullary differentiation, slitlike ventricles, and effaced subarachnoid spaces, significant changes in hemodynamic metrics may be observed on duplex sonography. **Increased mean CBFV** and **decreased RI values** (<0.55-0.60) may be seen on spectral Doppler imaging within 12 hours of injury, lasting up to several days after the initial insult (Fig. 46.7).[36,37] Furthermore, RI measurements, in conjunction with clinical markers, may serve as a safe and cost-efficient method for prognostication of outcome and success of hypothermic treatment after HII (Fig. 46.8). RI values below 0.60 **before cooling** may broadly differentiate neonates who are more likely to have outcomes of severe neurodevelopmental disability or death by age 20 to 32 months.[38] Persistent hypoxia or hypercapnia will also contribute to generalized vasodilation and abnormal Doppler spectra. Fluctuation of systolic velocities may be caused by hypoxia-related cardiac ischemia.[39,40]

Cerebral Edema

Cerebral edema may be seen in HII, congestive heart failure, and many infectious processes. In the early phases of brain edema the RI values typically decrease owing to related vascular vasodilation.[41] As cerebral edema worsens, cerebrovascular resistance increases, with resultant dampening of the diastolic blood flow velocities. Pulsed wave Doppler imaging typically shows subsequent progressive elevation of the RI values and may eventually be accompanied by a reversal of the diastolic flow in the intracranial arteries.[40,42]

Brain Death

Depending on local legislation, several strict criteria have to be fulfilled for clinical determination of brain death. Typically, absent pupillary responses, no cranial nerve reflexes, no spontaneous respiration, and a "flat" electroencephalogram are combined with neuroimaging techniques confirming absent brain perfusion on a radionuclide CBF study. Several studies have focused on the value of duplex sonography for determination of brain death.

Duplex sonography typically shows markedly elevated RI values (>1.0) with reversal of diastolic flow in brain death, likely secondary to increased ICP. However, it should be recognized that reversal of the diastolic blood flow may also be seen in children with significant hydrocephalus and patent ductus arteriosus.[43] In brain death, in addition, the pulsations of the middle and anterior cerebral arteries appear diminished. Eventually, flow during systole becomes diminished and present only during a brief portion of the cardiac cycle. This represents **nonviable brain blood flow**[42] (Fig. 46.9).

Although absence of intracranial flow demonstrated by Doppler techniques is a reliable sign of absent cortical function, the presence of flow does not guarantee functional integrity, and brain death may be present despite preserved intracranial blood flow.[43,44]

INTRACRANIAL HEMORRHAGE AND STROKE

Color flow Doppler imaging may be used to show initial displacement, gradual encasement, and **obstruction of the subependymal and terminal veins** by germinal matrix hemorrhage (GMH; Fig. 46.10). In one study, displacement or occlusion of the terminal vein could be demonstrated in 50% of GMHs and in 92% of periventricular white matter hemorrhages.[45] This finding may be useful in the early prediction of infants at risk for worsening intracranial hemorrhage.

Focal Arterial Ischemic Stroke

Focal disruption of CBF causes **arterial ischemic stroke** in the neonatal period. Perinatal complications are the most common cause of stroke in newborns. Other factors are meningitis, trauma, polycythemia, dehydration, hypercoagulability, and cerebral vasculitis.[46,47] These lesions typically occur in full-term infants, mostly affect the vascular territory of the MCAs (>50%), and are usually unilateral.

Not all cerebral infarcts show alterations in regional blood flow. Although magnetic resonance imaging (MRI) and catheter angiography are the imaging reference standards, during the subacute phase cranial Doppler sonography can show hypervascularity characterized by an increased size and number of visible vessels, and increased mean CBFV in the peripheral, penumbral region of the ischemic area[47-49] (Fig. 46.11). This

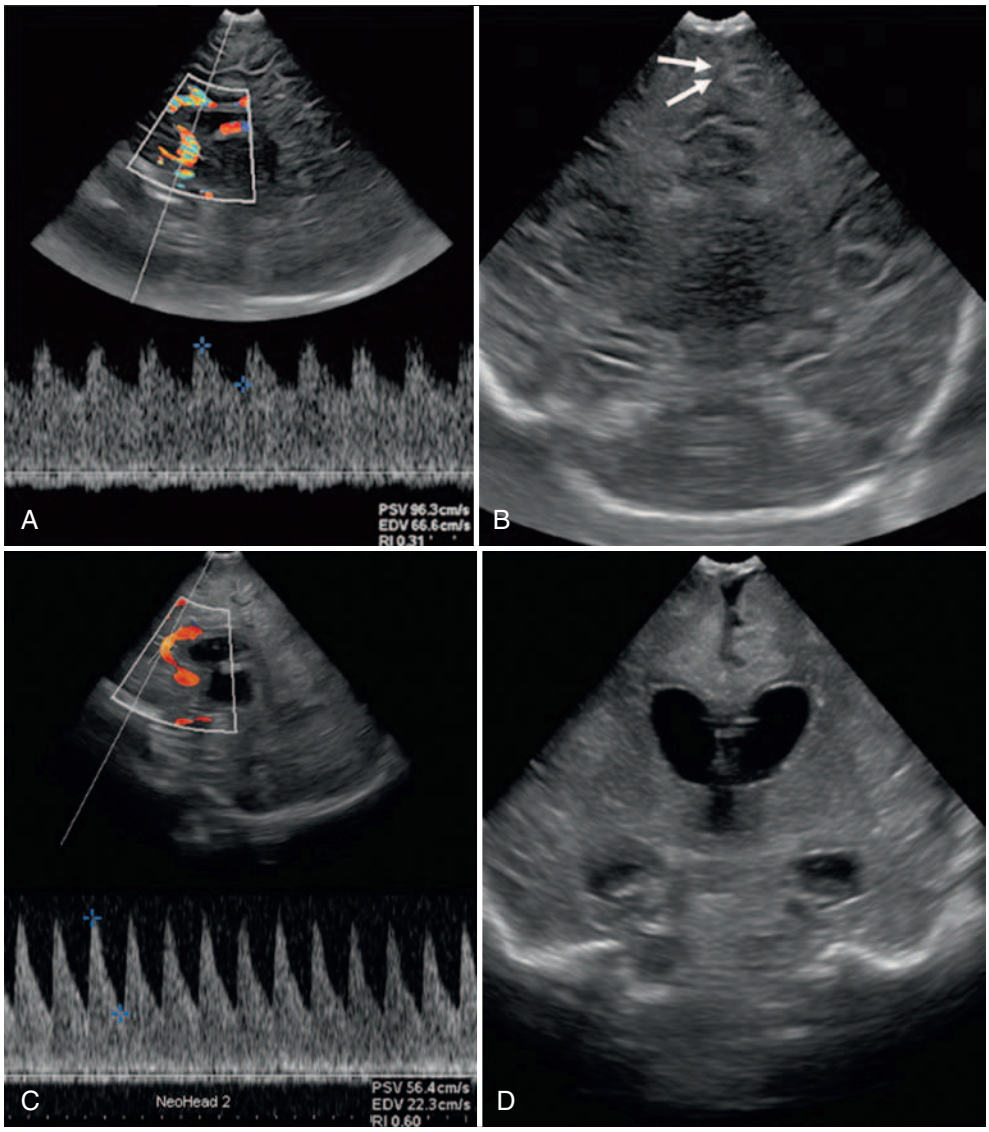

FIG. 46.7 Severe Perinatal Hypoxic Ischemic Injury in a Full-Term Infant With Additional Respiratory Distress Due to Meconium Aspiration. (A) and **(B)** Initial ultrasound study shows diffuse brain edema with increased echogenicity of the cerebral white matter, accentuated corticomedullary differentiation, partially interrupted cortex along the midline *(arrows),* and slitlike ventricles. Anterior cerebral artery Doppler shows elevated flow during diastole and a reduced resistive index (RI) value (0.31). **(C)** and **(D)** Follow-up imaging shows a progressive severe tissue injury with global gray and white matter echogenicity (loss of corticomedullary differentiation) and ventriculomegaly with pseudonormalization of the RI value (0.60).

pattern of vasodilation is thought to be caused by the uncoupling of CBF from local metabolic demands and is known as **luxury perfusion.**[50,51]

HYDROCEPHALUS

As ICP rises, arterial flow tends to be more affected during diastole than during systole, resulting in an elevated pulsatility of flow and increased RI. Seibert and colleagues showed that **increasing RI** correlates well with ICP elevation in an experimental canine model of hydrocephalus.[52] Also, significant decreases in pulsatility and RI values have been shown to occur after ventricular tapping and shunting in infants with hydrocephalus.[53,54] However, elevated ICP may not always be present in infants with ventricular dilation, and the RI values may be well within the normal range. Furthermore, the RI values vary with gestational and postnatal age, cardiac function, heart rate, patency of the ductus arteriosus, and executed treatment. Consequently, care should be taken to not use the RI value as a sole indicator of raised ICP.[54]

Several additional variations of the duplex Doppler technique can be applied to enhance the diagnostic sensitivity and specificity of the imaging. Doppler sonography of the anterior cerebral artery or MCA during fontanelle compression may be useful in the early identification of infants with abnormal intracranial compliance before development of increased ICP, as shown by elevated baseline RI.[21] Taylor and Madsen directly measured changes in ICP and intracranial RI before and after ventricular drainage procedures.[55,56] These studies showed that the change

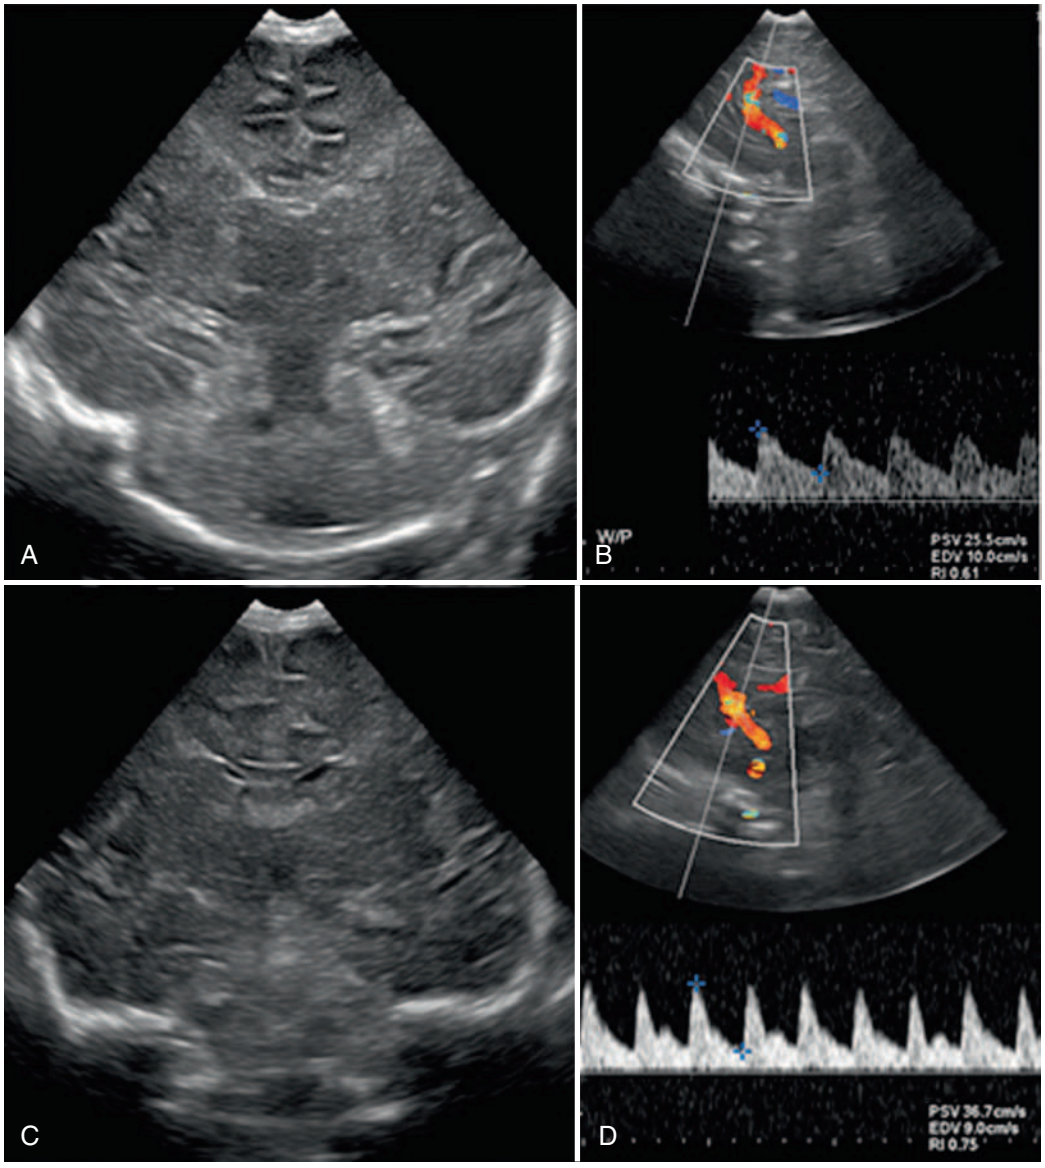

FIG. 46.8 Serial Imaging in a Neonate With Perinatal Hypoxic Ischemic Injury Treated With Therapeutic Hypothermia. (A) and **(B)** Initial ultrasound study shows diffuse brain edema with increased echogenicity of the cerebral white matter, accentuated corticomedullary differentiation, and slitlike ventricles. Anterior cerebral artery Doppler shows a resistive index (RI) value of 0.61. **(C)** and **(D)** Follow-up imaging shows normalization of the B-mode imaging findings after completion of hypothermic therapy and a normal RI value of 0.75. These findings matched the normal neurologic examination findings.

in RI during graded anterior fontanelle compression is a strong predictor of ICP and can help predict the need for shunt placement. This technique has also been used successfully to evaluate intracranial compliance in young children with **craniosynostosis** before surgical repair.[57]

According to the Monro-Kellie hypothesis, the volume of brain, cerebrospinal fluid (CSF), blood, and other intracranial components is constant.[58] During graded fontanelle compression in normal infants, CSF or blood can be readily displaced to compensate for the small increase in volume delivered by compression of the anterior fontanelle, causing no increase in ICP. In infants with hydrocephalus, however, the increase in intracranial volume with fontanelle compression is translated into a transient increase in ICP and an **acute increase in arterial pulsatility resulting in an increased RI** (Fig. 46.12). Serial examinations using this technique can follow an individual infant's ability to compensate for minor changes in intracranial volume, providing a noninvasive, indirect measure of intracranial compliance[59] (Fig. 46.13).

Karl-Heinz Deeg and his group showed that calculating the ratios of the peak systolic flow velocity, EDV, and time average flow velocity measured in the intracranial and extracranial carotid arteries (I/E ratio) can serve as an additional helpful method for semiquantitative estimation of ICP. Slightly increased ICPs below 20 cm H_2O were linked to an increase of the I/E ratio above 1, while the RI values remained unchanged. ICP increases above 20 cm H_2O lowered the I/E ratio significantly below normal values of 0.8, while the RI values increased. The

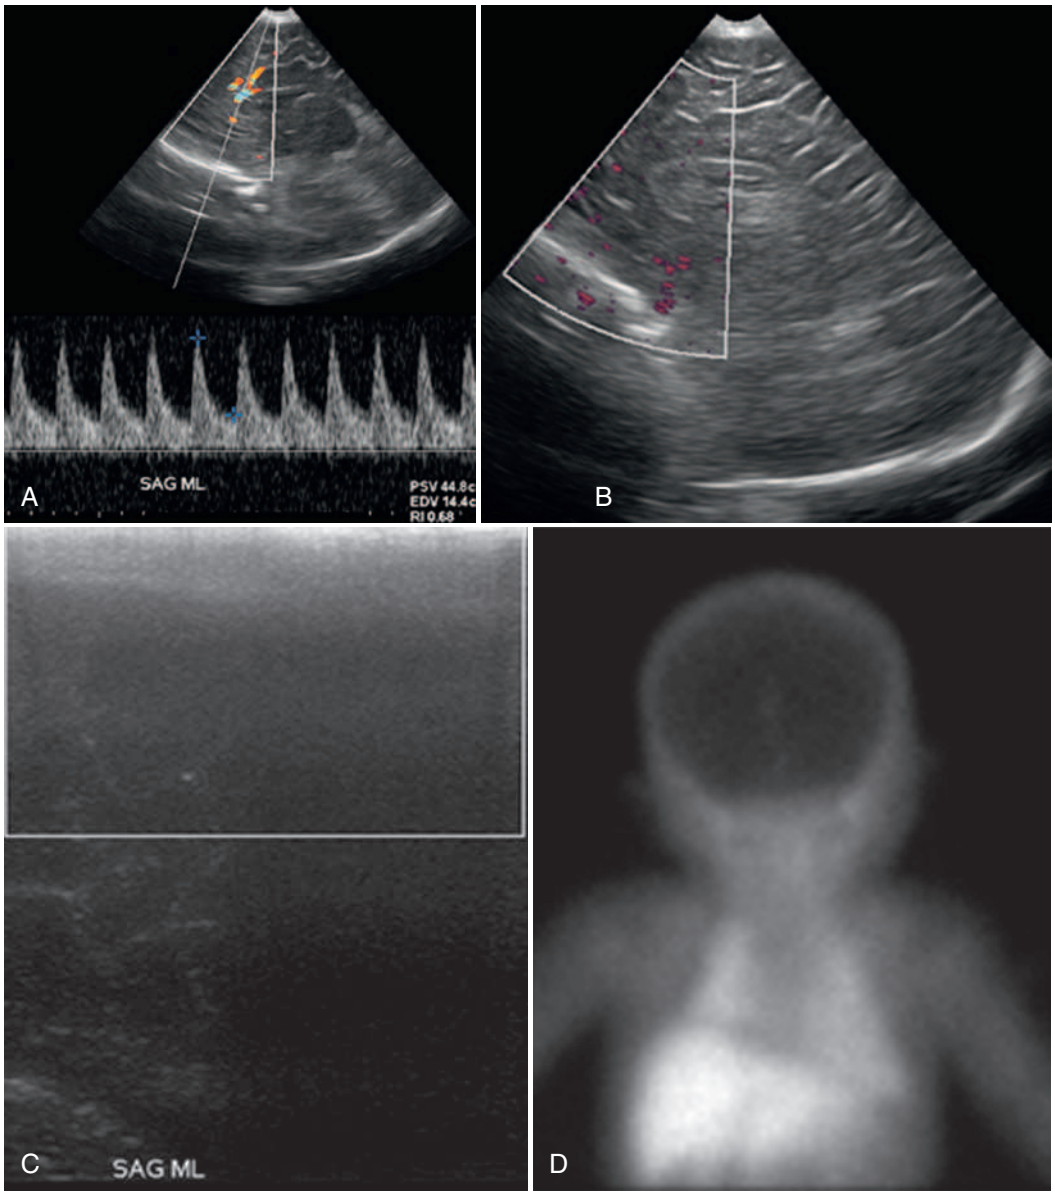

FIG. 46.9 Seven-Week-Old Infant With Progressive Liver Failure, Severe Neurologic Deterioration, and Brain Death. **(A)** Initial ultrasound study and pulsed wave Doppler tracing from anterior cerebral artery appear unremarkable. **(B)** Follow-up imaging during devastating neurologic deterioration shows no relevant brain perfusion on power Doppler imaging. **(C)** Sagittal midline power Doppler imaging also fails to show venous flow within the superior sagittal sinus, confirming lack of brain perfusion. **(D)** Complete lack of brain perfusion was also confirmed by nuclear medicine perfusion study.

decrease in the I/E ratio was more prominent for the EDV compared with the peak systolic flow velocity and time average flow velocity.[60]

VASCULAR MALFORMATIONS

Pediatric cerebral **arteriovenous malformations** (AVMs) differ substantially from adult forms in their angioarchitecture, clinical presentation, systemic hemodynamic impact, and overall functional outcome.[61] Pediatric AVMs are frequently fistulous or multifocal, often exert a hemodynamic effect on the entire venous system, and rarely manifest with high flow–related vasculopathy or flow-related aneurysms. Systemic manifestations with cardiac overload are a key clinical feature increasing morbidity and mortality. Chronic venous stasis and/or ischemia in combination with a vascular steal may cause chronic cardiac insufficiency and result in irreversible brain damage. The so-called **"melting brain"** is a well-known devastating complication of the **vein of Galen aneurysmal malformation** (VGAM), which is the most common neonatal intracranial vascular malformation. Differentiation between "true" and "false" VGAM is essential.[62] In the true VGAM, arteries drain directly into a dilated, persisting interhemispheric prosencephalic vein (Markowski vein) without connection to the deep venous system. In "false" VGAM, subpial AVMs adjacent to the cerebellum, brainstem, or deep supratentorial territories drain into a normally developed vein of Galen,

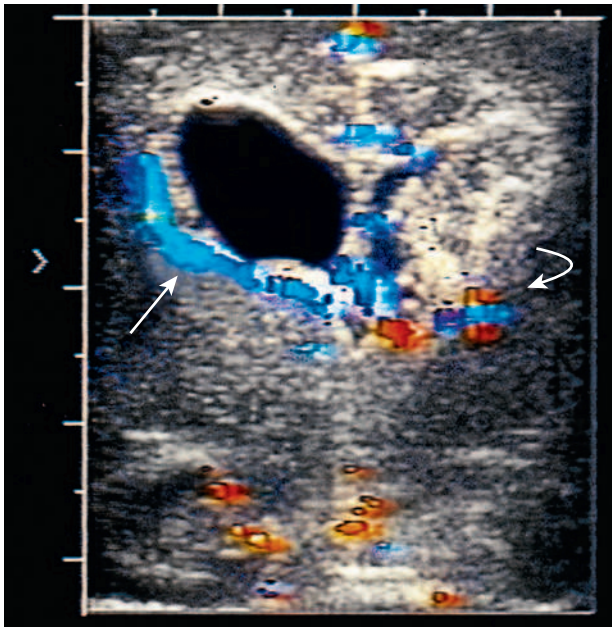

FIG. 46.10 Left-Sided Germinal Matrix Hemorrhage (GMH) With Obstruction of Terminal Vein Resulting in Periventricular Venous Stasis and Hemorrhagic Infarction. Flow in left subependymal vein *(curved arrow)* is obliterated by the hematoma. Flow in normal right subependymal vein *(straight arrow)* is shown.

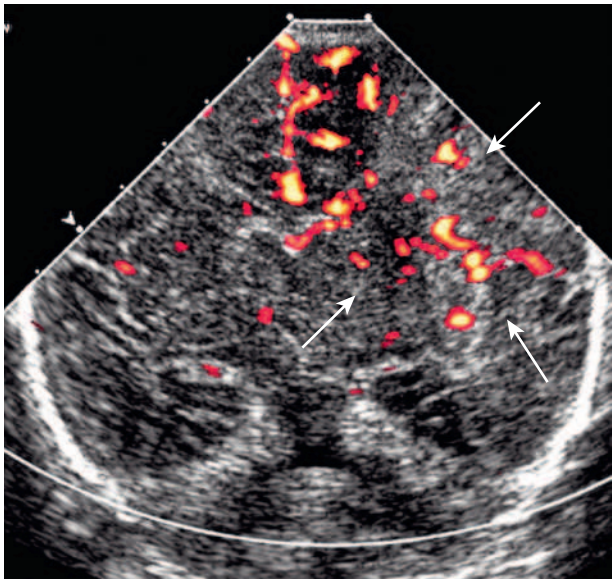

FIG. 46.11 Luxury Perfusion Secondary to Left Middle Cerebral Artery Ischemic Stroke in Full-Term Neonate. Coronal amplitude-mode Doppler image shows greatly increased blood flow to the ischemic mildly hyperechogenic area *(arrows),* consistent with luxury perfusion.

which may dilate owing to the venous overload. Consequently, the correct terminology would be **"vein of Galen aneurysmal dilation"** (VGAD). Ultrasound is an important imaging tool that allows the direct visualization of the dilated vessels of vein of Galen aneurysms as well as possible complications such as brain edema and hydrocephalus. VGAM and VGAD are typically diagnosed prenatally by ultrasound screening.[63] Prenatal and postnatal color flow sonography and spectral analysis of the blood flow curves within the supplying and draining vessels give

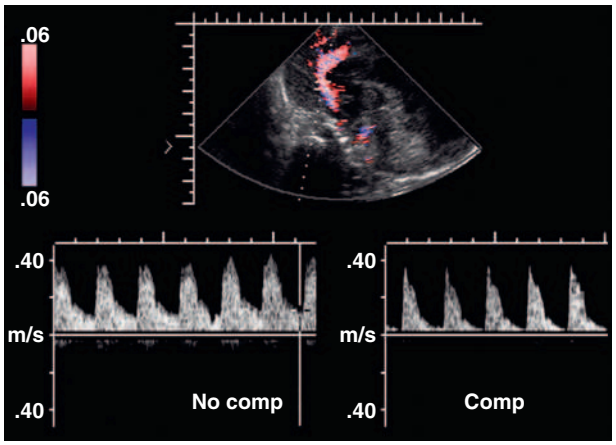

FIG. 46.12 Hydrocephalus Causes Increased Resistive Index (RI) When Gentle Anterior Fontanelle Pressure Is Added. Pulsed wave Doppler tracing of the anterior cerebral artery with transducer held lightly over anterior fontanelle *(No comp)* shows an RI of 0.69. Repeat tracing obtained a few seconds later with transducer firmly held over fontanelle *(Comp).* RI has increased to 0.99, indicating abnormal intracranial compliance. *Comp,* Compression.

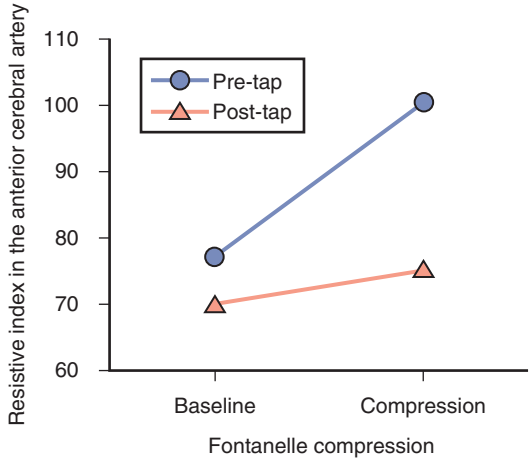

FIG. 46.13 Shunted Hydrocephalus Is Less Sensitive to Pressure Effects on Fontanelle. Graph of serial resistive index (RI) determinations in an infant with hydrocephalus before *(Pre-tap)* and after *(Post-tap)* shunt shows greatly diminished hemodynamic response to fontanelle compression after ventricular drainage. Note that RI is quite similar at baseline and increases with fontanelle compression.

important hemodynamic data both before and after treatment (Figs. 46.14 and 46.15). Spectral Doppler imaging typically shows arterialization of venous flow and increased flow velocities, with reduced pulsatility of the arterial feeders. Blood flow in the more peripheral portions of brain may show diminished or absent flow as a result of a "vascular steal" away from the normal cerebral circulation through the low-resistance malformation.[64,65]

Sinus pericranii is a congenital venous vascular malformation characterized by a fluctuating, compressible subcutaneous venous mass lesion in which the intracranial and extracranial veins are connected through a calvarial defect (Fig. 46.16). The lesion typically increases in size during crying. Duplex Doppler sonography easily differentiates the lesion from various differential diagnoses including meningoencephaloceles, dermoids (Fig.

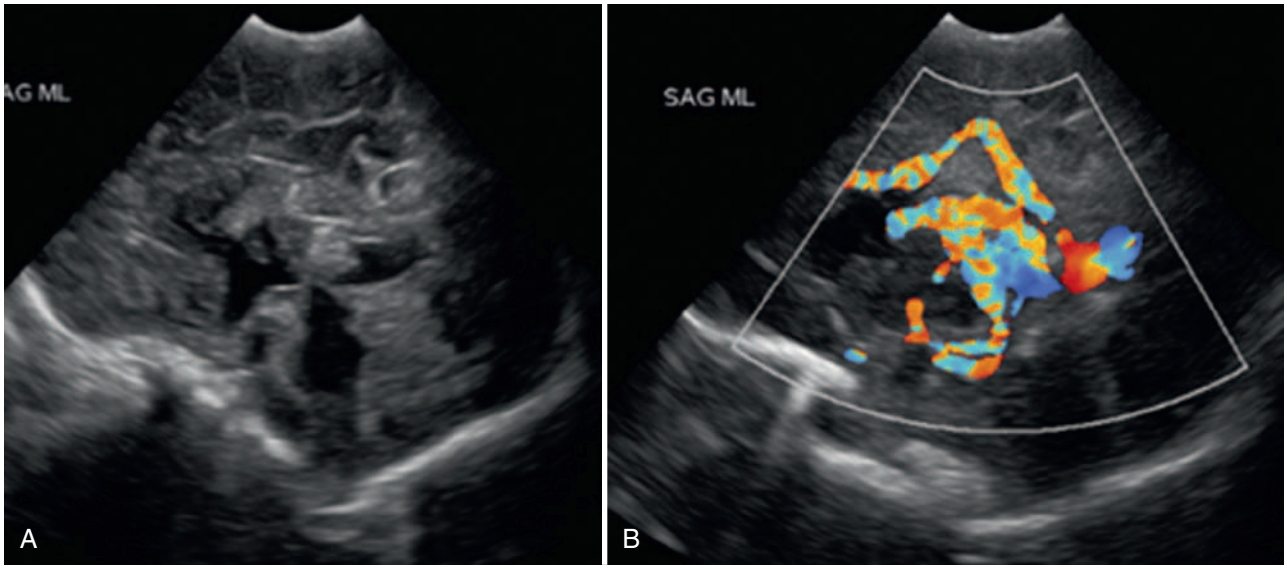

FIG. 46.14 Vein of Galen Aneurysmal Malformation. (A) Gray-scale and **(B)** color Doppler sagittal images show a vascular mass that on color flow Doppler is a dilated vein of Galen supplied by a dilated pericallosal artery and posterior choroidal artery. The vascular malformation appears hypoechoic on B-mode imaging and could be overlooked.

46.17), lipomas, AVMs, hemangiomas, cephalohematomas, or subgaleal effusions. On conventional gray-scale sonography the sinus pericranii is typically anechoic, whereas duplex Doppler sonography shows the venous nature of the lesion. A bidirectional, turbulent venous flow may be seen across the connecting, dilated transcalvarial veins.[66]

INTRACRANIAL TUMORS

Neonatal intracranial tumors are uncommon, and experience with Doppler characterization of these lesions is limited.[67] Doppler sonography may be helpful in characterizing the degree of intratumoral vascularity and in identifying its vascular supply[68] (Fig. 46.18).

NEAR-FIELD STRUCTURES

Differentiation of Subarachnoid From Subdural Fluid Collections

Color flow Doppler ultrasound with high-frequency linear transducers can be used to characterize extracerebral fluid collections as **subarachnoid, subdural,** or **combined.** Because superficial cortical blood vessels lie within the pia-arachnoid, fluid in the subarachnoid space surrounds and lifts the cortical vessels up and away from the brain surface (Fig. 46.19). Fluid in the subdural space pushes cortical vessels down toward the brain surface and is separated from these vessels by a thin membrane. Correlation with MRI and computed tomography (CT) suggests that color flow Doppler imaging is reliable in making this differentiation.[69] However, cortical veins drain into the superior sagittal sinus through emissary veins that course through the extra-axial spaces and can be mistaken for vessels in the subarachnoid space.[70]

Dural Venous Sinus Thrombosis

Dural venous sinus thrombosis may occur in the neonate as the result of systemic or localized infection, congenital heart disease, coagulation disorders, vascular malformations, trauma, and dehydration. Color flow Doppler ultrasound can be used as a noninvasive tool for initial identification and monitoring of dural sinus thrombosis.[46,52,71]

UNCOMMON VASCULAR APPLICATIONS

Duplex Doppler sonography may be helpful for the exploration and confirmation of the vascular nature of the linear hyperechogenic lesions that may be seen in the central gray matter of neonates, also known as **lenticulostriate "vasculopathy"**[72] (Fig. 46.20). Doppler may be used for various rare anatomic vascular anomalies such as hypoplasia of the internal carotid artery. Duplex sonography may also prove to be helpful in diagnosing and monitoring vasomotor reactivity and vasospasm after subarachnoid hemorrhage or traumatic brain injury.

PITFALLS OF DUPLEX SONOGRAPHY

As with any advanced imaging tool, the sonographer and radiologist should be aware of the potential pitfalls and limitations of duplex sonography. The insonication angle should be adapted to the course of the sampled vessel, the sample volume box should be centered within the vessel, and sharp curves should be avoided (turbulent flow with aliasing). Furthermore, the close proximity of the arterial circle of Willis and venous circle of Trolard may result in a simultaneous sampling of both the arterial and venous waveforms, affecting correct calculation of various hemodynamic markers such as the RI values (Fig. 46.21).[73,74] In addition,

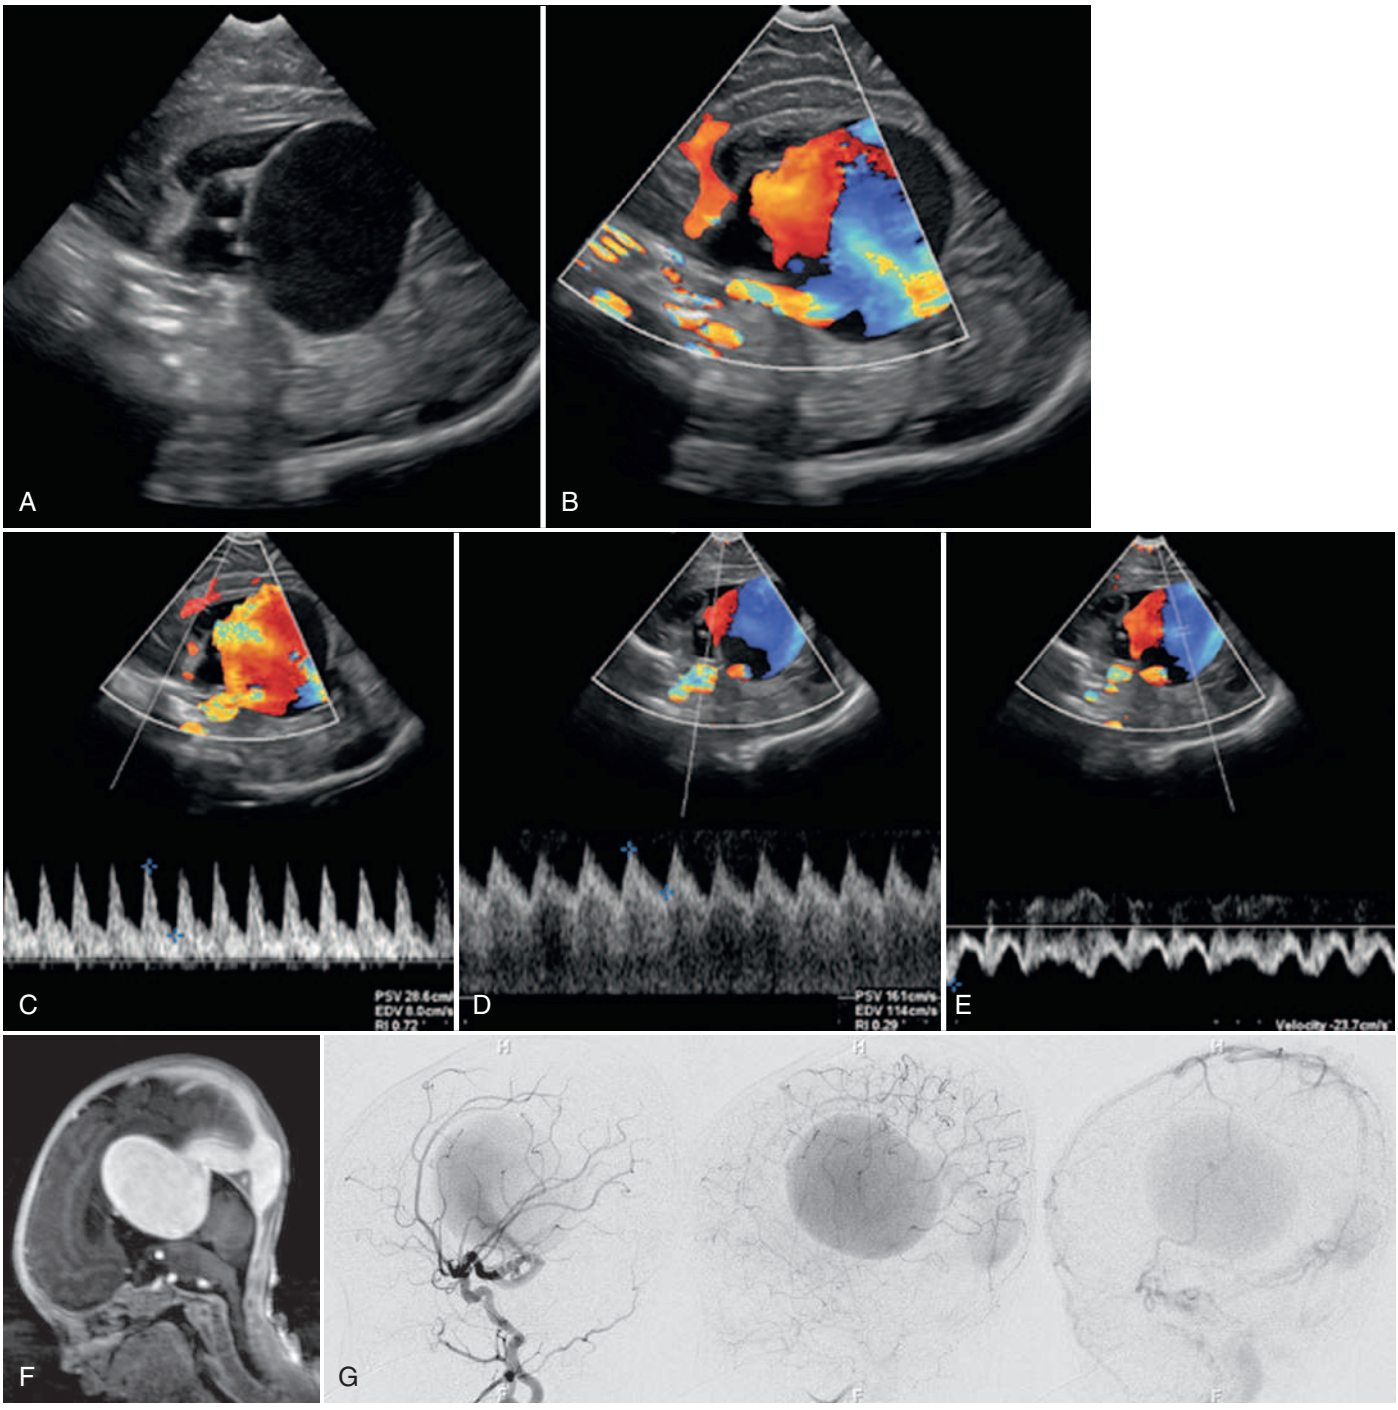

FIG. 46.15 Vein of Galen Aneurysmal Malformation. (A) Sagittal gray-scale and **(B)** color Doppler images show a vascular mass due to aneurysmal enlargement of the vein of Galen with prominent turbulent flow. The tectal plate is compressed downward and the supratentorial ventricles are dilated because of aqueductal obstruction and venous hypertension. **(C)-(E)** Color Doppler sonography with spectral analysis of the malformation allows study of the hemodynamic angioarchitecture of the malformation. Normal flow is noted within the pericallosal artery **(C),** whereas a high flow is noted within the feeding posterior choroidal artery **(D)** with matching low resistive index (RI) value (RI = 0.29) as a result of the arteriovenous shunting. Within the dilated vein of Galen **(E),** extensive referred cardiac pulsations are noted. **(F)** Contrast-enhanced magnetic resonance venography confirms the malformation. **(G)** Digital subtraction angiography shows that the vein of Galen aneurysmal malformation is supplied by dilated bilateral posterior choroidal arteries.

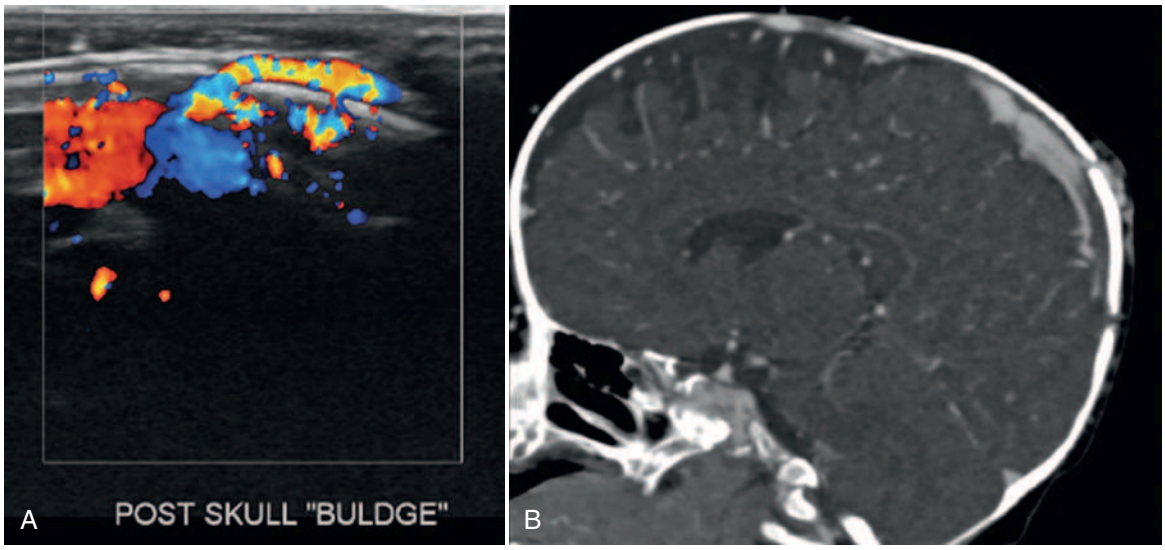

FIG. 46.16 Sinus Pericranii. (A) Midsagittal color flow Doppler sonography shows a prominent vein connecting the intracranial superior sagittal sinus with the subcutaneous venous network. **(B)** Correlative contrast-enhanced computed tomography scan with vessels crossing the calvarium through a small posterior bony defect.

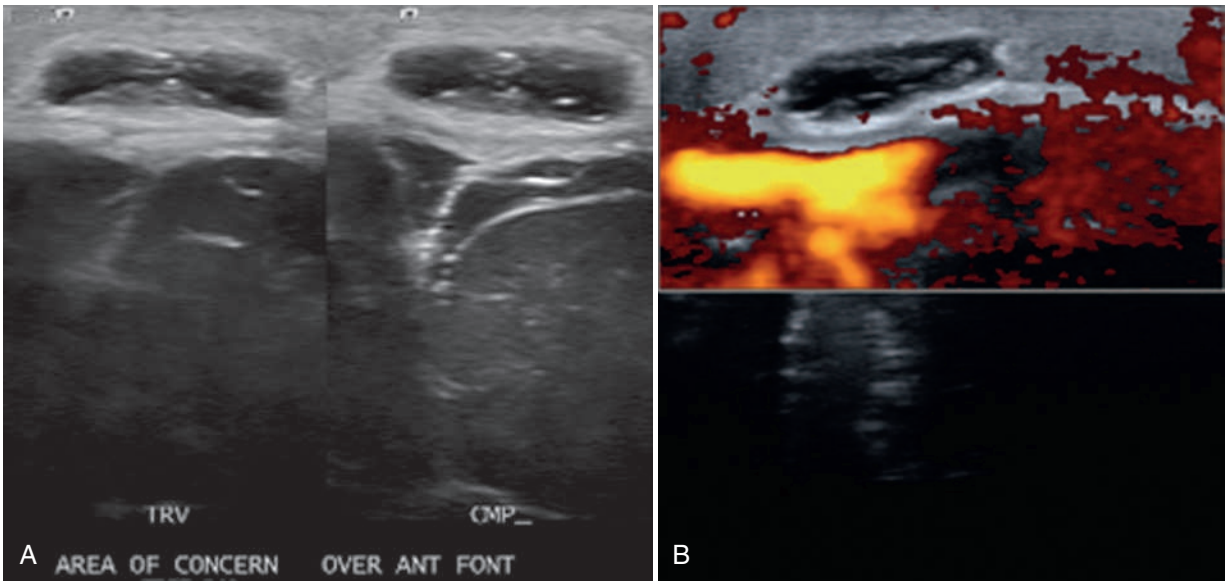

FIG. 46.17 Dermoid in the Sagittal Suture. (A) Gray-scale sonography shows a focal hypoechogenic lesion overlying the sagittal suture. **(B)** Power Doppler sonography shows the nonvascular nature of the focal "bump," excluding a sinus pericranii.

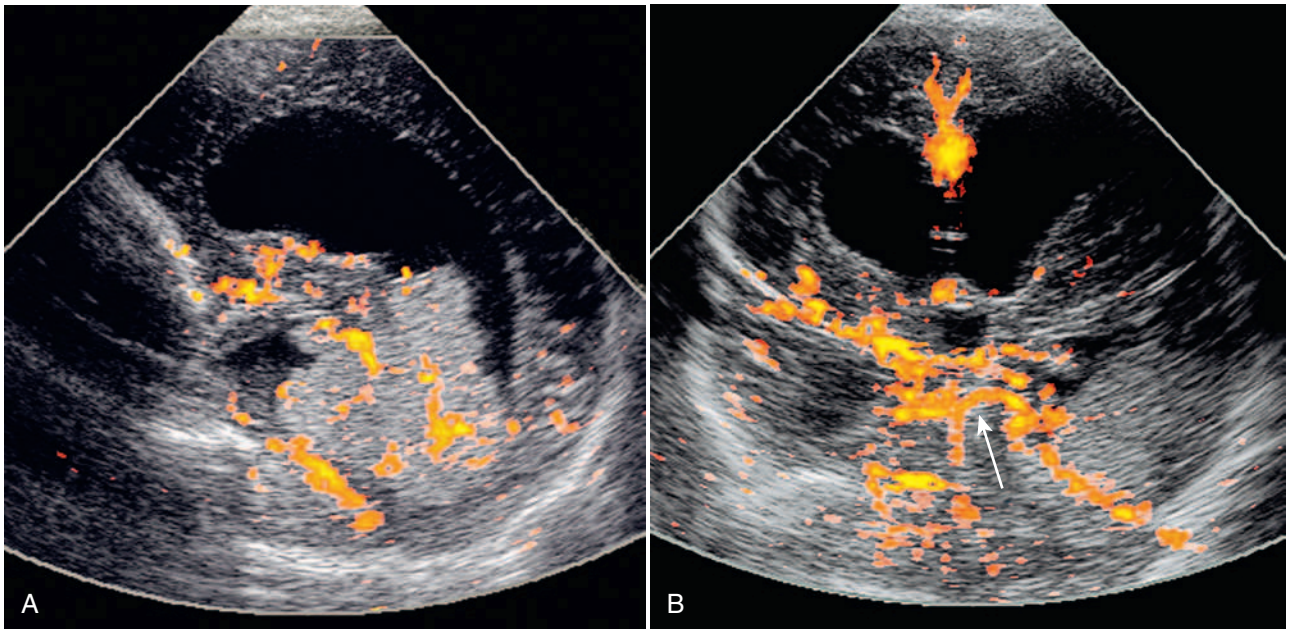

FIG. 46.18 Choroid Plexus Papilloma in 6-Week-Old Infant. (A) Angled sagittal and **(B)** coronal color amplitude (power) Doppler images show increased tumor vascularity within the echogenic mass, with arterial supply arising from a branch of the basilar artery *(arrow)*.

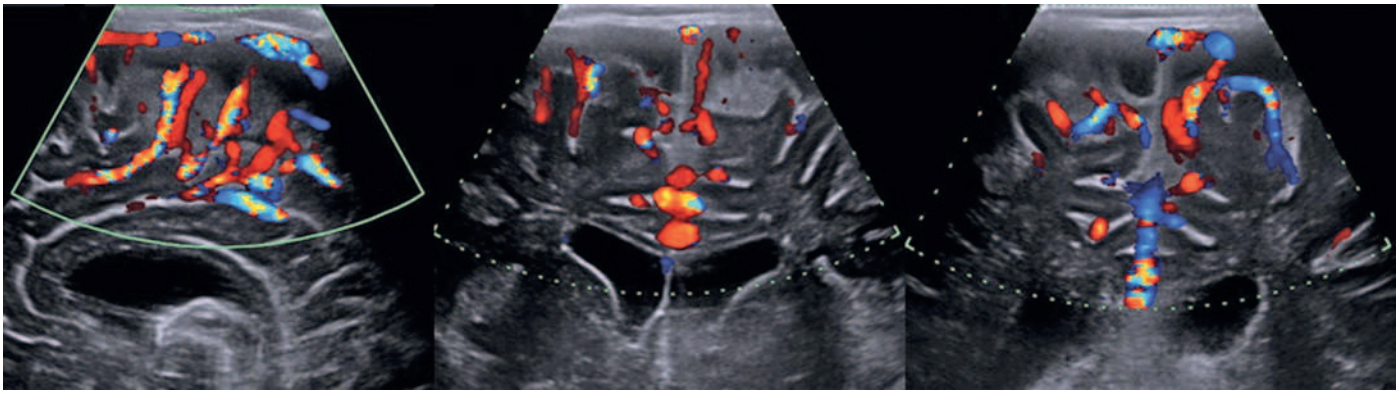

FIG. 46.19 Subdural and Subarachnoid Effusions From Meningitis. Magnified sagittal and coronal color Doppler images of interhemispheric fissure. Large bilateral partially hypoechogenic, partially hyperechogenic subdural and subarachnoid effusions. Superficial cortical vessels cross the subarachnoid and subdural space to drain into the superior sagittal sinus. The ventricles are mildly dilated; the leptomeninges are thickened and hyperechogenic.

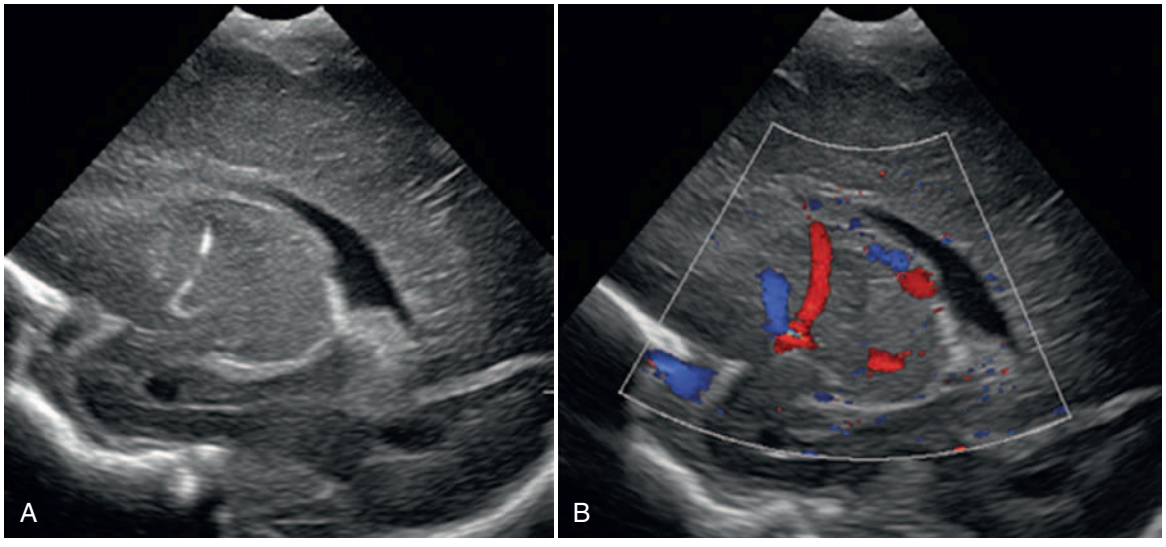

FIG. 46.20 Lenticulostriate Vasculopathy. (A) Gray-scale sagittal sonography shows moderately hyperechogenic linear lesions within the basal ganglia that prove to be prominent lenticulostriate vessels on color flow Doppler sonography **(B).**

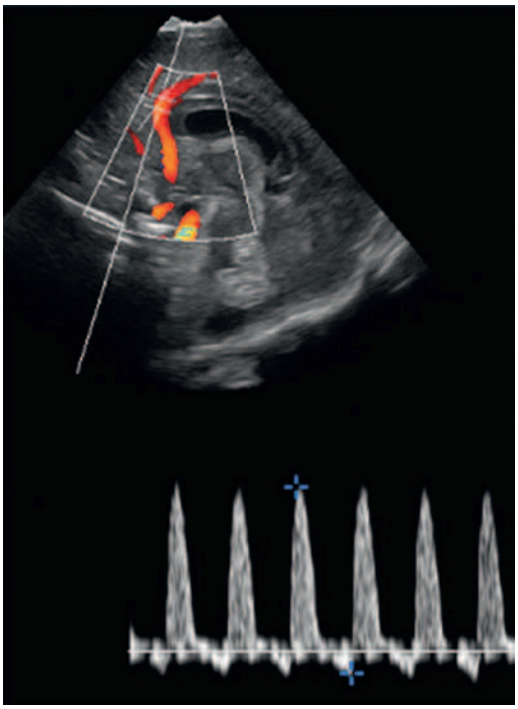

FIG. 46.21 Pitfall: Arterial and Venous Overlay on Spectral Flow Curve. Simultaneous sampling of the arterial flow within the pericallosal artery and adjacent inferior sagittal sinus may mimic a reversal of the diastolic flow with incorrect calculation of the resistive index values.

slow-flow vessels, deep-seated vessels, and superficial vessels obscured by the calvarial bone or outside the acoustic window may be overlooked. A dedicated familiarity with the studied pathologies is a sine qua non for sensitive and specific duplex sonography.

CHAPTER 47

Doppler Sonography of the Brain in Children

Dorothy Bulas and Alexia Egloff

SUMMARY OF KEY POINTS

- Transcranial Doppler (TCD) can be performed, with or without imaging. Four windows are available after closure of the anterior fontanelle—temporal, orbital, transforaminal, and submandibular.
- Physiologic variables including age, gender, hematocrit, viscosity, carbon dioxide, temperature, blood pressure, and mental or motor activity can impact flow velocity.
- There are several established clinical applications for TCD and many potential applications for the assessment of cerebral blood flow in the pediatric and adult age groups.
- TCD can be used as a screening test to assess for stroke risk in children with sickle cell disease. Those children with time-averaged maximum mean velocities higher than 200 cm/sec or peak systolic velocities greater than 250 cm/sec in the middle cerebral artery (MCA) or distal internal carotid artery are at highest risk for stroke.
- TCD can be used to assess for vasospasm and help guide therapy. A peak systolic velocity greater than 200 cm/sec is considered abnormal in the appropriate setting. The accuracy of TCD in the diagnosis of vasospasm can be increased by using the Lindegaard ratio (MCA/cervical internal carotid artery ratio). A ratio of higher than 6 suggests severe vasospasm; a ratio between 3 and 6 is associated with mild to moderate vasospasm, and less than 3 in patients with elevated flow velocities is likely secondary generalized hyperemia.

Transcranial Doppler and Tissue Plasminogen Activator
Functional Transcranial Doppler
Other Potential Uses

Duplex Doppler sonography with color flow imaging through the anterior fontanelle is simple and has proved useful in evaluating abnormalities of cerebral blood flow in the neonate and young child.[1-4] Once the fontanelle closes, transcranial Doppler (TCD) sonography can still be performed noninvasively using a low MHz (2- to 2.5-MHz) pulsed wave Doppler transducer through the thin temporal bone, the orbits, and the foramen magnum. This technique can be used to measure the velocity and pulsatility of blood flow within the intracranial arteries of the circle of Willis and the vertebrobasilar system.[5] TCD sonography has become a key tool in the management of children with sickle cell disease (SCD) and has proved to be a valuable adjunct in the evaluation of various intracranial pathologies in children, including vasospasm, vascular malformations, and brain death, as well as the assessment of cerebral hemodynamics after trauma, asphyxia, migraine, and stroke.

Two types of TCD sonographic equipment are available: **nonimaging** (TCD) and **imaging** (TCDI). The nonimaging technique uses continuous wave and pulsed wave Doppler to insonate specific vessels using strict criteria for vessel identification based on the depth and direction of flow for intracranial vessels through the temporal bone.[6,7] This blinded technique requires meticulous skill in obtaining the highest achievable audible Doppler frequency and the ability to maintain the mental image of the circle of Willis. Advantages of nonimaging TCD include the fact that the units designed for this exam are small, portable, and inexpensive; have good Doppler sensitivity; and have superior window maneuverability due to small transducer size. Limitations

include the need for intensive training, difficulty in finding specific vessels by sound, and lack of unit availability in radiology departments. Duplex Doppler sonography with color imaging using low MHz transducers via the temporal bone has increased the utility of TCD sonography. Advantages of TCDI include rapid vessel identification, a shorter learning curve, and availability of units in radiology departments. This imaging technique allows more confident vessel identification, resulting in easier, more reliable, and reproducible information.[8-11] However, with training and experience, both techniques have been shown to be reliable and reproducible.[12,13]

SONOGRAPHIC TECHNIQUE

The **anterior fontanelle** typically remains open through the first year of life. Once closed, three cranial windows (in addition to burr holes and surgical defects) can be used routinely to insonate the intracranial circulation: the **transtemporal window, orbital window,** and the **suboccipital window.** The **submandibular window** can also be used to complete the examination of the cervical segment of the internal carotid artery (ICA).[14]

The transtemporal approach is through the thin suprazygomatic portion of the temporal bone using a low MHz (2- to 2.5-MHz) transducer. The transtemporal acoustic window is usually found on the temporal bone just cephalad to the zygomatic arch and anterior to the ear. The intracranial anatomic landmark in this plane by gray-scale imaging is the heart-shaped **cerebral peduncles** (Fig. 47.1A). Just anterior to the peduncles is the star-shaped, echogenic interpeduncular or suprasellar **cistern.** Anteriorly and laterally from this basilar cistern lies the echogenic fissure for the **middle cerebral artery** (MCA). Color Doppler sonographic imaging (Fig. 47.1B, Video 47.1) and spectral analysis (Figs. 47.1C and 47.2A, Video 47.2) of this vessel show flow toward the transducer. Insonating the vessel deeper toward the midline directs the operator into the bifurcation of the A1 segment of the **anterior cerebral artery** (ACA) and the MCA (Video 47.3). Spectral analysis at this bifurcation landmark will show bidirectional flow, that is, flow toward the transducer in the MCA and flow in the ACA away from the transducer (Fig. 47.2B). As the Doppler gate is moved more medial anteriorly, flow is seen entirely in the ACA away from the transducer (Fig. 47.2C). The MCA should be studied from its most peripheral location to the point of bifurcation, and the ACA studied as medially as possible. The **distal internal carotid artery** (DICA) is just inferior to the bifurcation. The flow of the DICA may be dampened with a harsher sound from the increased angle of insonation, with flow typically directed toward the transducer (Fig. 47.2D). The **posterior cerebral artery** (PCA) can be visualized as it circles around the cerebral peduncles. Flow in this vessel may be away or toward the transducer depending on curser placement (Fig. 47.2E). At times, the MCA, the ACA, and the PCA on the opposite side may also be visualized. Ideally, each side should be studied through the ipsilateral window whenever possible.

The vertebral and basilar arteries can be studied through the suboccipital window via the **foramen magnum** with a low MHz transducer. The patient lies on one side or prone, and the head is bowed slightly so the chin touches the chest, causing a gap between the cranium and the atlas to enlarge. The transducer is placed midline in the nape of the neck and angled through the foramen magnum toward the orbits. The normal landmark is the rounded hypoechoic **medulla** just anterior to the echogenic **clivus** (Fig. 47.3A). The vertebral arteries appear in a V-shaped manner as they rise to the medullopontine junction to form the basilar artery between the hypoechoic medulla-pons junction and the echogenic clivus (Fig. 47.3B). From this posterior view, flow in the vertebral and basilar arteries should be directed away from the transducer (Fig. 47.3C).

The **transorbital window** allows for evaluation of the **ophthalmic artery** (OA), the retinal artery, and the **carotid siphon.** This evaluation is performed with the eyes closed using a higher MHz (5- to 7.5-MHz) transducer on its lowest power setting (Fig. 47.4). Unlike the temporal approach in which the bone attenuates a majority of sound thus requiring a low MHz transducer, the fluid-filled globe only minimally attenuates the sound waves. Although no bioeffects from the ultrasound evaluation of the eye are known, ocular damage can potentially occur as ultrasound energy can create cavitation and heat. The U.S. Food and Drug Administration (FDA) guidelines suggest limiting spatial peak temporal average to 17 mW/cm^2 for orbital imaging and limit the mechanical index to 0.28.[15,16] The time of insonation must also be as minimal as possible to decrease risk of damage to soft tissues.[17] The FDA has approved certain imaging transducers on various manufacturer equipment for the evaluation of the orbit. It is important for operators to determine which transducer is approved for orbital imaging for their system.

A liberal amount of gel is needed on the eyelid with only light pressure utilized on the globe. The orientation marker should be pointed medially toward the nose. Flow in the OA should be toward the transducer. The OA enters the optic foramen and lies lateral and slightly inferior to the optic nerve. It then usually crosses superior to the optic nerve and proceeds anteriorly on the medial side of the orbit. The color pulse repetition frequency should be decreased to visualize the OA. The mean velocity of the OA is 21 + 5 cm/sec with high pulsatility.[18] The central retinal artery branch of the OA is the easiest branch to interrogate with color flow Doppler imaging, just posterior to the retina. Because visualization of this central retinal artery entails directing sound waves through the lens, the lowest power setting must be used to minimize the risk of lens injury and subluxation. However, a large OA branch proceeds along the nasal or medial wall of the orbit. Because interrogating this vessel does not involve directing the sound beam through the lens, a higher power setting may be used for this branch. In the carotid siphon, flow direction varies depending on the segment: toward the probe in the infraclinoid segment, bidirectional in the genu, and away from the probe in the supraclinoid segment. The mean velocity of the carotid siphon is 47 + 14 cm/sec with a low resistance signal.[18]

The **submandibular window,** located at the angle of the jaw, allows for examination of the extracranial ICA, including morphology, flow direction, and velocities. Once the vessels have been identified, different information can be obtained through evaluation of the spectral waveform. Flow direction is one of the first parameters obtained with evaluations (by convention,

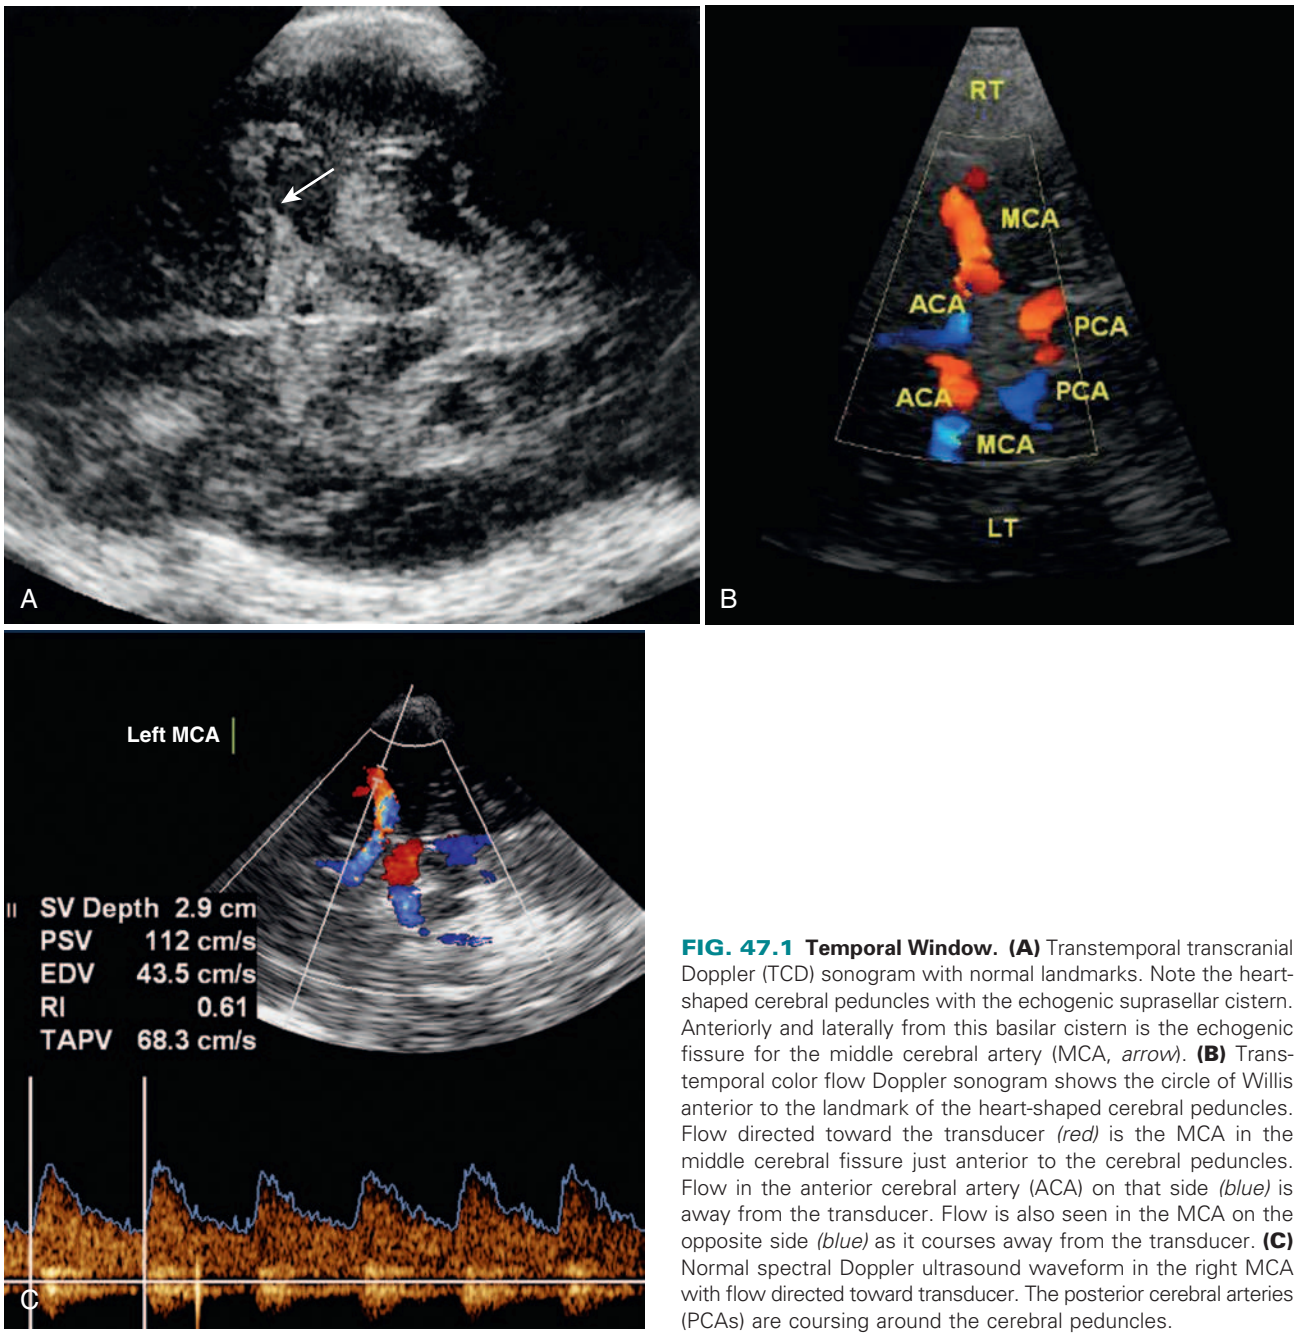

FIG. 47.1 Temporal Window. (A) Transtemporal transcranial Doppler (TCD) sonogram with normal landmarks. Note the heart-shaped cerebral peduncles with the echogenic suprasellar cistern. Anteriorly and laterally from this basilar cistern is the echogenic fissure for the middle cerebral artery (MCA, *arrow*). **(B)** Transtemporal color flow Doppler sonogram shows the circle of Willis anterior to the landmark of the heart-shaped cerebral peduncles. Flow directed toward the transducer *(red)* is the MCA in the middle cerebral fissure just anterior to the cerebral peduncles. Flow in the anterior cerebral artery (ACA) on that side *(blue)* is away from the transducer. Flow is also seen in the MCA on the opposite side *(blue)* as it courses away from the transducer. **(C)** Normal spectral Doppler ultrasound waveform in the right MCA with flow directed toward transducer. The posterior cerebral arteries (PCAs) are coursing around the cerebral peduncles.

flow toward the transducer is coded red and above the baseline, whereas flow away from the transducer is coded blue and below the baseline). A large sample volume (4-6 mm) allows for good signal to noise ratio. Velocities, such as peak systolic velocity (PSV), end diastolic velocity (EDV), and mean flow velocity, and indices reflecting vascular resistance including pulsatility index and resistive index are evaluated.

On spectral analysis of the waveform, the maximum, minimum, and mean velocities can be measured in centimeters per second. It is important to remember which velocity measures are used for various applications. For the STOP study assessing stroke risk in the sickle cell population, the **time-averaged mean of the maximum** (TAMM) **velocity** is followed, and is sometimes called the **time-averaged peak velocity.** This is not the same value as the mean velocity. PSV is the value followed for vasospasm. Terminology of the various mean and TAMM velocities can be vendor specific and need to be clarified dependent on the application TCD is being used for. At least two tracings should be made for each vessel. The highest velocity obtained is likely the most accurate, because it is believed to be the velocity obtained at the best insonating angle to the vessel.[19]

Angle correction cannot be performed with the nonimaging technique, and a 0-degree angle is assumed. Although angle correction is possible with the imaging technique because of visualization of the vessel course, published velocities typically have not been angle-corrected. In clinical applications such as

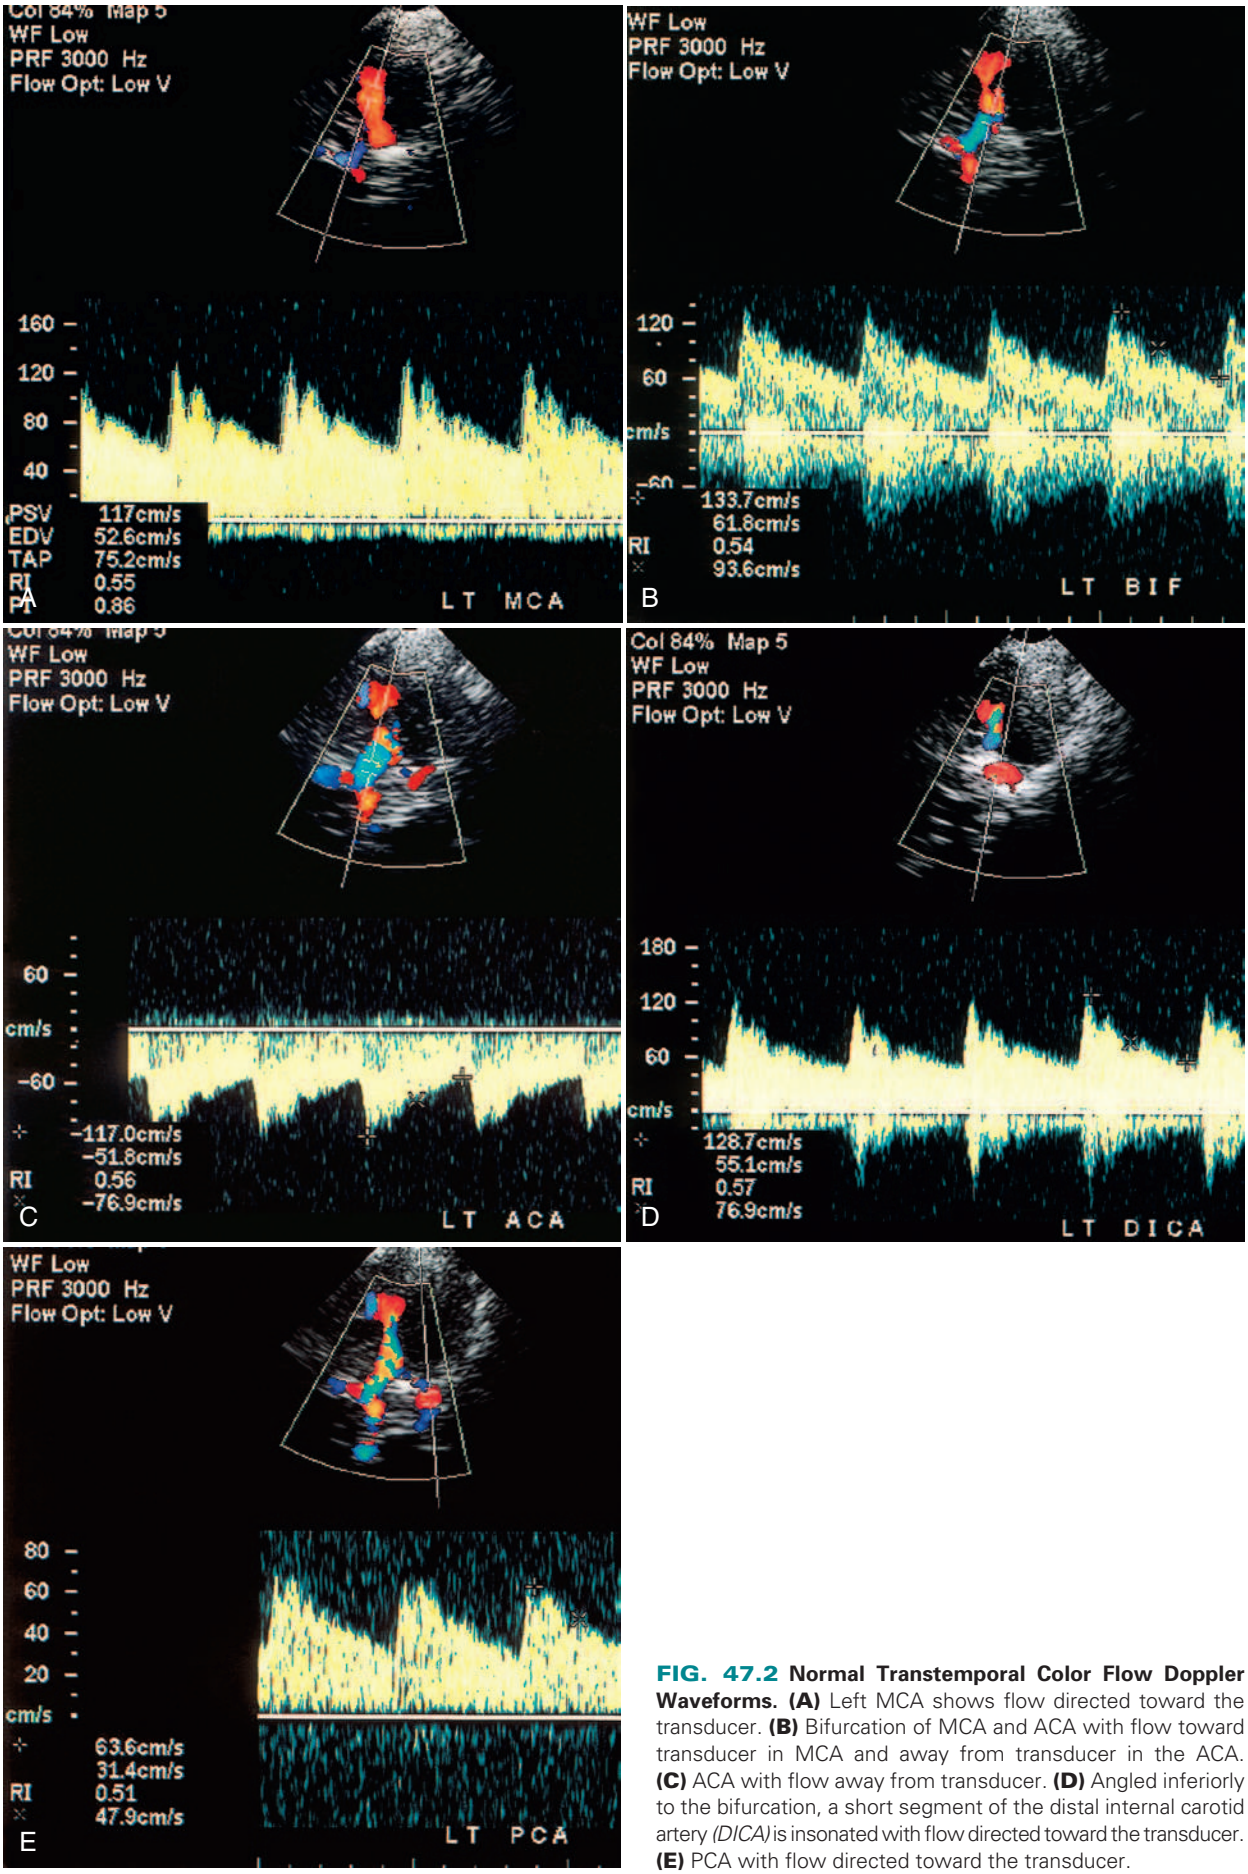

FIG. 47.2 Normal Transtemporal Color Flow Doppler Waveforms. (A) Left MCA shows flow directed toward the transducer. **(B)** Bifurcation of MCA and ACA with flow toward transducer in MCA and away from transducer in the ACA. **(C)** ACA with flow away from transducer. **(D)** Angled inferiorly to the bifurcation, a short segment of the distal internal carotid artery *(DICA)* is insonated with flow directed toward the transducer. **(E)** PCA with flow directed toward the transducer.

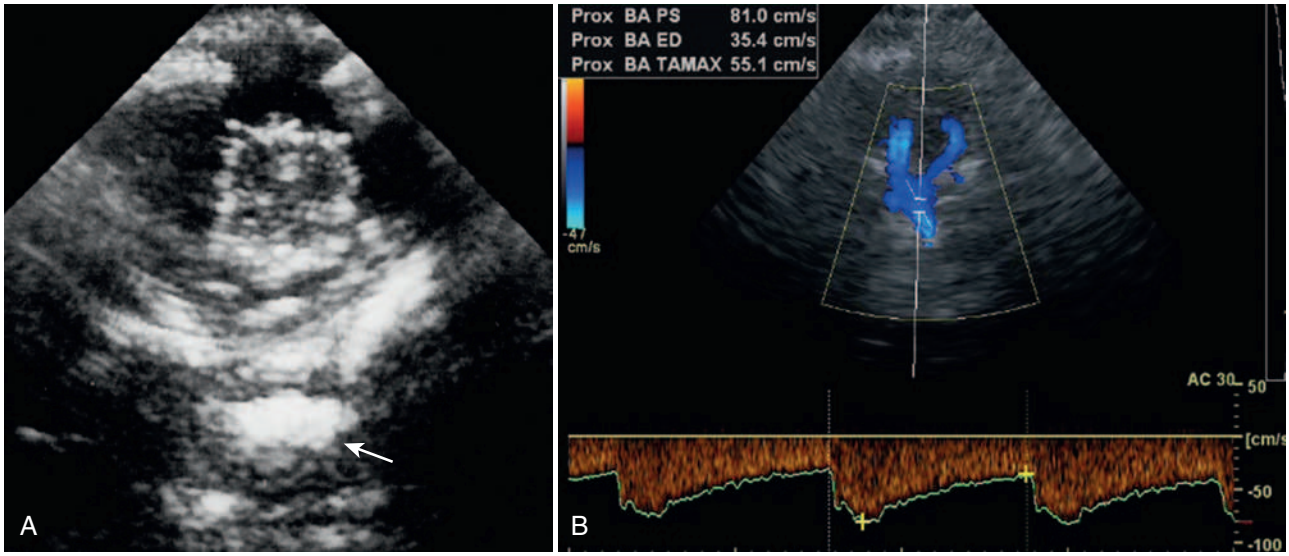

FIG. 47.3 Occipital View Through Foramen Magnum. (A) Normal landmark in the foramen magnum view shows rounded medulla just anterior to the very echogenic clivus *(arrow).* **(B)** With color flow Doppler imaging, the V-shaped vertebral arteries *(blue)* join to form the basilar artery at the medulla-pons junction. Cursor is on the left vertebral artery. Spectral Doppler ultrasound waveforms in the basilar artery show flow away from the transducer.

assessing stroke risk in children with sickle cell anemia, guidelines regarding normal versus abnormal/conditional velocities were validated in large clinical trials using nonduplex equipment that was not angle-corrected.[20-23] Angle correction can significantly increase velocities in vessels that are not coursing directly toward the transducer.[24] Although angle correction has been suggested as a way to correct for variations between the imaging and nonimaging examinations, the lack of published data for angle-corrected velocities currently limits this approach.[12,13,25] Audible optimization for curser placement is key in obtaining similar values with TCD and TCDI without angle correcting. Placing a cursor on a two-dimensional color image may not result in the most optimized tracing because the third dimension of the vessel may be out of the image plane. For this reason, curser placement based solely on a color image may result in a lower velocity than curser placement utilizing the highest achievable audible Doppler frequency. Because the MCA and OA usually course almost directly toward or away from the transducer using the technique described here, angle correction is less of an issue in these vessels. ACA and PCA velocities are more variable because of their tortuous course.

An index of pulsatility, either the **pulsatility index** (PI) (PSV – DV [diastolic velocity]/mean velocity) or **resistive index** (RI) (PSV – DV/PSV), can also be evaluated. Both of these indices are ratios and therefore minimize the effect of vessel angulation.

Physiologic variables including age, gender, hematocrit, viscosity, carbon dioxide, temperature, blood pressure, and mental or motor activity can impact flow velocity.[17] Age-dependent reference values are available for velocities of the various intracranial vessels.[26,27] Early in life, velocities increase with age, demonstrating a rapid increase after birth and a slower increase until 6 to 8 years of age. Afterward and through adolescence, a slow decrease is seen until 70% of the maximal velocity is reached around 18 years of age. Regarding gender, slightly higher velocities are observed in pubertal girls when compared to boys.[28] An inverse relationship is present between hematocrit and viscosity and flow velocity; a decrease in 30% to 40% of the hematocrit will result in an increase in velocities around 20%.[17] If anemia is the cause of elevated velocities, the changes should be detected in all of the intracranial arteries. A focal velocity increase suggests a focal cause.

Changes in arterial carbon dioxide (CO_2) affect cerebral blood flow and arterial velocities. **Hyperventilation** causes a decrease in the MCA mean velocity and an increase in the PI. **Hypoventilation** causes an increase in MCA mean velocity and decrease in PI. If a child is sleeping or in pain and is hyperventilating, TCD results may be affected.

Heart rate also influences intracranial arterial velocities. The sonographer may need to adjust Doppler display sweep time in extreme cases of bradycardia or tachycardia. If autoregulation is intact, cardiac output should not have an affect on TCD velocities.

Velocities can demonstrate daily and interobserver variability. Studies evaluating these variations suggest that normal daily changes should be less than 10 cm/sec and interobserver variability can be 7.5% (measured at the same time) to 13% (daily variation). They suggest that a variation of more than 14% be considered abnormal.[29]

Normal mean velocity in the MCA in adults range from 50 to 80 cm/sec; in the ACA, 35 to 60 cm/sec; in the PCA, 30 to 50 cm/sec; and in the basilar artery, 25 to 50 cm/sec. PSVs up to 150 cm/sec have been described in patients with SCD secondary to anemia.[30,31] The velocity in the OA is normally about one-fourth

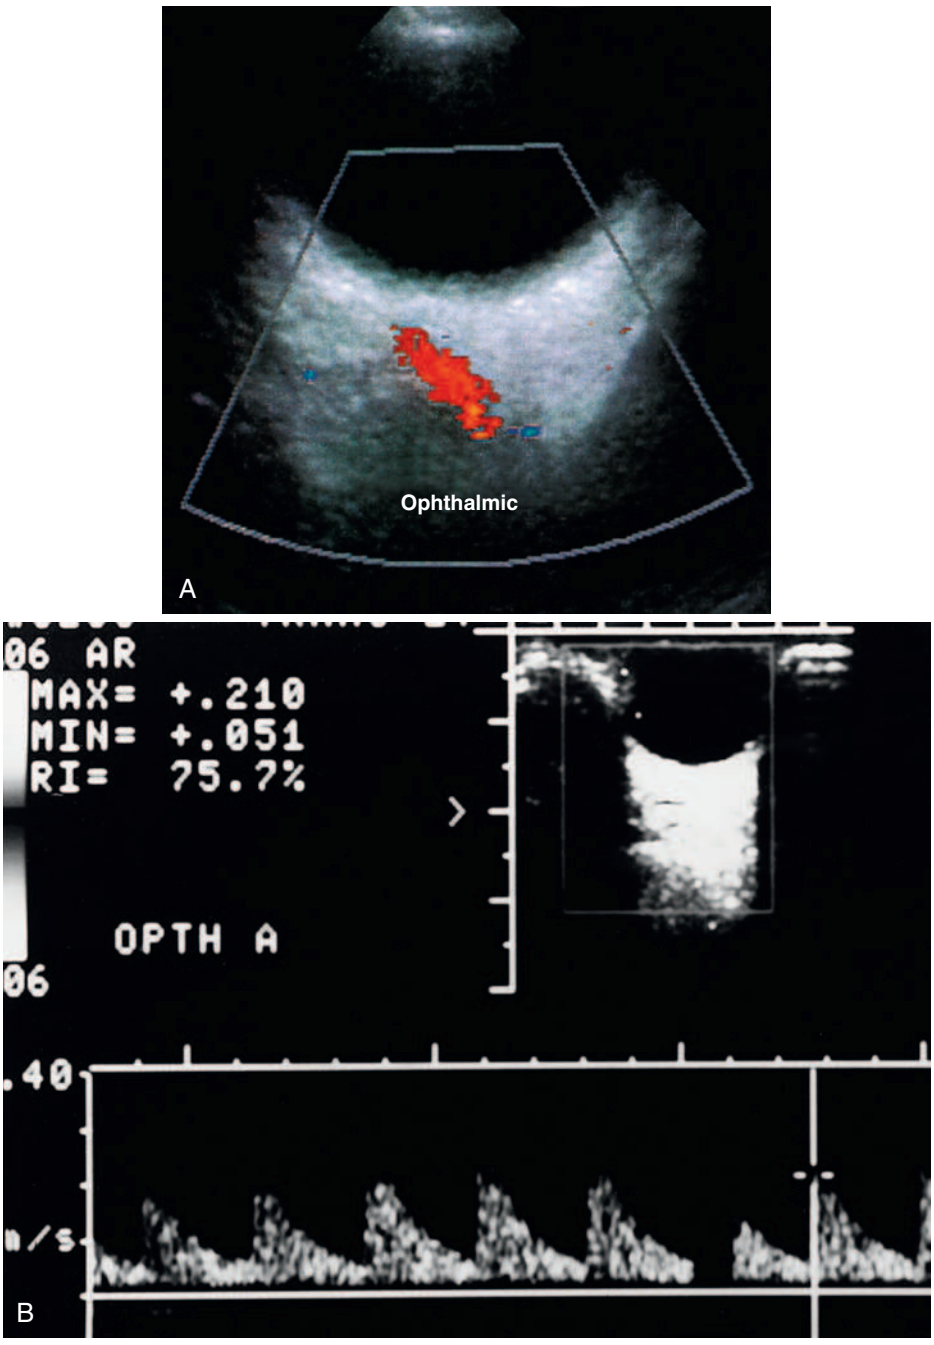

FIG. 47.4 Normal Transcranial Doppler Sonography Through Eye. (A) Color flow Doppler sonogram visualizing the ophthalmic artery (OA) posterior to the globe with flow directed toward the transducer *(red)*. **(B)** Normal waveform of OA with RI of 0.76.

the velocity in the MCA. The velocity in the PCA and vertebral and basilar arteries should be about one-half the velocity in the MCA.

The normal PI ranges from 0.7 to 1.1 and the normal RI ranges from 0.43 to 0.58 after fontanelle closure.[27] The OA has a higher RI, usually between 0.70 and 0.79, and less diastolic flow because it supplies a muscular bed[14] (see Fig. 47.4B). An increase in diastolic flow will result in a decrease in the RI, whereas a decrease in diastolic flow will result in an increase in the RI. As intracranial pressure increases above mean arterial pressure, diastolic flow may become reversed, demonstrating an RI of greater than 1.[32]

The **Lindegaard ratio** is a ratio between the velocity of the MCA or ACA and the ipsilateral extracranial ICA and can help differentiate changes caused by generalized hyperemia from vasospasm. A similar ratio can also be obtained between the basilar artery and the extracranial vertebral artery.[33]

ULTRASOUND POWER SETTINGS

The American Institute of Ultrasound and Medicine and the U.S. federal guidelines of the spatial peak temporal average intensity (I_{SPTA}) for the pediatric head recommend not to exceed 94 mW/cm^2. The limit decreases to 17mW/cm^2 when evaluating vessels in the eye.[34] A maximum mechanical index of 0.28 is also recommended with a limit in the time OA of insonation. The power settings of transducers of various manufacturers are different for each piece of equipment and each probe.[35] Depending on the manufacturer and transducer, energy levels may be within the guidelines only on the low power setting.

When the transtemporal approach is used, at least 65% (and likely more) of the energy is attenuated by the skull. Lower MHz transducers are thus needed for adequate penetration of the skull, and higher settings may therefore be used. It is important when moving to OA insonation that a different transducer with lower setting be used.[36] At any time, the "as low as reasonably achievable" (ALARA) principle should be followed by limiting the exposure time and increasing gain to improve signal and avoiding an increase in power output.

LIMITATIONS AND PITFALLS IN TRANSCRANIAL DOPPLER

TCD and TCDI are inexpensive, noninvasive, and widely available, but they are highly operator dependent. Thorough training and knowledge are required to adequately perform this type of examination.[37,38] Finding the best transtemporal window can be difficult. The transtemporal window varies in size and location. Anywhere from 10% to 37% of patients do not have a good acoustic window.[39] The inability to penetrate the temporal bone is influenced by age, sex, and race. Hyperostosis of the skull is most common in African Americans, Asians, and older females.[38] Contrast agents have been used in an attempt to improve vessel visualization.[40]

There are numerous pitfalls to performing a TCD sonographic examination in children (Table 47.1).[13,41,42] Low wall filter adjustments, high Doppler ultrasound frequency, and critical assessment of velocity spectral analysis are crucial for accurate interpretation of the data.[10] If the examiner becomes lost, it is best to start over, using a systematic search for a better window. First, with TCDI, identify the cerebral peduncles on gray scale. Then add color, optimizing color control settings, angling the transducer, and locating the MCA-ACA bifurcation. Then follow the exam protocol. Remember that although the clinician can assume a patent circle of Willis in children, one artery should not be used to represent the entire cerebral circulation.

TABLE 47.1 Tips for Performing Transcranial Doppler Sonography in Children

Issue	Suggested Tips
Child too active	Put the child at ease and answer all questions before starting the exam. Use distractors such as TV. Let younger children sit on the mother's lap.
Doppler signal is weak	Search for a better window. Change the angle of the transducer. Change the sample volume depth. Use maximum power if needed and adjust color gain/PRF setting. Use headphones to hear subtle Doppler signals.
Multiple Doppler signals are noted	Decrease sample volume size. Search for a better window.
Background noise is high	Adjust gain.
Motion artifact	Check for patient motion or transducer motion. Adjust sample volume.
Doppler signal aliasing	Increase PRF setting. Lower baseline.

PRF, Pulse repetition frequency.

CONTRAST ENHANCEMENT

Insufficient temporal bone windows, unfavorable insonation angles, and low flow velocities can result in nonvisualization of normal or pathologic flow with TCD sonography. In adult studies, echocontrast agents such as galactose microbubble suspensions and sulfur hexafluoride microbubbles have been used in an attempt to increase the applications of transcranial studies.[43-46] These contrast agents have been shown to facilitate visualization of vessel patency, stenosis, occlusion, and collateral flow.[47-49] Small-caliber arteries and vessels that run at unfavorable angles may be identified.[50] Velocities obtained using this method provide reliable data regarding stenosis and occlusion and comparisons with digital subtraction angiography have been favorable.[43,50,51]

Indications for echo-enhancing agents include depiction of vessel anatomy of tumors, vascular malformations, and stenosis. In the evaluation of brain death, use of contrast may improve the level of confidence of documenting low flow. Limitations of this technique include short duration of some of the contrast agents, blooming artifact, and limited availability for pediatric studies in the United States.

Contrast-enhanced three-dimensional power Doppler sonography has also been shown to improve identification of vessels. Using this technique in adults with inadequate windows, Postert et al.[50] noted clear three-dimensional visualization of most major intracranial vascular segments. The addition of contrast resulted in more sensitive sonographic imaging than unenhanced three-dimensional reconstructions. These studies were found to be easy to perform and interpret, increasing the level of operator diagnostic confidence.[52]

INDICATIONS FOR TRANSCRANIAL DOPPLER IMAGING

Indications for Transcranial Doppler in Adults

Detection and follow-up of stenosis or occlusion in major intracranial arteries
Monitoring of thrombolytic therapy
Detection of cerebral vasculopathy and evaluation of collateral intracranial flow
Detection and monitoring vasospasm
Detection right-to-left shunts and/or circulating cerebral microemboli
Assessment of cerebral vasomotor reactivity
Adjunct in evaluation of cerebral death
Intraoperative evaluation of embolization, thrombosis, and hyper/hypoperfusion
Assessment of arteriovenous malformations and intracranial aneurysms
Evaluation of positional vertigo or syncope

Additional Indications for Transcranial Doppler in Children

Evaluation of stroke risk in sickle cell disease
Detection and monitoring vasospasm
Assessment of intracranial pressure and hydrocephalus
Assessment of hypoxic ischemic encephalopathy
Assessment of cerebral vasomotor reactivity
Adjunct in evaluation of cerebral death
Assessment of dural venous patency and arteriovenous fistula
Intraoperative monitoring

Sickle Cell Disease

Neurologic manifestations are common in SCD and include overt infarction or stroke, **silent cerebral infarcts,** and hemorrhage (rare in children, more often seen secondary to aneurysm rupture in adults).[53] Stroke results in neurologic deficits, and silent cerebral infarcts can result in academic and behavioral difficulties and increase the risk of having a future stroke.[54] Patients present with vasculopathy involving the large intracranial arteries, most frequently the distal internal carotid artery and proximal middle and anterior cerebral arteries. The vasculopathy can progress for months to years before symptoms develop and can result in formation of numerous small collateral vessels, consistent with **moyamoya syndrome.** This occlusive vasculopathy is characterized by endothelial damage with intimal thickening, muscular proliferation, and inflammatory changes with or without in situ thrombosis.[53,55,56] Hemodynamic abnormalities in sickle cell anemia (including hyperemia, hypervolemia, and cerebral vascular dilation) play a role in the development of neurologic injuries, especially in the pathogenesis of silent cerebral infarcts.[54]

The incidence of stroke varies depending on the origin of the patient and haplotype of SCD; for example, the incidence is 4.1% in Mediterranean patients, 6.7% in first-generation African patients living in France, and 10% in African Americans younger than 20 years of age.[57] Silent cerebral infarcts are the more common type of cerebral injury in patients with SCD. They are described as a 3 mm or larger lesion seen on at least two T2-weighted magnetic resonance imaging (MRI) sequences with no history or clinical evidence of focal neurologic deficit.[56] Silent cerebral infarcts can be seen in patients younger than 1 year of age with reported incidences of 13% by 13.7 months, 27% in patients younger than 6 years and 37% in 14-year-olds.[54] First and recurrent strokes can be prevented, but not completely suppressed, by transfusion therapy in patients at risk.[19,58] With transfusion treatment the anemia is partially corrected and cerebrovascular reserve is improved,[59] resulting in a decrease in TCD velocities[60] and a reduction in the risk of stroke to less than 1%,[61] although patients may still develop new silent cerebral infarcts (18% at 1-year follow-up and 28% at 2-year follow-up).[54] **Bone marrow transplantation** has proved curative in young patients with symptomatic SCD and has led to stabilization of nervous system vasculopathy.[62]

TCD sonography has proved to be a safe, reliable, and cost-effective screening method for children at risk of stroke. A sensitivity of 90% and specificity of 100% detecting arteriopathy after stroke when compared to angiography has been described.[63] No significant association has been identified between silent infarcts and TCD velocities[54,64] or magnetic resonance angiography (MRA).[54]

Adams et al. first showed the effectiveness of nonimaging Doppler sonographic studies in screening for cerebrovascular disease in patients with SCD.[19,30,31,65] Using the transtemporal and suboccipital approach, Adams et al. screened 190 asymptomatic SCD patients and found in clinical follow-up that a TAMM velocity in the MCA of 170 cm/sec or greater indicated a patient at risk for development of cerebrovascular accident (CVA, stroke).[65]

Using duplex Doppler imaging, MRA, and MRI, Seibert et al.[66] described five indicators of cerebrovascular disease in patients with SCD: (1) maximum velocity in the OA of more than 35 cm/sec (Fig. 47.5), (2) mean velocity in the MCA of more than 170 cm/sec (Fig. 47.6), (3) RI in the OA less than 0.6 (Fig. 47.7), (4) velocity in the OA greater than that of the ipsilateral MCA, and (5) maximum velocity in the PCA or the vertebral or basilar arteries greater than maximum velocity in the MCA. An 8-year follow-up of 27 neurologically symptomatic and 90 asymptomatic sickle cell patients showed all five original TCD indicators of disease were still significant.[67] Four additional factors were also significant: (1) turbulence, (2) PCA or ACA visualized without seeing the MCA (Figs. 47.8, 47.9, 47.10), (3) any RI less than 0.3, and (4) maximum MCA velocity greater than 200 cm/sec (Fig. 47.11). The sensitivity of Doppler ultrasound as a predictor of stroke was 94% with a specificity of 51%.

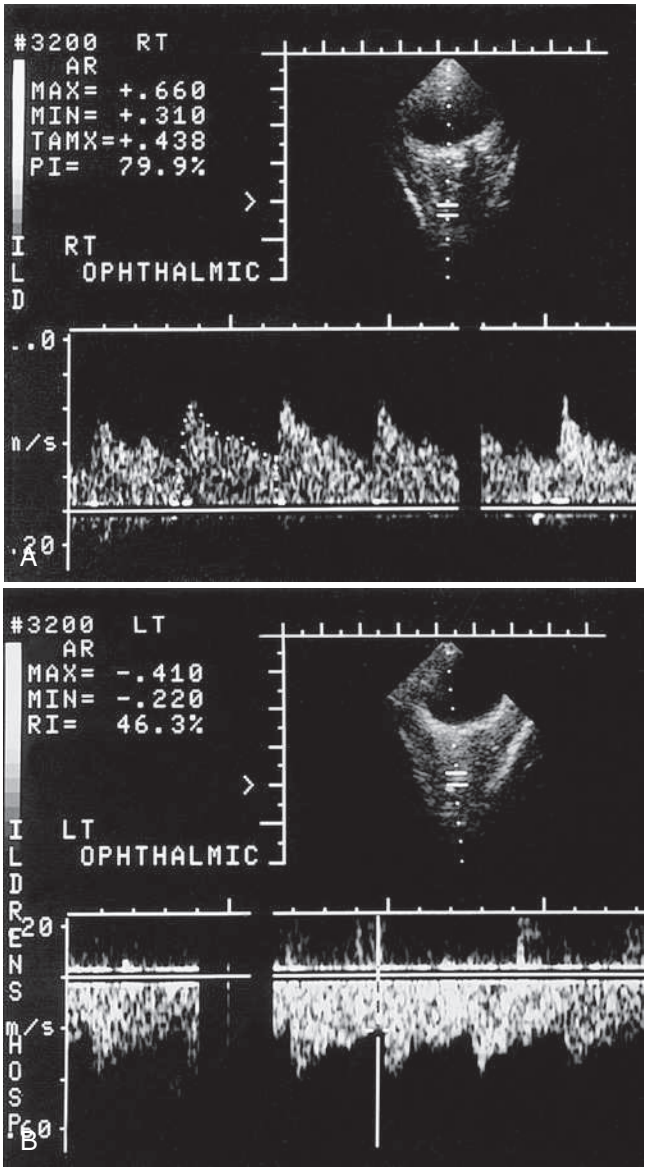

FIG. 47.5 Abnormal Ophthalmic Artery (OA) Flow in 16-Year-Old Boy With Sickle Cell Disease. Patient had his first left cerebrovascular accident (CVA, stroke) at age 7 years. Spectral Doppler ultrasound waveforms through the eye show increased diastolic flow in both OAs. **(A)** Increased velocity in the right OA with maximum velocity of 66 cm/sec; **(B)** reversed flow in the left OA.

Cerebrovascular Disease: Indicators in Children With Sickle Cell Disease

Maximum velocity, OA ≥ 35 cm/sec
TAMM velocity, MCA ≥ 170 cm/sec
RI in OA ≤ 0.6
Velocity in OA greater than velocity in ipsilateral MCA
Maximum velocity in PCA, vertebral, or basilar arteries greater than or equal to MCA velocity
Turbulence
Visualization of PCA or ACA without visualization of MCA
Any RI < 0.3
Maximum MCA PSV ≥ 200 cm/sec

ACA, Anterior cerebral artery; *MCA,* middle cerebral artery; *OA,* ophthalmic artery; *PCA,* posterior cerebral artery; *PSV,* peak systolic velocity; *RI,* resistive index, *TAMM,* time-averaged mean of the maximum.

Data from Seibert JJ, Miller SF, Kirby RS, et al. Cerebrovascular disease in symptomatic and asymptomatic patients with sickle cell anemia: screening with duplex transcranial Doppler US—correlation with MR imaging and MR angiography. Radiology. 1993;189(2):457-466[66]; Seibert JJ, Glasier CM, Kirby RS, et al. Transcranial Doppler, MRA, and MRI as a screening examination for cerebrovascular disease in patients with sickle cell anemia: an 8-year study. Pediatr Radiol. 1998;28(3):138-142.[67]

Siegel et al.[68] compared transtemporal TCD to neurologic examination and also found a maximum flow in the MCA of more than 200 cm/sec or less than 100 cm/sec (including no flow) as significant for disease. Verlhac et al.[63] studied SCD with duplex Doppler imaging with a 3-MHz transducer transtemporally and suboccipitally, as well as with MRA and MRI. Arteriography was performed in patients with suspected stenosis on TCD sonography. They found that patients with a mean velocity greater than 190 cm/sec had stenosis on arteriography. Kogutt et al.[69] evaluated symptomatic SCD patients and found 91% sensitivity and 22% specificity of TCD using MRA as the reference standard. Abnormal TCD values were (1) maximum and mean velocity (V_{max} and V_{mean}) greater than 2 standard deviations (SD) from normal values reported by Adams et al.[65,70] in SCD: V_{max} MCA > 168 ± −38 cm/sec and V_{mean} MCA 115 ± −31 cm/sec, and V_{max} ACA 138 ± 34 cm/sec and V_{mean} ACA 94 ± 28 cm/sec; (2) RI < 0.40; and (3) V_{max} MCA < V_{max} ACA (Fig. 47.12).

Screening sickle cell patients with the nonimaging pulsed Doppler ultrasound technique involves scanning the patient transtemporally to evaluate the MCA, bifurcation, DICA, ACA, and PCA. The OA can be evaluated through the orbit. The basilar and vertebral arteries can be evaluated from the occipital approach. The PSV, EDV, TAMM velocity, and RI of each of these vessels should be measured at least twice to obtain the most accurate measurement.[71] The MCA should be tracked from the peripheral branch to the bifurcation with velocities obtained every 2 mm. Optimizing the tracing is crucial in identifying regions of stenosis.[72] Color Doppler flow imaging (TCDI) can also be used to screen SCD patients. This technique is faster to learn, allows for quicker vessel identification, and improves gate placement. Because image-based probes tend to be larger than nonimaging probes, however, optimizing the tracing may be more difficult and can result in slightly lower velocities than those obtained by nonimaging methods.[20,21]

The Stroke Prevention Trial in Sickle Cell Anemia (STOP) study led by Robert Adams showed that regular transfusion of children at risk for stroke (based on Doppler sonography) could prevent CVA.[19,72-75] Adams studied children age 2 to 16 years, from 14 medical centers, who had MCA mean velocities higher than 200 cm/sec and were at risk of developing stroke. Half received blood transfusions every 3 to 4 weeks, enough to lower sickle cell hemoglobin to below 30%. After 1 year, the transfusions

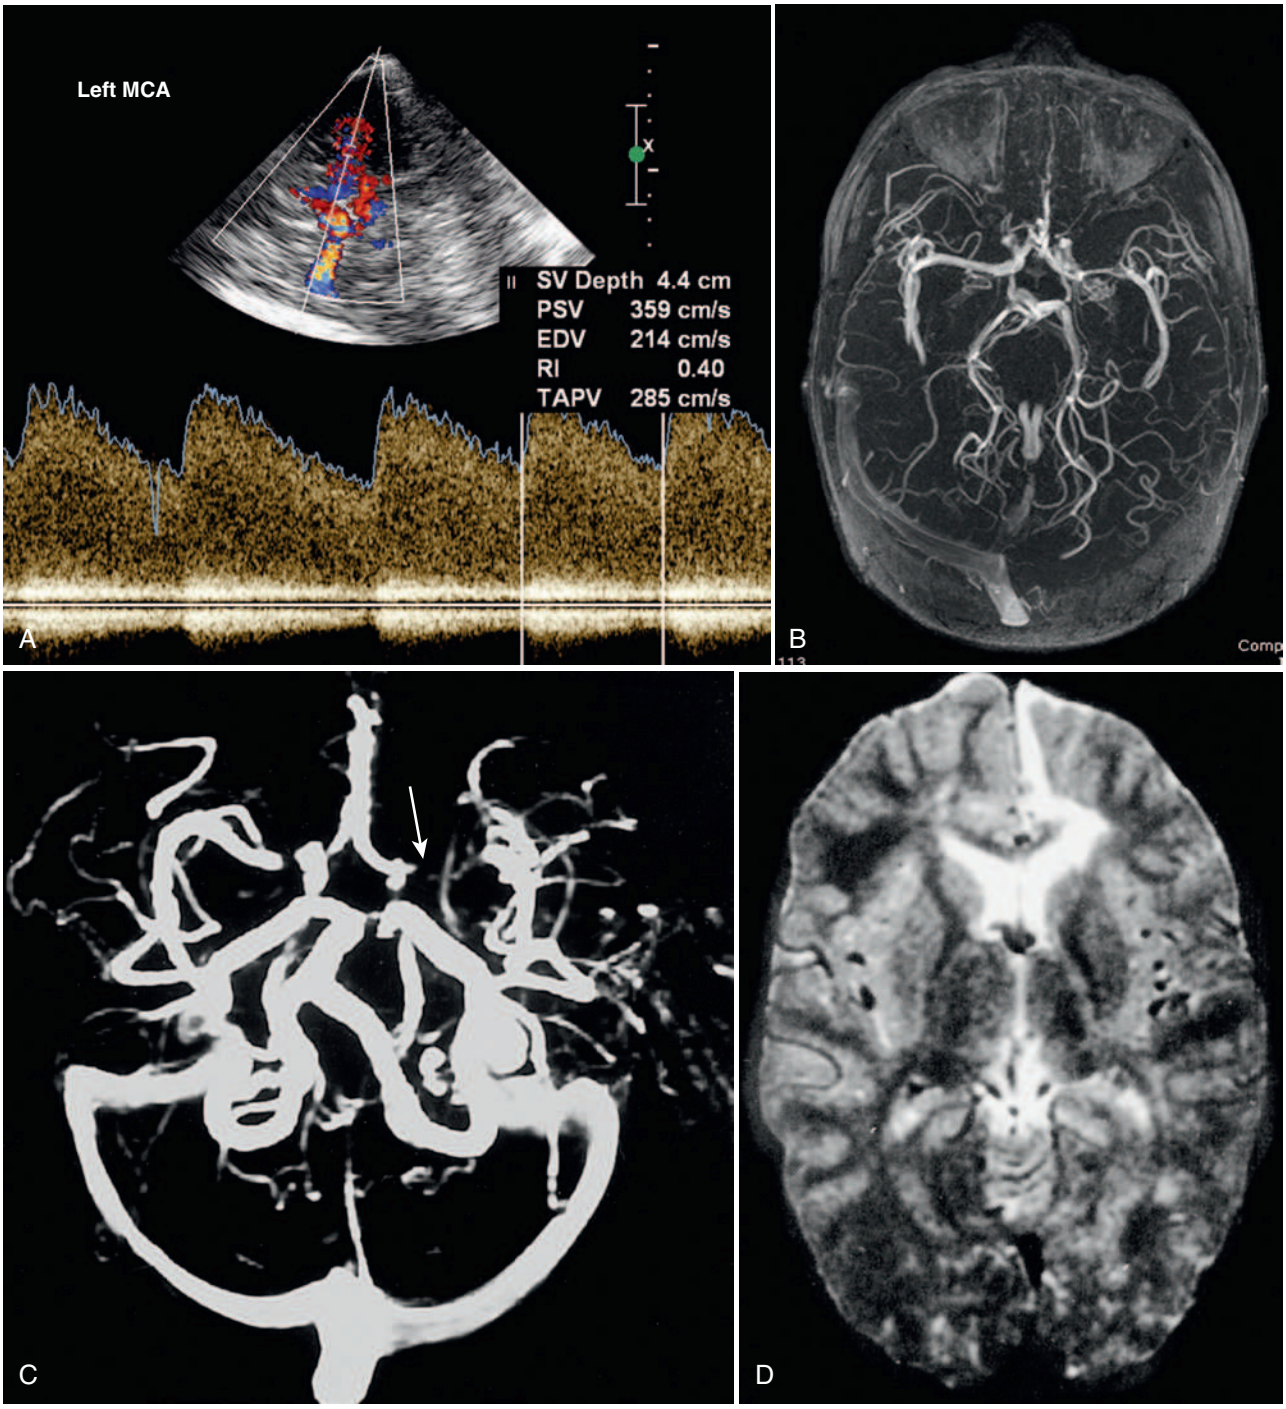

FIG. 47.6 Middle Cerebral Artery (MCA) Stenosis in 9-Year-Old With Sickle Cell Disease. (A) TCD sonogram demonstrates extremely elevated velocities in the left MCA, including a PSV of 359 cm/sec and time-averaged peak velocity of 285 cm/sec. **(B)** MRA 3D time-of-flight image of the circle of Willis demonstrates diffuse narrowing of the left MCA, with multiple small vessels suggestive of **moyamoya angiopathy. (C)** Reformatted maximum-intensity projection image of the same patient confirms narrowing of the left MCA *(arrow)*. **(D)** Axial fast spin-echo T2-weighted MR image demonstrates volume loss of the left basal ganglia and left hemispheric white matter, with signal voids secondary to multiple collaterals.

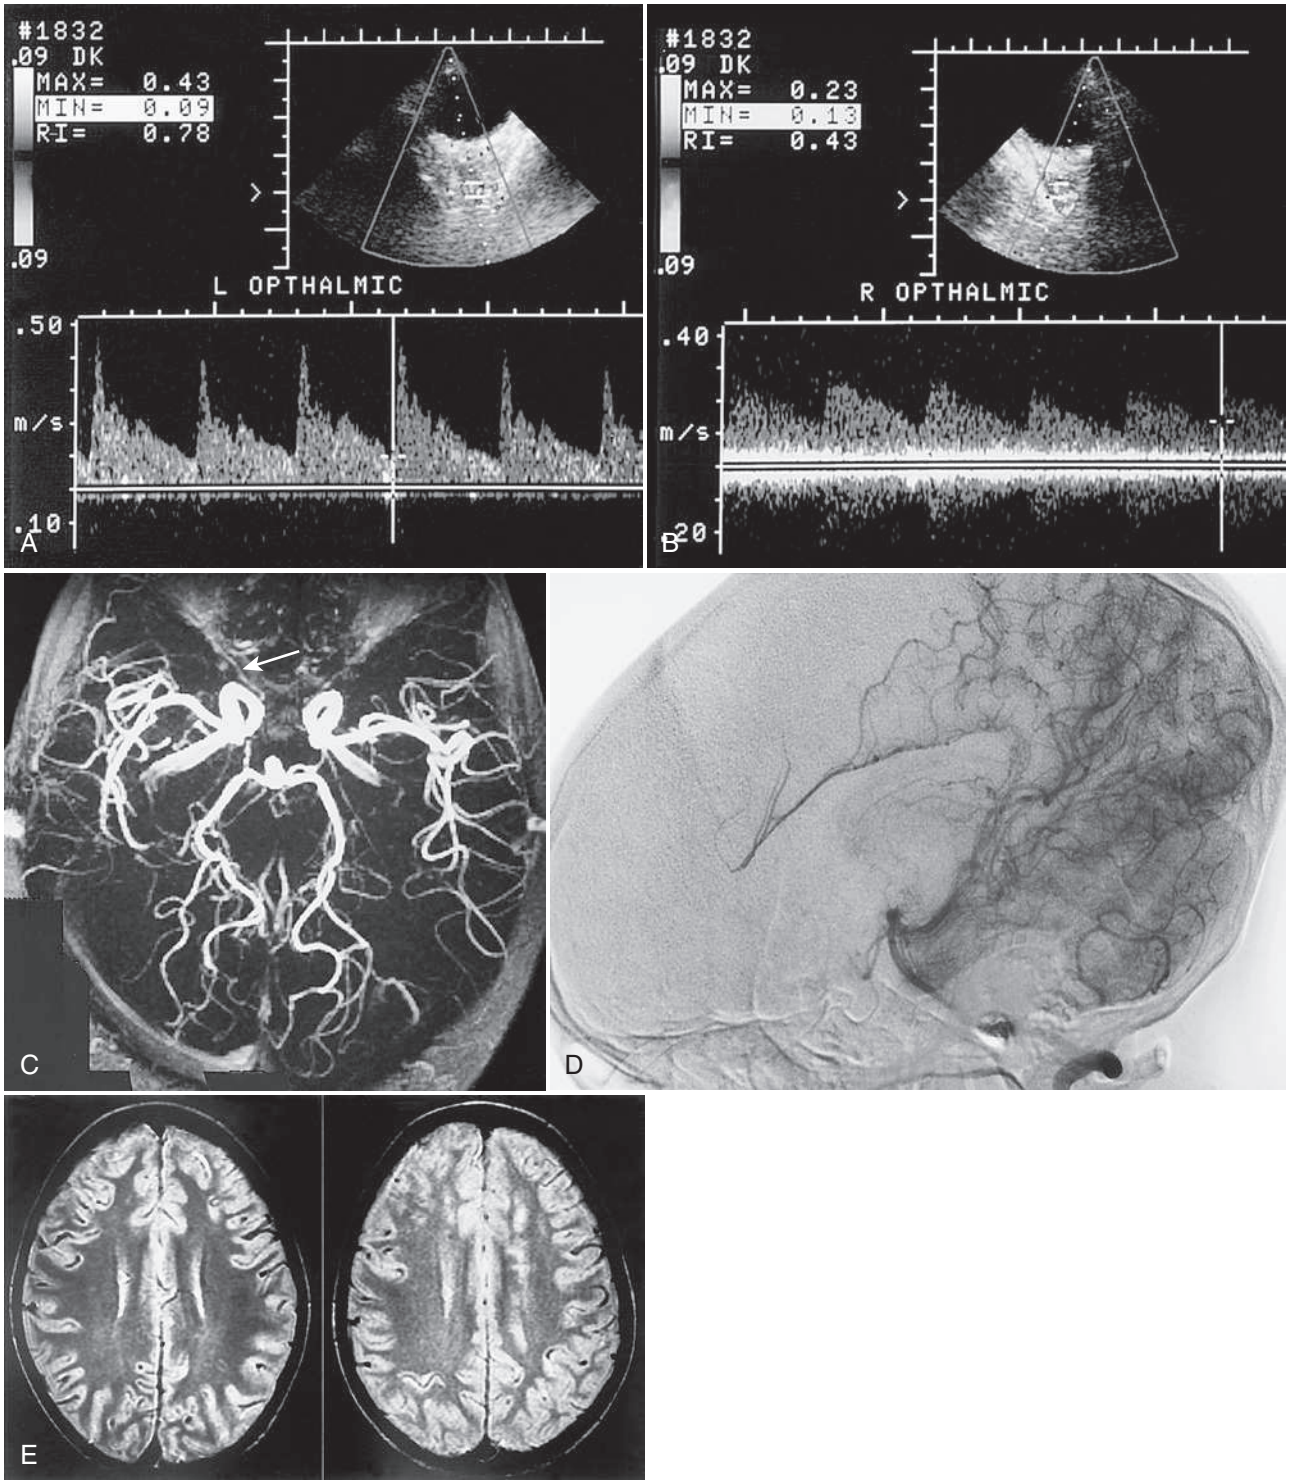

FIG. 47.7 Developing Stroke in Asymptomatic 13-Year-Old Boy With Sickle Cell Anemia. (A) TCD sonogram through the left eye shows relatively normal ophthalmic waveform with normal RI of 0.78 but increased flow with a maximum velocity of 43 cm/sec. **(B)** TCD sonogram through the right eye shows more abnormal waveform with increased diastolic flow in the right ophthalmic artery (OA) with a low RI of 0.43. **(C)** Axial 3D time-of-flight MR angiogram shows absent ACAs bilaterally with prominent right OA *(arrow).* **(D)** Vertebral arteriogram demonstrates retrograde filling of the ACA. **(E)** Initial image (on *left*) obtained at time of MRA is normal. Six months later, patient had acute stroke, and second MR angiogram now shows bilateral, spotty, hyperintense areas in the ACA distribution. Both images are axial proton density weighted.

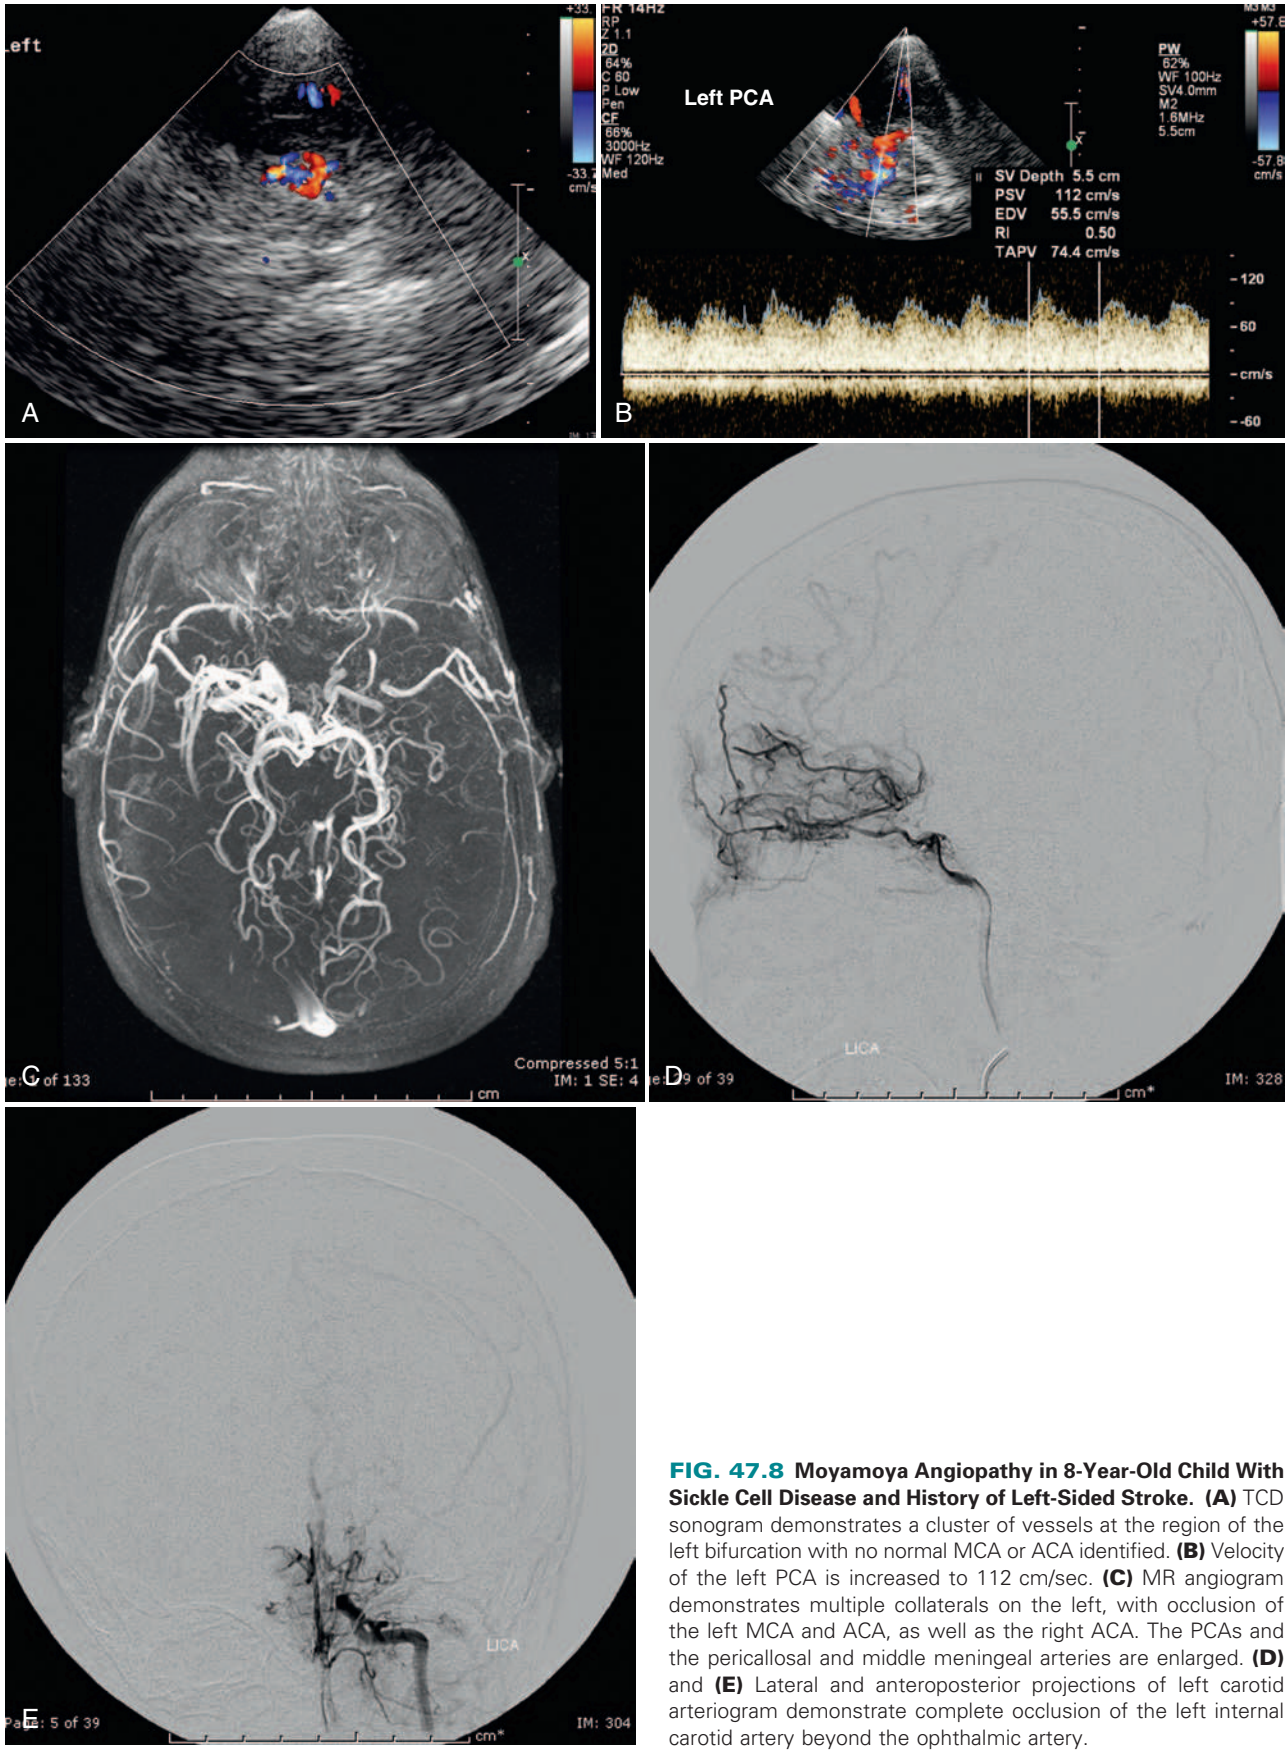

FIG. 47.8 Moyamoya Angiopathy in 8-Year-Old Child With Sickle Cell Disease and History of Left-Sided Stroke. (A) TCD sonogram demonstrates a cluster of vessels at the region of the left bifurcation with no normal MCA or ACA identified. **(B)** Velocity of the left PCA is increased to 112 cm/sec. **(C)** MR angiogram demonstrates multiple collaterals on the left, with occlusion of the left MCA and ACA, as well as the right ACA. The PCAs and the pericallosal and middle meningeal arteries are enlarged. **(D)** and **(E)** Lateral and anteroposterior projections of left carotid arteriogram demonstrate complete occlusion of the left internal carotid artery beyond the ophthalmic artery.

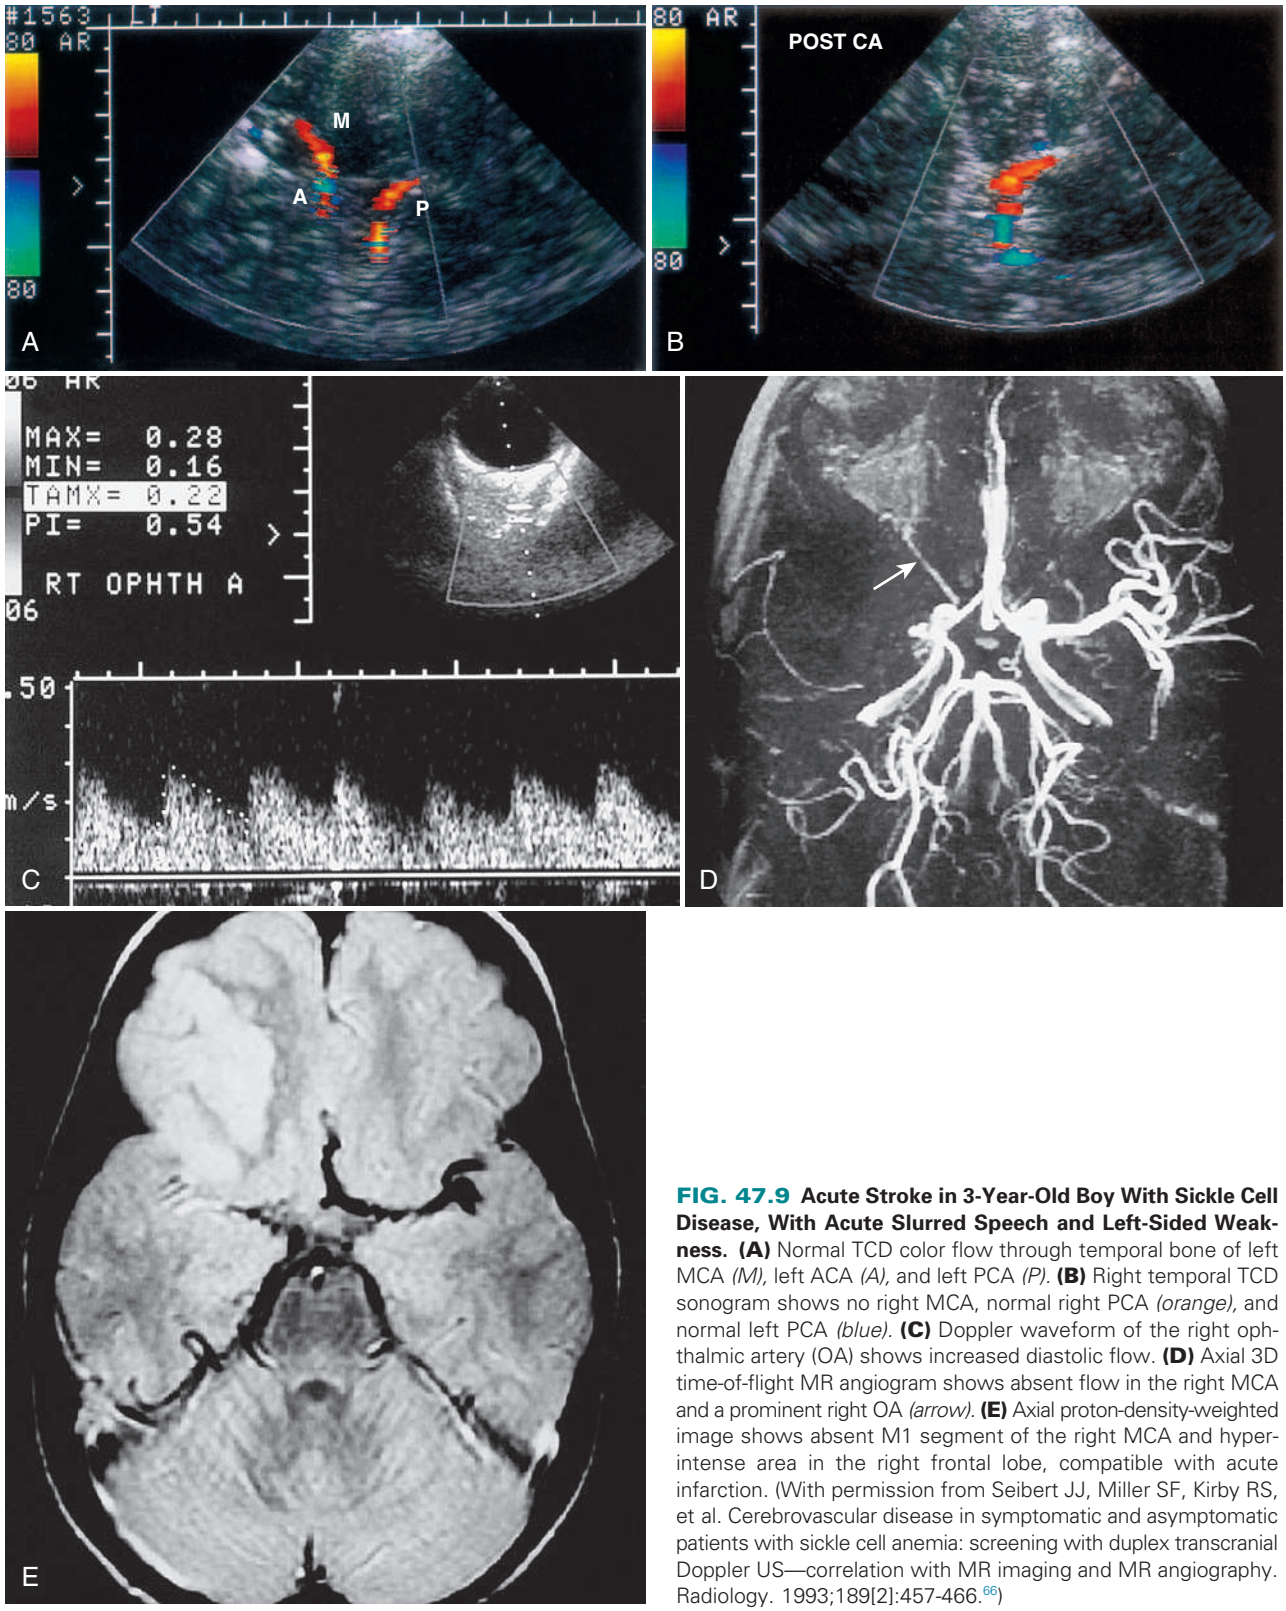

FIG. 47.9 Acute Stroke in 3-Year-Old Boy With Sickle Cell Disease, With Acute Slurred Speech and Left-Sided Weakness. (A) Normal TCD color flow through temporal bone of left MCA *(M),* left ACA *(A),* and left PCA *(P).* **(B)** Right temporal TCD sonogram shows no right MCA, normal right PCA *(orange),* and normal left PCA *(blue).* **(C)** Doppler waveform of the right ophthalmic artery (OA) shows increased diastolic flow. **(D)** Axial 3D time-of-flight MR angiogram shows absent flow in the right MCA and a prominent right OA *(arrow).* **(E)** Axial proton-density-weighted image shows absent M1 segment of the right MCA and hyperintense area in the right frontal lobe, compatible with acute infarction. (With permission from Seibert JJ, Miller SF, Kirby RS, et al. Cerebrovascular disease in symptomatic and asymptomatic patients with sickle cell anemia: screening with duplex transcranial Doppler US—correlation with MR imaging and MR angiography. Radiology. 1993;189[2]:457-466.[66])

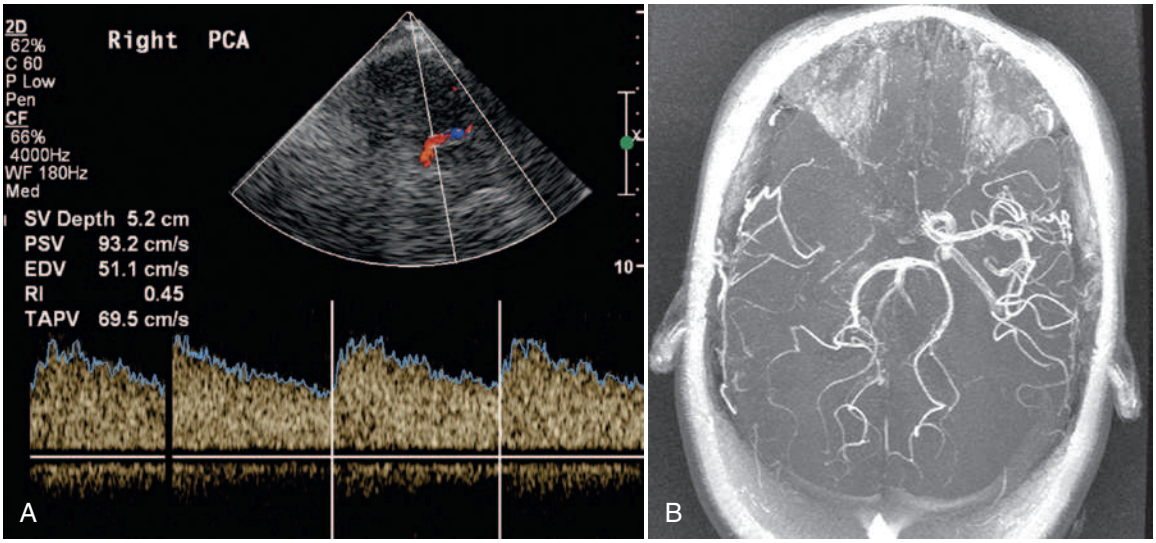

FIG. 47.10 Chronic Right ICA and MCA Stenosis in a 16-Year-Old Child Status Post Bilateral Encephaloduroarteriosynangiosis. (A) Color Doppler imaging demonstrates nonvisualization of the right ACA and MCA with flow documented in the right PCA suggesting an adequate window and appropriate optimization of settings. **(B)** Axial three-dimensional time-of-flight MR angiogram demonstrates absent flow in the right ICA, MCA, and ACA with peripheral collaterals.

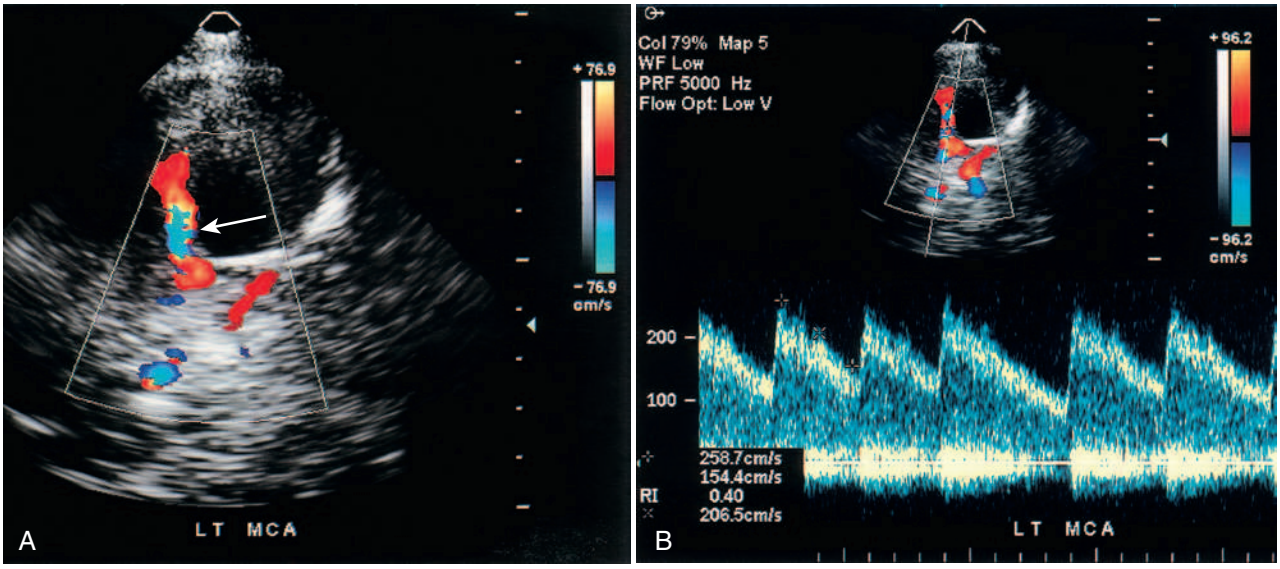

FIG. 47.11 Maximum MCA Velocity Greater Than 200 cm/sec Indicates Cerebrovascular Disease in 4-Year-Old Girl With Sickle Cell Disease. (A) Color Doppler imaging demonstrates a region of aliasing *(arrow)* at the proximal left MCA. **(B)** Doppler waveform confirms the presence of abnormally high mean and peak velocities (TAMM velocity, 206 cm/sec; PSV, 259 cm/sec), which stratify into the "high" stroke risk category. The child started receiving transfusion therapy.

lowered the stroke risk by 90%. Although only one transfusion patient had a stroke (1.6%), 11 (16%) nontransfusion children sustained a CVA (Table 47.2).

After early termination of the study, patients were offered to start or continue transfusion treatment, and an extended evaluation was performed confirming the efficacy of TCD in prediction of stroke risk (even during transfusion treatment) and the benefit of transfusion treatment reducing this risk.[76] This observation period also suggested that the risk of stroke decreases with age progression, even in the absence of transfusion treatment.[76] Reviewing the STOP data, Jones et al.[77] reported that a PSV greater than 250 cm/sec may be useful for assessing stroke risk in SCD patients.

The SIT trial, a multicenter clinical study aimed at evaluating the usefulness of transfusion therapy in the prevention of recurrence of silent clinical infarcts demonstrated that children with silent clinical infarcts and normal TCD who undergo transfusion therapy have a 58% relative risk reduction of infarct recurrence.[59] The results were positive although not as significant as those seen with STOP (92% relative risk reduction).[73]

Verlhac et al.[78] describe the use of evaluation of the extracranial ICA in patients with SCD and suggest that tortuosities of the

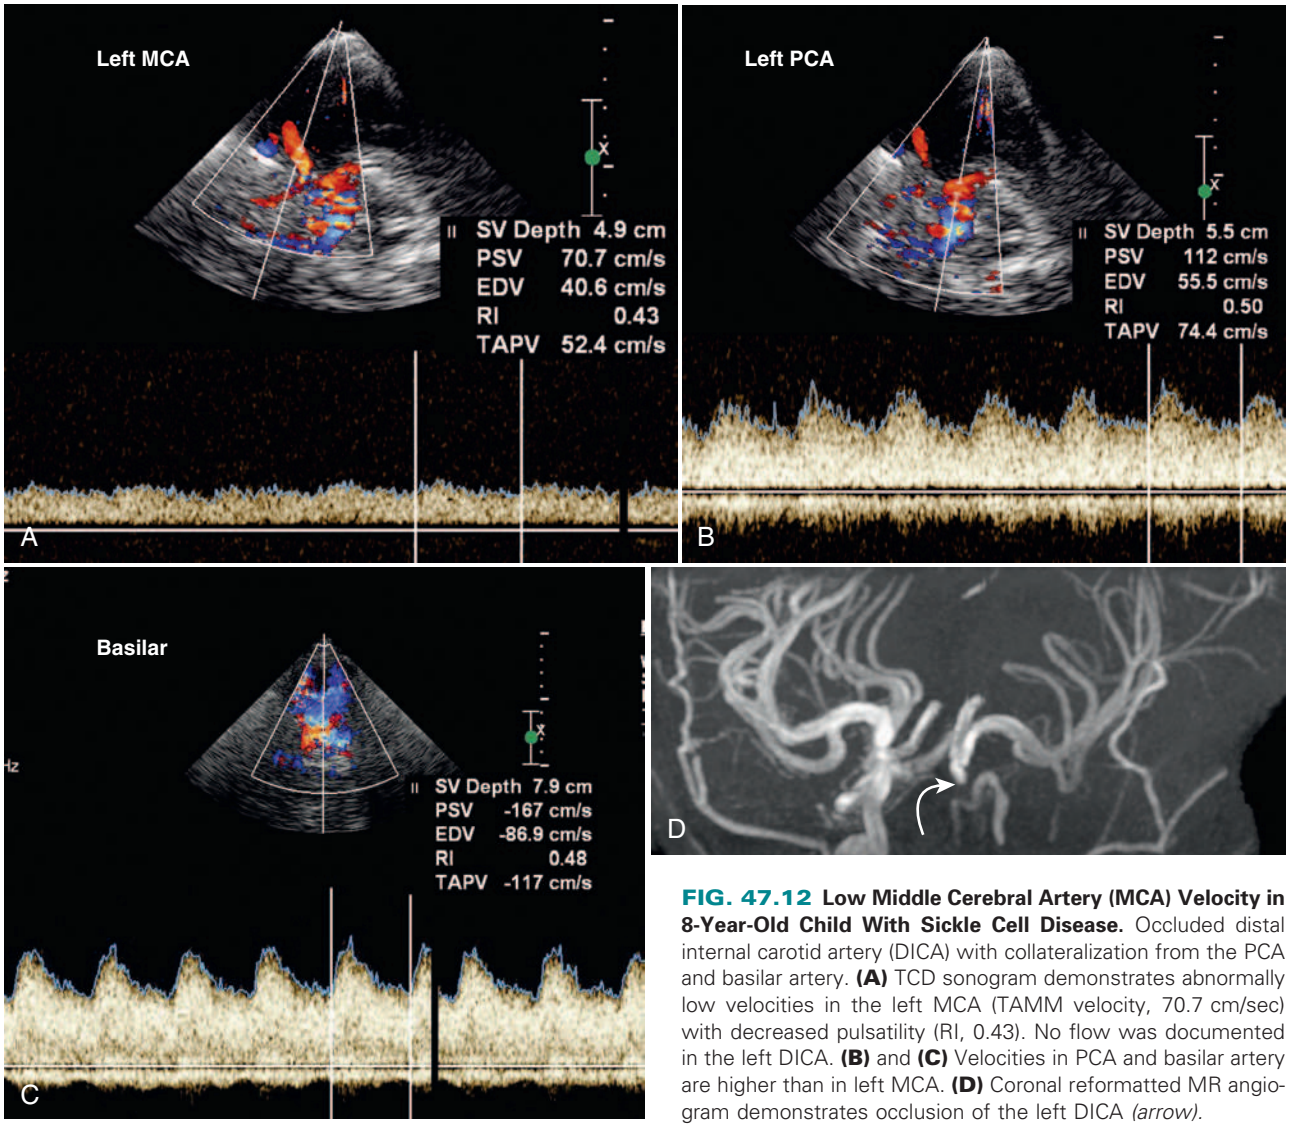

FIG. 47.12 Low Middle Cerebral Artery (MCA) Velocity in 8-Year-Old Child With Sickle Cell Disease. Occluded distal internal carotid artery (DICA) with collateralization from the PCA and basilar artery. **(A)** TCD sonogram demonstrates abnormally low velocities in the left MCA (TAMM velocity, 70.7 cm/sec) with decreased pulsatility (RI, 0.43). No flow was documented in the left DICA. **(B)** and **(C)** Velocities in PCA and basilar artery are higher than in left MCA. **(D)** Coronal reformatted MR angiogram demonstrates occlusion of the left DICA *(arrow)*.

TABLE 47.2 STOP Stroke Risk Categories

Category	Definition
Low	<170 cm/sec TAMM velocity
Conditional	170-199 cm/sec TAMM velocity
Abnormal	≥200 cm/sec TAMM velocity *or* >250 cm/sec PSV

PSV, Peak systolic velocity; *STOP,* Stroke Prevention Trial in Sickle Cell Anemia; *TAMM,* time-averaged maximum mean.
With permission from Adams RJ, McKie VC, Hsu L, et al. Prevention of a first stroke by transfusions in children with sickle cell anemia and abnormal results on transcranial Doppler ultrasonography. N Engl J Med. 1998;339(1):5-11.[73]

ICA increase the risk of developing stenosis. They also report that increased extracranial ICA velocities (>160 cm/sec), even in the absence of abnormal intracranial velocities, should be a considered risk factor for cerebrovascular complications.

TCD is recommended as a screening test for all 2- through 16-year-old children with SCD.[79,80] Optimal timing and frequency vary depending on the presence of velocities used as thresholds (TAMM velocity range cutoff of 155-170 cm/sec) and age.[56,81] It has been suggested that SCD patients with a normal TCD can be followed every 12 months, but closer follow-up should be performed in patients with results at or near the threshold ("conditional" velocities, at 3-6 months).[56] Patients with a TAMM velocity of greater than 200 cm/sec or a PSV greater than 250 cm/sec in the MCA on two examinations are at high risk of stroke and are recommended for transfusion therapy.[77]

All patients with abnormal TCD have vasculopathy, but some patients with vasculopathy and silent stroke can have normal TCD examinations. These patients have more than two times the risk of developing a stroke compared to the unscreened population.[61] In a study comparing the use of PSV versus TAMM velocity in predicting MRI/MRA abnormalities performed by Naffaa et al.,[61] PSV had a higher sensitivity (73% vs. 41%) and TAMM velocity had a higher specificity (100% vs. 81%). They suggest using the PSV as the measurement of choice for TCD screening and lowering the TAMM velocity threshold to 165 cm/sec to obtain a higher sensitivity in the prediction of vasculopathy apparent on MRI (92%). Correlation with MRI and MRA findings are useful because an association of abnormal TCD and MRI findings increases the risk for developing a new silent infarct or stroke when compared to those whose initial MRI is normal.[82] In the STOP trial, the rate of stroke was higher for patients with presence of silent cerebral ischemia and abnormal TCD (52%) compared to patients with abnormal TCD but no evidence of silent ischemia on MRI (21%).[54]

Low mean velocities may also be a marker for a high risk of stroke in the SCD population if the stenosis is so tight that minimal flow courses through the vessel (Fig. 47.13). Buchanan et al.[83] described cerebral insults in five patients with low TCD velocities (<70 cm/sec) and suggest these abnormal results also require further evaluation with MRI/MRA and closer follow-up examinations.

Elevated ACA velocity, although not part of the STOP criteria, also suggests an increased stroke risk (Fig. 47.14). Kwiatkowski et al.[84] found that an elevated ACA TAMM velocity higher than 170 cm/sec was associated with an increased risk of stroke. In subjects with normal ICA-MCA velocities and an elevated ACA velocity, the risk of stroke was greater than 10-fold, whereas the risk more than doubled with those who had both elevated ACA and elevated ICA-MCA velocities.

Although the STOP recommendations are for yearly exams from age 2 to 16, patients younger than 2 years of age can also benefit from TCD evaluation. The BABY HUG study[85] demonstrated that infants with lower hemoglobin levels at baseline have higher TCD velocities and a higher incidence of clinical events. Hydroxyurea treatment has been shown to reduce both the rise in TCD velocities and the presence of clinical events.[85] Further evaluation of the BABY HUG trial data may help determine whether early TCD evaluation can identify infants at risk of having a stroke during childhood.[86]

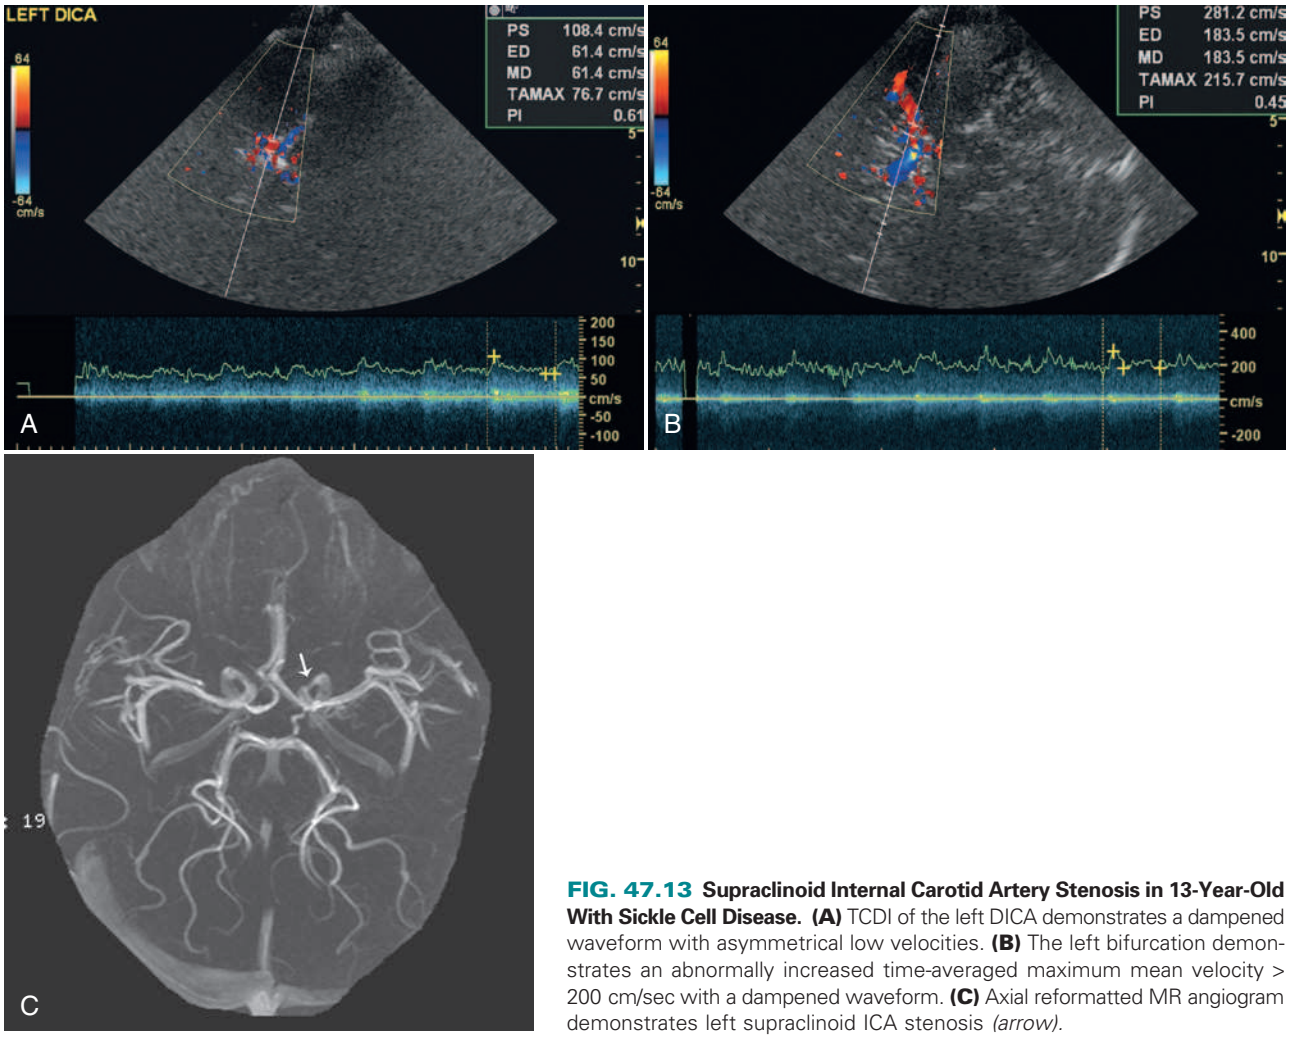

FIG. 47.13 Supraclinoid Internal Carotid Artery Stenosis in 13-Year-Old With Sickle Cell Disease. (A) TCDI of the left DICA demonstrates a dampened waveform with asymmetrical low velocities. **(B)** The left bifurcation demonstrates an abnormally increased time-averaged maximum mean velocity > 200 cm/sec with a dampened waveform. **(C)** Axial reformatted MR angiogram demonstrates left supraclinoid ICA stenosis *(arrow)*.

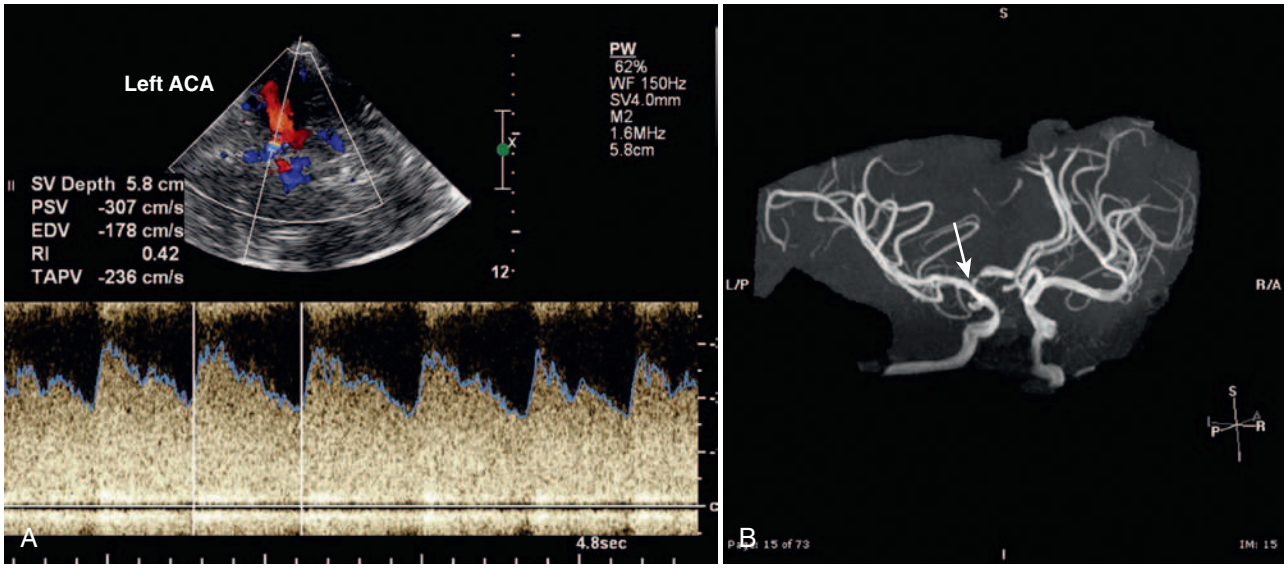

FIG. 47.14 Anterior Cerebral Artery (ACA) Stenosis in 11-Year-Old Child With Sickle Cell Disease. (A) TCD sonogram demonstrates abnormally elevated left ACA velocities. **(B)** Three-dimensional time-of-flight MR angiogram demonstrates stenosis at the origin of the A1 segment of the left ACA *(arrow)*.

When assigning the risk of stroke based on TCD velocities, it is important to consider how velocities may differ with the overall health of the patient, patient ethnicity, and the specific equipment used compared to those obtained with nonduplex equipment in the initial STOP studies. When ill, comorbidities including hypoxia, fever, hypoglycemia, and worsening anemia can increase the cerebral blood flow velocities, making the results invalid if conditional or abnormal.[56] In these cases, repeating the study when the patient is no longer ill will help verify the results. Because different ethnicities and haplotypes of the disease have different average velocities, risk of stroke, and prognosis, it is possible that different criteria have to be determined to assess risk for a specific ethnicity.[87]

Regarding the equipment used, studies have evaluated the differences in nonimaging TCD versus imaging TCD techniques. In studies performed in the early 2000s, nonangle-corrected velocities obtained with Acuson and ATL TCDI equipment were approximately 10% lower in the MCA than those obtained with Nicolet (Vascular, Madison, WI) nonimaging equipment.[20,21] Later studies showed no significant difference in TAMM velocity measurements obtained with General Electric TCDI equipment compared with Nicolet nonimaging equipment.[22,23] The reasons for these differing results are likely multifactorial. Early imaging probes were bulkier, making it more difficult to optimize Doppler tracings. Padayachee et al.[88] discussed how the TAMM velocity is quantified using the Doppler equation. Optimizing the waveform without angle correction can result in similar results compared to the nonimaging TCD technique negating the need for decreasing the threshold for TCDI cutoffs.[88] A 10% lower cutoff point for TAMM velocities has been suggested depending on the protocol and machine used.[13] Besides appropriate curser placement, instrument settings (volume size, gain, waveform display) should be optimized. Close attention to technique can reduce the differences between velocity data acquired with different ultrasound machines. Centers should be aware of these potential differences and perform their own comparison studies when using various imaging equipment before changing velocity thresholds for TCDI.[88]

Although **angle correction** with TCDI may be a way to correct for lower velocities obtained by TCDI compared with nonimaging TCD, this technique has not yet been validated and may overestimate stroke risk in children with SCD.[25] Therefore angle correction currently is not recommended when performing and interpreting TCDI for stroke risk assessment in pediatric SCD.[12,13]

The natural history of TCD velocities in sickle cell patients continues to be studied.[89-91] The STOP 2 trail was performed to assess when discontinuation of transfusion therapy was appropriate. After 30 months of transfusion treatment and normalization of TCD velocities, patients were randomized to continue or suspend transfusion therapy. STOP 2 demonstrated that patients in whom transfusion therapy was suspended after normalization of TCD have a return to abnormal TCD velocities with a higher occurrence of stroke, and are more likely to develop silent clinical infarcts, indicating the need to continue transfusion treatment.[92,93]

Optimal management for children with abnormal velocities remains problematic, with no consensus regarding long-term therapy in children with persistently abnormal velocities. The side effects of prolonged transfusion therapy have clinicians searching for other methods of improving stroke risk, including the use of hydroxycarbamide (hydroxyurea) therapy and bone marrow transplant.[62,94-96] Hydroxyurea with phlebotomy proved to be useful in the prevention of stroke recurrence during the SWiTCH protocol, but not as good as transfusion therapy with chelation.[97,98] Other studies (TWiTCH trial) are evaluating the use of hydroxyurea in the prevention of primary stroke in patients with abnormal TCD velocities.

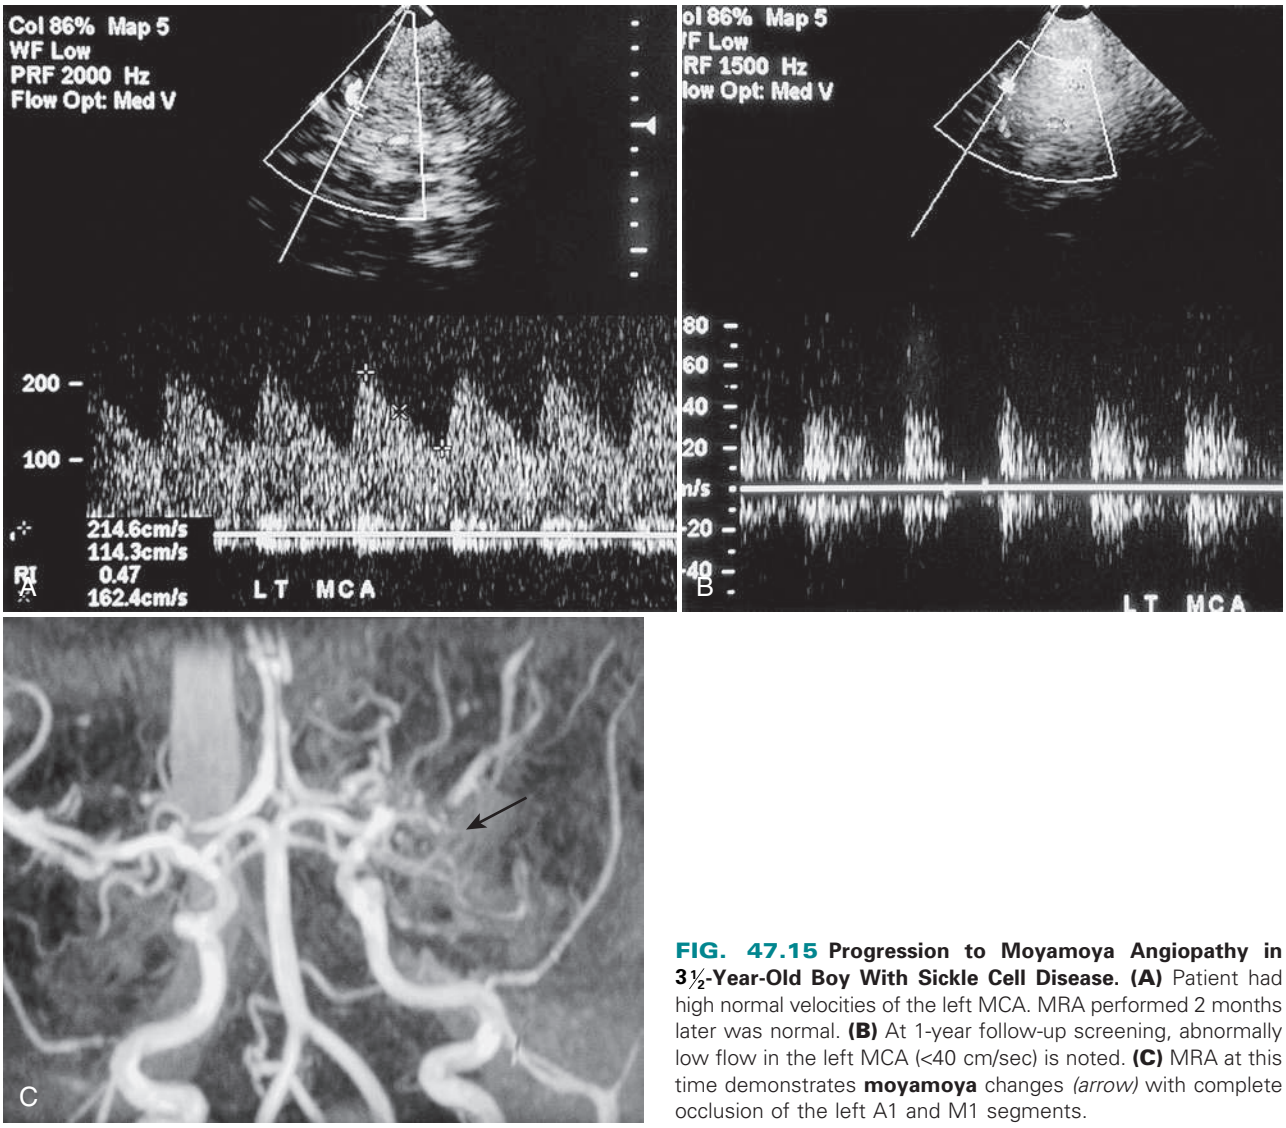

FIG. 47.15 Progression to Moyamoya Angiopathy in 3½-Year-Old Boy With Sickle Cell Disease. (A) Patient had high normal velocities of the left MCA. MRA performed 2 months later was normal. **(B)** At 1-year follow-up screening, abnormally low flow in the left MCA (<40 cm/sec) is noted. **(C)** MRA at this time demonstrates **moyamoya** changes *(arrow)* with complete occlusion of the left A1 and M1 segments.

The management of children with conditional velocities is also being studied. Many remain in the conditional range for years or eventually normalize, but up to 23% of this cohort convert over time to abnormal velocities[89,90] (Fig. 47.15). Protocols using less invasive therapies such as hydroxycarbamide (e.g., hydroxyurea therapy) in children with conditional velocities show promise and suggest that following these patients with TCD may be useful to assess treatment response.[94-96]

Vasospasm

Cerebral vasospasm can present as a complication of subarachnoid hemorrhage secondary to rupture of an intracranial aneurysm,[99] secondary to trauma with or without hemorrhage or secondary to other pathology.[33,100,101] TCD sonography has become an important tool in detecting vasospasm before the patient develops ischemic neurologic deficits or infarct.[37,102] High specificity has been described (100%) for vertebral/basilar vasospasm with PSV greater than 80 and 95 cm/sec, respectively,[102] and with high specificity in the diagnosis of MCA vasospasm (98%-100%) when PSV is greater than 200 cm/sec[103,104] but a sensitivity of only 59%.[105] Digital subtraction angiography continues to be the reference standard, but because of the cost, high radiation, and risk of the procedure, it is not as widely used.[37]

In adults with aneurysm rupture causing subarachnoid hemorrhage, vasospasm typically develops 4 to 14 days after the rupture,[33] gradually increasing and peaking between days 5 and 14.[99] Following traumatic brain injury, vasospasm can occur (19%-68% incidence) but usually without clinical deficits (4%-17%). Cerebral vasospasm in adults with traumatic brain injury presents in the first 2 days after the injury,[99] peaks around day 5 to 7 and has a shorter overall duration. Posttraumatic vasospasm can also occur in the absence of subarachnoid hemorrhage and has an even shorter duration (1.25 days).[99,106] Vasospasm has been seen in 17% of patients with ruptured brain arteriovenous malformation and presents in 4 to 11 days following rupture.[107] Patients with persistent severe vasospasm may develop permanent deficits from cerebral infarction with morbidity and mortality rates of 10% to 30%.[33] In a 2010 study of pediatric patients with moderate

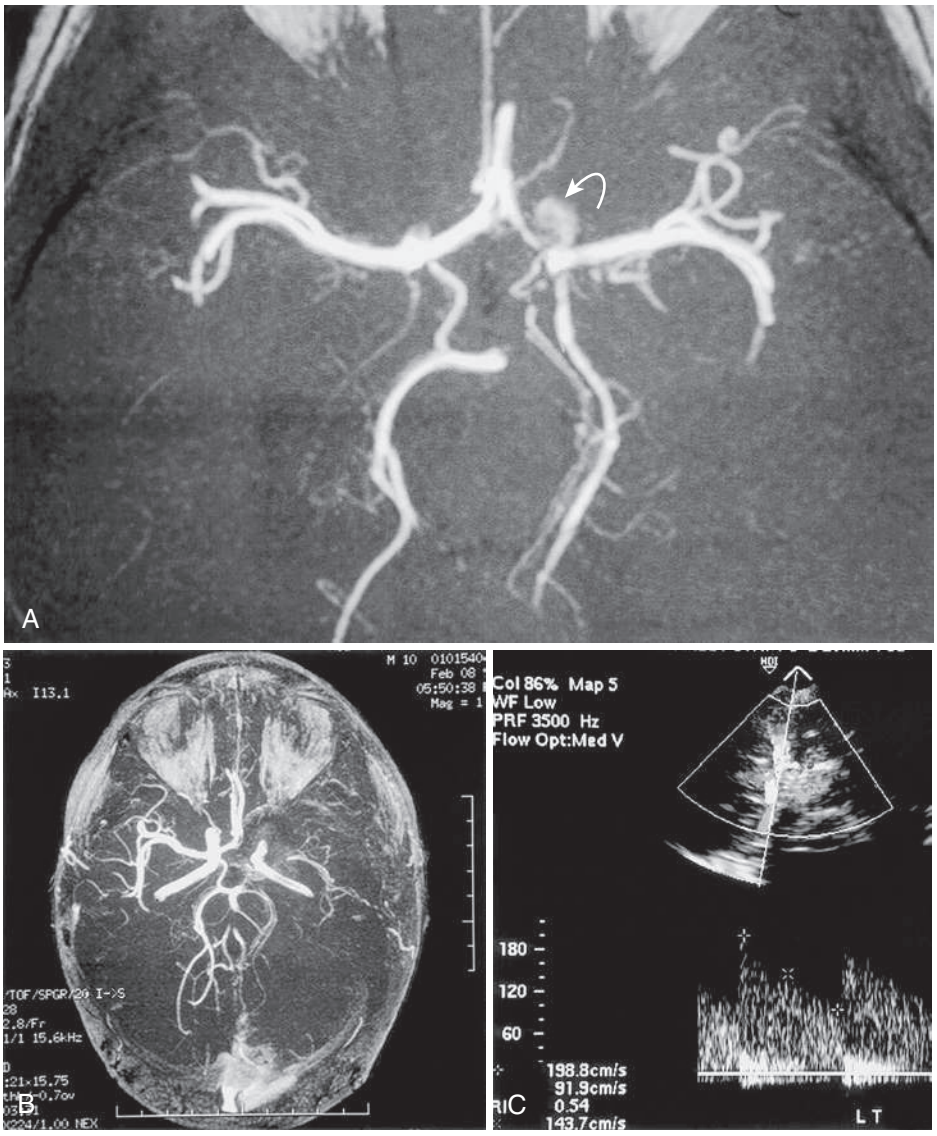

FIG. 47.16 Vasospasm With Aneurysm. Ten-year-old boy with acute headache. **(A)** MR angiogram demonstrates narrow supraclinoid carotid, narrow A1 segment, and small left bifurcation aneurysm *(arrow)*. **(B)** After clipping of aneurysm, susceptibility metal artifact limits MRA evaluation of the left proximal M1 segment. **(C)** On day 15, TCD sonogram demonstrates high PSV of 199 cm/sec, consistent with moderate vasospasm. Patient did well after medical management.

to severe head trauma, vasospasm peaked at day 2 or 3 and lasted for 2 to 4 days.[108]

In the presence of vasospasm, blood flow velocity increases because of a decrease in the luminal cross-sectional area of the affected vessel. Thus TCD can be used to optimize timing of therapy and is useful in following the effects of therapy (Fig. 47.16). When a hemodynamically significant vasospasm is suggested, emergency cerebral angiography with balloon dilation angioplasty or intraarterial infusion of vasodilating agents may be helpful.[109] Serial TCD studies showing reduction in velocities indicate the appropriate time to withdraw therapy, minimizing complications and shortening intensive care unit stays. TCD is most accurate in detecting vasospasm of the MCA. TCD cannot be used to assess the ACA beyond its A1 segment and is limited in the evaluation of the peripheral branches of the MCA.

It is important to remember that studies evaluating vasospasm assess the PSV. Depending on the mean velocities measured, vasospasm can be considered mild, moderate, or severe as demonstrated by angiography (Table 47.3).[29] Philip et al.[110] described increased arterial flow velocities as those elevated by more than 2 SD above normal for age and sex. TCD values should always be combined with clinical and laboratory data.[111,112]

A steep increase (>25 cm/sec/day) in velocity in the first few days after subarachnoid hemorrhage is associated with a worse prognosis. Sources of error in the detection of vasospasm by TCD sonography (vs. arteriography) include missing peripheral vasospasm, copresence of increased **intracranial pressure** (ICP), and low volume flow.[7] The **Lindegaard ratio** (ratio of velocities of the MCA/ipsilateral ICA) can be used to differentiate increased velocities due to vasospasm versus other causes. A Lindegaard ratio of 3 to 6 is suggestive of mild to moderate cerebral vasospasm

TABLE 47.3 Severity of Vasospasm With Typical Velocities[29]

	Mild (cm/sec)	Moderate (cm/sec)	Severe (cm/sec)
Terminal ICA	120-130	>130	
MCA	120-130	130-200	>200
Basilar	60-80	80-115	>115
Vertebral	60-80	>80	>80
ACA		>50% increase in 24 h	>50% increase in 24 h
PCA		>110	>110

and a ratio greater than 6 is suggestive of severe vasospasm. A ratio less than 3 in patients with elevated flow velocities is seen as a result of physiologic processes such as hyperemia or autoregulation.[29,113] In a similar way, a ratio between the basilar artery and the extracranial vertebral artery can also be obtained.[33] A basilar artery to vertebral artery ratio of 2.0 to 3.0 is associated with mild to moderate vasospasm and a ratio greater than 3 is suggestive of severe vasospasm.[113]

Evaluation of Collateral Flow

When stenosis or occlusive disease is present, collateral flow via the circle of Willis can be identified with TCD evaluation. Angiographic examinations provide a better evaluation and diagnosis, but TCD can help with screening and reduce the number of negative invasive procedures.[38]

Collateral flow can be seen in the anterior communicating artery with a high sensitivity (95%) and specificity (100%) (Fig. 47.17). It is difficult to distinguish from adjacent ACA flow but indirect signs can be identified.[38] It is slightly more difficult to evaluate the posterior communicating artery for collateral flow, with a sensitivity of 87% and specificity of 95%. Reversed OA flow with low pulsatility with or without delayed systolic flow acceleration helps in the diagnosis of occlusion or critical stenosis with high specificity (100%) and good sensitivity (75%); normal flow direction does not exclude proximal occlusion/stenosis of ICA or a stenosis of less than 80%.[38]

Leptomeningeal collaterals more commonly originate from the ACA and can be seen in patients with proximal MCA occlusion. **Leptomeningeal collateral** presence has a sensitivity of 81% and specificity of 77% for MCA occlusion. In the presence of leptomeningeal collaterals secondary to MCA occlusion, high velocity and low resistance flow in the ipsilateral ACA or PCA can be seen; a 30% velocity difference can be noted between the right and left ACA or PCA.[38] In the setting of basilar artery occlusion, reversal of basilar artery flow can be seen characterized by low resistance flow toward the probe via suboccipital window and decreased velocity and high resistance flow in vertebral arteries. Reversal of vertebral artery flow can also be seen as a collateral pathway.

Moyamoya angiopathy is a progressive stenosis of the terminal ICA and proximal MCA and ACA with development of a network of abnormal collateral vessels. It can be idiopathic (moyamoya disease) or associated with another disease (moyamoya syndrome) such as SCD, neurofibromatosis I, Down syndrome, or Turner syndrome (see Fig. 47.15). In patients with moyamoya angiopathy, TCD might be useful in monitoring, but more studies are needed to validate its use.[114]

Headaches

Prevalence of headache in children varies depending on the population studied and has been reported to range between 8% and 60%. Prevalence increases with age and the most common causes are tension and migraine. No statistical difference has been identified in the overall prevalence in SCD when compared to control population.

TCD has been used in the evaluation of adults with vascular headaches.[7] Thie et al.[115] found a significant increase in mean velocity in migraine patients compared to controls during headache-free periods. They then continued to evaluate the patients during headache episodes and demonstrated that those with common migraines had decreased intracranial velocities and increased pulsatility, whereas symptomatic patients with classic migraines demonstrated opposite findings with an increase in velocities and a decrease in pulsatility[116] (Fig. 47.18). Different studies have shown migraine headaches to be associated with mild to moderate vascular narrowing and/or decreased blood flow[117] as well as a decrease in RI and PI.[118]

In pediatric patients, Wang et al.[119] evaluated the utility of TCD sonography in the assessment of isolated headaches and demonstrated a sensitivity and specificity in detecting intracranial lesions of 75% and 99.7%, respectively. Another study evaluated children between 5 and 17 years of age and suggested the possibility of cerebral vasospasm in the headache-free periods.[120]

In a study of 1176 pediatric patients with SCD, 36% had recurrent headaches, with migraine in 15%. In this study, no association was seen between headaches and silent stroke. On the other hand, recurrent headaches and migraines were associated with lower hemoglobin concentration and higher pain event rates.[121] Lower hemoglobin levels are associated with increased cerebral blood flow velocities in children with SCD with normal neurologic examinations and vascular headaches when compared to those without headaches. Similar findings have been described in adults with SCD and severe/frequent headaches versus mild or absent headaches.[121] TCD sonography may assist in the

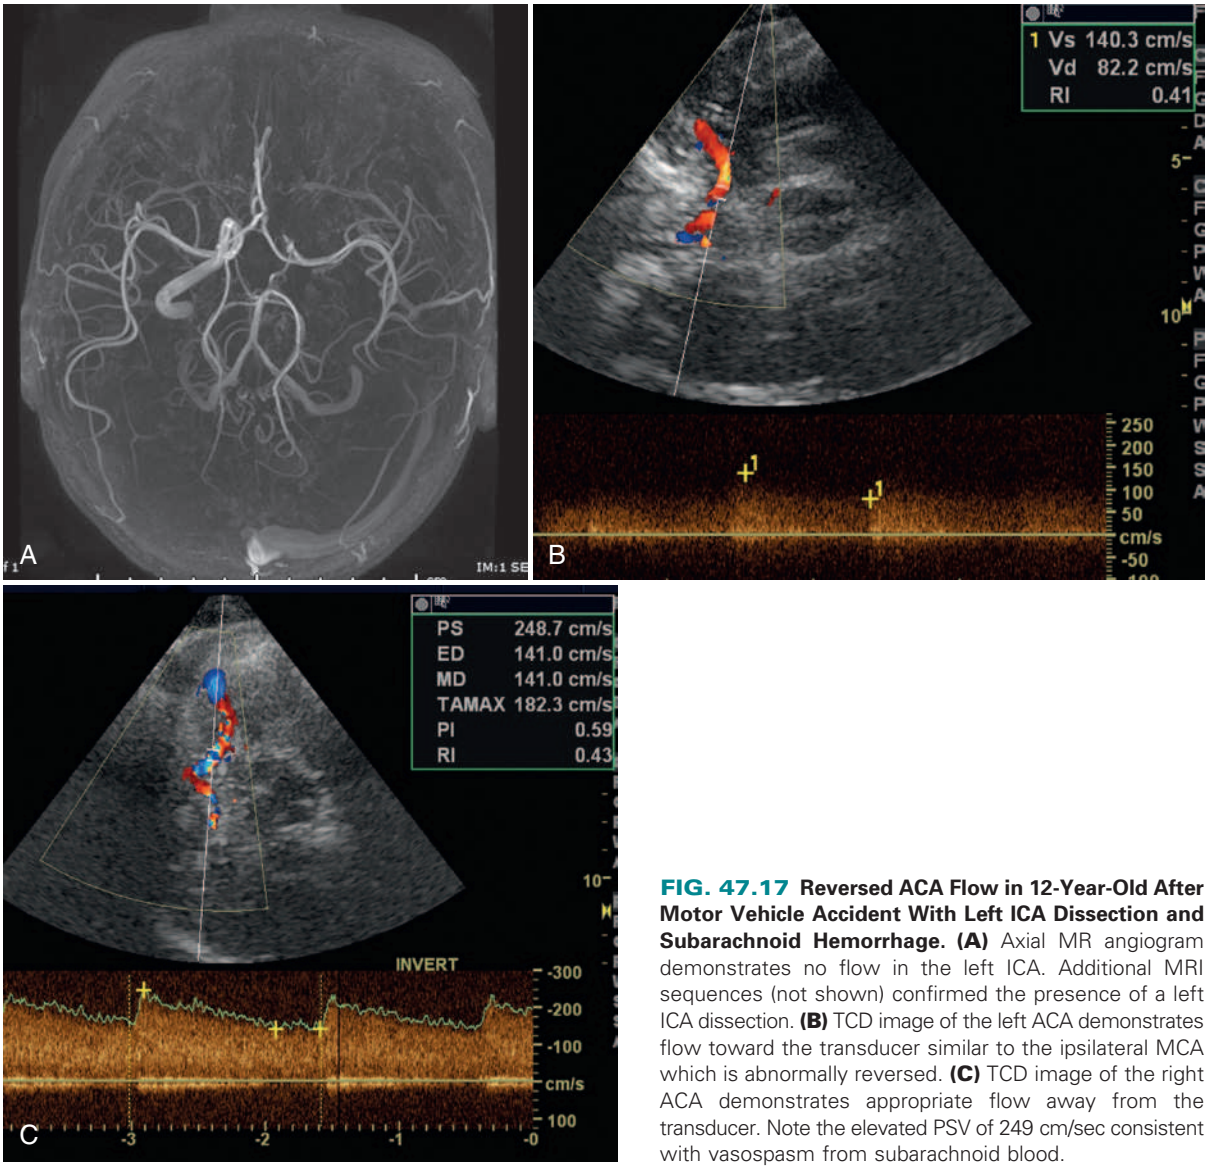

FIG. 47.17 Reversed ACA Flow in 12-Year-Old After Motor Vehicle Accident With Left ICA Dissection and Subarachnoid Hemorrhage. (A) Axial MR angiogram demonstrates no flow in the left ICA. Additional MRI sequences (not shown) confirmed the presence of a left ICA dissection. **(B)** TCD image of the left ACA demonstrates flow toward the transducer similar to the ipsilateral MCA which is abnormally reversed. **(C)** TCD image of the right ACA demonstrates appropriate flow away from the transducer. Note the elevated PSV of 249 cm/sec consistent with vasospasm from subarachnoid blood.

differential diagnosis of headaches of unknown causes and could prove useful in therapeutic interventions.

Sleep Apnea

Several studies have demonstrated changes in MCA velocities in children with **sleep-disordered breathing,** a spectrum of upper airway obstruction ranging from primary snoring to obstructive sleep apnea. Increases in MCA flow velocity have been documented in children with mild sleep-disordered breathing.[122] In a group of children with sleep-disordered breathing followed after adenotonsillectomy, MCA velocities decreased (suggesting a normalization of MCA velocities) with a resultant increase in mean overnight oxyhemoglobin saturation postoperatively. These children demonstrated an improvement in processing speed and visual attention postoperatively as well.[123]

In patients with SCD, sleep-disordered breathing and snoring have a high prevalence, with 37% snoring and 24% positive polysomnography findings.[124] In a study evaluating overnight pulse oximetry, TCD, and central nervous system events in patients with SCD, an association between nocturnal oxyhemoglobin desaturation and central nervous system event risk was seen. Evidence of obstructive sleep apnea, seen as dips in overnight pulse oximetry, was not useful to predict central nervous system events.[125] Another study evaluating the prevalence of sleep-disordered breathing and the association with high-risk TCD velocities in patients with SCD showed no significant difference in the TCD velocities and percentage of patients with high-risk velocities when comparing the snorers with the nonsnorers. Overall, there was no association between sleep-disordered breathing or snoring and cerebrovascular risk.[124]

Hydrocephalus

The ability to differentiate between **ventriculomegaly** and **hydrocephalus** (increasing ventriculomegaly and increasing ICP) can be difficult. When hydrocephalus develops, ICP increases, resulting in a decrease in diastolic flow. Stable ventriculomegaly

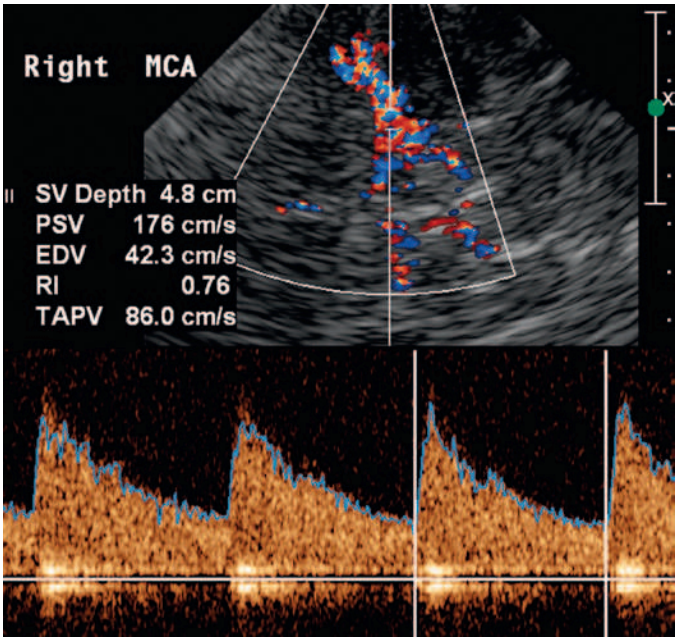

FIG. 47.18 Elevated Pulsatility of the MCA in 12-Year-Old With Headaches. TCD image of the right MCA demonstrates an elevated RI of 0.76. Normal RI values should range from 0.43 to 0.58 after fontanelle closure.

should have normal pulsatility; thus an elevated RI in cases where ventricular size is increased may imply the need for a shunt. Hill and Volpe[126] first described a decrease in diastolic/systolic flow in 11 hydrocephalic infants. Because it is noninvasive and repeatable, Doppler sonography has been increasingly used to assess changes in cerebral hemodynamics in hydrocephalus through the anterior fontanelle in infants. It can be used through the temporal bone in older children as well.[4,127,128] There is a direct correlation between the ICP (from experimental fontanometric and direct measurement evidence) and the RI. The increasing RI is predominantly caused by a reduction in the EDV.[128,129] The vascular indices most often applied in hydrocephalic patients are RI and PI. Both ratios minimize the error in estimating true velocity caused by a varying angle of insonation. This is particularly important in hydrocephalus because vascular anatomy can be distorted by ventricular enlargement, and a small angle of insonation cannot be assumed.[130] Difficulties with using the RI to determine hydrocephalus have occurred because (1) there is a wide range of normal RI values (0.65-0.85 in the neonate, 0.60-0.70 in the child before fontanelle closure, and 0.50-0.60 in older children and adults through temporal window after fontanelle closure),[14] and (2) many other intracranial and extracranial factors can change the RI other than increased ICP[131] (Table 47.4). Therefore the RI must be correlated closely with the clinical condition of the patient.

TABLE 47.4 Factors That Change Cerebral Doppler Indices

	Resistive Index	Systolic Velocity
INTRACRANIAL ABNORMALITIES		
Intracranial bleed	Increased	Beat-to-beat variation, risk factor for IVH
Periventricular leukomalacia	Increased	
Asphyxia	Decreased initially	
Brain edema	Increased	
Hydrocephalus	Increased, reverses after drainage	
Subdural	Increased	
Brain death	Increased	Decreased, reversed diastolic flow
ECMO	Decreased	
Vascular malformations	Decreased	Increased, turbulence
EXTRACRANIAL ABNORMALITIES		
P_{CO_2}	Inverse relationship	
Heart rate	Inverse relationship	
Shock		Decreased systolic/diastolic
Patent ductus arteriosus	Increased	
Pneumothorax	Increased	
Cardiac ischemia	Increased	
Gastrointestinal bleed	Increased	
Polycythemia, hyperviscosity	Increased	Decreased
Anemia	Increased	
DRUGS		
Indomethacin	Increased	Decreased
Maternal cocaine	Increased	
Exogenous surfactant	Increased	

ECMO, Extracorporeal membrane oxygenation; *IVH,* intraventricular hemorrhage; *P_{CO_2},* carbon dioxide partial pressure (tension).

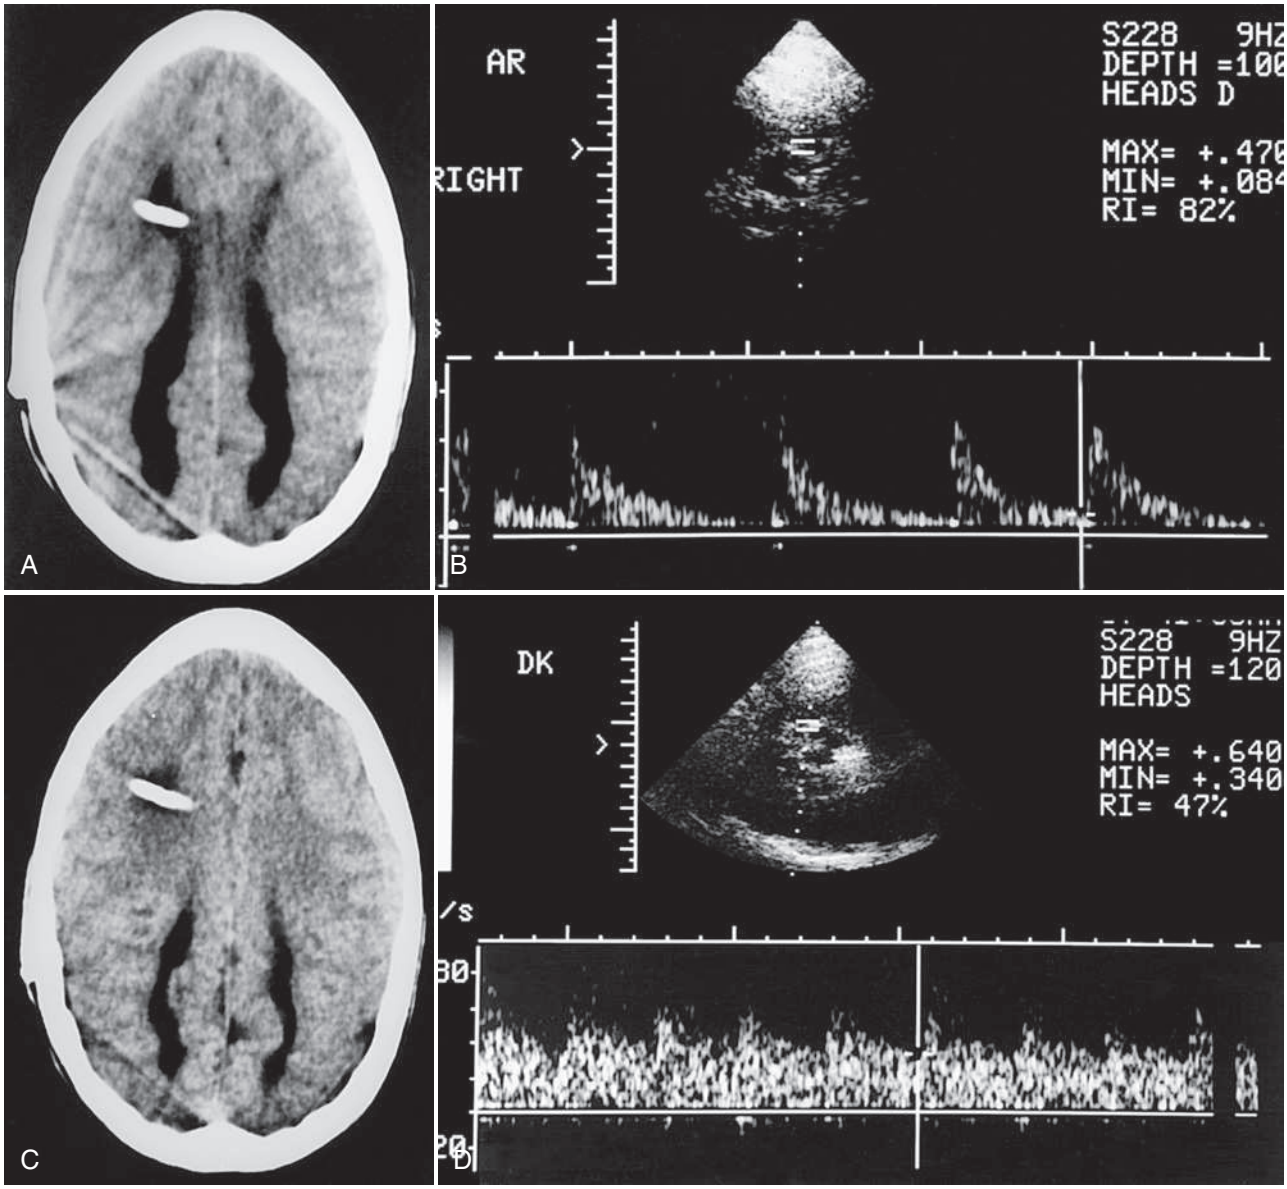

FIG. 47.19 Shunt Dysfunction in 8-Year-Old. (A) CT scan shows mildly dilated ventricles. **(B)** TCD image through the temporal window shows an increased RI of 0.82 in the MCA. **(C)** CT scan after shunt revision shows decrease in ventricular size. **(D)** TCD image of the MCA demonstrates a decrease in RI to 0.47, now in the normal range (after age 2 years with fontanelle closure, normal RI is 0.5). (With permission from Seibert JJ, Glasier CM, Leithiser JRE, et al. Transcranial Doppler using standard duplex equipment in children. Ultrasound Q. 1990;8:167-176.[14])

Goh et al.[128] used an RI of greater than 0.8 as a sign of increased ICP in the neonate and an RI of greater than 0.65 in children. Because of varying normal values and overlapping normal and abnormal values, RI is most useful on an individual basis following a patient's course to determine whether clinical changes and ventricular dilation are secondary to increased pressure (such as with shunt malfunction) or atrophy (Fig. 47.19). Any increase in RI should be considered as potentially important in terms of shunt malfunction. False-normal values may be the result of cerebral spinal fluid tracking along the shunt. Excessive thickness of the skull may prevent TCD ultrasound from being obtained successfully in some of these patients.[132,133]

Pediatric patients with tuberculous meningitis often have raised ICP and cerebral vasculopathies, and attempts to obtain a noninvasive technique to replace invasive ICP monitoring have been studied.[134] Some researchers have suggested that TCDI can help monitor pressure changes over time in these patients.[135] However, a study performed in children with tuberculous meningitis with communicating hydrocephalus demonstrated that PI obtained by TCD was not accurate in the assessment of ICP and might not change even in cases in which a change in ICP has been documented.[134]

The use of TCD has been studied in adult patients with idiopathic normal pressure hydrocephalus as a way of evaluating positive results of the cerebrospinal fluid tap and predict usefulness of a shunt. In a small study performed by Sedighi et al.,[136] patients with idiopathic normal pressure hydrocephalus underwent TCD evaluation before and after a cerebrospinal fluid tap test. In patients

with idiopathic normal pressure hydrocephalus, baseline TCD velocities were higher than in controls and demonstrated a significant decrease in those who reported clinical improvement after the tap.

Vascular Malformations

Intracranial Doppler imaging is useful for detecting vascular malformations in the unstable neonate.[3,137] The vascular malformation may be imaged with color or power Doppler ultrasound. Spectral analysis of the involved vessels will show high velocity, with low pressure and low pulsatility caused by increased diastolic flow. These hemodynamic qualities result in higher-than-normal mean and PSV, in conjunction with turbulence and lower-than-normal RIs (Fig. 47.20). TCD sonography can assess **arteriovenous malformation** (AVM) with a sensitivity of 87% to 95%,[126-133,137-140] particularly when contrast enhancement is used.[46] A study performed in adults comparing intraoperative contrast-enhanced TCD with angiography demonstrated that TCD is less sensitive (detected only 91.3% of AVMs diagnosed by angiography), underestimates the size of the AVM, and provides limited information regarding blood supply and venous drainage.[141] Because MRI affords an even higher sensitivity than TCD in screening, Doppler imaging is used more often to quantitate the hemodynamics of AVMs and to monitor the effects of surgical or endoluminal interventions.[142] After surgical or embolization treatment, the decrease in systolic velocity and increase in RI in the feeding arteries can be followed. In a study performed by Kaspera et al.[143] in patients after surgical resection or embolization of the AVM, an increase and normalization of PI was noted before a decrease in velocity. No correlation was seen between the degree of normalization of the parameters and the extent of the embolization of the AVM.

TCD ultrasound has also been used to assess other vascular anomalies, such as **Sturge-Weber syndrome, dural arteriovenous fistulas,** and **carotid-cavernous fistulas.**[144-146] In a series of patients with Sturge-Weber syndrome, decreased arterial flow velocity and increased PI was noted in the affected MCA, suggesting chronic hypoperfusion of the tissue secondary to venous stasis or cortical vessel hypoplasia due to cortical atrophy.[145] The fact that these findings were present even before the onset of symptoms suggests that venous stasis results in cortical injury.[147] A different study demonstrated increased velocities on the affected side during seizures and a fourfold to sixfold increase in flow in the contralateral side.[147] In cases of arteriovenous fistulas, an increase in flow velocity is present in at least one cerebral vein or venous sinus, which decreases after embolization. A venous flow velocity of more than 50 cm/sec is considered abnormal and should be further evaluated.[40] In patients with carotid cavernous fistulas, Doppler can be used for detection and to follow treatment.

Asphyxia

TCD sonography has been used in the evaluation of hypoxic-ischemic brain injury. Mild asphyxia typically does not alter cerebral hemodynamics.[148] Severe or prolonged asphyxia may result in impairment of cerebral autoregulation, producing an increase in diastolic blood flow and a decrease in cerebrovascular resistance.[2] Intracranial Doppler imaging in the neonate has been particularly helpful in predicting significant hypoxic-ischemic brain injury.[1,149-152] Archer et al.[151] found 100% sensitivity of a low RI caused by increased diastolic flow in the ACA and MCA and an adverse neurologic outcome when performed within the first 48 hours of the insult in the neonate. Stark and Seibert[149] reported 10 in 13 neonates with an initially low RI who later developed severe neurodevelopmental handicaps. The finding of increased diastolic flow can also be useful in evaluating the older child after head injury or cardiac arrest to predict significant cerebral injury before computed tomography (CT) findings become evident (Fig. 47.21).

Cerebral Edema and Hyperventilation Therapy

Head trauma initiates several pathologic processes that may result in significant changes in cerebral hemodynamics. Diagnosis of these abnormalities can be crucial for the appropriate management of such cases. After a significant cerebral hypoxic insult, vasodilation may initially occur with a resultant increase in diastolic flow velocity and a reduced RI during this early hyperemic phase. As ICP increases, however, the diastolic flow velocity begins to decrease, and the systolic peak velocity has a "spiky" appearance.[2] As cerebral edema develops, there is further loss of forward diastolic flow, and RI increases.[129] Sequential TCD readings after a cerebral insult have been helpful in evaluating the presence of edema and the course of treatment[153] (Fig. 47.22).

Treatment for cerebral edema includes hyperventilation. An inverse relationship exists between carbon dioxide partial pressure (P_{CO_2}) and the RI. The higher the P_{CO_2}, the greater the vasodilation, the greater the diastolic flow, and the lower the RI. When the P_{CO_2} is reduced, vasoconstriction results, with decreased diastolic flow and increased RI. Thus CO_2 reactivity can be measured assessing the RI. The cerebral blood flow increases 4% per mm Hg rise in P_{CO_2}.[1,26,129,152] The absence of change in the RI as the patient's ventilation is increased is described as an absent "CO_2 reactivity test" and is a sign of severe brain injury.[154] Because of this, RI can be used to monitor hyperventilation therapy in cerebral edema associated with head trauma.[2,155] As hyperventilation decreases the P_{CO_2}, the RI should increase with the concomitant vasoconstriction of cerebral vessels. The clinician must take into account, however, that increasing cerebral edema will also increase the RI. Therefore this measurement should be closely correlated with other clinical and laboratory findings. For example, hyperventilation treatment in a patient who has an increasing RI in the face of no change in ICP suggests that the treatment is causing too much cerebral vasoconstriction. In this scenario the patient may benefit from a decrease in the hyperventilation.

Evaluation of Right-to-Left Shunt

Although transesophageal echocardiogram provides a direct evaluation of the cardiac structures, TCD can also be used in the evaluation of right-to-left shunts.[156-158] TCD provides visualization of emboli through the cerebral circulation. Valsalva maneuver can be performed noninvasively at the bedside without requiring sedation.[29] The observation of 10 microbubbles of agitated saline

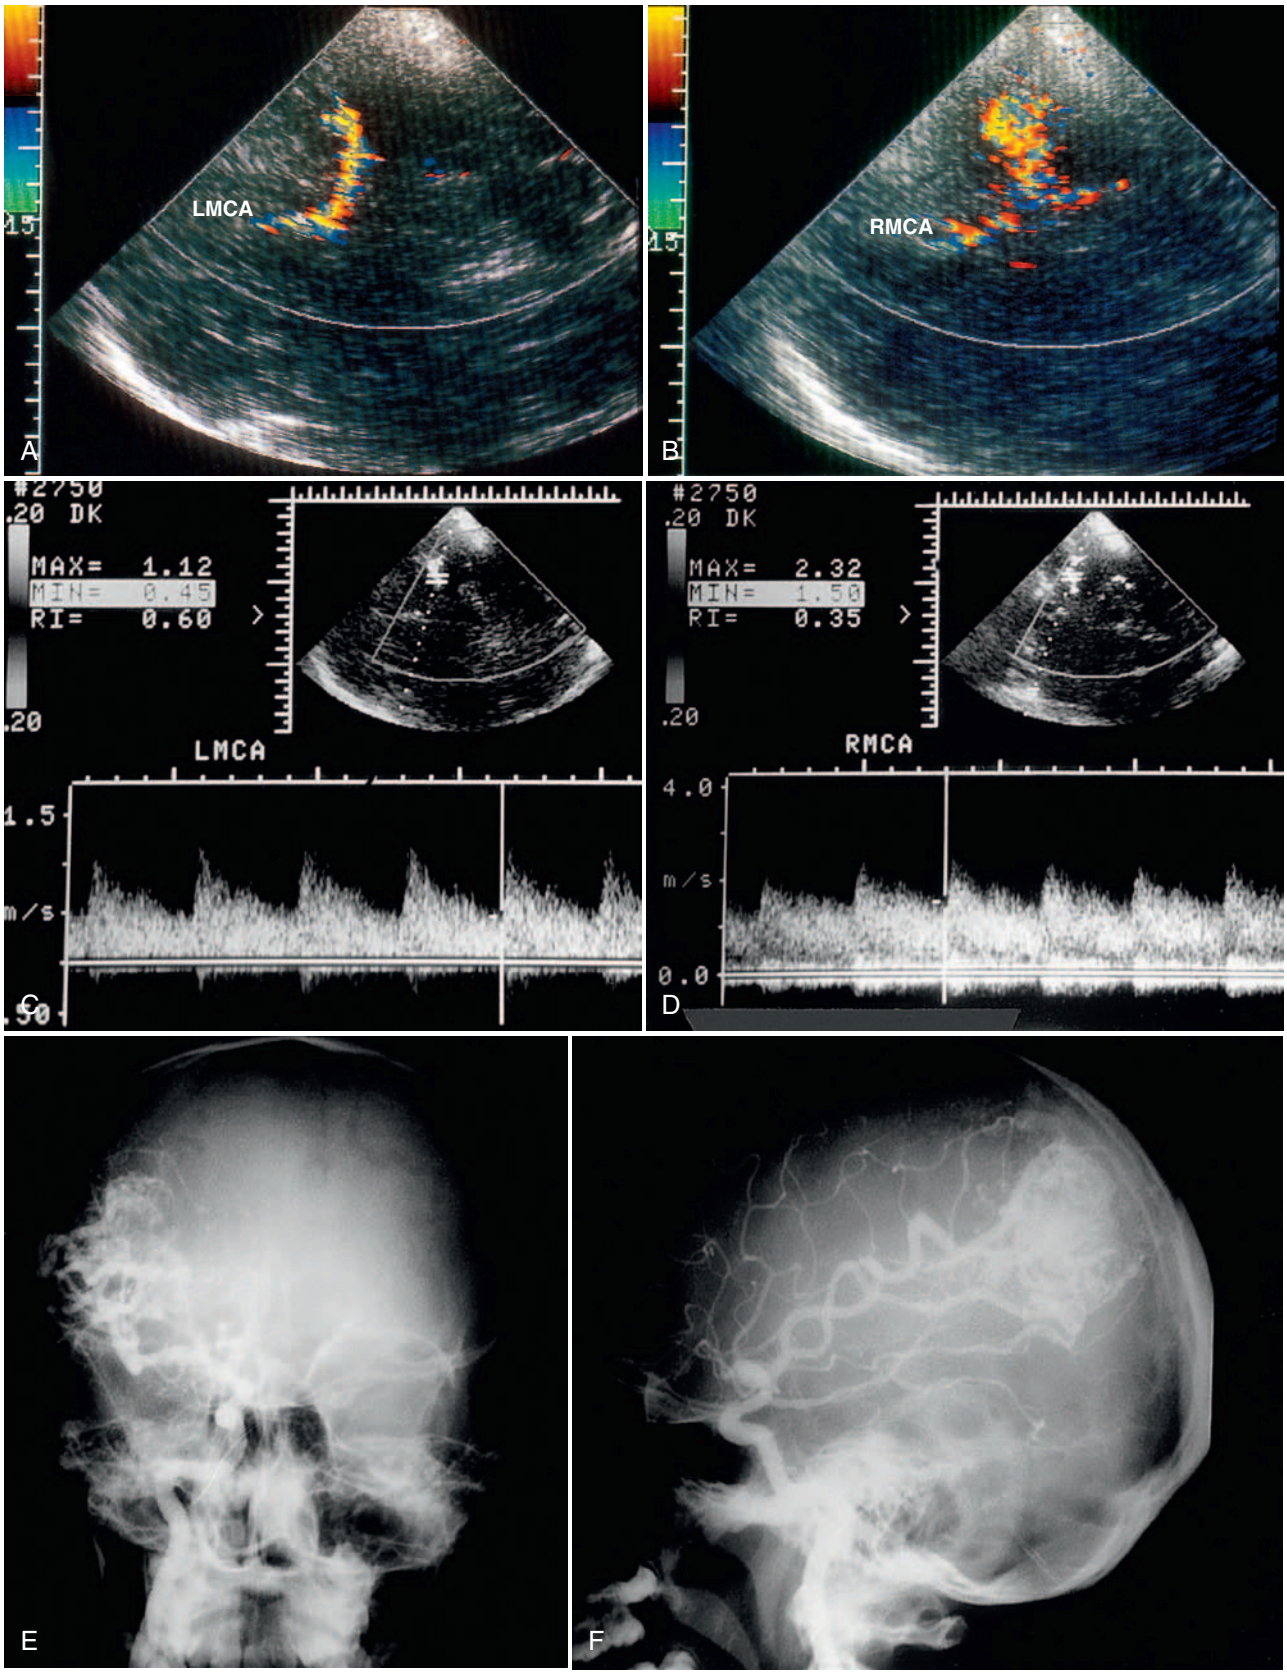

FIG. 47.20 Arteriovenous Malformation (AVM). (A) Normal color flow Doppler image of the left MCA. **(B)** Increased number of vessels in the region of AVM at the right MCA. **(C)** TCD spectral Doppler sonogram of left MCA shows normal maximum velocity of 112 cm/sec. **(D)** Velocity on the right is increased, with a maximum velocity of 232 cm/sec. **(E)** and **(F)** Anteroposterior and lateral views of an arteriogram demonstrates the large AVM.

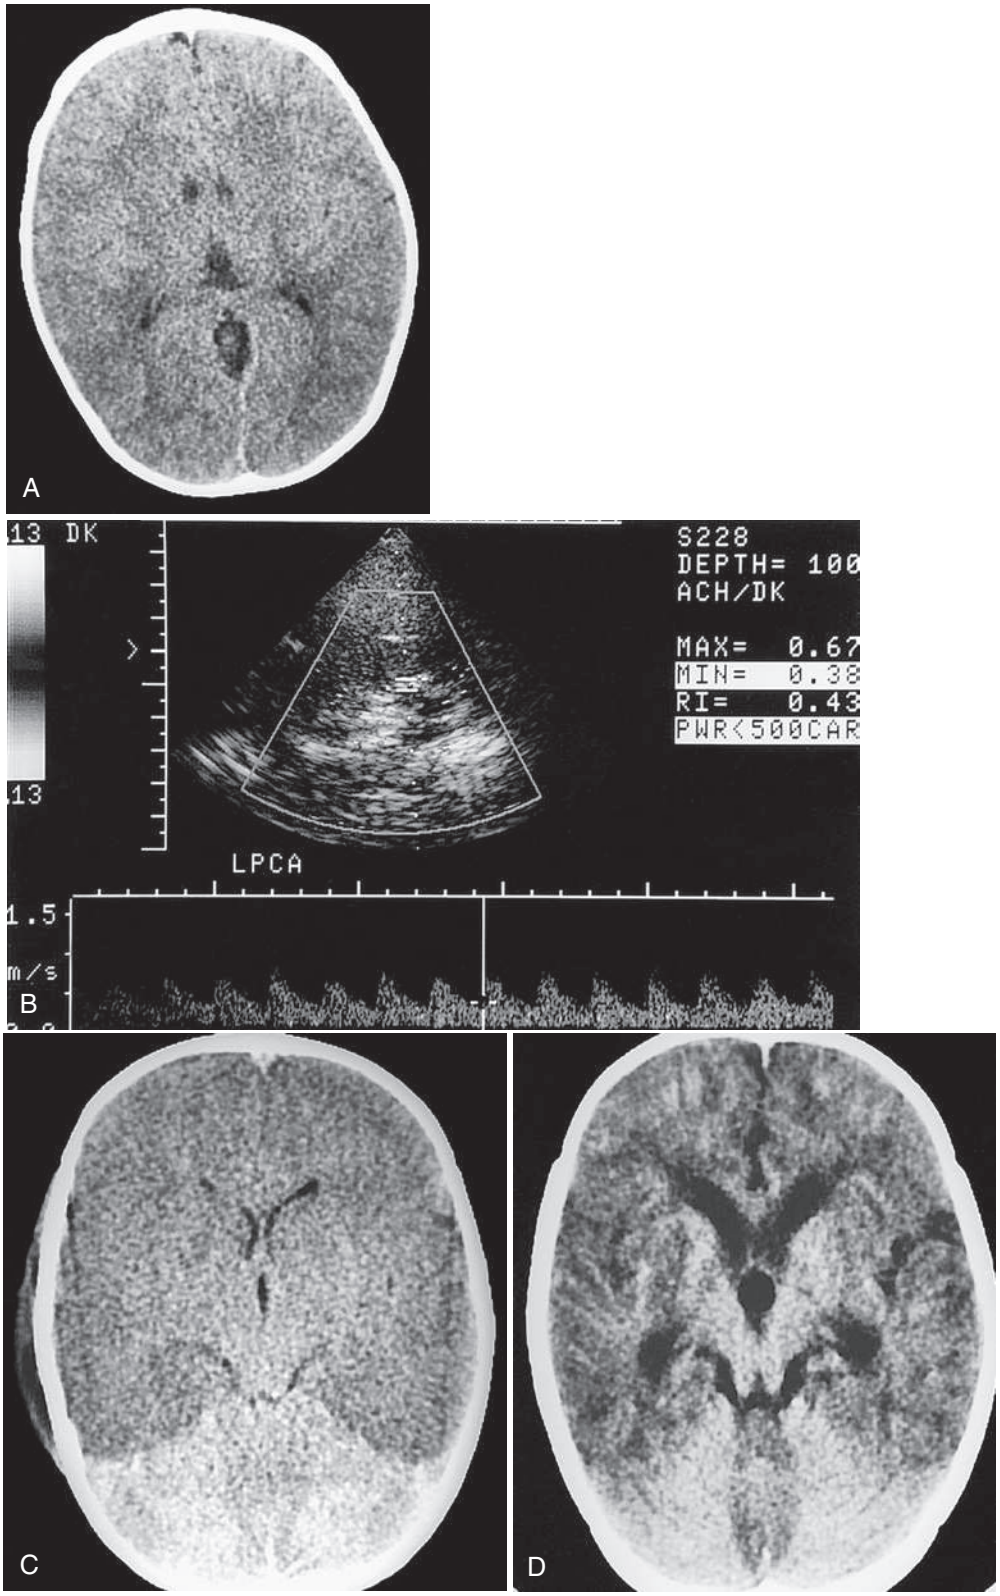

FIG. 47.21 Asphyxia. (A) One-year-old child after a respiratory arrest demonstrates mild cerebral edema on CT scan. **(B)** However, the RI in the left PCA is abnormally low, measuring 0.43, consistent with loss of autoregulation (normal range is 0.5-0.6). **(C)** CT scan 2 days later shows severe cerebral edema. **(D)** CT scan 1 month later shows marked atrophy.

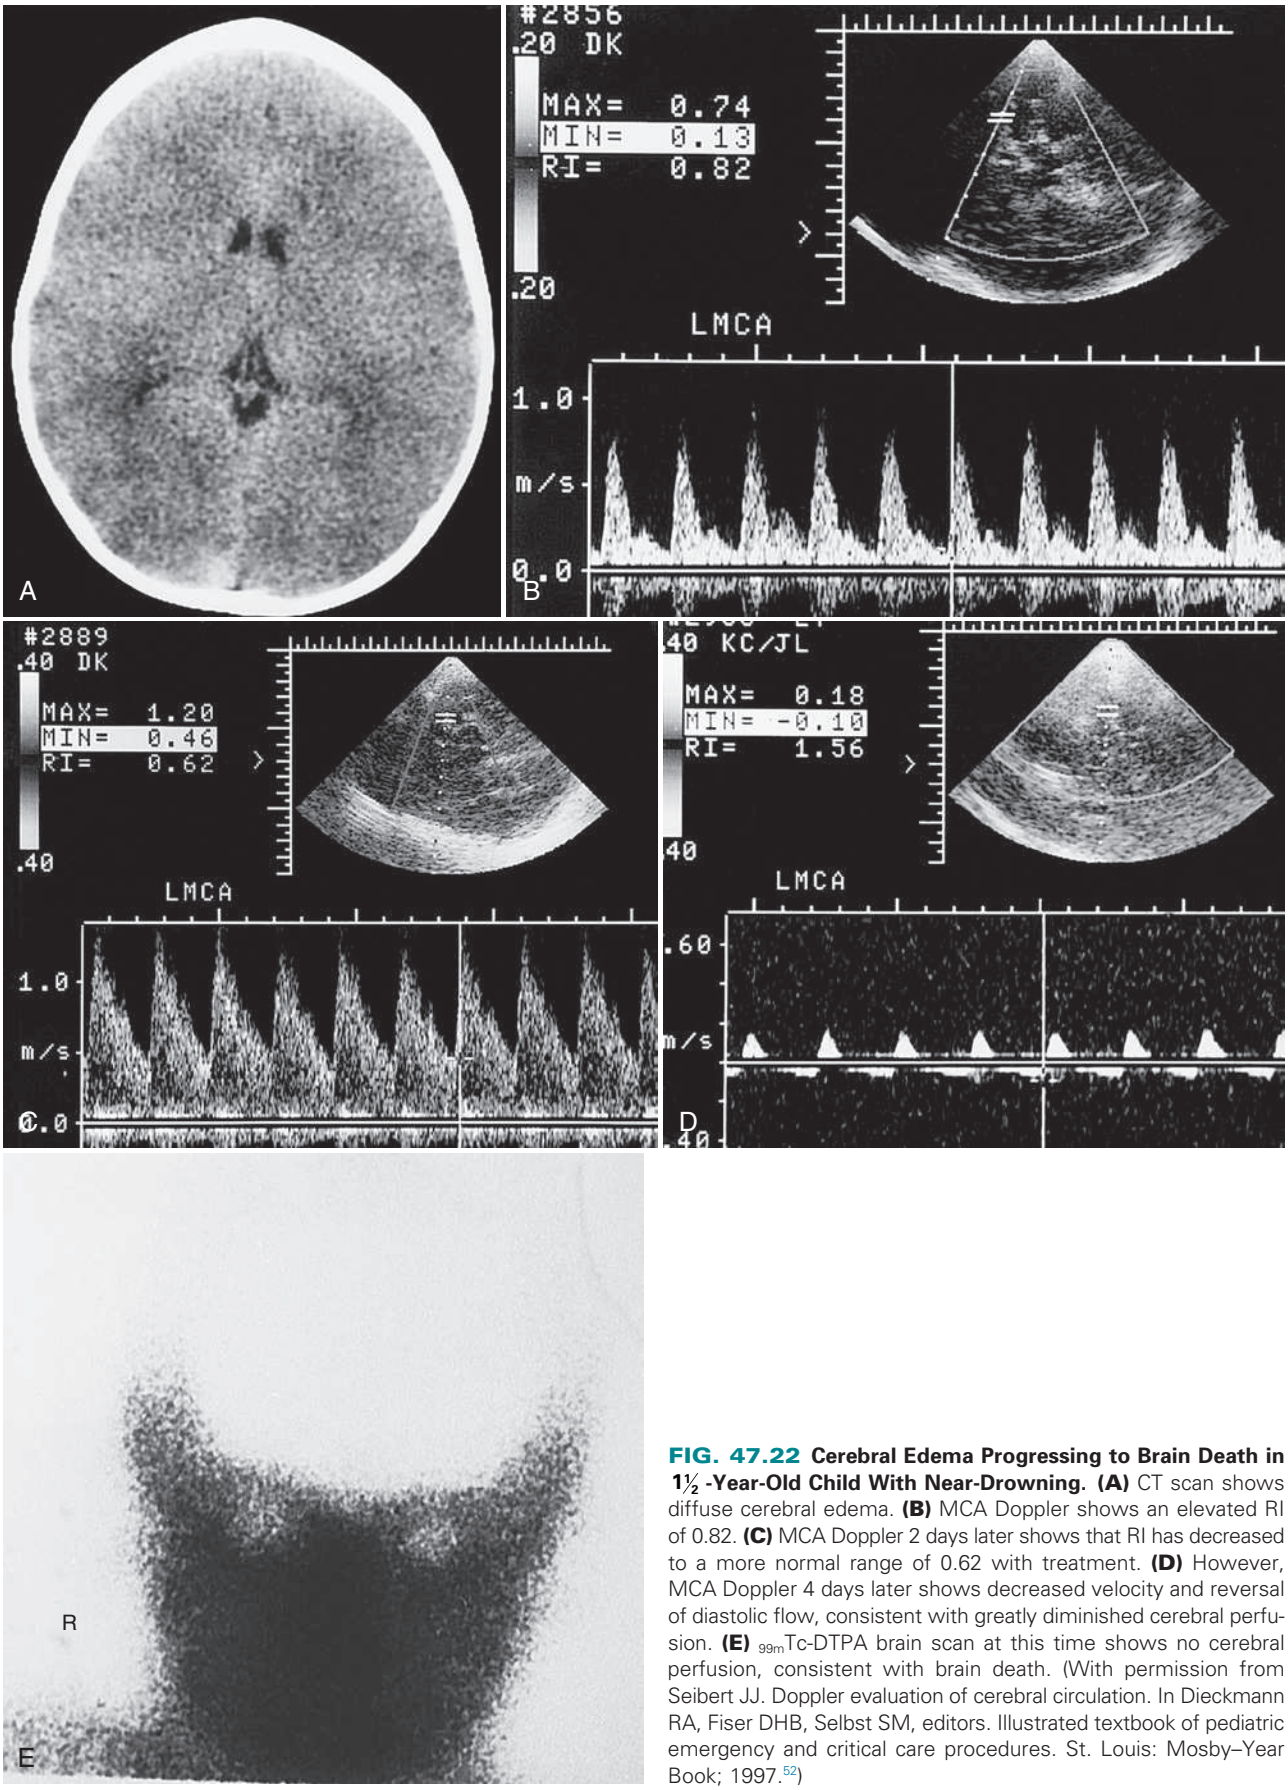

FIG. 47.22 Cerebral Edema Progressing to Brain Death in 1½ -Year-Old Child With Near-Drowning. (A) CT scan shows diffuse cerebral edema. **(B)** MCA Doppler shows an elevated RI of 0.82. **(C)** MCA Doppler 2 days later shows that RI has decreased to a more normal range of 0.62 with treatment. **(D)** However, MCA Doppler 4 days later shows decreased velocity and reversal of diastolic flow, consistent with greatly diminished cerebral perfusion. **(E)** $_{99m}$Tc-DTPA brain scan at this time shows no cerebral perfusion, consistent with brain death. (With permission from Seibert JJ. Doppler evaluation of cerebral circulation. In Dieckmann RA, Fiser DHB, Selbst SM, editors. Illustrated textbook of pediatric emergency and critical care procedures. St. Louis: Mosby–Year Book; 1997.[52])

at less than 10 seconds following contrast injection on TCD examination with Valsalva maneuver is diagnostic of right-to-left shunt with high sensitivity and specificity.[29] In pediatric patients, TCD can detect shunt resolution in patients with a moderate to large patent ductus arteriosus by a decrease in RI as the duct closes.[159]

Brain Death

Establishing brain death can be problematic, with rapid identification useful when considering organ transplant donation. Neurologic examination, electroencephalography, brainstem-evoked potentials, and nuclear blood flow studies can be used at times to establish brain death. TCD is another noninvasive tool, which can be repeated as often as required, is portable, inexpensive, and easy to perform. For patients in phenobarbital coma in which electroencephalography is not diagnostic, TCD is particularly helpful in demonstrating the severity of cerebrovascular compromise.[160-162]

After a severe asphyxiating event, an initial drop in RI may be caused by vasodilation from loss of autoregulation. As cerebral edema develops, there is loss of forward diastolic flow, followed by reversal of diastolic flow. Cessation of cerebral blood flow then occurs at the microcirculation level. The larger vessels will distend, then constrict, and eventually thrombose or collapse. As ICP increases above mean arterial pressure, arrest of cerebral circulation results in a decrease in antegrade systolic velocity. Small, early systolic spikes and complete cessation of antegrade flow then develops. Eventually, no systolic or diastolic flow can be detected[142,161] (Fig. 47.23, Videos 47.4 and 47.5).

Sonographic Criteria for Brain Death After Fontanelle Closure

Sustained reversal of diastolic flow
Small, early systolic spikes
No flow in middle cerebral artery (MCA), with reversal of diastolic flow in extracranial internal carotid artery (in patient with previously documented flow)
Mean velocity in MCA < 10 cm/sec for more than 30 minutes

There is some concern as to the reliability of TCD sonography in assessing infant brain death. Many factors are associated with reversal of diastolic flow (thus RI > 1.0) in the neonate, most often increased ICP with or without hydrocephalus and a patent ductus arteriosus[4,163] (see Table 47.4). In neonates, low RI has been described in patients clinically dead, whereas infants with high RIs have survived.[163,164] A greatly elevated RI (1-2) in a term infant with no evidence of hydrocephalus or a patent ductus arteriosus strongly suggests brain death.[165]

Sustained reversal of diastolic flow is characteristic of essentially absent effective cerebral blood flow in the adult and older child[164,166] (Fig. 47.24). In two independent studies of a total of 91 comatose patients, Petty et al.[167] and Feri et al.[168] found a TCD waveform of absent or complete reversed diastolic flow or small, early systolic spikes in at least two intracranial arteries in all 43 brain-dead patients, but in none of other patients with coma (age range, 2-88 years). Bulas et al.[169] reported a study in 19 children (aged 4-14 years) who sustained severe closed-head injury. All seven children with complete retrograde diastolic flow on the initial examination met brain death criteria within 24 hours of that study. Feri et al.[168] and Shiogai et al.[166] described three unstable patients who briefly showed diastolic reversal flow followed by a forward diastolic flow in the same waveform who improved, but of the patients Feri et al. observed, none with complete reversal of diastolic flow survived.

There have been a few reported pediatric cases of mild diastolic reversed flow who later demonstrate recovery of forward diastolic flow and brainstem function. Kirkham et al.[160] therefore suggested using a **direction of flow index** (DFI = 1 − maximum diastolic velocity area/maximum systolic velocity area). All children with substantial diastolic reversed flow and a time-averaged velocity of less than 10 cm/sec over a 30-minute period died. Some investigators have advocated continuous TCD monitoring. Powers et al.[161] showed that a mean velocity in the MCA of less than 10 cm/sec for longer than 30 minutes was not compatible with survival. Qian et al.[170] found that in children, reversed diastolic flow, small systolic forward flow, or a direction of flow index less than 0.8 in the MCA for more than 2 hours was a reliable indicator of brain death. Undetectable flow in the brain has also been described in brain death.[166,168-171] The occurrence of undetectable MCA flow, however, could sometimes be caused by technical factors, including absence of an appropriate acoustic window. The use of contrast agents may improve the level of confidence when no flow is encountered.

Some investigators have studied both the extracranial and the intracranial carotid circulation simultaneously in their evaluation of brain death. Feri et al.[168] described three waveform patterns in the MCA as well as in the extracranial internal carotid and vertebral arteries as **specific for brain death:** (1) diastolic reversed flow without systolic forward flow, (2) brief systolic forward flow, and (3) undetectable flow. Absence of MCA flow on TCD sonography, with a simultaneous recording of complete reversal of diastolic flow in the extracranial ICA, was a reliable sign of cerebral circulatory arrest. Some investigators have studied only the extracranial carotid circulation in the neck. Jalili et al.[172] reported 100% specificity for brain death with bilateral reversal of diastolic flow in the ICA of children with brain death.

The ease of performing TCD sonography and the ability to repeat the study as often as necessary also assist in proving the **absence of brain death,** particularly when a patient has taken sedative drugs (Fig. 47.25). It is important to remember that TCD examination is a proven useful confirmatory examination and is not used in isolation[173]; when used in combination with electroencephalography, specificity is up to 100%.[174] A recent study by Sharma et al.[175] evaluated the utility of TCD as a diagnostic test when clinical diagnosis was not possible due to confounding factors. They demonstrated that TCD can help make an early diagnosis of brain death and can also be used to assess prognosis. Thus, in patients where brain dead criteria are not met, the presence of a waveform consistent with cerebral circulatory arrest in at least one major cerebral artery is associated with

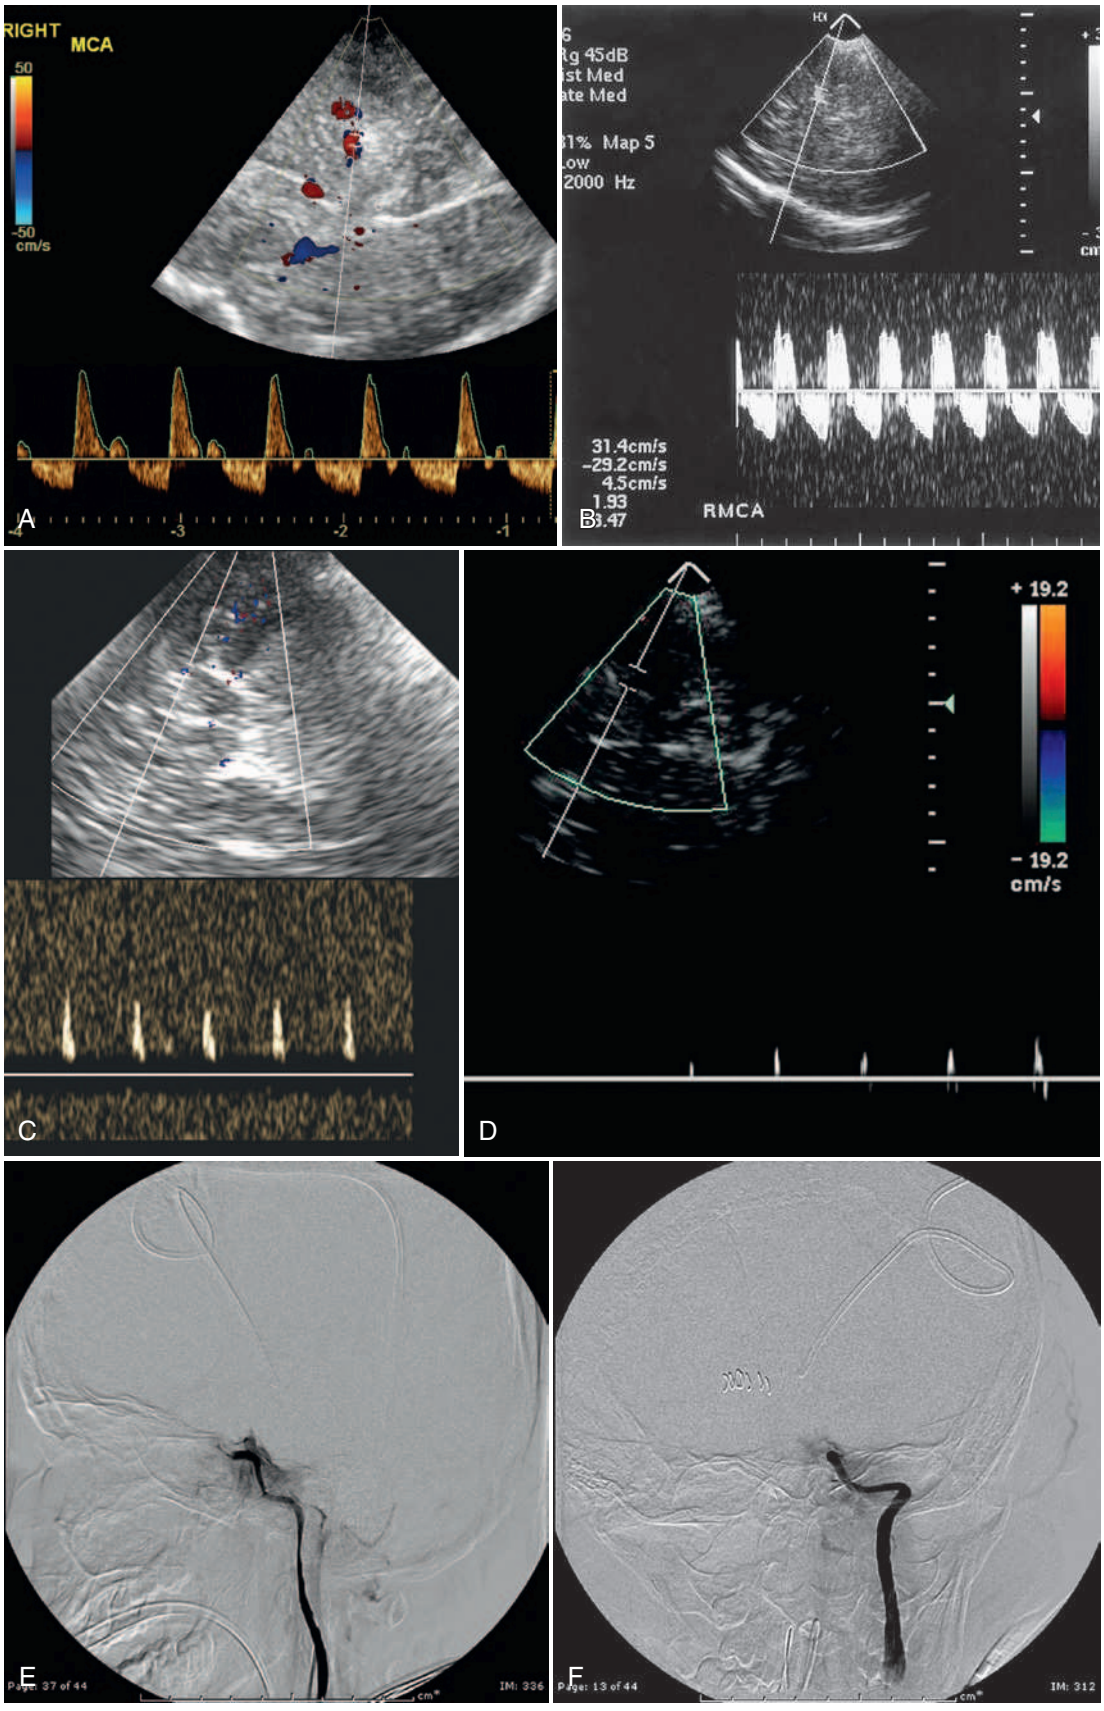

FIG. 47.23 Patterns of Pediatric TCD Spectral Doppler Waveforms in Impending Brain Death. (A) and **(B)** Reversal of diastolic flow. See also Videos 47.4 and 47.5. **(C)** Brief systolic forward flow with diminished peak velocity and no diastolic flow. **(D)** No discernible systolic or diastolic flow. **(E)** and **(F)** Lateral and anteroposterior projections of a carotid arteriogram in a 13-year-old status post motor vehicle accident demonstrate lack of intracranial circulation confirming brain death.

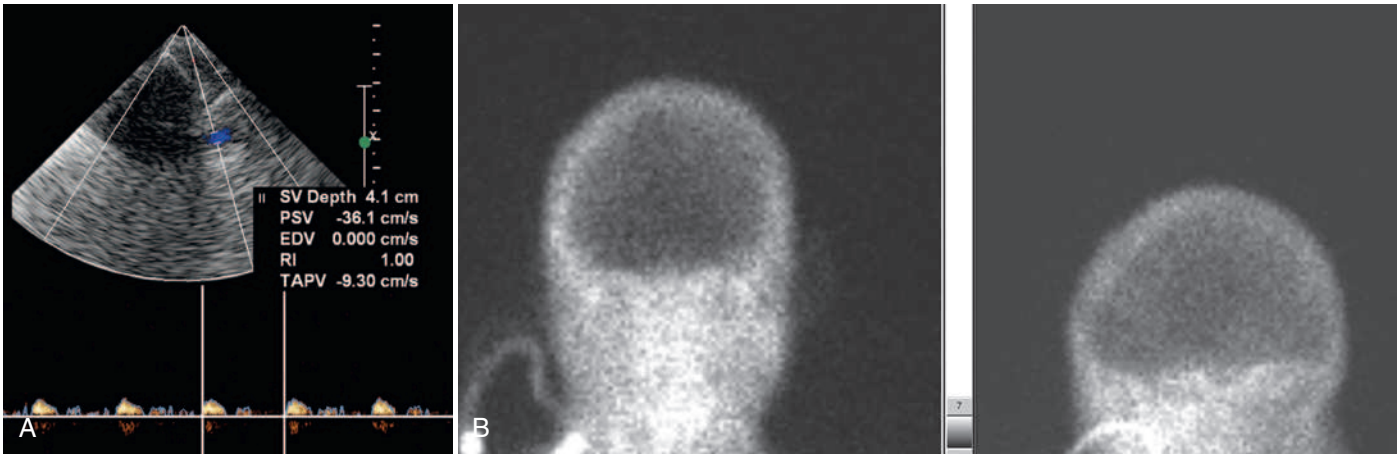

FIG. 47.24 Brain Death Following Hypoxic Insult in a 17-Year-Old Child. (A) TCD spectral waveform of the right MCA demonstrates no significant antegrade flow. **(B)** $_{99m}$Tc-HMPAO brain scan the same day demonstrates no intracranial update. Tracer in the convexity of the head is from the external carotid circulation.

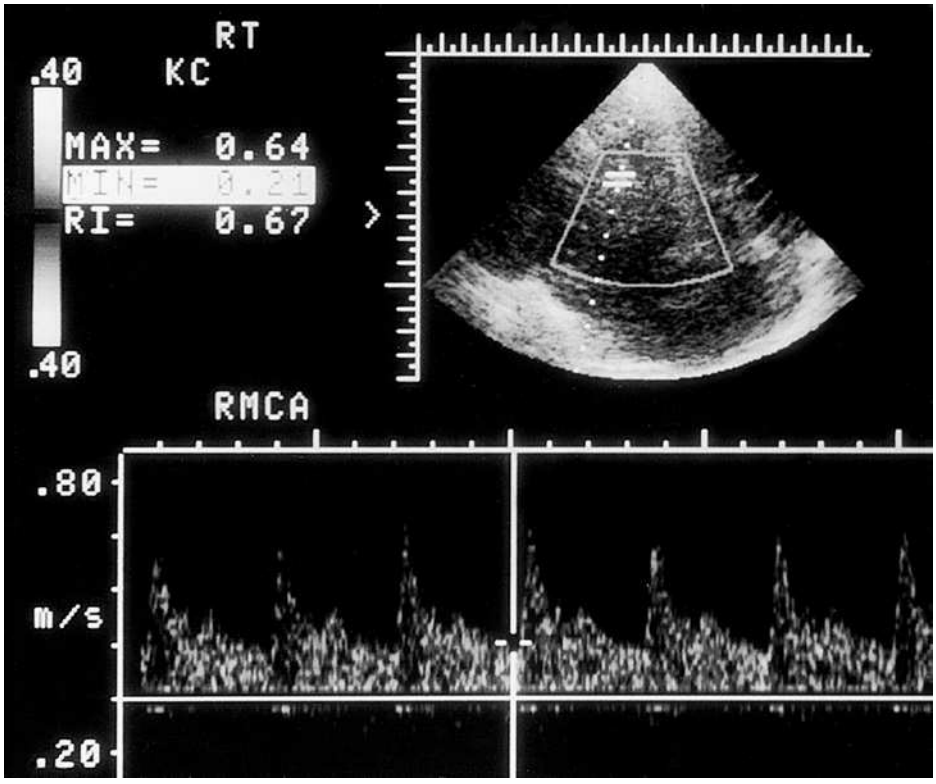

FIG. 47.25 Coma, Not Brain Death. Teenager in status epilepticus with flat electroencephalogram in phenobarbital coma with carbon dioxide tension (P_{CO_2}) of 27 mm Hg. TCD spectral waveform shows antegrade diastolic flow in the right MCA with slightly elevated RI of 0.67 but no evidence of brain death. Patient recovered without sequelae.

a poor prognosis and can help family and clinicians make decisions regarding care.

Neuromonitoring and Intraoperative Neuroradiologic Procedures

Neuromonitoring includes identifying loss of neurologic functions or appearance of secondary cerebral insults that could benefit from early intervention. Neuromonitoring provides physiologic information that can help clinicians better understand the affect of the illness on the brain, assess prognosis, and allow guidance of individualized therapy.[176]

TCD monitoring has been used in the evaluation of cerebral autoregulation in pediatric patients undergoing anesthesia. Blood pressure limits of autoregulation are poorly defined in pediatrics and multiple factors may have substantial impact on the capability of appropriate cerebral autoregulation, including age, gender, temperature, anesthesia, vasopressors, carbon dioxide, inflammation, and brain injury. By identifying the mean arterial pressure

range that has the most robust autoregulation, better neuroprotection can be provided during a procedure.[177]

Intraoperative TCD monitoring of the velocity in the MCA during **carotid endarterectomy** is an accepted clinical application in adults.[6] Intraoperative complications of carotid endarterectomy relate mainly to ischemia during cross-clamping, hyperemic phenomena, or embolization of atheromatous or gaseous materials. After ischemia, hyperemia can occur and is characterized by a sudden increase in flow velocity. High-amplitude spikes seen on TCD spectral waveform and associated with an audible chirping sound are caused by solid or gaseous microemboli as small as 30 to 50 µm.[178] Ischemia during cross-clamping is a classic complication occurring in up to 10% of patients; it is caused by incompetent intracranial collateral circulation, mainly the anterior and posterior communicating arteries and the leptomeningeal vessels. TCD ultrasound can be used to assess the effect of carotid cross-clamping on the MCA in both children and adults (Fig. 47.26).

TCD monitoring during **cardiopulmonary bypass** for cardiac surgery has also been studied. TCD sonography can demonstrate **emboli showers** that occur during aortic cannulation, cardiac manipulation, or other surgical maneuvers.[179-181] Doppler ultrasound has been used to monitor flow patterns during cardiopulmonary bypass with a decrease in mean velocity with increasing hypothermia noted.[182] Profound hypothermic circulatory arrest and profound hypothermia with continuous low-flow cardiopulmonary bypass are used to facilitate repair of complex congenital heart lesions. Extended periods of profound hypothermic arrest may impair cerebral function and metabolism and produce ischemic brain injury. TCD has enabled the noninvasive intraoperative monitoring of cerebral perfusion when using either circulatory arrest or low-flow bypass.

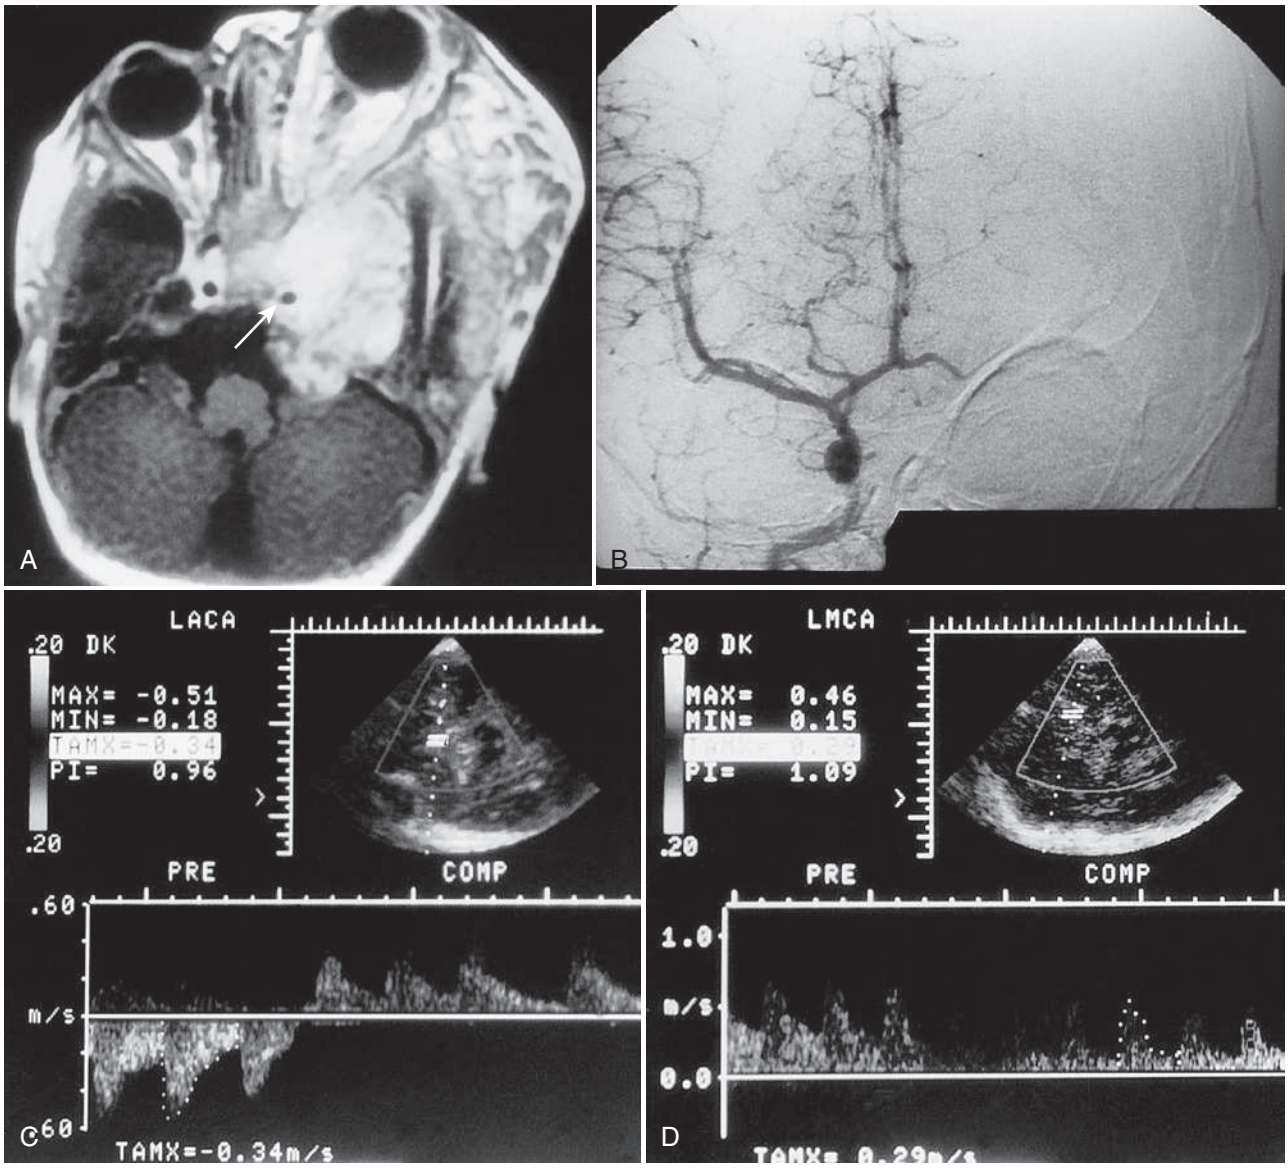

FIG. 47.26 Plexiform Neurofibroma. (A) Left internal carotid artery *(arrow)* is patent but surrounded by the plexiform neurofibroma on MRI. **(B)** Compression of left carotid artery at arteriography shows cross-filling from right side into left ACA. **(C)** TCD spectral waveform at time of compression also shows good filling of left ACA from right side (reverse flow in the left ACA). **(D)** Good filling of left MCA.

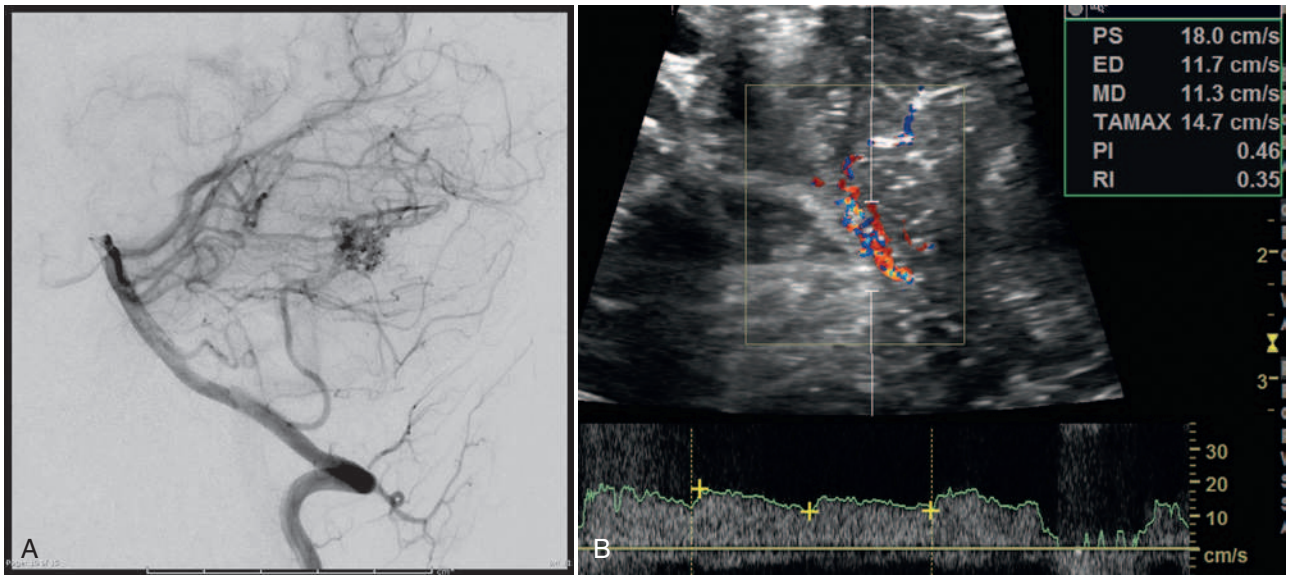

FIG. 47.27 Intraoperative Guidance for Resection of a Supracerebellar Arteriovenous Malformation With Residual Feeders Status After Glue Embolization. (A) Angiogram demonstrates a residual supracerebellar vascular malformation. **(B)** Intraoperative TCD via craniotomy helped identify the vascular nidus *(cursor)*.

A study evaluating the neurodevelopmental outcome in infants undergoing surgery for congenital heart defects indicates that low cerebral blood flow velocities on TCD obtained in the postoperative period is a marker of suboptimal cerebral perfusion.[183] Future TCD studies may help to develop improved methods of cerebral protection during repair of complex congenital heart lesions.[182,184,185]

TCD has also been used during diagnostic and therapeutic neuroangiographic and surgical procedures.[185] Asymptomatic **microemboli** have been shown to enter the cerebral circulation in large numbers during "routine" carotid angiography as well as pediatric scoliosis surgery. High rates of microemboli may be related to the presence of right-to-left cardiac shunts.[186] Intraoperative guidance using contrast agents and three-dimensional TCD is being investigated to improve the demonstration of vascular anatomy (Fig. 47.27).

Outside of surgery, neuromonitoring by TCD has also been done in patients with traumatic brain injury, intracranial hemorrhage, diabetic ketoacidosis,[187] and sepsis in the intensive care unit.[188] By evaluating flow velocity responses to spontaneous or induced changes in cerebral perfusion pressure, TCD can help modify treatment.[176]

A study evaluating the cerebral blood flow velocity in children on **extracorporeal membrane oxygenation** (ECMO) demonstrated that higher velocities suggested to be secondary to hyperemia were identified 2 to 6 days prior to recognizing cerebral hemorrhage. Further studies might demonstrate usefulness of TCD in the monitoring and management of patients on ECMO.[189]

Transcranial Doppler and Tissue Plasminogen Activator

Ultrasound enhances the activity of **tissue plasminogen activator** (TPA). TCD sonography can identify residual blood flow signals around thrombi and, by delivering mechanical pressure waves, expose more thrombus surface to circulating TPA. The CLOT-BUST international multicenter trial[190] showed that ultrasound can enhance the thrombolytic activity of a drug with clinical recovery from stroke with recanalization 2 hours after TPA bolus. This was seen in 25% of patients treated with TPA and TCD compared with 8% who received TPA alone ($p = .02$). The use of contrast-enhanced ultrasound and TPA was recently evaluated in animals and proved to be more effective than TPA with nonenhanced ultrasound, contrast-enhanced ultrasound without TPA, or ultrasound alone.[190] Current ongoing clinical trials include phase II studies of 2-MHz TCD ultrasound with contrast agents or microbubbles.[191,192] Future applications using contrast agents may include evaluating perfusion of brain tumors after chemotherapy and radiation.

Functional Transcranial Doppler

The use of TCD in functional evaluation of the brain is a complementary tool. It is useful in the measurement of the lateralization during cognitive tasks. It is noninvasive, has excellent temporal resolution, and is not affected by motion artifact.[193] Perfusion can also be evaluated and has a significant correlation with findings on functional MRI and positron emission tomography studies. Functional TCD is considered a useful examination in the elucidation of the hemispheric organization of cognitive, motor, and sensory functions in adults and children.[102]

Other Potential Uses

Patients with beta-thalassemia (minor) have an increased risk of stroke and may benefit from transfusion and splenectomy as treatment. Studies demonstrate an increase in mean arterial velocities in patients compared to controls.[194]

Using TCD alone thus far has not predicted stroke risk in patients with thalassemia major.[195] More studies are needed

in this area to better understand the potential benefits of TCD in the management of these patients.[194,195]

Another area of research is the use of TCD in the evaluation of the cognitive function of children. Various studies have associated cerebrovascular function using TCD measurements with cognitive performance. In neonates, a decrease in blood flow velocities is associated with poor cognitive performance and in patients with SCD, an increase in flow velocities is associated with poor outcomes.[102,196]

CHAPTER 48

The Pediatric Head and Neck

Rupa Radhakrishnan and Beth M. Kline-Fath

SUMMARY OF KEY POINTS

- Ultrasound is an excellent modality to evaluate head and neck masses in children because of its accessibility and lack of ionizing radiation.
- Lesion location is an important factor to consider in evaluation of head and neck masses in children.
- Common head and neck masses in children are related to lymph nodes, thyroglossal duct anomalies, branchial anomalies, inclusion cysts, and vascular anomalies.
- Use of spectral Doppler waveforms can aid in identification of arterial components in vascular anomalies to narrow the differential diagnoses.

NORMAL CERVICAL ANATOMY

The goal in pediatric imaging is to perform a study with the lowest possible radiation exposure and least sedation to adequately answer the clinical question.[1-4] Sonography, given a lack of ionizing radiation and its noninvasive approach, is almost invariably the initial imaging modality in a child with a neck lesion. Sonography is cost-effective, widely available, and portable. Ultrasound can illustrate normal cervical anatomy, evaluate vascular structures and lesions with spectral Doppler imaging, and delineate pathology with regard to location, size, and presence of calcification. Cystic masses are common pediatric neck lesions, and sonography is also exceptional at distinguishing solid from cystic lesions and assessing compressibility of lesions. Transducers with frequencies of 7.5 to 10 MHz are excellent for examination of the neck.

Limitations of ultrasound technique include the inability to evaluate bone, small field of view, and degree of soft tissue contrast. Because of these limitations, magnetic resonance imaging (MRI) and computed tomography (CT) are excellent adjunct modalities that can provide additional soft tissue and bone detail and further delineate extent of disease.[5]

An understanding of normal cervical anatomy is essential to appropriately evaluate head and neck pathology. The soft tissues of the neck can be separated into boundaries of the superficial and deep spaces.[6-8] The **superficial fascia** is primarily composed of subcutaneous fat. The platysma muscle, subcutaneous lymph nodes, and nerves lie within the superficial space. The **deep cervical fascia,** encircled by the superficial tissues, contains the major structures of the neck (Fig. 48.1). The deep cervical fascia includes superficial, middle, and deep layers (Fig. 48.2).

Simplifying the deep cervical fascial anatomy is best achieved by dividing the neck into suprahyoid and infrahyoid locations.[6,7] The **suprahyoid space** includes the areas of the neck between the skull base and hyoid bone.[6] The **infrahyoid space** is the area of the neck between the hyoid bone and clavicles.[7] Some deep

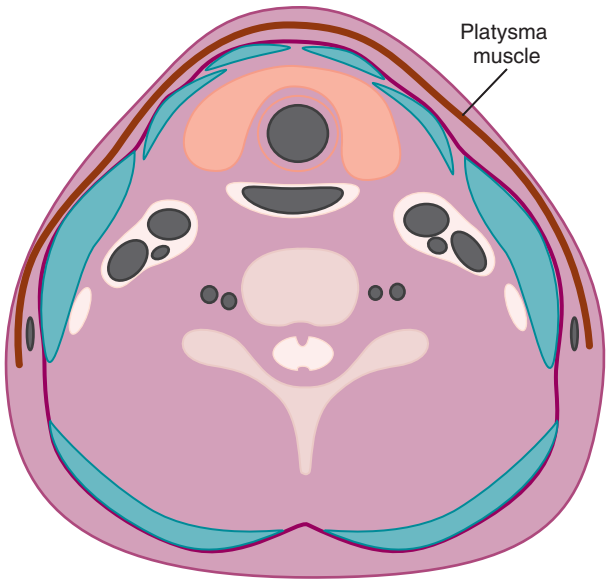

FIG. 48.1 Superficial and Deep Cervical Boundaries. Axial image of the neck at the level of the thyroid demonstrates the platysma muscle, which separates the peripheral superficial from central deep cervical fascial layers.

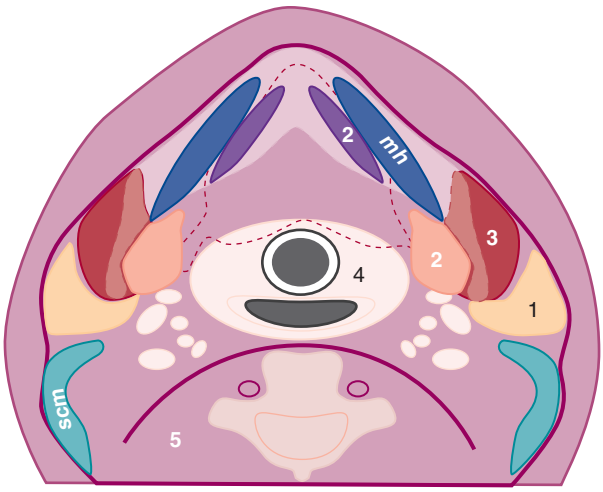

FIG. 48.3 Deep Cervical Fascial Layers of Suprahyoid Neck, Axial Image. The parotid, masticator, and submandibular spaces represent the superficial layer. *1,* Parotid gland. *2,* Submandibular space contains the sublingual *(brown)* and submandibular *(orange)* glands. *3,* Masticator space contains the masseter muscle. *4,* Middle layer; *5,* Deep fascial layer; *mh,* Mylohyoid muscle; *scm,* sternocleidomastoid muscle.

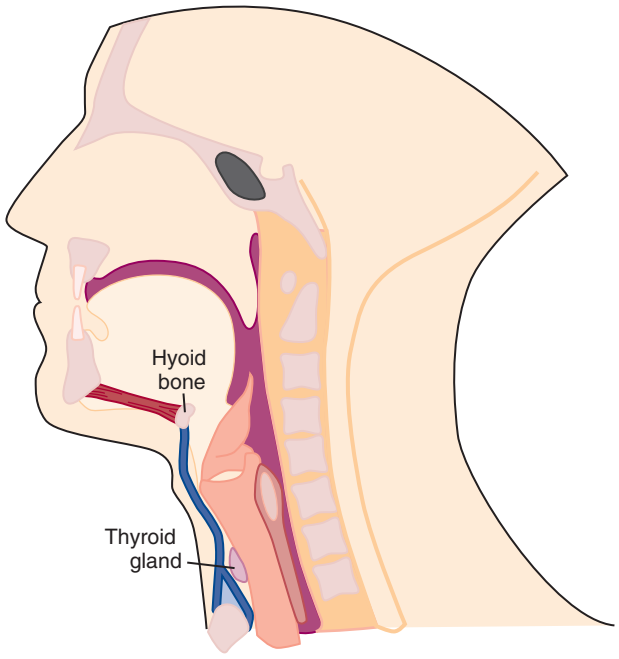

FIG. 48.2 Deep Cervical Fascial Layers. Sagittal image of the neck separates the deep cervical fascia into three boundaries: superficial *(blue),* middle *(orange),* and deep *(yellow).*

fascial planes and lesions extend within both the infrahyoid and the suprahyoid space. These spaces and lesions are described as "lacking definition by the hyoid." Using this organization, with the knowledge of the normal anatomic elements in each space, the appropriate differential diagnosis for a mass can be proposed.

SUPRAHYOID SPACE

The suprahyoid space includes the superficial, middle, and deep layers of the deep cervical fascia[9] (Fig. 48.3). The superficial layer envelops three spaces. The **parotid space** includes the parotid gland, intraparotid facial nerve, retromandibular vein, lymph nodes, and external carotid artery. The **masticator space** includes muscles of mastication and the posterior body of the mandible. The **submandibular space** includes the sublingual and submandibular glands, as well as the adjacent lymph nodes, muscles of the tongue, and hypoglossal nerve. Ultrasound is most useful in evaluation of the spaces in the superficial fascial layer.

The middle territory of the suprahyoid space lies between fascial layers and includes the **parapharyngeal** and **pharyngeal** spaces. This middle layer, which includes lymphoid tissue, minor salivary glands, and fat encircling the pharynx, is difficult to visualize with ultrasound and is not discussed separately. The **carotid space** is formed from fibers of the middle and deep layers of cervical fascia. The **retropharyngeal space** is contained by layers of the middle cervical space anteriorly and deep cervical layers posteriorly. However, because the retropharyngeal space and **prevertebral** layer, a deep cervical space, cannot be separated, it is easiest to consider these layers together in the deep cervical facial layer as the retropharyngeal space. The carotid space and retropharyngeal space extend above and below the hyoid and are discussed later.

Salivary Glands

Because the parotid and submandibular areas primarily contain salivary tissue and thus have similar pathology, these two spaces are considered together. The major salivary glands that occupy these spaces include the parotid glands, the submandibular glands, and the sublingual glands.

Normal Anatomy

The **parotid gland** is the largest salivary gland. This encapsulated gland, containing lymphoid tissue, vessels, and nerves, wraps around the angle of the mandible anterior to the mastoid tip (Fig. 48.4). Most parotid tissue lies superficial to the masseter muscle. In 20% of patients, an **accessory** parotid gland, which is a nodule of salivary tissue separate from the main parotid, can be identified on the masseter muscle.[10] The parotid gland contains acini that drain through the **Stensen duct,** a structure that extends anteriorly to exit above the upper second molar.[11] The duct lies approximately 1 cm below the inferior margin of the zygomatic arch.[12] The **facial nerve** travels within the parotid gland, lying lateral to the retromandibular vein and posterior belly of the digastric muscle, which is the muscle deep to the mastoid tip. The facial nerve acts a boundary to divide the parotid gland into superficial and deep components. The **deep lobe** of the parotid, which accounts for 20% of the gland, lies adjacent to the parapharyngeal space and beneath the angle of the mandible.

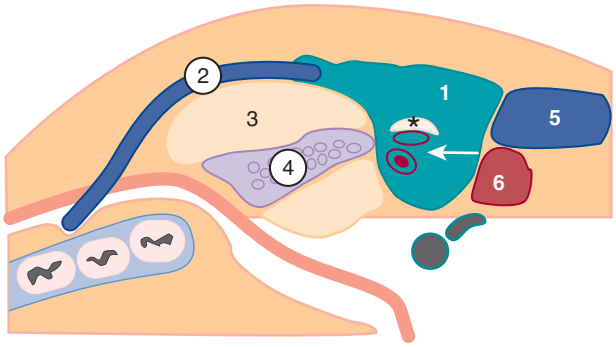

FIG. 48.4 Diagram of Parotid Space. *1,* Parotid gland; *2,* Stensen duct; *3,* masseter muscle; *4,* angle of mandible; *5,* mastoid; *6,* posterior belly of digastric muscle. Arrow points between the retromandibular vein *(open circle)* and external carotid artery *(partly solid circle),* demarcating superficial and deep lobes. Lenticular tan structure with * is the facial nerve.

Imaging of the parotid should be performed with a high-frequency transducer. Usually, linear transducers of 5 to 12 MHz are used. The entire gland should be evaluated in two perpendicular planes. Because the facial nerve is poorly delineated on ultrasound, the **retromandibular vein,** which lies directly deep to the nerve and lateral to the external carotid artery, is an excellent landmark to separate the superficial and deep lobes.[12,13] Typically, the deep lobe can only be partially visualized, concealed by acoustic shadowing of the mandibular ramus. On sonography, the parotid gland is generally homogeneous and hyperechoic with regard to the adjacent muscle (Fig. 48.5). The degree of echogenicity of the gland depends on the amount of intraglandular fatty tissue; the greater the fat content, the higher the echogenicity.

Normal intraparotid ducts may be visualized as linear reflective structures. The Stensen duct is usually not visible in the absence of dilation. In the parotid parenchyma, normal lymph nodes may be observed. Most nodes are identified at the upper or lower pole, are oval in shape, measure 5 to 6 mm in the short axis, and appear hypoechoic with a hyperechoic central hilum.[12] Ultrasound is especially useful in differentiating intraparotid lesions from extraparotid masses and separating solid and cystic lesions in this location.

The submandibular space contains both the submandibular glands and the sublingual glands in addition to submandibular lymph nodes. The submandibular glands lie within the posterior submandibular space, whereas the sublingual glands are anterior (Fig. 48.6). The **submandibular glands** are bordered by the mandible laterally and the mylohyoid muscle superiorly and medially. A small portion of the gland may pass posterior to the mylohyoid muscle to lie within the sublingual area. The space anterior to the submandibular gland contains lymph nodes. The torturous facial artery typically crosses the parenchyma laterally. The anterior facial vein can often be identified along the anterosuperior aspect of the gland.[14] Medially, the lingual artery and vein may be evident. The **Wharton duct,** the excretory duct for the gland, extends along the mylohyoid and medial part of the sublingual gland to its orifice at the floor of the mouth. On sonography, the submandibular glands should be examined in

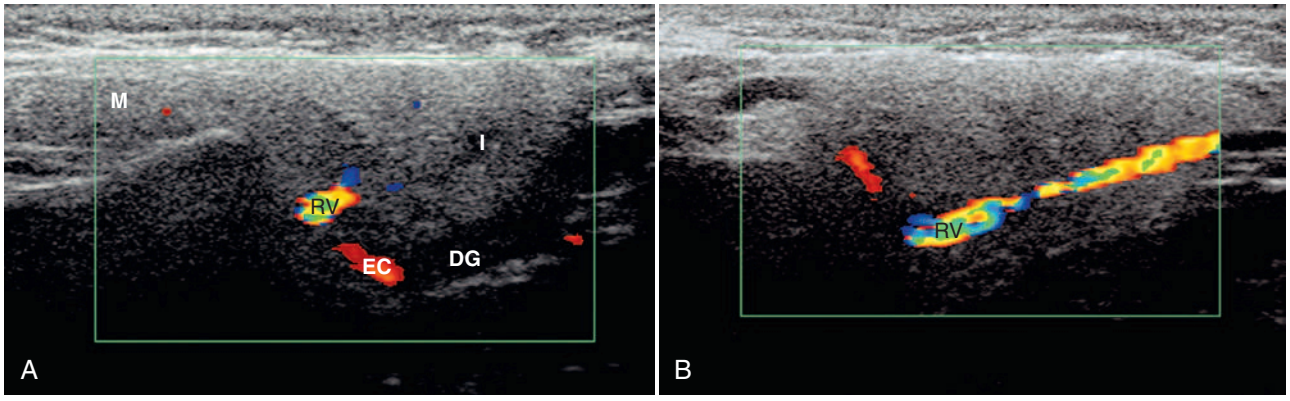

FIG. 48.5 Normal Parotid Gland. (A) Transverse color Doppler ultrasound shows mildly increased echogenicity compared with adjacent masseter muscle *(M).* Deep and superficial portions of the gland are separated by the retromandibular vein *(RV)* found lateral to the external carotid artery *(EC)* and posterior belly of the digastric muscle *(DG).* Small, hypoechoic intraparotid lesion is consistent with normal lymph node *(I).* **(B)** Longitudinal color Doppler sonogram shows normal parotid displaying homogeneous hyperechoic texture and retromandibular vein *(RV).*

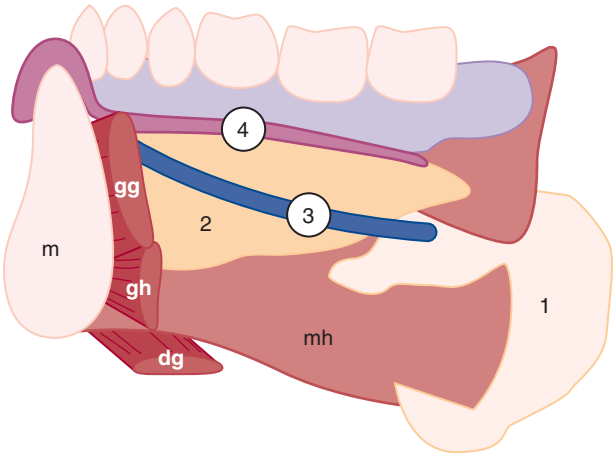

FIG. 48.6 Normal Submandibular Space. Sagittal diagram shows submandibular gland *(1)*, sublingual gland *(2)*, submandibular (Wharton) duct *(3)*, sublingual duct *(4)*, mylohyoid muscle *(mh)*, genioglossus muscle *(gg)*, geniohyoid muscle *(gh)*, anterior belly of digastric muscle *(dg)*, and mandible *(m)*.

two perpendicular planes, usually long and transverse, with a high-frequency linear transducer. The glands are triangular, homogeneous, and more echogenic than muscle but less echogenic than the parotids[15] (Fig. 48.7). On high-resolution sonography, **fine linear streaks** can be observed, representing intraglandular ductules. The Wharton duct may be visualized as a thin echogenic wall medial to the sublingual gland. Movement of the patient's tongue may aid in visualization of the duct.[16]

The **sublingual gland** lies on the mylohyoid muscle between the mandible and genioglossus muscle. In addition to the gland, the sublingual area includes the submandibular duct and sublingual vessels, which lie medial to the gland. Scanning of the gland should be performed with a high-frequency linear transducer submental in two perpendicular planes with the patient supine and the head retroflexed.[17] A standoff pad can be helpful in accessing the anatomy. On transverse imaging the gland is oval, whereas on long sections the gland has a lentiform shape (Fig. 48.8). The echogenicity of the sublingual gland is similar to the parotid and submandibular glands.[17]

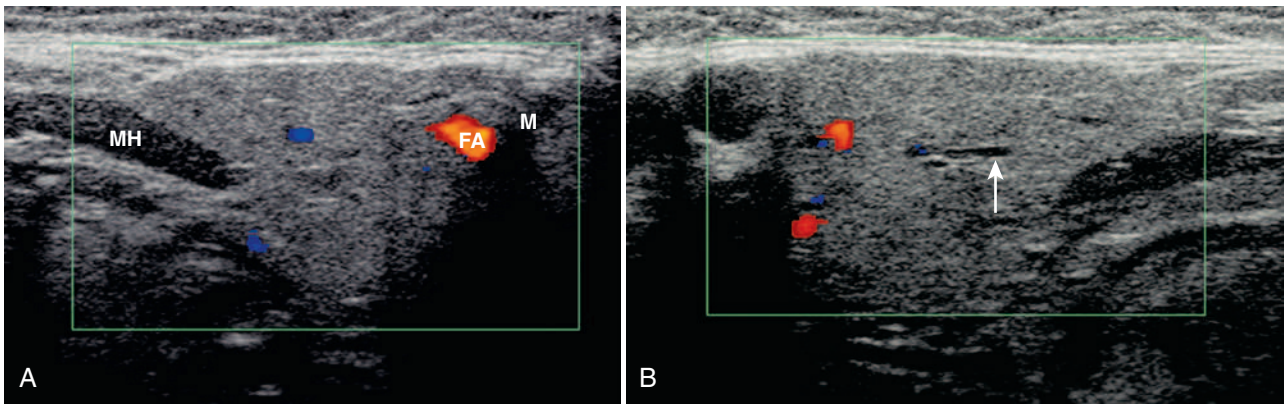

FIG. 48.7 Normal Submandibular Gland. (A) Transverse color Doppler scan shows homogeneous triangular gland with mandible *(M)* laterally and mylohyoid muscle *(MH)* medially. Facial artery *(FA)* is also present laterally along the gland. **(B)** Longitudinal color Doppler imaging shows central linear structure without color *(arrow)*, representing nondilated Wharton duct.

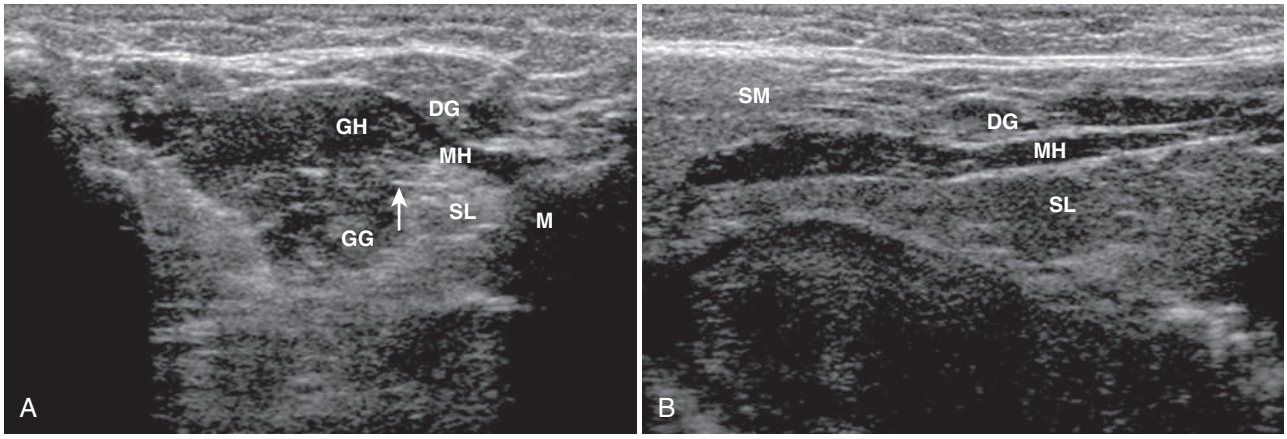

FIG. 48.8 Normal Sublingual Gland. (A) Transverse image shows triangular homogeneous sublingual glands laterally adjacent to mandible. *Arrow*, Wharton duct; *DG*, anterior belly of digastric muscle; *GG*, genioglossus; *M*, mandible; *MH*, mylohyoid; *GH*, geniohyoid; *SL*, sublingual gland. **(B)** Longitudinal ultrasound shows the submandibular gland *(SM)* posteriorly and the lenticular homogeneous sublingual gland *(SL)*.

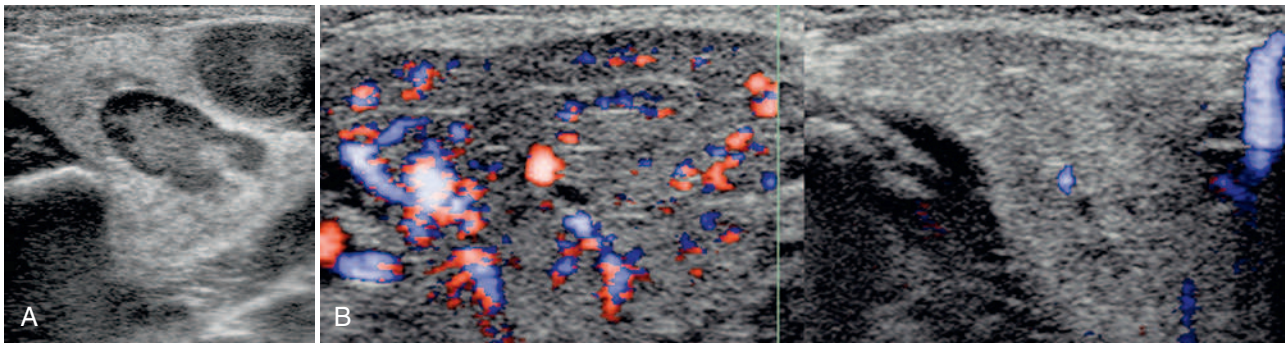

FIG. 48.9 Viral Salivary Gland Infection. (A) Mononucleosis of parotid gland in 10-year-old child. Transverse scan shows a swollen, mildly inhomogeneous parotid with enlarged intraparotid lymph nodes. **(B)** Color Doppler comparison sonograms of the submandibular glands shows decreased echogenicity and increased vascularity in the left and normal appearance of the right.

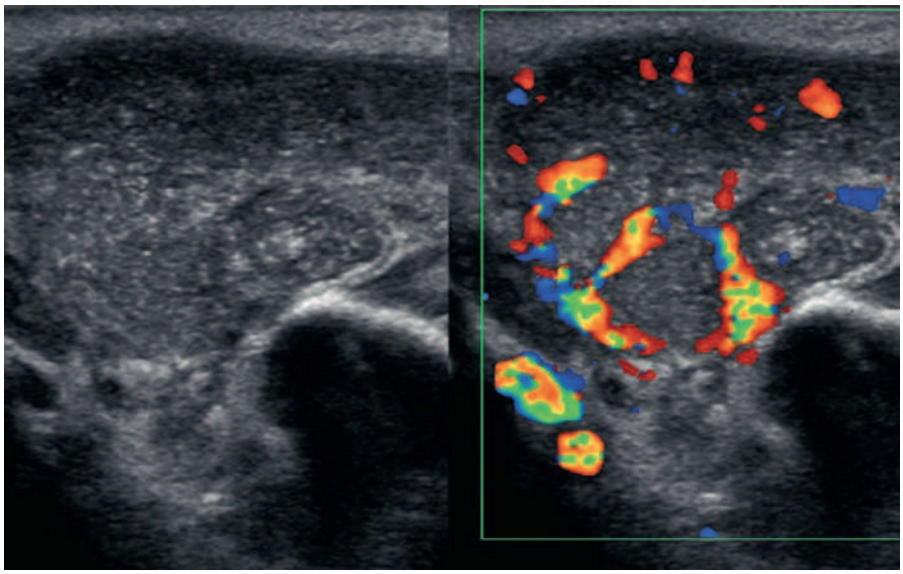

FIG. 48.10 Bacterial Parotid Infection. Split screen gray-scale and color Doppler images show a swollen, heterogeneous hypervascular parotid gland in a 17-day-old neonate infected with *Staphylococcus.*

Inflammatory Lesions

Most salivary gland pathology in children is caused by inflammatory lesions, which can be acute or chronic. The acute form may be secondary to viral or bacterial etiologies. The chronic form includes a long differential diagnosis (e.g., **human immunodeficiency virus [HIV], Sjögren syndrome, sialoadenitis, sarcoidosis,** other **granulomatous processes**).

Acute Salivary Gland Inflammation. In children, **viral salivary gland infections** are the most common cause of acute inflammation.[18] Endemic viruses, including mumps, mononucleosis, and cytomegalovirus (CMV), are the most common viral causes, causing painful unilateral or bilateral swelling of the salivary tissue. In 85% of cases, the parotid gland is involved. Although less prevalent with the advent of immunization, **mumps** is still the most common cause of **parotitis.**[11] Mumps, a highly contagious worldwide infection spread by airborne droplets, is typically encountered in the winter and spring and primarily affects children younger than 15 years.[18] The incubation period for this virus is 14 to 21 days, but the infection is contagious 3 days before the onset of swelling until the resolution of the swelling.[19] With ultrasound, viral salivary infections show a diffusely enlarged gland that may have a normal, heterogeneous and/or hypoechoic echotexture with increased vascularity[20,21] (Fig. 48.9). Frequently there is bilateral involvement, although unilateral involvement may be seen in up to one-third of patients.[21]

Bacterial infection is rare in children, primarily affecting the parotid gland. *Staphylococcus aureus* is the most common cause.[11,15,18,22] Children younger than age 1 year, especially premature infants (35%-40% cases), immunosuppressed patients, and children with severe dental and gingival disease are particularly vulnerable. Infection is typically unilateral and associated with fever, dehydration, and gland pain and edema. Proposed etiologies include infection in the mouth or stasis of salivary flow through the ducts.[18] Using ultrasound, the parotid gland appears enlarged and heterogeneous in echotexture with discrete, hypoechoic nodules representing enlarged intraparotid lymph nodes[11-13] (Fig. 48.10). There may be dilation of the central parotid ducts.[21] Adjacent cervical lymphadenopathy is common. In patients with uncomplicated parotitis, treatment is primarily

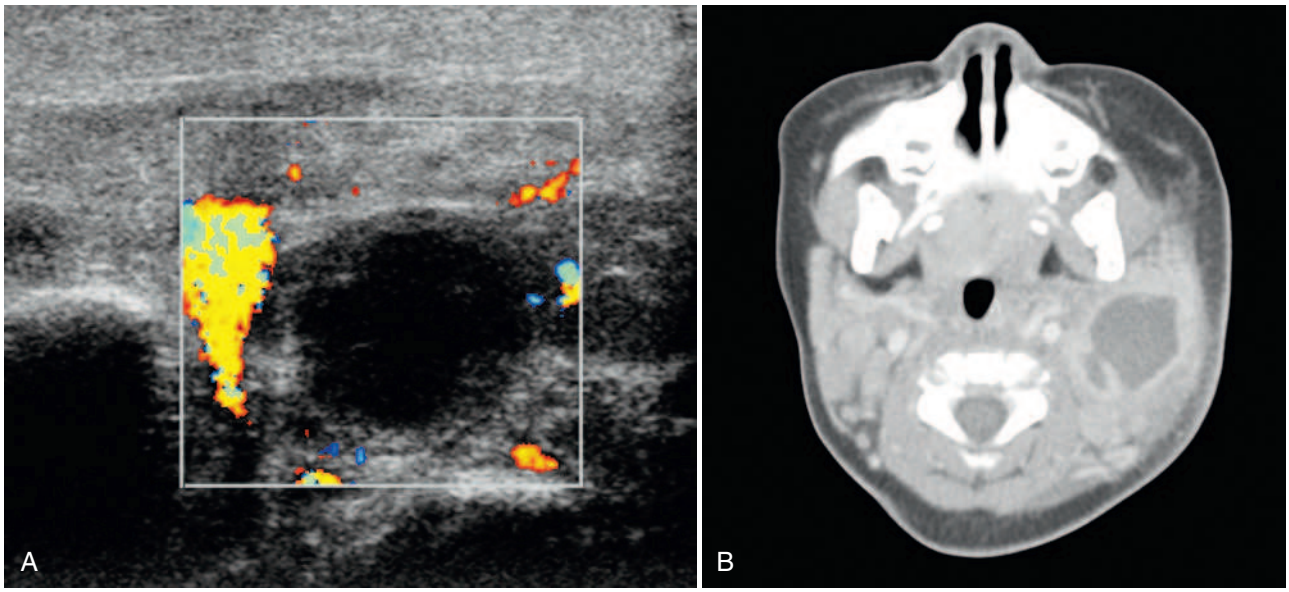

FIG. 48.11 Parotid Abscess. (A) Two-month-old infant developed swelling along the left ear. Sonogram of the parotid area demonstrates a round, well-defined, hypoechoic mass without internal blood flow within the deep parotid. **(B)** Contrast computed tomography scan performed 2 days later because of lack of response to intravenous antibiotics demonstrates a large, round, hypoattenuated lesion with partial enhancing peripheral wall within inflamed left parotid.

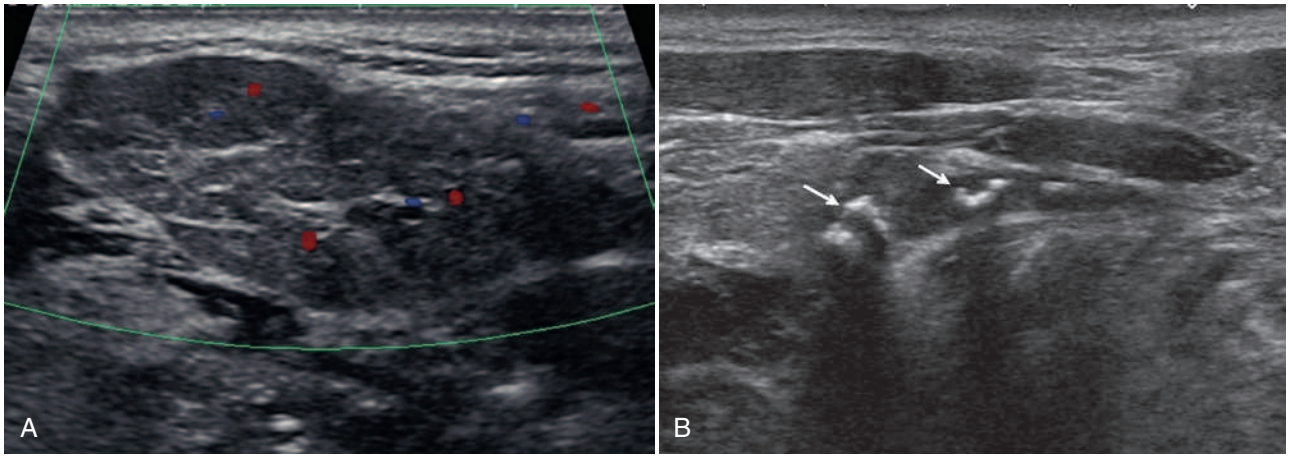

FIG. 48.12 Submandibular Gland Sialolithiasis. (A) Color Doppler of enlarged hypoechoic submandibular gland containing echogenic foci. **(B)** Dilated submandibular (Wharton) duct due to multiple obstructing echogenic shadowing foci, consistent with stones *(arrows)*. See also Video 48.1.

supportive with administration of intravenous (IV) antibiotics.[20] In the presence of severe dehydration and especially in neonates 7 to 14 days old with bacterial infection, an intraparotid abscess may develop. These collections typically appear hypoechoic or anechoic with posterior acoustic enhancement and occasionally a hyperechoic halo[12] (Fig. 48.11). Internal debris may be noted, and in some patients, hyperechoic foci consistent with gas bubbles. Ultrasound-guided drainage is useful when abscess is present. Recurrence is uncommon.

Sialolithiasis is uncommon in children, with 90% in the submandibular gland and 10% in the parotid.[12,18,20] In 25% of patients, stones are often multiple and intraglandular or intraductal in location. Submandibular glands are prone to calculi because of the alkaline nature and high viscosity of their secretions. The Wharton duct is long with an upward course and thus also has a higher propensity for stone formation. Clinically, recurrent swelling during eating and superimposed infection may result from partial or complete obstruction of the duct by a stone. Sonography is as sensitive as 94% in the detection of salivary calculi. Features include hyperechoic foci with acoustic shadowing representing stones (Fig. 48.12, Video 48.1). With duct occlusion, hypoechoic tubular areas are typically consistent with dilated ducts.[12,23] About 50% of patients have inflammation of the gland in conjunction with the calculus,[12] and the gland will demonstrate a heterogeneous architecture. Although 80% of submandibular and 60% of parotid stones are radiopaque on x-ray examination, when more information is needed beyond ultrasound, a CT scan provides the best detail.[24]

Nodal enlargement in the parotid is often present in association with cervical adenopathy caused by infection or neoplasm.

Parinaud oculoglandular syndrome presents with conjunctivitis and ipsilateral intraparotid or periauricular adenopathy and can result from ***Chlamydia*** **infection** or **cat-scratch disease.** In the submandibular space, sonography is useful to differentiate nodal from glandular disease.

Chronic Inflammatory Disease. Juvenile (recurrent) parotitis is the most common cause of childhood parotid swelling in developed countries.[22] This disorder manifests with intermittent pain, fever, and unilateral or bilateral parotid swelling. The submandibular and sublingual glands are not affected, and there is no known cause for the recurrent parotitis. Differential diagnosis includes mumps or suppurative parotitis, which is excluded by lack of pus from the parotid duct.[25] Age at presentation is typically 3 to 6 years, and the episodes tend to cease near puberty or in late adolescence.[26] Boys are more often affected than girls.[26,27] Some patients acquire superimposed acute infection, typically with *Streptococcus viridans.*[25,26]

Ultrasound is the favored imaging approach, demonstrating enlarged parotid glands containing multiple round, hypoechoic areas measuring 2 to 4 mm in diameter, likely representing peripheral sialectasis and lymphocytic infiltration[28] (Fig. 48.13). Some glands may be hypervascular, secondary to acute inflammation.[27] Treatment is generally supportive with analgesics and antibiotic administration.

Chronic sialadenitis is caused by an inflammatory process that damages the acini, altering the drainage system of the gland. The etiology may be infectious or noninfectious. Clinically, patients have gland swelling and pain, particularly postprandial. Patients with **chronic sialadenitis** on sonography often demonstrate a heterogeneous gland with small, punctate, echogenic areas or with multiple hypoechoic areas[15] (Fig. 48.14). Punctate areas are believed to represent mucus in the dilated ducts or walls of the dilated ducts. The hypoechoic areas likely represent edema and sialectasis. Increased vascularity can be demonstrated in areas of abnormal echotecture.[29] Findings may be bilateral and associated with intraglandular or adjacent lymph node involvement.

Infectious etiologies include granulomatous diseases such as **mycobacterial, actinomycosis,** and **histoplasmosis.** Primary tuberculosis of the salivary gland is rare; however, nontuberculous salivary gland infection, typically secondary to *Mycobacterium avium-intracellulare,* is more common, usually manifesting at age 16 to 36 months. It is important to remember that tuberculosis and actinomycosis can mimic neoplasm because as the disease progresses, the lesions may appear as hypoechoic masses with poorly defined margins. On color Doppler sonography, these infectious lesions, unlike neoplasms, show no color flow. Complications with actinomycosis and mycobacteria include draining sinuses and fistulas. Treatment is typically with antimicrobial therapy, although surgery may be necessary.

The most common **noninfectious** salivary gland inflammatory processes include autoimmune disease, sarcoid, and recurrent sialolithiasis (see Fig. 48.14). **Sjögren syndrome** is an autoimmune disorder that results in inflammation and destruction of the exocrine glands, primarily lacrimal and salivary tissue.[30] These patients are usually monitored with ultrasound because of increased risk for lymphoma. **Sarcoid** is an idiopathic granulomatous disease that is uncommon in children. Parotid involvement, noted in 30% of patients, may be the only initial finding. **Heerfordt disease** is the combination of parotid involvement,

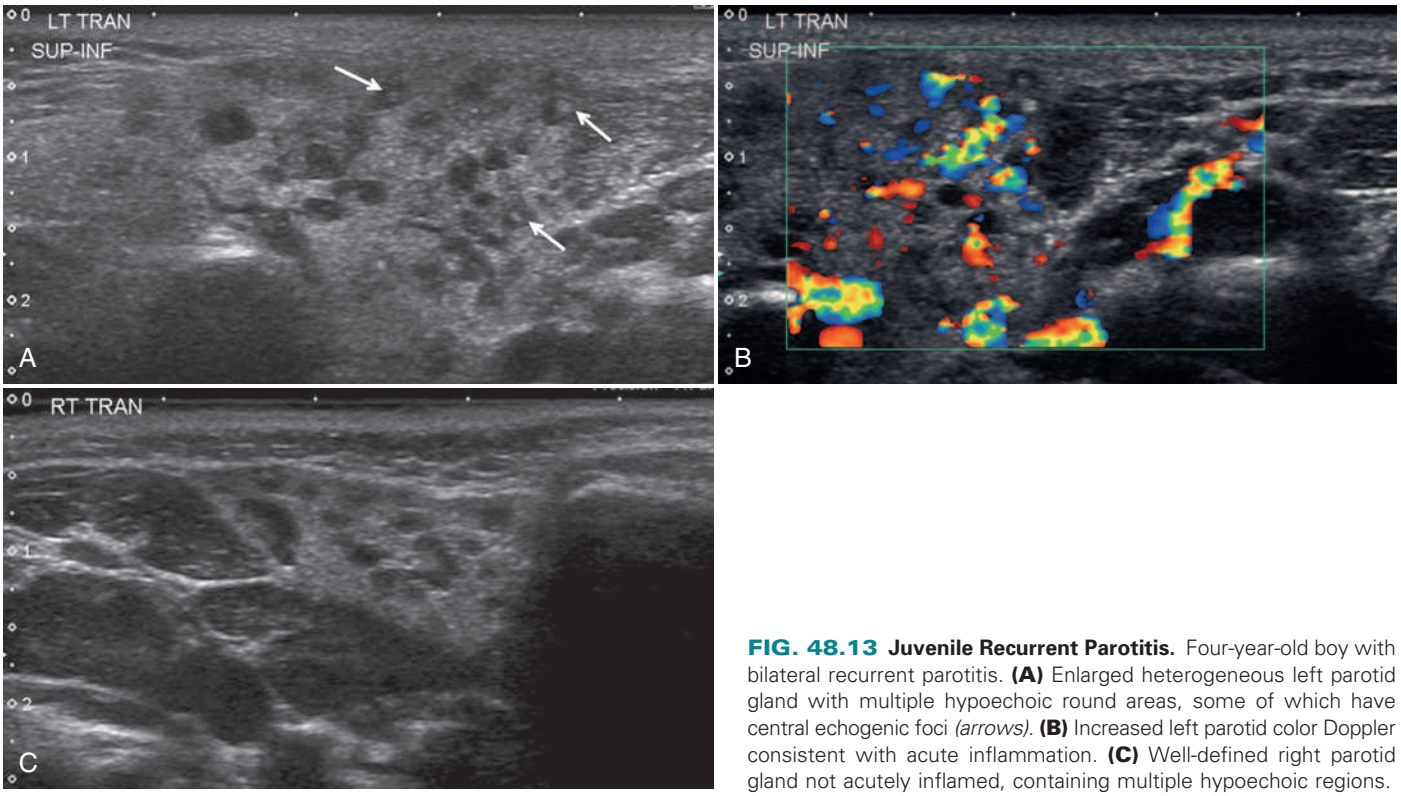

FIG. 48.13 Juvenile Recurrent Parotitis. Four-year-old boy with bilateral recurrent parotitis. **(A)** Enlarged heterogeneous left parotid gland with multiple hypoechoic round areas, some of which have central echogenic foci *(arrows).* **(B)** Increased left parotid color Doppler consistent with acute inflammation. **(C)** Well-defined right parotid gland not acutely inflamed, containing multiple hypoechoic regions.

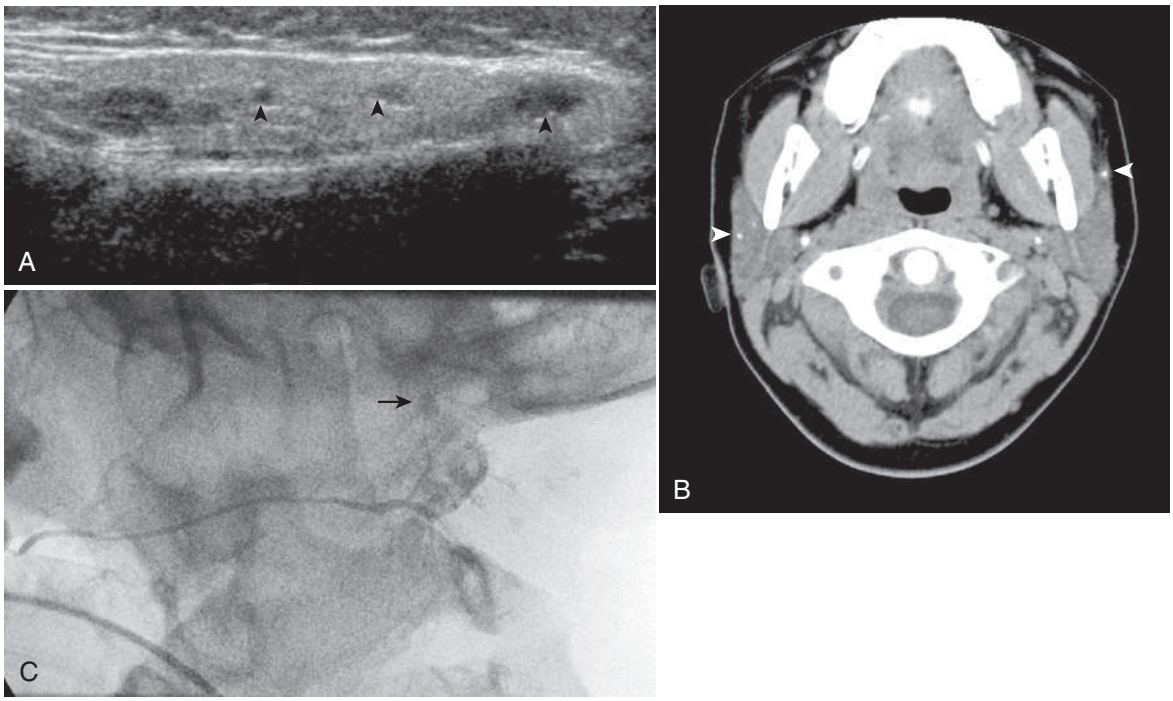

FIG. 48.14 Chronic Parotid Sialadenitis Secondary to Sialolithiasis. (A) Parotid contains round areas of decreased echogenicity typical of dilated ducts and small areas of increased echogenicity consistent with mucus and small calculi *(arrowheads).* **(B)** Computed tomography scan shows multiple calculi in the right and left parotid *(arrowheads)* and inhomogeneous density of the right parotid. **(C)** Sialogram excludes stone obstructing Stensen duct but shows pooling in peripheral dilated ducts, sialectasis *(arrow).*

uveitis, and facial paralysis.[20] Calcified hypoechoic lesions may be present. Treatment is primarily with steroids.

Salivary glands can also be involved in the spectrum of immunoglobulin G4 (IgG4)–associated disease **(IgG4-associated disease),** a systemic disease characterized by abundant infiltration of IgG4-positive plasma cells and lymphocytes with associated fibrosis resulting in multiorgan dysfunction.[31] There can be multiple sites of involvement in the head and neck. **Mikulicz disease** and chronic sclerosing sialadenitis **(Küttner tumor)** are the two manifestations of IgG4-associated disease in the salivary glands.[31] Both these conditions are more common in elderly men, but pediatric cases of Küttner tumor have been reported.[32-34] Mikulicz disease is characterized by painless swelling of the parotid, submandibular, and sublingual salivary glands, as well as the lacrimal glands. Küttner tumor is a hard masslike enlargement frequently involving the submandibular glands, either unilateral or bilateral.[31] In Mikulicz disease, sonography reveals multiple hypoechoic areas in enlarged salivary glands.[35] On sonography **Küttner tumor** often shows diffuse involvement of the salivary gland with heterogeneous echogenicity, dilated ducts, calculi, and prominent intraglandular vessels. Focal salivary gland lesions show hypoechoic heterogeneous regions with a radial branching vascular pattern demonstrated by Doppler.[36]

Kimura disease is a rare, possibly autoimmune inflammatory disorder with slow-growing painless soft tissue masses frequently in the subcutaneous tissues over the parotid, periauricular, and submandibular regions.[37,38] There can be contiguous extension of the lesions into the parotid gland.[39] These lesions are frequently described in adolescent and young adult Asian males.[37] There may be associated intraparotid, submental, and submandibular lymphadenopathy, with normal node morphology. On sonography the soft tissue masses are found to be heterogeneous hypoechoic centrally with echogenic hypervascular rim. Lymph nodes show exaggerated hilar and capsular vascularity.[37,38]

Human immunodeficiency virus (HIV) infection can affect all salivary glands, but primarily the parotid. The patient may demonstrate bilateral parotid swelling and lung disease from lymphocytic interstitial pneumonitis.[15] Infection is characterized by benign lymphoepithelial lesions, consisting of lymphoid hyperplasia accompanied by an intranodal cyst lined by epithelial cells.[40,41] Prevalence of salivary gland abnormalities in pediatric HIV can be as high as 58%, and they can be present even in the absence of a history of parotid enlargement.[42] Bilateral cystic enlargement of the parotid glands is a widely recognized cause of parotid gland swelling in patients with HIV infection but can be difficult to differentiate from recurrent parotitis, Sjögren syndrome, lymphoma, and Warthin tumor.[24,40] In 70% of patients, on sonography an enlarged gland is noted containing small, hypoechoic areas without acoustic enhancement and with thick septations consistent with lymphoid infiltration[15,43,44] (Fig. 48.15). In 30% there are large, anechoic areas consistent with lymphoepithelial cysts replacing the gland. From 40% to 70% of HIV patients have associated symmetrical cervical adenopathy and enlarged adenoids.[45]

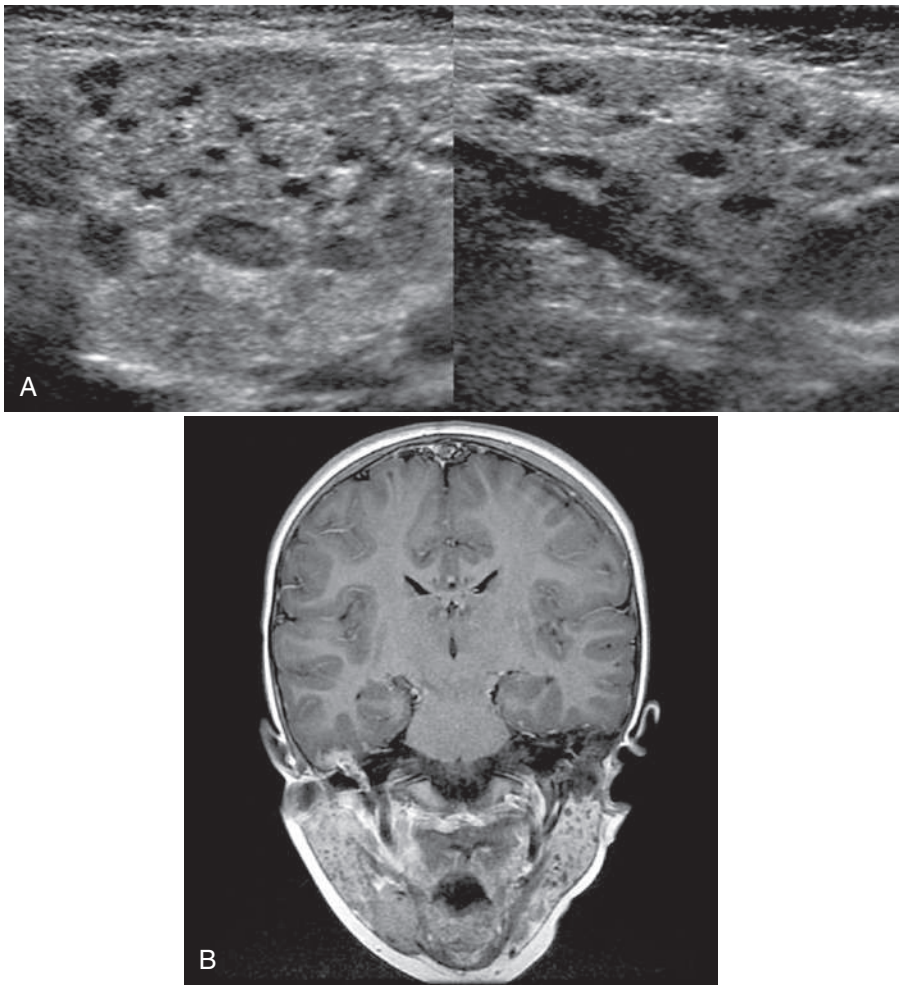

FIG. 48.15 Human Immunodeficiency Virus (HIV) Parotitis. (A) Transverse images of mildly enlarged right and left parotid glands containing small, hypoechoic areas. **(B)** Coronal postgadolinium T1-weighted magnetic resonance image demonstrates multiple lymphoepithelial cysts within enhancing parotid tissue bilaterally.

Masses

Vascular Masses. The common childhood salivary gland vascular masses include vascular neoplasms such as hemangiomas, and vascular malformations such as venous or lymphatic malformations. **Hemangiomas** represent 60% of all salivary gland neoplasms.[46,47] About 80% arise in the parotid, and 18% are present in submandibular tissue.[20] On ultrasound, the lesions are infiltrative or well circumscribed, usually hypoechoic relative to the glandular tissue, and may involve all or part of the gland (Fig. 48.16). In the proliferative phase, on color Doppler sonography there is a high vessel density, with both increased arteries and increased veins. Arterial spectral Doppler demonstrates high flow velocity and low resistive index (RI) with spectral broadening.[43,47] Because most infantile hemangiomas spontaneously regress, medical management with propranolol, laser therapy, or surgical excision is used only when symptoms warrant.[48,49] **Lymphatic malformations** may involve the parotid gland or may infiltrate the submandibular space. On ultrasound, a lymphatic malformation within the parotid gland shows cystic spaces of varying sizes, with or without solid elements, septations, and internal layering debris[11] (Fig. 48.17). **Venous malformations** can be small, involving only a portion of the salivary gland, or may be diffuse, involving multiple spaces of the neck. These lesions contain multiple cystic areas, ectatic venous channels, and often phleboliths, which aid in sonographic diagnosis.

Neoplasms. Tumors of the salivary glands account for only 1% of all pediatric tumors.[50] About 8% of primary tumors of the head and neck in children originate within the salivary glands[15]; 90% to 95% occur in the parotid and the rest in the submandibular and sublingual glands.[11] Most masses of the salivary gland are benign and have a vascular etiology, with only 13% reported to be solid salivary gland tumors.[20,50,51] Pediatric epithelial salivary masses tend to occur in children older than 10 years, with 23% to 50% of them reported to be malignant.[18,20,50] Most malignant tumors in children are of lower grade compared with adults, although children younger than 10 years tend to have higher grade tumors.[20]

In children, sonography is the first step, especially for palpable lesions because the majority of space-occupying lesions in the salivary glands are well delineated.[23] There are no specific sonographic findings differentiating malignant from benign salivary

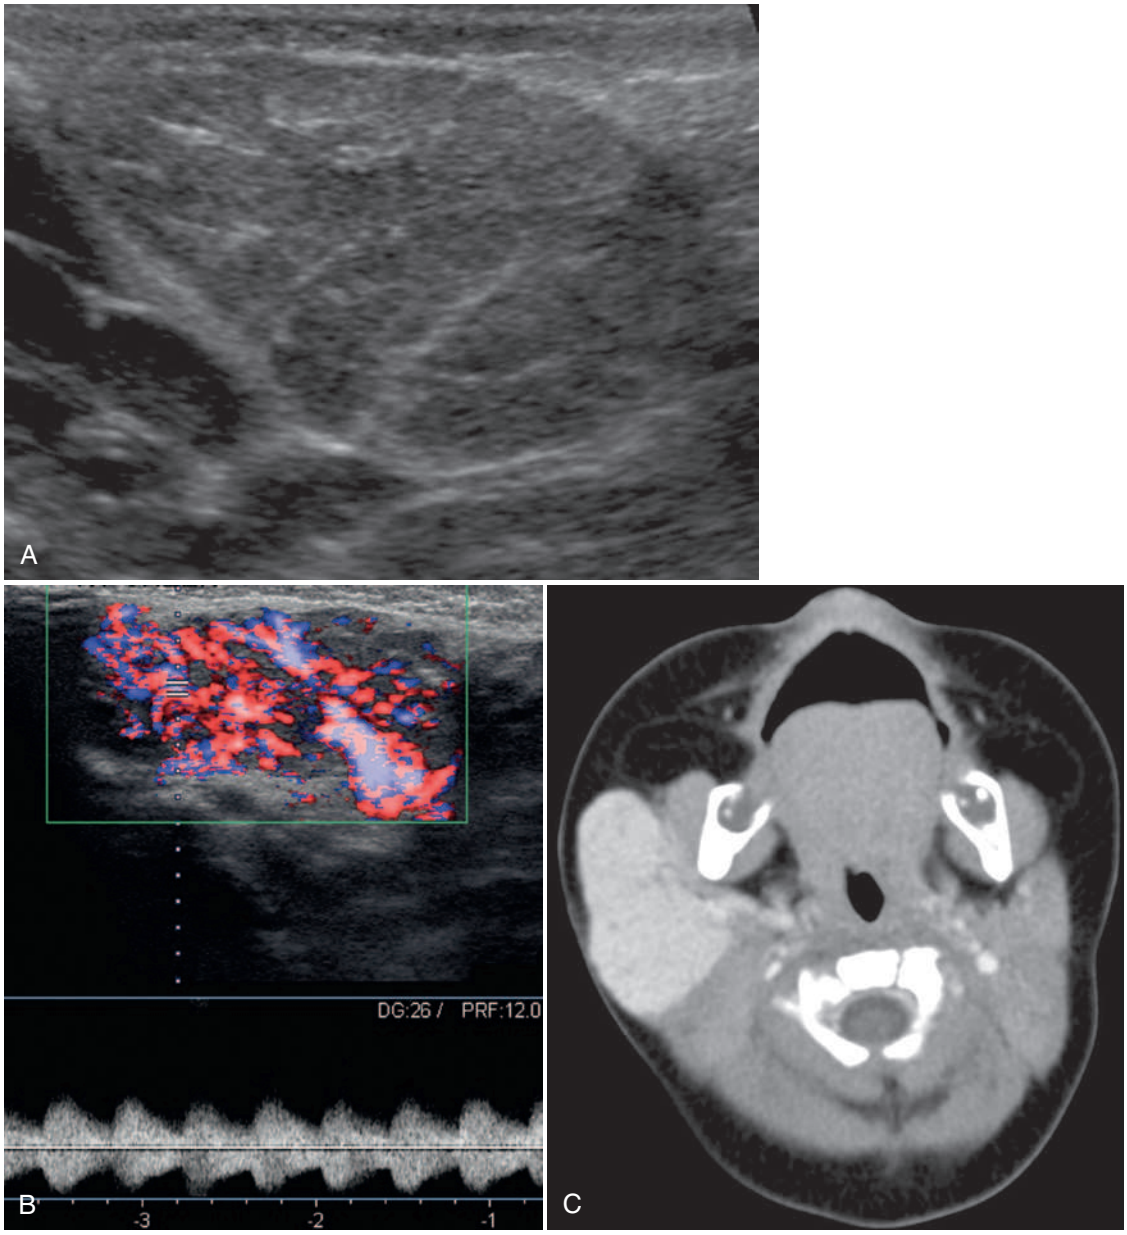

FIG. 48.16 Parotid Hemangioma. (A) Enlarged hypoechoic parotid gland with a few internal linear striations. **(B)** Color Doppler sonogram shows high vessel density with low–arterial resistance spectral waveform. **(C)** Computed tomography scan demonstrates intense enhancement of the right parotid mass.

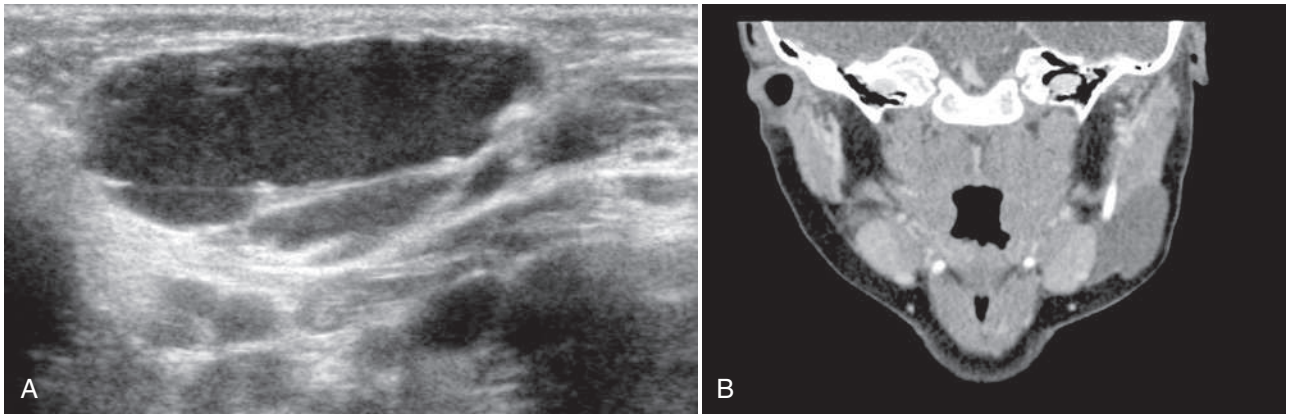

FIG. 48.17 Parotid Lymphatic Malformation. (A) Cystic septated mass within the superficial parotid. **(B)** Coronal computed tomography scan shows the cystic lesion lateral to and inseparable from the normally enhancing left parotid.

gland neoplasms, although ill-defined tumor margins and adjacent lymphadenopathy are suspicious features.[52,53] For further definition of a lesion, MRI is the method of choice because it provides precise information with regard to the nature of the mass as well as its extent, especially the presence of perineural invasion.[15,24]

Pleomorphic adenomas, also referred to as **benign mixed-cell tumors,** contain both mesenchymal and epithelial cell lines. These neoplasms are the most common benign salivary gland tumor in childhood and occur in all pediatric age groups (median, 15 years).[18,23] Most occur as a solitary, hard, painless, slow-growing mass.[54] Approximately 60% to 90% of these lesions originate in the parotid gland and 10% to 30% in the submandibular gland.[12,15] These lesions can recur (1%-50%) as multiple masses or rarely can develop late metastatic deposits.[54] On sonography, the lesion appears lobulated, well defined, and hypoechoic or isoechoic (with respect to normal salivary tissue) (Fig. 48.18). Cystic areas and hyperechoic shadowing foci representing small calcifications may be noted.[11] Typically, pleomorphic adenomas demonstrate peripheral vascularity with a hypovascular center.[13,24,29] Treatment includes surgical resection with facial nerve sparing procedures if in the parotid gland.

Warthin tumor, also referred to as papillary cystadenoma lymphomatosum or **adenolymphoma,** is a rare benign salivary gland neoplasm of children and solely identified in the parotid gland.[55,56] The lesion contains a double layer of epithelial cells resting on a dense lymphoid stroma and is believed to result from incorporation of lymphatic elements and heterotopic ductal epithelium within the parotid lymph nodes. Ultrasound findings include an oval, hypoechoic, well-defined mass containing multiple microcystic or anechoic areas, given the high propensity for cystic change.[12,13,55] With color and Doppler sonography, the tumor typically is hypervascular. Technetium 99m scintigraphy shows intense uptake in the tumor but is almost never performed in children.[11,12] Treatment is surgical resection; however, recurrence is possible from multifocality.

Mucoepidermoid carcinoma, the most common malignant salivary gland neoplasm in children, consists of cords, sheets, or cystic spaces lined by squamous and mucous cells.[11,15] Of the malignant salivary gland lesions, 60% are diagnosed as mucoepidermoid carcinomas, and about 50% arise from the parotid.[15] Clinically, these lesions may be tender, may grow rapidly, and may cause facial nerve paralysis.[12] Most (76%) mucoepidermoid carcinomas in children are of low grade.[57] Ultrasound characteristics depend on histologic grade. However, increased intratumoral RI and high peak systolic flow velocity (>60 cm/sec) should increase suspicion for malignancy.[29] Sonography should also be performed in the area of the lesion to assess for metastatic-appearing lymph nodes.[58]

Acinic cell carcinoma accounts for approximately 10% of malignant salivary gland tumors, most commonly arising from the parotid gland and less frequently from the submandibular or minor salivary glands.[57] On ultrasound, these lesions are usually irregular in shape with discrete margins, heterogeneous, hypoechoic, and poorly vascularized[59] (Fig. 48.19). Lesions may also demonstrate a mixed cystic and solid appearance and have posterior acoustic enhancement. Importantly, these lesions may be difficult to differentiate from other benign masses.[59] Treatment is usually wide surgical resection with radiotherapy reserved for extraglandular extension, lymph node metastases, or local recurrences.[57] This tumor has the best prognosis of all malignant salivary gland neoplasms.[60]

Adenoid cystic carcinoma accounts for approximately 9% of malignant salivary gland tumors in children, almost always in the parotid gland.[57] These are slow-growing tumors but have increased association with perineural invasion. No specific sonographic characteristics are described. Pain and numbness are present in 40% of children with adenoid cystic carcinoma and strongly correlate with perineural invasion.

Sialoblastoma is a rare neonatal neoplasm of the salivary gland, with less than 50 cases described in the literature.[61,62] This

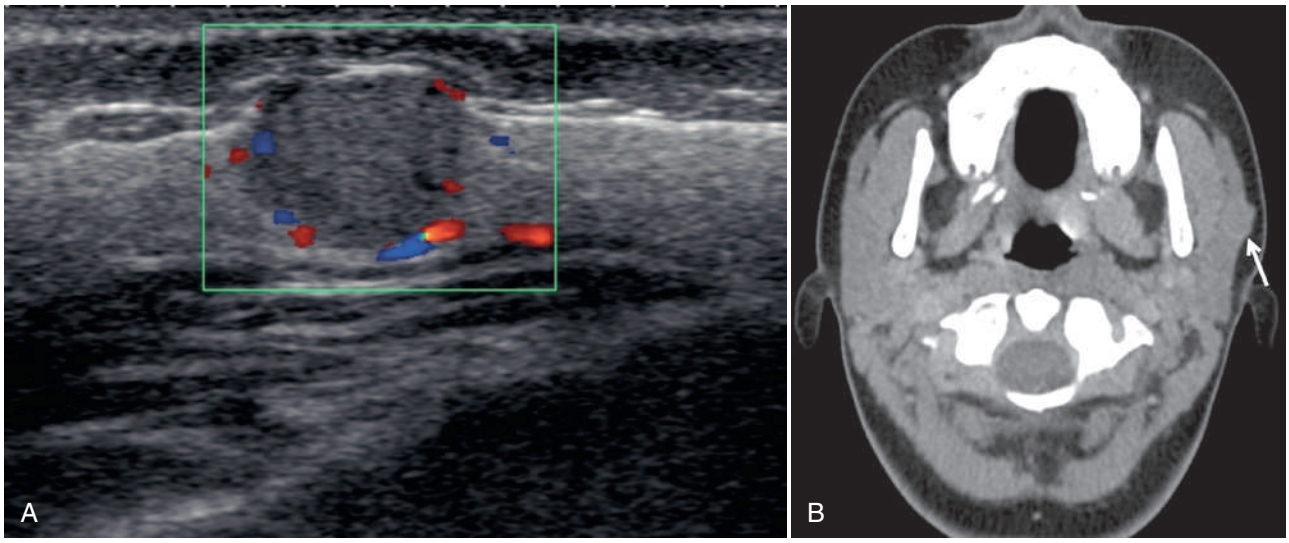

FIG. 48.19 Parotid Acinic Cell Carcinoma. (A) Color Doppler shows a round hypoechoic mass arising from the left parotid gland. The mass is hypovascular, but there is peripheral increased vascularity on color Doppler. **(B)** The mass in the left parotid gland is moderately enhancing and difficult to separate from the parotid gland *(arrow)*.

lesion consists of basaloid and myoepithelial cells that are reminiscent of the developing salivary anlage.[61] The lesion is most frequent in the parotid gland and less common in the submandibular gland. This lesion often manifests as a large parotid mass identified in early infancy or childhood, although prenatal and some adult cases have also been described. Sialoblastoma is a focally aggressive tumor, with local recurrences and infrequent distant metastases.[62] Sonographic characteristics are not well described. However, descriptions include that of a multinodular well-defined predominantly hypoechoic salivary gland mass with multiple septations and without increased vascularity.[63,64] On MRI, heterogeneous appearance is often described, with areas of hemorrhage or necrosis.[61,65,66] There are few case reports of combined sialoblastoma and hepatoblastoma.[63,67,68]

Other Salivary Gland Lesions. Lingual thyroid may appear as a homogeneous solid mass in the midline dorsum of the tongue. In 70% of patients, this ectopic tissue is the only functioning thyroid tissue.

Rhabdomyosarcoma occurs 40% of the time in the head and neck and can arise from any muscle. This is the second most common malignancy in the parotid and submandibular spaces in the pediatric population.[50] Salivary gland involvement is frequently by direct extension.[69]

Primary lymphoma of the salivary glands is termed MALToma, denoting origin from mucosa-associated lymphoid tissue. Patients with Sjögren syndrome and other autoimmune disease, including HIV, are at risk for primary lymphoma. Secondary involvement of lymphoma is rare, but more common in the parotid.[70] Ultrasound demonstrates a focal mass or diffuse infiltration with an enlarged gland. Lesions may consist of multiple small, hypoechoic nodules or an irregularly shaped, heterogeneous mass without calcification or cystic degeneration.[70] A reported case of submandibular gland involvement by MALToma showed hypoechoic compartments surrounded by hyperechoic lines, creating a tortoiseshell appearance.[71] Increased color Doppler flow is typical.

Lipomas represent 1% of parotid tumors; 57% of lipomas in the parotid area arise within the gland. These lesions are compressible, oval, and well defined. On ultrasound, lipomas contain striped or feathered internal echoes devoid of color and Doppler flow.[23] In younger children, lipoblastomas are more common.[72]

Leukemic infiltration is rare, with a presentation similar to lymphoma on ultrasound.[73]

Metastatic disease is rare in children but would include neuroblastoma and thyroid cancer.[43,74]

Peripheral nerve sheath tumors including neurofibroma and schwannoma can occur in the parotid gland, often in relation to the facial nerve.[75,76] Multiple or plexiform neurofibromas are typical in patients with neurofibromatosis type 1.[69] Sonography demonstrates multiple hypoechoic areas within the gland.[77]

Suprahyoid Cystic Lesions

In the parotid space, **type I branchial cysts** are most common. Simple cysts of the salivary glands are rare and likely caused by **mucous retention.** On ultrasound, the lesions are well defined and anechoic, with posterior acoustic enhancement and no internal blood flow.[12,74] In the preauricular region, superficial to the parotid gland, dermoid and epidermoid cysts may also occur.

In the submandibular space laterally, **type II branchial cysts** can be identified posterior to the submandibular gland. **Lymphatic malformations** may also extend into the space. **Ranulae** (sublingual cysts) are mucous retention cysts resulting from obstruction of the sublingual gland or duct. They present paramidline, in the area of the sublingual gland, as a painless swelling along the floor of the mouth. When large, sublingual cysts can extend

Differential Diagnosis of Suprahyoid Cystic Lesions

PAROTID SPACE
Branchial apparatus cyst type I
Parotid mucus retention cyst
Tumors with cystic components
Parotid abscess
Lymph node necrosis
Lymphatic malformation

SUBMANDIBULAR SPACE
Branchial apparatus cyst type II
Ranulae
Dermoid or epidermoid
Thyroglossal duct cyst
Vallecular cyst
Lymph node necrosis
Lymphatic malformation

below the level of the mylohyoid muscle, termed "plunging ranulae."[20] Rarely, the lesions are bilateral, and some large lesions extend into the parapharyngeal space. Imaging of a simple ranula on ultrasound demonstrates a unilocular cyst. If infected, the lesion may show internal debris, poorly defined borders, and adjacent inflammation (Fig. 48.20). These lesions are managed with intraoral marsupialization or surgical resection.

Midline lesions in the suprahyoid area include **dermoid** or **epidermoid** tumors and **thyroglossal duct cysts.** A **cyst of the vallecula** results from retained secretions in the mucous glands of the pharyngeal wall.[78] These cysts can be congenital or acquired and can cause upper airway obstruction resulting in death.[79,80] The lesions are midline and on sonography appear as a hypoechoic or an anechoic cystic mass, behind and below the tongue[81] (Fig. 48.21).

Masticator Space

Ultrasound is helpful in evaluating pathology in the masticator space as well as excluding parotid gland involvement. The two most common soft tissue masses to consider in the masticator space are **sarcomas** and **vascular malformations.** It is important to remember that the masseter and pterygoid muscles are often involved in venous malformations.[82] An uncommon homogeneous mass to consider is benign hypertrophy of the masseter muscle.[74] However, tumor infiltration of the muscle from leukemia or lymphoma can mimic hypertrophy; thus, clinical correlation is essential (Fig. 48.22). In the presence of trauma, a hematoma appearing as a hypoechoic area may be demonstrated. Inflammatory lesions also may develop, including secondary or primary myositis or osteomyelitis of the mandible, often in the presence of an infected tooth. Cellulitis and soft tissue abscesses may accompany these infections.[15]

INFRAHYOID SPACE

The infrahyoid deep cervical fascia is split into superficial, middle, and deep compartments[7] (Fig. 48.23). The superficial layer at this level is the **suprasternal space,** lying above the sternum and anterior to the sternothyroid and sternohyoid muscles. The **visceral space** is delineated by the middle layer of deep cervical fascia. The visceral space contains the thyroid, parathyroid, trachea, esophagus, paraesophageal lymph nodes, and recurrent laryngeal nerve.

Thyroid Gland

Normal Anatomy

The thyroid gland originates as an outpouching in the foramen cecum at the base of the tongue. The tissue descends by the seventh week of gestation to lie anterior to the larynx and upper

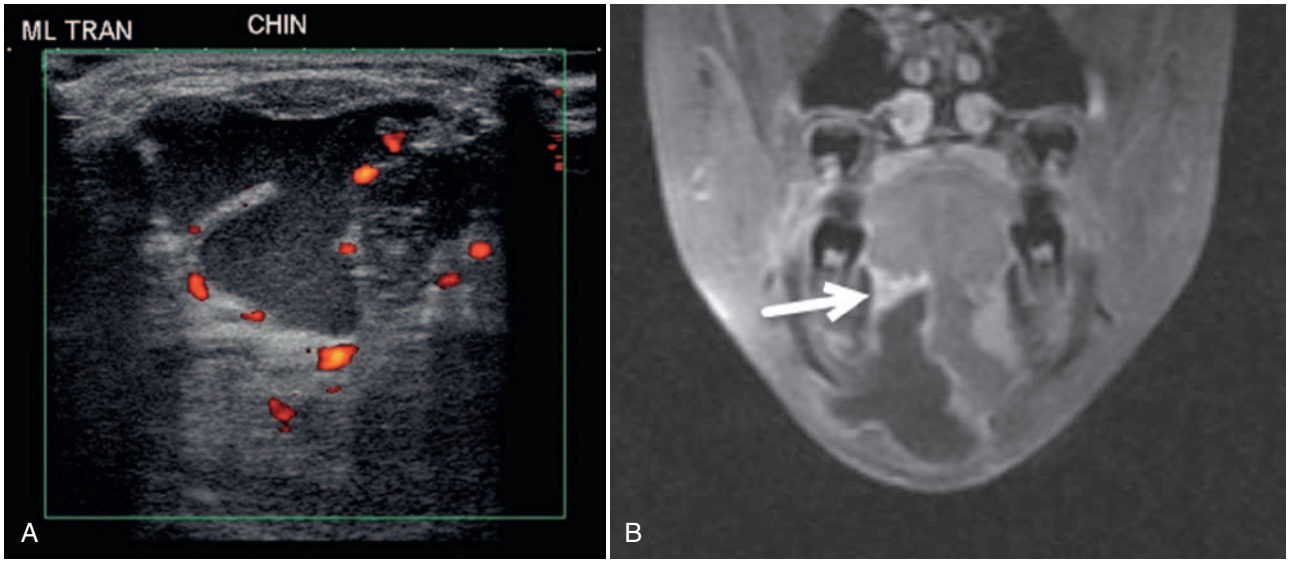

FIG. 48.20 Ranula. Ten-year-old child with neck pain. **(A)** Well-defined lobular hypoechoic lesion containing debris but with acoustic enhancement and lack of internal flow centered between the right sublingual gland and floor of the mouth. **(B)** Coronal fat-saturated T1-weighted magnetic resonance image after contrast showing the wall-enhancing cyst in continuity with the sublingual gland *(arrow),* plunging below the tongue.

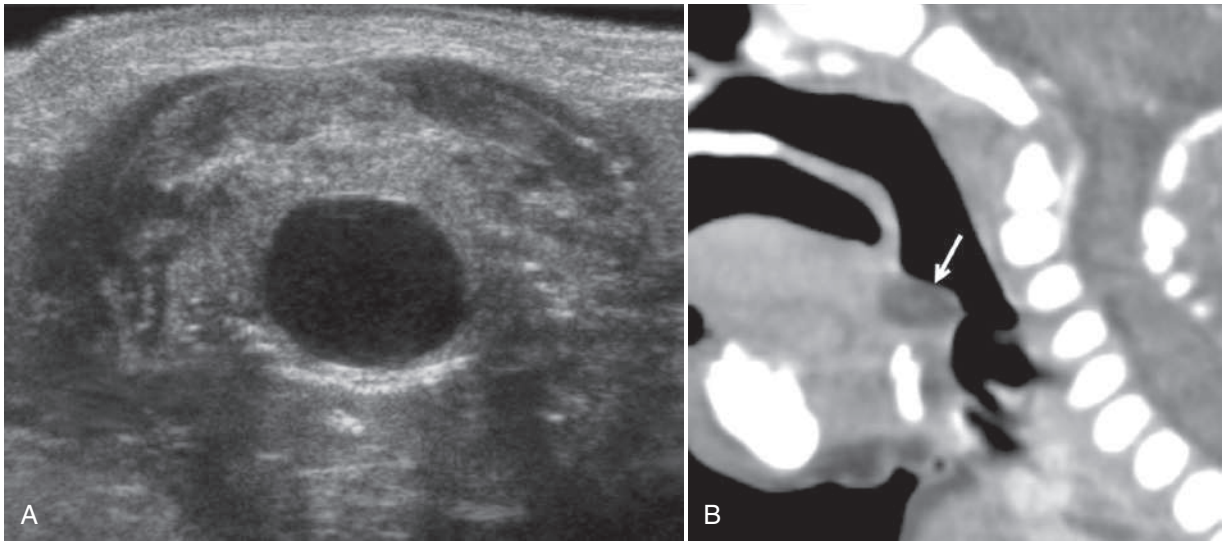

FIG. 48.21 Cyst of Vallecula. (A) Gray-scale ultrasound through the base of the tongue demonstrates a unilocular cyst with good through transmission. **(B)** Sagittal computed tomography image shows a simple cyst *(arrow)* along the base of the tongue at the level of the vallecula.

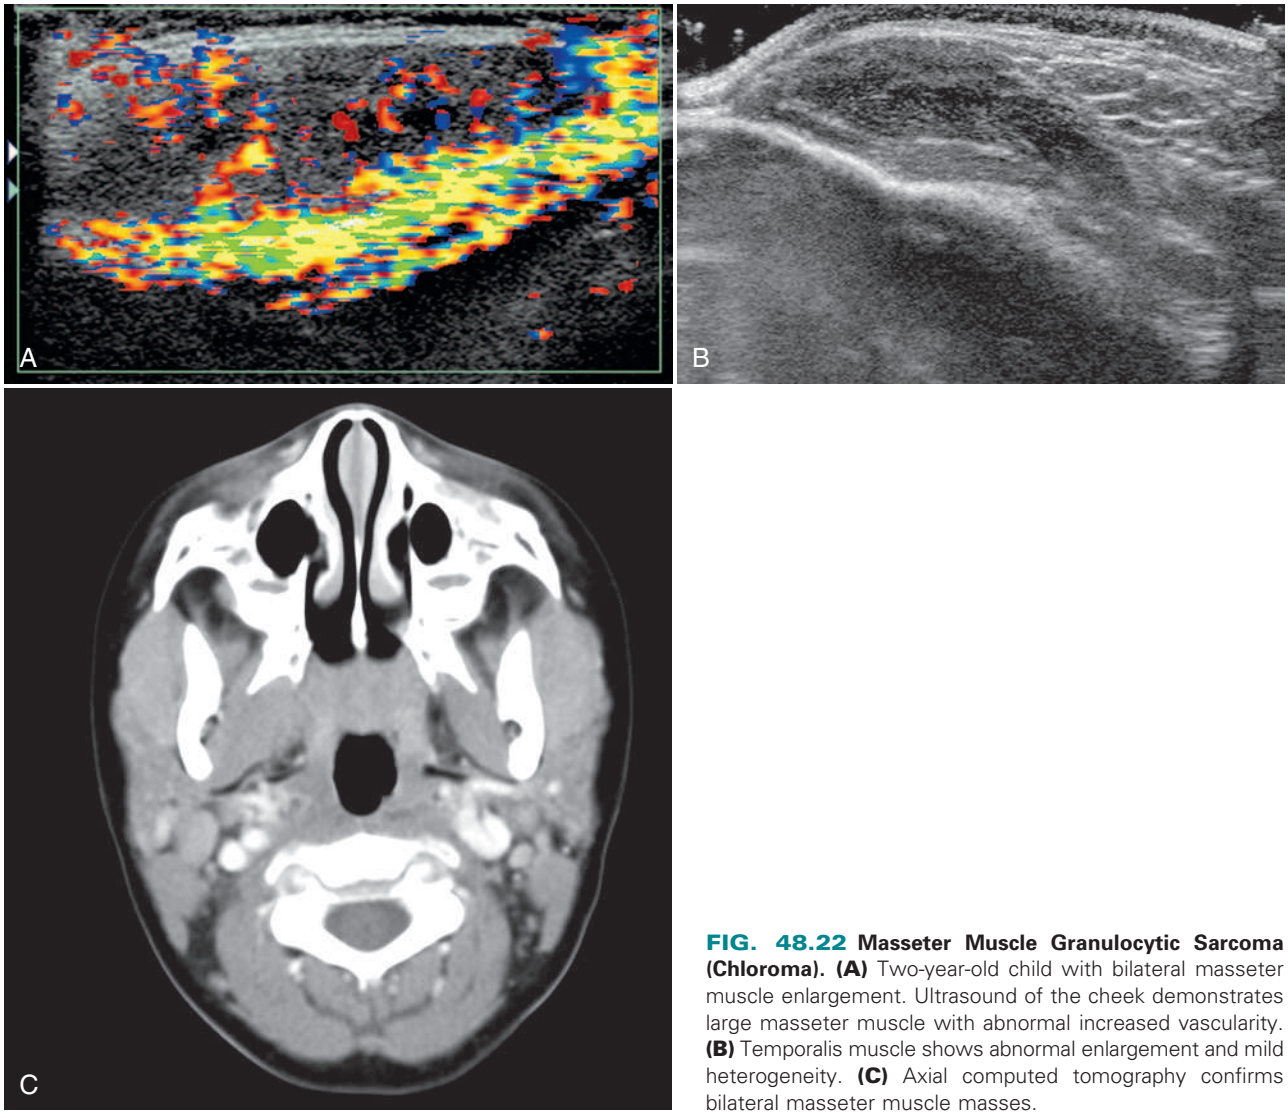

FIG. 48.22 Masseter Muscle Granulocytic Sarcoma (Chloroma). (A) Two-year-old child with bilateral masseter muscle enlargement. Ultrasound of the cheek demonstrates large masseter muscle with abnormal increased vascularity. **(B)** Temporalis muscle shows abnormal enlargement and mild heterogeneity. **(C)** Axial computed tomography confirms bilateral masseter muscle masses.

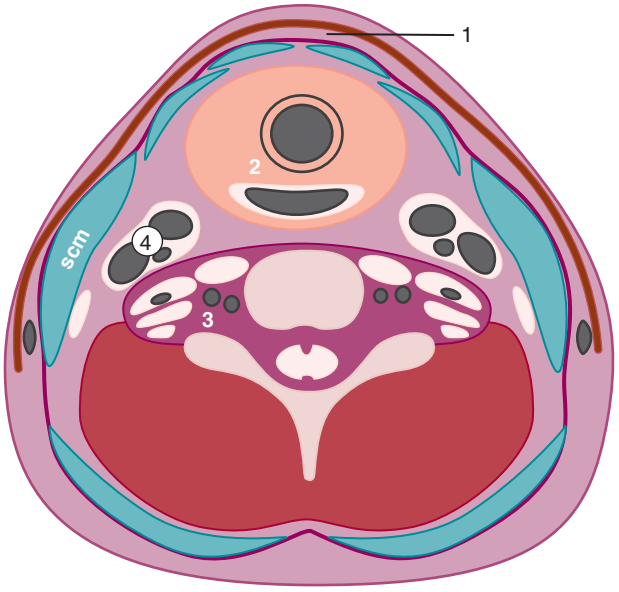

FIG. 48.23 Deep Cervical Fascial Layers of Infrahyoid Space. Axial diagram: *1,* superficial; *2,* middle (visceral); *3,* deep; *4,* carotid; *scm,* sternocleidomastoid muscle.

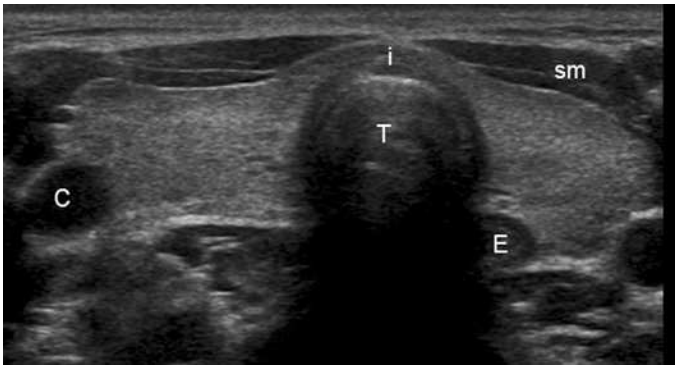

FIG. 48.24 Normal Thyroid. Transverse sonogram of the thyroid gland demonstrates homogeneous, increased echotexture compared with the sternohyoid and sternothyroid *(sm)* muscles. Normal right lobe, left lobe, and isthmus *(i).* Trachea *(T)* is midline and esophagus *(E)* is posterior to left lobe. Common carotid artery *(C)* is present along the peripheral margin.

trachea.[83] The common carotid arteries and internal jugular veins are present on the lateral edges, and the cervical esophagus is midline or to the left of the trachea. The thyroid gland contains two lobes and is connected by an **isthmus.** In 50% of patients, a **pyramidal lobe** extends superiorly from the isthmus. Four parathyroid glands lie along the posterior surface of the thyroid lobes.

Ultrasound is performed with the patient supine and the neck slightly hyperextended. A high-frequency linear array transducer (10-15 MHz) is necessary.[84] A standoff pad may be helpful. Longitudinal and transverse imaging of the entire thyroid tissue should be performed. Doppler imaging may be considered in the examination of masses or nodules. Adjacent neck structures, especially the jugular chain and supraclavicular nodes, should be imaged.

On ultrasound, the normal thyroid gland is homogeneous and hyperechoic compared with adjacent muscle (Fig. 48.24). The lobes of tissue are triangular on transverse and elliptical on sagittal images. The size of the thyroid gland changes with age; Tables 48.1 and 48.2 list normal values.[85,86]

Congenital Thyroid Lesions

Although some congenital thyroid lesions extend into both the suprahyoid and the infrahyoid space, the pathology is described here as it is inherent to the thyroid.

Because untreated hypothyroidism can result in severe mental retardation and delayed bone development, there is a nationwide program in the United States for neonatal screening. **Congenital hypothyroidism** is present in 1 per 4000 infants and is twice as common in girls as in boys.[87,88] Causes include agenesis, dysgenesis, and goiter from inborn error of metabolism, maternal thyrotoxicosis, or maternal ingestion of iodine, antithyroid medication, or lithium.[29,87] About 85% of cases are caused by **dysgenesis** (structural defects of the thyroid gland), either hypoplasia or ectopia.[88] Sonography is the best imaging modality in congenital hypothyroidism because it correctly defines presence of the thyroid gland, which may be classified as large, normal, small, or absent.[89] Large glands are typically goitrous. Normal-sized glands in children with congenital hypothyroidism have been observed in patients with pseudohypoparathyroidism, trisomy 21, hypopituitarism, maternal antibody–induced

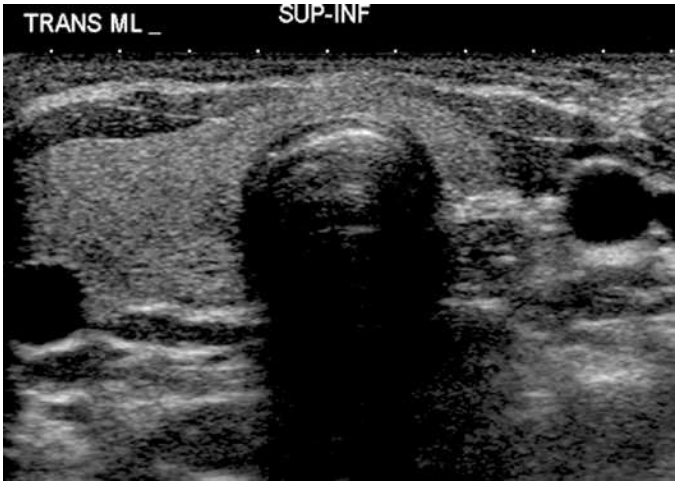

FIG. 48.25 Thyroid Hemiagenesis. Normal right lobe and isthmus of the thyroid are identified, but the left lobe is absent. Note that the left carotid vessel lies in the anatomic area of the left lobe.

hypothyroidism, and transient elevated thyrotropin.[88,89] Rarely (0.2% of cases), **thyroid hemiagenesis** can occur, with failure of development in either lobe, the left being absent in 60% of cases[88,90] (Fig. 48.25). On ultrasound, if no thyroid gland can be identified in the expected location, imaging should be performed superiorly in the midline to the base of the tongue because ectopic thyroid tissue may be present anywhere along the embryologic descent. **Ectopic thyroid tissue** is lingual and thus suprahyoid in 90% of cases, lying close to the hyoid bone and deep to the muscles of the tongue.[90] Ultrasound imaging in the neonate with ectopic thyroid typically shows a well-defined ovoid structure equal in echotexture to normal thyroid tissue and hyperemic on color Doppler (Fig. 48.26). In older children treated for hypothyroidism in the presence of ectopic tissue, the gland may appear hypoechoic with no vascularity.[91] Some children with ectopic tissue are euthyroid and have a mass at the base of the tongue. It is important to identify this tissue as thyroid because removal in the absence of other thyroid tissue will result in a hypothyroid individual. When ultrasound is unable to identify ectopic thyroid tissue, a nuclear medicine scan, given the high sensitivity, may be employed.[91,92] Scintigraphic studies are also useful in assessing thyroid function when apparently normal thyroid tissue is identified on ultrasound.[89]

Thyroglossal duct cyst, representing 70% of all congenital neck masses, is the most common midline cyst and developmental anomaly identified on ultrasound.[43,90,93] The anatomy of the thyroglossal duct follows the pathway of embryology from the foramen cecum of the tongue, along the inferior and posterior surface of the midline hyoid, to the pyramidal lobe of the thyroid. Persistence of the duct, which is lined by secretory epithelium, results in cyst or sinus formation. The classic presentation of a thyroglossal duct cyst is that of an asymptomatic mass adjacent to the hyoid bone, although the cyst can be located at any point of descent.[49,94] Anatomically, most are located in a midline or parasagittal position, particularly to the left of midline. The thyroglossal duct cyst may move with swallowing, and if suprahyoid, the lesion will classically elevate with tongue movement.[43] Congenital fistulas in association with these cysts are infrequent but can occur after inflammation.[95]

The classic sonographic appearance of a thyroglossal duct cyst is noted in less than half of cases and includes a thin-walled, anechoic unilocular cyst (Fig. 48.27). Typically, however, these cysts are caused by high protein content rather than inflammation so they are hypoechoic or heterogeneous, some appearing pseudosolid and mimicking ectopic tissue[95-97] (Fig. 48.28). Posterior acoustic enhancement is present in most cysts, and absence of color Doppler flow can be helpful in the diagnosis. However, demonstration of a normal thyroid gland while imaging a thyroglossal duct cyst is recommended to exclude the diagnosis of ectopic tissue. Up to one-third of patients with these cysts will develop superimposed infection and demonstrate imaging findings of thick walls, internal septation, and heterogeneous echotexture from debris.[95,98] There is a slightly increased risk of cancer, primarily papillary, and calcification or a soft tissue mass in the presence of a cyst should raise suspicion of malignancy.[82,93,99] Therapy is surgical resection with the Sistrunk procedure, which involves excision of the cyst, the remnant tract, and part of the hyoid bone. Recurrent thyroglossal duct cysts occur after a Sistrunk procedure in approximately 11% of patients.[100]

Differential diagnosis for cystic lesions in the infrahyoid space includes thyroglossal duct cyst, dermoid, epidermoid, branchial cyst, lymphatic malformation, laryngocele, necrotic adenopathy, teratoma, and thymic cyst.

Inflammatory Thyroid Disease

Acute bacterial infection of the thyroid is rare because the gland is highly resistant to infection by virtue of its high iodine content.[101,102] If present, infection is usually caused by staphylococci, streptococci, or anaerobic bacteria. On sonography, the gland demonstrates heterogeneous, poorly defined echotexture. If the left lobe of the thyroid is abnormal, a congenital piriform sinus, type III or IV branchial apparatus remnant, should be

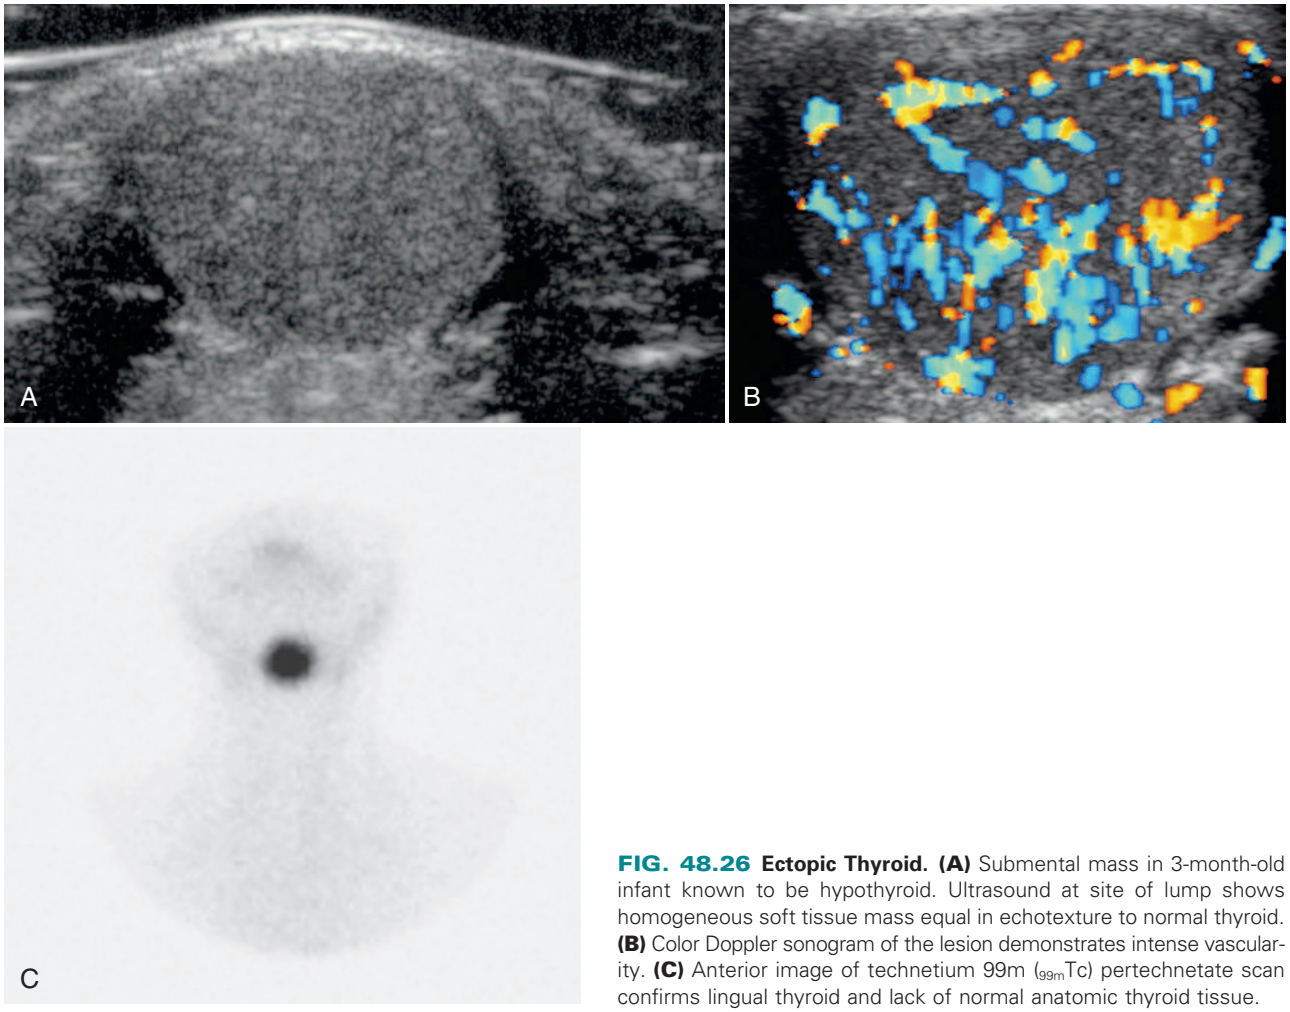

FIG. 48.26 Ectopic Thyroid. (A) Submental mass in 3-month-old infant known to be hypothyroid. Ultrasound at site of lump shows homogeneous soft tissue mass equal in echotexture to normal thyroid. **(B)** Color Doppler sonogram of the lesion demonstrates intense vascularity. **(C)** Anterior image of technetium 99m ($_{99m}$Tc) pertechnetate scan confirms lingual thyroid and lack of normal anatomic thyroid tissue.

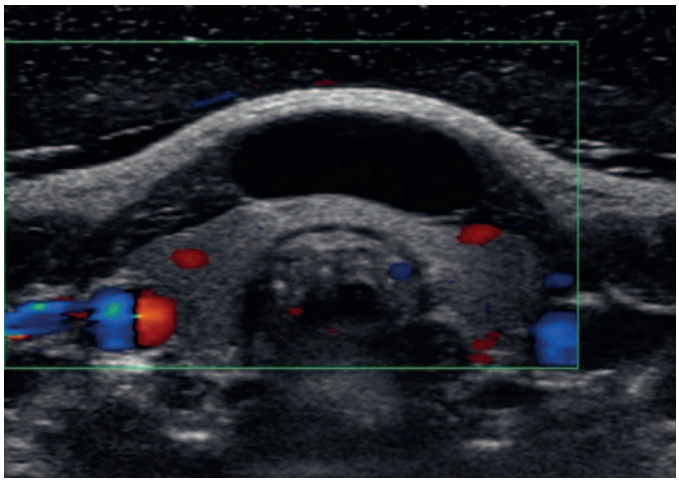

FIG. 48.27 Thyroglossal Duct Cyst. Color Doppler shows a large anechoic midline cyst immediately anterior to the thyroid gland and partly encased by the strap muscles.

Differential Diagnosis for Infrahyoid Cystic Lesions

MIDLINE
Thyroglossal duct cyst
Dermoid or epidermoid

Teratoma
Thymic cyst

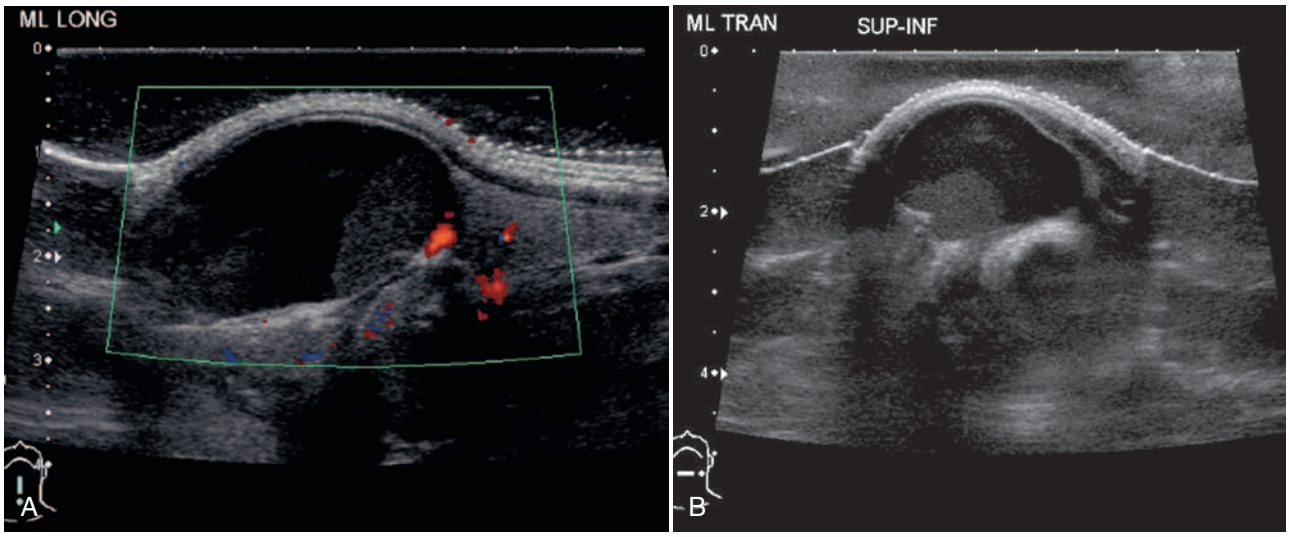

FIG. 48.28 Complex Thyroglossal Duct Cyst. (A) Sagittal color Doppler image of a complex cystic avascular lesion anterior to the trachea and superior to the isthmus of the thyroid. The lesion is hypoechoic with debris inferiorly. **(B)** Gray-scale axial ultrasound demonstrates heterogeneous mass with both hypoechoic and isoechoic components.

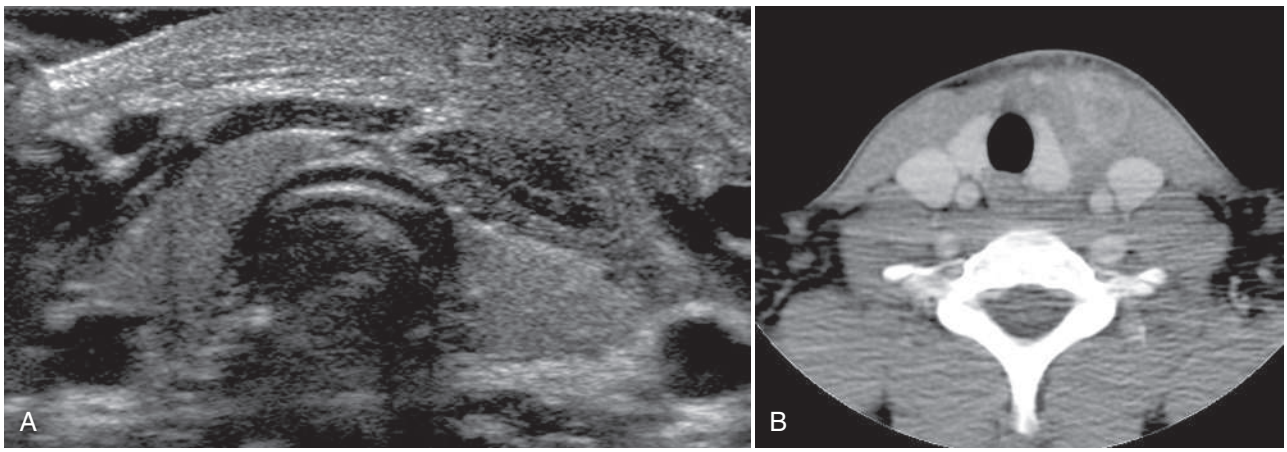

FIG. 48.29 Type IV Branchial Sinus Abscess. (A) Hypoechoic, poorly defined collection in left anterior neck distorting muscle and soft tissue planes, compressing the left thyroid gland. **(B)** Axial computed tomography scan at same level demonstrates inhomogeneously enhancing phlegmon adjacent to left lobe of the thyroid.

considered[101,102] (Fig. 48.29). These patients usually are presented at age 2 to 12 years with fever, sore throat, and swelling in the lower neck. On ultrasound, the left lobe of the thyroid gland may be heterogeneous. If an abscess has developed, typically a focal hypoechoic lesion is surrounded by hyperemia in the left perithyroid area.[87,90,101,102]

de Quervain thyroiditis, also known as **focal thyroiditis,** is an uncommon form of subacute thyroiditis likely caused by a viral infection.[83] Granulomatous inflammation of the gland can result in thyromegaly and heterogeneous echogenicity.

Hashimoto thyroiditis is the most common cause of thyroid disease in children and adolescents.[74] It is an autoimmune disorder caused by circulating antibodies. Injury to the gland results in a diffuse lymphocytic and plasma cell infiltration. The process is more common in girls than in boys, with a family history of thyroid disease in one-fourth of cases.[88,103] Clinically, the patient has painless enlargement of the thyroid. Although in the acute phase the patient may be hyperthyroid, most patients are hypothyroid at presentation. Hashimoto thyroiditis may be associated with several syndromes (e.g., Turner, Noonan, Down) and has been described in patients with juvenile diabetes, those receiving phenytoin therapy, and those with Hodgkin disease.[87] On ultrasound, the gland is enlarged with lobular margins and contains coarse septations and multiple hypoechoic micronodules measuring 1 to 6 mm in diameter[90] (Fig. 48.30). Normal, increased, or deceased color Doppler waveforms may be present. Adjacent cervical adenopathy is often noted. The majority of these patients have spontaneous resolution of symptoms. Suspicious nodules identified on thyroid ultrasound in the setting of Hashimoto thyroiditis are generally followed owing to increased risk of malignancy.[104,105]

Graves disease is the most common cause of hyperthyroidism in children. It is an autoimmune disease caused by thyroid-stimulated immunoglobulin binding to the thyroid-stimulating hormone (TSH) receptor, increasing the production of thyroid hormone. There is frequently a family history. It is more common in girls (5:1 female-to-male ratio) and has a peak incidence in adolescence, ages 11 to 15 years.[87,88] Diagnosis is usually clinical; children have an enlarged thyroid gland, exophthalmos, and hyperthyroidism. Fetuses and neonates born to mothers with Graves disease are also at risk for transient thyroid dysfunction and goiter because of transfer of thyroid-stimulating immunoglobulins.[88,103] During ultrasound examination, patients with Graves disease demonstrate diffuse enlargement of the thyroid gland, which appears heterogeneous and diffusely hypoechoic. Doppler imaging demonstrates intense hypervascularity, also known as "thyroid inferno"[90] (Fig. 48.31). Doppler waveform shows increased peak systolic velocity and decreased RI.[106]

Thyroid Masses

Thyroid nodules in pediatrics are uncommon, with an incidence of 1.5%.[107] Children with an asymptomatic palpable nodule typically have normal thyroid function.[108] In a child or adolescent, a solitary nodule should be approached with suspicion because there is a 33% risk of malignancy.[103] Ultrasound and radionuclide scintigraphy are the primary methods of imaging thyroid nodules. Fine-needle aspiration (FNA), especially with ultrasound guidance, may be helpful and has 80% to 95% accuracy for defining pathology in pediatric patients.[107-109] If FNA is not diagnostic, surgical excision may be required.[83] On sagittal imaging, the cricoid can appear as a round or oval mass, similar in echotexture to the normal thyroid and posteromedial to the gland.[110] A **pseudonodule** of the thyroid can be produced by uncalcified cricoid cartilage.

During ultrasound inspection, color Doppler flow imaging may be helpful to evaluate for injury to adjacent vessels.[111]

Thyroid cysts are the most common incidentally detected thyroid lesions in children.[112] These cysts are rarely true epithelial-lined cysts, usually degenerative because of necrosis within benign thyroid nodules. Most of these lesions are complex with mixed echotexture, thick irregular walls, septations, and in some cases, fluid-fluid levels from previous hemorrhage. Bright, echogenic internal areas result from **colloid** material, sometimes creating **comet-tail artifacts**[84,87] (Fig. 48.32). Calcifications in degenerative lesions may create echogenic foci of acoustic shadowing or peripheral eggshell calcifications. Doppler sonography typically shows peripheral vascularity, and nuclear medicine studies demonstrate variable uptake.

Although uncommon, **hemorrhage** within the thyroid, related to direct or indirect trauma, can mimic a nodule. The hematoma on sonography typically appears heterogeneous and hypoechoic (Fig. 48.33). Many of these masses contain cystic areas resulting from hemorrhage or necrosis. Nuclear medicine studies show variable uptake, with some follicular adenomas demonstrating intense activity. Because malignancy may appear as a cystic mass, close follow-up imaging and surgical diagnosis are typically indicated.[103,113]

Follicular adenomas, the most common benign lesions of the thyroid, arise from an overproliferation of follicular cells (hyperplasia).[90,107] Lesions may be solitary or multinodular, are round and well defined, and have decreased, increased, or honeycomb echotexture. About 60% of adenomas demonstrate a peripheral, 1- to 2-mm hypoechoic halo caused by a fibrous capsule and peripheral blood vessels best delineated with color Doppler sonography[90] (Fig. 48.34). Despite benign imaging

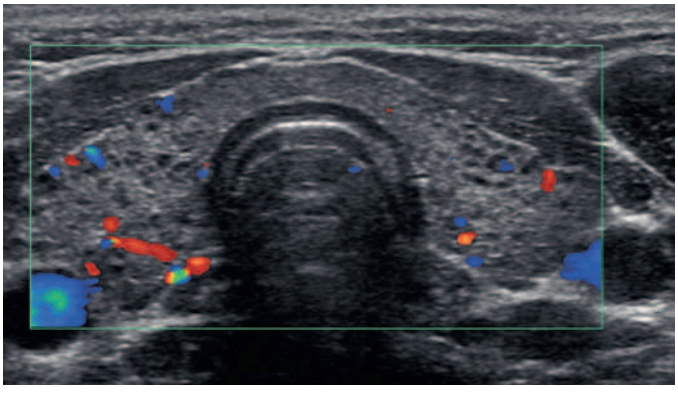

FIG. 48.30 Hashimoto Thyroiditis. Thyroid imaging with color Doppler shows coarse heterogeneous pattern with multiple hypoechoic micronodular areas, and mildly increased vascularity.

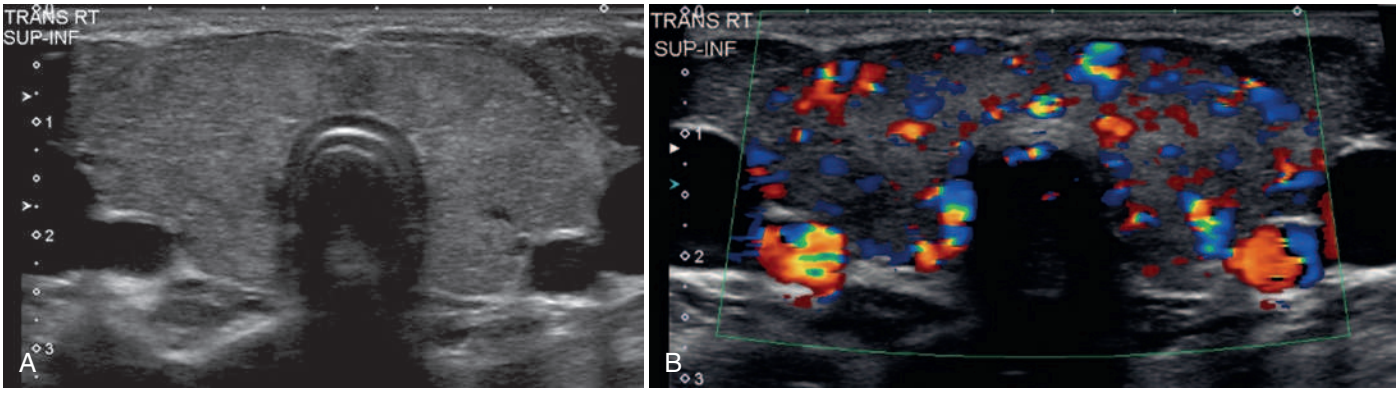

FIG. 48.31 Graves Disease. (A) Thyroid is diffusely enlarged and heterogeneously hypoechoic. **(B)** Color Doppler ultrasound demonstrates "thyroid inferno."

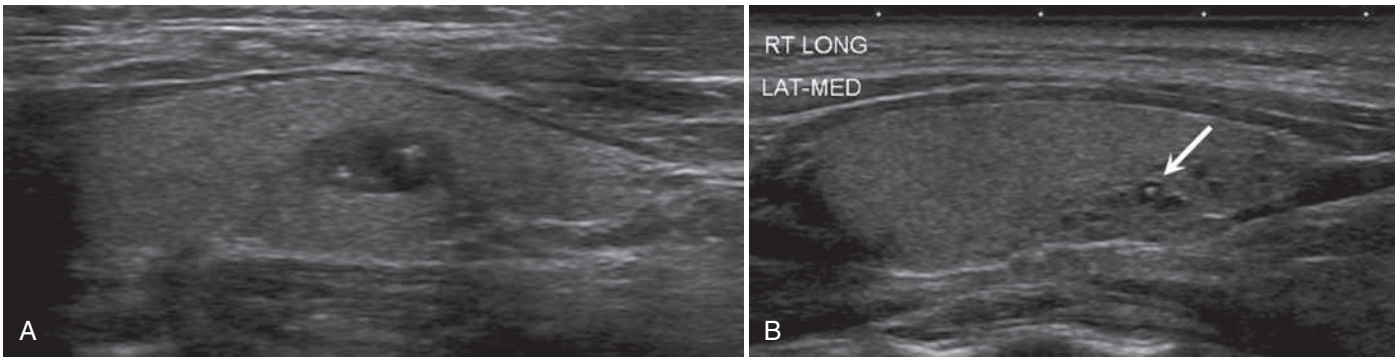

FIG. 48.32 Thyroid Degenerative (Colloid) Cyst. (A) Five-year-old with palpable mass demonstrates complex elliptical hypoechoic lesion with internal echogenic foci in the left lobe of the thyroid proven to represent colloid cyst. On color Doppler *(not shown),* no internal flow was present. **(B)** Smaller hypoechoic lesions were noted in right lobe of thyroid, one demonstrating comet-tail artifact *(arrow).*

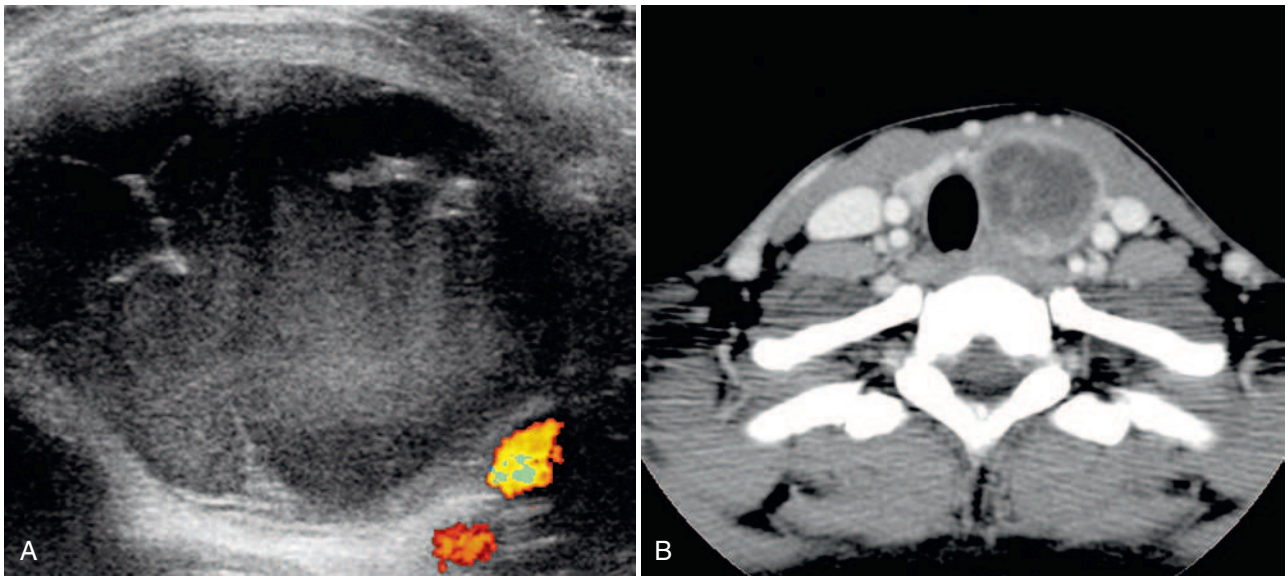

FIG. 48.33 Thyroid Hematoma. (A) Teenage girl was elbowed in the left side of the neck and developed a lump. Imaging of left lobe of thyroid demonstrates heterogeneous, well-defined, round avascular lesion. **(B)** Axial computed tomography scan shows hematoma replacing most of the left lobe.

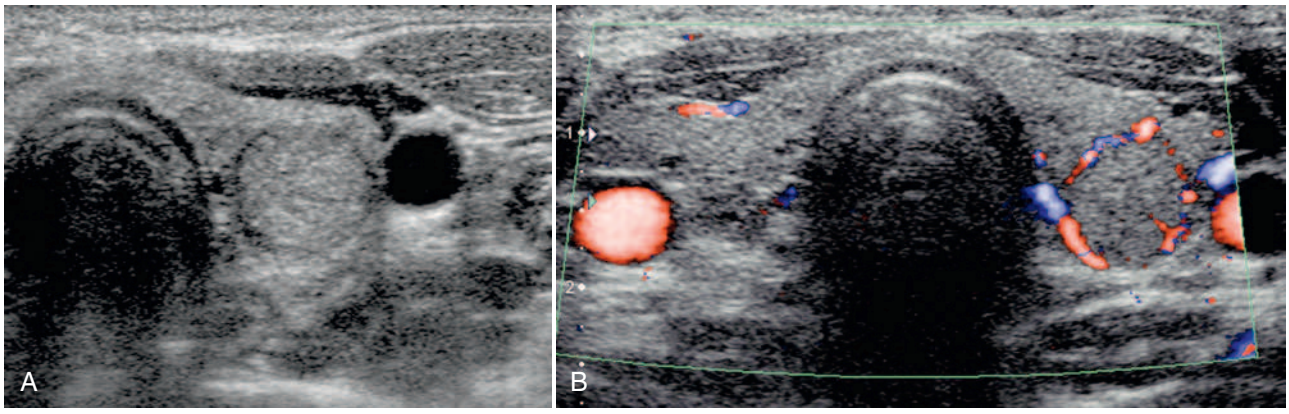

FIG. 48.34 Thyroid Follicular Adenoma. (A) Round, well-defined, almost-isoechoic lesion in the left lobe of the thyroid demonstrates a peripheral halo of decreased echogenicity. **(B)** Color Doppler sonogram demonstrates peripheral vascularity.

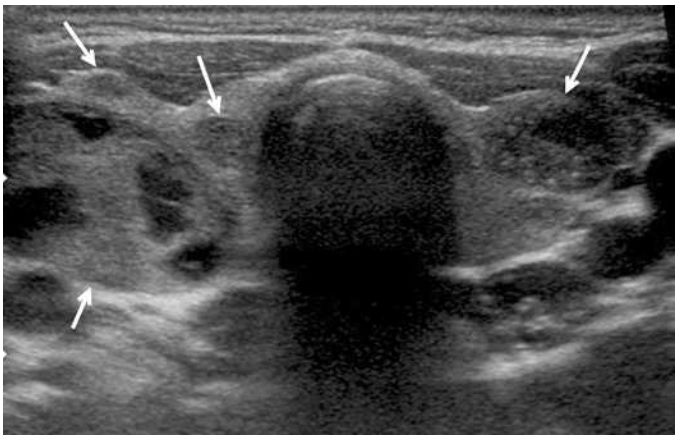

FIG. 48.35 Multinodular Goiter. Seventeen-year-old with thyroid enlargement. Thyroid ultrasound image shows multiple nodules within both lobes of the thyroid, some of which are small and hypoechoic and others large and complex. See also Video 48.2.

characteristics, these lesions can be difficult to differentiate from malignancy.[87,112]

Multinodular (adenomatous) goiter in children is uncommon but typically is diagnosed in adolescent girls near puberty.[114] In adults the etiology has been linked to iodine deficiency. In children, genetic susceptibility is more common, although autoimmune factors are also implicated.[115] Multinodular goiter has been described in patients with renal cystic disease, polydactyly, Hashimoto thyroiditis, McCune-Albright syndrome, and previous radiation therapy.[114] At presentation, children are typically euthyroid and clinically are diagnosed with a palpable nodule or nodules. On ultrasound, the nodules show variable heterogeneity with macronodular or micronodular formation (Fig. 48.35, Video 48.2). Some may become cystic because of necrosis or hemorrhage.[114] Continued ultrasound monitoring of these patients is warranted given the increased risk for nonmedullary cancer.[115]

Thyroid cancer is rare in children and represents only 1.5% of all malignancies in patients younger than 15 years.[90,106] However, there is a 1.5- to 5-fold greater chance of a thyroid nodule being malignant in children when compared with adults.[116,117] Among girls 15 to 19 years of age, thyroid cancer is the second most common malignancy.[118] Factors that are associated with increased risk of thyroid cancer include a positive family history of thyroid cancer, genetic predisposition, and radiation exposure, especially in patients with history of bone marrow transplant.[87,119] Multiple syndromes such as the PTEN hamartoma tumor syndromes (which are caused by germline mutations of the *PTEN* tumor suppressor gene), Cowden and Bannayan-Riley-Ruvalcaba syndromes, familial adenomatous polyposis, Gardner syndrome, Peutz-Jeghers syndrome, and Carney complex are associated with thyroid nodules and cancers.[120] Autoimmune thyroiditis has also been shown to be associated with a greater incidence of thyroid cancers.[120,121] The irradiated thyroid can show a spectrum of abnormalities, from cysts to benign or malignant nodules. Incidence of thyroid cancer after irradiation may increase more than 20-fold, with a mean latency period of about 15 years.[109] Risk factors in the presence of radiation include female gender, younger age at irradiation, and longer time since irradiation.[122]

Patients with thyroid cancer usually have a palpable nodule or cervical adenopathy and, rarely, hoarseness or pain. **Papillary cancer,** the most common pediatric thyroid neoplasm, represents 80% of all cases and is multicentric in 20% of cases[121] (Fig. 48.36). Metastatic disease with papillary tumor is through the lymphatics. **Follicular cancer** represents 17% of thyroid cancers and metastasizes through the bloodstream. **Medullary cancers** comprise 2% to 3% of thyroid cancers, secrete calcitonin, and are typically diagnosed in patients with a strong family history or features of multiple endocrine neoplasia type II (MEN IIa and IIb). At presentation, children with medullary cancer are usually at an advanced tumor stage, with lymph node involvement in 50% to 80% and metastasis to the lung in 6% to 18%.[90,109,123]

Children with thyroid cancer have cervical and pulmonary metastasis more frequently than adults. They also have more advanced disease and higher rate of recurrence.[116] Bone metastases are, however, rare in children. With sonography, it can be difficult to differentiate benign from malignant thyroid masses. Helpful differentiating ultrasound criteria for malignancy include a predominantly solid lesion, the presence of calcification (especially microcalcifications), hypoechogenicity, irregular margins, large height-to-width ratio, absence of peripheral halo, intranodular vascularity, and associated abnormal lymph nodes.[124-128] Unfortunately, no size criteria are provided to distinguish benign from malignant thyroid nodules. Needle biopsy or surgical resection should be considered in children with suspicious sonographic or clinical features, owing to the high increased risk (25%-50%) of thyroid malignancy.[129] Follicular cancers often mimic adenomas. Adjacent lymph nodes should always be inspected, as the presence of lymphadenopathy or calcification is concerning for metastatic disease.

Malignant Thyroid Nodule: Sonographic Characteristics

Predominantly solid lesion
Presence of calcification, especially microcalcifications
Hypoechogenicity
Irregular margins
Large height-to-width ratio
Absence of peripheral halo
Intranodular vascularity
Associated abnormal lymph nodes

Nuclear medicine (frequently iodine-123 and iodine-131 scintigraphy) has been used to guide therapy because "cold" nodules on scintigraphy are suspicious for malignancy. Although "hot" nodules on nuclear medicine scintigraphy are usually not malignant, exceptions can occur[103] (Fig. 48.37). In general, thyroid neoplasms (excluding the medullary type) have a good prognosis, with 10-year survival greater than 95% when treated with total thyroidectomy, lymph node dissection, and postoperative iodine-131 radioiodine therapy.[109]

Other pediatric thyroid neoplasms include **lymphoma** and **teratoma.** In pediatric patients with Hashimoto thyroiditis and a solitary or multiple hypoechoic lesions, lymphoma should considered.[90]

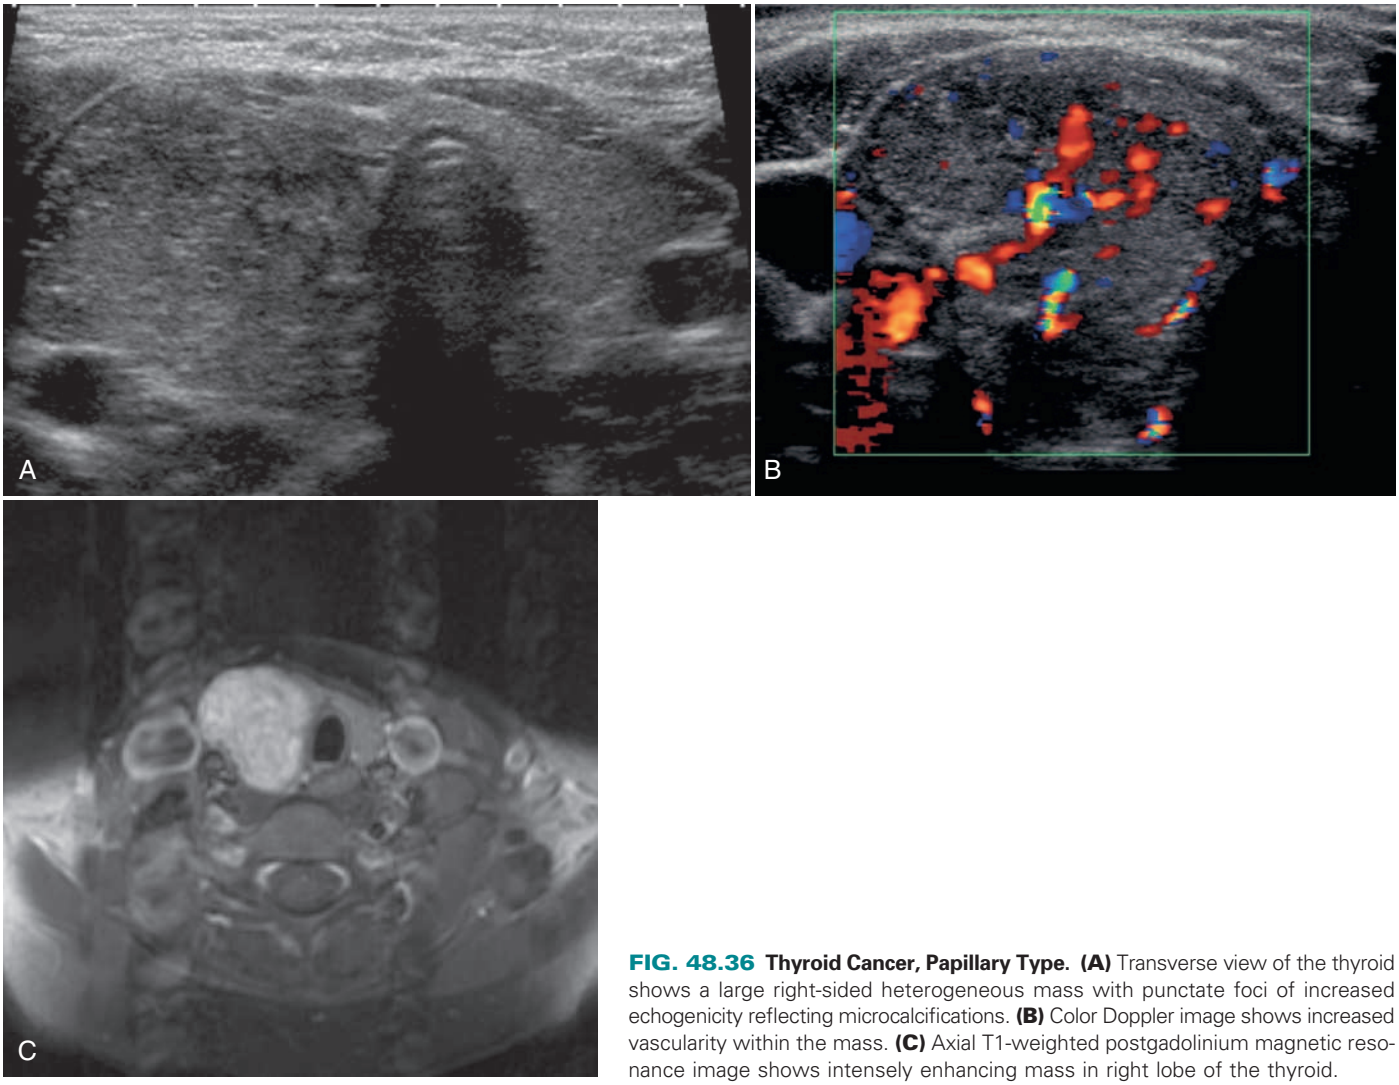

FIG. 48.36 Thyroid Cancer, Papillary Type. (A) Transverse view of the thyroid shows a large right-sided heterogeneous mass with punctate foci of increased echogenicity reflecting microcalcifications. **(B)** Color Doppler image shows increased vascularity within the mass. **(C)** Axial T1-weighted postgadolinium magnetic resonance image shows intensely enhancing mass in right lobe of the thyroid.

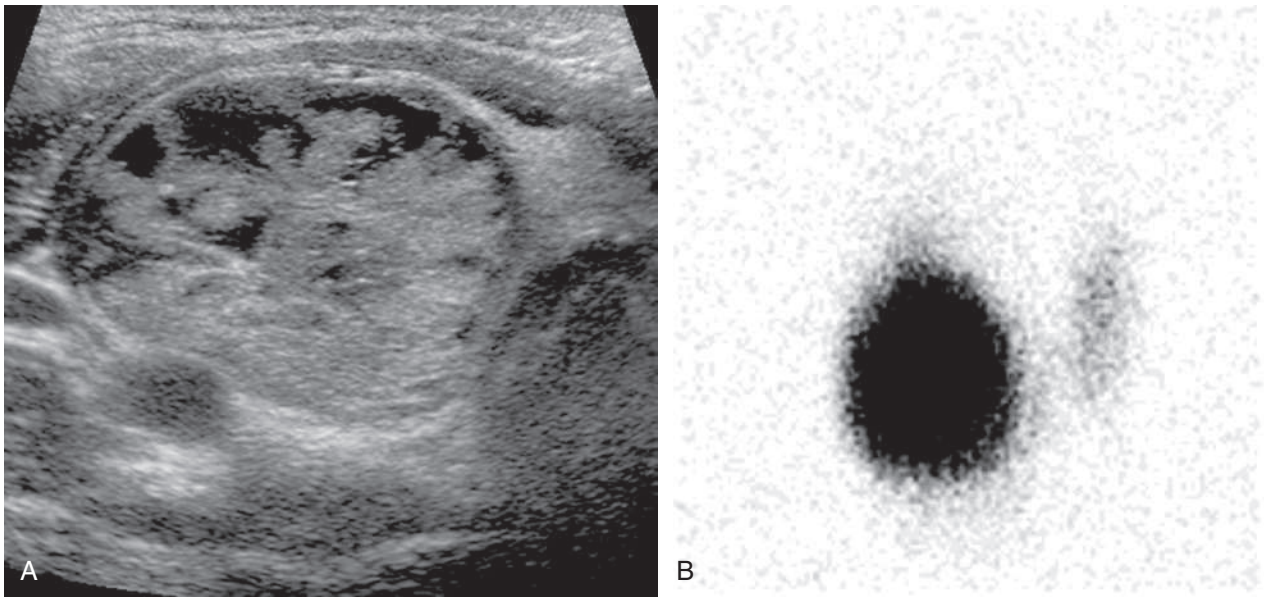

FIG. 48.37 Thyroid Cancer, Papillary Type. (A) Heterogeneous, well-defined right thyroid lobe nodule with peripheral halo, favored to represent follicular adenoma. **(B)** Technetium 99m ($_{99m}$Tc) pertechnetate scan demonstrates increased uptake suggesting hyperfunctioning adenoma, but pathology diagnosis was cancer.

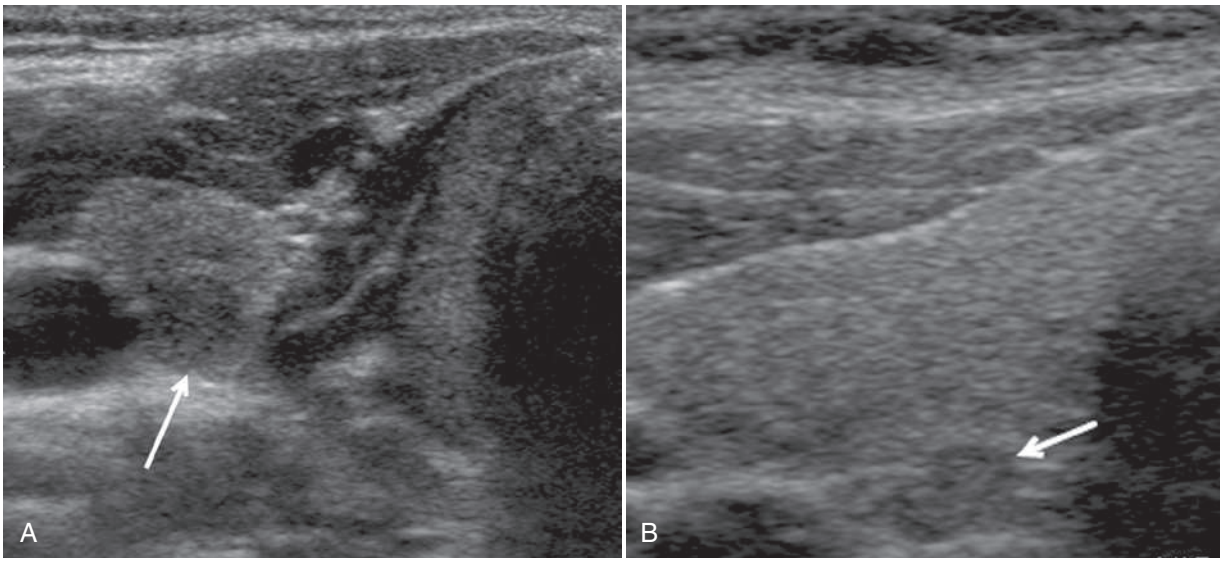

FIG. 48.38 Parathyroid Adenoma and Hyperplasia. (A) Patient with hyperparathyroidism demonstrates a hypoechoic nodule *(arrow)* posterior to the thyroid gland. **(B)** Patient with renal failure shows hypoechoic lenticular lesion *(arrow)* posterior to thyroid, consistent with parathyroid gland hyperplasia.

Parathyroid Glands

The parathyroid glands are two paired endocrine glands arising from the third and fourth branchial pouches.[130] **Normal parathyroid tissue** is infrequently identified separate from the thyroid because their echotexture is similar. Sonographic imaging of the parathyroid may be helpful in the presence of primary or secondary **hyperparathyroidism.** Parathyroid **adenomas** are rare in children but are the most common cause of primary hyperparathyroidism.[131,132] Children with chronic renal failure may develop parathyroid gland hyperplasia caused by secondary hyperparathyroidism.[133] Four-gland parathyroid hyperplasia is more common in patients with MEN I.[134] Ultrasound is 80% to 90% sensitive in detecting parathyroid tumors and gland enlargement.[131] Typical sonographic imaging findings of an adenoma and hyperplasia are similar, appearing as an oblong, sharply demarcated, hypoechoic solid mass aligned craniocaudal and posterior to the thyroid (Fig. 48.38). Less frequently, the mass may be cystic, calcified, multilobular, and giant.[43] Enlargement of the adjacent inferior thyroid artery may be identified as an **arc of vascularity,** providing clues to diagnosis of an adenoma.[135] Because 20% of the parathyroid tissue can be ectopic, MRI may be considered if ultrasound is unsuccessful in identifying the lesion.[136]

Other Cystic Lesions

Foregut cysts represent defective budding of the respiratory or intestinal tract. **Bronchogenic cysts** are usually mediastinal and rarely may occur as a mass in the lower neck.[94,137] **Esophageal cysts** are typically centered close to the esophageal wall. Foregut lesions usually occur as a palpable lump but can enlarge rapidly, causing airway obstruction and dysphagia. With sonography, the lesions are typically unilocular but may be complicated by hemorrhage and infection, especially in the presence of persistent communication with the airway or esophagus.

Laryngoceles are air- or fluid-filled dilations of the laryngeal saccule, a small pouch arising from the roof of the laryngeal ventricle.[93] Internal laryngoceles remain within the larynx, whereas external masses project through the thyrohyoid membrane.[138] When the laryngeal saccule is totally obstructed, the outpouching will appear as a smooth-walled anechoic mass projecting into the endolaryngeal or preepiglottic space.[138] In 8% to 10% of cases, laryngoceles develop superimposed infection, and there is a 15% association with neoplasm.[93] Children typically have airway obstruction or feeding difficulties.

LACKING DEFINITION BY THE HYOID

The carotid space and deep cervical fascial layers extend above and below the hyoid bone.[6,7] The **carotid space,** enveloped by all three layers, extends from the skull base to the aortic arch. Its contents include the internal carotid artery, jugular vein, cranial nerves IX to XII (vagus nerve, X), and deep cervical lymph node chain. The **retropharyngeal and prevertebral spaces** extend from the skull base to the level of the third thoracic vertebral body. The **danger space** is within the retropharyngeal space where a pathway exists for infection to spread inferiorly into the posterior mediastinum. The retropharyngeal space contains primarily lymph nodes, whereas the prevertebral space contains vertebral bodies, spinal cord, paraspinal and scalene muscles, and vertebral artery and vein. These spaces are not discussed separately because many diseases, especially nodal, involve multiple spaces simultaneously. It should be noted that ultrasound is especially useful in assessment of superficial lesions. Ultrasound is of limited value in deep space lesions involving the retropharyngeal space and prevertebral space, which typically require CT or MRI for better evaluation.[139]

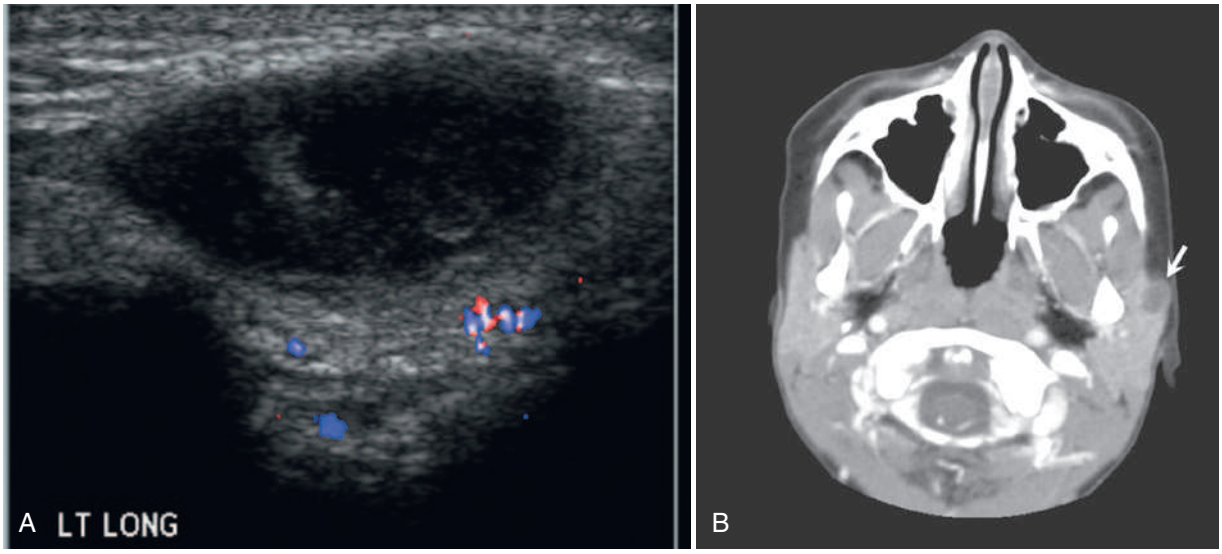

FIG. 48.39 Type I Branchial Cyst. (A) Four-year-old child with swelling and pain inferior to the left ear. Longitudinal sonogram demonstrates an elliptical heterogeneous hypoechoic lesion lacking color flow, superficial and inseparable from the parotid gland. **(B)** Axial computed tomography scan obtained 2 months later after treatment with antibiotics confirms well-defined cystic lesion *(arrow)* embedded in the superficial lobe of the left parotid.

Congenital Lesions

Branchial Anomalies

The **branchial (pharyngeal) apparatus** develops between the fourth and sixth week of gestation. The structure consists of six pairs of mesodermal **branchial arches** separated by five paired internal endodermal **pharyngeal pouches** and five paired external ectodermal **branchial clefts,** or grooves. Abnormalities in development of this apparatus may result in the formation of a cyst, sinus tract, or fistula, although most branchial lesions present as cysts.[140,141] Sinus tracts communicate with either skin or mucosa of the upper airway when a pouch or groove fails to obliterate; if both pouch and groove fail, then a fistula between skin and mucosa develops. A cyst occurs when a groove remnant forms an epithelial line space without communication.[142] Branchial anomalies, after thyroglossal duct cysts, are the second most common congenital head and neck lesions in children, with the majority arising from the type II apparatus.[141,142] Branchial anomalies, particularly when bilateral, may be part of branchio-oto-renal syndrome, a disorder that also manifests with bilateral preauricular pits and renal abnormalities.[143] On sonography, branchial malformations typically appear as a simple or complex cyst with through transmission. These lesions are susceptible to hemorrhage or superimposed infection, but predisposition to cancer remains controversial.[93] Treatment of choice is surgical resection or fistulectomy, with a 4% rate of recurrence.[143,144]

First branchial anomalies represent 8% to 10% of all anomalies and appear as a cyst or sinus adjacent to the external auditory canal, the pinnae, or the parotid gland, extending to the level of the mandible angle[143] (Fig. 48.39). These lesions can be superficial or deep, even embedded into the parotid gland with variable relationship to the facial nerve.[144,145] Some demonstrate a tract to the external auditory canal.

Second branchial anomalies represent 90% of all branchial apparatus malformations.[143] Cysts of the type II branchial anomaly result from persistence of the cervical sinus.[144-146] During development of the branchial apparatus, the second arch expands downward to meet and merge with the fifth arch, thus covering the second, third, and fourth arches and forming a cervical sinus of His.[130,146] Because of this embryology, many anatomic type II cysts are possible. These cysts are differentiated (Bailey) into four types.[144] Type I is deep to the platysma muscle. Type II, the most common, is anterior to the sternocleidomastoid, posterior to the submandibular gland, and lateral to the carotid sheath. Type III cysts are anatomically between the internal and external carotid arteries, posteromedial to the sternocleidomastoid and lateral to the pharynx (Fig. 48.40). Type IV cysts are adjacent to the pharyngeal wall.

Third and fourth branchial anomalies are rare, with incidence of type III 2% to 8% and type IV 1% to 2%.[143] Third branchial apparatus anomalies originate at the base of the pyriform sinus and pass above the superior laryngeal nerve (Fig. 48.41), whereas fourth branchial anomalies originate at the apex of the pyriform sinus and extend through the cricothyroid membrane and beneath the superior laryngeal nerve.[143,147] Third and fourth anomalies may manifest as a cyst in the lower anterior neck but more commonly appear as a pyriform sinus or fistula (Fig. 48.42). The anatomy of the lesion is typically a left-sided tract (89%) extending from the pyriform sinus to the anterior lower neck adjacent to the thyroid.[148] Patients may have recurrent neck infection, abscess (39%), or suppurative thyroiditis (33%).[101,148] On sonography, the thyroid often appears heterogeneous because of adjacent inflammation. In some cases, an air-containing intrathyroid or perithyroid cystic mass may be present, representing a complicating abscess.[49] A barium swallow study or CT with oral barium may be beneficial to define the tract, usually inconspicuous on sonography.[149]

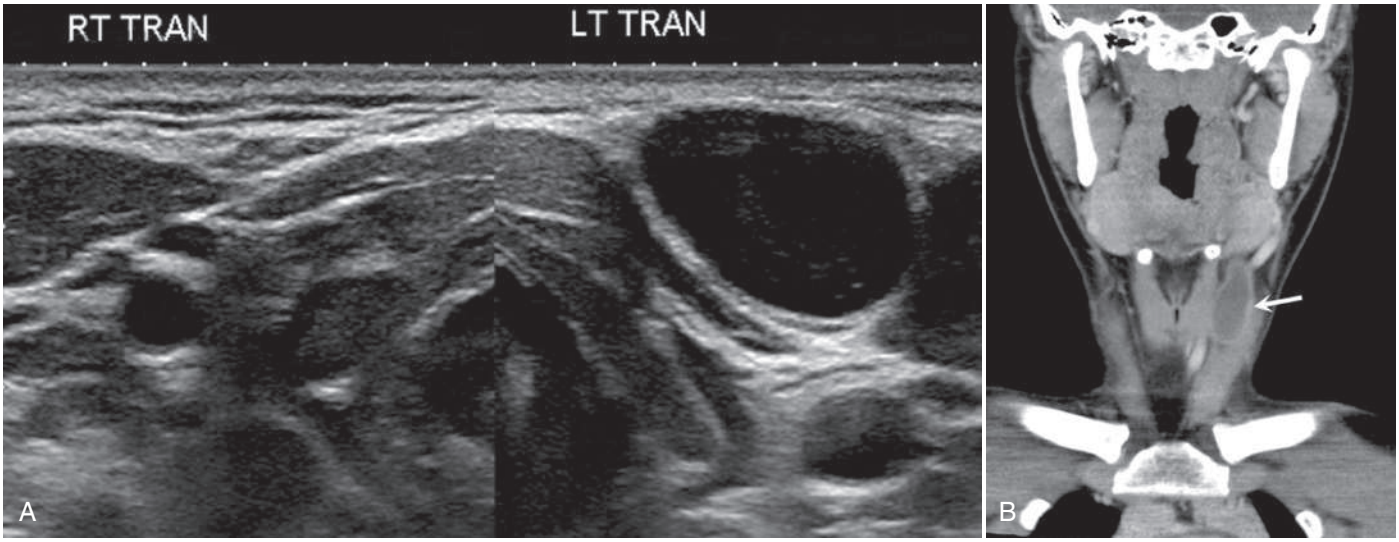

FIG. 48.40 Type II Branchial Cyst. (A) Transverse side-by-side image of the right and left sides of the neck. There is a unilocular, anechoic, encapsulated cystic lesion with through transmission in the left neck medial to the left sternocleidomastoid muscle. **(B)** Coronal computed tomography scan demonstrates the elliptical cyst *(arrow)* medial to the sternocleidomastoid muscle and lateral to the pharynx, type III of the second branchial apparatus anomalies.

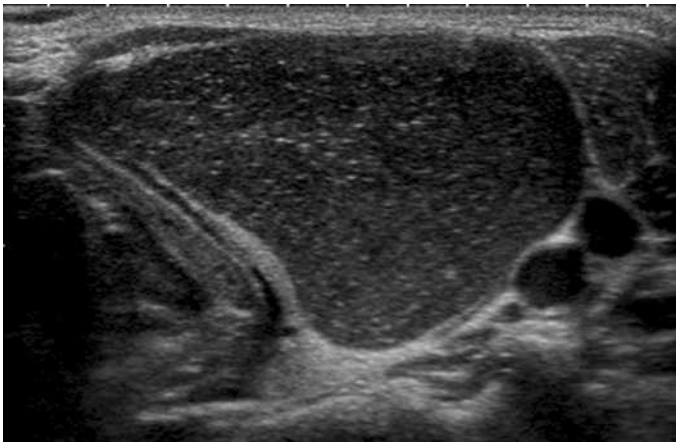

FIG. 48.41 Type III Branchial Apparatus Cyst. There is a unilocular complex hypoechoic cyst in the lower neck adjacent to the thyroid cartilage, suggesting hemorrhage or infection. No flow was present on color Doppler.

Ectopic Thymus

The thymus gland arises in the sixth week of gestation as outpouchings of primarily the third and a small portion of the fourth pharyngeal pouches.[93] Caudal elongation leads to the formation of tubular structures known as the **thymopharyngeal ducts.** By the ninth week, migration due to attachment to the pericardium is followed by obliteration of the duct from the angle of the mandible, along the carotid sheath, to the level of the superior mediastinum. The resulting migrating solid masses fuse to form thymus tissue anatomically located below the thyroid gland.[150] Superior cervical extension of the thymus is normal in children and young adults, seen in nearly 66% of these patients anywhere along the course of descent.[146,150,151] The ectopic thymus can be differentiated from other masses via sonography because of isoechogenicity and sometimes continuity with normal thymus, sharp angulated margins, parallel septa, pliability, lack of mass effect, and absence of central hilum with color Doppler imaging[43,150] (Fig. 48.43).

With persistence of the thymopharyngeal duct or progressive cystic degeneration of the thymic tissue, a **thymic cyst** may occur.[99,130] Most thymic cysts occur in the first decade of life, with a male and left-sided predominance.[152] Approximately 50% of cervical cysts are in continuity with a mediastinal mass.[43,153] On ultrasound, the lesions are typically large, unilocular or multilocular cysts intimately associated with the carotid space, often splaying the carotid artery and jugular vein[144,153] (Fig. 48.44). Intralesional debris can occur in the presence of hemorrhage or infection.[101] There are no reports of associated neoplasm, but surgical resection is the treatment of choice.[93,152]

Dermoid and Epidermoid Lesions

Dermoid and epidermoid lesions represent 7% of head and neck lesions and 25% of midline cervical anomalies.[93,98] These lesions develop when there is inclusion of ectodermal tissue during the fusion of the branchial arches.[146,154] **Dermoid cysts** contain two germ layers, both ectoderm and mesoderm, whereas **epidermoid cysts** consist of only one germ layer, ectoderm.[99,140] Although the majority of these masses are found around the orbit or adjacent to the nose, approximately 11% of these cysts occur in the floor of the mouth in the submandibular space.[93] With regard to imaging of the neck, most occur as a painless, slow-growing midline neck mass in the floor of the mouth, or less often in the thyroidal or suprasternal area.[43] Ultrasound of these lesions mimics a "pseudosolid" appearance, demonstrating a well-circumscribed, thin-walled unilocular mass with internal echoes and minimal posterior echo enhancement[152] (Fig. 48.45). Sometimes, there may be mixed echoes owing to internal fat or posterior shadowing in the presence of calcification.[152] Surgical resection is

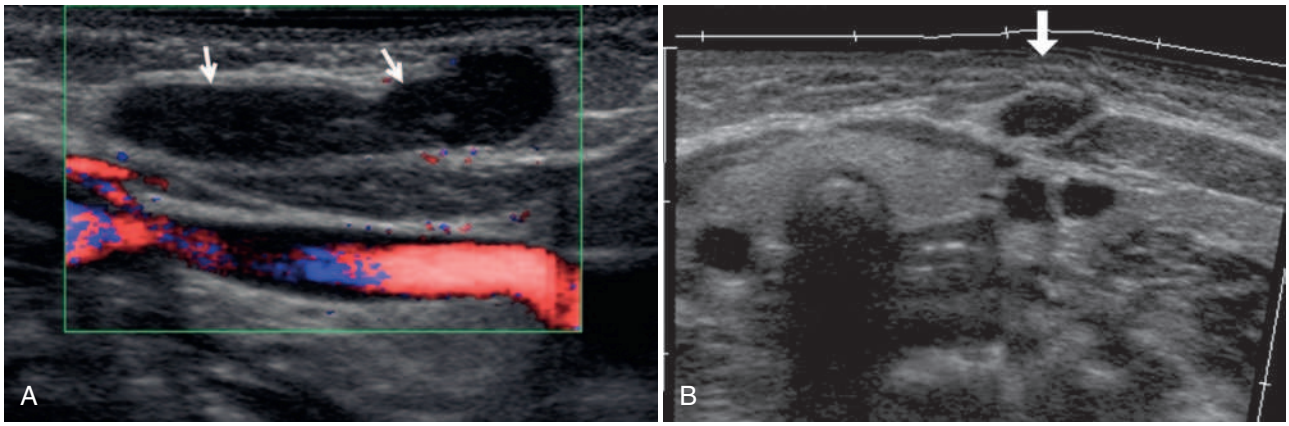

FIG. 48.42 Branchial Sinus. One-month-old child with draining sinus in the left neck. **(A)** Longitudinal ultrasound image shows a hypovascular tubular structure in the superficial soft tissues of the left side of the neck *(arrows)*. **(B)** Panoramic ultrasound of the neck shows the relationship of the branchial sinus *(arrow)* to the left lobe of the thyroid gland.

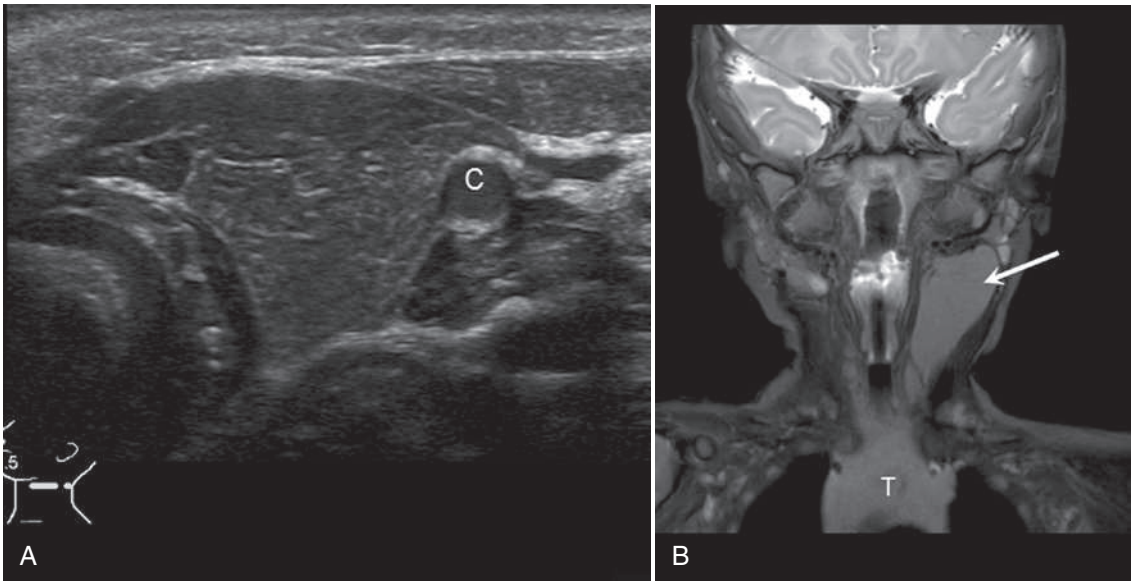

FIG. 48.43 Ectopic Thymus Tissue. Five-month-old child with fullness in the left side of the neck. **(A)** Ultrasound demonstrates an angular soft tissue mass with thin parallel septae medial to the carotid *(C)*. **(B)** Coronal short-tau inversion recovery (STIR) magnetic resonance image shows soft tissue in the left side of the neck *(arrow),* which is equal in signal to thymus *(T)* in the superior mediastinum.

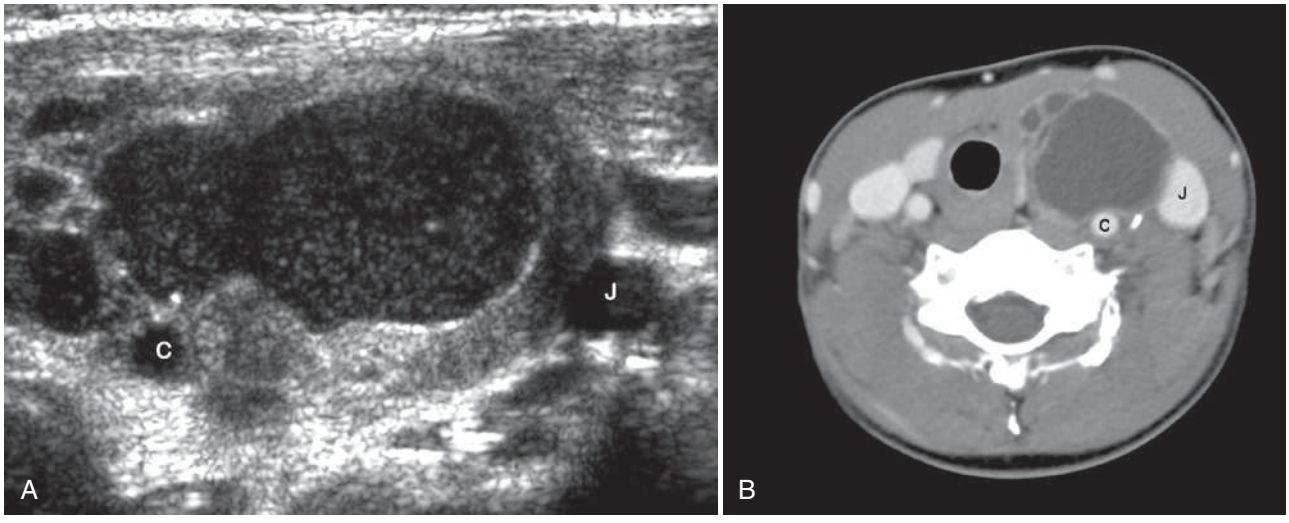

FIG. 48.44 Complicated Thymic Cyst. (A) Complex cystic mass with septation and thick peripheral wall splaying carotid artery *(C)* and jugular vein *(J)*. **(B)** Axial computed tomography scan shows complex mass at thoracic inlet displacing thyroid and airway.

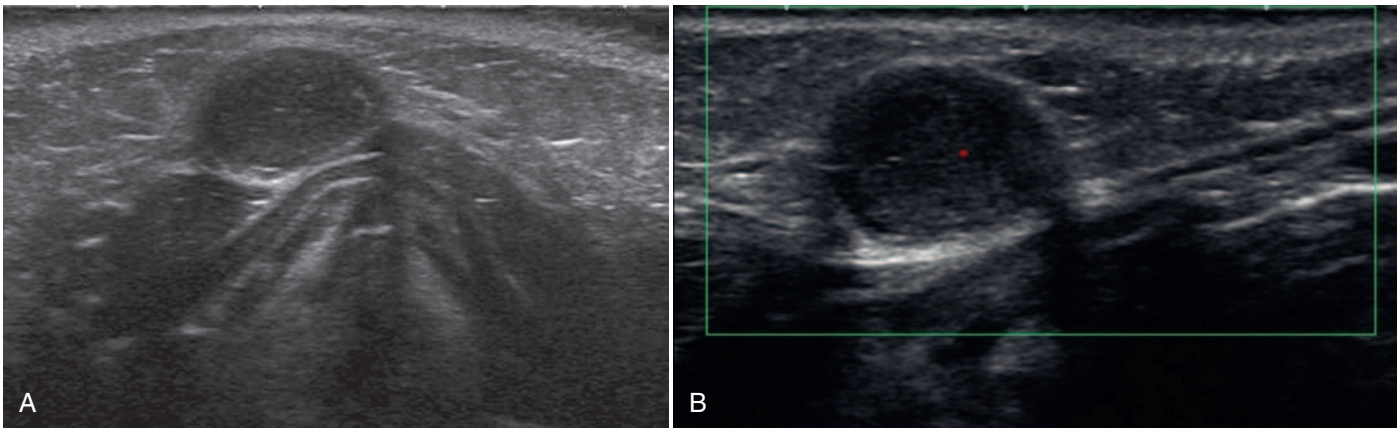

FIG. 48.45 Dermoid Cyst. Gray-scale **(A)** and color Doppler **(B)** transverse images show a well-defined, right paramidline, avascular infrahyoid lesion containing internal echoes and posterior through transmission. The lesion is in the deep subcutaneous layer, immediately superficial to the strap muscles.

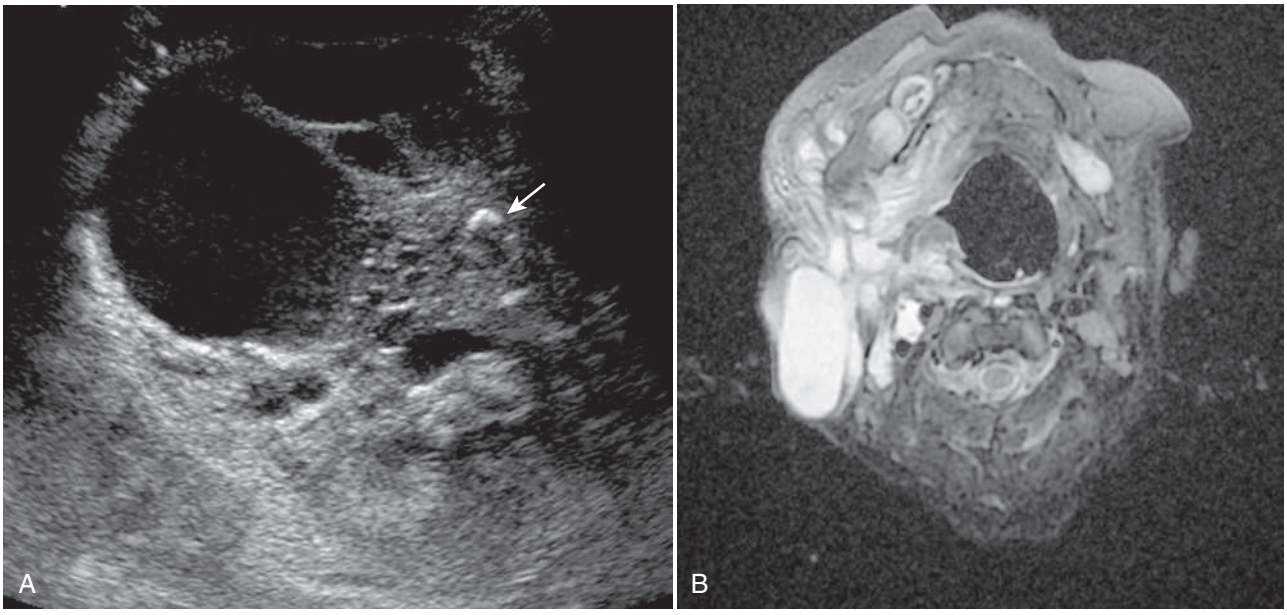

FIG. 48.46 Cervical Teratoma. (A) Poor definition of soft tissue planes caused by a complex infiltrative mass containing cystic, solid, and calcified areas *(arrow)*. **(B)** Axial T2-weighted magnetic resonance image shows complex cystic and solid mass infiltrating the parotid, masseter, submandibular, parapharyngeal, and carotid space soft tissues.

recommended because these anomalies are at risk for rupture or infection, and 5% will undergo malignant degeneration to squamous cell neoplasms.[93,98]

Teratomas

Cervical teratomas are rare, occurring in 1 per 40,000 live births but representing 5% to 14% of all neonatal teratomas.[154-156] These lesions are believed to arise from pluripotential cells of two or three germ layers isolated at sites distant to the anatomic site of origin.[154,157] About 90% of childhood teratomas consist of all three germ layers with variable differentiation, and 75% to 85% of head and neck tumors contain neuroectodermal tissue.[154] Most cervical teratomas are benign, with rare malignant diagnosis.[156,157] These lesions typically occur as a large, infiltrative cystic and solid mass in the anterior and lateral neck.[5,156] Airway impingement is the most common cause of morbidity; therefore, prenatal identification of the lesion may help define management at delivery.[156,158] Sonography demonstrates a multilocular heterogeneous mass containing solid and cystic components, with calcifications in 50% of cases[156,158,159] (Fig. 48.46). Mortality approaches 100% if the lesions are not immediately managed and resected.[158,160]

Vascular Lesions

Vascular Anomalies

In 1982, Mulliken and Glowacki[161] proposed a classification separating vascular anomalies into two groups, tumors versus

malformations, based on lesion growth patterns. Vascular masses that proliferate rapidly and can involute are regarded as **tumors.**[48] Vascular lesions that grow in proportion to the child and do not involute are considered **malformations.** With emerging knowledge about these vascular lesions, the International Society for the Study of Vascular Anomalies (ISSVA) provided a classification on vascular anomalies in 1996, and updated it in 2014. They acknowledge the fact that this classification scheme would be modified as new scientific information became available.[162]

Vascular Anomalies[ISSVA]

VASCULAR TUMORS
Benign
Locally aggressive or borderline
Malignant

VASCULAR MALFORMATIONS
Simple
Combined
Of major named vessels
Associated with other anomalies

Gray-scale and color and duplex Doppler ultrasound can help determine whether the anomaly is cystic or solid, evaluate for intralesional calcifications or phleboliths, and identify the presence of high-flow vessels.[163] CT scans may be helpful when a patient cannot be sedated, to confirm intralesional calcification and evaluate associated bone changes. Because of soft tissue definition, multiplanar capabilities, and ability to define high-flow vessels, MRI is the preferred imaging modality for vascular malformations.[161,163]

Vascular Tumors

Benign vascular tumors include infantile and congenital hemangiomas, pyogenic granuloma (lobular capillary hemangioma), tufted angioma, and a few other rare lesions. Kaposiform hemangioendothelioma is a locally aggressive vascular tumor seen in infants. Angiosarcoma and epithelioid hemangioendothelioma are malignant vascular tumors that may be seen in childhood.[162] The locally aggressive or malignant vascular lesions are extremely rare and frequently characterized by rapid growth. These lesions are best evaluated with MRI.

Infantile hemangiomas are the most common vascular lesions in infancy and childhood. These high-flow masses are benign neoplasms composed of proliferating endothelial cells.[161] Infantile hemangiomas represent 60% of head and neck hemangiomas.[47] Hemangiomas occur three times more often in girls than boys.[48] Most occur as a painless, compressible, growing mass, and half have a bluish or red stain in the skin superficial to the lesion.[157] These lesions typically become apparent within the first few weeks of life, undergo a phase of proliferation and peak in size at 1 year of age, then undergo spontaneous, slow involution over the first decade.[161] On ultrasound, these lesions are lobulated, well marginated, heterogeneously echogenic and compressible when superficial. On color Doppler imaging during the proliferative phase, there is exuberant vascularity within the lesion, with high vessel density of greater than five vessels per square centimeter[164] (Fig. 48.47, Video 48.3). These lesions are supplied by high-flow vessels with low-resistance arterial waveforms. Prominent draining veins are present, but there is no arterialization of venous waveforms.[164] Clinical and sonographic evaluation is generally sufficient for diagnosis, and biopsy is rarely indicated. During the involutional phase, there is a decrease in size of the lesion as well as a decrease in the vascularity and the high systolic flow.[164]

Hemangiomas are common in premature infants, usually evident shortly after birth, but 95% of these lesions manifest during the first 6 months.[157,163] Endothelial glucose transporter 1 (GLUT 1) is a diagnostic marker for infantile hemangioma. If one or multiple hemangiomas are present in a trigeminal dermatome distribution (frequently V1), the clinician should consider **PHACES syndrome** (*p*osterior fossa malformations, *h*emangiomas, *a*rterial anomalies, *c*oarctation of aorta and cardiac defects, *e*ye abnormalities, *s*ternal notching).[165] Infantile hemangiomas are treated only if symptomatic or if they endanger vital structures. Treatment options include propranolol, laser therapy, and surgery.

Congenital hemangiomas, less common than infantile hemangiomas, will be present at full size at birth. They are GLUT 1 negative, lack a gender predisposition, and commonly occur in the head or extremity joints.[166] They may subsequently involute before 1 year of age (rapidly involuting congenital hemangioma [RICH]), may be static (noninvoluting congenital hemangioma [NICH]), or may partially involute (partially involuting congenital hemangioma [PICH]). On Doppler sonography, congenital hemangiomas are heterogeneous and highly vascular with fast-flow low-resistance arterial vessels as well as channels with venous flow[166,167] (Fig. 48.48). Calcifications may occasionally be seen in RICH and NICH, differentiating these lesions from infantile hemangiomas.[166]

Vascular Malformations

Simple vascular malformations may be composed of only one type of vessel such as capillaries, lymphatics, or veins or, as in the case of arteriovenous malformations (AVMs) or arteriovenous fistulas (AVFs), may involve more than one type of vessel.[162] Simple capillary malformations frequently appear as cutaneous lesions, are diagnosed clinically, and are rarely imaged. Capillary malformations can occur combined with other anomalies, such as the Sturge-Weber syndrome with facial cutaneous capillary malformation (port-wine stain) frequently in the distribution of the ophthalmic segment of the trigeminal nerve.[162]

Lymphatic malformations, originating from a sequestered embryonic lymph sac, are composed of primitive lymphatic spaces of varying sizes separated by connective tissue stroma.[140] Lymphatic malformations may be macrocystic with large cysts (previously called **cystic hygromas**), microcystic (previously called **lymphangiomas**), or mixed cystic. There is no specific size criterion separating microcystic from macrocystic lymphatic malformations, but in general, if the size of the cyst is large enough for sclerotherapy, it is considered macrocystic. Lesion cyst size is likely caused by the stromal environment rather than lesion behavior.[99] Some lymphatic malformations are diagnosed

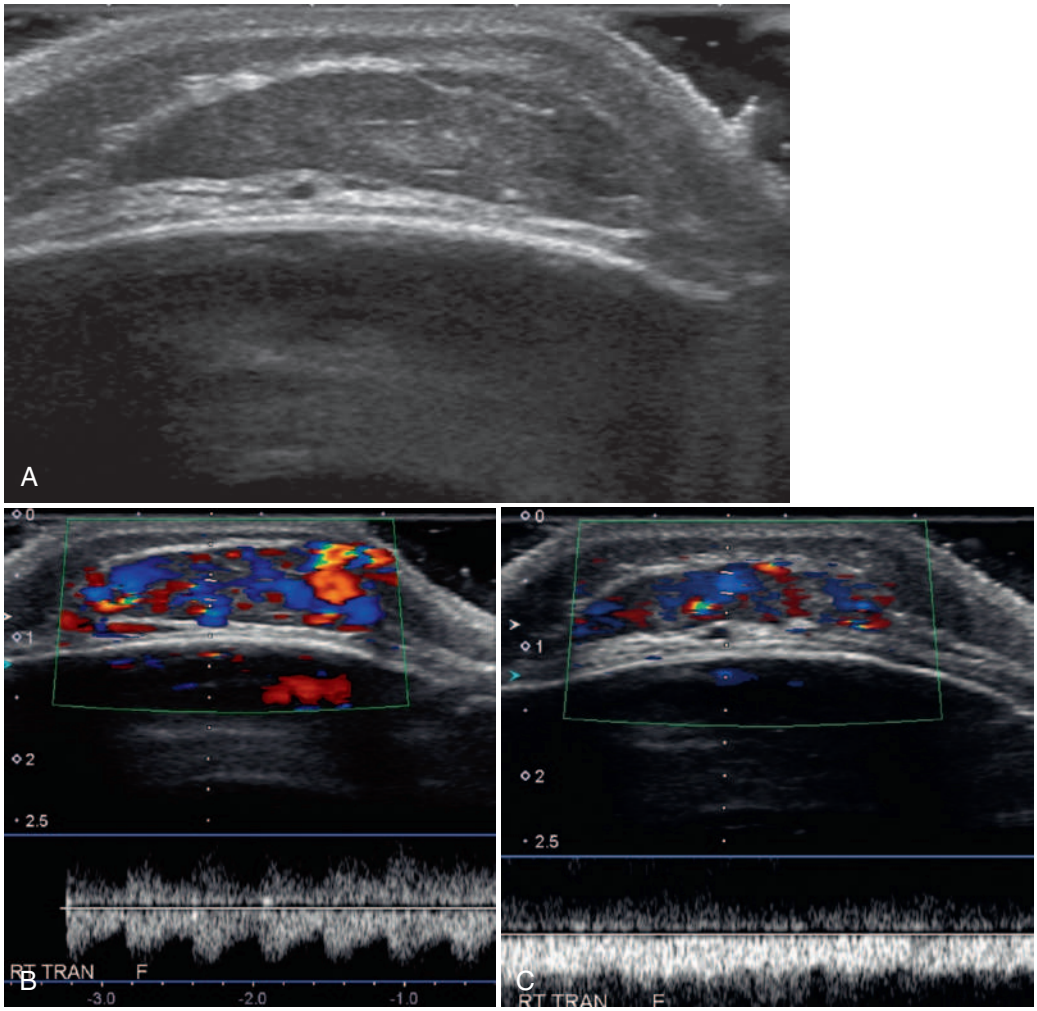

FIG. 48.47 Infantile Hemangioma. (A) Oblong heterogeneous echogenic right scalp mass in a 5-month-old infant. **(B)** The lesion is intensely vascular with low-resistance arterial waveforms. **(C)** Prominent veins are present without arterialization of flow. See also Video 48.3.

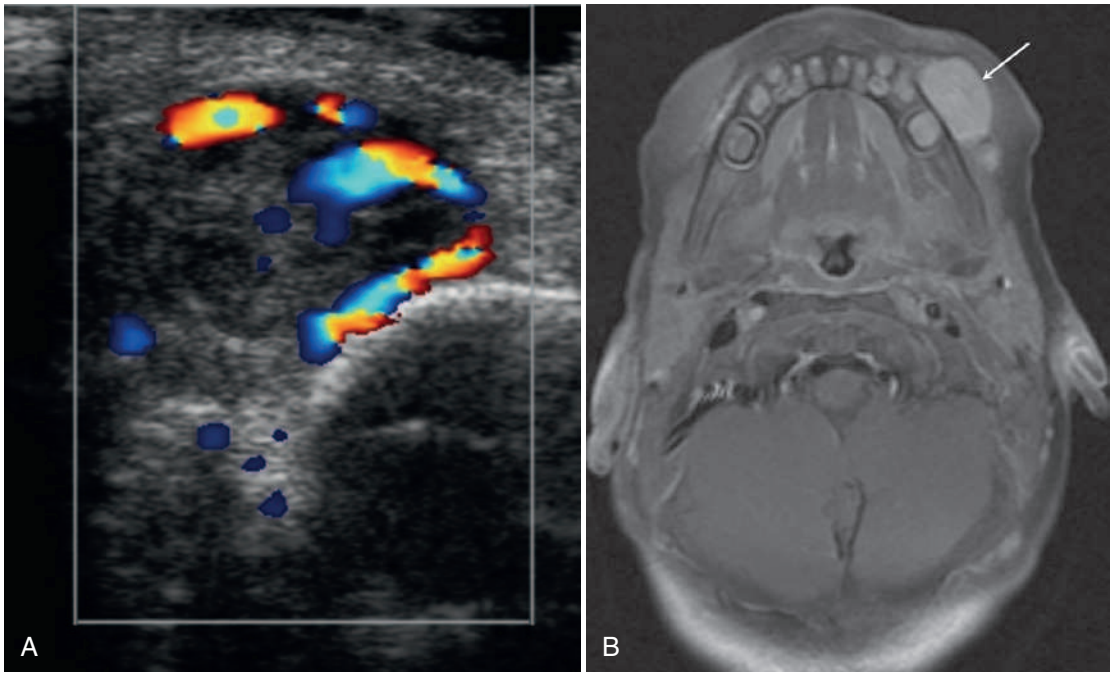

FIG. 48.48 Noninvoluting Congenital Hemangioma (NICH). (A) Heterogeneous hypoechoic mass with increased vascularity in an 8-month-old infant. The lesion was present since birth, and there was superficial cutaneous discoloration. **(B)** Postcontrast T1-weighted magnetic resonance image shows uniform enhancement of the left cheek mass. *(arrow).*

prenatally, with 90% presenting by age 2 years. Clinically, the skin is usually normal but may have a bluish hue, puckering, or tiny vesicles.[163] These lesions can be diffuse or focal, tend to invade multiple anatomic facial planes, and will rapidly enlarge if complicated by hemorrhage or infection. Hypertrophy and intraosseous invasion of adjacent bone, usually the mandible, can occur.

About 75% of lymphatic lesions occur in the neck, and most originate within the posterior triangle or oral cavity, with lesions occurring on the left side twice as often as on the right side.[43,48,82] Of infants with lymphatic malformations, 3% to 10% have airway compromise from respiratory obstruction or mediastinal extension.[47,157] Although most children with lymphatic malformation have a normal karyotype, several syndromes are associated, such as Turner, Down, Noonan, Roberts, and trisomy 13 and 18.[144] On ultrasound, most lymphatic malformations are multiloculated cystic masses with septa of variable thickness and solid components[47] (Fig. 48.49, Video 48.4). Fluid-fluid levels or echogenic debris can result from superimposed hemorrhage or infection. MRI provides optimum tissue characterization and lesion delineation before surgical intervention.[168] Surgical resection is the treatment of choice but can be difficult if the lesion invades neural, vascular, and muscular structures; therefore sclerotherapy, radiofrequency ablation, and laser therapy are other options.[48,168] Other malformations involving the lymphatic system include generalized lymphatic anomaly, Gorham-Stout disease, channel-type lymphatic malformation, primary lymphedema, and others.[162]

Venous malformations are soft, compressible lesions that may distend with increased venous pressure (Valsalva maneuver). About 40% of these lesions occur in the head and neck, and many invade multiple fascial planes and involve osseous structures.[163] These lesions, appearing clinically as soft, bluish, compressible masses, consist of thin-walled, dilated, dysplastic, small and large venous channels deficient in smooth muscle.[43] Rapid enlargement may occur secondary to phlebothrombosis. Multiple venous malformations are seen in **Maffucci syndrome** and **blue rubber bleb nevus syndrome, cerebral cavernous malformation,** and **glomuvenous malformation.**[162,169] **Phleboliths** are present in 16% of cases and can help confirm the diagnosis. Ultrasound demonstrates hypoechoic lesions with heterogeneous architecture. Acoustic shadowing secondary to phleboliths and fluid-fluid levels may be identified[48] (Fig. 48.50). On Doppler sonography, venous low-velocity flow is identified. Treatment includes elastic compression, sclerotherapy, and surgical excision.

Arteriovenous malformations (AVMs) represent collections of a nidus of tortuous abnormal, thin-walled vessels connecting dilated feeding arteries to draining veins. These lesions may be centered in cutaneous, muscular, or intraosseous structures.

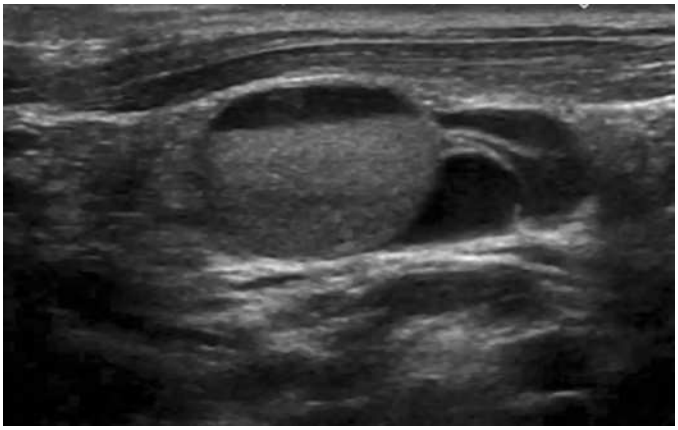

FIG. 48.49 Lymphatic Malformation. Lymphatic malformation in a 5-year-old child with long-standing left neck mass. Ultrasound shows a multilocular cystic lesion with a fluid-fluid level in one of the locules, indicating internal hemorrhage. See also Video 48.4.

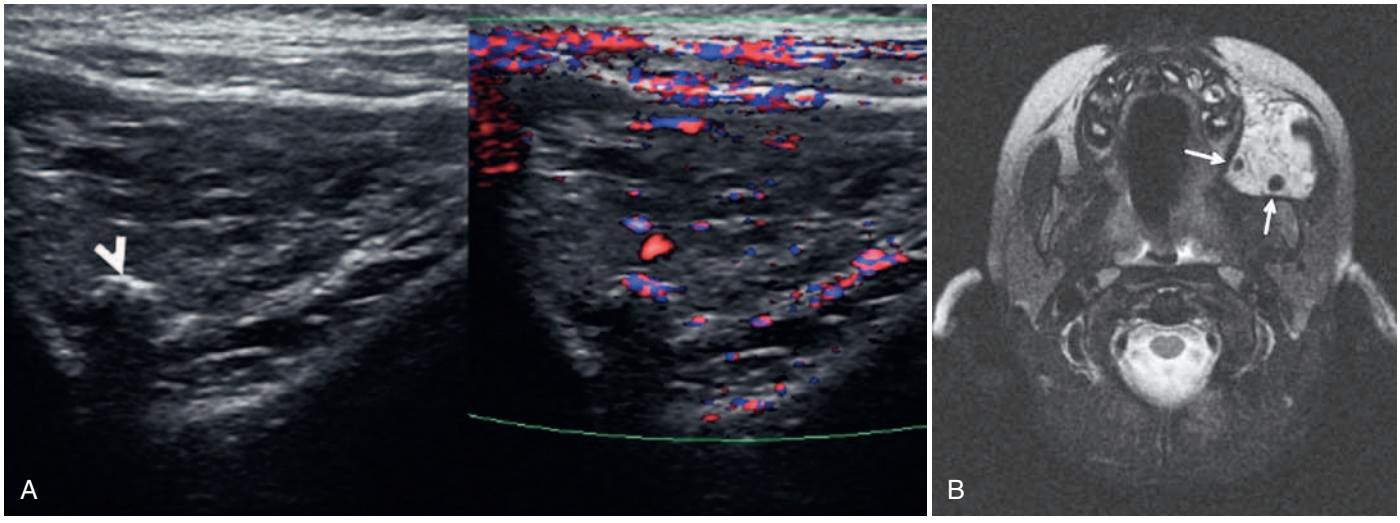

FIG. 48.50 Venous Malformation. (A) Side-by-side gray-scale and color Doppler. Masseter muscle is enlarged and heterogeneous with hypoechoic areas and a hyperechoic focus that shadows *(arrowhead),* consistent with phlebolith. Color Doppler demonstrates mild increase in vascularity. **(B)** Axial T2-weighted fat-saturated magnetic resonance image demonstrates high-signal lesion infiltrating the masseter muscle and parapharyngeal space. Dark foci are consistent with phleboliths *(arrows).*

Clinically, a blush hyperemia and thrill or bruit may be present. AVMs can enlarge acutely from increased blood flow, obstruction, or infection. An extensive lesion may cause congestive heart failure. AVMs also are affected by hormones, often increasing in size at puberty and during pregnancy.[48] The most common sites of AVMs in the head and neck include the cheek, followed by the ear, nose, and forehead.[43] On gray-scale ultrasound, AVMs demonstrate heterogeneity, with multiple hypoechoic channels and absence of soft tissue mass. Doppler sonograms show a high-flow lesion with low-resistance arteries and arterialized venous waveforms[47] (Fig. 48.51). Transcatheter embolization, sclerotherapy, and surgical excision are the mainstays of management.[48]

In **arteriovenous fistulas** (AVFs), there is direct communication between the arteries and veins without an intervening tangle of vessels; AVFs are frequently acquired during trauma. However, both AVMs and AVFs can occur sporadically, in the setting of hereditary hemorrhagic telangiectasia or capillary malformation–arteriovenous malformation (CM-AVM) syndrome.[162]

A combination of two or more simple vascular malformations is classified as a combined vascular malformation. Vascular malformations are also categorized based on involvement of major named vessels. It is important to recognize that both vascular tumors and vascular malformations can be associated with other anomalies and syndromes.[162]

Other Congenital Lesions

Cervical aortic arch is a rare congenital anomaly in which the arch is positioned high, above the clavicle, usually in the right side of the neck. This developmental variant occurs because of persistence of the embryonic third arch with regression of the fourth.[170] These patients are often asymptomatic but can have a pulsatile anechoic mass, dysphasia, and respiratory symptoms.[43]

Internal jugular phlebectasia is a rare congenital saccular or fusiform dilation of the internal jugular vein.[43,171] The lesion typically occurs on the right side with a history of asymptomatic neck swelling, although uncommon complications such as thrombosis and Horner syndrome have been reported.[172,173] Ultrasound demonstrates an echo-free, slow-flow vessel on color Doppler sonography that measures greater than 15 mm in anterior-to-posterior dimension and increases in size with Valsalva maneuver[171,172] (Fig. 48.52). Treatment is typically conservative.[173]

Iatrogenic Lesions

Color and duplex Doppler ultrasound are noninvasive techniques that provide information about blood vessel patency, size, and direction of blood flow.[174-176] Vascular lines are typically placed through the subclavian or jugular vein into the superior vena cava. Gray-scale and color Doppler sonograms can demonstrate **arterial** and **venous stenosis, thrombosis,** or **pseudoaneurysms,** which can result from central line placement or prior extracorporeal membrane oxygenation (ECMO) therapy[177] (Fig. 48.53). Ultrasound guidance has also proved useful for insertion of central venous and ECMO catheters to prevent morbidity related to malposition.[178-180]

Inflammatory Lesions

Lemierre syndrome is rare and typically occurs in young adults, more commonly male, after a primary oropharyngeal infection.[181] It is hypothesized that **thrombophlebitis** of tonsillar veins propagates into the internal jugular vein, resulting in *Fusobacterium necrophorum or streptococcal* **septicemia** and **septic emboli,** primarily to the lungs.[182,183] Ultrasound demonstrates an engorged, noncompressible vein that may contain echogenic thrombus. Color Doppler ultrasound can document absent flow and may show a lack of pulsation with Valsalva maneuver (Fig. 48.54). Blood cultures and chest radiography or CT scan secure the diagnosis so that appropriate antibiotic therapy can be instituted.[184]

Lymph Nodes

Lymph nodes consist of an outer cortex of lymphoid follicles and hilum containing lymphatic sinus, connective tissue, and blood vessels. Cervical lymph nodes, which number about 300, are located along the lymphatic vessels in the neck.[185] A normal infant lymph node measures less than 3 mm in diameter.[43] In children, lymph nodes larger than 1 cm in maximum dimension are considered enlarged. On ultrasound, a normal node is ovoid and hypoechoic, with an echogenic hilum containing central vascularity (Fig. 48.55). The normal length exceeds its width by 2 : 1.[74]

Lymph nodes can enlarge as a result of reactive hyperplasia, infection, inflammation, or malignancy.[186] Cervical lymphadenopathy is common and frequently a normal finding in children. From 47% to 55% of children of all ages and 80% to 90% of children aged 4 to 8 years have palpable reactive hyperplastic lymph nodes not originating from infection or systemic illness. Palpable lymph nodes in infants, however, are not normal and should be evaluated further. **Supraclavicular lymphadenopathy and large nodes** are concerning, associated with high risk of malignancy and requiring FNA and/or biopsy.[186-188]

The diagnosis of lymphadenitis is often clinical, and most cases are uncomplicated; therefore most patients are treated medically and require no additional imaging. If imaging is performed, key features include location, extent of cellulitis, myositis, presence of abscess, and vascular compromise.[144] With ultrasound imaging, **lymphadenitis** demonstrates multiple enlarged lymph nodes, normal in shape but with reduced echogenicity and increased central and peripheral vascularity[74,144,189] (Fig. 48.56). With progressive enlargement of the nodes and **cellulitis,** there is blurring of soft tissue planes, some septa may stand out, and color Doppler imaging shows increased blood flow[45] (Fig. 48.57). When an **abscess** forms, the nodes coalesce, central vascularity disappears, and a hypoechoic center, sometimes with posterior enhancement, is present and surrounded by a thick, hyperechoic, hypervascular irregular capsule (Fig. 48.58). Pus-fluid levels, fluid movement on Doppler ultrasound, and hyperechoic foci with comet-tail artifacts, signifying air, help confirm the diagnosis.[74] In severe cases, adenitis may spread to the deep cervical spaces such as retropharyngeal, parapharyngeal, or submandibular space.[190] In rare instances, sinus tracts and

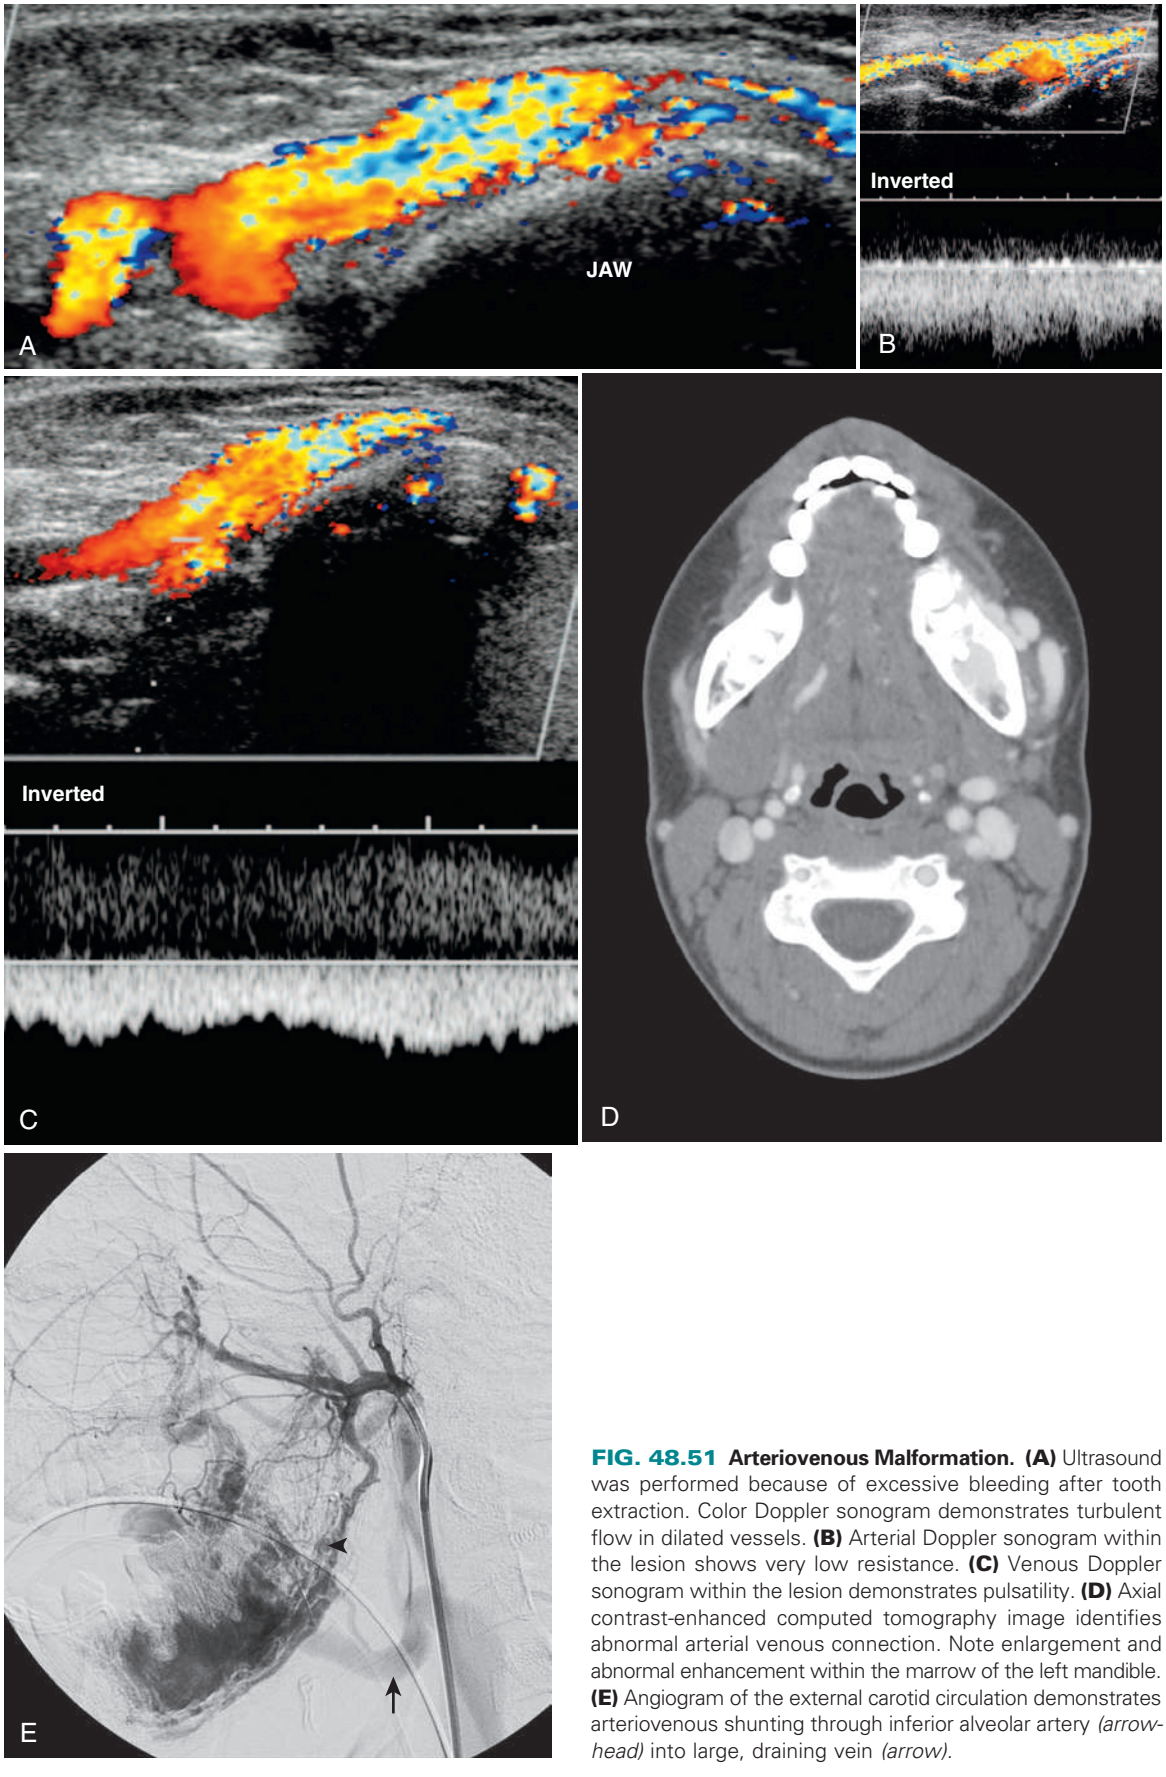

FIG. 48.51 Arteriovenous Malformation. (A) Ultrasound was performed because of excessive bleeding after tooth extraction. Color Doppler sonogram demonstrates turbulent flow in dilated vessels. **(B)** Arterial Doppler sonogram within the lesion shows very low resistance. **(C)** Venous Doppler sonogram within the lesion demonstrates pulsatility. **(D)** Axial contrast-enhanced computed tomography image identifies abnormal arterial venous connection. Note enlargement and abnormal enhancement within the marrow of the left mandible. **(E)** Angiogram of the external carotid circulation demonstrates arteriovenous shunting through inferior alveolar artery *(arrowhead)* into large, draining vein *(arrow)*.

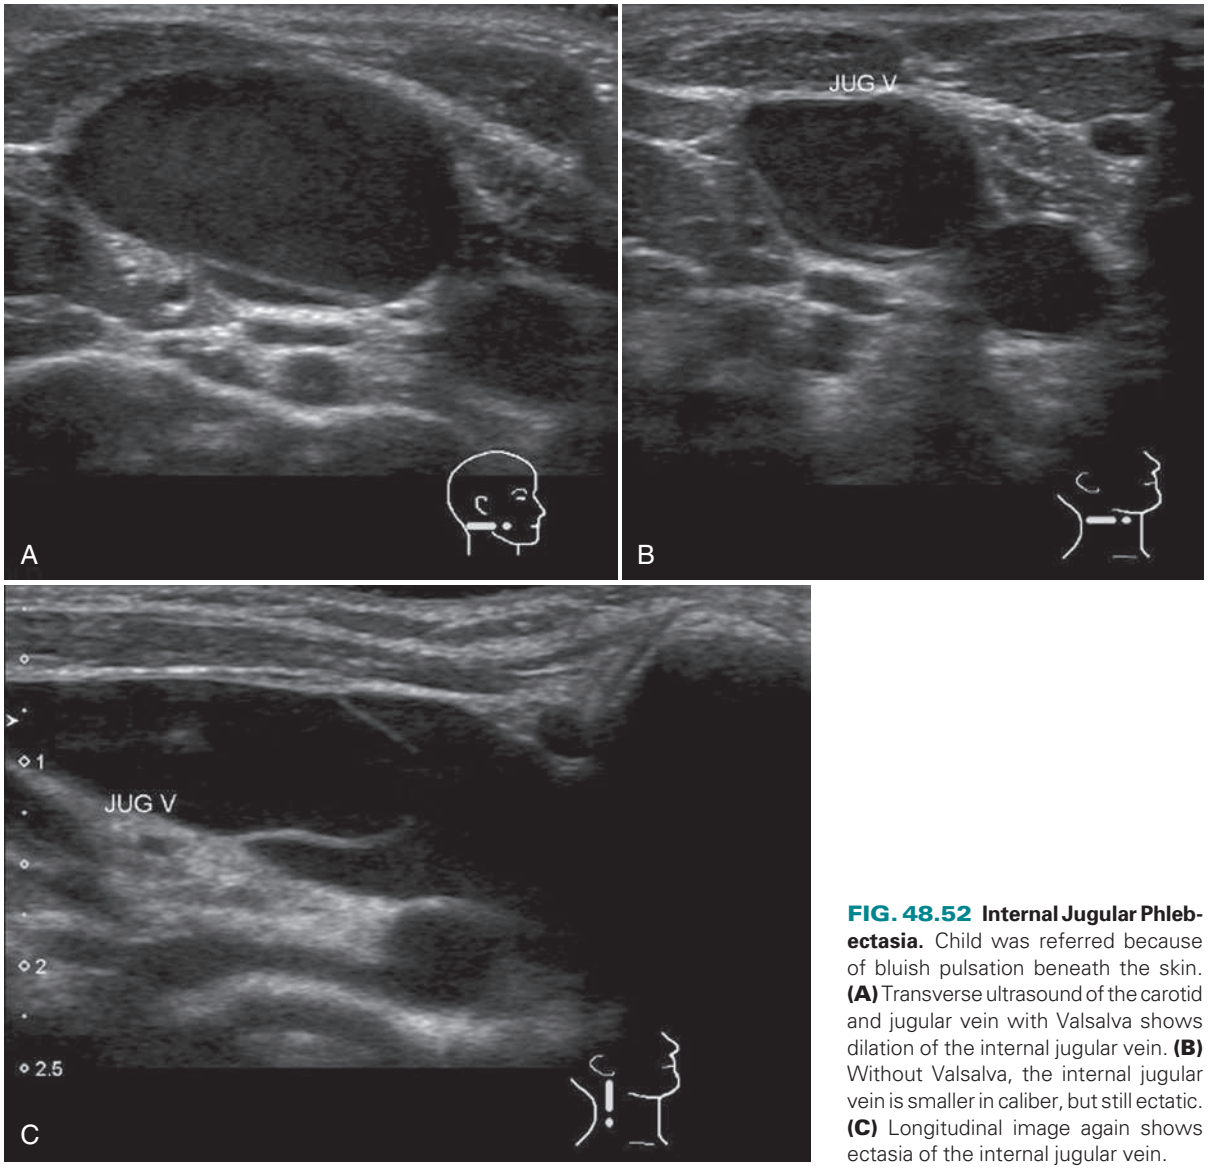

FIG. 48.52 Internal Jugular Phlebectasia. Child was referred because of bluish pulsation beneath the skin. **(A)** Transverse ultrasound of the carotid and jugular vein with Valsalva shows dilation of the internal jugular vein. **(B)** Without Valsalva, the internal jugular vein is smaller in caliber, but still ectatic. **(C)** Longitudinal image again shows ectasia of the internal jugular vein.

fistulas may develop.[45] FNA and surgical incision may be necessary to resolve the infection.[187]

Acute lymph node enlargement in children can be unilateral or bilateral. The anterior cervical nodes, which drain the mouth and pharynx, are most often affected.[187] In 80% of cases, acute **unilateral pyogenic lymphadenitis** is secondary to *S. aureus* or group A beta-hemolytic streptococci.[74,187,191] Many patients have respiratory tract infection, pharyngitis, tonsillitis, or otitis media in conjunction with tender, warm, and erythematous lymph nodes. A less common cause of acute bacterial lymphadenitis includes actinomycosis in a patient with poor dental hygiene.

The etiology of **bilateral cervical lymphadenopathy** tends to be viral, including rhinovirus, parainfluenza virus, and influenza.[191] **Epstein-Barr virus** can be difficult to differentiate from bacterial infections because the infection may be associated with exudative tonsillitis. In a patient with Epstein-Barr virus, the presence of diffuse lymphadenopathy and hepatosplenomegaly may help confirm the diagnosis.[5] Noting the age of the child and the sites involved may provide other clues[192] (Tables 48.3 and 48.4).

Subacute or chronic infection occurs when cervical lymph nodes enlarge slowly and are only minimally tender without substantial cellulitis. Differential diagnosis includes bacterial causes such as atypical mycobacteria, *Mycobacterium tuberculosis, Nocardia,* or cat-scratch disease; viral pathogens; or fungal infection such as histoplasmosis.[187,190] Most **mycobacterial infections** are caused by variant strains of *Mycobacterium avium-intracellulare-scrofulaceum* complex.[187] Infection typically is unilateral and occurs in children aged 1 to 5 years. *M. tuberculosis,* when it involves the cervical nodes, is thought to represent an extension of the primary pulmonary lesion or to be associated with acquired immunodeficiency syndrome (AIDS).[45] Nodes on sonography with low attenuation centers and small calcifications suggest mycobacterial infection.[77,144] *Nocardia* typically is seen

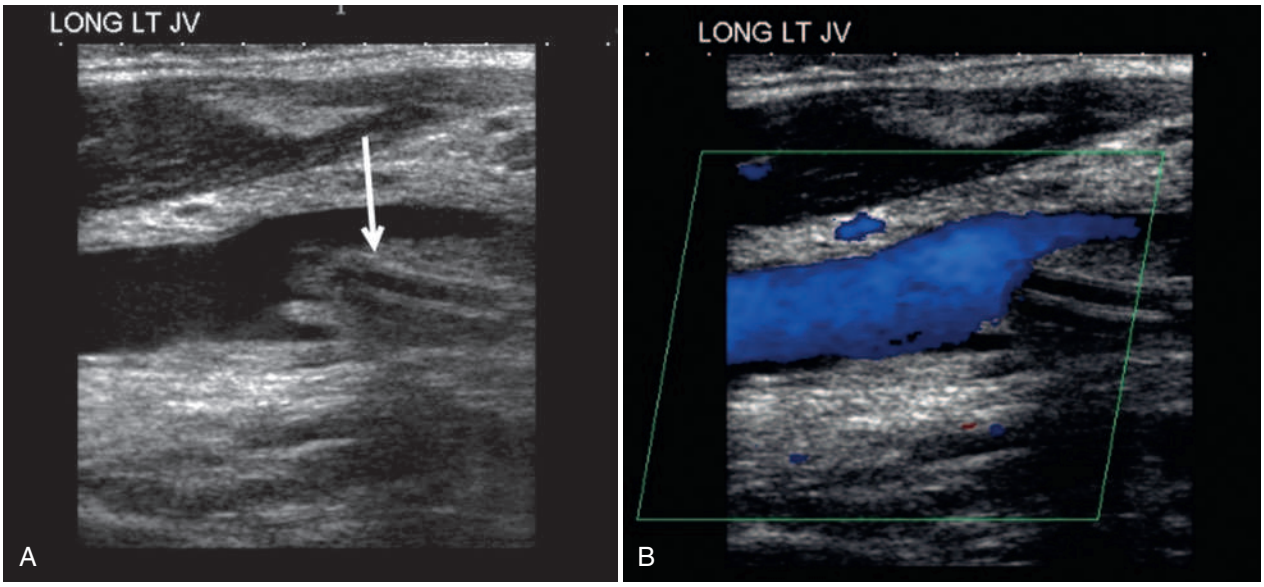

FIG. 48.53 Jugular Vein Thrombosis Caused by Central Line. (A) Longitudinal image of internal jugular vein with thrombus surrounding a vascular catheter *(arrow)*. **(B)** Color Doppler image shows partial occlusion at site of thrombus.

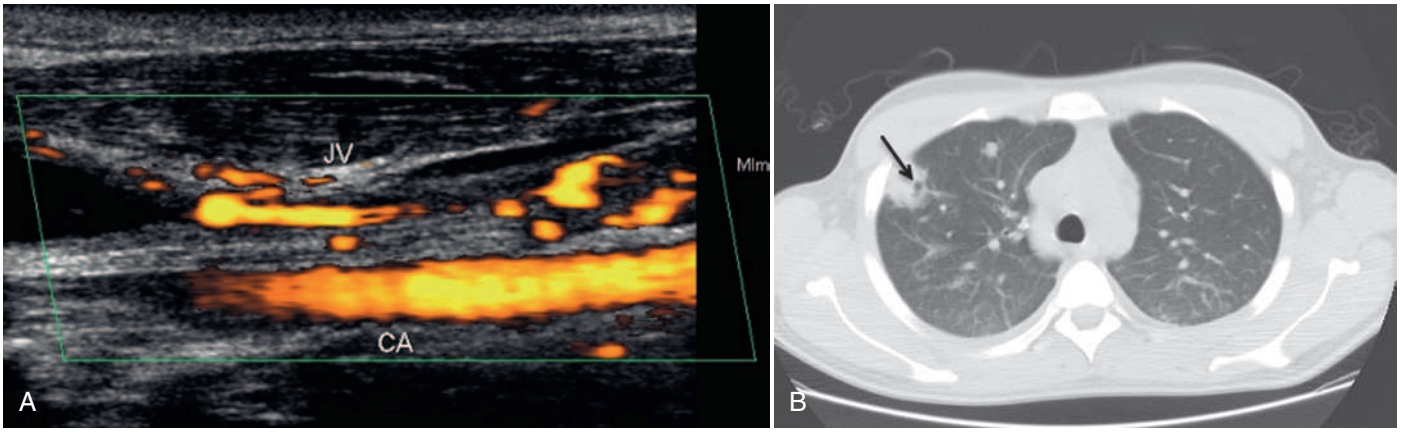

FIG. 48.54 Lemierre Syndrome. (A) Color Doppler sonogram of the internal jugular vein demonstrates near-occlusive clot within the lumen. **(B)** Axial chest computed tomography image shows two parenchymal nodules in the right upper lung with an area of central cavitation *(arrow)* caused by septic emboli.

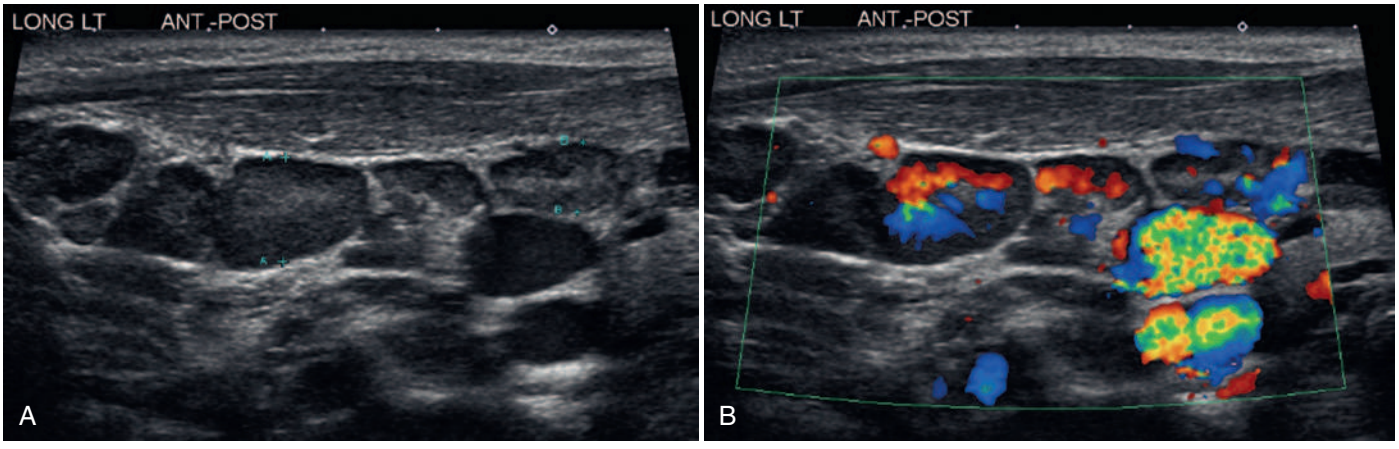

FIG. 48.55 Lymph Node Morphology. (A) Longitudinal scan of multiple normal sized (<1 cm) lymph nodes, ovoid and hypoechoic, with an echogenic hilum. **(B)** Color Doppler sonogram demonstrates central hilar vessels.

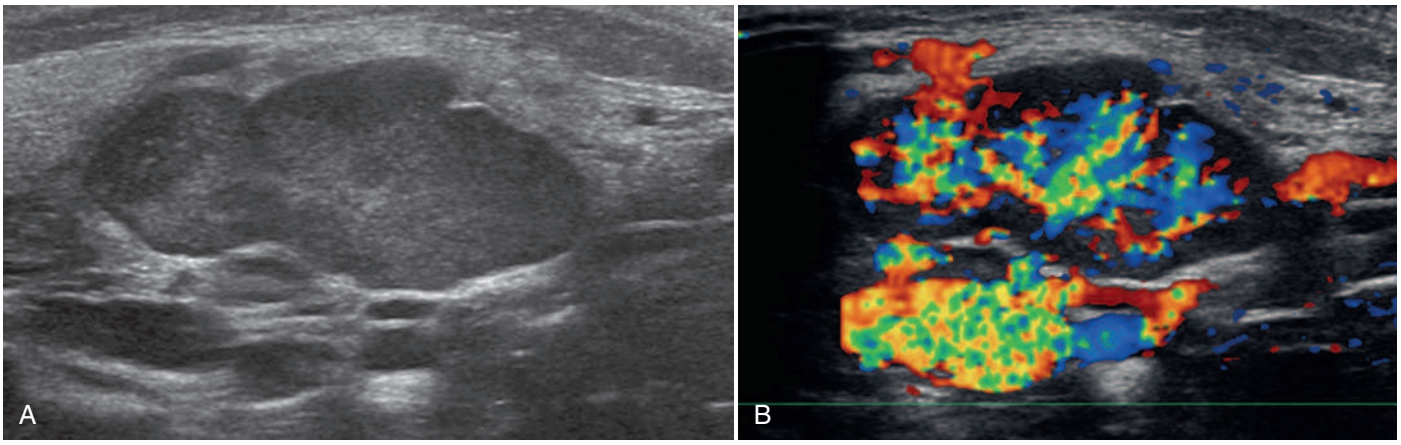

FIG. 48.56 Lymphadenopathy Related to Epstein-Barr Virus. (A) Left anterior cervical chain demonstrates enlarged hypoechoic nodal mass. **(B)** Color Doppler demonstrates increased central vascularity.

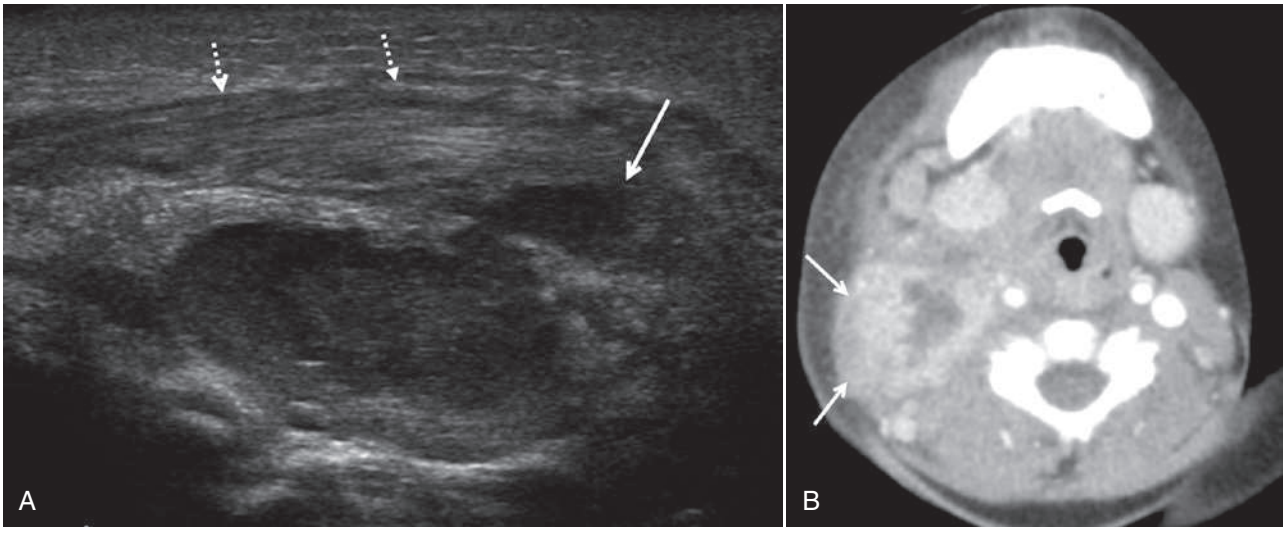

FIG. 48.57 Complicated Lymphadenitis With Myositis. (A) Ultrasound image shows a hypoechoic collection deep to the sternocleidomastoid muscle with extension of inflammatory material into muscle *(arrow).* The sternocleidomastoid *(dotted arrows)* is heterogeneous and swollen, consistent with myositis. **(B)** Axial contrast-enhanced computed tomography confirms presence of an abscess in the right upper neck and associated adjacent cellulitis and right sternocleidomastoid myositis *(arrows).*

TABLE 48.3 Age and Causes of Lymphadenopathy

Pediatric Category	Common Infectious Causes
Newborn	*Staphylococcus aureus* most common Occasionally, late-onset group B streptococci
Infant and child younger than 5 years	Group A streptococci and *S. aureus* Nontuberculous *Mycobacterium*
School-age child and adolescent	Epstein-Barr virus, cytomegalovirus, toxoplasmosis Tuberculosis or infectious mononucleosis

TABLE 48.4 Site of Node and Causes of Lymphadenopathy

Node Site	Common Causes
Occipital	Roseola, rubella, scalp infections
Periauricular	Eye infections, cat-scratch disease
Cervical	Streptococcal or staphylococcal adenitis or tonsillitis Mononucleosis, toxoplasmosis, malignancies, Kawasaki disease
Submandibular	Hodgkin or non-Hodgkin lymphoma, tuberculosis, histoplasmosis

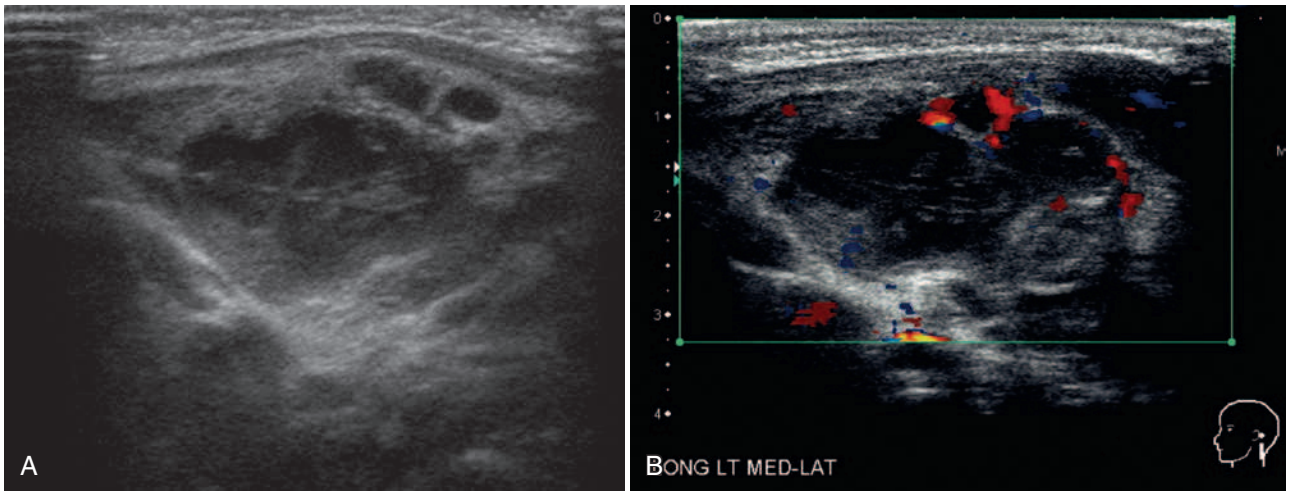

FIG. 48.58 Complicated Lymphadenitis With Abscess. (A) Gray-scale ultrasound image shows multilobulated, hypoechoic area with thick wall in the left upper cervical region. **(B)** Color Doppler image shows lack of vessels in the center of the collection but with peripheral vascularity.

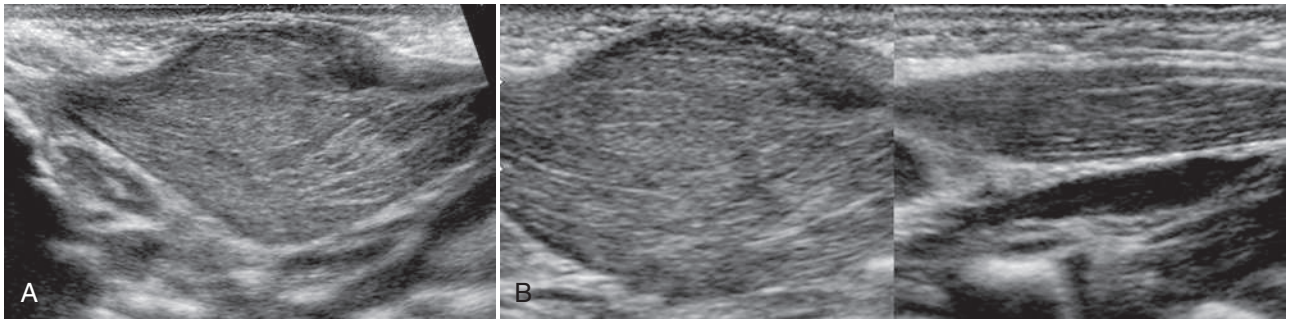

FIG. 48.59 Fibromatosis Coli. (A) Longitudinal ultrasound shows sternocleidomastoid muscle with enlargement, attenuation of striations, and mild increase in echotexture. **(B)** Longitudinal view shows comparison of abnormal left and normal right sternocleidomastoid muscle.

in immunocompromised children.[190] **Cat-scratch disease,** caused by the organism *Bartonella henselae,* manifests typically with a dominant unilateral node 2 to 4 weeks after a minor cat scratch, usually from a kitten.[187] **Histoplasmosis,** an infection prevalent in the Mississippi Valley and northeastern United States, manifests with cervical adenitis and a mediastinal mass and is typically asymptomatic but may be fatal if acutely disseminated.[190] FNA for cytopathology and culture may help confirm the diagnosis; these nodes often can persist for months, making distinction from neoplasm difficult.[45,190] Other inflammatory causes of lymphadenopathy in children include collagen vascular disease, sarcoid, immunologic deficiencies (HIV and chronic granulomatous disease), and postvaccination syndrome.[192] **Kawasaki disease,** a multisystem vasculitis of unknown origin, causes cervical adenopathy in 50% to 70% of patients with the disease.[193] Children with Kawasaki disease typically are presented before 5 years of age with enlarged unilateral lymph nodes greater than 1.5 cm in diameter.[193]

Fibromatosis Colli

Fibromatosis colli occurs in 0.3% to 1.9% of children. The etiology is still unclear but may involve intramuscular hemorrhage, venous occlusion, birth trauma, or in utero torticollis.[82,144,187,194] Pathologically, fibromatosis colli results from fibrosis and shortening of the sternocleidomastoid muscle, producing a soft tissue mass.[195] Peak incidence of presentation is 2 to 8 weeks after birth. Fibromatosis colli typically affects the firstborn boy with breech presentation or difficult delivery. Most infants have ipsilateral head tilt, contralateral chin deviation, and a palpable soft tissue mass.[196,197] From 6% to 20% of patients have associated musculoskeletal anomalies, including hip dysplasia and facial asymmetry.[49]

Sonography is the best technique to image the fibromatosis colli lesion. A normal sternocleidomastoid muscle demonstrates decreased echogenicity and long, thin, echogenic lines denoting the muscle fascicles along the length of the muscle. In the presence of fibromatosis colli, there is a focal or diffuse enlargement of the sternocleidomastoid, which typically shows homogeneous or heterogeneous increased echogenicity; however, mixed and hypoechoic lesions have been described[194,195] (Fig. 48.59). Focal lesions tend to involve the inferior third of the muscle.[194] In larger masses, there is distorted architecture with disruption of the normal muscle bundles.[195] Some cases may resolve spontaneously; however, physical therapy is the first line of therapy and

effective in 95% of children.[49] If head tilt persists, muscle release or tenotomy is performed to prevent development of significant craniofacial asymmetry and scoliosis.[5]

Masses

Pilomatricoma

Pilomatricomas (previously called "pilomatrixomas") are benign neoplasms arising from the hair follicles.[198] They are the second most frequently resected mass in the head and neck in children, after lymph nodes.[198] However, pilomatricomas are infrequently imaged because diagnosis is often made clinically. Imaging is often requested when the clinician is unfamiliar with the diagnosis or the lesion is in the preauricular region and needs to be excluded from an intraparotid mass or branchial apparatus remnant.[198,199] These lesions typically occur in the head and neck in children younger than 10 years, with a smaller peak occurring in the sixth and seventh decades.[199] Multiple pilomatricomas can be seen in the setting of Gardner syndrome, myotonic dystrophy, Steinert disease, Turner syndrome, and sarcoidosis.[199] Clinically, the lesions are firm nodules attached to the skin and are freely mobile over the subcutaneous tissues. On ultrasound, these lesions are frequently well-defined, hypoechoic lesions with mild internal heterogeneous echogenicity, speckled or chunky internal calcifications, and hypoechoic rim. The lesions may have internal vascularity demonstrated by spectral Doppler (Fig. 48.60). Rarely, when the lesion has ruptured, the mass has an irregular heterogeneous sonographic appearance, indistinguishable from other subcutaneous lesions.[200,201] There may be some perilesional hypoechogenicity, which is found to correlate with perilesional inflammation.[202] Complete surgical resection is curative.

Congenital Infantile Myofibromatosis

Congenital infantile myofibromatosis, although rare, is the most common fibrous tumor in the neonate and infant. The cause is unknown, although some familial cases have been reported.[203,204] Histologically, these lesions are composed of well-circumscribed nodules of plump spindle-shaped cells with staining characteristics intermediate between smooth muscle cells and fibroblasts. Often, there is central necrosis with focal calcifications.[203] These masses can occur in the skin, muscle, bone, or viscera or intracranially.[203,205,206] Infantile myofibromatosis lesions almost exclusively affect infants and young children, with 88% occurring before 2 years of age.[203] Over half of the lesions are identified in the neonatal period, and some cases are diagnosed prenatally.[203,207] The World Health Organization (WHO) classifies congenital infantile myofibromatosis into three types: the solitary type, also called "infantile myofibroma"; the multicentric form without visceral involvement; and the multicentric form with visceral involvement.[203,206] The solitary infantile myofibroma is more common in males (69%) and frequently occurs in the head, neck, and trunk. The multicentric form is more common in females (63%). The solitary form of infantile myofibromatosis and the multicentric form without visceral involvement generally have a good prognosis, and recurrence is rare. Surgical excision is the treatment of choice when feasible; chemotherapy is used in inoperable cases. Some cases may show spontaneous regression.[203]

On ultrasound, the lesions often show a lobulated heterogeneous appearance with central anechoic and hyperechoic structures (Fig. 48.61). Thick septations may separate the anechoic regions. The lesions are typically hypovascular.[205] CT and MRI are useful in assessment of disease extent and bone and soft tissue involvement and to screen for additional lesions.

Other, less common fibrous lesions that can occur in the head and neck include nodular fasciitis and inflammatory myofibroblastic tumor. These lesions have a nonspecific soft tissue mass imaging appearance and require additional imaging and biopsy for definitive diagnosis.

Malignant Neoplasms

Malignant neoplasms of the head and neck represent 12% of all childhood cancers. Lymphomas and sarcomas encompass 50%

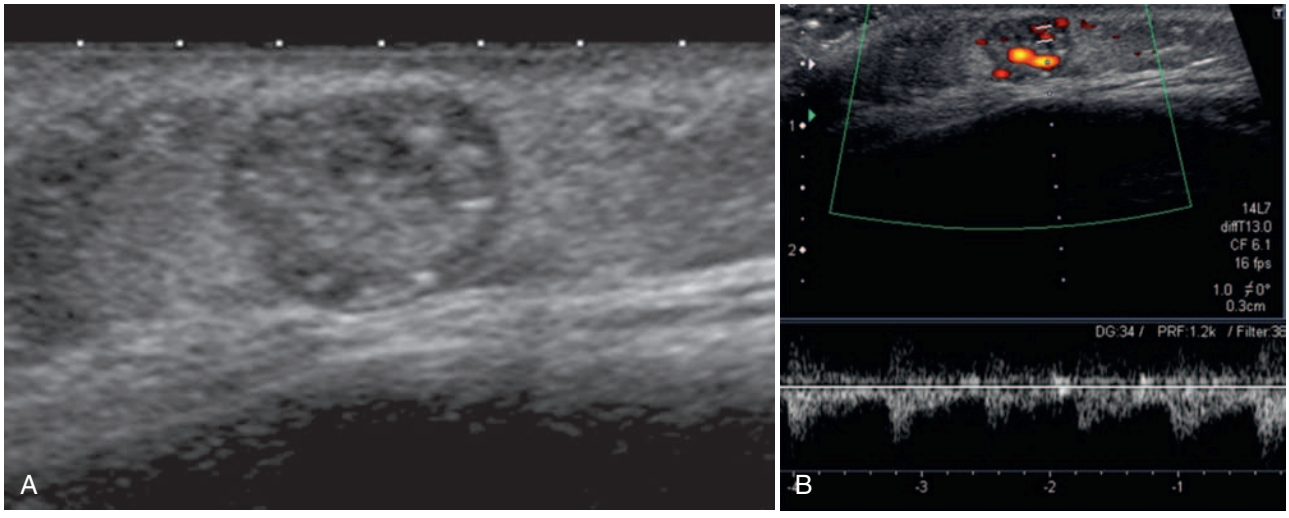

FIG. 48.60 Pilomatricoma. Seven-year-old girl with right scalp bump for 4 months. **(A)** Gray-scale ultrasound image shows a well demarcated heterogeneous hypoechoic lesion with internal echogenic foci. **(B)** Color Doppler image shows presence of internal vascularity within the lesion.

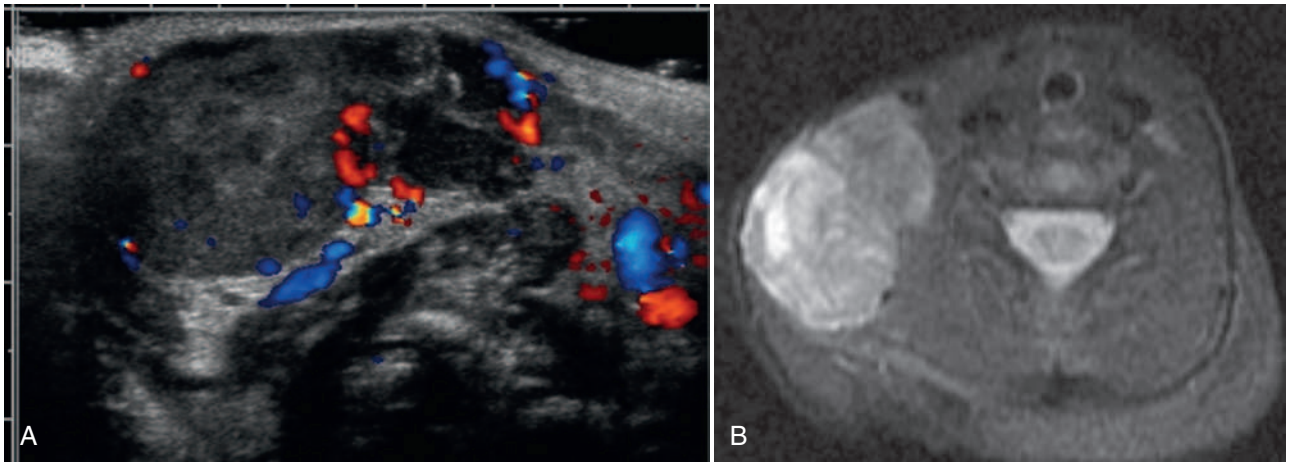

FIG. 48.61 Infantile Myofibroma. One-month-old with right neck mass since birth. **(A)** Ultrasound shows lobulated heterogeneous mass with solid and cystic components and predominantly peripheral vascularity. **(B)** On fat-suppressed T2-weighted magnetic resonance imaging, there is a heterogeneous lobulated hyperintense mass, with suggestion of cystic component superficially.

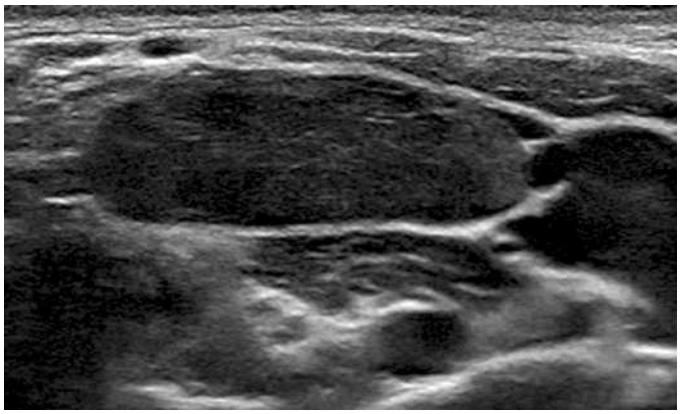

FIG. 48.62 Hodgkin Lymphoma. Sixteen-year-old with fullness in the right supraclavicular area. Ultrasound demonstrates large hypoechoic "pseudocystic" lymph node with loss of normal architecture, concerning for malignancy.

of these neoplasms. After puberty, lymphoma is the most common neoplasm.[187]

Lymphoma. **Lymphoma** is the most common head and neck malignancy, accounting for 27% of head and neck malignancies in children.[116] There is an equal 50% distribution of Hodgkin lymphoma and non-Hodgkin lymphoma.[144] Pediatric lymphoma has a greater association with Epstein-Barr virus and has a 2:1 male preponderance.[116] **Hodgkin lymphoma** typically manifests in adolescence as upper cervical and less frequently supraclavicular masses.[208,209] **Non-Hodgkin lymphoma** usually manifests at age 2 to 12 years with extranodal masses, diffuse nodal involvement, and rapid growth.[208,209] On gray-scale ultrasound, lymphoma often demonstrates a hypoechoic, pseudocystic appearance with sharp borders caused by reduced fat in lymph nodes, and lack of calcifications[210] (Fig. 48.62). Lymphomas do not necessarily follow malignant color vascular distribution, often with exaggerated hilar flow containing large, central branching vessels.[210] Extensive axillary and mediastinal adenopathy may be noted at presentation.[144] Imaging of these patients should include CT scans of the neck, chest, abdomen, and pelvis. Gallium-67 citrate scintigraphy and fluorodeoxyglucose–positron emission tomography (FDG-PET) are also helpful in further depiction of disease extent.[209]

Rhabdomyosarcoma. Rhabdomyosarcoma is a malignant tumor that arises from skeletal muscle cells. It is the third most common soft tissue tumor of childhood, after Wilms tumor and neuroblastoma, with 40% of cases originating in the head and neck.[116,144,211] About 85% of patients with rhabdomyosarcoma are younger than age 15 years.[212] A bimodal peak incidence occurs at age 1 to 3 years and in early adolescence.[74] The two main histologic types are embryonal and alveolar.[211] Embryonal rhabdomyosarcoma represents 60% of cases, is most common in the young child, and frequently arises in the head and neck.[212,213] Alveolar rhabdomyosarcoma, 20% of tumors, is more common in the older child and has a poorer prognosis. The most common sites of origin include the orbit, nasopharynx, middle ear or mastoid, and sinonasal cavity. These tumors tend to be aggressive, metastasize to lymph nodes, and rapidly invade bone, often with intracranial extension. Because of this aggressive course, MRI and CT scans are typically the first line of imaging to define the full extent of the lesion and exclude intracranial extension.[82] If a lesion is detected with ultrasound, however, the tumors typically are poorly vascularized and heterogeneous, with ill-defined hypoechoic areas caused by necrosis[74] (Fig. 48.63).

Neuroblastoma. **Neuroblastoma** is a neoplasm derived from the sympathetic neural crest cells, with the most common site of origin being the adrenal gland.[82] Primary cervical neuroblastoma can arise in the retropharyngeal area and is seen in only 5% of cases but usually has a favorable prognosis. Metastatic disease from a primary mass outside of the neck is more common and can occur in the cervical lymph nodes, calvaria, and facial bones.[74,214] Head and neck manifestations of neuroblastoma include Horner syndrome, proptosis, opsoclonus, and periorbital soft tissue masses.[215,216] Soft tissue or lymph node metastasis on ultrasound typically appears as an echogenic mass with or without calcification that displaces the great vessels of the neck and may extend into the mediastinum, spine, or skull base.[215] Expansile

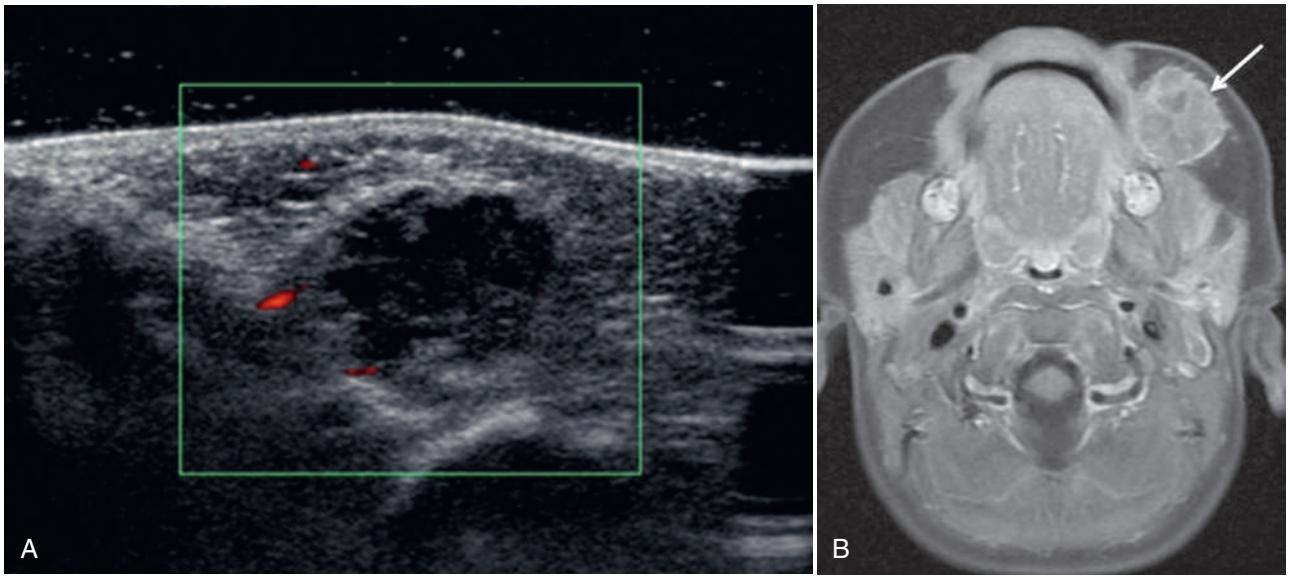

FIG. 48.63 Rhabdomyosarcoma. Five-month-old with hard mass in the left cheek. **(A)** Color Doppler ultrasound image shows a hypoechoic, hypovascular, irregular, poorly marginated mass in the left cheek. **(B)** T1-weighted postcontrast magnetic resonance image shows a heterogeneously enhancing mass in the left cheek *(arrow).* The mass had increased in size compared with the ultrasound performed 3 weeks beforehand.

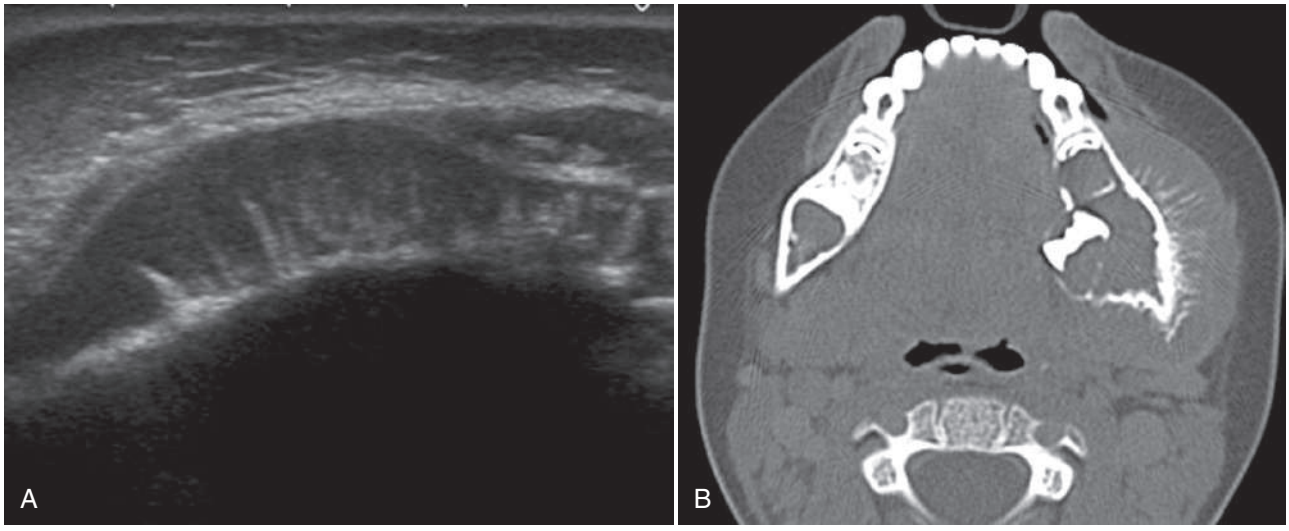

FIG. 48.64 Neuroblastoma. Three-year-old with left cheek swelling. **(A)** Ultrasound image shows a hypoechoic mass in the deep soft tissues of the left cheek inseparable from the left mandibular ramus, which is poorly defined and contains radiating echogenic bands consistent with aggressive periostitis. **(B)** Computed tomography image through the mandible shows expansion of the left hemimandible with aggressive periosteal reaction and soft tissue mass.

bony lesions may also manifest as facial or calvarial bumps referred for sonographic evaluation. Orbital metastasis of neuroblastoma is most frequent, but other facial bones such as the maxilla and mandible can be involved as well.[214] It is important to recognize underlying osseous involvement, which can be seen as radiating echogenic bands reflecting the aggressive periosteal reaction[214] (Fig. 48.64).

Other Neoplasms. An unusual soft tissue mass in the head and neck should raise concern for malignancy in children. Leukemic soft tissue deposits or granulocytic sarcomas (previously called "chloromas") should be considered (Fig. 48.65) in children with leukemia. Less common malignancies include other rare soft tissue sarcomas such as infantile fibrosarcoma, osteosarcoma, or Ewing sarcoma. The presentation and sonographic appearances may be nonspecific, and additional imaging with biopsy is frequently needed for diagnosis.

Metastatic Disease. Metastatic nodal disease is uncommon in pediatrics.[144] Neuroblastoma, rhabdomyosarcoma, and thyroid cancer are the most likely causes. Imaging usually cannot differentiate reactive, inflammatory, or neoplastic disease.[144,208] Clinical concerns for neoplasm include onset in neonatal period, rapid growth, skin ulceration, fixation to skin, and large, hard masses.[191] With ultrasound, suspicious findings have been defined. Tumor invasion typically starts in the cortex, so changes in the

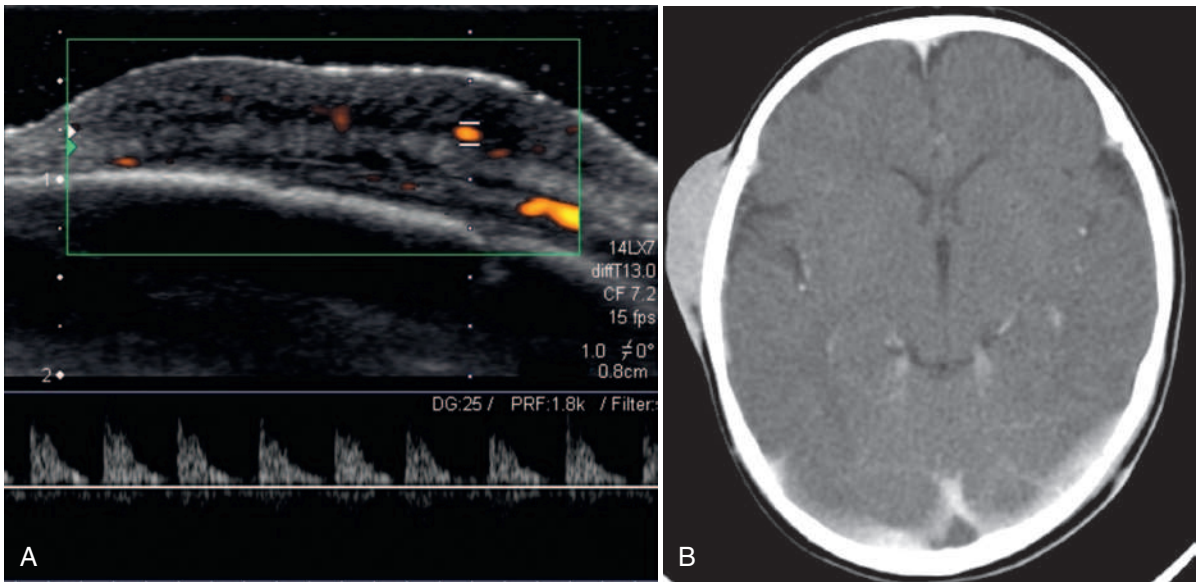

FIG. 48.65 Granulocytic Sarcoma (Chloroma). Three-month-old with right scalp bump for 2 weeks. **(A)** Ultrasound demonstrates an ill-defined mass that was not hypervascular, but had arterial waveforms. **(B)** Head computed tomography image shows avidly enhancing mass involving skin and soft tissues of the right scalp. Peripheral blood smear in this infant showed blast cells, and diagnosis was granulocytic sarcoma in the setting of acute myelogenous leukemia.

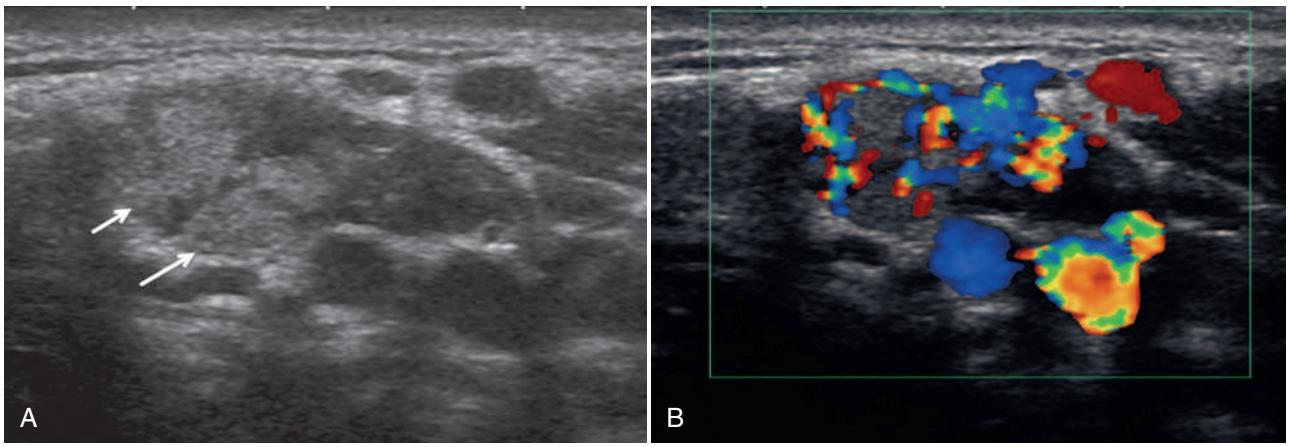

FIG. 48.66 Lymph Node Metastasis From Thyroid Cancer. (A) Enlarged node demonstrates lobular areas of increase echogenicity *(arrows),* poor definition of borders, and asymmetrical shape. **(B)** Color Doppler of the node shows increased asymmetrical vascularity in the area of abnormal echogenicity.

normal nodal shape from ovoid to round or asymmetrical are a concern.[43] Other imaging clues to malignant diagnosis include large size (>3 cm), heterogeneous echotexture, lack of echogenic hilum, and perinodal invasion.[156,158] Matted nodes and soft tissue edema are common findings in infectious or inflammatory disorders. Necrosis and calcification can be a sign of malignancy, but similar findings are noted in granulomatous lesions.[156] Thyroid nodal metastases are typically identified in the low neck and supraclavicular area.[217] On sonography, thyroid nodal disease demonstrates the same neoplastic findings, as well as increased echogenicity and cystic degeneration, with greater than 50% containing internal calcifications[185,217] (Fig. 48.66).

Color Doppler sonography of lymph nodes can be helpful when classified into four categories: hilar, peripheral, mixed, and avascular.[146,155] Color Doppler sonograms of benign lesions are typically avascular or hilar, whereas malignant nodes demonstrate peripheral or mixed vascular flow.[106,155,156] High Doppler RIs and pulsatility index have been noted in neoplastic adenopathy; however, other studies have not supported this finding. Therefore the accuracy of this technique is controversial.[146] Ultrasound is useful in guiding FNA biopsy.[156,160]

CHAPTER 49

The Pediatric Spinal Canal

Ilse Castro-Aragon, Deborah Levine, and Carol M. Rumack

SUMMARY OF KEY POINTS

- Spine ultrasound is used in the evaluation of neonates and infants (up to 3-4 months) with high- or moderate-risk cutaneous manifestations of closed spinal dysraphism, clinical signs of a tethered cord, or congenital anomalies that are frequently associated with spinal dysraphism.
- Additional indications for spine ultrasound include evaluation after failed lumbar puncture, guidance for lumbar puncture, and intraoperative guidance.
- The conus medullaris is usually at L1-2 and can extend to the superior endplate of L3.
- Neural tube defects can be open (nonskin-covered) or closed (skin-covered) spinal lesions, with or without a subcutaneous mass or other cutaneous stigmata.
- Understanding anatomy, embryology, normal variants, and scanning technique is important for accurate diagnosis.

CHAPTER OUTLINE

EMBRYOLOGY
SONOGRAPHIC TECHNIQUE AND NORMAL ANATOMY
SPINAL ANOMALIES
Tethered Spinal Cord
SPINAL DYSRAPHISM
Open Spinal Dysraphism
Closed Spinal Dysraphism With a Subcutaneous Mass
Closed Spinal Defects Without a Subcutaneous Mass
Simple Dysraphic States
Complex Dysraphic States (Disorders of Gastrulation)
TUMORS
HEMORRHAGE AND INFECTION
ARACHNOID CYSTS
INTRAOPERATIVE AND OTHER USES OF SPINAL SONOGRAPHY

In normal infants, the spinal canal and contents can be visualized because the nonossified state of the posteromedian intraneural synchondrosis provides an ample acoustic window (Fig. 49.1). The abnormal configuration of vertebral bodies in infants with certain dysraphic abnormalities opens the window even further. Although magnetic resonance imaging (MRI) is considered the examination of choice when evaluating the spine in children and adults, sonography of the spine in the newborn period can reveal details that are difficult to define with MRI. Several authors have recommended ultrasound as the initial imaging modality in patients younger than 6 months suspected of having a spinal disorder.[1] Others have recommended ultrasound in asymptomatic infants with cutaneous stigmata and MRI in the presence of deficits and cutaneous stigmata.[2] Fatty masses, cord position, and relationship of the cord to any mass, as well as presence or absence of nerve root pulsations, can be seen clearly.

EMBRYOLOGY

For a better understanding of spinal pathology, a general knowledge of the process of spinal cord and vertebral column formation is helpful. The trilaminar disc is formed by **gastrulation.** This is followed by **primary neurulation,** which forms the spinal cord from cervical through S5 sacral segments.[3] Distal to this level, the conus and the filum terminale are formed by a process termed **canalization and retrogressive differentiation** of the caudal cell mass, also referred to as **secondary neurulation.**

During weeks 2 and 3, the bilaminar embryonic disc (formed by layers of endoderm and ectoderm) is converted into a trilaminar disc through the process of **gastrulation.** The process starts with the appearance of the primitive streak, which forms caudally, adjacent to the area that eventually becomes the cloaca. The primitive streak actively forms mesenchymal cells that give rise to the mesoderm. Some mesenchymal cells migrate laterally, and the paired anlagen eventually fuse in the midline to form the notochord process, which contains a central lumen (notochordal canal).[4,5] The neuroenteric canal, which is the proximal part of the notochordal canal, normally obliterates when development of the notochord is complete.

The nervous system develops from the neural plate, which differentiates from the ectoderm overlying the notochord and paraxial mesoderm.[6] The neural plate is composed of neural ectoderm and is contiguous with the cutaneous ectoderm on both sides. The cells at the junction of the neural and cutaneous

ectoderm differentiate into neural crest cells. Primary neurulation (closure of the neural tube) begins during days 22 and 23. The lateral margins of the neural plate thicken to form the neural folds, and the thinner midline of the neural plate forms the neural groove. The neural folds bend dorsally, converge, and fuse in the midline to form the neural tube. The process of tube closure begins in the region of the craniocervical junction and extends cephalad and caudad with several fusion sites, and the posterior neuropore closes last by day 27. After closure of the neural tube, the overlying ectoderm separates from the neural tissue and fuses in the midline, forming a continuous ectodermal covering of the neural structures; this process is known as **disjunction.** After the neural tube has closed and separates from the superficial ectoderm, mesenchyme also migrates dorsal to the neural tube and forms precursors of the neural arches, in addition to meninges and paraspinous muscles. At the time of closure, the lateral edges of the neural plate, which form the neural crest cells, are extruded from the neural tube, move to the dorsum of the neural tube, and eventually migrate laterally and give rise to the sensory dorsal root ganglia, the autonomic nervous system, and other structures[7,8] (Fig. 49.2).

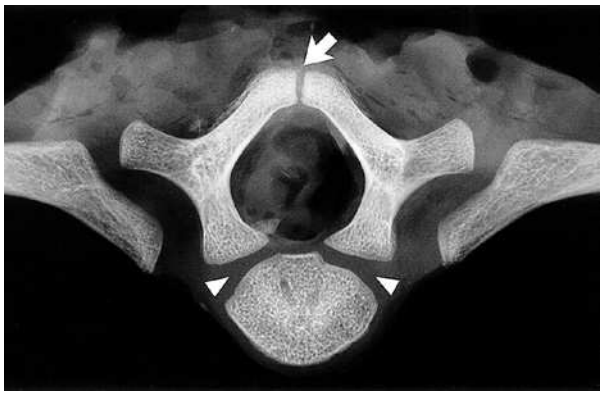

FIG. 49.1 Cartilaginous Gaps in Vertebral Ring Allow Penetration by Scanning Beam. Transverse radiograph through a thoracic vertebral body specimen from an infant demonstrates the cartilaginous posterior median intraneural synchondrosis *(arrow)* and the paired neurocentral synchondroses *(arrowheads).* (Courtesy of Dr. Paul Kleinman, Children's Hospital, Boston.)

The distal neural tube is formed by secondary neurulation. Distal to the posterior neuropore, undifferentiated cells from the primitive streak form the caudal cell mass (day 30). Microcysts develop and coalesce to form a tubular structure that unites with the more distal neural tube that was formed by primary neurulation. At 38 days the process of retrogressive differentiation occurs, with decrease in size of the cell mass and central lumen of the caudal neural tube. The segment formed by this process eventually forms the **filum terminale** and **cauda equina** and ascends to form the **conus medullaris** and **ventriculus terminalis.** The regression process continues into the postnatal period with minimal migration, and the conus reaches the adult level of L1-2 by approximately 3 months of age.[9]

The spinal column develops in parallel with the spinal cord beginning at the future occipital region and sweeps caudally.

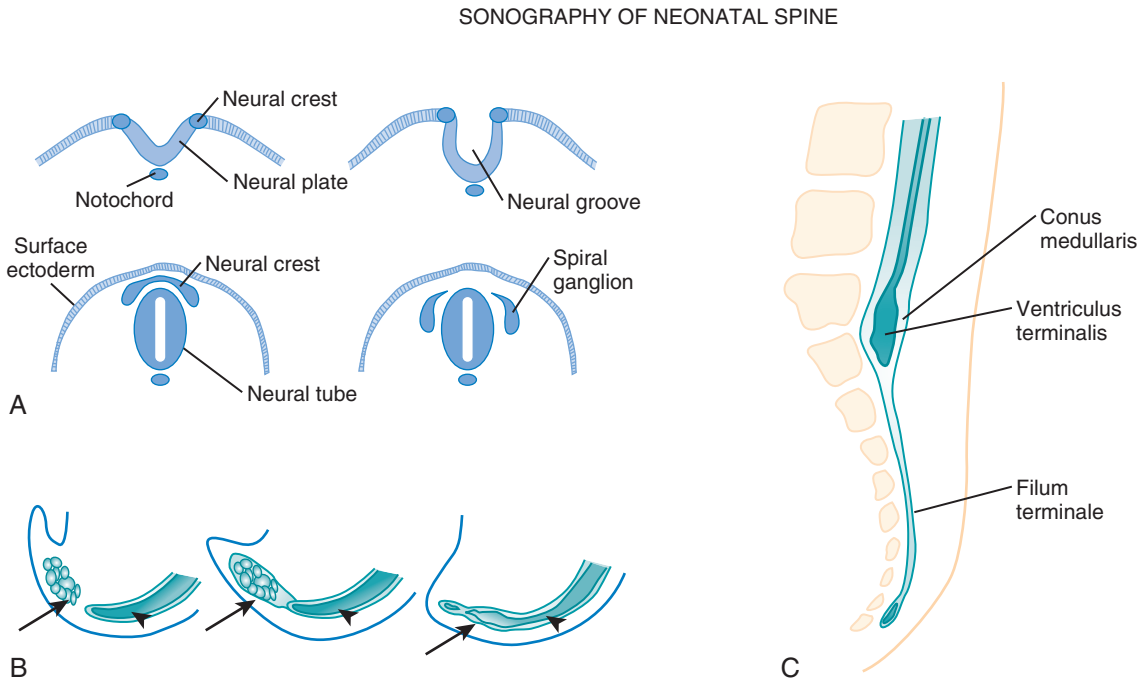

FIG. 49.2 Three Stages of Spinal Cord Development. (A) Neurulation (closure of neural tube) is the process of progression from neural plate to neural groove to neural tube. **(B) Canalization** occurs when multiple microcysts form and coalesce in caudal cell mass *(arrows),* which fuses to distal neural tube *(arrowheads),* forming the primitive spinal cord. **(C) Retrogressive differentiation** (programmed cell death) is the process by which the caudal cell mass and neural tube regress in size to form the **fetal conus medullaris, ventriculus terminalis,** and **filum terminale.** (**A** with permission from Sadler T. Langman's medical embryology. 5th ed. Baltimore: Lippincott; 1985; **B** and **C** with permission from Barkovich AJ. The nervous system. Pediatric neuroimaging. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2000.[8])

The mesenchyme lateral to the closing neural tube organizes into somites. The dorsolateral portion of each somite will become skeletal muscle and dermis, whereas the ventromedial portion will become the cartilage, bone, and ligaments of the vertebral column. The formation of the vertebrae at the caudal end of the embryo proceeds by a different process with a mass of cells of notochord, mesenchyme, and neural tissue that divides into somites.

One can readily see how failure of completion or error in organization at any of these levels might lead to anomalies in spinal formation. Complete nondisjunction of the cutaneous ectoderm and the neuroectoderm prevents mesenchymal migration and results in a nonskin-covered posterior dysraphism such as **myelomeningocele.** A focal nondisjunction results in a focal **ectodermal-neuroectodermal tract** or **dermal sinus tract.** In focal unilateral premature disjunction, the neural tube separates from cutaneous ectoderm before complete neural tube closure, and this allows access of mesenchymal cells to the neural groove and ependymal lining. The mesenchyme differentiates into fat and develops skin-covered abnormalities such as **lipomyelomeningoceles. Filum terminale lipomas** likely occur from abnormal development of the caudal cell mass. The caudal cell mass forms in close proximity to the **cloaca** (origin of the lower genitourinary and anorectal structures), which explains the high incidence of **lumbosacral hypogenesis** and **tethered spinal cords** in patients with anorectal and urogenital anomalies. Aberrations in gastrulation, which can interfere with primary and/or secondary neurulation, explain **diastematomyelia, neurenteric fistula, caudal agenesis,** and **segmental spinal dysgenesis.**[10]

SONOGRAPHIC TECHNIQUE AND NORMAL ANATOMY

In general, infants are scanned in the prone position, although it is possible to scan in a decubitus position while the infant is fed with a bottle or even breast-fed. A much better scan will be obtained if the caregiver is allowed to feed a struggling infant and return to the prone position in the postprandial state. A pacifier dipped in glucose can also be used to calm the patient during imaging. If possible, the lumbar lordosis is accentuated by elevating the shoulders, to aid determination of vertebral body level by defining the lumbosacral junction.[11] For an accurate definition of the level of the cord termination, an anteroposterior (AP) and lateral spine radiograph using a metal marker at the level of the end of the spinal cord by ultrasound can aid in documentation of the level, because the estimated level on ultrasound may be in error in the presence of spinal anomalies such as six lumbar vertebrae. In addition, elevation of the upper trunk and head can further distend the dependent caudal portion of the thecal sac. An excellent alternative approach is to place a rolled blanket under the lower abdomen in a prone position, to widen the acoustic window by separating the spinous processes.[12] The posterior elements of the spine ossify after birth (from caudally to cranially). There is reduced penetration of sound in the lumbar spine at 3 to 4 months, and in most patients the quality significantly decreases after 6 months. In the older infant and child, parasagittal scanning can better visualize the canal contents relative to midline sagittal scanning.[13]

High-frequency linear transducers allow visualization of fine details of anatomy, with the additional aid of saved clips and extended–field-of-view images, which are useful for counting vertebral segments (Fig. 49.3). A split screen can document the landmarks used for counting vertebral bodies and determining the level of the conus medullaris. Movement of the spinal cord and cauda equina with crying, respiration, and the cardiac cycle is seen in real time and documented with saved clips (Video 49.1). The normal movement can be seen in newborns but might not be noticeably brisk until approximately 2 postnatal months.[12] Although different indications for imaging may require varying views, it is best to scan the entire back in both the longitudinal and the transverse planes, with right and left labels on transverse images (which can be confusing when scanning in the prone position). This allows a thorough search for contiguity of vertebral body rings, an assessment of contour and position of the spinal cord, and a survey of the paraspinous musculature and overlying skin. A standoff pad or a good amount of gel can be used to evaluate a subcutaneous mass or other structures in the near field.

If the acoustic window is small, as occurs during the evaluation of the craniocervical junction, a smaller-footprint curvilinear, sector, or small linear transducer allows scanning at the base of the skull and through the foramen magnum. This view allows visualization of the cisterna magna, brainstem, inferior cerebellum, and proximal cervical cord[14-16] (Fig. 49.4).

The fine anatomic display possible with sonography has been shown in correlative studies between ultrasound and specimen anatomy.[17] Fig. 49.5 demonstrates the basic landmarks that should be visible. The cartilaginous spinous processes are hypoechoic (Fig. 49.6), and the epidural space, which contains a variable amount of fat, is visible anterior to the posterior dura mater. The dura is seen on longitudinal images as an echogenic line parallel to the posterior anechoic subarachnoid space that is anterior to the spinal cord. The cord is surrounded anteriorly by anterior subarachnoid space and echogenic vertebral bodies. The cord is hypoechoic, whereas the interfaces created by the fanning nerve rootlets are echogenic.

The central echo complex in the otherwise hypoechoic cord has been shown with ultrasound and histoanatomic correlation to be produced by the interface between the myelinated ventral white commissure and central end of the anterior median fissure.[18,19] Images obtained with high-frequency transducers sometimes reveal a column of fluid within the center of the central echo complex within the conus medullaris. The **ventriculus terminalis** is a persistent fetal terminal ventricle and appears as smooth dilation of the central echo complex within the conus medullaris. This normal finding is seen often in the neonate and regresses or disappears soon after birth (Fig. 49.7).[12,20]

The normal **filum terminale** is visible and mobile with cerebrospinal fluid (CSF) pulsations. The center of the filum tends to be relatively hypoechoic compared with its bright outer margins. The filum terminale extends from the tip of the conus medullaris, crosses the subarachnoid space, and inserts on the first coccygeal vertebral body. The filum is surrounded by the

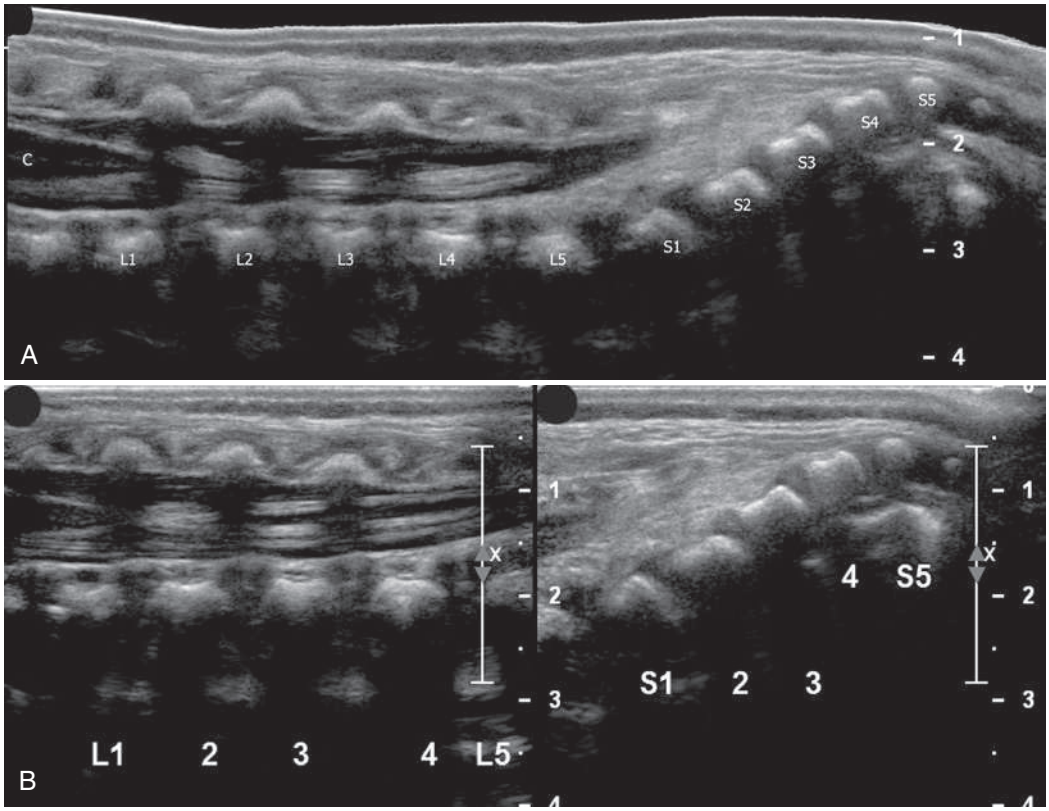

FIG. 49.3 Lumbosacral Spine in a 2-Week-Old Infant. (A) Extended–field-of-view image reveals detailed anatomy of the course and contour of the lumbosacral spine. The hypoechoic cord is visible *(C),* sacral and lumbar vertebral bodies are labeled, and the lumbosacral junction can be determined where S1 tilts posteriorly. **(B)** Split image in the same patient. The same landmarks can be documented with a dual image. Often this is technically easier than the panoramic view. See also Video 49.1.

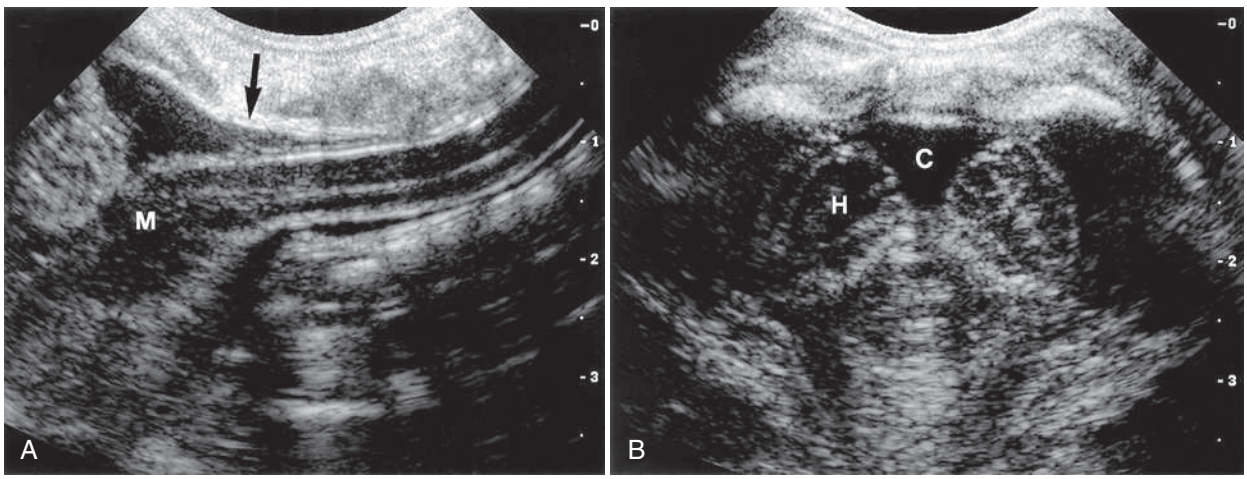

FIG. 49.4 Brainstem, Cisterna Magna, and Cerebellar Hemispheres. (A) Sagittal view of the craniocervical junction using the foramen magnum as a window. The arrow indicates the posterior margin of the foramen magnum. Visualization of the cerebellum and medulla *(M)* is also possible on this view. **(B)** On transverse view, the cisterna magna *(C)* and cerebellar hemispheres *(H)* are well shown.

cauda equina, and the normal thickness is 1 to 2 mm[21] (Fig. 49.8, Video 49.2). Sometimes it can be difficult to separate the filum terminale from the nerve roots in the cauda equina to obtain a good measurement. **Filar cysts** (Fig. 49.9) can be seen within or on the filum terminale and caudal to the conus medullaris and should be considered a variant of normal development when there is no other suggestion of pathology.[7,22] The incidence of filar cyst is up to 11.8% in the newborn period.[20] Detection is inversely related to age up to 6 months. These cysts are not seen on most neonatal or adult MRI studies. There is no proven explanation for their origin; possibilities include a true cyst, a pseudocyst, an embryonic remnant, or a developmental phenomenon that regresses with age. They do not require further imaging or follow-up.[20]

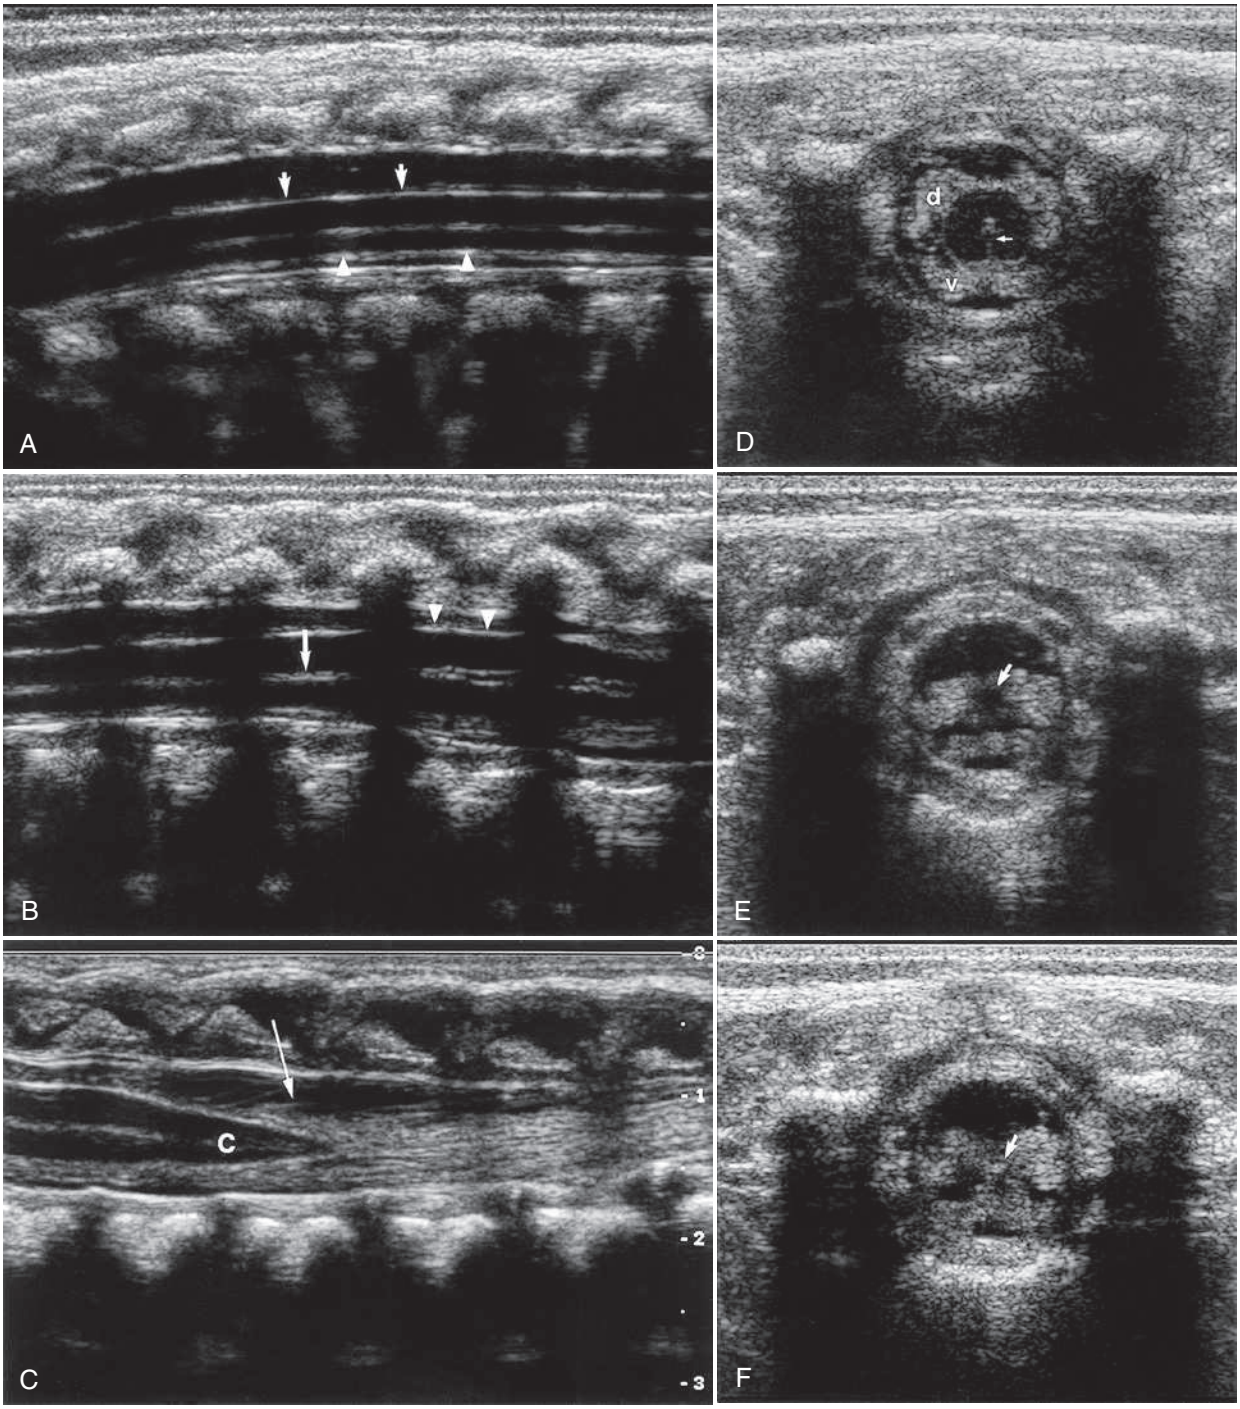

FIG. 49.5 Normal Spinal Cord. (A) Sagittal view shows posterior aspect *(arrows)* and anterior aspect of the thoracic spinal cord *(arrowheads).* Normal thoracic spinal cord is more anteriorly positioned within the vertebral canal than the more distal spinal cord. **(B)** Normal widening of the lumbar spinal cord *(arrowheads).* The central echo complex is visible as an echogenic line *(arrow).* **(C)** Tip of the conus medullaris *(C)* should taper gradually. Individual nerve rootlets are visible *(arrow).* **(D)** On transverse view of the lumbar spinal cord, dorsal *(d)* and ventral *(v)* nerve rootlets, as well as the anterior median fissure, are visible *(arrow).* **(E)** Transverse view near the tip of the conus medullaris demonstrates the hypoechoic substance of the cord *(arrow)* in the center of the more echogenic nerve rootlets. **(F)** The beginning of the filum terminale is seen as a central, slightly echogenic focus *(arrow)* in the transverse plane.

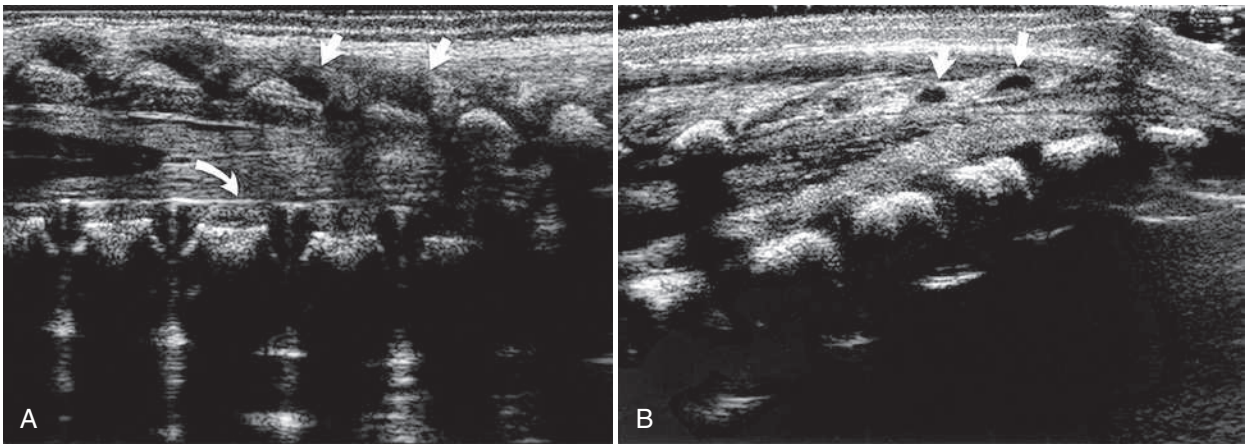

FIG. 49.6 Normal Vertebral Sonographic Anatomy. (A) Sagittal view of the distal lumbar spine shows fine definition of vertebral body anatomy. The cartilaginous tips of the posterior spinous processes are visible *(arrows),* as well as the posterior margin of the cartilaginous portion of the L3 vertebral body *(curved arrow).* **(B)** More distal sagittal view shows the cartilaginous posterior elements of the midsacral spine *(arrows).*

FIG. 49.7 Fluid Within Central Canal (Ventriculus Terminalis). Sagittal view of the lumbar spine. This is a common, normal variant *(arrow)* observed in many infants.

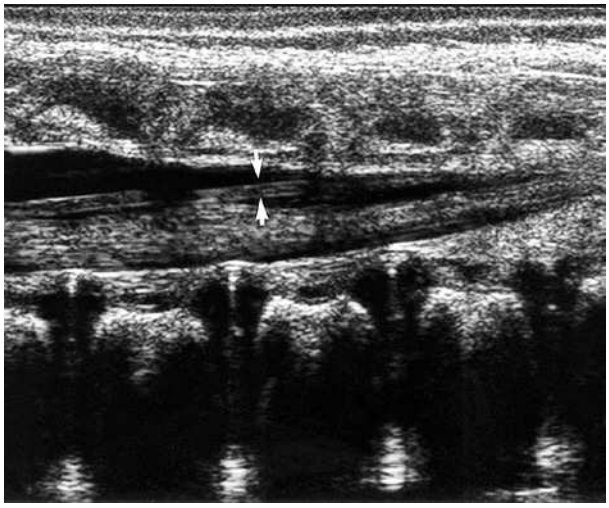

FIG. 49.8 Normal Filum Terminale. This can be clearly distinguished from the nerve roots and should be less than 2 mm in diameter *(arrows).* The external edges of the filum are relatively bright compared with the central portion of the filum. See also Video 49.2.

Some infants have more prominent epidural fat, which also should be considered a normal variant unless other signs suggest an abnormal fatty mass (Fig. 49.10). Color Doppler ultrasound can help localize the epidural venous plexus, anterior spinal arteries, and paired posterior spinal arteries. Malposition, compression, or distention of these vessels may help to distinguish an abnormal mass within the vertebral canal from normal nerve rootlets or epidural fat.

Determination of the **position of the tip of the conus medullaris** is the most common indication for spinal ultrasound and should always be included in a neonatal spine sonographic examination. Approaches, all of which presume normal anatomy, include (1) finding the lowest rib (presumably the 12th rib) on lateral parasagittal scanning, following medially to the vertebral body and counting down from this level; (2) defining the longitudinal lumbosacral junction where S1 is the first vertebral body that tilts posteriorly (similar to a lateral spine radiograph) and using that as a reference[12]; (3) defining the distal end of the thecal sac which is usually at S2[12]; and (4) counting upward from the last ossified "sacral" vertebral body. The fourth approach can be inaccurate because of the great variability in the ossification of the coccygeal vertebral bodies.[23] In general, ossified coccygeal vertebral bodies have a rounded central nucleus, whereas sacral ossification centers take on a more squared contour. If at least two methods are applied and the vertebral assignment is the same, it is likely correct. If these methods prove problematic owing to variants of ossification or segmentation anomalies, the ultrasound transducer can be used to locate the tip of the conus, mark the skin at that level with a **radiopaque BB marker,** and obtain AP and lateral radiographs of the entire spine to determine the corresponding vertebral level (Fig. 49.11). If this is done, a lateral film is helpful because distortion from beam angulation is less problematic. The AP spine view allows counting of ribs and vertebral bodies with accuracy. The degree of ossification of the coccyx can also be assessed with this film. As the sonographer gains experience in scanning the neonatal spine, the variability in the shape of the cartilaginous coccyx becomes evident (Fig. 49.12 and Video 49.3).

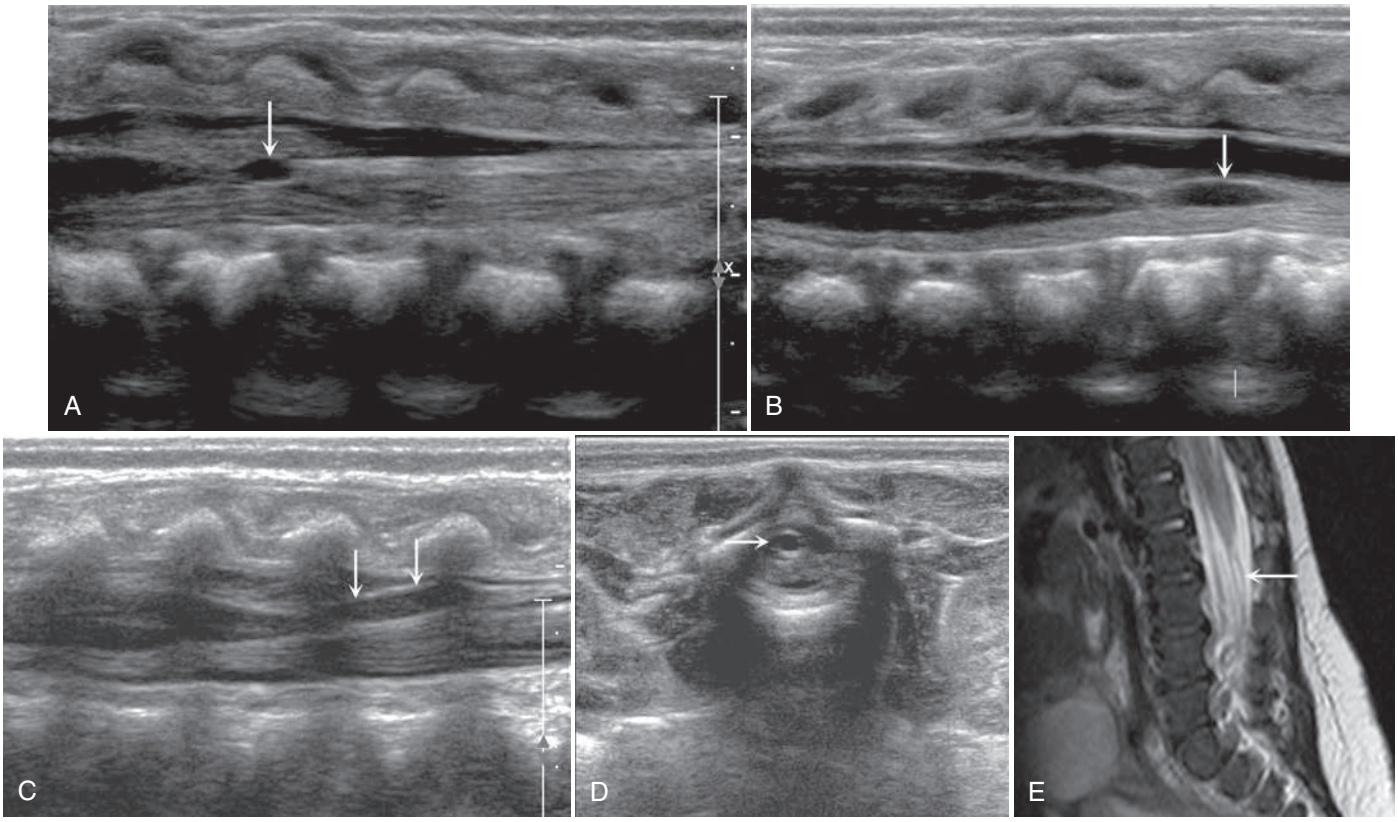

FIG. 49.9 Filar Cysts. (A) Small round cyst *(arrow)* distal to the conus medullaris is a normal variant. The rest of the filum terminale is seen distal to the cyst, has slightly echogenic borders and central hypoechogenicity, and can be distinguished from the nerve roots of the cauda equina. **(B)** Another patient with an oval filar cyst *(arrow);* in another patient, **(C)** and **(D)** sagittal and axial views of the spine and **(E)** T2-weighted sagittal magnetic resonance image show a large filar cyst *(arrow)*.

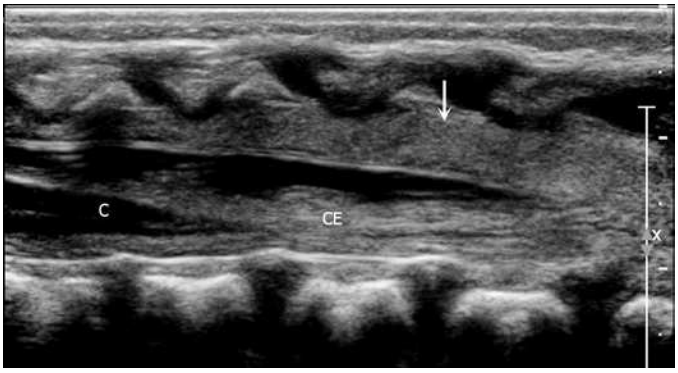

FIG. 49.10 Normal Epidural Fat. Epidural fatty layer can sometimes be prominent *(arrow)*. Note the distal cord *(C)* and the cauda equina *(CE)*.

The normal conus is typically located in the ventral thecal sac on prone position, between L1 and L2 and occasionally extending to the superior endplate of L3. However, the range of normal varies in children from T10-T11 to the superior end plate of L3.[24] On MRI, the position of the conus ascends from 20 to 38 weeks. The mean conus position is L4 from 21 to 25 weeks, L3-4 from 26 to 30 weeks, L2-3 from 31 to 35 weeks, and L2 after 36 weeks.[25] A conus position at the third lumbar vertebra (L3) or above by the beginning of the third trimester should be considered normal.[26-28] A conus tip at the L3-L4 disc space level is too low.[24,29-35] Therefore a conus position of L3 proper in the late preterm infant is equivocal, requiring follow-up.[8,32] Factors other than conus position alone need to be considered when determining the need, if any, for further evaluation with MRI. When an experienced spine sonographer finds that the tip of the conus medullaris is positioned over the upper third of the L3 vertebral body with normal nerve root pulsation, and if no other abnormalities are noted and the physical examination findings are not suspicious, we do not generally recommend further imaging.

If subsequent MRI is deemed prudent after an equivocal ultrasound examination, many pediatric neuroradiologists support waiting until the infant is at least 3 months old because there is poor tissue contrast (low signal to noise) in the newborn spine.[36] Greater anatomic detail can be displayed with MRI in the larger infant using standard techniques.

As vertebral ossification progresses and the infant becomes more active, fewer details are visible with ultrasound.

SPINAL ANOMALIES

Tethered Spinal Cord

Tethered cord syndrome is a clinical condition that can be seen with a spectrum of pathologic causes that tether the spinal cord in a lower-than-normal position and may lead to neurologic,

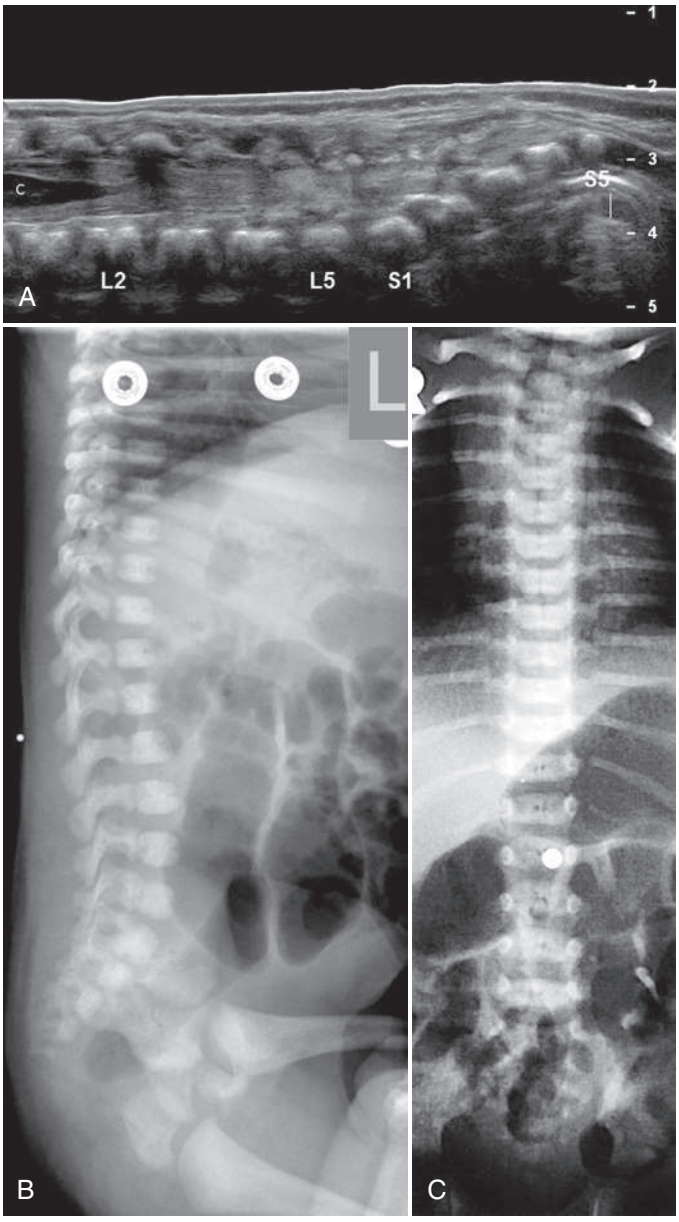

FIG. 49.11 Determining Level of Conus Medullaris. When it is difficult to determine the level of the conus medullaris by ultrasound alone, plain radiographs are often helpful. **(A)** Panoramic view shows round ossification center at S5; margins of other sacral vertebral bodies are square. BB is placed on the skin of the infant at L2, at the position of the tip of conus medullaris during sonography. **(B)** Lateral radiograph of the lower thoracic, lumbar, and sacral spine shows the marker at L2, confirming the counting done by ultrasound. Notice the inferior ribs at T12, the normal lumbosacral junction, and the round ossification at S5. **(C)** Frontal radiography in another patient. A BB was placed on the skin of an infant corresponding to the position of the tip of the conus medullaris during sonography, to help determine the associated vertebral body level.

musculoskeletal, urologic, or gastrointestinal abnormalities (Fig. 49.13). The clinical signs and symptoms are age dependent and develop as a complication of open neural tube repair or as the presentation of a closed spinal dysraphism. Spinal cord injury is theorized to result from cord ischemia caused by excessive tension or stretching of nerve fibers. The signs and symptoms have also been described in patients that have a conus medullaris in a normal position, although they usually have cutaneous stigmata, vertebral anomalies, or intradural lipomas.[9]

The treatment of a tethered cord in symptomatic patients is surgical release with total or near-total resection of the tethering mass and depending on the lesion repair of the dura. In asymptomatic patients with imaging abnormalities or in symptomatic patients with normal imaging, there is controversy with regard to treatment.[37-41]

Because newborns may have no neurologic deficits on presentation, the role of ultrasound is to identify the tethering lesion or condition and evaluate the position of the conus medullaris in patients with high- or intermediate-risk cutaneous markers. High-risk cutaneous markers include **focal hypertrichosis, infantile hemangioma, atretic meningocele, dermal sinus tract, subcutaneous lipoma, caudal appendage,** and **segmental hemangiomas** in association with **LUMBAR syndrome** (lower body hemangiomas, urogenital abnormalities, ulcerations, myelopathy, bony defects, anorectal malformations, arterial anomalies, and renal anomalies). Intermediate-risk cutaneous markers include **capillary malformations** (**salmon patches** or **port-wine stains**). Low-risk cutaneous markers do not require routine neuroimaging or follow-up and include coccygeal dimples, light hair, isolated café au lait spots, mongolian spots, hypomelanotic and hypermelanotic macules or papules, and deviated or forked gluteal clefts.[42]

Coccygeal dimples are present in 2% to 4% of newborns and are defined as a soft tissue depression located up to 2.5 cm above the anus, in proximity with the coccyx. They can be classified as shallow if the bottom is visible or deep if the bottom is not visible. A study of 84 infants with deep and shallow coccygeal dimples who underwent MRI at a mean age of 1 year identified **fibrolipomas** of the terminal filum in 16.7% of patients. The fibrolipomas were more common in patients with deep dimples. In addition, these researchers found a 7% incidence of a low conus, defined as conus below the L3 vertebral body.[43] A study of 50 neonates who underwent ultrasound examination and MRI showed no pathologic findings in infants with simple coccygeal dimples and deviated gluteal folds. In a group of 109 infants with simple dimples, ultrasound revealed no pathologic findings that needed surgery, but did show 20 cases of low dermal tracts, which had no continuity with intraspinal structures and no cord tethering.[44] These likely fibrous tracts track anteriorly and inferiorly from the dimple to the coccyx tip (see Fig. 49.12A).[12] In the group of 42 infants with deviated or split gluteal folds that were not caused by an underlying soft or bony mass, ultrasound revealed no pathologic findings.[44] Therefore in low-risk patients, if the need for imaging is questionable but imaging is desired, ultrasound provides a reliable screening tool.[44,45]

SPINAL DYSRAPHISM

The term "spinal dysraphism" stems from the Greek roots meaning bad ("dys") seam or suture ("raphe") and was first used in the literature by Tulpuis in 1641.[46] Currently, the **dysraphic lesions** describe a broad group of abnormalities that might be explained by an error in the embryologic processes of gastrulation, primary

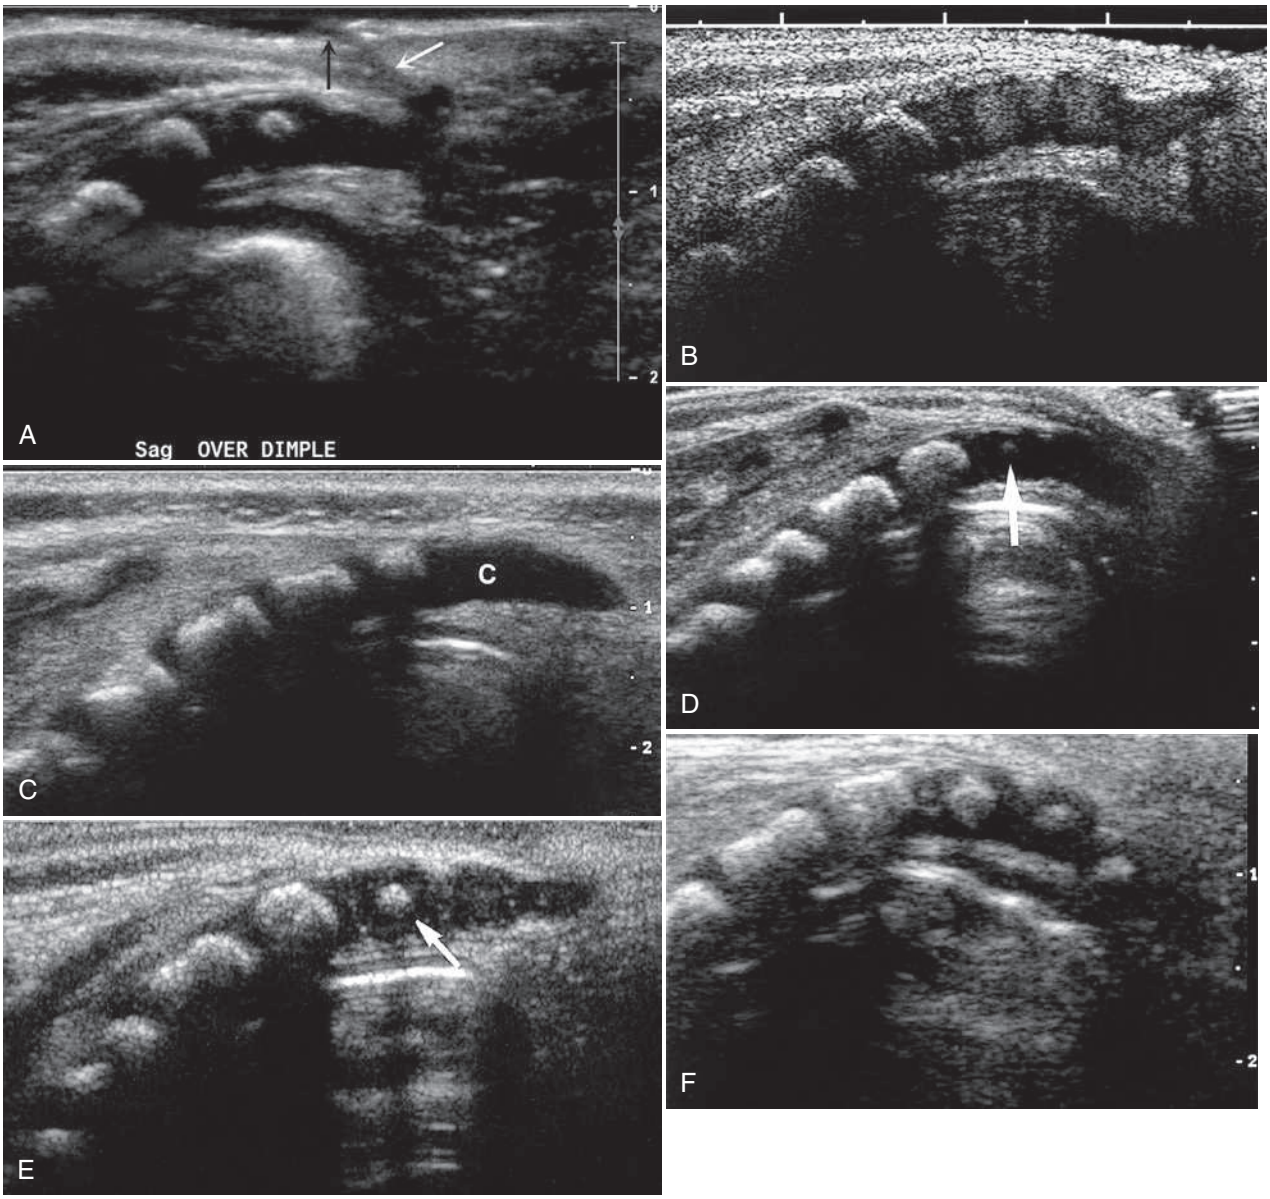

FIG. 49.12 Variation in Normal Development of Coccyx in Six Infants. (A) Dorsal curve of the distal coccyx. Notice coccygeal skin dimple *(black arrow)* and hypoechoic tract in the subcutaneous tissue *(white arrow)* that extends to the tip of the coccyx. See also Video 49.3. **(B)** The coccygeal curve is less severe. **(C)** Smooth, classic curve of the cartilaginous coccyx *(C)*. **(D)** A tiny ossification nucleus is seen in the C1 segment *(arrow)*. **(E)** Larger focus of ossification *(arrow)* and **(F)** ossification nuclei are visible within all coccygeal segments.

neurulation, disjunction, canalization, and/or retrogressive differentiation of the caudal cell mass. They can be grouped based on clinical characteristics: nonskin-covered open neural tube defects or skin-covered closed spinal lesions with or without a subcutaneous mass or other cutaneous stigmata.

The terminology used to describe this spectrum of anomalies can be confusing because there is a tendency to use the terms imprecisely and there are several proposed classifications. This can lead to confusion in interpreting the literature, inaccurate assumptions about prognosis, inappropriate management, and confusion in analyzing results of treatment.[39,47] Posterior **spina bifida** refers to incomplete closure of the posterior neural arch of a vertebra. It may be isolated, incidental, and of no clinical significance. The normal laminae at L5 remain unfused until 5 to 6 years. In the past, "spina bifida aperta" was used to refer to open spinal dysraphism and "spina bifida occulta" to refer to closed spinal dysraphism, but these terms are no longer favored.

A **placode** is a segment of flattened embryonic neural tissue that did not undergo normal neurulation. A placode can be terminal, if it is at the caudal end of the spinal cord, or segmental, lying at any level of the spinal cord. A terminal placode can be apical, involving the apex of the cord, or parietal if it involves a longer segment.

The first step of a clinical-neuroradiologic classification of spinal dysraphisms proposed by Tortori-Donati and Rossi,[5,10] is to determine whether the malformation is exposed to air (open

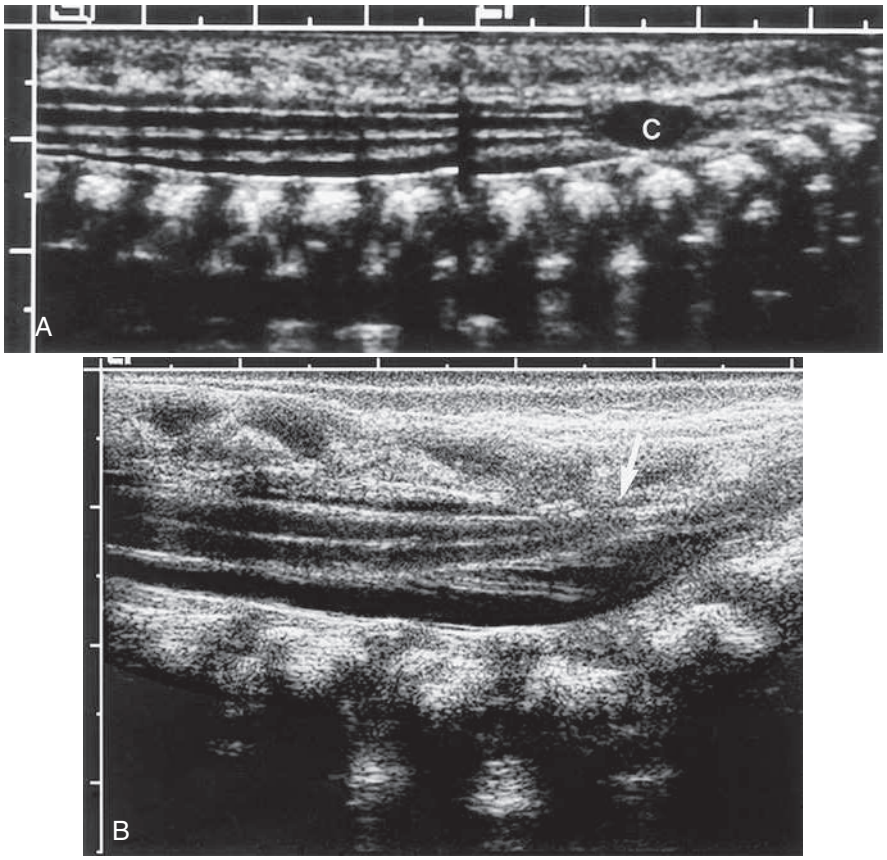

FIG. 49.13 Tethered Cord in Two Infants. (A) Newborn with tethered cord ending at S2 and an interposed filar cyst *(C).* **(B)** Newborn with a tethered cord in the setting of the VATER association (*v*ertebral defects, imperforate *a*nus, *t*racheo*e*sophageal fistula, and *r*adial and *r*enal anomalies). *Arrow* indicates the point of tethering.

spinal dysraphism) or covered by intact skin (closed spinal dysraphism) (Table 49.1). The abnormalities can be further characterized by the presence of a subcutaneous mass, which can be formed by neural elements, subarachnoid fluid, or fat.

Open Spinal Dysraphism

Open defects can occur at any level but are most common in the lumbosacral region. The diagnosis is often first suspected on maternal screening tests for elevated levels of alpha-fetoprotein (AFP) during pregnancy in maternal blood or amniotic fluid. Sonography of the fetus being screened for this condition is well established.[48-50] Open defects are generally repaired on the first or second day of life without preoperative imaging because the defect is readily apparent. Preoperative MRI can be performed to detect other abnormalities such as **syrinx, diastematomyelia,** and hydrocephalus and to understand the relationship between the placode and nerve roots.[10] Postoperative MRI can be also done to document associated anomalies. Ultrasound examination of the newborn spine with unrepaired defects is infrequently performed, in order to avoid the risk of ulceration or infection. In transverse prone views one would see the dorsal roots lateral and the ventral roots medial and posterior to the placode.[12] Ultrasound can be performed to detect other abnormalities of the spine above the open defect such as syrinx, atrophy of the thoracic and lumbar cord, arachnoid cyst, diastematomyelia, and intradural lipoma. Ultrasound and MRI of the brain are usually obtained to follow up hydrocephalus and Chiari II malformations before and after repair.

The most common open spine defect is **myelomeningocele** (98% of cases). The true incidence of neural tube defects is difficult to estimate and is approximately 2 per 1000 live births, with significant geographic and ethnic variations and increased incidence in certain high-risk groups.[51] The incidence has decreased over time, possibly the result of periconceptual folic acid, other environmental factors, and/or termination of affected pregnancies.[52] A myelomeningocele occurs when a placode is displaced dorsally by expanded subarachnoid space and is exposed to the environment by a bony defect in the midline (Fig. 49.14). Infants with **myelocele** have a flat neural placode (at the level of the skin of the back) that is exposed to the environment. The lack of expansion of the subarachnoid space distinguishes this lesion from the myelomeningocele (Fig. 49.15).

Hemimyelomeningoceles or hemimyeloceles are very rare causes of open neural tube defects that can be present if one side of a split cord malformation fails to neurulate. They are likely related to embryologic failures in gastrulation with superimposed neurulation.[5]

Open spinal defects are always associated with the **Chiari II malformation.** The proposed mechanism of this association is that leakage of CSF by the open spinal defect collapses the

TABLE 49.1 Clinical-Radiologic Classification System for Spinal Dysraphism

OPEN SPINAL DYSRAPHISM
Myelomeningocele (or hemimyelomeningocele)
Myelocele (myeloschisis)

CLOSED SPINAL DYSRAPHISM
With a Subcutaneous Mass
Lipomyelomeningocele
Lipomyelocele
Myelocystocele (terminal or cervical)
Meningocele
Cervical myelomeningocele

Without a Subcutaneous Mass
Simple dysraphic states
- Spina bifida
- Persistence of terminal ventricle
- Intraspinal lipoma
- Tight filum terminale

Complex dysraphic states
- Dorsal dermal sinus
- Caudal regression syndrome
- Split notochord syndrome (dorsal enteric fistula and neurenteric cyst)
- Split cord malformation (diastematomyelia)
- Segmental spinal dysgenesis

Modified from Barkovich AJ. Pediatric neuroimaging. 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2012.[36]

embryonic ventricular system and the lack of distention disrupts normal brain development.[53] The findings of hindbrain herniation can be mild early in pregnancy,[54] and although findings may progress, the severity of the hindbrain malformation varies and can lead to delay in diagnosis if the spinal abnormality is not recognized. The Chiari II malformation is absent in all types of closed spinal defects with the possible exception of large myelocystoceles.[5] The Chiari II malformation consists of a small posterior fossa with upward transincisural herniation of the superior cerebellum, as well as downward herniation through the foramen magnum with associated compression and distortion of the brainstem. This posterior fossa distortion can be seen by sonography of the brain through the anterior fontanelle and of the craniocervical junction through the foramen magnum.[55] Hydrocephalus may develop early in the second trimester but usually develops postnatally, typically after closure of the skin opening because this closes the CSF leak.[56] Sonography also has a potential role in the evaluation of the spinal cord in patients with repaired myelomeningocele. Specifically, real-time imaging, cine clips, or M-mode ultrasound, in conjunction with MRI, has the potential to suggest the redevelopment of the tethered cord syndrome, based on dampened nerve root pulsation in this high-risk group. The scarring that adheres the caudal cord to the dura rarely occurs in neonates. The cord should be central in the dependent portion of the canal, and cord and roots should move normally in both the anterior-posterior direction with normal respiration and craniocaudally with neck flexion.[12,57-60]

Closed Spinal Dysraphism With a Subcutaneous Mass

Closed spinal dysraphisms are defined as the group of spinal dysraphisms that exist beneath an intact covering of dermis and epidermis and that are therefore not discovered with AFP screening. Many patients are clearly identified by abnormal physical examination findings, but some defects are not clinically evident at birth and may manifest later in infancy (around 6 months of age) with tethered cord syndrome. Common closed spinal defects that manifest with a lumbar **subcutaneous mass** include lipomas with a dural defect (**lipomyelocele** and **lipomyelomeningocele**) and rare entities including **meningocele** and terminal **myelocystocele.** The main differential diagnosis for lumbar masses is sacrococcygeal teratoma and overgrowing fatty tissue in caudal regression. Cervical masses that occur as a closed dysraphism with a subcutaneous mass are very rare and include cervical myelomeningocele, myelocystocele, and meningocele. The differential diagnosis includes occipitocervical cephalocele and subcutaneous lymphatic malformations.

In **lipomyelocele** (lipomyeloschisis; Fig. 49.16, Video 49.4, Video 49.5, and Video 49.6), the neural placode-lipoma interface is within or at the edge of the spinal canal and the associated lipoma is continuous with the subcutaneous fat through a posterior bony defect; the overlying skin is frequently abnormal. The subcutaneous fatty mass is located above the intergluteal crease and usually extends asymmetrically into one buttock. The placode is terminal (apical or parietal) and may be asymmetrical, involving one edge of the neural plate. The placode-lipoma interface may extend over several vertebral levels. The size of the spinal canal may be increased depending on the size of the lipoma, but the size of the subarachnoid space ventral to the cord is normal.[10]

In **lipomyelomeningocele,** the ventral subarachnoid space is enlarged, the interface of the placode-lipoma is outside the spinal canal, and the lipoma is continuous with the subcutaneous fat through a posterior bony defect (Fig. 49.17, Video 49.7, Video 49.8). The placode is frequently segmental and may be deformed, stretched and rotated asymmetrically toward the lipoma on one side, with meninges herniating on the opposite side; therefore the lengths of the spinal roots can be asymmetrical. The spinal cord below the placode is normal and lies within the canal.

In both entities of lipomyelocele and lipomyelomeningocele, the mass is more commonly formed by mature adipocytes separated by collagen bands. Other tissues such as aberrant neuroglial tissue, cartilage, bone, or fibrous, muscular, or vascular structures can be present and form **"dysraphic hamartomas."** The lipoma can invade the extradural space **(lipomatous dura mater)** and hydromyelia can be present. The subcutaneous and intraspinal components of the lipomas can grow as part of normal increase in adipose tissue in childhood, with obesity or pregnancy.

A **posterior meningocele** is less common than lipomyeloceles and lipomyelomeningoceles and forms from extension of a CSF-filled sac lined by dura and arachnoid through a dorsal bony defect. Nerve roots or part of the filum terminale may course in the sac, but no part of the spinal cord is in the sac. The spinal cord itself is normal but can be tethered to the neck

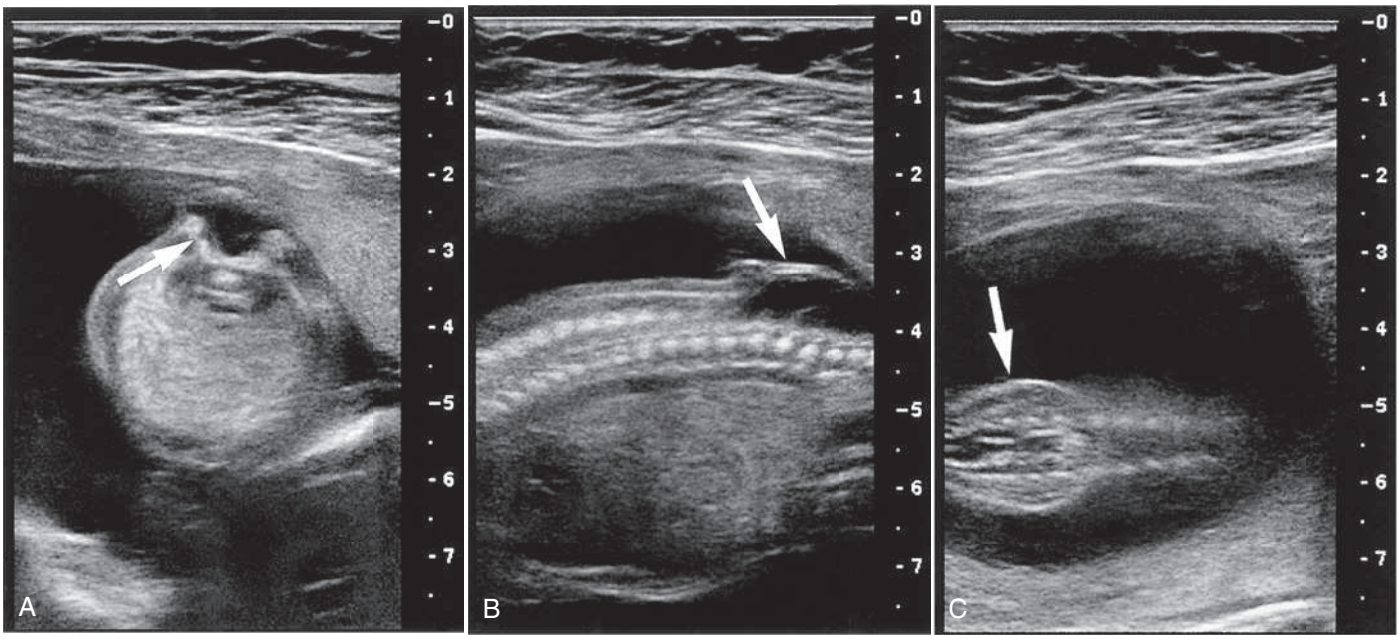

FIG. 49.14 Lumbosacral Myelomeningocele in 18-Week Fetus. (A) Transverse view shows the open nature of the posterior elements of the affected vertebral ring *(arrow)*. **(B)** Sagittal view shows the protuberance of the covering membrane and neural placode *(arrow)*. **(C)** Coronal view shows the thin nature of the covering membrane *(arrow)*.

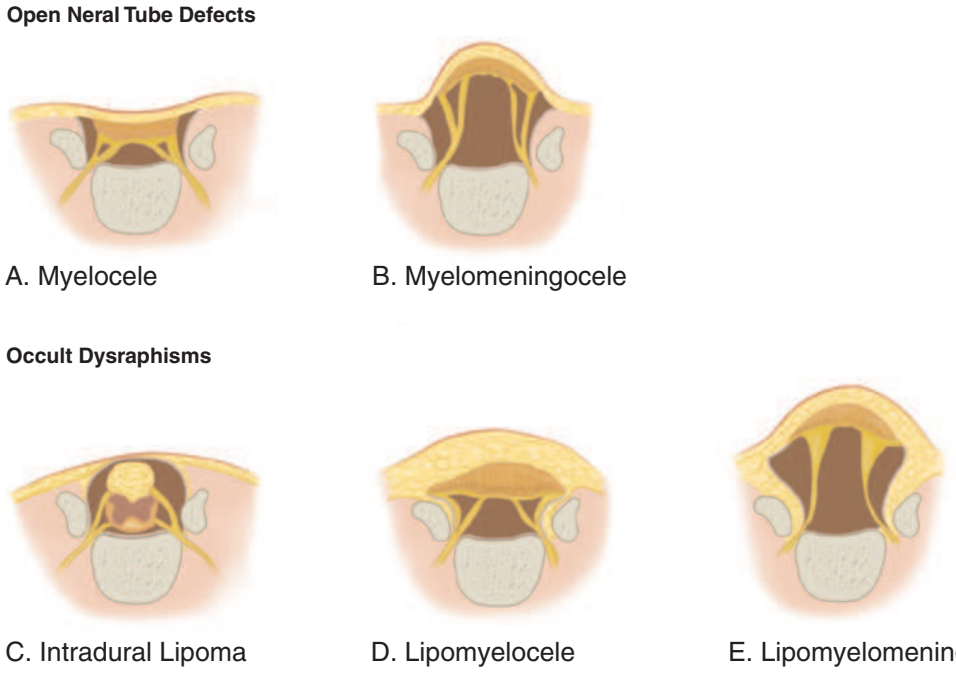

FIG. 49.15 Examples of Open Neural Tube Defects (A and B) and Examples of Closed Spinal Defects Without a Subcutaneous Mass (C) or With Subcutaneous Mass (D and E). Each diagram is positioned with the dorsal side up as one would scan the spine of an infant.

of a sacral meningocele. Their most common location is in the lumbar or sacral spine, but they can be seen in the thoracic or cervical spine. On ultrasound, the CSF-filled sac has a small neck and is continuous with the thecal sac. Small bands of pia, arachnoid, or dura can be seen, not nerves. An atretic meningocele is the condition in which an aberrant nerve adheres to the neck of the meningocele and is a cause of low conus with no apparent cause of tethering. Atretic meningoceles are associated with a midline scar that resembles a cigarette burn.[12]

Myelocystocele is a rare malformation in which the dilated central canal of the spinal cord protrudes dorsally through a dorsal bony defect. Myelocystoceles can occur at the cervical, thoracic, or lumbosacral levels. They are distinct from myelomeningoceles and are skin covered.[61,62] When occurring at the

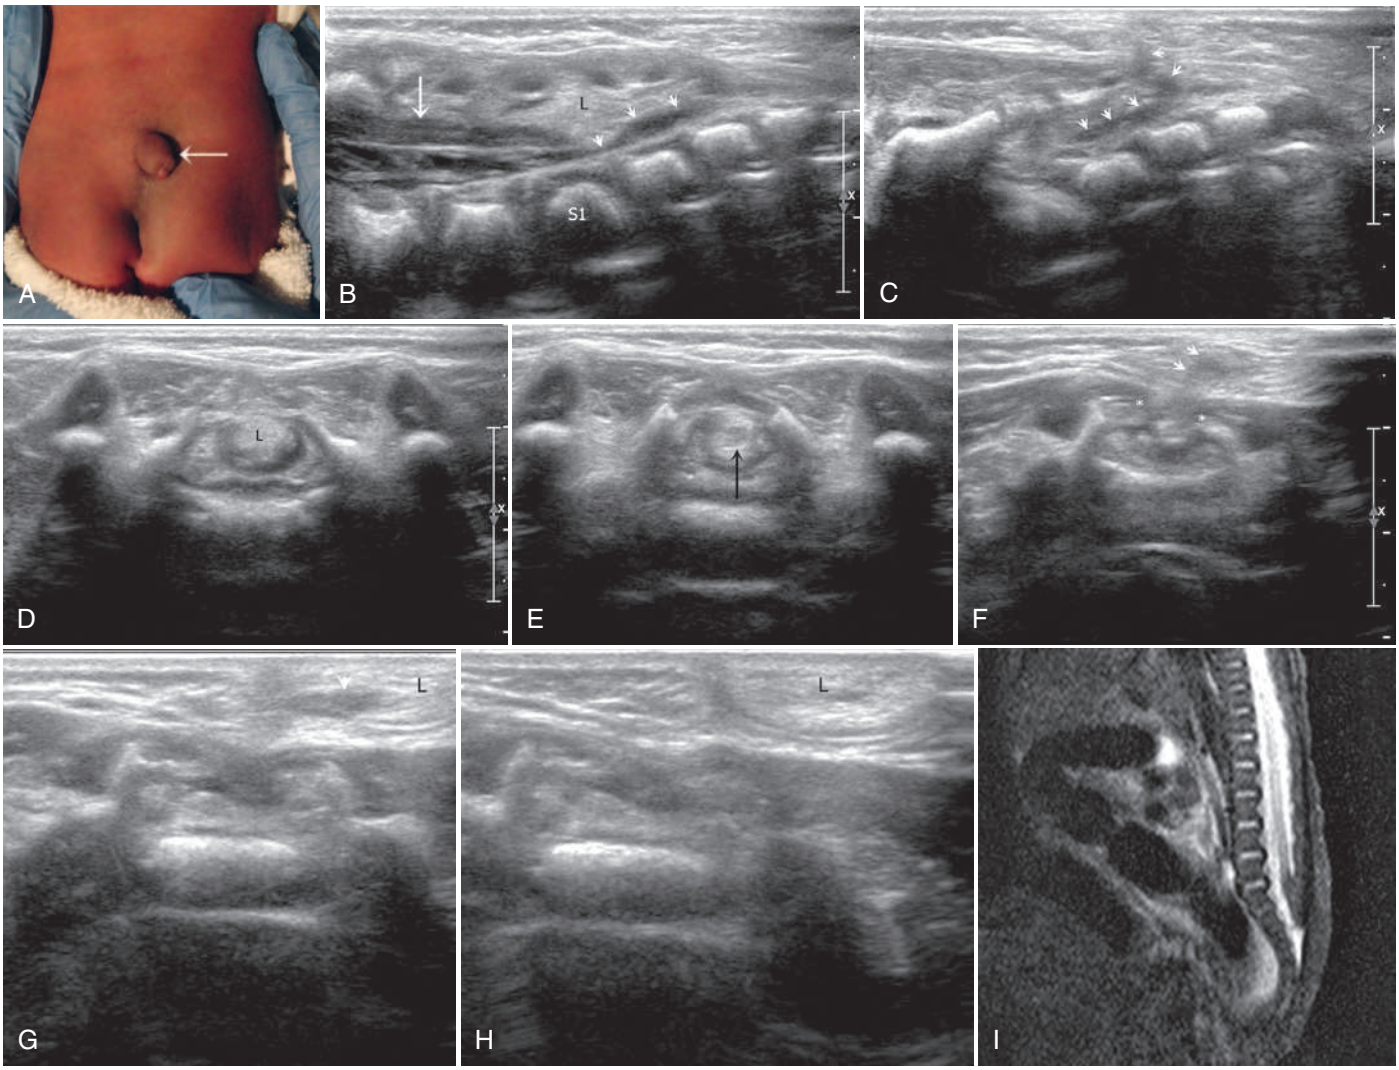

FIG. 49.16 Lipomyelocele. (A) Newborn with subcutaneous mass *(white arrow)* over the right sacrum and deviated gluteal cleft. **(B)** Sagittal view demonstrates a low-lying tethered cord that ends at S1 *(arrow points to the cord).* There is a terminal placode, and the placode-lipoma *(L)* interface lies within the canal. The lipoma and the fibrofatty filum terminale cannot be separated on this view. There is a small amount of fluid ventral to the lipoma *(small white arrows).* **(C)** Sagittal view shows fluid *(small white arrows)* extending through a defect in the right posterior elements of S2 and into the subcutaneous lipoma. **(D)** Transverse view showing intradural lipoma *(L)* extending dorsal and inferior to the conus medullaris. **(E)** Transverse view of the lipoma shows a central, tubular hypoechoic structure with more echogenic margins *(black arrow),* which corresponds to the fibrofatty filum. Note the intact cartilaginous posterior elements. **(F)** Transverse view at the level of the small right S2 posterior element defect *(outlined by *).* Note small amount of fluid extending in the central aspect of the subcutaneous mass *(small white arrows).* Transverse images are oriented with the right side of the patient to the left of the screen to maintain consistency with the position of the subcutaneous mass on the initial photograph. **(G)** Transverse view at the level of the subcutaneous mass shows central hypoechoic fluid *(white arrowhead)* and subcutaneous lipoma *(L).* **(H)** Transverse view at the level of the subcutaneous lipoma *(L).* **(I)** Sagittal T2 weighted image with fat saturation demonstrates the tip of the conus at the lumbosacral junction, and a hypointense terminal lipoma adjacent to the filum terminale. The subcutaneous mass is not seen at this level because it was to the right of midline. See also Video 49.4, Video 49.5, and Video 49.6.

lumbosacral level, they are designated **terminal myelocystoceles** (Fig. 49.18); these are quite rare.[63] The diagnosis can be established with ultrasound or MRI when the low-lying cord terminus ends in a cyst that is in communication with the central canal of the spinal cord **(syringocele).** Expanded subarachnoid space (meningocele) surrounds the distal cord and terminal cyst. Fluid within the terminal cyst does not communicate with the expanded subarachnoid space. They have a high association with cloacal exstrophy.[64-66]

Closed Spinal Defects Without a Subcutaneous Mass

Simple Dysraphic States

Filum terminale lipomas are characterized by fibrolipomatous thickening of the filum terminale. Both the intradural and extradural portions of the filum terminale can be involved, and the amount of fatty infiltration varies. Frequently the filum is slightly off midline as seen on transverse images. In this entity,

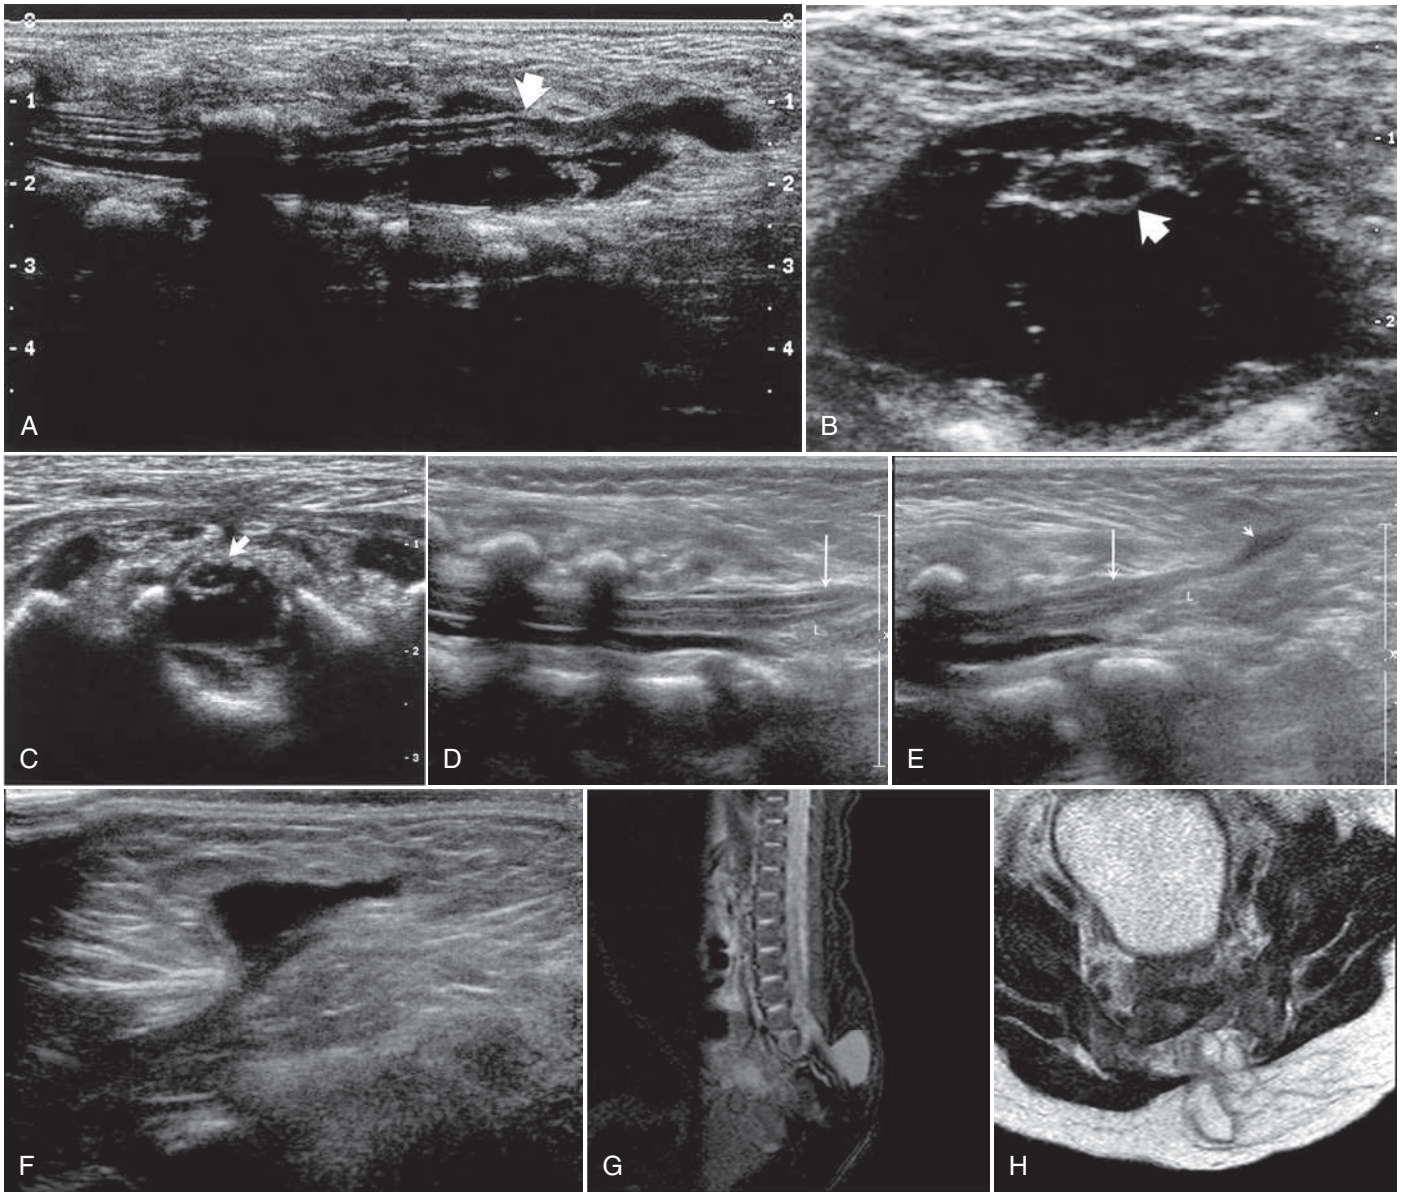

FIG. 49.17 Lipomyelomeningocele. (A) Sagittal split-screen collage of the low spinal cord *(arrow).* **(B)** Transverse view shows the neural placode posteriorly displaced *(arrow)* and the cerebrospinal fluid (CSF)–filled meningocele surrounding the placode. **(C)** Distal end of the tethered cord is incorporated into the lipoma *(arrow).* In another patient, **(D)** sagittal view shows a tethered cord *(arrow)* and a lipoma *(L)* that extends ventral to the terminal placode. Note the small ventriculus terminalis. **(E)** Sagittal view of the spine demonstrates a low-lying cord *(arrow)* with a placode that extends outside of the canal, fluid that extends to the subcutaneous mass *(small white arrow),* and a large lipoma *(L)* that extends ventral to the placode. **(F)** Sagittal view of the subcutaneous mass shows large amount of central fluid and subcutaneous fat. **(G)** Sagittal T2-weighted, fat-saturated image shows fluid in the subcutaneous fat, the placode, and hypointense ventral lipoma extending outside the spinal canal. **(H)** Axial T2 view of the pelvis shows the subcutaneous fatty and fluid mass extending beyond the spinal canal through a defect in the posterior elements of the sacrum. See also Video 49.7 and Video 49.8.

fatty tissue expands the filum terminale beyond 2 mm.[21,67] On ultrasound, this is seen as a thickened, echogenic filum terminale, sometimes with an undulating contour[68] (Fig. 49.19). In adults, "incidental" fatty infiltration of the filum has been found in 0.2% to 4% of asymptomatic patients who had no evidence of cord tethering and is considered a normal variant.[69,70]

The **abnormally long spinal cord** is a variant in which the conus medullaris does not taper and at the sacrum it connects with the lower end of the thecal sac. It may occur with intradural lipomas or lipomyelomeningoceles.

A **persistent terminal ventricle** (fifth ventricle) is a small ependyma-lined cavity in the conus medullaris. It is commonly considered a normal variant. If large, it may cause symptoms such as low back pain, sciatica, or bladder disturbance and it should be distinguished from an intramedullary tumor by its lack of enhancement and stable size.

Intradural lipomas (Fig. 49.20) can be found anywhere in the spinal canal but are more frequently lumbosacral. Their embryology and pathology is similar to lipomas with dural defects, but they are contained within an intact dural sac. They are located in the midline along the dorsal surface of the placode. They are generally subpial and may bulge posteriorly in the subarachnoid space. If large they can displace the cord laterally.[10] Their size can vary and they can be multifocal. **Intramedullary** lipoma refers to fatty infiltration within the cord; the lipoma does not extend beyond the pia.

Dorsal dermal sinuses (Fig. 49.21) are epithelium-lined fistulas that connect the skin to the central nervous system and meninges and are thought to result from focal incomplete disjunction of cutaneous ectoderm from neuroectoderm. They should be suspected on physical examination if there is a midline dimple or ostium above the gluteal cleft and more than 2.5 cm above the anus, which can be associated with a hairy nevus, capillary hemangioma, or hyperpigmented patch. The sinus is seen as a hypoechoic band that extends across the subcutaneous tissues, through an osseous defect, and into the spinal canal to the dural sac and may end in the subarachnoid space, the conus medullaris, the filum terminale, a nerve root, a dermoid, or an epidermoid cyst. The cord is usually low and tethered.[12] Sinuses can cause leakage of CSF if they are open to the subarachnoid space. In this situation, sterile gel and a probe cover should be used. The dermal sinus can originate from the skin overlying a lipomyelocele. Dermoids are common (11%).[5,10] They can be infected and are usually in the cauda equina or conus medullaris. The lumbosacral region is the most common site of such sinuses, and if present, the skin opening tends to be positioned cephalad to the point of contact with the dura. The sinus is easier to recognize in the midline sagittal plane than on transverse images. On sagittal views, the sinus is seen as a hypoechoic stipe in the subcutaneous fat. Occipital, cervical, and thoracic sinuses can all occur but are less common. The chief risks of undiagnosed dorsal dermal sinuses are infection, chemical meningitis from rupture into the subarachnoid space, and compression injury from any associated intradural mass.[71-76]

FIG. 49.18 Terminal Myelocystocele in a Fetus at 31 Weeks' Gestation. Oblique coronal view shows the well-defined, echogenic skin covering characteristic of these lesions *(arrows).*

Complex Dysraphic States (Disorders of Gastrulation)

Disorders of Midline Notochordal Integration. Abnormal development of the notochord results in complex malformations that involve the spinal cord and other organs. These disorders are present without a subcutaneous mass, except for the rare hemimyelocele and hemimyelomeningocele. The disorders of midline notochordal integration cause failure of fusion in the midline to form a single notochordal process and result in longitudinal notochordal splitting.[77]

The rarest and most severe entity is **dorsal enteric fistula,** in which an abnormal neurenteric canal connects the skin with the bowel and crosses a space between a duplicated spine and cord.[4] **Neurenteric cysts** are in the spinal canal, can remain trapped between a split notochord, and are lined by alimentary tract epithelium; their internal contents, although variable, are usually similar to CSF. They are typically intradural, in the

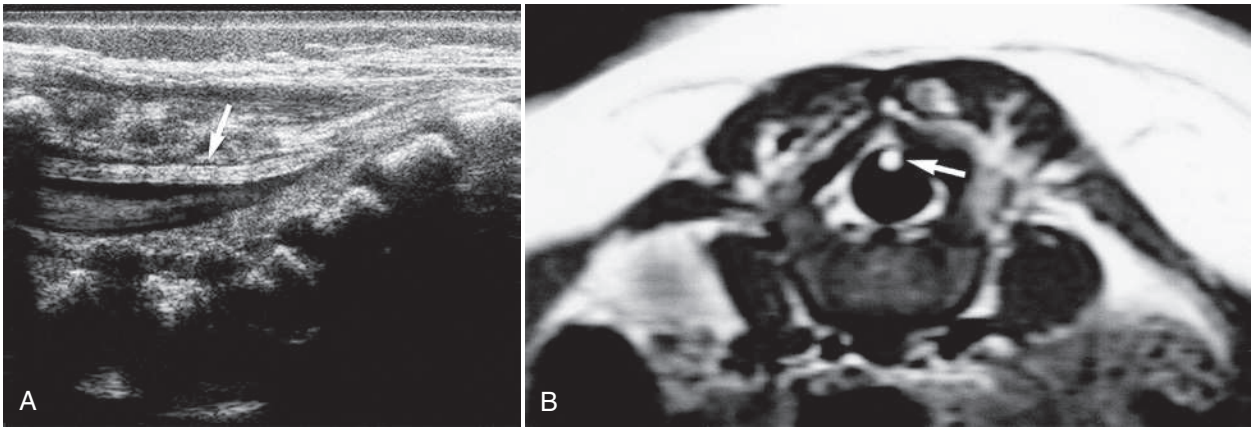

FIG. 49.19 Fibrolipoma of Filum Terminale. (A) Sagittal ultrasound and **(B)** transverse T1-weighted magnetic resonance image show that the filum terminale is abnormally thickened and echogenic *(arrow),* with high T1 signal in the filum *(arrow)* on magnetic resonance imaging.

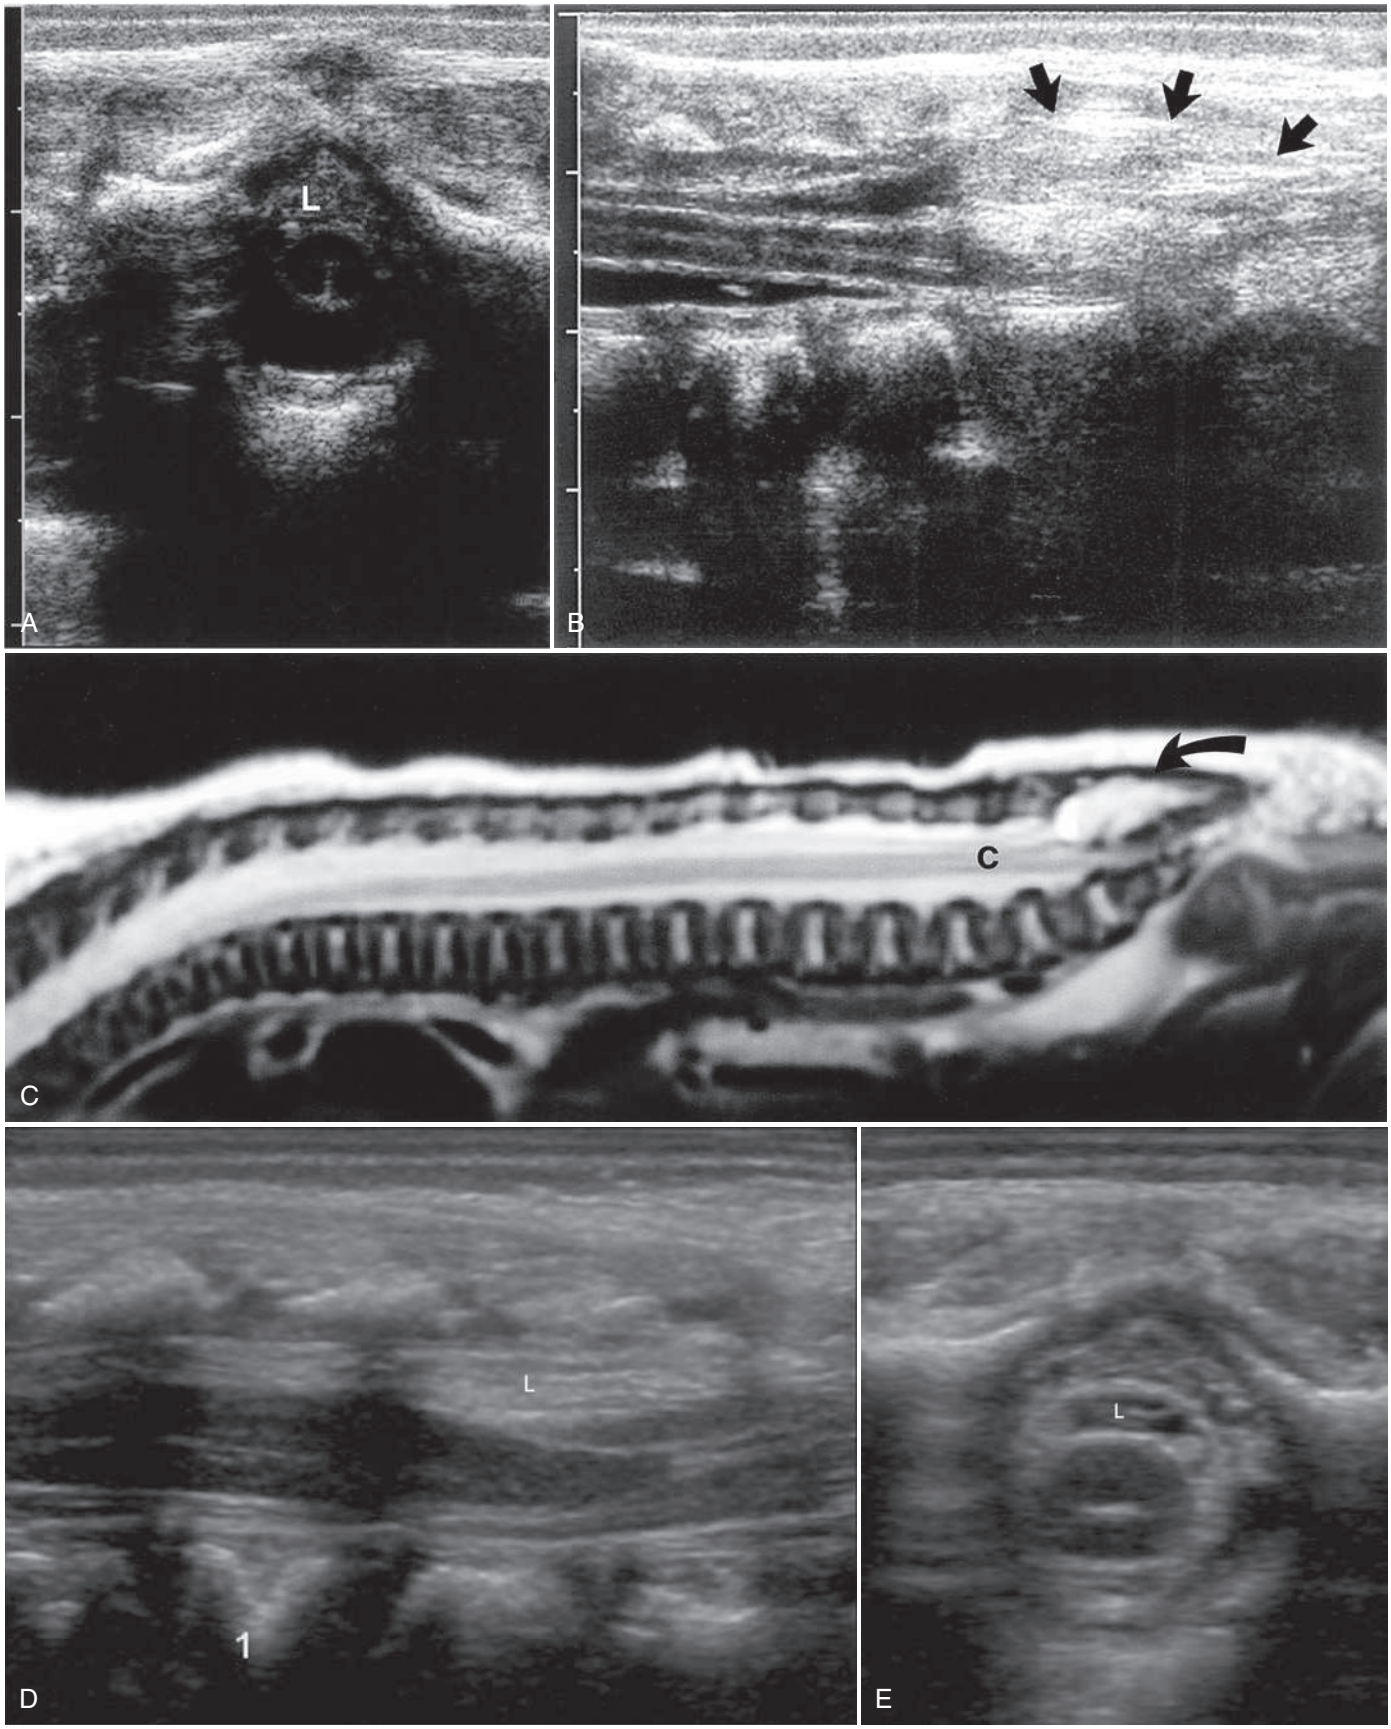

FIG. 49.20 Intradural Lipomas. (A) Transverse views in a 2-week-old girl demonstrate mild rightward deviation of the low spinal cord, which is also pulled into an abnormally dorsal position by the lipoma *(L).* **(B)** Sagittal views of the low cord with the clearly visible tethering lipoma *(black arrows).* **(C)** The correlative sagittal T2-weighted magnetic resonance image, oriented to match the ultrasound, reveals the abnormally low cord *(C)* and the lipoma *(curved black arrow).* In another newborn, **(D)** sagittal and **(E)** transverse views of the spine demonstrate a dorsal intradural lipoma tethering the spinal cord; the tip ends at mid L3. *1* indicates the 1st lumbar vertebral body. *L,* Lipoma. (**D** and **E** courtesy of Dr. Kathy McCarten.)

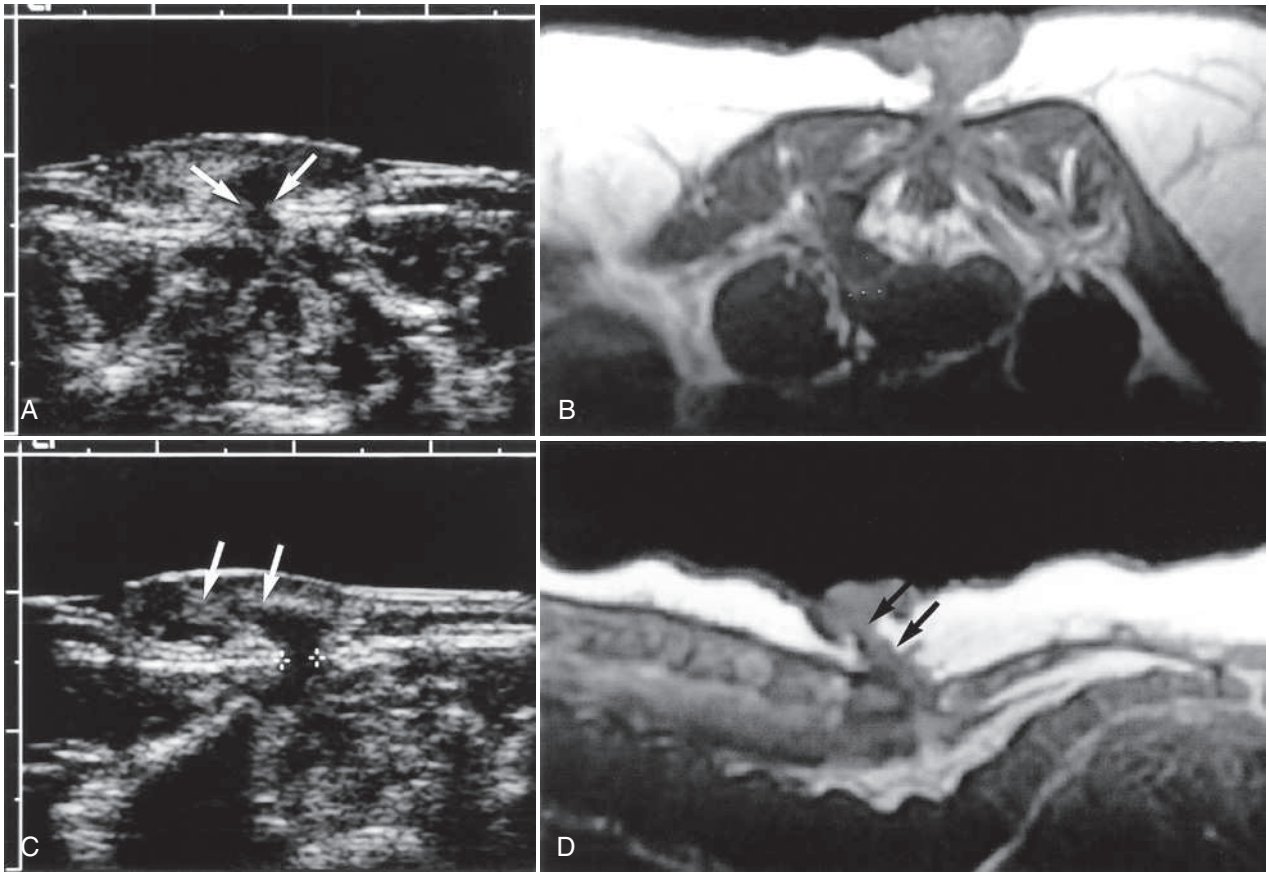

FIG. 49.21 Dorsal Dermal Sinus. Transverse and sagittal views, pairing ultrasound and T1-weighted magnetic resonance imaging. **(A)** and **(B)** Transverse views reveal the open connection among the subcutaneous fatty layer, overlying muscles, and vertebral canal *(arrows).* **(C)** and **(D)** Sagittal views show the obliquity of the connecting sinus *(arrows).* The skin-side opening is superior to the level of dural connection. This is a typical configuration.

cervicothoracic spine (less common in the lumbar spine or posterior fossa), and tend to be seen anterior to the vertebral column at a level well inferior to the associated vertebral anomaly.[5,78]

Diastematomyelia or split cord malformations are a spectrum of abnormalities in which there is sagittal division of the cord (Fig. 49.22). In **diastematomyelia type 1,** the two hemicords are contained in individual dural tubes. There is an extradural intervening bony or osteocartilaginous spur that extends from the vertebral body to the neural arches. Spurs can be complete or incomplete and are usually seen in the caudal end of the cord splitting. The hemicords can reunite caudal to the cleft or extend to the conus. **Hydromyelia** occurs in 50% of cases. Vertebral anomalies include **bifid lamina, widened interpediculate distance, hemivertebrae, fused vertebrae, intersegmental laminar fusion** (which limits acoustic window), and **scoliosis.**

In **diastematomyelia type II,** there are two hemicords and a single dural tube. Three variants consist of absent septum, fibrous septum, and partial cord splitting. The most common variant is absent septum, and the least common is when the cleft is partial and the splitting incomplete, which is best seen on

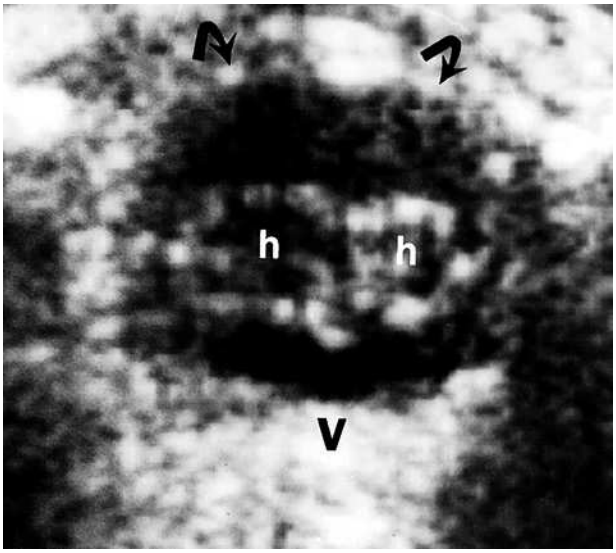

FIG. 49.22 Diastematomyelia in 3-Year-Old Girl. Transverse scan of lumbar canal shows two hemicords *(h),* confirmed on magnetic resonance imaging and at surgery. *V,* Vertebral body; *curved arrows,* dorsal dura.

transverse views. A fibrous septum can be seen on axial high-resolution magnetic resonance images. Hydromyelia may be present and the conus is typically low, strongly associated with filar lipomas and tight filum terminale. Vertebral anomalies are usually milder than in type I.[10,79,80]

The diagnosis of diastematomyelia can be made with ultrasound in the newborn period.[62,64,81,82] About one-half of patients with diastematomyelia have some surface stigmata of an underlying malformation, such as a **cranial hairy tuft, nevi, lipomas, dimples, or vascular lesions.**[61,79,80] Despite this, it is not unusual for the diagnosis to be delayed until older childhood because scoliosis or other characteristic neurologic or orthopedic symptoms develop. MRI is necessary beyond the neonatal period to establish the diagnosis. Definition of any dividing cartilaginous or bony septum is an important part of surgical planning and can be difficult to visualize with ultrasound,[45] sometimes necessitating the additional step of spinal computed tomography (CT).

Diastematomyelia may occur in isolation or in conjunction with other anomalies, such as myelomeningocele, lipoma, dermal sinus, and dermoid or teratoma.[61,83]

Disorders of Midline Notochordal Formation. The notochord induces the development of the spinal cord, spinal vertebrae, and other organs. If there are abnormal notochordal segments, vertebral malformations and segmental abnormalities of neurulation can exist. Most commonly the caudal segment is involved and caudal agenesis develops. If an intermediate segment is involved, this results in segmental spinal dysgenesis.

Caudal agenesis refers to a heterogeneous group of caudal anomalies that include **total or partial agenesis of the spinal column** (the majority involve the sacrum and coccyx), **imperforate anus, genital anomalies, renal dysplasia, pulmonary hypoplasia, and lower limb anomalies.**[84] Agenesis of the sacrum and coccyx may be part of syndromic associations including **Currarino triad**[85-88] (partial sacral agenesis, anorectal malformation, presacral teratoma or anterior meningocele), **OEIS**[89] (omphalocele, exstrophy of the cloaca, imperforate anus, spinal defects) and **VACTERL** (vertebral anomalies, imperforate anus, cardiac malformations, tracheoesophageal fistula, renal and limb abnormalities). Lipomyelomeningocele and terminal myelocystocele can be seen in up to 20%. Caudal agenesis is associated with maternal diabetes. It is seen in about 1% of babies born to mothers with uncontrolled type I diabetes mellitus; 16% of cases are associated with maternal diabetes.

Depending on the location and shape of the conus medullaris, caudal agenesis has been classified into two types.[3,90,91-95] **Type 1 or high-position caudal agenesis** (T12 or L1) involves a wedge-shaped or blunted contour of the conus owing to loss of anterior horn cells and small sacral nerve roots.[45,96] The degree of vertebral aplasia varies from absence of the coccyx to the lower thoracic vertebra, but most commonly the last vertebra is from L5 to S2. The dural sac ends at a high level. Clinically, neurologic deficits are stable. If the sacral vertebrae are absent, the iliac wings become closely opposed. There is often associated **dislocation of the hips** (Fig. 49.23).

Type II is **caudal agenesis** with **low and tethered conus medullaris** with mild vertebral dysgenesis (last vertebra up to S4). The partial agenesis of the conus may not be recognized owing to stretched conus and tethering to a tight filum, lipoma, or anterior meningocele. These patients clinically have tethered cord syndrome.[97]

Segmental spinal dysgenesis refers to a clinical and radiologic syndrome that includes segmental agenesis or dysgenesis of the lumbar or thoracolumbar spine, segmental abnormality of the underlying spinal cord and nerve roots, congenital paraplegia or paraparesis, and congenital lower limb deformities. The spine and cord can form an acute-angle kyphosis and the canal can be narrow or interrupted. The lower spinal cord is low lying and bulky and can be hypoplastic or interrupted (Fig. 49.24, Video 49.8, Video 49.9). Typically a horseshoe kidney and equinovarus feet are present.[10,98]

Several anomalies are associated with high incidence of dysraphism.[99] About one-third of infants with **high imperforate anus,** one-half with the **cloacal malformation,** and essentially all with **cloacal exstrophy** have associated spinal cord anomalies. One could argue that the cloacal exstrophy group should forgo the ultrasound step and go straight to MRI. A large percentage of the other groups can avoid sedated MRI if they are shown on ultrasound to have a normal-appearing spine in the newborn period. Because patients with spinal dysraphism often have associated renal anomalies, the kidneys should be examined as well as the spine.

Anomalies at Risk for Spinal Dysraphism

Cloacal exstrophy (100%)
Cloacal malformation (50%)
High imperforate anus (30%)
Ectopic or low imperforate anus

Hemivertebrae result from a disruption of the primary ossification center and pairing defects of the involved sclerotomes. Disorders of vertebral segmentation include **block vertebrae** and **unilateral unsegmented bars** (Figs. 49.25 and 49.26). Fusion can occur at myriad sites, including the anterior and posterior spinal column, or at facet joints.[100] Ultrasound can characterize many of the formational vertebral anomalies and is probably an underused tool.[101-104] The suspicion of a subtle vertebral anomaly seen on radiographs in the newborn period when ossification is incomplete can often be proved or refuted with spine sonography.

TUMORS

Tumors positioned in and around the vertebral canal are rare. In the neonatal period, **intraspinal neuroblastoma** is the most likely diagnosis when such a mass is discovered.[105] These lesions tend to calcify and extend into the vertebral canal from the retroperitoneum. Both the calcium and the course of extension can be observed with sonography (Fig. 49.27). These infants may have a palpable abdominal mass or signs of spinal cord compression. Other differential possibilities in the situation of intraspinal tumor extension include **hemangioma** and **rhabdoid tumor.**[106]

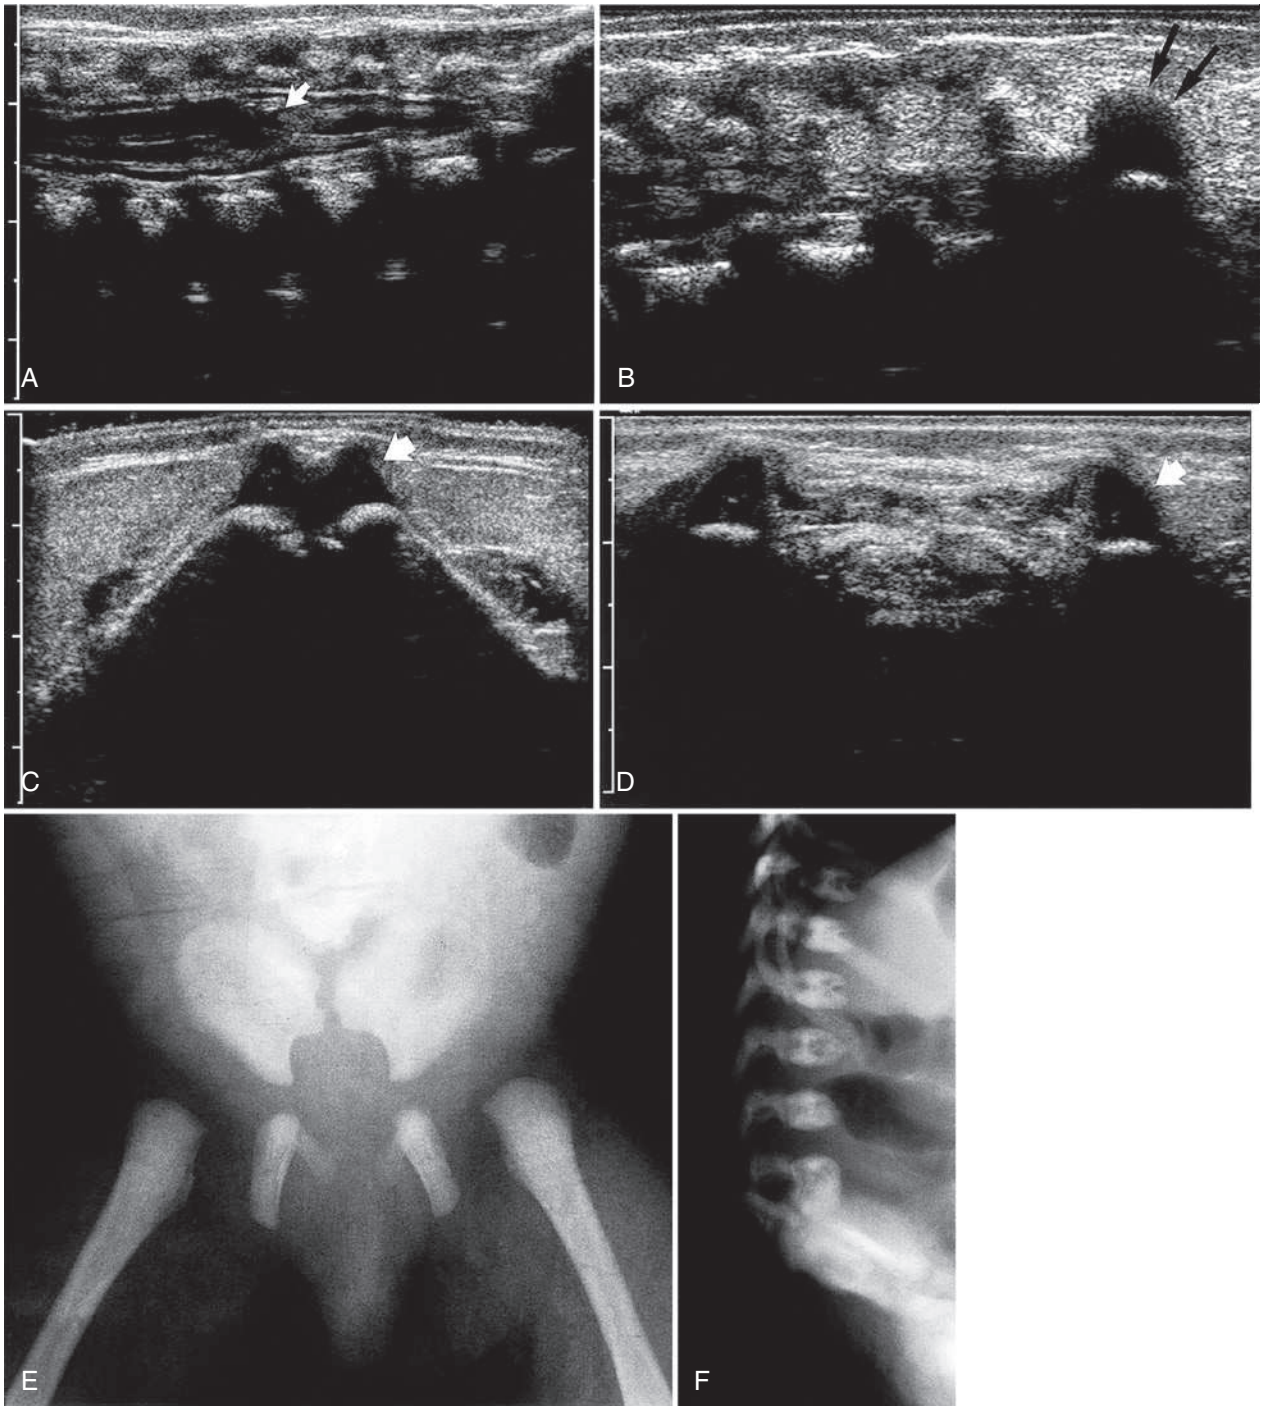

FIG. 49.23 Caudal Regression Syndrome in 4-Week-Old Girl. (A) Sagittal view of the conus medullaris reveals its tip is abnormally blunted *(arrow)*. **(B)** Sagittal view of the truncated, distal end of the vertebral column reveals an abnormally upturned and truncated cartilaginous tip *(black arrows)*. **(C)** Transverse view of absent sacrum at the expected position of the sacral spine shows the cartilaginous posterior margin of the iliac wings to be directly apposed *(arrow)* with no separating sacrum. **(D)** Normal comparison of the relationship of the posterior, cartilaginous iliac wings *(arrow)* in most infants. **(E)** Frontal radiograph of the pelvis demonstrates the directly apposed medial aspects of the iliac wings, absent distal lumbar and sacral spine, and dislocated hips. **(F)** Lateral radiograph demonstrates the truncated vertebral column.

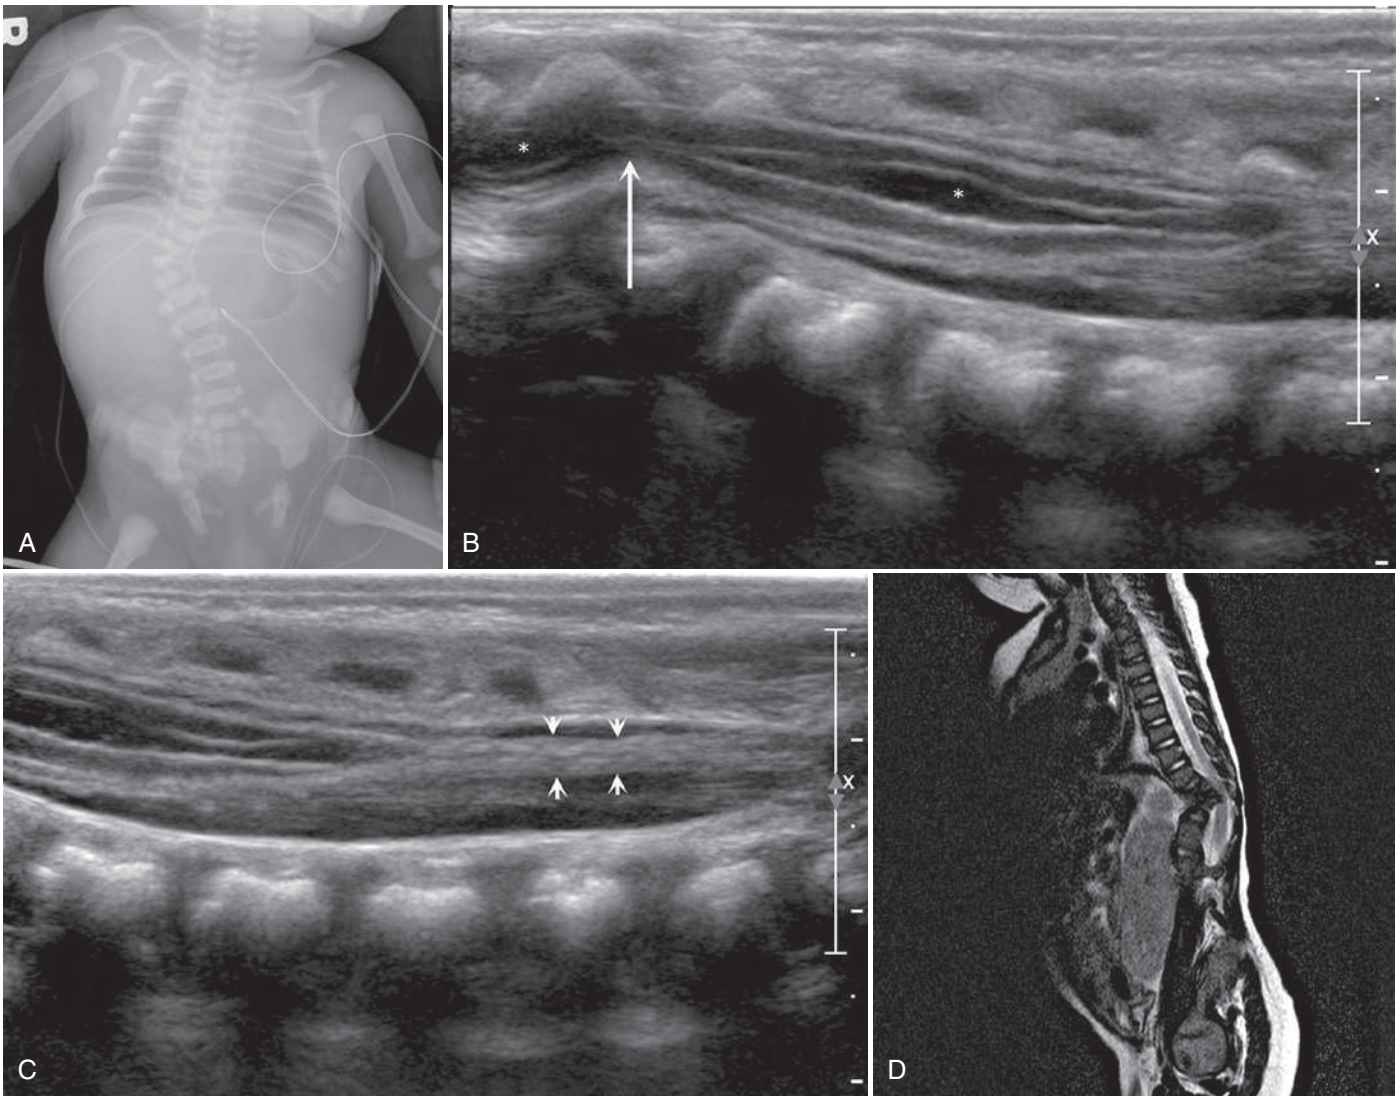

FIG. 49.24 Segmental Spinal Dysgenesis in a Newborn With Imperforate Anus, Clubfeet, and Gibbus Deformity. (A) Frontal radiograph demonstrates a kyphoscoliosis at the thoracolumbar junction with multiple hemivertebrae. There are fused sacral segments. **(B)** Sagittal view of the spine at the level of the thoracolumbar vertebral anomalies demonstrates thinning of the spinal cord, **syringomyelia** (*) above and below the area of narrowing *(white arrow)*, and a low conus medullaris. **(C)** Sagittal view of the spine shows a low lying conus medullaris that ends at L4. Note the dilation of the central canal. The filum terminale is thickened and echogenic *(arrowheads)* and showed little movement with respiration. **(D)** Sagittal T1-weighted image of the thoracolumbar spine demonstrates vertebral anomalies and marked kyphosis. There is significant segmental thinning of the spinal cord and segmental obliteration of the spinal canal. See also Video 49.8 and Video 49.9.

There are a few reports of primary intramedullary neoplasms, such as gliofibroma.[107]

Sacrococcygeal teratomas (Figs. 49.28, 49.29, and 49.30) most often are discovered in the fetal or newborn period and are the most common presacral tumors in that age group. These heterogeneous teratomas tend to recur and are generally described as **mature** or **immature.**[108-111] Altman's classification of sacrococcygeal teratomas is helpful for presurgical planning and describes the extent of the mass, which can be large and external or small and internal (Table 49.2)[112] These masses tend to have a very heterogeneous appearance on ultrasound, including solid, cystic components, fat, or foci of calcification.[113] Sacrococcygeal teratomas do not generally enter the vertebral canal, but there have been rare reports of such extension.[114]

TABLE 49.2 Altman's Classification of Sacrococcygeal Teratomas

Type	Description
I	The bulk of the mass is external, with only a minimal presacral component.
II	Both large external and large internal components are present.
III	A relatively small amount of tumor is external, but the bulk of the mass is internal.
IV	There is no external mass because the tumor is exclusively presacral.

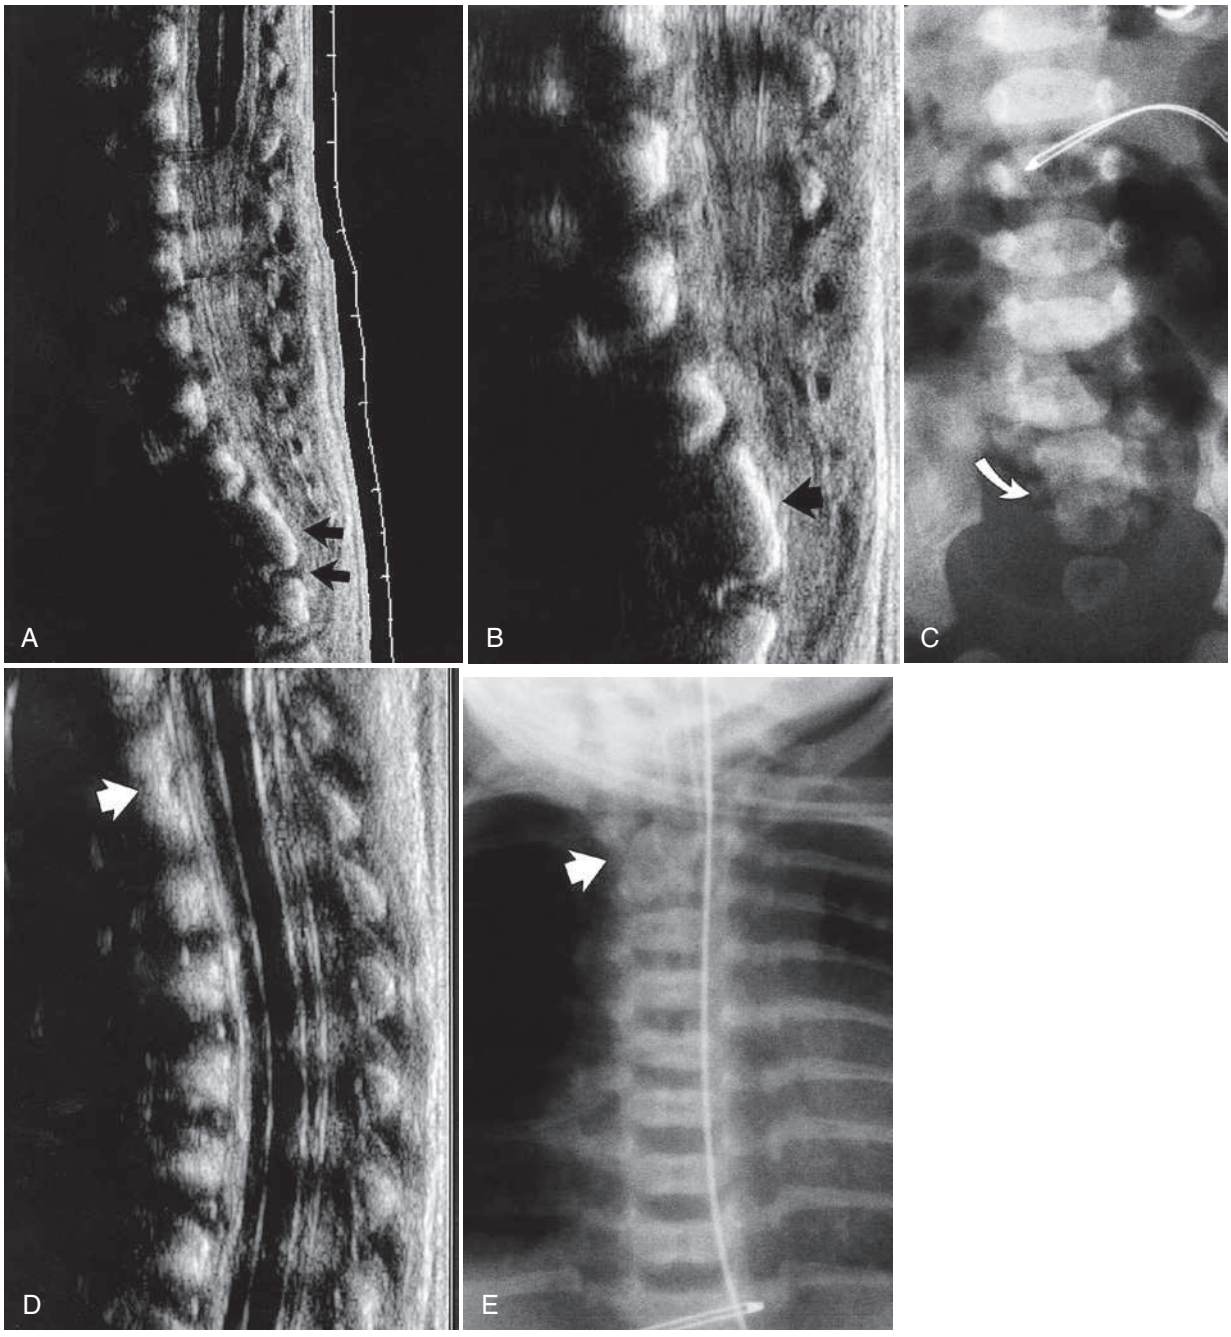

FIG. 49.25 Imperforate Anus With Block Vertebrae. (A) Extended–field-of-view image reveals the abnormal sacral truncation and block vertebrae *(arrows).* **(B)** Enlarged view of the same region. **(C)** Radiograph shows the area of vertebral fusion *(curved arrow).* **(D)** Sagittal view of the thoracic spine and **(E)** frontal radiograph reveal an additional block vertebrae *(arrows).*

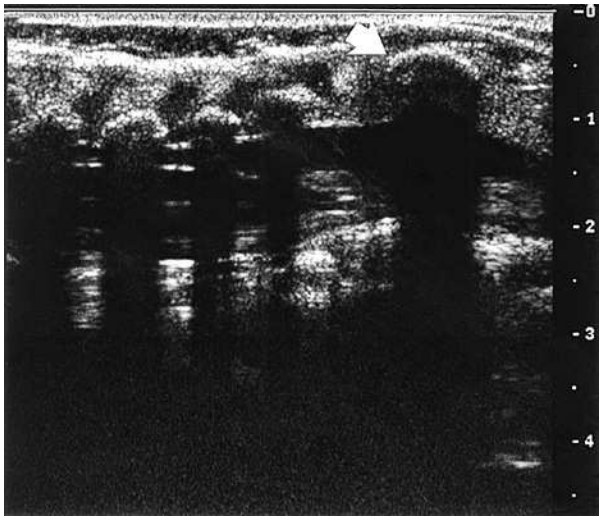

FIG. 49.26 Abnormal Fusion in 9-Week-Old Boy. Abnormal fusion of the posterior elements *(arrow)* created a firm mass to palpation.

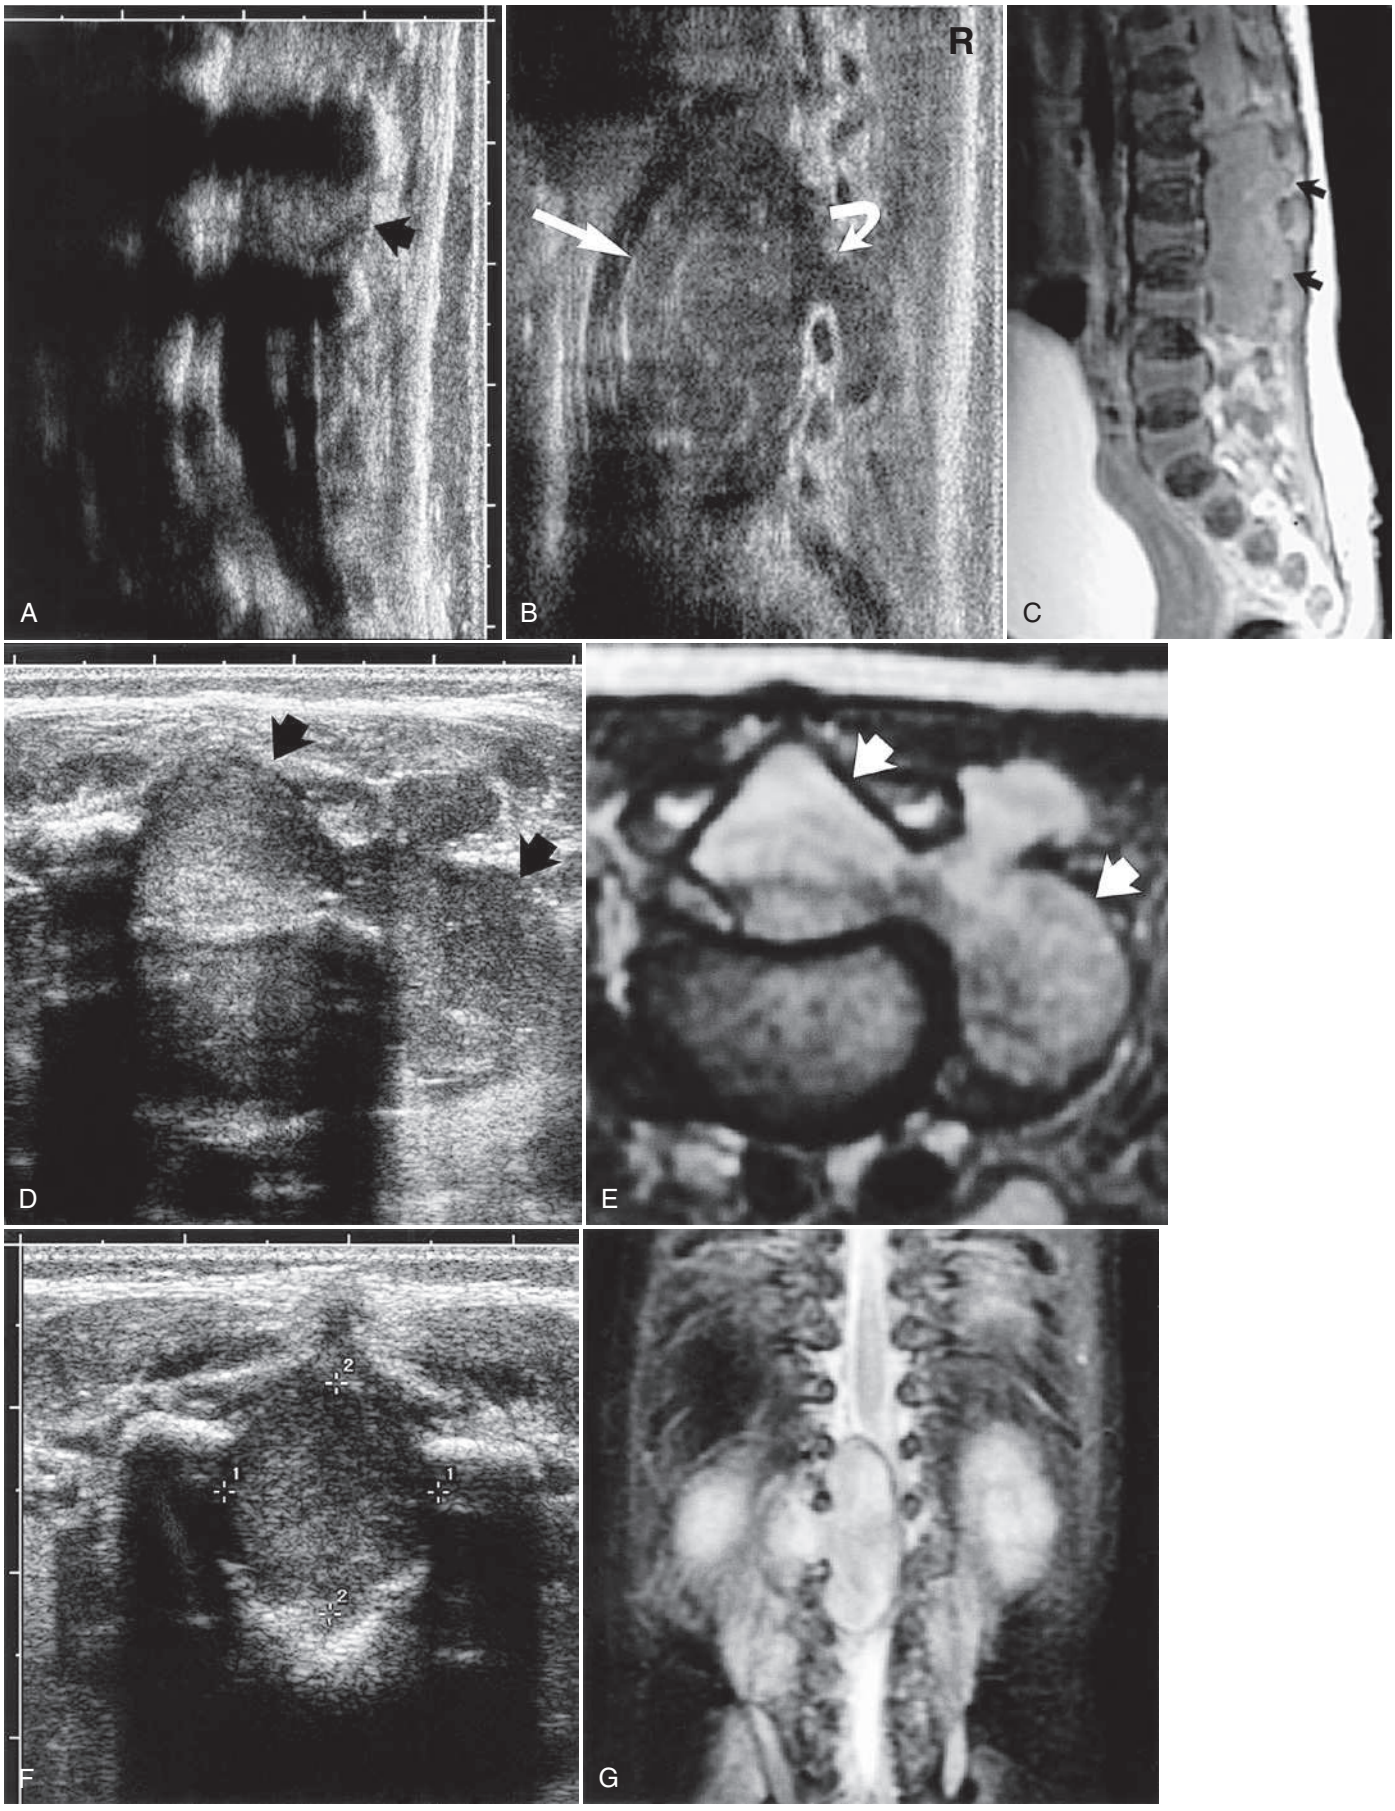

FIG. 49.27 Neuroblastoma With Intraspinal Extension. This 4-week-old girl had rectal prolapse. Initial imaging included spinal sonography. **(A)** and **(B)** On sagittal views (oriented to match magnetic resonance image), a homogeneously echogenic mass was discovered within the lumbar vertebral canal *(straight arrows)* and protrudes through the neural foramen *(curved arrow)*. **(C)** Corresponding T2-weighted magnetic resonance image shows hypointense intraspinal lumbar mass *(black arrows)*. Corresponding transverse sonogram **(D)** and magnetic resonance image **(E)** show the dumbbell-shaped mass with an intraspinal component and paraspinal/retroperitoneal extension *(arrows)*. **(F)** Axial ultrasound shows intraspinal component *(calipers)*. **(G)** Coronal T2-weighted magnetic resonance image reveals the intraspinal mass compressing the conus medullaris and extension into retroperitoneum.

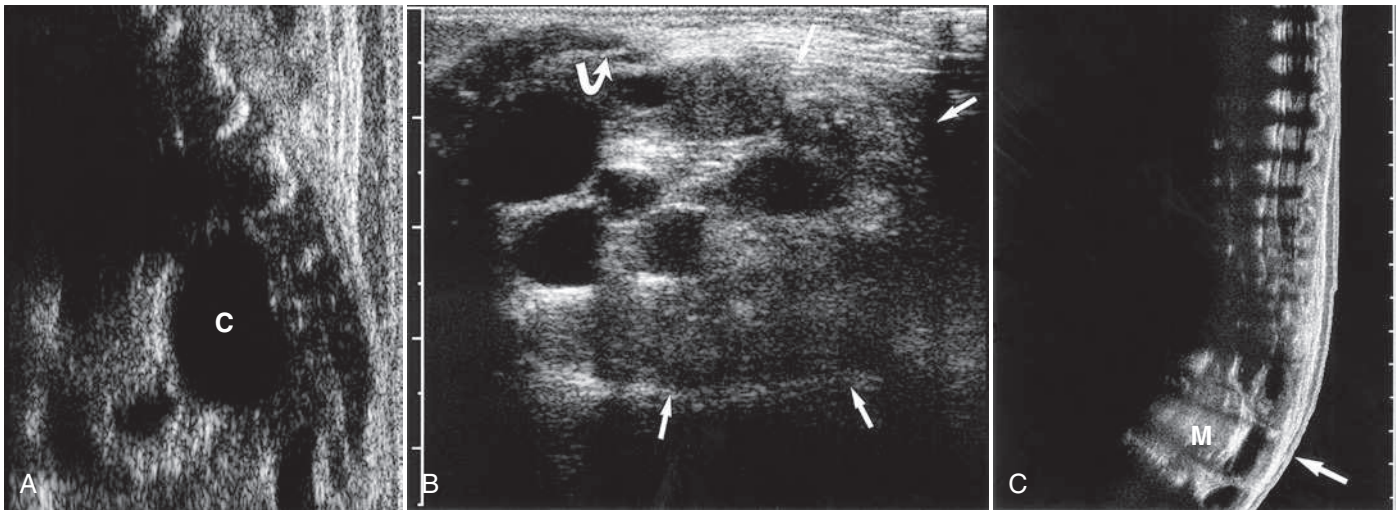

FIG. 49.28 Sacrococcygeal Teratoma. A 3-day-old infant girl with "fullness" in the buttocks. **(A)** Sagittal view shows a complex mass immediately anterior to the cartilaginous coccyx. Portions of the mass are cystic *(C).* **(B)** More distal view reveals the tip of the coccyx *(curved arrow).* The large mass extended even below the end of the coccyx *(straight arrows).* **(C)** Extended–field-of-view image gives another sense of the relative size of the mass *(M)* compared with the rest of the spine (*arrow,* end of coccyx), but the contour of the skin of the buttocks was not distorted.

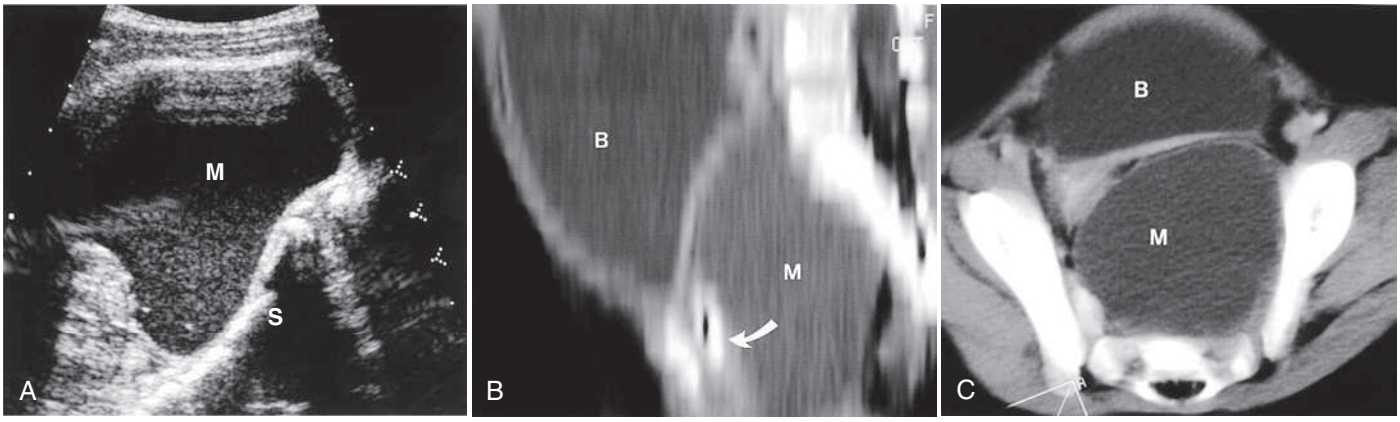

FIG. 49.29 Intrapelvic Sacrococcygeal Teratoma. A 3-year-old girl with bladder outlet obstruction. **(A)** Sagittal ultrasound view of the pelvis shows a complex cystic mass *(M)* that might have been mistaken for the urinary bladder. The mass was compressed immediately against the anterior wall of the sacrum *(S).* **(B)** Reconstructed sagittal and **(C)** direct axial computed tomography views reveal the mass *(M)* and the distended urinary bladder *(B).* High-intensity material is barium within the anteriorly displaced rectum *(curved arrow).*

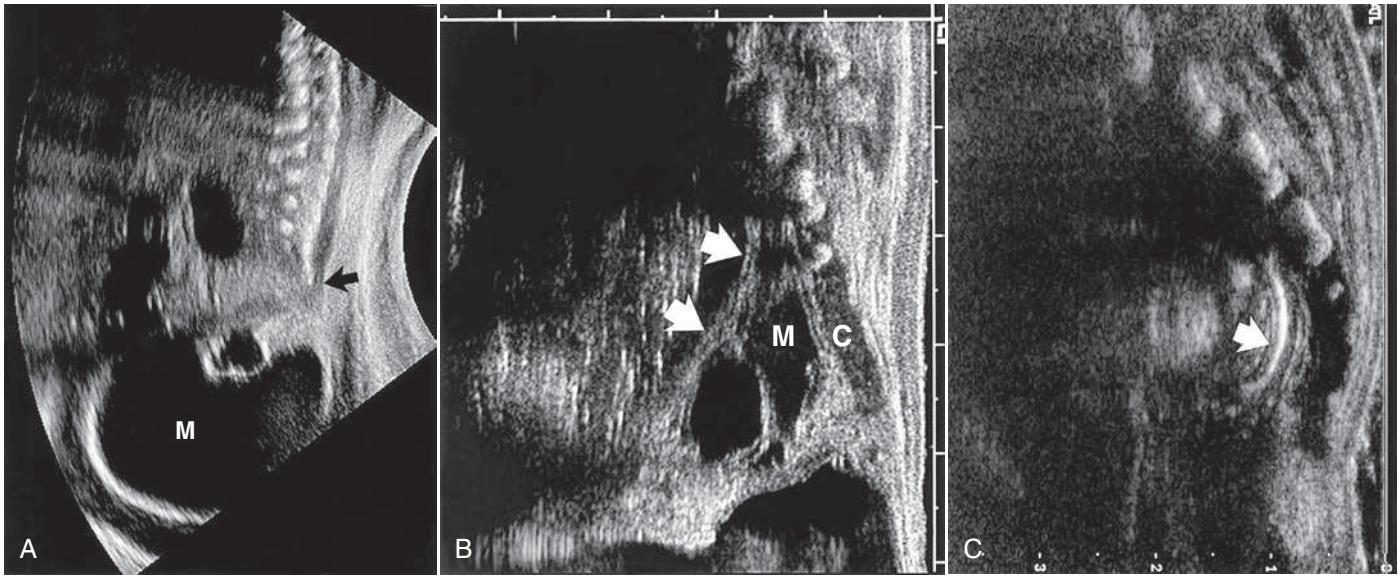

FIG. 49.30 Cystic Sacrococcygeal Teratoma. (A) Fetus at 25 weeks' gestation. The distal end of the calcified spine *(black arrow)* and the cystic portion of the mass *(M)* are demonstrated. **(B)** Postnatal ultrasound. The mass *(M)* is positioned immediately anterior to the coccyx *(C)* and immediately posterior to the posterior wall of the rectum *(arrows).* A large portion of the mass was external, and a small tongue of the tumor extended into a presacral, retrorectal position. **(C) Normal infant,** sagittal view, shows air within the rectum *(arrow),* which hugs the anterior aspect of the coccyx.

HEMORRHAGE AND INFECTION

Hemorrhage within the vertebral canal can occur in newborns in association with trauma, such as a birth injury, or with an invasive procedure such as failed lumbar puncture ("bloody taps"). Hemorrhage from birth trauma can be centered at any vertebral level. Hemorrhage related to lumbar puncture is originally centered at the point of needle placement but can extend superiorly and inferiorly for some distance. These primarily epidural collections can be visualized acutely as echogenic fluid that becomes heterogeneous and then anechoic in appearance, resolving in 2 to 4 days.[45,115] (Fig. 49.31). Injury to the spinal cord itself is also visible with ultrasound as a hyperechoic focus in the acute phase.[116] Echogenic debris within the subarachnoid space is sometimes visible with ultrasound after lumbar puncture (Fig. 49.32). This may represent hemorrhage from the trauma of the procedure or may be caused by redistribution of hemorrhage originally found in the cerebral ventricles of infants with known intraventricular hemorrhage.[117]

Ultrasound is useful for guiding percutaneous lumbar puncture[118] and for guiding anesthesiologists for caudal anesthesia in infants and neonates.[119] With a high-resolution transducer, the spinal needle can be followed from the skin to the thecal sac using midline sagittal scanning in the neonate and young infant and parasagittal scanning in the older infant and child.[45,120]

The importance of prompt recognition and treatment of epidural abscesses is well documented in the literature.[121] In the newborn and infant period, ultrasound is useful in detecting such collections.[122,123] This is particularly true if the infant is medically unstable and transfer to the MRI suite is deemed too risky. It is important to scan the entire length of the vertebral column and to pay special attention to the integrity of the vertebral bodies in these patients.

ARACHNOID CYSTS

Arachnoid cysts are infrequently found in infants, children and young adults. They can be incidental findings or they can cause

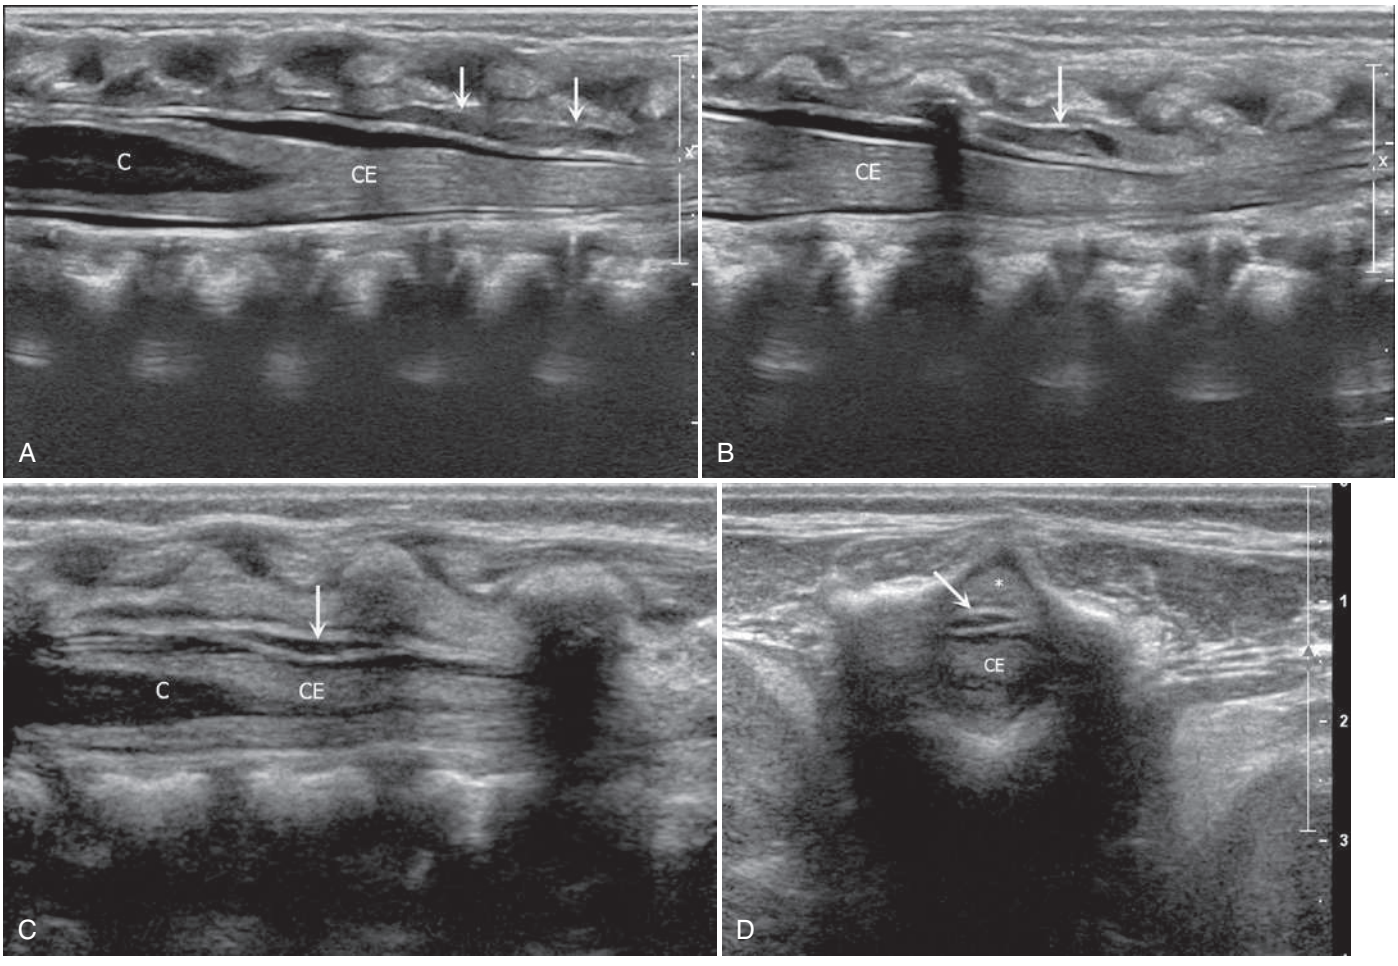

FIG. 49.31 Collections After Failed Lumbar Puncture. Epidural collection. (A) and **(B)** Sagittal views of the lumbar spine show the distal cord *(C)*. There is a large hypoechoic epidural collection *(arrows)*. The dura is the echogenic horizontal line deep to the collection. There is a small amount of subarachnoid fluid surrounding the nerve roots in the cauda equina *(CE)*. **Subdural collection. (C)** Sagittal view of the lumbar spine shows the distal cord *(C)* and cauda equina *(CE)*. There is a small subdural fluid collection seen between the dura and the arachnoid *(arrow)*. **(D)** Transverse view of the subdural collection confirms location of the fluid *(arrow)* below the dura. Note the fat (*) in the epidural space and the nerve roots in the cauda equina *(CE)*.

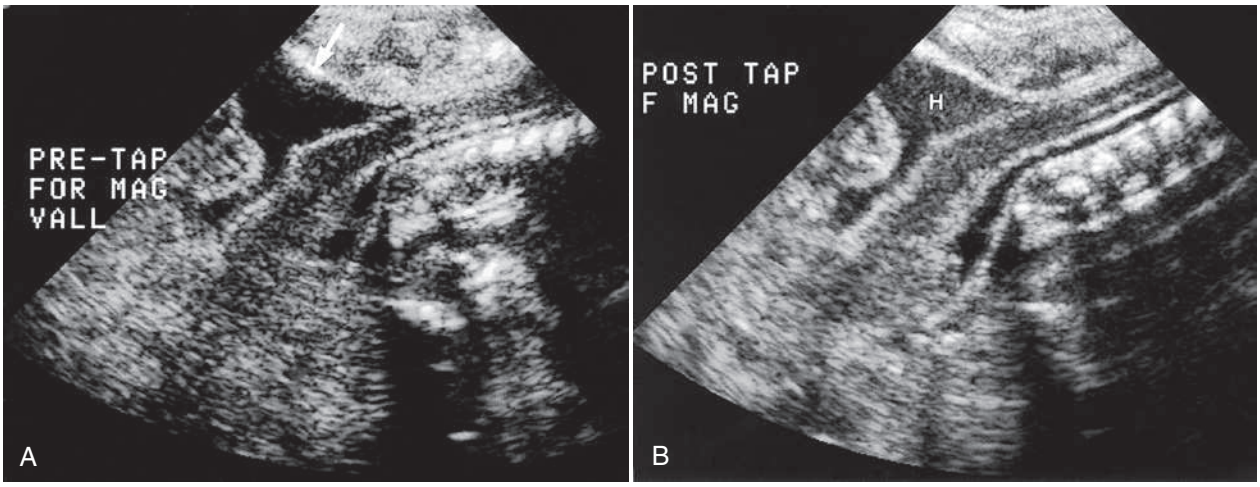

FIG. 49.32 Hemorrhage in Cisterna Magna After Lumbar Tap. (A) Sagittal view of the craniocervical junction before a lumbar tap using the foramen magnum as a window reveals anechoic fluid in the cisterna magna *(arrow)*. **(B)** The same region contains internal echoes, indicating the presence of hemorrhage *(H)*, after lumbar tap.

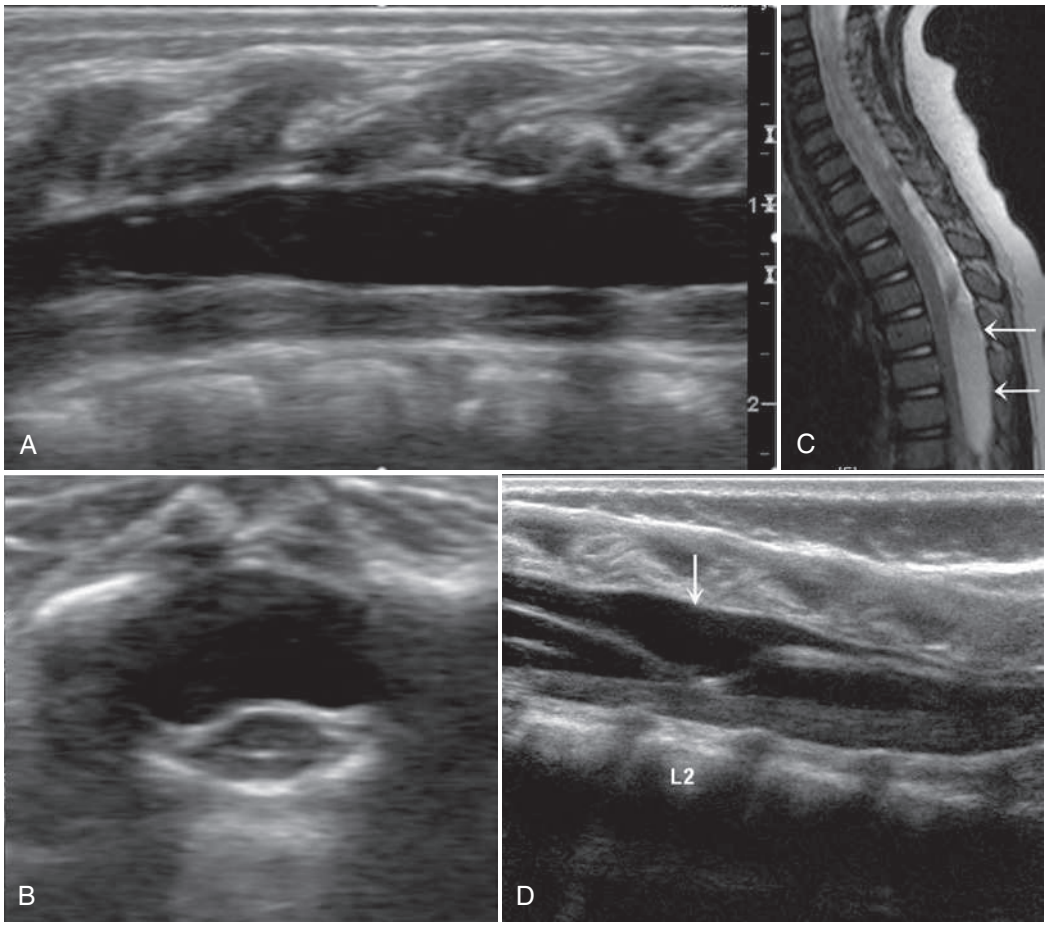

FIG. 49.33 Arachnoid Cysts. (A) and **(B)** Sagittal and transverse views of the thoracic spine in a 1-month-old demonstrate a large dorsal arachnoid cyst causing ventral displacement and compression of the spinal cord. **(C)** Sagittal T2-weighted image of the thoracic spine confirms a large arachnoid cyst *(arrows)* ventrally displacing the cord and causing thinning and compression of the cord. **(D)** Sagittal view in another newborn patient shows a small intradural arachnoid cyst *(arrow)* dorsal to the conus medullaris and proximal filum terminale. (**C** and **D** courtesy of Dr. Kathy McCarten.)

myelopathy and radiculopathy. They can be congenital or associated with trauma, surgery, arachnoiditis, neural tube defects, or neurocutaneous melanosis.

Arachnoid cysts can be intradural or less commonly extradural. Intradural cysts result from alterations of the arachnoid trabeculae, and extradural cysts from a defect in the dura that allows the subarachnoid space to herniate. They can occur in areas of prior surgery from arachnoid adhesions or abnormal CSF flow. They are most common in the thoracic spine (Fig. 49.33). When there are symptoms of cord compression, they should be treated with excision of the cyst wall. Widening of the spinal canal, bone erosion, displacement of the epidural fat, displacement of the thecal sac, and anterior compression of the cord can occur. The cysts are posterolateral to the spinal cord, and the walls can be difficult to differentiate from the fluid.[124-126]

INTRAOPERATIVE AND OTHER USES OF SPINAL SONOGRAPHY

Real-time ultrasound guidance is a valuable resource used by neurosurgeons during spine surgery to guide procedures and assess results in the setting of confined surgical fields. Many authors have described the use of intraoperative spinal sonography in minimizing surgical invasion of the vulnerable spinal cord and in analyzing normal and abnormal cord motion.[127-130] Once a **laminectomy** has been performed, the extended window into the vertebral canal makes highly detailed imaging possible, even in older patients.[131] Posterior fossa decompression for Chiari 1 malformation can be assessed intraoperatively with ultrasound if a water bath is created in the surgical bed after suboccipital craniectomy. Adequate cerebellar tonsillar motion and CSF pulsation is valuable information that can determine the need for dural incision without compromising the outcome of the decompression.[132] Masses can be precisely localized, and optimal position of the cervical cord can be determined before cervical vertebral fusion. Ultrasound has successfully guided fine-needle aspiration biopsy of lytic vertebral body and paraspinal mass lesions.[133] Definition of postoperative collections is also possible (Fig. 49.34). In general, the superficial soft tissues of the back are well defined by ultrasound. Superficial **hemangiomas** of the back, frequently the impetus to perform spine sonography, are well delineated on ultrasound (Fig. 49.35).

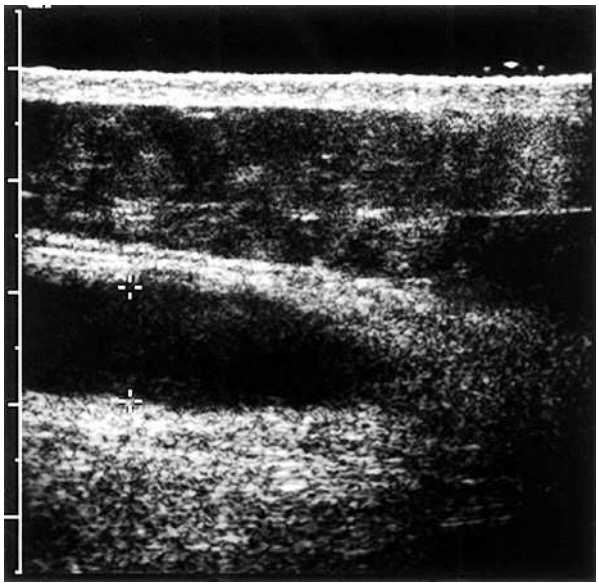

FIG. 49.34 Seroma. Transverse view of the back in a 6-year-old child after posterior spinal fusion for scoliosis. Cursors indicate the presence of a seroma.

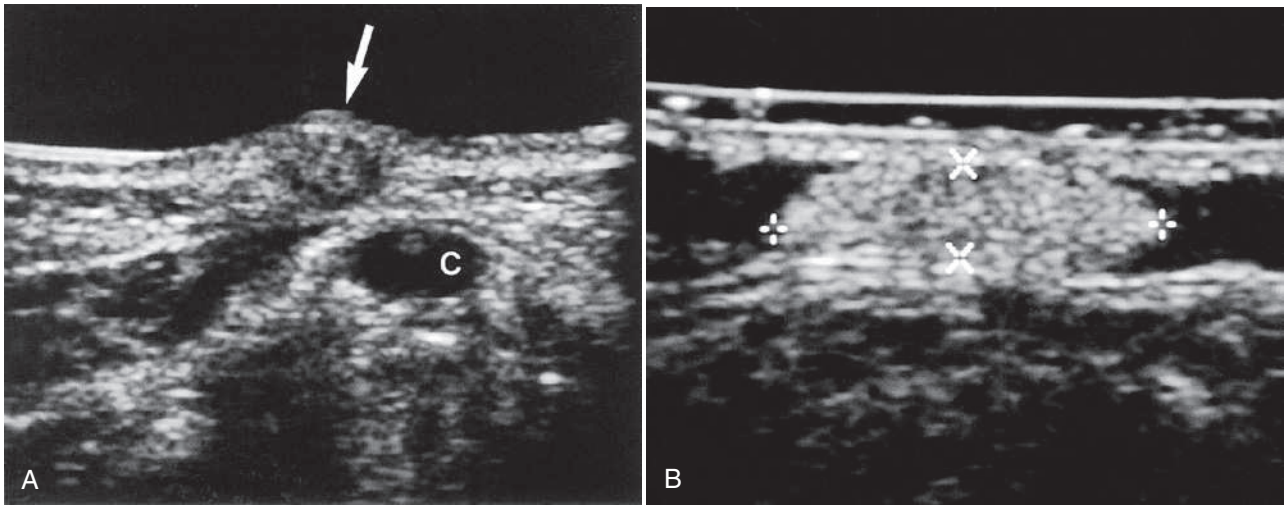

FIG. 49.35 Subcutaneous Hemangiomas. (A) Transverse ultrasound of a palpable, red mass adjacent to the coccyx *(C)* in a newborn. There is no extension into the vertebral canal, and the underlying spinal cord *(arrow)* is normal. **(B)** Sagittal ultrasound view of another infant shows an echogenic lesion *(calipers)* that does not distort the skin surface. The standoff pad is helpful to demonstrate or exclude changes in skin contour.

CHAPTER 50

The Pediatric Chest

Chetan Chandulal Shah and S. Bruce Greenberg

SUMMARY OF KEY POINTS

- Ultrasound of the chest plays an important role in diagnosis and treatment of pleural effusion and empyema.
- Real-time ultrasound is very useful in evaluation of diaphragmatic motion disorders.
- Ultrasound can determine if a neoplastic lesion is solid or cystic.
- Doppler and color ultrasound can evaluate vascularity of a lesion and vascular thrombosis.
- Ultrasound of the chest is very useful in differentiating among (1) solid mass and large or persistent pleural effusion when there is a totally or partially opaque hemithorax on chest radiographs; (2) round pneumonia and mediastinal mass; and (3) normal thymus and mediastinal mass.
- Ultrasound guidance is helpful for interventional chest procedures.

CHAPTER OUTLINE

ULTRASOUND TECHNIQUE
PLEURAL EFFUSION AND EMPYEMA
Sonographic Signs of Pleural Fluid
Free Fluid Movement With Respiration
Fluid Color Flow Doppler Signal
Diaphragm Sign
Displaced-Crus Sign
Bare-Area Sign
Sonography Versus Computed Tomography Scan
Mass Versus Fluid
Parapneumonic Collections and Empyema
Lung Abscess Versus Empyema
LUNG PARENCHYMAL DISORDERS
Pneumonia
Round Pneumonia
Chest Radiograph or Ultrasound?
Atelectasis
Congenital Pulmonary Airway Malformation
Bronchopulmonary Foregut Malformation
DIAPHRAGM DISORDERS
VASCULAR DISORDERS
Vascular Thrombosis
Lymphovascular Malformation
MEDIASTINAL MASSES
Thymic Index
Abnormal Location of Thymus Mimicking Mass Lesion
Anterior Mediastinal Masses
Lymphadenopathy
Posterior Mediastinal Masses
ULTRASOUND-GUIDED INTERVENTIONAL PROCEDURES
OTHER LESS ESTABLISHED INDICATIONS

Extracardiac chest sonography is limited by air in the lungs and bone in the thoracic cage. However, ultrasound is valuable for evaluating the abnormal chest in which fluid and solid structures interpose between the chest wall and lung. Sonography is particularly well suited for the evaluation of **pleural effusion and empyema.** The thymus, liver, and spleen provide windows for chest sonography. Any radiographically opaque chest can be further evaluated by sonography to determine whether there is pleural fluid, a chest mass, atelectasis, consolidation, or lung hypoplasia. Ultrasound may show the pulmonary mass reaching the periphery but may not be able to provide a specific diagnosis. Computed tomography (CT) is required for evaluation of the extent of the mass. Biopsy might be required to arrive at a specific diagnosis.

Ultrasound can be used to guide thoracentesis, chest tube placement, or biopsy of the pleura, the lung, or a mediastinal mass. The indications for extracardiac chest sonography are listed in the accompanying box. Breast, cardiac, and pericardial lesions are beyond the scope of this chapter.

ULTRASOUND TECHNIQUE

Linear transducers with frequencies ranging from 5 to 15 MHz are used for chest ultrasound.[1] Diaphragmatic motion can best be assessed using real-time ultrasound comparison of the diaphragmatic motion on the right and the left sides. Color flow Doppler sonographic imaging is useful to demonstrate vascular supply, which is important in the diagnosis of sequestration. The selection of the frequency of the transducer is inversely dependent on patient size. Higher frequencies are used for infants, and lower frequencies for adolescents.[2]

Indications for Extracardiac Chest Sonography

FLUID ACCUMULATION IN THE PLEURA
Pleural effusion
Empyema

LUNG DISORDERS
Pneumonia
Atelectasis
Sequestration
Congenital pulmonary airway malformation
Bronchopulmonary foregut malformation

DIAPHRAGM DISORDERS
Diaphragmatic paralysis
Diaphragmatic hernia or defect
Diaphragmatic rupture

VASCULAR DISORDERS
Vascular thrombosis
Vascular malformation

MASSES
Mediastinal, chest wall, and at times pulmonary masses

INTERVENTIONAL INDICATIONS
Thoracentesis
Biopsy of chest mass
Sclerotherapy of lymphatic malformation
Vascular access

OTHER INDICATIONS
Catheter position in vessels
Pneumothorax
Rib fracture
Rib osteomyelitis
Bronchiolitis

Sector or vector transducers are used for intercostal and suprasternal approaches. Linear transducers with the long axis of the transducer aligned with the intercostal space can also be used. We have found that the smaller footprint of newer linear transducers provides improved resolution compared with vector transducers using the intercostal window (Fig. 50.1). Newer technology has allowed for increased portability of ultrasound equipment such that some ultrasound probes can connect directly to a tablet or smart phone device. The resolution of these newer devices is currently a limiting factor.

In children younger than 1 year, sternal ossification centers are unfused, the mineral content of the bones and cartilage is lower than in older children, and the thymus is much larger relative to other structures. Acoustic windows through the sternum, costal cartilages, and thymus allow ultrasound evaluation of mediastinal structures. In older children transabdominal ultrasound of the lower chest, including the diaphragm, can be performed using the liver, spleen, or fluid-filled stomach as an acoustic window. Sector, vector, or linear array transducers can be used for this purpose.

Free pleural fluid is dependent in position and will shift with patient positioning. Ultrasound of the dependent areas will identify free pleural fluid. Loculated fluid will necessarily be in a dependent position but may move with positioning.

Three longitudinal planes are used for assessment of the mediastinum (Fig. 50.2): right parasagittal plane through the superior vena cava (SVC), sagittal plane through the aortic root, and left parasagittal plane through the pulmonary outflow tract. **Two distinct transverse planes** through the mediastinum are also routinely used (Fig. 50.3): the superior plane at the confluence of the brachiocephalic veins and SVC and a lower transverse plane where the SVC, aorta, and pulmonary outflow tract are visualized.

PLEURAL EFFUSION AND EMPYEMA

The most frequent use of chest sonography is for the evaluation of a completely radiopaque hemithorax (Fig. 50.4) or a partially radiopaque hemithorax (Fig. 50.5). Ultrasound distinguishes pleural from pulmonary causes of opacification. Chest ultrasound is more sensitive than decubitus radiographs for detecting small amounts of pleural fluid (Fig. 50.6). Pleural fluid collections less than 4 mm in thickness can be physiologic and detected in normal children placed on their elbow after lying for 5 minutes in a left lateral decubitus position.[3] Because pleural effusions transmit sound waves, they allow for visualization of structures deep to the pleura that are not normally identifiable.

Intercostal and subdiaphragmatic windows are used to access the pleural space. The **spleen** and **liver** are good windows to the pleural space because they are relatively homogeneous solid organs that provide good through transmission (Figs. 50.7 and 50.8). The classic appearance of transudative pleural effusion is an echo-free or hypoechoic collection without septations immediately deep to the chest wall. However, it should be recognized that exudates can also be anechoic and that transudative pleural effusions are anechoic and nonseptated in only 45% of patients.[4] Therefore echogenicity in pleural collections does not exclude the diagnosis of a transudate.

Exudates are usually complex collections with internal echoes and associated fibrin septations. The collections may be multiloculated with a honeycomb appearance.[5] Exudates are associated with pleural thickening and underlying parenchymal abnormality.[6] Complex collections such as a **hemothorax** (Fig. 50.9) or **empyema** (Fig. 50.10) have thicker fluid with **septations** (Fig. 50.11). Underlying consolidated or atelectatic lung is more echogenic than an effusion. Complicated effusions are characterized by an irregular or indistinct interface between pleura and the adjacent lung. A **fibrothorax** has a thick pleural rind that is echogenic. Multiple hyperechoic foci in the lung are caused by residual air within bronchi and alveoli and are called **sonographic air bronchograms** (Fig. 50.12).

Text continued on p. 1709.

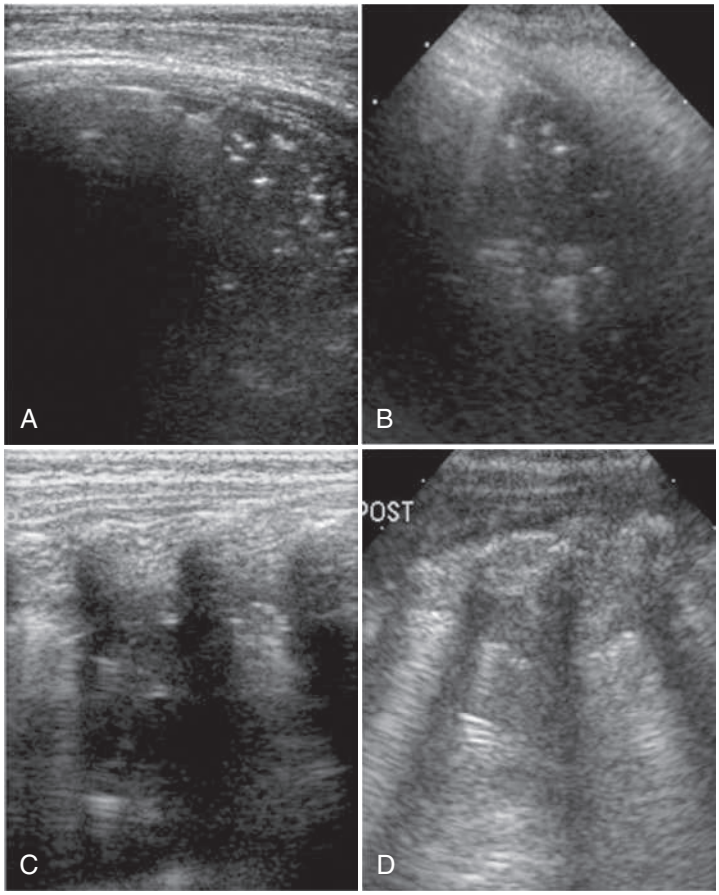

FIG. 50.1 Pneumonia on Chest Ultrasound. (A) Linear transducer. **(B)** Vector transducer. **Air bronchograms** from pneumonia are seen better with linear transducers than vector transducers, especially when the **air bronchograms** are closer to the chest wall and there is no intervening pleural fluid. **(C)** and **(D)** Air bronchograms within a **round pneumonia** in another child are better visualized with a linear transducer **(C)** than with a vector transducer **(D),** despite the intervening rib shadows.

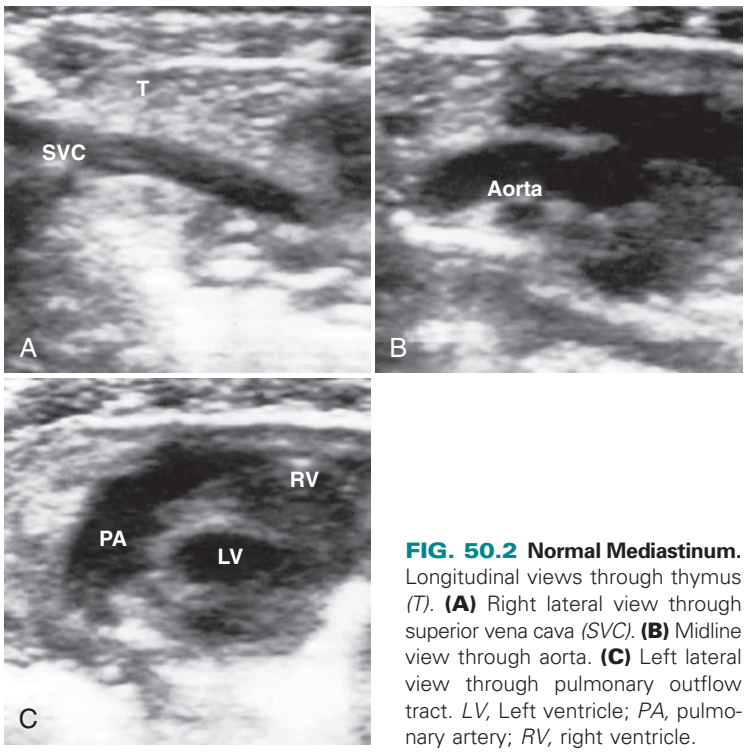

FIG. 50.2 Normal Mediastinum. Longitudinal views through thymus *(T).* **(A)** Right lateral view through superior vena cava *(SVC).* **(B)** Midline view through aorta. **(C)** Left lateral view through pulmonary outflow tract. *LV,* Left ventricle; *PA,* pulmonary artery; *RV,* right ventricle.

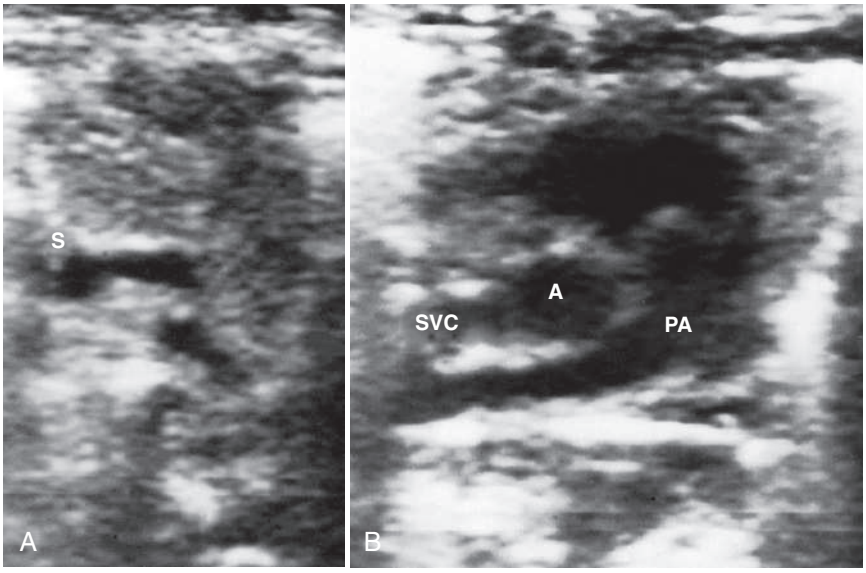

FIG. 50.3 Normal Mediastinum, Transverse View. (A) Superior plane with innominate vein catheter running through thymus to superior vena cava *(S).* **(B)** Inferior plane through superior vena cava *(SVC),* aorta *(A),* and pulmonary artery *(PA).*

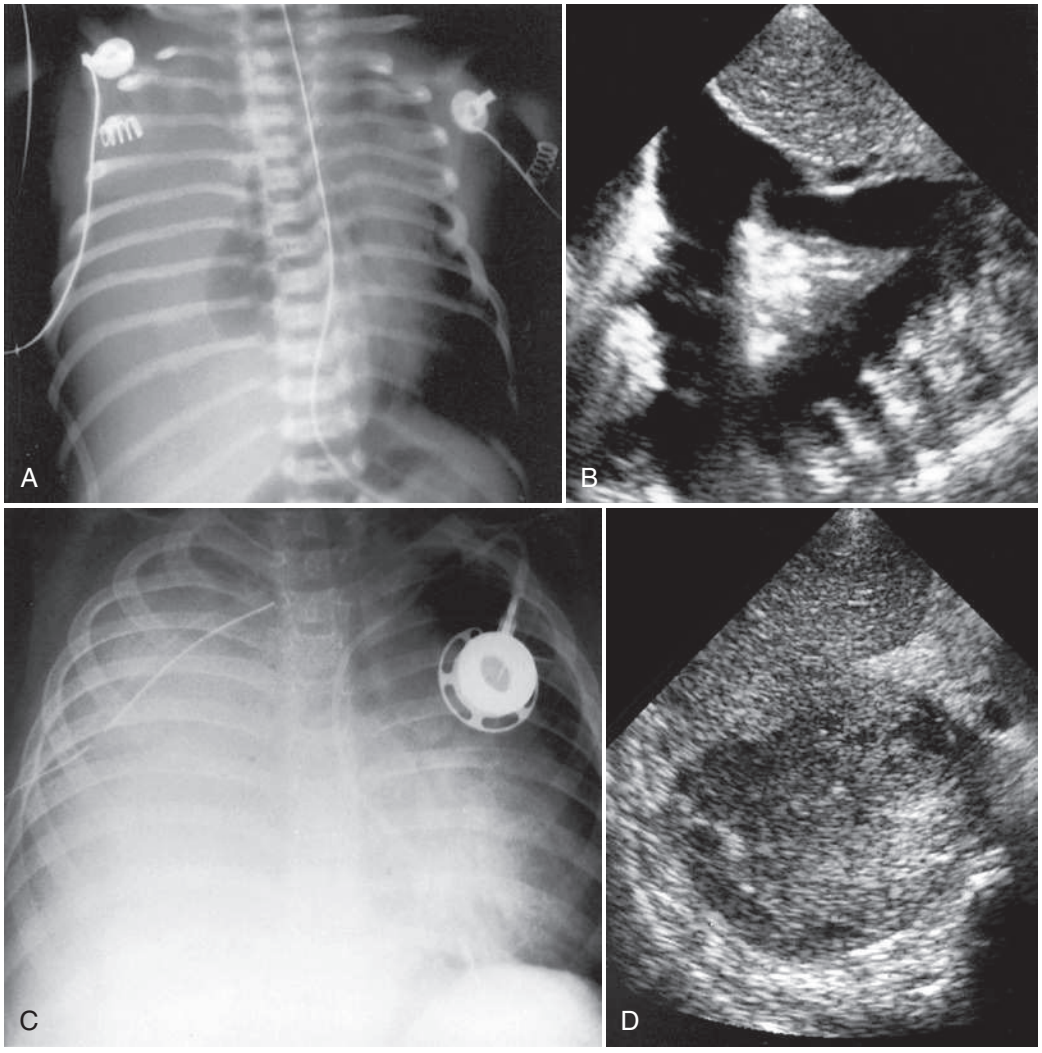

FIG. 50.4 Radiopaque Hemithorax: Neonatal Chylothorax. (A) Anteroposterior chest radiograph in 2-week-old infant shows opacified right chest and shift of heart and mediastinum to left. **(B)** Sonogram through liver shows that the opacity is a large accumulation of fluid around a collapsed lung. **(C)** Right chest opacification with shift of the heart to the left side, suggesting fluid in the right pleural space. No drainage was obtained from a chest tube. **(D)** Sonogram through liver shows that the right chest is filled with solid tissue, which at surgery was infected with **aspergillosis** extending from the liver. (With permission from Seibert RW, Seibert JJ, Williamson SL. The opaque chest: when to suspect a bronchial foreign body. Pediatr Radiol. 1986;16[3]:193-196.[76])

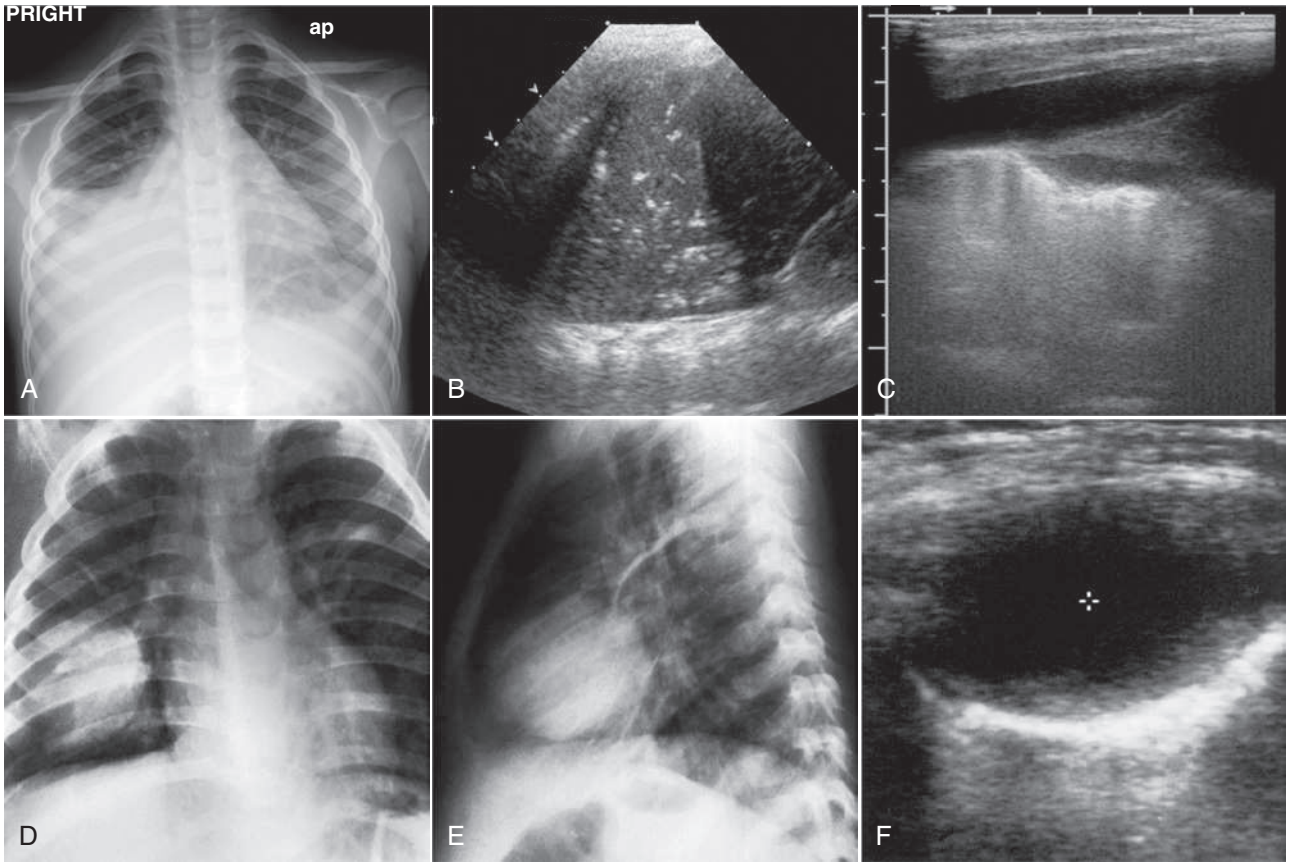

FIG. 50.5 Partially Radiopaque Hemithorax. (A) Radiograph. **(B)** and **(C)** Sonograms show left upper lobe pneumonia with left pleural fluid. **(D)-(F)** Another patient with partially opaque right hemithorax. **(D)** and **(E)** Posteroanterior and lateral chest radiographs. **(F)** Sonogram shows that the radiopacity is a hypoechoic, loculated fluid collection (+) in the minor fissure.

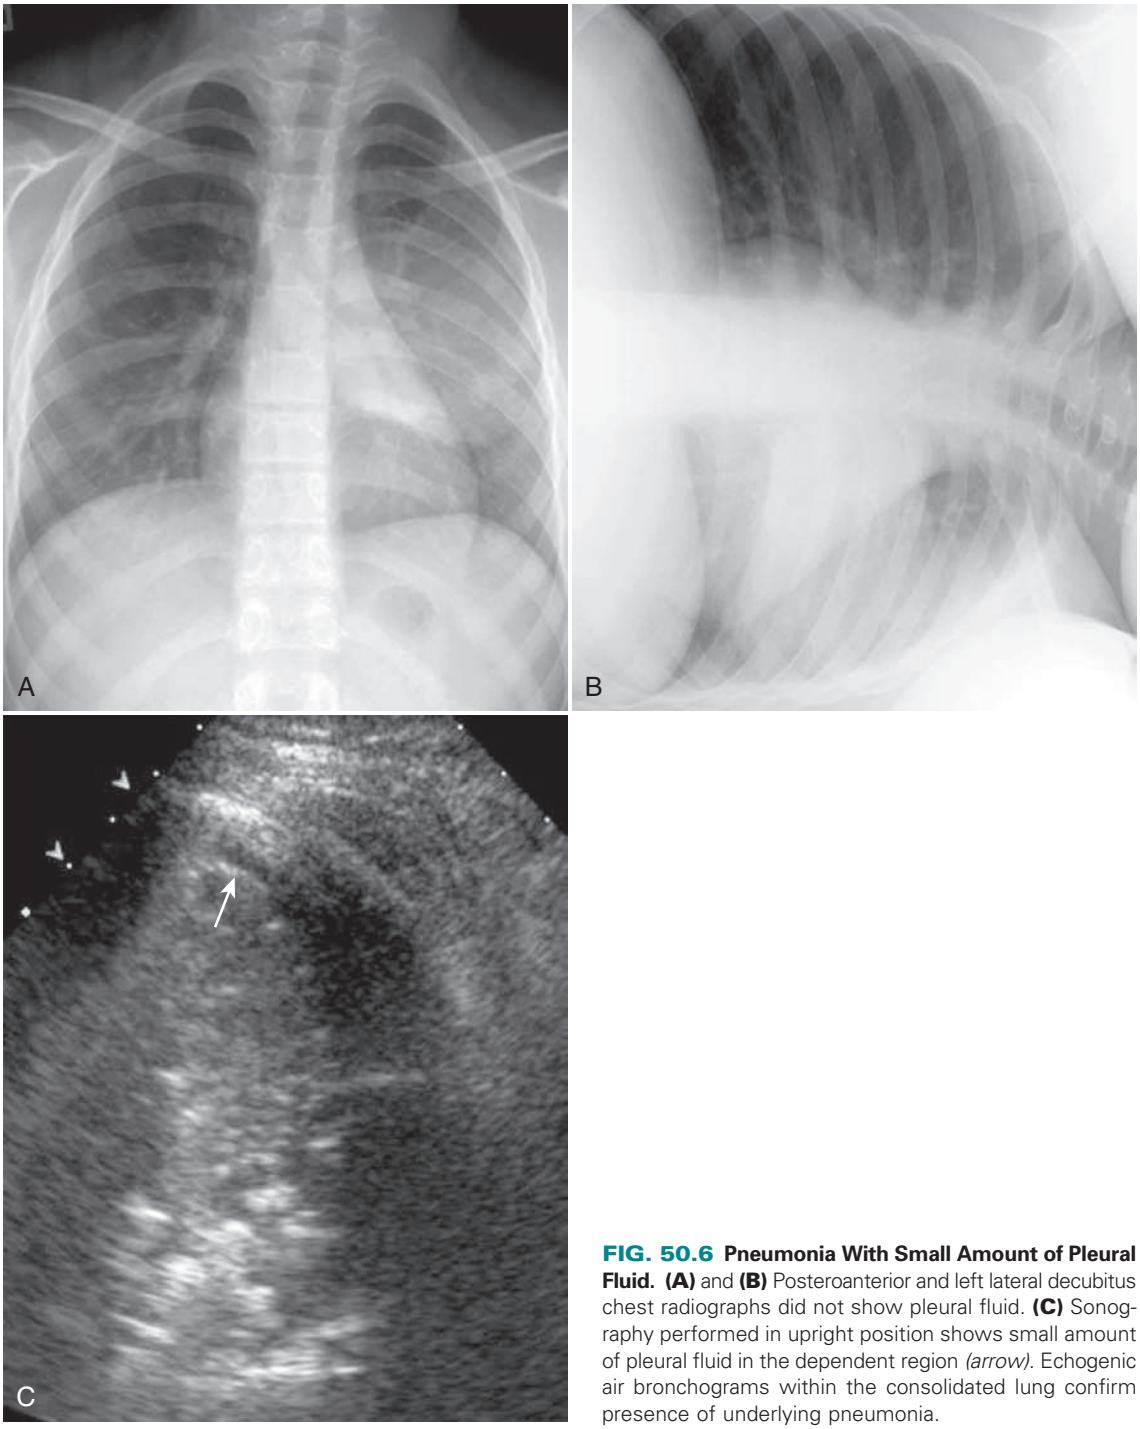

FIG. 50.6 Pneumonia With Small Amount of Pleural Fluid. (A) and **(B)** Posteroanterior and left lateral decubitus chest radiographs did not show pleural fluid. **(C)** Sonography performed in upright position shows small amount of pleural fluid in the dependent region *(arrow)*. Echogenic air bronchograms within the consolidated lung confirm presence of underlying pneumonia.

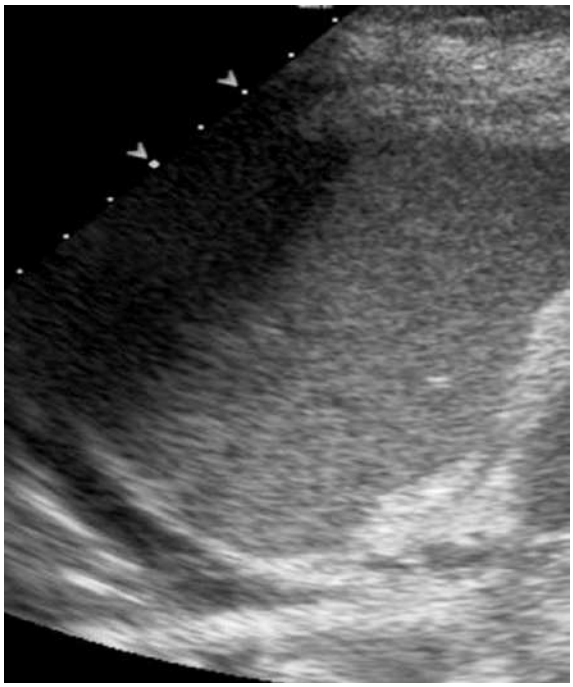

FIG. 50.7 Pleural Fluid Seen Through Splenic Window. Longitudinal sonogram shows a small amount of fluid in the left pleural space.

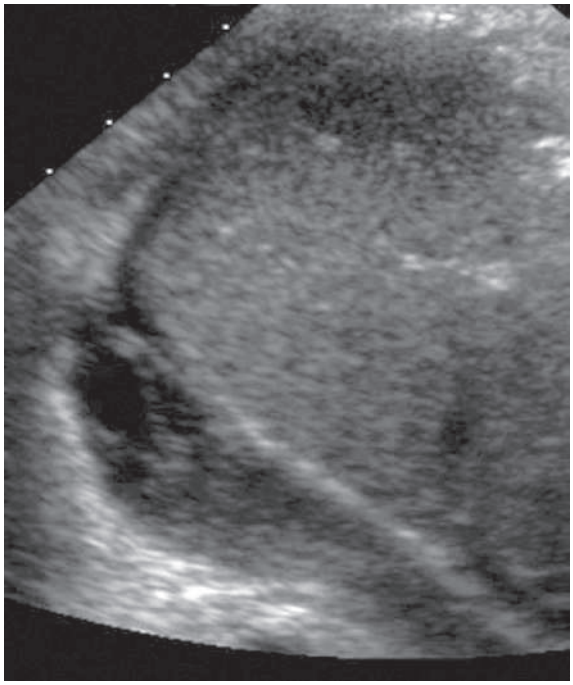

FIG. 50.8 Empyema Seen Through Hepatic Window. Sonography of pleural space through the hepatic window shows presence of echogenic fluid in the right pleural space.

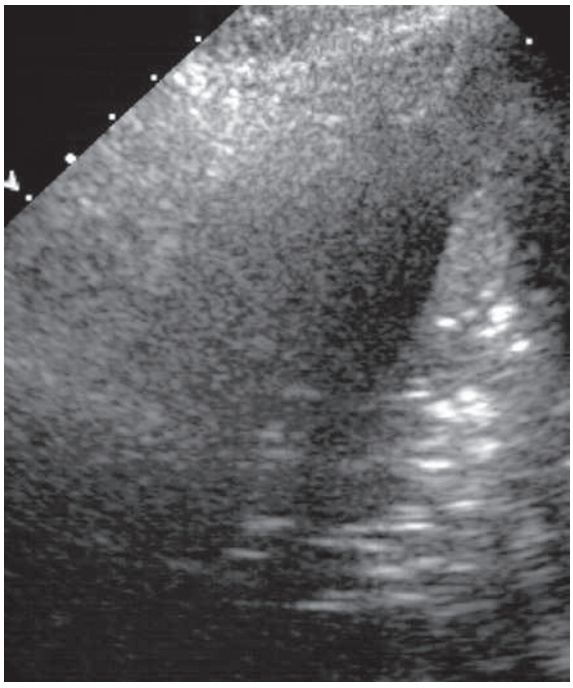

FIG. 50.9 Hemothorax. Moderately echogenic right effusion is present after trauma from four-wheeler crash. Atelectasis of the right lower lung is present, with some hyperechoic air bronchograms visible.

FIG. 50.10 Empyema Caused by Pneumonia. Longitudinal sonogram shows echogenic fluid in the right pleural space above the diaphragm. Purulent drainage contained gram-positive and gram-negative rods and gram-positive cocci.

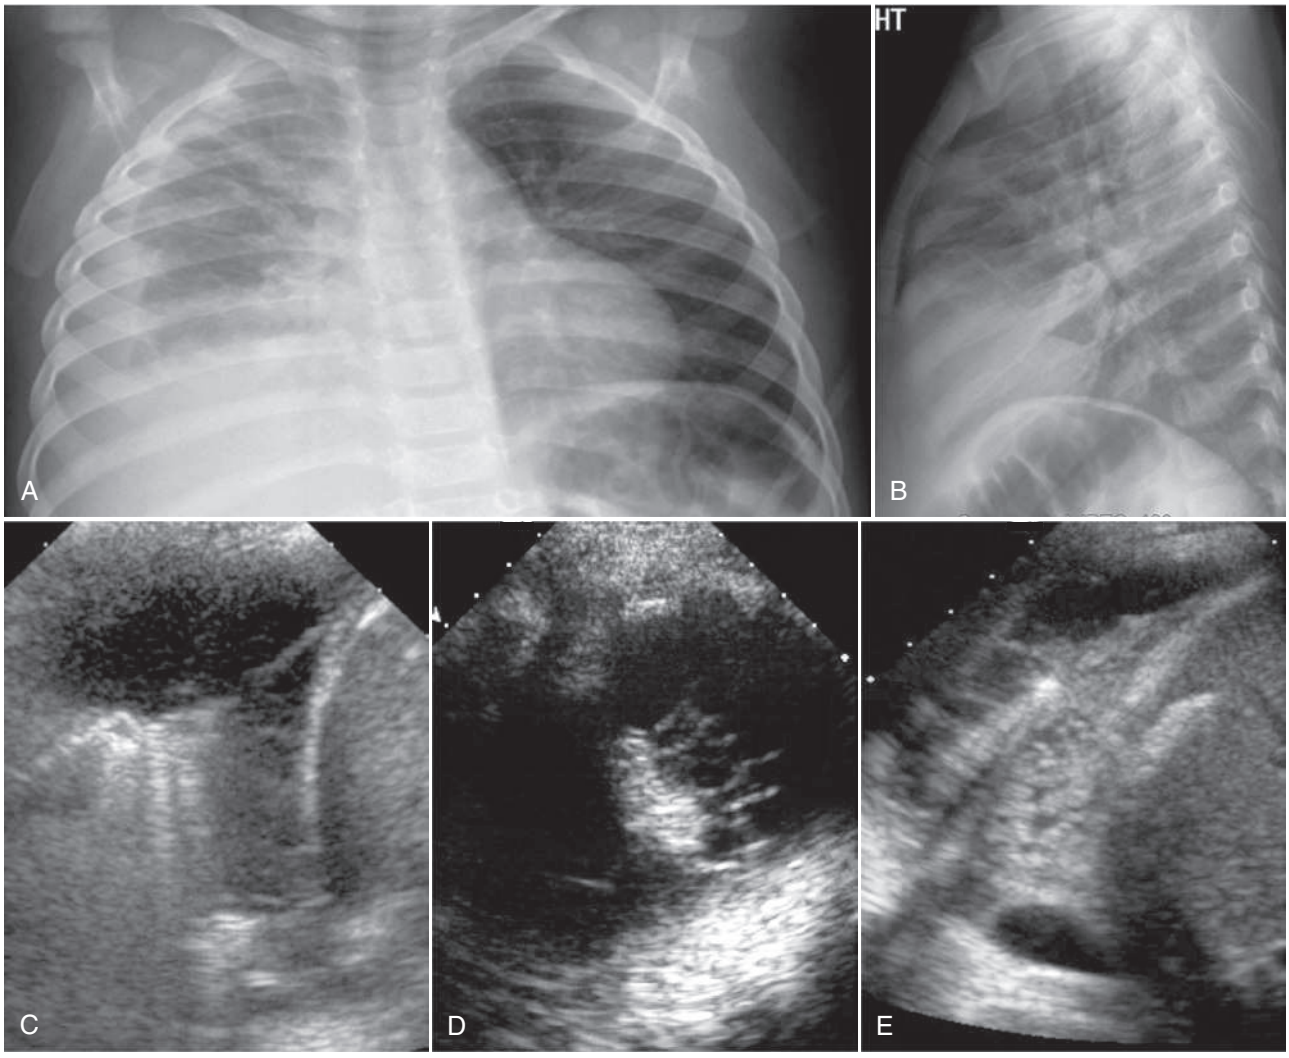

FIG. 50.11 Septated Pleural Fluid. (A) and **(B)** Posteroanterior and lateral radiographs show right pleural fluid with obliterated right hemidiaphragm. **(C)** Longitudinal sonogram shows septated pleural fluid. **(D)** and **(E)** Transverse and longitudinal sonograms of two other patients with septated pleural fluid.

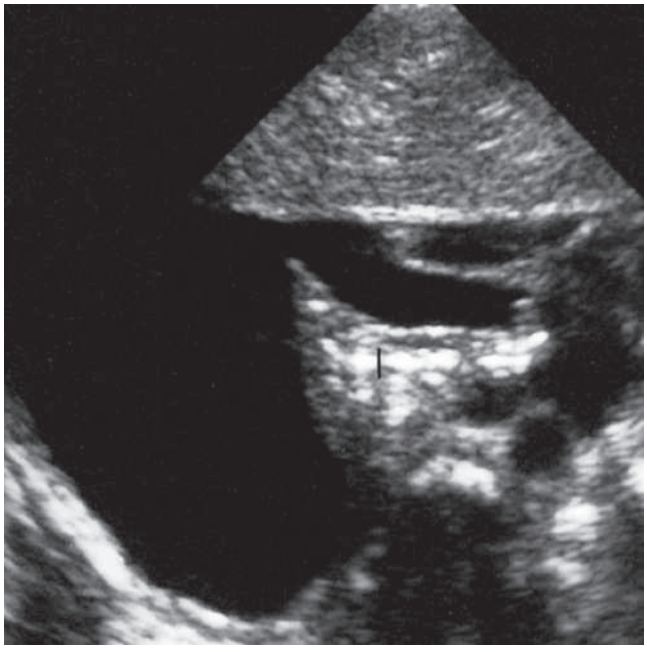

FIG. 50.12 Sonographic Air Bronchograms Within Pneumonia. Multiple echogenic linear air shadows called "sonographic air bronchograms" are seen within the consolidated lung *(l)* in this child with pneumonia.

Sonographic Signs of Pleural Fluid

Sonographic Signs of Pleural Fluid

- Fluid collection deep to the chest wall and/or above the diaphragm
- Posterior chest wall visualized behind the fluid
- Free fluid moves with respiration
- Septations move if fluid is loculated
- Color Doppler signal between visceral and parietal pleura and/or at costophrenic angle
- Diaphragm sign (fluid outside or peripheral to diaphragm)
- Displaced-crus sign
- Bare-area sign

Free Fluid Movement With Respiration

Free fluid changes position with changes in the patient's position. Fluid will move posterior to the liver and lungs when the patient is in a supine position (Fig. 50.13). When the patient is upright, the fluid will move between the lung and the diaphragm. Free fluid is indicated by change in the shape of pleural fluid with inspiration and expiration and the presence of **moving septations** within the pleural fluid[7] (Video 50.1). These septations are fibrin strands.

Fluid Color Flow Doppler Signal

Color flow Doppler ultrasound aids in distinguishing pleural effusion from pleural thickening.[7] Color Doppler signal is identified during respiratory motion between the visceral and parietal pleura in the presence of pleural effusion. Cell movement, debris, and fibrin scatter sound waves, producing the color flow Doppler signal in the pleural fluid collection (Fig. 50.14). Organized pleural thickening will appear as a colorless pleural lesion with no Doppler signal. The color flow Doppler signal has high sensitivity and specificity in determining if a fluid collection can be aspirated.[8] The fluid color flow Doppler signal is particularly useful in distinguishing if small, loculated collections can be aspirated.

Diaphragm Sign

When the liver or spleen is used as an acoustic window and fluid is seen adjacent to these organs, the location of the fluid is determined in reference to the diaphragmatic position. If the fluid is below the diaphragm and more centrally located, it is **ascites.** If the fluid is above the diaphragm and more peripherally located, it is in the pleural space (see Fig. 50.7).

Displaced-Crus Sign

There is fluid in the pleural space if the fluid is interposed between the crus and the vertebral column, displacing the crus away from the spine.

Bare-Area Sign

The posterior aspect of the right lobe of the liver is directly attached to the posterior diaphragm without peritoneum. Thus ascitic fluid in the subhepatic or subphrenic space cannot extend behind the liver at the level of the bare area. Pleural fluid will extend behind the liver at the level of the bare area (see Fig. 50.13).

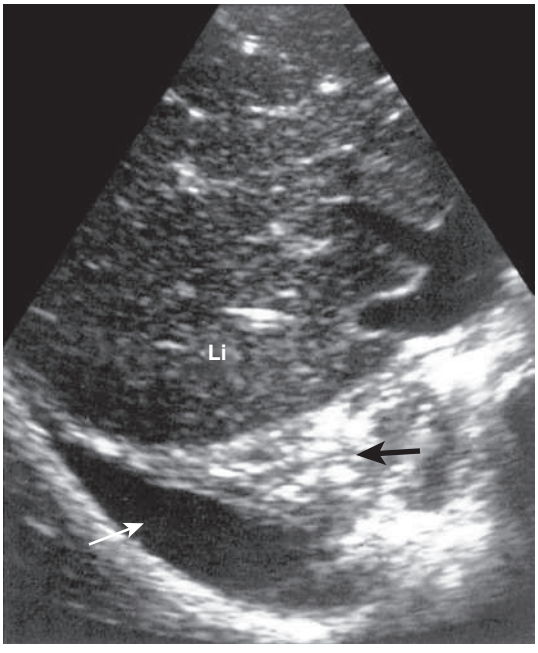

FIG. 50.13 Posterior Pleural Fluid Over Bare Area of Liver. Transverse scan through liver with patient in supine position shows triangular consolidated lung with air bronchograms *(black arrow)* behind the liver *(Li).* Fluid *(white arrow)* is posterior to lung and is behind the bare area of the liver, and therefore is in the pleural space.

Sonography Versus Computed Tomography Scan

Ultrasound, unlike CT, is a portable, bedside technique, making it ideal for evaluating chest opacification detected by conventional radiographs in the critically ill infant or child, to distinguish pulmonary from pleural disease (Fig. 50.15). Septations are better visualized by ultrasound than CT (Fig. 50.16). CT is better at identifying pulmonary parenchymal abnormalities, but this does not improve the outcome in managing empyema.[9]

Mass Versus Fluid

A limitation of chest sonography is that very homogeneous, solid, hypoechoic lesions may appear fluid filled. The criteria for fluid-filled structures are (1) lack of internal echoes; (2) a sharp posterior wall; and (3) increased through transmission of sound deep to the collection of fluid. The lack of echogenicity is a relative phenomenon that is judged by the echogenicity of the surrounding structures. The air-filled lung deep to a pleural collection will have a strong echogenic interface regardless of the nature of the pleural collection. Fluid in the pleural space produces **acoustic enhancement.** The lack of referenced solid or cystic structures in the chest makes detection of increased through transmission difficult to judge within the chest. Observing a change in shape of the pleural fluid during respiration, the movement of echogenic particles, and the fluid color flow Doppler signal is helpful in

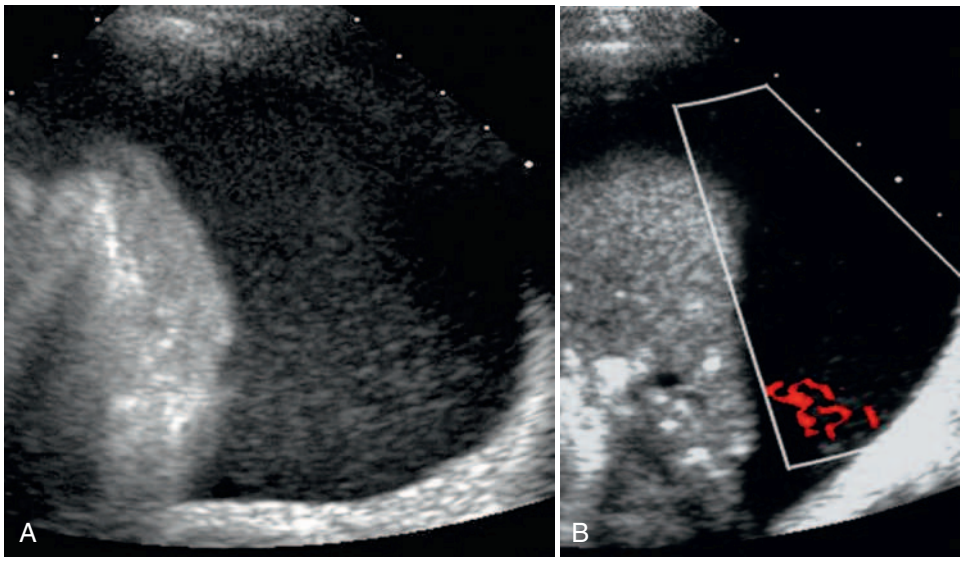

FIG. 50.14 Color Flow Doppler Signal in Pleural Fluid With Debris. (A) Gray-scale sonogram shows left pleural fluid with much debris. **(B)** Color flow Doppler signal.

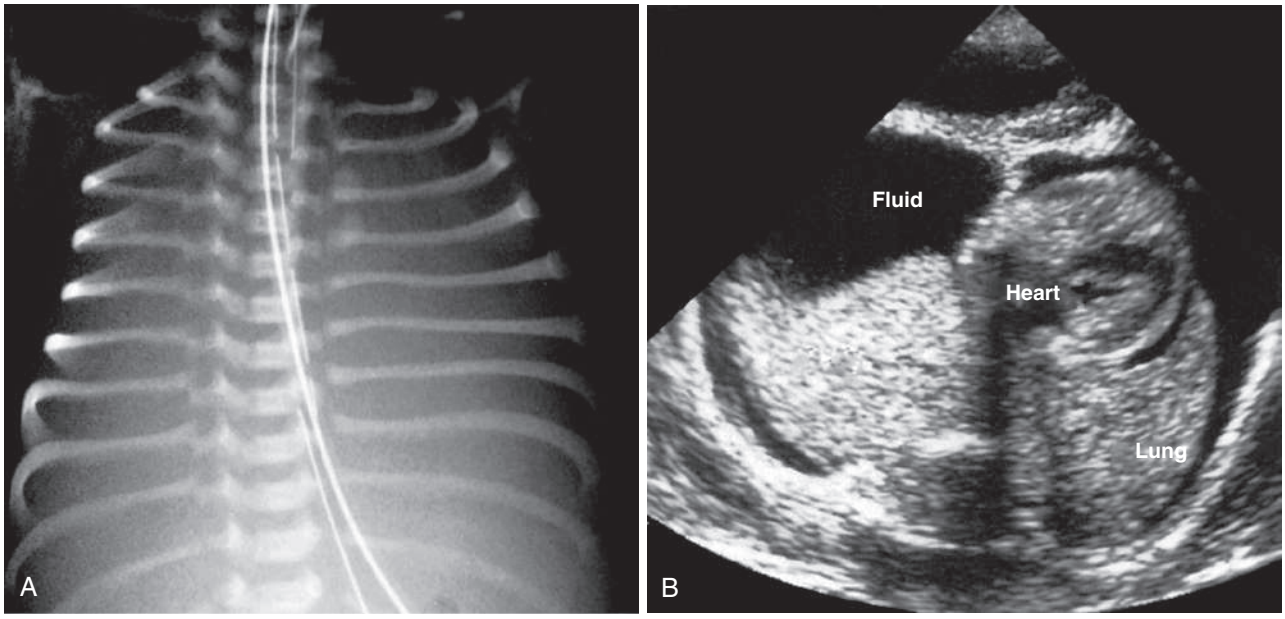

FIG. 50.15 Bilateral Pleural Fluid and Pericardial Fluid in Critically Ill Patient. (A) Chest radiograph of infant receiving extracorporeal membrane oxygenation (ECMO) shows complete lung opacification. **(B)** Transverse sonogram shows pleural fluid around both collapsed lungs and a small amount of pericardial fluid.

distinguishing thick pleural fluid from solid masses. Consolidated lung superficial to aerated lung will have increased through transmission compared with the aerated lung and can be identified as lung parenchyma by the presence of **air or fluid bronchograms.** Collapsed or consolidated lung tissue often has the appearance of the liver or spleen. A patient with persistent pleural fluid not responding to drainage can be evaluated by ultrasound for a possible underlying tumor (Fig. 50.17).

Another pitfall in the sonographic evaluation of the chest is the acoustic shadow cast by a rib **(rib shadowing),** which may confuse the inexperienced sonographer into misinterpreting that a mass is anechoic. The transducer should be placed between the ribs to avoid this pitfall. The echogenicity of the mass or pleural lesion can be compared with that of the liver.

Parapneumonic Collections and Empyema

Parapneumonic collections occur in up to 40% of children with bacterial pneumonia and are especially common in those younger than 4 years.[10] Most collections are not infected, but many evolve into **empyemas** with frank pus. Parapneumonic effusions detected by ultrasound can be prognostic in children with pneumonia. Children with complicated collections characterized by septations

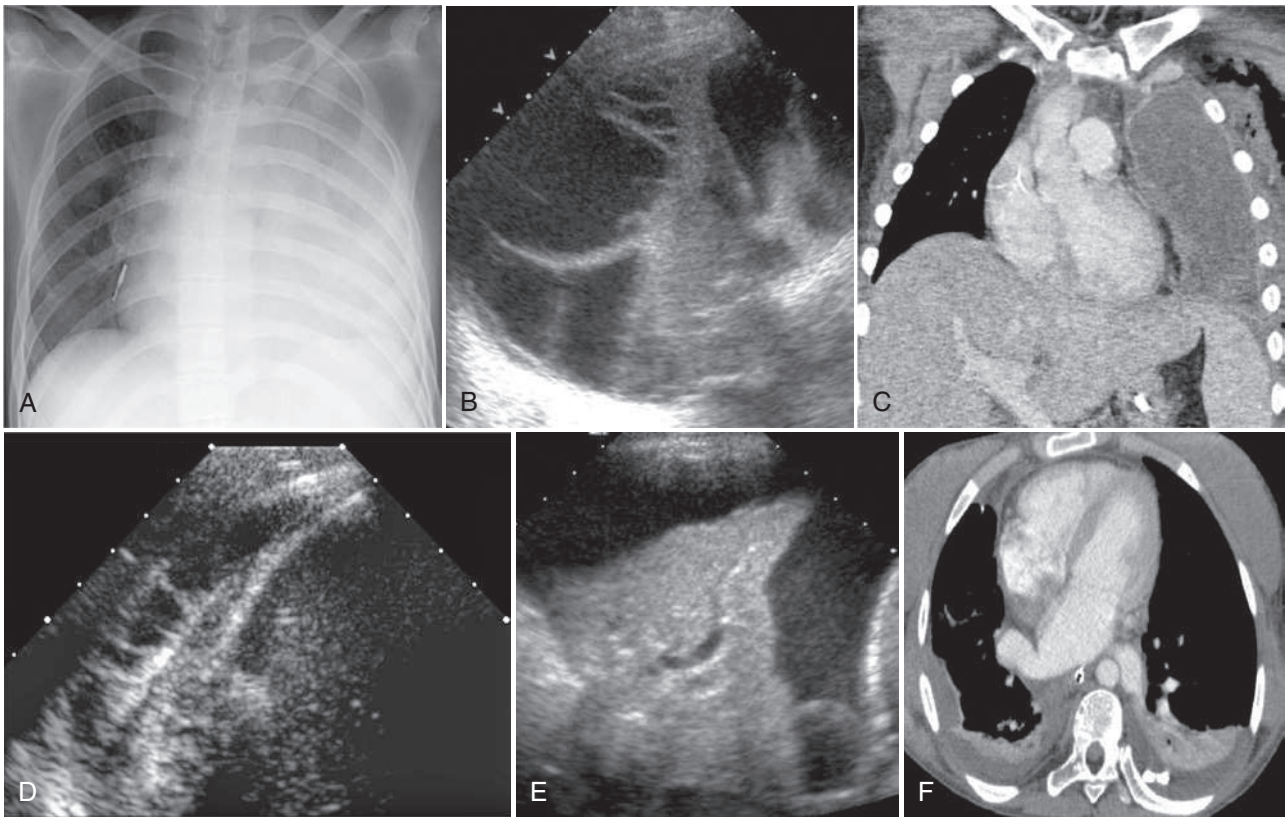

FIG. 50.16 Septations in Pleural Space Are Seen Better on Sonograms Than Computed Tomography (CT) Scans. (A) Chest radiograph shows opacified left hemithorax. **(B)** Sonogram shows a septated fluid collection. **(C)** CT scan shows pleural fluid, but the septa are not well visualized. **(D)** In another child with cystic fibrosis and lung transplant, sonogram shows septated pleural fluid on the right side, in addition to **(E)** echogenic pleural fluid with few septations on the left side. **(F)** CT scan shows bilateral pleural fluid, but septations at the right base are not well visualized.

have longer hospital stays and benefit from intrapleural fibrinolytic therapy or surgical procedures.[11]

Lung Abscess Versus Empyema

Lung abscess adjacent to the chest wall or to an acoustic window such as the liver or spleen usually appears as a complex collection with fluid-debris levels and septations just like an empyema. Abscesses and empyemas usually exhibit different types of motion when visualized by ultrasound. An abscess demonstrates expansion of the entire circumference with inspiration, whereas with an empyema, only the internal wall adjacent to the lung shows slight motion. Lung abscesses may be difficult to differentiate from empyema when the empyema contains multiple, loculated air collections caused by thoracentesis. Air-fluid collections move with patient repositioning, which can aid in distinguishing empyema from abscess (Figs. 50.18 and 50.19).

LUNG PARENCHYMAL DISORDERS

Pneumonia

Consolidated lung is hypoechoic relative to the highly reflective, air-filled, normal surrounding lung. Consolidated lung echogenicity is similar to that of liver (Fig. 50.20), but sonographic air bronchograms differentiate it from liver. Strong, nonpulsatile, branching, linear echoes produced by air-filled bronchi converge toward the root of the lung. The linear pattern of bright echoes is observed when scanning parallel to the long axis of the bronchi (Fig. 50.21). When the scanning is done at more acute angles, scattered echoes of variable lengths produced by the sonographic air bronchograms are observed (Fig. 50.22). If there is adjacent pleural fluid, the hypoechoic consolidated lung can be differentiated from the hypoechoic-to-anechoic pleural effusion by identification of these sonographic air bronchograms.

Round Pneumonia

Round pneumonia is more common in children younger than 8 years, but 15% occur between 8 and 12 years.[12] Young children do not have well-formed pores of Kohn and channels of Lambert for collateral air circulation. The inflammation spreads centrifugally as the strands of fibrin usually spread during the red hepatization phase of pneumonia through the pores of Kohn and channels of Lambert.[13] Owing to underdevelopment of these collateral circulations, the advancing front is sharply demarcated from the unaffected lung parenchyma and causes a focal round mass like pneumonia that mimics a posterior mediastinal mass on the radiograph of the chest. Most round pneumonias are posteriorly located and in lower lobes.

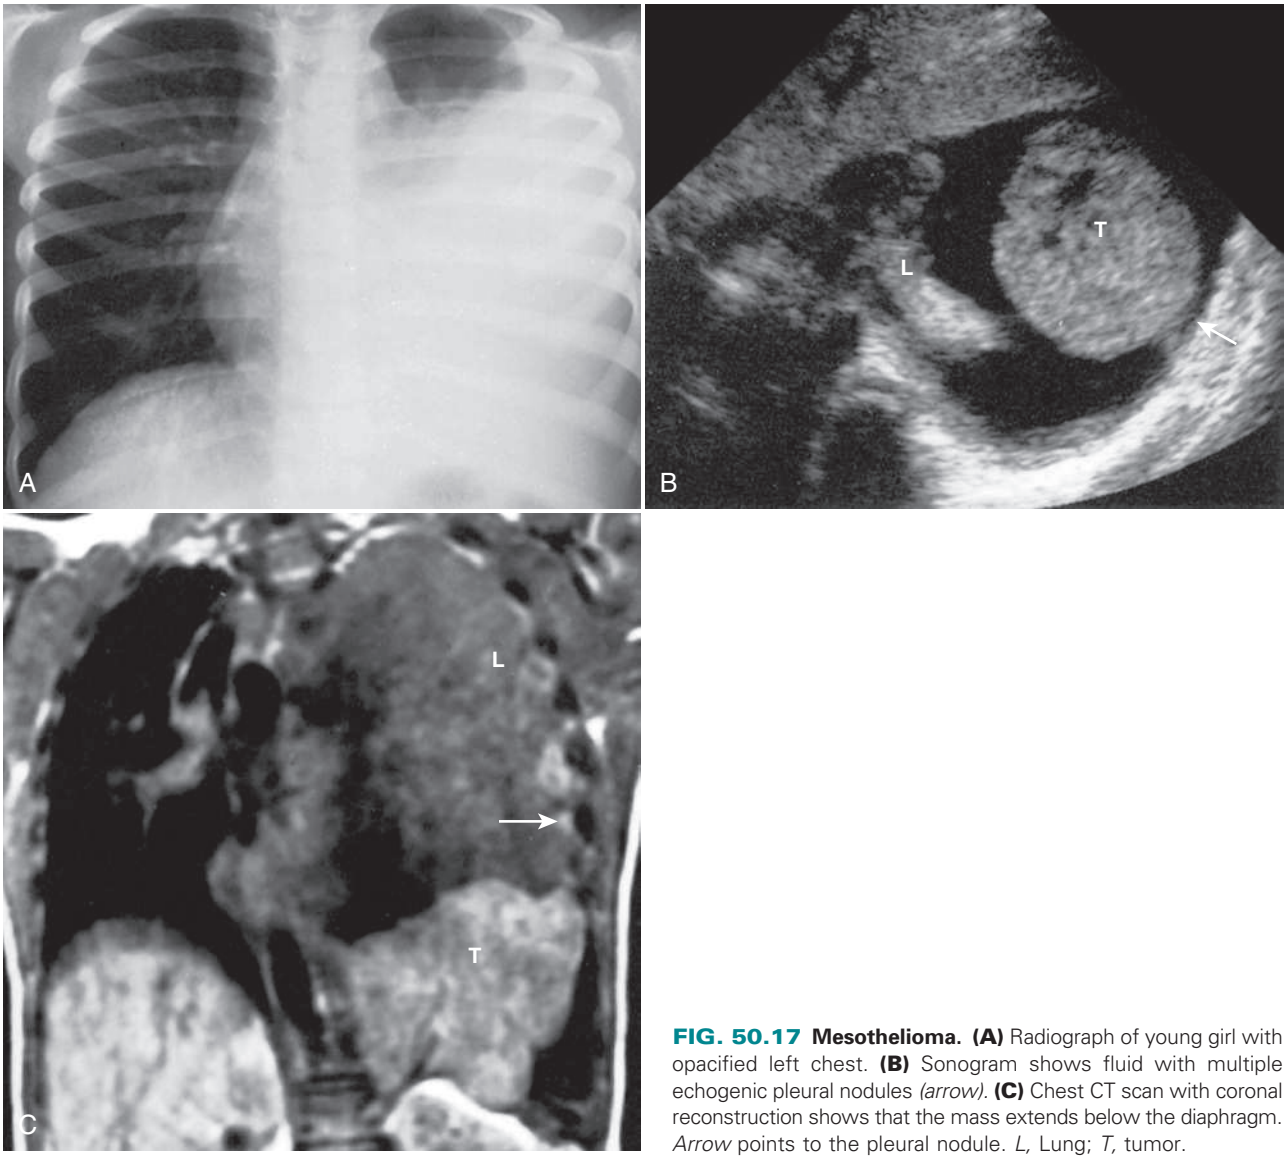

FIG. 50.17 Mesothelioma. (A) Radiograph of young girl with opacified left chest. **(B)** Sonogram shows fluid with multiple echogenic pleural nodules *(arrow)*. **(C)** Chest CT scan with coronal reconstruction shows that the mass extends below the diaphragm. *Arrow* points to the pleural nodule. *L,* Lung; *T,* tumor.

Unlike adults, children may not have typical signs and symptoms of pneumonia. A common etiological agent for round pneumonia is pneumococcus (streptococcus pneumonia). The diagnosis becomes clearer if the radiograph is repeated after a few days. On the follow-up radiograph after antibiotic therapy, most round pneumonias resolve without progression to lobar pneumonia.

Ultrasound can show the air bronchograms and confirm that it is a round pneumonia on the day of the presentation (Fig. 50.23), and one can avoid CT scan of the chest. However, a follow-up chest radiograph may still be indicated to exclude the remote possibility of mass or congenital anomaly.

Chest Radiograph or Ultrasound?

Many recent studies have reported that pneumonia can be diagnosed with ultrasound.[14-25] Ultrasound may supplement chest radiographs in certain circumstances, such as differentiation of round pneumonia from a mediastinal mass (see Fig. 50.23). However, replacing chest radiographs with ultrasound in suspected cases of pneumonia is not practical at many institutions. Meta-analysis[14] of eight studies performed from 2008 to 2014 shows that for most of these studies[15-21] the ultrasound examination was performed by a skilled physician or skilled sonographer. These studies did not specify the time required to perform the ultrasound examinations and interpret the findings. It is obvious that the time required to perform an ultrasound study is substantially longer than to obtain a radiograph. Professional time involvement of the physician in interpreting ultrasound findings is typically greater than for interpreting radiographs. Ultrasound is operator dependent, and interobserver variability has not been studied. A recent study[22] showed that pneumonia was missed by ultrasound in 5 of 76 children with pneumonia seen on radiographs. Missing these 6.6% of pneumonia cases to avoid minimal ionizing radiation from a chest radiograph probably

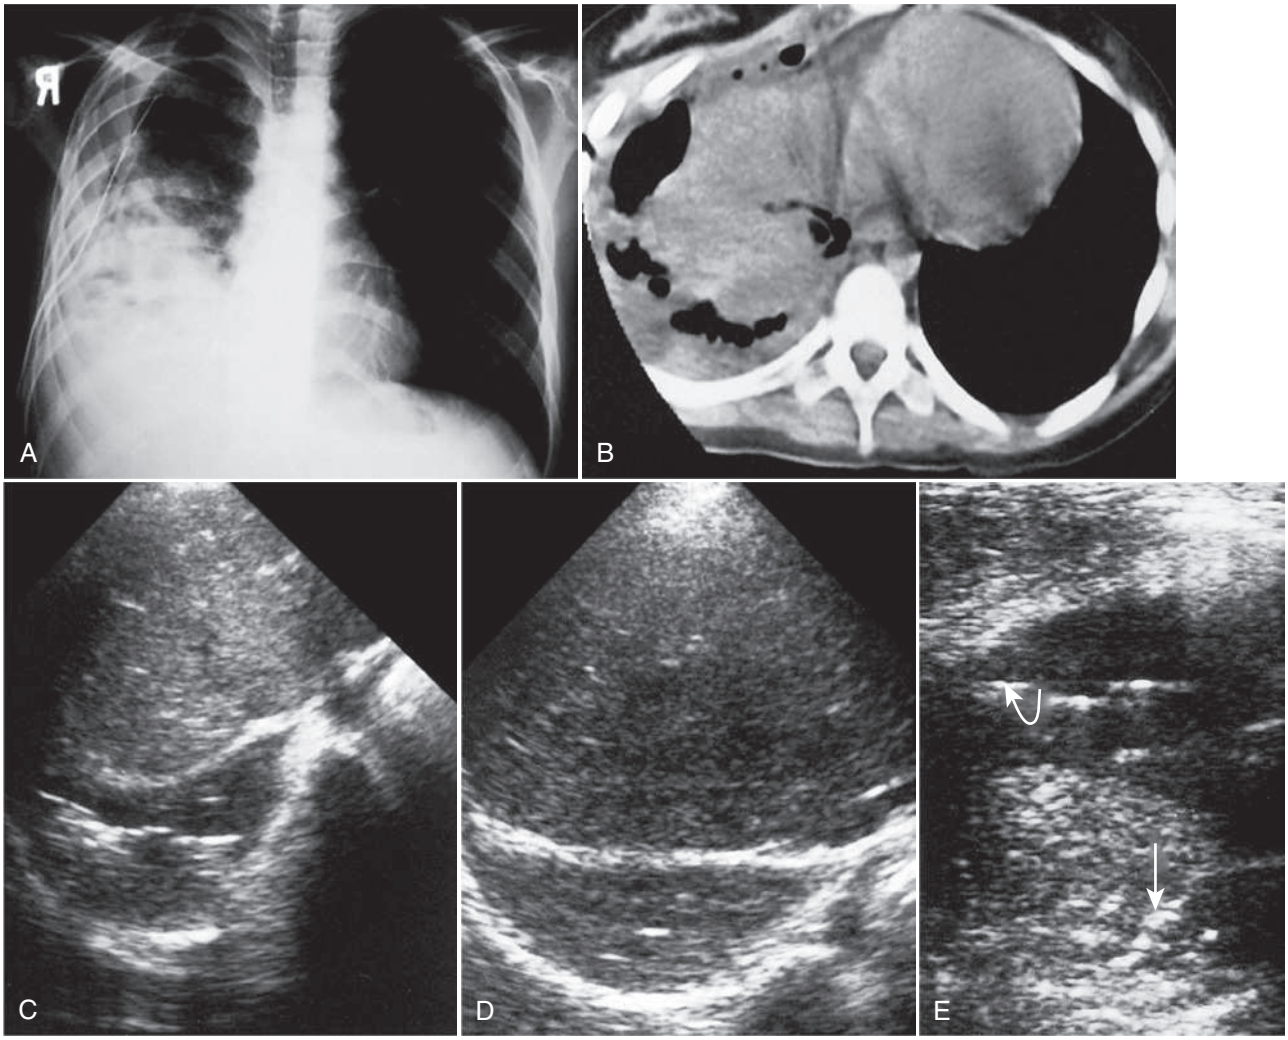

FIG. 50.18 Air-Fluid Levels in Complex Empyema. (A) Chest radiograph. **(B)** Computed tomography (CT) scan and **(C)** sonogram with patient supine and. **(D)** Upright. Air-fluid levels are seen on the supine view, but are out of the plane of the lower fluid in the upright view. **(E)** Transverse intercostal supine scan through anterior chest wall shows both the linear lines of bronchi *(arrow)* at random pattern and the linear lines of air *(curved arrow)* in the pleural fluid.

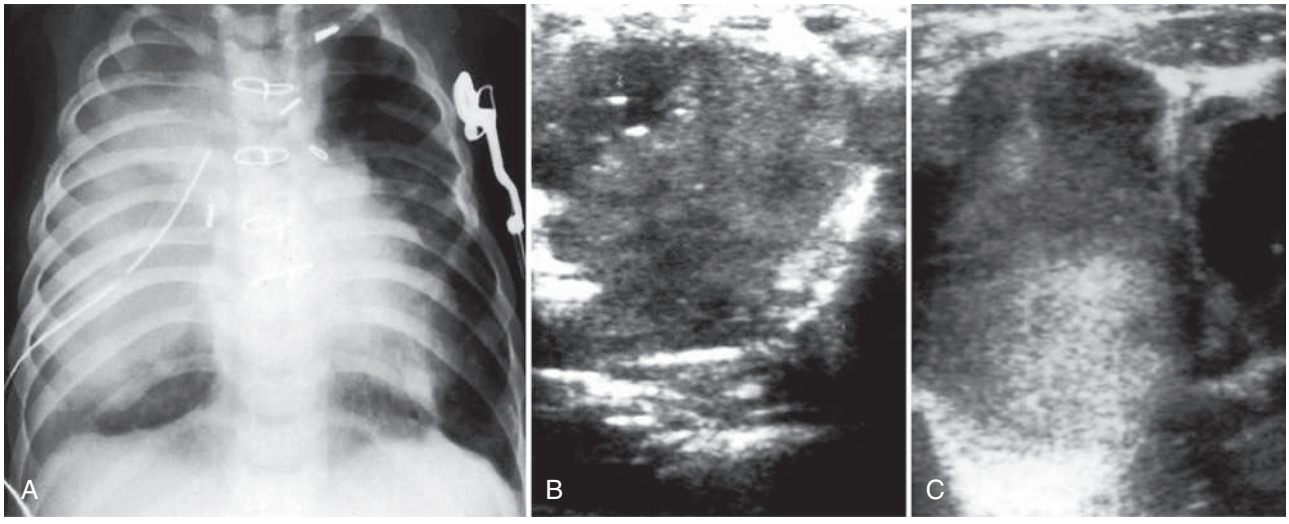

FIG. 50.19 Thick Pleural Fluid With Changing Appearance in Empyema. (A) Chest radiograph shows pleural fluid that is not draining by chest tube. **(B)** Transverse sonogram shows very thick fluid with no air bronchograms. **(C)** Differential thick fluid-fluid level caused by change in position.

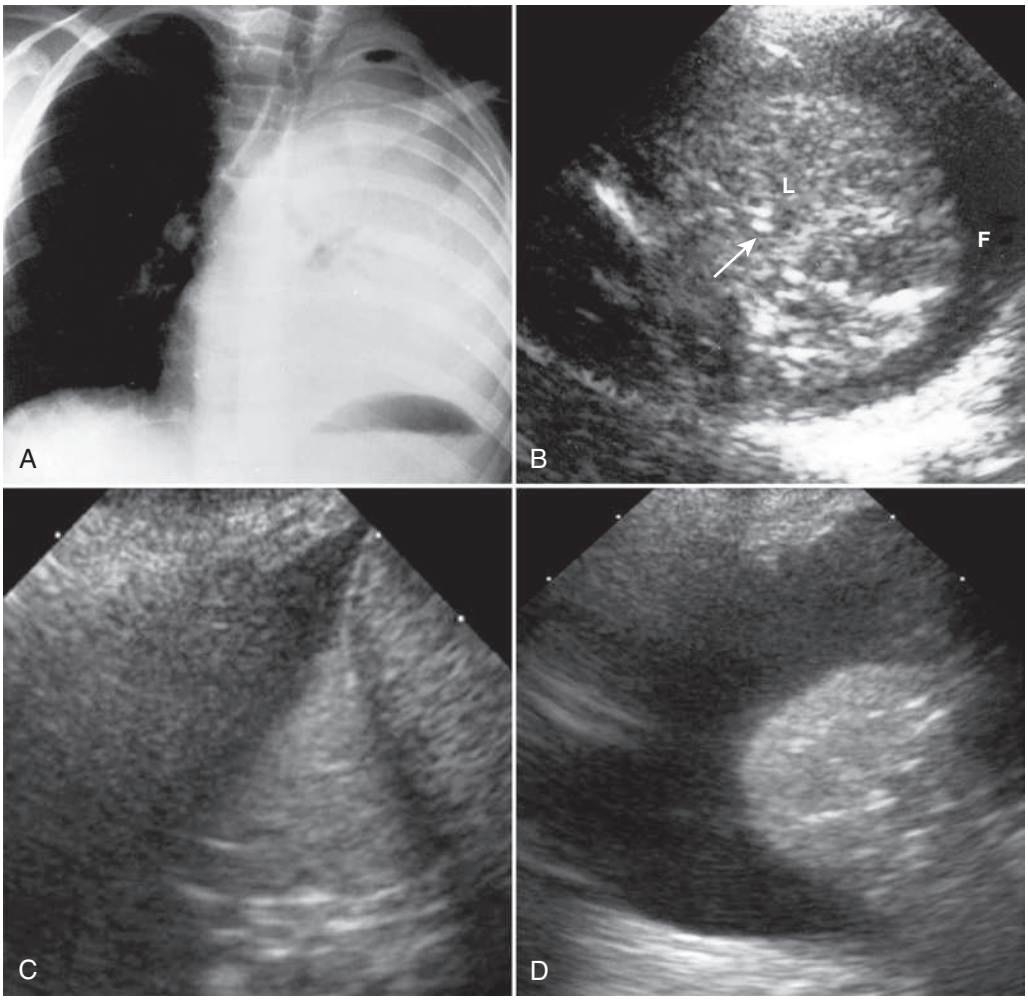

FIG. 50.20 Echogenicity of Air Bronchograms in Consolidated Lung. (A) Chest radiograph shows an opacified left chest with some air bronchograms. **(B)** Transverse scan shows fluid *(F)* around consolidated lung *(L),* which has echogenicity similar to the liver. Air bronchograms within the consolidated lung *(arrow).* **(C)** and **(D)** Sonograms of another patient show consolidated lung with air bronchograms and surrounded by fluid.

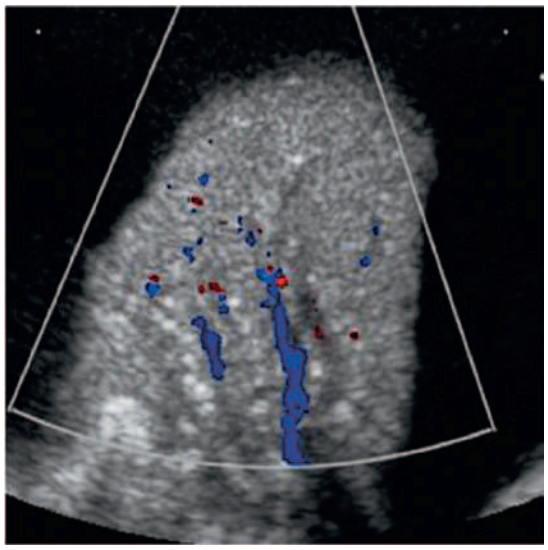

FIG. 50.21 Pneumonia Showing Tubular Air Bronchograms. Color flow Doppler sonogram shows echogenic branching air bronchograms with intervening branching vessels in consolidated lung surrounded by fluid.

defies the "reasonably achievable" part of the ALARA (as low as reasonably achievable) principle.[26] Typical radiation dose with a pediatric exposure setting for a frontal view chest radiograph is less than 0.1 mSv, which corresponds to natural background radiation for less than 10 days and is considered minimal risk.[26-28]

Atelectasis

Atelectatic lung is similar in echogenicity to liver (Fig. 50.24). Sonographic air bronchograms may be present in atelectatic lung, but the air bronchograms are more crowded than in pneumonia because the lung volume is decreased. Bronchi can be filled with fluid rather than air, creating fluid bronchograms. The echogenic, parallel, branching walls are filled with hypoechoic fluid, without the acoustic shadowing and reverberation artifacts normally seen with air. Color flow Doppler sonography differentiates fluid-filled bronchi from vessels because there will be no flow in the bronchi.

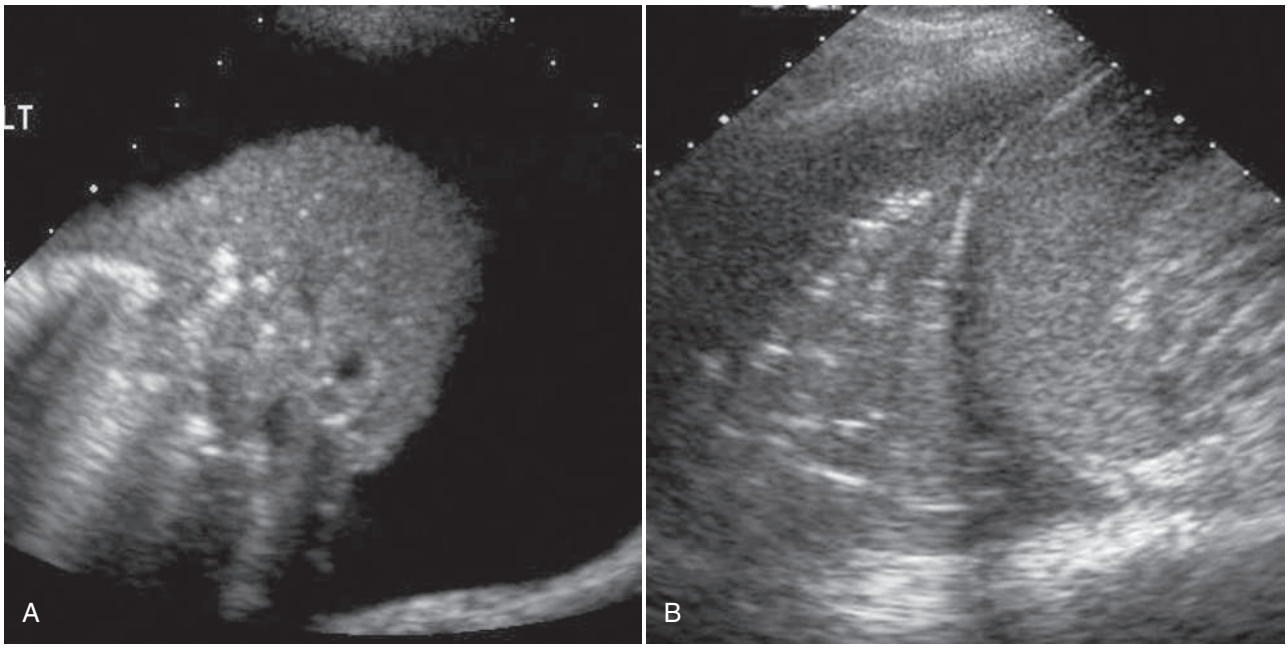

FIG. 50.22 Pneumonia Showing Scattered Air Bronchograms. (A) and **(B)** Transverse and longitudinal sonograms of two patients in a plane that is not parallel to the long axis of the bronchi show scattered echoes of variable lengths from scattered air bronchograms. Fluid surrounds the consolidated lung.

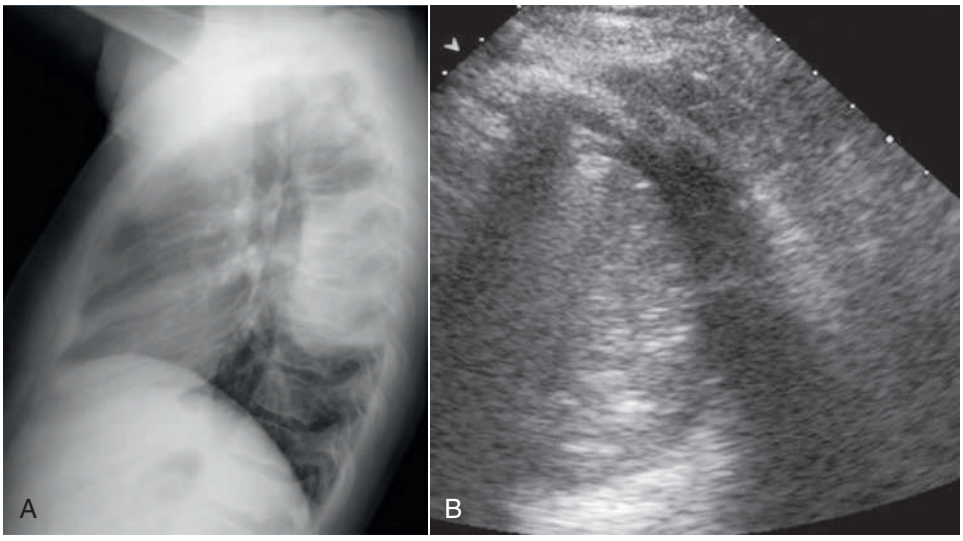

FIG. 50.23 Round Pneumonia. (A) Lateral chest radiograph shows a rounded opacity posteriorly in this 12-year-old child. **(B)** Transverse sonogram shows air bronchograms within the lesion, confirming it as round pneumonia, with a small amount of pleural fluid surrounding the consolidated lung. Ultrasound diagnosis helped avoid ionizing radiation from a computed tomography scan.

Congenital Pulmonary Airway Malformation

Congenital pulmonary airway malformation (CPAM) comprises a spectrum of disorders that include bronchopulmonary malformation, hybrid lesions (CPAM and sequestration), and congenital lobar overinflation.

Bronchopulmonary malformations may contain systemic and/or pulmonary vascularity and cysts. When only cysts are present with no systemic vascularity, these were previously called congenital **cystic adenomatoid malformation** (CCAM). Type I has one or more large cysts measuring more than 2 cm in size. Type II has multiple small cysts, less than 2 cm. Type III has microcysts but appears solid on ultrasound and on gross examination.[1]

Pulmonary sequestrations may be extralobar or intralobar, and have systemic vascular supply.[29,30] Extralobar sequestration[31] is congenital and has pulmonary tissue with a separate pleura. Extralobar sequestration typically manifests in infancy. Intralobar sequestration is acquired after recurrent infections causing

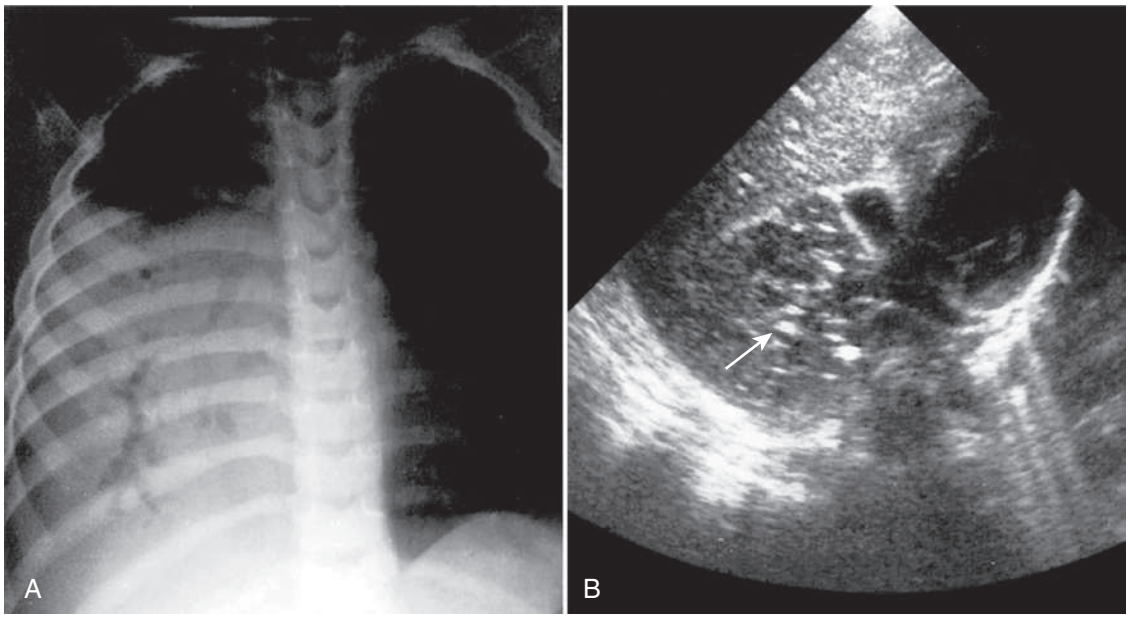

FIG. 50.24 Atelectasis From Foreign Body. (A) Chest radiograph shows air bronchograms in opacified right side of chest with shift of the heart to the right, indicating volume loss. **(B)** Transverse sonogram through liver shows no fluid in chest. Multiple air bronchograms *(arrow)* are visible within collapsed lung. At endoscopy, foreign body was found in right main stem bronchus. (With permission from Seibert RW, Seibert JJ, Williamson SL. The opaque chest: when to suspect a bronchial foreign body. Pediatr Radiol. 1986;16[3]:193-196.[76])

bronchial obstruction and compromised pulmonary artery supply as a result of inflammation. Inferior pulmonary ligament artery and phrenic artery normally supply inferomedial and diaphragmatic visceral pleura, respectively. These normal arteries may become parasitized to supply the infected portion of a lower lobe if the normal pulmonary arterial supply is compromised. The intralobar sequestered lung is typically present in the lower lobes and is enclosed by the visceral pleura of the parent lung. Ultrasound may show a hypoechoic mass in the lower lobe (Fig. 50.25). Color Doppler can demonstrate a systemic vessel supplying the hypoechoic mass in both extralobar and intralobar sequestration.

Bronchopulmonary Foregut Malformation

Bronchogenic cysts or **bronchopulmonary foregut malformations**[32] may be identified by chest ultrasound if they are adjacent to the chest wall (Fig. 50.26).

DIAPHRAGM DISORDERS

Sonography is particularly valuable in evaluating a paradiaphragmatic lesion, which may be a **diaphragm eventration,**[33] a **diaphragmatic hernia** (Fig. 50.27), a **subphrenic abscess,**[34,35] or an **intrathoracic kidney.**[36] These abnormalities frequently are associated with respiratory compromise, making bedside, portable sonography the study of choice. Less common diaphragmatic masses detected by sonography include hemangioma,[37] primitive neuroectodermal tumor, and primary embryonal rhabdomyosarcoma.[38-40]

Ultrasound is the bedside examination of choice for evaluation of suspected diaphragmatic motion abnormalities. Comparison of hemidiaphragm motion can be observed by placing the transducer in the subxiphoid position in a transverse orientation, angled upward toward the posterior leaflets of the hemidiaphragms. Such comparison can be done with transverse sonographic scanning in infants (Video 50.2), but in older children (Video 50.3), unilateral sagittal scanning of each diaphragm is necessary. A comparison of the maximal excursion of the diaphragm for each side using real-time ultrasound is more accurate than fluoroscopy in demonstrating diaphragmatic movement abnormality.[41] In the artificially ventilated patient, the respirator must be disconnected for 5 to 10 seconds to observe unassisted respiration. With paralysis, there is absent or **paradoxical motion** on one side and exaggerated excursions on the opposite side. **Diaphragm paralysis** is a frequent concern after cardiac surgery[42] (Video 50.4). Severe eventration and a diaphragmatic hernia may also show paradoxical motion. During real-time evaluation of diaphragm motion,[43] M-mode sonography can also be used in assessment of diaphragm function[44] (Figs. 50.28 and 50.29). Sonography can demonstrate **rupture of the diaphragm**[45] (Fig. 50.30).

VASCULAR DISORDERS

Vascular Thrombosis

The normal thymus is an excellent acoustic window to view normal mediastinal structures and mediastinal masses. The thymus is anterior to the great vessels and extends inferiorly to the upper portion of the heart. The great vessels, including the SVC, aorta, and pulmonary artery, are well imaged through the thymus. These vessels are more conspicuous with color Doppler ultrasound (Fig. 50.31). The left brachiocephalic vein courses

(A) Posteroanterior radiograph shows round mass in left upper lung. **(B)** Posterior sonogram shows fluid-filled cyst with back-wall enhancement caused by increased through transmission. **(C)** Computed tomography shows the fluid-filled chest mass.

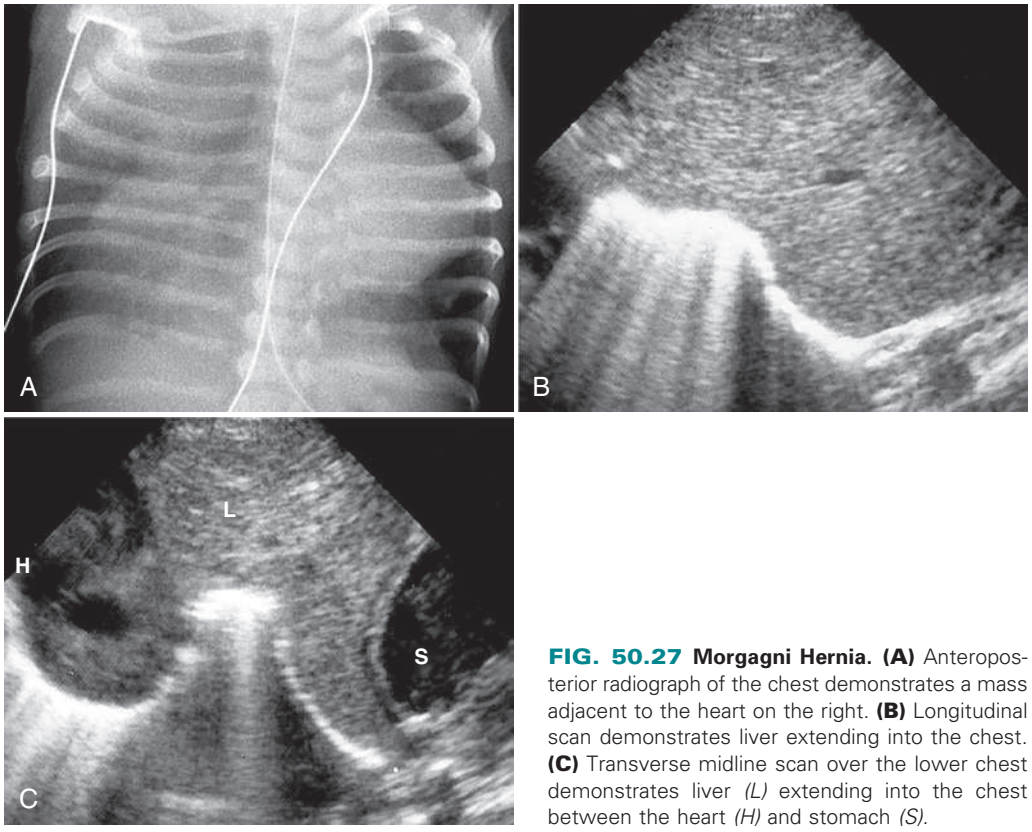

FIG. 50.27 Morgagni Hernia. (A) Anteroposterior radiograph of the chest demonstrates a mass adjacent to the heart on the right. **(B)** Longitudinal scan demonstrates liver extending into the chest. **(C)** Transverse midline scan over the lower chest demonstrates liver *(L)* extending into the chest between the heart *(H)* and stomach *(S)*.

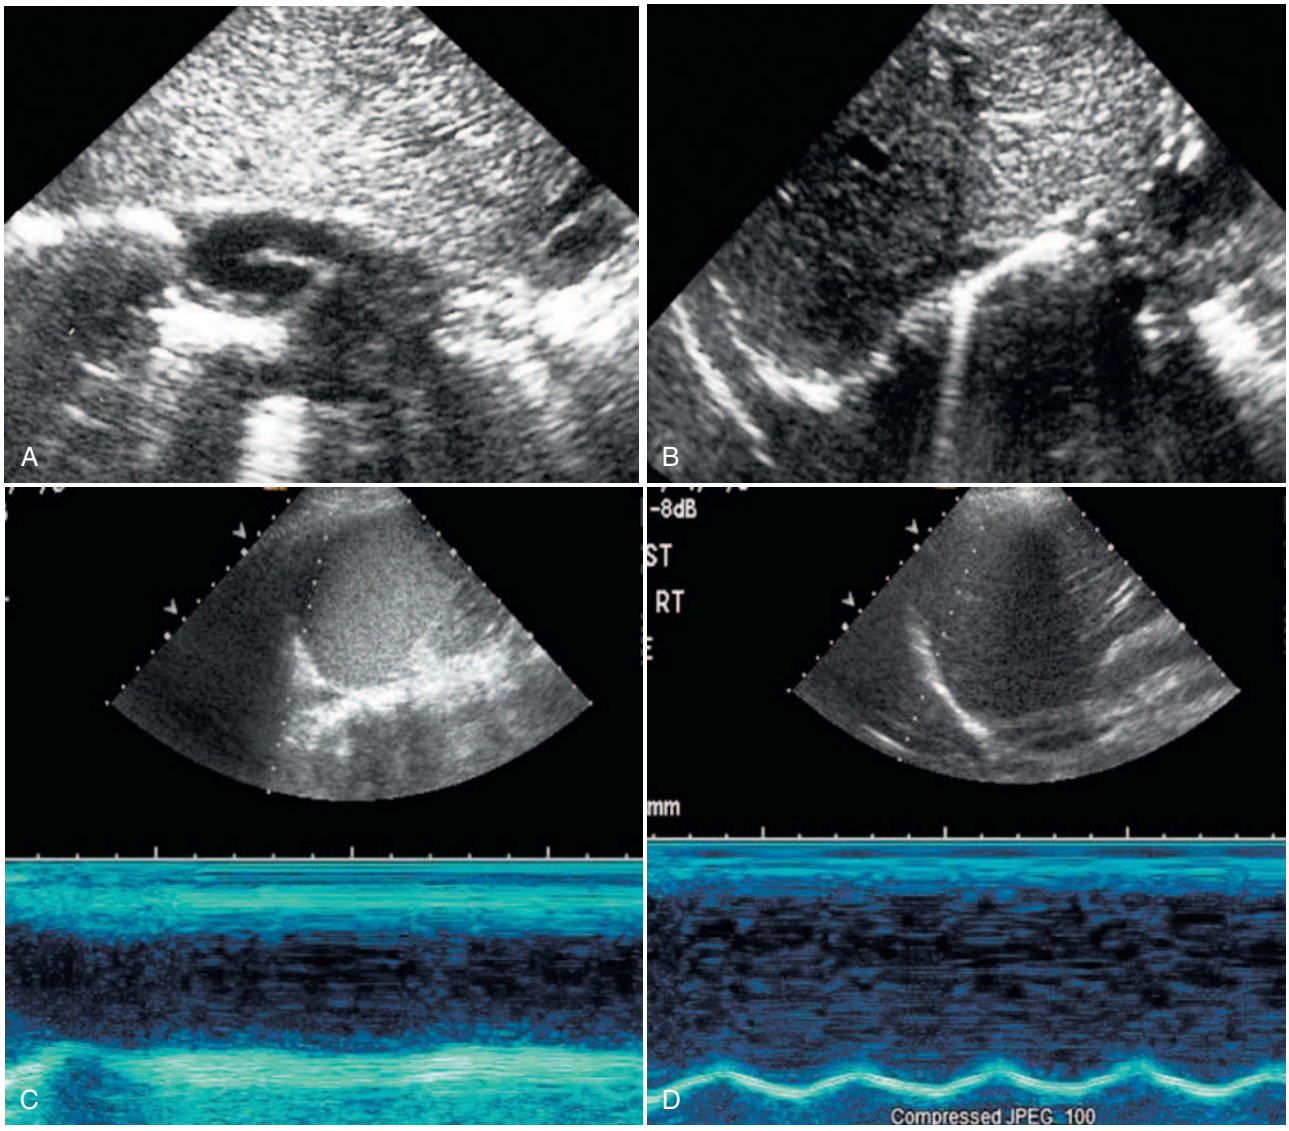

FIG. 50.28 Paralyzed Left Hemidiaphragm Compared With Normal Right Hemidiaphragm. B-mode sonogram of **(A)** left and **(B)** right hemidiaphragm. M-mode sonogram shows **(C)** left hemidiaphragmatic paralysis and **(D)** normal excursion of right hemidiaphragm.

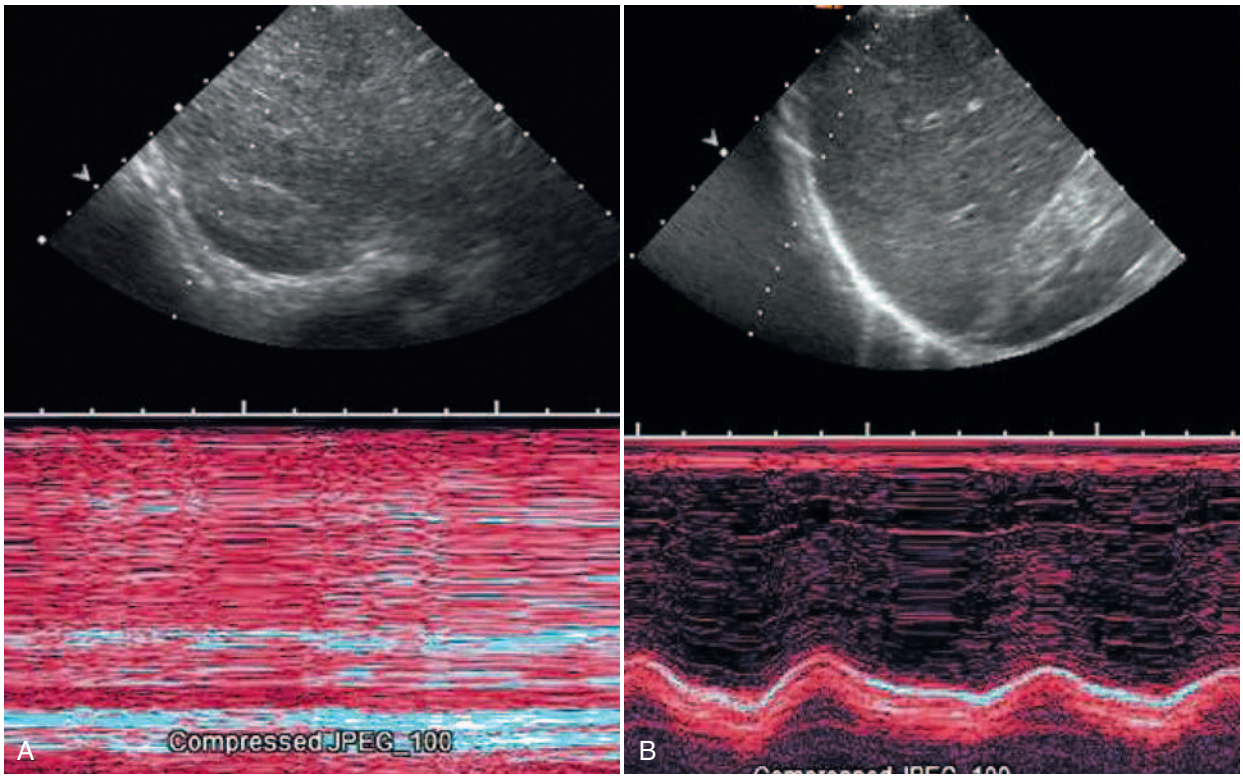

FIG. 50.29 Follow-Up of Diaphragmatic Paralysis. Gray-scale real-time and M-mode ultrasound. **(A)** Child with complex congenital heart disease shows left hemidiaphragmatic paralysis. **(B)** Spontaneous recovery of left hemidiaphragmatic motion was observed on follow-up sonogram.

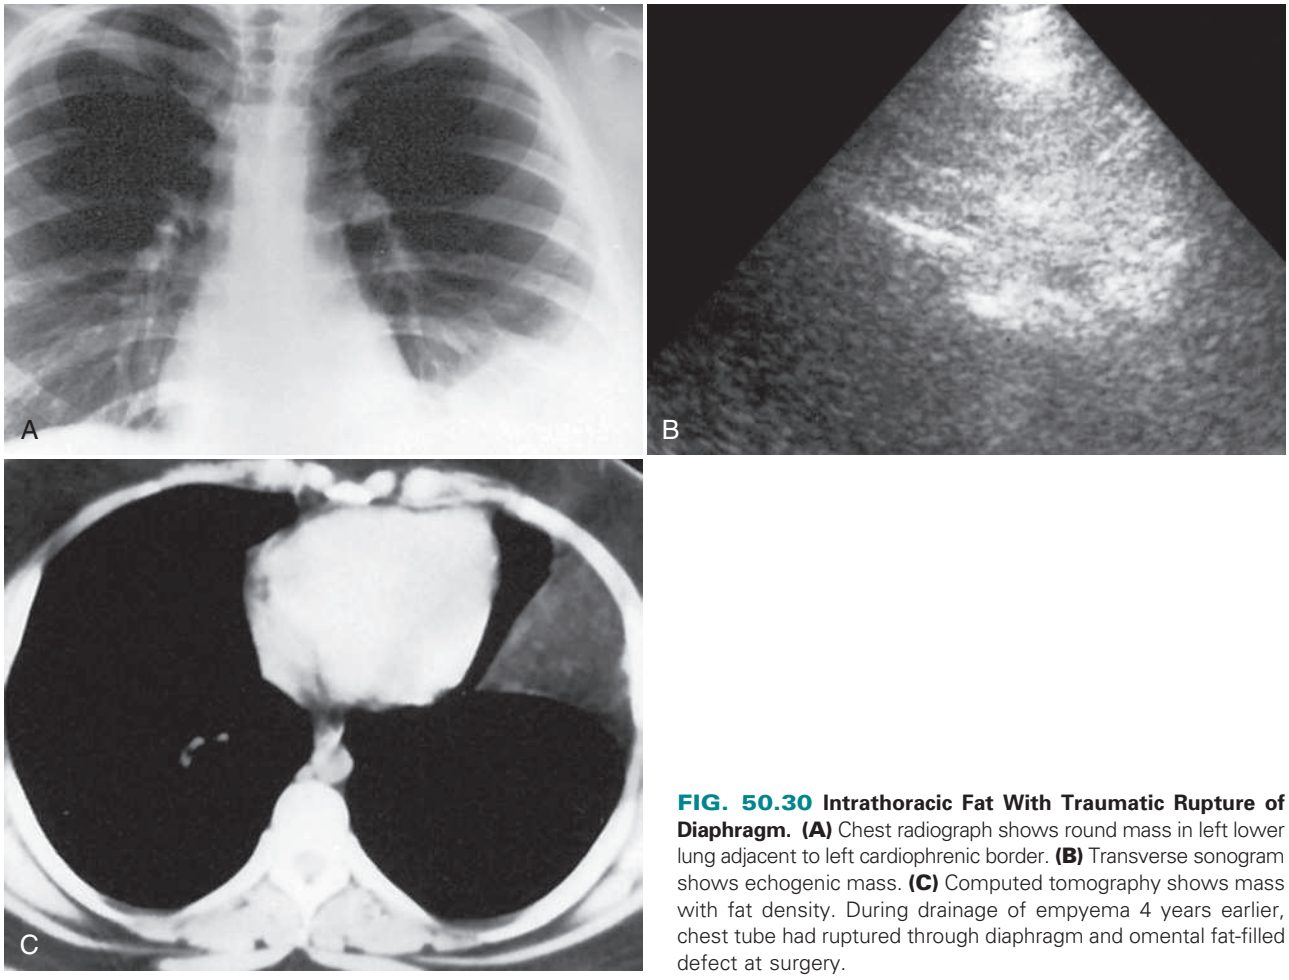

FIG. 50.30 Intrathoracic Fat With Traumatic Rupture of Diaphragm. (A) Chest radiograph shows round mass in left lower lung adjacent to left cardiophrenic border. **(B)** Transverse sonogram shows echogenic mass. **(C)** Computed tomography shows mass with fat density. During drainage of empyema 4 years earlier, chest tube had ruptured through diaphragm and omental fat-filled defect at surgery.

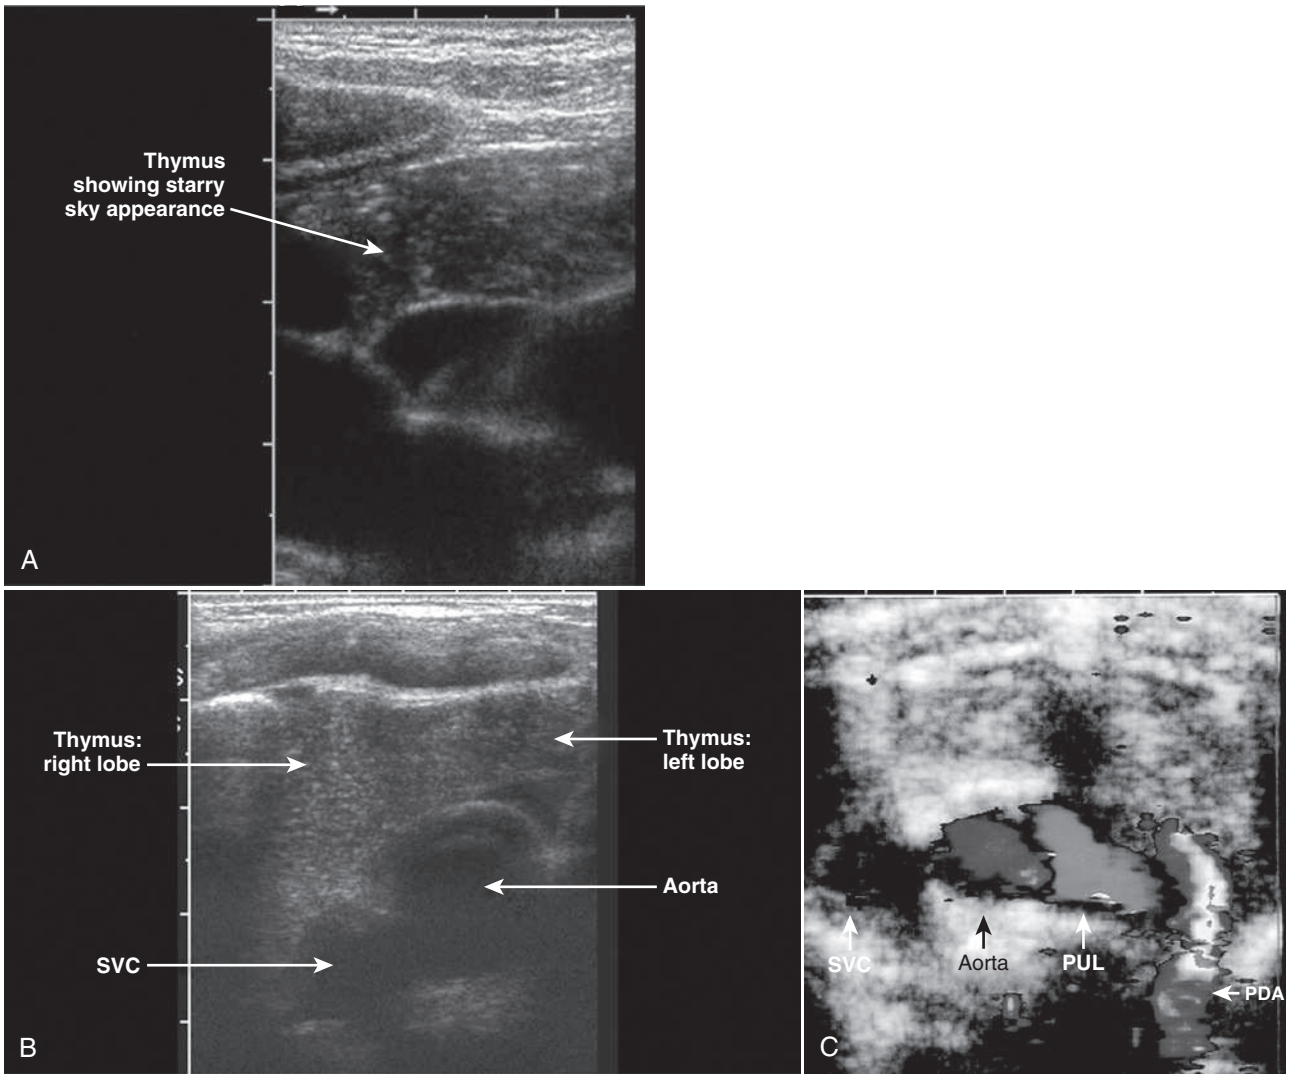

FIG. 50.31 Normal Thymus and Great Vessels of Chest. (A) and **(B)** Longitudinal and transverse sonograms show normal thymus echotexture in a 31-month-old boy. Superior vena cava *(SVC)* and aorta are visible through the thymic window. **(C)** Gray-scale rendering of a color Doppler image shows normal great vessels in the chest in transverse scan through the thymus in another child. *PDA,* Posterior descending artery; *PUL,* pulmonary artery.

transversely from left to right, posterior to the thymus, to enter the SVC. This is useful to determine catheter position (Fig. 50.32) and the presence of a thrombus in children with central venous catheters.

Doppler examination is useful in identifying **thrombus** within the subclavian vein, SVC, and pulmonary artery (Fig. 50.33). Thrombosis of the axillary or subclavian vein secondary to thoracic outlet syndrome[46] is seen on ultrasound Doppler study in **Paget-Schroetter syndrome**[47] (Fig. 50.34). It results from an abnormal insertion of the costoclavicular ligament laterally on the first rib, along with hypertrophy of the scalenus anticus muscle.

The Doppler waveform is abnormal when **thrombosis** or **obstruction** of the SVC is present. Doppler ultrasound findings include (1) loss of biphasic SVC waveform, (2) continuous forward flow rather than distinct systolic and diastolic peaks, (3) a turbulent flow profile, (4) increased velocity downstream, and (5) decreased velocity upstream.[48] Venous thrombosis is reported in 20% of children receiving extracorporeal membrane oxygenation (ECMO).[49] Doppler waveforms may be different in patients receiving ECMO because their resistive indices are low. Recurrent SVC thrombosis has been reported in a child with activated protein C resistance.[50]

Superior Vena Cava Thrombosis: Doppler Sonographic Findings

Loss of biphasic waveform
Continuous forward flow (no systolic or diastolic peaks)
Turbulent flow
Increased downstream velocity
Decreased upstream velocity

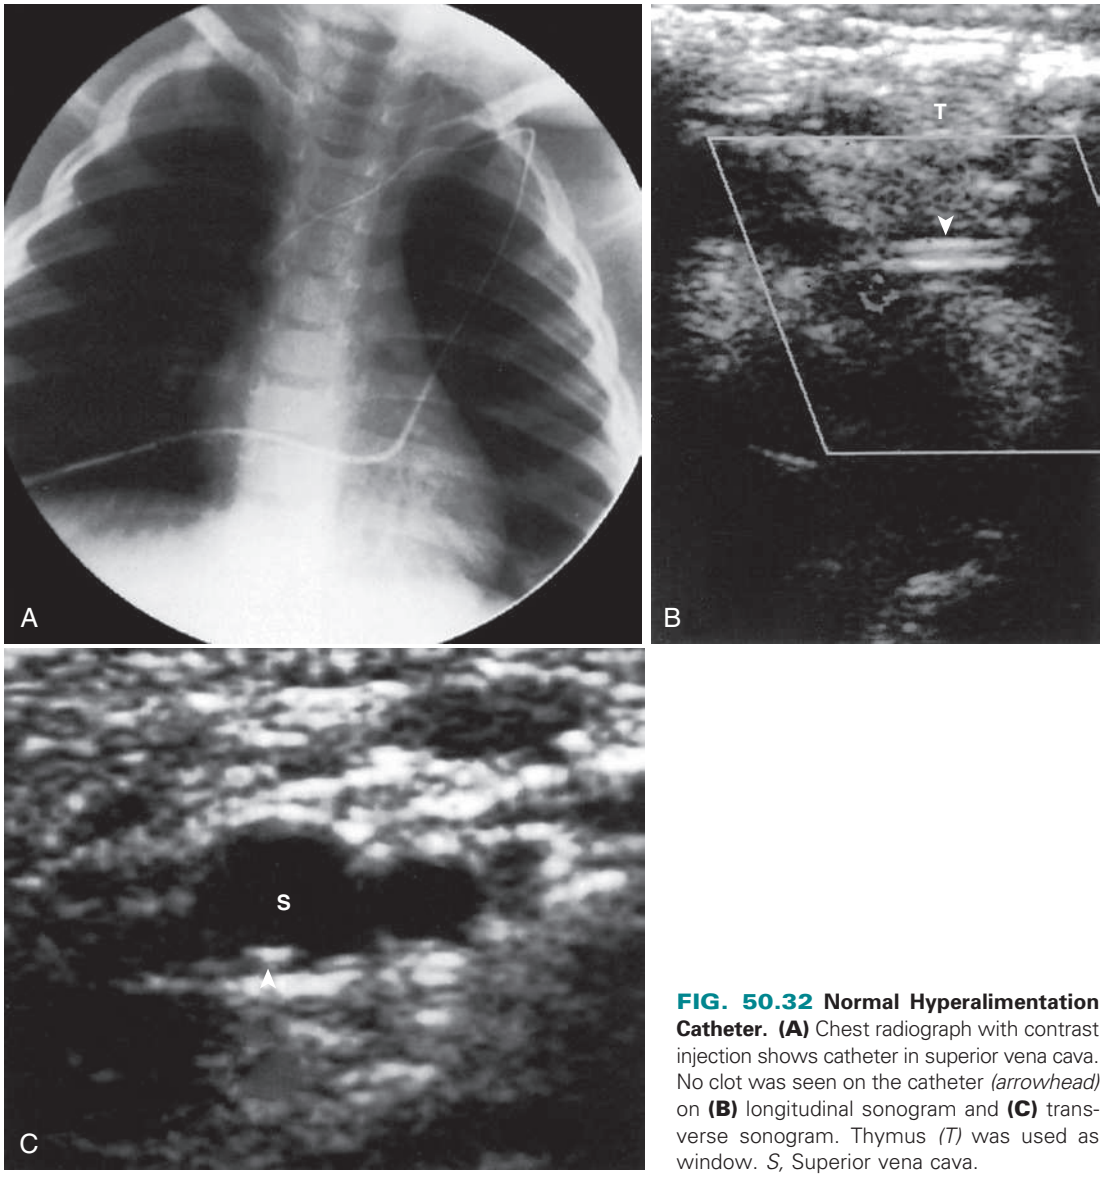

FIG. 50.32 Normal Hyperalimentation Catheter. (A) Chest radiograph with contrast injection shows catheter in superior vena cava. No clot was seen on the catheter *(arrowhead)* on **(B)** longitudinal sonogram and **(C)** transverse sonogram. Thymus *(T)* was used as window. *S,* Superior vena cava.

FIG. 50.33 Pulmonary Embolus. Lymphovascular Malformation

Lymphatic malformations[51] (Fig. 50.35) are composed of dilated lymphatic sacs of variable size, which may appear unilocular or multilocular. Lymphatic malformations may undergo hemorrhage, in which case the lesion appears as a uniformly echogenic mass or multiple cysts containing echogenic debris. Septations in cystic lesions are better identified by ultrasound than by CT or magnetic resonance imaging (MRI).

MEDIASTINAL MASSES

CT and MRI are the primary modalities for evaluation of mediastinal masses detected by chest radiography. Suprasternal sonography[52] can be useful for detecting small and large mediastinal masses, particularly lymphoma. Mediastinal sonography for masses should include major vessels or cardiac chambers in the field of view so that mass and vessel echogenicity can be compared directly. This prevents the pitfall created by reducing the gain setting in response to the hyperechoic appearance of adjacent lung. The reduced gain setting gives a falsely anechoic appearance to a solid mass. **Juxtaphrenic paravertebral masses** may be detected with a subxiphoid or transdiaphragmatic approach.

Mediastinal ultrasound can also determine whether chest masses extend into the neck. **Retrosternal thyroid** mass extension detection by ultrasound is helpful for surgical planning. Ultrasound allows characterization of masses as solid or cystic. Doppler imaging may be helpful in evaluating whether a chest mass is vascular in origin. Malignant chest masses demonstrate a low-impedance, high–diastolic-flow Doppler signal.[53] Color Doppler ultrasound before percutaneous biopsy can rule out vascular lesions that would preclude biopsy.

A widened superior mediastinum detected on chest radiography can be evaluated initially by sonography. Detection of a normal but prominent thymus rather than a mediastinal mass precludes the need for CT. The thymus is normally located in the superior mediastinum anterior to the great vessels in the superior mediastinum, from the superior edge of the manubrium to the fourth costal cartilage. The thymus is mildly hypoechoic relative to liver, spleen, and thyroid. It shows some echogenic strands. A fine granular echotexture gives the thymus a "starry sky" appearance (see Fig. 50.31). A fibrous capsule gives the thymus a smooth, well-defined margin.

Thymic Index

Thymic index is the product of thymic width measured on transverse images and the area of the largest lobe measured on a longitudinal image[54-56] (Table 50.1). The thymic index has acceptable correlation with actual thymus weight and volume. The measurement is performed during expiration to obtain a standardized size. Thymic index is greater in children with active atopic dermatitis than in healthy controls[57] (Fig. 50.36). Larger thymic index at birth is associated with lower infant mortality rate.[58] Thymic size varies with age, and normal thymic index values have been established[54-56] (Table 50.2).

Abnormal Location of Thymus Mimicking Mass Lesion

Superior herniation of thymus into the neck is a rare entity in which there is intermittent migration of the broadest part of the normal thymus out of the thorax into the suprasternal region. Real-time ultrasound shows that the mass moves into the neck during Valsalva maneuver, with an increase in the intrathoracic pressure, and has typical echotexture of thymus, thereby avoiding unnecessary biopsy and surgery.[59] **Cervical ectopic thymus** is an uncommon variant. A hypoechoic mass with characteristic thymic ultrasound echotexture is identified along the track of the thymopharyngeal duct.[60,61] The thymus can **protrude into the chest wall** as a bulging mass because of a congenital sternal defect. Real-time ultrasound can demonstrate movement of herniated thymus during respiratory cycles.

Anterior Mediastinal Masses

Benign abnormalities of the thymus in children include thymic cyst, intrathymic hemorrhage, thymolipoma, and thymoma. The thymus may also be involved by a hemangioma, lymphatic

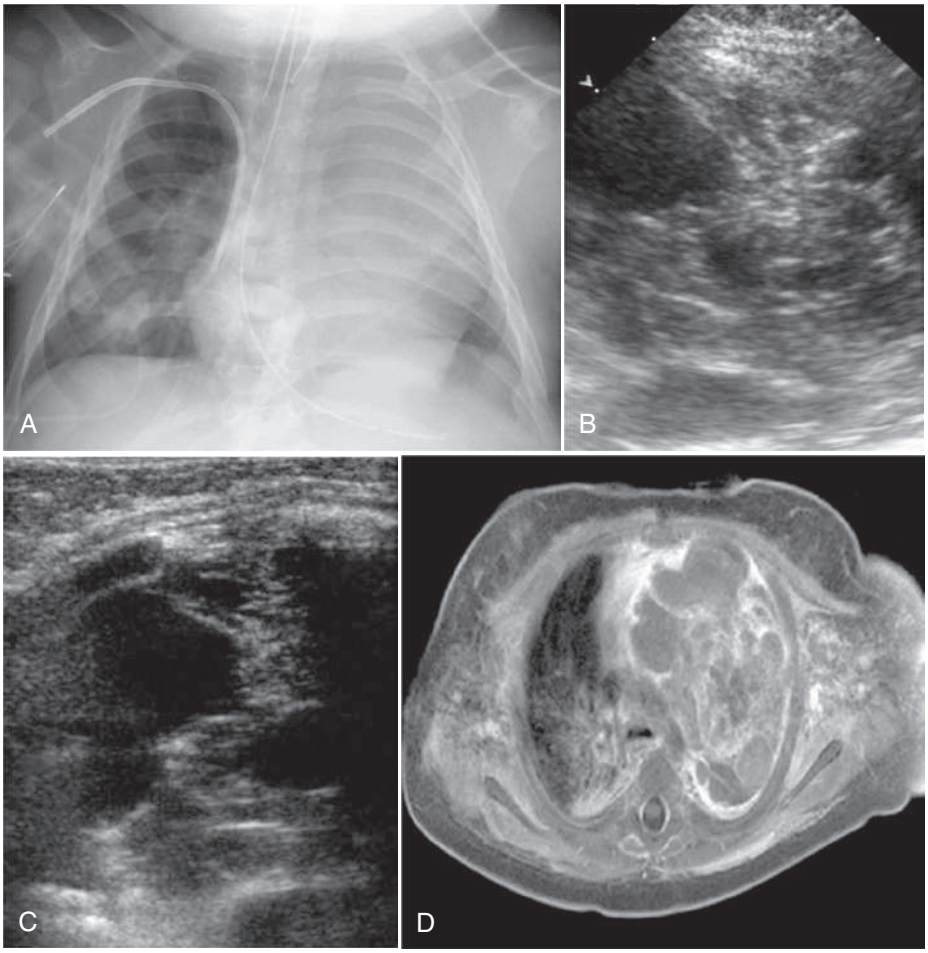

FIG. 50.35 Macrocystic Lymphatic Malformation in 7-Month-Old Girl. (A) Chest radiograph shows opacity in left upper chest and neck. **(B)** and **(C)** Sonograms show multiple cystic spaces. **(D)** T1-weighted postcontrast, axial magnetic resonance image defines the extent of the lesion.

TABLE 50.1 Formula for Calculation of Thymic Index

Thymic index (cm^3)	=	Area of the largest lobe (cm^2)	×	Transverse dimension of thymus from right lateral edge to left lateral edge (cm)
Area of the lobe of thymus (cm^2)	=	Craniocaudad dimension (cm)	×	Anteroposterior dimension (cm)

malformation, or Langerhans cell histiocytosis. Malignant infiltration of the thymus is also seen in lymphoma and leukemia. **Thymic cysts** are anechoic. Other abnormalities of the thymus may show irregular or lobular margin, heterogeneous echogenicity, and coarse echotexture. **Germ cell tumors** can have variable appearance. **Teratomas** are heterogeneous masses that contain fat, bone, calcification, and cystic elements.

Lymphadenopathy

The most common mediastinal mass in older children is lymphadenopathy resulting from **leukemia** or **lymphoma. Lymphadenopathy** appears as hypoechoic nodules. Lymph nodes in lymphoma are more hypoechoic and more hypovascular than inflammatory lymph nodes.[62]

Posterior Mediastinal Masses

Posterior mediastinal masses, including neurogenic tumors, make up the majority of mediastinal masses in young infants. **Neurogenic tumors** appear as a lobulated or well-defined hypoechoic mass with granular or flecklike calcifications. Neurenteric cysts are well-defined, anechoic lesions with thin walls. When inflammation and hemorrhage occur, the cyst may contain echogenic debris from proteinaceous fluid, mucus, or blood.

ULTRASOUND-GUIDED INTERVENTIONAL PROCEDURES

Sonography is an excellent method for guiding postoperative fluid collections[63] (Fig. 50.37), **pleural fluid aspiration,**[64]

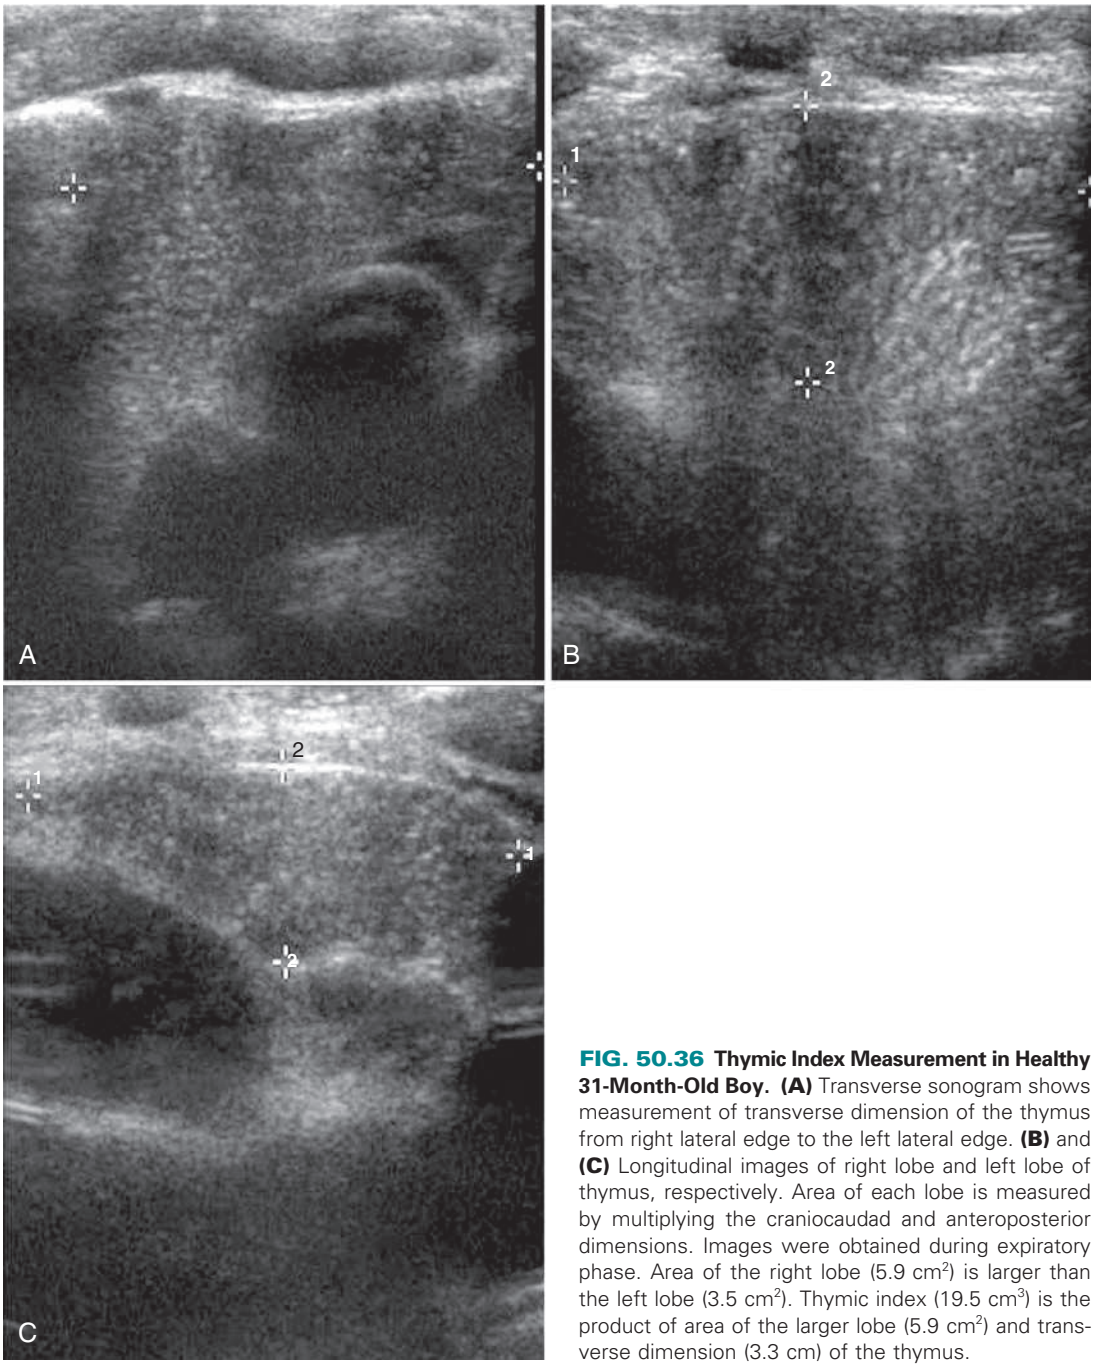

FIG. 50.36 Thymic Index Measurement in Healthy 31-Month-Old Boy. (A) Transverse sonogram shows measurement of transverse dimension of the thymus from right lateral edge to the left lateral edge. **(B)** and **(C)** Longitudinal images of right lobe and left lobe of thymus, respectively. Area of each lobe is measured by multiplying the craniocaudad and anteroposterior dimensions. Images were obtained during expiratory phase. Area of the right lobe (5.9 cm^2) is larger than the left lobe (3.5 cm^2). Thymic index (19.5 cm^3) is the product of area of the larger lobe (5.9 cm^2) and transverse dimension (3.3 cm) of the thymus.

mediastinal mass biopsy, and chest wall **lesion biopsy.** Ultrasound can be used either for marking the skin overlying a fluid collection or for directly visualizing a needle during insertion into a collection (Fig. 50.37). Ultrasound is particularly helpful in determining whether the pleural effusion will respond to **simple drainage** or will require **surgical decortication.**[65] If the fluid is relatively anechoic or clear, simple drainage with thoracentesis or chest tube drainage is an adequate treatment. If the fluid is thick with multiple septations, and if the patient does not respond promptly to antibiotic therapy, decortication or video-assisted thoracic surgery may be required.[11,66] Complicated parapneumonic effusions and empyemas have been successfully treated in up to 93% of children, using tissue plasminogen activator administered through a small-bore chest tube.[67]

Empyema surrounded by lung may appear to be a pulmonary abscess on sonography. Changing the patient position and the viewing planes can help distinguish an empyema from a lung abscess (Fig. 50.38). Ultrasound can be used to guide needle aspiration for etiologic diagnosis in patients with complicated pneumonia, as well as aspiration of microabscesses in necrotizing pneumonia.

Sonography can detect **pneumothoraces**[68] after thoracentesis.[69] Before and after thoracentesis, the ipsilateral pulmonary apex and adjacent lung should be examined in the upright position

for normal pleural respiratory movement. If the pleural respiratory motion is absent, a pneumothorax should be suspected.

Central venous catheters can be placed under ultrasound guidance, and the catheter tip position can be determined using ultrasound.[70] **Sclerotherapy** for macrocystic lymphatic malformation under ultrasound guidance has the advantage of dynamically visualizing the procedure reaction that causes obliteration of the macrocysts[71] (Fig. 50.39). Unlike fluoroscopy guidance, the residual cysts are easily seen under ultrasound guidance and can be targeted for further sclerotherapy.

TABLE 50.2 Normal Thymic Index Values for Children Younger Than 2 Years

Age in Months	THYMIC INDEX (cm^3)	
	Average	Standard Deviation (SD)
Premature	11.9	3.9
0-1	18.1	6.7
1-2	25.4	9.4
2-3	22.3	6.9
3-4	26.8	10.3
4-5	29.7	17.6
5-6	24.2	9.3
6-8	22.2	8.9
8-10	21.5	6.8
10-12	23.2	7.2
12-18	17.2	6.4
18-24	15.4	5.6

Modified from Yekeler E, Tambag A, Tunaci A, et al. Analysis of the thymus in 151 healthy infants from 0 to 2 years of age. J Ultrasound Med. 2004;23(10):1321-1326.[56]

Acute rib pain from cystic fibrosis exacerbation has been managed with ultrasound-guided placement of a continuous thoracic paravertebral catheter.[23,28]

OTHER LESS ESTABLISHED INDICATIONS

Pneumothorax,[2,24,25,72,73] rib fracture,[74] and bronchiolitis[75] can be detected sonographically. However, use of ultrasound may not

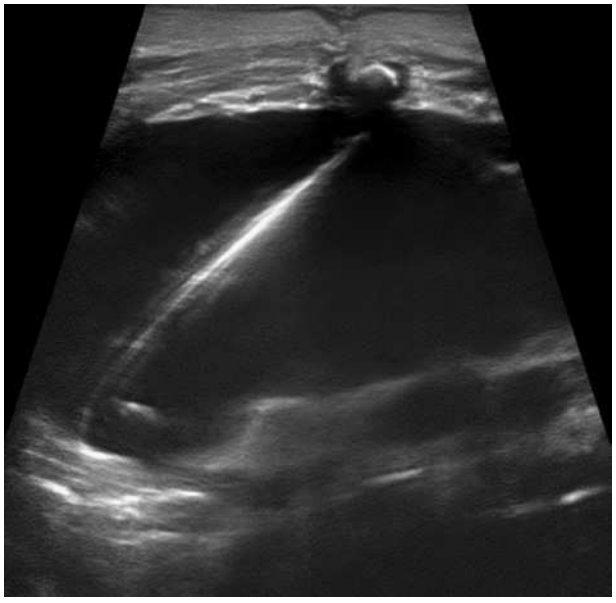

FIG. 50.37 Retrosternal Seroma. Sonogram shows anechoic fluid collection in retrosternal space in 7-week-old girl with history of surgery for ventricular septal defect and hypoplastic aortic arch performed 5 weeks before the ultrasound. Needle is visible within the fluid collection during ultrasound-guided aspiration of the fluid.

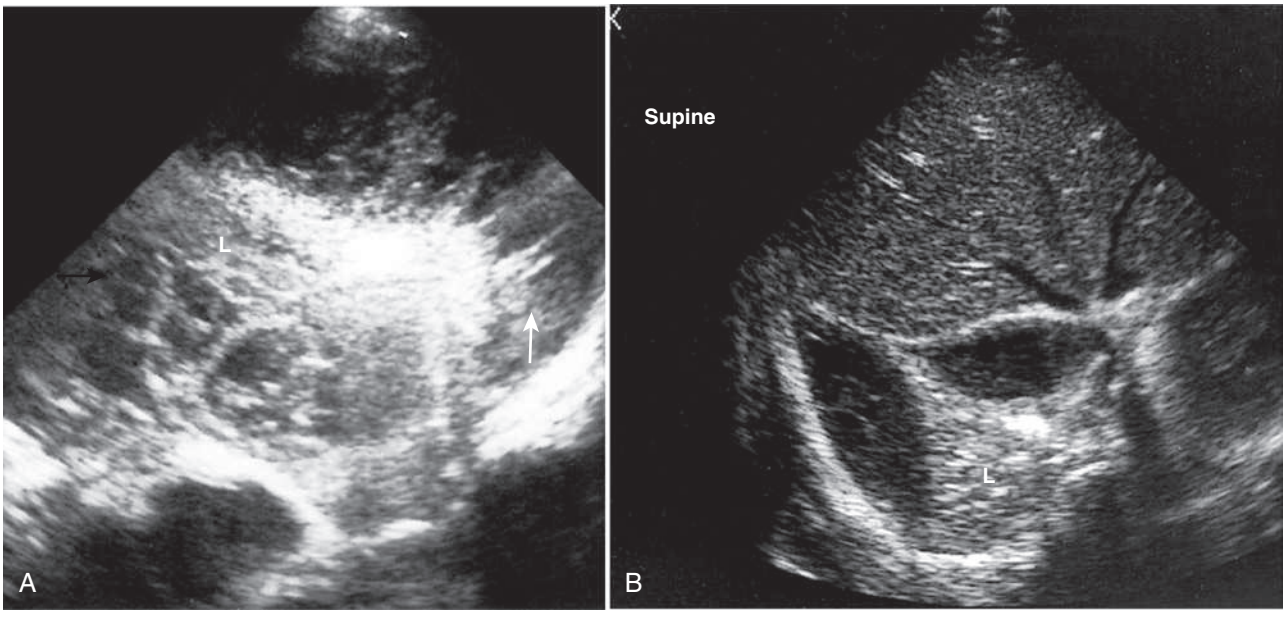

FIG. 50.38 Empyema Requiring Surgical Decortications in Patient With Sickle Cell Anemia. (A) Thick fluid *(black arrow)* around lung *(L)* with multiple loculations. Thick putty rind was found at surgery. Possible intraparenchymal abscesses *(white arrow)* on upright transverse scan. **(B)** On supine scan through the liver, only empyema surrounds the lung *(L);* no abscess is present.

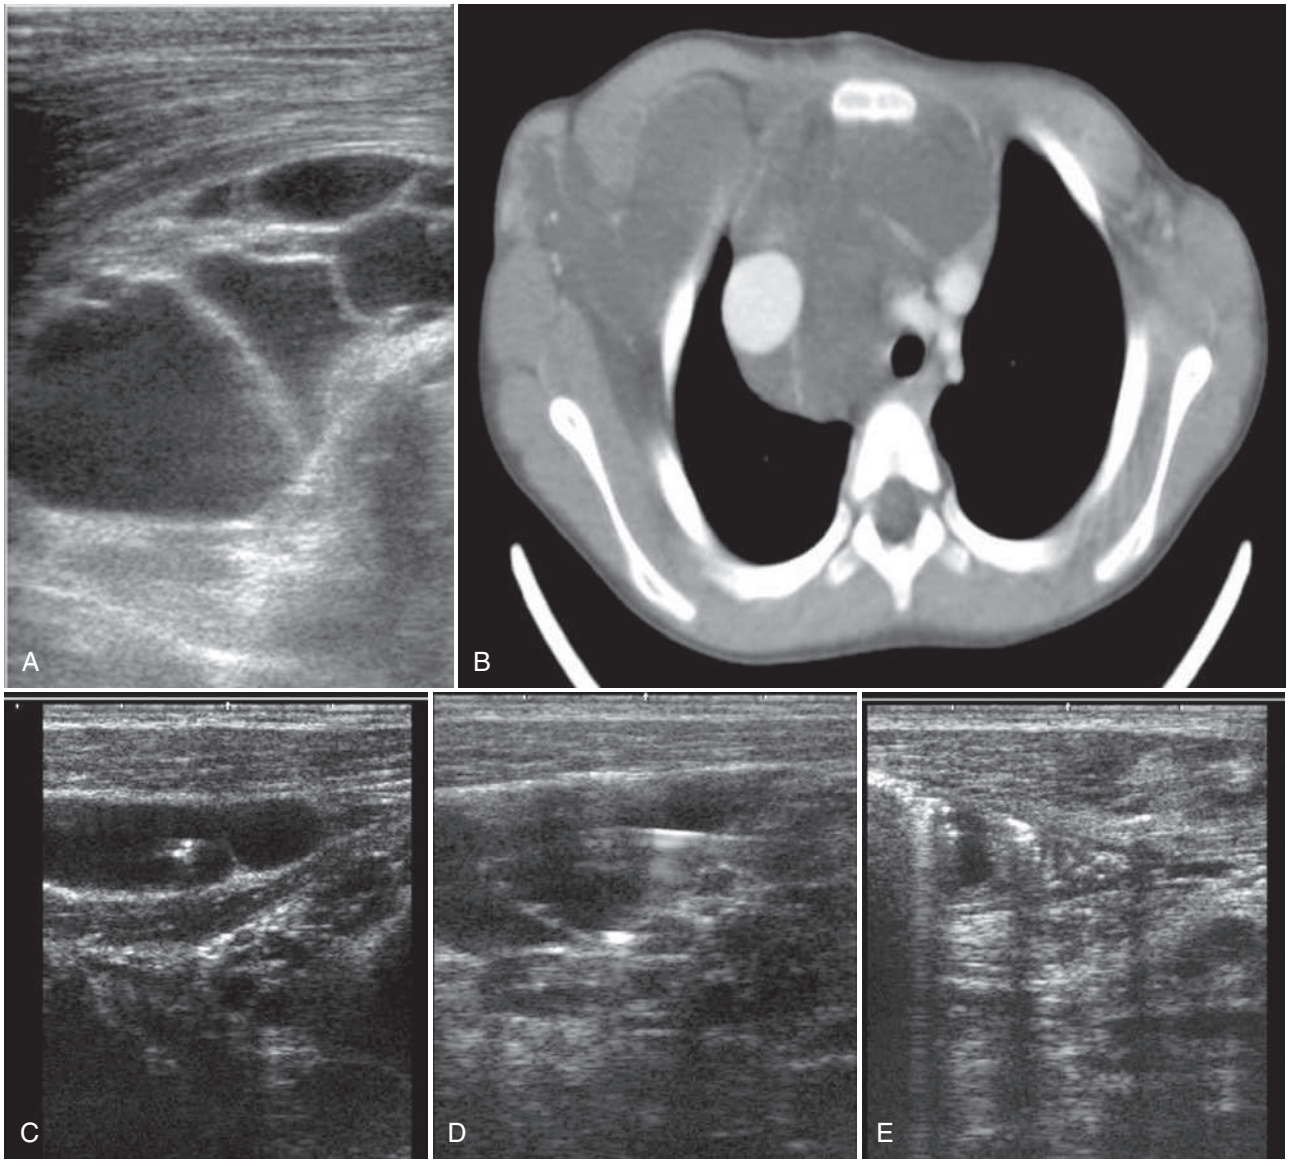

FIG. 50.39 Ultrasound-Guided Sclerotherapy of Macrocystic Lymphatic Malformation. (A) Sonogram shows multiple cysts within the right chest wall and axilla extending into the mediastinum. **(B)** Computed tomography scan shows extent of the lesion. **(C)** and **(D)** Sonograms show needle and dilator, respectively, within the lesion. **(E)** Sonogram immediately after sclerotherapy injection shows excellent response.

be practical compared with the current usual diagnostic methods because chest radiographs are quickly and cheaply performed compared with ultrasound, with a very low radiation dose. Ultrasound requires more time to perform, is operator dependent, and may not be practical in critically ill children or in very young children.

Pneumomediastinum may be misinterpreted on ultrasound as pneumothorax.[72] In a patient with suspected rib fractures, radiographs may still be required to look for other fractures. Severity of bronchiolitis can be determined by ultrasound.[75] However, it can easily be determined by clinical scoring by evaluating respiratory rate, dyspnea, use of accessory respiratory muscles, and auscultation. Moderate and severe cases are given supplementary oxygen. Why would we want to replace a stethoscope with ultrasound at unnecessary additional cost without any incremental additional benefit?

CHAPTER 51

The Pediatric Liver and Spleen

Sara M. O'Hara

SUMMARY OF KEY POINTS

- Infants with neonatal jaundice should be imaged before 2 months of age to optimize surgical treatment of biliary atresia, if present.
- Steatosis and cirrhosis both attenuate the ultrasound beam, making imaging challenging, but it is important for determining the underlying cause of disease.
- Approximately 40% of liver tumors in children are benign, and hemangiomas are the most common of these.
- Among malignant liver tumors in children, hepatoblastoma is most common.
- Doppler assessment of the liver provides critical information used to differentiate among numerous causes of hepatic disease.
- Knowledge of common spontaneous portosystemic collateral pathways facilitates the sonographic examination and a search for root causes of cirrhosis.
- Effective examination of pediatric segmental liver transplants requires familiarity with their substantially altered anatomy.

ANATOMY

The anatomy of the liver can be explored in many planes with sonography. The usual course of intrahepatic vessels and their normal variants can be traced.[1] There is a simple sonographic approach to the segmental anatomy of the liver based on the nomenclature of the French surgeon Couinaud,[2] who described the segments according to the distribution of the portal and hepatic veins. Each segment has a branch (or a group of branches) of the **portal vein** at its center and a **hepatic vein** at its periphery.

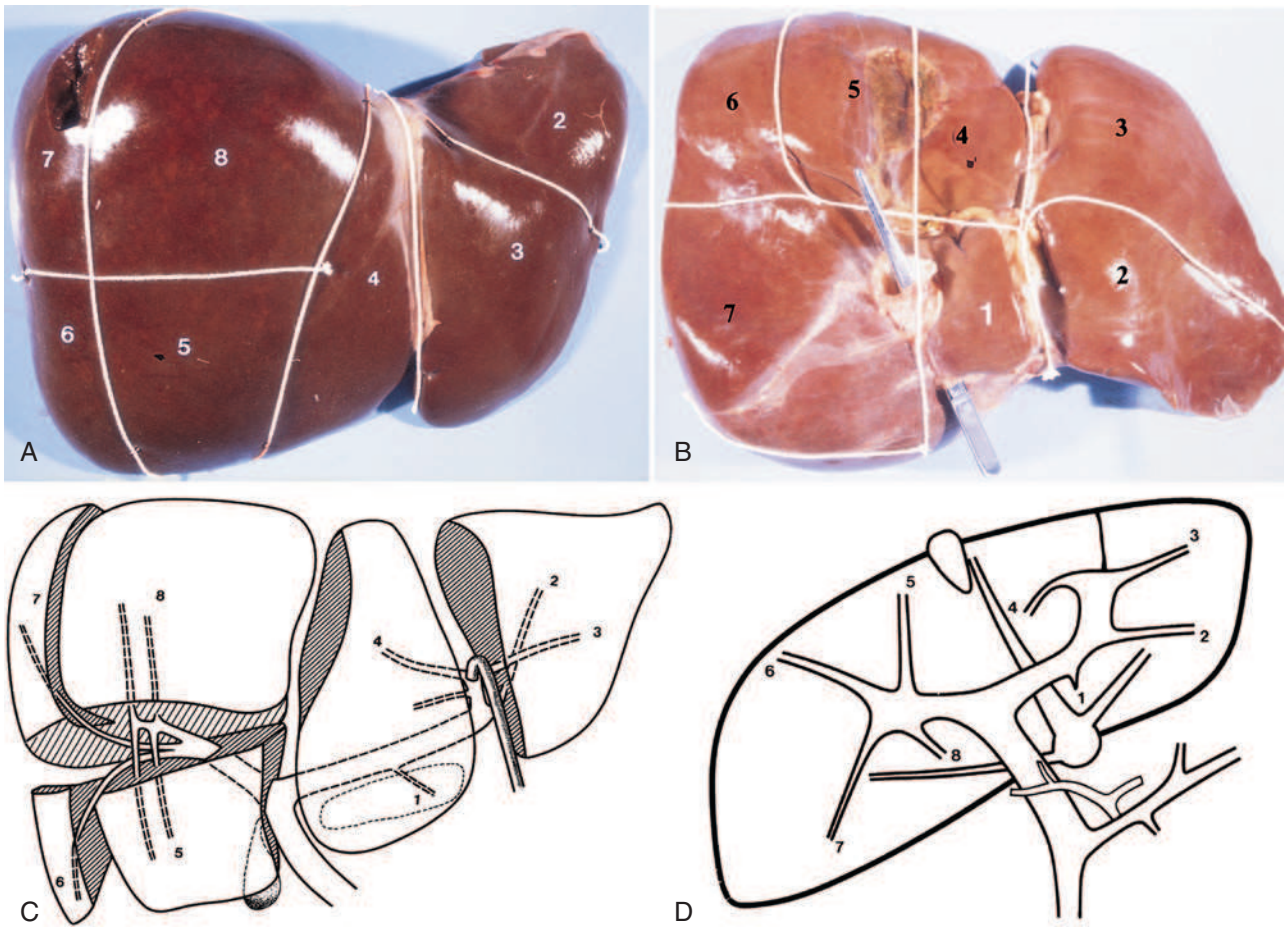

FIG. 51.1 External Segmental Anatomy of the Liver. Segments are numbered in a counterclockwise direction. Their borders are marked with string. **(A)** Upper and anterior surface. Note the whitish falciform ligament that separates segments 3 and 4. **(B)** Lower surface: the forceps are in the main portal vein. The gallbladder has been removed from its bed, which separates segments 4 and 5. The vertical string between segments 4 and 5 and between 1 and 7 follows the gallbladder/middle hepatic vein axis and marks the main hepatic fissure, the division between right and left lobes. Segment 1, the caudate lobe, is to the right of the forceps. Segments 3 and 4 are separated by the falciform ligament; 1 and 2 by the ligamentum venosum. **(C)** Schema of the hepatic segments with their portal venous branches (upper anterior, viewed as in **[A]**). **(D)** Diagram of the portal and hepatic veins and their relationship to the segments (lower liver surface, viewed as in **[B]**). (With permission from Ikeda S, Sera Y, Yamamoto H, Ogawa M. Effect of phenobarbital on serial ultrasonic examination in the evaluation of neonatal jaundice. Clin Imaging. 1994;18[2]:146-148.[4])

Each lobe of the liver contains **four segments.** The segments are numbered counterclockwise: 1 through 4 make up the **left lobe,** and 5 through 8, the **right lobe.** Segment 1 is the **caudate lobe** or Spiegel lobe. The right and left lobes are separated by the **main hepatic fissure,** a line connecting the neck of the gallbladder and the left side of the inferior vena cava (IVC) (Fig. 51.1).

The segmental branches of the portal vein (each one of which leads into a segment) can be outlined in the form of two Hs turned sideways, one for the left lobe (segments 1-4) and one for the right lobe (segments 5-8) (Fig. 51.2).

Portal Vein Anatomy

Left Lobe of Liver

The H of the left lobe is visualized with an oblique, upwardly tilted subxiphoid view. The H is formed by the left portal vein, the branch entering segment 2, the umbilical portion of the left portal vein, and the branches to segments 3 and 4. To this recumbent H are attached two ligaments, the **ligamentum venosum,** also called the "lesser omentum" or the "hepatogastric ligament," and the **falciform ligament.** The ligamentum venosum separates segment 1 from segment 2. The falciform ligament is visible between the umbilical portion of the left portal vein[2] and the outer surface of the liver. It separates segment 3 from segment 4.

Segment 1, the caudate lobe, is bordered posteriorly by the IVC, laterally by the ligamentum venosum, and anteriorly by the left portal vein. Unlike the other segments of the liver, segment 1 may receive branches of the left and right portal veins. The portal veins to segment 1 are usually small and are rarely seen sonographically. The caudate lobe has one or more hepatic veins that drain directly into the IVC, separately from the three main hepatic veins.[3] This special vascularization is a distinctive characteristic of segment 1.

The portal vein leading to **segment 2** is a linear continuation of the left portal vein, completing the lower horizontal limb of the H. Segmental branches to segments 3 and 4 form the other horizontal limb. **Segments 2 and 3** are thus located to the left

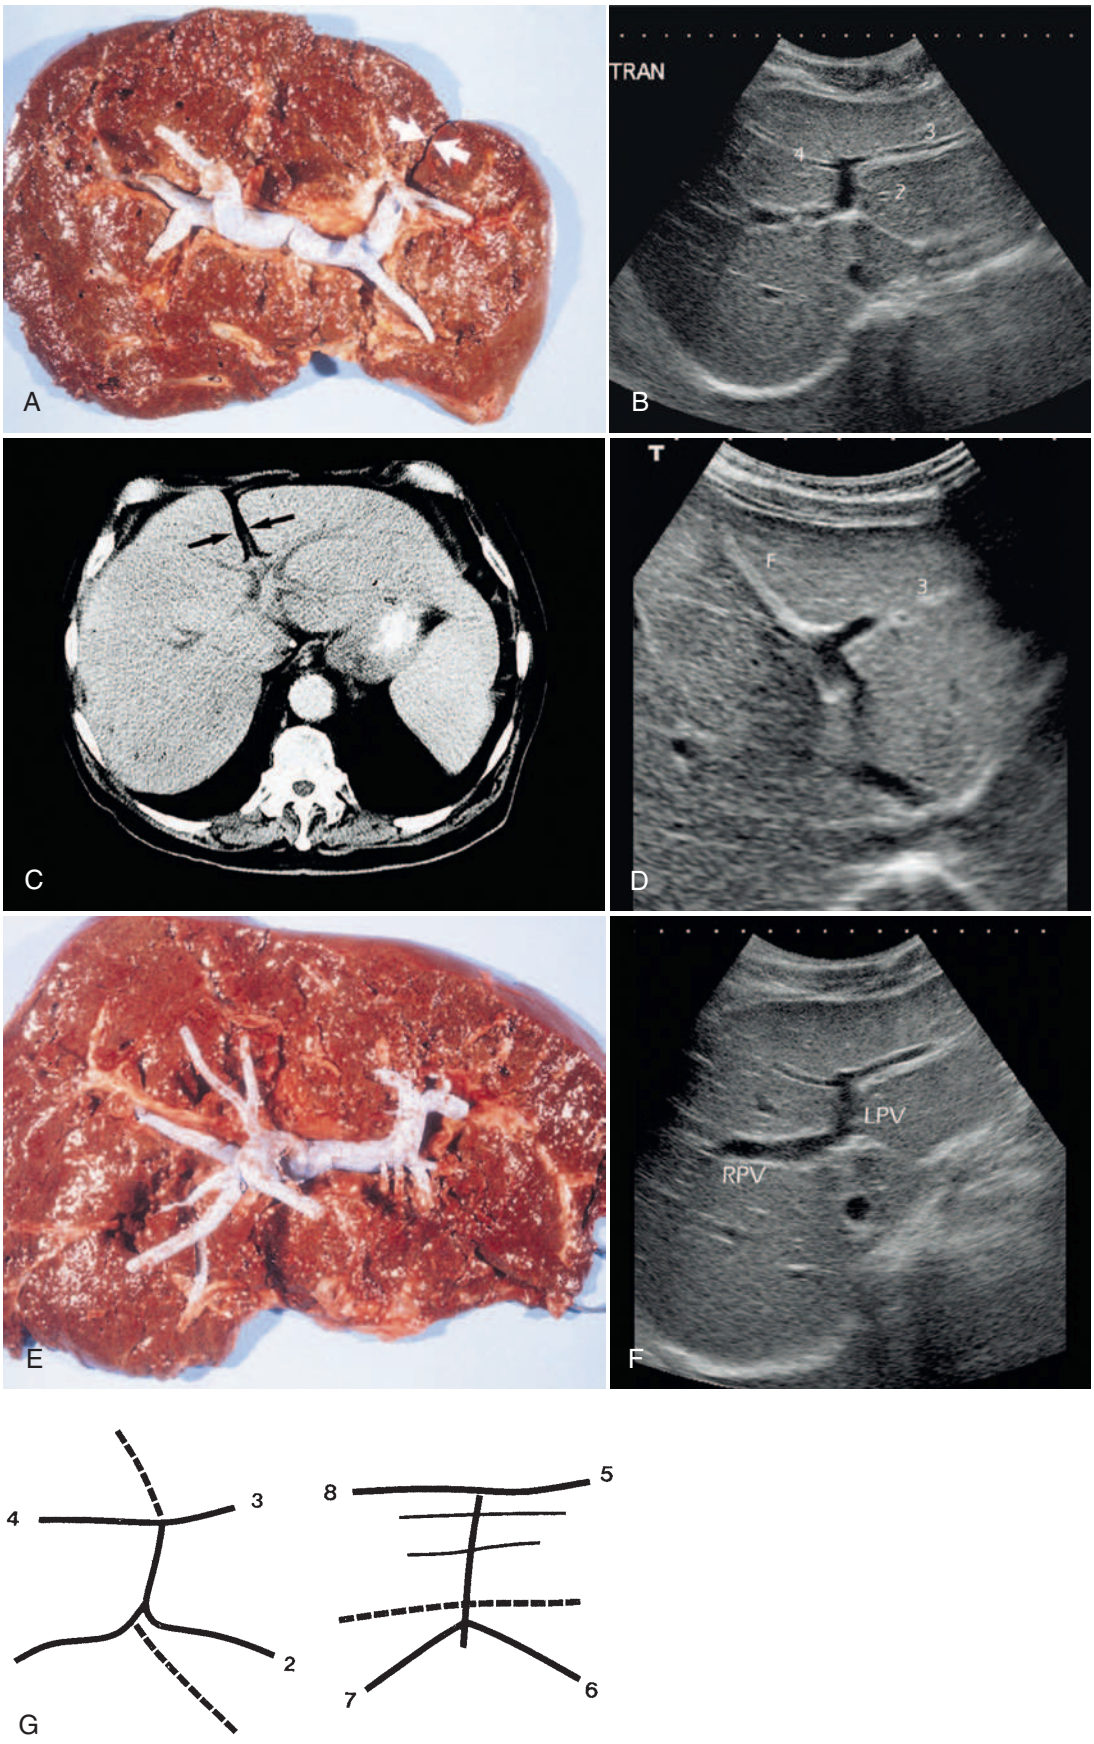

FIG. 51.2 Anatomy of Segmental Portal Veins. (A) Left hepatic lobe, shown on a dissected specimen (with pale-blue dye in portal vein); **(B)** on a subxiphoid transverse sonogram; **(C)** on computed tomography (CT) scan; and **(D)** on more cephalad transverse sonogram. The left portal vein, with branches to segments 2, 3, and 4, forms a horizontally placed H. The umbilical portion of the left portal vein forms the crossbar of the H. Falciform ligament (*arrows* in **[A]** and **[C]** and *F* in **[D]**) is an extension of the umbilical part of the left portal vein. **(E)** Right hepatic lobe of a dissected specimen, and **(F)** on a transverse sonogram obtained at the branch point of the main portal vein into right and left branches. **(G)** *Left* and *right,* Diagrams of the portal vein branches to the left and right lobes. Portal vein branches to segments 5 through 8 and 6 and 7 form the main limbs of the H, and the right portal vein forms its crossbar. Once again, the H is turned horizontally. (With permission from Bismuth H. Surgical anatomy and anatomical surgery of the liver. World J Surg. 1982;6[1]:3-9.[1])

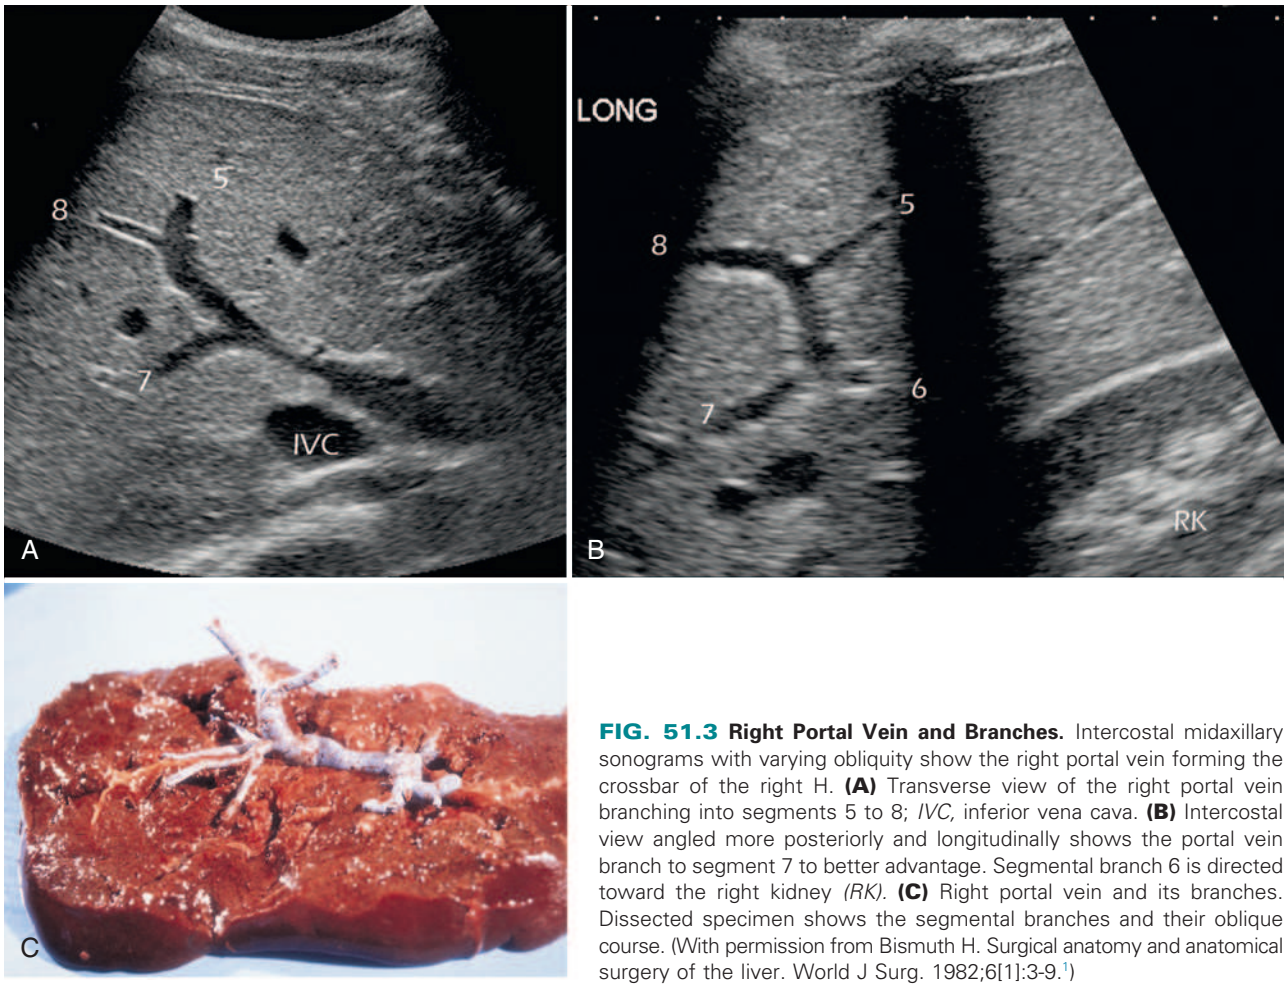

FIG. 51.3 Right Portal Vein and Branches. Intercostal midaxillary sonograms with varying obliquity show the right portal vein forming the crossbar of the right H. **(A)** Transverse view of the right portal vein branching into segments 5 to 8; *IVC,* inferior vena cava. **(B)** Intercostal view angled more posteriorly and longitudinally shows the portal vein branch to segment 7 to better advantage. Segmental branch 6 is directed toward the right kidney *(RK).* **(C)** Right portal vein and its branches. Dissected specimen shows the segmental branches and their oblique course. (With permission from Bismuth H. Surgical anatomy and anatomical surgery of the liver. World J Surg. 1982;6[1]:3-9.[1])

of the umbilical portion of the left portal vein, the ligamentum venosum, and the falciform ligament. **Segment 4,** the **quadrate lobe,** is situated around the right anterior limb of the portal venous H, to the right of the umbilical portion of the left portal vein and the falciform ligament. Segment 4 is separated from segment 5 by the main hepatic fissure and from segments 5 and 8 by the middle hepatic vein. The quadrate lobe is separated from segment 1 by the left portal vein.

Right Lobe of Liver

The right portal vein and its branches are best seen with a sagittal or oblique midaxillary intercostal approach. In some patients a subcostal approach is also useful. The right portal vein follows an oblique or vertical course, directed anteriorly.

The branches leading to the segments of the right lobe of the liver are also distributed in the shape of a sideways H. The right portal vein forms the crossbar of the H. The branches to segments 5 and 8 form the upper limb of the H, and the branches to segments 6 and 7 form its lower portion. The branches of segments 6 and 7 are more obliquely oriented, and the transducer should be rotated slightly upward for segment 7 and downward in the direction of the right kidney for segment 6.

The middle hepatic vein separates segments 5 and 8 from segment 4. The right hepatic vein separates segments 5 and 8 from segments 6 and 7 (Fig. 51.3). **Segment 5** is bordered medially by the gallbladder and the middle hepatic vein and laterally by the right hepatic vein. The right portal vein serves as a landmark for the separation of segment 5 from segment 8. Segment 8 is separated from segment 7 by the right hepatic vein and from segment 4 by the middle hepatic vein.

Segments 6 and 7 are separated from segments 5 and 8 by the right hepatic vein. **Segment 6** is the part of the liver closest to the kidney; its lateral border is the rib cage. **Segment 7** is separated from segment 8 by the right hepatic vein and is bordered laterally by the rib cage and cephalically by the dome of the diaphragm.

Hepatic Vein Anatomy

When seen with an oblique coronal subxiphoid view, the three hepatic veins form a W, with its base on the IVC. The left and middle hepatic veins join the left anterior part of the IVC (Fig. 51.4). The hepatic veins separate the following segments: the **left hepatic vein** separates segment 2 from segment 3; the **middle hepatic vein** separates segment 4 from segments 5 and

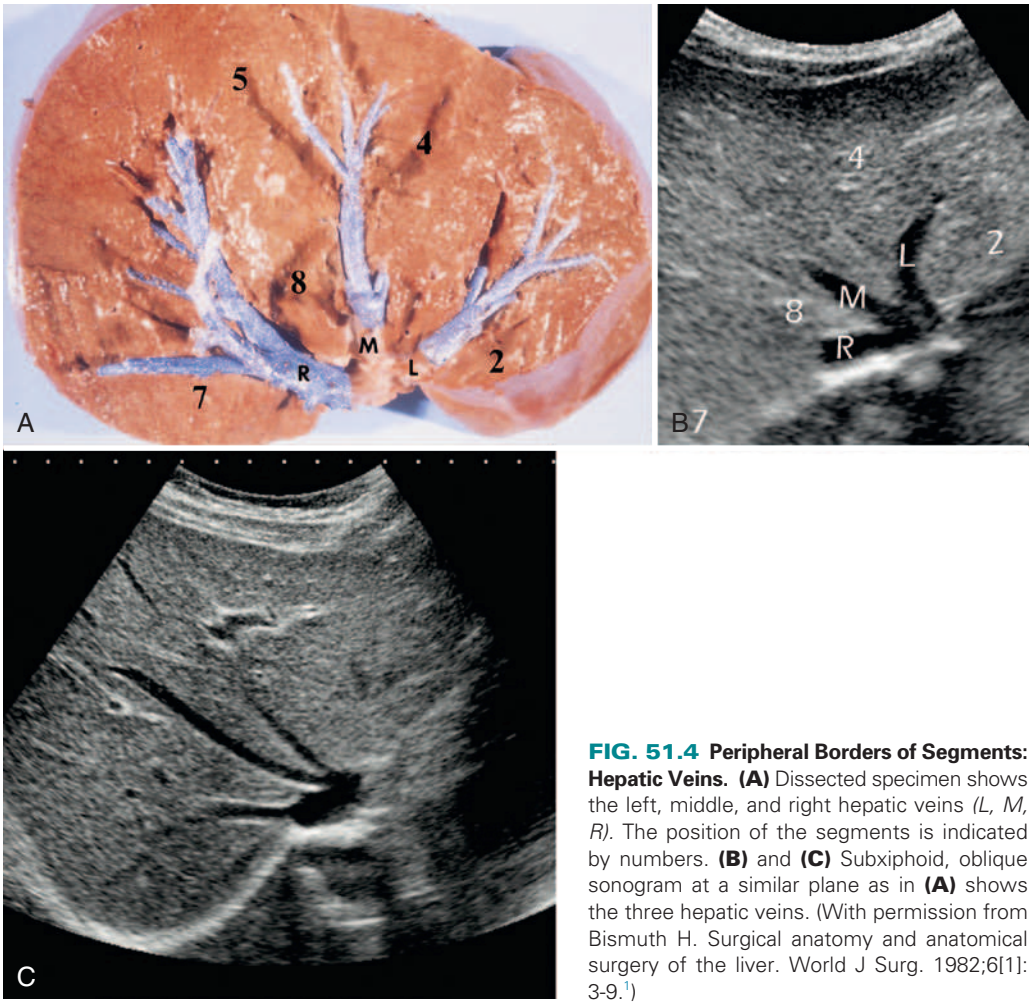

FIG. 51.4 Peripheral Borders of Segments: Hepatic Veins. (A) Dissected specimen shows the left, middle, and right hepatic veins *(L, M, R)*. The position of the segments is indicated by numbers. **(B)** and **(C)** Subxiphoid, oblique sonogram at a similar plane as in **(A)** shows the three hepatic veins. (With permission from Bismuth H. Surgical anatomy and anatomical surgery of the liver. World J Surg. 1982;6[1]: 3-9.[1])

8; and the **right hepatic vein** separates segments 5 and 8 from segments 6 and 7. With the oblique subxiphoid view, the right portal vein is seen en face, which helps separate the superficial segment 5 from the more deeply situated segment 8.

The sonographic examination of the child's liver should include visualization of the **right and left portal veins** and their segmental branches, as well as the hepatic veins. Not only can focal lesions be identified and accurately localized, but thrombosis, compression, or tumor invasion of vessels can be outlined. Doppler sonography is added when the presence and direction of blood flow within these veins need to be assessed. Exploring the liver through its vessels is an excellent way to ensure that the sonographic examination is complete and not just an arbitrary glance at this otherwise homogeneous organ with variable contours and few landmarks except for its veins. Because the branches of the hepatic artery and the bile ducts are neighbors of the portal veins, the examination of the lobar and segmental portal veins ensures a complete assessment of these structures as well.

NEONATAL JAUNDICE

The cause of persistent jaundice in the newborn is often difficult to define because clinical and laboratory features may be similar in hepatocellular and obstructive jaundice. If bile obstruction, biliary atresia, or metabolic diseases such as galactosemia and tyrosinemia are to be treated effectively with surgery or specific diet and medication, the diagnosis must be made early, in the first 2 to 3 months, before irreversible cirrhosis has occurred.

Sonography plays an important role in defining causes of **extrahepatic obstruction to bile flow** that may be effectively treated with early surgery, including **choledochal cyst, biliary atresia,** and **spontaneous perforation of the bile ducts.** (Other causes of bile duct obstruction, such as cholelithiasis, tumors of the bile ducts or pancreas, and congenital stenosis of the common bile duct (CBD), usually appear later in childhood.) Intrahepatic causes of neonatal jaundice include **hepatitis** (bacterial, viral, or parasitic) and **metabolic diseases** (e.g., galactosemia, tyrosinemia, fructose intolerance, α_1-antitrypsin deficiency, cystic fibrosis, paucity of interlobular bile ducts, North American Indian cirrhosis). **Systemic diseases** that cause cholestasis include heart failure, shock, sepsis, neonatal lupus, histiocytosis, and severe hemolytic disease.

The infant with jaundice is usually screened with sonography. When dilation of the bile ducts is found, percutaneous cholangiography or cholecystography may be performed if the cause

Causes of Neonatal Jaundice

OBSTRUCTION OF BILE DUCTS
Choledochal cyst
Biliary atresia
Spontaneous perforation of the bile ducts
Paucity of interlobular bile ducts (Alagille syndrome)

HEPATOCELLULAR DAMAGE (CHOLESTASIS)
Hepatitis
Bacterial
Syphilis
Listeria
Staphylococcus

Viral
Hepatitis B
Hepatitis C
Cytomegalovirus
Human immunodeficiency virus
Rubella
Herpesvirus
Epstein-Barr virus

Toxoplasma

Systemic Diseases
Shock
Sepsis
Heart failure
Neonatal lupus
Histiocytosis
Hemolytic diseases

METABOLIC LIVER DISEASES
Galactosemia
Tyrosinemia
Fructose intolerance
α_1-Antitrypsin deficiency
Cystic fibrosis

and anatomy of the obstruction are unclear. If sonography fails to outline an anatomic abnormality, hepatobiliary scintigraphy may define patency of the CBD, unless hepatocyte damage is extensive. If no radionuclide reaches the gut, liver biopsy is typically performed. Both scintigraphy and the sonographic search for the gallbladder are enhanced by the bile-stimulating effect of phenobarbital administered for 3 to 5 days before the test.[4] The **triangular cord sign,** an echogenic cone-shaped density just cranial to the portal vein bifurcation on longitudinal or transverse scans, is highly predictive of biliary atresia. An **absent or small gallbladder** (<1.5 cm in length) coupled with the triangular cord sign is even more specific for the diagnosis.[5]

Choledochal Cyst

Dilation of varying lengths and severity of the CBD, termed "choledochal cyst," usually manifests as jaundice in infancy,

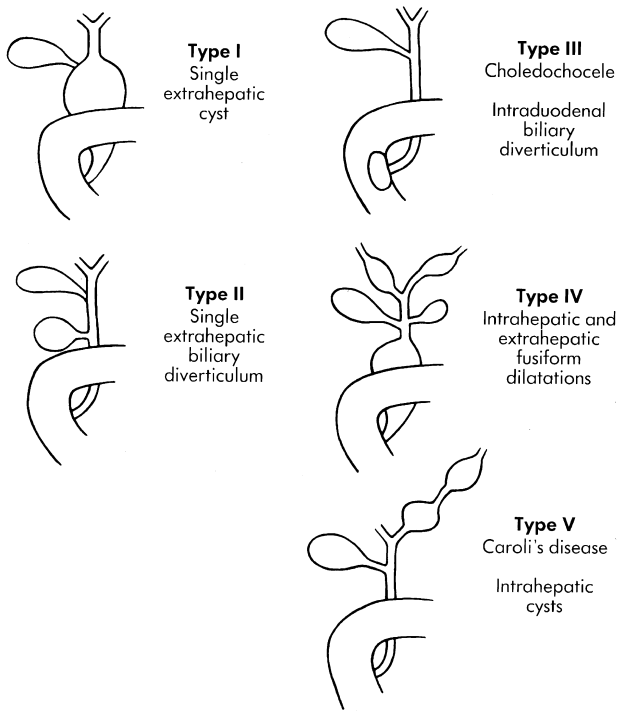

FIG. 51.5 Choledochal Cyst Classification.

clinically mimicking neonatal hepatitis and biliary atresia (Fig. 51.5). Todani's classification describes five types.[6] Type I, **cylindrical or saccular dilation of the common bile duct,** is most common (80%-90%) and is thought to be caused by an abnormal insertion of the CBD into the pancreatic duct, forming a common channel and facilitating reflux of enzymes into the CBD, with consequent inflammation. Because choledochal cysts have been detected in 15-week gestational age fetuses, when amylase is not yet present, and because surgically treated cysts in the newborn period show minimal inflammation, there must be causative factors (as yet unknown) other than the common-channel theory. Two rare but well-documented causes of bile duct dilation (choledochal cyst) in the newborn are localized atresia of the CBD and multiple intestinal atresias in which the CBD empties into a blind pouch of bowel.[7] A choledochal cyst manifesting later in childhood may have a different pathogenesis. It is usually complicated by cholangitis and classically causes abdominal pain, obstructive jaundice, and fever. In some cases the cyst is palpable as a mass.

Choledochal cyst type II consists of one or more **diverticula** of the CBD (2% of cysts). **Choledochocele** (type III) is a dilation of the intraduodenal part of the CBD (1%-5%). **Multiple intrahepatic and extrahepatic cysts** make up type IV (10%), sometimes subcategorized into types IVa and IVb, which has only extrahepatic cysts. **Caroli disease** (type V) affects intrahepatic bile ducts.

Sonographic screening of the jaundiced infant shows one or several thin-walled cysts at the liver hilum or within the liver (choledochal cyst type I; Fig. 51.6). The gallbladder is identified separately. Dilation of intrahepatic ducts, as well as stones, may occur later as a result of bile stasis and cholangitis. Scintigraphy

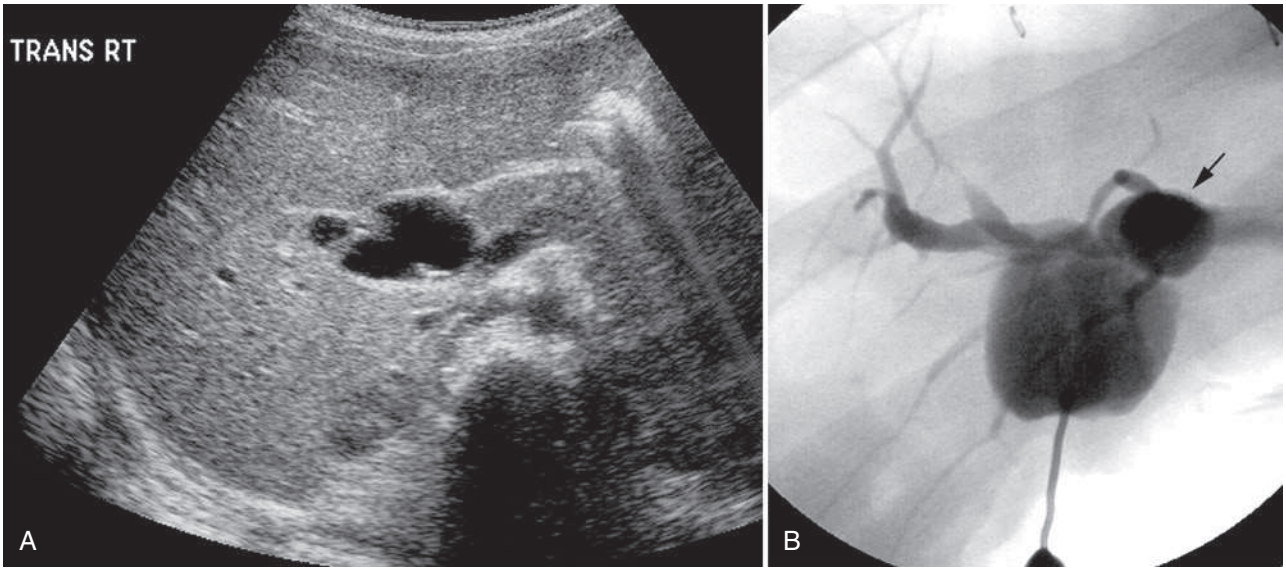

FIG. 51.6 Choledochal Cyst Type I in Infant With Jaundice. (A) Transverse sonogram. A large cyst that is the greatly dilated common bile duct is visible entering the pancreatic head. **(B)** Intraoperative cholangiogram shows injection of the gallbladder and filling of the choledochal cyst *(arrow).*

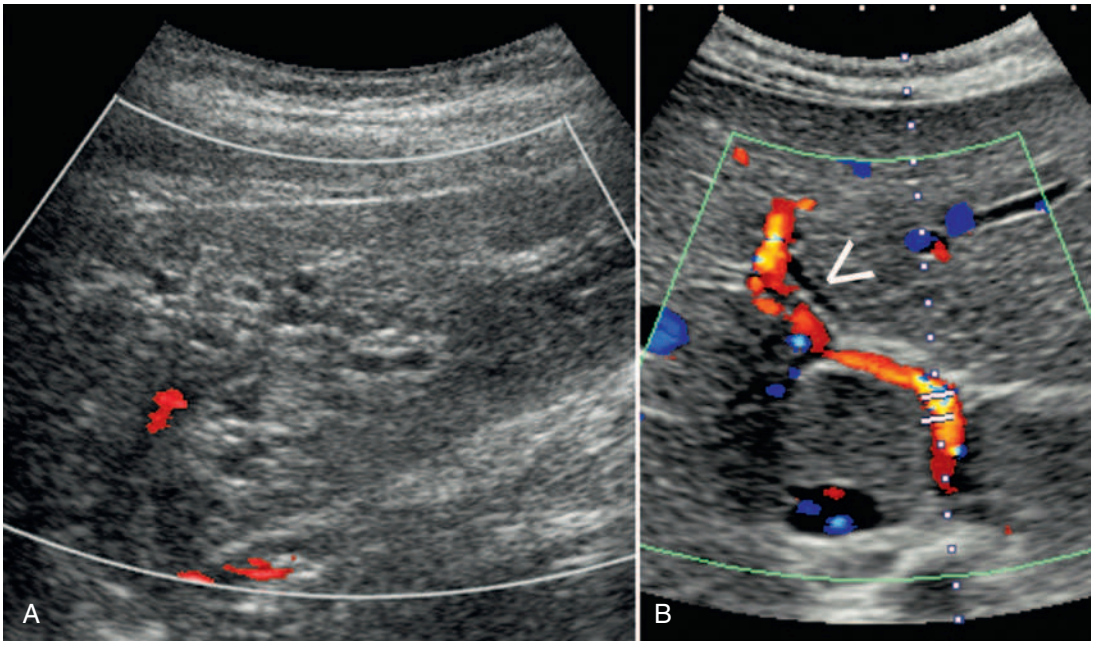

FIG. 51.7 Biliary Ductal Dilation. (A) Caroli disease, type V choledochal cyst. Longitudinal color Doppler image of the left lobe of the liver shows saccular dilation of bile ducts with thickened echogenic walls and few vessels in the deeper aspect of the liver. Cholangitis, caused by obstruction of the bile ducts or by ascending infection, leads to dilation of the intrahepatic and common bile ducts. **(B)** Central bile duct dilation on transverse sonogram in a different patient, with concentric smooth dilation of main intrahepatic duct *(arrowhead)* caused by distal common bile obstruction.

is used to document bile flow into the cyst, and percutaneous cholecystography/cholangiography or endoscopic retrograde cholangiopancreatography is performed if detailed mapping of the bile system is deemed necessary before surgery.

Caroli disease (type V choledochal cyst) consists of nonobstructive dilation of intrahepatic bile ducts[8,9] and is often associated with congenital hepatic fibrosis and autosomal recessive polycystic kidney disease.[10] The disease is caused by the arrest of or derangement in embryologic remodeling of ducts, resulting in segmental dilation. Patients tend to seek medical attention later than with other types of choledochal cysts, usually after cholangitis and stones have formed in childhood (Fig. 51.7). At sonography, Caroli disease has dilated ducts surrounding branches of the portal vein.[9] Sludge and stones are often visible within

the dilated ducts. Abscesses complicating cholangitis are seen as cavities with walls thicker than those of the ducts and filled with heterogeneous material. Polycystic kidneys, when present, are another clue to the diagnosis of Caroli disease; Caroli disease and autosomal recessive polycystic kidney disease may occur together because both are associated with mutation in the *PKHD1* gene.[11]

Spontaneous Rupture of Bile Duct

Rupture of the bile duct is rare. Rupture in newborns leads to jaundice, abdominal distention, and substantial morbidity. Because the site of rupture is usually the junction of the cystic duct and CBD, it is believed that a developmental weakness at this site leads to the rupture. The biliary system is undilated, but there are ascites and loculated fluid collections around the gallbladder. Although the condition was previously treated surgically, the recent trend is toward percutaneous drainage and conservative management.[12]

Paucity of Interlobular Bile Ducts and Alagille Syndrome

Manifesting with chronic cholestasis, usually within the first 3 months of life, ductal paucity and **arteriohepatic dysplasia** (Alagille syndrome [ALGS]) are diagnosed histologically by noting a reduced number of interlobular bile ducts compared with the total number of portal areas. Because of cholestasis, the gallbladder may be very small (disuse). The CBD is normal (Video 51.1). The liver is usually enlarged, especially the left lobe. Portal hypertension ensues, with splenomegaly and esophageal varices. In children with ALGS, paucity of bile ducts is associated with a characteristic facies, pulmonary artery stenosis, butterfly vertebrae, segmentation anomalies, and, infrequently, renal abnormalities (renal tubular acidosis).[13] ALGS is inherited as an autosomal dominant disease with variable penetrance, most commonly due to mutation in *JAG1* (ALGS type 1), but in a small proportion of cases mutation in *NOTCH2* (ALGS type 2).[14]

Biliary Atresia

The incidence of biliary atresia varies from 1 in 8000 to 1 in 10,000 births. Boys and girls are equally affected. Biliary cirrhosis occurs early, often in the first weeks after birth. Biliary atresia is characterized by absence or obliteration of the lumen of the extrahepatic and intrahepatic bile ducts (Fig. 51.8). It is associated with the **polysplenia syndrome** (biliary atresia, situs inversus, polysplenia, symmetrical liver, interrupted IVC, preduodenal portal vein) in about 20% of patients,[15] as well as with **trisomy 17 or 18.** Because the disease is extremely rare, and because the pancreatic duct, which develops with the bile ducts, is normal in affected children, biliary atresia likely develops after the bile ducts have formed. The etiology of biliary atresia is still unclear, although there is evidence pointing to viral, toxic, and multiple genetic factors. An in utero insult to the hepatobiliary system may result in a progressive sclerosis of the extrahepatic and intrahepatic bile ducts. In addition, certain drugs (e.g., carbamazepine) have been associated with biliary atresia.[16]

Jaundice classically develops gradually, 2 to 3 weeks after birth. The diagnosis is readily made if there are radiologic or sonographic signs of the polysplenia syndrome (see Fig. 51.8C-G). Because the flow of bile is interrupted, the gallbladder is typically very small (20%) or absent (80%).[15] After having the infant fast for 4 to 6 hours, a specific search with a high-frequency transducer will demonstrate a very small gallbladder **(microgallbladder)** in about 20% of patients. When the gallbladder is visible, the "ghost triad" appearance has been reported to help in making the correct diagnosis of biliary atresia.[17] The **ghost triad** consists of gallbladder length less than 1.9 cm, irregular or incomplete mucosal lining, and irregular or lobular contour. The echogenic fibrotic remnant of the CBD seen adjacent to the portal vein has been called the **triangular cord sign.** The combination of a small gallbladder, less than 1.5 cm in length, and the triangular cord sign are very specific for the diagnosis of biliary atresia.[5] Any intrahepatic bile duct remnants may dilate and be visible at sonography as bile duct dilation or small cysts. In addition, the cholangitis that complicates biliary atresia may result in cystic areas within the liver.[18]

Surgical treatment creates communication between a loop of jejunum (transposed to the liver after a Roux-en-Y anastomosis) and any patent bile "ductules" at the liver hilum. This is the classic hepatoportoenterostomy described by Kasai in 1959.[19] Even if there is no mucosal contact between intestine and the bile ducts, the procedure permits bile drainage, with complete clinical remission in 30% and partial drainage in 30% of affected children. The prognosis becomes much more guarded when the Kasai procedure is delayed to more than 60 days after birth.[20] Despite successful Kasai procedures, 75% of patients require liver transplantation before age 20 years.[21] Biliary atresia remains the most common reason for liver transplant in pediatric patients.

Neonatal Hepatitis

Defined as an infection of the liver occurring before the age of 3 months, neonatal hepatitis is now considered an entity distinct from toxic or metabolic diseases affecting the neonate. The causative agent (bacterium, virus, or parasite) reaches the liver through the placenta, via the vagina from infected maternal secretions, or through catheters or blood transfusions. Transplacental infection occurs most readily during the third trimester, and syphilis, *Toxoplasma,* rubella, and cytomegalovirus (CMV) are the most common agents[16] (Fig. 51.9, Video 51.2).

Neonatal bacterial hepatitis is usually secondary to upward spread of organisms from the vagina, infecting endometrium, placenta, and amniotic fluid. In twin pregnancies, the fetus nearest the cervix is more frequently affected. *Listeria* and *Escherichia coli* are the usual organisms. During vaginal delivery, direct contact with herpesvirus, CMV, human immunodeficiency virus (HIV), and *Listeria* organisms may lead to hepatitis. Blood transfusions may contain hepatitis virus B or C, CMV, Epstein-Barr virus, and HIV. Infected umbilical vein catheterization usually results in bacterial hepatitis or abscesses.[16]

With the exception of diffuse hepatomegaly, there are no specific sonographic signs of hepatitis, unless abscesses (usually

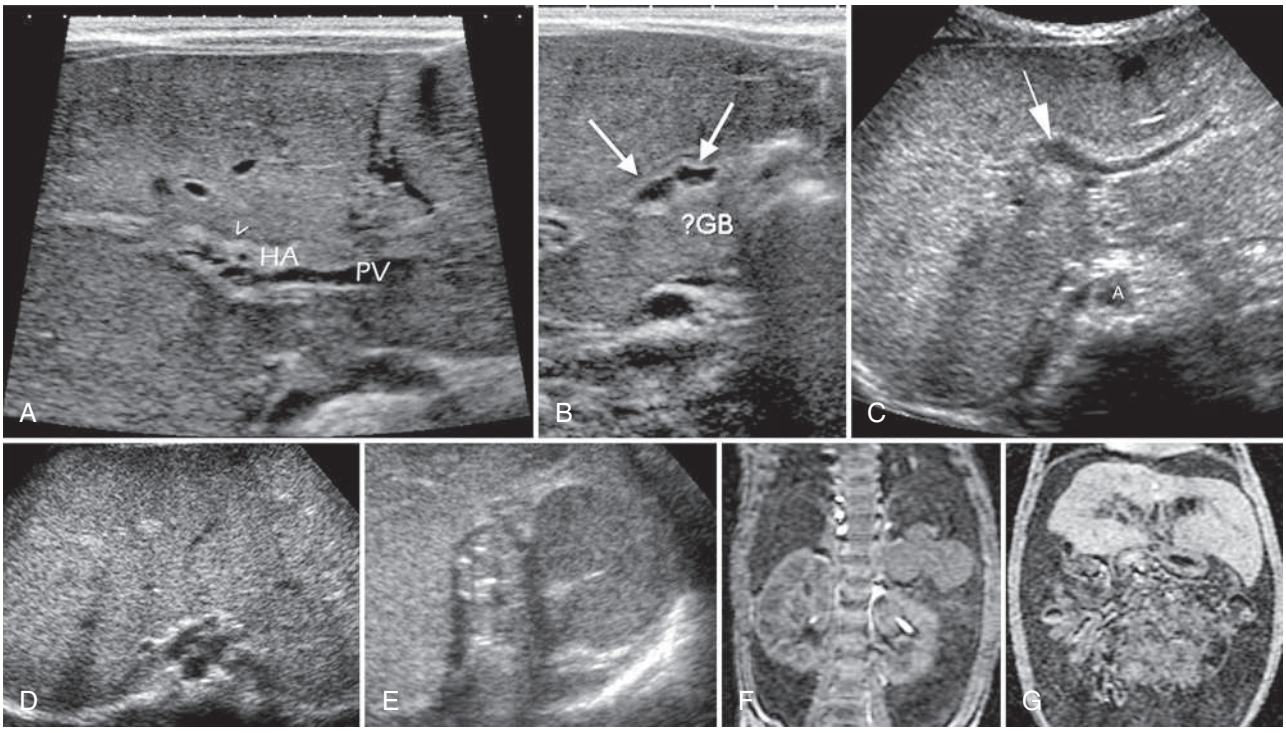

FIG. 51.8 Biliary Atresia Spectrum. (A) Transverse sonogram near the porta hepatis. **Triangular cord sign** is linear, echogenic fibrous tissue *(arrowhead)* anterior to a normal portal vein *(PV)* and hepatic artery *(HA)*. Failure to visualize the common bile duct in a newborn with jaundice is strongly suggestive of biliary atresia. **(B) Gallbladder ghost triad:** small gallbladder *(arrows),* irregular and incomplete echogenic lining, and indistinct lobular wall. Highly specific finding for biliary atresia. **(C)** to **(G) Polysplenia syndrome** in a different patient, with preduodenal portal vein and interruption of inferior vena cava (IVC). **(C)** Transverse liver sonogram shows aorta *(A)* anterior and left of the spine in newborn girl. The bifurcation of the portal vein *(arrow)* is more anterior than usual. **(D)** Right transverse sonogram shows liver extending across the entire upper abdomen. IVC is missing on both views. **(E)** In left upper quadrant, several small spleens are present. No gallbladder was found in this patient with biliary atresia. **(F)** Coronal magnetic resonance spoiled gradient echo (SPGR) images performed for ascites and elevated liver enzymes shows polysplenia. **(G)** Transverse liver with anteriorly positioned portal vein several months after Kasai procedure.

bacterial in origin) occur.[22,23] The gallbladder wall may be thickened, probably from hypoalbuminemia. Dystrophic calcifications in the hepatic parenchyma may be seen.

Neonatal Jaundice and Urinary Tract Infection or Sepsis

The association of jaundice with urinary tract infection or sepsis occurs more often in male than female newborns. Jaundice, hepatomegaly, and vomiting are common clinical signs. Urinary tract symptoms are uncommon, as are shock and fever. A thorough examination of the kidneys, ureters, and bladder should therefore accompany sonography of the liver in the infant with jaundice. Similarly, the diaphragm and lung bases should be examined to look for pleural effusions and pneumonia, which may be accompanied by sepsis and jaundice in the newborn.

Inborn Errors of Metabolism

Because these disorders cause liver damage in the newborn, some rapidly destroying the liver if untreated, and because several can be treated effectively with diet or drugs once diagnosed, pediatricians and radiologists should be well acquainted with inborn errors of metabolism. Liver damage is caused by storage of a hepatotoxic metabolite or by absence of an essential enzyme that impairs the detoxification process of the liver.

Steatosis is especially prominent in the **glycogen storage diseases, galactosemia, tyrosinemia,** and **cystic fibrosis. Cirrhosis** eventually develops in all the diseases that cause liver damage, and portal hypertension then follows. The risk of **hepatocellular carcinoma** is significantly increased in **α_1-antitrypsin deficiency,** in **tyrosinemia,** and in **glycogen storage disease type I. Liver adenomas** also develop in the last two entities, as does **renal tubular disease,** which is usually characterized by acidosis and nephrocalcinosis.[16]

Tyrosinemia is best treated by transplantation. Until drug therapy became available for the treatment of the acute neurologic crises in infants with acute tyrosinemia, transplantation was performed as a lifesaving procedure as soon as surgically feasible. Currently, transplantation is done once liver nodules appear because hepatocellular carcinoma develops in about 30% of children with tyrosinemia who survive the neonatal period. A review of livers dissected at liver transplantation found that preoperative sonograms and computed tomography (CT) scans were not accurate in distinguishing regeneration nodules, adenomas, and carcinomas, nor was alpha-fetoprotein (AFP) analysis[24] (Fig. 51.10).

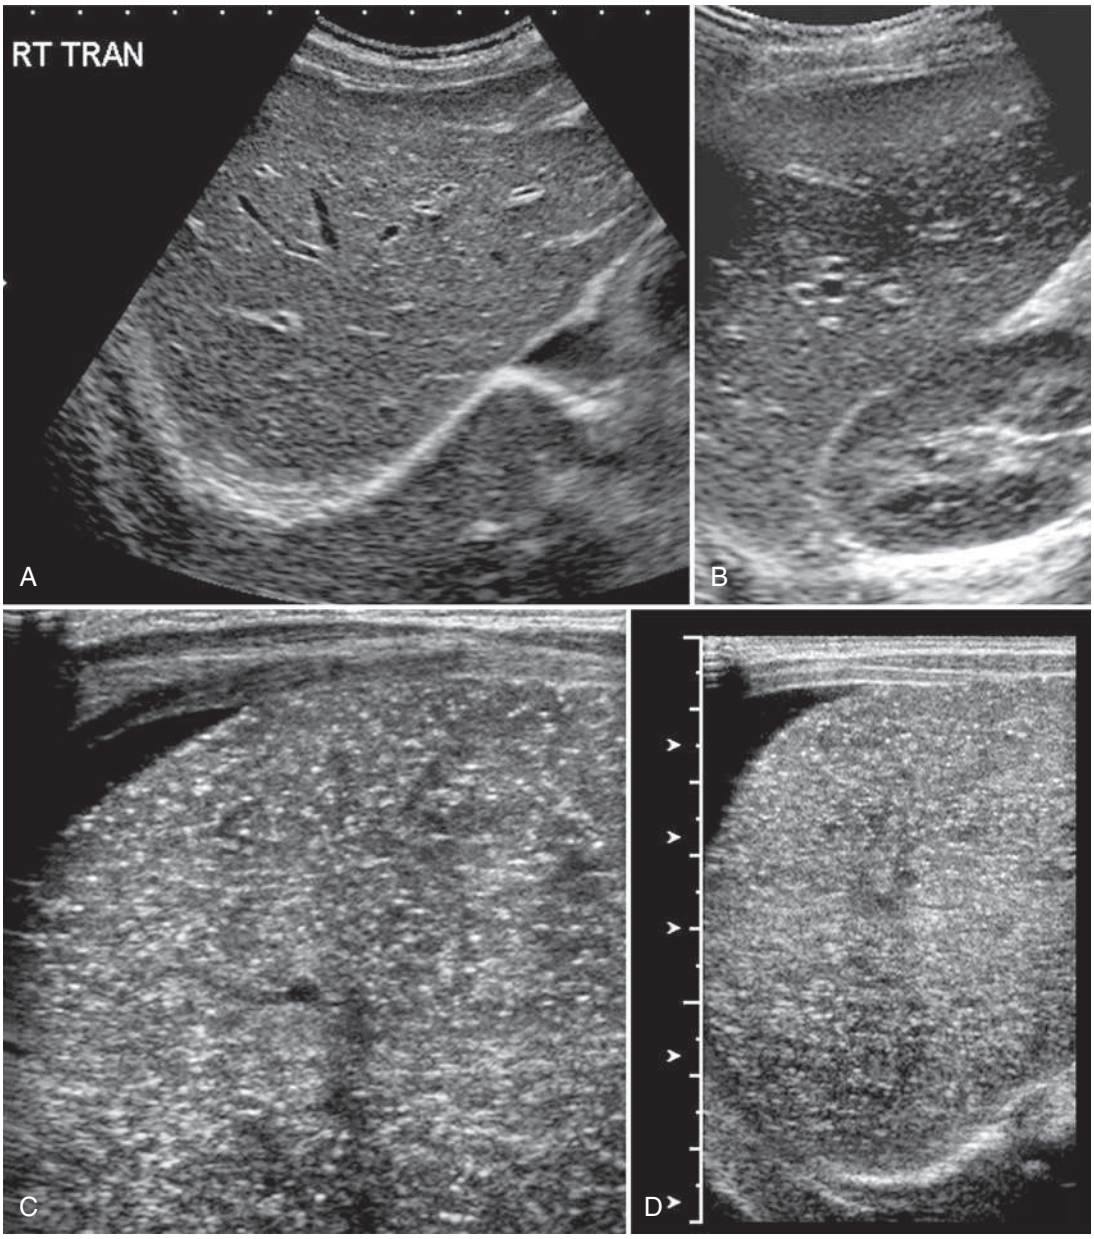

FIG. 51.9 Hepatitis. (A) Transverse sonogram in a teenage boy with acute hepatitis shows echogenic portal triads and hypoechoic parenchyma. **(B)** Longitudinal image in same patient showing hepatic hypoechoic echotexture similar to adjacent right kidney. **(C)** Transverse magnified sonogram and **(D)** conventional linear array image show **congenital herpes infection** in an infant with dystrophic calcification throughout the liver. HEPATOCYTE INJURY SOMETIMES
α_1-Antitrypsin deficiency
Cystic fibrosis
Glycogen storage disease (I and III)

NO HEPATOCYTE DAMAGE (STORE METABOLITES)
Mucopolysaccharidoses
Gaucher disease

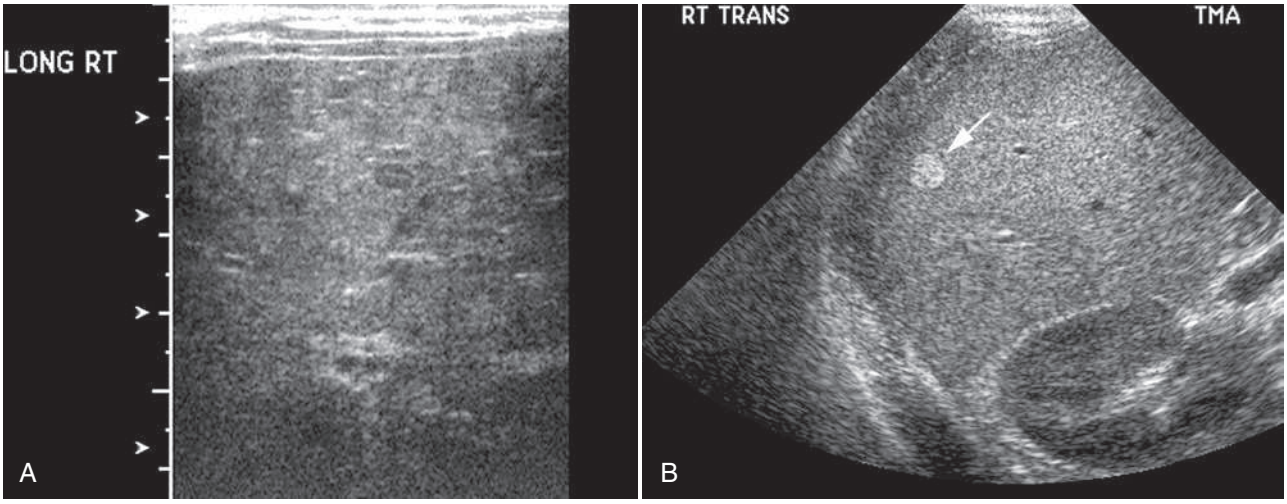

FIG. 51.10 Tyrosinemia and Glycogen Storage Disease (Type I, von Gierke Disease). (A) Longitudinal sonogram shows heterogeneous echotexture, likely a combination of regenerating nodules and adenomas of the liver, in a patient with tyrosinemia awaiting liver transplant. **(B) Echogenic adenoma** *(arrow)* in the liver of another child with glycogen storage disease type I. Follow-up was done because of this patient's increased risk of hepatocellular carcinoma.

The sonographic examination of children with possible metabolic disease includes a careful analysis of liver size and architecture, searching for steatosis, cirrhosis, and nodules; an analysis of renal architecture, searching for increased size and nephrocalcinosis; and a Doppler examination of the abdomen searching for signs of portal hypertension.

STEATOSIS

Fat accumulates in hepatocytes after cellular damage **(fatty degeneration),** through the overloading of previously healthy cells with excess fat **(fatty infiltration),** or in certain enzyme deficiency syndromes, through the inability of fat to be mobilized out of the liver. Drugs (acetylsalicylic acid, tetracycline, valproate, warfarin [Coumadin]) and toxins (aflatoxin, hypoglycine) as well as alcohol abuse lead to fatty degeneration of liver cells. Steatosis is also seen in metabolic liver disorders such as galactosemia, fructose intolerance, and Reye syndrome. Obesity (Video 51.3), corticosteroid therapy, hyperlipidemia, and diabetes are examples of increased fat mobilization and its entry into the liver. In malnutrition, nephrotic syndrome, and cystic fibrosis, not only does excess fat enter the liver, but mobilization of fat out of the hepatocyte is deficient as well. When parenteral nutrition does not include lipids, steatosis results from a deficiency of essential fatty acids. Most inherited disorders of the liver mentioned previously involve an enzyme deficiency and result in steatosis.

Fatty changes are reversible, may be diffuse or focal, and are often detected on ultrasonography before clinically suspected.[25] On sonography, areas of steatosis are highly echogenic, blurring vessel walls. The nearby kidney cortex appears much less echogenic. When focal, steatosis usually has smooth, geometric, or fingerlike borders[26] (Fig. 51.11). Intervening normal liver may appear hypoechogenic and masquerade as mass lesions (metastases or abscesses), especially if the ultrasound gain is adjusted by using the fatty areas as a normal reference. Segments 4 and 5 are often spared in steatosis, perhaps because of favorable blood supply by the gallbladder and its vessels.[27] Nodules of steatosis may mimic metastases on CT. Areas of abnormal echotexture on sonographic studies can be further evaluated with CT; the two modalities are complementary in this situation. Ultrasound grading of steatosis is subjective; magnetic resonance spectroscopy can reliably quantify fat content. Magnetic resonance imaging (MRI) sequences and various MRI contrast agents can characterize focal lesions in the liver. Despite sophisticated imaging, occasionally biopsy may be necessary.

FIG. 51.11 Fatty Infiltration of Liver (Steatosis) in Patient With Cystic Fibrosis. Sagittal view shows increased hepatic echotexture, with some sparing posteriorly. The cortex of the right kidney is much less echogenic than the fatty liver.

Causes of Steatosis

Drugs
- Acetylsalicylic acid
- Tetracycline
- Valproate (and other antiepileptic medications)
- Warfarin (Coumadin)
- Toxins
- Aflatoxin
- Hypoglycine

Alcohol abuse
Metabolic liver disease
- Galactosemia
- Fructose intolerance
- Reye syndrome

Obesity
Corticosteroid therapy
Hyperlipidemia
Diabetes
Malnutrition
Nephrotic syndrome
Cystic fibrosis

CIRRHOSIS

The usual forms of cirrhosis in childhood are **biliary** and **post necrotic.** Morphologically, the cirrhotic liver consists of regenerating nodules devoid of central veins and surrounded by variable amounts of connective tissue. Hepatic architecture is sufficiently distorted to disturb hepatic circulation and hepatocellular function. Increased resistance to blood flow through the liver leads to portal hypertension.

The sonographic appearance of the liver depends on the severity of the cirrhosis. With progressive replacement of hepatocytes by fibrous tissue, the liver attenuates sound increasingly, and sound penetration of the liver, even with low-frequency (2 or 3 MHz) transducers, becomes difficult. The macronodules of advanced cirrhosis become visible sonographically at the surface of the liver (contrasted to the neighboring lesser omentum, peritoneum, or ascites, if present) or within its substance (nodular architecture, increased hyperechogenic fibrous tissue around portal vein branches and the ligamentum teres).[26] The caudate lobe is often prominent[28] (Fig. 51.12). Parts of segment 4 of the right lobe of the liver may atrophy in advanced disease.

CHOLELITHIASIS

Gallstones are less common in children than in adults and are usually related to an associated disease. Their composition can be mixed or of calcium bilirubinate. The "adult" cholesterol stone is rare except in children with cystic fibrosis.[29] Gallstones are mobile and hyperechogenic, and they cast acoustic shadows only if they are of appropriate size and composition.

In some children, especially those receiving total parenteral nutrition, thick bile can be observed to form **sludge,** loosely formed "sludge balls" or **"tumefactive sludge,"** and finally **stones,** when serial sonograms are performed over several weeks (Fig. 51.13). **Stasis of bile flow** is the probable cause of sludge and stone formation, also seen in utero and in premature infants and usually regressing spontaneously.[30]

Gallbladder wall thickening occurs in children with acute hepatitis, hypoalbuminemia, obstructed hepatic venous return, and ascites.[22,23] The classic signs of impacted gallstone, thick gallbladder wall, and fluid around the gallbladder seen in adults with **acute cholecystitis** are rare in children. The gallbladder becomes dilated and rounded (rather than the normal oval shape) in fasting children (especially infants receiving total parenteral nutrition), children with sepsis (especially streptococcal), and those in the acute phase of **Kawasaki disease.** When distended, the gallbladder may become tender and painful. It heals with the underlying disease. **Acalculous cholecystitis** in children is rare and should be diagnosed only if no disease causing gallbladder distention or wall edema is found.[31]

Diseases Associated With Gallstones in Children

HEMATOPOIETIC
Hemolytic anemias or hemolysis (artificial heart valve)
Rh incompatibility
Blood transfusions
Sickle cell anemia

GASTROINTESTINAL
Cystic fibrosis
Bile duct anomalies
Ileal dysfunction (Crohn disease, short bowel)
Total parenteral nutrition
Metabolic liver diseases

OTHER
Immobilization (scoliosis surgery)
Dehydration
Obesity
Sepsis
Oral contraceptives

LIVER TUMORS

Identification

It is sometimes difficult to define the origin of an abdominal mass, especially when it is large. The following questions are helpful in tracing a mass to hepatic origin:

- **Vascular anatomy:** Can a feeding hepatic vessel be identified by means of Doppler sonography? Are segmental portal veins displaced or invaded by the tumor[32]? What liver segments are involved? Is the main hepatic artery enlarged? (This usually signals the presence of a highly vascular hemangioendothelioma.)
- **Biliary anatomy:** Are the bile ducts normal? Has the gallbladder been identified?
- **Anatomy of the abdomen:** Does the mass move with the liver during respiration? Is the liver parenchyma normal or

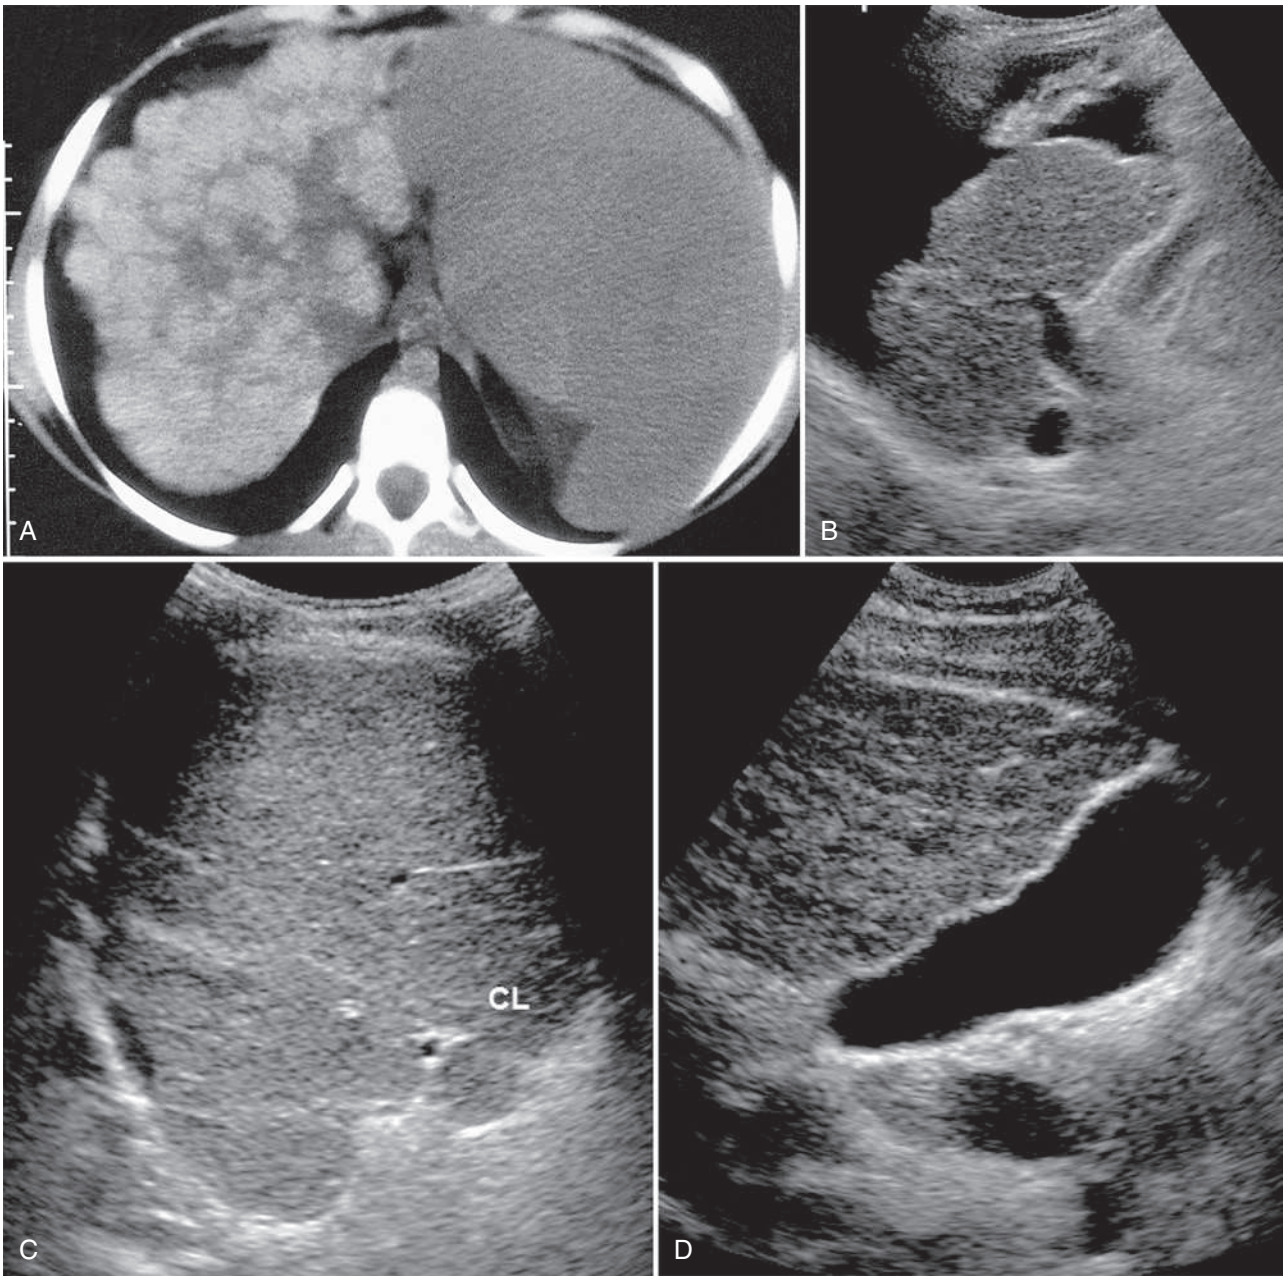

FIG. 51.12 Cirrhosis. (A) Computed tomography (CT) scan of the upper abdomen in a 6-year-old child shows a small liver with multiple nodules visible both along the cortex and within the liver. Microscopy of the native liver after transplantation showed regenerating nodules and severe cirrhosis (portal hypertension). **(B)** Sonogram of another child shows macronodules of cirrhosis at the surface of the liver outlined by ascitic fluid. **(C)** Sonogram in a teenager with cystic fibrosis and cirrhosis shows diffusely increased echotexture of the liver. Note the nodular lateral surface of the liver and the larger caudate lobe *(CL)*. **(D)** Nodular contour may also be appreciated against a fluid-filled gallbladder margin in patients without ascites. This 17-year-old patient had autoimmune hepatitis and developing cirrhosis.

cirrhotic? Is there ascitic fluid available for cytology? Is there another abdominal, retroperitoneal, para-aortic, or pelvic mass that could be a primary tumor?

Benign Liver Tumors

About 40% of primary liver tumors in children are benign. Hemangiomas are by far the most common. Mesenchymal hamartomas, adenomas, and focal nodular hyperplasia together constitute about one-half of benign liver tumors in the child.[33]

Hemangiomas

Hemangiomas are vascular, mesenchymal masses that may be focal (solitary), multifocal, or diffuse. All are characterized initially by active endothelial growth (angiogenesis). During this stage, the tumor is highly vascular and may cause sufficient arteriovenous (AV) shunting to result in high-output heart failure. When associated with hydrops or congestive heart failure and thrombocytopenia, this lesion may be called **neonatal hemangiomatosis.** Hemangiomas in the liver are often associated with cutaneous

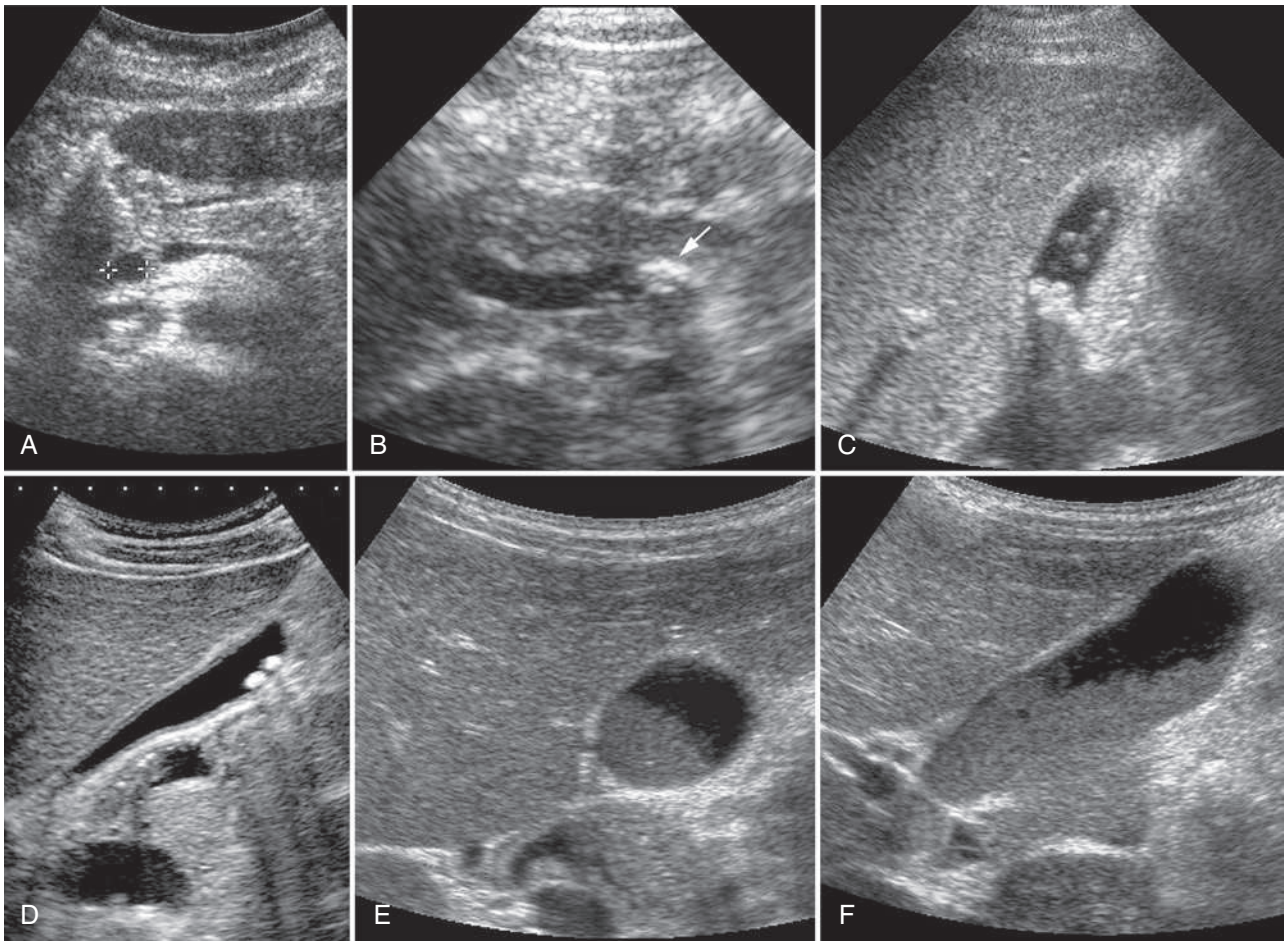

FIG. 51.13 Cholelithiasis. (A) Transverse and **(B)** longitudinal views of a dilated common bile duct (between cursors in **[A]**) containing an echogenic shadowing stone (stone seen only on **[B]** *[arrow]*) in a teenager with acute right upper quadrant pain. **(C)** and **(D)** Multiple echogenic, shadowing gallstones in two other patients, with hemolytic anemia. Note that the stones show variable degrees of shadowing, likely related to their mineral composition. **(E)** and **(F)** Gallbladder sludge without stones or gallbladder wall thickening in a patient receiving total parenteral nutrition.

Liver Masses in Children

SOLID
Hemangioendothelioma (single or multiple)

Lymphoma
Metastasis

CYSTS IN OR NEAR THE LIVER
Congenital cysts
Congenital hepatic fibrosis
Choledochal cysts
Duodenal duplication cyst
Hydatid cyst ("sand," daughter cysts)
Caroli disease
Hamartoma

hemangiomas as well (Fig. 51.14, Video 51.4, Video 51.5). Solitary hemangiomas are now recognized to be the hepatic form of **cutaneous rapidly involuting congenital hemangiomas** (RICH), which are fully developed at birth and demonstrate an accelerated involution over the first year of life. Multifocal and diffuse hemangiomas are still actively proliferating lesions, also known as **infantile hemangiomas.** Diffuse hemangiomas are more likely to have complications of hemorrhage, cardiac compromise, hepatic failure, hypothyroidism, or coagulopathy, and may be treated with propranolol, embolization, resection, or transplant. Steroids and chemotherapy are less frequently used.[34,35] As a typical solitary hemangioma matures, vessel growth slows. Existing vessels may enlarge and form "lakes" with minimal blood flow. This is the cavernous hemangioma typically seen in adults and rarely in children.[36]

Infantile Hemangioendotheliomas

Infantile hemangioendotheliomas are single or multiple solid masses of varying echogenicity, often containing fine, linear foci of calcium.[37] Doppler sonography shows blood flow in multiple tortuous vessels both within and at the periphery

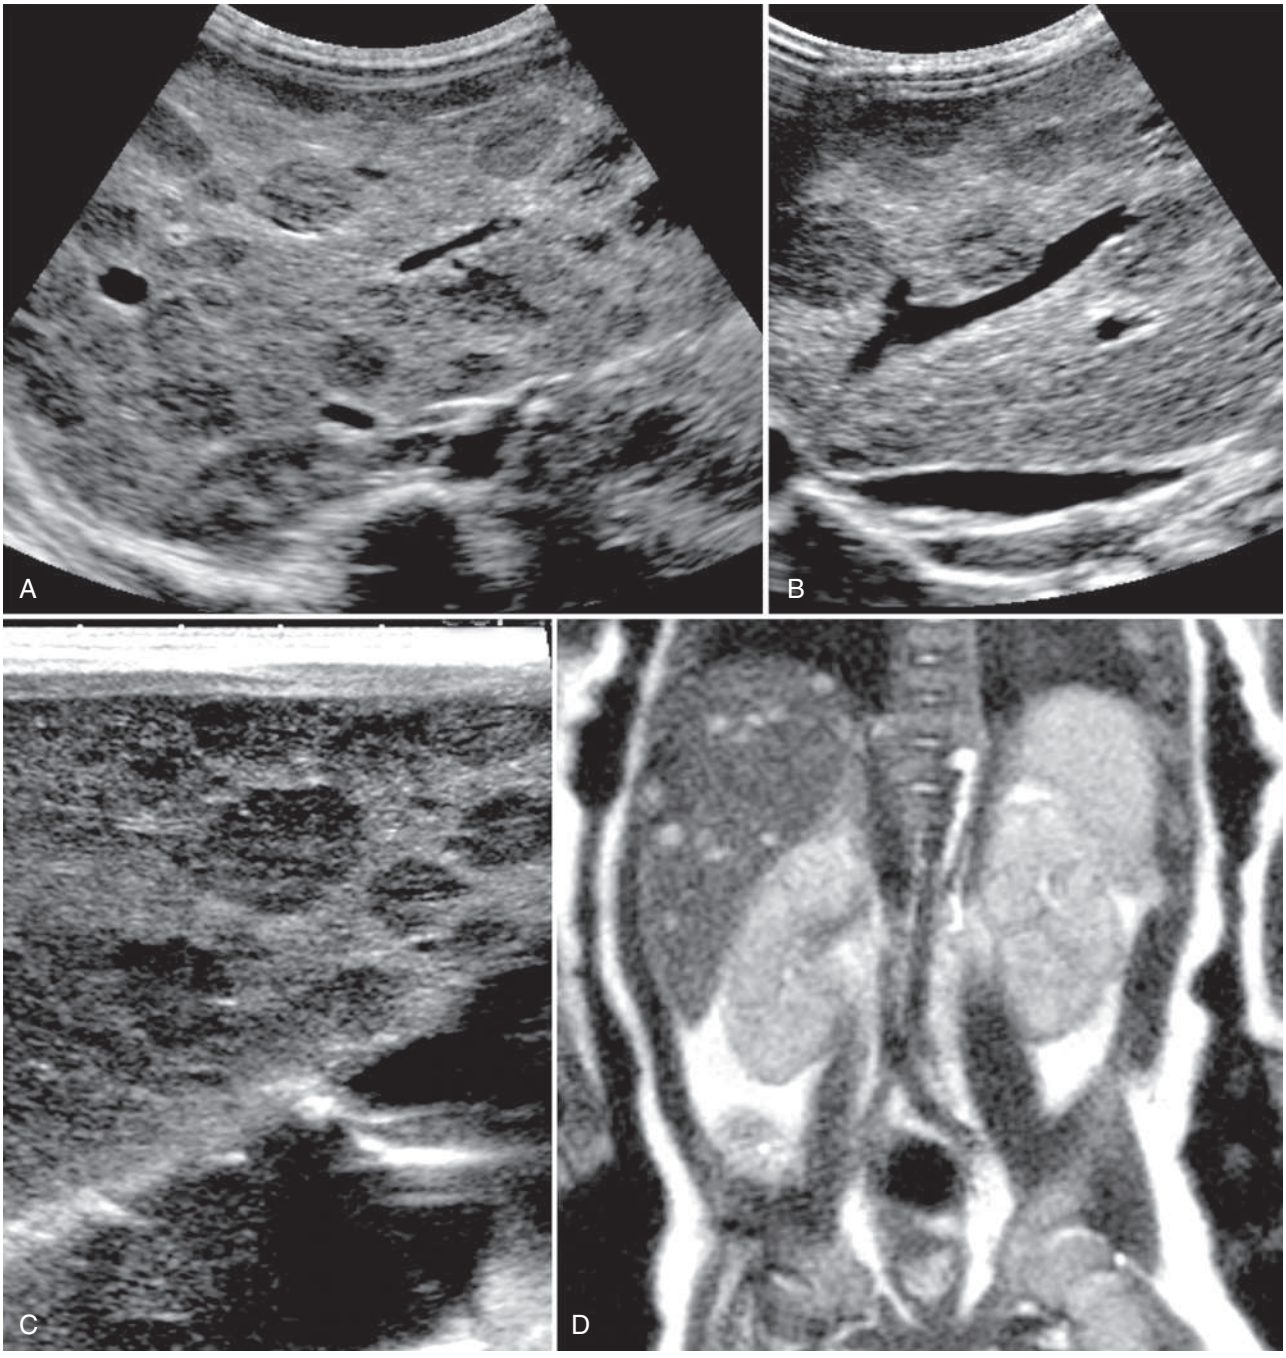

FIG. 51.14 Hemangiomas. Multiple visceral and cutaneous hemangiomas were found in this newborn with enlarged liver at birth. **(A)** Transverse sonogram showing innumerable hypoechoic lesions enlarging the liver. **(B)** Longitudinal sonogram of the liver showing one hemangioma deforming the adjacent hepatic vein. **(C)** Transverse linear array image showing the lesions in greater detail. **(D)** Coronal magnetic resonance single shot fast spin echo (SSFSE) image shows only a few remaining liver lesions several months after treatment. See also Video 51.4 and Video 51.5.

of the mass (Fig. 51.15). Doppler shifts exceed those seen in normal intrahepatic arteries. When AV shunting is severe, the celiac axis, hepatic artery, and veins are dilated, and the infraceliac aorta is small. Doppler shifts (low-resistance high-diastolic flow) from hemangioendothelioma vessels may resemble those from malignant tumors.[38] The vascular nature of these lesions is confirmed by bolus injection CT and the search for rapid filling and rapid washout in these masses. Angiography is usually reserved for patients considered for embolization.

Mesenchymal Hamartomas

Mesenchymal hamartomas are rare, usually multiseptate, cystic masses derived from periportal mesenchyma. Calcifications occur rarely. Hamartoma typically manifests as an asymptomatic mass in the right lobe of the liver in children younger than 2 years.[39]

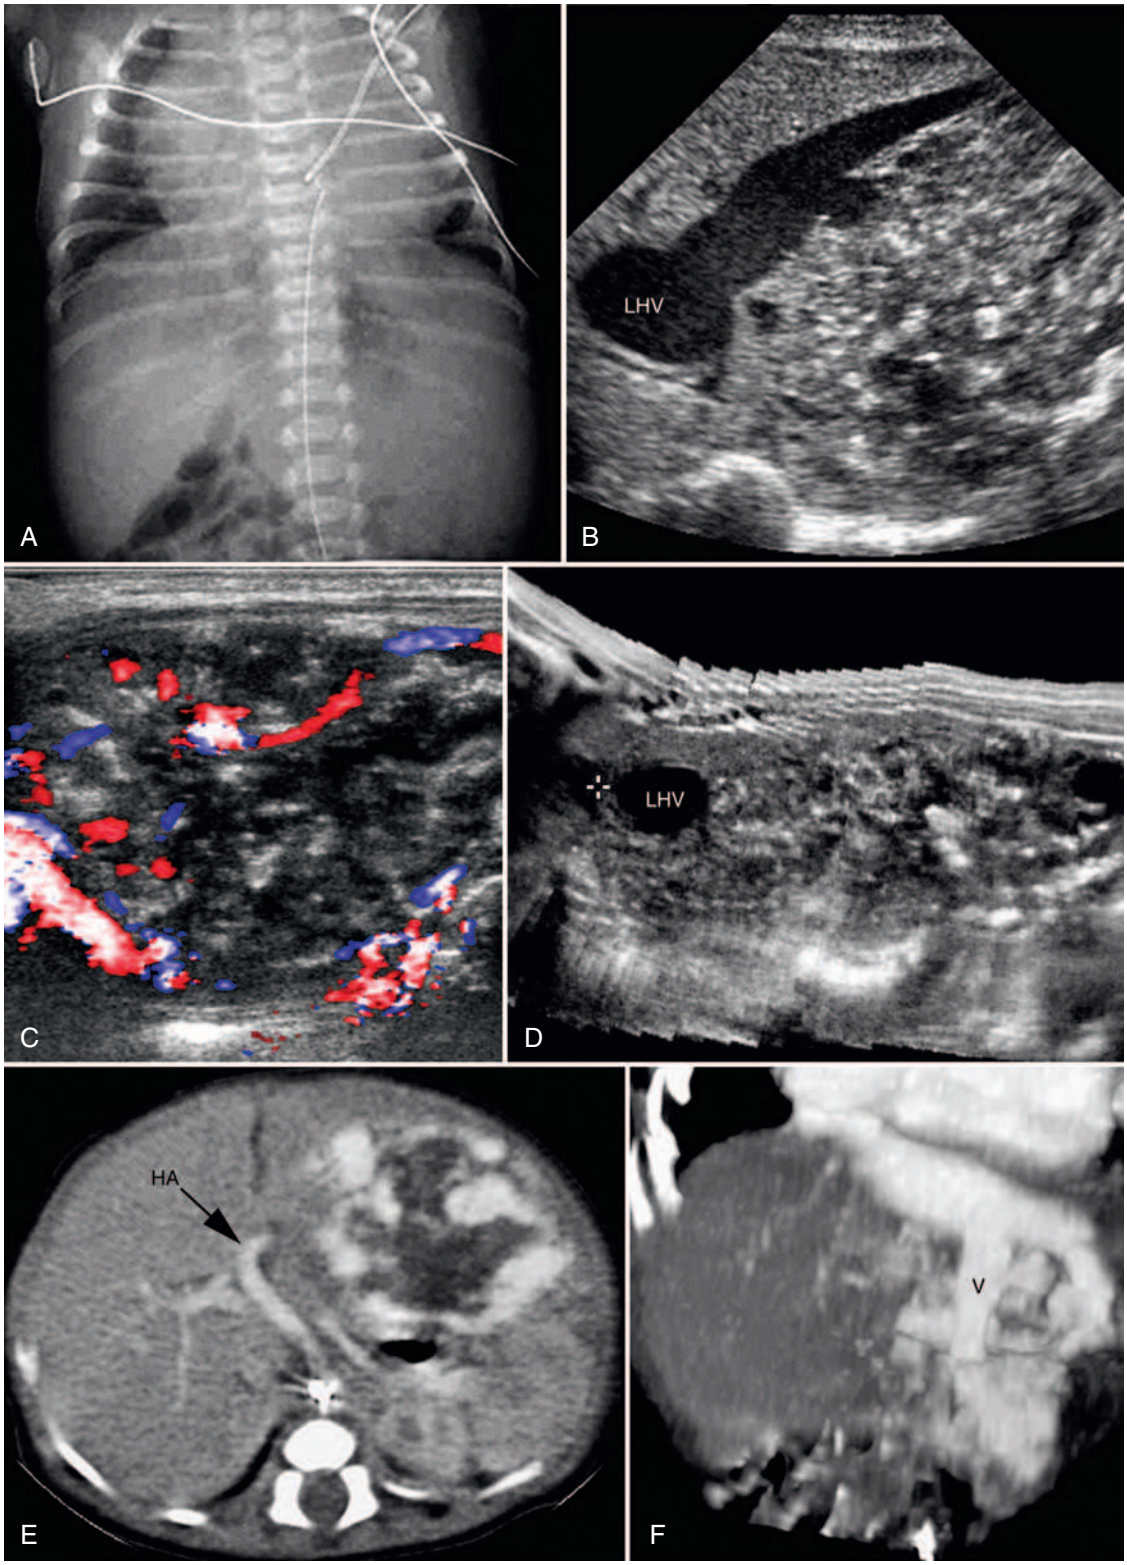

FIG. 51.15 Infantile Hemangioendothelioma. (A) Chest and abdominal radiograph of newborn shows left upper quadrant soft tissue mass and congestive heart failure. **(B)** Longitudinal gray-scale ultrasound; *LHV,* left hepatic vein. **(C)** Color Doppler ultrasound. **(D)** Extended-view longitudinal ultrasound. **(E)** Contrast medium–enhanced axial computed tomography (CT) scan. **(F)** Images of the mass show an enlarged hepatic artery (*HA* in **[E]**) feeding the lesion and large veins (*V* in **[F]**) draining into the right atrium and creating a left-to-right shunt and heart failure.

Adenomas

Adenomas are rare except in association with metabolic liver disease, especially **glycogen storage disease type I**[40]; **oral contraceptive therapy;** and **anabolic steroid therapy** for **Fanconi anemia,** which may result in development of hepatocellular carcinoma. Serum AFP levels are normal. Sonographic appearance varies from hyperechoic to hypoechoic. Malignant degeneration is rare. The distinction between adenoma and a malignant mass is difficult with sonography, CT, and MRI because imaging findings vary and are nonspecific. In patients with Fanconi anemia after bone marrow transplant, adenomas may mimic abscess during sepsis evaluation.

Focal Nodular Hyperplasia

Focal nodular hyperplasia is a benign tumor caused by a hyperplastic response to a vascular abnormality, most often following chemotherapy. It typically shows a central scar, which may be visible sonographically or at CT or MRI. The pattern of contrast uptake and washout on CT and MRI is very characteristic.[41]

Malignant Liver Tumors

Most solid liver tumors in children are malignant and are derived from epithelium. When tumor involvement is locally extensive, liver transplant is a consideration.

Hepatoblastoma

Hepatoblastoma, the most common primary liver tumor in childhood, occurs in children younger than 3 years and may be considered the infantile form of hepatocellular carcinoma. There is an association with **Beckwith-Wiedemann syndrome, hemihypertrophy,** and the **11p13 chromosome.**[42] Serum AFP levels are almost always elevated. Some tumors secrete gonadotropins and lead to **precocious puberty.**

The tumor is usually single, solid, large, of mixed echogenicity, and poorly marginated, with small cysts and rounded or irregularly shaped deposits of calcium (Fig. 51.16). These calcifications are quite different from the fine, linear calcifications seen in hemangioendotheliomas.[43] The remaining liver is usually normal, although metastases are found in 20% at diagnosis. Intrahepatic vessels are displaced and amputated by the mass. Tumor thrombi are less common than in hepatocellular carcinoma. Doppler sonography is helpful in diagnosing vessel invasion and detecting flow in malignant neovasculature.[44,45] Complete resection of the tumors results in a cure rate of 83% to 95%. Resectability depends on the number of segments and vessels involved and is best determined with MRI.[46]

Hepatocellular Carcinoma

The incidence of hepatocellular carcinoma, the second most common primary malignant liver tumor in children, has two peaks, at 4 to 5 years and at 12 to 14 years. About one-half of affected children have preexisting liver disease, especially tyrosinemia, glycogen storage disease type I, α_1-antitrypsin deficiency, Byler disease, and ALGS. Approximately one-third have hepatitis B or C cirrhosis or biliary cirrhosis related to biliary atresia. Serum AFP levels are usually elevated. The tumor is often multicentric; masses are solid, rarely calcify, and have variable echogenicity. Portal venous invasion is common and easily detected with Doppler sonography, as is the high-velocity flow in peripheral neovasculature.[44,45,47,48]

Undifferentiated Embryonal Sarcoma

Undifferentiated embryonal sarcoma (malignant mesenchymoma) is considered the malignant counterpart of the hamartoma. It is rare; occurs in children 6 to 10 years of age, which is older than those with hamartomas; grows rapidly; and develops central necrosis and cysts. Serum AFP levels are normal. Masses are typically large and appear heterogeneous (Fig. 51.17).

Biliary Rhabdomyosarcoma

An unusual site for primary rhabdomyosarcoma, tumors of the biliary tree tend to occur in young children, with a mean age of 3½ years. Rhabdomyosarcoma may originate in the intrahepatic and extrahepatic ducts, gallbladder, cystic duct, or ampulla of Vater. Children typically have intermittent obstructive jaundice, hepatomegaly, abdominal distention and pain, weight loss, dark urine, and acholic stools. Intraductal location is the best imaging clue to the diagnosis of this otherwise heterogeneous, occasionally cystic mass (Fig. 51.18). Tumors spread locally and metastasize to lung and bone.

Metastases

Metastases to the liver usually arise from **neuroblastoma** (Fig. 51.19), **Wilms tumor, leukemia,** or **lymphoma.** Diffuse infiltration of the liver (or multiple nodules) in stage 4S neonatal neuroblastoma is remarkable for its good prognosis.

Detection of Tumor Angiogenesis

Hepatoblastoma and hepatocellular carcinoma frequently produce a network of microscopic, parasitic tumor vessels at their periphery. Flow in these vessels, which lack a normal muscularis, produces Doppler shifts (low-resistance, high-velocity flow) greater than those seen in the aorta.[45,47] New Doppler techniques that are more sensitive, **superb microvascular imaging** (SMI) and **intravenous ultrasound contrast agents,** have potential to improve visibility of primary liver tumors and metastases.

LIVER ABSCESS AND GRANULOMAS

Pyogenic Abscess

Pyogenic liver abscesses are rare in the typical child. Abscesses generally occur in association with sepsis, in children with depressed immunity (leukemia, drugs), in those with primary immune defects (chronic granulomatous disease, dysgammaglobulinemia), and with contiguous infection (appendicitis, cholangitis). At sonography, abscesses are generally well-defined masses, with or without heterogeneous fluid content and small air bubbles producing ring-down artifacts (Fig. 51.20, Video 51.6). Abscesses displace but do not invade neighboring vessels. A Doppler examination may be used to confirm the patency of nearby portal venous branches. Fluid in the pleural space or Morison pouch should be sought in the supine position.

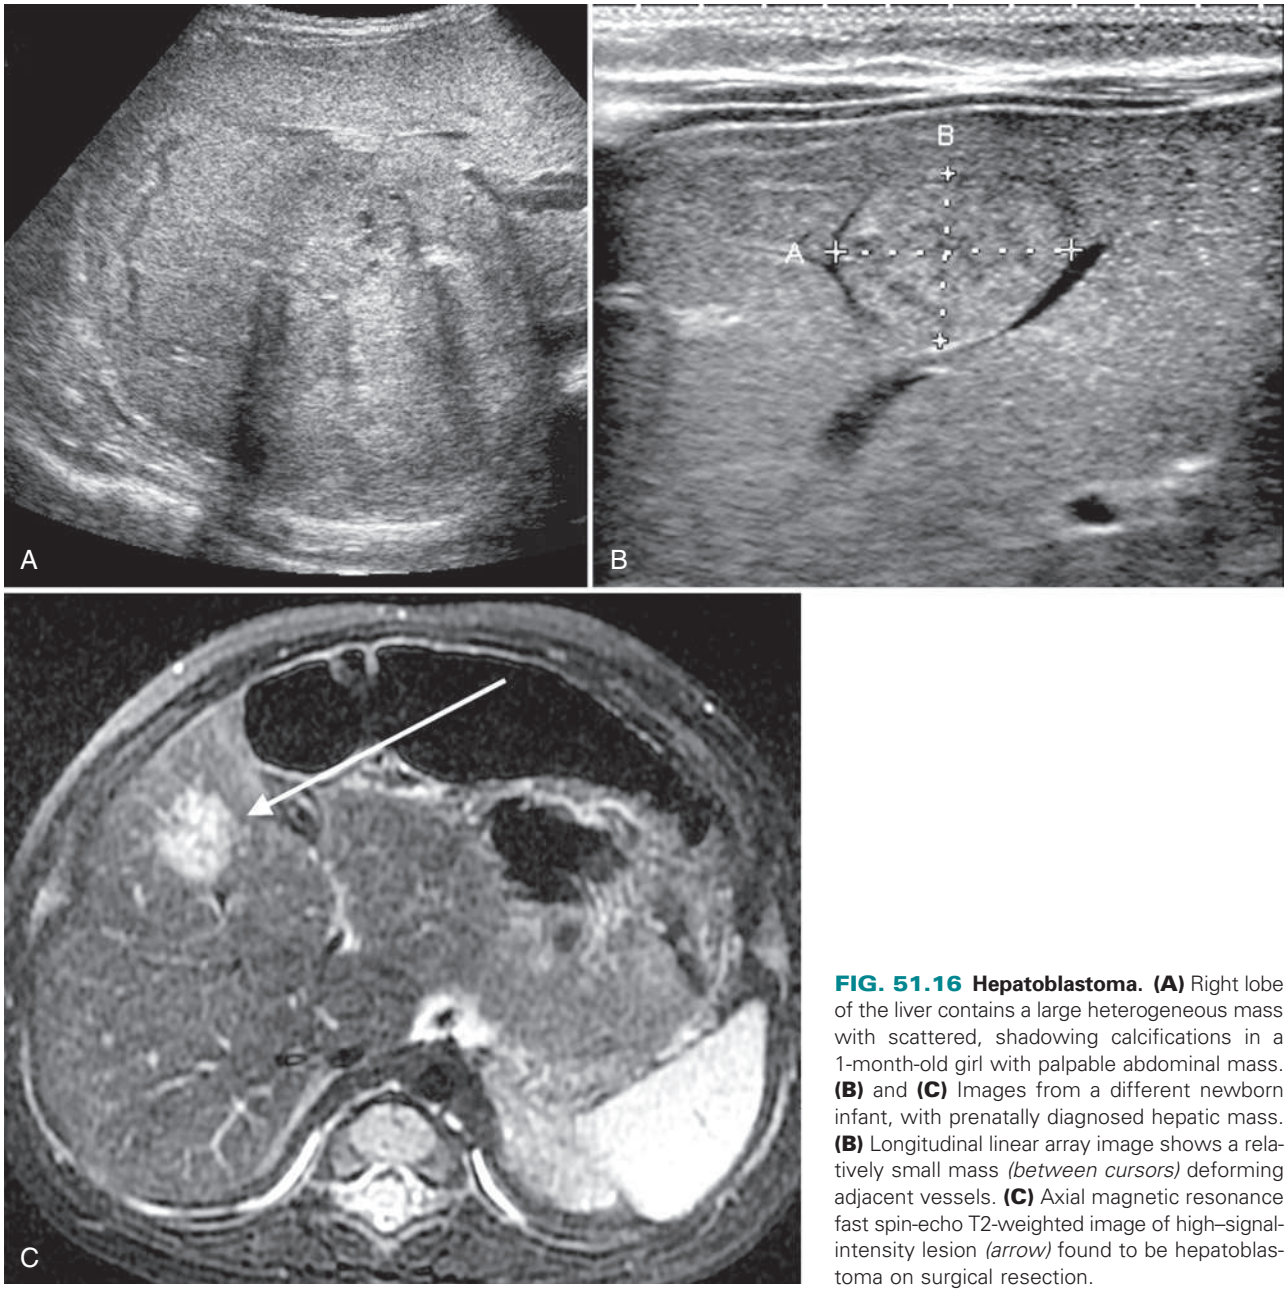

FIG. 51.16 Hepatoblastoma. (A) Right lobe of the liver contains a large heterogeneous mass with scattered, shadowing calcifications in a 1-month-old girl with palpable abdominal mass. **(B)** and **(C)** Images from a different newborn infant, with prenatally diagnosed hepatic mass. **(B)** Longitudinal linear array image shows a relatively small mass *(between cursors)* deforming adjacent vessels. **(C)** Axial magnetic resonance fast spin-echo T2-weighted image of high–signal-intensity lesion *(arrow)* found to be hepatoblastoma on surgical resection.

Aspiration, with or without drainage of abscesses, under sonographic or CT guidance is the preferred treatment in many centers. Some abscesses, especially those accompanying chronic granulomatous disease, gradually calcify during medical treatment.[49] Multiple small abscesses, usually seen in the immunosuppressed child, may result in an enlarged, painful liver. Distinguishing these tiny hypoechogenic lesions from normal liver parenchyma is a challenge to the resolution of the equipment and the skill of the examiner. Scanning the anterior surface of the liver with a high-frequency linear transducer often outlines some of the multiple lesions that are otherwise missed. I routinely complement the ultrasound examination with high-resolution CT in these children because small abscesses are often better seen with CT. Use of sensitive Doppler techniques and intravenous microbubbles may decrease the need for CT.

Parasitic Abscesses

Amebiasis

The incidence of parasitic abscesses in children, although low, is increasing because of expanding travel and immigration. Amebiasis is endemic in the tropics and spreads through person-to-person contact. The protozoan *Entamoeba histolytica* is ingested, invades the colonic mucosa, enters intestinal veins, and spreads into portal venous branches. The organism secretes proteolytic enzymes, and hepatic abscess formation occurs rapidly.

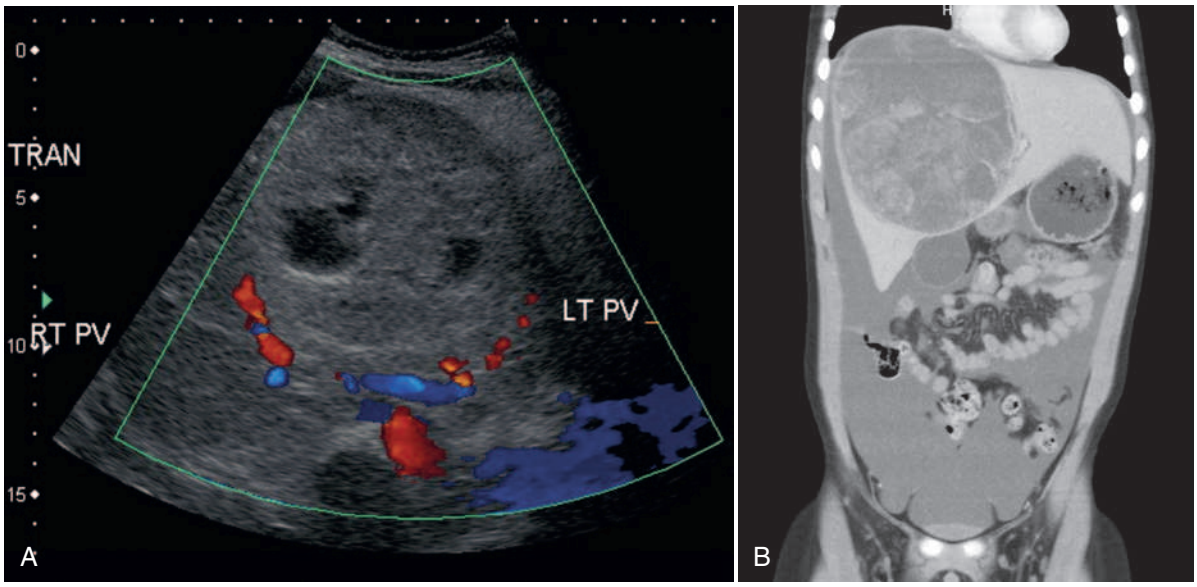

FIG. 51.17 Undifferentiated Embryonal Sarcoma. (A) Transverse color Doppler ultrasound shows a large heterogeneous echotexture mass, splaying the right and left portal veins in the liver of a 10-year-old child. **(B)** Coronal reformatted computed tomography scan shows variable contrast enhancement in the large mass, which replaces most of the right lobe. A large amount of ascites may be related to biopsy or spontaneous hemorrhage.

It is the most frequent extraintestinal complication of **amebic infection.** In children, abscesses are usually multiple and occur most often in infants younger than 1 year and are life-threatening. Fever spikes and hepatomegaly without jaundice are the usual forms of presentation. Diagnosis is made by serologic testing, although the result is not always positive in infants.

Both sonographic and CT imaging modalities are highly sensitive but fail to differentiate amebic from pyogenic abscesses. The sonographic pattern of hypoechoic, homogeneous, or heterogeneous target masses may mimic that of hematoma or neoplasm. Abscess rupture into the thorax, although rare in childhood, is pathognomonic for amebic abscess. Extension into subphrenic or perihepatic spaces, peritoneum, and nearby abdominal organs is more frequent. Diagnostic puncture is disappointing because of the low yield of organisms. Because pyogenic abscesses usually occur in the immunodeficient child, an abscess occurring in an otherwise healthy infant should be considered amebic until proven otherwise. In the past, high mortality rates (60% in infants) have been caused by late diagnosis. They have been reduced to near zero with early detection through the use of cross-sectional imaging (sonography, CT, and MRI).[50]

Echinococcosis

The adult tapeworm, *Echinococcus,* lives in the jejunum of the dog, where it lays its eggs, which are spread through feces and then swallowed by the intermediate host (usually sheep but sometimes humans). Endemic areas include the Middle East, the southern United States, and northern Canada. Embryos, freed in the duodenum, invade the mucosa to enter a mesenteric vein, which flows to the liver, where a slowly growing cyst composed of an acellular outer layer and an endothelialized inner layer may develop. Compressed surrounding liver tissue forms a third layer. The inner layer forms freely floating embryos (scolices), "snowflakes" or "hydatid sand," which are visible with sonography. **Daughter cysts** form within the main cyst under certain circumstances and, when seen sonographically, suggest the diagnosis of **hydatid cyst.** Ruptured daughter cysts form floating membranes. A dead cyst decreases in size and gradually calcifies.[51-53]

Schistosomiasis

Invasion of the portal vein by the ova of *Schistosoma* leads to portal hypertension without cirrhosis. Liver disease progresses so slowly that portal hypertension is rarely seen in a child.

Granulomas of the Liver

Granulomas are circumscribed, focal, inflammatory lesions that may be of bacterial (*Mycobacterium tuberculosis,* other mycobacteria, *Listeria,* spirochetes), fungal *(Candida, Histoplasma, Aspergillus),* parasitic *(Toxocara, Ascaris),* or malignant (lymphoma) origin. Clinical features are those of the underlying disease, and the liver is usually enlarged. Confluent granulomas or abscesses may be recognized as distinct masses at sonography.

DOPPLER ASSESSMENT OF LIVER DISEASE AND PORTAL HYPERTENSION IN CHILDREN

Basic Principles

The physics of Doppler ultrasound and the details of instrumentation have been well described.[54,55] The principles essential to the performance of a successful clinical examination with real-time

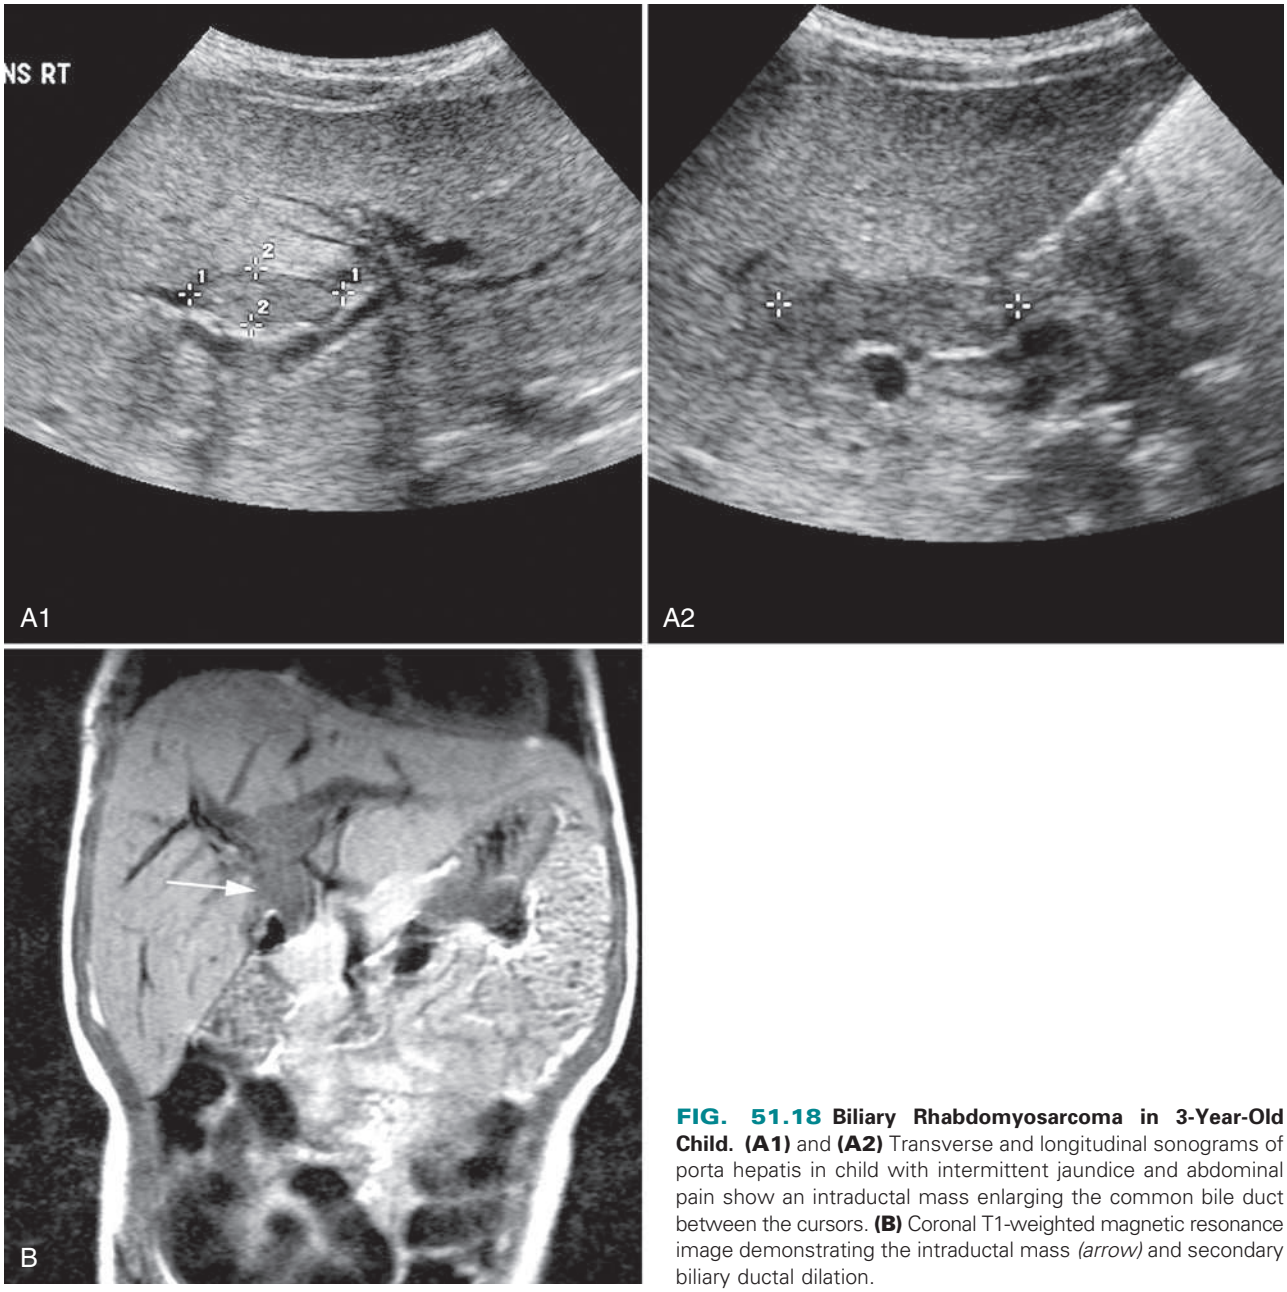

FIG. 51.18 Biliary Rhabdomyosarcoma in 3-Year-Old Child. (A1) and **(A2)** Transverse and longitudinal sonograms of porta hepatis in child with intermittent jaundice and abdominal pain show an intraductal mass enlarging the common bile duct between the cursors. **(B)** Coronal T1-weighted magnetic resonance image demonstrating the intraductal mass *(arrow)* and secondary biliary ductal dilation.

ultrasound coupled to a spectral or color Doppler display are discussed in Chapter 1.

Most of the abdominal vessels studied in children have a low flow velocity. Therefore the wall filter should be as low as possible, preferably at 50 Hz or less. The pulse repetition frequency should be as low as possible for the same reason, unless there is **aliasing.**

There are great advantages to color mapping (Video 51.7) because entire segments of vessels are seen at a glance (e.g., portosystemic collateral veins in portal hypertension or stenoses of vessels). When examining small vessels in children, motion may produce flashes or dots of color artifact. Pulsed Doppler sampling of such doubtful signals distinguishes these artifacts from flow signals. Because of their small body size and ready access to the Doppler beam, children are particularly suited to color, power, and pulsed Doppler abdominal examinations.

New Doppler techniques that are more sensitive to low-velocity flow, which was previously obscured by noise or "signal clutter," have the potential to reveal isoechoic lesions in the liver, including metastases. **Superb microvascular imaging** shows third- and fourth-order branches of the portal veins[56] (Fig. 51.21, Video 51.8, Video 51.9). SMI takes the same returning ultrasound signal and declutters the information to depict very-low-velocity flow. **Intravenous Doppler contrast agents,** various formulations of microbubbles, are now approved by the U.S. Food and Drug Administration (FDA) for cardiac and liver use in the United

FIG. 51.19 Metastatic Liver Disease in 4-Year-Old Child. Transverse sonogram in right upper quadrant shows well-defined right adrenal neuroblastoma *(cursors)* and multiple echogenic hepatic metastases.

States and have been shown to be efficacious. Guidelines for Doppler contrast agent use have been published by the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB) at www.efsumb.org. Contrast-enhanced ultrasound requires intravenous access, and the cost of the microbubble agent is added to the cost of the examination.[57]

Normal Flow Patterns in Splanchnic Vessels

Arteries to the liver and spleen supply a low-resistance vascular bed and normally show forward flow throughout the cardiac cycle. Blood flow in the mesenteric arteries shows few or no diastolic Doppler shifts. The superior mesenteric artery in the fasting person has very little forward flow during diastole. Shortly after a meal, its diastolic flow increases considerably.[58] The Doppler profile of the abdominal aorta changes throughout its course. Continuous forward diastolic flow in the upper abdominal aorta is no longer seen beyond the origins of the low-resistance branches to the liver, spleen, intestine, and kidneys. In the distal abdominal aorta, flow reverses during diastole. Fig. 51.22 shows Doppler spectral waveforms of some arteries and veins pertinent to this discussion.[59]

The **systemic veins of the abdomen** (IVC and hepatic and renal veins) show a pulsatile flow pattern that reflects cardiac contractions; two flow peaks toward the heart occur during atrial and ventricular diastole (filling). A short spurt of reversed flow occurs in the hepatic veins and proximal IVC with atrial systole. In addition, the phase of respiration will influence the flow pattern of the systemic intraabdominal veins (with increasing velocity in expiration). Consequently, the Doppler sonographic characteristics of these veins are variable in the breathing child.

Flow in splanchnic veins is steadier, with only gentle undulations that mirror cardiac motion.[59] Blood is constantly directed toward the portal vein and into the liver. Flow velocity in the portal vein increases greatly after a meal and decreases with exercise.[60,61] **Hepatofugal** portal venous flow (away from liver) can be reversed to **hepatopetal** (into liver) flow after a meal.[61]

Possibilities and Pitfalls

The hepatic veins, difficult to outline with angiography, are easily identified with sonography and their flow pattern outlined. The major splanchnic vessels, such as the splenic, mesenteric, and portal veins, are readily opacified with arterioportography, but small vessels are difficult to explore. This is particularly true of the branches of the **left portal vein,** which often are not opacified. The intrahepatic portal circulation can be readily studied with Doppler sonography, both in health and in disease. Each segmental branch of the portal vein is usually accessible to the Doppler beam. Regional flow patterns and the result of compression, obstruction of flow, reversal of flow, or AV fistulas can be assessed. With angiography and MRI, to-and-fro flow in a splanchnic vein is difficult to perceive. The Doppler examination yields clear signals of to-and-fro flow motions both on spectral display and with color. If questions remain about examination details or changes in the patient's condition, the Doppler examination can be repeated without risk.

These advantages are counterbalanced by certain limitations, most of which are identical to those of real-time sonography. The examination is operator dependent and requires training not only in sonography but also in the physics of Doppler and in the normal anatomy and physiology of the liver and splanchnic circulation. Doppler sonography is subject to the same physical laws as is real-time ultrasound. One cannot expect a good Doppler examination in a patient who just had a poor real-time sonogram. The child's cirrhotic liver may be enlarged with increased sound attenuation. Penetrating all this tissue with a real-time or Doppler beam can be a challenge.

Quantitative analysis of splanchnic blood flow with Doppler instrumentation could allow more intensive study of physiologic flow as well as portal hypertension and response to various drugs. However, because the technique depends on exact vessel beam angle and vessel diameter measurements, it is currently fraught with inaccuracies.[54,62]

In the present state of the art, despite the limitations just cited, the Doppler examination of the splanchnic circulation is valuable. If a noninvasive test can determine whether the patient has portal hypertension, the location of the level of obstruction to blood flow, and whether esophageal varices exist, it is indeed a useful clinical tool. For this reason, the Doppler examination has become the screening method of choice for children with liver disease and potential portal hypertension.

Sonographic Technique

Children older than 5 years are usually examined after a 4- to 6-hour fast. Normally, their cooperation can be obtained if the procedure is explained to them and distractions are provided. Sedation is seldom necessary. Whenever possible, respiration is stopped during the Doppler examination of a vessel so as to

minimize its movement. The frequency for the examination may vary from 3.0 to 7.5 MHz, depending on the child's size and transducer availability. Because a small or upset child tends to breathe rapidly, the examiner must be familiar with the Doppler equipment to manipulate it quickly. All technical settings should be preadjusted or preprogrammed to minimize examination time. The vessel to be examined is identified with real-time sonography. Color Doppler ultrasound can be used to guide the placement of the sample volume. A spectral display of the Doppler shift is then usually readily obtained, even though it may disappear during part of the respiratory cycle.

Child With Liver Disease: Doppler Examination for Portal Hypertension

The aim of the Doppler examination is to assess the presence and direction of flow in splanchnic veins, the main portal vein and its segmental intrahepatic branches, the hepatic veins, and the IVC[63-66] (Fig. 51.23). In addition, the presence of flow in the main hepatic artery and its intrahepatic branches should be determined. When the clinical or basic Doppler examination raises suspicion for **portal hypertension,** a systematic search for portosystemic collateral veins follows. Fig. 51.24 outlines the usual sites for spontaneous portosystemic shunts.[65,67] The lesser omentum[68] (from splenomesenteric junction to esophagus) and the renal, splenic, and hepatic hila as well as the pelvis are screened for the presence of dilated, tortuous veins. If hepatofugal (reversed) flow is found in a splanchnic vein, this vein is traced to the recipient systemic vessel. In cases of portal hypertension, the **left gastric vein** drains blood into the inferior esophageal vein; the **splenic vein** drains into the renal (or pararenal) veins; the **superior and inferior mesenteric veins** drain into gonadal, retroperitoneal, or hemorrhoidal veins; and the **paraumbilical veins** follow the round and falciform ligaments to drain into the anterior abdominal and iliac veins to form the classic **caput medusae** or into veins of the anterior chest wall and the internal mammary vein.

Direction of flow in one or several veins of the portal venous system may change in portal hypertension, and it is essential to record the flow direction accurately. The Doppler sample volume should be placed in the center of the vessel lumen. If the direction of flow within a vessel is difficult to ascertain, a nearby vessel with known flow direction can be used as a reference (e.g., splenic or hepatic artery or adjacent vein).

The **main portal vein** and its right hepatic branches are best studied through a right intercostal approach. Sometimes the superior mesenteric vein is also clearly seen from this position. The **left portal vein** and three of its four branches (portal branch to caudate lobe is rarely seen) and the **hepatic veins** are best seen through an oblique subcostal approach. The **splenic vein** is explored through a transverse approach over the spleen. The **superior mesenteric vein** and **main portal vein** are best visualized through a sagittal right paramedian approach. The **left gastric vein** usually ends near the splenoportal junction and, when enlarged, is easily observed through a sagittal left paramedian view. The **inferior mesenteric vein,** when normal, can rarely be visualized sonographically. When enlarged, it may be traced through a left lateral approach to its junction with the splenic or superior mesenteric vein.

The various possible origins of the **hepatic artery** may be difficult to recognize. We first look for the artery at its usual origin from the celiac axis and also as it passes between the portal vein and the CBD. When the left hepatic artery arises from the superior mesenteric artery, it passes through the ligamentum venosum. The intrahepatic arterial branches accompany branches of the portal vein and can be detected with a slightly enlarged Doppler sample volume placed over a portal venous branch, even when the arterial branch cannot be seen with

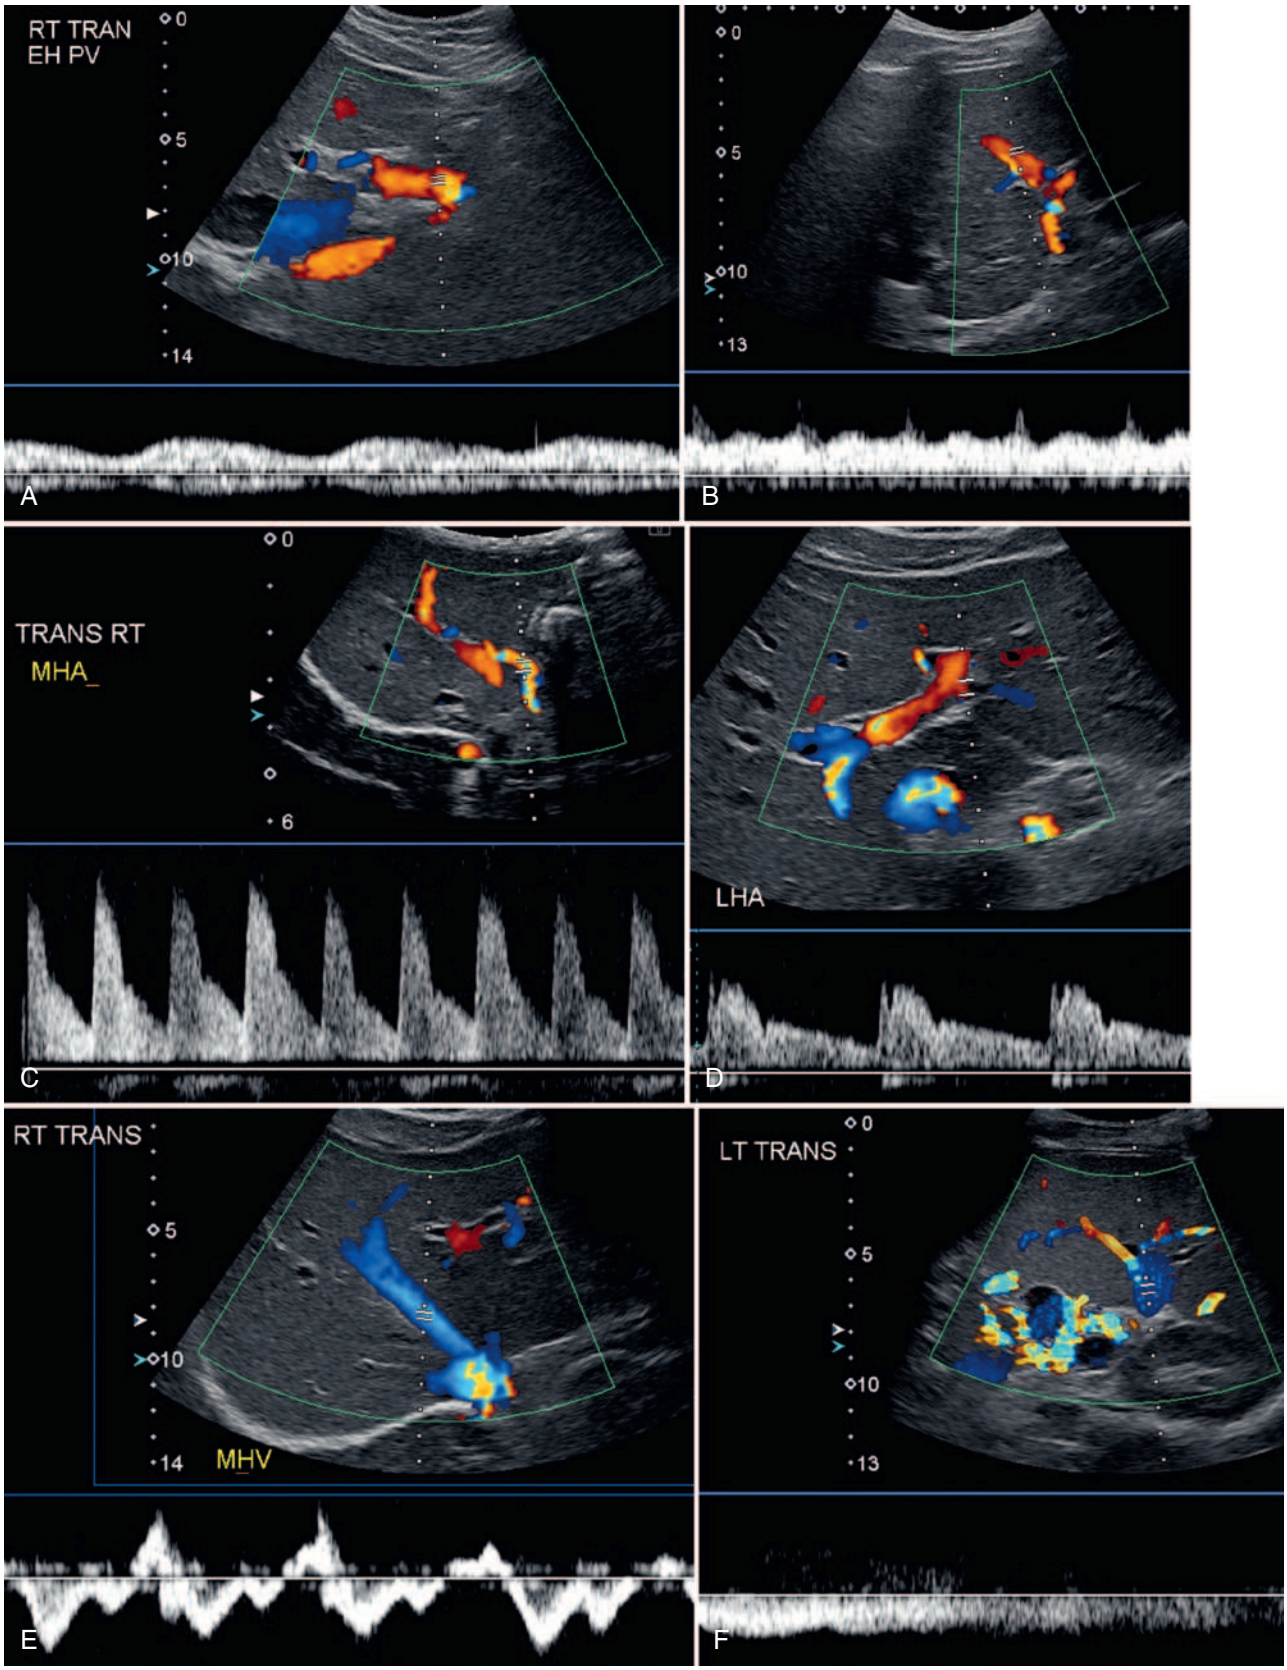

FIG. 51.22 Typical Duplex Doppler Images of Splanchnic Vessels. (A) Normal portal vein examined through a transverse, paramedian, subcostal approach. Flow fluctuates slightly with cardiac systole. Note aliasing artifact from low pulse repetition frequency. **(B)** Normal right branch of portal vein seen from an oblique right subcostal approach. Note that a few arterial pulsations are seen as a result of respiratory motion. **(C)** Normal main hepatic artery at the porta hepatis, with typical forward flow throughout systole and diastole. **(D)** Normal left hepatic artery branch with preservation of the dicrotic notch during systole. **(E)** Normal hepatic vein, transverse subcostal view, with triphasic flow, away from transducer except during right atrial systole when flow is toward the transducer. **(F)** Enlarged splenic vein at hilum with monophasic flow away from the spleen and numerous adjacent varices medially.

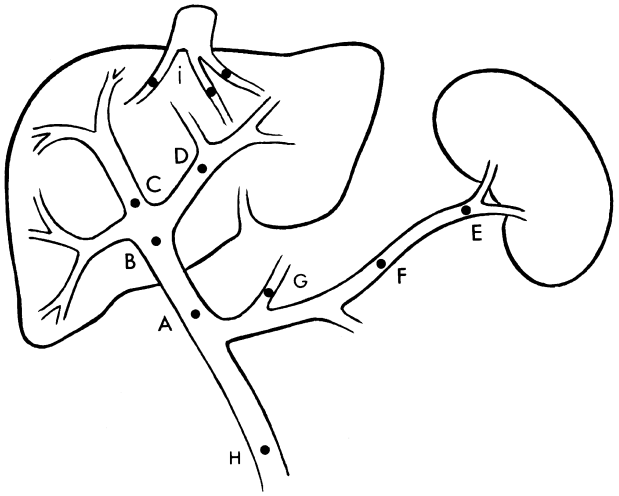

FIG. 51.23 Essential Splanchnic Vein Reference Points in Doppler Sampling for Possible Portal Hypertension in Children With Liver Disease. *A,* Main portal vein; *B,* intrahepatic portal vein; *C,* right portal vein; *D,* left portal vein; *E,* splenic vein at hilum; *F,* splenic vein; *G,* left coronary vein; *H,* superior mesenteric vein; *I,* hepatic veins. Evaluation of the hepatic artery and inferior vena cava should be done as well. (With permission from Patriquin H, Lafortune M, Burns PN, Dauzat M. Duplex Doppler examination in portal hypertension: technique and anatomy. Am J Roentgenol. 1987;149[1]:71-76.[64])

real-time ultrasound. The arteries to the right lobe of the liver (especially segments 5, 7, and 8) are usually easy to identify in this manner. The hepatic arterial branch accompanying the umbilical portion of the left portal vein (to segment 4) is especially easy to examine with Doppler imaging because of the almost ideal vessel beam angle, which can be obtained through an anterior abdominal approach (Fig. 51.25). For this reason, I routinely look for arterial Doppler signals at this site in children who have undergone liver transplantation.

Abnormal Flow Patterns Within the Portal System

Absent Doppler Signal

Proof of absence of a Doppler signal is much more difficult to establish than is its presence. The examiner who fails to obtain a Doppler signal from a given vessel usually questions the sensitivity of the machine and tests other nearby vessels. Failure to obtain a pulsed, color, or power Doppler signal from a splanchnic vein examined at an angle of less than 60 degrees, full Doppler gain, and low pulse repetition frequency, with 50-Hz wall filter and restricted Doppler window, means that blood is flowing at a velocity of less than 4 cm/sec (extremely slow). Thus absence of a Doppler signal in this situation generally means absence of flow or a prethrombotic state.

Arterialized Portal Venous Flow

When the normal, gently undulating flow within a portal vein is replaced by systolic peaks and high diastolic Doppler shifts, this is termed an "arterialized flow pattern" and may signal the presence of an arterioportal fistula.[69]

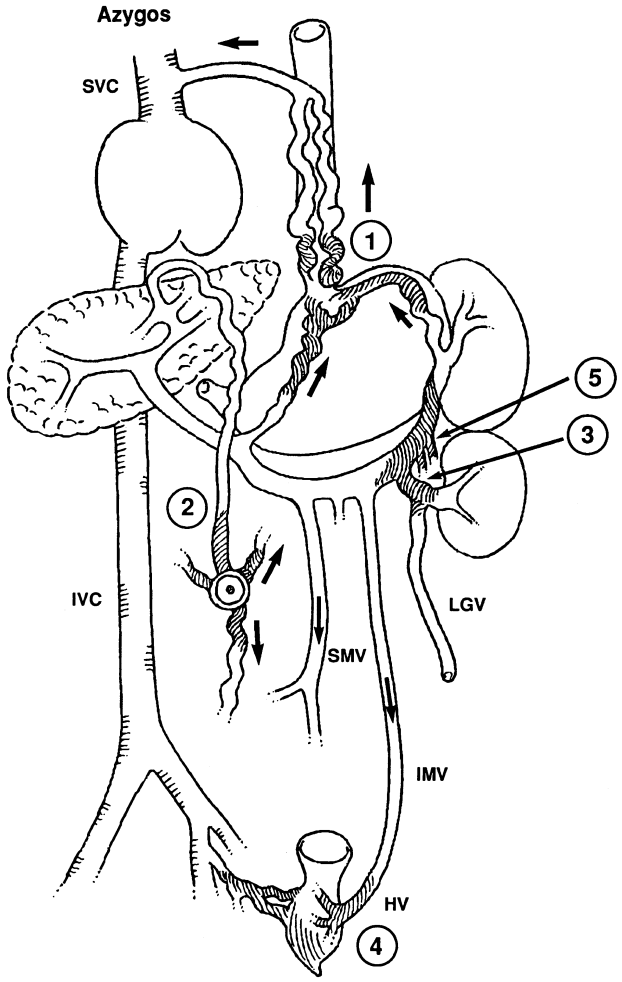

FIG. 51.24 Diagram of Common Spontaneous Portosystemic Collateral Routes. *HV,* Hemorrhoidal vein; *IMV,* inferior mesenteric vein; *IVC,* inferior vena cava; *LGV,* left gonadal vein; *SMV,* superior mesenteric vein; *SVC,* superior vena cava; *1,* left gastric-azygos route (esophageal varices); *2,* paraumbilical-hypogastric/internal mammary route (caput medusa); *3,* splenorenal route; *4,* IMV-hemorrhoidal route; *5,* spleno-retroperitoneal-gonadal route. (With permission from Patriquin HB, LaFortune M. SPR Annual Meeting Syllabus. Pediatr Radiol. 1994.[67])

Causes of Absent Doppler Signal

Doppler angle greater than 60 degrees
Low Doppler gain
Low pulse repetition frequency
High filter (best is 50 Hz)
Small sample volume
Portal vein flow decreases when fasting
Hepatic artery flow decreases after a meal

Reversed or To-and-Fro Flow

Reversed flow in a splanchnic or intrahepatic portal vein is the most reliable Doppler sign of portal hypertension. However, hepatofugal flow in the portal vein occurs late and relatively rarely in patients with liver disease. To-and-fro flow in the portal vein also suggests the presence of portal hypertension. Highly

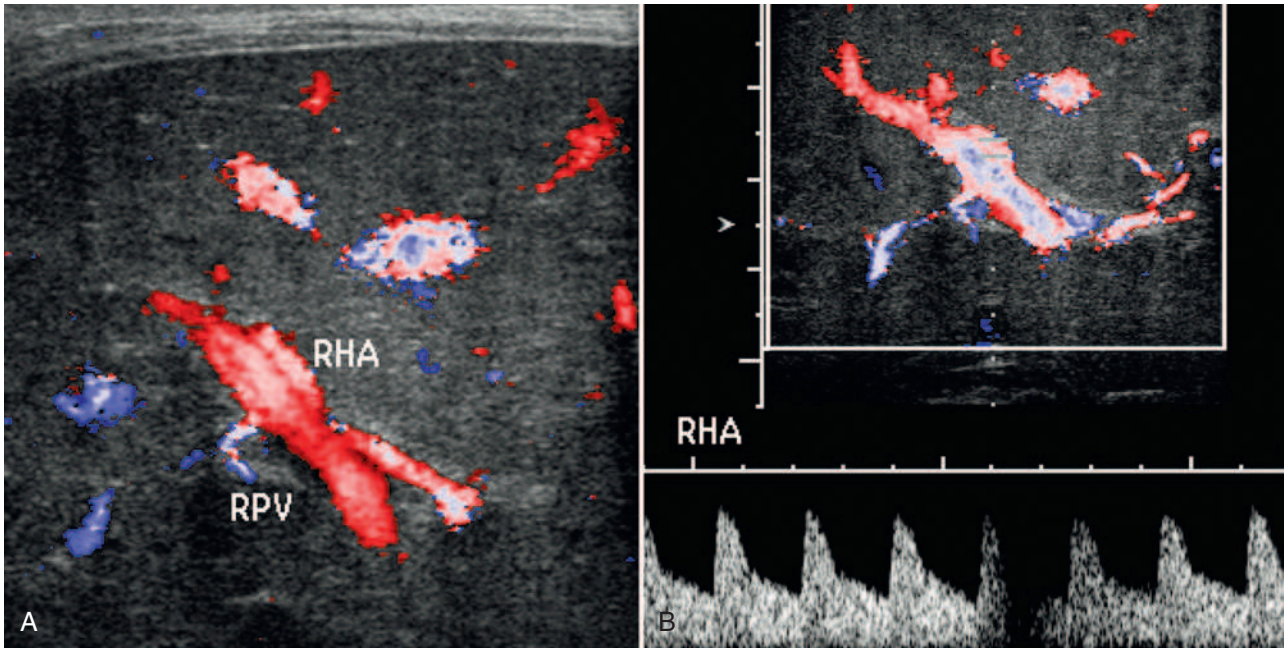

FIG. 51.25 Normal Liver and Right Hepatic Artery *(RHA)* in an Infant. Oblique subcostal color Doppler sonograms. **(A)** Right portal vein *(RPV)*. **(B)** Cursor in RHA shows normal arterial flow waveform. Doppler shifts from normal hepatic artery and portal vein have identical directions of flow.

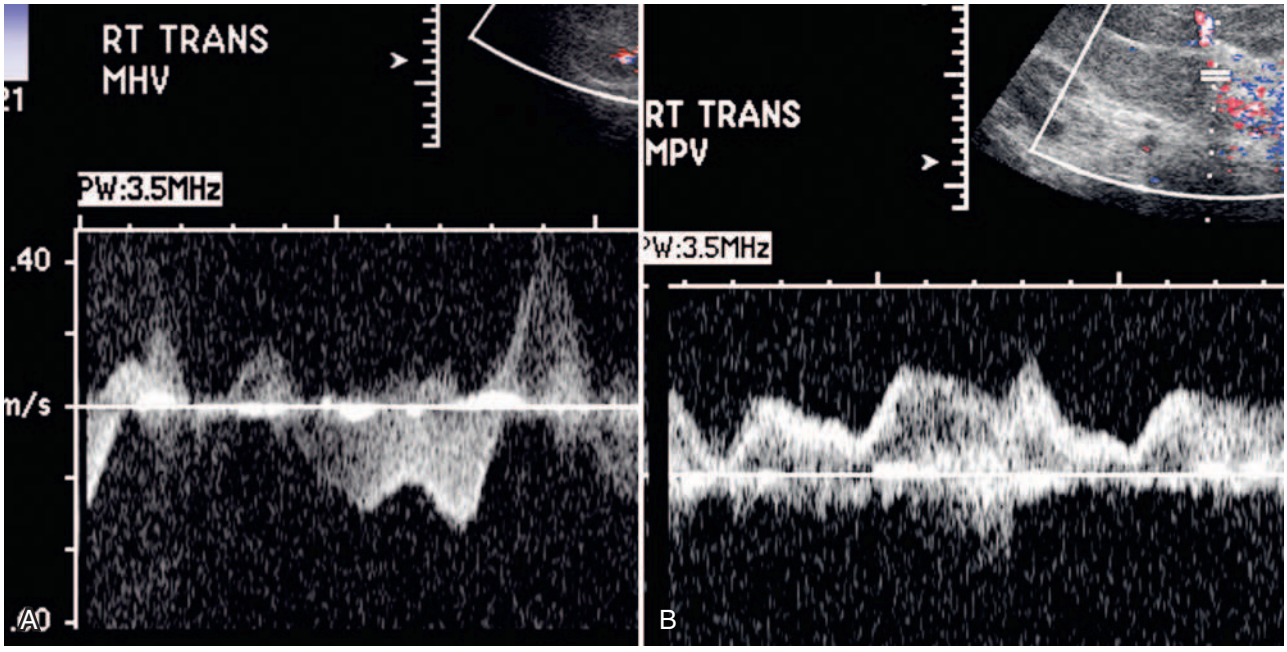

FIG. 51.26 Postfontan Procedure Hepatic and Portal Venous Flow Increase in a Child With Congenital Heart Disease. (A) Highly pulsatile hepatic venous flow and **(B)** portal venous flow. Right atrial pressure is transmitted through the hepatic veins, across the hepatic sinusoids to the portal vein.

pulsatile or to-and-fro flow in the portal vein may also be seen in right-sided heart failure (Fig. 51.26) or tricuspid insufficiency, resulting from transmitted pressure across the hepatic sinusoids.

Abnormal Hepatic Arterial Doppler Patterns

Absence of a hepatic artery Doppler signal suggests arterial thrombosis, spasm, or reduced flow in prethrombotic states.[69] Locally increased systolic Doppler shifts or peripheral tardus-parvus curves may be the result of stenosis or spasm of the hepatic artery, as at any other arterial site.

The portal vein and hepatic artery act in concert to nourish the liver. Changes in flow volumes in one affect the other. After a meal, portal venous flow increases and hepatic arterial flow diminishes, probably by vasoconstriction. Postprandially, hepatic arterial diastolic flow is decreased and systolic peaks are lower

when measured at the same sites in the same person.[70] Arterial signals within the liver may be difficult to find after a meal. This is particularly disturbing in the patient who has received a liver transplant, in whom a false diagnosis of thrombosis may be considered.

Portal Venous Hypertension

Portal venous hypertension is a pathologic condition characterized by increased pressure in the portal vein or one of its tributaries. The normal pressure in the portal vein is between 5 and 10 mm Hg. When the pressure in the portal vein is more than 5 mm Hg above IVC pressure, portal hypertension is present.

The many sequelae of portal hypertension include splenomegaly, collateral vein formation, and a thickened lesser omentum. In children the lesser omentum is observed between the left lobe of the liver and the aorta on sagittal images. Lesser omentum thickness should not exceed the diameter of the aorta[70,71] (Fig. 51.27). In portal hypertension it is thickened by lymphatic stasis and an engorged left gastric vein. Morphologic changes of the liver architecture are usually present as well.

An increased caliber of the portal vein and a lack of variation in the caliber of the splenic and mesenteric veins have been described in portal hypertension in adults. The accuracy of these findings in the assessment of portal hypertension in children

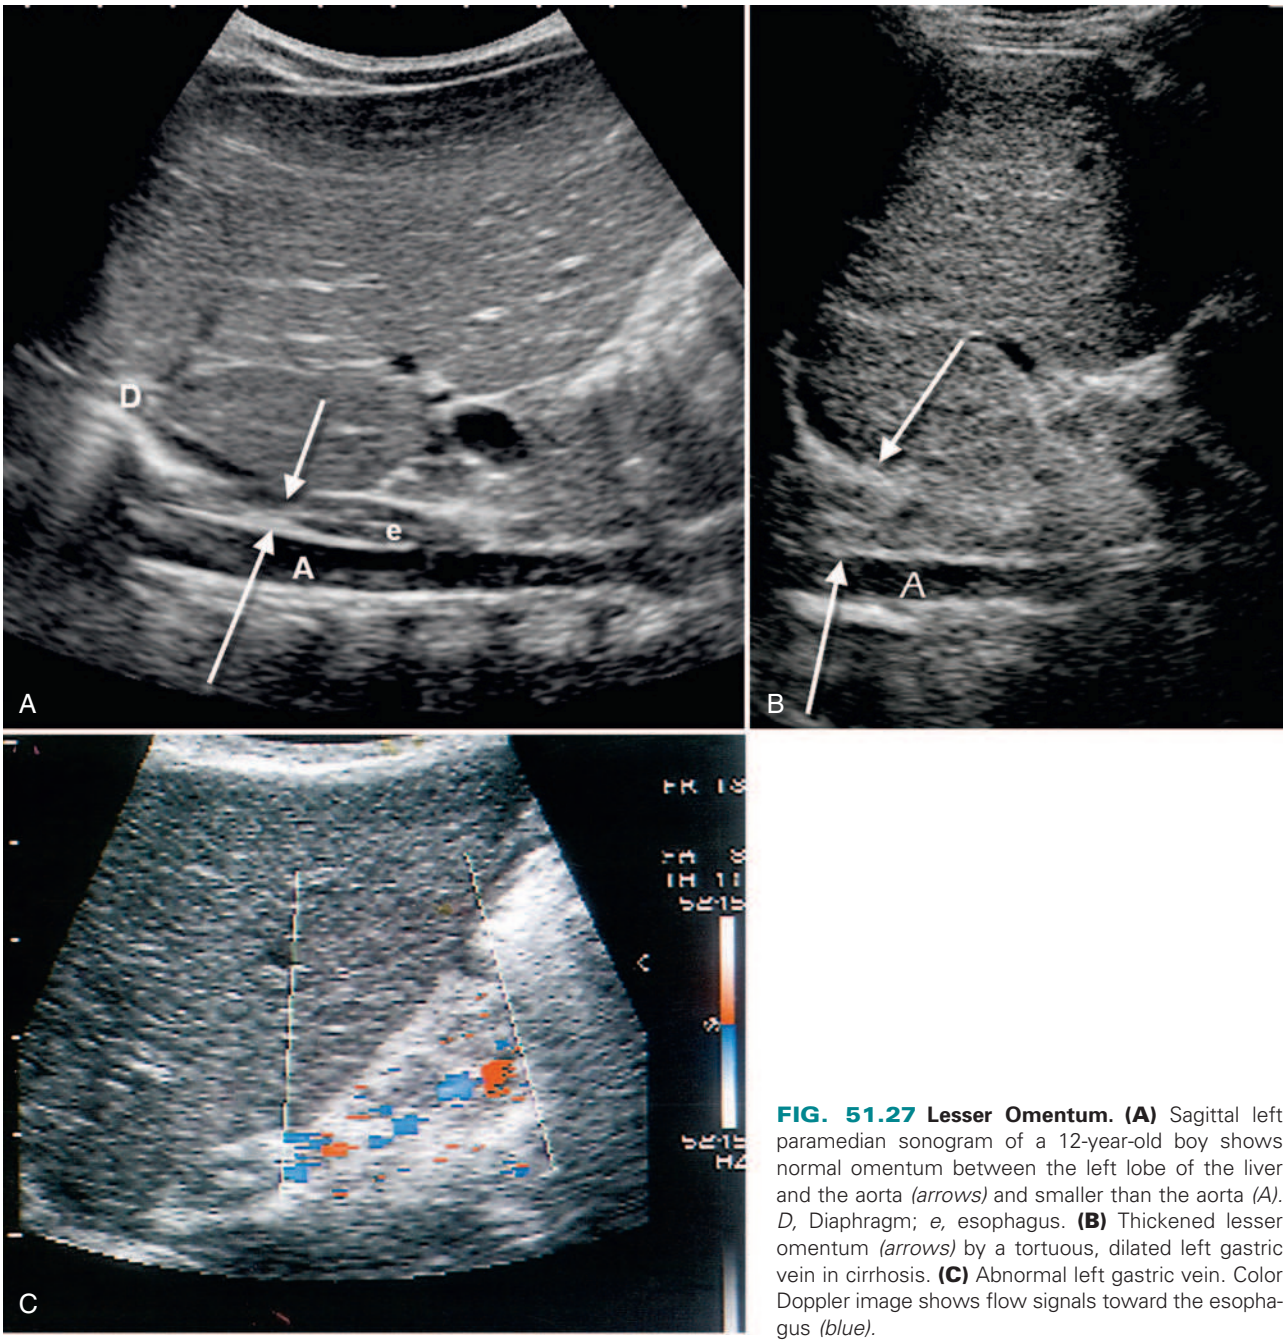

FIG. 51.27 Lesser Omentum. (A) Sagittal left paramedian sonogram of a 12-year-old boy shows normal omentum between the left lobe of the liver and the aorta *(arrows)* and smaller than the aorta *(A). D,* Diaphragm; *e,* esophagus. **(B)** Thickened lesser omentum *(arrows)* by a tortuous, dilated left gastric vein in cirrhosis. **(C)** Abnormal left gastric vein. Color Doppler image shows flow signals toward the esophagus *(blue).*

has not been established. Anecdotally, in children with biliary cirrhosis, portal venous caliber has decreased as cirrhosis progressed.

The hemodynamic information gleaned from the Doppler examination usually answers the following questions: Is portal hypertension present? What is the level of obstruction? What is the direction of flow within the system? Are there portosystemic collaterals?

Hepatofugal flow away from the liver in a portosystemic collateral vein establishes the diagnosis of portal hypertension. Clinically, the most important route is through the left gastric vein, which supplies esophageal varices. The **left gastric vein** is rarely visible sonographically in the normal child. When it dilates to a diameter of greater than 2 to 3 mm, it can be traced from the splenic vein near the splenomesenteric junction through the lesser omentum (behind left lobe of liver and anterior to aorta) to the esophagus. A venous Doppler flow pattern makes it possible to distinguish the vein from the nearby left gastric or hepatic arteries. Flow direction is determined at the same time. The caliber of the left gastric vein is usually related to the size of esophageal varices, and increased diameter is associated with increased risk of bleeding.[72]

The **paraumbilical vein** classically shunts blood from the left portal vein to the periumbilical venous network. It follows a vertical, right paramedian course to enter the falciform ligament through the left lobe of the liver[73,74] (Fig. 51.28). With a high-frequency transducer (7.5-10 MHz), its subcutaneous course is easily seen on sonography from the lower tip of the left lobe of the liver to the umbilicus. Other spontaneous portosystemic collateral veins should be sought near the spleen, left kidney, and flanks, where splenorenal shunts (Fig. 51.29) or dilated perirenal, retroperitoneal, or gonadal veins receive blood from the splenic or mesenteric veins; in the pelvis (Fig. 51.30), around the right kidney; and near the porta hepatis and gallbladder (Fig. 51.31, Video 51.10), where portocaval, paraduodenorenal, or veins of Sappey may shunt the blood between portal and hepatic veins. The variety of spontaneous portosystemic collaterals is almost limitless.

All portosystemic collaterals should be traced to their recipient systemic vein, which is usually dilated where the shunt enters. The "donor" splanchnic vein is also dilated. When portal hypertension decreases after shunt surgery or transplantation, portosystemic collaterals decrease in size (as do the enlarged spleen and lesser omentum).

If a spontaneous or surgical portosystemic shunt is large, **hepatic encephalopathy** may ensue. The Doppler examination, being "physiologic," may reveal unusual portosystemic collateral routes difficult to demonstrate with arterioportographic studies (locally inverted flow in intrahepatic portal venous branches, "neo" veins leading from portal veins to abdominal wall, or hepatofugal flow in splenic vein).

Prehepatic Portal Hypertension

Prehepatic portal hypertension results from obstruction of the splenic, mesenteric, or portal vein. As with other venous thromboses, predisposing factors involve the vessel wall (trauma, catheters), stagnant blood flow, and abnormal clotting factors. Principal causes of **thrombosis of the portal vein** include (1) trauma such as umbilical venous catheterization; (2) dehydration or shock; (3) pyophlebitis following appendicitis or abdominal sepsis; (4) coagulopathy, with protein C deficiency increasingly recognized; (5) portal vein invasion by adjacent tumors; (6) compression of the vein by pancreatitis, lymph nodes, or tumor; and (7) increased resistance to portal venous flow into the liver in cirrhosis or the Budd-Chiari syndrome.

Recanalization of portal venous thrombi usually occurs rapidly in children. In addition, paraportal venous channels and the cystic veins draining the gallbladder dilate and channel blood into the liver if there is no obstruction at this site (in cirrhosis or hepatic vein thrombosis). The resultant collection of tortuous veins is called **cavernous transformation** of the portal vein or a **cavernoma** (see Fig. 51.31). Hepatopetal flow toward the liver in these vessels is easily detected with Doppler sonography. Despite these collateral channels, portal hypertension follows, often with esophageal varices.[75]

Causes of Portal Vein Thrombosis

Trauma
Catheters
Dehydration
Shock
Pyelophlebitis
Coagulopathy, especially protein C deficiency
Portal vein invasion
Portal vein compression
Cirrhosis
Budd-Chiari syndrome

After thrombosis of the portal vein, the peripheral intrahepatic portal veins become small and threadlike. The lumen of portal branches may not be visible. Careful examination of these vessels with Doppler sonography usually shows hepatopetal venous flow, likely the result of shunting through the vessels at the porta hepatis, which constitute the "cavernoma." Because the obstruction to venous flow occurs at the porta hepatis, it is not surprising that children with portal venous thrombosis do not have enlarged paraumbilical veins and a caput medusa; this portosystemic route relies on abundant flow in the left portal vein.[75]

Another cause of prehepatic (or intrahepatic "presinusoidal") portal hypertension in children is **congenital hepatic fibrosis** (Fig. 51.32). This autosomal recessive disease is characterized by fibrosis at the portal triad, where terminal branches of the portal vein and small bile ducts are compressed. Hepatocytes and liver function are normal.[10] Liver architecture is disturbed by linear or cystlike structures representing variable bile duct ectasia, as well as paraportal collaterals (cavernoma).[76,77] These children usually have bleeding esophageal varices. Sonography shows hallmarks of portal hypertension: splenomegaly and a thick lesser omentum in which a dilated tortuous left gastric vein may be visible, with hepatofugal flow detected with Doppler sonography. Congenital hepatic fibrosis is usually associated with

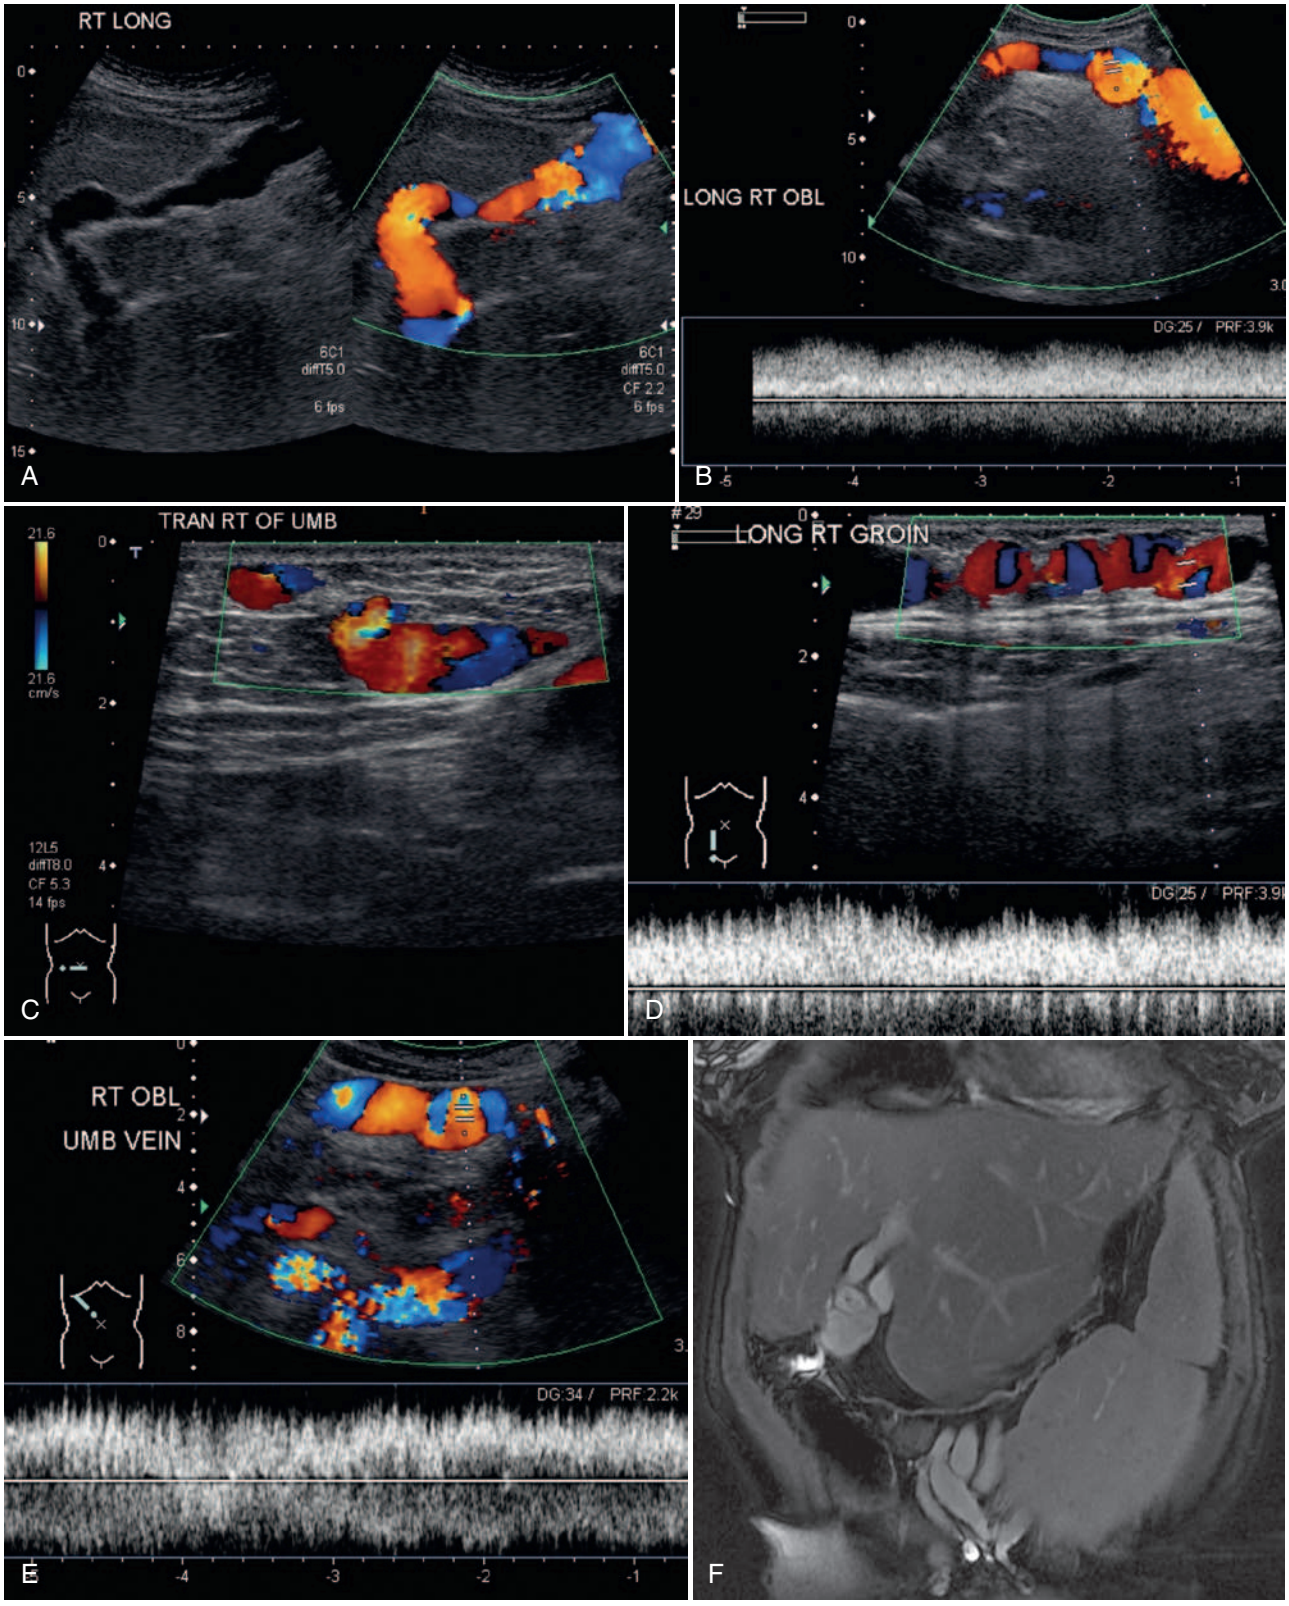

FIG. 51.28 Paraumbilical Collateral Route. (A) and **(B)** Transverse paramedian gray-scale and color Doppler sonograms show left lobe of liver in a child with cirrhosis and portal hypertension. **Recanalized umbilical vein,** with venous flow signals directed toward the transducer, anteriorly out of the liver. **(C)-(E)** Sagittal and oblique color Doppler images showing flow leaving the liver through a patent paraumbilical vein that courses to the periumbilical area and right groin area. Pulsed Doppler waveforms show low velocity venous flow "hum" in these vessels. **(F)** Coronal Fiesta magnetic resonance image shows pericholecystic tortuous varices and infraumbilical vessels in the same patient.

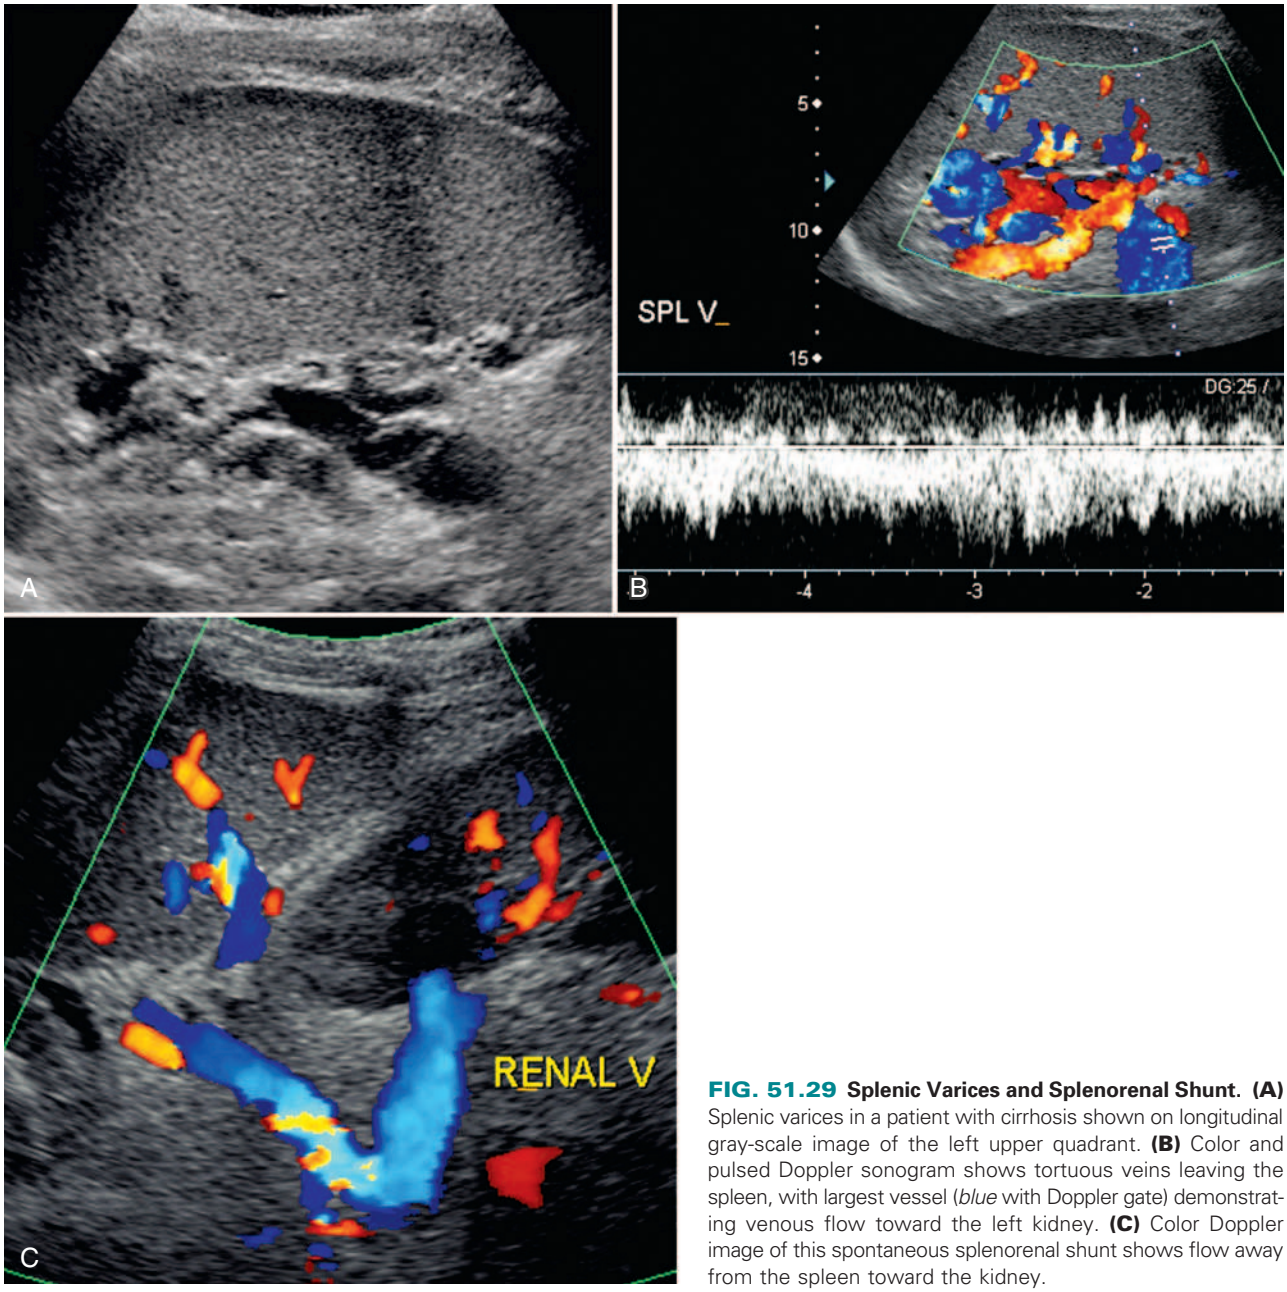

FIG. 51.29 Splenic Varices and Splenorenal Shunt. (A) Splenic varices in a patient with cirrhosis shown on longitudinal gray-scale image of the left upper quadrant. **(B)** Color and pulsed Doppler sonogram shows tortuous veins leaving the spleen, with largest vessel (*blue* with Doppler gate) demonstrating venous flow toward the left kidney. **(C)** Color Doppler image of this spontaneous splenorenal shunt shows flow away from the spleen toward the kidney.

autosomal recessive polycystic kidney disease.[78] The dilation of renal collecting ducts in these children is variable and less severe than in the neonatal form, and renal impairment is less marked. However, renal architecture is greatly disturbed. The pyramids are hyperechoic and may contain calcium; small cysts may be seen; and the kidneys are usually enlarged. These features enable informed sonographers to find the cause of upper intestinal bleeding in these children during their first abdominal sonogram.

Intrahepatic Portal Hypertension

Serious insult to the hepatocyte results in **necrosis.** Unless necrosis is overwhelming, scarring and the formation of multiple regenerating nodules follow. The process of **cirrhosis** results in scarred and obstructed sinusoids and abnormal portal venous blood flow through the regenerated nodules. In children, cirrhosis may result from the following:

- Hepatitis
- Destruction of the hepatocyte by toxins accumulated in inherited metabolic diseases, such as tyrosinemia, some forms of glycogen storage disease, and Wilson disease
- Bile stasis, as in biliary atresia and cystic fibrosis

Although different types of cirrhosis cause initial obstruction at presinusoidal (schistosomiasis, biliary cirrhosis), sinusoidal (Laennec cirrhosis), and postsinusoidal levels, progressive scarring usually spreads to the entire sinusoid. As intrahepatic portal venous flow stagnates, portosystemic collaterals open. Portal blood flow decreases. Total hepatic blood supply is usually maintained by an increase of blood flow in the hepatic artery.

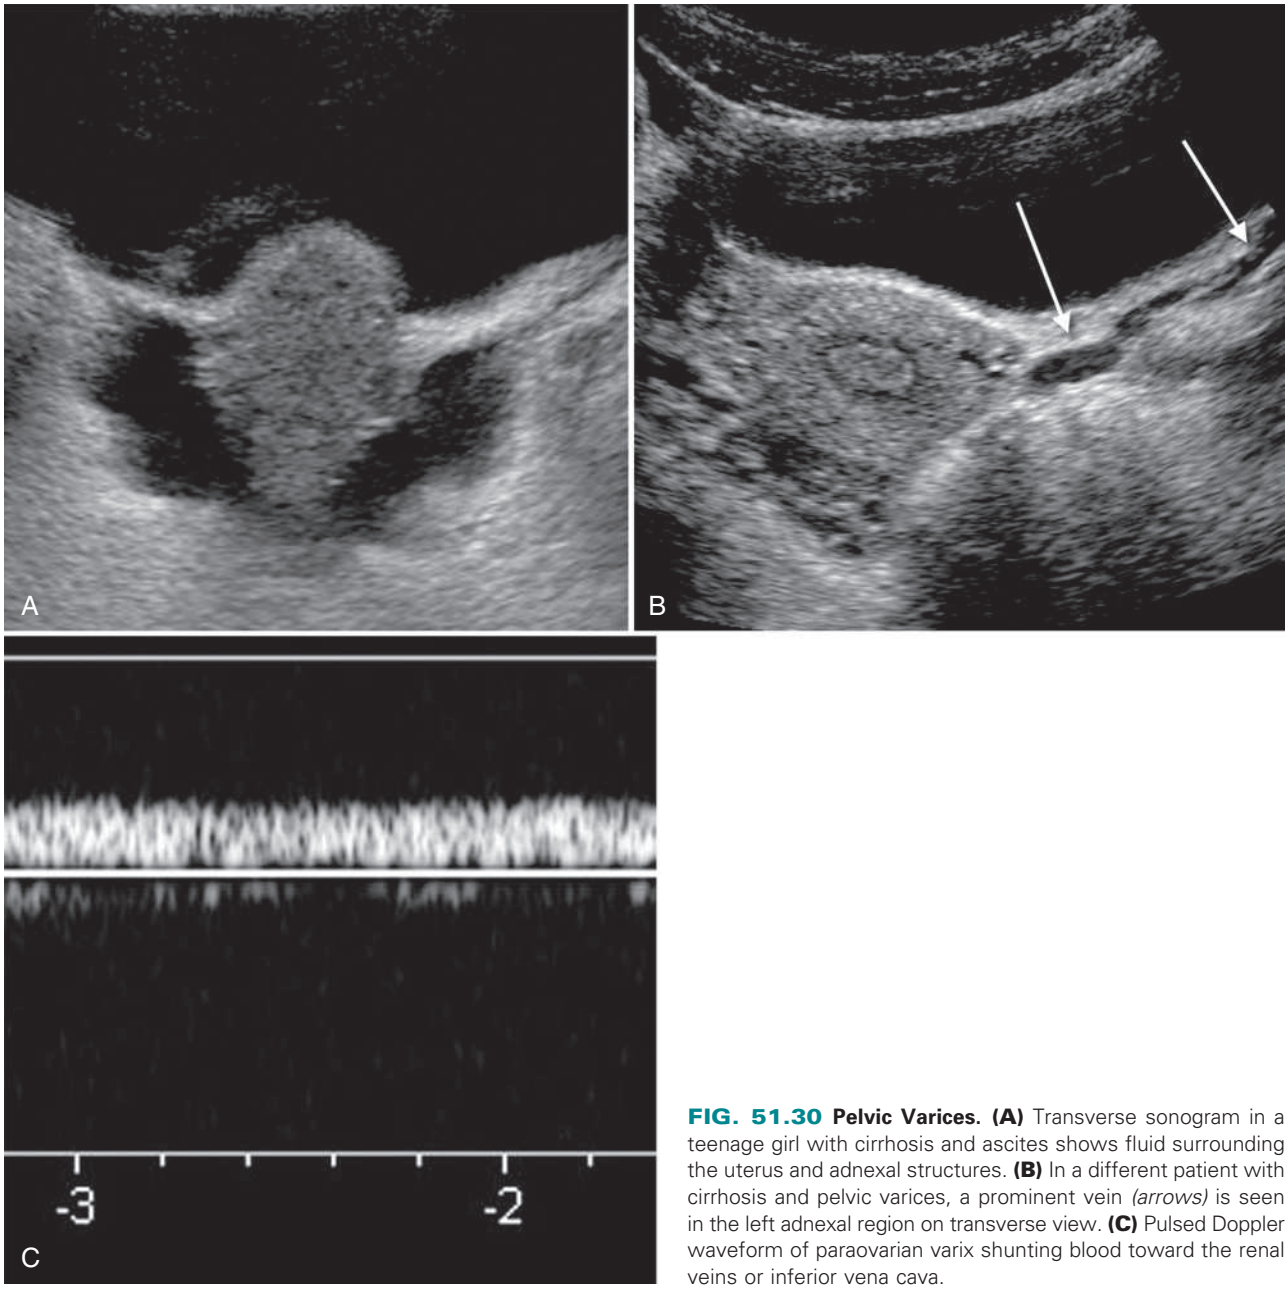

FIG. 51.30 Pelvic Varices. (A) Transverse sonogram in a teenage girl with cirrhosis and ascites shows fluid surrounding the uterus and adnexal structures. **(B)** In a different patient with cirrhosis and pelvic varices, a prominent vein *(arrows)* is seen in the left adnexal region on transverse view. **(C)** Pulsed Doppler waveform of paraovarian varix shunting blood toward the renal veins or inferior vena cava.

Causes of Cirrhosis in Children

Hepatitis
Toxins accumulated in inherited metabolic diseases
Biliary atresia
Cystic fibrosis

Sonographically, these changes in hemodynamics are signaled by decreasing diameter of the portal vein and its segmental branches, to the point at which they are reduced to threadlike structures. Flow velocity, when measurable, is reduced. Conversely, branches of the hepatic artery (normally difficult to see in children) may become visible with gray-scale sonography. Doppler sonography mirrors the increased hepatic arterial caliber and flow seen angiographically. Doppler shifts from segmental arteries are increased compared with their portal venous neighbors.

Two hemodynamic mechanisms appear to operate in patients with portal hypertension, especially in those with cirrhosis. The **backward-flow theory** explains portal hypertension by the increased resistance to portal venous flow caused by the intrahepatic block described earlier. In response to stagnating intrahepatic flow, portosystemic collaterals form and drain blood away from the liver, finally resulting in hepatofugal flow in some or all segmental branches and in the main portal vein, which is easily demonstrated with Doppler sonography. Why does the portal pressure remain elevated despite the presence of such a

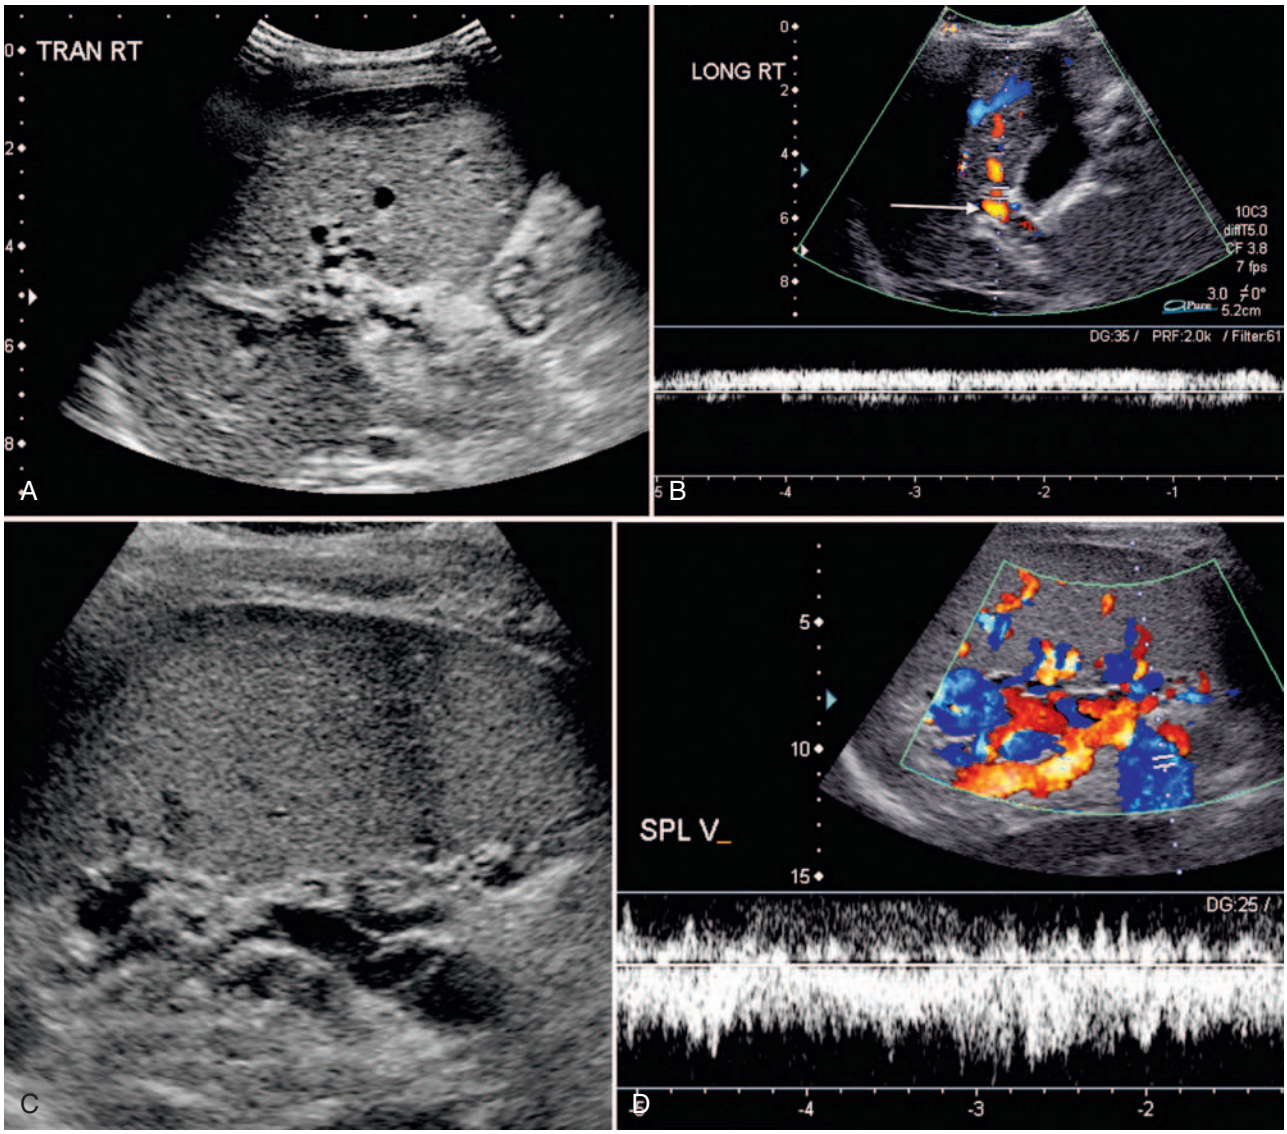

FIG. 51.31 Cavernous Transformation of Portal Vein in Child After Umbilical Vein Catheterization in Infancy. (A) Transverse sonogram of the liver shows several tortuous tubular veins, but no large main portal vein at the porta hepatis. **(B)** Color and pulsed Doppler waveform within one of these veins shows slow hepatopetal flow. The **main hepatic artery** is large *(arrow)* just deep to the vein being interrogated, a typical finding in cavernous transformation of the portal vein. **(C)** Despite the venous collaterals transporting blood into the liver around the thrombosed main portal vein, the child had **splenic varices** seen on longitudinal sonogram. **(D)** Color and pulsed Doppler waveform of the splenic varices shows brisker venous flow than that seen in the porta. See also Video 51.10.

decompression mechanism? This question may be answered by the **forward-flow theory.** In the backward-flow theory, portal blood flow is unchanged or even diminished. The forward-flow theory proposes that splanchnic arterioles dilate in patients with cirrhosis. The resultant decreased splanchnic resistance leads to increased flow in the intestinal arteries and veins, with subsequently increased portal venous blood flow. This would explain why portal hypertension is maintained despite extensive portosystemic shunting.

Because the obstruction to portal blood flow in cirrhosis is within the liver, periportal and pericholecystic venous collaterals rarely develop. However, blood is often shunted from the left portal vein through one or several tortuous **paraumbilical veins** to veins of the anterior wall of the abdomen and thorax. Documenting hepatofugal flow in such a vein situated within the falciform ligament is an easy way to establish the diagnosis of portal hypertension in children. The superficial abdominal (thoracic) wall collaterals are readily traced with color Doppler sonography if a high-frequency transducer is used.

The **left gastric vein,** shunting blood from the liver to esophageal varices, although dilated, becomes increasingly difficult to detect sonographically in children with advanced cirrhosis. Atrophy of the left lobe of the liver abolishes the acoustic window through which the lesser omentum is normally explored.

All the other portosystemic shunts described in Fig. 51.24 are possible in children with cirrhosis; thus the entire abdomen

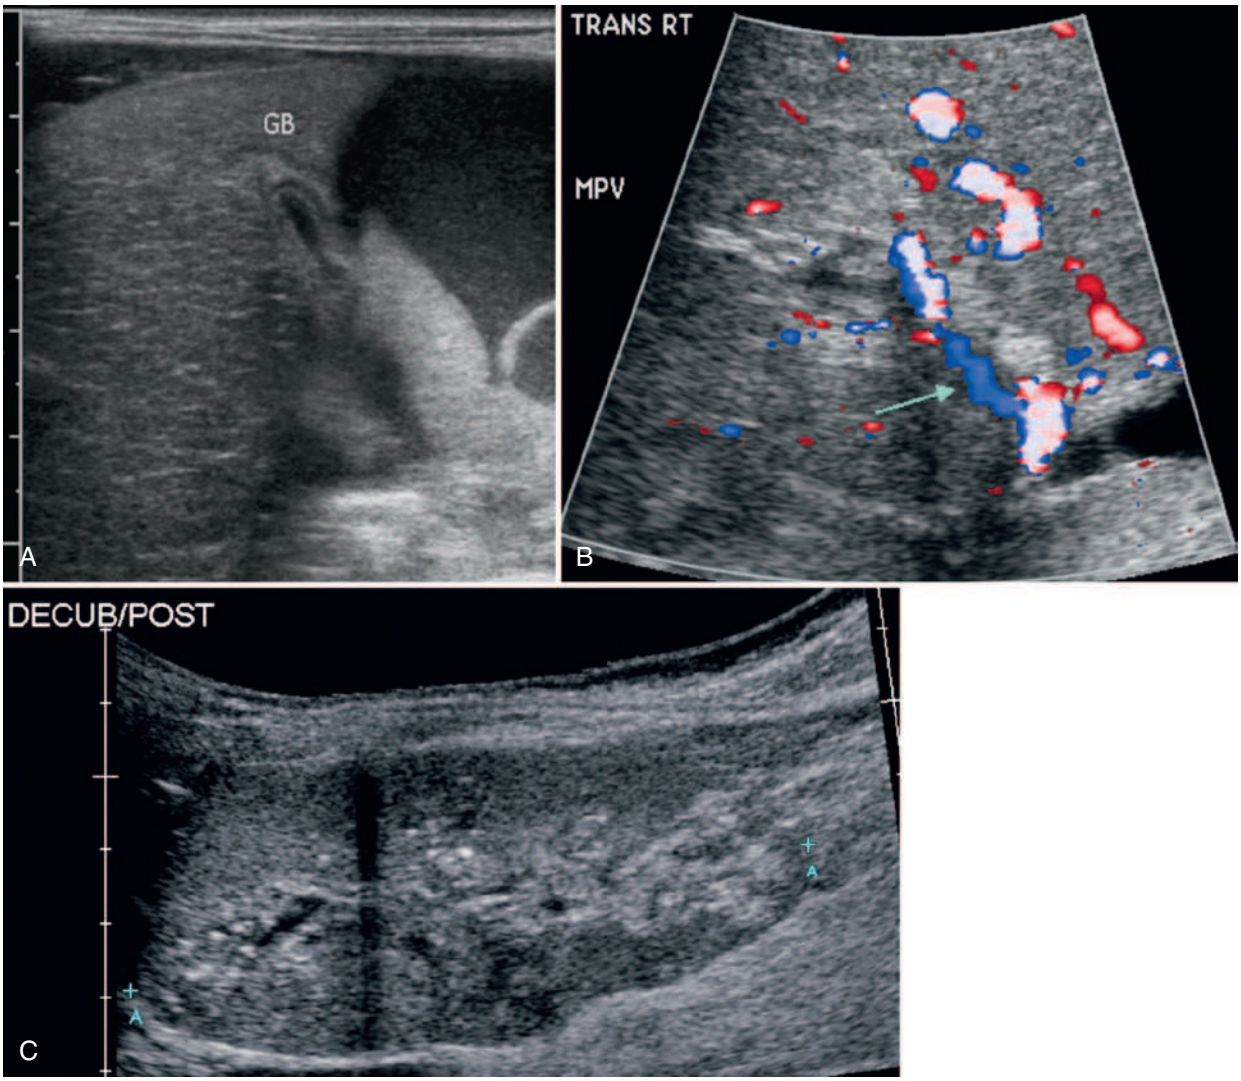

FIG. 51.32 Congenital Hepatic Fibrosis Causes Portal Vein and Biliary Obstruction. (A) Transverse grey-scale ultrasound shows ascites, gallbladder wall thickening, and coarse hepatic echotexture reflecting biliary ductal ectasia. **(B)** Color Doppler image in the same infant shows flow away from the liver in tortuous vessels *(arrow)* in the porta hepatis due to cavernous transformation of the portal vein. **(C)** Longitudinal prone image of the kidney in this infant shows abnormal renal echotexture with echogenic foci related to dilated collecting ducts, microscopic cysts, and dystrophic calcification.

and pelvis should be explored with sonography. The principle of **shunting** is constant in all portosystemic collaterals; a dilated, often tortuous splanchnic vein with reversed (hepatofugal) flow shunts blood into a systemic vein that is equally dilated at the site of the shunt. Rapid venous blood flow produces high, steady Doppler shifts. Turbulence and bidirectional flow often occur at the shunt site. A diagram that summarizes the Doppler findings is extremely helpful in visualizing the entire shunt route as well as the intrahepatic circulation. A few patients with severe portal hypertension develop reversal of flow in the main portal vein, sometimes because of the proximity of a large shunt near the porta hepatis. However, it must be recognized that if one were to depend on reversed portal venous flow to make the diagnosis of portal hypertension, one would miss the diagnosis in the majority of such patients.[79]

Suprahepatic (Posthepatic) Portal Hypertension

The clinical quartet of ascites, abdominal pain, jaundice, and hepatomegaly that follows obstruction of the hepatic veins is called the **Budd-Chiari syndrome** (Fig. 51.33). It is rare in children. Doppler sonography is particularly useful in excluding the diagnosis, because the four clinical signs that make up the syndrome are quite common in children with other forms of portal hypertension. The first patients with thrombosis of the hepatic veins described by Budd (1846), Fredrichs, Lange, and Chiari (1899) were thought to have hepatic phlebitis secondary to sepsis or syphilis, with primary involvement of small branches of the hepatic veins. Since then, other causes have been recognized, now classified as obstruction of the central and sublobular veins,

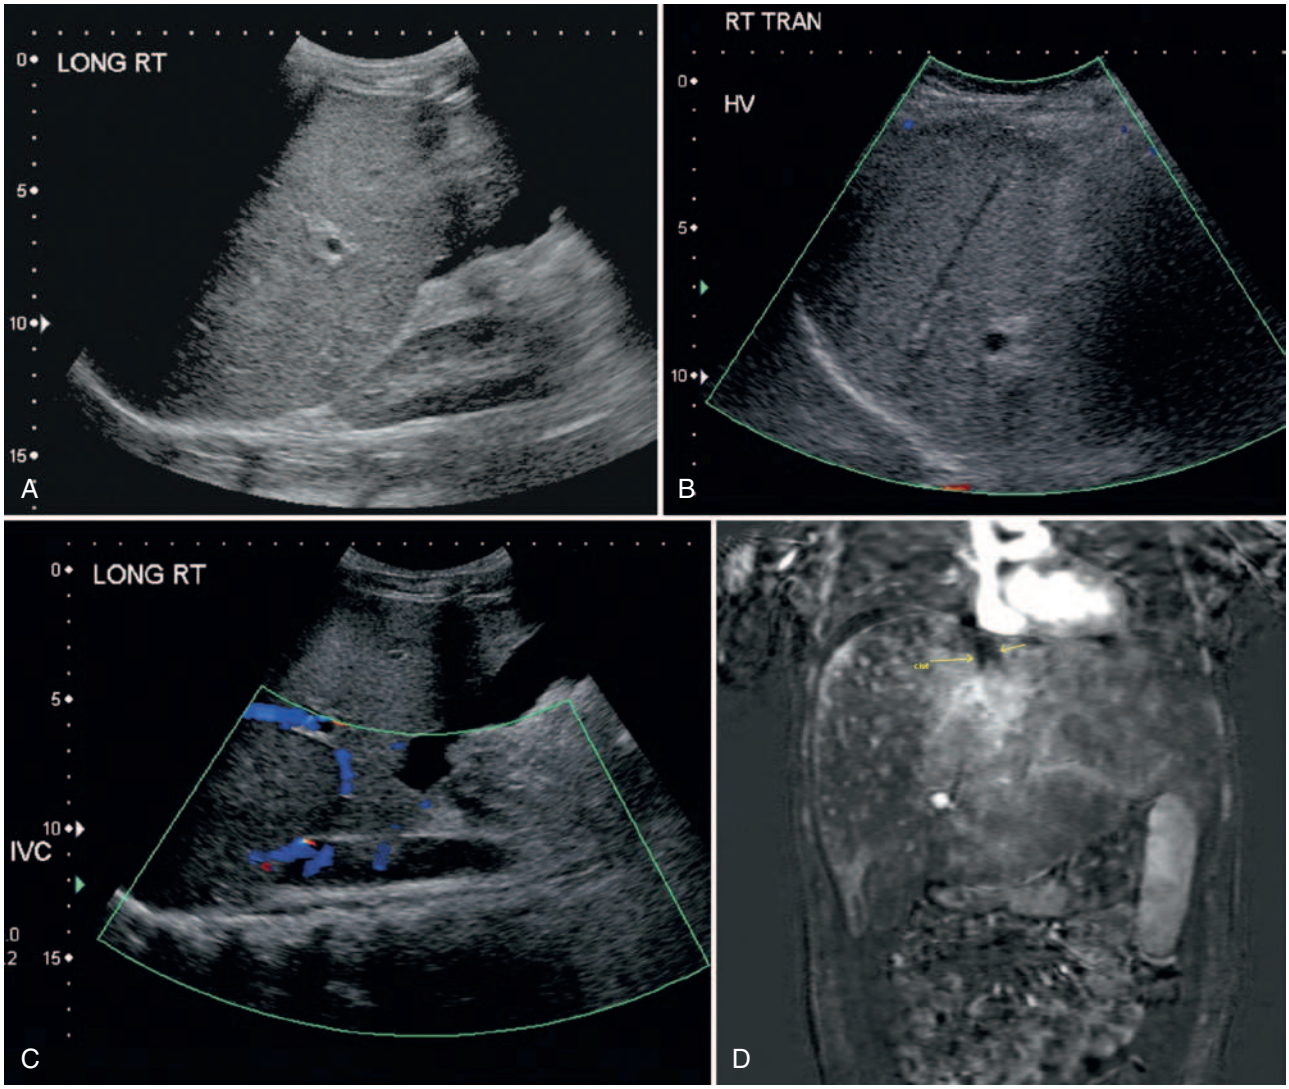

FIG. 51.33 Budd-Chiari Syndrome. (A) Acute appearance: the liver is enlarged, surrounded by ascitic fluid. **(B)** The diagonal course of a hepatic vein is filled with echogenic clot. **(C)** Longitudinal image of the inferior vena cava shows abrupt truncation and lack of intrahepatic flow. **(D)** Thrombus at the hepatic venous confluence *(arrows)* was confirmed with magnetic resonance flow-sensitive imaging.

the major hepatic veins, or the IVC near the hepatic vein ostia.[80] **Small-vessel hepatic venous occlusive disease** (VOD), also known as **sinusoidal obstruction syndrome** (SOS), is caused by toxins (pyrrolizidine alkaloids contained in ragwort or Jamaican bush tea); chemotherapy; bone marrow and stem cell transplantation; lupus erythematosus; hepatic irradiation; and oral contraceptives. This VOD involves primarily small hepatic venous radicles, although the major branches may be secondarily involved.

Sonographic findings of VOD include splenomegaly, ascites, small-caliber hepatic veins, and flow in paraumbilical veins. The sonographic diagnosis of VOD remains difficult; clinical and laboratory criteria are better indicators of the severity of VOD and its response to medical therapy.[81] **Thrombosis of the main hepatic veins** is usually caused by coagulation abnormalities or congenital malformations of the hepatic vein ostia. Obstruction of the hepatic portion of the IVC may result in thrombosis of the hepatic veins. Congenital membranes of the IVC resulting from faulty embryologic fenestration of its lumen can also lead to obstruction of hepatic veins.[82,83] The most common position for such a membrane is below an obstructed left hepatic vein and above a patent right hepatic vein, probably a result of an obstructing fibrous remnant of the left umbilical vein and ductus venosus.

Causes of Hepatic Venous Occlusive Disease

- Toxins
  - Pyrrolizidine alkaloid
  - Ragwort or Jamaican bush tea
- Chemotherapy
- Bone marrow transplantation
- Lupus erythematosus
- Hepatic irradiation
- Oral contraceptives
- Coagulation abnormalities
- Congenital malformations of hepatic vein ostia
- Obstruction of hepatic portion of inferior vena cava
- Congenital membranes of inferior vena cava

After any obstruction of the hepatic veins, the liver becomes enlarged and congested. Because the caudate lobe has its own hepatic vein that drains into the IVC below the others, it is often spared and serves as the only initial venous drainage route for the entire liver. The caudate lobe enlarges quickly and often compresses the IVC. This is followed by ascites, often pleural effusions, splenomegaly, and the formation of portosystemic collaterals. Doppler sonography shows absence or reversal of flow in the hepatic veins. Areas of high-velocity flow near stenoses of hepatic veins are easily detected with color-guided, pulsed Doppler sonography. In the absence of hepatic venous drainage, arterial blood may be shunted into the portal vein through microscopic shunts at the portal triad or through larger intrahepatic shunts. Portal venous flow may reverse. Alternately, the portal vein may thrombose when liver congestion is severe. **Wedge hepatic venography,** which shows a spider web network of intrahepatic veins instead of the usual hepatic venous lumens, is now rarely performed, because the hepatic vasculature is well assessed with Doppler sonography.

The patient with acute Budd-Chiari syndrome rarely has time to form portosystemic collateral routes. If present, shunt routes are similar to those seen in cirrhosis. Periportal and pericholecystic veins do not usually serve as shunt routes because they drain into the segmental branches of the right portal vein, which are highly congested in response to hepatic vein obstruction. Extensive intrahepatic shunts may form.

The treatment of hepatic vein occlusion is anticoagulant therapy, defibrotide, ablation of obstructive webs, or emergency portocaval shunting. The recanalization of hepatic veins, the regression of portal hypertension (decreased caliber and flow velocity in portosystemic shunts, smaller spleen, absorption of ascites), and the patency of therapeutic shunts can be assessed with Doppler sonography.

Surgical Portosystemic Shunts

Previously, definitive treatment of children with bleeding esophageal varices was surgical portosystemic shunts. These shunts are now created only when sclerotherapy of varices has failed or liver transplantation is not feasible. Children with healthy livers and prehepatic portal hypertension are still candidates for shunt procedures. **Transjugular intrahepatic portosystemic shunt** (TIPS) procedures are being performed as an alternate to classic surgical shunts in adults, with increasing use in children. The patency of transjugular shunts is monitored with Doppler sonography, which shows blood flowing from the "donor" right portal vein through the intrahepatic stent and into the right (or another) hepatic vein. Shunt stenoses, thrombosis, and flow around the stent are readily visible with Doppler sonography.

Surgical portosystemic shunts can be total or partial. **Total shunts** direct the entire venous blood flow from the congested splanchnic system into a systemic vein, as in the end-to-side portocaval shunt, in which the main portal vein is redirected. The hepatic end is ligated and the splanchnic end is connected to the IVC. In this situation, portal venous perfusion of the liver is minimal. **Partial shunts** divert only some of the splanchnic blood into a systemic vein, thereby yielding better liver perfusion and reducing the incidence of hepatic encephalopathy. The distal splenorenal (Warren) shunt connects the splenic vein to the left renal vein. The side-to-side, H-type, portocaval shunt connects the portal vein to the IVC at the porta hepatis. The REX shunt connects the left portal vein to the IVC using a donor vein. Many variants of these surgical procedures exist.

Doppler study of the intrahepatic portal veins is invaluable in the assessment of **portocaval shunt patency.** In the majority of patent shunts, flow in the intrahepatic portal veins is hepatofugal.[84] It is easy to understand why this should be so in side-to-side portocaval shunts, in which high-pressure intrahepatic venous blood flows through the shunt into the low-pressure vena cava. It is more difficult to explain hepatofugal flow in the intrahepatic portal veins in patients with an end-to-side portocaval shunt, in which the hepatic end of the portal vein has been ligated and cut. Blood may leave the liver through a system of collateral veins between intrahepatic branches of the portal vein and low-pressure systemic veins. This phenomenon has been demonstrated on angiography.[85]

Signs of shunt obstruction include the following:

- The shunt site is difficult or impossible to detect, and no Doppler signals can be obtained.
- Blood in the splanchnic vein feeding the shunt no longer flows toward the shunt.
- The direction of intrahepatic portal venous flow returns to normal.
- Spontaneous portosystemic shunts and other signs of portal hypertension reappear.

Hepatic Shear Wave Elastography

Real-time shear wave elastography (SWE) is a rapidly expanding method to assess liver stiffness or fibrosis in cirrhosis, inflammatory conditions, and tumors. An earlier technique for **mechanical compression without imaging** (Fibroscan), **transient elastography** (TE), was rapidly adopted by gastroenterologists and hepatologists but has been shown to be less reliable and reproducible than **shear wave elastography** (SWE) (Fig. 51.34). A third type of elastography, **acoustic radiation force imaging** (ARFI) (Fig. 51.35), uses a B-mode ultrasound image to position a fixed region of interest (ROI) box, which is measured in real time during a button push (which sends the shear wave pulse). ARFI is similar to TE with the added benefit of seeing the segment of liver being interrogated. Ultrasound elastography is readily performed in children without sedation, and measurements can be timed during respiratory pauses. Ultrasound elastography has shown good correlation with magnetic resonance elastography (MRE) and liver biopsy. Both techniques have potential to decrease the need for liver biopsy in children.[86-89]

DOPPLER SONOGRAPHY IN CHILDREN RECEIVING LIVER TRANSPLANT

Pretransplantation Evaluation

Before liver transplantation can be considered, the caliber and patency of the main portal vein and IVC must be assessed. This is usually done with Doppler sonography and supplemented with MRI.[90-92] If the portal vein diameter is less than 4 mm (as

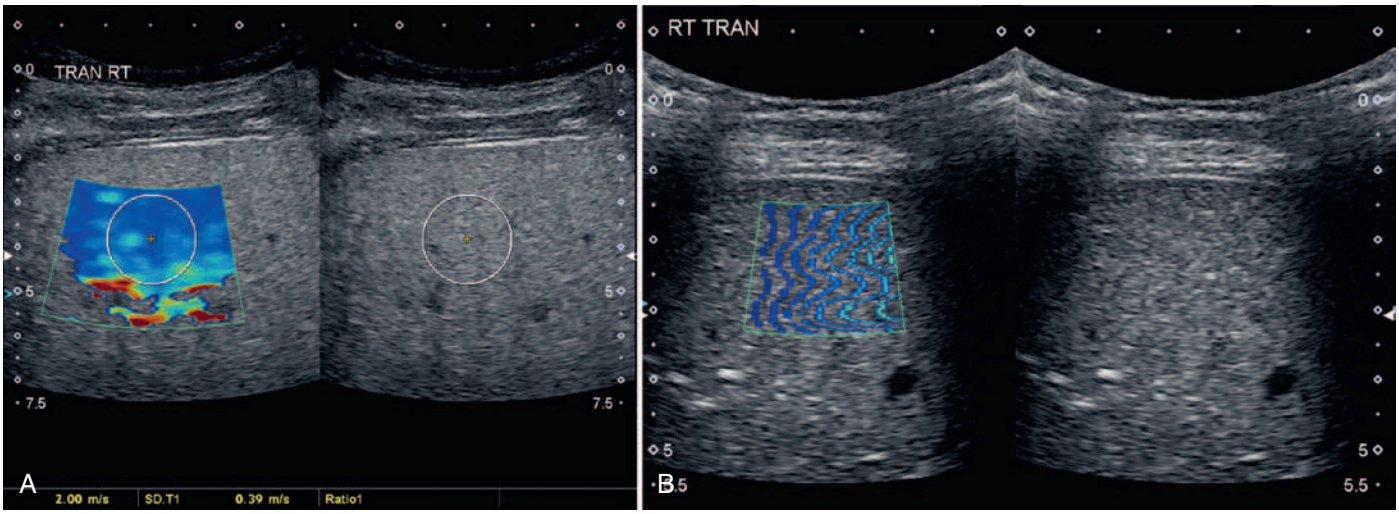

FIG. 51.34 Chronic Liver Disease Due to Hepatitis B. (A) Shear wave elastography color map and circular region of interest placed over a relatively homogenous area of liver, yielding a shear wave velocity of 2 m/sec. **(B) Propagation wave display** shows vertical blue bands of the shear wave front passing through the liver. Regular wave contours and intervals favor a homogenous site for measurements.

(A) Shear wave region of interest is selected perpendicular to the liver capsule and more than 1 cm deep to the liver margin. **(B)** Color display of elastography to aid in selecting an appropriate site. **(C)** Larger box in which multiple shear wave measurements have been made. **(D)** Table of results to look for erroneous data and spurious results, average values, standard deviation, and interquartile range (IQR).

in advanced cirrhosis) or if Doppler flow studies are equivocal, MRI or angiography may be performed. Children with biliary atresia may have an associated **polysplenia syndrome** (see Fig. 51.8C-G), which includes intestinal malrotation, bilaterally symmetrical patterns of the major bronchi, abnormal location of the portal vein anterior to the duodenum, and interruption of the IVC.[15,90] Liver transplantation may be more difficult in these children. It is essential that the surgeon be aware of this anatomic abnormality before transplantation.

In addition, portocaval or mesenteric-caval shunts, whether created surgically or occurring naturally, change both the flow pattern and the caliber of the main portal vein and may alter the surgical approach to transplantation. The anatomic variants of the hepatic artery are not always demonstrated on sonography, but angiography is rarely performed for the purpose of outlining the anatomy of the hepatic artery. The examination of the child before transplantation should also include several organs: the kidneys, lungs, heart, and intestinal tract.[90,92] During liver transplantation in the child, the donor hepatic artery is sometimes removed with a cuff of aorta and anastomosed to the recipient's abdominal aorta or iliac artery. An adult liver is usually divided before being transplanted into a small child. Although the left lobe (segments 2 and 3) is preferred, an adult liver may be divided and used for two recipients. A **transient fluid collection** often forms around the cut surface of the transplanted lobe or segments, even though the cut is packed with hemostatic material such as Gelfoam or fibrin glue. Because the anatomy involved in segmental or lobar liver transplantation differs considerably from the normal anatomy and from the anatomy involved in whole-organ transplantation, a diagram of the procedure is a useful guide for the sonographer assessing patency of anastomosed vessels.

Posttransplantation Evaluation

The most common complications in the immediate postoperative period are **hepatic artery stenosis, spasm,** and **thrombosis.** Although collateral vessels may form in the child and shunt arterial blood into the liver, bile duct injury frequently occurs, followed by the formation of bile lakes and recurrent infection. Retransplantation is almost invariably necessary.

Immediate Doppler examination either in the surgical suite or at the child's bedside soon after surgery and then daily for 5 to 7 days is typically performed to confirm patency of the anastomosed vessels, before clinical or biochemical liver examination findings become abnormal.[93] The hepatic arterial anastomosis can be difficult to see adjacent to the Roux loop, so it is important to examine the intrahepatic arterial branches adjacent to intrahepatic portal veins, with both gray-scale and Doppler techniques. Optimal sites for the detection of hepatic arterial Doppler signals in whole-liver transplants are adjacent to the umbilical branch of the left portal vein and adjacent to the branch to segments 3 and 4, and alongside the right portal vein and the branches to segments 6 and 7. The presence of arterial signals at these sites usually establishes patency of the hepatic artery. In segmental liver transplants, the "porta hepatis" is located eccentrically along the right lateral costal margin.[94-96] Given the variability of graft size and orientation in the right upper quadrant, the sonographer must find optimal imaging windows by trial and error. In the immediate postoperative period, hepatic arterial flow (both systolic and diastolic) is generally brisk. However, in the next 2 to 3 days, graft edema may result in transiently decreased diastolic flow. As long as systolic upstroke remains sharp and there are other signs of graft swelling (i.e., periportal edema), patients are watched expectantly. If the patient's liver enzyme levels rise, further Doppler evaluation or surgical reexploration is generally performed. Tardus-parvus waveforms in the hepatic artery in the immediate perioperative period are most likely related to arterial spasm and are treated pharmacologically.

Children with clinically undetected, chronic obstruction of the main hepatic artery have been reported in whom dampened intrahepatic arterial flow was detected with Doppler sonography. Angiography in these patients shows obstruction of the hepatic artery and liver perfusion through extensive arterial collaterals around the site of a portoenterostomy at the porta hepatis.

In patients well enough to eat or receive gastric tube feedings, remember that hepatic arterial Doppler shifts are difficult to detect after a meal.[70] A repeat examination after a fast may show much stronger signals. Failure to detect intrahepatic arterial Doppler shifts indicates thrombosis or a prethrombotic state. Given the risk of graft injury, arteriography is generally performed in this situation, with the intent to treat with thrombolytics or angioplasty.

Although hepatic artery interrogation is the most important part of the posttransplant examination, the Doppler study is also helpful in assessing the patency of the venous anastomoses—the portal and hepatic veins and the IVC. The sites of venous anastomosis are clearly visible with gray-scale sonography and should be demonstrated (Fig. 51.36). **Portal venous thrombosis** at the anastomosis may occur but is less frequent than arterial occlusion. Turbulence may be expected at the anastomotic site of the portal vein, especially when there is discrepancy in the size of anastomosed vessels. **Stenosis** or compression of the portal vein is accompanied by locally increased Doppler shifts (Fig. 51.37). Portal hypertension may follow. Poststenotic dilation of the portal vein may occur without serious sequelae. In some patients with a small portal vein from a segmental transplant, prolonged fasting may increase hepatic arterial flow and make visualization of the portal vein difficult. A limited follow-up scan, after feeding the patient, can vastly improve visualization of portal venous flow.

Inferior vena cava thrombosis is usually asymptomatic in the child because collateral flow through the paravertebral venous system is quickly established. The sonographic diagnosis of an IVC thrombus in a child with liver transplantation can be difficult. The IVC lumen is obliterated by thrombus, and the vessel becomes very difficult to visualize (Fig. 51.38). However, even a patent IVC can be difficult to find because anatomic relationships are greatly altered in these children. At Doppler sonography, flow in a hemiazygos vein is easily mistaken for flow in the IVC. The IVC is frequently compressed by a large donor graft, so careful examination of the draining hepatic veins is important.

During segmental transplantation, the recipient's IVC is left intact and the hepatic vein(s) directly anastomosed to the

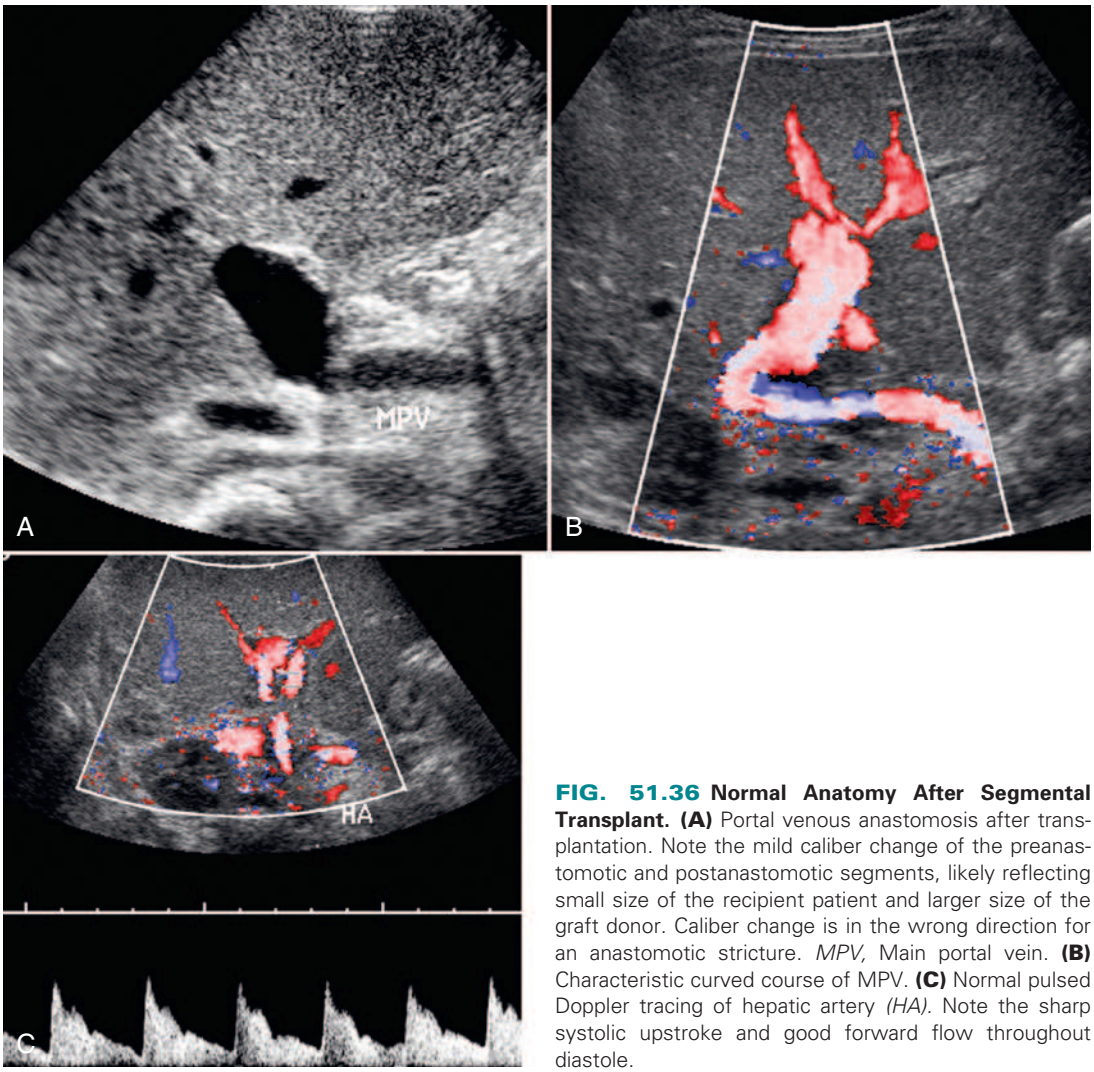

FIG. 51.36 Normal Anatomy After Segmental Transplant. (A) Portal venous anastomosis after transplantation. Note the mild caliber change of the preanastomotic and postanastomotic segments, likely reflecting small size of the recipient patient and larger size of the graft donor. Caliber change is in the wrong direction for an anastomotic stricture. *MPV,* Main portal vein. **(B)** Characteristic curved course of MPV. **(C)** Normal pulsed Doppler tracing of hepatic artery *(HA).* Note the sharp systolic upstroke and good forward flow throughout diastole.

IVC or right atrium. Both the hepatic veins and the IVC may thrombose, starting at the anastomosis. The immediate postoperative examination outlines the surgical anatomy in these children and serves as a useful standard for comparison in assessing the continued patency of the anastomosed vessels. Stumps of oversewn graft IVC are also frequently encountered, lying between the liver parenchyma and native IVC. Thrombus in the remnant of donor IVC seldom propagates but can be seen as intraluminal echoes perioperatively. With time, these donor IVC remnants become less visible, collapsing and blending into the medium-level echoes of the retroperitoneum.

Graft rejection does not result in predictable flow alterations of the hepatic artery, unlike the increased intrarenal resistance to flow noted in acute renal allograft rejection. However, changes in the normal phasicity of hepatic venous blood flow have been linked to graft rejection. Specifically, when normal triphasic hepatic venous blood flow becomes monophasic, biopsy specimens show evidence of acute rejection (sensitivity 92%, specificity 48%) or other hepatic disease (cholangitis, fibrosis, centrilobular congestion and necrosis, lymphoproliferative disease, cholestasis, hepatitis).[95,97] Some liver transplant recipients never demonstrate triphasic flow, presumably because of poor elasticity in the donor graft, and thus these criteria are not useful in this subgroup.

Biliary air or **pneumobilia** is another common finding in patients after liver transplant (see Fig. 51.38H, Video 51.11). Anecdotally, it is less frequent in the immediate postoperative period (despite routine stenting of the duct) and is more likely to be noted on routine follow-up scans several months later. The source of air is retrograde passage from the gastrointestinal tract, through the Roux loop and choledochoenterostomy and into the bile ducts. Careful examination of the liver parenchyma on routine follow-up sonography is important to exclude biliary tree abnormalities, abscess, focal areas of ischemia, and complications of percutaneous biopsy (e.g., bile lake, AV shunts, hemorrhage). Biliary ductal dilation may be caused by stenosis of the choledochoenterostomy, bile duct ischemia with secondary stricture, stone disease, and compression of ducts by external

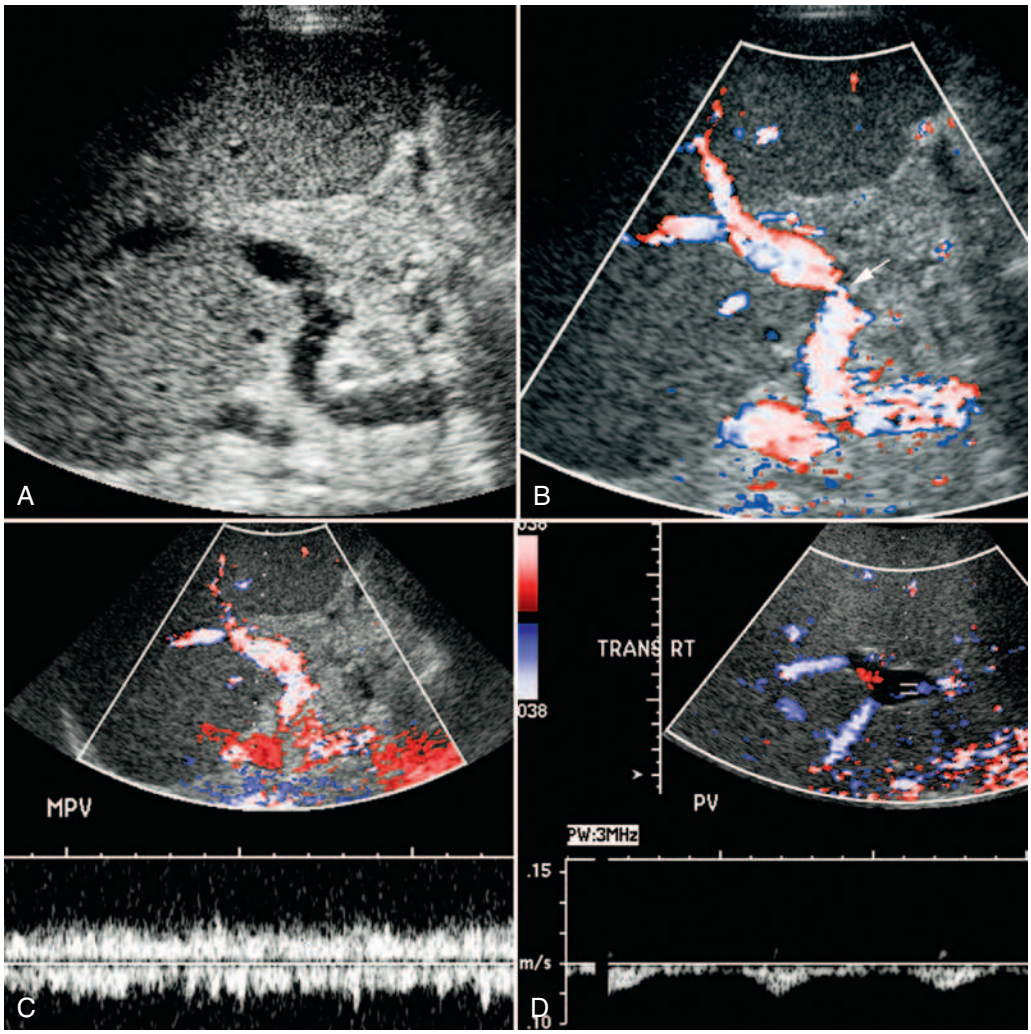

FIG. 51.37 Portal Vein Stenosis After Transplantation. (A) Subcostal oblique sonogram and **(B)** color Doppler image show a narrowed segment of the portal vein at the anastomotic site *(arrow).* **(C)** Pulsed Doppler tracing just beyond the site of stenosis shows turbulent, high-velocity, bidirectional flow. *MPV,* Main portal vein. **(D)** Color and pulsed Doppler images in a different transplant patient show impending thrombosis of the portal vein *(PV),* with absent color signal and minimal flow on low scale settings.

masses, fluid collections, or adenopathy. Perioperative **fluid collections** are common and typically resolve in weeks to months. Persistent collections may represent lymphocele or persistent bile leak. New collections are most often related to infection, iatrogenic injury, trauma, or graft failure.

Long-term survival of pediatric liver transplant patients continues to improve, bringing a new set of long-term complications to search out during imaging examinations. **Aneurysms** may develop in the portal vein or hepatic arteries (see Fig. 51.38E-G), particularly at anastomoses or where segments of donor vessel were used. A careful search of the entire length of donor portal vein and hepatic artery to the point of connection to native vasculature is recommended. In the case of infrarenal aortic anastomoses, the entire length of the hepatic artery conduit may be difficult to identify. Intervening bowel gas may be compressed out of the way, or a far lateral, midaxillary line of scanning through the flank may show the graft site along the anterior surface of the aorta just below the renal arteries. Cross-sectional imaging with CT angiography, MRI, and occasionally angiography are sometimes needed. Hepatic vein stenosis can also be a cause of cryptic graft failure. Careful examination of the hepatic venous outflow may still show only indirect evidence of stenosis: loss of phasicity in the hepatic veins, with change in phasicity in only one of the three hepatic veins. Given the location of the upper hepatic venous or caval anastomosis, sonographic evaluation is challenging. Occasionally, venography will clearly show a tight stenosis where one was only suspected sonographically. Fortunately, venous access in these cases can also be used to treat the lesion with angioplasty.

Additional complications in long-term liver transplant survivors include renal cystic disease,[96] chronic renal failure, graft-versus-host disease, lymphoproliferative disorders, and other complications of immune suppression.

Multiorgan Transplants

A growing new subset of liver transplant recipients involves those receiving combined liver–small intestine transplants. Sonographic evaluation of the whole-liver transplant is unchanged, although the addition of a second donor pancreas and donor aorta with

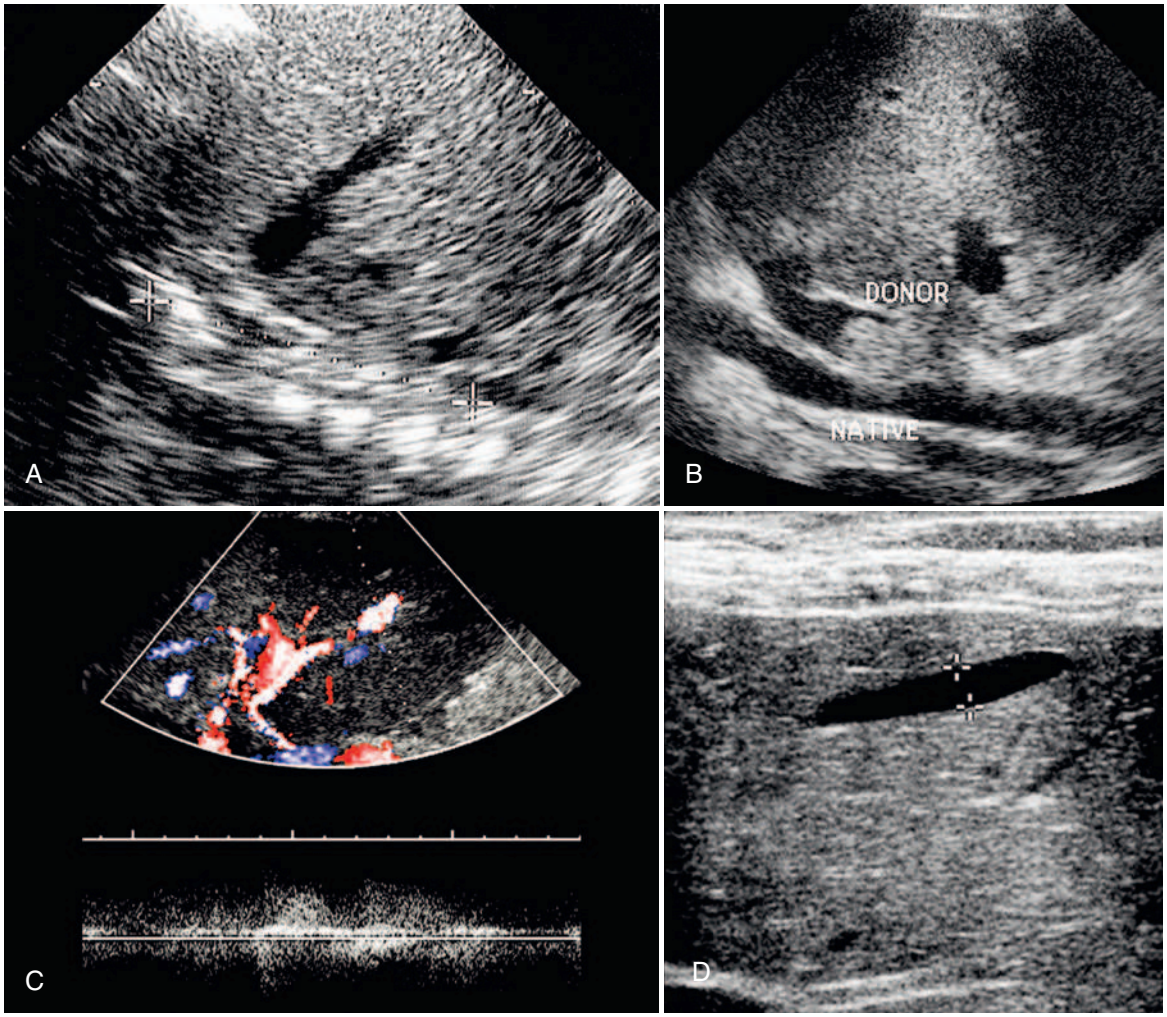

FIG. 51.38 Transplant Complications. (A) Thrombosis *(cursors)* of inferior vena cava (IVC) after bisegmental liver transplantation in a 2-year-old child contrasts with the hypoechoic lumen of a nearby patent hepatic vein. **(B) Partial thrombosis** of oversewn donor IVC interposed between native IVC and hepatic parenchyma. This is not usually problematic unless the clot propagates. **(C)** Color and pulsed Doppler image shows **arteriovenous fistula** with turbulent flow in a transplant liver after biopsy. **(D)** Focal dilation *(cursors)* of a bile duct in the left lobe of the transplant liver. This may be caused by hepatic arterial compromise and duct stenosis or ductal injury from previous percutaneous biopsy.

Continued

celiac and superior mesenteric arteries can create Doppler imaging challenges.[97] Evaluation of the small bowel is limited when there is postoperative ileus. Color Doppler evaluation of donor small bowel wall perfusion is useful in the immediate perioperative period. As bowel function returns, other clinical parameters replace Doppler evaluation of bowel viability. When complications arise, sonographic evaluation of the small bowel is similar to the approach used for necrotizing enterocolitis, looking for pneumatosis, poor perfusion, complicated ascites, and signs suggesting perforation. Sonographic imaging experience with these patients continues to expand.

THE SPLEEN

Examination of the spleen is an integral part of the sonographic assessment of the child with liver or pancreatic disease or with infection or trauma.

Cysts of the spleen are congenital (epithelial lined),[98] posttraumatic (pseudocyst without lining),[99] or hydatid (unilocular and later daughter cysts).[51] Splenic cysts associated with polycystic kidney disease are rare in childhood. Splenic **abscesses** are found most frequently in immunosuppressed or leukemic children with candidiasis. The abscesses within the enlarged spleen usually become visible long after the diagnosis of *Candida* sepsis has been made. Cat-scratch disease is another cause of multiple splenic abscesses. Splenic **calcifications** may be the result of granulomatous infections (histoplasmosis, tuberculosis) or chronic granulomatous disease of childhood.

Splenic enlargement accompanies many systemic infections, including infectious **mononucleosis** and other viral infections, typhoid fever, malaria, and fungal infections. Both the length and the width of the spleen increase (Fig. 51.39). The lower tip of the spleen becomes rounded. Other causes of enlargement include congestion in portal hypertension and infiltration with leukemic or lymphomatous tissue, which is usually impossible to distinguish from normal splenic parenchyma sonographically. These conditions underline the importance of examining the spleen in the context of the entire abdomen (e.g., for liver disease and portosystemic collaterals or for lymphadenopathy).[31]

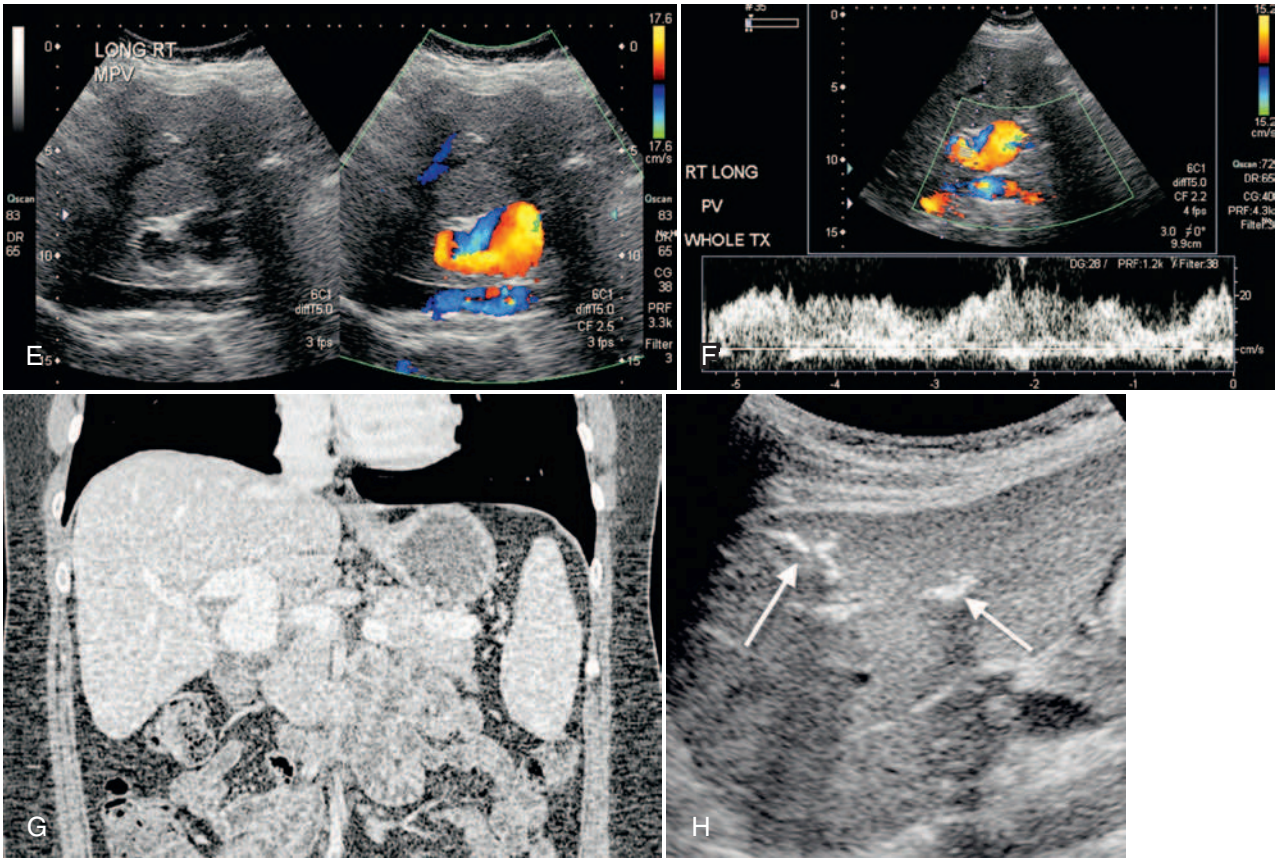

FIG. 51.38, cont'd **(E)-(H)** Portal vein **aneurysm** several years after whole-liver transplant. **(E)** Twin screen (gray-scale and color Doppler) display of swirling blood flow in the main portal vein. **(F)** Color and pulsed Doppler waveform shows turbulent flow within the aneurysm. **(G)** Coronal computed tomography (CT) image of same patient shows the portal vein aneurysm displacing the hepatic artery. Note the perisplenic and perigastric varices, best seen on the coronal reformatted CT image. **(H) Pneumobilia.** Transverse sonogram shows branching echogenic lines of air with "dirty" shadowing *(arrows)*. Air within the biliary tree is common after choledochoenterostomy and is not itself a complication, although it can impair sonographic evaluation of the transplant liver. See also Video 51.11.

Causes of Splenic Enlargement

Infection (bacterial, viral, protozoal, fungal)
Lymphoma, leukemia
Lymphoproliferative disorders
  Chronic granulomatous disease
Cirrhosis, portal hypertension
Sequestration
  Sickle cell disease
Hemolytic anemia, extramedullary hematopoiesis
Langerhans cell histiocytosis
Storage diseases
  Gaucher disease
  Niemann-Pick disease
  Mucopolysaccharidoses
Collagen vascular disease
Congestive heart failure
Sarcoidosis

The spleen is one of the most frequently injured organs when abdominal trauma has occurred. **Splenic hematomas** are usually hypoechoic lesions, often located under the capsule (Fig. 51.40C). Fresh hematomas may be isoechoic or hyperechoic, and some linear lacerations are difficult to see on sonography. Hemoperitoneum is almost always present. Sonography is being used as the initial screening examination in children with abdominal trauma with variable results.[100,101] CT may be used only in doubtful cases or when there is concomitant spinal or head trauma. Proponents of sonography state that despite underdiagnosis of some pancreatic and exceptional splenic hematomas as well as some mesenteric tears, the surgical management of the children was not affected, and no child died because lesions were missed at the initial examination.[101] In these cases, CT was performed if sonography was difficult because of rib fractures, or if there was doubt or increasing unexplained hemoperitoneum. CT remains the standard of care for pediatric abdominal trauma in the United States, whereas ultrasound is favored in Canada and some European countries.

Spontaneous rupture of the spleen occurs in the enlarged fragile organ in infectious mononucleosis and is heralded by hemoperitoneum.[102]

Splenic infarcts occur frequently in children with sickle cell anemia and also in children with various forms of vasculitis (see Fig. 51.40D). Lesions are usually triangular and hypoechoic. If the ligamentous attachments of the spleen are lax or absent, the spleen may move about in the abdomen **(wandering spleen)** and occasionally may undergo torsion on its pedicle. Torsion

and splenic infarction can manifest as acute abdominal pain or a palpable mass.

Acknowledgment

This chapter is an update and revision of the previous excellent work by Heidi Patriquin, MD, who died in November 2000. Dr. Patriquin was a pioneer in pediatric ultrasound and particularly in abdominal visceral Doppler. She developed novel techniques for evaluating blood flow, and described important differences in pediatric and adult sonography. I had the pleasure of knowing her briefly and found her enthusiasm for pediatric ultrasound contagious. I think she would enjoy the advances described and new images included in the chapter.

CHAPTER 52

The Pediatric Urinary Tract and Adrenal Glands

Harriet J. Paltiel and Diane S. Babcock

SUMMARY OF KEY POINTS

- Ultrasound can reliably characterize renal duplication, fusion, and rotational anomalies.
- Ultrasound is useful in evaluating renal, ureteral, and bladder anatomy in patients with suspected hydronephrosis.
- Contrast-enhanced voiding urosonography (CEVUS) is a promising technique that may eventually replace conventional voiding cystourethrography (VCUG) in selected cases.
- Ultrasound is used to assess renal size and to exclude anatomic abnormalities as the cause of acute kidney injury (AKI).
- Ultrasound is the initial imaging study of choice in patients with suspected urolithiasis, with noncontrast computed tomography reserved for cases in which ultrasound is nondiagnostic.
- Intravenous contrast-enhanced ultrasound may provide valuable information regarding renal injury in patients with blunt abdominal trauma.
- Ultrasound plays a key role in the evaluation of patients with renal transplants, in both early and later postoperative periods.
- Renal ultrasound is often helpful in distinguishing among different types of renal cystic disease.
- Ultrasound is employed to distinguish cystic (usually benign) from solid (often malignant) renal masses.
- Ultrasound is used to differentiate between neonatal adrenal hemorrhage and neuroblastoma.

CHAPTER OUTLINE

PEDIATRIC URINARY TRACT SONOGRAPHY
Technique
Normal Renal Anatomy
Normal Bladder Anatomy
CONGENITAL ANOMALIES OF THE URINARY TRACT
Renal Duplication
Other Renal Anomalies
CAUSES OF HYDRONEPHROSIS
Ureteropelvic Junction Obstruction
Ureteral Obstruction
Bladder Outlet Obstruction
Vesicoureteral Reflux
Prune-Belly Syndrome
Megacystis-Microcolon-Malrotation–Intestinal Hypoperistalsis Syndrome
Bladder Exstrophy
Urachal Anomalies
URINARY TRACT INFECTION
Acute Pyelonephritis
Chronic Pyelonephritis
Neonatal Candidiasis
Cystitis
MEDICAL RENAL DISEASE
Acute Kidney Injury
Chronic Kidney Disease
URINARY TRACT CALCIFICATION
Renal Cortical Calcification
Medullary Nephrocalcinosis
Urinary Stasis
Renal Vein Thrombosis Calcifications
Dystrophic Calcification
Urolithiasis

RENAL VASCULAR DISEASE
Doppler Sonographic Examination Technique
Normal Vascular Anatomy and Flow Patterns
Causes of Increased Resistance to Intrarenal Arterial Flow
Clinical Applications
Vessel Patency
Acute Renal Vein Thrombosis
Renal Artery Stenosis
Intrarenal Arterial Disease
RENAL TRANSPLANTATION
Vascular Complications
Perinephric Fluid Collections
Parenchymal Abnormalities
Urologic Complications
Tumors
RENAL CYSTIC DISEASE
Autosomal Recessive Polycystic Kidney Disease
Autosomal Dominant Polycystic Kidney Disease
Multicystic Renal Dysplasia
Nephronophthisis and Medullary Cystic Disease
Congenital Renal Cysts
Tuberous Sclerosis and Von Hippel–Lindau Disease
Acquired Cysts
RENAL TUMORS
Wilms Tumor
Mesoblastic Nephroma
Renal Cell Carcinoma
Angiomyolipoma
Multilocular Cystic Nephroma
Renal Lymphoma
Bladder Tumors
PEDIATRIC ADRENAL SONOGRAPHY
Normal Anatomy
Congenital Adrenal Hyperplasia
Neonatal Adrenal Hemorrhage
Neuroblastoma
Pheochromocytoma
Adrenocortical Neoplasm

PEDIATRIC URINARY TRACT SONOGRAPHY

Technique

Sonography plays a major role in the evaluation of the pediatric urinary tract and adrenal glands. Ultrasound examination of the pediatric urinary tract should include imaging of the kidneys, ureters (if visualized), and urinary bladder. For most patients, no special preparation is required. The child's parents are asked to bring the patient for the study with a full urinary bladder when a study is performed for evaluation of hematuria or urinary tract stones (Table 52.1). These children are requested to drink fluids during the hour before the examination. Patients scheduled for renal Doppler examination should have nothing to eat or drink (NPO) before the study for a time period determined according to patient age. For a young child who is not yet toilet-trained, the bladder should be checked first and frequently because it may fill and empty suddenly.

Although children vary in their ability to hold still, sedation is rarely needed. Infants younger than 1 year can be fed or given a pacifier during the examination. The patient older than 1 year can be distracted or entertained by watching movies, playing with toys, or reading a book. The addition of cine clips often compensates for movement of the child.

A variety of ultrasound equipment can be used. The highest frequency transducer that will penetrate the area being examined is optimal. Harmonic imaging may aid in visualization of the difficult-to-scan patient. Different types of transducers are used for different parts of the body. Scans of the kidneys from the back are best performed with a linear or curved linear transducer, whereas frontal scans of the kidney are best performed with a curved linear or sector transducer that penetrates between the ribs. Views of the bladder are obtained with a curved linear transducer. The ureters are evaluated as they leave the renal pelvis and enter the bladder. Images are recorded and stored on digital media.

Routine examination includes longitudinal and transverse views of both kidneys (Fig. 52.1). In the pediatric patient, the kidneys are imaged in the supine and prone positions. The supine sagittal or coronal image allows optimal visualization of the upper pole, which may be obscured by ribs in the prone position. The echogenicity of the kidney should always be compared with the adjacent liver and spleen. Decubitus positioning is helpful to visualize the upper pole for measurement when the upper kidney is obscured by the ribs. The prone image allows optimal visualization of the lower pole of the kidney, but the upper pole may be obscured by overlying ribs or aerated lung in the costophrenic angle. **Kidney volumes** can be determined by obtaining a transverse image through the midkidney and measuring its anteroposterior (AP) and transverse dimensions (see Fig. 52.1C). The formula for determining the volume of a prolate ellipsoid is used:

$$\text{Kidney volume} = \text{Length} \times \text{Width} \times \text{Height} \times 0.523$$

Normal sonographic measurements of **renal length** and volume in comparison to patient age, height, weight, and/or body surface area have been determined and are useful in evaluation of the abnormal kidney[1-6] (Fig. 52.2, Tables 52.2, 52.3, 52.4, and 52.5). Length and volume data for single functioning kidneys in children have also been reported.[7,8] Compensatory renal growth of a single functional kidney occurs in utero, and its relative size difference

TABLE 52.1 Patient Preparation for Urinary Tract Ultrasound

Indication	Preparation
Hematuria	Full bladder
Urinary tract stones	Full bladder
Renal Doppler examination	NPO for time period determined according to age <1 year of age: NPO for 2 hours >1 year and <5 years of age: NPO for 4 hours ≥5 years of age: NPO for 6 hours
All other indications	None

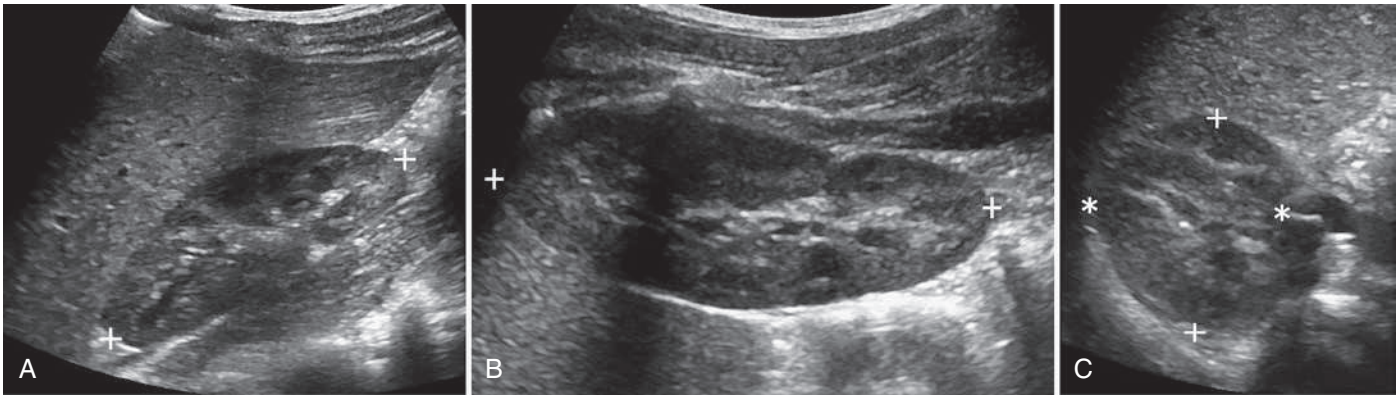

FIG. 52.1 Renal Length and Volume. (A) Longitudinal supine image. **(B)** Longitudinal prone image. Length measurements are obtained from either the supine or prone view (+). **(C)** Transverse image through the midkidney with anteroposterior height (+) and width (*) measurements (volume = length × width × height × 0.52).

With permission from Vujic A, Kosutic J, Bogdanovic R, et al. Sonographic assessment of normal kidney dimensions in the first year of life—a study of 992 healthy infants. Pediatr Nephrol 2007;22(8):1143-1150.[3]

continues throughout infancy and childhood (Table 52.6). Renal size in premature infants has also been compared with gestational age or birth weight[9-12] (Fig. 52.3). In patients with chronic problems, such as recurrent urinary tract infection (UTI), reflux, or neurogenic bladder, renal growth can be monitored on follow-up examinations.

Doppler ultrasound of the kidneys is performed in select patients when renal arterial or venous disease is suspected, using techniques similar to those employed in adults (see **Renal Vascular Disease** below).

Longitudinal and transverse views of the urinary bladder are obtained in both distended and postvoid states. Images are obtained with a convex linear transducer using the highest frequency that will penetrate the patient. Harmonic imaging may be useful to minimize artifacts. Bladder volume may be determined on longitudinal and transverse views of the urinary bladder when maximally but comfortably distended (Fig. 52.4). Because the bladder varies in shape, various formulas have been suggested to calculate its volume.[13,14] The most commonly used method calculates bladder volume using the formula for determining the volume of a prolate ellipsoid, noted earlier.

Bladder wall thickness in children has been evaluated in only a few studies using different techniques and leading to somewhat different results and conclusions.[15,16] A retrospective study by Jequier and Rousseau[16] measured the wall posterolateral to the trigone on transverse or sagittal images in 410 children and 10 adults whose bladders were filled to a variable degree. They determined that the normal mean wall thickness is 2.8 mm when the bladder is almost empty, and 1.5 mm when it is distended. There was a linear relationship between bladder fullness and wall thickness, with upper limits of 3 mm and 5 mm for a full or empty bladder, respectively. In a more recent prospective study of children with full bladders by Uluocak and colleagues,[15] thickness measurements were obtained from the anterior, posterior, and lateral walls. Mean anterior, posterior, and lateral wall thicknesses were 1.4 mm (range 0.8-2.8), 1.6 mm (range 0.7-3.1),

and 1.5 mm (range 0.6-2.6), respectively. Strong positive correlations were found between anterior and posterior wall thickness and increased age and body mass index (BMI). However, in contrast to the study of Jequier and Rousseau, there was no correlation between bladder volume and anterior or posterior wall thickness. Further studies are required in order to better delineate the effects of measurement technique as well as patient age, height, and BMI on bladder wall thickness.

Scans of the bladder are best performed with the bladder comfortably full so that abnormalities, including wall thickening and trabeculation, can be seen. Dilation of the distal **ureters** and **ureteroceles** is also sought. The thickness of the bladder wall may be increased with inflammation or muscular hypertrophy. Postvoid views of the bladder and kidneys may be helpful in patients with a **neurogenic bladder** or **dilated upper collecting system,** because a distended bladder may cause increased dilation but improve after voiding.

Color Doppler sonography is used in selected clinical situations to evaluate the ureteral jets[17,18] (Fig. 52.5).

Normal Renal Anatomy

Throughout the second trimester, the fetal kidney consists of a collection of renunculi (small kidneys), each composed of a central large pyramid with a thin peripheral rim of cortex. As the renunculi progressively fuse, their adjoining cortices form a **column of Bertin.** The former renunculi are then called "lobes." Remnants of these lobes with incomplete fusion are recognized by a lobulated surface of the kidney. This **"persistent fetal lobulation"** (Fig. 52.6) should not be confused with renal scarring[19] and may persist into adulthood.[20] Fetal lobulation is distinguished from scarring by the presence of a smooth renal contour, regular spacing, and absence of calyceal blunting. The indentations spare the renal pyramids, unlike scarring, in which the renal parenchyma overlying the pyramids appears thinned.

The **renal junctional parenchymal defect** (interrenicular septum or fissure) is the most prominent of these grooves, extending from the hilum to the cortex, and is caused by perirenal fat adherent to the renal capsule along a cleft on the renal surface. It is frequently seen in the anterosuperior aspect of the kidney[20] (Fig. 52.7). At birth, the pyramids are still large and hypoechoic compared with the thin rim of echogenic cortex that surrounds them. Glomerular filtration rate shortly after birth is low and increases rapidly after the first week postpartum. Throughout childhood, there is significant growth of the cortex, and the pyramids gradually become proportionately smaller.

The anatomy and sonographic appearance of the pediatric kidney depend on age.[5,21,22] The **normal infant kidney** has several features that differ from the normal adult kidney (Fig. 52.8). The

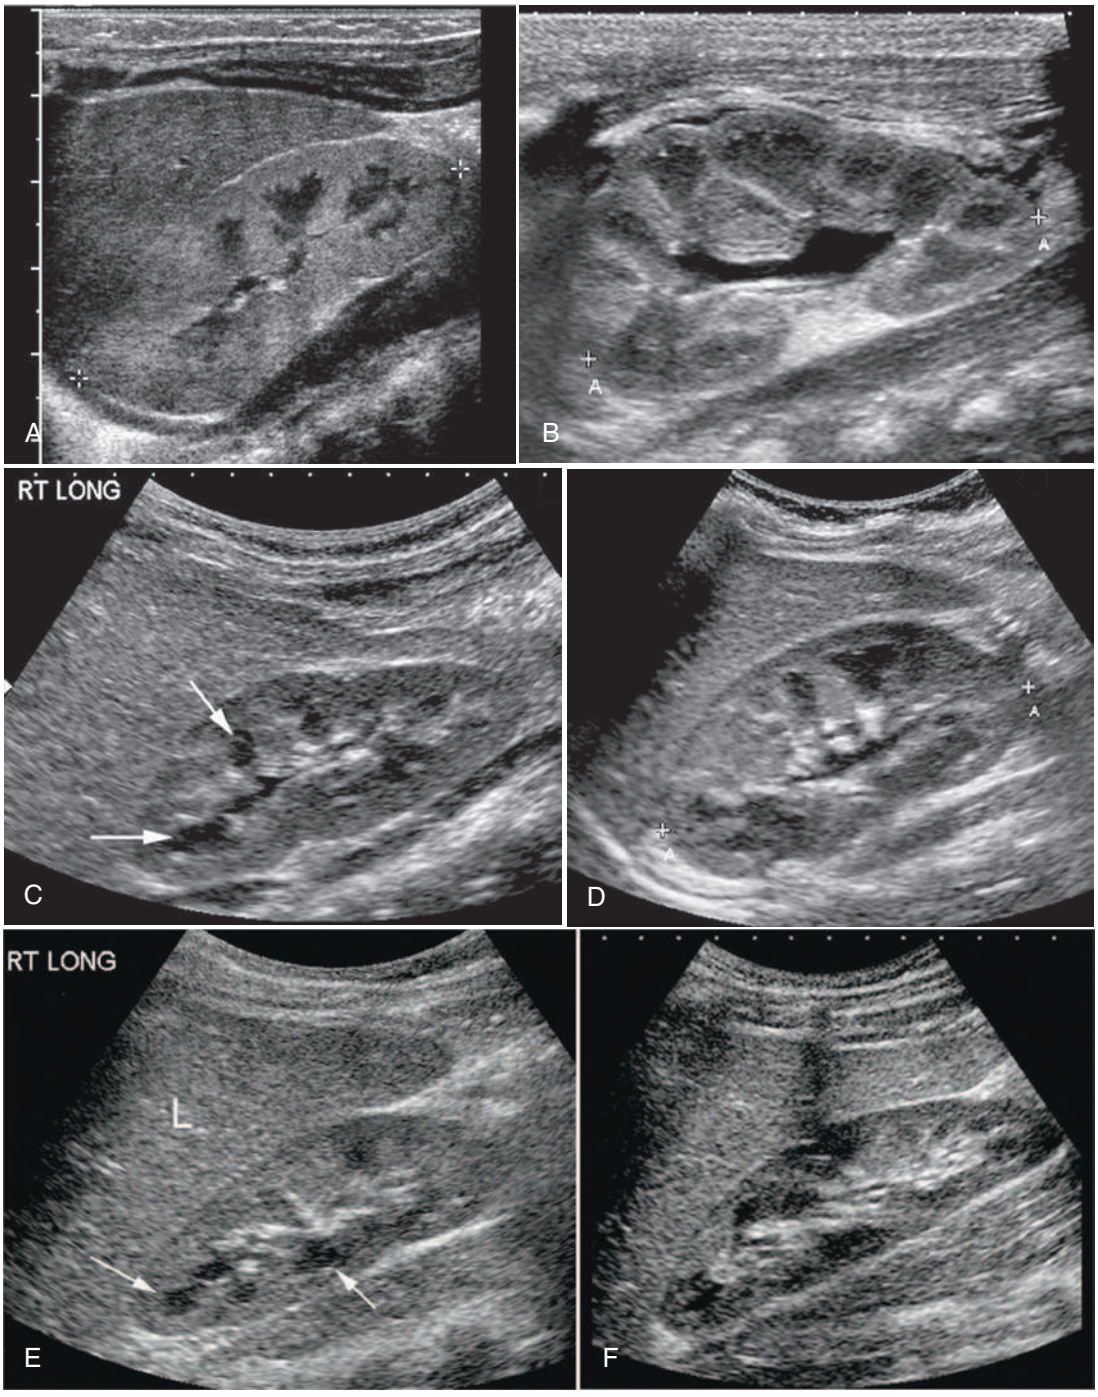

FIG. 52.8 Normal Renal Appearances at Different Ages. (A) Premature infant. Cortex is prominent and more echogenic than the liver. Prominent hypoechoic renal pyramids. **(B) Term infant.** Normal fetal lobulations of renal cortex are isoechoic or slightly hyperechoic to liver and spleen. Prominent renal pyramids are hypoechoic. **(C) Term infant.** Central echo complex is not prominent because of less peripelvic fat. Renal cortex equals the liver in echogenicity. Medullary pyramids *(arrows)* are relatively larger and appear more prominent. **(D) Two-year-old child.** Renal cortex is slightly less echogenic than liver. Renal sinus fat begins to develop central echogenicity around vessels. **(E) Ten-year-old child.** Normal cortex is less echogenic than liver *(L)* or spleen. Medullary pyramids *(arrows)* are relatively hypoechoic around the central echo complex of strong specular echoes. **(F) Fourteen-year-old child.** Renal cortex is less echogenic than liver or spleen. Pyramids are much less prominent. Renal sinus fat is increased.

central echo complex is much less prominent compared with the renal parenchyma because there is less peripelvic fat in the infant than in the adult. Renal cortical echogenicity is typically increased in the **normal premature infant kidney** compared with the liver and spleen. The echogenicity of the renal cortex in the **normal term infant kidney** is often the same as the echogenicity of the adjacent normal liver, whereas in the **older child and adult kidney,** the renal cortex is less echogenic than the liver. The medullary pyramids in the infant are relatively larger and tend to appear more prominent (more hypoechoic). The corticomedullary differentiation is greater in the infant and child's kidney than in the adult, possibly because of increased resolution from higher frequency transducers and less overlying body fat tissue. It may also result from differences in the cellular composition of the renal parenchyma in the infant. These prominent pyramids in the pediatric kidney can easily be mistaken for multiple cysts or dilated calyces by those not familiar with the differences. Normal pyramids line up around the central echo complex in a characteristic pattern and can therefore be differentiated from cysts. The position of the arcuate artery at the corticomedullary junction can also help to identify a structure as a pyramid.

Renal anatomy in the teenager and older child is similar to that in the adult[5,21,22] (see Fig. 52.8). The renal parenchyma consists of the cortex, which is peripheral, contains the glomeruli, and has several extensions to the edge of the renal sinus (the septa or column of Bertin); and the medulla (containing the renal pyramids), which is more central and adjacent to the calyces. The normal cortex produces low-level, backscattered echoes. The medullary pyramids are relatively hypoechoic and arranged around the central, echo-producing renal sinus. The arcuate vessels can be demonstrated as intense specular echoes at the corticomedullary junction. This corticomedullary differentiation can be identified in most children but occasionally cannot be visualized in those with increased overlying soft tissues. The central echo complex consists of strong specular echoes from the renal sinus, including the renal collecting system, calyces and infundibula, arteries, veins, lymphatics, peripelvic fat, and part of the renal pelvis. With distention of the renal collecting system, these echoes become separated and small degrees of hydronephrosis can be demonstrated. Mild degrees of distention can be seen in normal children, particularly after recent high intake of fluids or diuretics. A normally distended urinary bladder can also cause functional ureteral obstruction and mild distention of the renal collecting systems. Rescanning when the bladder is empty will usually result in resolution of both collecting system and ureteral distention in an otherwise normal urinary tract.

Normal Bladder Anatomy

The normal urinary bladder is thin walled. Bladder volume and wall thickness are influenced by the degree of bladder distention.[15,16] The distal ureters may be visible at the bladder base, especially if the child is well hydrated, likely related to the normal transient passage of urine associated with peristalsis (Fig. 52.9). Bladder wall thickness may increase with inflammation or muscular hypertrophy.

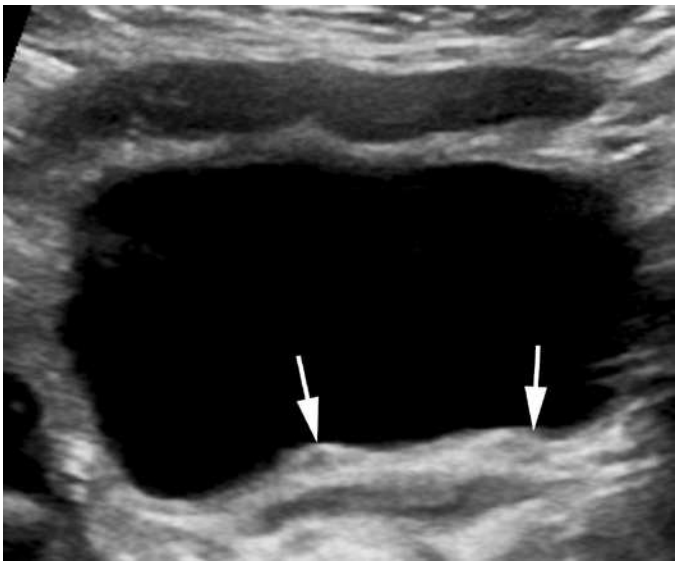

FIG. 52.9 Normal Distal Ureters. Transverse bladder image depicts distal ureteral insertions at the level of the trigone *(arrows)*.

CONGENITAL ANOMALIES OF THE URINARY TRACT

Renal Duplication

A common congenital anomaly of the urinary tract is duplication of the collecting system, which may be partial or complete. In complete duplication, two pelves and two separate ureters drain the kidney. The lower-pole ureter usually inserts into the bladder at the normal site. However, the intramural portion of the ureter may be shorter than usual, and vesicoureteral reflux (VUR) frequently results.[23] The upper-pole ureter often inserts ectopically, inferior and medial to the site of the normal ureteral insertion **(Weigert-Meyer rule).** Its orifice may be stenotic and obstructed. Ballooning of the submucosal portion of this upper-pole ureter causes a **ureterocele.** In some patients, the upper-pole ureter may have an insertion entirely outside the bladder including the urethra (above, at, or below the external urinary sphincter), in the uterus or vagina, or in the ejaculatory duct, seminal vesicle, or vas deferens.[24]

Patients with unobstructed duplications have no more clinical problems than their normal counterparts. Patients with complicated renal duplications may have UTI, failure to thrive, abdominal mass, hematuria, or symptoms of bladder outlet obstruction from a ureterocele. Female patients with urethral insertion of the upper-pole ureter below the external urinary sphincter or with vaginal or uterine insertion may have chronic, constant urinary incontinence or frequent dribbling.

Duplication of the renal collecting system is diagnosed on sonography when the central echo complex separates into two parts with an interposed column of normal renal parenchyma **(column of Bertin)** (Fig. 52.10). Unless collecting system dilation and/or ureteral dilation are present, it is usually impossible to distinguish a partial, uncomplicated duplication from a complete duplication because a normal ureter is difficult to visualize sonographically.[25]

With obstruction of an upper-pole moiety, dilation of the upper-pole collecting system and its entire ureter is seen. The renal parenchyma may be thinned over the upper-pole collecting system. If the obstruction is associated with a ureterocele, views of the bladder may demonstrate the ureterocele as a rounded, anechoic structure within the bladder in addition to the dilated distal ureter adjacent to the bladder (Fig. 52.11). A large ureterocele may cross the midline and obstruct the contralateral ureter or bladder outlet and cause bilateral hydronephrosis. Ureteroceles can be difficult to diagnose if they are large enough to mimic the bladder. If this is a concern, a postvoid scan will be diagnostic. With reflux into the lower-pole moiety, the lower-pole collecting system and its ureter will be dilated to a varying degree. If reflux is mild, there may be no lower-pole dilation.

Other Renal Anomalies

Other renal anomalies include congenital absence of the kidney, abnormal position of the kidney (e.g., pelvic kidney, crossed ectopia), and horseshoe kidney with fusion of the lower poles in the midline.[26] **Congenital absence of the kidney** or ectopia of the kidney is suspected when no renal tissue can be identified in the renal fossa on sonography. At birth, the adrenal gland will not present as the usual inverted V above the kidney but assumes a flat shape often called a **"lying-down adrenal"** (Fig. 52.12). Care must be taken to search for the kidney not only in its usual location in the renal fossa, but also in the lower abdomen or pelvis. The contralateral kidney, when healthy, shows compensatory hypertrophy when one kidney is absent or severely damaged. Nuclear scintigraphy may be helpful in identifying a small, functioning kidney not visualized by ultrasound.

With a **horseshoe kidney** the longitudinal axis of the kidneys is abnormal. The lower poles are rotated medially and will be fused in the midline anterior to the spine by a fibrous band or renal parenchyma (Fig. 52.13). The kidney is also positioned somewhat lower than usual. A horseshoe kidney can be overlooked if the abnormal renal axes are not recognized. The central fused renal tissue may also be thin and easily missed, particularly if it solely fibrous in nature.

Crossed renal ectopia is a rare congenital anomaly wherein both kidneys are located on the same side of the abdomen. There is at least some degree of fusion in approximately 90% of cases, with the usual pattern consisting of fusion of the orthotopic

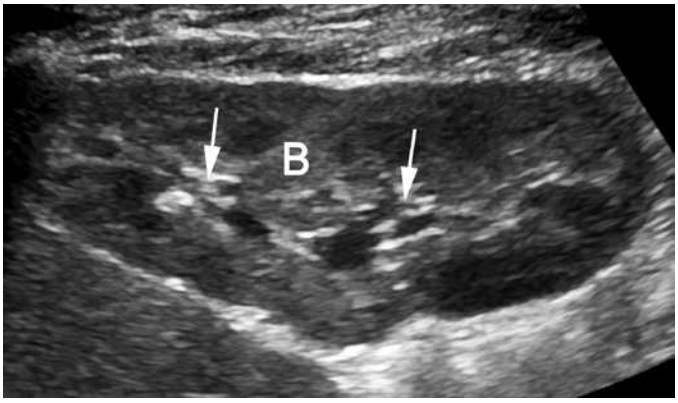

FIG. 52.10 Renal Duplication. Longitudinal prone image of the right kidney demonstrates normal renal parenchyma, a column of Bertin *(B)* dividing the central echo complex into two parts *(arrows)*.

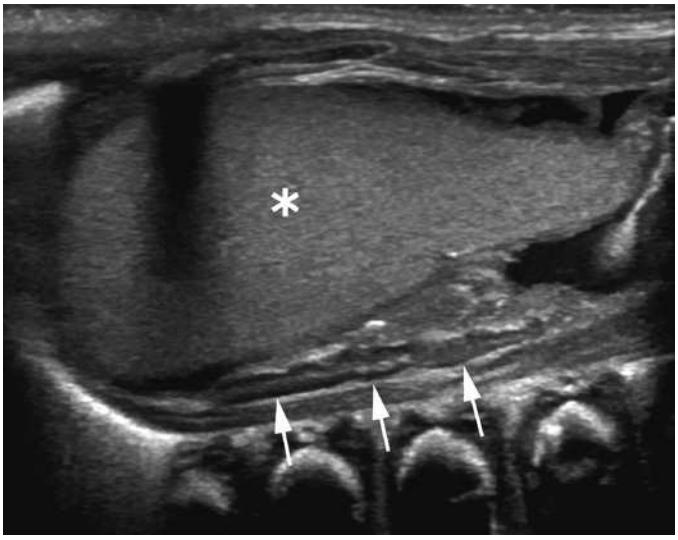

FIG. 52.12 "Lying Down" Adrenal Sign in a Neonate With Absence of the Left Kidney. Longitudinal image depicts an elongated and flattened adrenal gland *(arrows)* along the spine. *, Spleen.

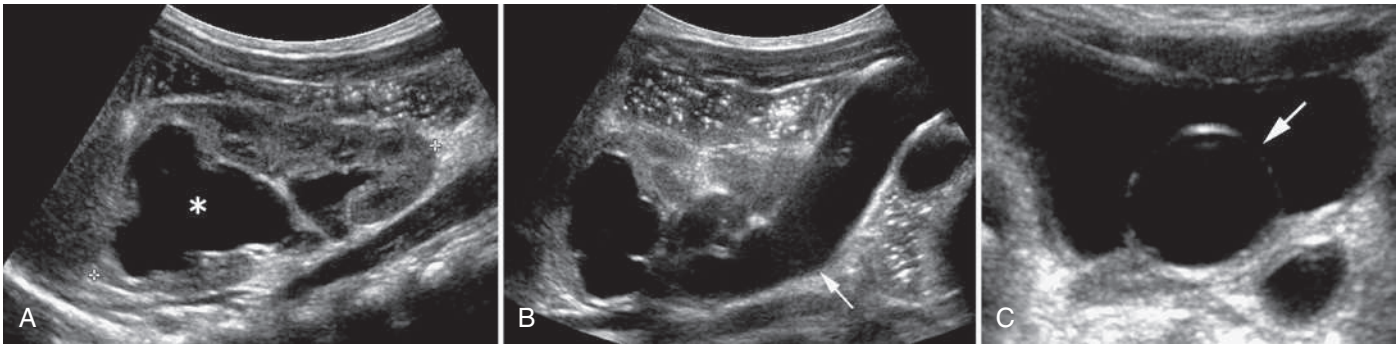

FIG. 52.11 Renal Duplication With Ectopic Ureterocele of Upper-Pole Moiety. (A) Longitudinal image of left kidney reveals dilation of the upper-pole collecting system (*) and less dilated lower-pole renal pelvis. **(B)** Longitudinal image of left flank depicts dilated upper-pole ureter *(arrow)* extending from renal pelvis. **(C)** Transverse bladder image shows **ureterocele** within the bladder *(arrow)*.

lower renal pole to the ectopic upper renal pole (Fig. 52.14, Video 52.1). The ureter of the ectopic kidney crosses the midline to insert normally within the bladder. Crossed renal ectopia is more frequent in boys than girls (male-to-female ratio is 1.4:1), and is two to three times more common on the right side than on the left.[27] As with other renal anomalies, crossed ectopia can be an incidental finding but is also associated with other congenital anomalies.[28]

Rarer patterns include crossed unfused ectopia and solitary or unfused bilateral crossed ectopy. Another pattern of combined ectopy and fusion of two pelvic kidneys is variably referred to as a **"pancake"** or **"cake"** kidney, depending on the extent of fusion and the resultant appearance. These more complex abnormalities can be isolated or associated with other congenital conditions.

CAUSES OF HYDRONEPHROSIS

Dilation of the renal collecting system—hydronephrosis—is a fairly common problem in the pediatric patient. It is frequently, but not always, associated with obstruction, and ultrasound is particularly sensitive for its detection. Investigation of a child with suspected hydronephrosis usually begins with sonography to evaluate the anatomy of the kidneys, ureters, and bladder.[29] The degree of functional obstruction is evaluated by diuretic renography.[30] If the obstruction is mild, the patient is followed because the obstruction and dilation often resolve as the patient grows older.[31,32]

Congenital hydronephrosis is almost always initially detected on fetal sonography and the infant referred for evaluation after birth. Fetal hydronephrosis may be due to obstruction, VUR, or a physiologic variant without obstruction.[33] Small amounts of fluid may be detected in the normal renal pelvis. However, dilation of the renal calyces is abnormal and suggests significant pathology. To make a more precise diagnosis and to estimate severity, information regarding renal length, parenchymal thickness and echogenicity, degree of pelvicalyceal and ureteral dilation, bladder wall thickness, and volume should be obtained with sonography.[31] Voiding cystourethrography (VCUG) and nuclear scintigraphy using technetium 99m (^{99m}Tc) mercaptoacetyltriglycine (MAG3) with furosemide (diuretic renography) are often performed for complete evaluation.[30,34]

Significant variation currently exists in the clinical management of infants and children with prenatally diagnosed urinary tract dilation (UTD) that is related to a lack of evidence-based information correlating the severity of prenatal dilation to postnatal urologic abnormalities. To address the perceived need for a unified classification system with a widely accepted terminology for the diagnosis and management of prenatal and postnatal UTD, a UTD classification system was devised in 2014 during a consensus meeting of eight medical societies concerned with the prenatal and postnatal diagnosis and management of UTD.[35,36] This grading system is correlated with the risk of postnatal uropathies and is based on six sonographic features: (1) anterior-posterior renal pelvic diameter (APRPD), (2) calyceal dilation with distinction between central and peripheral calyceal dilation postnatally, (3) renal parenchymal thickness, (4) renal parenchymal appearance, (5) bladder abnormalities, and (6) ureteral abnormalities. For prenatal studies, the seventh

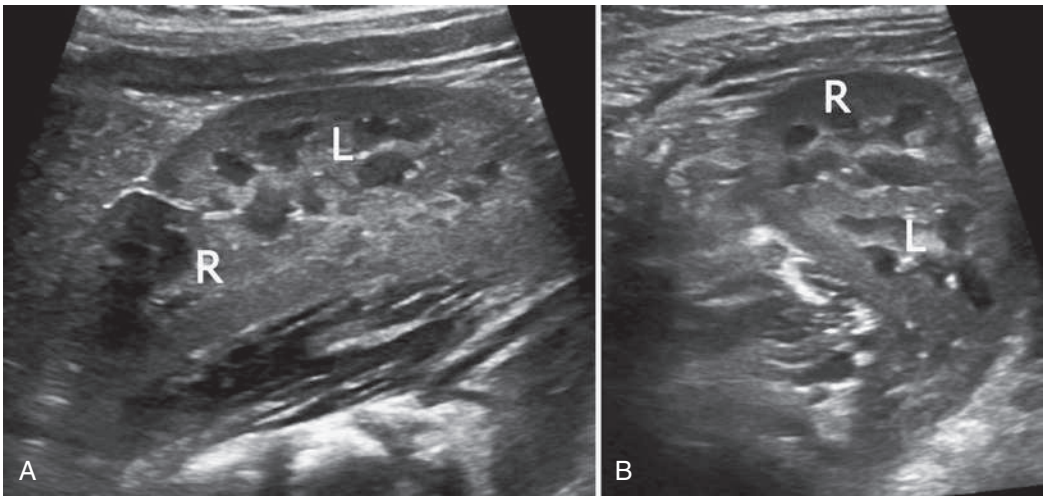

FIG. 52.14 Crossed Renal Ectopia. (A) Longitudinal and **(B)** transverse images of the right flank reveal fusion of the lower pole of the orthotopic right kidney *(R)* to the upper pole of the ectopic left kidney *(L)*. The left kidney is medially rotated. See also Video 52.1.

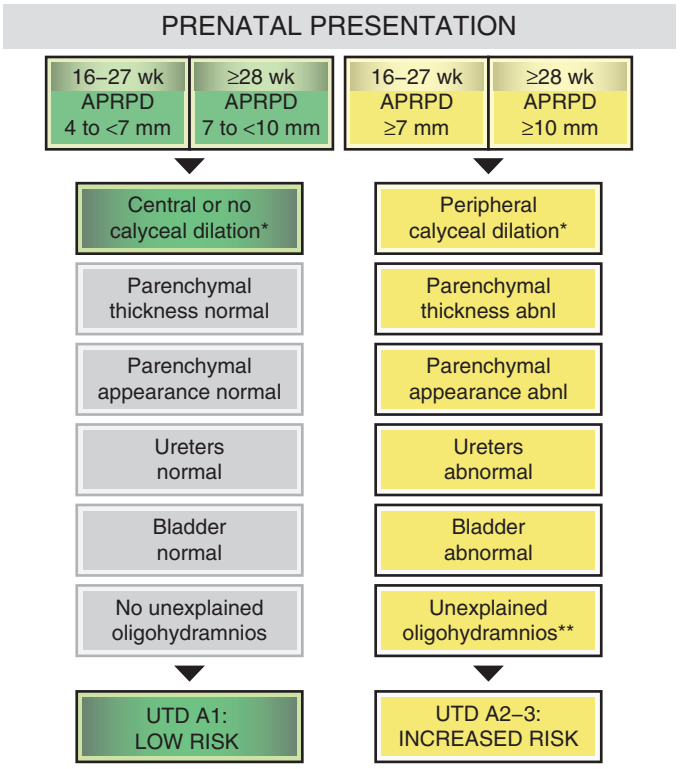

FIG. 52.15 Urinary Tract Dilation *(UTD)* Risk Stratification—Prenatal Presentation for UTD A1 (Low Risk) and UTD A2-3 (Increased Risk). Classification is based on the presence of the most concerning feature. *abnl,* Abnormal; *APRPD,* anterior-posterior renal pelvic diameter; *GU,* genitourinary. (With permission from Nguyen HT, Benson CB, Bromley B, et al. Multidisciplinary consensus on the classification of prenatal and postnatal urinary tract dilation [UTD classification system]. J Pediatr Urol. 2014;10[6]:982-998.[36])

sonographic finding to report is the quantity of amniotic fluid. Normal imaging parameters are also defined (Figs. 52.15 and 52.16). It is anticipated that future research will result in a refinement of this classification system that can be correlated with other clinical outcomes such as renal function and the need for surgical intervention.

Ureteropelvic Junction Obstruction

Ureteropelvic junction obstruction (UPJO) is the most common cause of significant prenatal hydronephrosis. It is usually results from a functional stricture at the ureteropelvic junction (UPJ) or a crossing lower-pole renal vessel. UPJO results in a functional disturbance in either the initiation or the propagation of normal peristaltic activity within the ureter. The obstruction produces proximal dilation of the renal collecting system. There is also an associated increased incidence of congenital anomalies of the contralateral kidney.

Ultrasound diagnosis of hydronephrosis is based on the presence of a dilated renal pelvis and caliectasis. A variable amount of renal parenchymal tissue can be visualized. The ureter is normal in size and is not usually visualized by ultrasound (Fig. 52.17).

Ureteral Obstruction

Congenital ureterovesical junction obstruction (UVJO) is a result of narrowing and aperistalsis of the distal ureter, or an ectopic insertion. With so-called **"primary megaureter"** the juxtavesicular ureter may be devoid of ganglion cells or may demonstrate muscular hypoplasia and/or mural fibrosis.[37-39] The submucosal tunnel and ureteral orifice are normal. There is a variable degree of dilation of the intrarenal collecting system and of the ureter proximal to the narrowing. Ultrasound typically shows hydronephrosis and hydroureter with a narrow segment of the distal ureter behind the bladder (Fig. 52.18). MAG3 diuretic renography

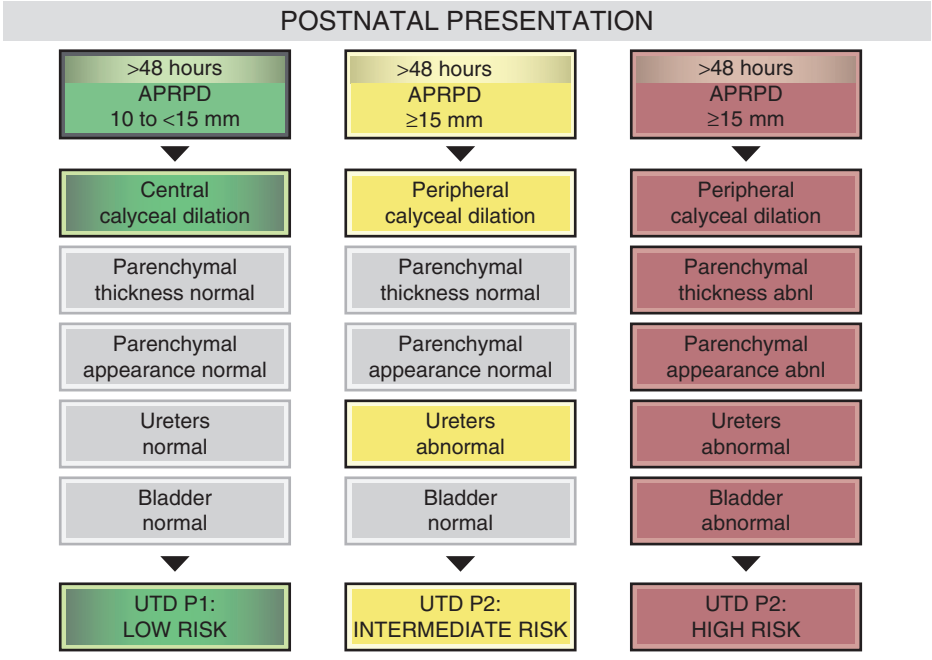

FIG. 52.16 Urinary Tract Dilation *(UTD)* Risk Stratification—Postnatal Presentation for UTD P1 (Low Risk), UTD P2 (Intermediate Risk), and UTD P3 (High Risk). Stratification is based on the most concerning ultrasound finding. *abnl,* Abnormal; *APRPD,* anterior-posterior renal pelvic diameter. (With permission from Nguyen HT, Benson CB, Bromley B, et al. is typically used to clarify whether the dilation is caused by obstruction.

An obstructed ureter can result from many causes. **Ectopic insertion of a ureter** can cause obstruction either with or without a ureterocele and may result in dilation of the more proximal collecting system and ureter, typically manifesting with ureteral duplication. The ureter can also be obstructed by an intraluminal abnormality, such as a stone, blood clot, or fungus ball. Increased peristalsis in the ureter proximal to the obstruction may be detected with real-time sonography. Doppler sonography may show a diminished or abnormal ureteral jet on the side of obstruction.[18,40,41] The ureter can also be obstructed anywhere along its course by extrinsic compression from a mass, such as a lymphoma or abscess. The exact site of obstruction may be difficult to visualize by ultrasound because of overlying bowel gas.

Bladder Outlet Obstruction

Bilateral hydronephrosis is frequently caused by obstruction at the level of the bladder or bladder outlet. Congenital obstruction due to **posterior urethral valves** (PUVs) results in an irregular, thick-walled bladder. PUV can occasionally be diagnosed by ultrasound, with demonstration of a dilated posterior urethra. Transperineal contrast-enhanced ultrasound (CEUS) diagnosis of PUV has also been described[42,43] (Fig. 52.19). However, VCUG should be performed for optimal visualization of the valves.

Patients with spinal dysraphism and hyperreflexive detrusor muscle activity will have a functional obstruction due to a neurogenic bladder that produces high bladder pressure during voiding. These patients may develop a thick-walled, trabeculated bladder[44] (Fig. 52.20, Video 52.2, Video 52.3, Video 52.4). Congenital anomalies of the spine should be sought with radiographs and spinal ultrasound in neonates, if not obvious clinically.

A pelvic mass that obstructs the bladder outlet, such as **rhabdomyosarcoma,** or less commonly, a **fibroepithelial polyp,** can also be associated with bilateral hydronephrosis and hydroureter.[45]

Vesicoureteral Reflux

Dilation of the renal collecting system is not always caused by obstruction, and other abnormalities, such as VUR, should be considered. In a child with hydronephrosis detected by ultrasound, the bladder size and contractility and the urethra should be further evaluated with VCUG. In addition, VUR can be diagnosed and may be the cause of the UTD.

Contrast-enhanced voiding urosonography is a safe, nonionizing, radiation-free alternative to the fluoroscopic VCUG that is used by experienced investigators in some centers throughout the world for the management of VUR. Its sensitivity is comparable to or greater than that of VCUG or radionuclide cystography in the diagnosis of VUR.[46] Published studies reporting use of this technique in the United States to date have been limited.[47,48] Contrast-enhanced voiding urosonography is performed after bladder catheterization and intravesical infusion of normal saline containing the ultrasound contrast agent. Sequential imaging of the bladder, kidneys, and urethra is performed during bladder filling and voiding. Ultrasound contrast-specific settings are used to image the microbubbles. Digital ultrasound still images as well as image clips are used for documentation purposes (see Fig. 52.20). The severity of VUR can be graded using a scale similar to the International Grading System used for conventional VCUG.[49] Patients with reflux are often treated endoscopically with a submucosal, subureteric injection of a bulking agent. Follow-up sonography of the bladder will depict the implants, which over time may undergo changes in size and shape as well as calcification[50,51] (Fig. 52.21). Paltiel and colleagues[52] showed that nonvisualization of the implant or a multilobed contour is associated with persistent reflux.

Prune-Belly Syndrome

Prune-belly syndrome, also known as **Eagle-Barrett syndrome,** is a rare congenital disorder that occurs almost exclusively in males and is thought to result from urethral obstruction early in development. Abnormalities include absence or deficiency of the abdominal musculature; large, hypotonic, dilated and tortuous ureters; a large bladder; a patent urachus bilateral cryptorchidism; and a dilated prostatic urethra. There are decreased muscular fibers throughout the urinary tract and prostate, resulting in dilation and hypoperistalsis. Renal dysplasia and hydronephrosis can occur to varying degrees. Associated malformations of the cardiopulmonary, gastrointestinal, and skeletal systems are common.[53]

Megacystis-Microcolon-Malrotation–Intestinal Hypoperistalsis Syndrome

Megacystis-microcolon-malrotation–intestinal hypoperistalsis syndrome (MMIHS), a rare syndrome, is an inherited, autosomal recessive disorder that falls on the spectrum of chronic intestinal pseudo-obstructive disorders, which includes **chronic adynamic ileus, hypoganglionosis, Hirschsprung disease, intestinal neuronal dysplasia, and total colonic aganglionosis.** It is more common in girls than boys. Presentation is usually in the neonatal period, although the diagnosis can also be suspected on prenatal sonography.[54] Typical clinical features include abdominal distention, hypoactive or absent bowel sounds, and an inability to void spontaneously. A markedly dilated, nonobstructed bladder, a microcolon, and decreased or absent intestinal peristalsis are characteristic findings. Other frequent abnormalities include hydroureteronephrosis, VUR, intestinal malrotation, and a shortened bowel. Although the exact etiology has not yet been elucidated, smooth muscle myopathic changes have been demonstrated at pathology. Marked abnormality of the detrusor muscle of the bladder results in voiding dysfunction.[55] Most patients with MMIHS eventually succumb to sepsis, malnutrition, or multiorgan failure. Recurrent UTIs result from the need for chronic bladder catheterization. Intestinal function is resistant to surgical intervention. Children who survive beyond the neonatal period require long-term total parenteral nutrition (TPN), which eventually results in TPN-associated chronic liver disease. Transplantation is currently the only successful management option for those patients who cannot tolerate TPN. The

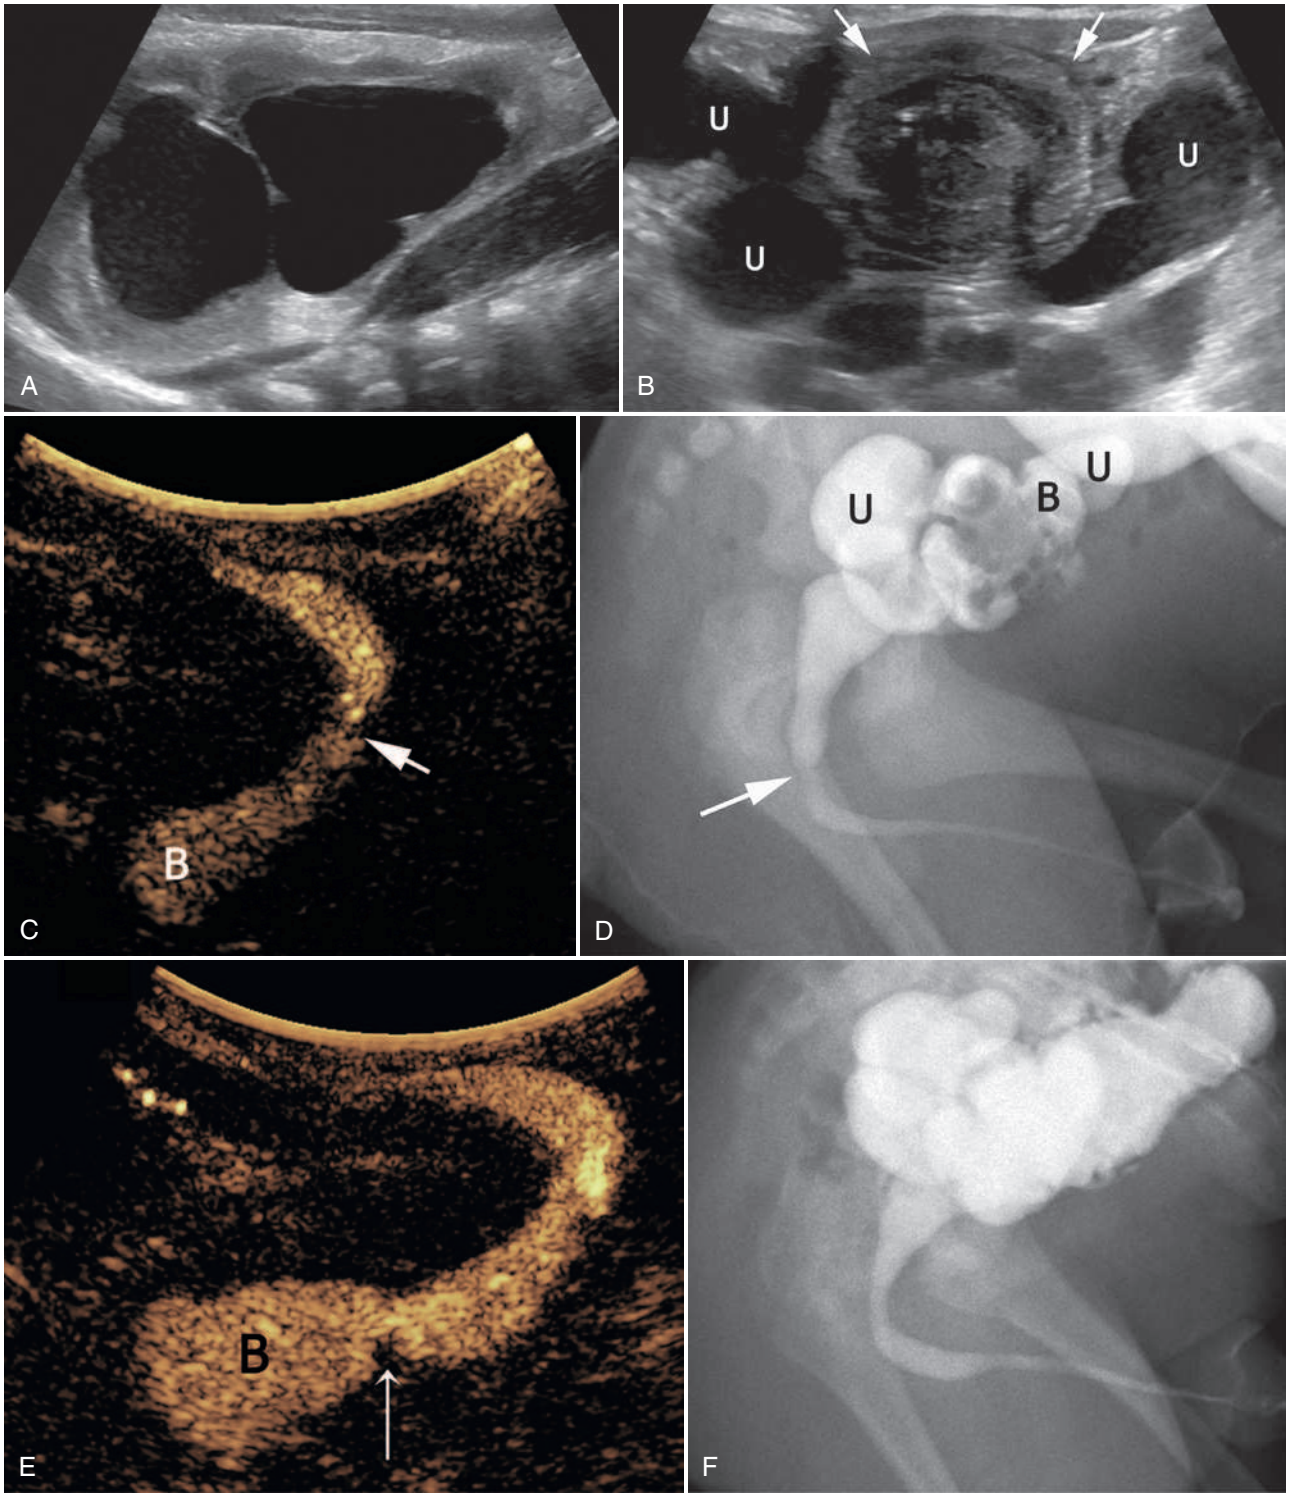

FIG. 52.19 Bilateral Hydronephrosis Secondary to Posterior Urethral Valves. (A) Longitudinal image of kidney shows hydronephrosis, which was present bilaterally. **(B)** Transverse image of the pelvis reveals thick-walled bladder *(arrows)* and tortuous, dilated ureters *(U)*. **(C)** Transperineal contrast-enhanced ultrasound image and **(D)** voiding cystourethrogram demonstrate dilated posterior urethra with indentation at the site of the obstructing valves *(arrows)*. *B,* Bladder; *U,* ureter. **(E)** Postoperative transperineal contrast-enhanced ultrasound image and **(F)** Postoperative voiding cystourethrogram reveal improvement in urethral contour.

appropriate choice of transplant is dictated by the presence or absence of coexistent TPN-related chronic liver disease or chronic kidney failure resulting from urologic disease.[56] These options include isolated intestinal transplantation, combined liver-intestinal transplantation, and multivisceral transplantation.

Bladder Exstrophy

Bladder exstrophy is a rare congenital malformation characterized by an infraumbilical abdominal wall defect, incomplete bladder closure with mucosal continuity with the anterior abdominal wall, epispadias, and associated abnormalities of the pelvic bones and musculature. This disorder is a component of the **exstrophy-epispadias complex,** with epispadias at the mild end of the spectrum and cloacal exstrophy at the severe end. Bladder exstrophy is the most common of these abnormalities and occurs most often in boys.[57] Clinical features include bladder eversion, epispadias, wide diastasis of the pubic bones, and anterior displacement of the anus as a result of muscular deficiency. In boys, the penis will be shortened with wide separation of the corporal attachments and dorsal curvature. In girls, there is a bifid clitoris. The ureters have a low bladder insertion with a characteristic J-shaped course due to an enlarged pouch of Douglas that displaces the ureters inferolaterally. Unless ureteral reimplantations are performed, these patients will all develop VUR after exstrophy closure.[57]

Modern staged repair of bladder exstrophy is a two-step process in girls and a three-step process in boys. In stage I, the bladder and abdominal wall defects are closed in both sexes 48 to 72 hours after birth, with epispadias repair only in girls. If the pubic diastasis is greater than 4 cm or the malleability of the pelvis is poor, iliac osteotomies may be performed at this time. In stage II, the male urethra is closed, usually between 6 and 12 months of age. In stage III, bladder neck reconstruction and bilateral ureteral reimplantation are performed, generally at 4 to 5 years of age, when the child can take part in a voiding program.[58]

After repair, the bladder will appear small on ultrasound imaging with irregular contours and a thickened wall. The kidneys generally have a normal appearance, although hydronephrosis may occur as a result of VUR, bladder outlet obstruction, or urethral stricture. Renal scarring can develop from recurrent pyelonephritis or obstructive uropathy after bladder neck reconstruction.

Bladder augmentation using a segment of bowel is an option for children who cannot undergo bladder neck reconstruction because of a low bladder capacity, abnormal bladder compliance, or incontinence.[59] Ileocystoplasty is the most popular choice, although other bowel segments can be used. By ultrasound, the augmented bladder segment will be identified superior to the native bladder, and will demonstrate an undulating contour. The characteristic "gut signature" of the augmented segment is readily identified[59] (Fig. 52.22). Echogenic intraluminal mucus or debris is often noted.

Urachal Anomalies

The fetal urachus is a tubular structure extending from the umbilicus to the bladder. It normally closes by birth, and a urachal remnant may be visible as a hypoechoic, elliptical mass on the anterosuperior aspect of the bladder (Fig. 52.23). A **patent urachus** is present if there is a complete tubular connection from the bladder to the skin surface at the umbilicus (about 50%), or only a portion may be open as a blind-ending **urachal sinus** arising either from the bladder dome (**vesicourachal diverticulum,** about 3%-5%, Fig. 52.24) or from the umbilicus (umbilicourachal sinus, about 15%). When only the midportion of the urachus remains patient, a **urachal cyst** is the result (about 30%)[60] (Fig. 52.25).

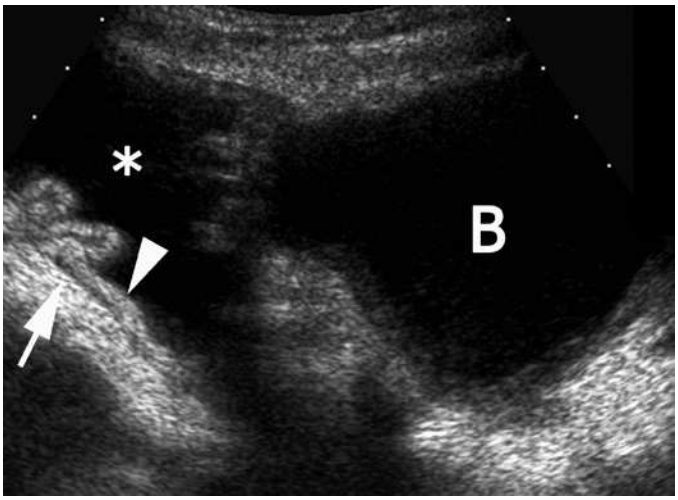

FIG. 52.22 Sigmoid Cystoplasty in Patient With History of Bladder Exstrophy. Longitudinal image demonstrates bladder *(B)* with augmented segment located superiorly (*). Note the undulating contour of the augmented segment with the outer hypoechoic muscular layer *(arrow)* and the inner hyperechoic layer of bowel mucosa *(arrowhead)*.

The literature is inconclusive on how to manage pediatric urachal lesions, especially those discovered incidentally. Both the therapeutic and the prophylactic value of surgical resection are ill defined. A recent retrospective review of 721 patients by Gleason and colleagues concluded that urachal anomalies are more common than previously reported, and that children with asymptomatic lesions do not appear to benefit from prophylactic excision, as the risk of malignancy later in life is remote.[61]

URINARY TRACT INFECTION

UTI is a common clinical problem in children and a frequent indication for renal sonography. The imaging workup of the child with a UTI is usually performed after the first culture has documented infection in an infant or child. The purpose of the workup is to identify congenital anomalies, obstruction, and other abnormalities that may predispose the patient to infection. Sonography of the urinary tract, including the kidneys and bladder, is used for initial screening. VCUG is indicated after a first UTI only if ultrasound reveals hydronephrosis, scarring, or other abnormalities suggestive of high-grade VUR or obstructive uropathy or in patients with complex clinical conditions. VCUG is also recommended if there is a recurrence of a febrile UTI.[62]

In most centers in the United States, conventional fluoroscopic VCUG is performed for evaluation of the bladder and urethra

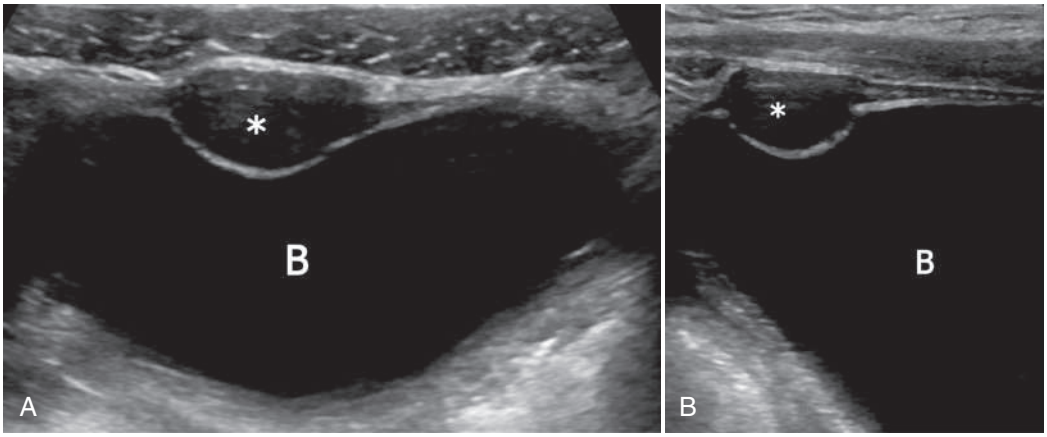

FIG. 52.23 Urachal Remnant. (A) and **(B)** Transverse and longitudinal images depict the hypoechoic, elliptical urachal remnant (*) in the anterosuperior bladder wall. *B,* Bladder.

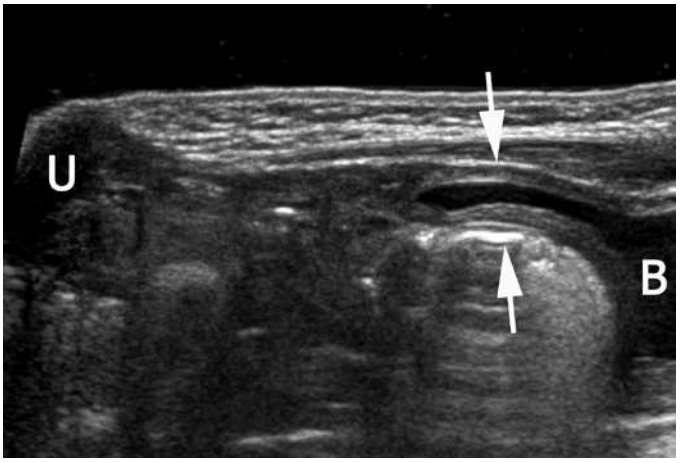

FIG. 52.24 Vesicourachal Diverticulum. Longitudinal image reveals a diverticulum *(arrows)* arising from the bladder dome and extending superiorly. *B,* Bladder; *U,* umbilicus.

and to detect the presence of VUR. Nuclear cystography can also be used for diagnosis of VUR and is associated with a lower radiation dose to the gonads in boys. In some centers nuclear cystography is used as the initial study for girls with normal renal and bladder sonograms, because girls rarely have urethral abnormalities. Some centers also use it to follow reflux in all children. At Boston Children's Hospital, we recently introduced contrast-enhanced VCUG and plan to eventually pilot its use in the follow-up of patients with prior VCUG documentation of VUR, as an initial imaging study in selected patients with normal ultrasound imaging of the kidneys and bladder, and in patients whose parents have serious concerns about radiation exposure (see Fig. 52.20, Video 52.2, Video 52.3, Video 52.4).

Diuretic renography with MAG3 can be performed to differentiate between obstructive and nonobstructive causes of renal or ureteral dilation, and to assess renal function.[30,63] Renal nuclear scintigraphy with ^{99m}Tc dimercaptosuccinic acid (DMSA) is extremely sensitive for demonstrating focal areas of inflammation and parenchymal scarring. Although mild scarring may be missed with sonography, power Doppler sonography increases the sensitivity of scar detection.[64,65] Because mild scars do not alter the course of therapy, the radiation dose of a renal cortical scan is not required[66-69] and the increased time and expense of Doppler sonography may also be avoided.

Acute Pyelonephritis

Acute pyelonephritis is one of the most serious bacterial illnesses of childhood. It may be diagnosed clinically in patients with a sudden onset of fever, flank pain, costovertebral angle tenderness, and microscopic evidence of urinary infection. VUR is clearly a risk factor for the development of acute pyelonephritis, which often starts as an ascending infection from the bladder. It can also occur by hematogenous spread. In infants, symptoms are often ambiguous, and fever is not always helpful in identifying patients at risk for complications of acute pyelonephritis such as sepsis and meningitis.[70,71]

In general, there are few findings of acute pyelonephritis on conventional gray-scale sonography. There may be swelling of the infected kidney and altered renal parenchymal echogenicity from edema causing triangular areas of increased echogenicity or rounded hypoechoic zones. **Focal pyelonephritis** can appear sonographically as a localized mass with abnormal echogenicity compared with the remainder of the kidney and loss of corticomedullary differentiation (Fig. 52.26). There may be thickening of the wall of the renal pelvis and ureter, also caused by edema and inflammation[72] (Fig. 52.27). Sequential examinations of these focal infected areas will typically demonstrate a rapid change, with resolution of the mass in response to antibiotic therapy.

Power Doppler sonography, DMSA scintigraphy, computed tomography (CT), and magnetic resonance imaging (MRI) may all show absent or decreased perfusion in a diffuse or lobar distribution, especially in the upper or lower poles.[73] CEUS has also been used to identify adults with acute pyelonephritis,[74] but there have been no reports yet regarding its use in children. When patients with UTIs do not respond rapidly to antibiotic therapy, repeat sonographic and/or CT examinations are indicated to search for complications that require drainage.

Acute lobar nephronia is a localized, nonliquefactive, severe interstitial bacterial infection of the renal parenchyma. Sonography

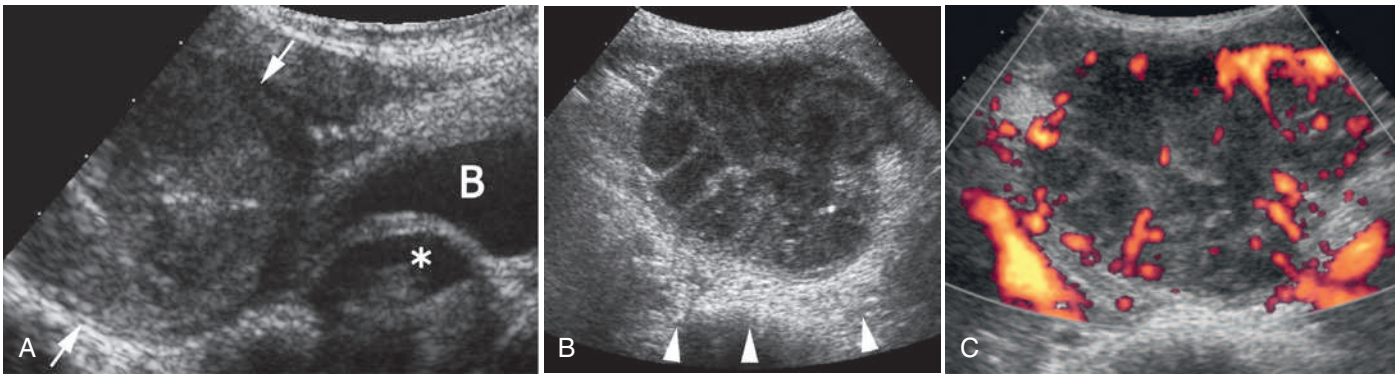

FIG. 52.25 Infected Urachal Cyst. (A) Longitudinal image shows a complex, lobulated mass *(arrows)* adjacent to the superior aspect of the bladder *(B)*. *, Free pelvic fluid. **(B)** Transverse image of the mass depicts increased through transmission of sound *(arrowheads)* in keeping with the fluid nature of the lesion. **(C)** Color Doppler image depicts hyperemia at the periphery of the lesion indicative of its inflammatory nature.

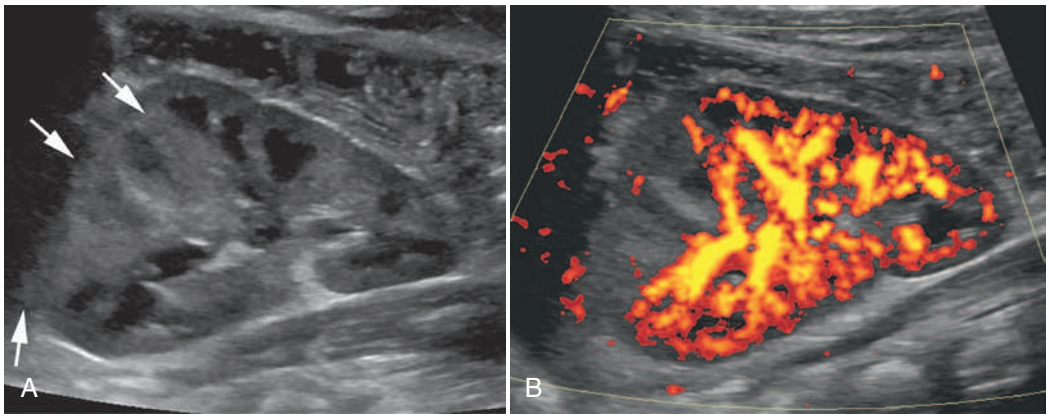

FIG. 52.26 Acute Pyelonephritis in 2-Month-Old Girl. (A) Longitudinal image demonstrates a swollen, echogenic upper pole with loss of normal corticomedullary differentiation *(arrows)*. **(B)** Power Doppler sonography reveals markedly diminished blood flow in this region.

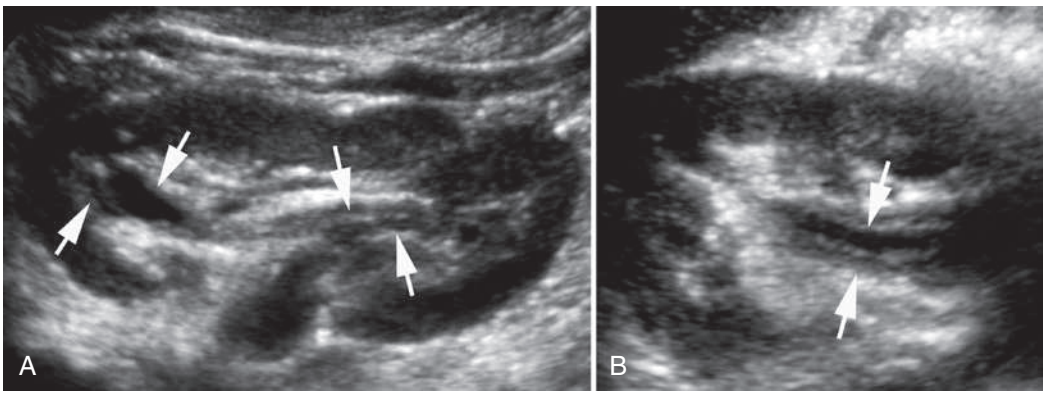

FIG. 52.27 Thickening of the Renal Pelvic Wall. (A) and **(B)** Longitudinal and transverse images demonstrate thickening of the renal pelvic wall *(arrows)*, which can occur as a result of inflammation or reflux, as well as after relief of obstruction.

may demonstrate a focal mass of variable echogenicity with ill-defined borders. CT is considered a more sensitive and accurate imaging modality for the diagnosis of acute lobar nephronia. Affected patients have a more protracted clinical course than those with acute pyelonephritis, and there is a higher incidence of renal scarring.[75] If response to antibiotic therapy is inadequate, the mass may liquefy centrally and become a renal abscess that requires drainage. Sonography of an abscess shows a focal mass with a hypoechoic central area representing liquefied pus (Fig. 52.28).

Another potential complication of acute pyelonephritis that requires drainage is pyonephrosis, which appears on sonography as echogenic material filling a dilated collecting system (Fig. 52.29).

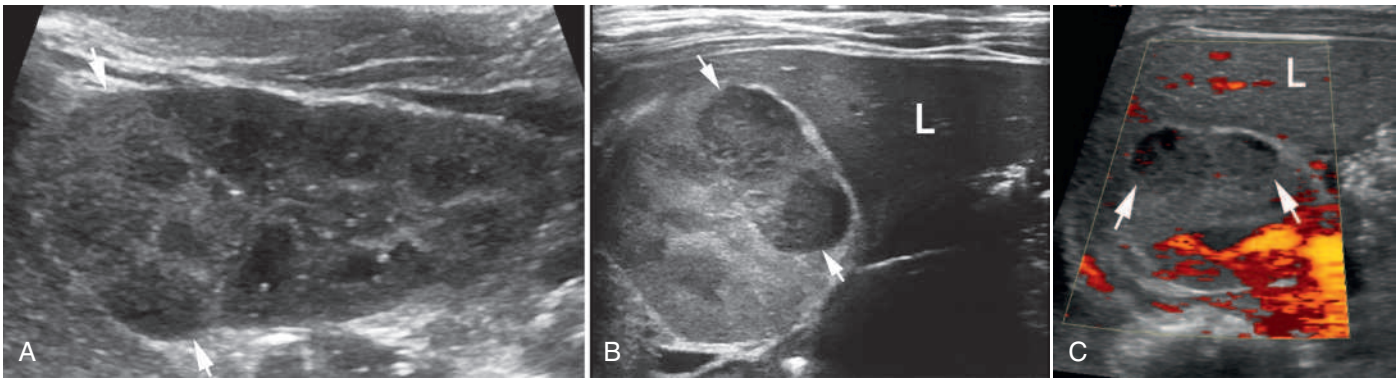

FIG. 52.28 Renal Abscess. (A) Longitudinal image of the right kidney reveals upper-pole swelling with loss of normal corticomedullary differentiation *(arrows).* **(B)** Transverse image of the right upper renal pole depicts an irregular intraparenchymal fluid collection *(arrows).* **(C)** Power Doppler image of the right upper pole shows diminished blood flow as well as the intraparenchymal fluid collection *(arrows). L,* Liver.

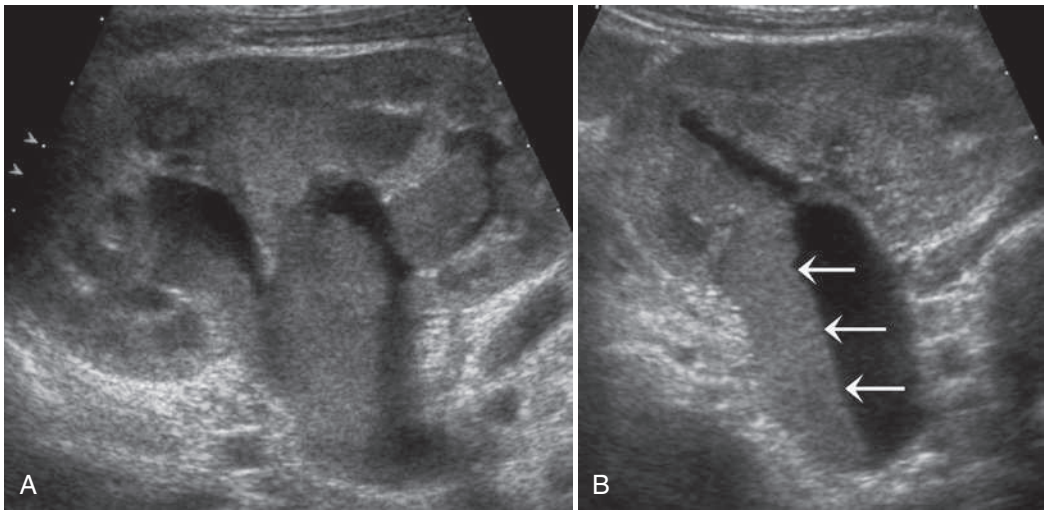

FIG. 52.29 Pyonephrosis in a 4-Month-Old Infant With Underlying Ureteropelvic Junction Obstruction. (A) and **(B)** Sagittal and transverse images of the left kidney depict moderate hydronephrosis with echogenic material in the collecting system and a prominent fluid-fluid level in the renal pelvis *(arrows).*

Chronic Pyelonephritis

Chronic pyelonephritis is caused by repeated episodes of acute pyelonephritis and results in a small, scarred kidney, indicative of end-stage renal disease. The kidney is usually irregular in outline because of focal parenchymal loss. The renal cortex is typically more echogenic than the adjacent hepatic or splenic parenchyma, and there may be decreased corticomedullary differentiation (Fig. 52.30). These findings are not specific and can also be seen in children with **chronic glomerulonephritis, renal dysplasia, hypertension, or renal ischemia.**

Neonatal Candidiasis

Candida albicans is a saprophytic fungus that usually infects immunocompromised patients, particularly neonates with indwelling catheters receiving broad-spectrum antibiotics. Systemic candidiasis leads to infection of multiple organs, including the kidneys, and neonates may have anuria, oliguria, a flank mass, or hypertension. Sonography may show diffuse enlargement of the kidney, with loss of normal architecture and increased parenchymal echogenicity. Fungus ball formation due to mycelial clumping may occur in the collecting system, resulting in echogenic masses and hydronephrosis secondary to obstruction[76] (Fig. 52.31).

Cystitis

Inflammation of the urinary bladder may occur in children as a result of infection or drug therapy, as with the antineoplastic agent cyclophosphamide. The bladder wall becomes thickened and irregular, with hypervascularity identified with color and power Doppler imaging. Echogenic debris or blood clot may be seen in the bladder lumen[77] (Fig. 52.32). Rarely, an **inflammatory pseudotumor** may result, with visualization of a bladder mass[78] (Fig. 52.33, Video 52.5).

MEDICAL RENAL DISEASE

The term "medical renal disease" refers to disorders that primarily affect the renal parenchyma and may be acute or chronic. Ultrasound is usually the initial imaging study performed in the

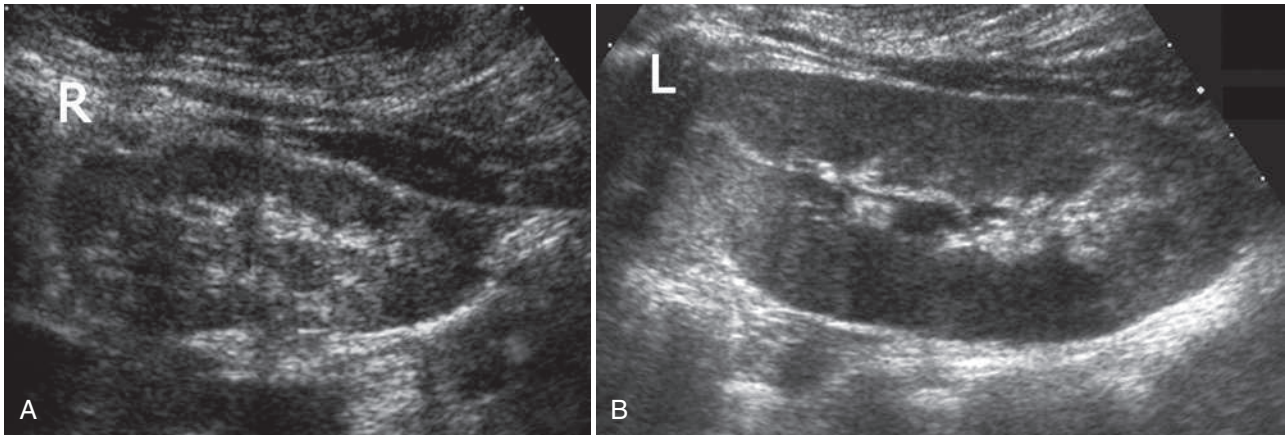

FIG. 52.30 Chronic Pyelonephritis in 12-Year-Old Boy With a History of Urinary Tract Infection. (A) and **(B)** The right kidney *(R)* is small (7.6 cm) compared with the left kidney (*L;* 11.5 cm), and demonstrates thin, echogenic parenchyma. The left kidney is hypertrophied but otherwise appears normal.

evaluation of patients who typically have hematuria, proteinuria, or renal failure.[79]

Acute Kidney Injury

Acute kidney injury (AKI), defined as a sudden loss of renal function, may be caused by inadequate renal perfusion, renal cell injury, or urinary tract obstruction. AKI usually develops in hospitalized children as a consequence of systemic illness or its treatment, and not from primary renal disease. The most common causes of AKI in children are renal ischemia, nephrotoxic drugs, and sepsis. Other important causes are listed in the accompanying box. All forms of AKI can lead to chronic kidney disease (CKD). Recovery of renal function depends on the underlying events leading to injury.[80]

Ultrasound is usually the initial diagnostic imaging study performed in the workup of children with AKI, and is often the only imaging required. The role of ultrasound is to assess renal size and to exclude anatomic abnormalities as the cause of AKI. Pathologic changes of the renal cortex, medulla, and collecting system are readily detected and correlate well with histologic findings. Doppler ultrasound yields information about renal perfusion and vascular abnormalities. Ultrasound is also used to localize the kidneys for percutaneous biopsy. Functional information may be obtained with nuclear medicine studies that can aid in more precisely differentiating among prerenal, renal, and postrenal causes of AKI.[80]

In the setting of prerenal injury, the kidney is intrinsically normal, and renal function is diminished as a result of decreased renal perfusion. The kidneys are sonographically normal, and restoration of renal perfusion results in a prompt return of renal function.

Renal ischemia caused by prolonged prerenal injury or by a severe hypoxic or ischemic insult can result in **acute tubular necrosis** (ATN). Imaging findings depend on the severity of parenchymal injury. A generalized increase in renal cortical echogenicity indicates intrinsic renal disease (Fig. 52.34). In mild

Common Causes of Acute Kidney Injury

PRERENAL FAILURE
Decreased true intravascular volume
Decreased effective intravascular volume

INTRINSIC RENAL DISEASE
Acute tubular necrosis (vasomotor neuropathy)
- Hypoxic or ischemic insults
- Drug induced
- Toxin mediated
  - Endogenous toxins—hemoglobin, myoglobin
  - Exogenous toxins—ethylene glycol, methanol

URIC ACID NEPHROPATHY AND TUMOR LYSIS SYNDROME
INTERSTITIAL NEPHRITIS
Drug induced
Idiopathic

GLOMERULONEPHRITIS
VASCULAR LESIONS
Renal artery thrombosis
Renal vein thrombosis
Cortical necrosis
Hemolytic uremic syndrome

HYPOPLASIA OR DYSPLASIA WITH OR WITHOUT OBSTRUCTIVE UROPATHY
Idiopathic
Exposure to nephrotoxic drugs in utero

HEREDITARY RENAL DISEASE
Autosomal dominant polycystic kidney disease
Autosomal recessive polycystic kidney disease
Alport syndrome
Sickle cell nephropathy
Juvenile nephronophthisis

OBSTRUCTIVE UROPATHY AND LOWER TRACT LESIONS
Obstruction in a solitary kidney
Bilateral ureteral obstruction
Urethral obstruction
Bladder rupture

FIG. 52.32 Hemorrhagic Cystitis Caused by the Polyomavirus BK Virus in Patient With Leukemia. Transverse bladder image shows thick-walled bladder containing echogenic debris and blood clot (*).

cases, the kidneys may appear normal or may demonstrate slightly increased renal cortical echogenicity. Loss of corticomedullary differentiation can occur. Doppler flow may be normal in mild disease, whereas poor peripheral perfusion and diminished arterial diastolic flow due to increased peripheral vascular resistance occur in more severe cases.[80] Decreased renal cortical echogenicity is typical of **acute cortical necrosis.**

Nephrotoxic drugs commonly associated with AKI include antibiotics, chemotherapeutic agents, and nonsteroidal antiinflammatory medications. Some medications such as aminoglycoside antibiotics cause tubular injury. Methicillin and other penicillin analogues, cimetidine, sulfonamides, rifampin, and nonsteroidal antiinflammatory drugs may cause acute interstitial nephritis, which in some cases leads to a hypersensitivity reaction with development of antitubular basement membrane antibodies.

Children with **B-cell lymphoma** and **acute lymphocytic leukemia** are at risk for the development of uric acid nephropathy and tumor lysis syndrome. In patients with **septic shock,** AKI can develop from hypotension, leading to renal ischemia and ATN.[80]

Chronic Kidney Disease

The classification of CKD published by the National Kidney Foundation Kidney Disease Outcomes Quality Initiative is based on estimated glomerular filtration rate and is applicable to children older than 2 years and to adults[82] (Table 52.7). The most common causes of pediatric CKD in North America are congenital disorders such as **obstructive uropathy, renal dysplasia,** and **reflux nephropathy.** In contrast, in Japan, 34% of pediatric CKD is due to **glomerulonephritis, primary focal segmental glomerulosclerosis,** and **immunoglobulin A nephropathy.** In Jordan and Iran, where consanguinity is more common, heritable disorders such as **cystic kidney disease, primary hyperoxaluria, cystinosis, Alport syndrome,** and **congenital nephrotic syndrome** represent a greater proportion of cases of CKD. In the

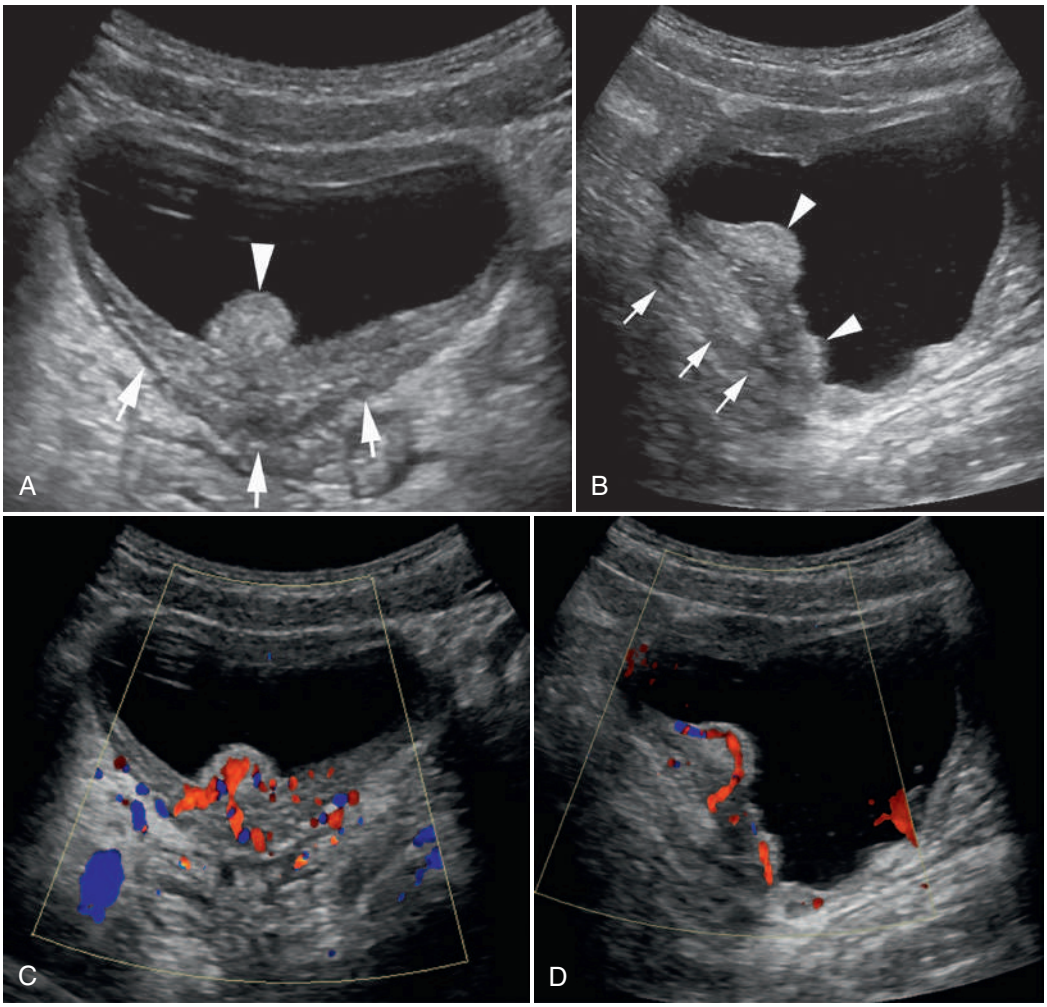

FIG. 52.33 Inflammatory Pseudotumor in Patient With Hemorrhagic Cystitis Secondary to Cyclophosphamide Treatment. (A) and **(B)** Transverse and longitudinal images demonstrate diffuse thickening and irregularity of the bladder wall *(arrows)* as well as multiple nonmobile, echogenic lesions *(arrowheads)*. **(C)** and **(D)** Transverse and longitudinal color Doppler images reveal hyperemia of both bladder wall and lesions. developing world, acquired causes of CKD predominate, particularly infection-related glomerulopathies. The worldwide incidence and prevalence of CKD are greater for boys than for girls because of the higher incidence of congenital causes of CKD in boys.[80]

As with AKI, ultrasound is the primary imaging modality used to investigate CKD. Congenital anomalies such as UPJO, PUV, duplex collecting systems and ureters, and ectopic ureteral insertion are well depicted by sonography. Determination of kidney size is critical for long-term follow-up. Enlarged kidneys can occur in the setting of obstruction, cystic disease, and glomerulonephritis. Hypoplastic and scarred kidneys usually are small. A gradual reduction in kidney size usually occurs in patients with CKD. With progressive CKD, a concomitant loss of corticomedullary differentiation usually occurs, and most kidneys will have echogenic parenchyma. However, increased renal parenchymal echogenicity is a nonspecific finding and is not correlated with the severity of disease. **Dysplastic kidneys** have disordered development that usually results in a combination of echogenic parenchyma and cysts (Fig. 52.35). Dysplasia may be focal or diffuse and is usually depicted sonographically as echogenic tissue without identifiable corticomedullary differentiation.[80] Renal vascularity reflects functional status and will decrease in persons with CKD. The renal arterial resistive index (RI) correlates with creatinine levels and appears to be an independent risk factor for the progression of CKD.[83]

URINARY TRACT CALCIFICATION

Renal Cortical Calcification

Renal cortical calcification most commonly occurs as a result of acute cortical necrosis or chronic glomerulonephritis.[84] Additional causes are listed in the accompanying box. In the setting of acute cortical necrosis, the renal cortex will appear echogenic by ultrasound within a few weeks of injury, with calcification increasing over time (Fig. 52.36). Progressive renal atrophy also occurs.[85]

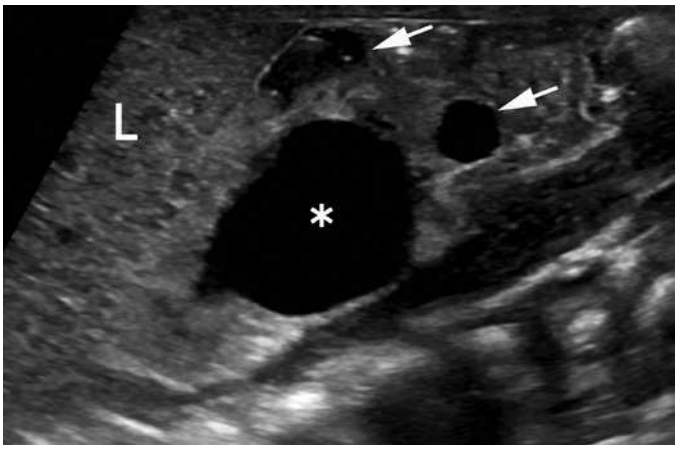

FIG. 52.35 Renal Dysplasia. Longitudinal image of right kidney demonstrates echogenic parenchyma with absent corticomedullary differentiation and peripheral cysts *(arrows)*. *, Dilated renal pelvis; *L*, liver.

Causes of Cortical Nephrocalcinosis

Renal cortical necrosis
Chronic glomerulonephritis
Renal transplant rejection
Alport syndrome
Ethylene glycol poisoning
Hyperoxaluria
Acquired immunodeficiency syndrome–associated infections

Medullary Nephrocalcinosis

In more than 90% of children with nephrocalcinosis, calcification is mainly located in the medullary pyramids. The most common causes in children are metabolic disorders resulting in **hypercalcemia** and **hypercalciuria, renal tubular acidosis,** and **diuretic therapy.** Additional causes are listed in Table 52.8.

Prolonged administration of diuretics such as furosemide is a significant cause of medullary nephrocalcinosis in neonates. In these conditions an increased calcium load is presented to the kidney. The mineral content within the kidney increases progressively from the glomerulus to the collecting ducts, and thus the greatest concentration of calcium is found in the pyramids, especially at their tips. The **"Anderson-Carr-Randall progression"** of calculus formation postulates that microscopic calcifications within a renal pyramid may fuse to form a plaque that migrates toward the calyceal epithelium, eventually

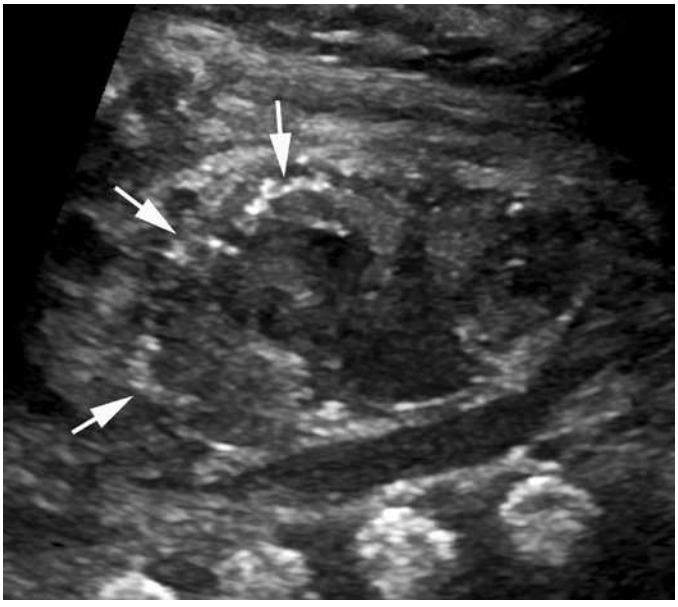

FIG. 52.36 Acute Cortical Necrosis in Infant With History of Aortic and Vena Caval Thromboses and Severe Renal Functional Impairment. Longitudinal image reveals thin, echogenic parenchyma with loss of corticomedullary differentiation and cortical calcifications *(arrows)*.

TABLE 52.8 Causes of Medullary Nephrocalcinosis[86]

Category	Examples

Urinary Stasis	Obstructive uropathy
	Medullary sponge kidney
Hyperoxaluria	Primary
Hyperuricosuria	Secondary

perforating it and thereby providing a nidus for urinary stone formation.[87] Sonography readily demonstrates calcium deposits within the renal medullae (Fig. 52.37).

Urinary Stasis

Any form of urinary stasis predisposes not only to infection, but to calcium deposition as well. Thus the tubular ectasia encountered in **medullary sponge kidney** and in **autosomal recessive polycystic kidney disease** (ARPKD) often shows deposits of calcium in the pyramids, at the site of the dilated tubules. Similarly, milk of calcium, a viscous colloidal suspension of various calcium salts, may deposit in calyceal diverticula or in the renal pelvis in the setting of UPJO[88] (Fig. 52.38). **Staghorn calculi** occasionally occur in children with renal obstruction and infection (Fig. 52.39).

Renal Vein Thrombosis Calcifications

The finely branching calcifications within the cortex and medulla of the kidney that develop after renal vein thrombosis represent microthrombi in the intrarenal veins[89] (Fig. 52.40).

Dystrophic Calcification

Dystrophic calcification of abnormal tissue can occur anywhere in the urinary tract, including sites of inflammation resulting from chronic infection or within a tumor or the wall of a cyst.

Urolithiasis

"Urolithiasis" refers to the presence of stones at any site within the renal collecting system, ureter, bladder, or urethra. The prevalence of urolithiasis varies according to age, sex, race, and geographic region.[90] In the United States, urolithiasis occurs in about 50 per 100,000 adolescents.[91] It is more common in Caucasians than in African Americans. In adults, the highest

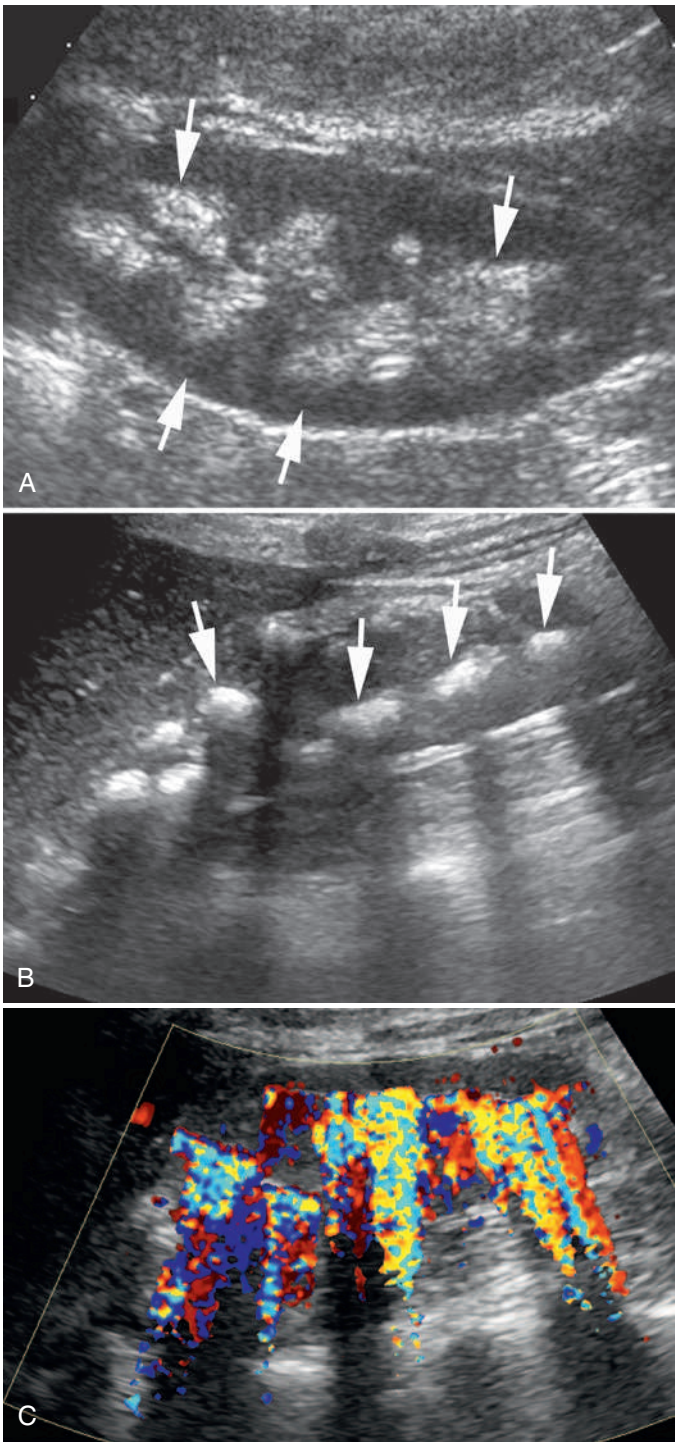

FIG. 52.37 (A) Renal medullary nephrocalcinosis in 13-year-old boy with **hypervitaminosis D.** Longitudinal image of the left kidney demonstrates echogenic calcium deposits completely filling the renal pyramids *(arrows).* **(B) Nephrocalcinosis in 18-year-old girl with Bartter syndrome.** Longitudinal image of the right kidney shows multiple shadowing stones at the tips of the renal pyramids *(arrows).* **(C)** Longitudinal color Doppler image of the right kidney reveals the **twinkling artifact** associated with the stones.

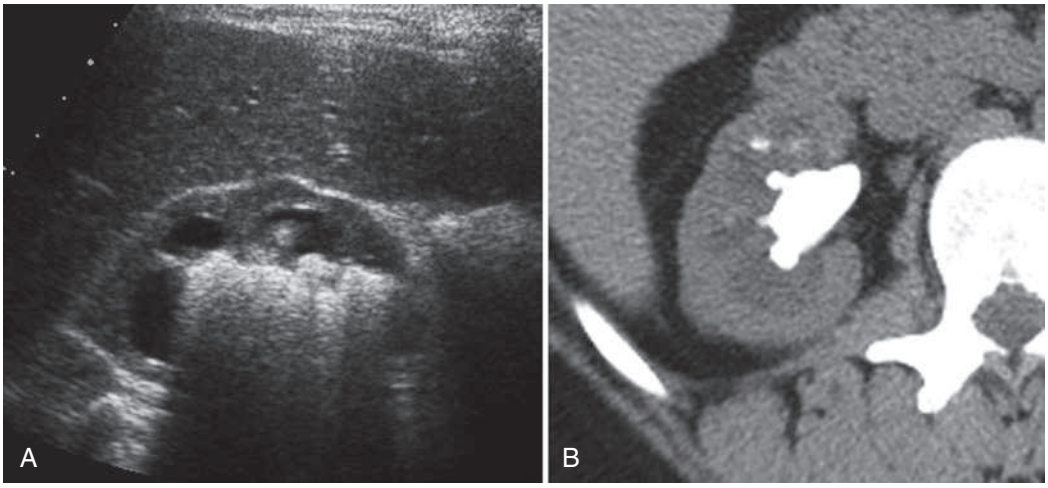

FIG. 52.39 Staghorn Calculus in 18-Year-Old Female Patient With Tyrosinemia. (A) Longitudinal image of the right kidney shows extensive echogenic foci filling the collecting system with prominent distal shadowing. **(B)** Axial computed tomography image confirms the presence of a large branching stone within the right renal calyces and pelvis.

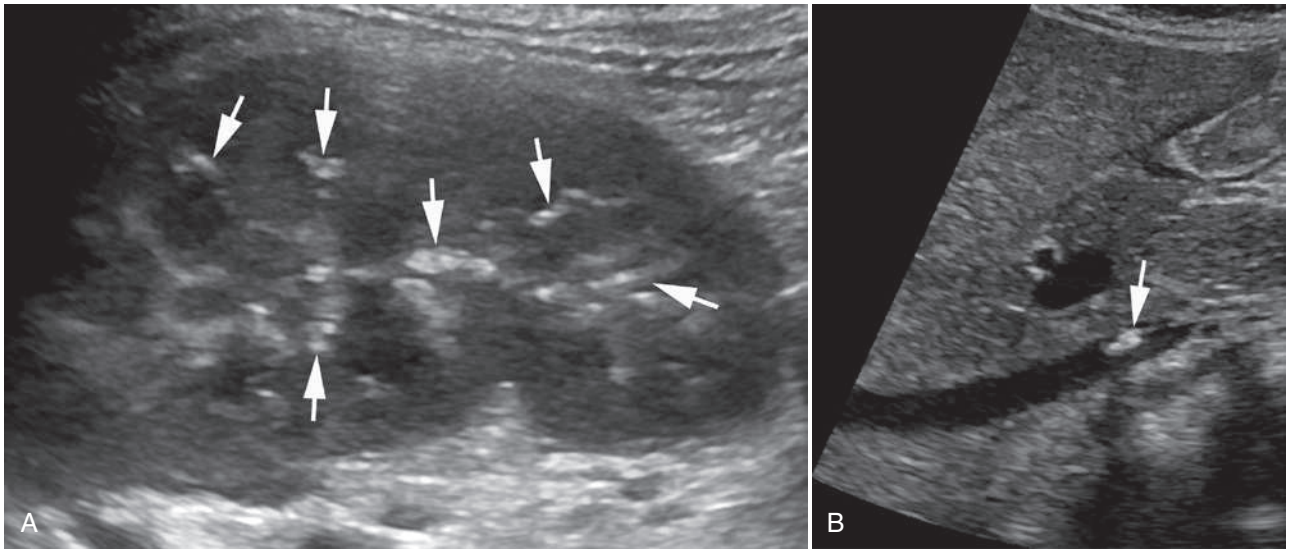

FIG. 52.40 Three-Year-Old Girl With a History of Congenital Vena Caval and Bilateral Renal Vein Thrombosis. (A) Longitudinal image of left kidney depicts multiple linear, branching, echogenic foci representing small, calcified veins *(arrows)*. **(B)** Longitudinal image of the inferior vena cava shows a residual calcified mural thrombus *(arrow)*.

prevalence of stones occurs in the southeastern United States; the geographic distribution of stone disease in children has not been reported.[92] Approximately 70% of children with urolithiasis have an underlying predisposing condition such as **urinary stasis, hypercalciuria, or chronic infection.** Approximately 40% to 60% of stones are predominantly composed of calcium oxalate, 10% to 20% are mainly calcium phosphate, 10% to 25% are mixed stones containing both calcium oxalate and calcium phosphate, 17% to 30% are magnesium ammonium phosphate (struvite or infection related), 6% to 10% are cystine, and 2% to 10% are uric acid.[93] Ultrasound is the initial imaging study of choice, with noncontrast CT reserved for cases in which ultrasound is nondiagnostic.[94] Urinary tract stones appear as foci of increased echogenicity with or without associated acoustic shadowing. In general, acoustic shadowing is present when the stone is 5 mm or more in diameter.[95] The color comet tail artifact **"twinkle sign"** is a rapidly alternating color Doppler signal that occurs immediately deep to the object that causes it, and appears as a linear aliased band of color[96] (see Fig. 52.37C). This artifact can be useful in the diagnosis of small stones in the absence of hydronephrosis or hydroureter. Color Doppler evaluation of the ureteral jet may be helpful in diagnosing obstruction because it is absent or of diminished velocity in the setting of high-grade obstruction.[17]

RENAL TRAUMA

After blunt abdominal trauma, the kidney is the most commonly injured organ in children. The pediatric kidney is believed to be at increased risk of injury compared with the adult kidney because of its larger size relative to the abdomen, and less protection from unossified ribs, weaker abdominal muscles, and minimal perinephric fat.[97] Renal trauma in children is often associated with other organ injury, particularly of the liver and spleen.

Most children with clinically significant kidney trauma have hematuria. Asymptomatic, microscopic hematuria is a low-yield sign for the presence of renal injury, whereas patients with gross hematuria have a much higher incidence of renal injury (22%) than those who do not (8%).[98] Preexisting and often clinically silent renal abnormalities such as hydronephrosis or ectopic kidney may make the kidney more susceptible to injury by minor trauma.

CT is the primary imaging modality for suspected blunt abdominal trauma in the pediatric patient.[99,100] Ultrasound is used primarily in the follow-up of injuries found on CT.[101] Parenchymal contusion is the most common kidney injury. It is characterized by microscopic hemorrhage and edema and is best depicted by CT, although ultrasound may show distortion of the normal renal architecture. Perirenal hematoma may occur as a complication of renal injury, and is subcapsular or perinephric in location. Renal hematoma can vary in appearance, but is usually echogenic at first and becomes hypoechoic as it liquefies. Injury to the renal collecting system leads to extravasation of urine. A urinoma results when the extravasated urine is limited to the perirenal space, which can be difficult to distinguish from hypoechoic blood by ultrasound. When the hematoma results from injury to the vascular pedicle, there will also be absent flow in the renal vessels and/or within the renal parenchyma.

The introduction of ultrasound contrast agents into clinical practice has permitted their use in the assessment of patients with mild to moderate blunt abdominal trauma, particularly when there is clinical concern but conventional ultrasound reveals no solid organ injury (Fig. 52.41, Video 52.6). Menichini and colleagues[102] and Valentino and colleagues[103] have shown that CEUS is nearly as accurate as contrast-enhanced CT in depicting solid organ injuries in children. One important limitation of the technique, however, is that the ultrasound contrast agent is not filtered by the kidney, so a urinoma cannot be readily distinguished from a hematoma.

RENAL VASCULAR DISEASE

Doppler Sonographic Examination Technique

Infants and small children are examined without special preparation, but they may be given clear liquids to drink during the examination to calm them, to increase hydration, and to provide an acoustic window through the fluid-filled stomach. Sedation is rarely necessary. The older child is best examined after a 4- to 6-hour fast (to reduce intestinal gas) only if a detailed examination of the main renal artery is planned. Color and spectral Doppler examinations are performed. Power Doppler may also be useful to evaluate the presence of vascular flow. Doppler settings should be adjusted for maximal detection of slow flow using the highest possible transducer frequency, relatively small color area of interest, low pulse repetition frequency, and low wall filter. Pulse repetition frequency is augmented if aliasing occurs. A small sample volume and an insonating angle of 60 degrees or less are needed.[104]

The aorta is examined by means of an anterior left paramedian as well as a left axillary approach, with longitudinal and transverse views. The main renal arteries are often best imaged through the flanks, although an anterior midline approach can also be used. Color Doppler is used to trace the renal arteries, which are then examined with serial pulsed Doppler samples, especially in areas of high-velocity flow. Even if the entire renal artery cannot be outlined because of overlying intestinal gas, the retrocaval portion of the right renal artery and the hilar arteries can usually be analyzed. A segmental or interlobar artery in each third of the kidney (upper, middle, and lower) is then studied with spectral Doppler, and the RI or pulsatility index is calculated.

Normal Vascular Anatomy and Flow Patterns

The intrarenal arteries and veins and their relationship to the renal cortex, pyramids, and calyces are exceptionally well outlined with color Doppler ultrasound.[105] The main renal artery or arteries divide in the renal hilum to form several pairs (anterior and posterior) of segmental arteries. These course toward the pyramids and divide into the interlobar branches, which follow the periphery

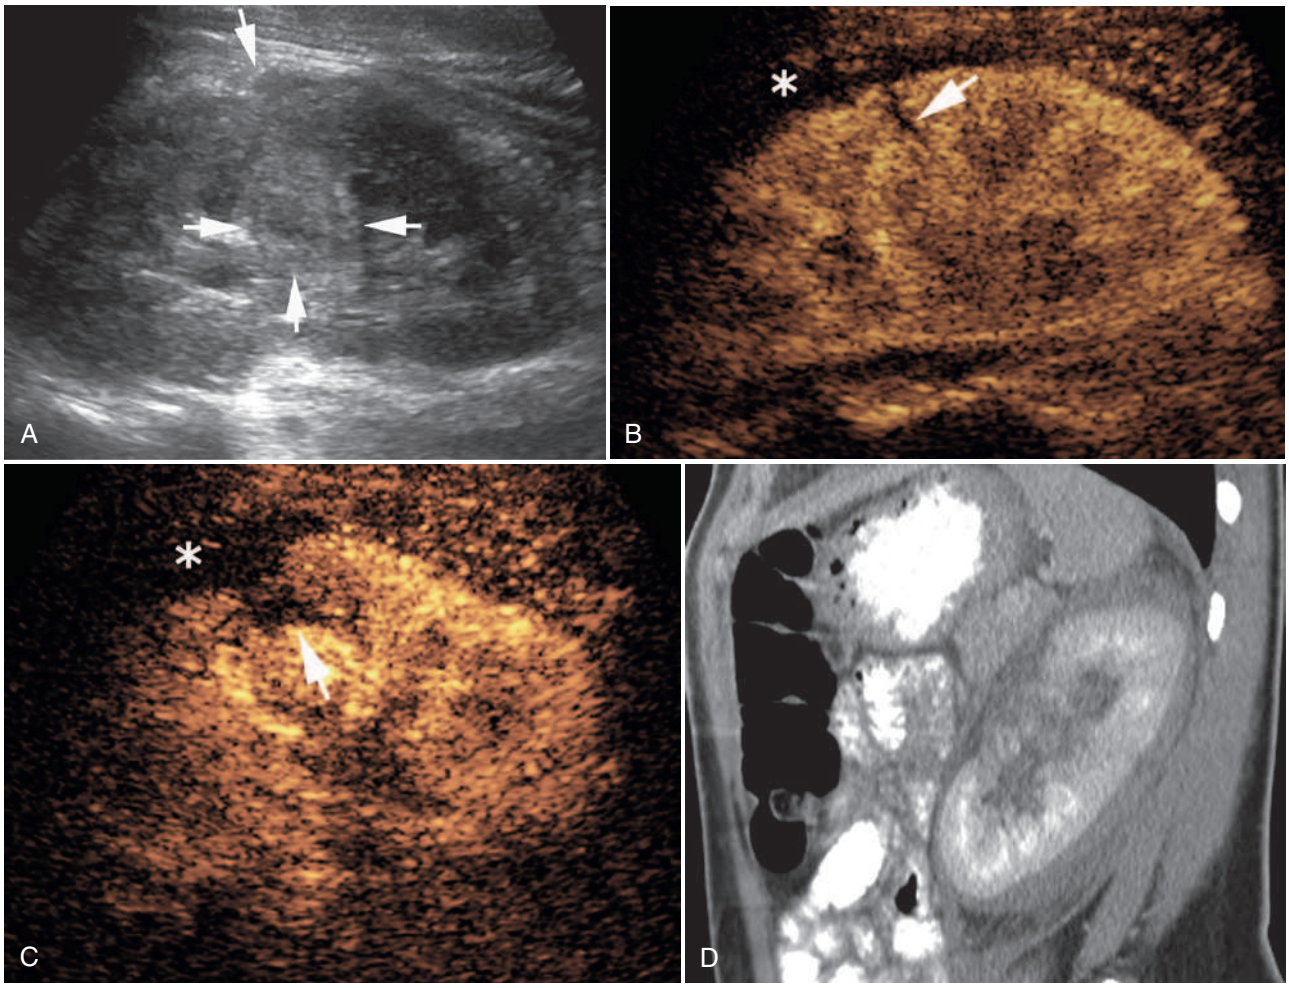

FIG. 52.41 Renal Laceration and Perirenal Hematoma. (A) Longitudinal gray-scale image shows swelling, contour irregularity, and loss of corticomedullary differentiation in the midportion of the left kidney *(arrows)*. **(B)** and **(C)** Longitudinal intravenous (IV) contrast-enhanced ultrasound images readily depict the parenchymal defect *(arrow)* and adjacent hematoma (*). **(D)** Longitudinal reformatted IV contrast-enhanced computed tomography image demonstrates the midrenal laceration and surrounding hematoma. See also Video 52.6.

of the pyramids. At the outer edge of the pyramids, the interlobar arteries give rise to the arcuate arteries, which follow the outer contour of the pyramids. Cortical arteries arise from the arcuate arteries and radiate into the cortex, following a direction similar to that of the interlobar vessels. The venous circulation follows that of the arteries, and simultaneous adjacent signals are often depicted with both color Doppler sonography and on spectral analysis (Fig. 52.42).

The renal arterial bed normally has low resistance, and there is a constant flow of blood into the kidney throughout the cardiac cycle. The normal adult renal arterial RI is estimated at 0.58 ± 0.05. Renal RI is age dependent, with children having higher RI values and a trend toward decreasing values with increasing age. This age dependency of the renal RI and, therefore of renal vascular resistance, has been postulated to be dependent on serum levels of active renin, because the maturational profile of the renal RI more closely parallels that of active renin than of other renal functional parameters.[106] Because there is a range of normal RI values in children, and the renal RI is highest in the first 3 months of life,[106] the diagnosis of abnormal intrarenal resistance is much more reliably made in children by comparing waveforms from the pathologic kidney with those of the normal kidney, or tracings of the pathologic kidney obtained from one day to the next.

Pulsed Doppler ultrasound tracings from the normal intrarenal and main renal veins are somewhat variable: in some children the pulsations from right atrial systole and diastole are clearly visible, whereas in others the flow is steadier. To-and-fro venous flow throughout the cardiac cycle may be seen in right-sided heart failure or in the absence of arterial perfusion, as in the setting of end-stage renal disease.

Causes of Increased Resistance to Intrarenal Arterial Flow

Any increase in intrarenal arterial pressure results in decreased flow. Diastolic flow occurs at the lowest pressure during the cardiac cycle, so it will decrease or disappear before systolic Doppler flow curves are appreciably affected. The causes of increased intrarenal resistance to flow can be classified as

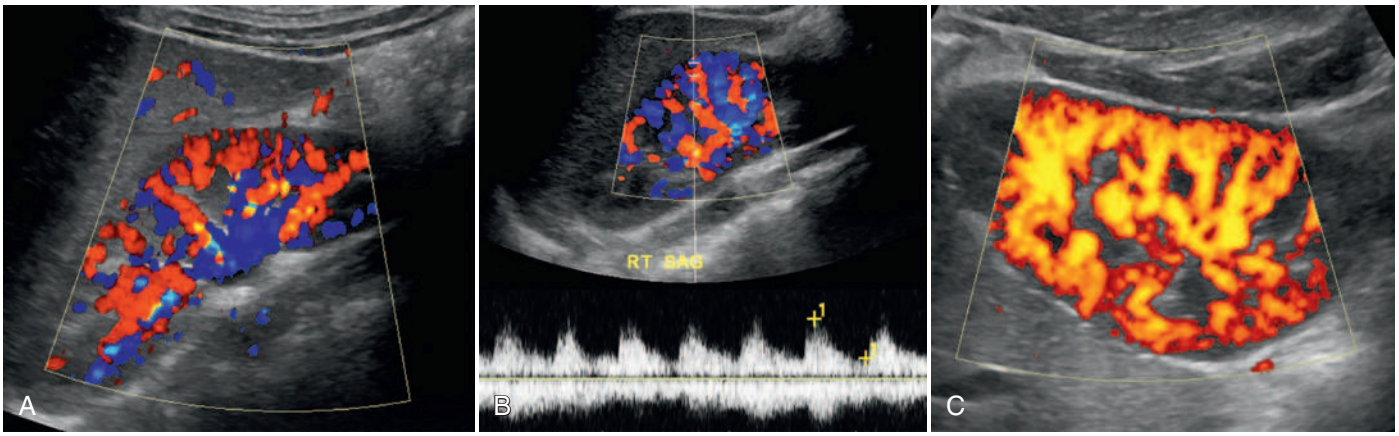

FIG. 52.42 Normal Intrarenal Circulation in a 3-Year-Old Boy. (A) Longitudinal color Doppler sonogram shows the segmental vessels at the hilum, the interlobar vessels alongside the pyramids, and the arcuate vessels at the inner edge of the cortex. **(B)** Spectral display from a normal interlobar artery (low resistance, high diastolic flow) and vein (pulsatile, reflecting right atrial pulsations). **(C)** Power Doppler sonogram displays blood flow extending to the periphery of the renal cortex.

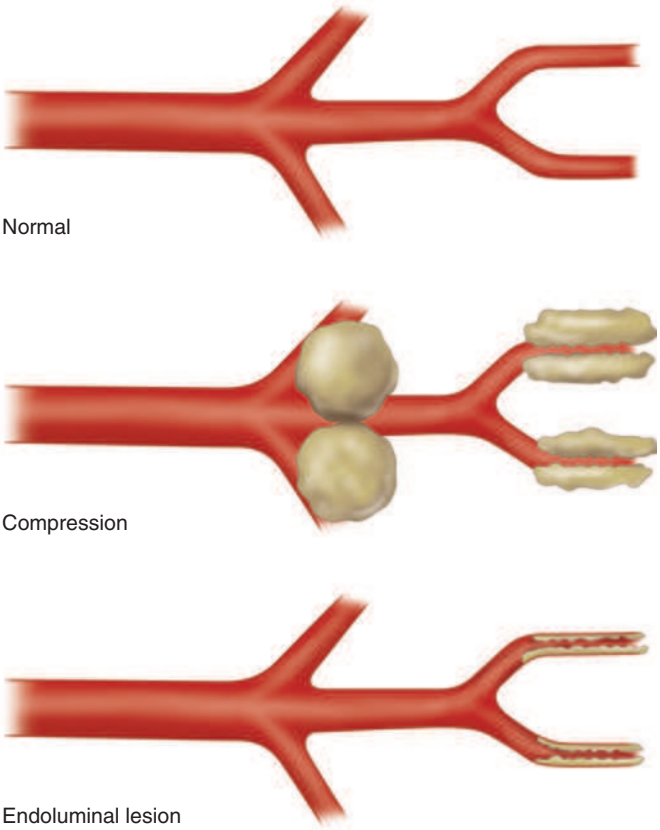

FIG. 52.43 Causes of Increased Resistance to Intrarenal Arterial Flow.

intravascular, perivascular, and perirenal (Fig. 52.43). Any decrease in the size of the lumen of small intrarenal arteries or arterioles (spasm, as in shock; endothelial inflammation, as in hemolytic-uremic syndrome [HUS]) leads to increased resistance to arterial inflow. Compression of small vessels by intrarenal edema (e.g., secondary to renal vein thrombosis) may result in identical arterial Doppler tracings. Back pressure from an acutely obstructed ureter has the same result. Finally, significant compression from a hematoma, lymphocele, or the tight abdominal wall around an adult kidney transplanted into a small child can also cause compression of vessels and decrease intrarenal arterial flow.

The successful Doppler examination of intrarenal arteries therefore includes the following two steps:

1. Comparing the RI with either the RI on the other side or the RI from a previous examination
2. Reviewing the pertinent pathophysiologic factors involved in a patient with high RI

Causes of Increased Resistive Index in Renal Arteries

INTRAVASCULAR
Vascular spasm in shock
Endothelial inflammation in hemolytic-uremic syndrome

PERIVASCULAR
Intrarenal edema
Renal vein thrombosis
Acutely obstructed ureter

PERIRENAL COMPRESSION
Hematoma
Lymphocele
Tight abdominal wall

Clinical Applications

Vessel Patency

The Doppler examination is a reliable indicator of the patency of the renal arteries, of the veins, and of the presence of intrarenal perfusion. Therefore the examination is particularly useful in the evaluation of renal allograft perfusion immediately after surgery. It is also useful in the exclusion of arterial injury after trauma, especially when the renal architecture is sonographically normal and other, more invasive examinations are not indicated.

Color Doppler sonography is especially valuable in the search for postbiopsy arteriovenous fistulas (AVFs) and aneurysms.[107]

Acute Renal Vein Thrombosis

Acute renal vein thrombosis may follow shock or occur as a complication of the nephrotic syndrome, secondary to abnormal coagulation, or in the presence of a nearby malignant mass, such as **Wilms tumor.** In the neonate, thrombosis is usually associated with dehydration, decreased renal perfusion and oxygenation, and polycythemia. It is more prevalent in infants of diabetic mothers. The clinical presentation includes hematuria, palpable flank mass, proteinuria, and decreased renal function. Sonography typically shows an enlarged kidney with altered parenchymal echogenicity (Fig. 52.44). The normal corticomedullary differentiation is obliterated. Patchy areas of decreased and increased echogenicity are secondary to edema and parenchymal hemorrhage. Sonography may demonstrate echogenic thrombus within the renal vein and inferior vena cava. Thrombi are initiated in small venules and propagate toward the hilum, so that renal parenchymal abnormalities are often present without clear visualization of a thrombus.[89,108] In contrast, in the renal allograft, thrombosis usually starts at the venous anastomosis.

Causes of Acute Renal Vein Thrombosis

Shock
Nephrotic syndrome
Coagulopathy
Adjacent tumors (e.g., Wilms tumor)
Neonatal dehydration, especially infants of diabetic mothers

Doppler sonography may show decreased or absent flow in the renal veins, as well as a significantly increased RI in the involved renal arteries. This decreased renal arterial diastolic

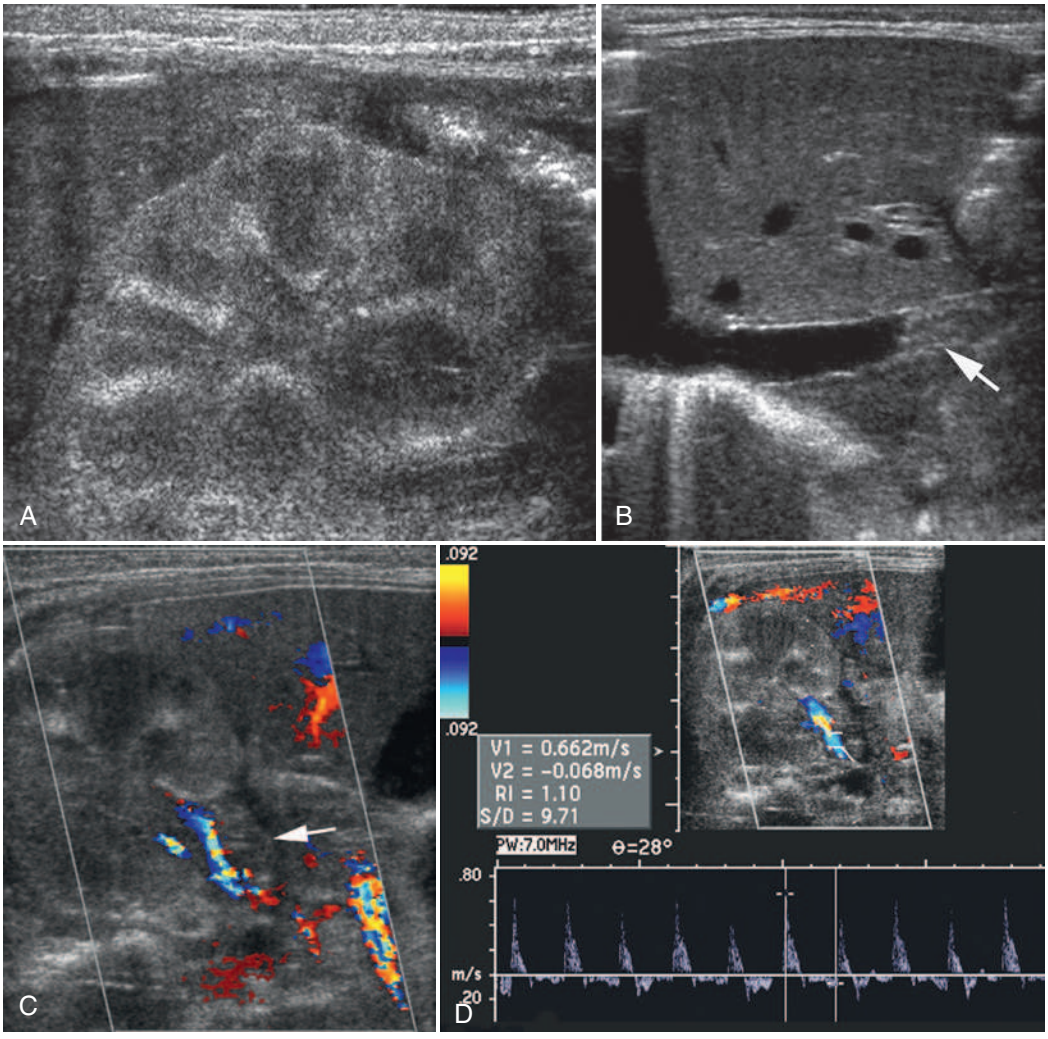

FIG. 52.44 Acute Renal Vein Thrombosis in Premature Infant. (A) Longitudinal image of the right flank demonstrates an edematous kidney with echogenic parenchyma and decreased corticomedullary differentiation. **(B)** Longitudinal image of the inferior vena cava reveals a large intraluminal clot *(arrow).* **(C)** and **(D)** Color and spectral Doppler images of the right renal artery reveal high-velocity arterial blood flow with diastolic reversal due to increased perivascular resistance secondary to intrarenal edema. No flow is documented within the thrombosed main renal vein *(arrow).*

flow is caused by edema and obstruction to outflow of arterial blood entering the kidney. In babies, these signs are much less reliable because flow is rapidly reestablished in the main renal vein, as well as within intrarenal veins. The pathophysiologic response of the kidney to renal vein thrombosis depends on the acuity of the occlusion, extent of thrombosis, and the development of venous collateral circulation. This reestablishment of venous flow occurs not only in native kidneys but also in renal transplants, although the process takes much longer, up to 3 weeks in the transplanted kidney. The degree of recovery of the affected kidney after acute renal vein thrombosis ranges over a wide spectrum, from full recovery to a variety of abnormalities, including complete absence of function, to tubular disorders and renovascular hypertension.[89]

Renal Artery Stenosis

Approximately 1% to 3% of children have hypertension, with an increasing prevalence caused by the childhood obesity epidemic. Most hypertensive children are at low risk for renovascular hypertension, which accounts for approximately 5% to 10% of all childhood hypertension.[109] The most common underlying cause of renovascular hypertension in infants is thromboembolism related to umbilical artery catheterization,[110] whereas renal arterial fibromuscular dysplasia and Takayasu arteritis are the most common causes in older children.[111] There are many other developmental and acquired causes of renovascular hypertension in the pediatric population (Table 52.9).

The precise role of noninvasive imaging in children with suspected renovascular hypertension is unclear. There is no imaging technique currently available that can reliably exclude every potentially treatable cause of renovascular hypertension.[113] Ultrasound of the abdominal aorta and depiction of renal size and architecture are useful to exclude global nephropathy, focal scarring, or tumor. Doppler ultrasound can be used to demonstrate an increase in blood velocity as it passes through a stenotic arterial lumen. The presence of a proximal stenosis can also be inferred from the depiction of a *tardus* (late) and/or *parvus* (flat) arterial waveform in vessels distal to a stenosis.[114,115] However, even in experienced hands, localization of an accessory renal artery stenosis or branch vessel stenosis can be time-consuming and challenging.

The classic signs of stenosis described in adults and also applied to children include increased resistance to flow proximally (decreased or absent diastolic or even systolic flow), high velocity at the site of narrowing (>180 cm/sec), turbulence immediately distally, and flow possibly returning to normal at some distance from the stenosis (Fig. 52.45). The following renal arterial Doppler criteria have been found to suggest significant stenosis[114]:

1. Flow velocity measurements exceeding 180 cm/sec
2. Velocity ratio between renal artery and abdominal aorta greater than 3.5:1

Doppler ultrasound waveforms return to normal immediately after repair of stenosis. It must be remembered that the parvus-tardus waveforms identified in the downstream circulation will reflect any stenosis occurring upstream, including Takayasu aortitis and aortic coarctation.

TABLE 52.9 Causes of Renovascular Hypertension[112]

Category	Examples
Fibromuscular dysplasia	
Inflammatory disease	Takayasu arteritis
	Kawasaki disease
	Moyamoya disease
	Irradiation
Genetic disorders	Williams syndrome
	Neurofibromatosis
	Klippel-Trénaunay-Weber syndrome
	Feuerstein-Mims syndrome
	Rett syndrome
	Degos-Kohlmeier disease
	Marfan syndrome
Atherosclerosis	Hyperlipidemias
Vascular anomaly	Renal arteriovenous malformation
	Renal artery aneurysm
	Renal artery hypoplasia
	Renal arteriovenous malformation
Thromboembolism	Umbilical artery catheterization
	Neonate of diabetic mother
	Sepsis, dehydration
Renal transplantation	Rejection
	Arterial narrowing
Other	Congenital rubella
	Compression by mass
	Congenital fibrous band
	Posttraumatic cause
	Retroperitoneal fibrosis

Intrarenal Arterial Disease

Hemolytic-uremic syndrome is one of the most common causes of AKI in nonhospitalized infants and children. It is characterized by endothelial cell injury, intravascular platelet-fibrin thrombi, and vascular damage. It may occur sporadically, in epidemic outbreaks, or as a genetic or familial disorder. Patients with typical HUS will experience bloody diarrhea associated with Shiga toxin–producing bacteria, predominately *Escherichia coli* O157:H7.[116] Atypical HUS occurs without bloody diarrhea and is due to defective complement system activation and regulation.[117]

The lesions of HUS cause increased resistance to renal arterial inflow. At sonography, the renal cortex is uniformly hyperechoic, and the pyramids are sharply demarcated (Fig. 52.46). The kidneys may greatly enlarge. A study of 20 children with HUS found that during the phase of anuria there was no diastolic flow.[118] As the acute vascular lesions healed, diastolic flow returned, followed by diuresis within 24 to 48 hours. Because the Doppler examinations predicted the onset of diuresis, the duration of peritoneal dialysis was kept to a minimum, thereby reducing the risk of complications.

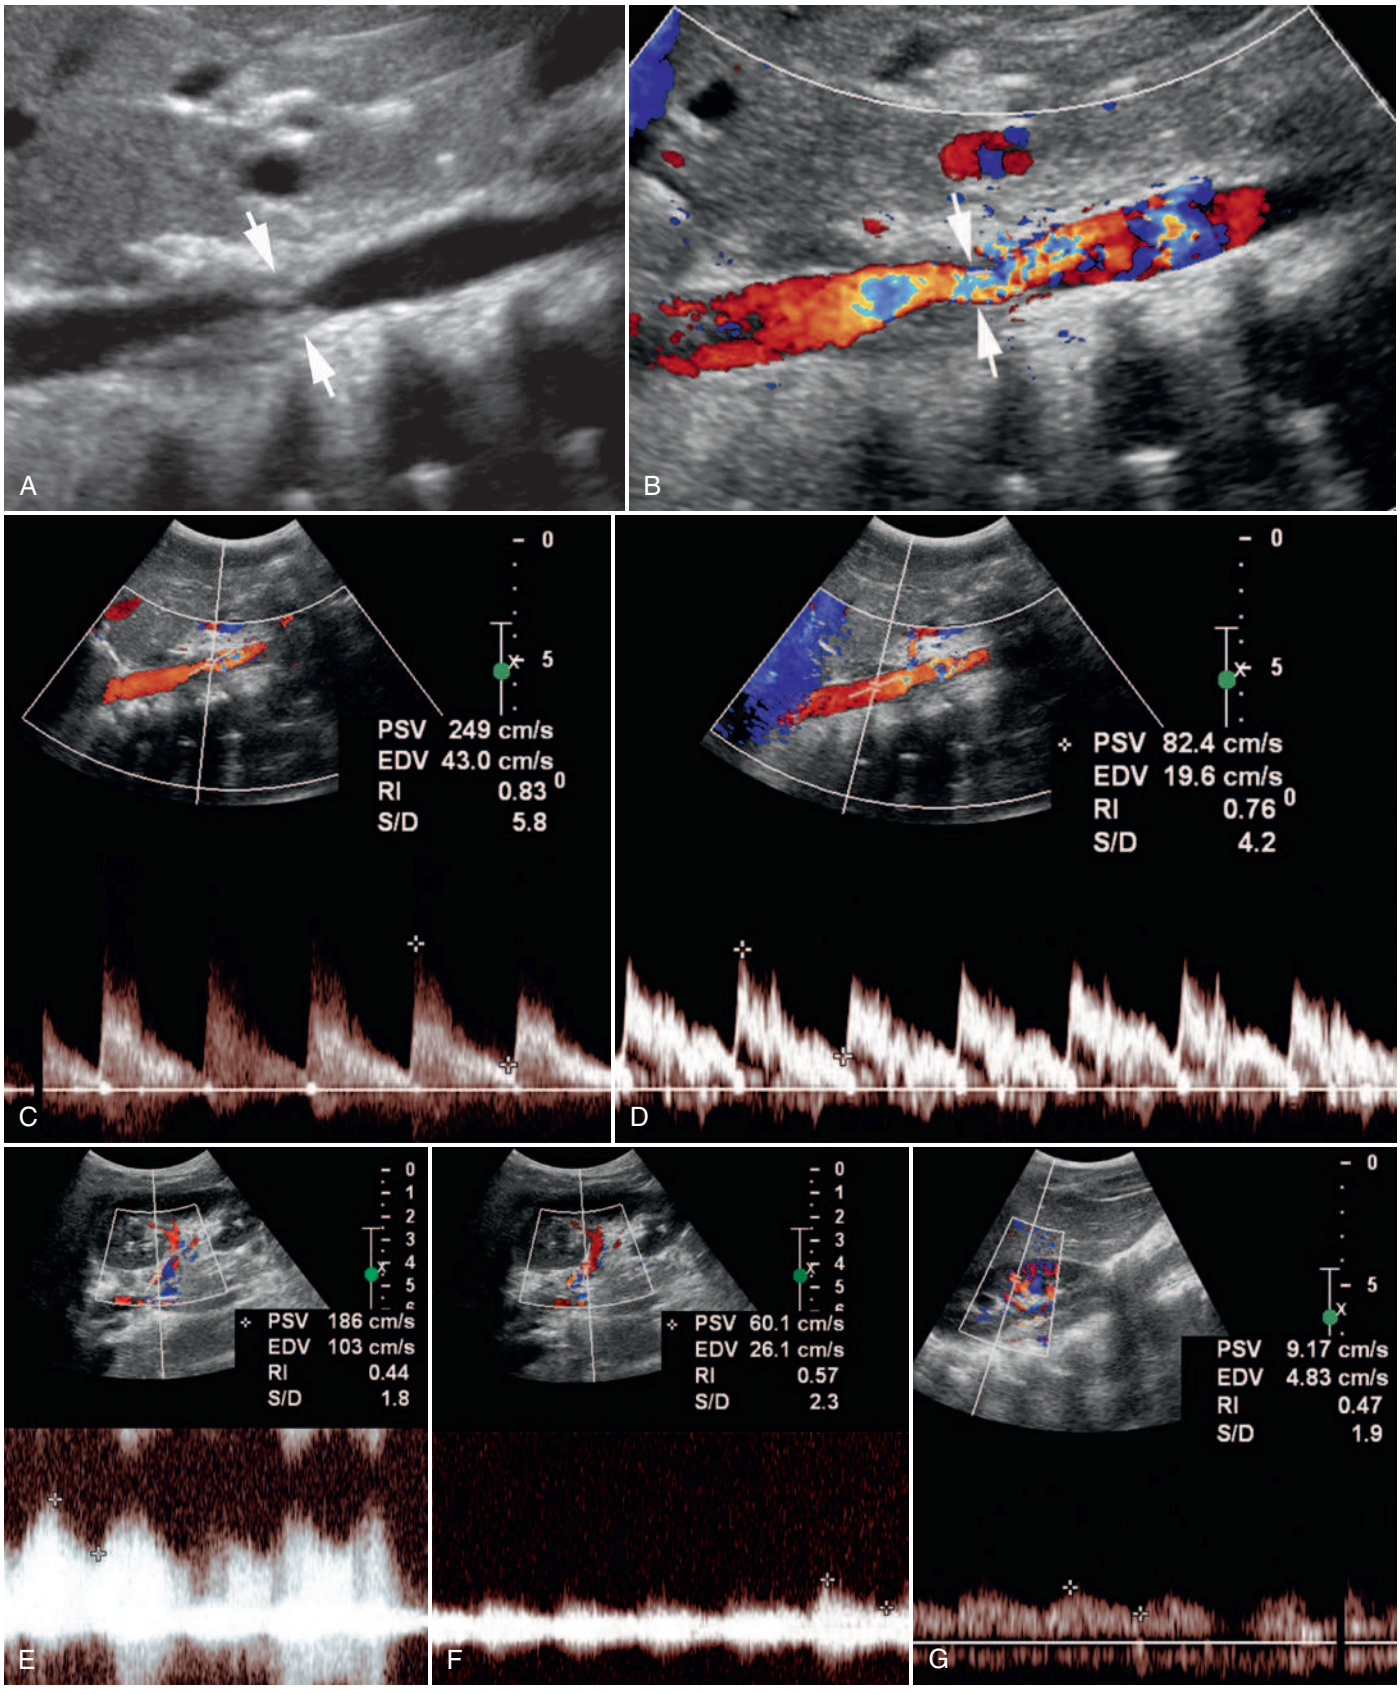

FIG. 52.45 Renal Artery Stenosis in a 4-Year-Old Boy With Midaortic Syndrome and Hypertension. (A) and **(B)** Longitudinal gray-scale and color Doppler images of the abdominal aorta show focal marked mural thickening and significant luminal narrowing as well as color aliasing at the site of stenosis *(arrows).* **(C)** and **(D)** Spectral Doppler display reveals an elevated peak systolic velocity within the aorta at the site of narrowing **(C)** compared with the peak systolic velocity within a more proximal portion of the aorta **(D).** Peak systolic velocity within the proximal right main renal artery is elevated **(E)** compared with the velocity obtained from a more distal portion of the artery **(F).** The distal artery also demonstrates a delayed systolic upstroke with diminished amplitude and rounding of the systolic peak (tardus-parvus waveform). **(G)** A similar tardus-parvus spectral Doppler waveform is obtained from the interlobar vessels of the right kidney.

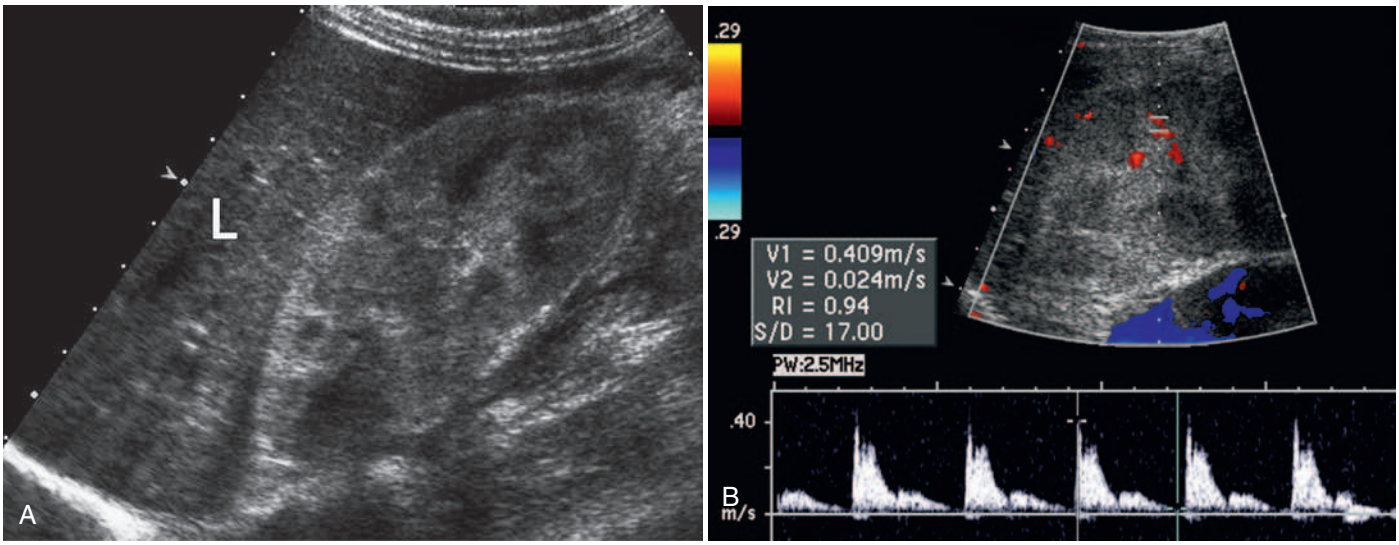

FIG. 52.46 Hemolytic-Uremic Syndrome in a 6-Year-Old Girl. (A) Longitudinal image reveals increased right renal cortical echogenicity, greater than that of the adjacent liver *(L)*. **(B)** Spectral Doppler display reveals diminished diastolic blood flow with an elevated resistive index in a right renal interlobar artery.

RENAL TRANSPLANTATION

Renal transplantation is the treatment of choice for end-stage kidney disease in children. Gray-scale and color Doppler ultrasound imaging provide a comprehensive assessment of transplant morphology, depiction of perirenal and pelvic fluid collections, and evaluation of graft vascularity. At our hospital, an initial postoperative ultrasound examination is performed with short-term follow-up studies performed as clinically indicated. Long-term follow-up consists of yearly ultrasound studies. Ultrasound is also used to guide allograft biopsy.

Approximately half of all renal transplants in children are obtained from living donors, usually a parent.[119,120] In older children, surgical technique is identical to that used in adults, with the allograft placed in an extraperitoneal location in the right or left iliac fossa, and end-to-side vascular anastomoses to the ipsilateral external iliac artery and vein. If there is a significant size discrepancy between the donor and an infant or small child recipient, the allograft may be placed intraperitoneally, with an end-to-side anastomosis of the transplant renal artery to the aorta and of the transplant renal vein to the inferior vena cava, in order to optimize graft perfusion.

Ultrasound evaluation of a normal renal allograft demonstrates an intraabdominal or intrapelvic kidney with gray-scale and Doppler imaging features identical to those of a native kidney. Immediately postoperatively, moderately elevated peak systolic velocity and turbulent flow in the main renal artery are common and probably related to edema at the arterial anastomosis with functional narrowing. Associated diminished downstream peak systolic velocities can result in diminished arterial RIs at the level of the interlobar arteries. Conversely, elevated arterial RIs can occur as a result of diffuse graft edema and diminished diastolic flow. These abnormalities often improve or normalize within in the first 24 hours after transplantation.[121] Recently, CEUS has been used to provide both qualitative and quantitative assessment of renal allograft blood flow and perfusion. CEUS has been shown to be superior to conventional ultrasound in combination with Doppler imaging in detecting even subtle microvascular disturbances in allograft perfusion. In addition, quantitative perfusion parameters derived from CEUS show predictive capability regarding long-term kidney function.[122,123] To date, there is limited experience in the use of CEUS for evaluation of renal allografts in the United States.

Vascular Complications

Vascular complications occur in 0.8% to 13.9% of pediatric renal transplants,[124,125] and include renal artery thrombosis, renal vein thrombosis, renal artery stenosis, AVF, and arterial pseudoaneurysm. Children are at increased risk of early vascular thrombosis compared with adults because of their small size and frequent discrepancies between the size of the donor and recipient vessels.[126] According to data from the North American Pediatric Renal Transplant Cooperative Study, graft thrombosis is the most common cause of first-year allograft loss in children, accounting for as many as 35% of cases.[127] Sonographic assessment of the transplanted pediatric kidney is an important and useful tool in the detection of early vascular complications.[121]

Renal artery thrombosis with associated graft infarction is an unusual complication of renal transplantation, occurring in only 3% to 4% of all pediatric renal transplants.[128,129] It usually develops within the first 48 hours after transplantation and is associated with en bloc transplants from young cadaveric donors that contain paired renal allografts as well as the ureters, main renal arteries and veins, and segments of the juxtarenal aorta and inferior vena cava. Most cases are related to arterial kinking or intimal dissection (Fig. 52.47). Segmental infarctions sometimes occur in the early postoperative period in allografts with multiple renal arteries, but these lesions more commonly develop as a late complication in association with acute or chronic rejection[130] (Fig. 52.48). Clinical symptoms of infarction include tenderness

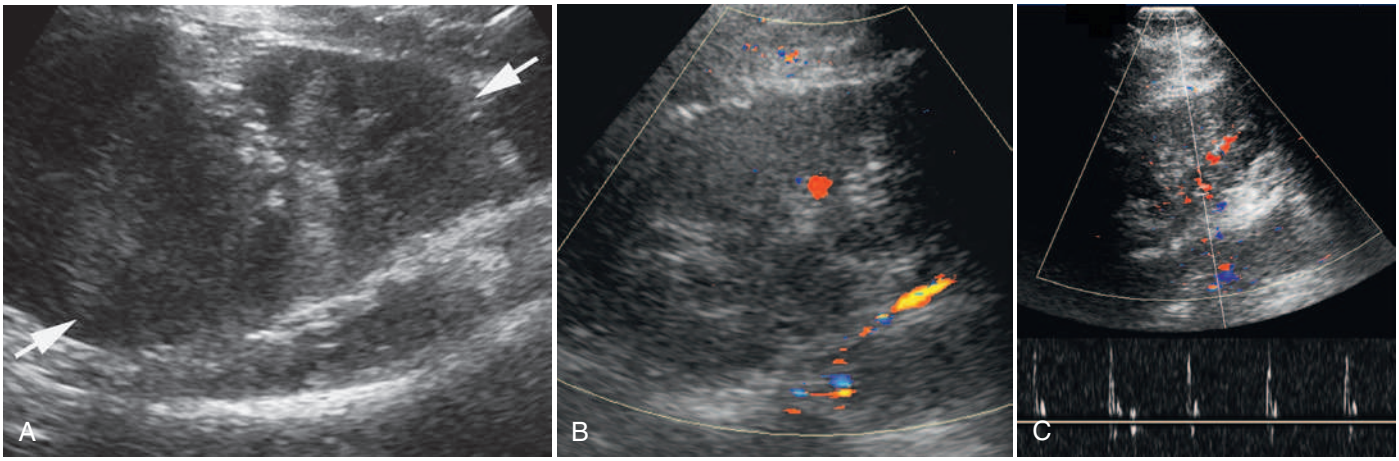

FIG. 52.47 Arterial Thrombosis in a 15-Year-Old Boy 1 Day After Kidney Transplantation. (A) Longitudinal sonogram of renal allograft shows a swollen kidney with poor corticomedullary differentiation *(arrows)*. **(B)** Color Doppler imaging reveals minimal intrarenal flow. **(C)** Spectral Doppler analysis of the main renal artery in the hilum of the kidney depicts systolic spikes with no appreciable diastolic flow.

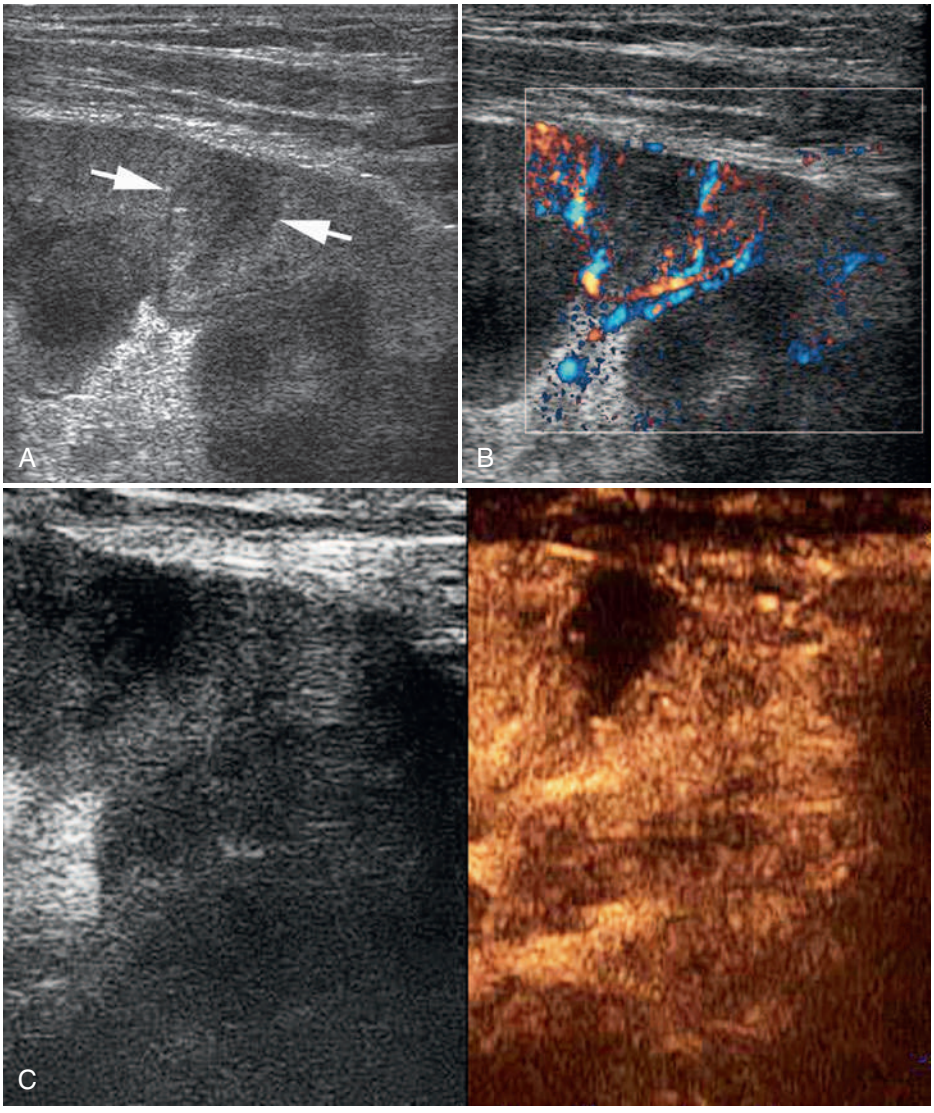

FIG. 52.48 Segmental Infarction of Renal Allograft 5 Years After Transplantation. (A) Longitudinal gray-scale image demonstrates a hypoechoic, triangular zone in the renal cortex *(arrows)*. **(B)** Color Doppler image shows displacement of vessels around this zone. **(C)** Contrast-enhanced ultrasound reveals focal absence of perfusion in keeping with infarction (reference gray-scale image in left panel). (Courtesy of Dr. Ákos Járay, University of Pécs, Hungary.)

and swelling over the graft and anuria. However, severe rejection has been reported to cause markedly diminished blood flow that mimics arterial thrombosis. Thus optimization of Doppler imaging parameters for the detection of slow flow is mandatory to prevent misdiagnosis of arterial thrombosis when acute rejection is present.[131] Unfortunately, graft failure is the usual outcome of arterial thrombosis, although urgent thrombolytic therapy or thrombectomy can be attempted.

Renal vein thrombosis is also uncommon in pediatric renal transplants, occurring in approximately 2% of allografts.[129] Virtually all cases occur within the first postoperative month.[127] The clinical symptoms are similar to those associated with renal artery thrombosis. Sonography often shows edema and abnormally increased echogenicity of the renal parenchyma. Venous flow is absent within the main renal vein, and there is associated reverse diastolic flow within the main renal artery. Early recognition of renal vein thrombosis is critical because graft salvage is potentially possible with either thrombolytic therapy or thrombectomy.[132]

Renal artery stenosis is a late complication, with a reported incidence of 4% to 18%.[124,133] Clinical presentations include new or progressive hypertension, marked hypertension refractory to medical therapy, hypertension associated with graft dysfunction in the absence of rejection, and hypertension associated with a systolic bruit audible over the graft.[134] The incidence of renal artery stenosis in children is difficult to determine because there is no consensus as to what degree of arterial narrowing is clinically significant. The most widely accepted criterion is elevation of peak systolic velocity at the site of narrowing, although there is conflicting literature regarding optimal cutoff values.[135-137] In adults, peak systolic values greater than 250 or 300 cm/sec have been shown to be highly sensitive and specific for the diagnosis of renal artery stenosis.[138,139] However, there are minimal data regarding the usefulness of these criteria in children.[140]

Sonographic evaluation with color and spectral Doppler reveals elevated velocities in the narrowed segment with spectral broadening of the arterial waveform. There is sometimes an associated downstream tardus-parvus waveform in the intrarenal arteries with associated low RIs. There may be color aliasing within the stenotic portion of the artery and perivascular soft tissue vibration artifacts caused by turbulent flow in the stenotic segment.[141] For this reason, the velocity measurements in the main renal artery, the iliac artery, and the segmental renal arteries should be interpreted together.[142] Magnetic resonance angiography (MRA) or CT angiography can be performed before conventional angiography, the current reference standard imaging test. These investigations may detect a significant stenosis of the transplant main renal artery. However, even in these patients there can be stable graft function with conservative treatment.[124,138]

Renal biopsies are routinely performed for graft surveillance and for assessment of graft dysfunction. An **arteriovenous fistula** (AVF) is the most common complication of graft biopsy, reported in 8% of cases by Schwarz and colleagues,[143] and is almost always inconsequential. Most AVFs are asymptomatic, and more than three-quarters will resolve spontaneously. Symptomatic fistulas resulting in ischemia because of a vascular steal phenomenon are treated with embolization. Sonographically, an AVF may be missed on gray-scale imaging but obvious with color and spectral Doppler evaluation (Fig. 52.49). Pseudoaneurysm is another complication of renal biopsy, and also tends to be asymptomatic and usually resolves spontaneously. With gray-scale sonography, pseudoaneurysms appear as simple or complex cystic structures. Color Doppler imaging reveals the classic **"yin-yang" pattern** of to-and-fro flow (Fig. 52.50). Spectral Doppler analysis at the neck of the pseudoaneurysm demonstrates disordered bidirectional blood flow. Progressive enlargement of the pseudoaneurysm or a diameter greater than 2 cm is an indication for embolic therapy.[130,144]

Perinephric Fluid Collections

Perinephric fluid collections are the most common nonrenovascular complications of kidney transplantation in children and occur with a frequency similar to that observed in adults.[129] ultrasound cannot definitively differentiate among hematoma, seroma, lymphocele, and abscess.

Lymphocele is the most common perinephric collection, and is usually an incidentally noted, well-defined, anechoic fluid collection adjacent to the graft (Fig. 52.51). A urine leak, or **urinoma,** can appear as an amorphous, anechoic fluid collection surrounding the graft or can have a more complex appearance **Hematomas** and **abscesses** usually appear as complex perinephric collections. Follow-up studies are useful in documenting changes in collection size. Progressive decrease in size can obviate the need for further workup, and ultrasound-guided percutaneous aspiration can be performed when further characterization of the fluid is necessary.[142]

Parenchymal Abnormalities

In the immediate postoperative period, diffuse parenchymal abnormality of the renal graft is caused by **acute tubular necrosis** (ATN), **rejection,** and **drug toxicity.** ATN occurs to some degree in most renal grafts immediately after surgery, wherein it is also referred to as "preservation injury." It is characterized clinically by oliguria and poor renal function and is more pronounced in kidneys obtained from cadaveric donors and from donors with prolonged ischemic times.[144]

Acute rejection, humoral or cellular, is the most common type of rejection. Symptoms commonly include poor renal function, tenderness over the graft, oliguria, and edema. Improvements in immunosuppressive therapy have resulted in a substantial decrease in the incidence of acute rejection over the last 10 to 15 years.[145] The cornerstone of immunosuppressive therapy in pediatric renal transplantation is the calcineurin inhibitors cyclosporine and tacrolimus, but their nephrotoxic potential can lead to graft injury. Clinical findings are similar to those associated with ATN and rejection—commonly, decreasing urine output, rising serum creatinine, abdominal pain, and fever. The imaging features of these disorders also overlap with one another, including graft enlargement, loss of corticomedullary differentiation, and decreased diastolic arterial blood flow with increased RIs. Sonography is most helpful in ruling out other causes of graft dysfunction such as compression from a perinephric fluid collection, urinary collecting system obstruction, or large vessel abnormality.[130] When there is significant graft dysfunction and

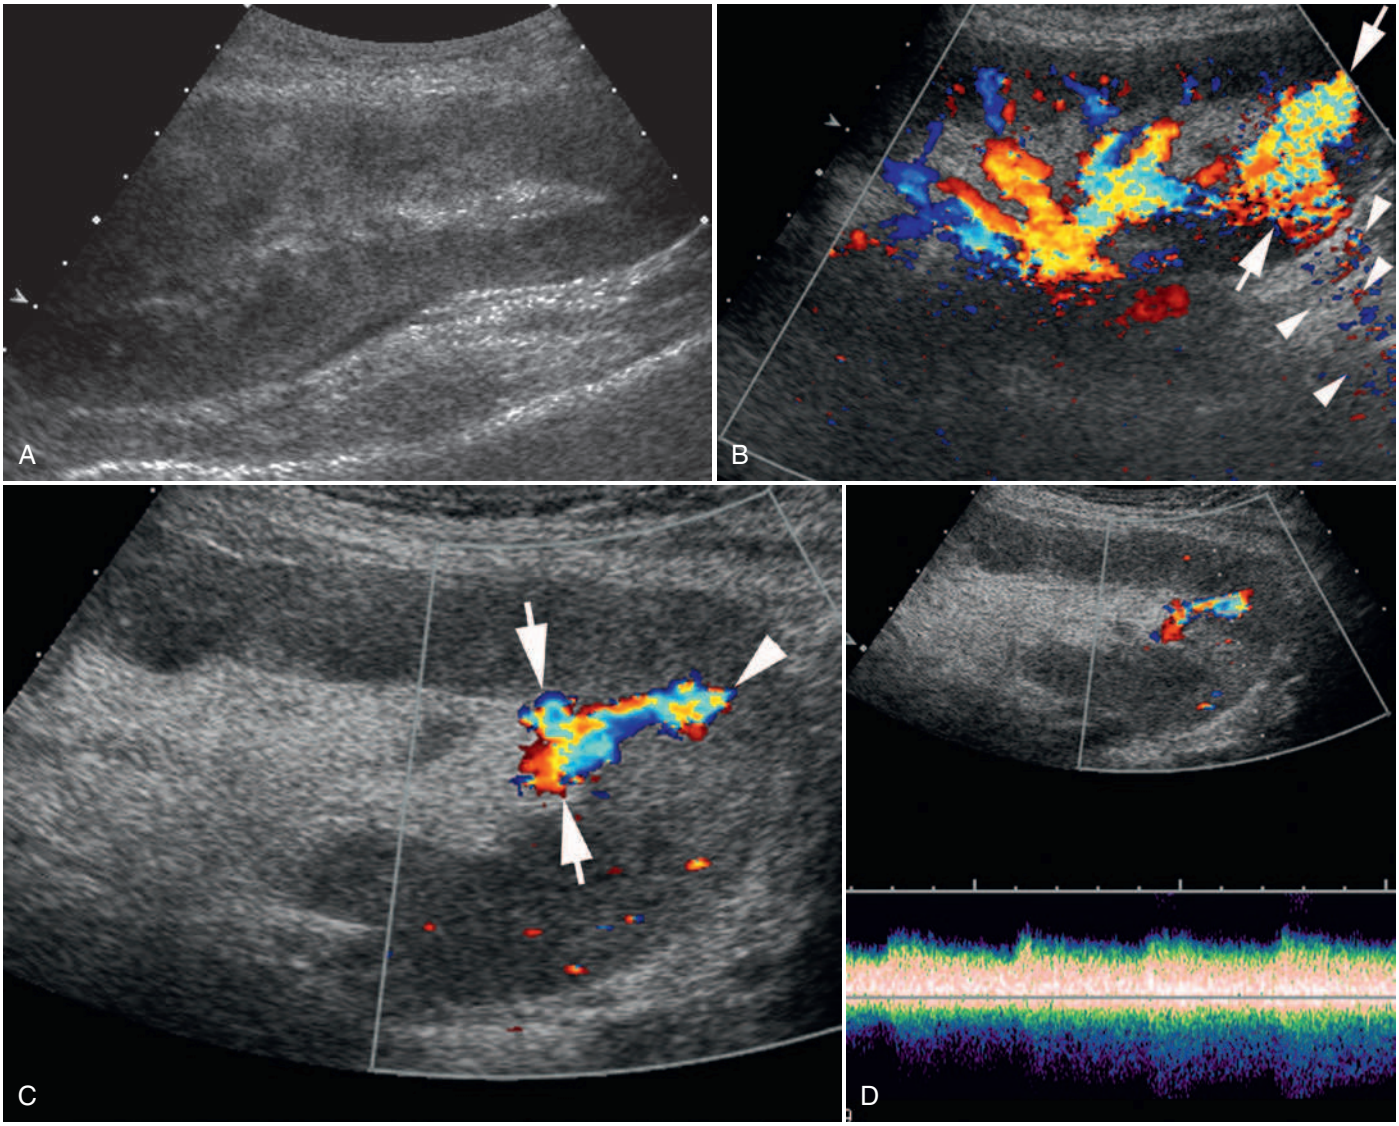

FIG. 52.49 Postbiopsy Arteriovenous Fistula (AVF). (A) Longitudinal gray-scale image of a renal allograft reveals no abnormality. **(B)** Color Doppler image shows markedly increased lower-pole blood flow *(arrows)* with adjacent soft tissue color artifact related to tissue vibration *(arrowheads).* **(C)** Color Doppler image with significantly increased velocity setting shows a focal, rounded AVF in the lower pole *(arrowhead)* with associated feeding and draining vessels *(arrows).* **(D)** Spectral Doppler waveform analysis depicts AVF high-amplitude, low-resistance arterial blood flow above the baseline, and arterialized venous flow below the baseline.

nonspecific sonographic findings, renal biopsy is usually indicated for a definitive diagnosis.

With improving early graft survival in children, **chronic rejection** currently represents the most common cause of overall pediatric graft failure, accounting for one-third of all graft loss.[146] This fact is particularly important in the pediatric population because of high rates of medication noncompliance during adolescence. Noncompliant periods are believed to increase the risk for chronic rejection by permitting subclinical chronic immune injury.[147]

Chronic allograft injury demonstrates similar imaging findings regardless of cause. Sonography demonstrates progressive volume loss with diffuse cortical atrophy, often with superimposed focal cortical scarring. Mild to moderate collecting system dilation can be seen in the absence of obstruction (Fig. 52.52).

Urologic Complications

Urologic complications are the most frequent cause of surgical morbidity in the pediatric transplant population, occurring in up to 23% of transplant recipients. There is a higher incidence in children with underlying malformations of the urinary tract, such as obstructive lesions, lower urinary tract dysfunction, and/or previous urologic reconstruction.[148-152] Common complications include urine leak, ureteral obstruction, VUR, and pyelonephritis.

A **urine leak** usually develops as a complication of ischemic necrosis or increased urinary pressure due to obstruction, and can occur anywhere in the urinary tract, from the renal calyces to the site of the ureterocystostomy.[153] It typically manifests within the first 2 weeks after transplantation with oliguria and azotemia, frequently associated with severe pain in the region of the graft.

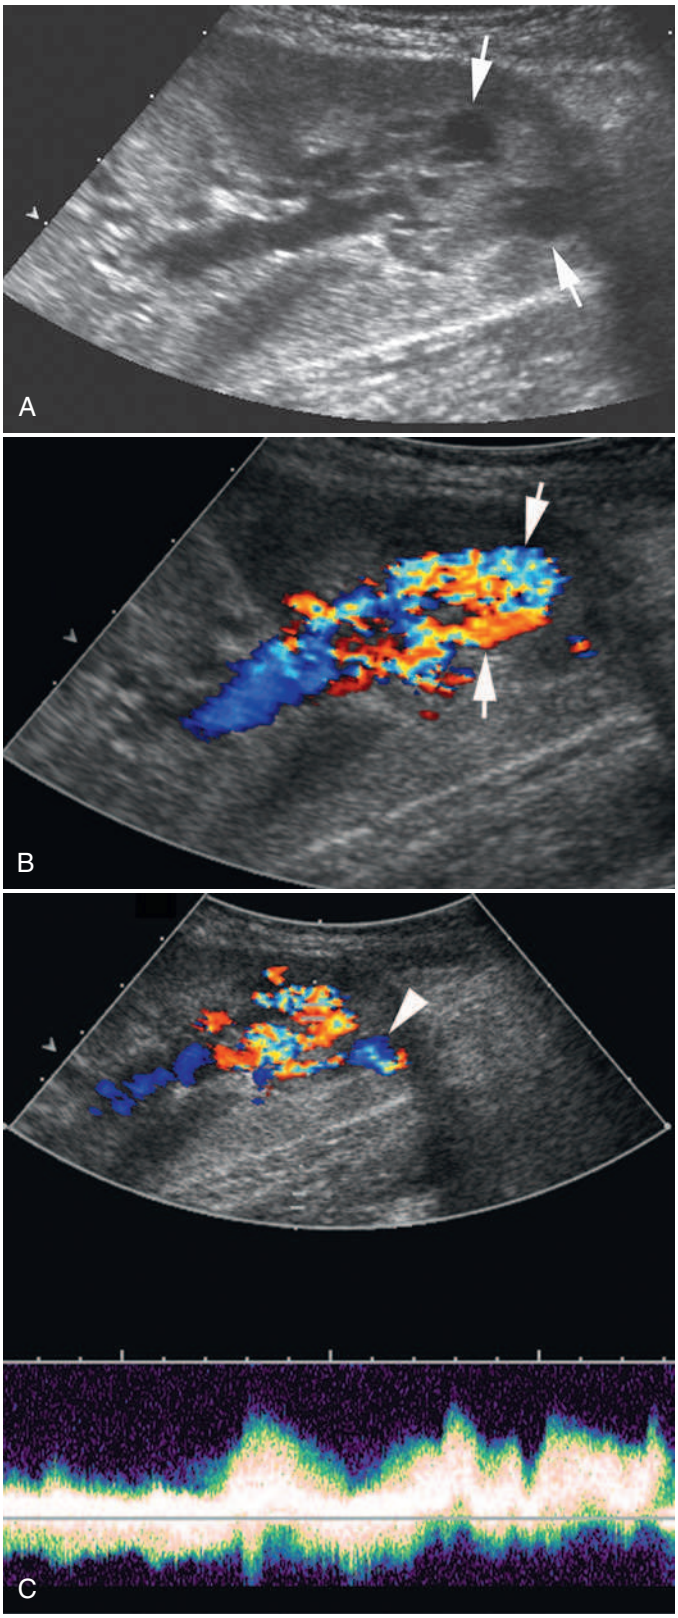

FIG. 52.50 Postbiopsy Pseudoaneurysms. (A) Longitudinal gray-scale image of a renal allograft shows two rounded lower-pole anechoic cystic structures *(arrows).* **(B)** Color Doppler imaging reveals a "yin-yang" sign caused by swirling blood flow within the upper pseudoaneurysm *(arrows).* **(C)** Spectral Doppler analysis depicts disordered blood flow above and below the baseline. Arrowhead indicates lower pseudoaneurysm.

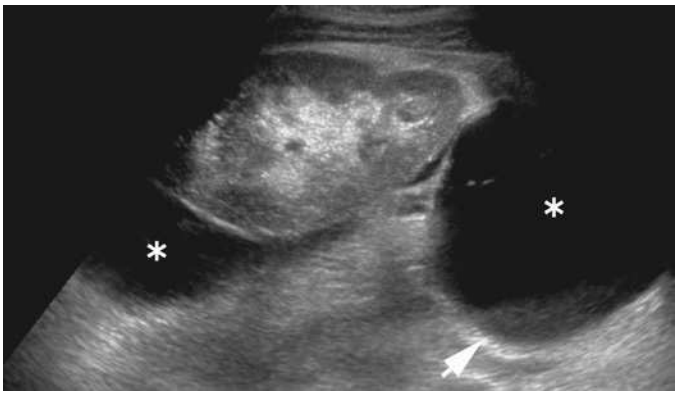

FIG. 52.51 Lymphocele. Longitudinal gray-scale image demonstrates two anechoic fluid collections adjacent to the upper and lower poles of a renal allograft (*). The lower collection is separate from the bladder *(not shown)* and contains a small amount of echogenic, dependent debris *(arrow).*

Depending on whether the allograft is located intraperitoneally or extraperitoneally, the leak can result in a localized perinephric urinoma or urine ascites.[130] A urinoma will usually appear as an anechoic, well-circumscribed, perinephric fluid collection. If clinically indicated, ^{99m}Tc-mertiatide renal scintigraphy, contrast-enhanced CT, or magnetic resonance urography can be performed to differentiate urinoma from seroma or lymphocele.

Urinary tract obstruction usually becomes apparent in the first few months after transplantation, and in general manifests clinically with nonspecific graft dysfunction. About 50% of the time, obstruction is related to an **ischemic stricture** at the ureteroneocystostomy. Other causes include midureteral stenosis, stone, blood clot, fungus ball, and extrinsic compression. Midureteral stenosis usually occurs in the setting of chronic rejection. Some degree of hydronephrosis is commonly identified after renal transplantation in both children and adults as a result of denervation with loss of muscle tone of the donor collecting system. The presence or absence of mild to moderate collecting system dilation has been shown to correlate poorly with the presence or absence of urinary tract obstruction in the post-transplant patient.[154] However, sonographic depiction of moderate to severe hydronephrosis and hydroureter that increase progressively over time warrants further evaluation for posttransplant urinary tract obstruction. MAG3 renal scintigraphy or magnetic resonance urography can be performed, with the more invasive method of percutaneous antegrade urography used to localize the site of obstruction. A nephrostomy tube can be placed for purposes of urinary tract decompression and to permit stent placement or balloon ureteroplasty.[130]

Vesicoureteral reflux (VUR) has been documented in approximately one-third to one-half of children after renal transplantation.[155,156] However, the presence of VUR does not appear to be associated with either an increased frequency of posttransplant urinary tract infection or decreased long-term graft function.[149,156] Patients with VUR into the transplant kidney usually have an underlying urologic abnormality, most commonly PUVs.[157,158]

Allograft infection may manifest as pyelonephritis, perinephric or parenchymal abscess, pyonephrosis, or fungus ball. Although

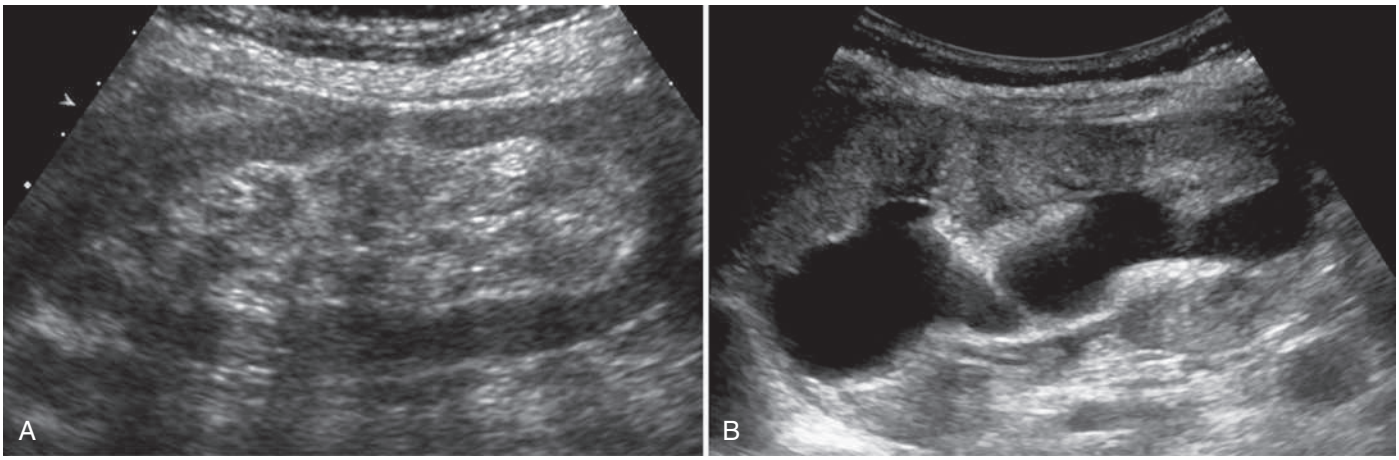

FIG. 52.52 Chronic Allograft Nephropathy. (A) Longitudinal gray-scale image of a renal allograft reveals diffuse cortical atrophy. **(B)** Longitudinal gray-scale image of a different patient demonstrates echogenic cortex and decreased corticomedullary differentiation. There is also moderate collecting system dilation.

pyelonephritis after renal transplantation in children is relatively common in comparison to adult transplant recipients, if treated promptly it does not appear to adversely affect graft function.[159,160] Pyelonephritis is associated with VUR in pediatric renal transplant recipients.[160] As with the native kidney, the sonographic appearance of pyelonephritis is variable, ranging from normal to swelling and altered parenchymal echogenicity related to edema.

A **perinephric** or **parenchymal abscess** is an uncommon complication of graft pyelonephritis. Other causes include infection of the surgical site or spontaneous or iatrogenic infection of a previously sterile fluid collection. They commonly appear within the first postoperative month. Although the sonographic appearance of an abscess is relatively nonspecific, a complex appearance with prominent septations, internal debris, and mural hyperemia documented with color and spectral Doppler is suggestive of an infectious etiology. In the setting of pyelonephritis, the presence of mobile, hyperechoic foci within a dilated collecting system should raise concern for pyonephrosis.[161] Fungus balls manifest as discrete intraluminal masses.[153]

Urinary tract stones occur with the same frequency in renal transplant recipients as in the general population.[162] Sonography is helpful in identifying stones within the renal parenchyma, collecting system, ureter, and bladder, as well as documenting any associated hydronephrosis or hydroureter.

Tumors

Long-term immunosuppression predisposes renal transplant recipients to the development of neoplasia, both within the transplant kidney and in other organs.[80] **Posttransplant lymphoproliferative disorder (PTLD)** and **inflammatory myofibroblastic tumor** have been reported.

The imaging appearance of PTLD depends on the site of involvement (Fig. 52.53). When the allograft is affected, it typically appears as multiple ill-defined, hypoechoic parenchymal masses.[130] Inflammatory myofibroblastic tumor is a rare and usually benign neoplasm that can develop after bone marrow solid organ and bone marrow transplantation.[163] It may occur anywhere in the body, although it favors certain locations, including the lung, liver, gastrointestinal tract, and bladder.

RENAL CYSTIC DISEASE

The category of renal cystic diseases includes a large group of disorders with variable phenotypic expression. Cystic diseases may be diagnosed in utero or may be seen in infancy, childhood or adulthood. They can usually be differentiated on the basis of clinical findings, including age at presentation, renal imaging features (including cyst distribution), and the presence and nature of extrarenal manifestations. Ultrasound evaluation plays a central role in the diagnostic evaluation of patients with renal cysts. In individuals with an atypical presentation, additional imaging studies and/or genetic testing may be necessary to establish a diagnosis.[164]

Autosomal Recessive Polycystic Kidney Disease

ARPKD is a severe hepatorenal fibrocystic disorder characterized by nonobstructive renal collecting duct dilation and malformation of the portobiliary system.[164] It is caused by mutations in the polycystic and hepatic disease gene 1 *(PKHD1),* which encodes fibrocystin-polyductin complex, a protein expressed in primary cilia of kidney and bile duct epithelial cells.[165] ARPKD occurs in approximately 1 : 20,000 live births.[166] In general, it is diagnosed prenatally in association with oligohydramnios or at birth when it is characterized by progressive renal insufficiency and portal hypertension. Oligohydramnios results in the so-called "Potter sequence" consisting of pulmonary hypoplasia, limb defects, and characteristic dysmorphic facies. There is an estimated perinatal mortality rate of 30% as a result of respiratory insufficiency.[167,168] However, in infants who survive the first month of life, 1-year survival rates of 92% to 95% have been reported.[166] The kidneys are enlarged and echogenic, with loss of normal parenchymal corticomedullary differentiation. Medullary echogenicity is increased as a result of the multiple interfaces associated with the

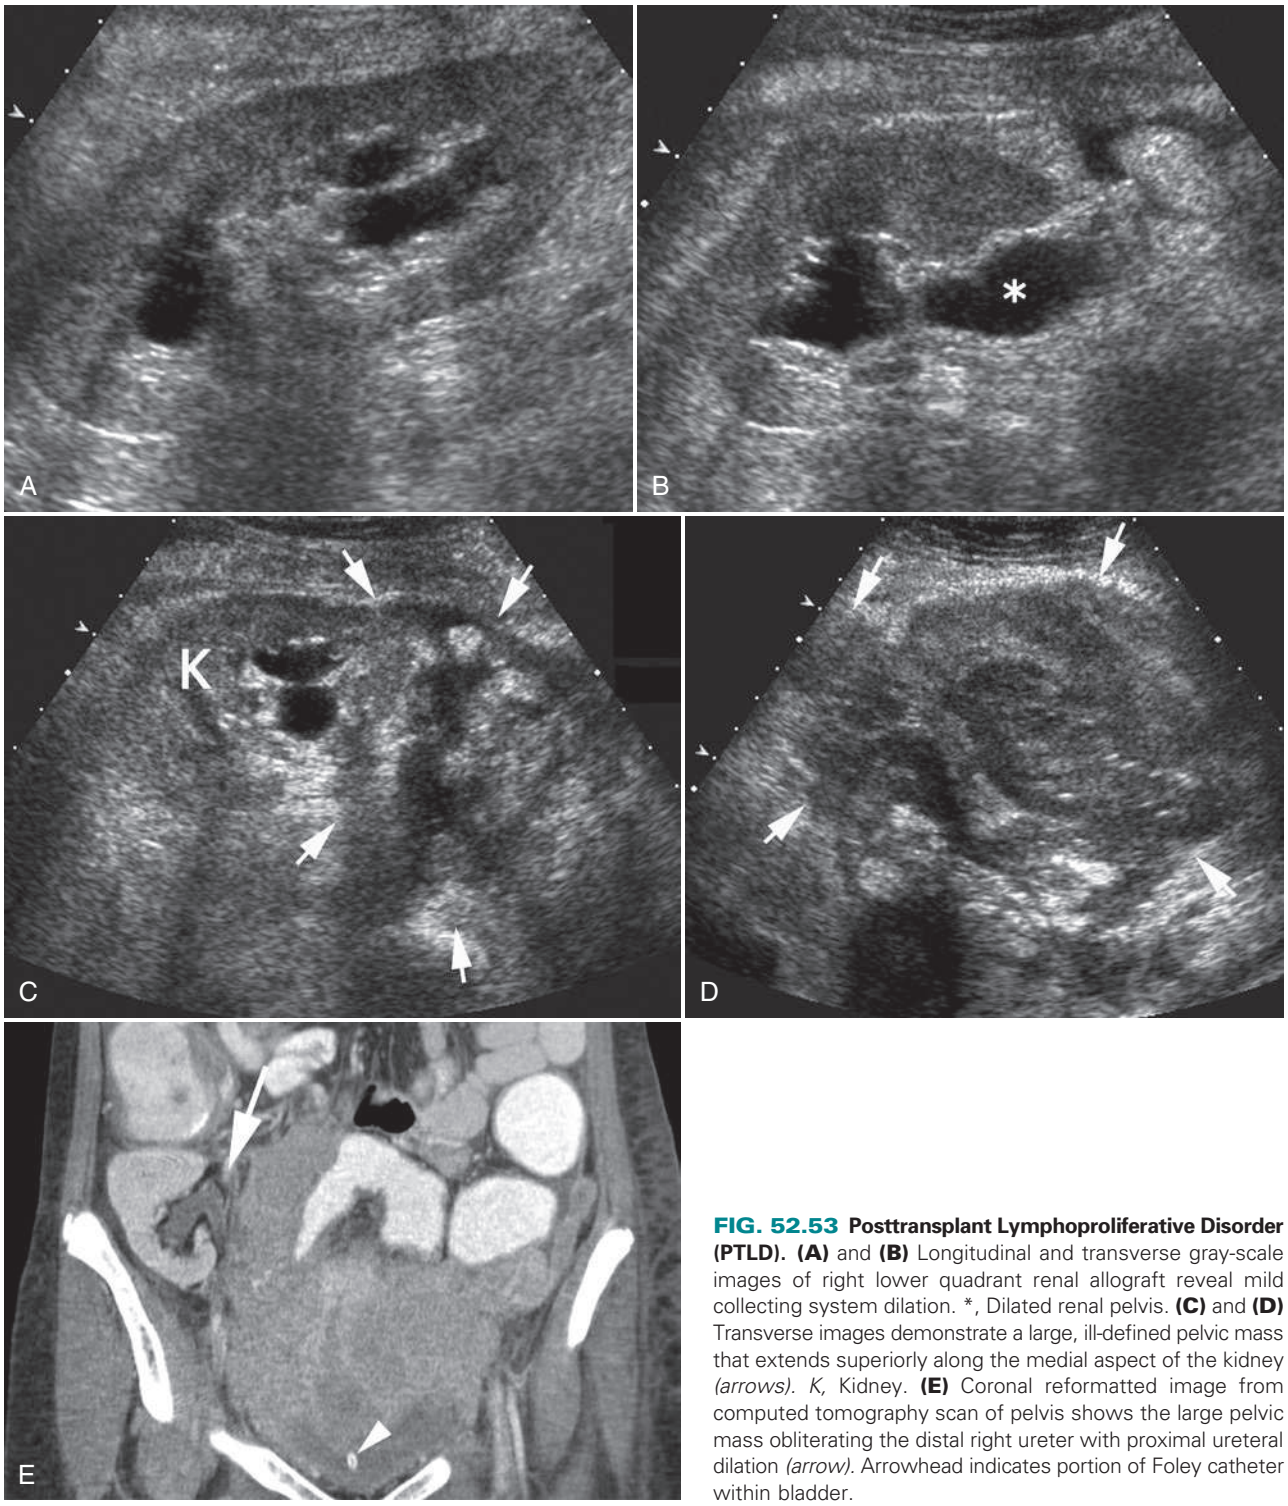

FIG. 52.53 Posttransplant Lymphoproliferative Disorder (PTLD). (A) and **(B)** Longitudinal and transverse gray-scale images of right lower quadrant renal allograft reveal mild collecting system dilation. *, Dilated renal pelvis. **(C)** and **(D)** Transverse images demonstrate a large, ill-defined pelvic mass that extends superiorly along the medial aspect of the kidney *(arrows). K,* Kidney. **(E)** Coronal reformatted image from computed tomography scan of pelvis shows the large pelvic mass obliterating the distal right ureter with proximal ureteral dilation *(arrow).* Arrowhead indicates portion of Foley catheter within bladder.

dilated collecting ducts that reflect sound. The cortex is frequently compressed by the dilated medullary collecting ducts, leading to a hypoechoic halo. Dilated cortical collecting ducts located immediately beneath the renal capsule may be seen with high-resolution ultrasound (Fig. 52.54). They tend to lie in parallel columns with a distribution that is radial to the kidney as a whole.[169] Renal size stabilizes or decreases over time. Macrocysts are not usually noted at birth but may develop later in childhood.

Histologic hepatic involvement is present in all patients with ARPKD. In embryonic life, biliary precursor cells form a periportal sheet known as the "ductal plate" that is progressively remodeled to generate intrahepatic bile ducts. A remodeling defect in patients with ARPKD leads to intrahepatic ductal dilation and progressive portal tract fibrosis. Patients who survive the neonatal period may develop portal hypertension as a result of the periportal fibrosis.

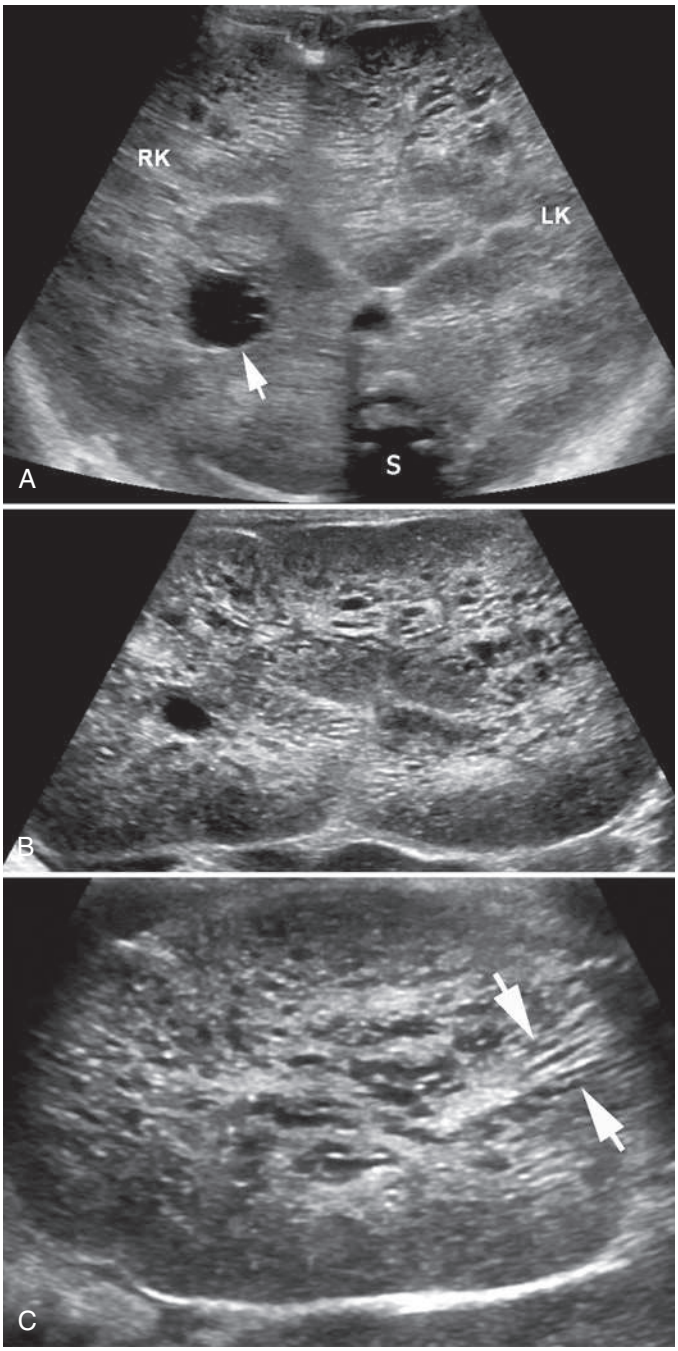

FIG. 52.54 Autosomal Recessive Polycystic Kidney Disease (ARPKD). (A) Transverse image of neonate shows symmetrically enlarged kidneys filling the abdomen. *LK,* Left kidney; *RK,* right kidney; *S,* spine. A macrocyst is present in the right kidney *(arrow).* **(B)** Longitudinal image of right kidney demonstrates loss of normal corticomedullary differentiation, hypoechoic subcapsular cortex, and multiple cysts of varying size within the medullary region. **(C)** High-resolution transverse image of left kidney reveals multiple dilated subcapsular cortical collecting ducts *(between arrows).*

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common inherited form of kidney failure that eventually results in end-stage renal disease. It is characterized by bilateral, progressive enlargement of focal cysts that occur in all portions of the nephron, and variable extrarenal manifestations also occur. Approximately 600,000 individuals in the United States are affected, and 13 million people worldwide.[170]

ADPKD is usually asymptomatic until middle age. However, in about 2% to 5% of patients, ADPKD is seen in the neonatal period, with substantial morbidity and mortality. These early manifestations of ADPKD may be indistinguishable from ARPKD and can be differentiated only on the basis of histologic or genetic analysis. There is a familial incidence of childhood presentation, with siblings of affected children demonstrating a greater risk of early disease.[171]

ADPKD is caused by dominant transmission of one of two defective genes, *PKD1* (mapped to chromosome 16p13.3 in 85% of patients) or *PKD2* (mapped to chromosome 4q13–23 in 15% of patients). *PKD1* encodes the protein polycystin-1 and *PKD2* encodes polycystin-2. These two proteins are localized to the primary cilia in the epithelial cells that line the renal tubules and interact to form a calcium channel receptor. Both are important in the differentiation, maintenance, and repair of renal tubular cells and in determining the morphology of the renal tubules. *PKD1*-associated disease is generally more severe than *PKD2*-associated disease. However, there is significant phenotypic heterogeneity. Unusually mild cases are believed to be due to the transmission of so-called "hypomorphic" alleles (i.e., those that have retained partial activity).[170,172]

Most children with ADPKD are born with normal kidneys. Normal ultrasound examination findings cannot exclude ADPKD until after the age of 35 years, particularly for *PKD2* mutations.[173] The presence of at least two renal cysts (unilateral or bilateral) in an individual younger than 30 years of age with a 1 in 2 risk of *PKD1* is sufficient to establish the diagnosis.[174] Even a single cyst in a genetically predisposed child is highly suspicious for ADPKD because the prevalence of renal cysts in the general pediatric population is low[175,176] (Fig. 52.55). The concomitant presence of an extrarenal cyst in the liver or pancreas indicates the diagnosis of ADPKD, although these are rare at initial presentation in children.[176,177] Older children have larger and more numerous renal cysts and develop progressive renal enlargement (Fig. 52.56). Results from the Consortium of Renal Imaging Studies in Polycystic Kidney Disease have shown that the larger the cyst mass or renal volume, the worse the prognosis, regardless of whether the cysts derive from an *ADPKD1* or *ADPKD2* gene defect.[178]

In third-trimester fetuses and infants with ADPKD in the neonatal period, the kidneys are normal in size to mildly enlarged. The cortex is hyperechoic compared with the liver or spleen with hypoechoic medulla resulting in increased corticomedullary differentiation[179] (see Fig. 52.55). This appearance differs from the usual appearance of ARPKD, in which the kidneys are markedly rather than mildly enlarged and the medullae are hyperechoic. A few small cysts may be seen in the cortex, medulla, or both in ADPKD. Unlike the tubular cysts of ARPKD, the cysts in the dominant form appear round.[167,180]

Extrarenal manifestations include cysts of the liver, spleen, pancreas, seminal vesicles, and arachnoid membrane. The liver is the most common extrarenal site of involvement. Aneurysms

of the intracranial vessels and aorta and aortic dissection are additional associations.[181]

Multicystic Renal Dysplasia

Multicystic dysplastic kidney (MCDK) is a congenital malformation, with an incidence of about 1 per 4000 live births.[182] Histologically, multiple noncommunicating cysts are separated by dysplastic parenchyma. The etiology of MCDK is uncertain, although various theories have been proposed. The "ureteric bud theory" of Mackie and Stephens hypothesizes that MCDK may result from a ureteric bud that is atretic or connects abnormally with the metanephric mesenchyme and the developing bladder, resulting in obstruction.[183] Work by Batourina and colleagues[184] and Viana and colleagues[185] suggests that an abnormal interaction between the developing bladder trigone and the distal ureter may result in dysfunction at the ureterovesical junction and subsequent obstruction. Bilateral MCDK disease is usually lethal shortly after birth, owing to associated pulmonary hypoplasia secondary to prolonged oligohydramnios in utero. With unilateral MCDK, renal function is usually maintained by the contralateral kidney.[186] Although MCDK can be an isolated finding, it frequently occurs in association with other anomalies of the urinary tract, most commonly VUR, UPJO, and UVJO.[186] It is also a common or characteristic finding in multisystemic genetic disorders such as **branchio-oto-renal syndrome** and **renal-coloboma syndrome.**[183]

MCDK is usually diagnosed by prenatal sonography (Fig. 52.57, Video 52.7), or if unilateral may be found as an abdominal mass at birth. The common pelvoinfundibular form of MCDK manifests as numerous, randomly distributed noncommunicating cysts of varying size. There is no renal pelvis or renal sinus, and renal parenchyma is absent or dysplastic. The less common hydronephrotic form of MCDK consists of multiple small, peripheral cysts and a larger central cyst, with some connections between the peripheral cysts and the central cyst. The entire kidney is usually involved and may be small, normal in size, or enlarged. There is no or minimal functional renal tissue.[187] The contralateral kidney usually demonstrates compensatory hypertrophy. Segmental involvement may occur, most often in the upper-pole moiety of a duplex kidney.[188] In patients with no other urologic abnormalities, MCDK is managed nonoperatively, as the risk of associated malignancy is low. Most affected kidneys will undergo partial or complete involution.[189]

FIG. 52.55 Autosomal Dominant Polycystic Kidney Disease (ADPKD). Longitudinal gray-scale image of 33-week gestational age fetus of a mother with ADPKD reveals a small, round cyst in the upper pole of the right kidney consistent with ADPKD *(arrow)*. Renal parenchymal echogenicity is slightly increased and the medullary pyramids are hypoechoic. Both right and left kidneys were mildly enlarged for gestational age.

Nephronophthisis and Medullary Cystic Disease

Nephronophthisis (NPHP) is an autosomal recessive tubulointerstitial disorder, and one of the most common causes of inherited end-stage kidney disease in children and young adults.[190] To date, 19 causative genes have been identified, although the causative genes are still unknown in approximately 70% of affected patients.[164] At presentation children usually are 4 to 6 years of

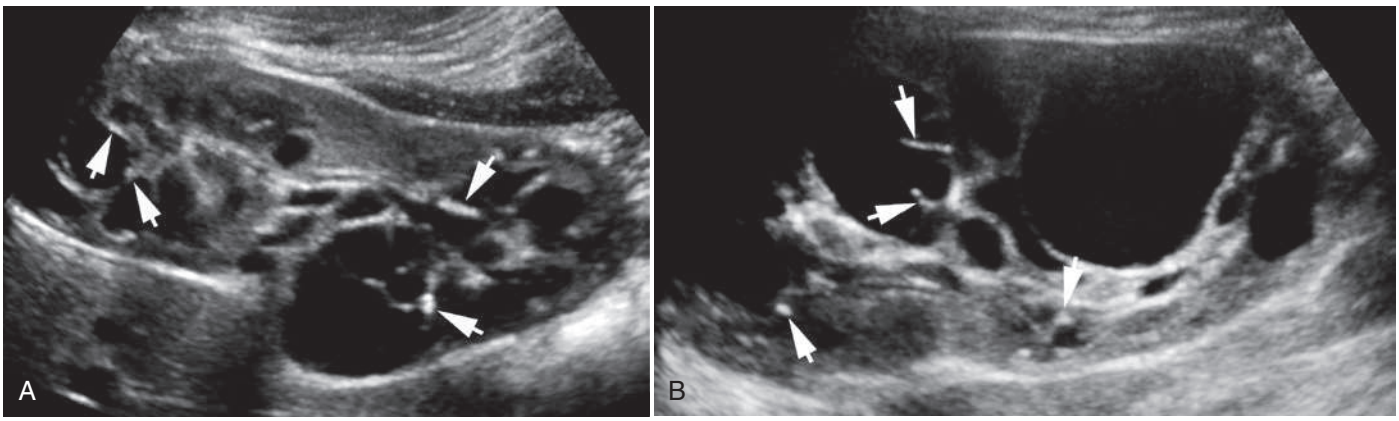

FIG. 52.56 Autosomal Dominant Polycystic Kidney Disease (ADPKD). (A) and **(B)** Longitudinal prone gray-scale images in a 17-year-old girl demonstrate enlarged right and left kidneys, respectively, containing multiple cysts of varying size. Scattered linear and punctate echogenic foci may represent mural calcifications and/or stones *(arrows)*.

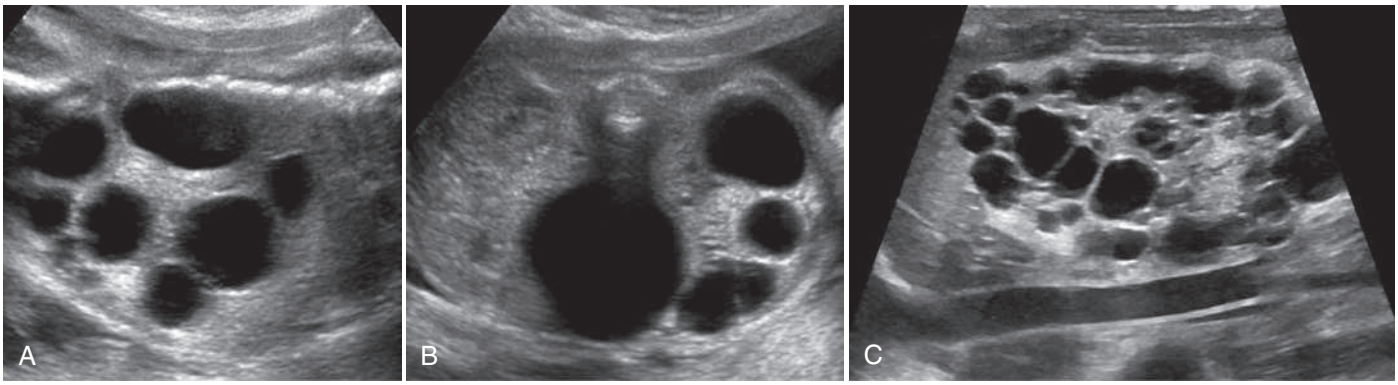

FIG. 52.57 Multicystic Dysplastic Kidney (MCDK). (A) and **(B)** Longitudinal and transverse gray-scale images of a 27-week gestational age fetus depict the presence of multiple cysts of varying size surrounded by echogenic cortex. **(C)** Longitudinal gray-scale image of a different patient at birth shows near-complete replacement of the left kidney by numerous cysts. See also Video 52.7.

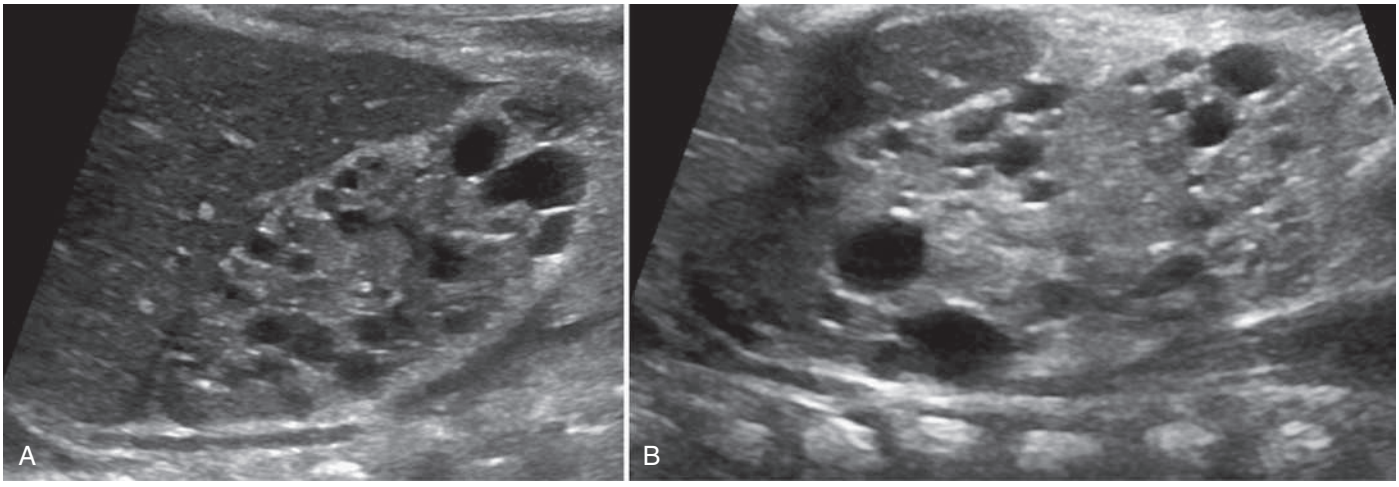

FIG. 52.58 Nephronophthisis. Neonate With Homozygous NPH3 Mutations Associated With Anuria and Pulmonary Hypoplasia. (A) and **(B)** Longitudinal gray-scale images of the right and left flanks, respectively, reveal echogenic parenchyma with loss of corticomedullary differentiation and multiple cysts located throughout both kidneys.

age and have polydipsia and polyuria and decreased urinary concentration. A slowly progressive decline in renal function typically occurs. An exception to this clinical presentation is the infantile variant, usually a result of mutation in the *NPHP2* or *NPHP3* gene, which is seen in patients in the first few months of life with renal insufficiency and hypertension, and rapid progression to end-stage renal disease.[191] The kidneys are normal in size or small, except in the infantile form, in which they are enlarged.[192] On ultrasound, the kidneys are echogenic with decreased corticomedullary differentiation (Fig. 52.58). Cysts may be observed at the corticomedullary junction.

Medullary cystic kidney disease is an autosomal dominant tubulointerstitial disorder that usually manifests in the third to sixth decades of life. As with NPHP, there may be a history of polydipsia and polyuria, and urinary concentrating ability is decreased. Type 1 disease is caused by heterozygous mutations in the *MUC1* gene. Type 2 disease is caused by heterozygous mutations in the uromodulin gene.[164] On ultrasound, the kidneys are normal to small in size, and often echogenic. Similar to NPHP, cysts can occur at the corticomedullary junction (Fig. 52.59).

Congenital Renal Cysts

Tuberous Sclerosis and Von Hippel–Lindau Disease

Although renal cysts occur in many syndromes, two of the most common are tuberous sclerosis and Von Hippel–Lindau Disease. **Tuberous sclerosis** is an autosomal dominant disease consisting of mental retardation, epilepsy, adenoma sebaceum, multiple ectodermal lesions, and mesodermal hamartomas. Renal lesions are present in more than 40% of patients and include cysts, which can be multiple and resemble ADPKD with renal enlargement (Fig. 52.60).

Von Hippel–Lindau disease is an autosomal dominant disorder characterized by the formation of tumors and cysts in many different organs throughout the body. Renal cysts and renal cell carcinoma are common visceral manifestations of this disorder, with the latter a significant cause of mortality.[193]

Acquired Cysts

Patients with **chronic renal failure,** especially those receiving long-term dialysis, often develop renal cysts (Fig. 52.61).

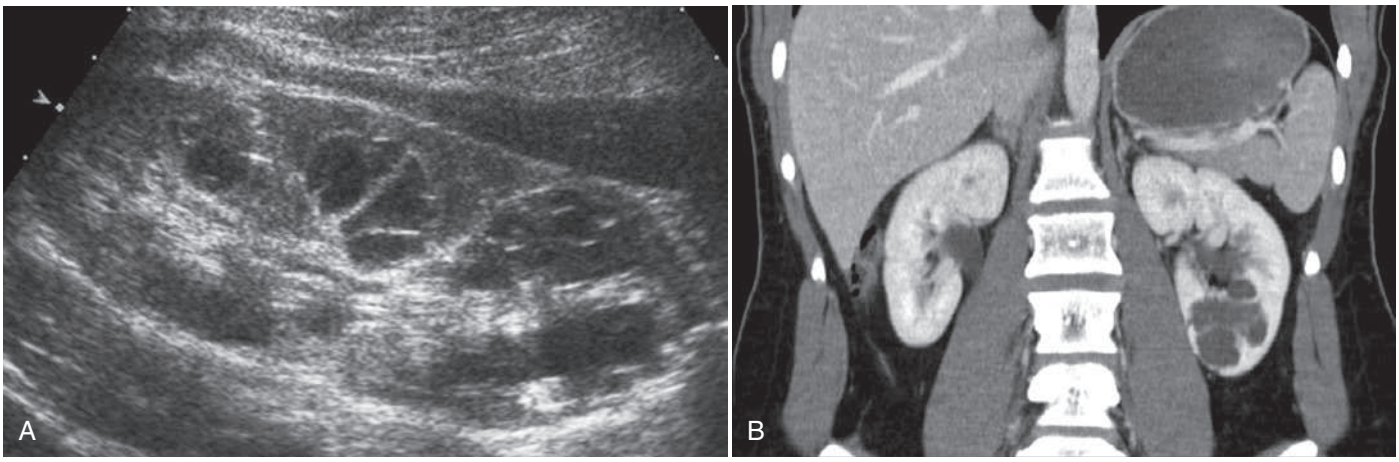

FIG. 52.59 Medullary Cystic Disease. Asymptomatic 17-year-old girl who underwent renal imaging after trauma. **(A)** Longitudinal gray-scale image of left kidney demonstrates multiple anechoic cysts within the medullary pyramids. **(B)** Coronal reformatted intravenous contrast-enhanced computed tomography image depicts the medullary cysts in the lower left renal pole.

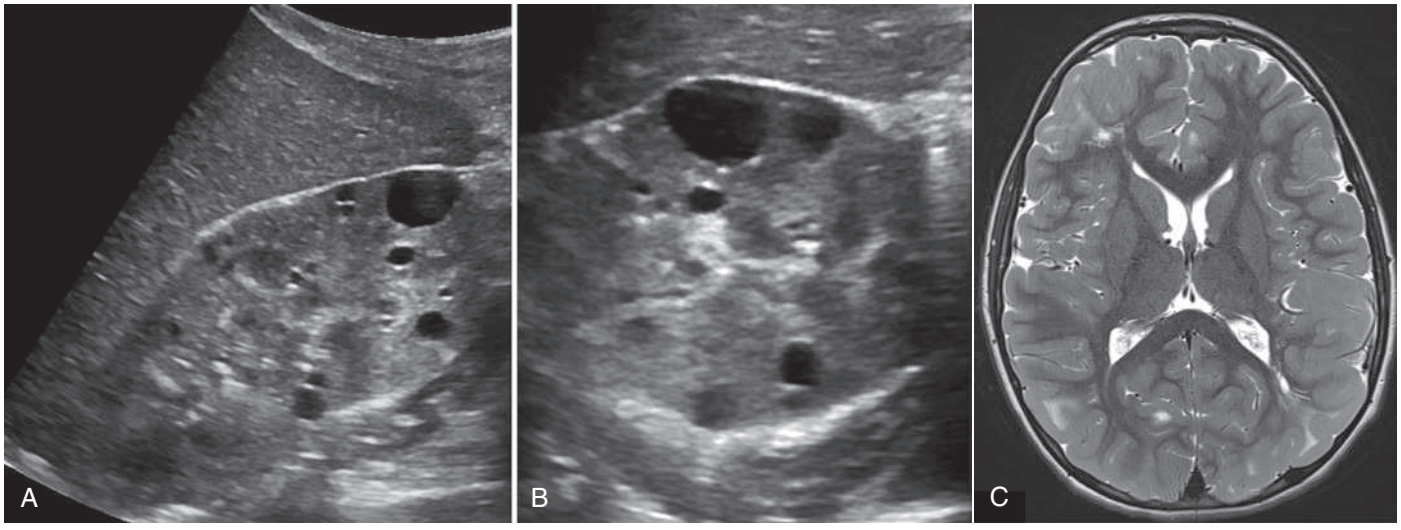

FIG. 52.60 Tuberous Sclerosis. **(A)** and **(B)** Longitudinal and transverse gray-scale images of the right kidney in a 6-year-old boy show multiple anechoic parenchymal cysts. **(C)** Axial T2 fluid-attenuated inversion recovery (FLAIR) magnetic resonance image of the brain demonstrates multiple foci of abnormally high signal in the subependymal and subcortical regions typical of tubers.

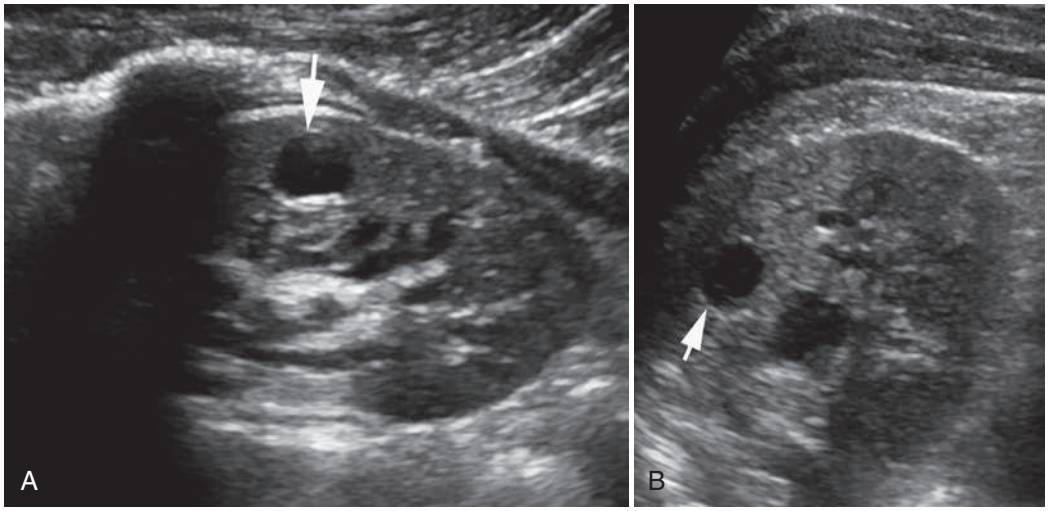

FIG. 52.61 Dialysis-Associated Renal Cyst. A 17-year-old boy on chronic hemodialysis for end-stage renal disease (ESRD). **(A)** and **(B)** Longitudinal and transverse images reveal a single anechoic cyst in the upper pole of the right kidney *(arrows).* There is loss of normal renal corticomedullary differentiation in keeping with ESRD.

Spontaneous hemorrhage within the cysts may also occur.[194,195] Renal cysts have also been reported to develop after **liver transplantation.** Patients at risk are at least 10 years posttransplant, have been treated with cyclosporine, and have impaired renal function.[196,197]

Simple cysts are generally asymptomatic and are much less common in children than in adults. They typically appear as a single mass arising from the renal parenchyma.[198] They may occasionally be complicated by infection, hemorrhage, or calcification.[199]

RENAL TUMORS

The most common abdominal masses in the child are of renal origin: hydronephrosis and MCDK. Solid tumors are less common. Initial imaging includes sonography and often a plain film of the abdomen. The site of origin of the mass, its architecture (cystic or solid), and vascularization can usually be determined with sonography.

If the mass is cystic and arises from the kidney, the usual differential diagnosis is between a hydronephrotic kidney and MCDK. The configuration of the cysts on sonography and, if needed, presence of function on nuclear renography help distinguish these two entities. If the mass is solid and related to the kidney, Wilms tumor is the most likely diagnosis. Metastases and tumoral invasion of the renal vein or inferior vena cava are sought during the sonographic survey of the abdomen. Staging of the tumor is usually done with CT or MRI.[200,201] If the kidney is normal and the mass is related to another organ, the workup continues with imaging that is optimal for that organ.

Wilms Tumor

Wilms tumor, or **nephroblastoma,** is the most common intra-abdominal malignant tumor of childhood. Approximately 80% of patients are aged 1 to 5 years at presentation, with a peak incidence at 3 to 4 years of age.[202] When the tumor is large, it may be difficult to differentiate from **neuroblastoma,** which frequently arises from the adrenal gland and occurs in a similar age group. Wilms tumor is usually bulky and expands within the renal parenchyma, resulting in distortion and displacement of the collecting system and capsule. It is usually sharply marginated. Five percent to 10% of patients have bilateral tumors, and **nephroblastomatosis** may be present in both kidneys in children with unilateral Wilms tumor. Screening is recommended for children at high risk for the development of Wilms tumor, including those with **hemihypertrophy, sporadic aniridia, Beckwith-Wiedemann syndrome, WAGR syndrome** (Wilms tumor, aniridia, genitourinary anomalies, and intellectual disability [mental retardation]), and nephroblastomatosis.[202]

Typically, Wilms tumor is a large solid mass distorting the renal sinus, pyramids, cortex, and contour of the kidney as depicted with sonography. Although usually quite hyperechoic and homogeneous, there may be hypoechoic areas that represent hemorrhage and necrosis. Decreased blood flow compared with the adjacent renal parenchyma is usually seen with color and power Doppler ultrasound (Fig. 52.62).

Wilms tumor spreads via direct extension into the renal sinus and peripelvic soft tissues, the lymph nodes in the renal hilum, and the paraaortic regions. Because extension is possible into the renal vein, inferior vena cava, right atrium, and liver, these areas should also be examined for the presence of tumor (Fig. 52.63). Color and spectral Doppler sonography are useful in detecting residual flow around a tumor clot, as well as tumor arterial signals both from the periphery of the tumor and from within the tumor thrombus. The opposite kidney should be carefully examined for the presence of tumor. Although to date there have been few reports on the use of CEUS in the diagnosis of pediatric renal masses, this modality is potentially of great usefulness (Fig. 52.64). CT and MRI are usually performed for further workup and staging.[202]

Mesoblastic Nephroma

Mesoblastic nephroma or **fetal renal hamartoma** is the most common neonatal renal neoplasm, and is sometimes detected in the fetus. It is a benign tumor but can spread through local

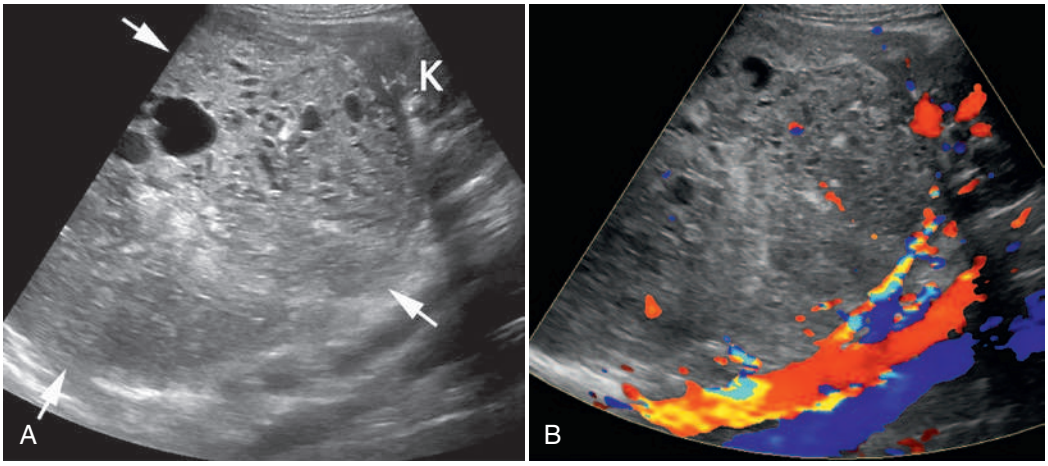

FIG. 52.62 Wilms Tumor. (A) Longitudinal gray-scale image depicts a large, hyperechoic mass *(arrows)* arising from the upper and middle portions of the left kidney *(K).* Multiple anechoic zones within the tumor are the sequelae of hemorrhage and/or necrosis. **(B)** Longitudinal color Doppler image depicts less blood flow within the tumor than in the adjacent renal parenchyma.

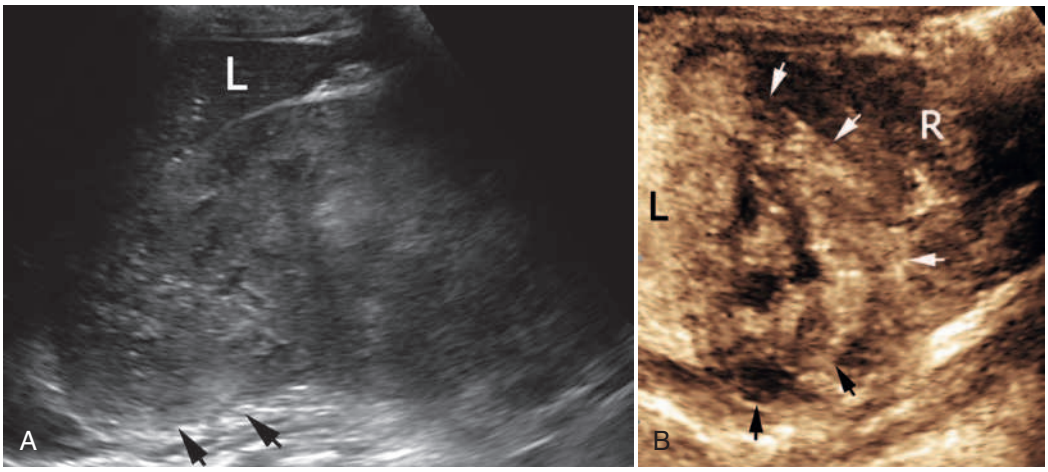

FIG. 52.64 Contrast-Enhanced Ultrasound (CEUS) of Wilms Tumor. (A) Longitudinal gray-scale image of right kidney reveals a bulbous appearance of the upper pole *(arrows)* without a clearly-defined mass. *L,* Liver. **(B)** Longitudinal CEUS image better defines the upper-pole mass *(arrows). L,* Liver; *R,* right kidney. (Courtesy of Dr. Erika Rubesova, Stanford University.)

invasion and is usually treated by simple nephrectomy. Sonography demonstrates a mass arising within the kidney, similar in appearance to a Wilms tumor. It is solid but may have cystic-appearing areas of hemorrhage and necrosis (Fig. 52.65). There are two main pathological types: the classic variant, and the more aggressive cellular variant. The cellular variant is characterized by hemorrhage and necrosis, with invasion of perirenal fat and adjacent organs, and local recurrence. Cystic components are readily identified by ultrasound, whereas central hemorrhage is better depicted by CT. MRI shows high sensitivity for both.[203]

Renal Cell Carcinoma

Renal cell carcinoma is rare in childhood. It occurs later than Wilms tumor, with a median age at diagnosis ranging between 8 and 17 years. Unlike adults, in whom up to 67% of renal cell carcinomas are found incidentally, most children are symptomatic, and approximately 30% have metastatic disease on presentation. There is also no gender predominance in children. Children and adolescents with renal cell carcinoma have much higher rates of translocation tumors than adults. Children with translocation tumors tend to have indolent disease with good outcomes compared with adults, even those with advanced disease.[204] Renal cell carcinoma cannot be distinguished from Wilms tumor by imaging, but calcification is more common (25%-53%) in renal cell carcinoma (Fig. 52.66) than in Wilms tumor (9%).[205]

Angiomyolipoma

Angiomyolipoma is a form of hamartoma that can be complicated by hemorrhage and/or rupture. In children, these tumors are usually multiple and are associated with tuberous sclerosis. Sonography typically shows multiple masses of varying echogenicity depending on their fat content. Masses containing a large amount of fat are very echogenic[206,207] (Fig. 52.67).

Multilocular Cystic Nephroma

Multilocular cystic nephroma is a rare lesion that is generally considered benign. It can occur at any age but is uncommon in children younger than 2 years. The mass is composed of multiple cysts of varying size joined by connective tissue septa. It may be difficult to distinguish from a cystic, well-differentiated Wilms tumor containing nephroblastoma components in the walls of the cysts. Sonography demonstrates a well-circumscribed, multiloculated cystic mass with septations (Fig. 52.68). Some suggest a malignant potential for these lesions and recommend nephrectomy.[208-210]

Renal Lymphoma

Lymphomatous involvement of the kidney is usually a secondary process and can be seen on sonography as single or multiple, relatively hypoechoic or slightly echogenic masses within the kidney. The kidney may be enlarged and lobulated in outline. Diffuse infiltration of the kidney can also occur[211,212] (Fig. 52.69, Video 52.8).

Bladder Tumors

Primary tumors of the lower urinary tract are uncommon in children. **Sarcoma botryoides** is a **rhabdomyosarcoma** arising in the bladder base in males, manifesting with bladder outlet obstruction (Fig. 52.70). In girls, this rare tumor typically occurs in the uterus or vagina.[78,213,214]

PEDIATRIC ADRENAL SONOGRAPHY

Normal Anatomy

The adrenal gland is relatively prominent in the neonate and is easily visualized with ultrasound above the kidneys. At birth, the adrenal gland is relatively large, representing 0.2% to 0.3% of total body weight, compared with 0.001% in adults. There is a linear relationship between body weight and gland length in healthy neonates. However, in premature neonates, gestational age and gland length have a linear relationship. In the neonate, there is a thick fetal zone that occupies about 80% of the adrenal cortex. After birth, the fetal zone of the adrenal cortex undergoes involution. The linear dimensions of the adrenal continually decrease during the first 6 months of life (Table 52.10). In addition, the appearance of the adrenal gland changes as the cortex involutes, the overall echogenicity of the gland increases, and

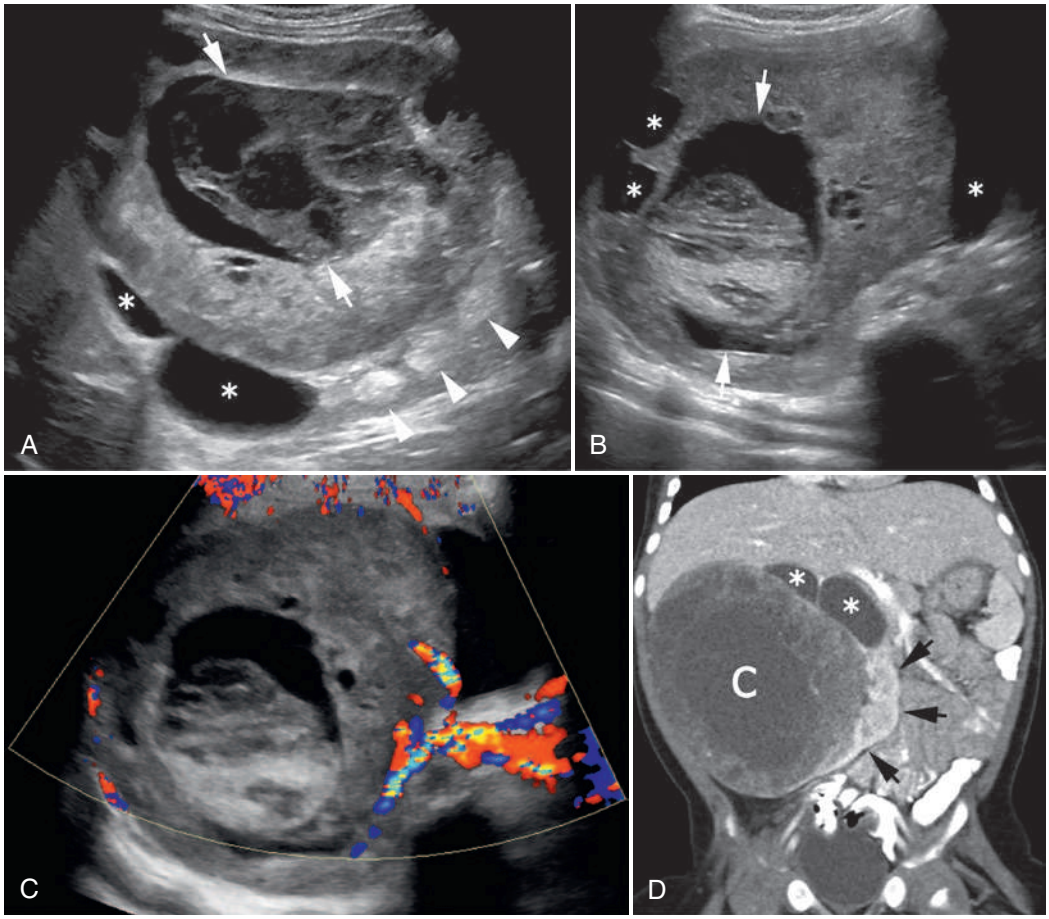

FIG. 52.65 Mesoblastic Nephroma. (A) and **(B)** Longitudinal and transverse gray-scale images of the right kidney depict a mass with peripheral cysts (*) and a centrally located, heterogeneous zone surrounded by fluid *(arrows)*. Incidental echogenic renal pyramids due to medullary nephrocalcinosis *(arrowheads)*. **(C)** Transverse color Doppler image shows no flow within the heterogeneous central portion of the tumor typical of cystic necrosis or resolving hemorrhage. **(D)** Coronal intravenous contrast-enhanced computed tomography image demonstrates a large right renal mass with little contrast enhancement compared with the adjacent compressed renal parenchyma *(arrows)*, a relatively low-attenuating central zone *(C)*, and peripheral cysts (*).

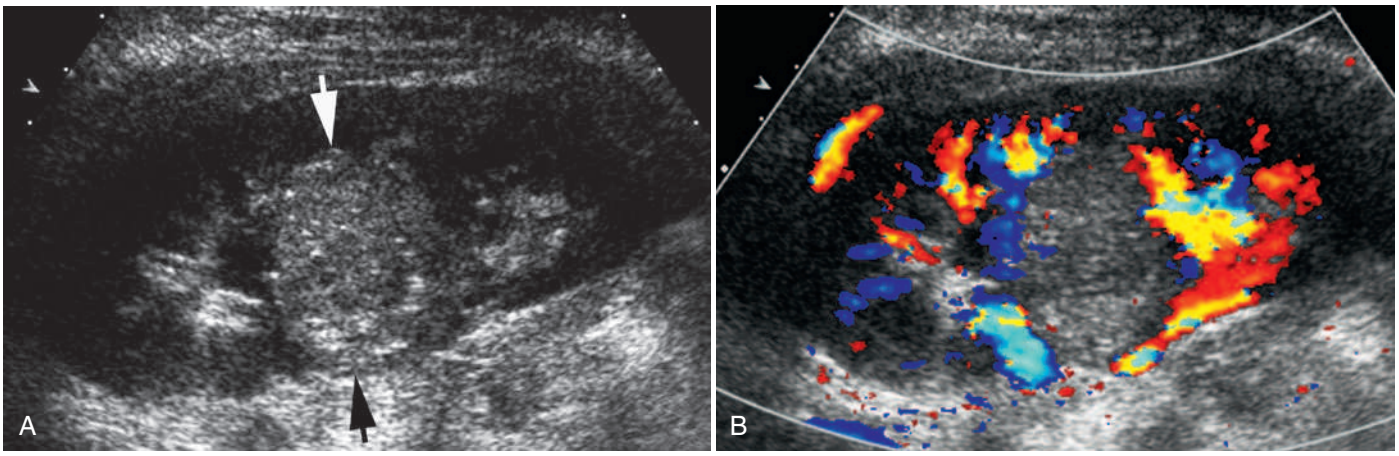

FIG. 52.66 Renal Cell Carcinoma. Eleven-year-old girl with prior history of medulloblastoma. Renal tumor detected incidentally during surveillance imaging. **(A)** Longitudinal gray-scale image reveals a round mass in the renal sinus *(arrows)* that contains multiple tiny calcifications. **(B)** Longitudinal color Doppler image shows peripheral displacement of the renal hilar vessels around the mass.

there is decreased sonographic differentiation between the cortex and medulla.[215,216]

Longitudinal and transverse images of the adrenal gland are best obtained with a high-frequency convex or sector transducer. From the transverse images of the gland, AP and transverse dimensions are measured. From the longitudinal images, the cephalocaudal length is measured from the apex to the midpoint of the base of the gland (Fig. 52.71).

If there is renal agenesis or ectopia, the neonatal gland will appear flattened and "lying down" along the psoas muscle on

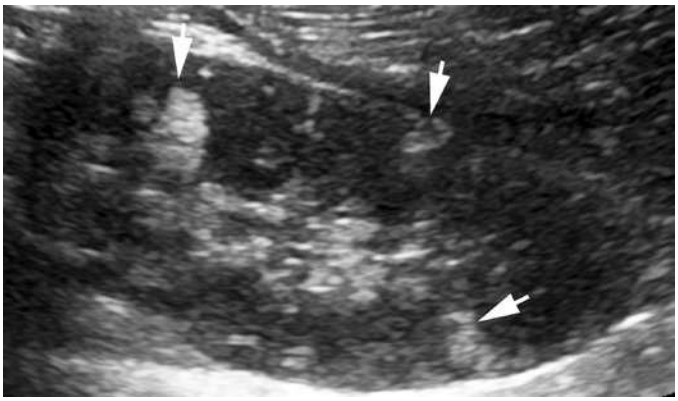

FIG. 52.67 Angiomyolipomas. Twelve-year-old boy with **tuberous sclerosis.** Longitudinal gray-scale image demonstrates multiple hyperechoic masses in keeping with angiomyolipoma *(arrows).*

longitudinal sonograms, the so-called "lying down" adrenal sign[217] (see Fig. 52.12).

In the older child and teenager, the adrenal gland is not easily depicted by ultrasound, and other imaging modalities are preferable for evaluation.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is an inherited form of adrenal insufficiency caused by autosomal recessive mutation of genes that encode the production of enzymes involved in the corticosteroid synthetic pathway. There is impaired synthesis of cortisol by the adrenal cortex that results in an excessive accumulation of androgenic precursors and adrenal gland enlargement. The majority of cases are caused by a mutation of the *CYP21A2* gene that leads to a deficiency of the 21-hydroxylase enzyme. Infants may have salt-wasting, virilization of the external genitalia in girls, and precocious puberty in boys.[218]

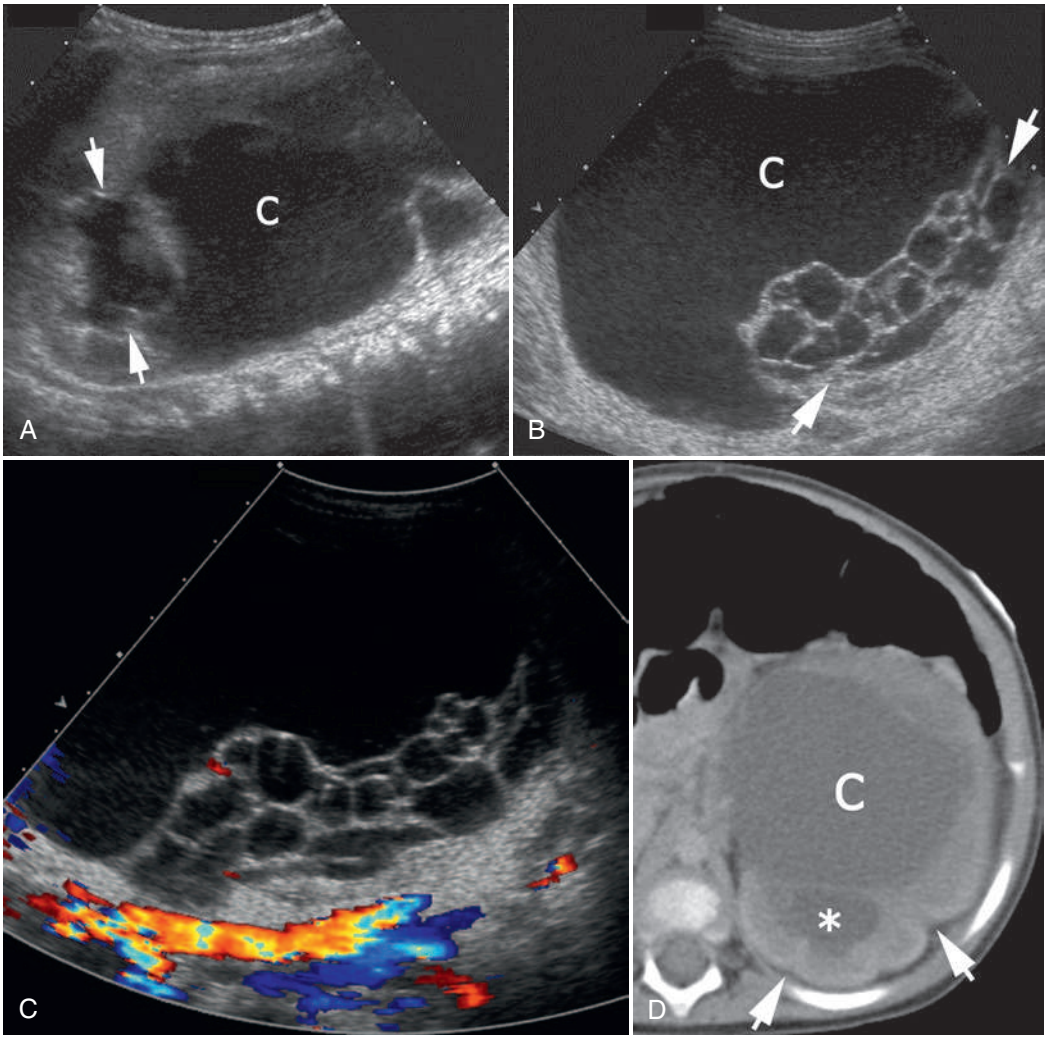

FIG. 52.68 Multilocular Cystic Nephroma. A 10-month-old boy with large abdominal mass. **(A)** Longitudinal gray-scale image depicts a large cyst *(C)* arising from the left kidney. The upper-pole calyces are dilated *(arrows)* secondary to obstruction by the cyst. **(B)** Longitudinal gray-scale image reveals complex nature of the lesion with the large central cyst *(C)* and multiple smaller mural cysts *(arrows).* **(C)** Longitudinal color Doppler image confirms the cystic, avascular nature of the lesion. **(D)** Axial intravenous contrast-enhanced computed tomography image reveals cyst (C) surrounded by compressed renal parenchyma *(arrows)* and dilated posterior calyces (*).

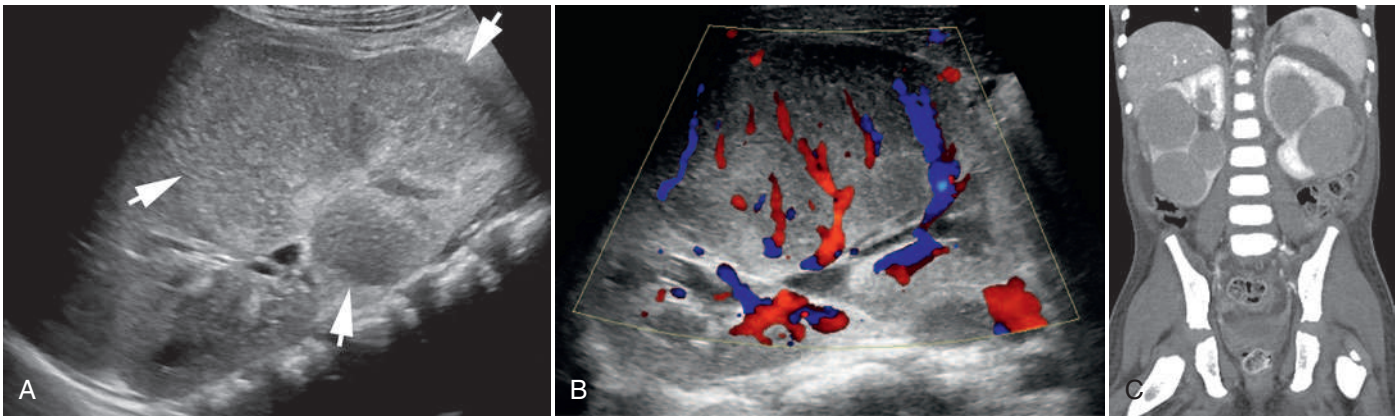

FIG. 52.69 Renal Lymphoma. A 4-year-old boy with **Burkitt lymphoma and secondary involvement of the kidneys. (A)** Longitudinal gray-scale image demonstrates several rounded, echogenic masses in the middle and lower portions of the right kidney *(arrows)*. **(B)** Longitudinal color Doppler image of the right kidney depicts prominent blood flow within one of the masses. **(C)** Coronal intravenous contrast-enhanced image shows multiple hypoenhancing masses of both kidneys. FIG. 52.71 Normal Neonatal Adrenal Gland. (A) and **(B)** Longitudinal and transverse gray-scale images of the right adrenal gland show a Y-shaped configuration with a hypoechoic rim representing the fetal adrenal cortex and a central echogenic adrenal medulla. +, Length; *, width; x, thickness.

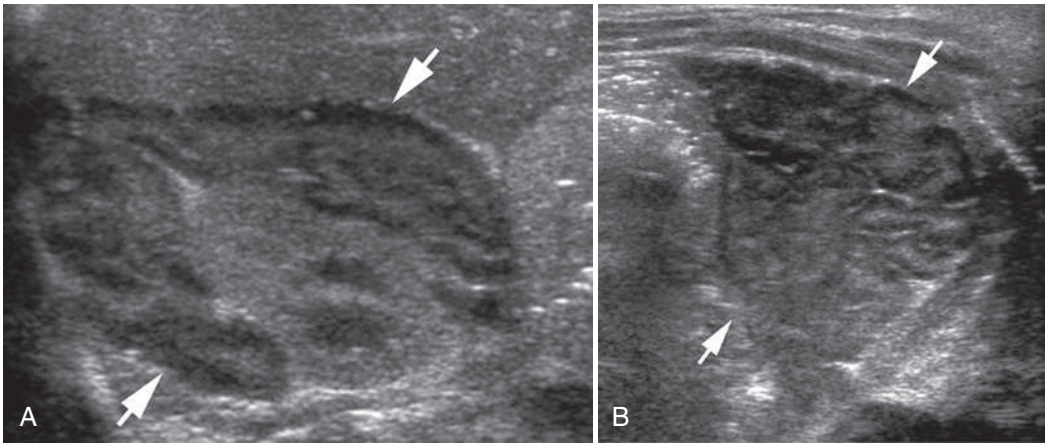

FIG. 52.72 Congenital Adrenal Hyperplasia. Neonate With Ambiguous Genitalia. (A) and **(B)** Transverse images of the right and left adrenals, respectively, reveal enlarged glands with a cerebriform appearance *(arrows)*.

CAH causes bilateral adrenal gland enlargement, which may be asymmetrical. An adrenal gland limb thicker than 4 mm is considered enlarged, even in the neonatal period.[219] However, adrenal gland enlargement alone is not sensitive or specific for the diagnosis of CAH. A normal-sized adrenal gland does not exclude the diagnosis of CAH, and some healthy babies have adrenal glands in the size range typical of CAH.[219] Specific features in the evaluation of the adrenal glands can make ultrasound a sensitive and specific presumptive test for CAH pending the results of laboratory studies. These include a cerebriform appearance of the gland[220] (Fig. 52.72) and stippled echoes, or diffusely increased central glandular echogenicity[221] rather than the normal central echogenic stripe. Pelvic sonography is extremely valuable in the evaluation of female infants with suspected CAH and if there are ambiguous genitalia. Although the external genitalia are masculinized, the internal female genitalia are present. In neonates, the presence of the uterus is exceptionally well demonstrated because of the normal maternal hormones that stimulate development of a prominent echogenic endometrial stripe in the uterine cavity.

Testicular adrenal rest tumors are very common, particularly in postpubertal boys with poorly controlled **congenital adrenal hyperplasia.** These tumors are small, generally multiple, and often bilateral. The involved testis may be enlarged, but its contour is not distorted. The masses are eccentric and commonly surround the mediastinum testis.[222,223]

Neonatal Adrenal Hemorrhage

Hemorrhage into the adrenal gland occurs in the neonate and may even start in utero. It is associated with fetal macrosomia, fetal acidemia, stress, birth trauma, asphyxia, sepsis, bleeding disorders, and maternal diabetes.[224] It occurs most frequently between the second and seventh day of life, with an abdominal mass, hyperbilirubinemia, and occasionally, hypovolemic shock. In some cases, the hemorrhage is asymptomatic and may be discovered incidentally or appear as a palpable mass. About 70% of adrenal hemorrhages are right-sided.[225] Sonography demonstrates a suprarenal mass of variable echogenicity, depending on the age of the bleed. Acute hemorrhage usually appears echogenic or isoechoic to the normal gland, without internal vascularity

on color Doppler imaging. Over several weeks, the hemorrhage becomes anechoic, reflecting blood clot lysis and liquefaction (Fig. 52.73). The hemorrhage gradually decreases in size and may result in adrenal calcification. Differentiation from a neonatal neuroblastoma is important.[226] Follow-up demonstrating a progressive decrease in size and eventual resolution confirms the diagnosis of an adrenal hemorrhage.

Neuroblastoma

Neuroblastoma is the most common extracranial solid tumor of childhood. It arises from neural crest tissue and represents the malignant end of a spectrum of related tumors that includes the **benign ganglioneuroma** and **ganglioneuroblastoma,** an intermediate-grade neoplasm with mixed histology. Neuroblastoma may demonstrate spontaneous regression from an undifferentiated state to a totally benign appearance. It is classified into three risk categories: low, intermediate, and high risk. Low-risk disease is common in infants and good outcomes frequently occur with observation or surgery. High-risk disease is very difficult to treat successfully, even with intensive, multimodal therapy.[227] Neuroblastoma is associated with the **Beckwith-Wiedemann syndrome, Hirschsprung disease, neurofibromatosis type 1, DiGeorge syndrome,** and **central hypoventilation syndrome.**[228]

Two-thirds of the time, neuroblastoma develops in the abdomen, with approximately two-thirds of the tumors arising from the adrenal gland. The remainder may develop anywhere along the sympathetic nerve chain.[229] In the majority of children with neuroblastoma the disease is found between 1 and 5 years of age, with the most common age at presentation being 18 months. Boys and girls are equally affected.[230]

At sonography, adrenal neuroblastoma is heterogeneous in echotexture, with irregular, hyperechoic areas caused by calcification. Its margins tend to be poorly defined. Extension of tumor around the aorta and celiac and superior mesenteric arteries helps to distinguish neuroblastoma from Wilms tumor, which is usually well defined and relatively homogeneous in echotexture (Fig. 52.74, Video 52.9). Sonography needs to be followed by CT or MRI for disease staging. MRI is particularly useful because the tumor can extend into the spinal canal and cause neurologic symptoms. It is critical to know if this extension has occurred before the tumor is surgically removed because the child may

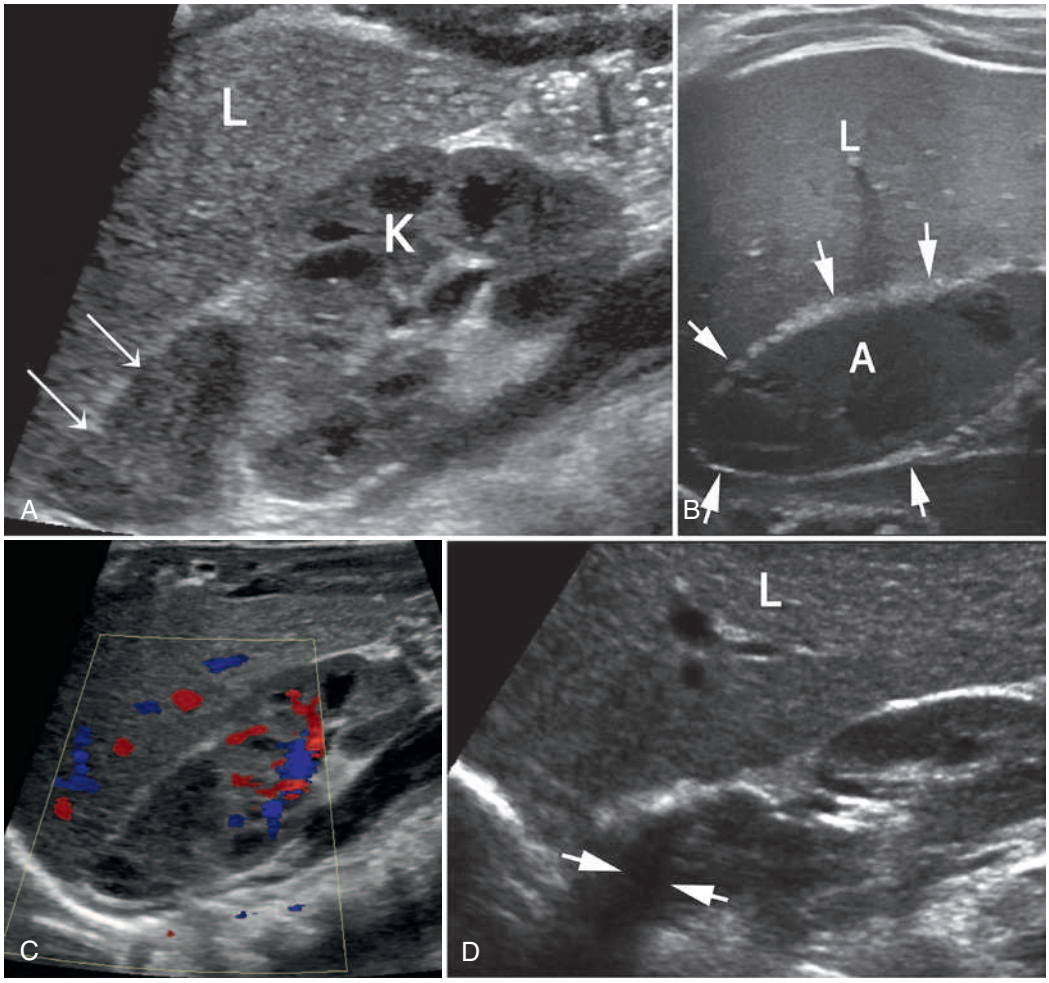

FIG. 52.73 Neonatal Adrenal Hemorrhage. (A) and **(B)** Longitudinal gray-scale images of the right flank demonstrate a suprarenal hypoechoic "mass." The overall shape of the adrenal gland is preserved and there is peripheral calcification *(arrows). A,* Adrenal; *K,* kidney; *L,* liver. **(C)** Longitudinal color Doppler image demonstrates the avascular nature of the adrenal lesion. **(D)** Longitudinal gray-scale image 18 months later reveals complete involution of the "mass" and replacement by dense calcification with distal shadowing *(arrows),* typical of a resolved hemorrhage.

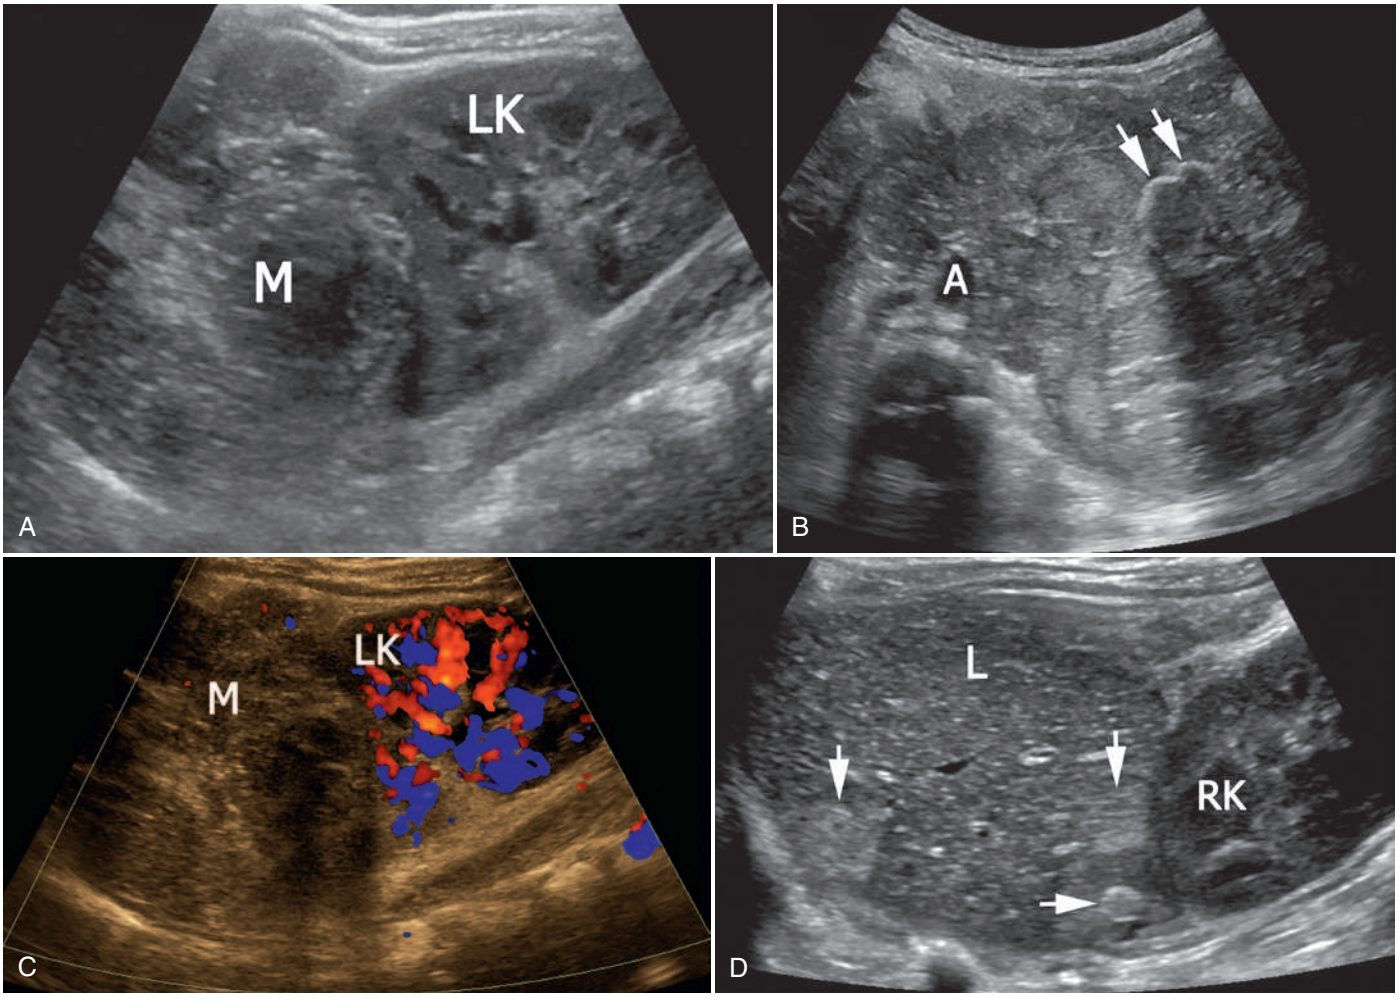

FIG. 52.74 Neuroblastoma in 4-Month-Old Boy With Stage IV Disease. (A) Longitudinal gray-scale image demonstrates a heterogeneous, lobulated mass arising from the left adrenal gland *(M)* and compressing the upper pole of the left kidney *(LK)*. **(B)** Transverse gray-scale image depicts the mass crossing the midline and encasing the aorta *(A)*. The mass contains calcifications with associated distal shadowing *(arrows)*. **(C)** Longitudinal color Doppler image shows hypovascularity of the mass *(M)* compared with the underlying left kidney *(LK)*. **(D)** Longitudinal gray-scale image of the liver *(L)* depicts three hyperechoic metastatic deposits *(arrows)*. *RK,* Right kidney. See also Video 52.9.

develop neurologic symptoms postoperatively, including paralysis, if the tumor is not carefully resected.

Pheochromocytoma

According to the World Health Organization classification of endocrine tumors, a pheochromocytoma is an intraadrenal paraganglioma arising from catecholamine-producing chromaffin cells in the adrenal medulla.[231,232] These tumors may occur sporadically, or as a component of a hereditary tumor syndrome, including **von Hippel–Lindau disease, multiple endocrine neoplasia** (MEN) types IIA and IIB, and the **familial paraganglioma syndromes.** Rarer associations include **neurofibromatosis type 1, MEN type I, tuberous sclerosis complex,** and **Carney triad.**[231,233]

About 56% of apparently sporadic pheochromocytomas in children 18 years of age or younger are caused by a mutation in the germline DNA, and the percentage of children younger than 10 years of age with hereditary disease is as high as 70%.[234] Hereditary pheochromocytoma is often bilateral and is more common in children than adults.[235,236]

Pheochromocytoma in children usually is discovered as a result of catecholamine hypersecretion, because of tumor mass effect, as an incidental finding at imaging, or after family screening for one of the hereditary syndromes. Signs and symptoms suggestive of pheochromocytoma include sustained hypertension, paroxysmal episodes of headache, palpitations and diaphoresis, pallor, orthostatic hypotension and syncope, tremor, and anxiety.[231] Quantification of plasma free metanephrine and normetanephrine, or measurement of 24-hour urinary fractionated metanephrines are the most accurate biochemical tests used for diagnosis of pheochromocytoma in adults. Although fewer studies have been performed in children, metanephrine quantification is thought to be a superior method in this population as well.[237]

At sonography, a pheochromocytoma will appear as a solid, highly vascular, round or oval mass of variable echogenicity.[225]

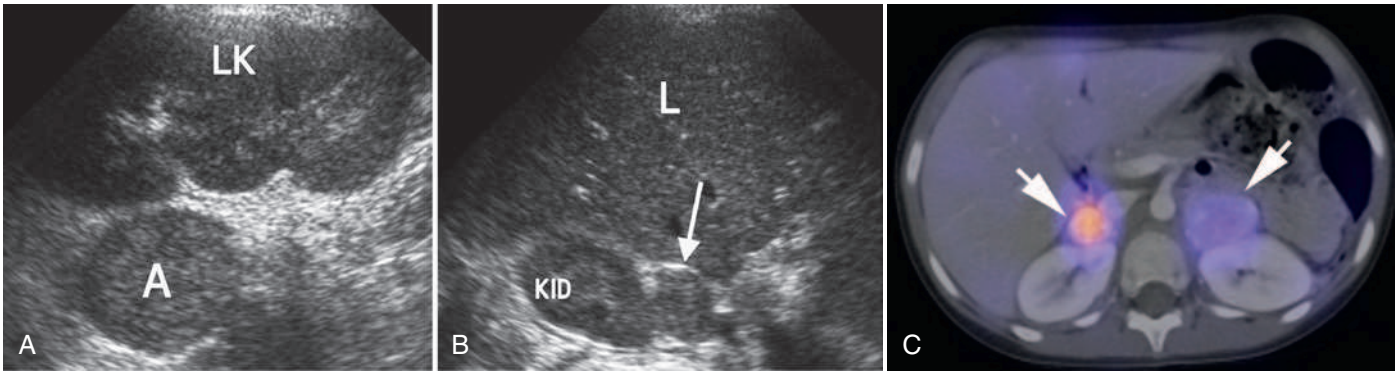

FIG. 52.75 Pheochromocytoma in 6-Year-Old Boy With von Hippel-Lindau Syndrome and Bilateral Adrenal Pheochromocytoma. (A) Longitudinal gray-scale image of the left flank reveals the presence of a solid, round adrenal mass *(A)* medial to the left kidney *(LK)*. **(B)** Transverse gray-scale image demonstrates a solid, rounded mass *(arrow)* medial to the right kidney *(KID)*. *L,* Liver. **(C)** Iodine-123 metaiodobenzylguanidine (MIBG) image fused to an intravenous axial contrast-enhanced computed tomography image depicts the bilateral adrenal tumors *(arrows)*. The right-sided mass shows greater radiopharmaceutical uptake than the left-sided mass.

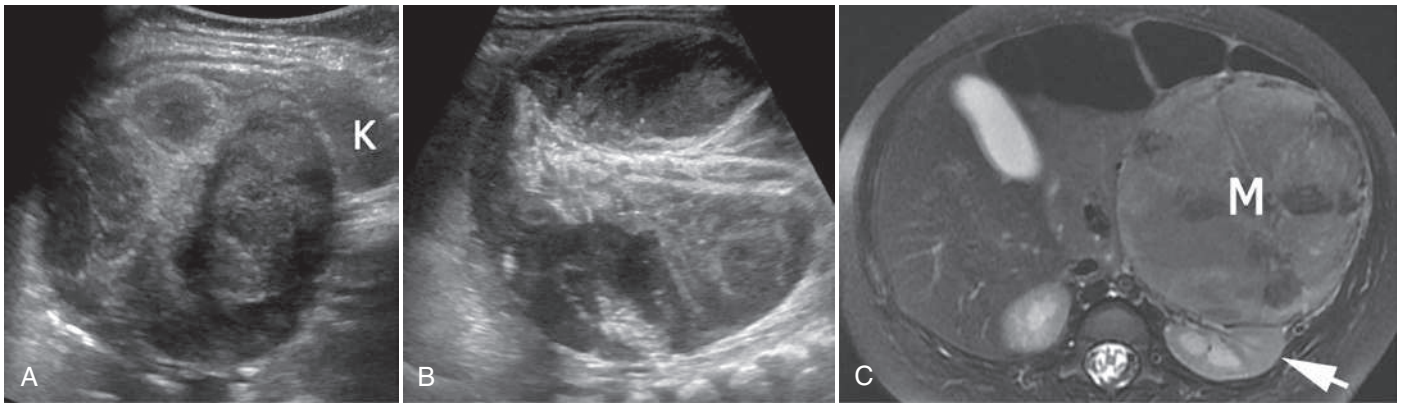

FIG. 52.76 Adrenal Carcinoma in 8-Month-Old Girl With Virilization and Precocious Puberty. (A) and **(B)** Transverse and longitudinal gray-scale images of the left flank demonstrate a large, round, heterogeneous mass replacing the adrenal gland. *K,* Left kidney. **(C)** Intravenous contrast-enhanced axial computed tomography image shows the left adrenal mass *(M)* displacing and rotating the left kidney *(arrow)*.

Masses generally range from 2 to 5 cm in diameter at presentation, although they may exceed 10 cm. Larger lesions tend to be heterogeneous as a result of hemorrhage, necrosis, and/or calcification (Fig. 52.75). Cross-sectional imaging of the abdomen and pelvis with CT or MRI is performed for surgical planning. Functional imaging with ^{123}I-labeled metaiodobenzylguanidine (MIBG) is a highly specific test that can confirm the catecholamine-secreting nature of a tumor, localize tumors not seen with cross-sectional imaging, and identify other sites of disease. Because MIBG testing is not 100% sensitive, additional nuclear medicine imaging tests may need to be performed. Chest CT is performed in patients with suspected lung metastases.[238]

Adrenocortical Neoplasm

Primary tumors of the adrenal cortex are rare in children, with an incidence of 0.3 to 0.4 cases per million per year before the age of 15 years.[239] Because reliable histologic differentiation between cortical adenomas and carcinomas in children may be difficult, the inclusive term "adrenocortical neoplasm" is often used.[240] Most tumors develop before 5 years of age, with a female predominance, although the sex ratio is equal in adolescence. In contrast to adults, most pediatric adrenocortical neoplasms are hormonally active. The presence of increased hormone levels is useful both for initial diagnosis and in the detection of tumor recurrence. Androgen overproduction leads to virilization in girls and precocious puberty in boys; most tumors also cause an overproduction of mineralocorticoids.[238] Although the majority of affected children will not have an underlying disorder, there is a known association with **Beckwith-Wiedemann syndrome** and **Li-Fraumeni syndrome.**[238]

Tumors larger than 5 to 10 cm in diameter; a tumor weight greater than 200 g; and aggressive growth features such as invasion into the periadrenal soft tissues, kidneys, and/or inferior vena cava (IVC) suggest malignancy. Small lesions tend to be homogeneous, whereas larger lesions often contain foci of hemorrhage, necrosis, or calcification.[241] **Adrenal carcinoma** in an 8-month-old girl with virilization and precocious puberty is typical of these rare lesions (Fig. 52.76). Metastases occur most often to the liver, lung, and bone.[238] Sonography is particularly helpful in the detection of tumor invasion into the IVC. Cross-sectional imaging with CT and MRI is used for more precise delineation.

CHAPTER 53

The Pediatric Gastrointestinal Tract

Susan D. John and Martha Mappus Munden

SUMMARY OF KEY POINTS

- Successful bowel ultrasound is facilitated by use of high-frequency transducers and real-time viewing of the bowel activity. Oral fluid administration and graded compression techniques help displace interfering bowel gas.
- Accurate measurement of the pyloric muscle thickness with adequate distention of the stomach with fluid is the key to correct diagnosis of hypertrophic pyloric stenosis. When the pylorus is normal, the duodenum should be examined, as well as the mesenteric vessels.
- The diagnosis of ileocolic intussusception can be made with ultrasound with a high degree of accuracy, precluding the need for a diagnostic enema when normal. Transient small bowel intussusceptions are common, have a different appearance on ultrasonography, and do not require treatment or follow-up unless very long or persistent.
- Inflammatory conditions of the small and large intestine can be easily evaluated with ultrasound. Specific features such as mucosal or transmural edema, echogenicity, and blood flow assessment with Doppler imaging can help to narrow the range of differential diagnoses and can be used to monitor therapy.
- Ultrasound findings of bowel wall thickening and pneumatosis intestinalis can help make the diagnosis of necrotizing enterocolitis when not evident on radiographs. Complex fluid in the abdomen helps to diagnose perforation in infants with a gasless abdomen.
- Ultrasound is the procedure of choice for the initial evaluation of the child with acute abdominal pain. Appendicitis can be detected in the majority of children with experience and proper technique. Secondary findings such as absent bowel peristalsis, mesenteric edema, and free or loculated fluid collections can help make the diagnosis of appendicitis, even when the appendix itself is not visible.
- Cystic abdominal masses are well seen with ultrasound and may be associated with the gastrointestinal tract. Wall characteristics and presence of internal septations, debris, calcifications, or fat can help to determine the etiology of the mass.
- Ultrasound of the pancreas in children is most helpful for identifying peripancreatic fluid collections or pseudocysts resulting from pancreatitis and detecting cystic pancreatic masses.

ESOPHAGUS AND STOMACH

Normal Anatomy and Technique

Sonography has become an important diagnostic imaging modality in the evaluation of the gastrointestinal (GI) tract of children. Ultrasound permits direct visualization of the various mural layers of the GI tract. The ability to observe GI dynamics without exposure to ionizing radiation is an added asset of sonography. Video clips made during scanning can be a valuable resource to view peristalsis and to capture subtle abnormalities in mobile children. Ultrasound is most suitable for portions of the GI tract that are not surrounded by or filled with large amounts of gas. The stomach is best evaluated after allowing the patient to ingest clear fluids. Sugar water works well for infants.

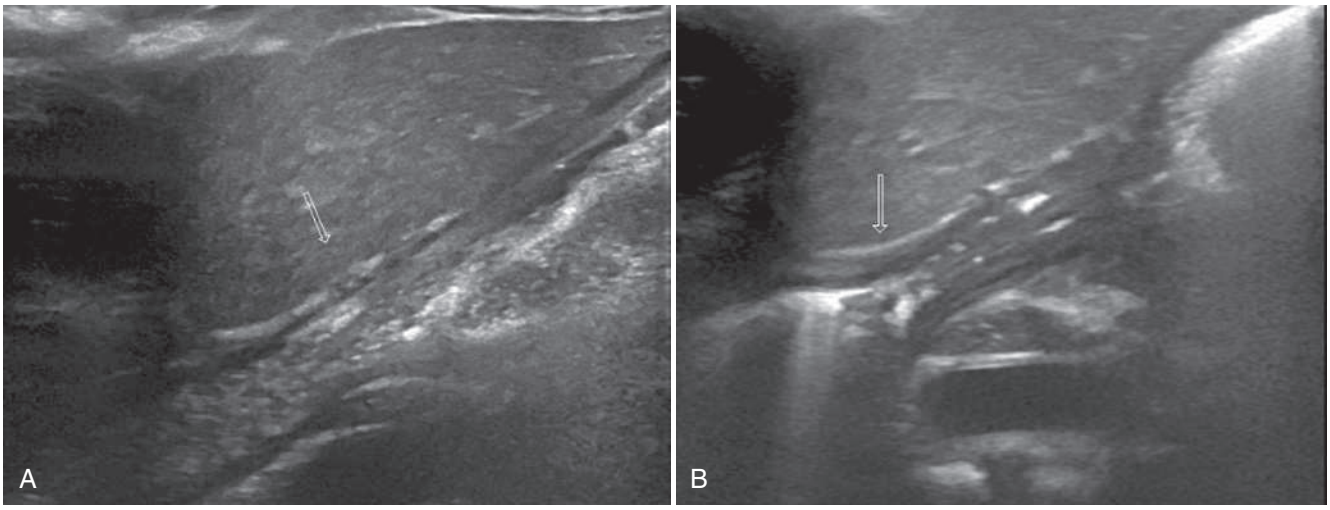

FIG. 53.1 Gastroesophageal Reflux. (A) Normal contracted gastroesophageal junction *(arrow)*. **(B)** Later, the lower esophageal sphincter opens, and reflux of fluid and formula into the esophagus is visible *(arrow)*.

Stomach: Optimal Measurements

Normal pyloric muscle thickness ≤2 mm
Normal gastric mucosa thickness ≤2-3 mm
Peristalsis through pylorus

Esophagus

Most of the esophagus is inaccessible by sonography because of surrounding aerated lung. Only the subdiaphragmatic portion of the esophagus is usually visible (Fig. 53.1A). The gastroesophageal junction can be seen by examining the patient with sagittal images in the supine or right-side-down decubitus position.[1-3] This technique permits observation of the function of the gastroesophageal junction and can be used to detect gastroesophageal reflux. Reflux is noted when fluid is regurgitated into the retrocardiac portion of the esophagus (Fig. 53.1B). Color Doppler sonography may facilitate the detection of gastroesophageal reflux.[4] **Hiatal hernias** can also be detected with sonography, which may be more sensitive than barium studies for detecting small degrees of herniation[5,6] (Fig. 53.2). However, the sonographic techniques required are operator dependent and have not gained much popularity. Therefore esophageal abnormalities are usually assessed with other imaging modalities, such as fluoroscopy or endoscopy.

Stomach

Most abnormalities of the stomach in infants and children involve the gastric antrum and distal third of the stomach. This portion of the stomach is easily evaluated using the liver as an acoustic window. Distending the stomach with clear fluid facilitates evaluation of the mucosal, submucosal, and muscular layers of the stomach (Fig. 53.3). Furthermore, gastric peristalsis and emptying can be evaluated.

FIG. 53.2 Hiatal Hernia. The fluid-distended stomach extends through the esophageal hiatus *(arrow)*.

Normal gastric mucosa, including the muscularis mucosae and submucosal layers, measures 2 to 3 mm, whereas the outer circular muscle layer measures between 1 to 2 mm in thickness.[7,8] These measurements should be obtained with the stomach fully distended with fluid, and the scan should be performed in the midlongitudinal plane of the stomach or, on cross section, proximal to the pyloric canal, measuring the single muscle wall thickness, excluding the mucosa. On cross-sectional imaging, if the image obtained is too close to the contracted pyloric canal,

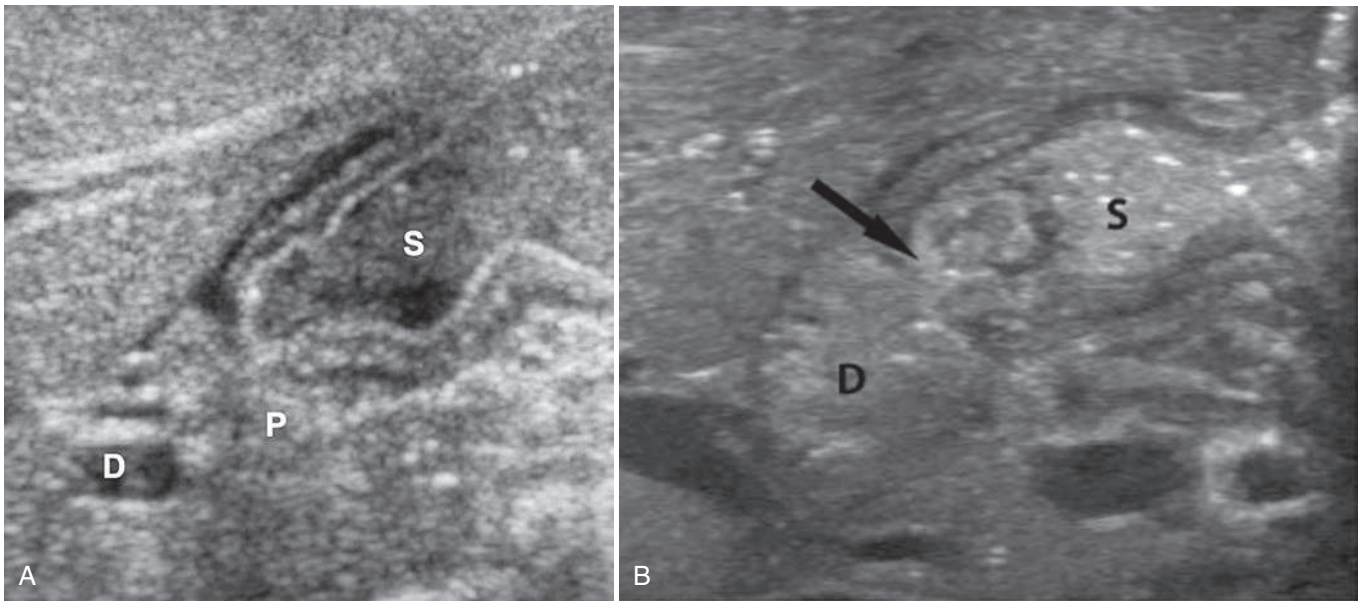

FIG. 53.3 Normal Stomach. (A) Normal antrum of stomach *(S),* pyloric canal *(P),* and proximal duodenum *(D).* Four gastric wall layers are visible (from inside out): echogenic mucosa, hypoechoic muscularis mucosae, echogenic submucosa, and hypoechoic outer circular muscle. **(B)** Fluid passes freely through the normal pylorus *(arrow). D,* Duodenum; *S,* stomach.

thickening of the pyloric muscle can be suggested erroneously. Similarly, if tangential images are obtained on the longitudinal plane, the muscle may erroneously appear thickened (Fig. 53.4). This same phenomenon is also seen with the echogenic mucosal layer.

Hypertrophic Pyloric Stenosis

Muscle width ≥3 mm
Pyloric canal length ≥1.5 cm
No peristalsis through pylorus

Hypertrophic Pyloric Stenosis

During the past decade, sonography has replaced the radiographic upper GI series for the diagnosis of infantile hypertrophic pyloric stenosis (HPS). Unlike the upper GI series, which demonstrates only the indirect effects of pyloric muscle hypertrophy on the gastric lumen, ultrasound allows direct visualization of the gastric muscle thickening that is the hallmark of the disease. Although a few pitfalls in the sonographic diagnosis of HPS exist, the technique is relatively easily mastered and results in greatly improved accuracy of diagnosis and patient outcome. Indeed, the accuracy approaches 100%, and ultrasound is now the procedure of choice for the detection of pyloric stenosis.[9-12]

After the initial documentation of the sonographic detection of the hypertrophied pyloric muscle in pyloric stenosis by Teele and Smith,[13] many studies described the characteristic findings of HPS.[14-18] Increased pyloric muscle thickness and canal length; increased transverse diameter of the pylorus; thickened, redundant mucosa; estimation of the degree of gastric outlet obstruction; and calculation of pyloric muscle volume have all been used to diagnose pyloric stenosis. However, of all the criteria, thickening of the pyloric muscle and elongation of the pyloric canal have emerged as the most consistently useful. The thickness at which the muscle is considered **hypertrophied is 3 mm or greater when measuring the hypoechoic single muscle layer transversely.**[7] Pyloric canal length of 1.5 cm is considered diagnostic of pyloric stenosis when seen in conjunction with thickened pyloric muscle.

In the classic case of HPS, the thickened muscle mass is seen as a hypoechoic layer just superficial to the more echogenic mucosal layer of the pyloric canal (Fig. 53.5). In cross section, this **"olive,"** on clinical palpation, resembles a sonolucent **"doughnut"** medial to the gallbladder and anterior to the right kidney. Often, small amounts of fluid are visible trapped between the thickened echogenic mucosal folds, corresponding to the **"string"** (elongated canal) and **"double tract"** (folded mucosa) signs previously described on radiographic upper GI series.[19] In longitudinal section, sonography also permits evaluation of functional alterations at the pylorus. Active gastric peristalsis that ends abruptly at the margin of the hypertrophied muscle, absence of a normal opening of the pylorus, and diminished passage of fluid from the stomach into the duodenum are useful adjunctive findings in pyloric stenosis. Thickened mucosa within the pylorus often accompanies the muscle hypertrophy.[20] Although most often an isolated abnormality, HPS occasionally accompanies other obstructive antropyloric lesions, such as duodenal feeding tubes (Fig. 53.6), eosinophilic gastroenteritis, antral polyps,[21] and idiopathic or prostaglandin-induced foveolar hyperplasia.[22]

The length of the pyloric channel is typically shorter in premature infants with pyloric stenosis, but normal pyloric measurements for premature infants are not well established. At surgery of premature infants with HPS, the mass is reportedly

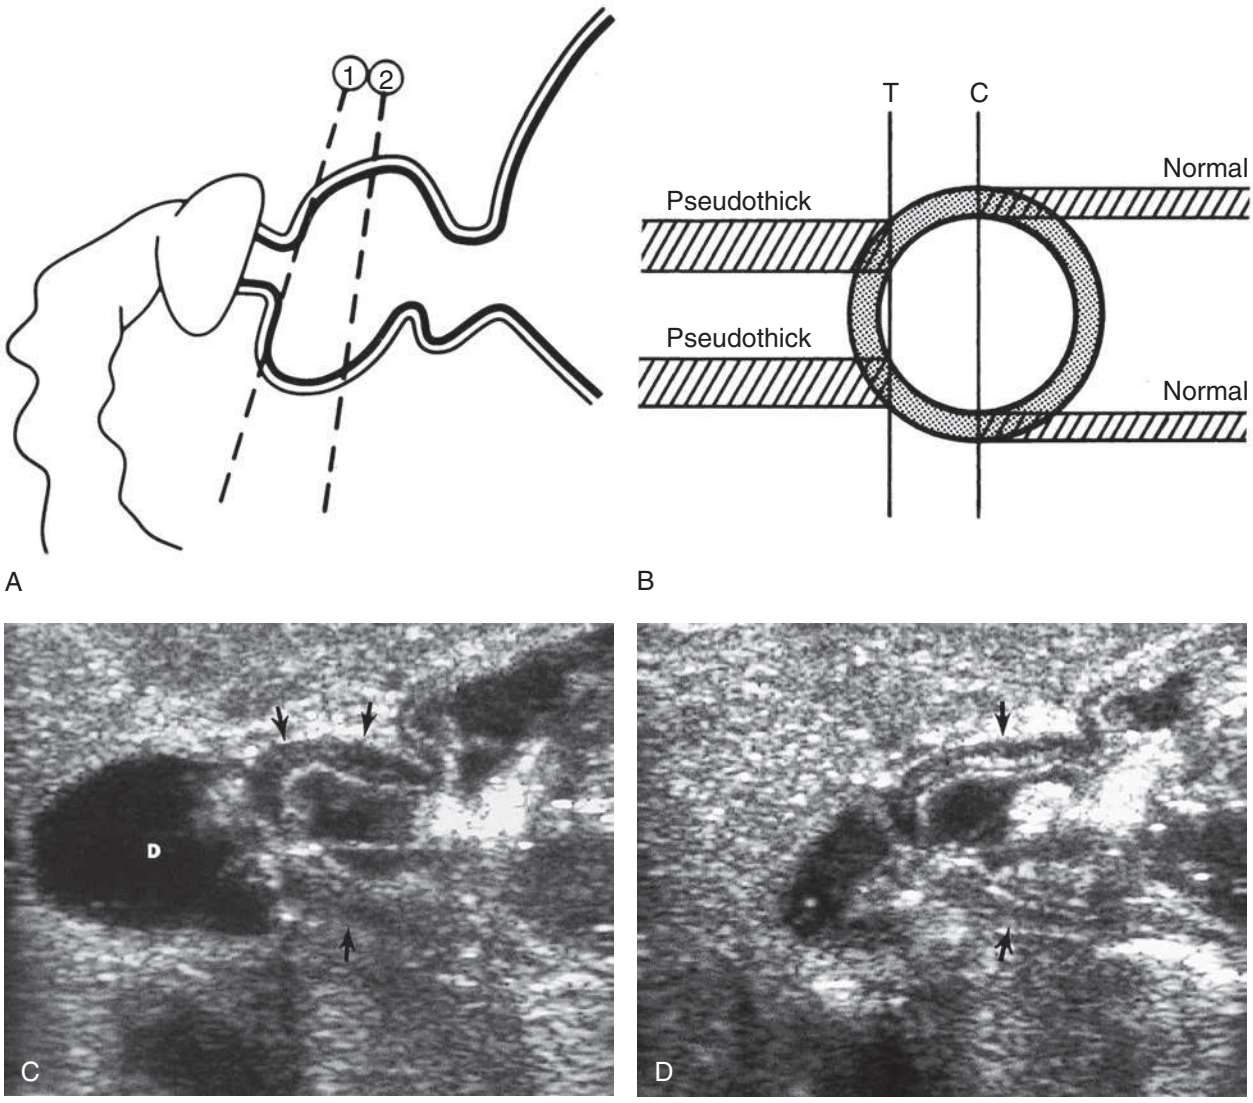

FIG. 53.4 Pyloric Muscle Tangential Imaging Artifacts. (A) When imaging the antrum in cross section, the muscle will appear thickened if obtained through plane 1, but will show normal thickness if obtained through plane 2. **(B)** Longitudinal scan, tangential plane *(T),* shows pseudothickening. Imaging in center *(C)* shows true normal muscle thickness. **(C)** Tangential scan shows muscle pseudothickening *(arrows). D,* Duodenum. **(D)** Antrum distended with fluid shows normal muscle *(arrows).*

softer, more pliable, and thinner. Rarely, HPS manifests during the first 14 days of life and can be challenging to diagnose because most consider HPS to occur after 2 weeks of age. These infants are often thought to have severe reflux, and ultrasound criteria for these younger infants are also not established. Those with presentation before the expected age range are more likely to have a positive family history than those with presentation after 2 weeks of age, and more of these infants have been breast fed. The muscle thickness is also decreased relative to the older HPS patient, with some advocating a muscle thickness of greater than or equal to 2.5 mm and channel length of greater than or equal to 14 mm for criteria in these younger patients.[23-25]

Ultrasound also is very useful for the evaluation of persistent vomiting in the postpyloromyotomy patient. The fluoroscopic upper GI series is of limited value in such cases because it tends to show persistent deformity and narrowing of the canal even in asymptomatic patients. However, sonography can definitively identify persistently thickened muscle, although cautious interpretation in postpyloromyotomy patients is recommended because the pyloric muscle may not reach its normal thickness until 8 months after surgery[26] (Fig. 53.7).

Pylorospasm and Minimal Muscular Hypertrophy

In some vomiting infants, sonography shows a persistently contracted and elongated canal, but the degree of muscular thickening is less than the criterion of 3 mm for surgically correctible HPS. With extended observation, eventually the canal opens and fluid is seen to pass into the duodenum,[27] but the periods of spasm predominate (Fig. 53.8). In the vast majority of cases, there is no thickening of the pyloric muscle or mucosa, and the problem is primarily nonspecific **pylorospasm (antral**

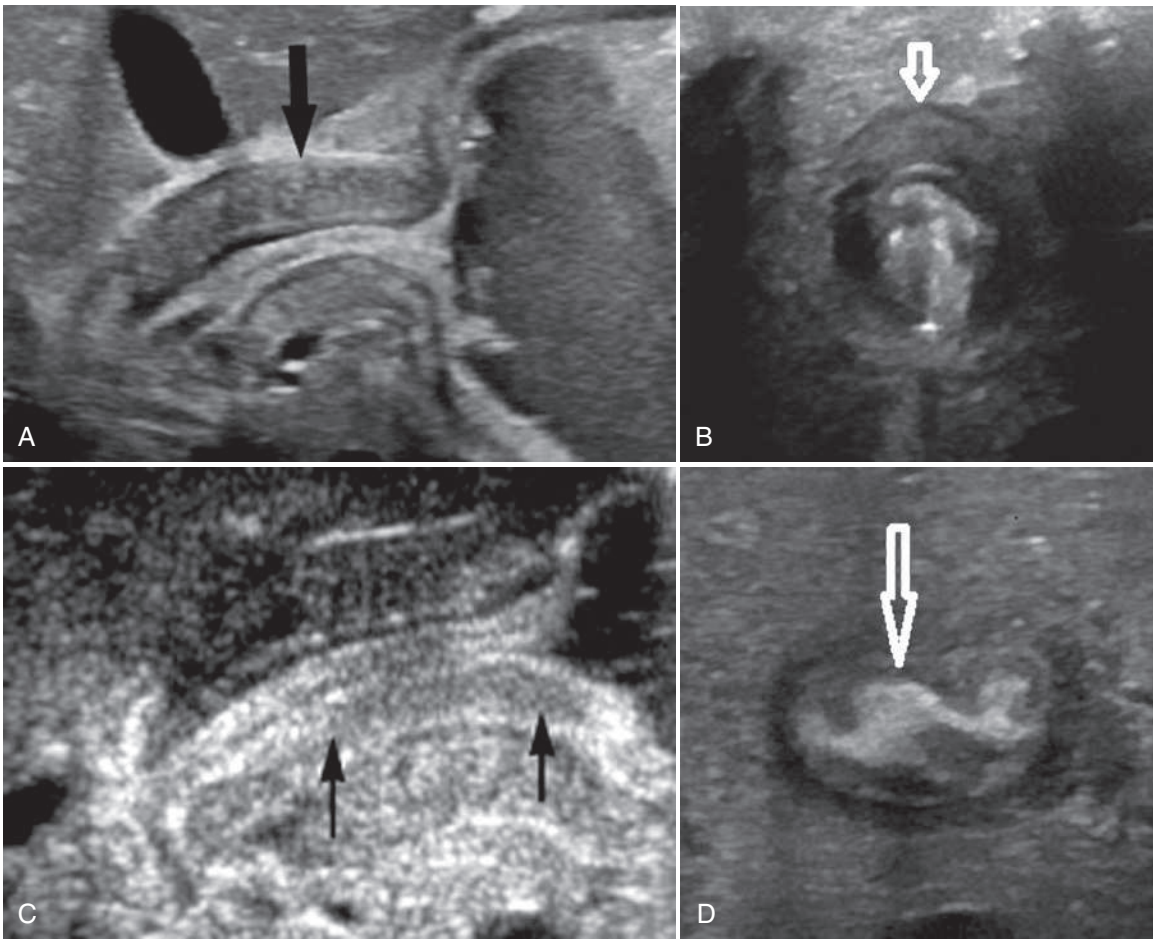

FIG. 53.5 Hypertrophic Pyloric Stenosis. (A) Longitudinal scan shows markedly thickened, hypoechoic gastric antral muscle *(arrow)*. Elongated canal is nearly 2 cm in length. **(B)** Transverse scan shows typical, hypoechoic "doughnut" *(arrow)*. Central echogenic mucosa with anechoic fluid-filled crevices. **(C)** In another patient, longitudinal image of the pylorus shows the thick echogenic mucosa *(arrows)* within the thickened muscle mass. **(D)** Transverse image shows similar echogenic mucosal thickening *(arrow)*.

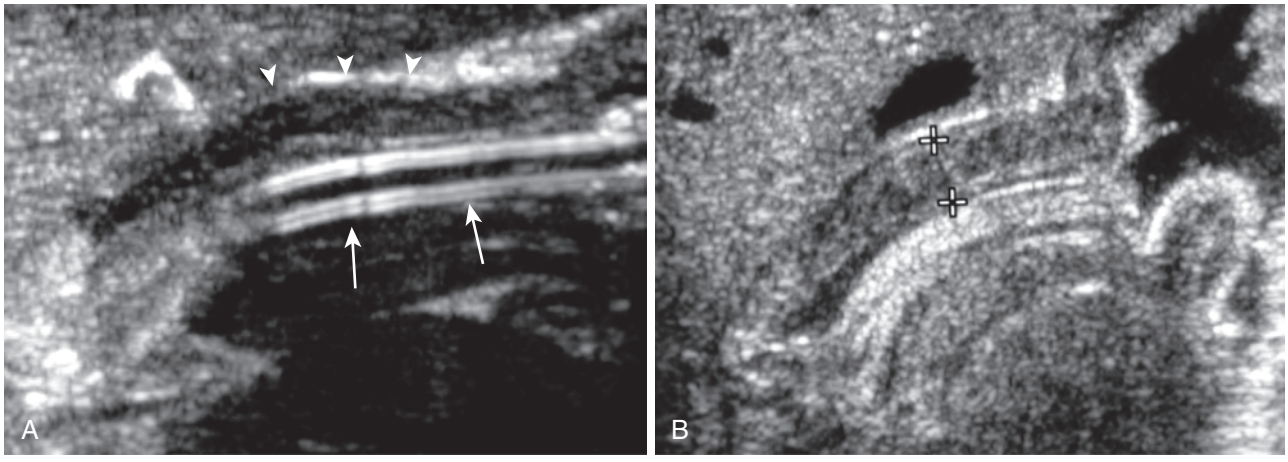

FIG. 53.6 Minimal Pyloric Muscle Thickening Progresses to Hypertrophic Pyloric Stenosis. (A) Longitudinal scan in infant with a duodenal feeding tube *(arrows)* shows contracted pyloric canal and 2.3-mm-thick pyloric muscle *(arrowheads)*. **(B)** Two weeks later the muscle was hypertrophied (4 mm).

dyskinesia). This condition can accompany milk allergy or other forms of gastritis.

In some cases the pyloric muscle is mildly thickened, measuring 2 to 3 mm.[7] Such patients should be distinguished from those with normal muscle thickness (<2 mm) because in some patients minimal muscle hypertrophy can eventually progress to classic pyloric stenosis. In other infants, minimal muscle thickening will resolve spontaneously, but such patients should be followed closely with ultrasound until the muscle regresses to a normal thickness.

Pitfalls in Sonographic Diagnosis

The echogenicity of the pyloric muscle varies according to the angle at which the ultrasound beam crosses the muscle fibers. During sonography of HPS, the hypertrophied muscle appears echogenic rather than hypoechoic when imaged in the midlongitudinal plane. This alteration of echogenicity is caused by an artifact called the **anisotropic effect,** which occurs at about the 6 and 12 o'clock positions of the muscle, where the ultrasound beam is perpendicular to the muscle fibers.[28] With current high-resolution linear array transducers, the echogenic appearance of the muscle does not substantially decrease its visibility (Fig. 53.9A). The position of the antropyloric canal can change during the examination, especially if the stomach becomes overly distended with fluid. The distended antrum causes the pylorus to become more posteriorly directed, making it more difficult to follow with ultrasound. In such cases the gastric antrum may have a squared-off configuration (Fig. 53.9B). When this occurs, the pylorus may be located by cephalad angulation of the transducer or by imaging from a more lateral position on the abdomen.

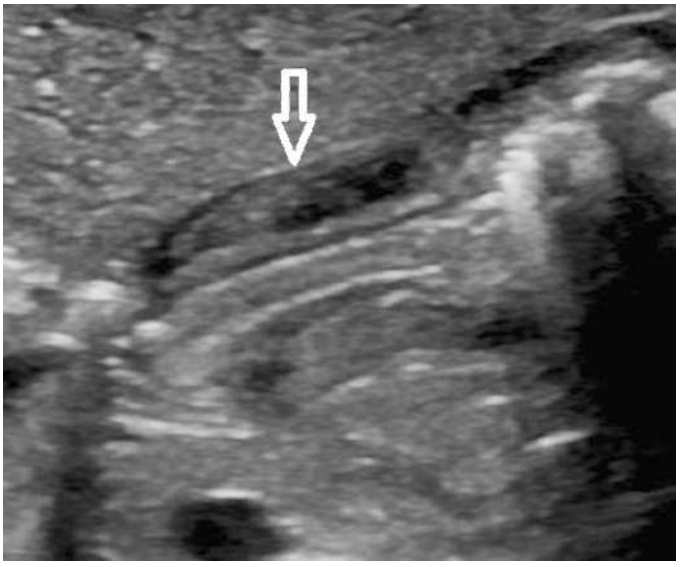

FIG. 53.7 Muscle Thickening After Pyloromyotomy. Note the persistent muscle thickening *(arrow)* in this infant 21 days after surgery.

Pitfalls in Diagnosis of Hypertrophic Pyloric Stenosis (HPS)

- Echogenic muscle at 90 degrees to beam (anisotropic effect)
- Posteriorly oriented antropyloric canal (overdistended stomach)
- Prostaglandin-induced HPS (mucosal, not muscular thickening)
- Minimal pyloric muscle thickening; may progress to HPS

Perhaps the most common pitfall in the sonographic diagnosis of pyloric muscle hypertrophy is inadequate distention of the gastric antrum with fluid. When the antrum is relatively empty, it remains contracted, and the muscle layer can appear falsely thickened (Fig. 53.10). When administering oral fluids for this study, keeping the infant in a right posterior oblique position helps to ensure that the fluid will fully distend the antrum. Despite these occasional pitfalls, the sonographic diagnosis of pyloric stenosis is generally straightforward.

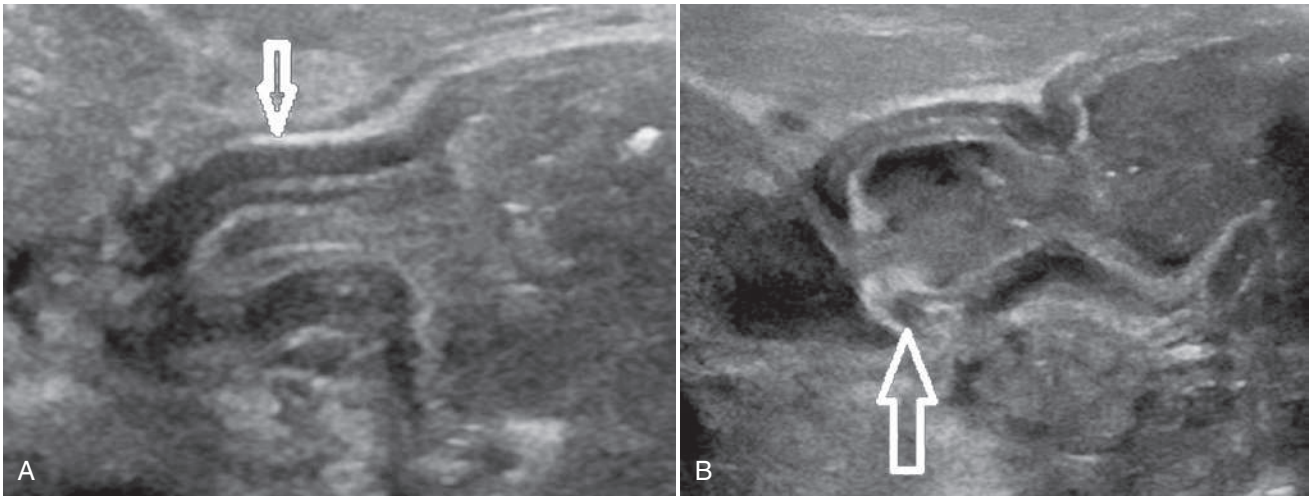

FIG. 53.8 Pylorospasm. (A) The pylorus remained contracted early in the examination of this infant, causing the muscle to appear slightly thickened *(arrow).* **(B)** After giving more oral water and a slightly extended period of viewing, the pylorus relaxed and appeared normal *(arrow).*

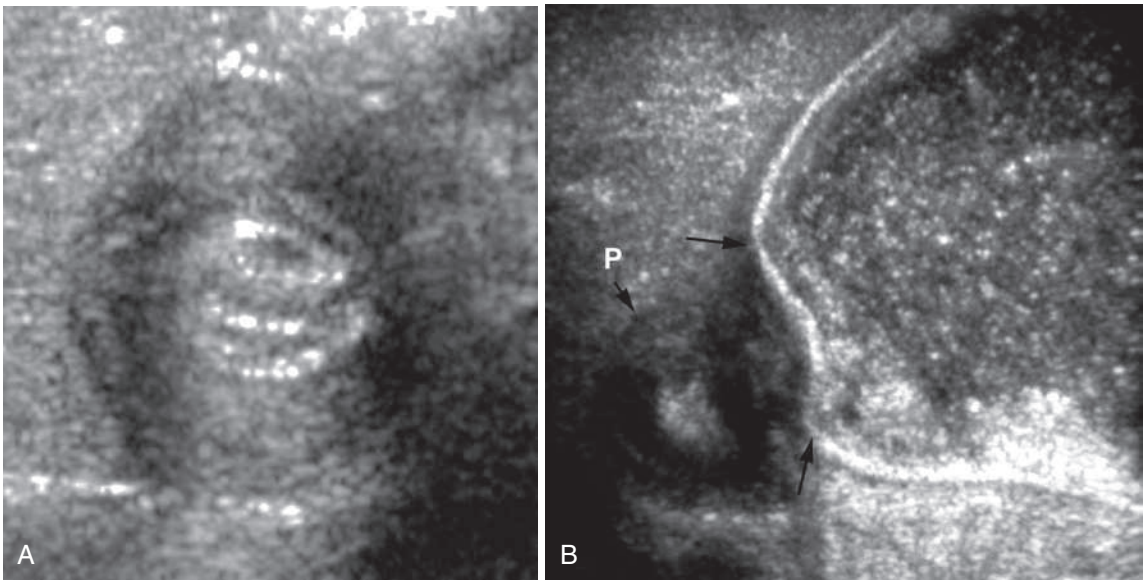

FIG. 53.9 Hypertrophic Pyloric Stenosis. (A) Echogenicity artifact at 6 and 12 o'clock positions (anisotropic effect). Cross-sectional image through the pylorus shows the thickened muscle with increased echogenicity at 6 and 12 o'clock positions. **(B)** Posteriorly directed canal artifact. Note the squared-off appearance of the gastric antrum *(arrows)*. The thickened pylorus *(P)* is only partially visible in this imaging plane.

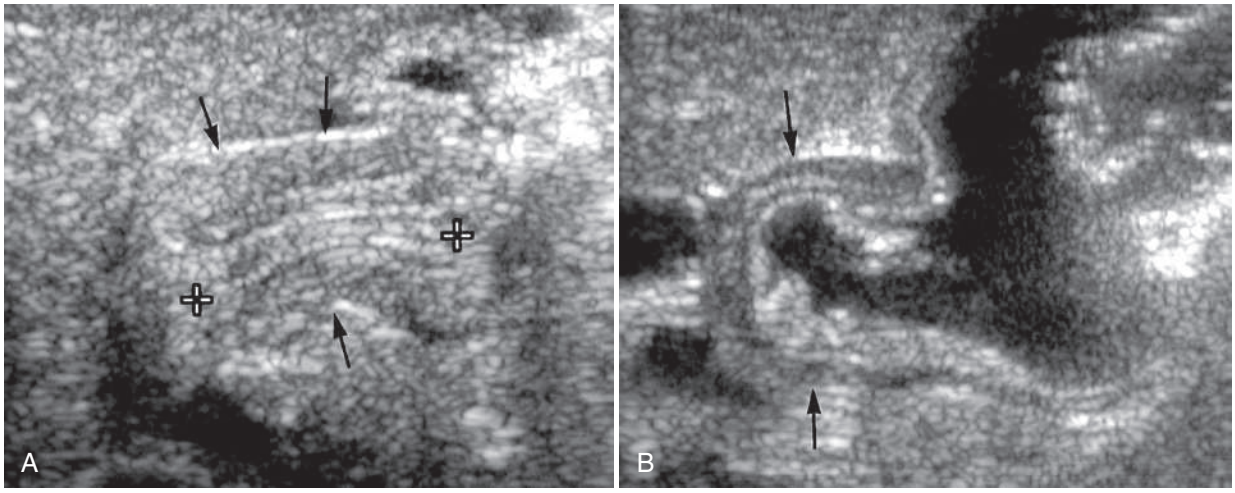

FIG. 53.10 Empty Stomach Artifact. (A) Before fluid is administered, the antrum is contracted and the pyloric muscle appears thickened *(arrows)*. **(B)** When fluid distends the antrum, the true normal thickness of the muscle is seen *(arrows)*.

Gastric Diaphragm

The gastric diaphragm, or antral web, consists of a congenital membrane that extends across the gastric antrum. These diaphragms most often lie less than 2 cm from the pylorus and are therefore usually visible on ultrasound examination. Complete diaphragms are considered one form of gastric atresia, but many diaphragms are incomplete and cause variable degrees of obstruction. On sonography, the web appears as an echogenic band across the distal gastric antrum (Fig. 53.11). Care must be taken to image such webs in the true midlongitudinal plane because if an incomplete diaphragm is imaged at its periphery, a complete diaphragm may be erroneously suggested.

Gastritis and Ulcer Disease

Peptic ulcer disease in pediatric patients is probably more common than generally is appreciated.[29] **Gastric ulcers** are more common than duodenal ulcers in younger children (median age of 6.5 years) and ***Helicobacter pylori*** infection is less prevalent with gastric ulcers than with duodenal ulcers.[29] Sonography is not particularly helpful with duodenal ulcers, but gastric inflammatory disease may be visible sonographically. Barium radiographic studies often reveal nothing more than persistent deformity or spasm of the antropyloric region. Ultrasound of the fluid-filled stomach permits direct visualization of the thickened gastric mucosa and submucosa,[30] which often is accompanied by loss

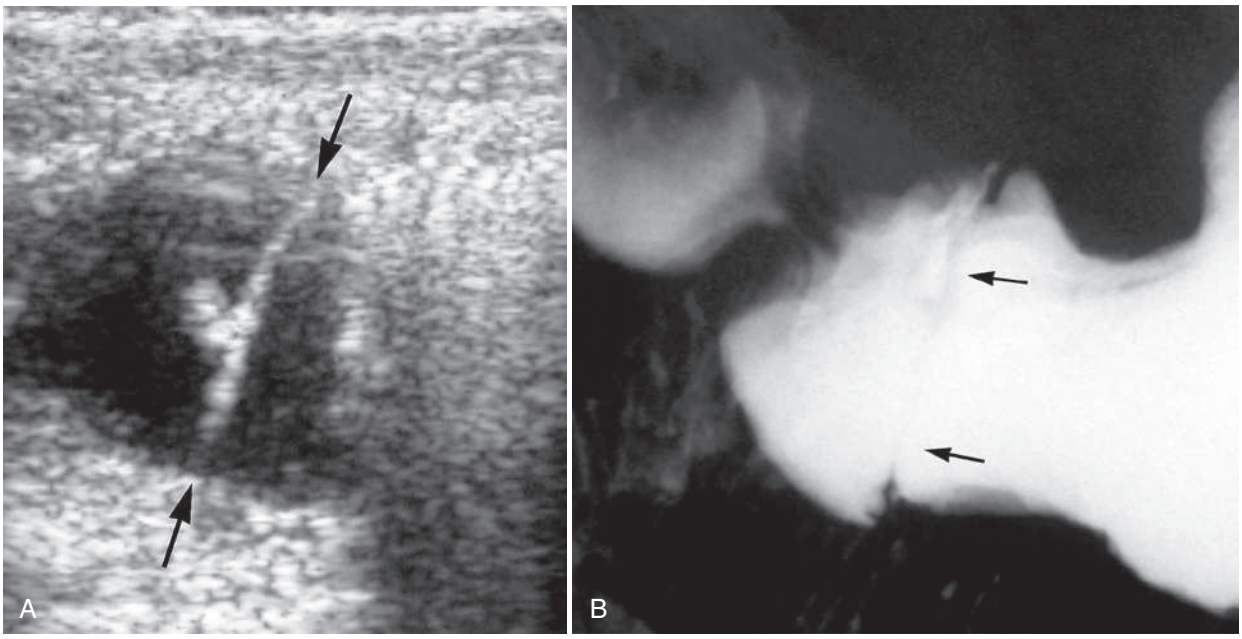

FIG. 53.11 Gastric Diaphragm. (A) Note the thin membrane *(arrows)* crossing the fluid-filled gastric antrum. **(B)** The same diaphragm seen during a contrast upper gastrointestinal series *(arrows)*.

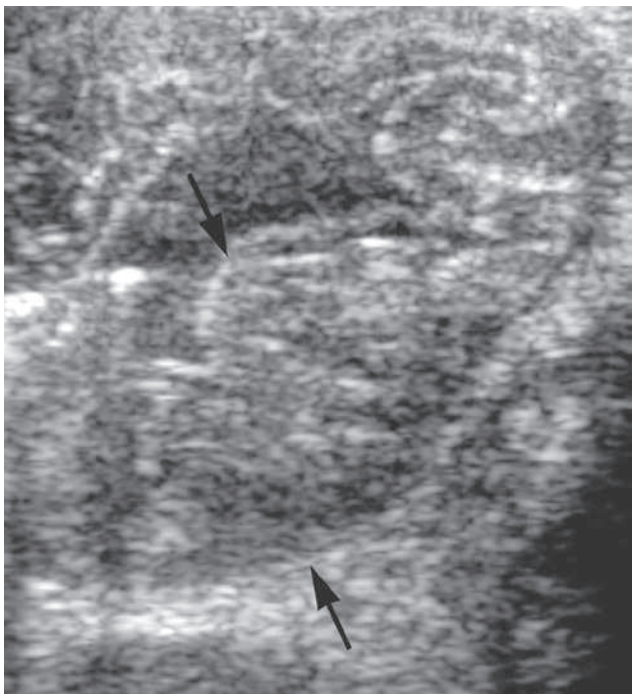

FIG. 53.12 Gastritis. Marked thickening of the gastric mucosa *(arrows)* is visible in this immunosuppressed transplant patient.

of definition of the individual layers of the gastric wall (Fig. 53.12). The ulcer crater itself usually is not visualized sonographically. Ultrasound can also be used to follow therapy, showing a return of the normal gastric wall layers as the ulcer heals. Thickening of the gastric mucosa is not a specific finding and can be seen with other conditions, such as **eosinophilic gastritis, inflammatory pseudotumor,**[31] **chronic granulomatous disease, Ménétrier disease,**[32] **milk allergy,** and **prostaglandin-induced antral foveolar hyperplasia.**[33,34] The last condition is self-limiting and can be seen in asymptomatic infants.[35]

Bezoar

Lactobezoars are the most common form of bezoar in children, occurring predominantly in infants who are fed improperly reconstituted powdered formula. In older children, **trichobezoars,** caused by the ingestion of hair, are more common. Both types of bezoar can be easily identified with ultrasound, especially if the patient is given clear fluid to help outline the mass. Lactobezoars appear as a solid, heterogeneous, echogenic intraluminal mass[36] (Fig. 53.13). With trichobezoars, air tends to be trapped in and around the hair fibers, which causes a characteristic arc of echogenicity that obscures the mass but conforms to the shape of the distended stomach. Distending the stomach with water and scanning in decubitus and upright positions allows the bezoar to be separated from the gastric wall, clinching the diagnosis[37] (Fig. 53.14). Trichobezoars can rarely lead to small bowel obstruction in cases where the bezoar extends beyond the stomach, called **Rapunzel syndrome** when extending through a large portion of the small intestine.[38]

In the case of small bowel obstruction, a bezoar proximal to the obstruction has a **twinkling artifact,** a characteristic arclike shadow with strong posterior acoustic shadowing, whereas fecal material has neither the posterior shadowing nor the twinkling artifact. Bezoars can be difficult to differentiate from fecal material proximal to a small bowel obstruction by computed tomography (CT).[39]

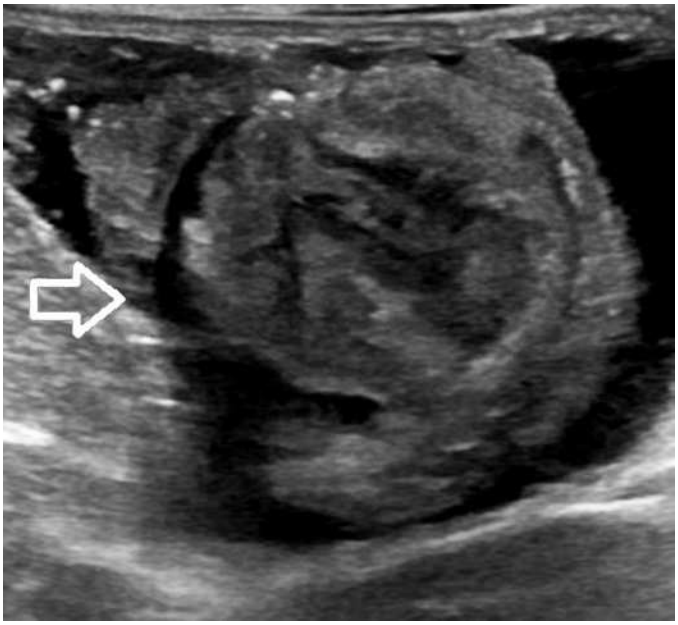

FIG. 53.13 Lactobezoar. Longitudinal ultrasound of the stomach. Note large filling defect caused by the lactobezoar in an otherwise fluid-filled stomach *(arrow).* The child had had nothing by mouth for 6 hours.

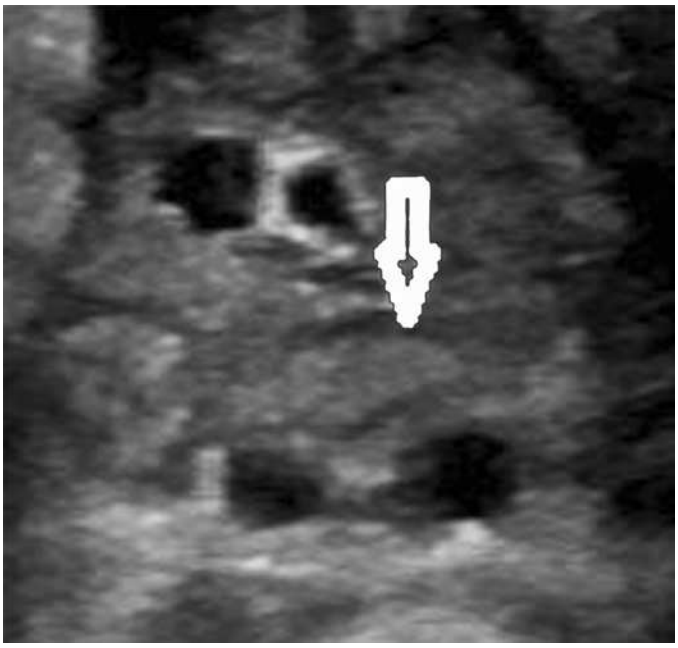

FIG. 53.15 Normal Duodenum. The third portion of the duodenum *(arrow)* is visible between the aorta and superior mesenteric vessels.

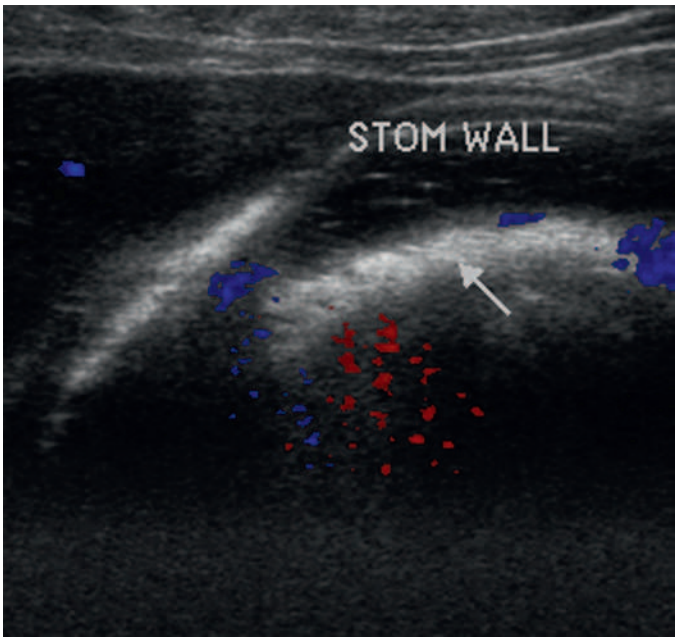

FIG. 53.14 Trichobezar. Echogenic arc is caused by air trapped within the mass of hair fibers *(arrow).*

DUODENUM AND SMALL BOWEL

Normal Anatomy and Technique

Normally, intestinal gas prevents complete visualization of the duodenum and small bowel with ultrasound. However, if the stomach is filled with fluid, it is often possible to identify the duodenal bulb, descending duodenum, and third portion of duodenum located between the aorta and the superior mesenteric vessels (Fig. 53.15). In addition, gradual compression of the abdomen with the transducer during scanning often encourages the gas to move to other areas, allowing previously obscured small bowel loops to be examined. The mucosa, submucosa, and muscular layers can be delineated,[28] especially in those loops that contain fluid (Fig. 53.16).

Congenital Duodenal Obstruction

Sonography can readily identify an obstructed, fluid-filled, distended duodenum, and frequently the level of obstruction can be determined. Complete duodenal obstruction in the newborn is often readily apparent on radiographs, and ultrasound generally provides little additional useful information. However, in patients in whom the stomach and duodenum are filled with fluid rather than air, ultrasound can be quite useful.

Proximal duodenal obstruction resulting in the classic double-bubble sign occurs with **duodenal atresia,** with or without associated annular pancreas (Fig. 53.17). Plain radiograph findings usually are diagnostic, showing two air-filled bubbles representing the dilated stomach and proximal duodenum. Similar findings can be seen with **severe duodenal stenosis** and **duodenal diaphragms or webs.** Usually, sonography is not needed to identify obstructions in this portion of the duodenum. However, when duodenal atresia is associated with esophageal atresia, air cannot reach the stomach and duodenum, making radiographic diagnosis more difficult. Sonography is diagnostic in such infants by demonstrating the grossly distended, fluid-filled duodenal bulb, stomach, and distal esophagus.[40,41]

Sonography has been used for diagnosis of **intestinal malrotation with midgut volvulus** in an infant with bilious vomiting, although the fluoroscopic upper GI series remains the reference standard. If an ultrasound is performed in a patient with volvulus,

FIG. 53.16 Normal Small Bowel. High-frequency ultrasound images show the thin, distinct layers of normal bowel loops.

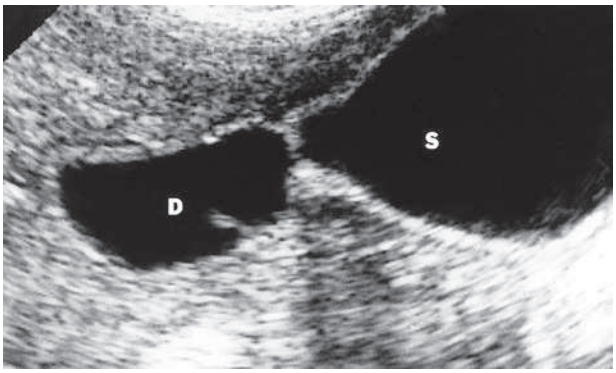

FIG. 53.17 Duodenal Atresia. The presence of grossly distended duodenal bulb *(D)* and stomach *(S)* constitutes the sonographic "double bubble" sign.

vigorous peristalsis of the dilated, obstructed duodenal C-loop is seen (Fig. 53.18) and characteristic tapering of the distal, twisted end can be visualized.[42] Color Doppler will show the **"whirlpool" sign** of twisted mesenteric veins around the superior mesenteric artery (SMA) (Fig. 53.19). Obstruction from **peritoneal (Ladd) bands,** which also accompanies rotational anomalies of the intestine, can have a similar appearance. In addition to these findings, an abnormal position of the superior mesenteric vein (SMV) and artery can be seen in patients with intestinal malrotation, with or without volvulus (Fig. 53.20). Failure of normal embryologic bowel rotation leaves the SMV anterior to or to the left of the SMA[43,44] as opposed to its normal position to the right of the artery. Although this finding is not always present in volvulus,[45] it is probably worthwhile to observe the relationship of these vessels in any child who is undergoing sonography for the evaluation of vomiting. In addition, documentation of the normal position of the third portion of the duodenum posterior to the SMA and anterior to the aorta can be used to exclude malrotated bowel. With practice, this becomes easier.[46,47] Although these findings are valuable for suggesting the diagnosis, absence of these findings does not exclude malrotation or volvulus.[48]

A final cause of distal duodenal obstruction is a **duodenal diaphragm** that has stretched into a **windsock configuration** (Fig. 53.21). The distal end of the obstructed duodenum will have a rounded shape in this condition,[49] as opposed to the tapered end, which is seen more often with midgut volvulus.

Duodenal Hematoma

Duodenal hematoma is a common complication of blunt abdominal trauma in children, including those with battered child syndrome. Sonography can demonstrate the dilated, obstructed duodenum and more specifically can show evidence of an intramural hematoma[50-52] (Fig. 53.22). The intramural hemorrhage initially causes echogenic thickening of the wall of the duodenum, but as time passes, the hematoma undergoes liquefaction and the thickened wall becomes hypoechoic. Similar hematomas can occur with **Henoch-Schönlein purpura.**[53]

Small Bowel Obstruction

The diagnosis of small bowel obstruction is usually accomplished with plain radiographs. At times, however, ultrasound can be used to help determine the site or cause of the obstruction. In cases of mechanical small bowel obstruction, the fluid-filled, dilated, hyperperistaltic loops of small bowel proximal to the obstruction are usually clearly visible with ultrasound (Fig. 53.23). One can also assess small bowel in both lower quadrants in an attempt to ascertain the level of obstruction and also try to determine the cause of obstruction if lesions such as duplication cysts, small bowel intussusception, or even interloop collections from a perforated appendix are present.

In neonates with congenital causes of small bowel obstruction (e.g., ileal atresia, meconium ileus), prenatal intestinal perforation can occur, releasing variable amounts of meconium into the peritoneal cavity. In some of these fetuses, the perforation heals in utero, and the only clues that remain after birth are scattered

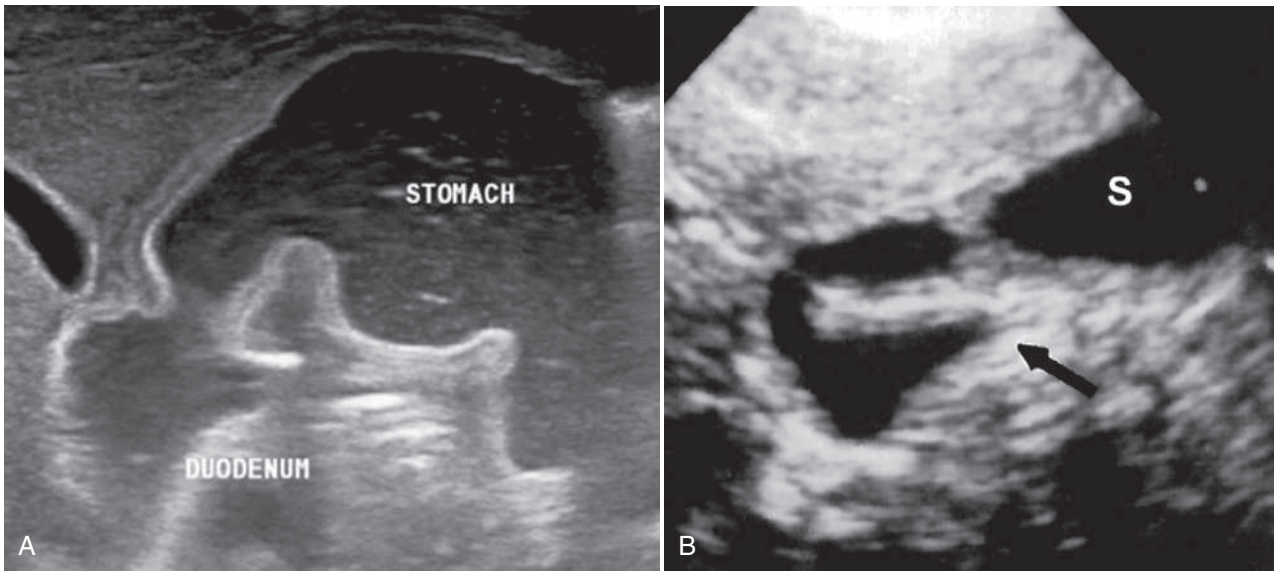

FIG. 53.18 Midgut Volvulus. (A) The pylorus is widely patent and the proximal duodenum is dilated and shows vigorous peristalsis. The point of obstruction is not clearly visible in this patient. **(B)** In a different child, vigorous peristaltic activity fails to empty the duodenum, and the third portion of the duodenum has **beak deformity** *(arrow). S,* Stomach.

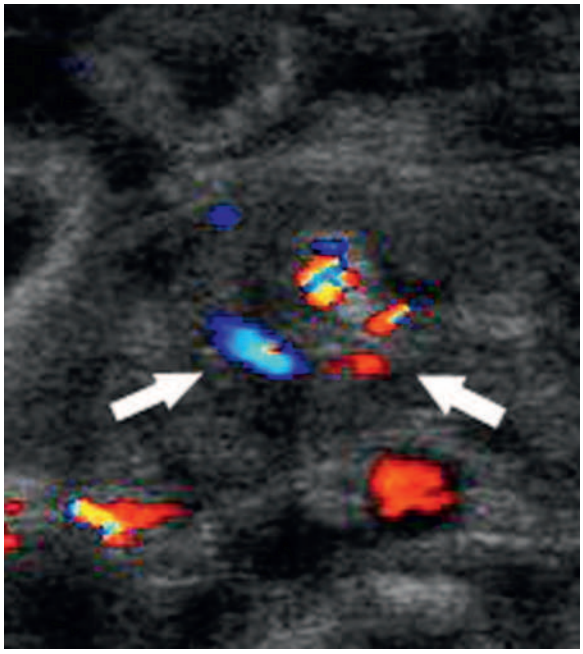

FIG. 53.19 Midgut Volvulus "Whirlpool" Sign. Color Doppler shows a clockwise **whirlpool** of vessels *(arrows)* around a volvulus.

calcifications in the peritoneal cavity. In patients in whom larger amounts of meconium have leaked, or in whom an active leak remains after birth, cystic masses can be found in the peritoneal cavity, giving rise to the term **cystic meconium peritonitis.** Sonographically, these cysts are of variable size and are fairly well defined, often with very heterogeneous cystic fluid.[54,55] The highly echogenic calcifications can also be found with ultrasound (Fig. 53.24). Echogenic ascitic fluid may also be present after perforation, whether in utero or neonatal.

Small bowel obstruction from **intestinal hematomas** usually occurs as a result of **Henoch-Schönlein purpura, blunt abdominal trauma, or coagulopathies.** In any of these conditions, the mural hemorrhage can be detected sonographically as asymmetric or circumferential areas of intestinal wall thickening that can vary from echogenic to hypoechoic.[53]

Intussusception

Intussusception is the most common cause of small bowel obstruction in children between the ages of 6 months and 4 years. Clinical findings of crampy, intermittent abdominal pain, vomiting, palpable abdominal mass, and "currant jelly" stools are classic. Patients with these characteristic symptoms probably do not require ultrasound diagnosis before attempted enema reduction. Many of these clinical features are present in young children with abdominal pain for other reasons, and some children with intussusception do not exhibit all the classic features. In such children, sonography can help confirm or exclude intussusception. Sensitivity and specificity for the diagnosis of intussusception with ultrasound are very high, approaching 100%.[56-60] If an intussusception is not demonstrated sonographically, an enema need not be performed unless clinical suspicion is high. False positives can occur occasionally in other conditions causing thickened bowel wall[61] (Fig. 53.25).

Sonographic Signs of Intussusception

Oval hypoechoic mass
  Pseudokidney or doughnut sign
Hypoechoic rim with central echogenicity
Multiple layers and concentric rings
Small amount of peritoneal fluid
Large amount of peritoneal fluid suggests perforation, especially echogenic ascites

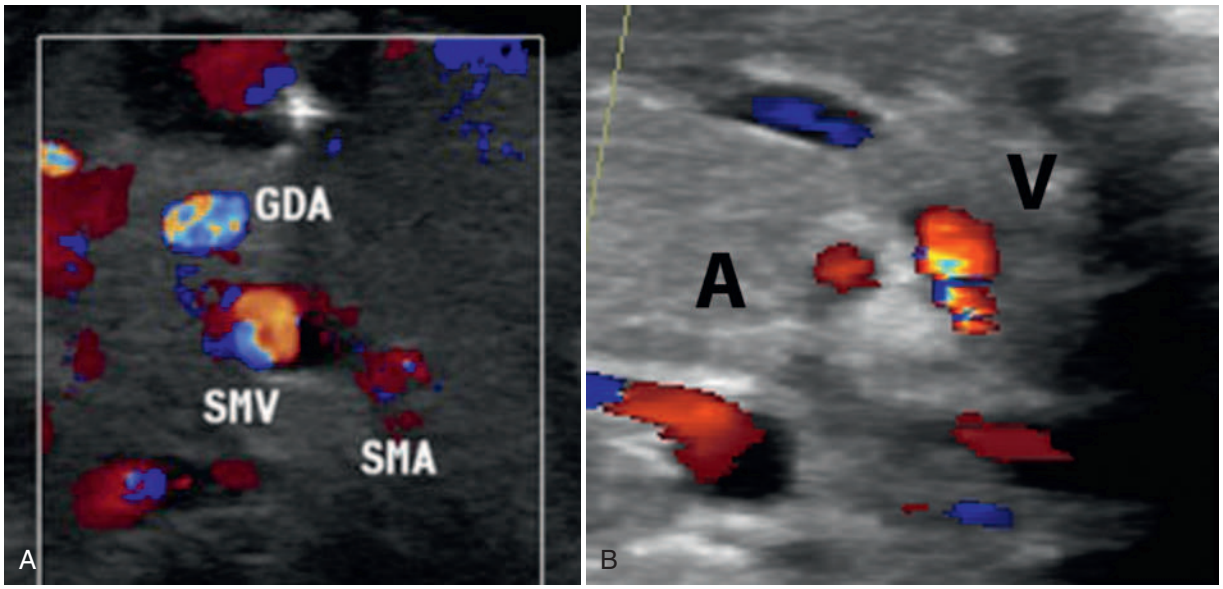

FIG. 53.20 Midgut Volvulus: Altered Relationship of Mesenteric Vessels. (A) Normal relationship of superior mesenteric artery *(SMA)* and the superior mesenteric vein *(SMV). FIG. 53.21 Duodenal Web. (A) Ultrasound shows a markedly dilated duodenum *(D)* filled with fluid. Note the rounded configuration at the point of obstruction in the duodenum *(white arrow)* and the widely patent pylorus *(black arrows). S,* Stomach. **(B)** Contrast upper gastrointestinal image shows similar findings, with the rounded end of the duodenum *(white arrow). Black arrow,* Pylorus.

Ultrasound for suspected intussusception is best performed with a 5- to 10-MHz curved array or linear transducer. The intussusception appears as an oval, hypoechoic mass with bright, central echoes on longitudinal imaging (i.e., **pseudokidney**) and a **hypoechoic doughnut,** or **target configuration with echogenic central echoes.**[62-64] The hypoechoic rim represents the edematous walls of the loops of bowel comprising the intussusceptum, and the central echogenicity represents compressed mesentery, mucosa, and intestinal contents. Linear array transducers display the intussusceptum with greater clarity, showing multiple layers and concentric rings representing the bowel wall, mesentery, and even lymph nodes that have been drawn into the intussusception[65,66] (Fig. 53.26D). In some cases, anechoic fluid is also seen trapped within the incompletely compressed head of the intussusception. Rarely, the lead point of an intussusception can be identified within the intussusceptum (Fig. 53.27).

Once an intussusception has been documented by sonography, the patient usually proceeds to nonsurgical reduction, unless clinical or radiographic evidence of perforation is found. Currently, air reduction is the most popular method of treatment, although hydrostatic reduction using water-soluble contrast remains a viable alternative. **Ultrasound-guided hydrostatic reduction** is an alternative method that avoids the ionizing radiation of standard fluoroscopic examinations.[67-70] Sonography can also be used to identify the ileo-ileal intussusception that sometimes remains after the successful hydrostatic reduction of

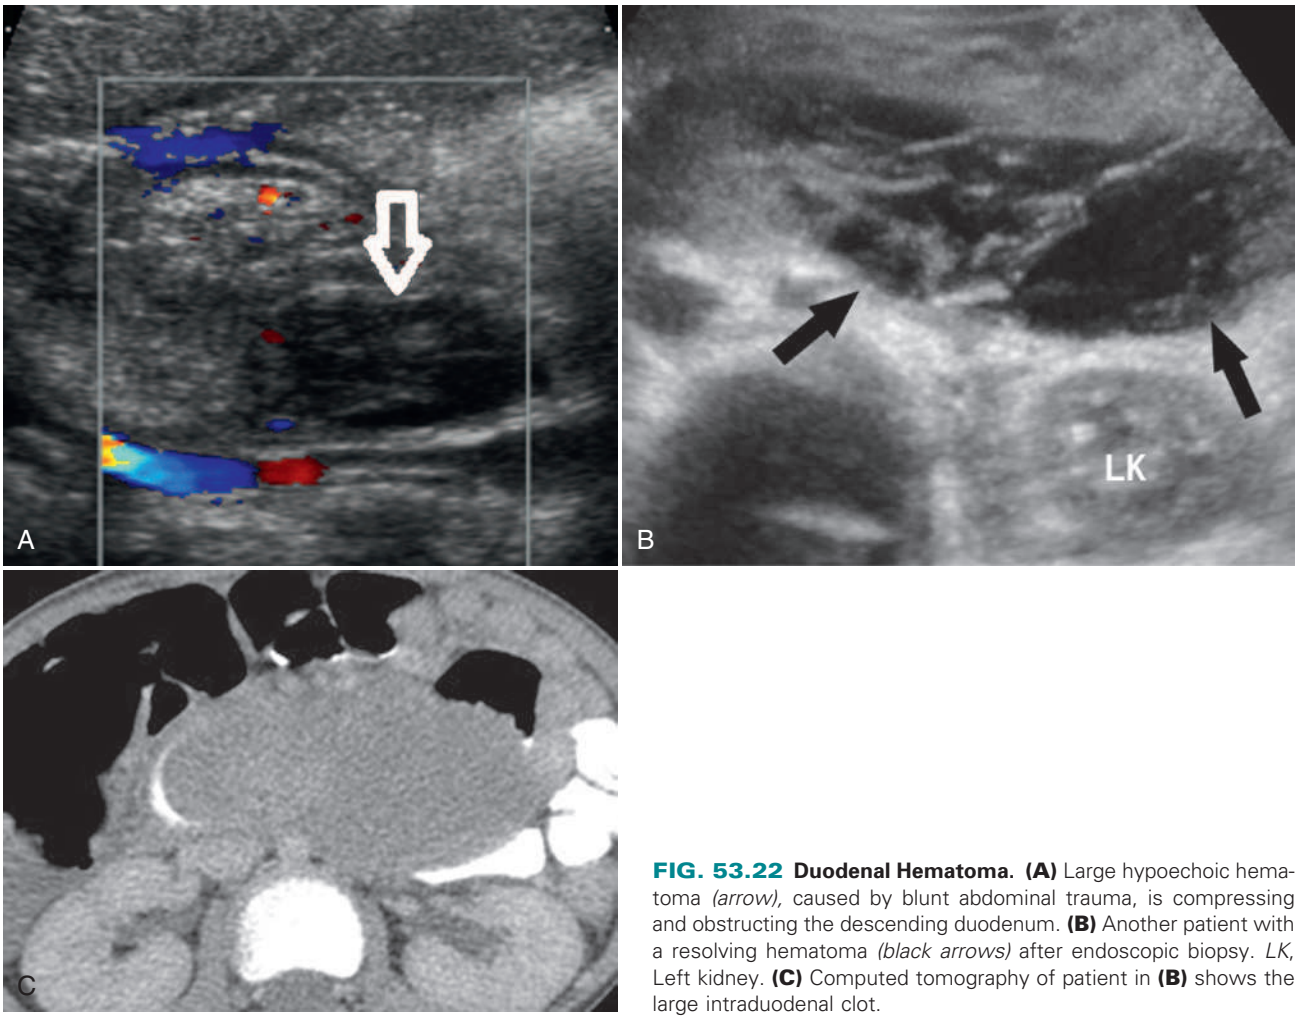

FIG. 53.22 Duodenal Hematoma. (A) Large hypoechoic hematoma *(arrow),* caused by blunt abdominal trauma, is compressing and obstructing the descending duodenum. **(B)** Another patient with a resolving hematoma *(black arrows)* after endoscopic biopsy. *LK,* Left kidney. **(C)** Computed tomography of patient in **(B)** shows the large intraduodenal clot.

the ileocolic portion of an intussusception. **Recurrent intussusception** occurs in 4% to 10% of cases, and thus ultrasound is worthwhile in children with recurrent symptoms after successful enema reduction. Fixed small bowel intussusception is less common in children but can occur when lead points such as **polyps** or **Meckel diverticulum** are present or may occur as a postoperative complication of major abdominal surgeries[71] (Fig. 53.28). Enema examinations are not helpful for diagnosis or treatment of intussusceptions restricted to small bowel, but ultrasound can provide prompt identification of the abnormality in most cases.[64]

Spontaneous reduction of intussusception is a well-known phenomenon that has been documented sonographically. In such patients, when symptoms subside between the time the diagnosis is made and the time a reduction procedure is begun, ultrasound can verify resolution of the intussusception and spare the patient an unnecessary enema procedure.[72] **Transient small bowel intussusception** is a common occurrence, especially in patients with hyperperistalsis. These intussusceptions are not associated with substantial edema in the intussuscepted loops, and therefore the peripheral rim of the intussusception appears thinner and more echogenic than firmly impacted intussusceptions.[73,74] The patient is usually asymptomatic, and spontaneous resolution of the intussusception usually can be observed at ultrasound with a little patience. Intussusception of the small bowel associated with gastrojejunal feeding tubes can also be identified sonographically.[75]

The only absolute contraindication to nonsurgical reduction of an intussusception is radiographic evidence of rupture (free intraperitoneal air or a large amount of complex ascites) or clinical signs of peritonitis. A small amount of free peritoneal fluid is typically seen during ultrasound in patients with intussusception, even in the absence of perforation.[76,77] Therefore a small amount of ascites is not a contraindication to nonsurgical reduction. However, if a large amount of ascites is found or the fluid appears complex, perforation should be considered.

Investigators have attempted to correlate certain ultrasound features of intussusception with the subsequent ability to reduce them nonsurgically. Findings such as peripheral rim thickness of greater than 1 cm, large amounts of internal trapped fluid, and lymph nodes larger than 1 cm within the intussusception have shown some correlation with decreased success of enema reduction.[66,78] Color Doppler assessment of blood flow to the intussusceptum has been used to identify patients who have

FIG. 53.25 False-Positive Intussusception. Thickened loops of small bowel secondary to an adjacent perforated appendicitis resembles an intussusception.

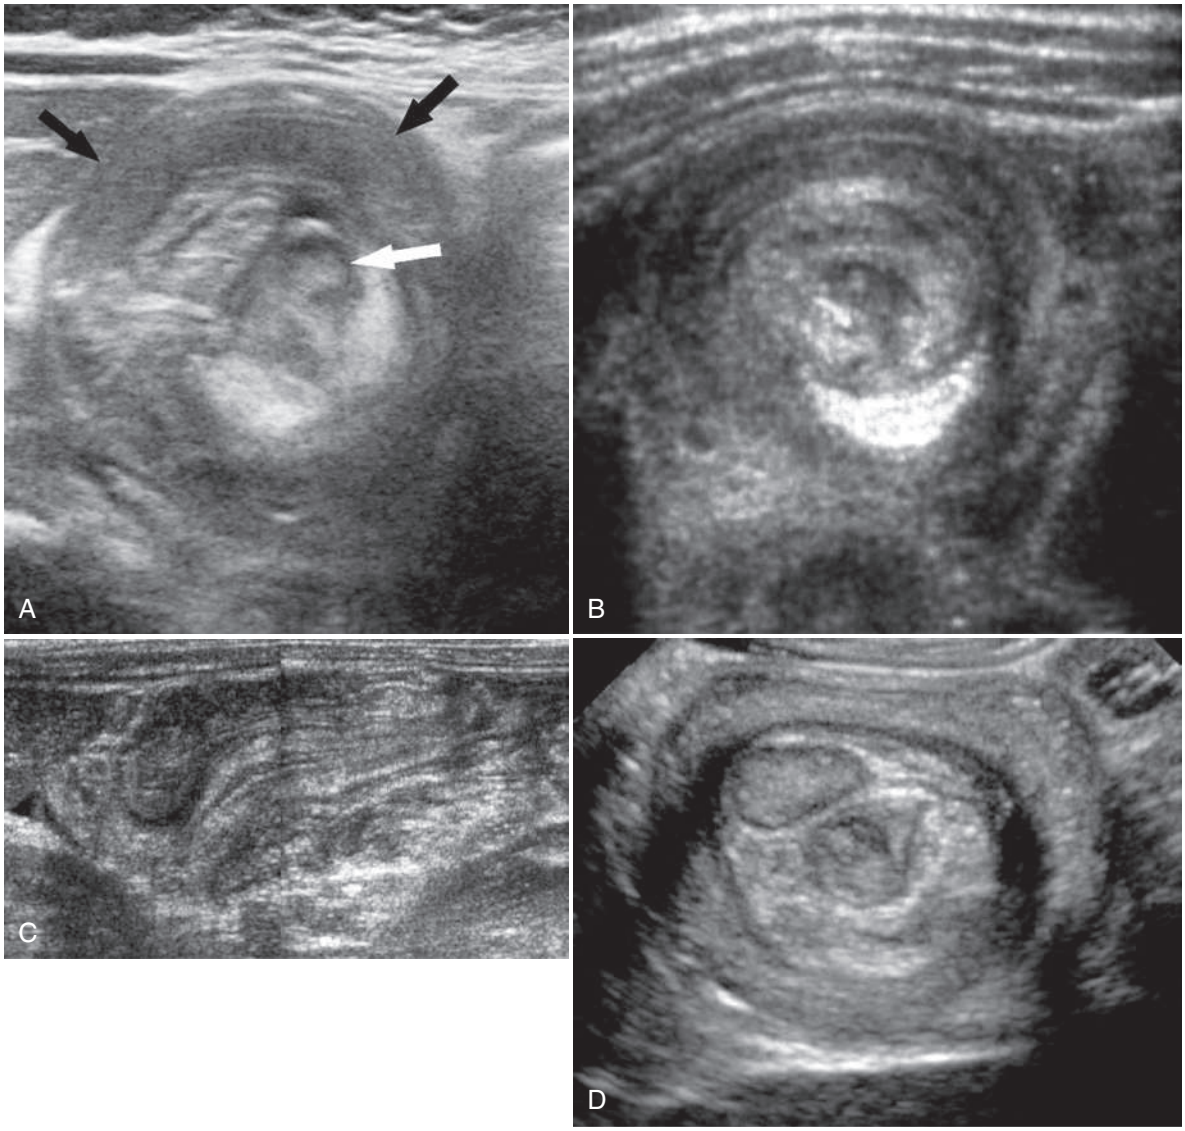

FIG. 53.26 Ileocolic Intussusception. (A) Linear transducers clearly show the concentric rings of the edematous intussusceptum *(black arrows)* with echogenic fat, mesenteric lymph nodes *(white arrow),* and a small amount of fluid trapped in the center. **(B)** Intussusception, showing concentric rings of bowel within bowel. **(C)** Longitudinal image of intussusception. **(D)** In another patient, transverse ultrasound shows ileocolic intussusception with multiple lymph nodes that have been drawn into the intussusception.

substantial bowel ischemia and who may be at greater risk of perforation during attempted nonsurgical reduction[79,80] (Fig. 53.29). Although such findings may portend more difficult enema reduction or increased risk of perforation, none are considered contraindications to nonsurgical reduction procedures.

COLON

Normal Anatomy and Technique

Sonographic evaluation of the colon can be compromised by the gas and excessive fecal material. However, in most patients the characteristic haustral markings in the multilayered wall of the ascending colon can easily be identified (Fig. 53.30). When pathologic wall thickening occurs, ultrasound can be used to assess degree and distribution of wall thickening of the ascending and descending colon and rectum, whereas the transverse colon can be more difficult to assess because of bowel gas. Patterns of inflammation and mural stratification have been described to assist in the diagnosis of colitis, with **pseudomembranous colitis** easy to diagnose based on its typical pancolonic distribution[81] (Fig. 53.30B). Some authors advocate graded compression for sonographic evaluation of colonic polyps, although this can be challenging.[82]

Ectopic or Imperforate Anus

Sonography in the neonate can also be used to study imperforate or ectopic anus.[83-85] In patients with ectopic or imperforate anus, it is important to determine where the distal end of the hindgut terminates. Well-known pitfalls in attempting this with plain

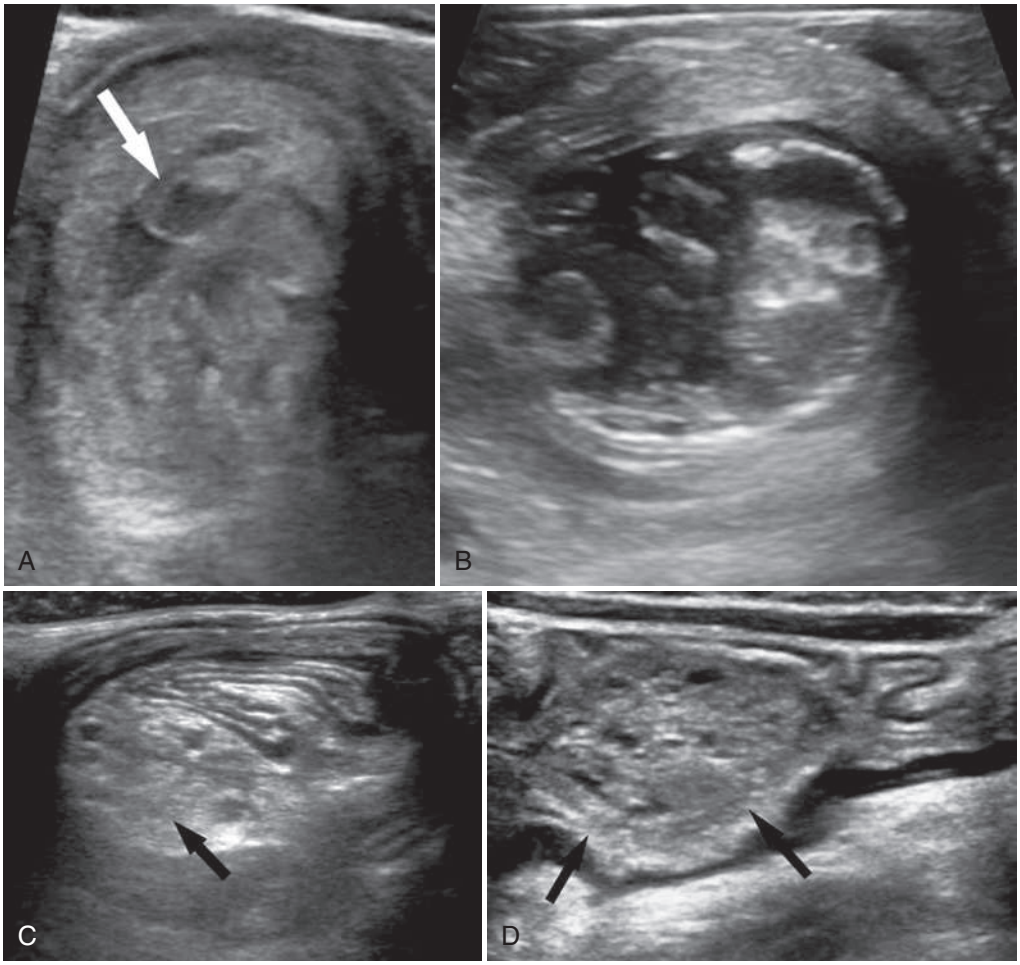

FIG. 53.27 Ileocolic Intussusception With Lead Point. (A) A small fluid-filled structure within this intussusception *(arrow)* represents the Meckel diverticulum found at surgery. **(B)** Intussusception with internal mass representing Burkitt lymphoma. **(C)** Another patient with intussusception caused by a juvenile polyp. The mass is difficult to see within the intussusception *(arrow)*. **(D)** Same patient as in **(C).** The polyp is easily visible after the intussusception is reduced *(arrows)*. (**C** and **D** courtesy of Clara Neira, MD.)

radiographs include those taken in the cross-table prone position. Radiographically, the colon can erroneously appear to end in a high position if the air column fails to progress to the end of the colon because of impacted meconium. Imperforate anus in the newborn can be assessed sonographically via a perineal approach. The low type of imperforate anus passes through the levator ani muscle complex and is managed with transperineal anoplasty. Intermediate and high imperforate anus are supralevator and are managed by initial diverting colostomy. Scanning with a high-resolution transducer via a midsagittal transperineal approach gives excellent detail of the wall of the distal rectal pouch. Fistula location can also be detected in some sonographically (Fig. 53.31). The study should not be performed in a crying infant because the increased abdominal pressure moves the rectal pouch closer to the perineal surface. Haber and colleagues used a pouch-to-perineum distance of 15 mm with a sensitivity and specificity of 100% and 86% in separation of low from high and intermediate imperforate anus and found that with lack of an anocutaneous fistula and rectal pouch–to–perineal distance of greater than 15 mm, the diagnoses of intermediate or high imperforate anus can be made.[83]

INTESTINAL INFLAMMATORY DISEASE

Ultrasound and magnetic resonance imaging (MRI) are being used more often to evaluate GI disorders in the pediatric patient, with decreasing emphasis on CT because of associated exposure to ionizing radiation. High-resolution linear array transducers allow direct and detailed evaluation of the intestinal wall, showing up to five distinct layers in the wall of normal intestine. Lower-frequency transducers can be used to evaluate for mesenteric edema or abscess collections. Intravenous microbubble ultrasound contrast has added to the capability of ultrasound in assessment of inflammatory conditions, especially in the assessment and follow-up of therapy in Crohn disease. Wall thickening is nonspecific[86] and can be seen in a variety of inflammatory

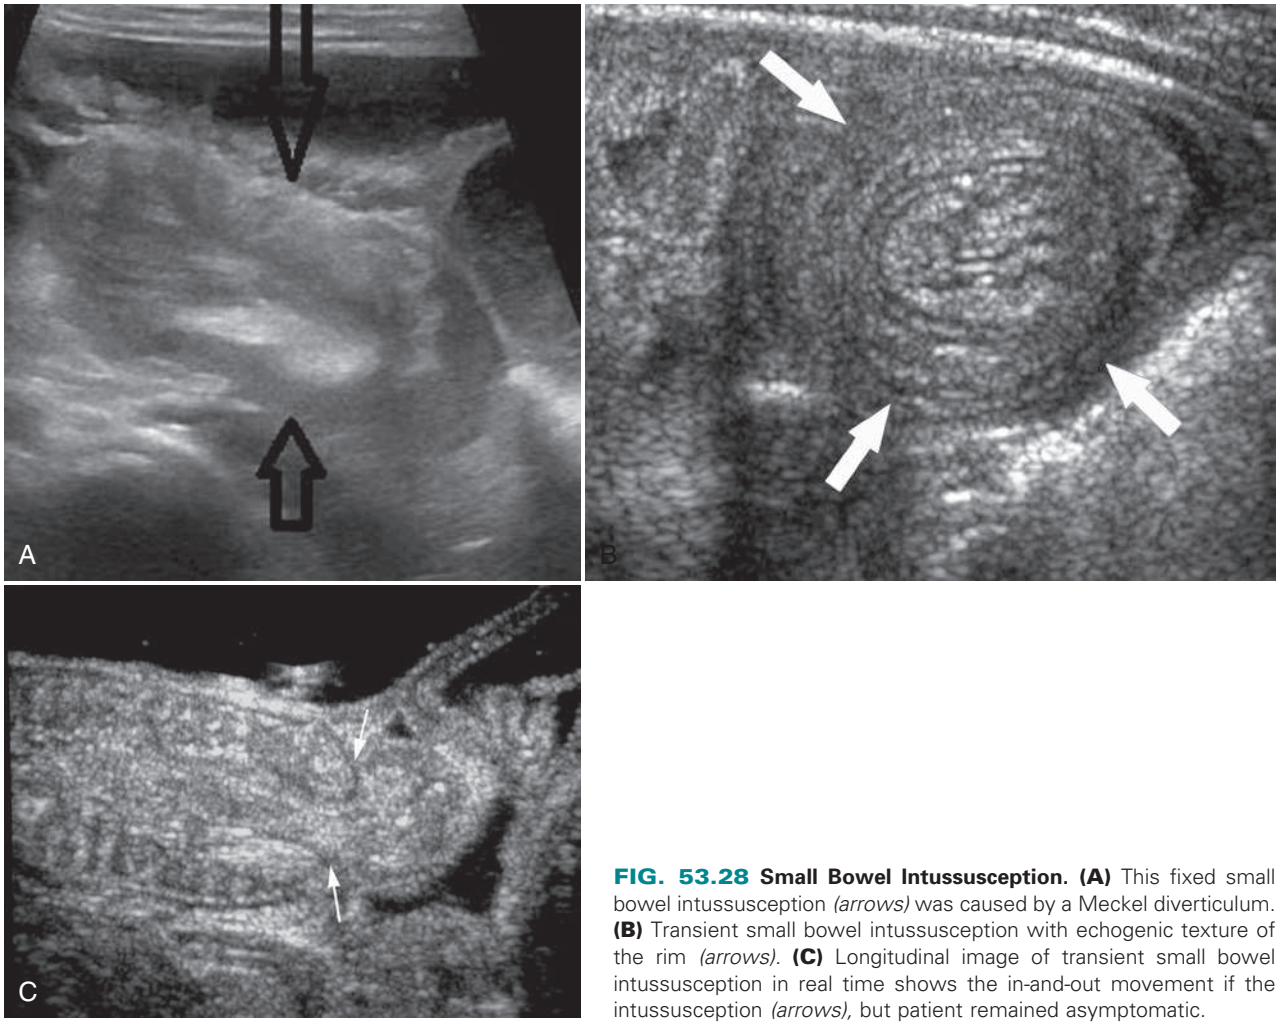

FIG. 53.28 Small Bowel Intussusception. conditions, including Crohn disease,[87,88] ulcerative colitis,[88] pseudomembranous colitis,[89,90] neutropenic colitis (typhlitis),[91] infectious colitis,[92-94] allergic colitis,[95] Kawasaki disease,[96] necrotizing enterocolitis (NEC),[97] hemolytic uremic syndrome,[98] graft-versus-host disease,[99,100] glycogen storage disease type 1B,[101] and chronic granulomatous disease of childhood.

Causes of Intestinal Wall Thickening

Inflammatory bowel disease (Crohn disease or regional enteritis, ulcerative colitis)
Yersinia, Campylobacter ileocolitis
Colitis
Perforated appendicitis
Rotavirus
Cytomegalovirus (CMV) infection
Typhlitis
Chronic granulomatous disease
Eosinophilic enteritis
Hematoma (Henoch-Schönlein purpura, trauma)
Hemolytic uremic syndrome
Graft-versus-host disease
Intussusception
Lymphoma
Benign tumor
Tuberculosis (rare)
Celiac disease

Sonography can sometimes differentiate **mucosal** from **transmural** inflammation. If the inflammatory process involves primarily the mucosa (e.g., **ulcerative colitis, pseudomembranous colitis, typhlitis**), the inner echogenic mucosal layer becomes thickened and sometimes nodular or irregular, but the outer muscular layer of the wall remains thin (Fig. 53.32). When the inflammation involves the entire intestinal wall (e.g., **regional enteritis**), thickening of the entire wall is seen (Fig. 53.33). Color Doppler sonography demonstrates increased blood flow to the thickened intestinal loops with most inflammatory bowel conditions, with the submucosa containing the main vascular channels[102] (Fig. 53.34). Hypovascularity is more typical in hemolytic uremic syndrome.[98] Normal bowel wall also shows little signal with color or power Doppler imaging.

For elective procedures, patients should avoid eating solid foods for 4 hours before the examination, but noncarbonated liquids are encouraged to help displace bowel gas and partially fill the urinary bladder to displace small bowel from the pelvis. Compression techniques to displace bowel gas are well established for the evaluation of the cecum and appendix, ascending colon, descending colon, rectosigmoid colon, and small bowel loops in the left upper quadrant and right lower and left lower quadrants. Normal small bowel wall thickness is less than 2.5 mm and less than 2 mm for large bowel.[103] Wall thickness of greater than 3 mm is considered abnormal for the colon.[104] Stratification of wall layers is well depicted in normal small and large bowel. Loss of stratification

and loss of haustration are important indicators of wall inflammation.

Infectious colitis is a common cause of acute abdominal pain in children, primarily diagnosed by stool culture. However, ultrasound is helpful in distinguishing infectious bowel pathology from other causes such as intussusception and appendicitis in the young child and appendicitis or Crohn disease in the older child. Viral infections and gram-negative bacterial infections such as ***Shigella, Salmonella, Campylobacter, Escherichia coli,*** and ***Yersinia*** are common causes of enteritis.[105] Enterohemorrhagic ***E. coli*** can cause hemorrhagic colitis after ingestion of contaminated foods.

Lymphoid hyperplasia can be detected within the small bowel, and mesenteric lymph node enlargement may also be seen, especially with *Yersinia* and *Salmonella* (Fig. 53.35). History and immune status are important in creating a differential diagnosis, with ultrasound primarily used to exclude appendicitis, intussusception, and Crohn disease while confirming that there is an underlying enteritis present. Pneumatosis intestinalis can

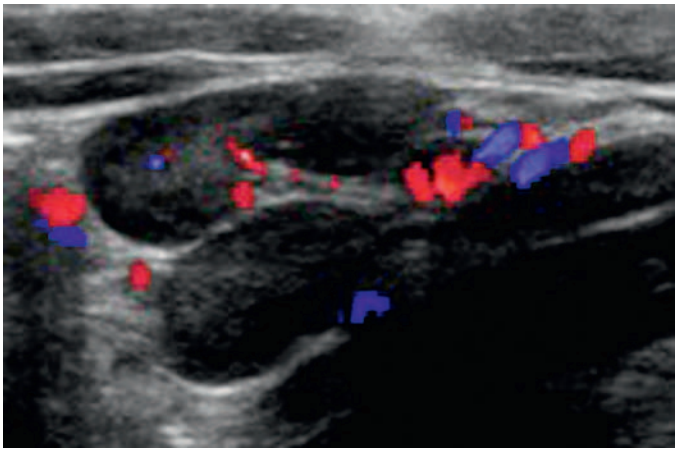

FIG. 53.35 Hypertrophied Lymphoid Tissue. A cluster of enlarged mesenteric lymph nodes in a child with ***Yersinia*** **colitis.**

FIG. 53.36 Ascariasis. The long slender parasite is clearly visible within the bowel on ultrasound *(arrows)*.

sometimes occur in infants and children with inflammatory conditions such as rotavirus infection or milk allergy.[106] *Mycobacterium tuberculosis,* a rare entity in developed countries, can be transmitted to bowel, with 90% of GI tuberculosis involving the distal ileum or cecum owing to the abundant lymphoid tissue. However, GI tuberculosis is an increasingly common disease in developing countries.[107]

On occasion, parasites may be found unexpectedly on ultrasound. **Ascariasis** is one of the most common intestinal infestations, prevalent in areas with poor sanitation. Eggs are passed with the feces of an infected person and can be transmitted by the fecal-oral route. Eggs hatch in the small intestine and can penetrate the intestinal mucosa and travel to the lung. On occasion, the worms can be identified in the bowel by their characteristic slender appearance and thin echogenic line within the body, representing the alimentary tract[108] (Fig. 53.36).

Enterobius vermicularis organisms, or **pinworms,** are the most common helminthic infection in the United States and Western Europe. Mobile pinworms have been seen within the appendix during sonographic studies as well as in the surgical setting.[109]

Crohn disease is the most common form of chronic inflammatory bowel disease in children. Ultrasound can be used as a screening tool for inflammatory bowel disease and also has value for assessing success of treatment and potential complications. Ultrasound sensitivity for the diagnosis of Crohn disease is comparable to that of other imaging modalities such as magnetic resonance enterography or CT,[110,111] and ultrasound is probably more suitable for use in young children. Bowel wall inflammation in Crohn disease is segmental and transmural and tends to be asymmetrical, with greater involvement of the mesenteric border of bowel (Fig. 53.37). A wall thickness of greater than 3 mm is a sign of active disease on follow-up ultrasound examinations.[112] In early Crohn disease, wall stratification may be preserved with thickening of the submucosal layer.[113] With more advanced disease, actively inflamed bowel wall shows loss of normal stratification and is hyperemic with decreased peristalsis. Skip areas and mesenteric inflammatory changes are characteristic of the disease. Lymph node hypertrophy and mesenteric fibrofatty proliferation also favor Crohn disease (Fig. 53.37B). Mesenteric inflammation that accompanies Crohn disease can be profound and can mimic other diagnoses in children on initial presentation with the disease.

Contrast-enhanced ultrasound (CEUS) has been shown to improve identification of the affected bowel loops in children with Crohn disease and can also depict the microvasculature of the bowel wall and surrounding mesentery.[114,115] Some studies have suggested that CEUS may help to distinguish inflammatory strictures from fibrotic strictures, which can help solve a common therapeutic dilemma in resolving Crohn disease.[116] Doppler measurement of the resistive index in the SMA has been used to assess progression of disease in patients with active Crohn disease with only partial correlation.[117] Investigations into use of ultrasound elastography to detect diminished tissue elasticity in the affected bowel are in the early stages. Sonography is indicated in children with suspected complications of regional enteritis. Ultrasound may identify distal right ureteral involvement by the inflammatory mass that can result in hydronephrosis. Although the fistulas and sinus tracts that develop in regional enteritis are usually not discernible sonographically, ultrasound can be used to identify associated intraabdominal abscesses (see Fig. 53.37C).

Henoch-Schönlein purpura, a condition caused by an **autoimmune vasculitis** involving small vessels in a variety of body systems, frequently involves the GI tract. Of these patients, 50% to 60% develop abdominal pain from intramural hemorrhage in the intestines, and this symptom may precede the development of the more characteristic purpuric skin rash. In such patients, sonography may detect the involved intestinal loops, which usually show circumferential, echogenic wall thickening, sometimes associated with small amounts of free abdominal fluid[53] (Fig. 53.38). Sonography also can be used to follow the resolution of the intestinal hemorrhage. **Intussusception** is a major complication of Henoch-Schönlein purpura, and sonography is highly useful to identify such an intussusception,[118] which usually involves only the small bowel and does not extend into the colon. Intestinal hemorrhage may also complicate bleeding diatheses or blunt abdominal trauma.

A variety of other conditions can result in thickening of the wall of the small bowel or colon, but few show distinguishing characteristics at imaging. **Hemolytic uremic syndrome** is associated with *E. coli* 0157:H7 infection, characterized by hemolytic anemia, thrombocytopenia, and renal failure. Hemolytic uremic syndrome is usually preceded by a severe hemorrhagic colitis. Color Doppler imaging reveals that the thickened bowel segments are hypovascular,[98] probably secondary to fibrin microthrombi that develop from factors released by the damaged endothelium (see Fig. 53.32D). **Graft-versus-host disease** in bone marrow transplant patients occurs when the transplanted tissue mounts an attack on host tissues. Skin, liver, and GI involvement is common. Acute graft-versus-host disease occurs within 100 days and involves the small intestine in 75% to 100% of cases.[119] Circumferential bowel wall thickening and mucosal hyperemia, representing the neovascularization driven by

FIG. 53.37 Crohn Disease. vasculogenesis in the early stages, are the predominant findings on ultrasound with mild bowel dilation. Graft-versus-host disease involves diffuse long segments of bowel and may extend from duodenum to rectum. Intestinal injury results in abdominal pain, vomiting, and diarrhea. The thickened, featureless intestinal loops are visible with ultrasound. A thin rim of echogenic material lining the mucosal surface of the affected loops has been described[99] (Fig. 53.39). This membrane is thought to represent the fibrinous exudate often seen covering the ulcerated mucosa at endoscopy in this condition.

Necrotizing enterocolitis (NEC) is an important problem in premature newborns, affecting close to 10% of infants weighing less than 1500 g. NEC can also affect term and near-term infants. The etiology is believed to be multifactorial involving altered bacterial flora, ischemia, and activated proinflammatory intracellular cascades. NEC is usually detected radiographically, but early in the disease, the classic findings of bowel dilation and pneumatosis intestinalis may not be apparent. In such cases, high-resolution sonography can assess the thickness of the intestinal loops, pattern of bowel wall perfusion, pneumatosis, peristalsis, free air, and subsequent fluid collections with perforation (Fig. 53.40). Early in NEC, there is bowel thickening, but wall thinning of less than 1 mm was seen by Faingold and colleagues as highly suggestive of severe ischemia.[120,121] **Pneumatosis intestinalis** may be visible on sonography before it is seen on radiographs, appearing as small, punctate, echogenic foci in the nondependent wall

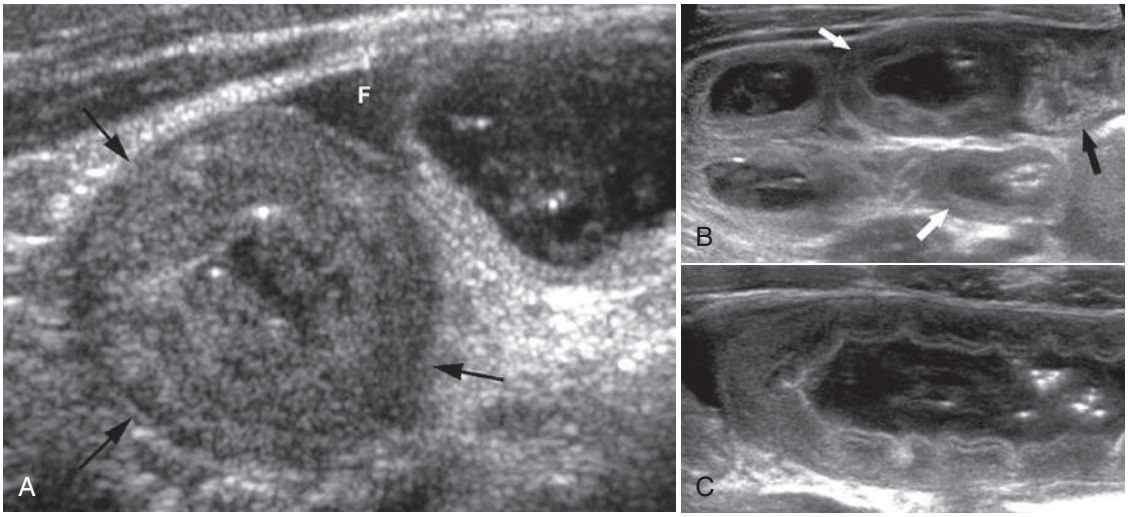

FIG. 53.38 Henoch-Schönlein Purpura. (A) Slightly hypoechoic, circumferential wall thickening of a single intestinal loop *(arrows),* with a small amount of adjacent anechoic free fluid *(F)* in a child with Henoch-Schönlein purpura. Note the normal thin wall of the adjacent bowel loop. **(B)** Another child with echogenic, small bowel thickening caused by Henoch-Schönlein purpura *(white arrows).* Note the normal wall on an adjacent loop of small bowel *(black arrow).* **(C)** Hypoechoic wall thickening in a different child with Henoch-Schönlein purpura.

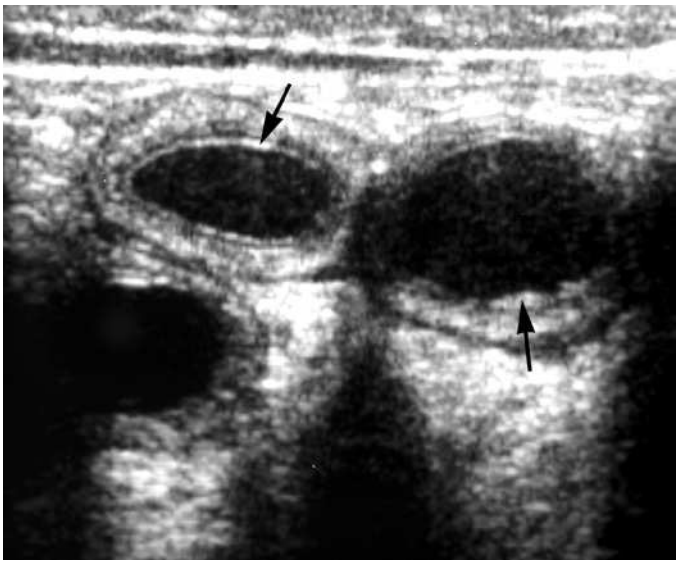

FIG. 53.39 Graft-Versus-Host Disease. Multiple thick-walled small bowel loops. A thin echogenic layer on the superficial surface of the mucosa *(arrows)* represents characteristic fibrinous deposit.

or as a granular echogenic ring within the bowel wall with posterior reverberation when more diffuse.[99,100] Intramural gas will not change with peristalsis or shift with change in positioning of the patient, which helps distinguish intramural from intraluminal gas. In addition, sonography can detect small amounts of gas within the portal venous system, which appear as small echogenic mobile foci within the liver, well before the gas is evident on plain films.[120-122] The patchy pattern with large amounts of mobile gas within the liver can be quite striking. **Pericholecystic hyperechogenicity** has also been described in infants with NEC.[123] The most serious complication is **bowel necrosis with perforation.** Increased flow velocity in the splanchnic arteries, most likely caused by vasoconstriction, has been suggested as a reliable early finding on Doppler sonography in NEC infants.[124] Free intra-abdominal air is detectable in infants who have minimal intestinal gas that has escaped through the perforation. Early free intraperitoneal gas can be detected most easily along the surface of the liver or within free intraperitoneal fluid.[100] The sonographic demonstration of **complex fluid collections with debris** can suggest perforation in such patients[125] (see Fig. 53.40E).

Sonographic Signs of Necrotizing Enterocolitis

- Thickened bowel loops with thinning of loops a late finding
- Echogenic foci caused by portal venous air
- Echogenic ring of intramural pneumatosis
- Pericholecystic hyperechogenicity
- Increased flow in superior mesenteric artery and celiac artery
- Complex fluid collections with perforation of bowel

Appendicitis

Ultrasound is now the recommended initial examination for those suspected of having appendicitis.[126] MRI is being used more often for those with large body habitus when ultrasound is unsuccessful.[127] Although CT is effective in diagnosing appendicitis, the growing trend to avoid unnecessary ionizing radiation is causing a shift away from the frequent use of CT.[128,129]

When appendicitis is not found, ultrasound often can help to suggest or confirm an alternative diagnosis.[130] In the end, the diagnostic approach to the acute abdomen remains a surgical management decision, but sonography is increasingly used to help diagnose appendicitis and to help manage postoperative complications.

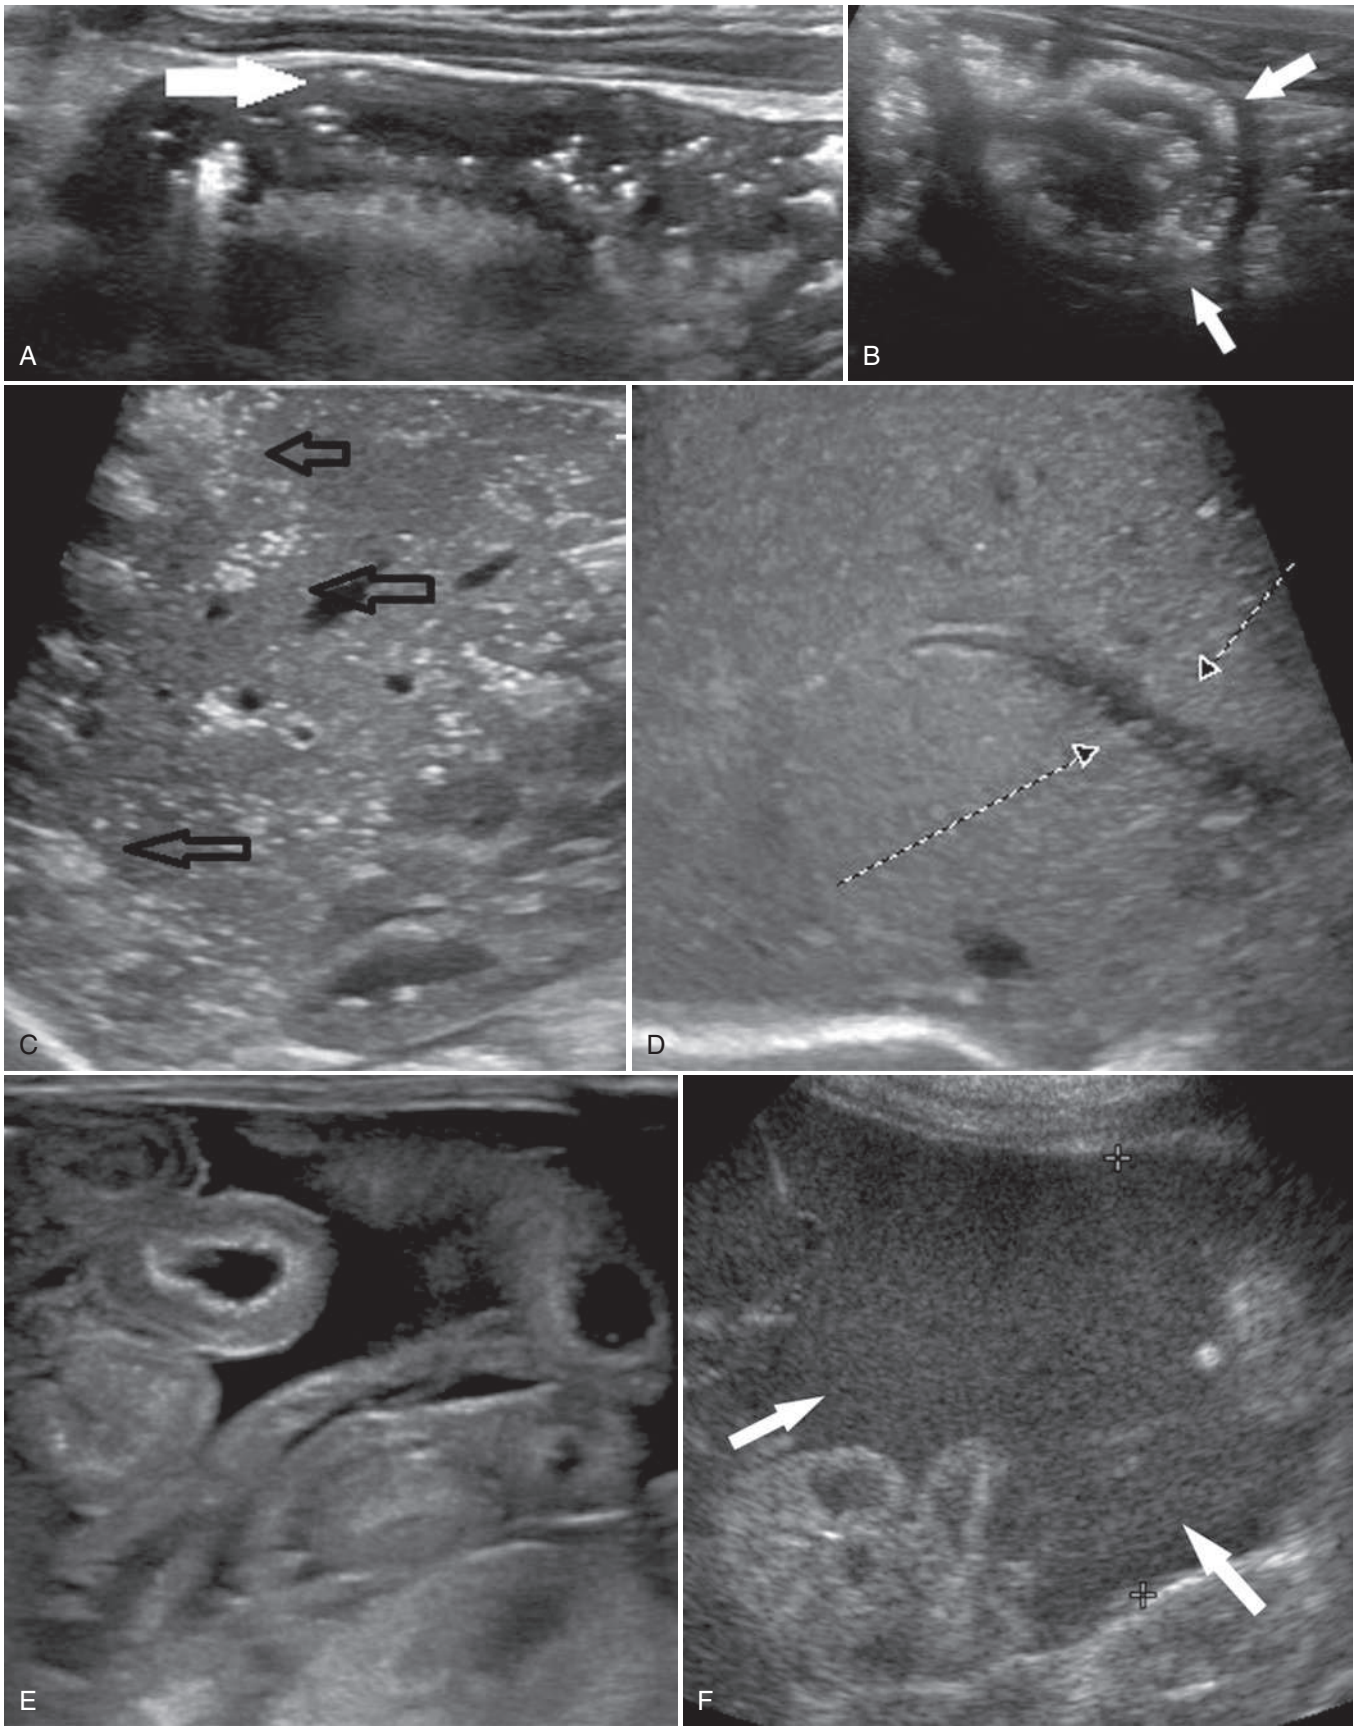

FIG. 53.40 Necrotizing Enterocolitis. (A) Mucosal and submucosal wall thickening with echogenic gas bubbles *(arrow)*. **(B)** Intramural gas (pneumatosis intestinalis) creates an echogenic ring *(arrows)*. **(C)** Widespread echogenic bubbles of gas in the portal venous system within the liver *(arrows)*. **(D)** Gas bubbles in the portal vein *(arrows)*. **(E)** Another infant shows thickened bowel loops with no pneumatosis and anechoic free fluid. **(F)** Fluid with echogenic debris *(arrows)* was caused by perforation in this infant.

Sonographic Signs of Appendicitis

Noncompressible, blind-ended, tubular structure
Diameter of tube ≥6 mm
Fluid trapped within nonperforated appendix
Target appearance of echogenic mucosa around fluid center surrounded by hypoechoic muscle
Fecalith: echogenic focus with pronounced posterior acoustic shadowing
Hypervascular appendix on color Doppler ultrasound
Gangrenous appendix: lack of flow on color Doppler ultrasound

Sonography of a child with acute abdominal pain is a procedure that requires patience and experience. The examination is facilitated by clinically localizing the pain, and even young children can help to guide the examination if asked to point with one finger to the site of maximal tenderness. Posterior manual compression and left lateral decubitus positioning may help to identify the appendix in patients whose appendix is not initially seen with graded-compression technique.[131] The ascending colon can be used as a helpful landmark, following the lateral border identified by haustrations to identify the cecum, then localizing the terminal ileum as the appendix, which arises 1 to 2 cm below the origin of the terminal ileum. The appendix is retrocecal in position in up to 68% of cases and within the pelvis in up to 53%.[132,133] Thus the examination should include the paracolic gutter, and a larger curvilinear probe may be needed to assess a low-positioned pelvic appendix. The normal appendix is easily compressible and smaller than the inflamed appendix, usually measuring less than 6 mm in diameter (Fig. 53.41). When the appendix cannot be found sonographically, the study findings are generally considered indeterminate. Standardized interpretive schemes that evaluate integrity of the appendix and assess inflammatory changes of the right lower quadrant have been shown to improve diagnostic accuracy.[134,135]

Sonographically, the acute, inflamed appendix appears as a blind-ending tubular structure that is noncompressible and measures 6 mm or greater in diameter[136] (Fig. 53.42). Size of the appendix can vary significantly in patients with both normal and abnormal appendices, and the 6-mm criterion is more useful for excluding appendicitis than for confirming it.[137] Viral-associated lymphoid hyperplasia thickens the hypoechoic appendiceal wall and can increase the maximum outer diameter of the appendix but should have no intraluminal fluid and no periappendiceal fat because the serosa is not involved (Fig. 53.43). However, there can be mural hyperemia and recurrent pain, sometimes leading to surgical intervention, although typically the lymphoid hyperplasia spontaneously resolves.[105] It is interesting to note that this was described by Symmers in *JAMA* in 1919.[138] Careful examination of the appendiceal tip should be performed in the presence of lymphoid hyperplasia, because the lymphoid tissue can predispose to appendicitis of the tip in some cases.[139] Fecal material impacted within the appendix, a nonsurgical condition treated with a bowel cleansing regimen, also increases the outer diameter, but the wall stratification of the appendix should be preserved and there should be no inflammatory change or hyperemia.[140]

Demonstration of other, associated sonographic abnormalities improves confidence in the diagnosis of appendicitis. **Fluid** is often seen trapped within a nonperforated appendix, and the surrounding echogenic mucosal layer and hypoechoic muscular layer of the appendiceal wall, combined with the central anechoic fluid, give the appendix a target appearance in cross section. **Fecaliths,** even those not calcified, can often be identified, appearing as echogenic foci with pronounced posterior acoustic shadowing (see Fig. 53.42D). A small amount of fluid may be seen adjacent to the appendix, even in the absence of perforation. Mesenteric lymphadenopathy frequently accompanies appendicitis, but alone is a nonspecific finding seen with other types of abdominal inflammation.[141] Thickening and increased echogenicity of the periappendiceal mesenteric fat is a valuable secondary finding, and the presence of more than one ultrasound sign of inflammation should be considered strong evidence of appendicitis, even if other definitive signs are absent.[142-144]

An advantage of sonography over other imaging modalities is the ability to correlate the pain of appendicitis with the imaging findings. Pinpoint tenderness with compression over the appendix is diagnostic in many children.[136] In cases of **perforated** appendicitis, the appendix itself is often more difficult to identify than in acute nonperforated appendicitis.[145] With perforation, the appendix becomes decompressed, and increasing intestinal gas from adynamic ileus and functional obstruction can interfere with the ultrasound examination Nevertheless, a careful, graded-compression technique may allow detection of focal aperistaltic bowel in the right lower quadrant, or a complex fluid collection representing an **abscess**[146] (Fig. 53.44A). Loss of the normal echogenic mucosal integrity suggests a **gangrenous appendix** (Fig. 53.44B-C), often associated with signs of perforation including echogenic periappendiceal fluid, abscess, interloop fluid collections, marked periappendiceal fat thickening, and aperistaltic bowel loops (Fig. 53.44D-E).

The risk of appendiceal perforation is greater in children younger than 4 years, because of many factors including limited verbal skills and lower incidence and thus less suspicion at younger ages.[147] The omentum is also poorly developed and almost devoid of fat in young children and thus is unable to contain a perforation. Diarrhea is a common presenting sign in young children and often confused with gastroenteritis, leading to a delay in diagnosis and the greater incidence of perforation.[148,149] After perforation, increasing flow may be seen in the soft tissues surrounding the appendix, and widespread abdominal fluid collections may be present at time of diagnosis owing to the lack of omental containment.[150,151]

Sonographic Signs of Appendiceal Perforation

Abscess formation
Loss of integrity of mucosal layer of the appendix
Presence of a fecalith in children younger than 8 years
Large amount of periappendiceal echogenic fat

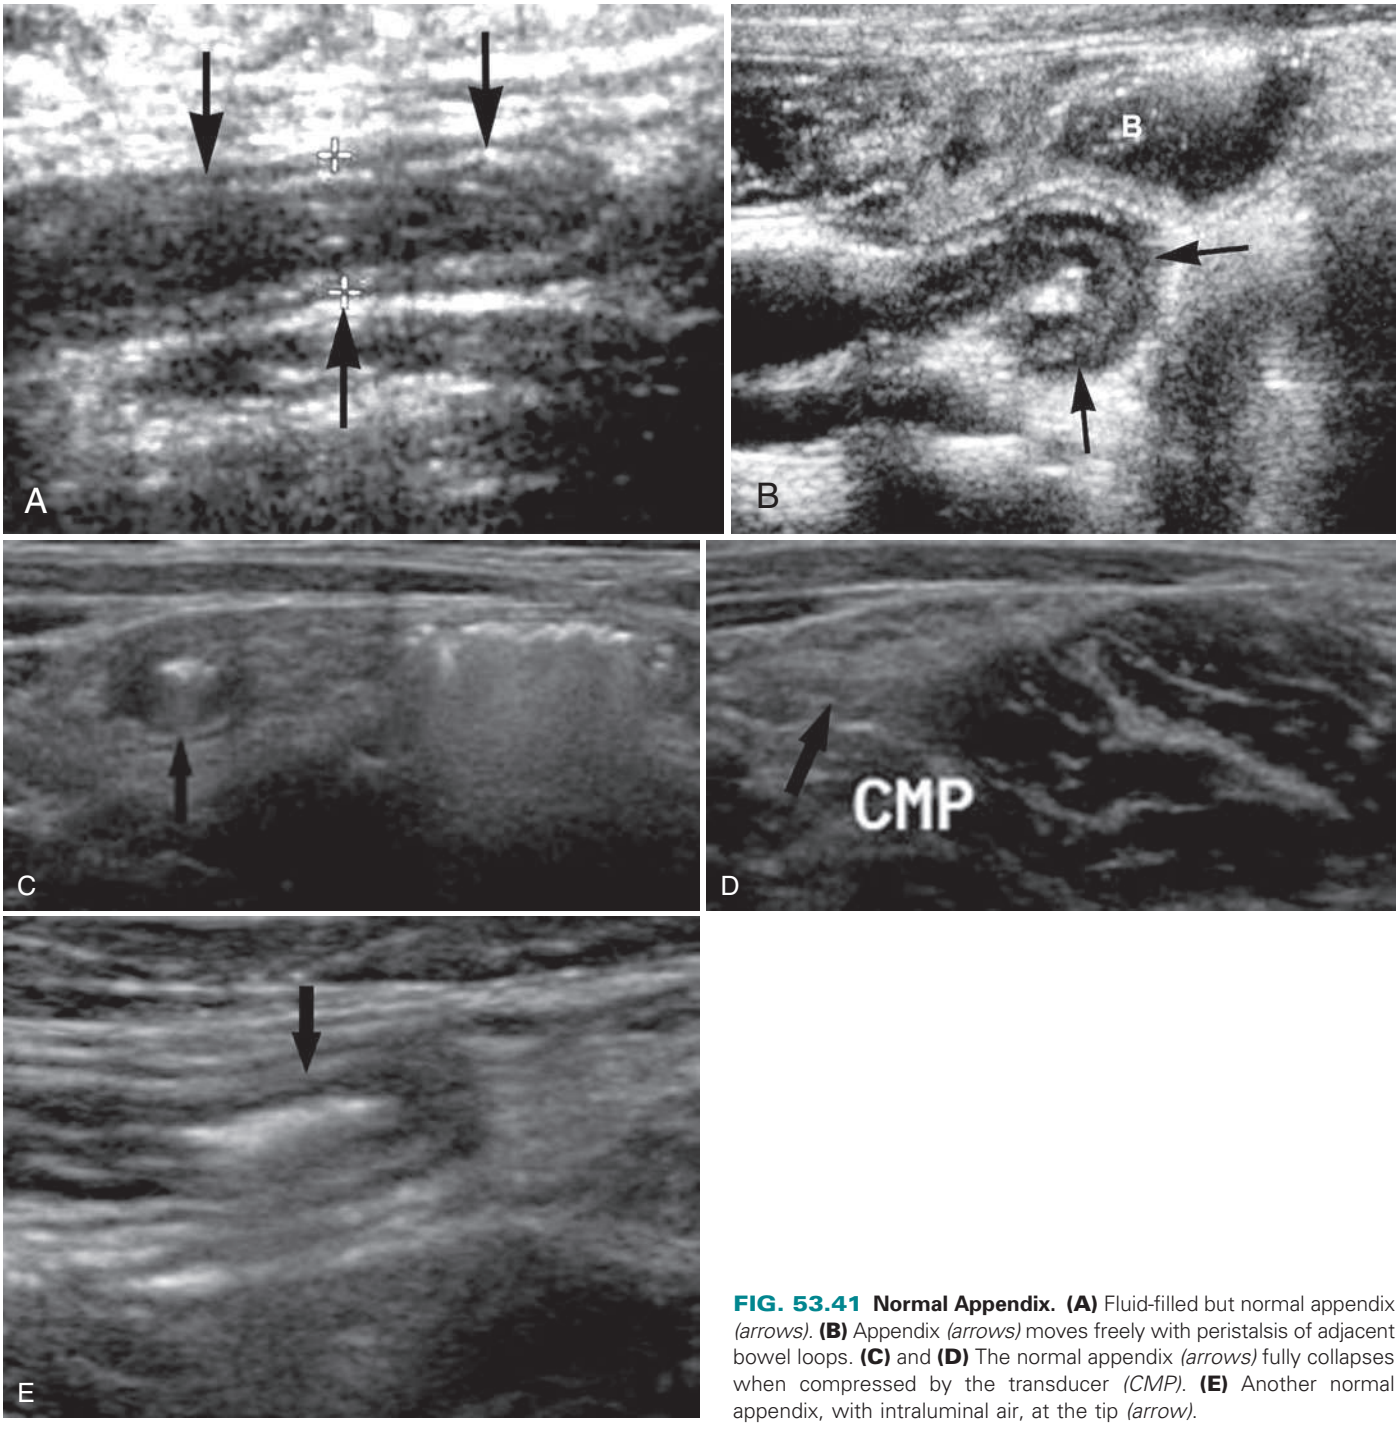

FIG. 53.41 Normal Appendix. (A) Fluid-filled but normal appendix *(arrows)*. **(B)** Appendix *(arrows)* moves freely with peristalsis of adjacent bowel loops. **(C)** and **(D)** The normal appendix *(arrows)* fully collapses when compressed by the transducer *(CMP)*. **(E)** Another normal appendix, with intraluminal air, at the tip *(arrow)*.

It is important to remember that many inflammatory conditions of the intestine other than appendicitis may be associated with small amounts of **free fluid surrounding the bowel loops.** Therefore small collections of simply echolucent fluid without other definitive evidence of appendicitis should not necessarily suggest an appendiceal abscess.

Other inflammatory conditions in the right lower quadrant may resemble appendicitis clinically but may be identified sonographically. **Mesenteric adenitis** refers to inflammation confined to the mesenteric lymph nodes in patients with a normal appendix. The condition is often associated with viral infection and usually is self-limited. Clusters of enlarged mesenteric lymph nodes that number more than five and are tender with compression suggest the diagnosis,[102] especially when a normal appendix is also seen. Mild mucosal thickening in the distal ileum is a common associated finding (Fig. 53.45). Isolated mesenteric lymph nodes are common and should not be considered abnormal. **Omental infarction** is a less common cause of acute abdominal

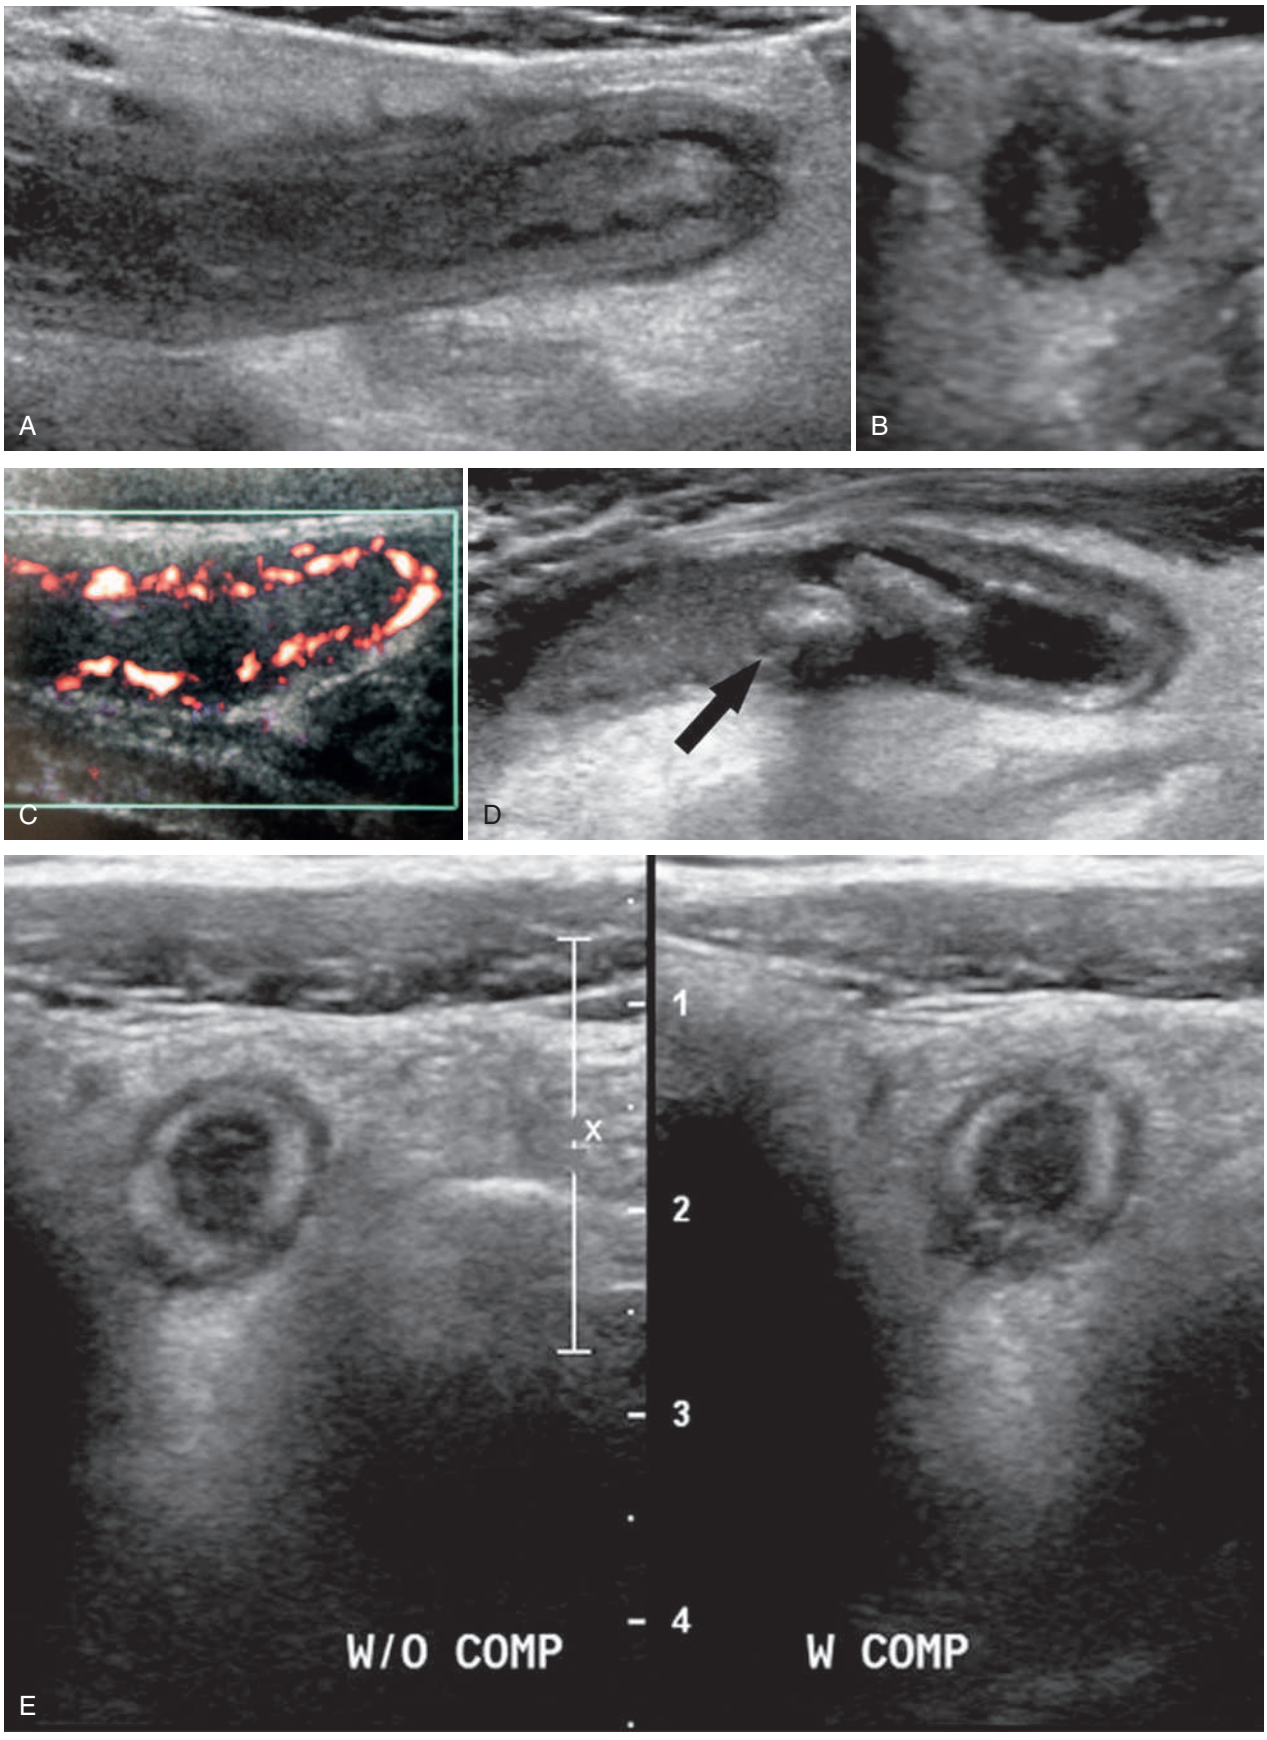

FIG. 53.42 Acute Appendicitis. (A) and **(B)** Longitudinal and transverse scans show a distended, fluid-filled appendix that measures 7 mm in diameter. **(C)** Power Doppler imaging reveals hyperemia of the appendiceal wall. **(D)** Echogenic fecalith with posterior shadowing *(arrow)* within a fluid-filled dilated appendix. Note the surrounding echogenic fat, indicating edema. **(E)** The inflamed appendix does not collapse with compression.

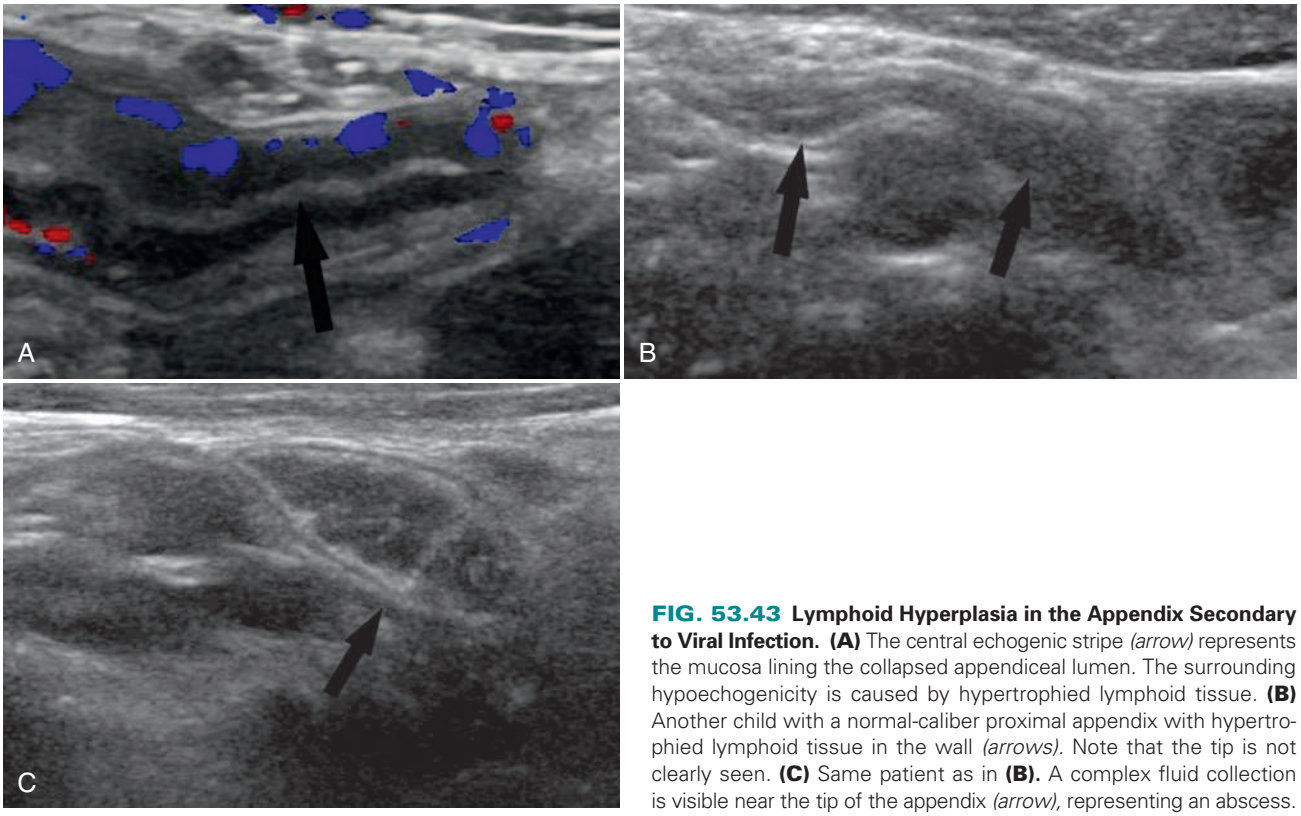

FIG. 53.43 Lymphoid Hyperplasia in the Appendix Secondary to Viral Infection. (A) The central echogenic stripe *(arrow)* represents the mucosa lining the collapsed appendiceal lumen. The surrounding hypoechogenicity is caused by hypertrophied lymphoid tissue. **(B)** Another child with a normal-caliber proximal appendix with hypertrophied lymphoid tissue in the wall *(arrows).* Note that the tip is not clearly seen. **(C)** Same patient as in **(B).** A complex fluid collection is visible near the tip of the appendix *(arrow),* representing an abscess.

pain in children. Ultrasound may reveal a heterogeneous mass or a localized focus of increased echogenicity in the omentum, characteristically located between the anterior abdominal wall and the colon.[151,152] **Meckel diverticulum** may become torsed or inflamed and may resemble an inflamed appendix or a complex pelvic mass sonographically[153,154] (Fig. 53.46A). The initial presentation of Crohn disease can be mistaken for appendicitis (Fig. 53.46B).

Gastrointestinal Neoplasms and Cysts

The superior ability of sonography to distinguish solid from cystic masses makes this examination an excellent choice for the diagnosis of the various types of cysts that can occur in the abdomen. The most common cysts associated with the GI tract are mesenteric cysts and GI duplication cysts. Characteristically, GI **duplication cysts** are filled with anechoic fluid and have a well-defined, double-layered wall that consists of an inner echogenic mucosal layer and a thin, outer hypoechoic muscular layer (Fig. 53.47A-C). These two layers are usually continuous throughout the cyst wall,[155,156] helping to distinguish GI duplication cysts from other simple-walled cysts, such as **mesenteric cysts** or **pseudocysts** (Fig. 53.47D-E). Occasionally, single-walled cysts appear to have a double-layered wall because of a fibrinous layer that can be deposited along the inner cyst wall after intracystic bleeding, but this is a relatively uncommon occurrence. Duplication cysts frequently contain foci of ectopic gastric mucosa, which can become inflamed and ulcerated. In such cases, intracystic hemorrhage may occur, and the resulting debris within the cystic fluid can cause the cyst to appear solid.[157] Some GI duplication cysts are pedunculated and therefore may be located at a site remote from the actual point of origin. Occasionally, active peristalsis of the cyst wall can be seen at real-time ultrasound.

Burkitt lymphoma is the most rapidly growing tumor in childhood, with a doubling time of about 24 hours.[158] The GI tract is involved in 22.5% of patients, with abdominal or pelvic masses in 45%. Burkitt lymphoma primarily affects the ileocecal region, unlike desmoplastic small round cell tumors, and can lead to secondary intussusception. Diffuse bowel wall thickening with adjacent nodal mass lesions in the mesentery and retroperitoneum are often seen at presentation. Ascites and rare peritoneal involvement can be seen. A solid mesenteric mass could be confused with a desmoplastic small round cell tumor. The appendix is infrequently involved, but appendiceal intussusception of the appendix secondary to Burkitt lymphoma has been observed (see Fig. 53.27B). Burkitt lymphoma does not commonly have calcifications at presentation.

Desmoplastic small round cell tumors represent a rare but highly malignant neoplasm, most commonly found in the peritoneal cavity with a male preponderance.[159] Disseminated tumor is often present at time of diagnosis, and distinguishing this from Burkitt lymphoma is difficult, although desmoplastic small round cell tumors have frequent calcification and extensive peritoneal involvement at presentation with a tendency to involve the retrovesical region.[159]

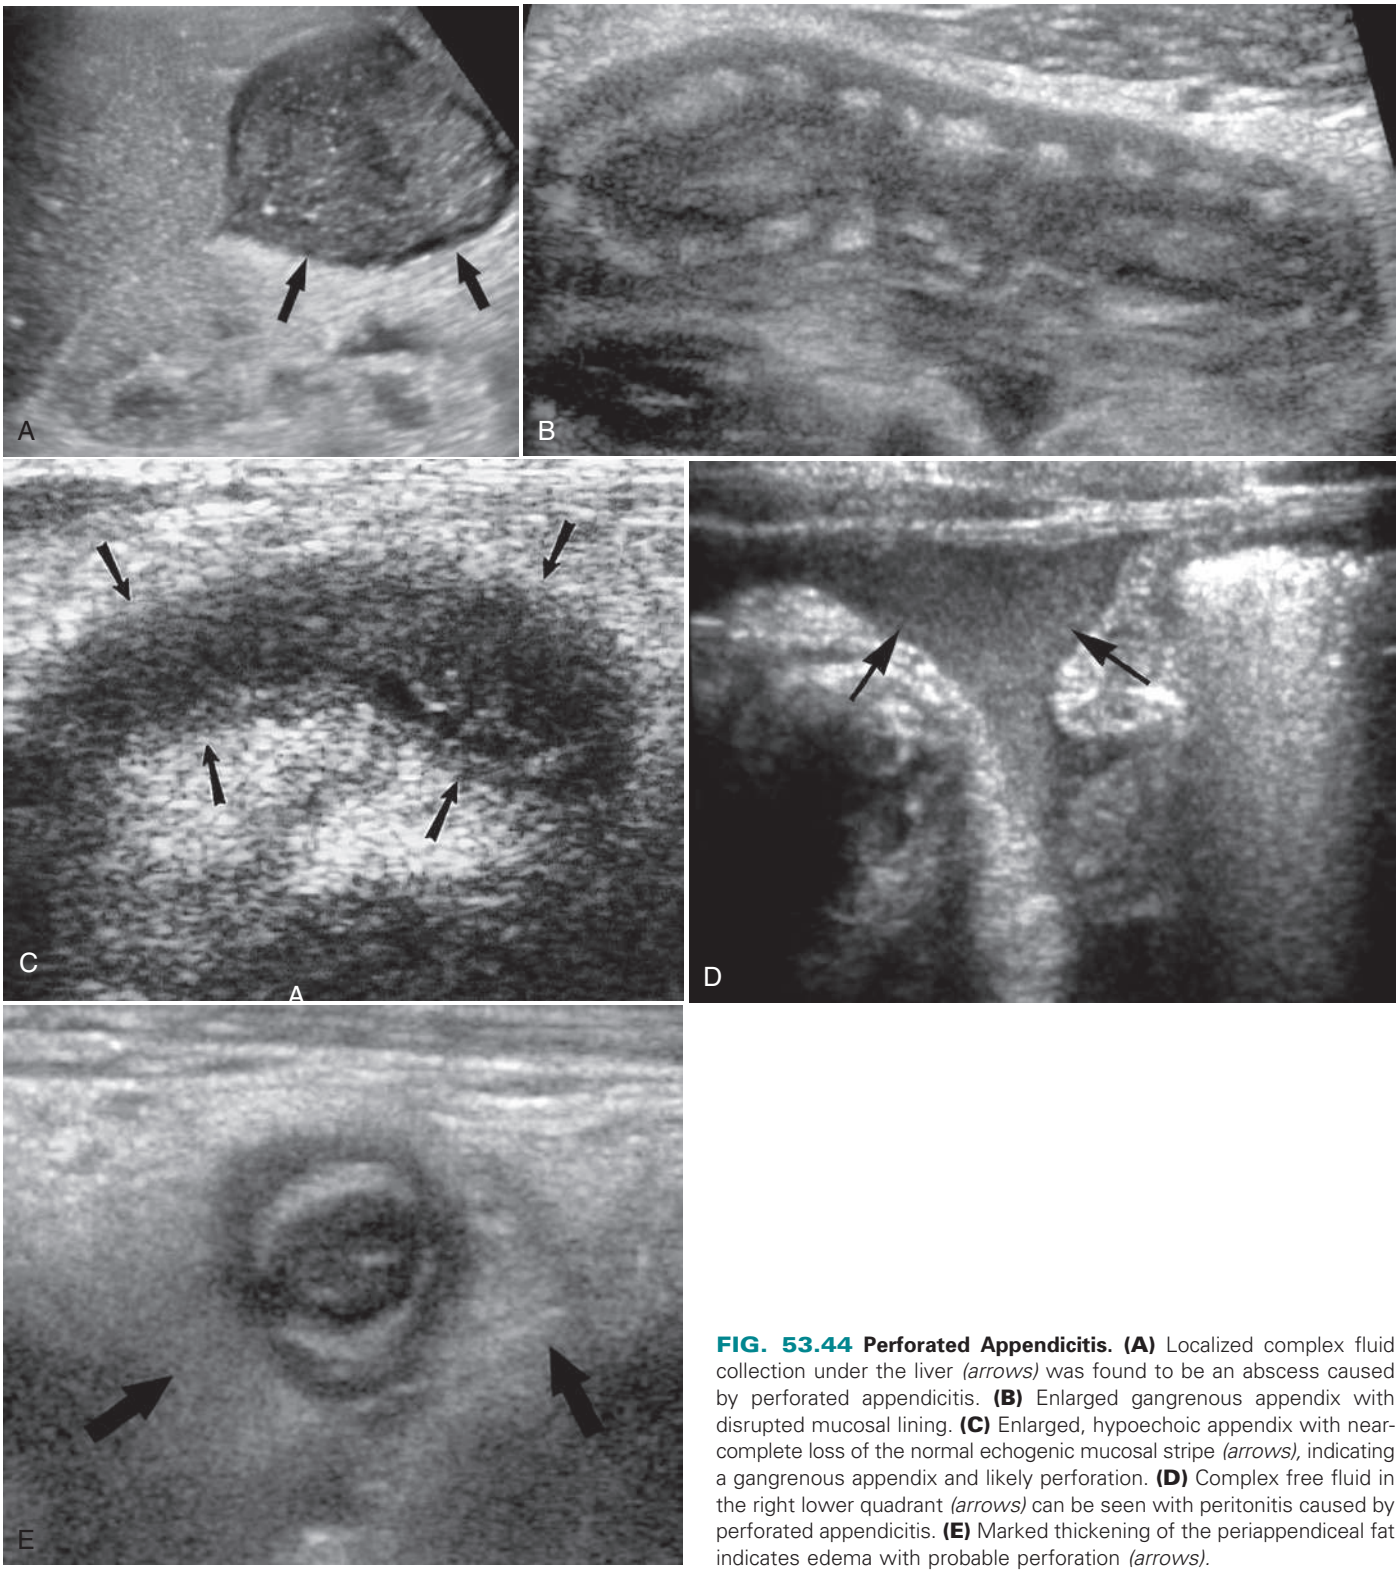

FIG. 53.44 Perforated Appendicitis. (A) Localized complex fluid collection under the liver *(arrows)* was found to be an abscess caused by perforated appendicitis. **(B)** Enlarged gangrenous appendix with disrupted mucosal lining. **(C)** Enlarged, hypoechoic appendix with near-complete loss of the normal echogenic mucosal stripe *(arrows),* indicating a gangrenous appendix and likely perforation. **(D)** Complex free fluid in the right lower quadrant *(arrows)* can be seen with peritonitis caused by perforated appendicitis. **(E)** Marked thickening of the periappendiceal fat indicates edema with probable perforation *(arrows).*

Abdominal desmoid tumors are a rare, benign type of tumor that can occur as a mass or masses in the mesentery, abdominal wall, retroperitoneum, and pelvis. There is an association with Gardner syndrome, and these will not have metastatic lesions.

Gastrointestinal stromal tumors rarely occur in the pediatric population and have a propensity to occur in females with a mean age of 12.6 years.[160] They arise in the muscularis propria, most commonly in the antrum and body of the stomach. Internal cystic areas are common and can represent hemorrhage or necrosis.

Sonography does not play a major role in the evaluation of GI neoplasms, but masses or polyps may be identified in some patients when the bowel is filled with fluid.[82,161] More often, intraluminal GI masses in children manifest with obstruction caused by intussusception. The mass that acts as a lead point for the intussusception may not always be sonographically discernible. Most solid tumors appear with a variably echogenic pattern and cannot be reliably distinguished by their sonographic characteristics.[45,162-164] **Lymphoma** tends to be hypoechoic and may be associated with ulceration. The tumors most likely to appear predominantly cystic are teratomas and lymphangiomas.[165-169] **Abdominal lymphangiomas** most frequently occur in the mesentery and can appear as solitary cysts or as multiloculated cystic masses[168] (Fig. 53.48A-B). **Gastrointestinal teratomas** usually have large cystic components, but echogenic fat and calcifications are also often visible[165,167,168] (Fig. 53.48C). **Hemangiomas** may involve the mesentery and are usually associated with hypervascularity and large feeding vessels.

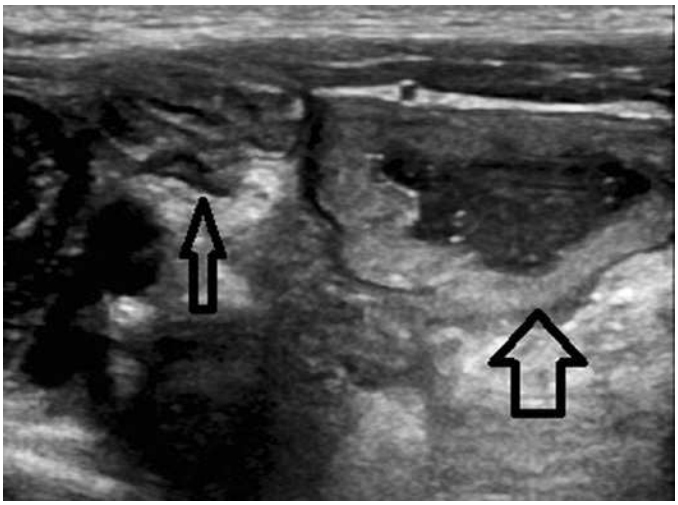

FIG. 53.45 Mesenteric Adenitis/Ileitis. Thickened mucosa in a small bowel loop *(large arrow)* with a normal appendix nearby *(small arrow)*.

PANCREAS

Normal Anatomy and Technique

The pancreas is easily imaged in children and normally appears relatively generous in size compared with the pancreas of an adult. The normal echotexture of the pancreas in childhood is homogeneous and most often isoechoic or hyperechoic compared with the liver. The normal pancreatic duct is usually not visible sonographically, unless a high-resolution linear transducer is used.

Pancreatitis

Pancreatitis is less common in children than in adults and is more likely to be acute rather than chronic. The most common causes of acute pancreatitis in children include blunt abdominal trauma (including abusive abdominal trauma), viral infection, and drug toxicity. Regardless of the cause, sonographic findings are usually sparse unless a complicating pseudocyst arises. The most common abnormal sonographic finding is pancreatic enlargement (Fig. 53.49A), but a normal-sized pancreas does not exclude the diagnosis. Decreased echogenicity of the pancreas can occur with pancreatitis,[170,171] but this is a difficult finding to substantiate because of the variable echogenicity of the normal pancreas in children.[171] Occasionally, increased echogenicity of the pararenal space may be encountered, the result of lipolysis of normal fat by pancreatic enzymes that have leaked into the hepatorenal space.[172]

Chronic or recurrent pancreatitis in children is most likely caused by congenital abnormalities affecting the biliary tract (e.g., **choledochal cysts, pancreas divisum, cystic**

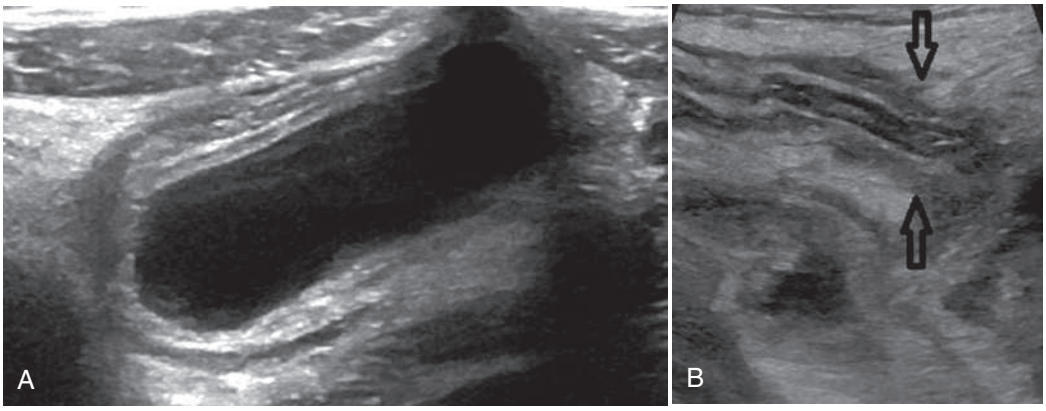

FIG. 53.46 Other Conditions Resembling Appendicitis. (A) Inflamed Meckel diverticulum. Transverse ultrasound of the right lower quadrant in a child with clinically suspected acute appendicitis. **(B)** Profound mesenteric inflammation in the region of the appendix was actually caused by **Crohn disease** *(arrows)*. The appendix was normal.

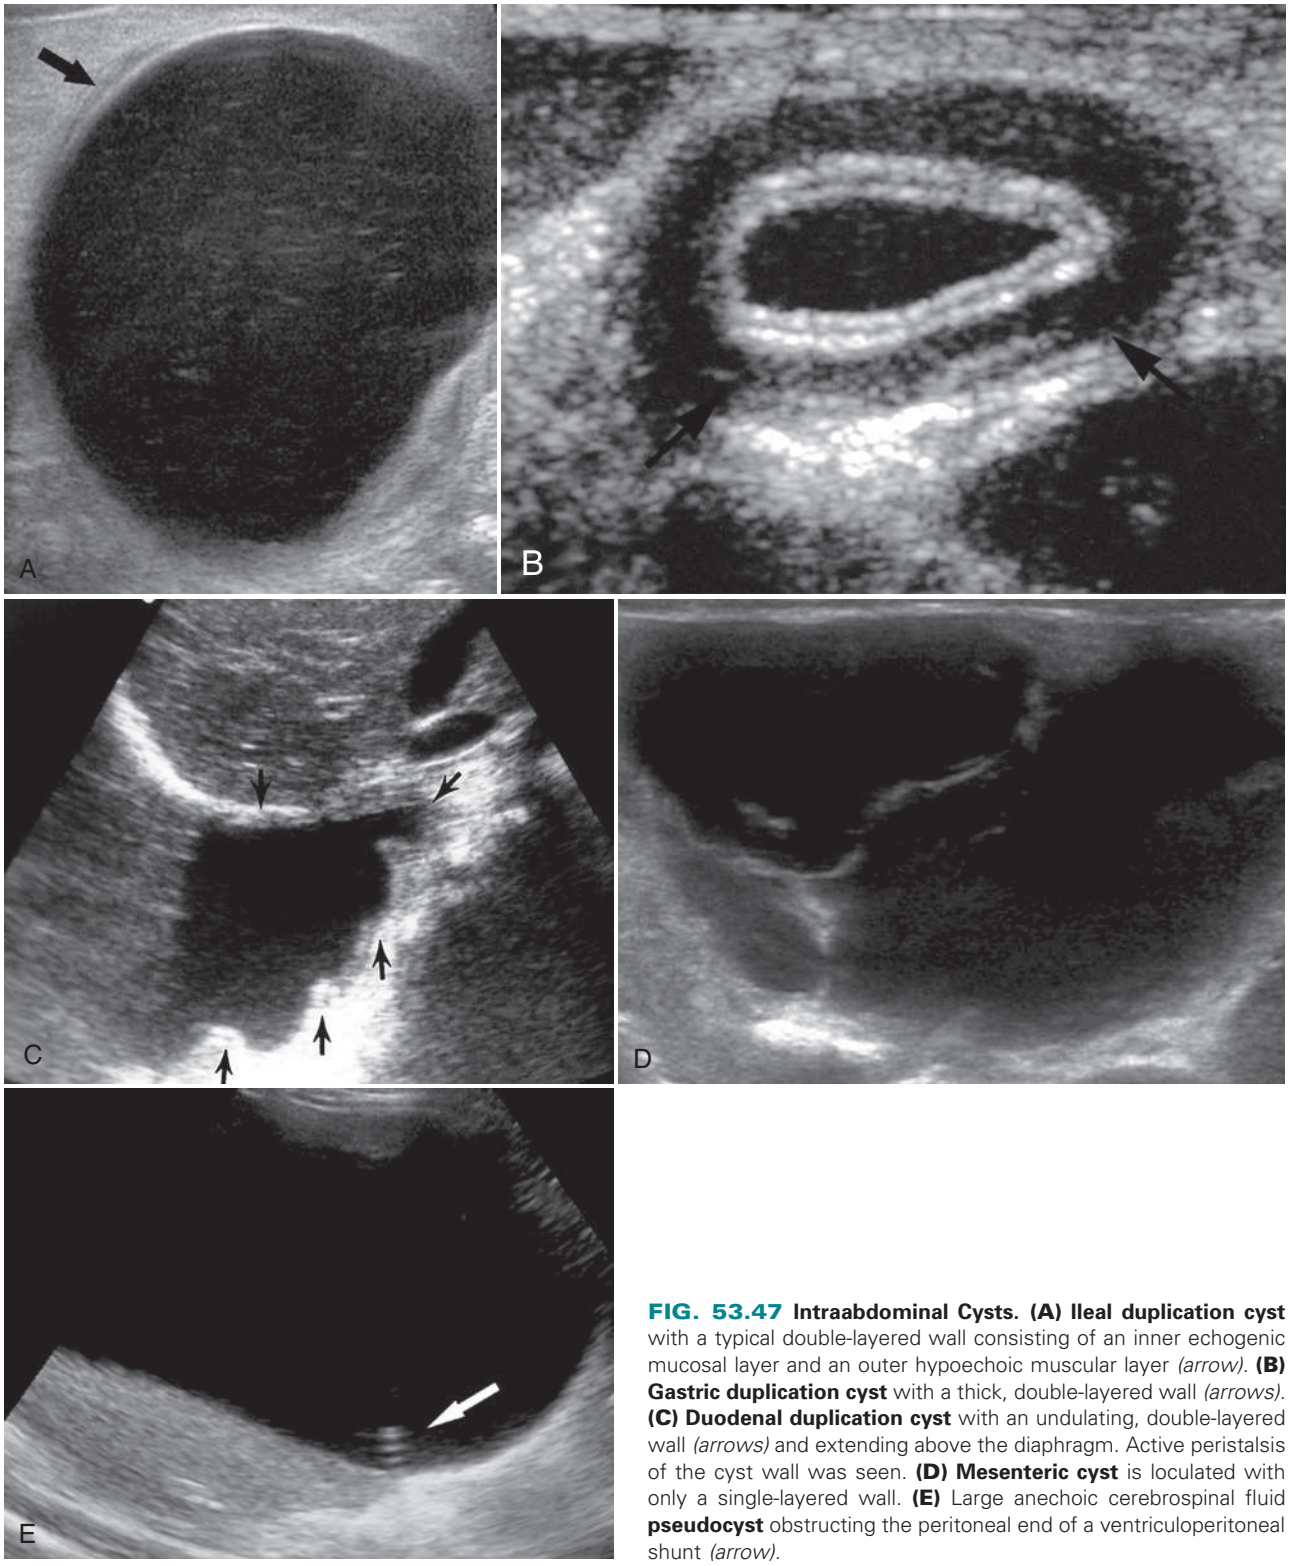

FIG. 53.47 Intraabdominal Cysts. (A) Ileal duplication cyst with a typical double-layered wall consisting of an inner echogenic mucosal layer and an outer hypoechoic muscular layer *(arrow).* **(B) Gastric duplication cyst** with a thick, double-layered wall *(arrows).* **(C) Duodenal duplication cyst** with an undulating, double-layered wall *(arrows)* and extending above the diaphragm. Active peristalsis of the cyst wall was seen. **(D) Mesenteric cyst** is loculated with only a single-layered wall. **(E)** Large anechoic cerebrospinal fluid **pseudocyst** obstructing the peritoneal end of a ventriculoperitoneal shunt *(arrow).*

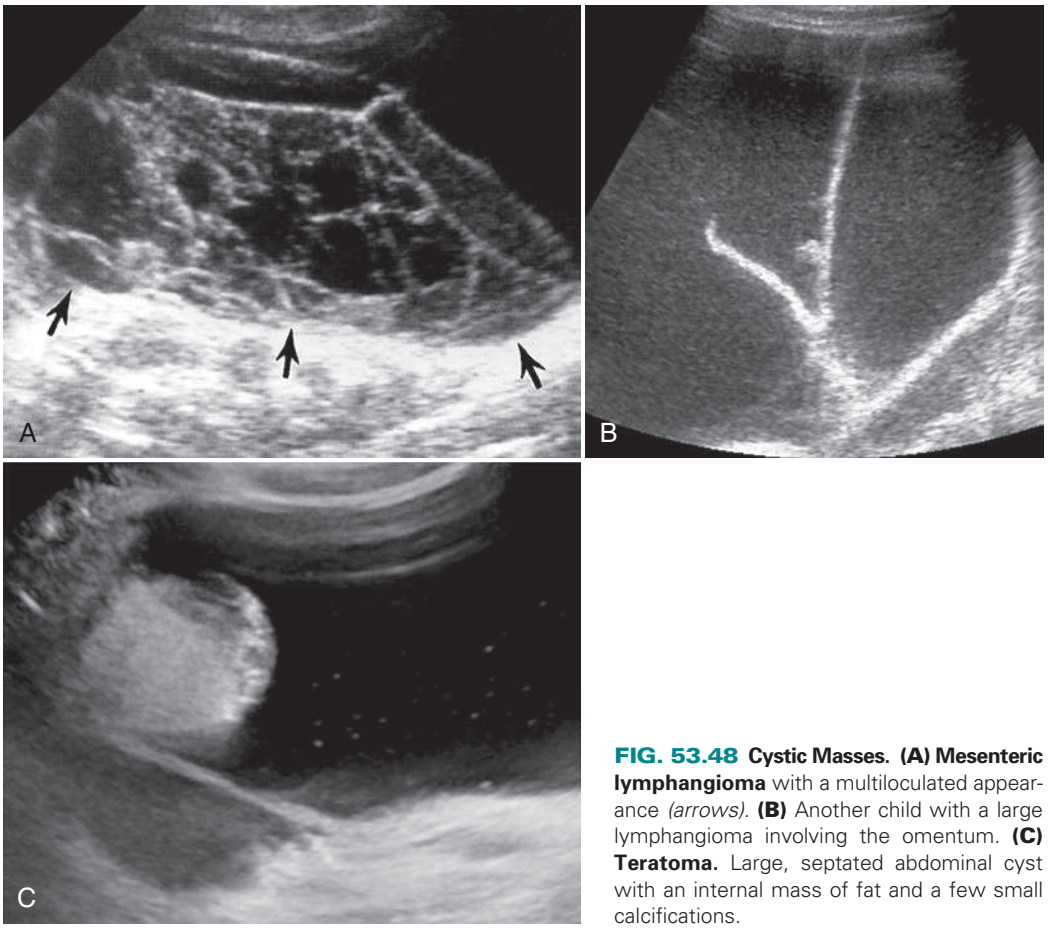

FIG. 53.48 Cystic Masses. (A) Mesenteric lymphangioma with a multiloculated appearance *(arrows)*. **(B)** Another child with a large lymphangioma involving the omentum. **(C) Teratoma.** Large, septated abdominal cyst with an internal mass of fat and a few small calcifications.

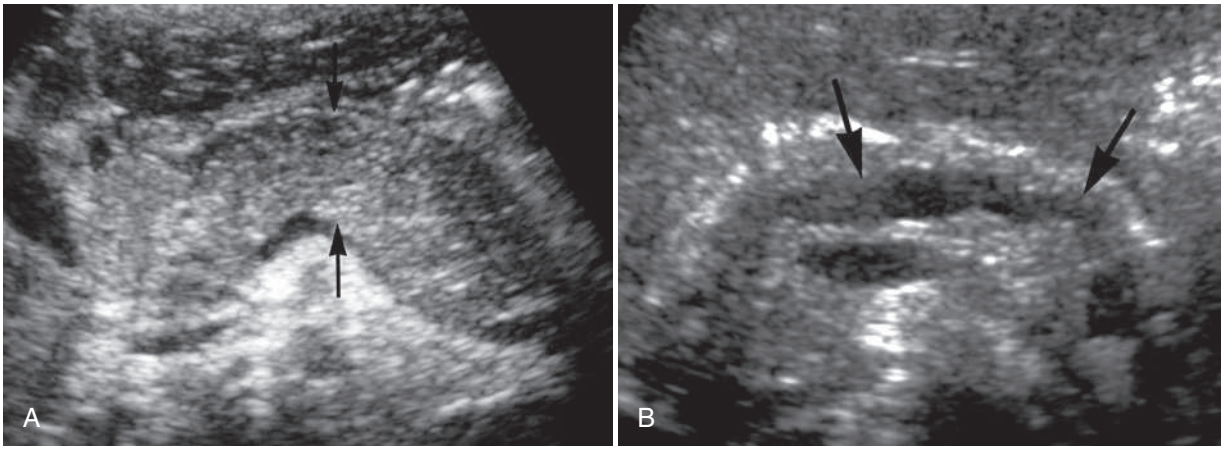

FIG. 53.49 Pancreatitis. (A) Child with pancreatic enlargement secondary to viral pancreatitis *(arrows)*. **(B)** Chronic pancreatitis in a 7-year-old child with **pancreas divisum** shows atrophic pancreas and a dilated pancreatic duct *(arrows)*.

fibrosis). With **cystic fibrosis,** precipitation or coagulation of secretions in the small pancreatic ducts leads to ductal concretions and obstruction. Distention of the ducts and acini leads to degeneration and replacement by small cysts. This ductal obstruction, along with atrophy of glandular elements and ensuing fibrosis, creates increased echogenicity of the pancreas[173-175] (see Fig. 53.49B). The gland is often small, and calcifications may be seen as punctate, echogenic foci within the hyperechoic pancreas. A similar appearance may be found in patients with hereditary autosomal dominant pancreatitis.[176]

Peripancreatic fluid collections often accompany acute pancreatitis, but such collections are not considered **pseudocysts** until they become persistent and are surrounded by a well-defined echogenic wall (Fig. 53.50). Many pancreatic pseudocysts are now treated conservatively, and sonography is useful for following

such patients to verify the spontaneous resolution of the fluid collection.[177] When the pseudocysts do not adequately resolve, sonography can be used to suggest suitability for percutaneous or endoscopic drainage.[178,179]

Pancreatic Masses

Tumors of the pancreas are extremely uncommon in children. The most common primary neoplasms are the benign insulinoma and adenocarcinoma.[180] **Insulinomas** are often difficult to detect sonographically, but intraoperative sonography has been used with success. Carcinoma of the pancreas usually appears as an echogenic or complex pancreatic mass. **Pancreatoblastoma** is a rare invasive tumor that is heterogeneous in texture, can encase vessels, and may metastasize widely.[181-183] Cystic masses of the pancreas include **lymphangioma, solid pseudopapillary tumor of the pancreas** (Fig. 53.51), and the rare **congenital pancreatic cyst.**[184,185] **Autoimmune pancreatitis** can cause focal enlargement of the pancreas that resembles a mass.[186]

Diffuse echogenic enlargement of the pancreas can be seen with **nesidioblastosis.** This is a tumorlike condition of the pancreas characterized by diffuse proliferation and persistence of primitive ductal epithelial cells. Nesidioblastosis is often associated with hypoglycemia and the **Beckwith-Wiedemann syndrome.** Diffusely increased echogenicity of the pancreas can also occur with fatty infiltration in the **Shwachman-Diamond syndrome** (Fig. 53.52), but in this condition the pancreas usually remains normal in size. Fatty replacement of the pancreas also can occur in children with cystic fibrosis or nonalcoholic fatty liver disease. Rarely, other types of tumors, such as in **leukemia,**[187] can infiltrate and enlarge the pancreas.

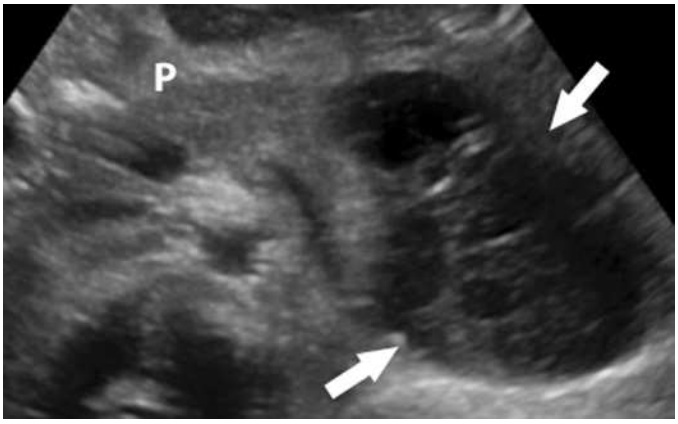

FIG. 53.50 Pancreatic Pseudocyst in Battered Child. Loculated fluid collection *(arrows)* in the region of the tail of the pancreas *(P).*

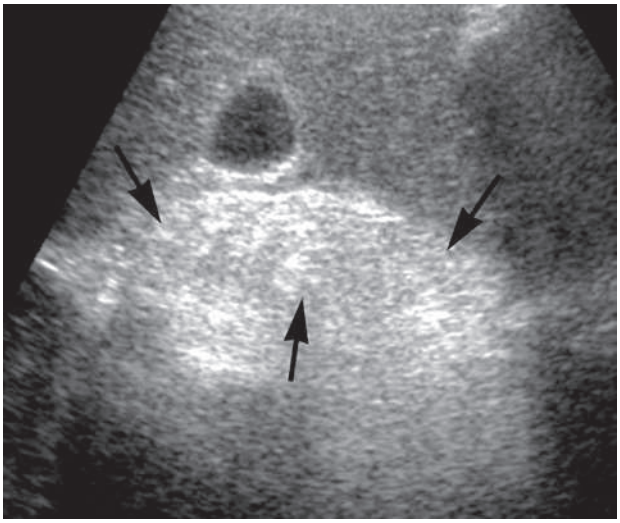

FIG. 53.52 Pancreatic Enlargement. Lipomatosis associated with Shwachman-Diamond syndrome. Echogenic enlargement of the pancreas *(arrows).*

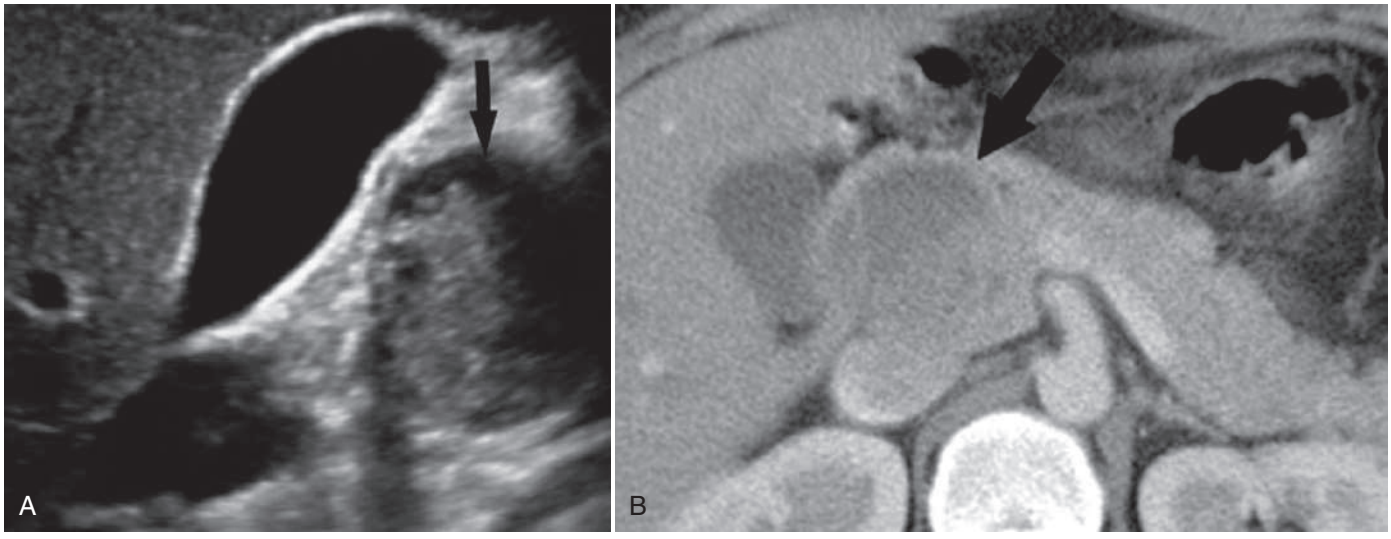

FIG. 53.51 Solid Pseudopapillary Tumor of the Pancreas. (A) Ultrasound shows a heterogeneous but predominantly cystic mass in the head of the pancreas that is only partially visible because of intestinal gas *(arrows).* **(B)** Computed tomography shows the partially cystic mass in the same child *(arrow).*

CHAPTER 54

Pediatric Pelvic Sonography

William L. Simpson, Jr., Humaira Chaudhry, and Henrietta Kotlus Rosenberg

SUMMARY OF KEY POINTS

- Ultrasound is well suited for evaluation of the pediatric pelvis by providing excellent image quality without the use of radiation or the routine use of contrast material and without the need for sedation or anesthesia.
- Sonography of the pelvis is an excellent modality for serial assessment of pediatric pelvic abnormalities.
- Ultrasound can be used to evaluate congenital, infectious, inflammatory, endocrine, and neoplastic abnormalities of the pediatric pelvis.
- The appearance of the gonads of both sexes undergoes changes throughout the pediatric age range as they grow and develop adult characteristics.
- Water can be used as a contrast agent to distend structures that are normally collapsed (e.g., bladder, ureter, vagina, rectum) to facilitate evaluation and diagnosis.
- Although transvaginal ultrasound (TVS) provides high-resolution imaging of the female pelvis, its use in most pediatric female patients is precluded because they are not sexually active.

CHAPTER OUTLINE

SONOGRAPHIC TECHNIQUE
NORMAL FEMALE ANATOMY
The Uterus
The Vagina

Postoperative Bladder
PRESACRAL MASSES

SONOGRAPHIC TECHNIQUE

High-resolution, real-time, gray-scale and color Doppler sonography has emerged as the modality of choice for the evaluation of the pelvis in infants, children, and adolescents. Using the distended bladder as an acoustic window, the lower urinary tract, uterus, adnexa, prostate gland, seminal vesicles, and pelvic musculature and vessels can be easily evaluated.[1-6]

Depending on the size of the child, a 5-2, 9-4, or 8-5 MHz real-time curvilinear broad-bandwidth or sector transducer is used to obtain scans, usually in the transverse and sagittal planes. Linear probe technology is useful for evaluation of the bowel, peritoneum, perineum, and superficial lesions using a 12-5 MHz, 17-5 MHz, or other high-frequency linear broad-bandwidth probes.

Patients should be well hydrated before pelvic sonography so that the bladder will be optimally filled. In infants and young children who are unable to maintain a full bladder despite drinking clear liquids, it may be necessary to catheterize and fill the bladder with sterile water through a 5- or 8-French feeding tube, although this is rarely necessary. The use of sterile water as a contrast agent to outline the vagina **(hydrosonovaginography)** (Fig. 54.1, Video 54.1), rectum (water enema)[7,8] (Fig. 54.2), or urogenital sinus may be very helpful in the evaluation of the pediatric patient with a pelvic mass or complex congenital anomalies of the genitourinary tract. Meticulous real-time scanning is essential

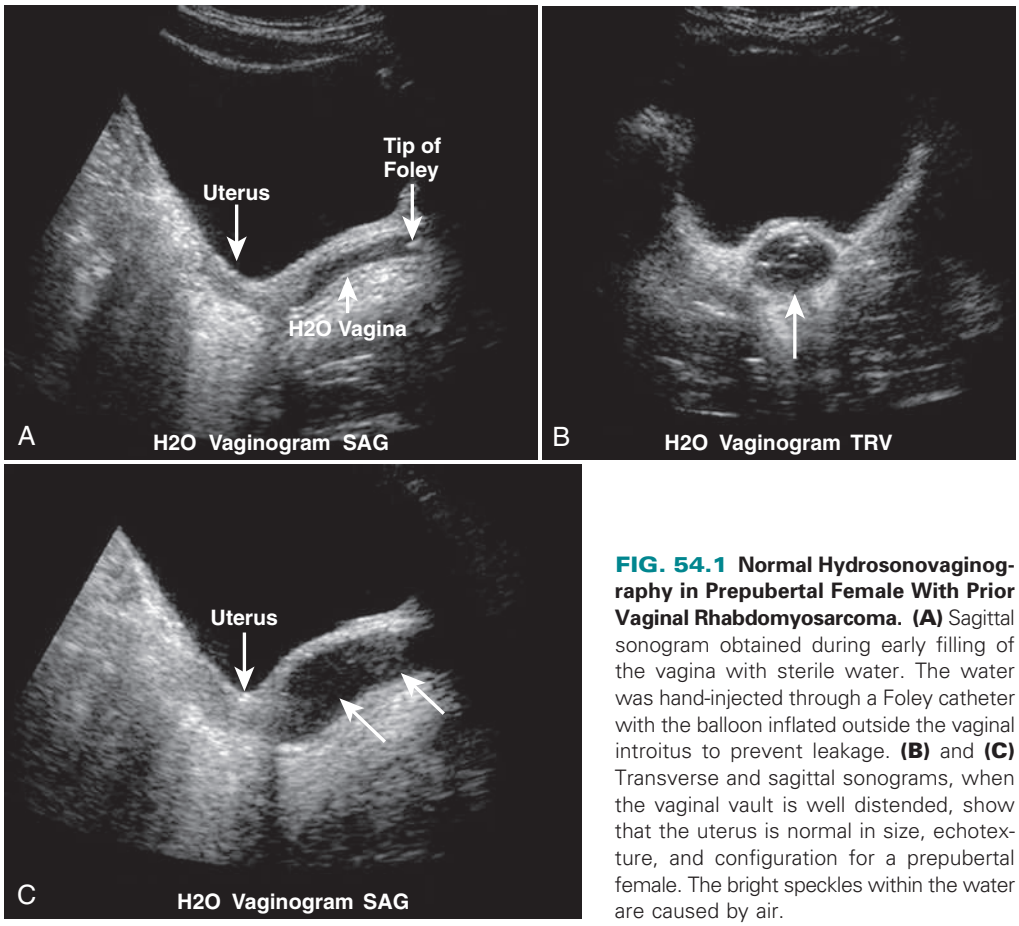

FIG. 54.1 Normal Hydrosonovaginography in Prepubertal Female With Prior Vaginal Rhabdomyosarcoma. (A) Sagittal sonogram obtained during early filling of the vagina with sterile water. The water was hand-injected through a Foley catheter with the balloon inflated outside the vaginal introitus to prevent leakage. **(B)** and **(C)** Transverse and sagittal sonograms, when the vaginal vault is well distended, show that the uterus is normal in size, echotexture, and configuration for a prepubertal female. The bright speckles within the water are caused by air.

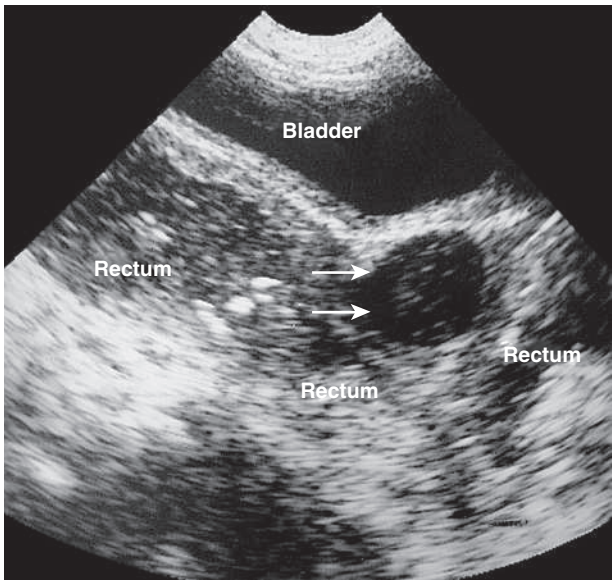

FIG. 54.2 Water Enema Technique in 5-Year-Old Boy With Appendiceal Abscess. Sagittal sonogram shows a small, hypoechoic fluid collection *(arrows)* located posterior to the bladder and anterior to the water-filled rectum.

because these structures are filled in a retrograde manner. When transabdominal sonography (TAS) provides suboptimal images in mature, sexually active teenage girls, **transvaginal ultrasound** (TVS) can provide higher resolution with more detailed images, thus aiding in the elucidation of the origin and characteristics of pelvic masses and complex adnexal lesions.[6,9]

The wall of the urinary bladder should be smooth in a distended state, with the wall thickness not greater than 3 mm during bladder distention, with a mean of 1.5 mm.[10] The wall should not be greater than 5 mm thick with the bladder empty or partially distended. In the nondistended state the internal aspect of the bladder wall generally appears slightly irregular sonographically. A **urachal remnant** may be visualized on sonography, as a structure of variable form and size, lying ventral to the peritoneum and situated between the umbilicus and the apex of the urinary bladder.[11] The distal ureters, with the exception of the submucosal intravesical portion, are not usually visualized unless abnormally dilated.[12] The **trigone,** however, is easily demonstrated (Fig. 54.3). The bladder neck and urethra can be demonstrated in both males and females by angling the transducer inferiorly[13] (Fig. 54.4). If a urethral abnormality is noted on suprapubic imaging, scans through the perineum or transrectally can confirm these findings using a different imaging plane.[14]

Hydrosonourethrography may be used to detect anterior urethral abnormalities (strictures, calculi, anterior or posterior urethral valves, foreign bodies, bladder neck dyssynergia, diverticula, trauma) by scanning the penis with a linear array transducer during real-time observation during voiding or during a retrograde hand-injection of saline into the urethra.[15] **Postvoid scanning** of the bladder can provide information about bladder function, differentiate the bladder from cystic masses or fluid collections in the pelvis, and evaluate the degree of drainage from dilated upper urinary tracts. When children cannot void, films taken after a Credé maneuver or catheterization indicate the effectiveness of these bladder-emptying procedures. We measure the postvoid residual of the bladder using the following formula:

$$\text{Length} \times \text{Width} \times \text{Depth (in cm)} \div 2 = \text{Volume (in mL)}$$

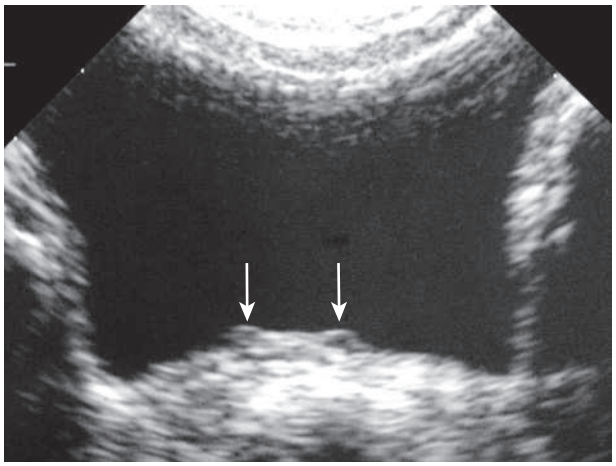

FIG. 54.3 Normal Trigone. With meticulous scanning, it is possible to identify the trigone *(arrows)* in pediatric patients.

NORMAL FEMALE ANATOMY

The Uterus

The uterus and ovaries undergo a series of changes in size and configuration during normal growth and development.[5,13] The **newborn female uterus** is prominent and thickened with a brightly echogenic endometrial lining caused by in utero hormonal stimulation[16] (Fig. 54.5). In the first 3 days of life, mean length and mean volume of the uterus are 4.2 cm and 10.0 cm^3.[17] The uterine configuration is spade shaped with a fundus-to-cervix ratio of 1:2. At 2 to 3 months of age the prepubertal uterus regresses to a smaller size and flat configuration (Fig. 54.6), with a length of 2.5 to 3 cm and a fundus-to-cervix ratio of 1:1, and with the endometrial stripe (when seen) appearing as thin as a pencil line. This tubular uterine configuration is maintained until puberty. The **postpubertal uterine length** gradually increases

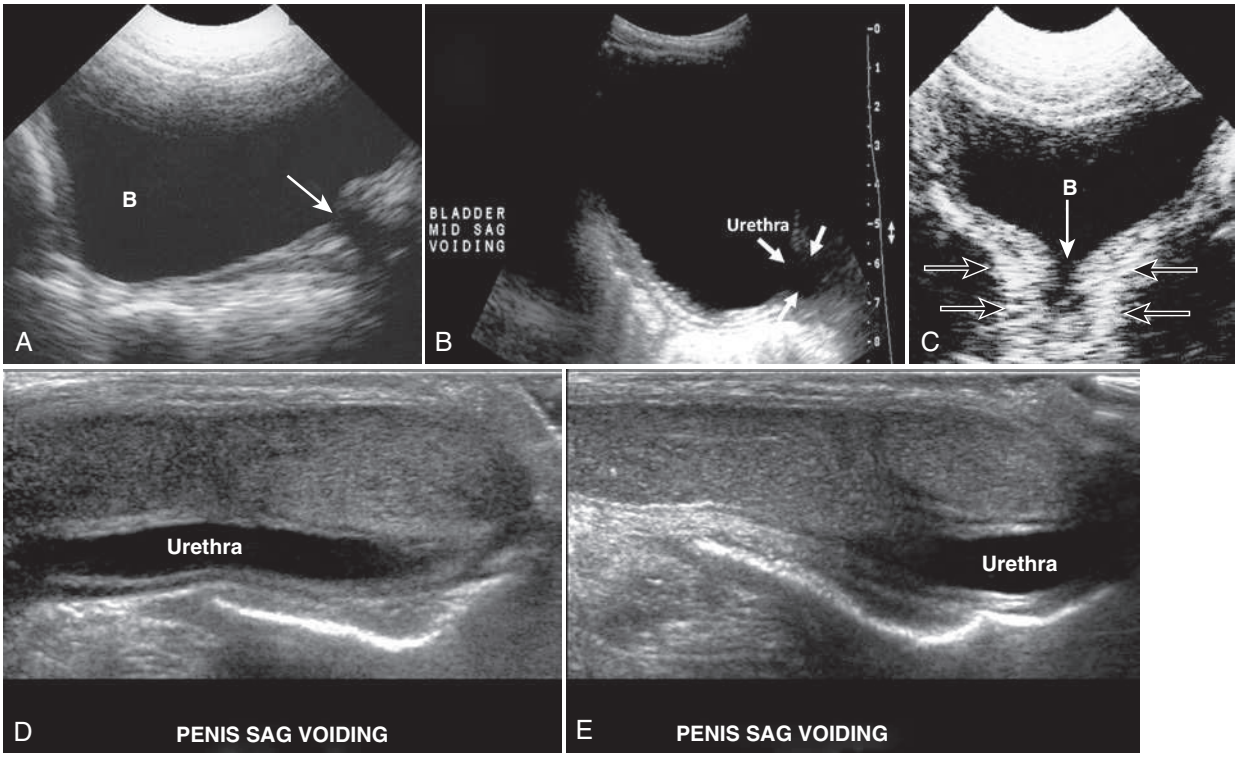

FIG. 54.4 Normal Urethras. (A) Normal female urethra. Using bladder *(B)* as an acoustic window, urethra *(arrow)* may be seen. **(B)** Voiding sonourethrography findings in a female. With use of a sagittal suprapubic approach during voiding, the female urethra can be seen as a fluid-distended structure. **(C)** Normal posterior urethra in young boy. Transverse scan through moderately distended bladder *(B)* shows posterior urethra *(white arrow)* and prostate gland *(black arrowheads)* surrounding the urethra. **(D)** and **(E)** Voiding sonourethrography findings in a male. Sagittal scan demonstrating normal-appearing penile urethra in **(D)**, and the normal-appearing, most distal urethra at the fossa navicularis in the glans of the penis. (**C** with permission from Rosenberg H. Sonography of the pediatric urinary tract. In: Bush WH, editor. Urologic imaging and interventional techniques. Baltimore: Urban & Schwarzenberg; 1989. p 164-179.[16])

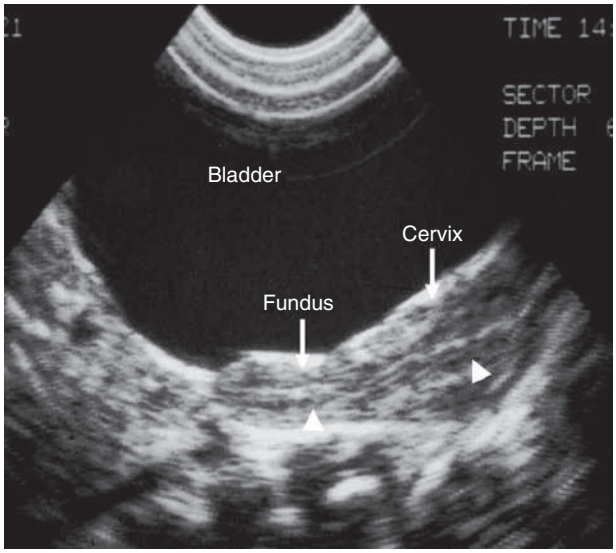

FIG. 54.5 Normal Newborn Uterus. Sagittal view shows that ratio of fundus to cervix is 1:2 for length, and the somewhat thick endometrial lining is prominently echogenic as a result of in utero hormonal stimulation *(arrowheads)*.

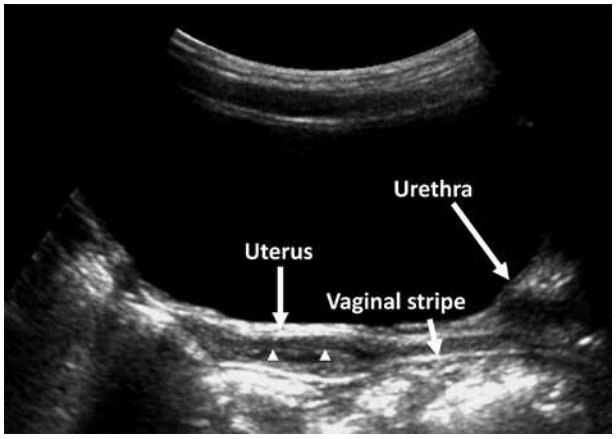

FIG. 54.6 Normal Prepubertal Uterus in 2-Year-Old Girl. Sagittal sonogram through the bladder demonstrates a fundus-to-cervix ratio of 1:1 and shows a pencil-line thin, unstimulated endometrial stripe *(arrowheads)*.

to 5 to 7 cm, and the fundus-to-cervix ratio becomes 3:1[13,16] (Table 54.1). The echogenicity and thickness of the endometrial lining then vary according to the phase of the menstrual cycle, as in adult women. The uterus is supplied by bilateral uterine arteries, which are branches of the internal iliac arteries. Color Doppler imaging generally demonstrates flow in the myometrium, with little or no flow in the endometrium.[15]

The Vagina

In children, digital and visual examination of the vagina is difficult. Often, physical examination of the vagina is performed with the patient under general anesthesia. High-resolution, real-time sonography can now obviate this need in many cases. In the infant or young girl with an interlabial mass, sonography in conjunction with other imaging modalities can usually determine the cause. The vagina is best visualized on midline longitudinal scans through the distended bladder. It appears as a long, tubular structure in continuity with the uterine cervix. The apposed mucosal surfaces cause a long, bright, slender, central linear echo. Hydrosonovaginography (see Fig. 54.1) under real-time sonography guidance can provide additional information about vaginal patency or confirm the presence or absence of a vaginal mass.

TABLE 54.1 Pediatric Uterine Measurements

Age	Uterine Length	Fundus-to-Cervix Ratio
Newborn	3.5 cm	1:2
Prepubertal[a]	2.5-3 cm	1:1
Postpubertal	5-8 cm	3:1

[a]Beginning at age 2-3 months.
Data from Comstock CH, Boal DK. Pelvic sonography of the pediatric patient. Semin Ultrasound. 1984;5:54-67[13]; and Rosenberg HK. Sonography of the pediatric urinary tract. In: Bush WH, editor. Urologic imaging and interventional techniques. Baltimore: Urban & Schwarzenberg; 1989. p. 164-179.[16]

The Ovary

Sonographic visualization of the ovaries in children can vary, depending on their location, size, and the age of the patient (Fig. 54.7, Video 54.2). Because of a typically long pedicle and a small pelvis, the neonatal ovaries may be found anywhere between the lower pole of the kidneys and the true pelvis (Fig. 54.8). Ovarian size is most reproducible and best described by measurement of the ovarian volume, which is calculated by a prolate ellipse formula (Length × Depth × Width [in cm] × 0.523 = Volume [in mL]).

The **mean ovarian volume** in neonates and girls younger than 6 years is usually 1 mL or less.[18] Ovarian volume gradually begins to increase at about age 6 years. The mean ovarian volume measurement in **premenarchal girls** aged 6 to 11 years ranges from 1.2 to 2.5 mL (Table 54.2). There is marked enlargement in ovarian size after puberty; thus ovarian sizes in **menstruating females** in late childhood will be larger than their premenarchal counterparts. Cohen and colleagues[19] reported a mean ovarian volume of 9.8 mL, with a 95% confidence interval between 2.5 and 21.9 mL, in menstruating females.

Beginning in the neonatal period, the appearance of the typical ovary is heterogeneous secondary to small cysts. Cohen and colleagues[17] reported observing **ovarian cysts** in 84% of children 1 day to 2 years of age and 68% of children 2 to 12 years of age. **Macrocysts** (>9 mm) were more frequently seen in the ovaries of girls in their first year of life compared with those in their second year. This probably accounts for the larger mean and top-normal ovarian volume measurements obtained in girls up to 3 months of age (mean ovarian volume, 1.06 mL; range, 0.7-3.6 mL) versus those 13 to 24 months of age (mean ovarian volume, 0.67 mL; range, 0.1-1.7 mL). These findings probably result from the higher residual maternal hormone level in younger infants. Orbak and colleagues[20] concluded that ovarian volume

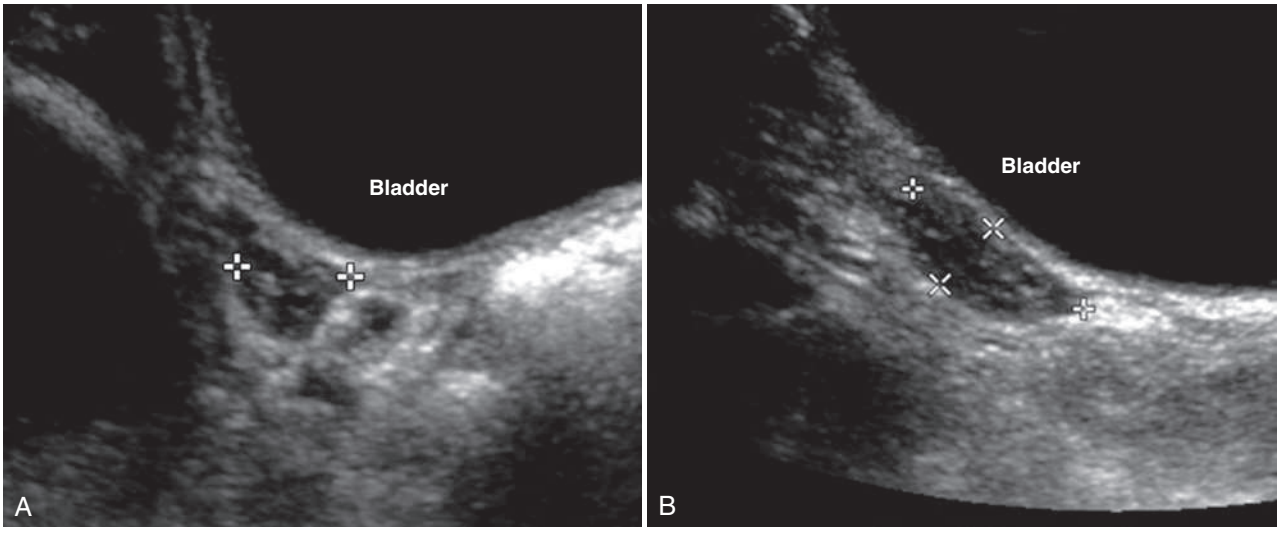

FIG. 54.7 Normal Ovary in 2-Year-Old Child. (A) and **(B)** Transverse and sagittal views of the ovary *(calipers)*. Note that small follicles are normal in the prepubertal ovary and can be easily visualized with high-resolution technology.

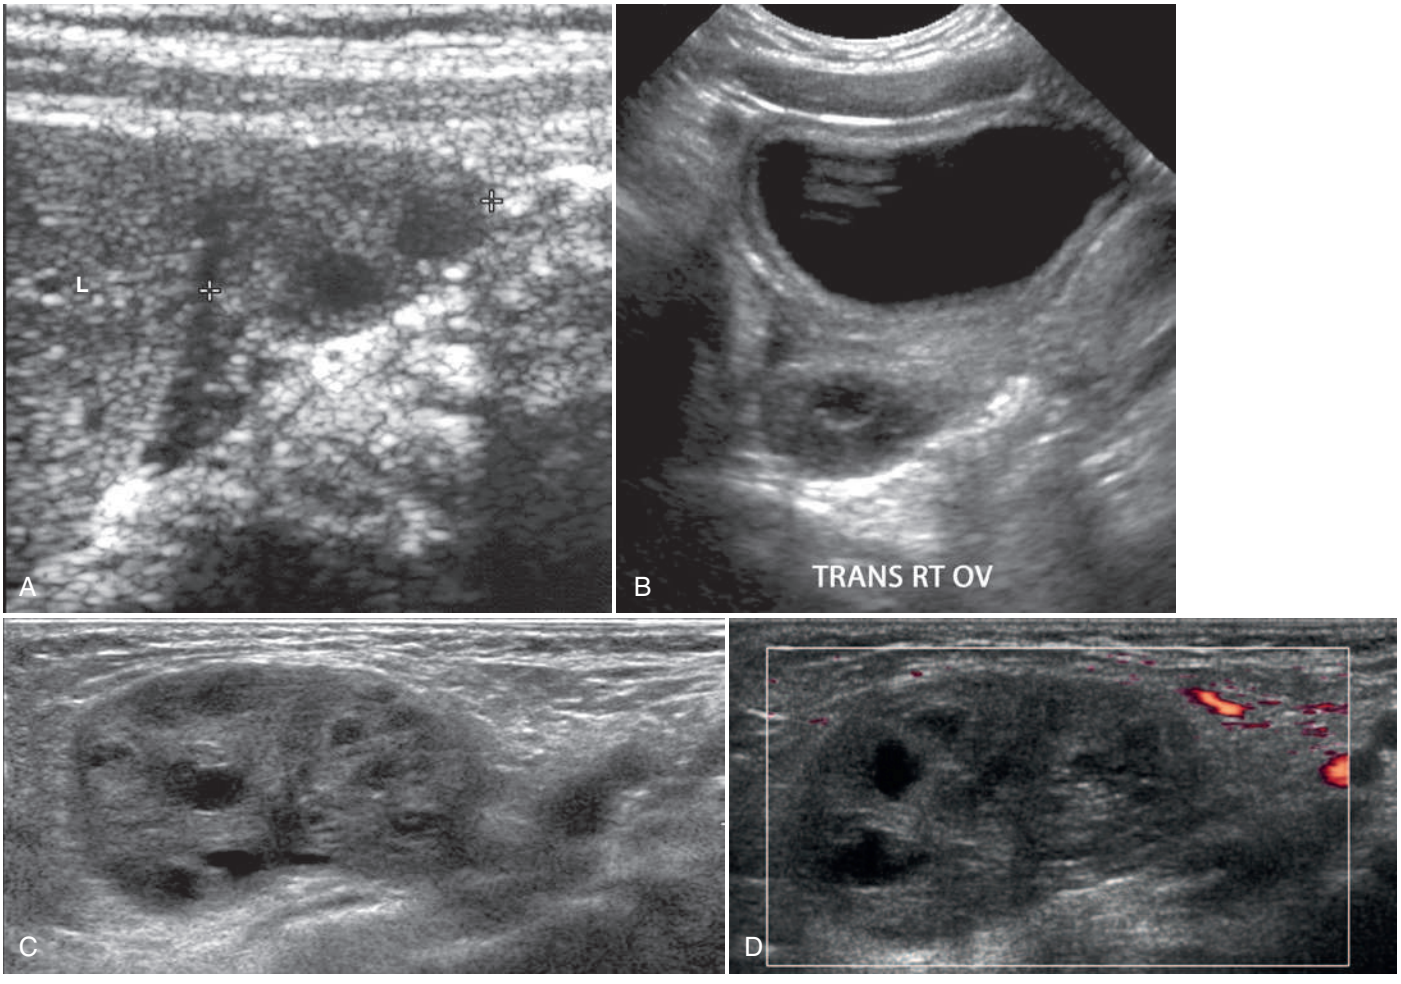

FIG. 54.8 Ectopic Ovary. (A) Ectopic ovary in 18-year-old female with cyclic right upper quadrant pain thought to be caused by recurrent "gallbladder attacks." The liver and gallbladder were normal *(not shown)*. The ectopic right ovary *(cursors)* is just below the inferior edge of the right lobe of the liver *(L)*. **(B)-(D)** Ectopic ovary in the left inguinal canal in a 4-month-old girl with groin mass and vomiting. Transabdominal sonography **(B)** revealed a normal right ovary in the right adnexa, but the left ovary was not seen. An oval structure with no internal vascularity was identified within the left groin (**[C]** and **[D]**); it contains multiple follicles and was enlarged compared with the normally positioned right ovary, consistent with a **torsed herniated left ovary.**

TABLE 54.2 Pediatric Ovarian Volume Measurements

Age	Mean Ovarian Volume, mL (±SD)
PREMENARCHAL	
0-5 yr	**≤1 mL**
1 day to 3 mo	1.06 (±0.96)
4-12 mo	1.05 (±0.67)
13-24 mo	0.67 (±0.35)
3 yr	0.7 (±0.4)
4 yr	0.8 (±0.4)
5 yr	0.9 (±0.02)
6-8 yr	**1.2 mL**
6 yr	1.2 (±0.4)
7 yr	1.3 (±0.6)
8 yr	1.1 (±0.5)
9-10 yr[a]	**2.1 mL**
9 yr	2.0 (±0.8)
10 yr	2.2 (±0.7)
11 yr[a]	**2.5 mL (±1.3)**
12 yr[a]	3.8 mL (±1.4)
13 yr[a]	4.2 mL (±2.3)
MENSTRUAL	
	9.8 mL (±5.8)

[a]Note that these measurements may differ, depending on degree of maturation and presence of menarche.
SD, Standard deviation.
Data from Cohen HL, Shapiro MA, Mandel FS, Shapiro ML. Normal ovaries in neonates and infants: a sonographic study of 77 patients 1 day to 24 months old. AJR Am J Roentgenol. 1993;160(3):583-586[17]; and Rosenberg H. Sonography of the pediatric urinary tract. In: Bush WH, editor. Urologic imaging and interventional techniques. Baltimore: Urban & Schwarzenberg; 1989. p. 164-179.[16]

was reduced in newborns with relatively low birth weight and intrauterine growth restriction, and that functional cysts were more prevalent among low-birth-weight girls.

The blood supply of the ovary is dual, arising from the **ovarian artery,** which originates directly from the aorta, and from the **uterine artery,** which supplies an adnexal branch to each ovary. Blood flow can be seen in 90% of the adolescent ovary, but Doppler imaging cannot distinguish between the two blood supplies. Typically, on color Doppler imaging the intraovarian arteries appear as short, straight branches located centrally within the normal ovary.[21]

OVARIAN ABNORMALITIES

Ovarian Cysts

Simple ovarian cysts in children are relatively common.[22] Small cysts (1-7 mm) have been detected on sonograms in the third-trimester fetus and the neonate and are secondary to maternal and placental chorionic gonadotropin. There is a higher incidence of larger ovarian cysts in infants of mothers with toxemia, diabetes, and Rh isoimmunization, all of which are associated with a greater-than-normal release of placental chorionic gonadotropin.[23] Large ovarian cysts in the fetus can cause mechanical complications during vaginal delivery. As a result of the small size of the true pelvis in infants and young children, ovarian cysts are often intraabdominal in location and must be differentiated from **mesenteric** or **omental cysts, gastrointestinal duplication cysts,**[24] and **urachal cysts.** Ovarian cysts are associated with **cystic fibrosis, congenital juvenile hypothyroidism,**[25] **McCune-Albright syndrome** (fibrous dysplasia and patchy cutaneous pigmentation), and **peripheral sexual precocity.** Autonomously functioning ovarian cysts can cause **precocious pseudopuberty.**

Although neonatal ovarian cysts were surgically removed in the past, spontaneous resolution of some cysts has been demonstrated on sonography[23] (Fig. 54.9). When a follicle continues to grow after failed ovulation or when it does not collapse after ovulation, follicular and corpus luteal cysts may result. Most **follicular cysts** are unilocular, contain clear serous fluid, and range in size from 3 to 20 cm. **Corpus luteal cysts** can contain serous or hemorrhagic fluid and generally range in size from 5 to 11 cm. **Theca lutein cysts** are thought to represent hyperstimulated follicles caused by gestational trophoblastic disease or a complication of drug therapy to stimulate ovulation. Rarely, **parovarian cysts** are diagnosed in childhood (Fig. 54.10). They are of mesothelial or paramesonephric origin and arise in the broad ligament or fallopian tubes.

Complications: Torsion, Hemorrhage, Rupture

Most ovarian cysts are asymptomatic. Symptoms of pain, tenderness, nausea, vomiting, and low-grade fever usually indicate complications of torsion, hemorrhage, or rupture. **Torsion** can occur in normal ovaries but is more often caused by an ovarian cyst or tumor. In children, torsion of the normal ovary can occur because the fallopian tube is relatively long and the ovary is more mobile. The typical presentation is sudden onset of acute lower abdominal pain, often associated with nausea, vomiting, and leukocytosis. Torsion of **normal adnexa** usually occurs in prepubertal girls and is thought to be related to excessive mobility of the adnexa, allowing torsion at the mesosalpinx with changes in intraabdominal pressure or body position. Torsion of the **ovary and fallopian tube** results from partial or complete rotation of the ovary on its vascular pedicle. This results in compromise of arterial and venous flow, congestion of the ovarian parenchyma, and, ultimately, hemorrhagic infarction.[26] The sonographic findings in **acute ovarian torsion** are often nonspecific and include ovarian enlargement, fluid in the cul-de-sac, and other adnexal pathologic findings, such as cyst or tumor (Fig. 54.11 and see Fig. 54.8C-D). A predominantly cystic or complex adnexal mass with a fluid-debris level or septa correlates with pathologic evidence of ovarian hemorrhage or infarction. In 28 of 32 patients, Lee and colleagues[27] showed that ultrasound could demonstrate preoperatively the twisted vascular pedicle in surgically proven torsion, giving a diagnostic accuracy of 87%. This appeared as a round, hyperechoic structure with multiple concentric hypoechoic stripes (target appearance), as a beaked structure with concentric hypoechoic stripes, or as an ellipsoid or tubular structure with internal heterogeneous echoes. Concentric hypoechoic intrapedicular structures could be identified as

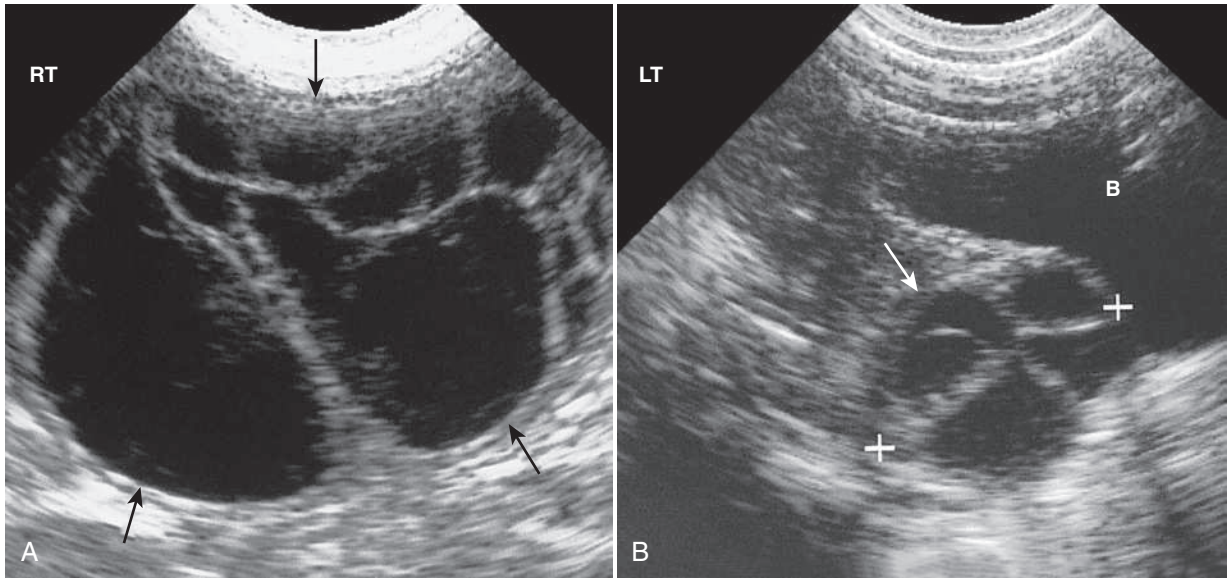

FIG. 54.9 Ovarian Cysts in Newborn Girl. (A) Right ovary. **(B)** Left ovary. Cysts manifested as a lower abdominopelvic mass. Multiple anechoic cystic areas with septations are noted in ovaries bilaterally *(arrows)*. Ovarian cysts were believed to be secondary to in utero hormonal stimulation. Follow-up studies *(not shown)* showed complete regression. *B,* Bladder.

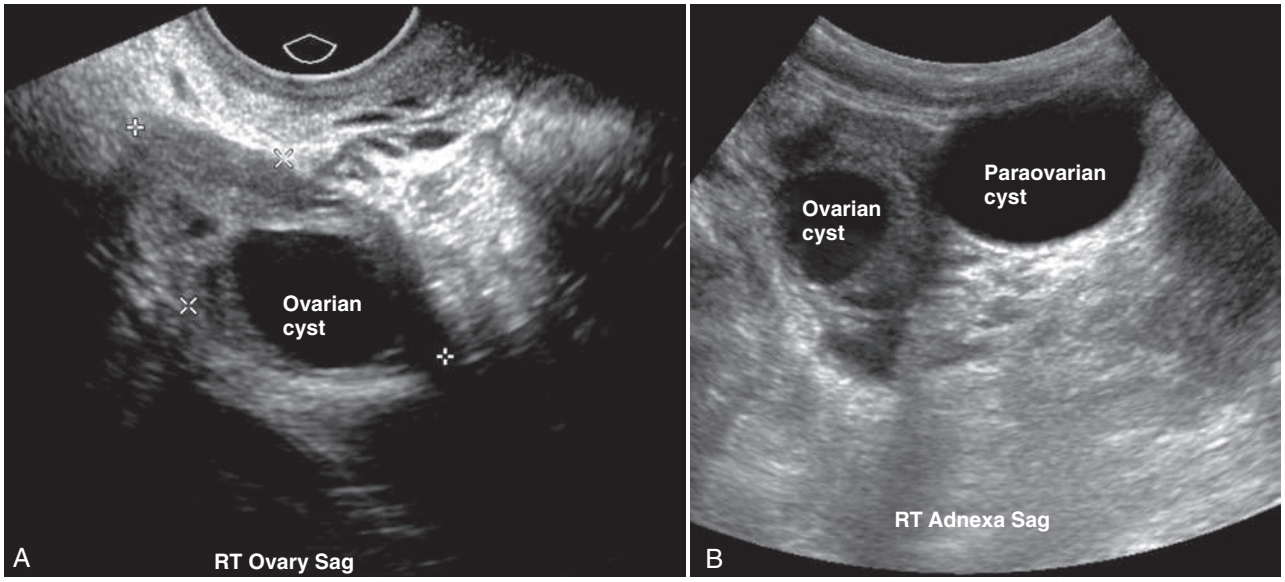

FIG. 54.10 Adnexal Cysts in Teenager. (A) and **(B)** Sonograms demonstrate a simple cyst within the right ovary. In addition, a simple parovarian cyst is demonstrated in **(B)**.

vascular structures on color Doppler sonography ("whirlpool sign"). The absence of flow on color Doppler ultrasound is not a reliable diagnostic criterion because peripheral (or even central) arterial flow can be seen in surgically proven twisted ovaries. This may be explained by the duality of the ovarian arterial perfusion.[28] The demonstration of **multiple follicles** (8-12 mm in size) **in the cortical or peripheral portion of a unilaterally enlarged ovary** has been reported as a specific sonographic sign of torsion.[29-31] These cystic changes occur in up to 74% of twisted ovaries and are attributed to transudation of fluid into follicles secondary to vascular congestion. At times, isolated fallopian tube torsion occurs in perimenarcheal girls with acute pelvic pain and in whom a cystic mass in a midline position is demonstrated (either in the cul-de-sac or superior to the uterus) in association with a normal ipsilateral ovary.[32]

Acute Ovarian Torsion: Sonographic Findings

Ovarian enlargement
Fluid in cul-de-sac
Adnexal mass (ovarian hemorrhage or infarction)
Cystic or complex
Fluid-debris level
Multiple peripheral follicles
"Whirlpool sign" on color Doppler

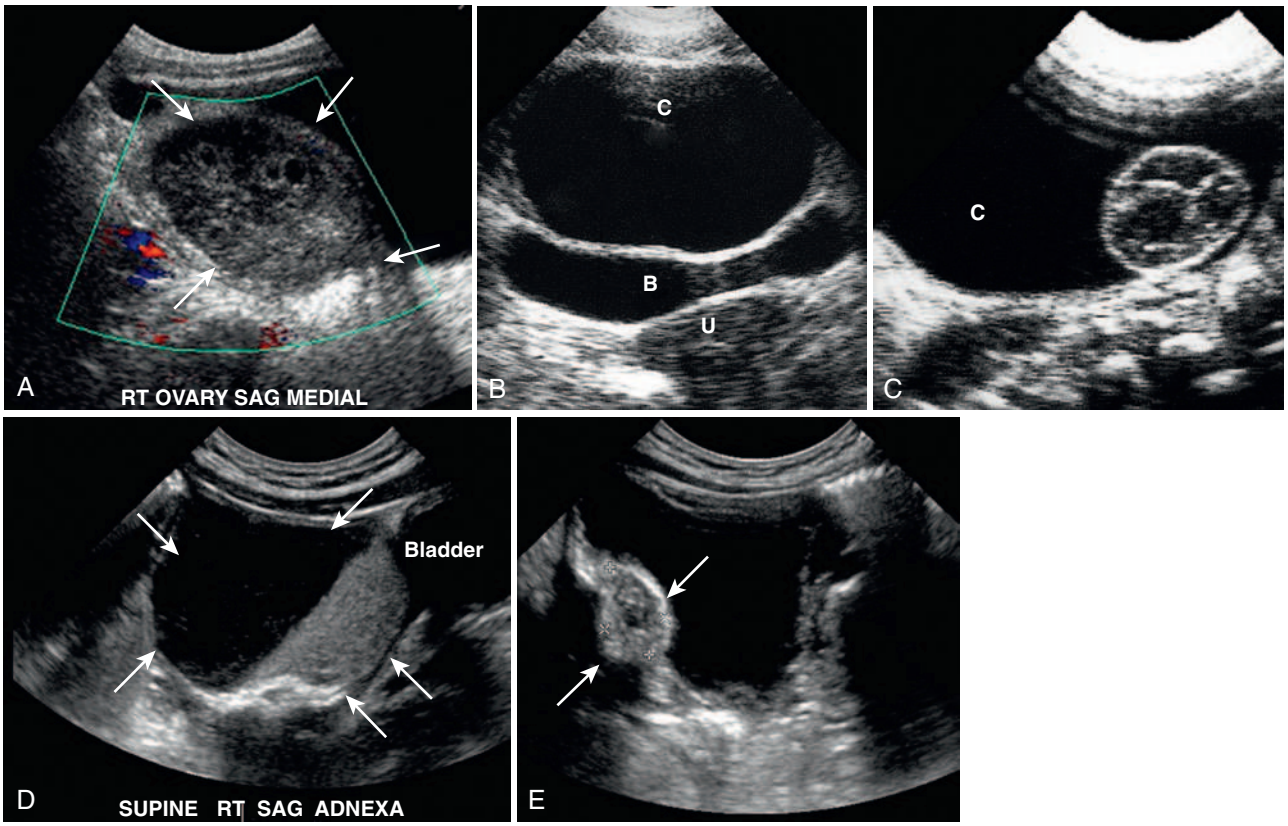

FIG. 54.11 Ovarian Torsion. (A) Sagittal sonogram in 9-year-old girl with right lower quadrant pain demonstrates a greatly enlarged avascular right ovary that contains multiple, variably sized cysts. The ovary was easily untwisted at surgery and immediately regained normal color. **(B)** Ovarian torsion complicating an ovarian cyst in a 16-year-old girl with pelvic pain. Transverse view of the pelvis shows the large anterior ovarian cyst *(C)* compressing the bladder *(B)* (surgical proof of torsion). No ovarian parenchymal tissue was seen sonographically. *U,* Uterus. **(C)** Infarcted, encysted, ovarian torsion in a 6-day-old girl with an abdominal mass. Sonogram of the right lower abdomen and pelvis demonstrates an oval, complex structure within a larger cystic mass *(C).* **(D)** Sagittal view shows infarcted, encysted, torsed right ovary in newborn with cystic mass noted on prenatal sonogram. A fluid-debris level is noted within the cyst *(arrows).* **(E)** Transverse left decubitus scan shows encysted right ovary *(arrows)* embedded in the wall of the cyst.

Hemorrhagic ovarian cysts occur in adolescents and have a variety of sonographic patterns caused by internal blood clot formation and lysis (Fig. 54.12). The most common appearance is a heterogeneous mass that is predominantly anechoic and contains hypoechoic material. Less often, hemorrhagic ovarian cysts are homogeneous, either hypoechoic or hyperechoic. Almost all hemorrhagic cysts (92%) have increased sound through transmission, indicating the cystic nature of the lesion. Additional sonographic features include a thick wall (e.g., 4 mm), septations, and fluid in the cul-de-sac. Although the sonographic findings are nonspecific, the changing appearance of hemorrhagic ovarian cysts over time, as a result of clot lysis, can help establish the diagnosis.[33] In some cases the diagnosis can be confused with **appendiceal abscess, dermoid cyst,** or **teratoma.** Rarely, **pelvic varices** can masquerade as a multiseptated cystic mass (Fig. 54.13).

Polycystic Ovarian Disease (Stein-Leventhal)

The primary clinical manifestations of polycystic ovarian disease (polycystic ovary syndrome [PCOS], Stein-Leventhal syndrome) are hirsutism and irregular menstrual bleeding caused by excess ovarian androgens and chronic anovulation.[34] These features emerge late in puberty or shortly thereafter. In patients with obesity or insulin resistance, the severity of the presentation is amplified. The evolution of this condition during early adolescence is not well understood, but it appears that abnormal activation of the hypothalamic-pituitary-ovarian-adrenal axis occurs, accompanied by specific morphologic changes in the ovaries.[34] The changes in the ovaries have been termed "polycystic ovarian morphology." It was defined in adults by the Rotterdam criteria as (a) one or both ovaries demonstrate 12 or more follicles measuring 2 to 9 mm in diameter, or (b) the ovarian volume exceeds 10 cm[35] (Fig. 54.14, Video 54.3). However, there is controversy as to whether the same criteria can be applied to adolescents.[36-39] These criteria are based on TVS in adults. In the adolescents, sonography is predominately performed transabdominally. The transabdominal approach has decreased resolution compared with TVS, which can limit evaluation of follicle number, especially in obese patients.[36,39] However, sonography is still valuable and frequently is used in the evaluation of an adolescent girl suspected of having PCOS.[39,40] Long-term follow-up is important in these patients because of the increased incidence

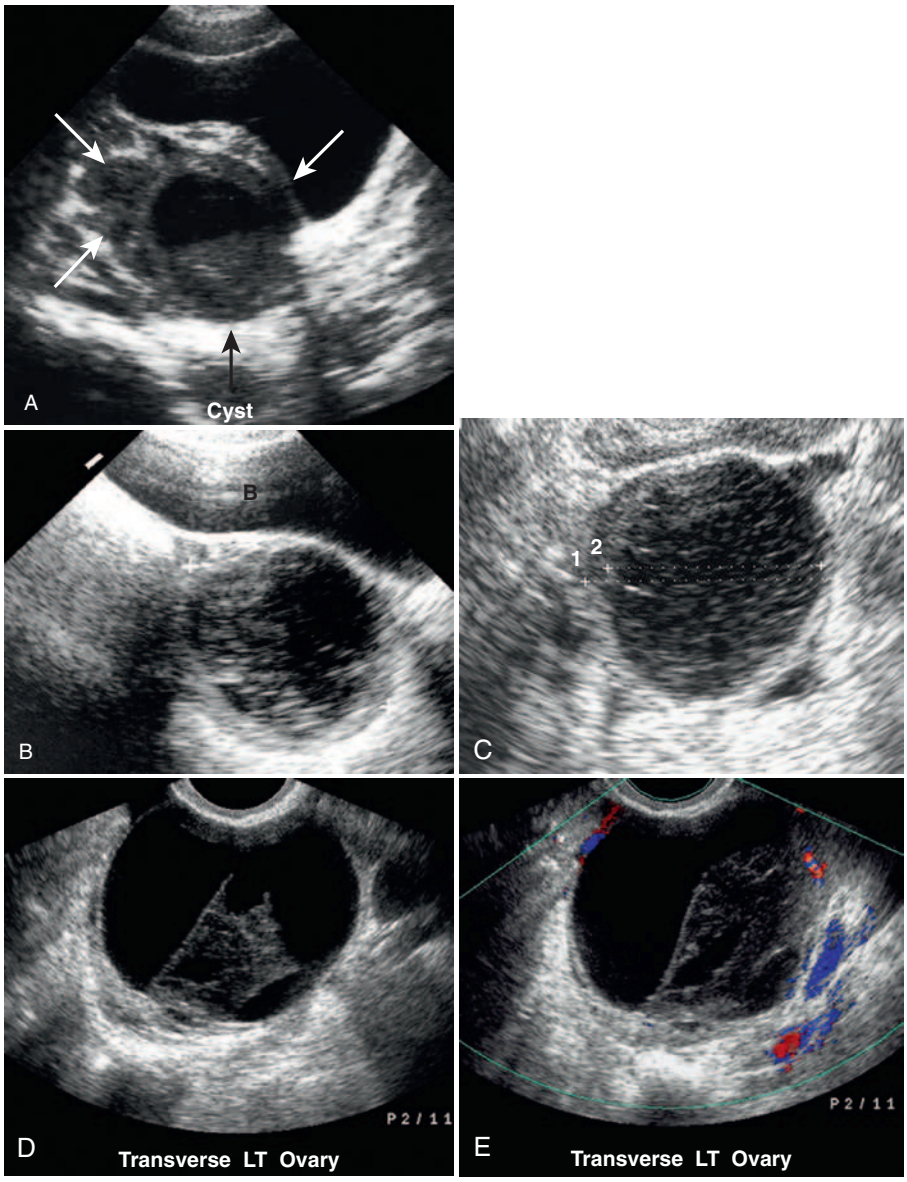

FIG. 54.12 Hemorrhagic Ovarian Cysts in Four Teenagers With Left Pelvic Pain: Spectrum of Appearances. (A) Transverse view of the pelvis reveals a large, round cyst within the ovary (*arrows,* ovary) that contains a fluid-debris level representing a hemorrhagic cyst. **(B)** Sagittal transabdominal sonography (TAS) shows enlargement of the left ovary with a rim of ovary surrounding a cyst that contains multiple, echogenic, streaky densities. *B,* Bladder. **(C)** Transvaginal ultrasound (TVS) confirms the presence of surrounding ovarian tissue and the heterogeneous appearance of the contained fluid. **(D)** and **(E)** TVS images of left ovary demonstrate jagged material within the clearly defined cyst.

of **endometrial carcinoma** from long-term unopposed estrogen.[37,41]

Massive Ovarian Edema

Massive edema of the ovary manifests with marked enlargement of the affected ovary caused by accumulation of edema fluid in the stroma, separating normal follicular structures (Fig. 54.15). It is thought to result from partial or intermittent torsion that interferes with venous and lymphatic drainage. It affects patients during their second to third decades of life and causes acute abdominal pain, palpable adnexal mass, menstrual disturbances at times, masculinization, and Meigs syndrome. Two-thirds of patients have right-sided ovarian edema, thought to be related to high pressure in the right ovarian vein caused by direct drainage into the inferior vena cava (IVC) or increased pressure secondary to uterine dextroposition. The ovaries may be massively enlarged, with diameter up to 35 cm. Grossly, the external surface is soft and pearly white and appears similar to **fibromatosis,** a condition likely to occur in young women (up to 25 years of age) in which primary proliferation of the ovarian stroma may result in torsion and ultimately edema. The sonographic features of ovarian edema include a solid, hypoechoic mass, enhanced through transmission, and cystic follicles within the lesion.[42,43] The masculinization is thought to be caused by stromal luteinization that results from mechanical stretching of the stromal cells by the edema fluid. In addition, human chorionic gonadotropin–like substance may

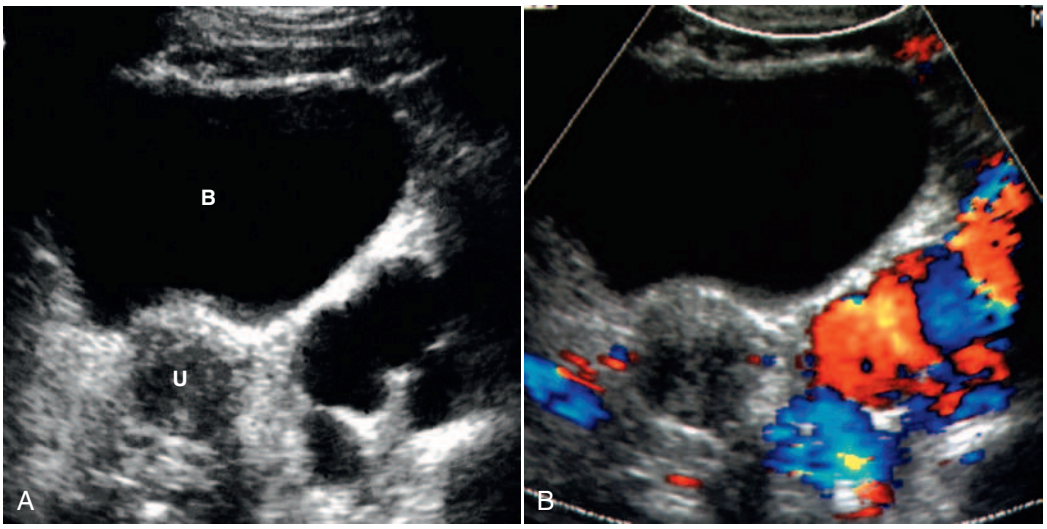

FIG. 54.13 Pelvic Varices Mimicking a Multiseptated Ovarian Cyst. Young woman with chronic liver disease and portal hypertension. **(A)** Transverse sonogram of pelvis shows a multiseptated left adnexal mass. *B,* Bladder; *U,* uterus. **(B)** Transverse color Doppler sonography of pelvis clearly demonstrates the vascular nature of the lesion. Pulsed Doppler showed venous waveforms *(not shown).*

FIG. 54.14 Polycystic Ovarian Disease: Stein-Leventhal Syndrome. Sagittal sonogram of the left ovary in 21-year-old woman with secondary amenorrhea, obesity, and hirsutism. The ovary is round and contains multiple peripheral follicles ("string of pearls"), each of which measures greater than 5 mm (and less than 9 mm).

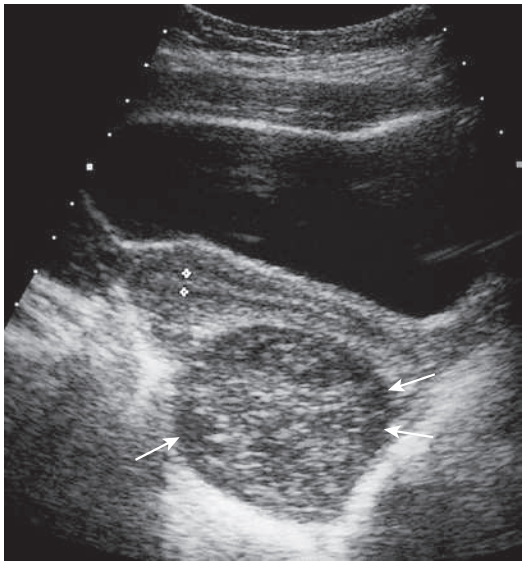

FIG. 54.15 Ovarian Edema. Massive ovarian edema in a 13-year-old girl with masculinization and intermittent pelvic and abdominal pain. Sagittal sonographic image demonstrates a large, heterogeneous, primarily hypoechoic mass posterior and separate from the uterus. This mass contains marked sound through transmission and multiple tiny follicles *(arrows). Calipers,* Endometrial stripe. (Courtesy of Marilyn Goske, MD.)

accumulate in edema fluid and promote luteinization, and level of 17-ketosteroids may be increased.

Ovarian Neoplasms

Ovarian neoplasms account for 1% of all childhood tumors, and 10% to 30% of these are malignant. These neoplasms may develop at any age but most frequently occur at puberty. Abdominal pain or a palpable abdominal or pelvic mass is the usual presenting symptom. Symptoms may develop as a result of torsion or hemorrhage into the tumor. Ovarian torsion is more common in adolescents than in adults; however, ascites is less common in girls.[44,45]

Primary ovarian tumors can be classified into three types of cell origins: **germ cells, epithelial cells,** and **stromal cells.** In children, 60% of primary ovarian tumors are of germ cell origin, in contrast to adults, in whom 90% are epithelial in origin. About 75% to 95% of germ cell tumors in childhood are benign teratomas. However, there is a higher incidence of malignancy in younger patients. In girls younger than 10 years, 84% of ovarian germ cell tumors are malignant. The presence of ascites suggests malignancy.

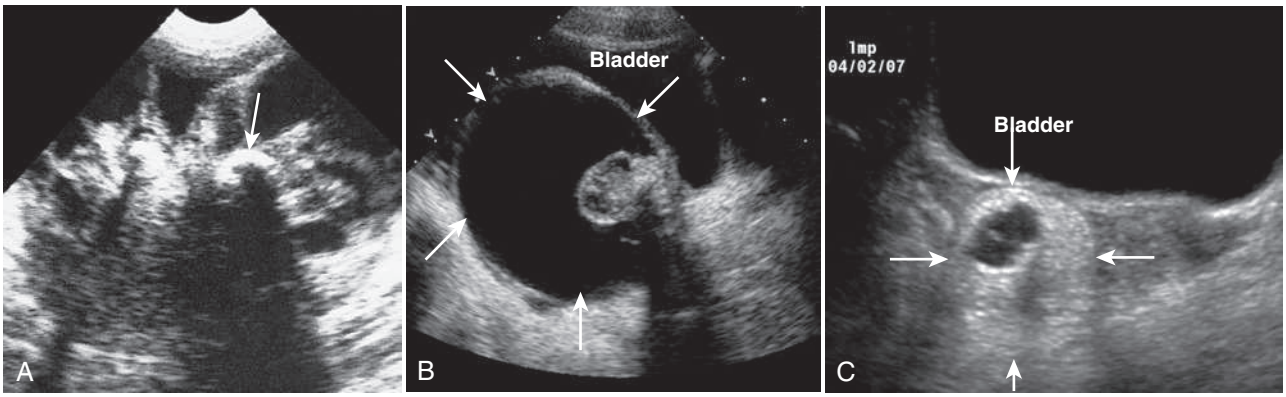

FIG. 54.16 Benign Ovarian Teratomas. (A) Transverse sonogram of pelvis in 6-year-old girl with constipation and large abdominal mass revealed very large, complex mass filling pelvis and lower two-thirds of abdomen, containing multiple shadowing, echogenic foci *(arrow)* consistent with calcifications. **(B)** Midline sonogram in a 12-year-old girl with right lower quadrant pelvic pain demonstrates a complex, primarily cystic mass *(arrows)* that contains a small area of shadowing calcification in the dermal plug. **(C)** Young girl with a history of urinary tract infection. Sonography demonstrates a complex, round, primarily brightly echoic mass *(arrows)* with smaller, hypoechoic cystic areas.

Ovarian Masses in Children

Benign ovarian teratomas (almost 60%)
Dysgerminoma
Embryonal carcinoma
Endodermal sinus tumor
Epithelial tumors of ovary (postpuberty)
Granulosa theca cell tumor (precocious puberty)
Arrhenoblastoma (rare, virilizing)
Gonadoblastoma (in dysplastic gonads—e.g., Turner syndrome)
Acute leukemia

Benign teratomas have a wide spectrum of sonographic characteristics (Fig. 54.16). Teratomas may be predominantly cystic. The most common sonographic appearance is a cystic mass with an echogenic mural nodule, the so-called "Rokitansky nodule" or "dermoid plug."[46-49] Cystic teratomas are usually freely mobile on a pedicle; 10% are bilateral, and 90% are less than 15 cm in diameter.[50]

Dysgerminoma is the most common malignant germ cell tumor of the ovary in childhood. This tumor frequently occurs before puberty, and 10% are bilateral. The tumor is usually a large, solid, encapsulated, rapidly growing mass containing hypoechoic areas as a result of hemorrhage, necrosis, and cystic degeneration. Retroperitoneal lymph node metastases may occur. Dysgerminoma is more radiosensitive than the other malignant ovarian tumors.[47,48]

Embryonal carcinoma and **endodermal sinus tumors** are less common malignant germ cell tumors. **Choriocarcinoma** is rare in children. All these are rapidly growing, highly malignant, solid neoplasms. Embryonal carcinoma is often associated with abnormal hormonal stimulation. These tumors tend to spread by direct extension to the opposite adnexa and retroperitoneal lymph nodes. Peritoneal seeding and hematogenous metastases to liver, lung, bone, and mediastinum are common.

Epithelial tumors of the ovary, which include serous and mucinous **cystadenoma** or **cystadenocarcinoma,** represent 20% of ovarian tumors in children.[51] Epithelial lesions are rare before puberty. On sonography, they are predominantly cystic masses with septa of variable thickness. It is often difficult to differentiate benign from malignant and serous from mucinous cystadenomas or cystadenocarcinomas based only on sonographic criteria.

Granulosa theca cell tumor is the most common stromal tumor in children. It is often associated with feminizing effects and precocious puberty as a result of estrogen production. Of these tumors, 10% are bilateral; only 3% are malignant. Sonographic appearance is nonspecific, and they may be solid, cystic, or mixed.[47-49] **Arrhenoblastoma** (Sertoli-Leydig cell tumor) is rare but may result in virilization. **Gonadoblastoma** is composed of germ cells admixed with sex cell and stromal elements and usually arises in dysplastic gonads. Bilateral involvement occurs in one-third of cases, and 50% contain dysgerminoma elements.

In **leukemic infiltration,** the ovaries, as well as the testes and central nervous system, are sanctuary sites for acute leukemia. Ovarian involvement in autopsy series ranges from 11% to 50%. In leukemia with ovarian relapse, most patients have large, hypoechoic, pelvic masses with smooth, lobulated margins. The tumor can infiltrate the pelvic organs and bowel loops to such a degree that the uterus and ovaries cannot be separately identified. Secondary hydronephrosis may develop. Bickers and colleagues[52] suggested that pelvic sonography should be used to monitor and detect early leukemic relapse in the ovaries of children in clinical remission. The ovaries may also be a site for metastatic spread from **neuroblastoma, lymphoma,** and **colon carcinoma.** The tumors rarely grow large enough to produce a mass and are usually asymptomatic. Typically, the secondary neoplasms appear on sonography as enlargement of one or both ovaries, which are hypoechoic or hyperechoic to the uterus. Less often, a discrete solid or complex mass is seen.

It was originally thought that Doppler sonography would serve to differentiate between benign and malignant ovarian masses. In adolescents and adult women, malignant ovarian

tumors generally have central, low-resistance arterial Doppler waveforms (resistive index [RI] < 0.4, or pulsatility index [PI] < 1.0), thought to be caused by a relative paucity of a muscular layer in the neoplastic vessels,[53] thereby limiting the specificity of Doppler imaging.[54] Benign ovarian masses tend to have peripheral, high-resistance flow (RI > .7 or PI > 1.0). However, nonneoplastic lesions (e.g., tubo-ovarian abscess, ectopic pregnancy, functioning corpus luteum) also have low-resistance flow, and some malignant tumors show high-resistance flow.

UTERINE AND VAGINAL ABNORMALITIES

Congenital Anomalies

Congenital anomalies of the uterus and vagina in children are uncommon and usually manifest as an abdominal or pelvic mass secondary to obstruction. There is a high incidence of associated renal anomalies (50%) and an increased incidence of skeletal anomalies (12%).[55] The uterus, cervix, and upper two-thirds of the vagina are formed by the fused caudal ends of the müllerian (paramesonephric) duct. The paired fallopian tubes are formed by the unfused upper ends. The lower third of the vagina is derived from the urogenital sinus. Müllerian duct development into the uterus is dependent on the formation of the wolffian (mesonephric) duct. Therefore abnormal development of the müllerian duct, resulting in uterine and vaginal anomalies, is often associated with renal anomalies.[56,57]

The **bicornuate uterus** is the most common congenital uterine anomaly. It results when the two müllerian ducts fuse only inferiorly[58] (Fig. 54.17). The two separate uterine horns, which are joined at a variable level above the cervix, are best demonstrated on transverse sonograms through the superior portion of the uterus. Most often only one cervix is visualized (when there are two, this is a bicornis bicollis) and one vagina is identified. With **complete duplication of the müllerian ducts (didelphys),** there is a septated vagina and duplicated cervix and uterus. In either anomaly, obstruction of one uterine horn can result in a pelvic mass from unilateral hydrometra or hematometra. Other septation anomalies of the uterus can result from incomplete involution of the midline septum between the paired müllerian ducts. A **unicornuate uterus** is formed from the agenesis of one müllerian duct.[59] In utero exposure to **diethylstilbestrol** (DES) has been associated with development of a **T-shaped uterus.** Sonography shows a narrow uterus caused by absence of the normal, superior, bulbous expansion of the uterine fundus. Three-dimensional sonography is an excellent modality for obtaining planar reformatted sections through the uterus, which allows for precise evaluation of the anatomy.[57]

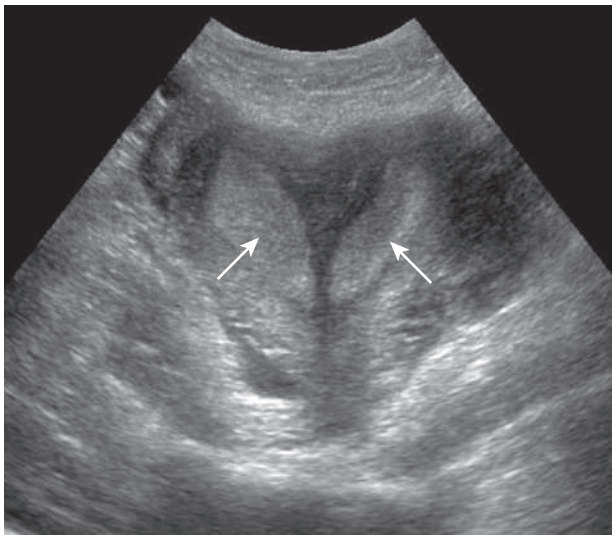

FIG. 54.17 Bicornuate Uterus. Transverse image of the uterus in a 20-year-old woman with acute lower abdominal and pelvic pain reveals two separate endometrial cavities *(arrows)* in the middle to fundal region of the uterus.

Hydrocolpos or **hydrometrocolpos,** caused by obstruction of the vagina, accounts for 15% of abdominal masses in newborn girls (Fig. 54.18). The obstruction is secondary to an **imperforate hymen,** a **transverse vaginal septum,** or a **stenotic or atretic vagina.** There is an accumulation of mucous secretions proximal to the obstruction. The secretions are secondary to intrauterine and postnatal stimulation of uterine and cervical glands by maternal estrogens. A simple imperforate hymen is not usually associated with other congenital anomalies. However, there is a high incidence of genitourinary, gastrointestinal, and skeletal anomalies associated with **vaginal atresia** or a **midtransverse or high-transverse vaginal septum.** Combined perineal-abdominal sonography is an excellent method for accurate assessment of these anomalies.[60] Although TAS is useful to determine if hydrocolpos or hydrometrocolpos is present, this method does not allow measurement of the thickness of a caudally placed obstructive septum. On sonographic examination, hydrocolpos appears as a large, tubular, cystic mass posterior to the bladder and extending inferior to the symphysis pubis.[61] Low-level echoes within the fluid represent mucous secretions in neonates and blood in postpubertal girls[62] (Fig. 54.19). There may be secondary urinary retention and hydronephrosis. Imperforate anus, cloacal exstrophy, and persistent urogenital sinus often have associated hydrometrocolpos.[63-65] Rarely, one may see peritoneal calcifications complicating hydrometrocolpos because of a sterile inflammatory reaction to spillage into the peritoneal cavity of accumulated secretions.[66]

The **Mayer-Rokitansky-Küster-Hauser syndrome,** the second most common cause of primary amenorrhea, comprises vaginal atresia, rudimentary uterus, normal fallopian tubes and ovaries, and broad and round ligaments.[55] The spectrum of uterine anomalies (hypoplasia or duplication) ranges from a partial lumen to a septate or bicornuate uterus with unilateral or bilateral obstruction. These girls have a normal female karyotype, secondary sexual development, and external genitalia. There are high incidences of unilateral renal (50%) and skeletal (12%) anomalies. Unilateral renal agenesis and ectopia are the most common renal anomalies. The most common sonographic findings are uterine didelphys with unilateral hydrometrocolpos and ipsilateral renal agenesis. Water vaginography can help identify the septated vagina with unilateral vaginal obstruction[55] (Fig. 54.20). The analogous genitourinary defects in the male result in duplicated müllerian

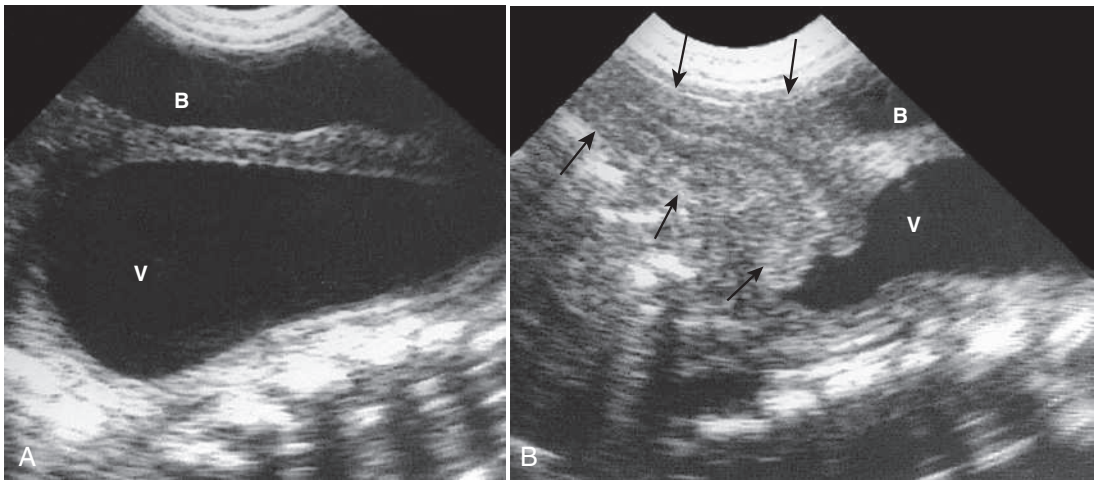

FIG. 54.18 Hydrocolpos. (A) Sagittal scan of pelvis in newborn showing large, conical, fluid-filled mass representing obstructed vagina *(V)* behind bladder *(B).* **(B)** Sagittal scan, angled higher than in **(A)**, shows uterus *(arrows)* with cervix projecting into dilated vagina *(V). B,* Bladder. (With permission from Rosenberg H. Sonography of pediatric urinary tract abnormalities. Part I. Am Urol Assoc Weekly Update Series. 1986;35:1-8.[231])

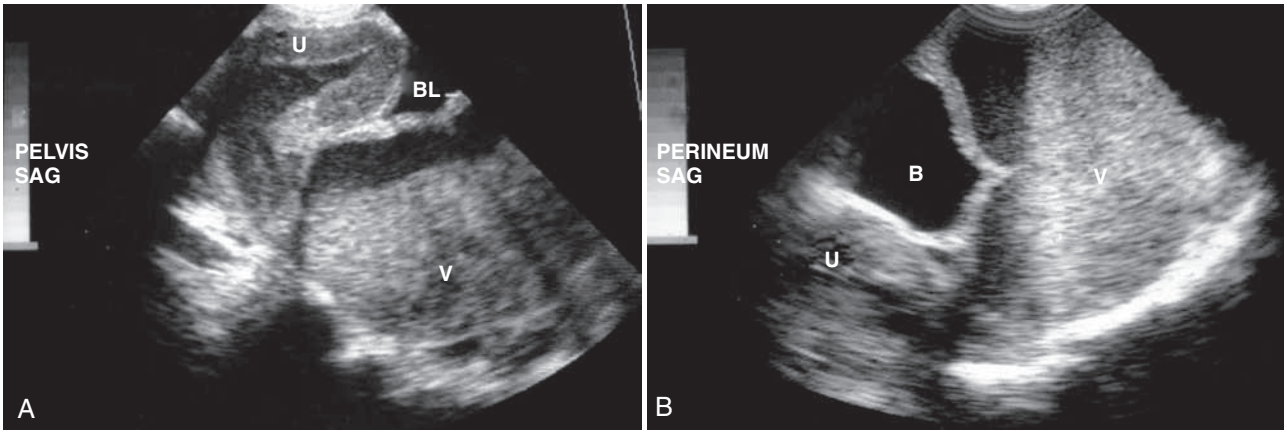

FIG. 54.19 Hematometrocolpos. (A) Sagittal scan of pelvis shows dilated uterine cavity *(U)* filled with echogenic debris (blood). Fluid-debris level is seen in dilated, obstructed vagina *(V). BL,* Bladder. **(B)** Perineal scan confirming the massively dilated vagina with the distal end immediately below the skin surface. *B,* Bladder; *U,* uterus, *V,* vagina. (With permission from Fisher MR, Kricun ME, editors. Imaging of the pelvis. Gaithersburg, Md: Aspen; 1989.[62])

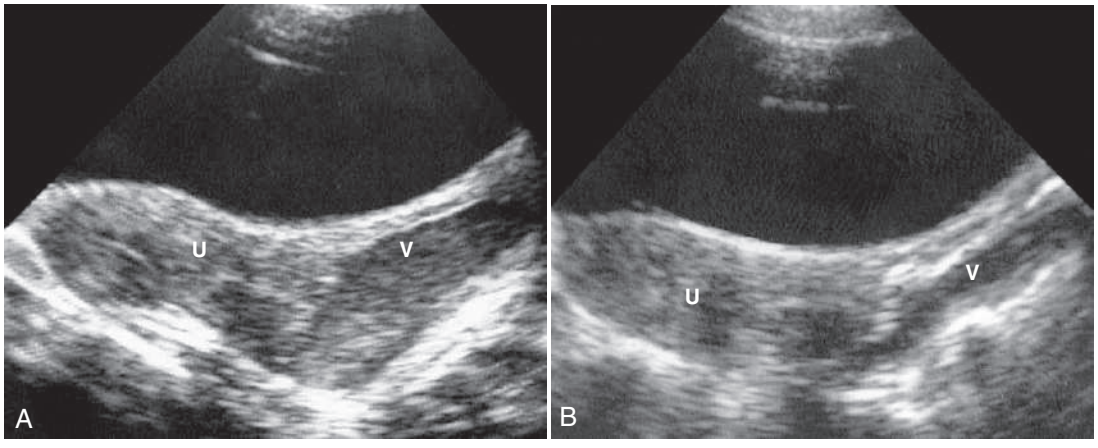

FIG. 54.20 Mayer-Rokitansky-Kuster-Hauser Syndrome. This 13-year-old girl had duplication of uterus and vagina, obstructed right-sided vagina, and fenestrated vaginal septum with cyclic pelvic pain and normal menstrual periods. **(A)** Sagittal scan of pelvis demonstrates a normal right uterus *(U)* and a distended vagina *(V)* filled with echogenic material that moved at real time. **(B)** Left-sided uterus *(U)* is clearly seen in the sagittal plane, and following hand-injection of sterile water into the single introitus, the left-sided vagina *(V)* was demonstrated. During real-time observation, tiny amounts of water could be seen intermittently in the right-sided vagina, suggesting the presence of a fenestrated vaginal septum.

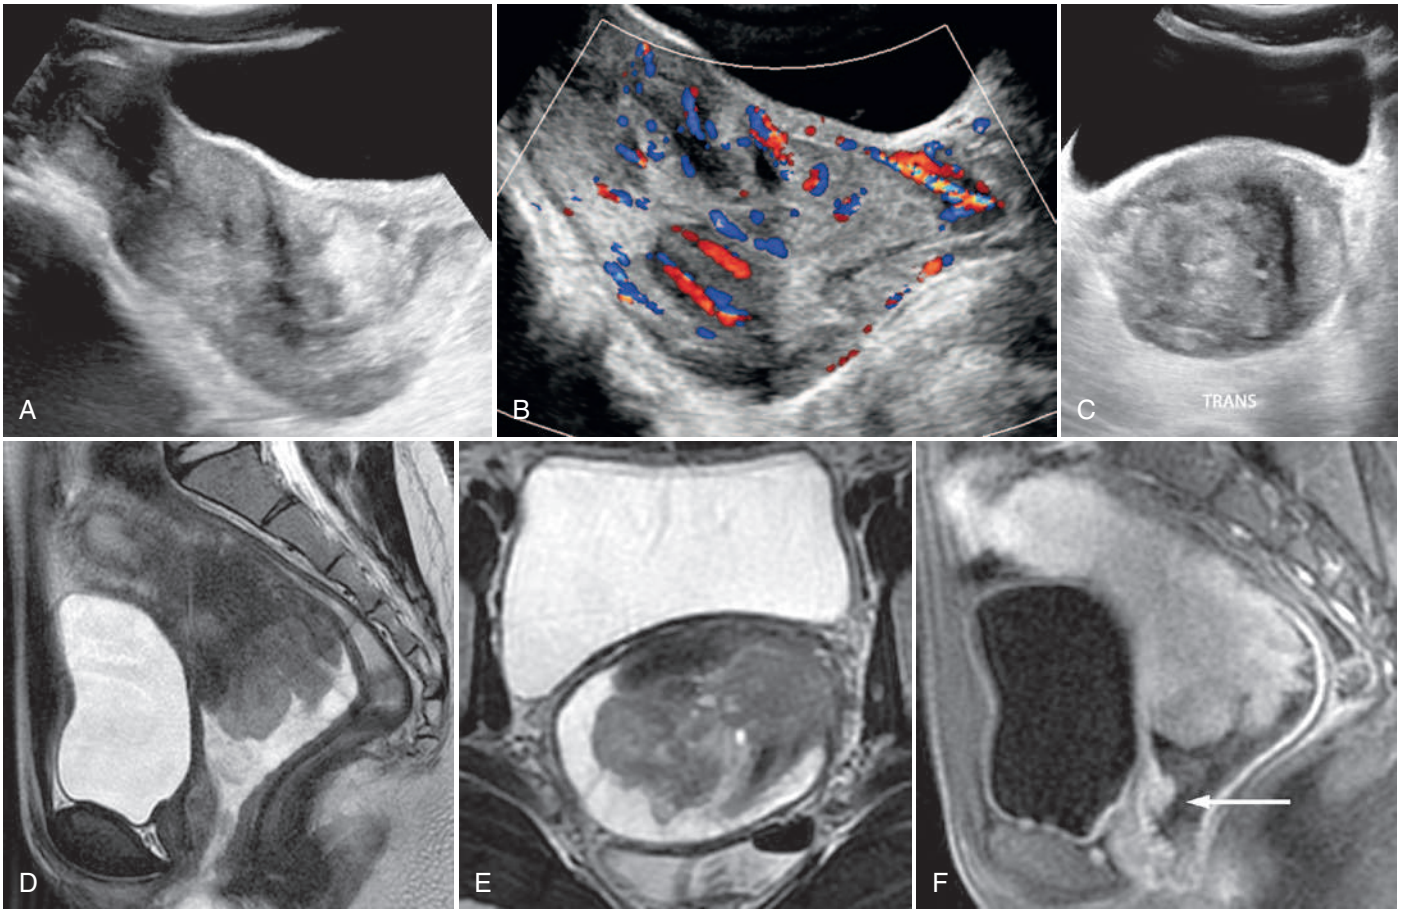

FIG. 54.21 Rhabdomyosarcoma of Vagina. Sagittal **(A)** scan through the uterus shows a heterogeneous solid mass in the upper vagina inseparable from the cervix. Normal fundus and endometrial echo are visible superior to the mass, with significant vascularity on color Doppler imaging **(B)**. Transverse scan **(C)** shows a heterogeneous mass that expands the upper vagina and cervix. Magnetic resonance image shows intermediate signal mass with a frondlike configuration on sagittal **(D)** and transverse **(E)** T2-weighted imaging with high signal in the surrounding vagina as a result of fluid and blood. The mass avidly enhances after gadolinium administration **(F)** with extension along the anterior vaginal wall *(arrow)*.

duct remnants (müllerian cyst and dilated prostatic utricle) with unilateral renal agenesis.

Neoplasm

Tumors of the uterus and vagina are uncommon in the pediatric patient. Malignant tumors are more common than are benign tumors, and the vagina is a more common site than is the uterus. **Rhabdomyosarcoma** is the most common primary malignant neoplasm (Fig. 54.21).[67] It can arise from the uterus or vagina, although uterine involvement is more frequent by direct extension from a vaginal tumor. Presentation is usually at 6 to 18 months of age with vaginal bleeding or protrusion of a polypoid cluster of masses **(sarcoma botryoides)** through the introitus. Rhabdomyosarcoma most often arises from the anterior wall of the vagina near the cervix. It may also arise in the distal vagina or labia. Direct extension of the tumor into the bladder neck is common, but posterior invasion of the rectum is infrequent. Lymphadenopathy and distant metastases are uncommon at presentation. On sonographic examination, these tumors are solid, homogeneous masses that fill the vaginal cavity or cause enlargement of the uterus with an irregular contour.

Endodermal sinus tumor, a less common genital neoplasm, is a highly malignant germ cell tumor that can arise in the vagina. It has clinical and sonographic presentations similar to those of rhabdomyosarcoma Other malignant tumors of the uterus and vagina are rare. Adenocarcinoma of the cervix in adults arises from the endocervix, whereas in children it is a polypoid lesion that originates from the ectocervix and upper vagina. **Carcinoma of the vagina** (usually clear cell adenocarcinoma) usually occurs in teenagers with a history of in utero DES exposure. Leukemic infiltration of the uterus can occur secondary to contiguous extension from an ovarian relapse. Sonography shows a large, homogeneous, hypoechoic, pelvic mass incorporating the uterus and ovaries, which cannot be separately identified. There may be associated hydronephrosis caused by distal ureteral obstruction.

Benign, solid neoplasms of the uterus and vagina are rare in children. However, benign cystic vaginal masses can occur. The most common cystic lesion of the vagina is **Gartner cyst.** A remnant of the distal wolffian (mesonephric) duct, Gartner cysts may be single or multiple and typically arise from the anterolateral vaginal wall. They appear as fluid-filled cysts within the vagina

on ultrasound. Other cystic vaginal masses include **paraurethral cysts, inclusion cysts,** and **paramesonephric** (müllerian) **duct cysts.**

Pregnancy

Intrauterine pregnancy must always be considered in the differential diagnosis of a pelvic mass in girls 9 years of age or older. There is an increased incidence of complications in pediatric pregnancy. These include **toxemia, preeclampsia, placental abruption, lacerations,** and **cesarean section.** Prematurity and perinatal mortality are also increased in infants of teenage mothers.

When the sonographic findings show a distended endometrial cavity in a sexually active girl, molar pregnancy should be considered (Fig. 54.22). In girls postpartum, a well-defined, heterogeneous endometrial mass raises the possibility of **retained products of conception** (Fig. 54.23).

Although **ectopic pregnancy** accounts for approximately 2% of all pregnancies and is less common in young adolescents, the diagnosis should be considered in the presence of pelvic pain, an abnormal **beta human chorionic gonadotropin** (β-hCG) level, irregular vaginal bleeding, and missed menstrual period. An ectopic pregnancy is most likely located in a fallopian tube (ampulla 70%, isthmus 12%, fimbria 11.1%). The two most common sonographic signs of ectopic pregnancy include an **adnexal mass** that is separate from the ovary and the **tubal ring sign** (Fig. 54.24). The diagnosis is more certain when a yolk sac or a living embryo is demonstrated within the adnexal mass.[68] The tubal ring sign consists of a hyperechoic ring surrounding an extrauterine gestational sac. The additional demonstration

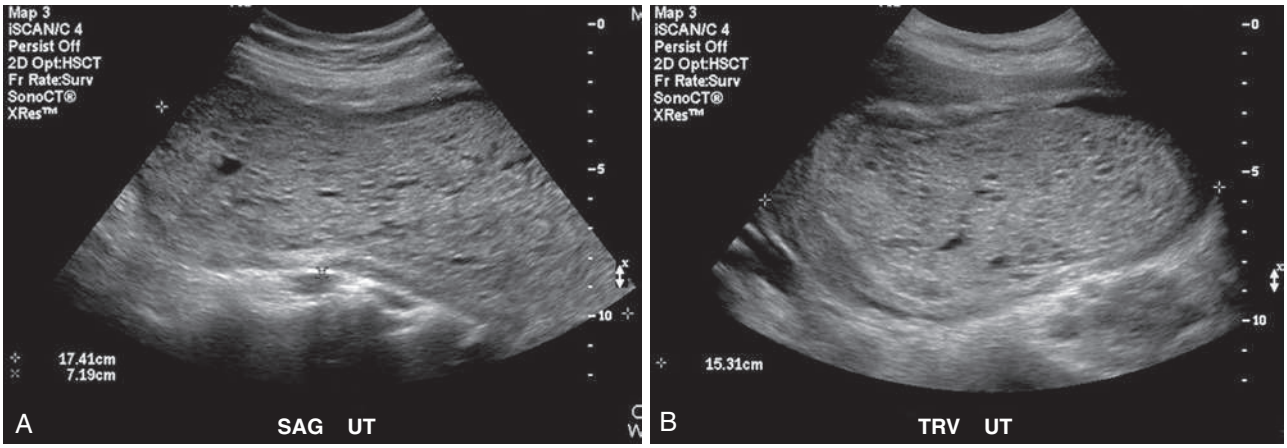

FIG. 54.22 Molar Pregnancy in 20-Year-Old Patient With Vaginal Bleeding and Abdominal Pain. (A) and **(B)** Sagittal and transverse sonograms of the uterus demonstrate a 17.4 × 15.3 × 7.2–cm complex, mainly solid mass, throughout the uterus with the exception of the distal end of the cervix, which is characterized by diffuse heterogeneity from myriad tiny cystic spaces. The mass is hypovascular and does not contain calcifications.

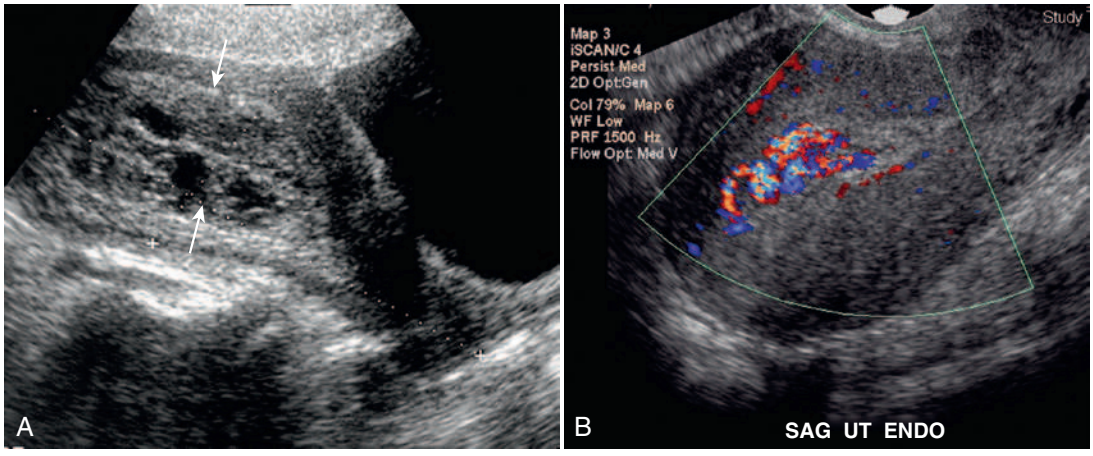

FIG. 54.23 Retained Products of Conception. (A) This 15-year-old girl had ongoing cramps and vaginal bleeding after a spontaneous abortion. Sagittal sonography shows elongation of the uterus (13 cm) with a heterogeneous, fairly well-defined, oval masslike area *(arrows)* occupying the fundus. **(B)** Another teenager with vaginal bleeding a few days after a therapeutic abortion. Sagittal color Doppler sonogram of the uterus demonstrates endometrial hypervascularity, consistent with retained products of conception.

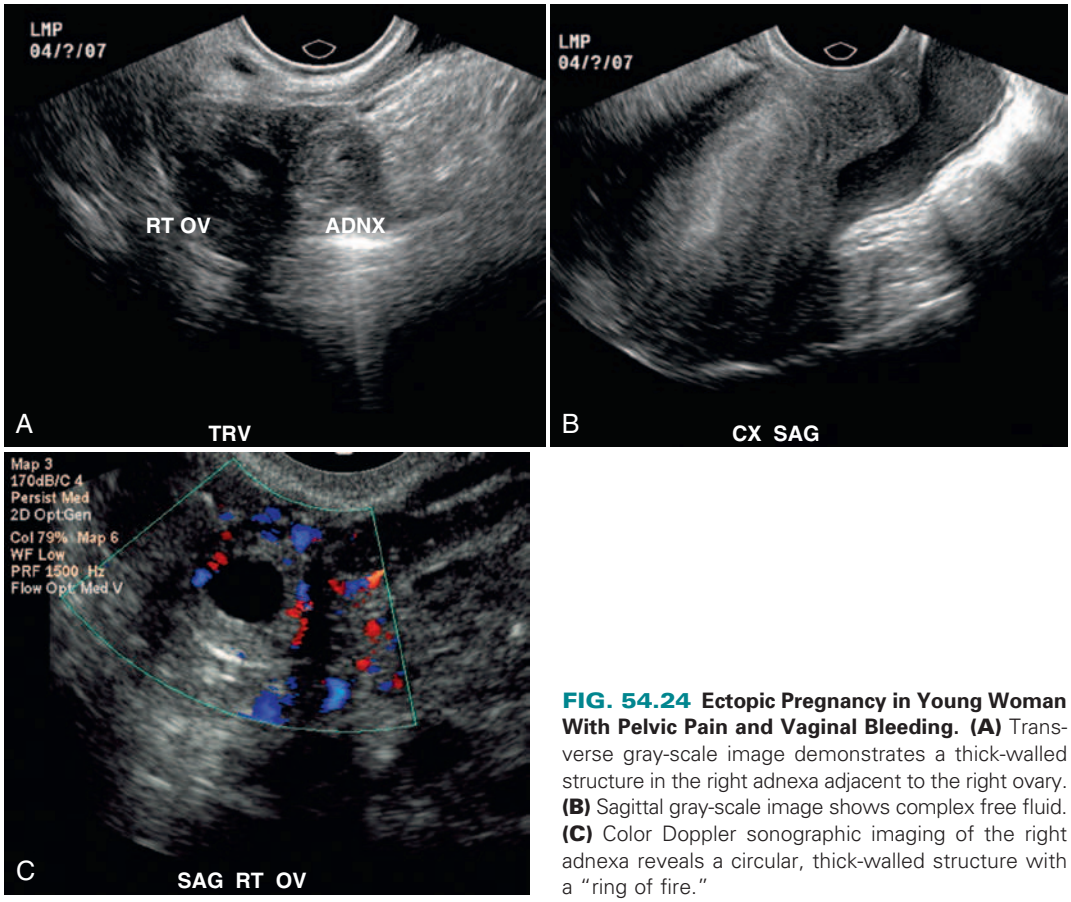

FIG. 54.24 Ectopic Pregnancy in Young Woman With Pelvic Pain and Vaginal Bleeding. (A) Transverse gray-scale image demonstrates a thick-walled structure in the right adnexa adjacent to the right ovary. **(B)** Sagittal gray-scale image shows complex free fluid. **(C)** Color Doppler sonographic imaging of the right adnexa reveals a circular, thick-walled structure with a "ring of fire."

of the **"ring of fire" sign,** which consists of high-velocity, low-impedance flow within the hyperechoic ring, may be another useful finding.[69] However, this sign is nonspecific and may be seen surrounding a normal corpus luteal cyst. Hypotension or overt shock suggests ruptured ectopic pregnancy. Although TVS has greatly improved the diagnostic evaluation of suspected ectopic pregnancy, TAS plays a complementary role by providing a global view of the pelvis and abdominal contents.[70] β-hCG measurements are essential for establishing the diagnosis. This glycoprotein hormone begins to increase in a curvilinear fashion early in pregnancy and continues to increase until approximately 9 to 11 weeks, when it normally reaches a plateau. The plateau lasts for a few days and declines at 20 weeks. β-hCG level doubles on an average of approximately 48 hours when the pregnancy is normal. In the presence of an ectopic pregnancy, however, serum β-hCG levels often rise much more slowly, and a plateau is reached early in the pregnancy. A less than 50% increase in β-hCG level in a 48-hour period is almost always associated with a nonviable pregnancy, whether intrauterine or extrauterine.[71]

Infection

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an infection of the upper genital tract, usually related to *Neisseria gonorrhoeae* or *Chlamydia trachomatis* infection. The serious sequelae of this disease include ectopic pregnancy, infertility, and chronic pelvic pain. Adolescent females are in a higher-risk group, and thus PID should be considered in sexually active females with pelvic pain. The ascending infection may affect uterus, fallopian tubes, and ovaries, causing endometritis, salpingitis, oophoritis, pelvic peritonitis, and tubo-ovarian abscess.

In a study by Bulas of PID in adolescents,[72] anatomic detail was improved with TVS compared with TAS. Transvaginal scans showed new abnormalities in 71% of patients, and the level of disease severity was changed in 33% of patients, which affected treatment decisions in many of these patients.

Acutely, the pelvic sonogram may be normal.[70,73] In the **endometritis** stage of PID, the uterus may be enlarged and more hyperechoic, may contain a small amount of fluid in the endometrial canal, and may have indistinct margins. The normal fallopian tube is usually not visualized on sonography. As the infection ascends, however, the fallopian tubes become thick walled and fill with purulent material[72] (Fig. 54.25). A **pyosalpinx** is a dilated, occluded fallopian tube that contains echogenic purulent fluid. A residual **hydrosalpinx** is a tubular or round structure with anechoic fluid. Ovarian changes from PID may include enlargement secondary to the production of inflammatory exudate and edema and development of many tiny cysts, which may represent small follicles or abscesses (Fig. 54.26).

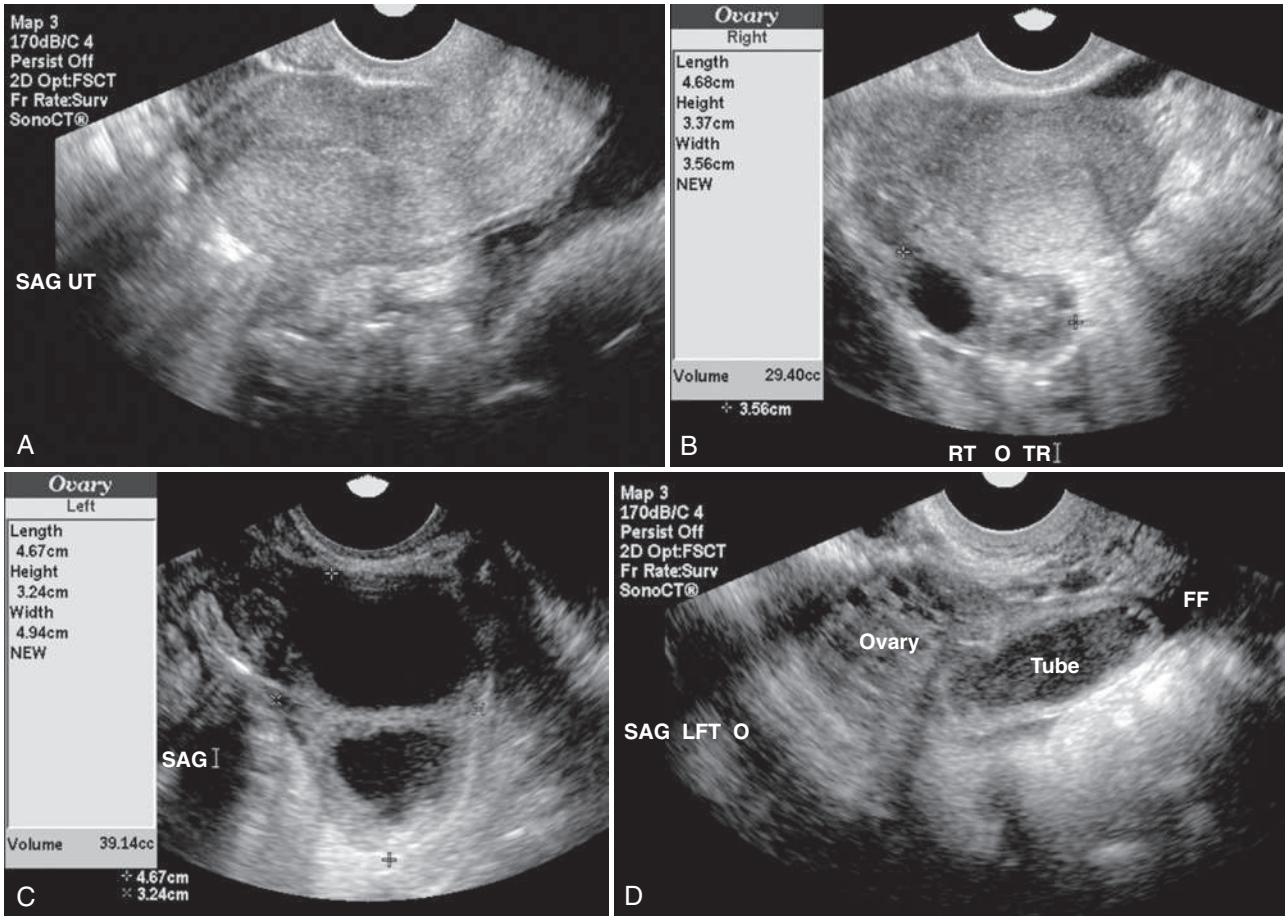

FIG. 54.25 Pelvic Inflammatory Disease With Tubo-Ovarian Complex. Transvaginal ultrasound in 16-year-old girl with pelvic pain. **(A)** Sagittal image of the uterus shows free fluid in the cul-de-sac. **(B)** The right ovary is normal sized *(calipers)*, although there is an anechoic dominant cyst. **(C)** Sagittal image of greatly enlarged left adnexa demonstrates a tubo-ovarian complex (one cyst within ovary and one anterior to ovarian border). **(D)** Fluid-distended fallopian tube is noted with surrounding free fluid *(FF)*. The fluid within the tube is complex with heterogeneous internal echoes, implying purulent material.

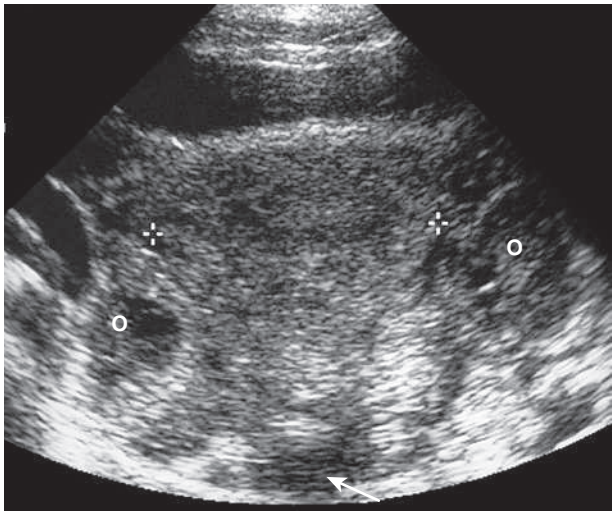

FIG. 54.26 Pelvic Inflammatory Disease. Transverse transabdominal sonography reveals increased, poorly defined, soft tissue echogenicity representing inflammatory material causing indistinct uterine and ovarian margins and haziness in the parametrial area. A small amount of echogenic fluid is seen posteriorly *(arrow)*. *Calipers,* Uterus; *O,* ovary.

Pelvic Inflammatory Disease: Sonographic Findings

Enlarged, hyperechoic uterus
Indistinct uterine margins
Fluid in endometrial cavity
Pyosalpinx (dilated tube with thick walls with echogenic fluid)
Ovarian enlargement with tiny cysts
Tubo-ovarian abscess (heterogeneous adnexal mass)

Periovarian adhesions may form, resulting in fusion of the ovary and thickened tube, forming a tubo-ovarian complex. Further progression leads to tissue breakdown and formation of a **tubo-ovarian abscess,** which usually appears as a heterogeneous, adnexal mass with enhanced through transmission, internal debris, and septations. Color Doppler evaluation of pelvic masses in patients with PID is not specific and overlaps with other entities. Flow in an abscess may be seen along its periphery;

however, this pattern may also be seen in other cystic lesions.[21,72] In **extensive cases of PID** the pelvis is diffusely filled with a heterogeneous echo pattern containing cystic and solid components that obscure tissue planes and uterine margins.

A complication of PID is **gonococcal or chlamydial perihepatitis (Fitz-Hugh–Curtis syndrome).** The patient has right upper quadrant pain caused by localized peritonitis of the anterior liver surface and parietal peritoneum of the anterior abdominal wall. Sonographic findings include the presence of ascitic fluid and thickening of the right anterior extrarenal tissue between the liver and right kidney.[74,75]

Foreign Bodies

A vaginal discharge may be a sign of vaginal infection or trauma. Foreign bodies in the vagina are a cause of 4% of cases of **vaginitis.** A wad of toilet paper is the most common foreign body in the vagina in the pediatric population. Vaginal foreign bodies are seen in 18% of children with vaginal bleeding and discharge and in 50% of children with vaginal bleeding and no discharge. Sonography, either transabdominal or transperineal, with or without water vaginography, can identify both radiopaque and nonradiopaque foreign bodies within the vagina as echogenic material with distal acoustic shadowing. A retained vaginal foreign body can be demonstrated on sonography as a slight indentation on the posterior bladder wall. Acoustic shadowing is characteristic but may not be present.[76,77]

ENDOCRINE ABNORMALITIES

Ultrasound is integral to the evaluation of children with endocrine abnormalities. In the newborn with ambiguous genitalia, pelvic sonography can quickly determine the presence or absence of the uterus and vagina. Identification of the ovaries or testes is more difficult because normal neonatal ovaries are difficult to visualize with ultrasound. Using a high-resolution (12-17 MHz) linear transducer, the gonads may be found in the inguinal canal or in the ambiguous labioscrotal folds. **Differentiation of the gonads** between ovaries and testes may be possible because ovaries often have small, hypoechoic follicles and testes have a solid, homogeneous echotexture.[78]

Causes of Primary Amenorrhea

Sonographic assessment of the uterine size, shape, and maturity and ovarian development can provide a clue to the many causes of primary amenorrhea. A small or absent uterus may be an indication of gonadal dysgenesis, **chromosomal abnormalities, decreased hormonal states, testicular feminization,** or **isolated uterine hypoplasia or agenesis.** In **Turner syndrome** (45,XO karyotype), the most common form of **gonadal dysgenesis,** there is delayed or absent puberty associated with short stature, webbed neck, renal anomalies, and coarctation of the aorta. Turner syndrome is almost always mosaic (45,XO/46,XX). The ovaries vary from nonvisualized streak ovaries to normal-appearing ovaries. The uterine configuration also varies from prepubertal to an intermediate length that is less than that of the normal adult female. Cleeman and colleagues[79] demonstrated in a group of 41 patients with Turner syndrome that one or both ovaries were detected in 37% by ultrasound. The mean ovarian volume was lower in those with Turner syndrome than in the controls ($p = .001$) (1.1 mL vs. 11.52 mL). The mean uterine volume was not significantly different from that in the normal controls.

Other forms of gonadal dysgenesis are also associated with nonvisualization of the ovaries as a result of absent or streak gonads. In **pure gonadal dysgenesis (Swyer syndrome),** the patients have 46,XX or 46,XY karyotypes and normal height. **Mixed gonadal dysgenesis** is a genetic mosaic of karyotypes 45,XO/46,XY with a streak ovary and a contralateral intra-abdominal testicle. Both these forms of gonadal dysgenesis have an increased risk of gonadal tumors as a result of the presence of the Y chromosome. **Noonan syndrome (pseudo–Turner syndrome)** is characterized by phenotypic changes of Turner syndrome, normal ovarian function, and normal ovaries on ultrasound.

Testicular feminization is another cause of primary amenorrhea. It is a sex-linked recessive abnormality, resulting in end-organ insensitivity to androgens. These patients are phenotypic females with a 46,XY karyotype. The uterus and ovaries are absent, the vagina ends blindly, and the testes are ectopic (usually pelvic or within inguinal canals or in labia majora).

Precocious Puberty

Precocious puberty is the development of secondary sexual characteristics, gonadal enlargement, and ovulation before age 8 years. In true precocious puberty, the endocrine profile is similar to that of normal puberty, with elevated levels of estrogen and gonadotropins. The uterus has an enlarged, postpubertal configuration (fundus-to-cervix ratio of 2:1 to 3:1) with a more prominent echogenic endometrial canal than seen in prepubertal females. The ovarian volume is greater than 1 mL, and functional cysts are often present. Precocious puberty is classified into two types: central and peripheral. **Central precocious puberty** (true precocious puberty) is gonadotropin dependent.[80,81] More than 80% of these cases are idiopathic. Intracranial tumors, usually a **hypothalamic glioma or hamartoma,** account for 5% to 10% of cases. There are occasional cases that follow development of increased intracranial pressure, such as **postmeningitis hydrocephalus.** The augmented uterine and ovarian volumes shown on ultrasound occur before the typical changes in secretion patterns of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) revealed with the luteinizing hormone–releasing hormone (LHRH) test. Pelvic sonography during treatment with long-acting gonadotropin-releasing hormone analogues will show decreased uterine and ovarian volume compared with pretreatment values, and the hormonal status will become appropriate for age.[82,83]

In **pseudoprecocious puberty,** the peripheral type, the endocrine profile is variable because this type is gonadotropin independent. Usually, the estrogen levels are elevated and the gonadotropin levels are low. The cause is outside the hypothalamic-pituitary axis—usually an **ovarian tumor. Granulosa tumor** is the most common lesion. Other, less frequent causes are functioning ovarian cysts, **dysgerminoma, teratoma,** and **choriocarcinoma.** Ultrasound will identify the ovarian mass and a mature uterus.

Although **feminizing adrenal tumors** are a rare cause of pseudoprecocious puberty, sonographic examination of the adrenal areas should be performed in all patients with precocious puberty who are referred for pelvic ultrasound. The liver should be examined as well because precocious puberty has been associated with **hepatoblastoma.** In isolated premature **thelarche** (breast development) or premature **adrenarche** (pubic or axillary hair development), sonography shows normal prepubertal uterus and ovaries.

NORMAL MALE ANATOMY

The Prostate

The configuration of the prostate is ellipsoid in boys compared with the more conical shape seen in men. The prostatic echogenicity is hypoechoic and more homogeneous than in the adult prostate, which is frequently heterogeneous secondary to central gland nodules, calcifications, and corpora amylacea.[84,85] Prostate volume may be calculated by using the formula for a prolate ellipsoid (mentioned earlier for ovarian volume).

Ingram and colleagues[86] showed that in a group of 36 boys, ages 7 months to 13.5 years (mean 7.7 years), the prostatic volume ranged from 0.4 to 5.2 mL (mean 1.2 mL). The seminal vesicles may be identified in young boys and adolescents and are best seen in the transverse plane as small, hypoechoic structures giving an appearance similar to a bow tie or the wings of a seagull (Fig. 54.27).

The Scrotum

Before sonographic examination of the scrotum, the clinician should carefully palpate the entire scrotum. The pediatric scrotum is examined with a high-frequency linear array broadband transducer, generally a 12-5 MHz for children and teenagers and a 17-5 MHz, small-footprint, "hockey stick" probe for very small testes in infants and young children and for atrophic testes. It is helpful to elevate and immobilize the testes by gently placing a rolled-up towel posterior to the scrotum between the legs. For accurate measurements of larger adolescent testes, a curvilinear, broad-bandwidth probe, either a 9-4 or 5-2 MHz, and a stepoff pad may be necessary. In infants or any patient with a painful scrotum, a stepoff pad is essential to perform this valuable study. Both hemiscrota should be routinely examined so that differences in size and echogenicity of the intrascrotal contents can be recognized. Color Doppler imaging parameters should be optimized for the best detection of low-velocity and low-volume blood flow typically seen in the scrotum (color gain settings are maximized until background noise becomes visible, and wall filter and pulse repetition frequencies are adjusted to the lowest settings). Power Doppler imaging, with its increased sensitivity for the detection of blood flow, is useful for examination of slow flow states in the cooperative patient and particularly in very young children who normally have low testicular flow. In very small testes, power output may need to be increased to detect flow. Color flow in the two hemiscrota should be compared for symmetry. The addition of pulsed Doppler imaging allows for quantitative evaluation of arterial waveforms and measurements of velocity.

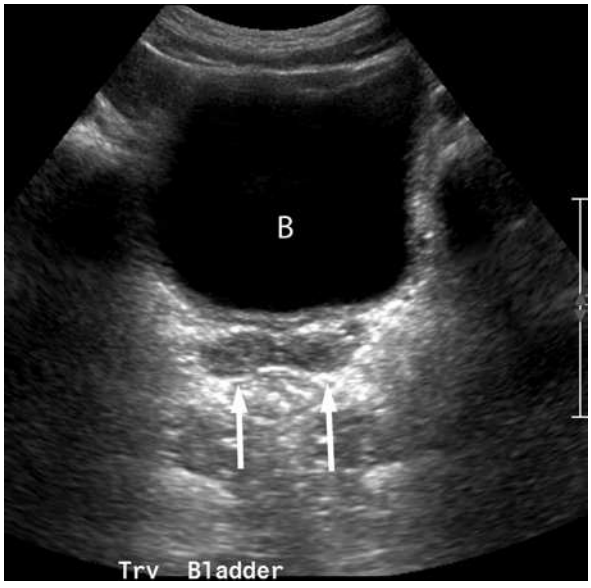

FIG. 54.27 Seminal Vesicles. Through a well-distended bladder *(B)*, the seminal vesicles *(arrows)* are seen as hypoechoic, bilaterally symmetrical structures with a "bow tie" appearance.

The Testes

The normal **newborn testes** have a homogeneous low- to medium-level echogenicity and are spherical or oval in shape with a length of 7 to 10 mm (Fig. 54.28). The epididymis and **mediastinum testis** are usually not seen in the neonate. By puberty, the testis contains homogeneous medium-level echoes and an echogenic linear structure along its superoinferior axis, which represents the mediastinum testis (Fig. 54.29, Video 54.4). The testis measures 3 to 5 cm in length and 2 to 3 cm in depth and width after puberty. Studies of testicular sizes during infancy and adolescence performed using orchidometers report the range of mean testicular volumes as 1.10 mL (standard deviation [SD] ± 0.14) and 30.25 mL (SD ± 9.64).[87] Normal testes smaller than 1 mL can be present in young infants and children.[88,89] The **tunica albuginea** may be seen as a thin echogenic line around the testis. Occasionally, a hypoechoic linear band is noted in the normal testis, usually in the middle third, corresponding to sites of **intratesticular vessels.**[90]

The normal color Doppler appearance of the testes changes with age. Despite optimized slow-flow settings, it may not be possible to detect color flow in normal, small, prepubertal testes.[88,89,91] Atkinson and colleagues[88] reported that centripetal arterial flow could be identified with color Doppler imaging in only 6 (46%) of 13 testes measuring less than 1 mL and in all testes measuring greater than 1 mL. When color flow is seen in prepubertal testes, it generally appears as pulsatile foci of color without the linear or branching pattern seen in adolescents or adults[88] (see Fig. 54.29). The recurrent rami arteries are usually too small to be identified in children, although they may be seen in adolescents. Color Doppler can demonstrate flow in 60% to 83% of prepubertal testes, and power Doppler imaging can demonstrate flow in 73% to 92% of prepubertal testes. Luker and Siegel[91] showed that power mode Doppler ultrasound

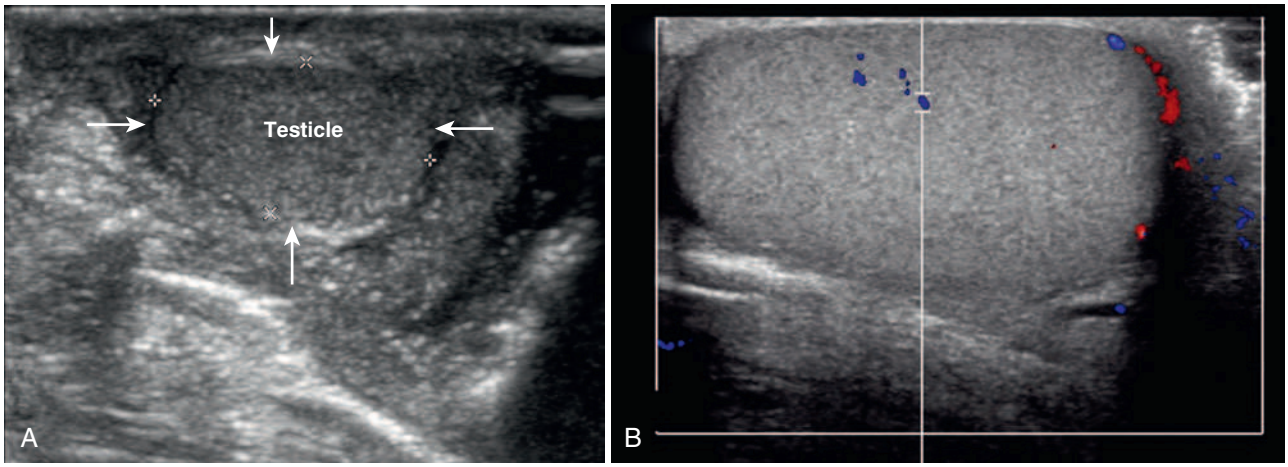

FIG. 54.28 Normal Infant Testis. (A) Gray-scale sagittal image shows the normal, homogeneous, relatively low-level echogenicity of this normal infant testis. **(B)** Some color Doppler flow is demonstrated within the testis.

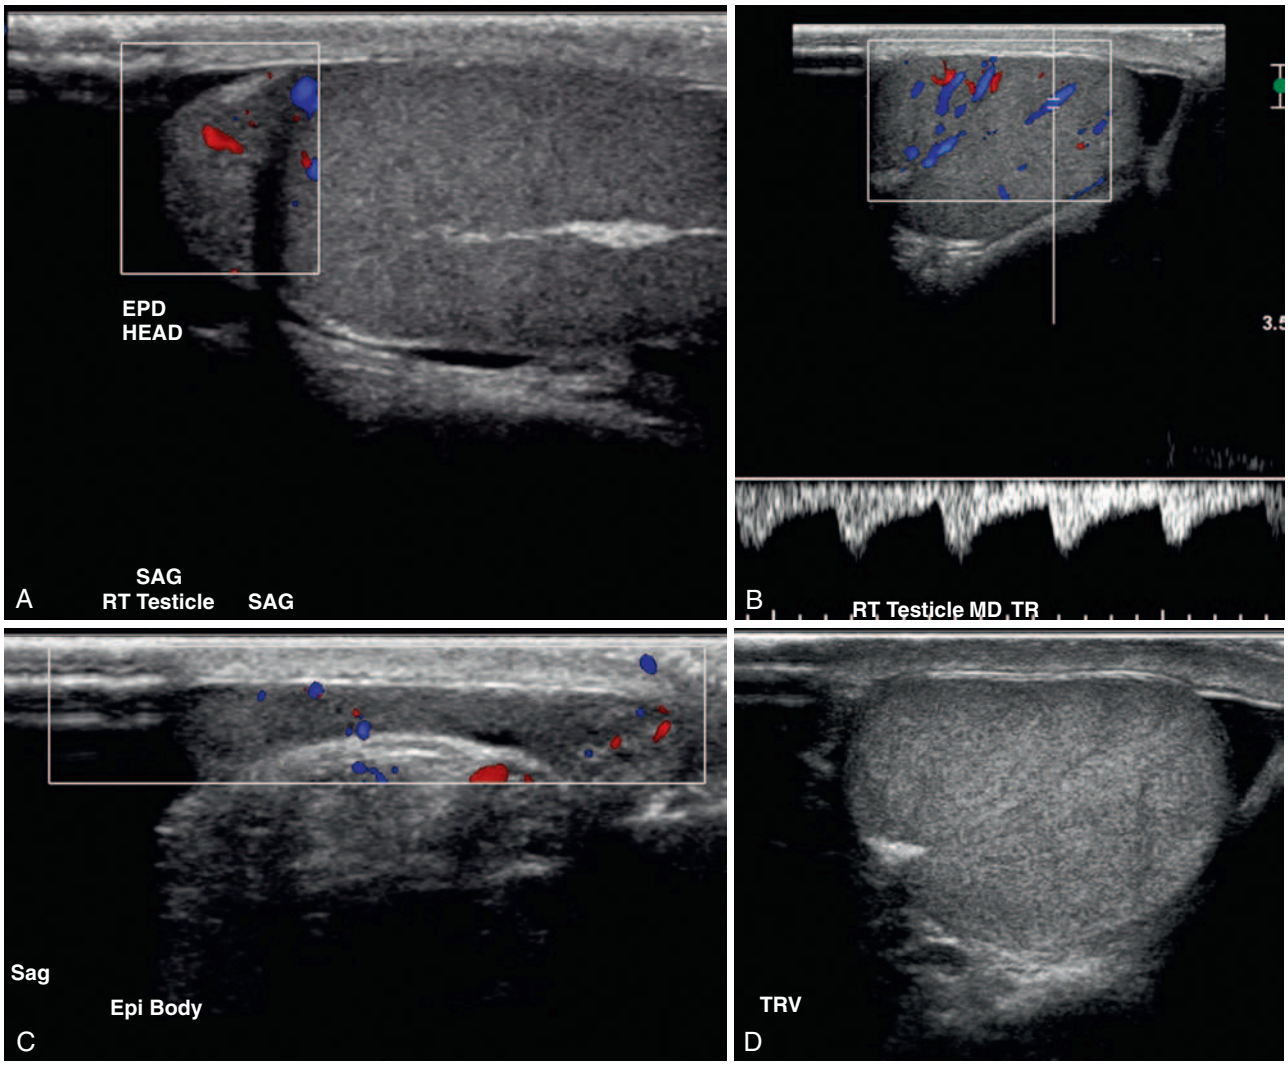

FIG. 54.29 Normal Postpubertal Testis. (A) Color Doppler image demonstrates flow within the head of the epididymis. The testis demonstrates normal homogenous echogenicity, with the mediastinal testis appearing as a white stripe. *EPD*, Epididymal; *Sag*, sagittal. **(B)** Normal duplex color Doppler flow in the centripetal arteries of this normal-appearing testis. *MD*, Mid; *TR*, transverse. **(C)** There is also normal flow in the body and tail of the epididymis. **(D)** Transverse image of testis. A small hydrocele is present. See also Video 54.4.

improved depiction of intratesticular vessels in normal prepubertal and postpubertal testes, but that there was still a lack of visualized flow in several normal prepubertal testes.

Normal pulsed wave Doppler testicular flow reflects its supply from the testicular artery, which has a low-resistance pattern (low peak systolic velocities and relatively high diastolic velocities). Flow in extratesticular vessels reflects supply from the cremaster and deferential arteries and has a higher resistance pattern (low diastolic flow). Because the periphery of the testis contains capsular branches of the testicular artery and branches of the cremasteric and deferential arteries, the patency of the testicular artery can be established reliably only by placing the Doppler sample volume in the center of the testis. The RI of the testicular artery in young men ranges from 0.48 to 0.75 (mean 0.62), and the RI of the capsular arteries ranges from 0.46 to 0.78 (mean 0.66). The RI of the supratesticular arteries varies from 0.63 to 1.00 (mean 0.84). The RI in intratesticular arteries is lower in postpubertal than in prepubertal boys.[92]

The examiner must compare the symmetry of color Doppler flow in both testes to detect disease more accurately and to ensure the system is optimally set to detect flow in the clinically normal testis. Absent flow may not be valid if the ultrasound equipment being used is insufficiently sensitive to detect low flow or if faulty technical settings are used (e.g., high wall filter, low gain, high pulse repetition frequency, low transducer frequency). Power Doppler is often better than color Doppler sonography in assessing symmetry of blood flow.[93]

The **epididymis** lies along the posterolateral aspect of the testis. The triangular epididymal head is isoechoic with the testis or slightly hyperechoic, whereas the echogenicity of the epididymal body is isoechoic or slightly hypoechoic in relationship to the testis. Flow may not be detected in the normal prepubertal epididymis but is generally seen on both color flow and power mode Doppler imaging in postpubertal epididymides.[91]

CONGENITAL MALE ABNORMALITIES

In **cryptorchidism** the testis does not descend through the inguinal canal into the scrotum as expected between the 25th and 32nd week of gestation. In most cases the testes are located within the scrotum at birth or within 4 to 6 weeks after birth. Undescended testes are seen in 4% of full-term newborns and in approximately 33% of premature male infants weighing less than 2500 grams. Testicular descent continues during the first year of life, so that by the end of the first year, only 0.7% to 0.8% of these infants have true cryptorchidism, and in 10% to 25%, it is bilateral cryptorchidism.[94] Although the malpositioned testis may lie anywhere along its course from the retroperitoneum to the scrotum, most undescended testes (80%-90%) are located at or below the inguinal canal and thus are amenable to sonographic localization[95] (Fig. 54.30). Magnetic resonance imaging (MRI) may be employed for localizing intraabdominal cryptorchid testes.[96] Localization of the undescended testis is important in disease prevention because cryptorchidism is associated with increased risks of malignancy, infertility, and torsion.[95] Rarely, the testis is found in the perineum or at the base of the penis.

Aberrations in testicular descent may result in **transverse testicular ectopia,** an anomaly in which both testes are located in the same hemiscrotum. Clinical presentation includes a nonpalpable testis on one side and a scrotal "mass" on the other.[97] About 20% of patients have associated anomalies, such as seminal vesicle cysts, renal dysplasia, hypospadias, ureteropelvic junction obstruction, and ipsilateral inguinal hernia.

Anorchidism, bilateral testicular absence, occurs in 1 per 20,000 newborn males. **Monorchidism,** unilateral testicular absence, occurs in 1 per 5000 boys and is usually left sided. This is thought to result from an in utero torsion or vascular accident because of the associated blind-ending spermatic vessels and spermatic cords.[98]

FIG. 54.30 Undescended Right Testis. The right testis *(between calipers)* is located in the right hemipelvis inside the inguinal ring between a bowel loop and the bladder. A normal left testis was seen in the left hemiscrotum; the right testis was not seen in the right hemiscrotum *(not shown)*.

The number of testes may vary. **Polyorchidism (testicular duplication)** typically manifests in the older child as an asymptomatic scrotal mass, but occasionally it will manifest with pain due to torsion. The testes share a common epididymis, vas deferens, and tunica albuginea. Usually, a single, small, **accessory testis** is demonstrated within the scrotum in addition to two normal testes **(triorchidism).**[99] A **bilobed testis** may mimic a duplicated testis. Polyorchid and bilobed testes have medium-level homogeneous echogenicity and are smaller than the contralateral testis.

Testes smaller than normal may result from cryptorchidism, torsion, inflammation, varicocele, prior inguinal hernia repair, radiation treatment, and trauma. Congenital causes include **Klinefelter syndrome** and **primary hypopituitarism.** These small gonads may have normal, increased, or decreased echogenicity.[97]

True hermaphroditism is an intersex condition in which the patient has both ovarian and testicular tissue, in the form of either separate structures or an **ovotestis.** Ultrasound can demonstrate the textural difference within an ovotestis in that the testicular portion is more homogeneous with medium-level echoes, whereas the ovarian tissue is more heterogeneous with small, anechoic, cystic follicles interspersed with the low- to medium-level parenchymal echogenicity[100] (Fig. 54.31). These patients are seen either prepubertally with ambiguous genitalia or postpubertally with the development of gynecomastia, cyclic hematuria, or cryptorchidism in a patient reared as a boy, or amenorrhea in a patient reared as a girl (Fig. 54.32).

Cystic dysplasia of the testis is a rare congenital condition consisting of dilated rete testis and efferent ducts, as well as adjacent parenchymal atrophy. Patients typically have painless scrotal enlargement at a mean age of 5.8 years.[101] The ultrasound appearance consists of multiple, small, anechoic, cysts predominantly in the region of the mediastinum testis (Fig. 54.33). The

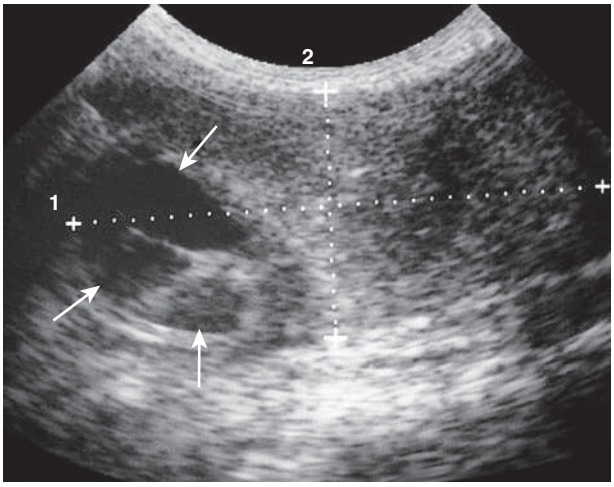

FIG. 54.31 Ovotestis. Ovotestis in a 15-year-old phenotypic boy with gynecomastia, intermittent scrotal pain and swelling, and recent scrotal trauma. Sagittal sonography of the right hemiscrotum revealed a heterogeneous right gonad *(calipers)* with focal cystic areas representing follicles in the upper pole *(arrows).* This gonad contained ovarian and testicular tissue.

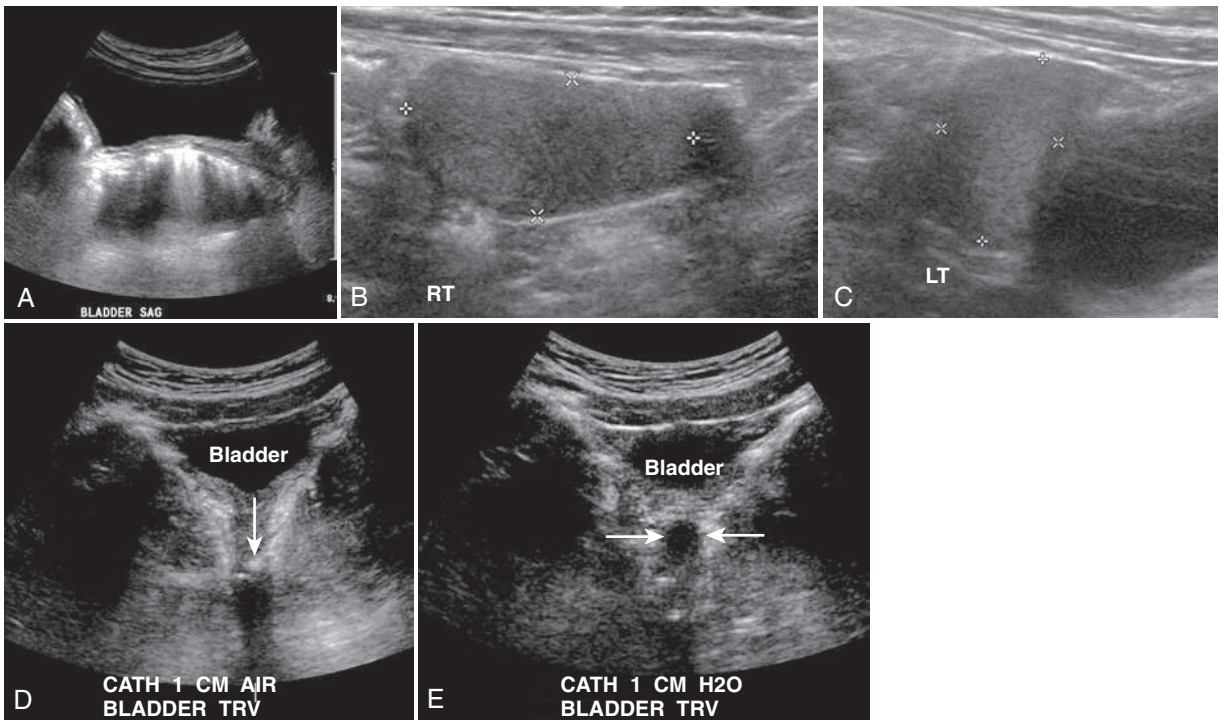

FIG. 54.32 Testicular Feminization Syndrome. This 5-year-old girl underwent bilateral inguinal herniorrhaphies. At surgery, the tissue within each of the inguinal canals felt firmer than expected in the presence of normal herniated ovaries, and thus both were biopsied. **(A)** Sagittal scan of the normal-appearing urinary bladder reveals no evidence of a uterus or ovaries. **(B)** and **(C)** Male-type gonads are seen bilaterally, as evidenced by the homogeneity and lack of follicles in either gonad. Biopsy of both gonads revealed normal, male-type gonads. **(D)** and **(E)** Using the bladder as a sonic window, the length of the vaginal canal was assessed by injecting air and then sterile water into the vaginal opening during sonographic observation. The vaginal canal was extremely short, approximately 1 cm in length.

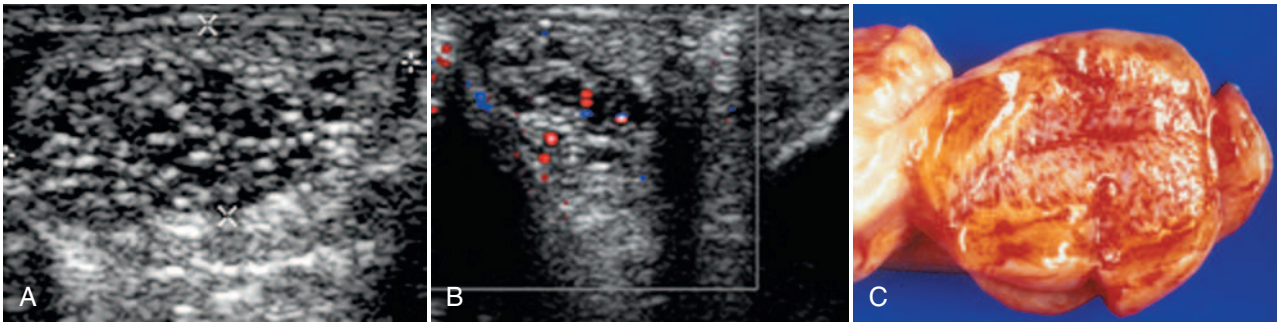

FIG. 54.33 Cystic Dysplasia of Testis. (A) Sagittal sonogram and **(B)** color Doppler sonography show multiple tiny cysts in the testicle. **(C)** Pathologic specimen shows tiny cysts. (Courtesy of Janet Strife, MD, Cincinnati Children's Hospital.)

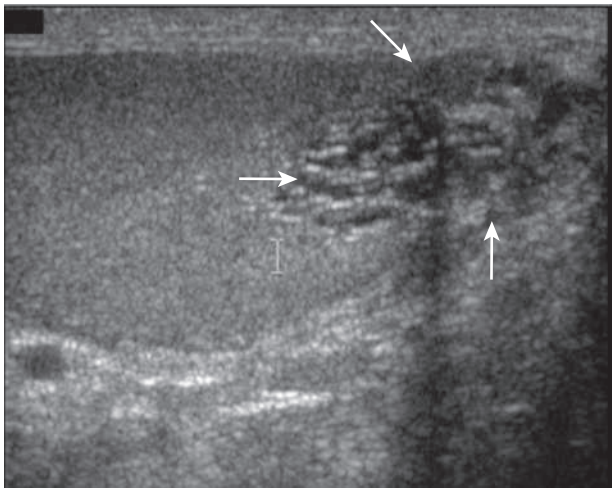

FIG. 54.34 Tubular Ectasia of the Rete Testis. This 9-year-old boy had left scrotal pain. Sagittal sonogram demonstrates a focal cluster of tiny, oval cysts *(arrows)* in the symptomatic area.

defect may result from an embryologic defect preventing fusion between the rete testis tubule (arising from the gonadal blastema) and efferent ductules (arising from the mesonephros). Several reported cases in children were associated with ipsilateral renal agenesis, multicystic dysplastic kidney, or renal dysplasia.[101,102] The appearance in the scrotum is similar to the incidentally noted condition of tubular ectasia of the rete testis described in adults, which probably represents an acquired condition secondary to prior inflammation or trauma[102,103] (Fig. 54.34). The lack of color flow within these cystic structures distinguishes tubular ectasia from **intratesticular varicocele,** which can have a similar gray-scale appearance but demonstrates venous flow on color Doppler imaging.[104] This condition may mimic a cystic neoplasm such as teratoma. If filled with mucoid material or debris instead of anechoic fluid, the cysts may mimic a solid mass.

ACUTE SCROTAL PAIN OR SWELLING

The most common causes of acute pain and swelling in the pediatric scrotum include **testicular torsion, epididymitis** with or without **orchitis, torsion of the testicular appendages, testicular trauma, acute hydrocele, and incarcerated hernia.** Less common causes are idiopathic scrotal edema, **Henoch-Schönlein purpura, scrotal fat necrosis, familial Mediterranean fever,** and secondary scrotal involvement from abdominal pathology.[102-106] It is often impossible clinically to differentiate between the conditions that require conservative medical treatment and those that demand immediate surgery.[107] However, the combination of gray-scale and color Doppler sonography provides information about morphology and testicular perfusion.[108-111]

Acute Scrotal Pain or Swelling

COMMON
Testicular torsion
Epididymitis with and without orchitis
Torsion of testicular appendages
Testicular trauma
Acute hydrocele
Incarcerated hernia

UNCOMMON
Idiopathic scrotal edema
Henoch-Schönlein purpura
Scrotal fat necrosis
Familial Mediterranean fever
Abdominal pathology

Testicular torsion and **epididymitis** (with or without orchitis) are the two most frequently encountered causes of the acute scrotum in the pediatric population. High-resolution ultrasound with color Doppler imaging is the method preferred for distinguishing between these two entities.[108-117] This is crucial because testicular torsion is treated surgically and epididymitis with or without orchitis is treated medically. To confirm the diagnosis of testicular torsion unequivocally, the clinician must demonstrate absence of flow in the painful testis and normal flow in the asymptomatic normal testis,[89] keeping in mind that the presence of flow in the painful testis does not exclude torsion. In the patient with incomplete or partial spermatic cord torsion (twist of ≤360 degrees), normal arterial flow may be demonstrated, although it is usually quantitatively diminished compared with the asymptomatic contralateral testis.[115,117]

Torsion of the spermatic cord is found in 14% to 31% of children and adolescents with an acute scrotum. Testicular torsion results when the testis and spermatic cord twist one or more

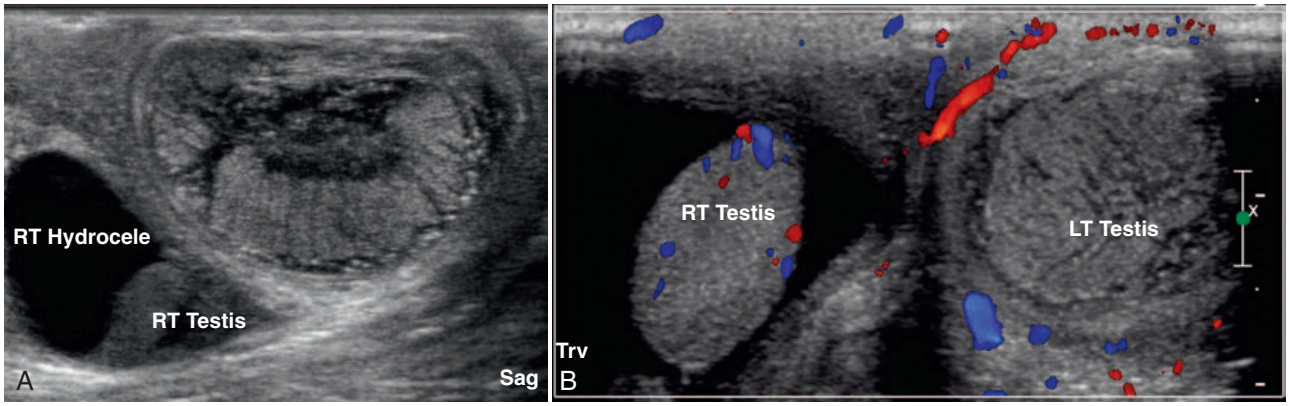

FIG. 54.35 Extravaginal Testicular Torsion. Newborn with hard, nontender, left testicular mass. **(A)** Sagittal sonogram of the scrotum reveals an enlarged, heterogeneous left testis with dilated rete testes. There are multiple foci of bright echogenicity surrounding the left testis, suggesting an intrauterine torsion—"missed" torsion. Note the normal right testis with surrounding hydrocele. **(B)** Normal flow is shown in the normal-appearing right testis. However, a surrounding rim of color Doppler flow can be seen around the avascular, swollen left testis.

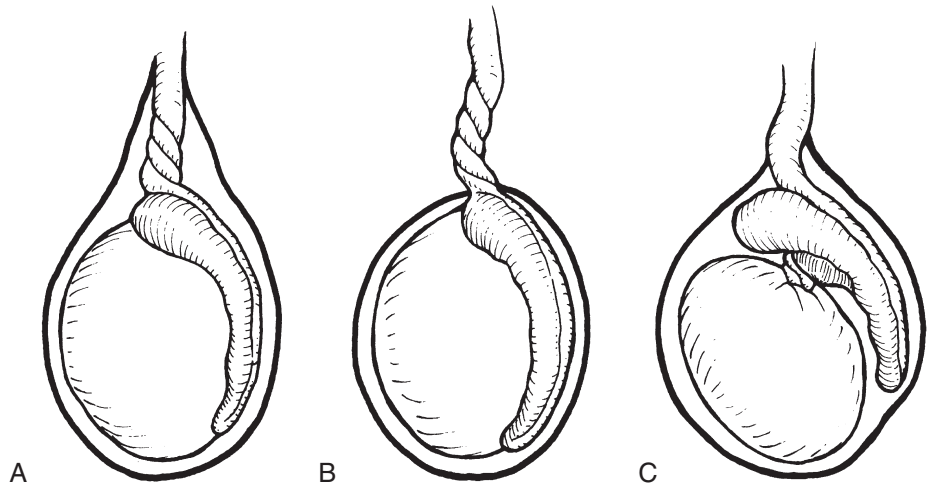

FIG. 54.36 Types of Testicular Torsion. (A) Intravaginal torsion above the epididymis. **(B)** Extravaginal torsion. **(C)** Torsion of the testis below the epididymis. (With permission from Leape LL. Torsion of the testis. In: Welch KJ, Randolph JG, Ravitch MM, editors. Pediatric surgery. St. Louis, 1986, Mosby.[123])

times, obstructing blood flow. Torsion of the testis has the highest prevalence during two age peaks—infancy and adolescence.[89] Two types of torsion have been described—extravaginal and intravaginal, with the latter being more common. **Extravaginal torsion** is generally found in neonates at the level of the spermatic cord, which is poorly fixed in the inguinal canal. All the scrotal contents are strangulated in this type of torsion.[89,100,118] Extravaginal torsion is thought to occur in utero.[119] The loose attachment of the spermatic cord and testes to surrounding structures may account for increased mobility and may predispose to the extravaginal type of torsion seen in neonates (Fig. 54.35). The scrotum is swollen and red with a firm, painless enlarged testicle, which is generally unilateral. Surgical salvage at birth is unlikely because the testis is already necrotic, but occurrence of extravaginal torsion after birth demands emergency surgery.[120] The ultrasound findings vary according to the duration of the torsion. In more recent torsion, the testis is heterogeneously enlarged with hypoechoic and hyperechoic areas. When the torsion is less acute, the testis may be normal or slightly enlarged, with peripheral echogenicity corresponding to calcifications in the tunica albuginea. Often, associated scrotal skin thickening and hydroceles are present.[118,119] There is no Doppler signal in the spermatic cord or the testis. Chronic torsion ultimately leads to small testicular size. Contralateral compensatory hypertrophy may be seen.[121] Other conditions that mimic extravaginal torsion in patients with a swollen scrotum in the neonatal period include **meconium peritonitis,** intraperitoneal bleeding tracking through the patent processus vaginalis, and tumor.

With **intravaginal torsion** the tunica vaginalis completely surrounds the testis and inserts high on the spermatic cord, preventing fixation of the testis to the scrotum and allowing the testis to rotate freely on its vascular pedicle, known as the **bell-and-clapper deformity.**[122] Another, less frequently encountered type of intravaginal torsion is **torsion of the mesorchium,** the tissue attachment between the testis and epididymis[89,97,123] (Fig. 54.36). In this situation, the testis twists within the tunica vaginalis without torsion of the epididymis. **Torsion within the scrotal sac,** or intravaginal torsion, may occur in any age group but is seen more often in adolescents and young adults.[89] The boys develop sudden onset of scrotal or lower abdominal pain. There

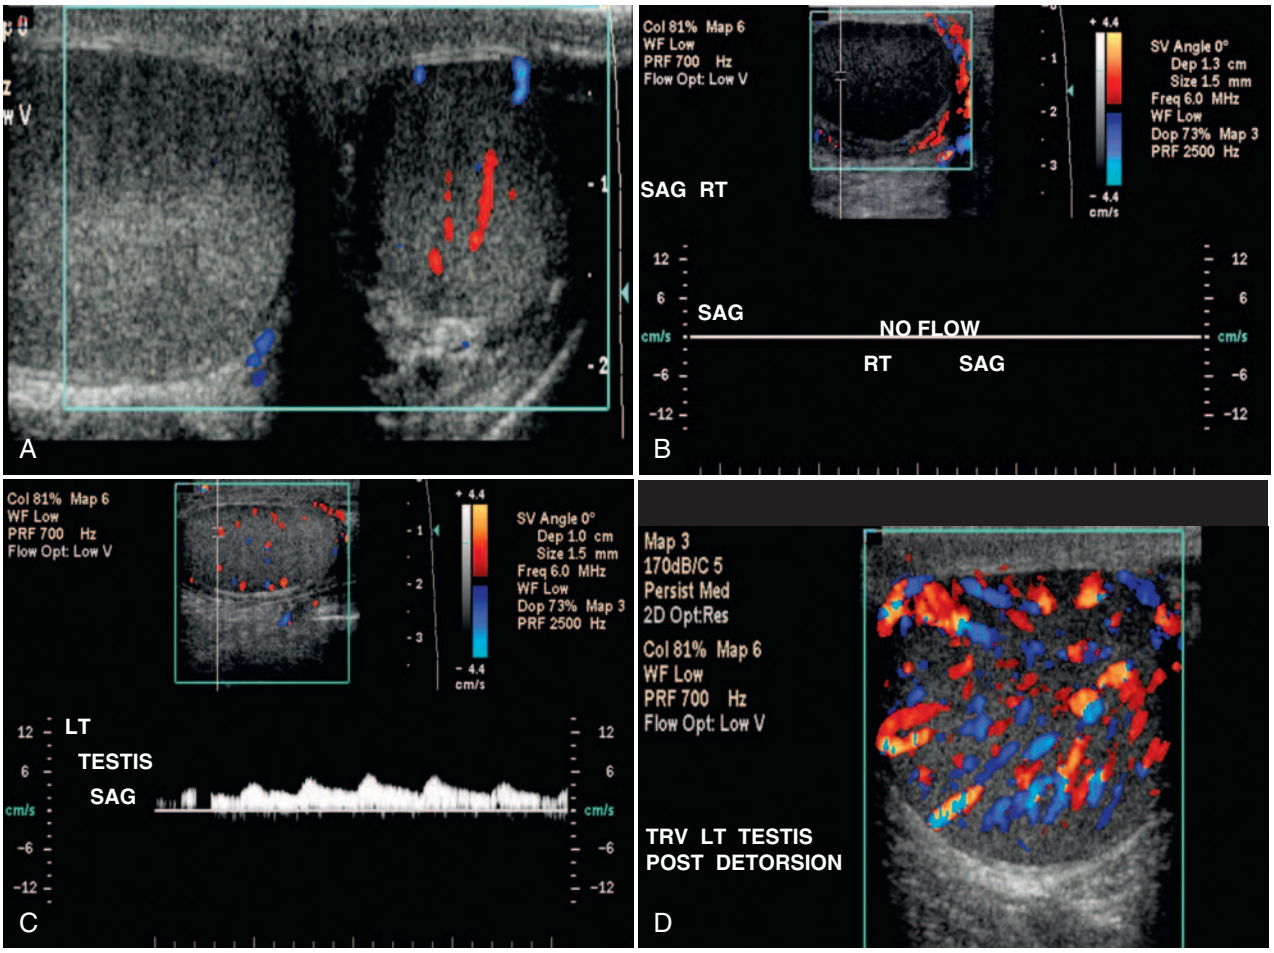

FIG. 54.37 Acute Testicular Torsion. This 13-year-old boy had acute, excruciating right-sided scrotal pain. **(A)** Transverse gray-scale image of both testes demonstrates enlargement of the avascular right testis. **(B)** Absence of both color and pulsed Doppler flow is noted on this sagittal image of the right testis. **(C)** Normal pulsed and color Doppler flow confirmed in asymptomatic, normal-appearing left testis. **(D)** Teenage boy with acute left-sided testicular torsion. Closed manual detorsion of the left testis was done at diagnosis in the ultrasound suite. Color Doppler sonogram of the left testis obtained immediately after detorsion shows dramatic hyperemia throughout the left testis.

is often a history of similar previous self-limited episodes, suggesting prior torsion and detorsion. Nausea and vomiting are more frequently seen in testicular torsion than in other causes of acute scrotum, with a positive predictive value of more than 96%. The boys may also have anorexia and low-grade fever. Physical examination is difficult because of severe tenderness. The affected hemiscrotum is swollen and erythematous with the affected testis often oriented transversely. The cremasteric reflex may be absent.[114] Most important, patients with suspected intravaginal torsion require emergency surgery to optimize testicular salvage. If it is clinically obvious that a patient has an acute torsion, emergency surgery should be done, even without imaging, because any delay in surgical treatment reduces the likelihood of testicular salvage. Some believe that closed manual detorsion may improve salvage rates and convert an emergent situation to an elective surgical procedure for future orchiopexy (Fig. 54.37); however, this is controversial.[124,125] The best results are obtained in those who have immediate detorsion and fixation to the scrotal wall and orchiopexy of the contralateral testis.[97] The salvage rate is greater than 80% when surgery is performed within 6 hours of the onset of symptoms; approximately 70% when performed within 6 to 12 hours of symptoms; and less than 20% if surgery is delayed for 12 to 24 hours after the onset of pain.[89,115,126] After 24 hours, the testis is virtually never salvageable. The sonographic features in testicular torsion depend on the duration and severity of the vascular compromise.

Sonographic Signs of Testicular Torsion

TESTES
Normal early
Hypoechoic after 4-6 hours from edema
Heterogeneous after 24 hours from hemorrhage and infarction ("missed" torsion)

PERITESTICULAR
Hypoechoic epididymis
Reactive hydrocele
Skin thickening
Enlarged, twisted spermatic cord

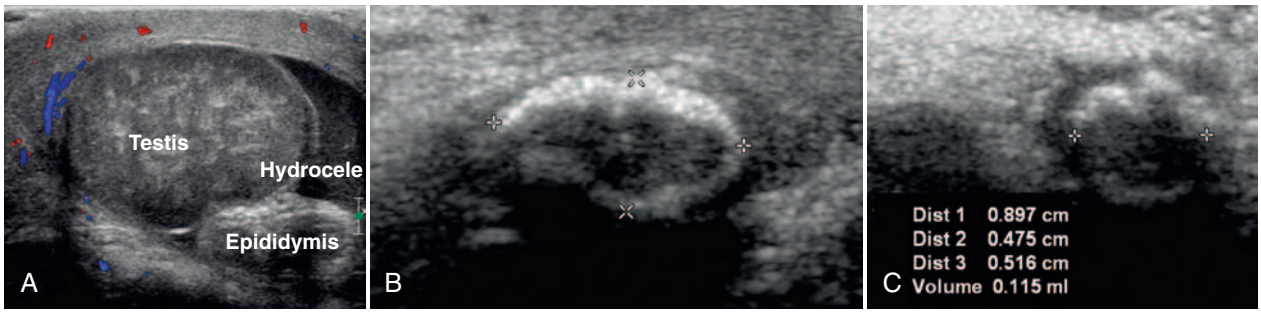

FIG. 54.38 "Missed" Testicular Torsion. (A) This 18-year-old male patient had a 2-day history of left scrotal pain and swelling. Sagittal sonogram demonstrates an enlarged (volume, 22.6 mL), hypoechoic, heterogeneous left testis and epididymis with increased echogenicity and thickening of the tunica albuginea. There is no arterial or venous flow within the left testis or epididymis, although there is hyperemia around the testis. This constellation of findings is consistent with a missed testicular torsion of a subacute nature. A reactive hydrocele is seen around the left testis, which contains complicated fluid. **(B)** and **(C)** Sagittal and transverse sonograms in 5-month-old male infant with missed torsion of the left testis, with history since birth of a normal size right testis *(not shown)* and a small hard left testis. The tiny left testis (volume, 0.1 mL) is shown in the left hemiscrotum, with the tunica albuginea appearing brightly echoic and demonstrating partial shadowing of the ultrasound beam, consistent with delayed (missed) torsion, the insult presumably having occurred in utero.

The gray-scale appearance of the torsed testis ranges from normal (early) to enlarged and hypoechoic secondary to edema (usually after 4-6 hours) and then to a heterogeneous appearance with areas of increased echogenicity secondary to vascular congestion, hemorrhage, and ischemia (usually after 24 hours)[89,115] (Fig. 54.38). The last appearance is also known as **"missed" torsion.** Surgical removal is recommended if the testis is clearly necrotic because if left in situ, the contralateral testis may be adversely affected because of a presumed antibody-induced immunologic process.[97] Other gray-scale findings in the presence of torsion include abnormal orientation of the testis within the scrotum (e.g., transverse lie) as well as abnormally thickened paratesticular structures. The epididymis is usually enlarged because of vascular congestion and may be isoechoic, hypoechoic, or hyperechoic to the testis. There may be scrotal wall thickening and reactive hydrocele formation. Another associated finding includes an enlarged, twisted spermatic cord.[116]

Color Doppler Sonography in Testicular Torsion

To make the diagnosis of acute testicular torsion, the clinician must unequivocally demonstrate absent blood flow in the painful testis and normal blood flow in the contralateral asymptomatic testis. The color flow examination includes careful comparison of the symmetry of flow in both testes. The sensitivity of color Doppler for detecting acute testicular torsion in pediatric patients is 90% to 100%, whereas the sensitivity of scintigraphy approaches 100%.[124,125,127] In technically adequate studies performed on state-of-the-art equipment, the specificity of color flow imaging is almost 100%.[115] Important to note, presence of flow in the painful testis does not exclude the diagnosis of torsion.[126,128,129] In patients with incomplete or partial spermatic cord torsion (≤360 degrees), arterial flow may be demonstrated, although diminished in quantity compared with the asymptomatic testis.[126] Power Doppler, with its greater sensitivity to minimal flow, may be helpful.[120]

In cases of **detorsion,** color Doppler may demonstrate increased flow within the painful testis and paratesticular soft tissues caused by **reactive hyperemia.** This phenomenon may mimic the reactive hyperemia that occurs in inflammatory conditions such as epididymo-orchitis.[126] The clinical findings should help to differentiate between torsion and inflammation. In the patient with acute scrotal pain that spontaneously resolves and in whom color Doppler imaging shows hyperemia, detorsion is likely. Spontaneously or manually reduced torsion does not require emergency surgery, but these patients are at risk for subsequent torsion and can benefit from orchiopexy.[126,130] In cases of **late torsion** (>24 hours), color Doppler typically shows marked hyperemia of the scrotal wall and paratesticular soft tissues with absent testicular flow, analogous to the scintigraphic doughnut sign. Pulsed Doppler waveform analysis is unnecessary for the diagnosis of torsion. The sensitivity of pulsed Doppler for detecting torsion ranges from 67% to 100%. In small children, identification of flow can be difficult in normal testes because of the small size of the testicular arteries. In addition, it may be difficult to distinguish between paratesticular and intratesticular arterial pulsations, and thus scrotal wall hyperemia associated with torsion may be mistaken for normal flow.

With **chronic torsion** the testis will begin to atrophy after 14 days. During this phase, the testis may remain hypoechoic, or it may become hyperechoic if fibrosis or calcification develops.[126] The ipsilateral epididymis is often enlarged and echogenic, often with an accompanying hydrocele. Other causes of **testicular infarction** include trauma, polyarteritis nodosa, and subacute bacterial endocarditis. Extrinsic compression of the cord or testis leading to testicular infarction can occur with hernias,[115] hydroceles,[131,132] and epididymitis.

Acute epididymitis accounts for 28% to 47% of cases of acute scrotal pain in children and is more common in pubertal than prepubertal boys. It is thought that many cases of prepubertal epididymitis are actually cases of **appendiceal torsion,** especially in patients with a negative urine culture.[114] Patients with epididymitis typically have a more gradual onset of pain with fewer

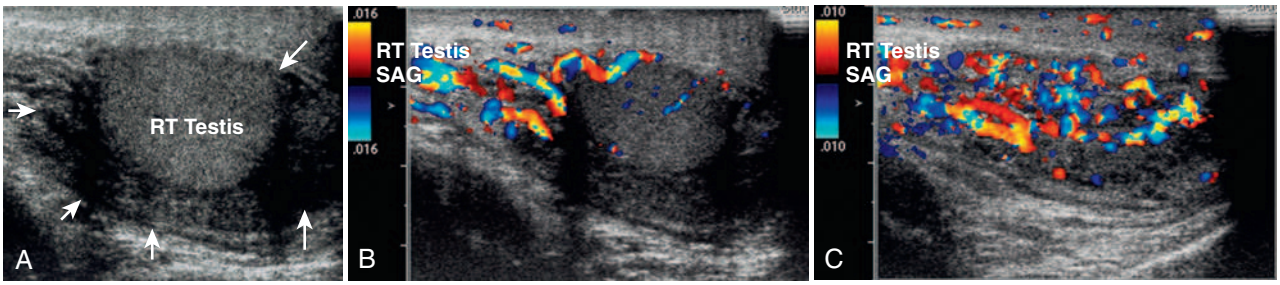

FIG. 54.39 Acute Epididymitis in 8-Year-Old Boy With Right Scrotal Pain. (A) Sagittal sonogram of the right testis shows a normal-appearing testis surrounded posterolaterally by a prominent, hypoechoic heterogeneous epididymis *(arrows)*. **(B)** Longitudinal color Doppler image of the scrotum reveals increased flow in the head of the epididymis with normal flow in the testis. **(C)** Marked hypervascularity is noted throughout the body and tail of the epididymis. Skin thickening is also present.

constitutional symptoms compared with patients with testicular or appendiceal torsion.[115,133]

On sonography, the inflamed epididymis may be focally or diffusely enlarged with coarse echoes. The overall echo pattern is usually decreased, but normal or increased echogenicity may be observed.[134] Associated orchitis is more often diffuse; when focal, however, it is usually close to the inflamed epididymis. The involved portion of the testis is usually hypoechoic and enlarged. On color Doppler imaging, the inflamed epididymis and testis are typically hyperemic (Fig. 54.39), although occasionally, normal flow may be seen in the involved organs.[14,133,134] Pulsed Doppler evaluation is not necessary to establish the diagnosis of acute epididymitis, but when performed, there is elevated diastolic flow in the epididymal arteries, a low-resistance waveform (RI < 0.7 for epididymal arteries), and detectable venous flow.[134,135]

With **orchitis** there may also be abnormally decreased vascular resistance (RI < 0.5) for testicular arteries. In testicular tumors, there may be hyperemia, but the RI is usually greater than 0.5. Therefore **pulsed Doppler** may be useful to differentiate hyperemic tumor from testicular hyperemia.[133,135] Associated sonographic findings include reactive simple or complex hydrocele and skin thickening. Complications of severe epididymo-orchitis include abscess formation and ischemia leading to infarction. Testicular infarction secondary to severe epididymo-orchitis is indistinguishable from infarction secondary to torsion.

Torsion on Color Doppler Ultrasound

Decreased or absent flow
Spontaneous detorsion—normal or increased flow
Incomplete torsion—normal or decreased flow

Because there is overlap in the gray-scale appearance of both testicular torsion and epididymo-orchitis, their differentiation depends on color Doppler imaging.[127,136] **Torsion** typically is characterized on Doppler imaging by decreased or absent flow within the involved testis. The classic appearance of **epididymitis and orchitis** is increased flow within the epididymis and the involved testis if orchitis is present.

Epididymitis on Color Doppler Ultrasound

Increased flow in epididymis
Increased flow in testes if also infected
Ischemia may cause decreased flow

However, the overlap between the two may lead to false-positive or false-negative diagnoses. The hyperemia or normal color flow seen in testes with **spontaneous detorsion** may be confused for epididymitis.[133] **Incomplete torsion** of the testis may reveal normal or decreased color flow.[116] **Ischemia** and **infarction** may also be seen with severe epididymitis, although this is usually less of a diagnostic dilemma because these patients also require surgery. Because Doppler imaging is limited in young patients with testes less than 1 mL, power and contrast agents may be helpful in distinguishing between torsed and normal testes.[124,127]

With **chronic epididymitis** the epididymis becomes enlarged and heterogeneous, and the testicular tunica becomes thickened, appearing as an echogenic hyperemic rim around the testis. Small calcifications may develop in the epididymis and the tunica albuginea. Ultimately, the testis may atrophy and become diffusely or focally hypoechoic.[97] **Isolated orchitis** is unusual and in general has a viral etiology. **Mumps orchitis** is seen in about 30% of prepubertal boys infected with mumps. The testes are usually enlarged and hyperechoic bilaterally during the initial phase, resulting in testicular atrophy and reduced fertility.

Clinical findings should aid in the differentiation of detorsion and scrotal inflammation. Detorsion is more likely in the presence of spontaneously resolved acute scrotal pain and hyperemia on color Doppler imaging. Pulsed Doppler waveform analysis is not necessary to establish the diagnosis of epididymitis, but if used, it shows elevated diastolic flow in the epididymal arteries, a low-resistance waveform (RI < 0.7 for epididymal arteries), and detectable venous flow. Abnormally decreased vascular resistance (RI < 0.5 for testicular arteries) is also seen in orchitis.[135] When surgery is not done to remove an infarcted testis, the infarcted testis will begin to atrophy after 14 days. During this chronic phase, the testis may be hypoechoic, but when fibrosis and calcification develop, the gonad may become hyperechoic.

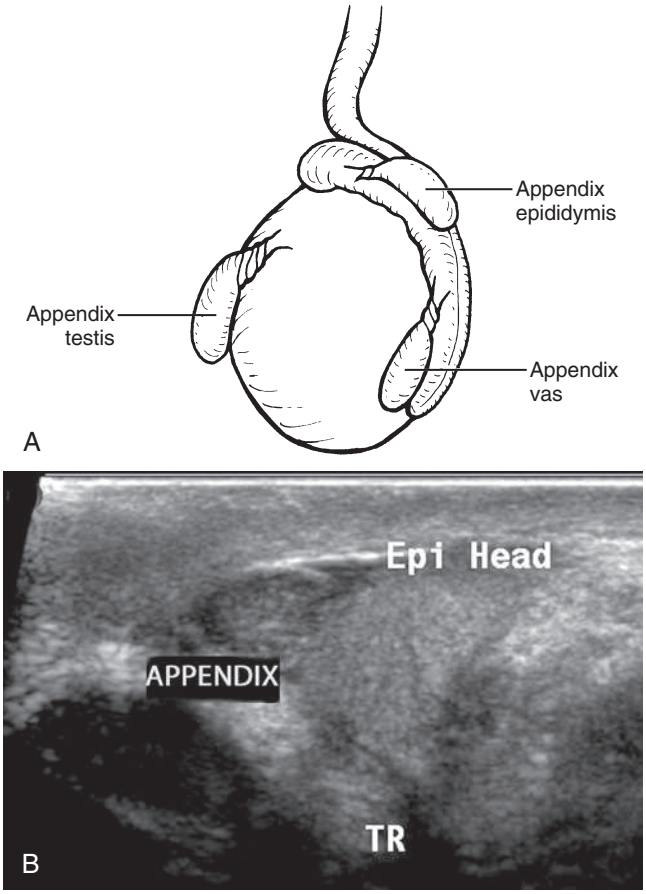

FIG. 54.40 Testicular Appendages. (A) Appendix testis, appendix epididymis, and appendix vas **(vas aberrans of Haller). (B)** Transverse image in a normal male through the epididymal head shows the epididymal appendage to be an isoechoic nodule adjacent to but separate from the head. (**A** with permission from Leape LL. Torsion of the testis. In: Welch KJ, Randolph JG, Ravitch MM, editors. Pediatric surgery. St. Louis, 1986, Mosby.[123])

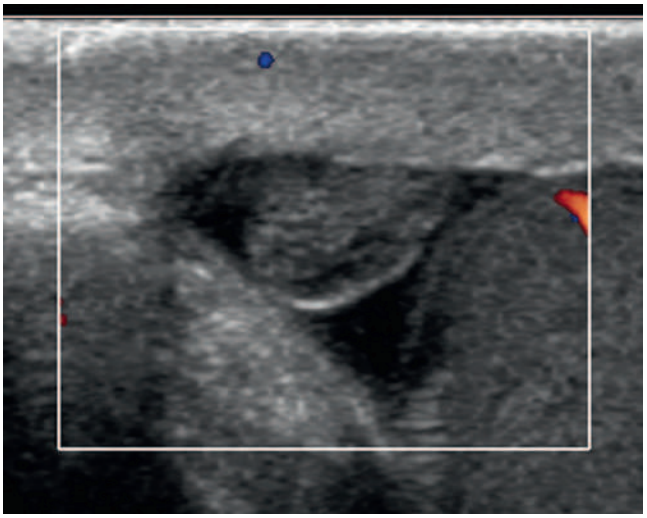

FIG. 54.41 Torsion of Appendix Epididymis in 12-Year-Old Boy With 10 Hours of Scrotal Pain. Transverse power Doppler image through the superior scrotum reveals an enlarged paratesticular mass with no vascularity consistent with a torsed epididymal appendix. Flow is detected in the adjacent testicle, excluding testicular torsion.

In younger boys, epididymitis is more often secondary to genitourinary abnormalities, such as ectopic ureter draining into the vas deferens or seminal vesicles.[137] **Bladder outlet obstruction** (e.g., posterior urethral valve and dysfunctional voiding) can cause reflux of urine into the ejaculatory ducts and lead to epididymitis even if the urine is sterile.[128,138] Epididymitis may also follow **trauma.** With epididymitis, patients typically have a more gradual onset of symptoms and fewer constitutional symptoms than with torsion. There may be mild scrotal tenderness to severe scrotal pain and tenderness with fever and pyuria. In adolescent boys, most cases are secondary to **sexually transmitted organisms** (e.g., *C. trachomatis, N. gonorrhoeae*). In young boys, *Escherichia coli* is found in 10% to 25% of patients.[114,136]

Torsion of a testicular appendage, or appendix epididymis, is the most common cause of acute scrotal pain in prepubertal boys, with an incidence of 26% to 67% peaking between 6 and 12 years of age[88,138,139] (Fig. 54.40). Torsion of a testicular appendage may produce the same clinical signs and symptoms of testicular torsion or epididymitis, but there is generally no nausea and vomiting. If the classic clinical finding of a small, firm, round, mobile, tender paratesticular mass, which often exhibits bluish discoloration visible through the skin **(blue-dot sign),** in the superior aspect of the scrotum is not found, then ultrasound is recommended to avoid unnecessary surgery.[97,140,141] The diagnostic sonographic appearance of a **torsed appendage** is that of a solid, ovoid mass with a variably sized hypoechoic center and hyperechoic rim adjacent to the superior aspects of a testis or epididymis that is avascular[138,142] (Fig. 54.41). Reactive hydroceles, scrotal skin thickening, testicular and epididymal enlargement, and hypoechogenicity may be seen, as well.[142,143] In acute torsion of an appendix, the torsed appendix appears avascular and the epididymis hyperemic. In late torsion (>1 day), a zone of reactive hyperemia may surround the torsed appendage.[140,141] Depending on the extent of the associated inflammatory process, the testis may have normal or increased vascularity.[90,142-145] The testicular appendages are embryologic remnants of blind-ending mesonephric tubules.[138] The **appendix testis** is attached to the tunica albuginea on the superior pole of the testis, and the **appendix epididymis** is located on the epididymal head. Both appendages are pedunculated and thus predisposed to torsion; 92% of males have an appendix testis, and 25% have an appendix epididymis.[97] Most torsed appendices atrophy, with resolution of symptoms with supportive care. Surgery is reserved for persistently symptomatic appendages. Eventually, infarcted appendages shrink in size, may calcify, and may break free to become **scrotoliths.**[90,139]

Trauma to the scrotum most often results from sporting injuries but may be seen in straddle or handlebar injuries, motor vehicle crashes, child abuse, or birth trauma. Trauma can cause a testicular hematoma, fracture, or rupture.[146,147] Testicular rupture is a surgical emergency. Improved salvage rates have been shown if surgery to repair a ruptured testis is performed within 72 hours of the traumatic event.[138] Sonographic findings of rupture (Fig. 54.42) include diffuse parenchymal heterogeneity with loss of a normal, smooth contour and disruption of the tunica

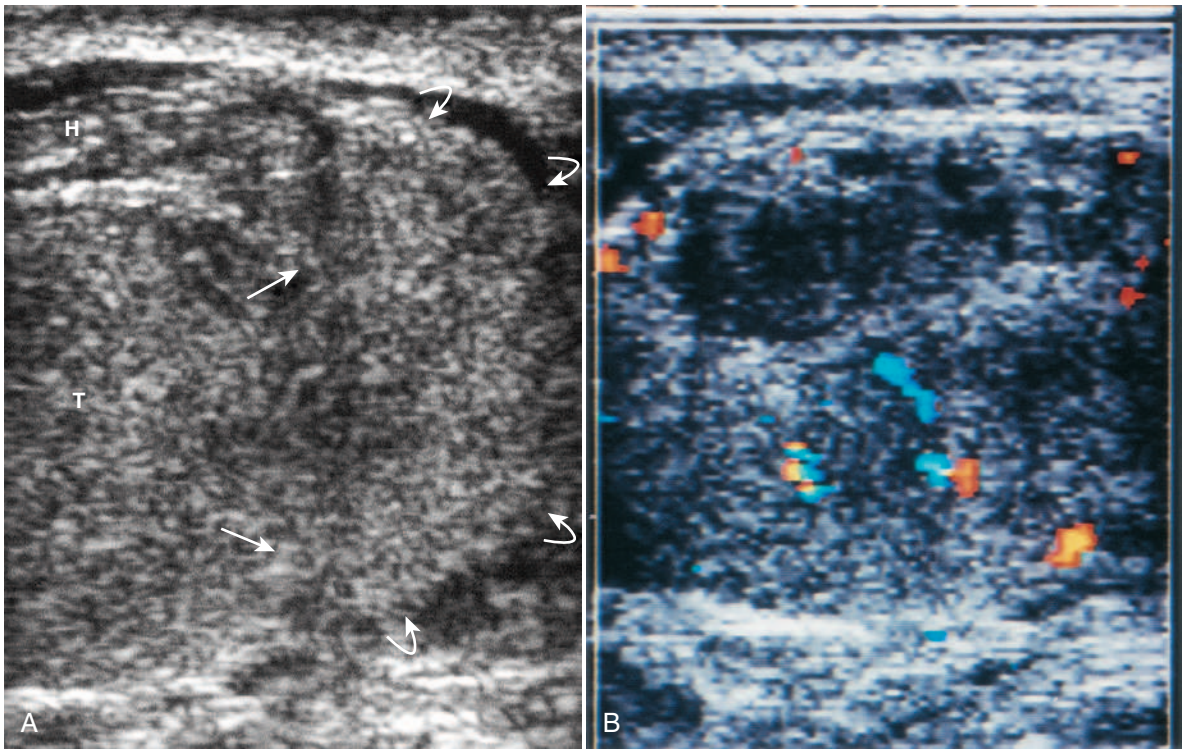

FIG. 54.42 Testicular Rupture in Patient With Scrotal Pain After Groin Kick. (A) Longitudinal view of the inferior aspect of the left testis shows disruption of the tunica albuginea *(straight arrows)* with extrusion of seminiferous tubules *(curved arrows)*. Associated hematocele *(H)* is present. *T,* Testis. **(B)** Color Doppler image of the left testis reveals heterogeneity, representing contusion and hemorrhage within the testicular parenchyma. Intratesticular flow excludes infarction.

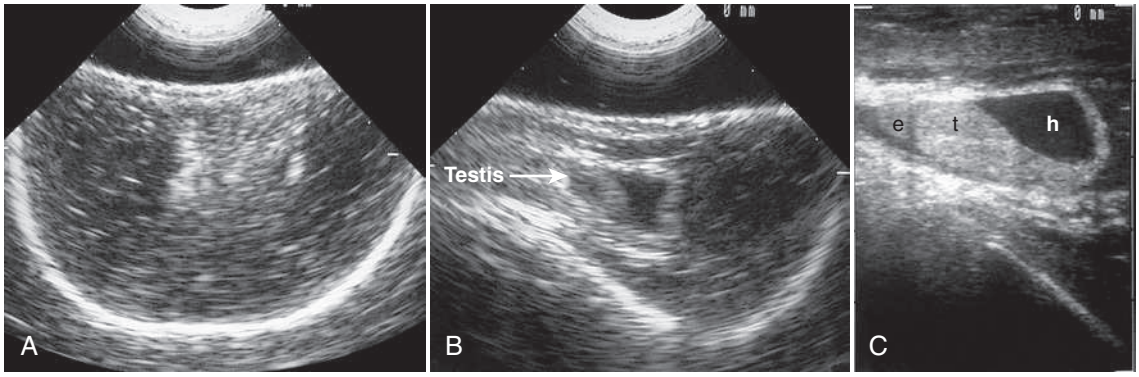

FIG. 54.43 Acute Idiopathic Scrotal Edema With Normal Testes in 4-Year-Old Boy With Sudden, Painless, Scrotal Swelling. Transverse **(A)** sonogram of the scrotum and sagittal (**[B]** and **[C]**) images of the left hemiscrotum using a stepoff pad reveal marked scrotal swelling, normal right testis *(t),* and epididymis *(e)* with an adjacent hydrocele *(h)*. The left testis and epididymis *(not shown)* were also normal.

albuginea, extrusion of seminiferous tubules, and nonvisualization of the testis. The presence of flow on color Doppler imaging in the traumatized testis is helpful in excluding testicular ischemia. Conversely, with testicular fracture, there is discontinuity of the normal testicular parenchyma, but the tunica albuginea remains intact. On ultrasound, a fracture is seen as a hypoechoic line within a normally shaped testicle.[117,129] **Testicular hematomas** appear as avascular masses, the echogenicity of which varies depending on the age of the hematoma.[90] Associated findings include scrotal hematomas, hematoceles, and wall thickening. Complications of testicular rupture include infarction, chronic pain, abscess, and infertility. Although ultrasound may aid in evaluating the traumatized scrotum, controversy surrounds its usefulness because some clinicians question its accuracy and recommend early surgical exploration even in the absence of testicular rupture.[146]

Acute **idiopathic scrotal edema** is a rare cause of scrotal edema that may involve one or both testes. It typically affects boys 5 to 11 years of age, and presenting signs and symptoms include scrotal swelling, erythema, and typically no pain[148] (Fig. 54.43). Swelling may extend to the anterior abdominal wall and perineum. Sonographic findings include marked thickening of the scrotal wall, with normal testes and epididymides.[91,97,148,149] Color Doppler imaging may show normal or slightly increased

flow to the scrotal wall with normal flow to the testes and epididymides.[122,148-151] Acute scrotal edema resolves spontaneously within several days without sequelae.

Scrotal or testicular involvement is estimated in 15% of patients with **Henoch-Schönlein purpura,** a vasculitis involving small vessels and affecting the skin, gastrointestinal tract, joints, and kidneys. Sonographic findings include diffuse swelling of the scrotum and contents with intact testicular flow, obviating the need for surgery in this entity, which usually resolves spontaneously and completely.[152] The echotexture of the testes is normal, but there is generally bilateral epididymal enlargement with a heterogeneous echo pattern, reactive hydrocele, and scrotal wall thickening.[150,151] Color Doppler imaging reveals hypervascularity, especially in the thickened scrotal wall and epididymis with normal intratesticular flow.[153] Careful examination for the classic purpuric rash over the buttocks, lower extremities, and perineum aids in diagnosis.[92]

Scrotal swelling and pain may also be secondary to an intraabdominal process, especially in neonates with a patent processus vaginalis. Various fluids, such as blood, chyle, pus, dialysis fluid, cerebrospinal fluid from ventriculoperitoneal shunt, or other intraperitoneal fluids can drain into the scrotum. Blood from the abdomen can enter the scrotum through extravasation into the tissue planes or through a patent processus vaginalis and can be the presenting sign in patients with adrenal hemorrhage,[109] hepatic laceration, or delayed splenic rupture in a battered child. Scrotal swelling has been reported in association with inflammatory or infectious conditions, such as acute appendicitis, perforated appendicitis,[108] or Crohn disease.[111] Another unusual cause for scrotal swelling is testicular vein thrombosis from a femoral venous line during cardiac catheterization. In the neonate with scrotal swelling and in older children with scrotal swelling of uncertain cause, abdominal sonography may help diagnose a primary abdominal event as the cause for secondary scrotal pathology.[109]

SCROTAL MASSES

Intratesticular Causes

Sonography plays an important role in the evaluation of scrotal masses by confirming the presence of a lesion, determining its site of origin, and characterizing its contents. Ultrasound has almost 100% sensitivity in detecting testicular tumors.[154,155] Ultrasound is able to distinguish intratesticular from extratesticular tumors in 90% to 100% of cases.[103] This distinction is important because most intratesticular masses are malignant and most extratesticular masses are benign. Benign and malignant testicular tumors are the seventh most common neoplasm in children. **About 80% of testicular tumors are malignant.** In the pediatric age group, there are two peak incidences of testicular neoplasms: in children younger than 2½ years (60%) and in late adolescence (40%). The incidence of malignancy in a cryptorchid (abdominal) testis is increased by a factor of 30 to 50. Both **seminomas** (malignant) and **gonadoblastomas** (the majority of which are benign) often develop in dysplastic gonads associated with **undescended testes, testicular feminization syndrome, male pseudohermaphroditism,** and **true hermaphroditism.**[151]

Testicular tumors account for about 1% of all childhood neoplasms and for 2% of solid malignant tumors in boys.[156,157] **Primary testicular neoplasms** are divided into those of germ cell and non–germ cell origin. In prepubertal children, 70% to 90% of primary testicular neoplasms are of germ cell origin, and most of these (66%-82%) are **endodermal sinus tumors** (yolk sac carcinomas). Yolk sac tumor is localized to the scrotum at presentation in most patients (≥80%).[156,157] The remaining 20% of patients have lymphatic spread to regional and retroperitoneal lymph nodes or hematogenous spread to distant sites. Survival is 70% or greater with disease restricted to the testis.[156] **Embryonal cell carcinomas, teratocarcinomas,** and **choriocarcinomas** are more aggressive tumors and metastasize early through lymphatic and hematogenous routes. **Endodermal sinus tumors** occur primarily as a painless scrotal mass in infants 12 to 24 months of age. There may be an associated ipsilateral **hydrocele** (25%) or **inguinal hernia** (21%). The tumor may metastasize to the lungs, especially in older children, but retroperitoneal lymph node metastasis is rare. **Embryonal carcinoma** usually occurs in adolescence or young adulthood. It is highly malignant and usually spreads to retroperitoneal and mediastinal lymph nodes, with hematogenous metastases to the lung, liver, and brain.[151] Elevated serum alpha-fetoprotein levels are common in yolk sac and embryonal cell tumors, whereas elevated serum levels of β-hCG are seen most often with embryonal cell tumors and teratocarcinomas.[156,157]

The remaining germ cell tumors seen in adolescents and adults are benign teratomas, teratocarcinomas, and choriocarcinomas.[156] **Testicular teratoma** is the most common benign germ cell tumor of the testis in infants and young children. Teratomas are most often seen in children younger than 4 years. Patients with testicular neoplasms usually have painless scrotal or testicular enlargement. Pain secondary to torsion or hemorrhage into the tumor is rare.[99] About 85% of benign teratomas contain well-differentiated elements from all three germ cell layers. There are poorly differentiated elements in approximately 15% of these tumors, but even so, the tumor usually has a benign course.[156] In pubertal patients, however, teratomas are often malignant and tend to behave more aggressively, necessitating orchiectomy.

Seminoma, the most common testicular tumor in adults, is rare in children, is most often associated with cryptorchidism, and when present, is usually in adolescents. In general, seminomas are uniformly hypoechoic masses, rarely containing areas of necrosis and hemorrhage[103,158] (Fig. 54.44). On the other hand, **teratomas** and **teratocarcinomas** are complex masses with hypoechoic areas from serous fluid and hyperechoic areas representing fat and calcifications.[103,157-159] The remaining germ cell tumors have nonspecific, variable appearances.[158] When the tunica is invaded by aggressive tumors, the testicular contour appears irregular. Testicular tumors are accompanied by reactive hydroceles in 20% to 25% of cases.[156,160] The scrotal skin is rarely thickened in the presence of tumors, and when observed in the presence of a mass, is usually indicative of an inflammatory process.

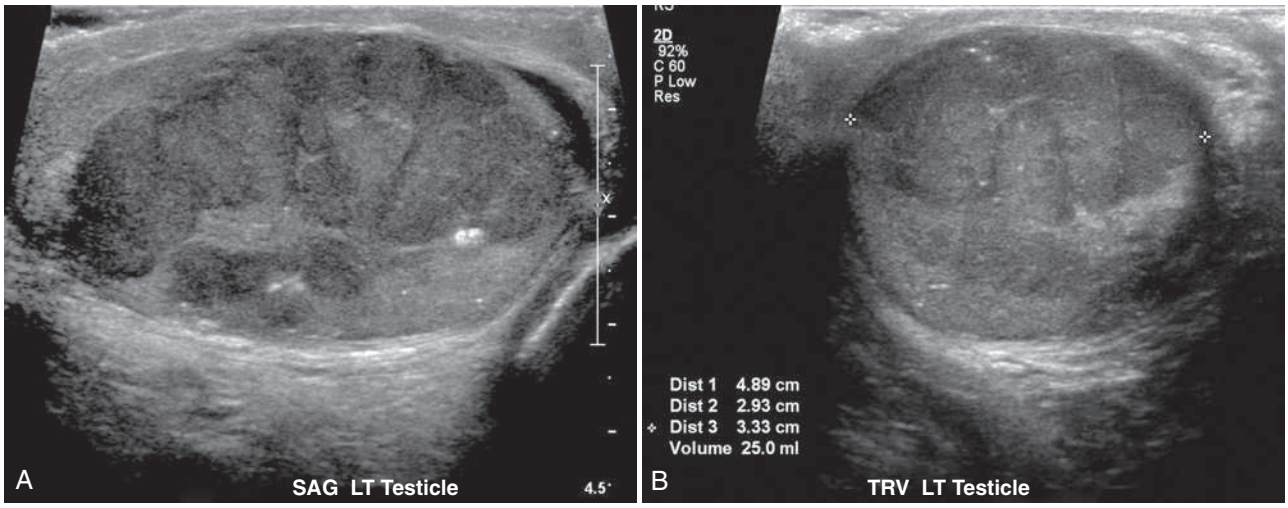

FIG. 54.44 Seminoma in 18-Year-Old Patient With Painless Left Scrotal Mass. (A) and **(B)** Sagittal and transverse sonograms of the left testis demonstrate a testicular volume of 25 mL, with a lobulated, heterogeneous, relatively hypoechoic mass occupying most of the testis with a thin rim of normal testis and a few tiny clusters of calcification, as well as multiple tiny echogenicities both inside and outside the mass **(microlithiasis).**

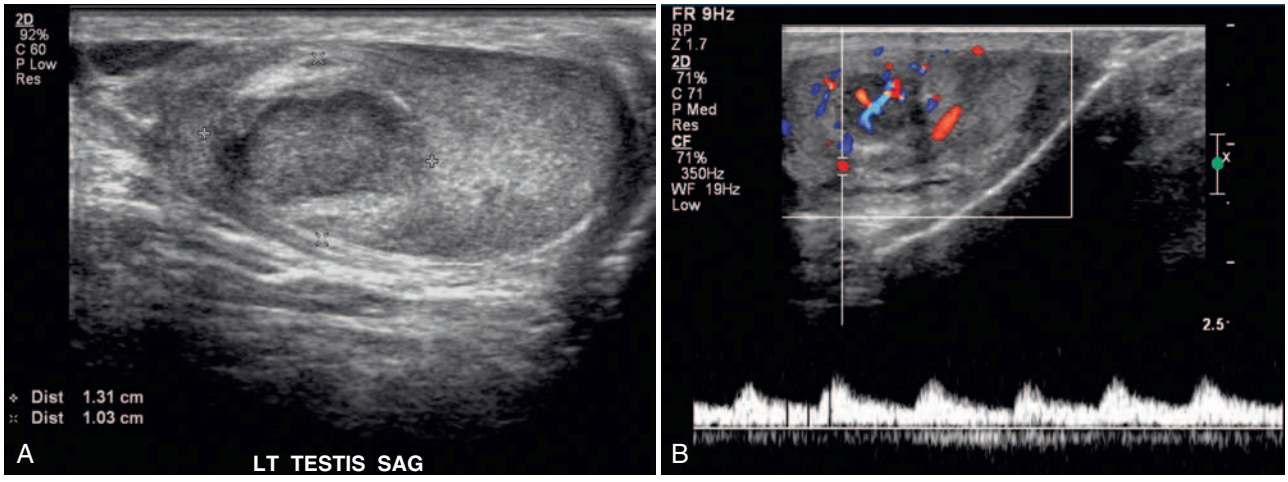

FIG. 54.45 Leydig Cell Tumor in 8-Year-Old Boy With 6-Month History of Precocious Puberty. (A) Sagittal sonogram of left testis demonstrates a 1.3 × 1.0 × 1.0–cm hypoechoic, well-defined mass with peripheral areas of brighter echogenicity. **(B)** Color and spectral Doppler demonstrate arterial flow within the mass.

Doppler is useful in the evaluation of testicular tumors, with degree of vascularity dependent on tumor size. Larger tumors are usually hypervascular, but tumors less than 1.5 cm in diameter tend to be avascular or hypovascular.[161] One may demonstrate tumor vascular displacement or compression or a normal vascular course. In some cases a tumor may not be obvious on gray-scale imaging but is obvious with color Doppler imaging. RI determinations do not aid in diagnosis.[162]

The most common primary non–germ cell tumors of the testes are **Leydig cell and Sertoli cell tumors.**[163] These stromal tumors account for about 10% of testicular neoplasms and are usually hormone secreting.[157] Leydig cell tumors account for about 60% of the non–germ cell tumors, and Sertoli cell tumors about 40%. Leydig cell tumors are typically seen in patients aged 3 to 6 years and produce testosterone, which results in precocious virilization. Patients with Sertoli cell tumors usually develop painless masses within the first year of life. Most are hormonally inactive, but some secrete estrogen, which results in gynecomastia. Both these non–germ cell tumors are slow growing and virtually always benign in prepubertal patients.[151] These tumors are usually small, well-circumscribed hypoechoic lesions[103,158] (Fig. 54.45). In larger lesions, cystic spaces may develop secondary to hemorrhage and necrosis. Orchiectomy is curative, although tissue-sparing surgery is possible for Leydig cell tumors.

Another rare tumor is the **gonadoblastoma,** which is found in phenotypic females with streak gonads or in patients with a male karyotype and testes.[97,156,157] These tumors are usually small, well circumscribed, and hypoechoic.[103,158] In larger lesions, cystic spaces may develop secondary to hemorrhage and necrosis. They are generally benign and are usually found at surgery to remove intraabdominal dysplastic gonads.[156,164] Other benign testicular masses include hemangiomas, neurofibromas, lipomas, fibromas,

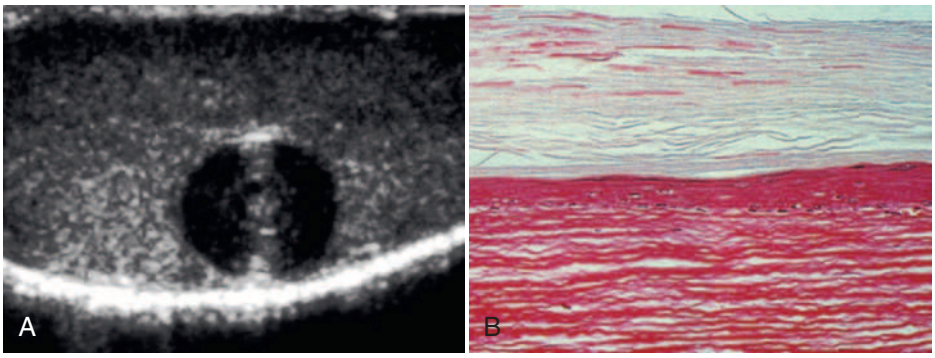

FIG. 54.46 Epidermoid Cyst. (A) Sagittal, magnified sonogram shows a sharply defined lesion composed of multiple circular layers caused by epidermal tissue. **(B)** Histologic specimen. (Courtesy of Janet Strife, MD, Cincinnati Children's Hospital.)

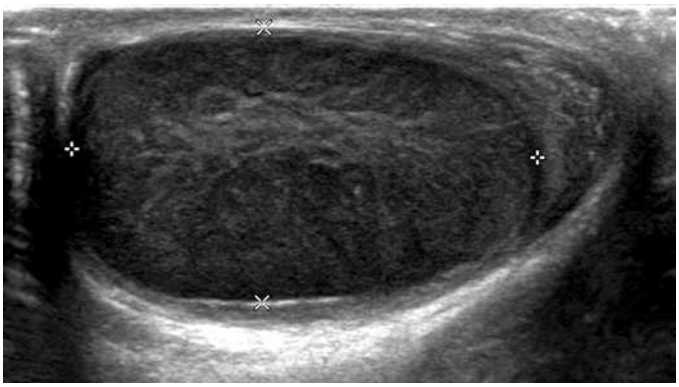

FIG. 54.47 Leukemic Infiltration of Testis in 13-Year-Old Male With B-Cell Leukemia Relapse and an Enlarged Right Testis. Sagittal image reveals a predominately hypoechoic and enlarged (6.7 mL) right testis representing diffuse leukemic infiltration. The normal left testis *(not shown)* was 1.1 mL in volume.

epidermoids, and cysts.[156,165] There are also nonneoplastic lesions that resemble benign solid neoplasms, including **cystic dysplasia, adrenal rests, hematomas,** and **Leydig cell hyperplasia.**[166] The sonographic appearance is quite variable, but characteristically the **epidermoid cyst** is hypoechoic, is well circumscribed, and contains internal echoes or an onion-skin lamellated appearance[167] (Fig. 54.46). **Adrenal rests** appear in the testes when fetal adrenal cortical cells migrate coincidentally with the gonadal tissue during embryologic development. Adrenal rests form tumorlike masses in response to increased levels of adrenocortical hormones, usually caused by **congenital adrenal hyperplasia** or **Cushing syndrome.** On sonography, adrenal rests appear as round, variably sized, hypoechoic, solid intratesticular nodules, usually located near the mediastinum testis.[166,168,169] They are usually bilateral intratesticular nodules that may enlarge or regress over time.[169] The rests resemble Leydig cell tumors histologically and sonographically, but the clinical setting of abnormal hormonal levels associated with hyperfunctioning adrenals usually clarifies the diagnosis.[170]

The testes are a well-known sanctuary site for **leukemia** and **lymphoma** (Fig. 54.47). Clinically silent testicular involvement may be seen in 25% of boys with newly diagnosed acute lymphoblastic leukemia. The testes may be enlarged and homogeneously hypoechoic or may contain focal hypoechoic masses.[171,172] Bilateral involvement is most common, and color Doppler flow is almost always increased, with a disorganized vascularity.[173] **Neuroblastoma, Wilms tumor, Langerhans cell histiocytosis, retinoblastoma, rhabdomyosarcoma,** and **sinus histiocytosis** may metastasize to the testes.[174] The spread may be lymphatic or hematogenous or by direct extension from contiguous tumor. The masses are painless and firm, or there may be diffuse testicular enlargement. The sonographic findings in these testicular tumors are not specific. The involved testicle is usually enlarged with a globular or lobulated contour. Both primary and metastatic tumors may result in focal masses or diffuse involvement. The echogenicity ranges from hypoechoic to hyperechoic, and the parenchyma may be homogeneous or heterogeneous with areas of decreased echogenicity, reflecting hemorrhage or necrosis or areas of increased echogenicity reflecting calcification.[162,171,173,175,176] At times, the echogenicity will be normal.[173] Gray-scale abnormalities may be seen more frequently in the testes of older postpubertal patients with testicular tumors. This may reflect the histologically different tumors affecting different age groups.

Color Doppler imaging is helpful in the evaluation of pediatric testicular tumors. Disorganized hypervascular blood flow was seen in six (86%) of seven patients in a study of pediatric patients with testicular tumors by Luker and Siegel.[173] Although all the patients had testicular enlargement, the testicular echotexture in four (57%) of seven patients was normal; thus color Doppler was helpful in depicting the tumor in these patients. Hypervascularity with normal echogenicity may be seen in orchitis; however, orchitis without epididymitis is uncommon, especially in prepubertal children, and history helps in distinguishing the two entities because tumor frequently manifests as an enlarged, nontender mass.[173] The management of testicular tumors in childhood has evolved during the last 20 years as a result of a multicenter retrospective survey that identified the preoperative and intraoperative criteria of nonmalignancy and analyzed the results of conservative management of a testicular mass. Valla[177] reported the findings of the Study Group in Pediatric Urology. A testicular tumor in children had a 50% chance of being benign, and ultrasound results were more conclusive than clinical criteria in limiting the preoperative diagnosis to teratoma, epidermoid cyst, and, particularly, simple cyst. The group concluded that treatment selection according to clinical, biologic, radiologic, and frozen-section findings should allow appropriate decision

FIG. 54.48 Bilateral Hydroceles in Newborn. Transverse view of the scrotum shows both testes outlined by large, anechoic fluid collections.

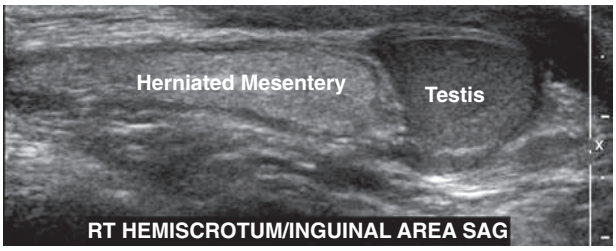

FIG. 54.49 Inguinal Hernia in Baby With Right Inguinal Mass. Sagittal sonogram of the right hemiscrotum and inguinal area demonstrates brightly echoic fatty mesentery extending from the peritoneal cavity into the right inguinal canal, abutting the right testis.

making regarding testis-sparing surgery without additional oncologic risk, and with an esthetic, psychological, and functional benefit.[177] Patients with **solitary simple cysts,** which are uncommon testicular masses, have painless scrotal enlargement.[178] The cysts are anechoic masses with smooth walls, no nodular or solid elements, and increased sound transmission. They differ from epidermoid cysts and other cystic neoplasms that contain internal echoes. These simple cysts are benign and thus may be followed with sonography. In infants, growth of the cyst may cause compression and replacement of testicular parenchyma. Thus early conservative surgery with removal of the cyst and preservation of the adjacent parenchyma may be performed.[179] Simple enucleation suffices when sonography demonstrates that the cyst is undoubtedly simple.

Extratesticular Causes

Hydroceles are an abnormal collection of serous fluid in the scrotal sac and represent the most common cause of painless scrotal enlargement in children. Hydroceles may be congenital or acquired. In neonates and infants, virtually all hydroceles are congenital. As the testis descends into the scrotum, it becomes invested with a portion of peritoneum, the **processus vaginalis.** At birth, the processus vaginalis normally closes off proximally and forms the **tunica vaginalis.** A variable amount of peritoneal fluid may be trapped within the tunica vaginalis, forming a stable hydrocele in the neonate. This fluid is resorbed slowly during the first 18 months of life. If the processus vaginalis fails to close, an open communication exists between the peritoneal cavity and the scrotum. This can result in a **scrotal hernia** or a **communicating hydrocele** with a varying amount of fluid. Extension of the hydrocele into the pelvis can be seen in a communicating hydrocele. Surgical ligation is required to close the **patent processus vaginalis.**[180]

The usual sonographic appearance of a hydrocele is anechoic fluid in the scrotum (Fig. 54.48). In older children, hydroceles are usually acquired. The presence of echoes or septations in the fluid suggests a **reactive hydrocele** caused by infection, torsion, trauma, or tumor. Other collections, such as chronic hemorrhage or lymphoceles (associated with ipsilateral renal transplantation), may be seen and mistaken for a reactive hydrocele. These result from lymphatic disruption with leakage of lymph fluid into the tunica vaginalis or from direct extension of a periallograft lymphocele through the inguinal canal.[181] They appear on ultrasound as septated fluid collections surrounding the testes.

Hematoceles are collections of blood in the tunica vaginalis. Most are the result of surgery or trauma,[180] but they may also be secondary to bleeding disorders or malignant tumors.[182,183] They appear on sonography as fluid collections with low-level internal debris, septations, or fluid-debris levels. Scrotal wall thickening may be present with chronic hematoceles.

Scrotal hernia is a common mass in boys that is usually evident clinically. **Inguinal hernias** are almost always the result of a patent processus vaginalis **(indirect hernia)** into the scrotal sac. Hernias are more frequently right-sided because the right processus vaginalis closes after the left. Sonography may demonstrate bowel loops in the scrotum, normal testis, and epididymis, and an echogenic area representing herniated omentum[184] (Fig. 54.49). Lack of peristalsis within herniated bowel loops suggests ischemia. Ischemia and incarceration (nonreducibility of bowel loops) convert an elective procedure to emergent surgery. Extratesticular pathology, such as **hematoceles, loculated hydroceles, scrotal abscesses,** and **urinomas,** can mimic fluid-filled bowel loops, and **herniated omentum** can be confused for a primary scrotal mass. Thus examination of the inguinal canal and the region of the Hesselbach triangle is recommended to evaluate for a hernia sac and exclude a primary scrotal pathology.

Other scrotal masses often identified in adolescent and postpubertal males are varicoceles, spermatoceles, and epididymal cysts.[184] **Varicoceles** represent dilated veins in the pampiniform plexus positioned posterior to the testis. The majority (85%-98%) are on the left side.[185] The presence of varicoceles in young boys is uncommon and may result from compression of the spermatic cord by tumor. Sonographic evaluation reveals small serpentine structures that display flow on color Doppler imaging and venous waveforms on spectral Doppler imaging. Augmentation of Doppler flow occurs with a Valsalva maneuver and upright positioning (Fig. 54.50). **Spermatoceles** occur in the epididymal head and consist of fluid, spermatozoa, and sediment. **Epididymal cysts** contain no spermatozoa and can occur in the epididymal head, body, or tail. Sonographic examination shows round structures with good through transmission and well-defined back

FIG. 54.50 Left Varicocele in Postpubertal Patient Complaining of Feeling "Wormlike" Structures in Left Side of Scrotum. (A) Transverse color Doppler sonogram of the left testis shows multiple areas filled with color in the paratesticular tissues lateral to the normal-appearing left testis. **(B)** Sagittal scan of the paratesticular tissues demonstrates prominent, anechoic, tortuous, tubular structures. **(C)** Exuberant color Doppler flow and enlargement of these paratesticular veins is seen after Valsalva maneuver.

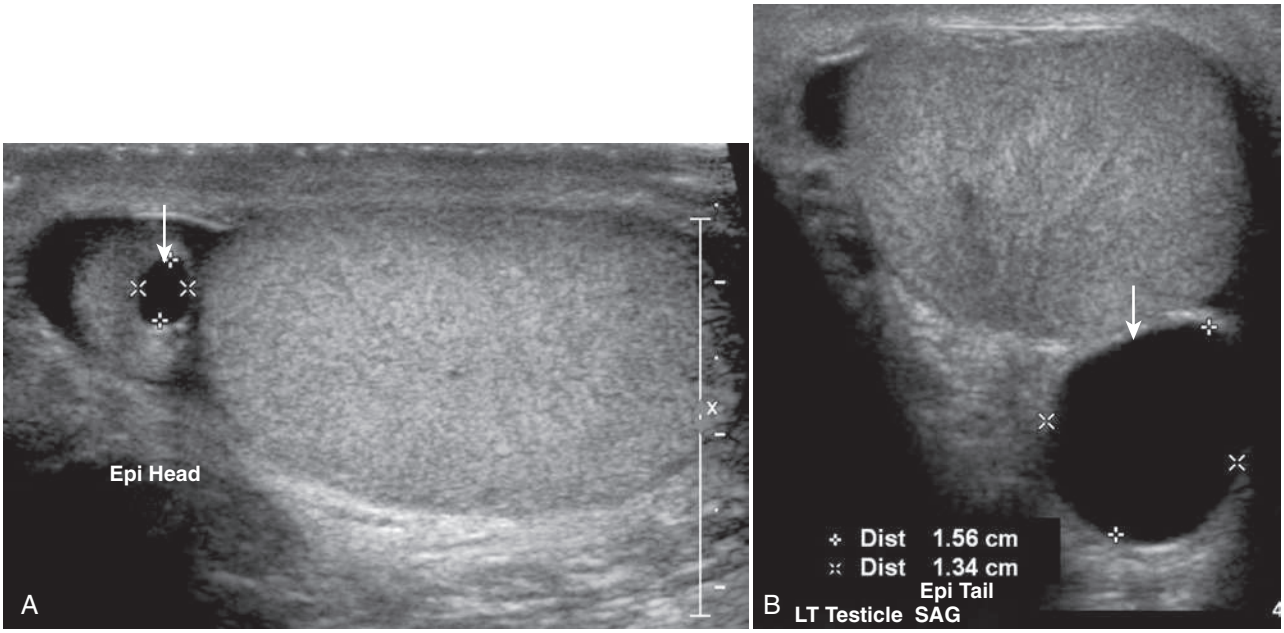

FIG. 54.51 Epididymal Cysts. Teenage boy with left-sided scrotal masses. **(A)** Sagittal scan demonstrates a small cyst *(arrow)* in the head of the epididymis and a normal left testis. **(B)** Transverse scan of the inferior aspect of the left testis demonstrates a larger cyst *(arrow)* in the adjacent tail of the epididymis. A small hydrocele is present.

walls, which may contain debris (Fig. 54.51). They range in size from a few millimeters to several centimeters.[182] Other cystic lesions include **spermatic cord cysts** and **cysts of the tunica vaginalis.**

Paratesticular Tumors

Both benign and malignant paratesticular tumors are rare and typically involve the epididymis or spermatic cord. They may also arise in the appendix testis or the tunica. About 30% of spermatic cord tumors are malignant and in general are caused by **embryonal rhabdomyosarcoma**[156,186] (Fig. 54.52). This tumor usually appears as a rapidly growing, painless, intrascrotal mass in boys younger than 5 years. Up to 40% have retroperitoneal lymph node involvement at diagnosis.[186] Other malignant lesions include **metastatic neuroblastoma, lymphoma, leiomyosarcoma,** and **fibrosarcoma.**[175,187,188] They are usually well-defined, homogeneous or heterogeneous, hypoechoic solid masses. Benign paratesticular tumors include **fibromas, hemangiomas, lipomas, leiomyomas, lymphangiomas,** and **neurofibromas.** Both benign and malignant paratesticular tumors may appear hypoechoic,

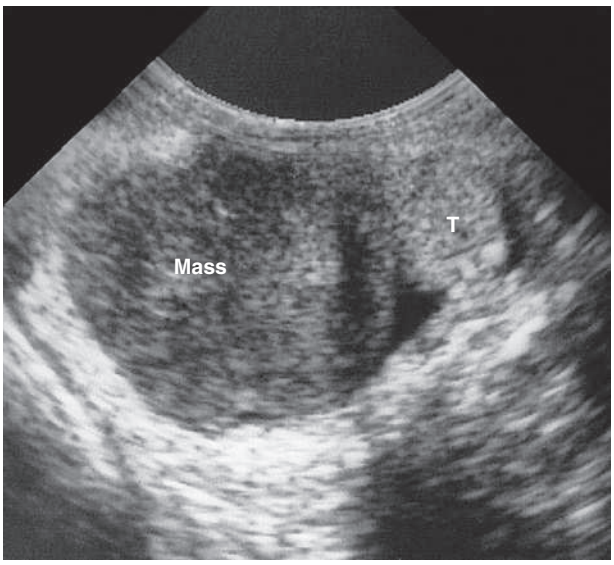

FIG. 54.52 Paratesticular Rhabdomyosarcoma. Large, solid mass was identified medial to left testis *(T)* with a small hydrocele in this 18-month-old boy.

hyperechoic, or heterogeneous. Ultrasound cannot clearly distinguish benign from malignant lesions.[189] Increased vascularity on Doppler imaging in a paratesticular rhabdomyosarcoma may mimic that seen with epididymitis.[186] Thus follow-up should be performed in cases of suspected epididymitis to ensure resolution of any mass because rhabdomyosarcoma can manifest this way.[189]

The most common benign paratesticular masses include adenomatoid tumors as well as fluid-filled masses, such as **spermatoceles** and cysts of the epididymis or tunica albuginea. **Adenomatoid tumors** are usually seen in the body of the epididymis and less often in the spermatic cord or testicular tunics. They are solid, well-circumscribed, with variable echogenicity. **Epididymal cystadenomas** (associated with **von Hippel–Lindau disease**)[190] and **lymphangiomas** are septated cystic masses.[182,191] With **splenogonadal fusion,** a rare congenital anomaly, a mass of ectopic splenic tissue may be noted adjacent to the left testis.[192]

Focal calcifications from meconium periorchitis may appear as palpable scrotal masses (Fig. 54.53). These dystrophic calcifications result from in utero bowel perforation during the second or third trimester of gestation. Sterile intestinal contents (meconium) leak into the peritoneal cavity and enter the scrotum through a patent processus vaginalis and elicit a foreign body inflammatory response that results in focal calcifications. As with calcification elsewhere, these areas are echogenic with strong posterior shadows and may mimic a solid neoplasm, particularly a teratoma. Differentiation is based on the finding of additional intraperitoneal calcifications on sonography or plain film radiography of the abdomen.[189] Eventually, spontaneous regression of these calcifications occurs, and thus conservative management is recommended.[193] Differential diagnosis of scrotal or testicular calcifications in the pediatric patient includes teratoma, gonadoblastoma, Leydig cell tumor, testicular microlithiasis, calcified loose bodies, phleboliths, meconium peritonitis, calcified hematomas, and postinflammatory or infectious scrotal calculi.

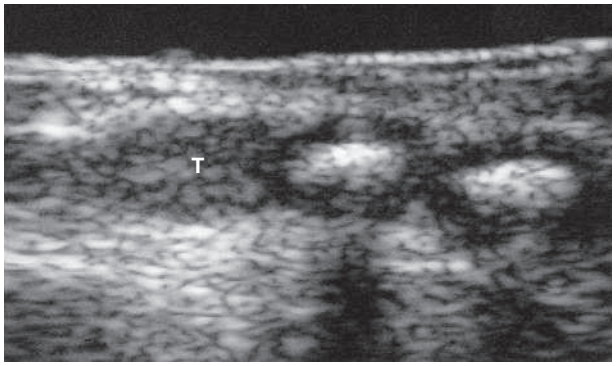

FIG. 54.53 Meconium Periorchitis in 5-Year-Old Boy With Painless Scrotal Masses. Sagittal view of the left hemiscrotum using a stepoff pad shows two well-defined, oval, brightly echogenic masses with hypoechoic halos and acoustic shadows, which lie inferior to the normal left testis *(T)*. (With permission from Mene M, Rosenberg HK, Ginsberg PC. Meconium periorchitis presenting as scrotal nodules in a five year old boy. J Ultrasound Med. 1994;13[6]:491-494.[193])

Testicular microlithiasis is an asymptomatic condition that has a characteristic sonographic appearance and usually is discovered incidentally. It has been reported in normal patients and those with **Down syndrome, cryptorchidism,** and **Klinefelter syndrome.** Testicular microlithiasis represents calcified debris within the seminiferous tubules. The cellular debris has a calcific core and surrounding lamellated collagen, resulting from a failure of Sertoli cell phagocytosis. On ultrasound there are tiny (1-3 mm), hyperechoic, most often nonshadowing foci[189] (Fig. 54.54, Video 54.5). The number of echogenic foci within the testis can range from a few to many, but at least five microliths on a single image should be visualized to meet ultrasonographic criteria.[194] The association between testicular microlithiasis and malignancy remains unclear. Ultrasound follow-up should be considered in symptomatic patients, in patients with a history of malignancy, or on patient request. Self-examinations can be used to follow asymptomatic patients.[195]

LOWER URINARY TRACT

Congenital Anomalies

Duplication anomalies of the collecting systems and ureters are the most common congenital anomalies of the urinary tract. In **complete ureteral duplication** the lower ureter inserts orthotopically into the trigone, often resulting in vesicoureteral reflux. The upper-pole ureter usually inserts ectopically in the bladder (at the bladder neck) or in the trigone (inferomedial to the normal location). It can also insert into the urethra, vagina, or uterus

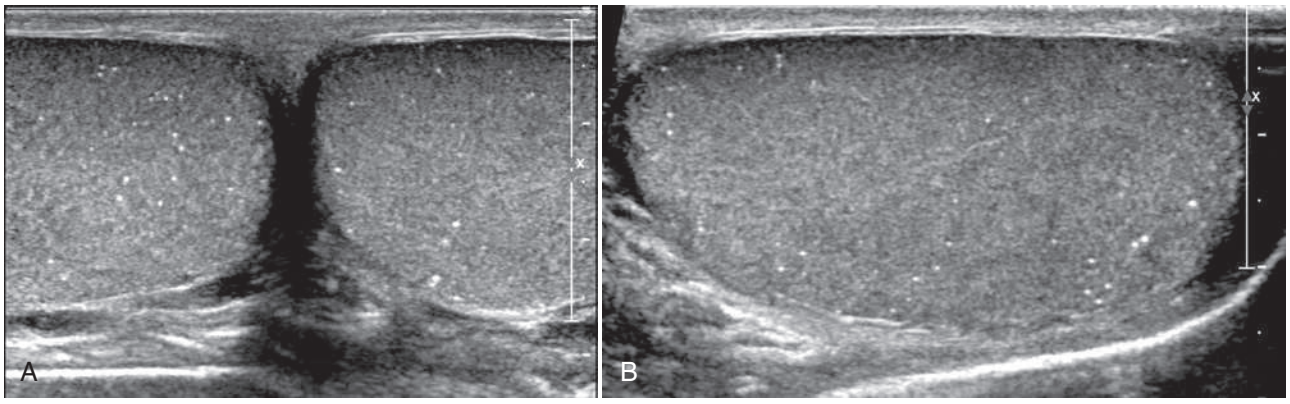

FIG. 54.54 Testicular Microlithiasis. Transverse image of both testicles **(A)** and sagittal image of the right testicle **(B)** in an 18-year-old male with testicular pain reveal multiple punctate echogenic foci without acoustic shadowing. See also Video 54.5.

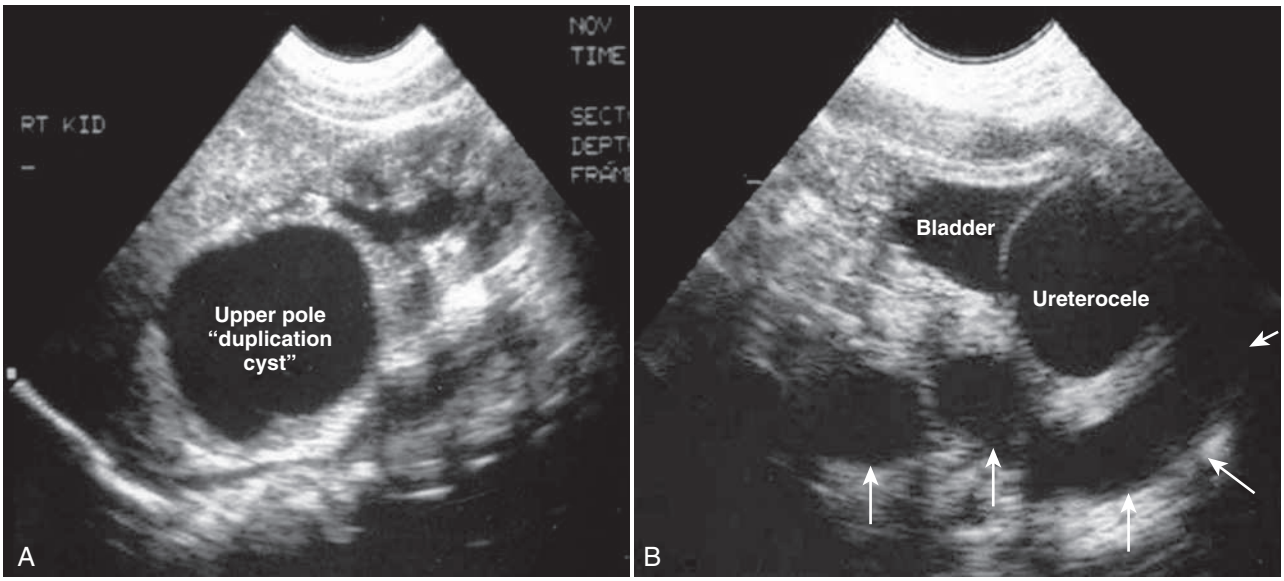

FIG. 54.55 Ectopic Ureterocele. Obstructed upper-pole moiety of a duplex kidney in a baby with urinary tract infection. **(A)** Sagittal sonogram of right kidney showing upper-pole "duplication cyst" and mild dilation of the intrarenal collecting system in the lower pole surrounded by normal parenchyma. **(B)** Sagittal view of the pelvis demonstrates a large, ectopic ureterocele within the urinary bladder, which is in continuity with the greatly dilated, tortuous, upper-pole ureter *(arrows).*

in girls, resulting in urinary dribbling. In boys the **ectopic ureter** can insert in the proximal urethra, seminal vesicle, vas deferens, or ejaculatory duct. Urinary incontinence is not a presenting symptom in boys because the ectopic insertion is always proximal to the external sphincter. Duplication anomalies are often asymptomatic; **urinary tract infection** (UTI) is the most common initial presentation. The upper-pole moiety often becomes obstructed as a result of an **ectopic ureterocele.** Sonography demonstrates a dilated upper-pole collecting system and ureter that ends distally as a well-defined, thin-walled cystic protuberance into the bladder base (Fig. 54.55). The lower-pole system is often dilated secondary to reflux.[196] Less frequently, the lower-pole moiety may be dilated from obstruction of the ureteral orifice by the adjacent ectopic ureterocele or because of vesicoureteral reflux. About 10% to 20% of ectopic ureters are associated with a single collecting system (Fig. 54.56). The renal parenchyma associated with an ectopic ureter may be dysplastic (containing echogenic parenchyma, loss of corticomedullary junction, and variably sized cysts).

Sonography is well suited for screening siblings of patients with **vesicoureteral reflux,** who are at greater risk of having reflux than the general population. Giel and colleagues[197] showed that given the seemingly innocuous nature of vesicoureteral reflux in older asymptomatic siblings of known patients with reflux, observation alone in this group is an acceptable form of management.

Posterior urethral valves are a common cause of urinary tract obstruction in boys. Signs and symptoms at presentation include palpable flank masses caused by hydronephrosis or urinoma, poor urine stream, UTI, and failure to thrive. On sonography, the bladder has a thick, trabeculated wall, and the posterior urethra is dilated (Fig. 54.57). There may be marked hydronephrosis with dilated, tortuous ureters secondary to vesicoureteral reflux. Occasionally, the reflux is unilateral, resulting

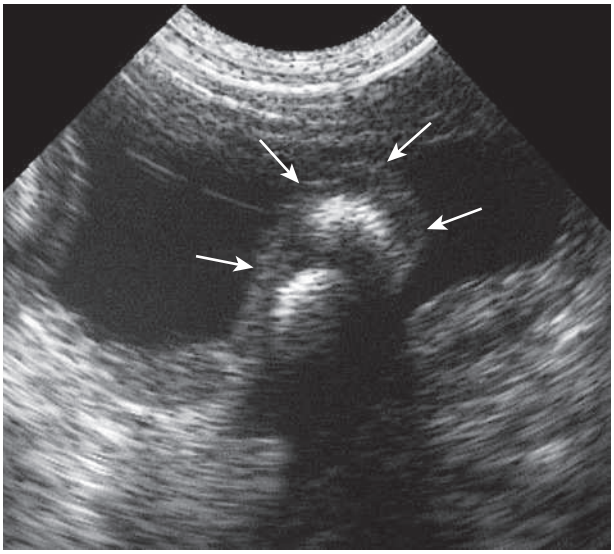

FIG. 54.56 Simple Ureterocele With Stones in 7-Year-Old Child With Recent Mild Trauma. Sagittal view of the left side of the bladder demonstrates a simple ureterocele *(arrows)* protruding into the bladder lumen, containing two brightly echogenic, shadowing calculi.

Anterior urethral diverticulum
Posterior urethral polyp

in ipsilateral hydroureteronephrosis. The renal parenchyma may be thin and the echogenicity may be abnormally increased as a result of long-standing reflux or obstructive nephropathy. Many infants with posterior urethral valves have secondary renal dysplasia, manifesting on sonography as brightly echogenic kidneys usually devoid of corticomedullary differentiation and often containing tiny cysts.[198] The appearance of the renal parenchyma has predictive value in infants with posterior urethral valves with regard to potential renal function.[199]

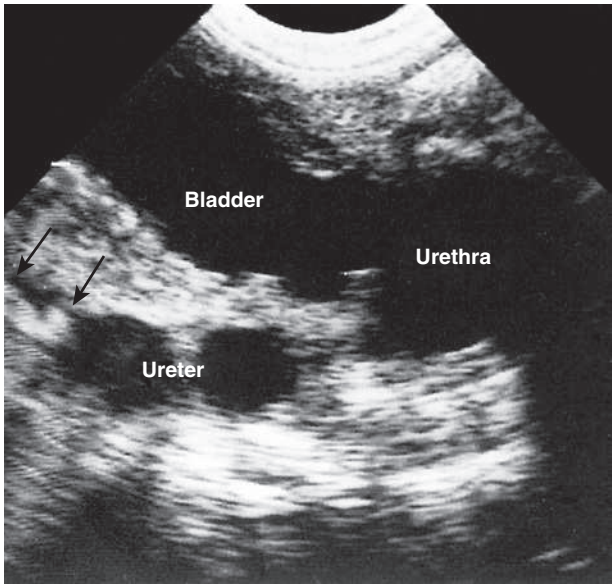

FIG. 54.57 Posterior Urethral Valves in Newborn Boy. Midline sagittal scan shows irregularly thickened bladder wall (caused by obstruction), massively dilated posterior urethra, and moderately dilated tortuous distal ureter. Arrows show the serosal surface of the bladder wall. (With permission from Rosenberg H. Sonography of pediatric urinary tract abnormalities. Part I. Am Urol Assoc Weekly Update Series. 1986;35: 1-8.[231])

The **prune-belly syndrome** (abdominal muscle deficiency or **Eagle-Barrett syndrome**) is another common cause of urinary tract obstruction in infant boys. The syndrome is composed of a triad of absent abdominal musculature, bilateral hydroureteronephrosis, and cryptorchidism. There are three forms of urinary tract abnormality. In the most severe form, urethral atresia and renal dysplasia are present; these children have a very poor prognosis and typically die in infancy. Associated congenital anomalies are frequent and include intestinal malrotation or atresia, imperforate anus, Hirschsprung disease, congenital heart defects, skeletal anomalies, and cystic adenomatoid malformation of the lung. In the less severe form of urinary tract abnormality, the bladder is large and atonic, and there is bilateral hydroureteronephrosis, impaired renal function, and no urethral obstruction. The changes are thought to be caused by a neurogenic dysfunction rather than a mechanical obstruction. There are usually no associated congenital anomalies, and these infants have a better prognosis.[200] In the mildest type of prune-belly syndrome, the urinary tract is only mildly affected.

Other uncommon forms of bladder outlet obstruction include anterior urethral valves, urethral duplication, congenital urethral stricture, anterior urethral diverticulum, posterior urethral polyp[201] (Fig. 54.58), and stones[202] (Fig. 54.59). Rarely, a giant bladder diverticulum many descend below the bladder neck and lead to bladder outlet obstruction.[203] Voiding cystourethrography (VCUG), in addition to sonography, is usually necessary to identify these urethral obstructions.

The Ureter

The ureters cannot be visualized on ultrasound unless they are dilated. Real-time sonography can sometimes differentiate between

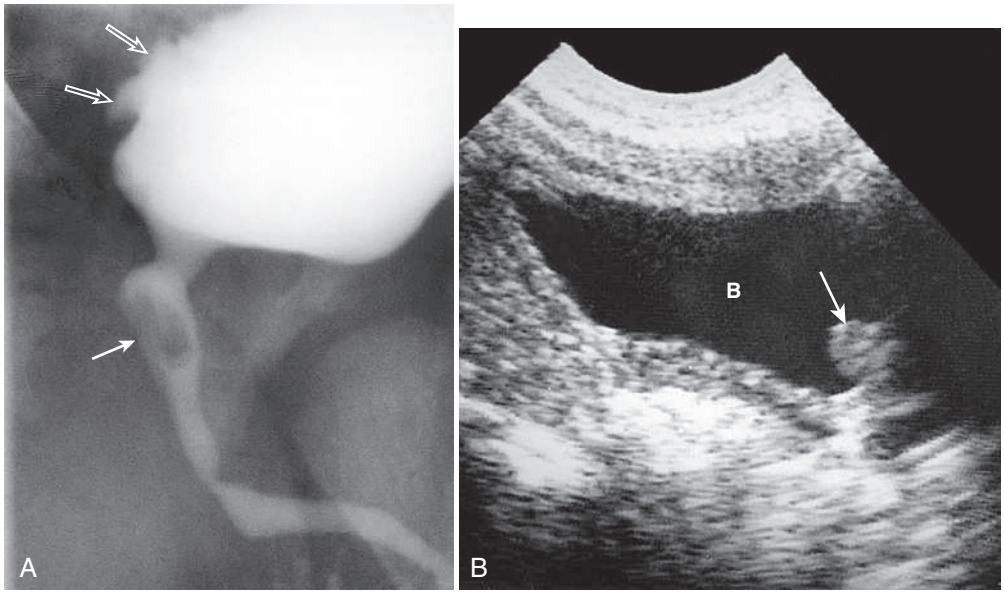

FIG. 54.58 Congenital Urethral Polyp That Caused Prenatal Hydroureteronephrosis in Newborn Boy. (A) Voiding cystourethrography demonstrates an oval, polypoid mass in the posterior urethra *(solid arrow)* and posterior bladder wall thickening *(open arrows)*. **(B)** Sagittal sonogram of the bladder *(B)* 4 months later shows a solid polypoid mass *(arrow)* protruding from the bladder neck into the bladder lumen. (With permission from Caro PA, Rosenberg HK, Snyder 3rd HM. Congenital urethral polyp. AJR Am J Roentgenol. 1986;147[5]:1041-1042.[201])

mechanical obstruction and vesicoureteral reflux. In **ureterovesical junction obstruction** the distal ureter is dilated but may taper, making it difficult to visualize at the level of the bladder trigone, and at times, ureteral peristalsis is absent (Fig. 54.60). Sonography is useful for identification of a stone as the cause of distal ureteral obstruction (Fig. 54.61). With **vesicoureteral reflux** the ureterovesical junction is often gaping or patulous, and active peristalsis is demonstrated.[94,204] In patients with a dilated tubular structure posterior to the bladder, Doppler ultrasound can be used to differentiate a ureter, artery, or vein. In addition, color Doppler sonography allows reliable visualization of the **ureteric jet phenomenon.**

Marshall and colleagues[205] found that the distance of the ureteric orifice from the midline of the bladder correlated with vesicoureteric reflux when the mean distance was 10.25 mm ± 2.40 SD. Jequier and colleagues[206] used color Doppler imaging to show that (1) the duration of the ureteric jet varied from 0.4 to 7.5 seconds and depended largely on fluid intake, (2) the direction of the normal jet was anteromedial and upward, (3) jets from refluxing ureters could appear normal, and (4) Doppler analyses of the ureteric jet do not allow either the diagnosis or the exclusion of vesicoureteral reflux.[206] Berrocal and colleagues[207] demonstrated that cystosonography with SHU 508A appears comparable to VCUG in the depiction of vesicoureteral reflux. Darge and colleagues[208] showed that the number of VCUG procedures was significantly reduced as a result of implementation of voiding urosonography using the intravesical application of the ultrasound contrast agent Levovist.

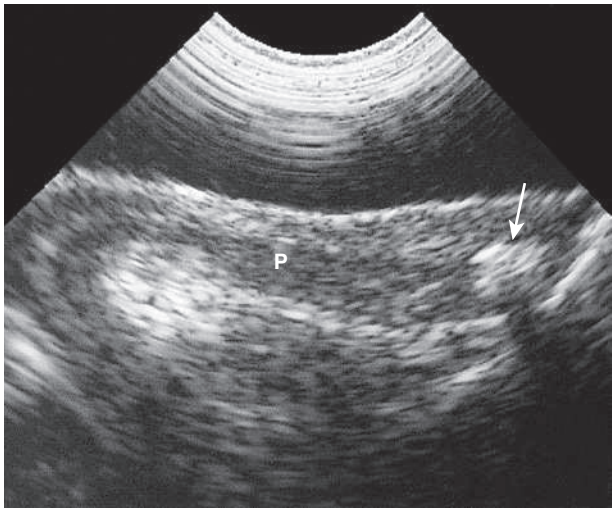

FIG. 54.59 Urethral Stone in Fossa Navicularis. Sagittal image of penis *(P)* using stepoff pad reveals a 7-mm calculus *(arrow)* in the distal urethra of this 6-year-old boy with gross hematuria, dysuria, and suprapubic pain.

Neurogenic or Dysfunctional Bladder

Urinary tract sonography has become a routine screening procedure in children with neurogenic or dysfunctional bladders. The most common cause of neurogenic bladder in children is **myelomeningocele.** Other acquired forms of dysfunctional bladder include **traumatic paraplegia, cerebral palsy, spinal cord tumor,** and **encephalitis** or **transverse myelitis.** These children have a higher incidence of UTI, bladder stones, and reflux. Sonography of a neurogenic bladder demonstrates an irregularly thickened, trabeculated bladder wall, often with multiple diverticula. Echogenic material within the bladder lumen may represent complications of infection, hemorrhage, stone formation, or foreign body insertion via the urethra.[209] Ultrasound can also be used to assess the patient's ability to empty the bladder spontaneously or after Credé maneuver or catheterization. Residual urine volumes can be measured.[210]

Urachal anomalies can be identified on ultrasound when there is persistence of the embryonic tract between the dome of the bladder and umbilicus. Cacciarelli and colleagues[211] identified a normal urachal remnant in 62% of bladder sonograms in children.[10,212] A normal urachal remnant appears as a small (6 mm depth × 13 mm length × 12 mm width), elliptical, hypoechoic structure located posterior to the rectus abdominis muscle and

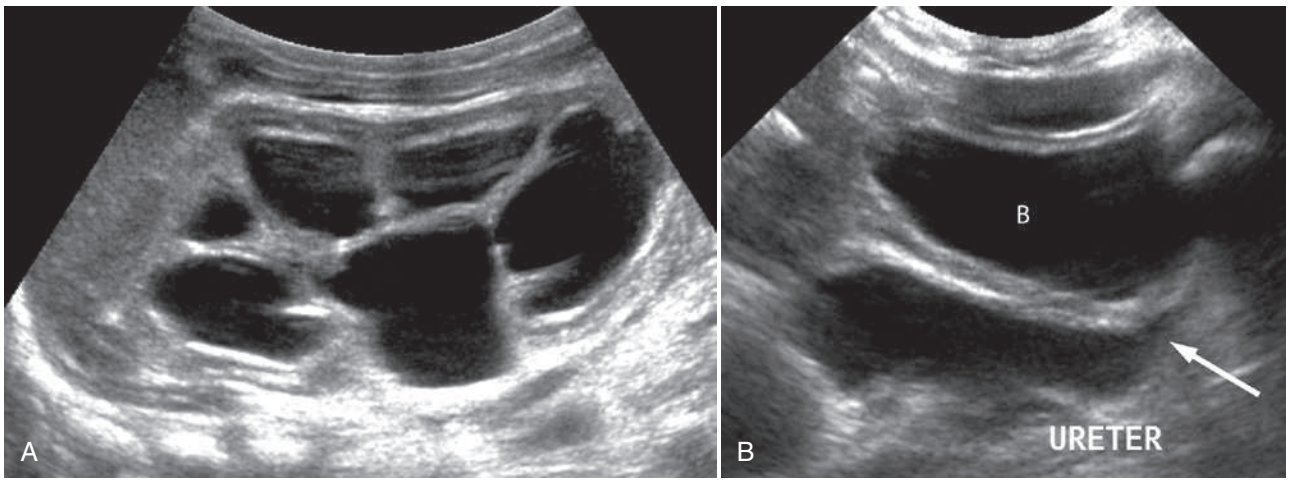

FIG. 54.60 Congenital Ureterovesical Junction (UVJ) Obstruction in Infant With Urinary Tract Infection. (A) Sagittal view of the left kidney reveals severe hydronephrosis with a markedly thin parenchyma with compression of the corticomedullary differentiation. **(B)** Sagittal sonogram of the bladder *(B)* shows the dilated ureter, which tapers inferiorly at the UVJ *(arrow).*

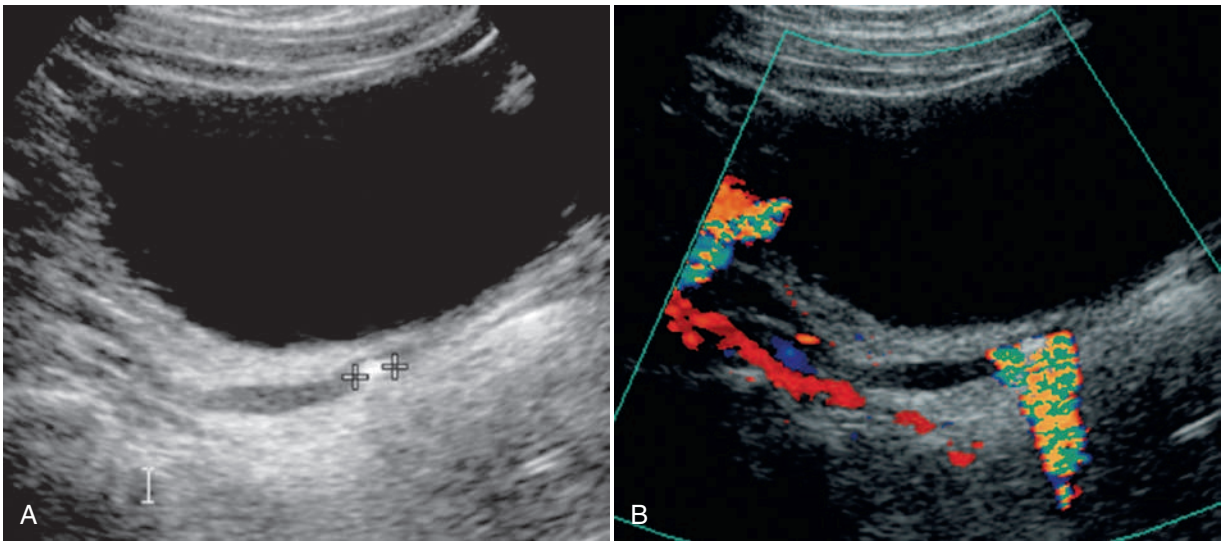

FIG. 54.61 Distal Ureter Stone. This 14-year-old patient had hematuria and right flank pain that radiated to the right groin. Mild right-sided hydronephrosis *(not shown)* was present. **(A)** Small stone *(arrow)* is lodged in the mildly dilated distal ureter, with distal acoustic shadowing. **(B)** Color Doppler shows "twinkle" artifact, confirming the presence of a stone.

on the midanterosuperior surface of the distended bladder. Involution of the urachus is not complete at birth and can be followed on sonography during the first months of life. Thus young infants with a discharging umbilicus or an infected urachus may benefit from a conservative approach using serial sonography as a guide because sonography can document spontaneous involution as well as abnormal development.[10] There are four types of urachal anomalies: **patent urachus** (completely open urachal lumen associated with urinary drainage from umbilicus), **urachal sinus** (opening to umbilicus), **urachal diverticulum** (opening to bladder), and **urachal cyst** (urachus obliterated at both ends with extraperitoneal position of isolated cyst)[213] (Fig. 54.62). Two sonographic patterns have been described in urachal anomalies: (1) a cystic mass, often with internal echoes or septations caused by infection, and (2) an echogenic, thickened, tubular sinus tract (8-15 mm in diameter).[213]

Other anomalies of the lower urinary tract that can be identified on ultrasound include **ectopic pelvic kidney, seminal vesicle cysts** (Fig. 54.63), **müllerian duct (prostatic utricle) cysts** (Fig. 54.64), and congenital or acquired **bladder diverticula.**[214]

Infection

UTIs are common in children, especially girls, and are usually the result of cystitis. Clinically, these children have urinary frequency, incontinence, dysuria, and/or hematuria.[215,216] The UTI is usually bacterial. **Hemorrhagic cystitis** can develop secondary to a viral infection (Fig. 54.65), chemotherapy with cyclophosphamide, or indwelling catheters. **Granulomatous cystitis** in a patient with chronic granulomatous disease of childhood can be detected on ultrasound. On sonography, the bladder may appear normal in mild cases of cystitis. More specific signs of cystitis are diffuse or focal bladder wall thickening and irregularity (Fig. 54.66). Echogenic material in the bladder lumen may represent purulent or hemorrhagic urine. **Bladder calculi** are more common with *Proteus* or *Pseudomonas* infections. With **cystitis cystica** or **cystitis glandularis,** rounded, isoechoic or hypoechoic, polypoid lesions may protrude into the lumen, mimicking a bladder tumor (Fig. 54.67). Rosenberg and colleagues[217] reported that in children with hematuria, dysuria, and frequency plus cystographic or sonographic demonstration of a bladder with reduced capacity and circumferential wall thickening, or sonographic findings of isoechoic bladder wall thickening (focal, multifocal, or circumferential distribution), intact mucosa, and bullous lesions, these findings should strongly suggest inflammation and not malignancy. In addition, changing mass contour and thickness with increasing bladder filling are particularly suggestive of inflammatory thickening. When an inflammatory lesion is suspected, follow-up imaging should be performed in 2 weeks, which will preclude biopsy if findings are normal.[217]

Neoplasm

Rhabdomyosarcoma is the most common tumor of the lower urinary tract in children, with 21% arising from the genitourinary tract. The most frequent primary sites are the bladder trigone or prostate. Less frequent sites of origin are the seminal vesicles, spermatic cord, vagina, uterus, vulva, pelvic musculature, urachus, and paratesticular area.[44,218] There is a male predominance of 1.6:1. The peak incidence occurs at 3 to 4 years of age; a second, smaller peak is seen in adolescence. The most common rhabdomyosarcoma cell type is the embryonal form, of which **sarcoma botryoides** is a subtype. The **alveolar** form is next in frequency; **undifferentiated** and **pleomorphic types** are uncommon. Tumors arising from the bladder, prostate, or both usually manifest early with symptoms from urinary tract obstruction and hematuria. Rhabdomyosarcoma has been reported to be associated with **neurofibromatosis, fetal alcohol syndrome,** and **basal cell nevus syndrome.**

On sonographic examination, rhabdomyosarcoma appears as a homogeneous, solid mass with an echotexture similar to

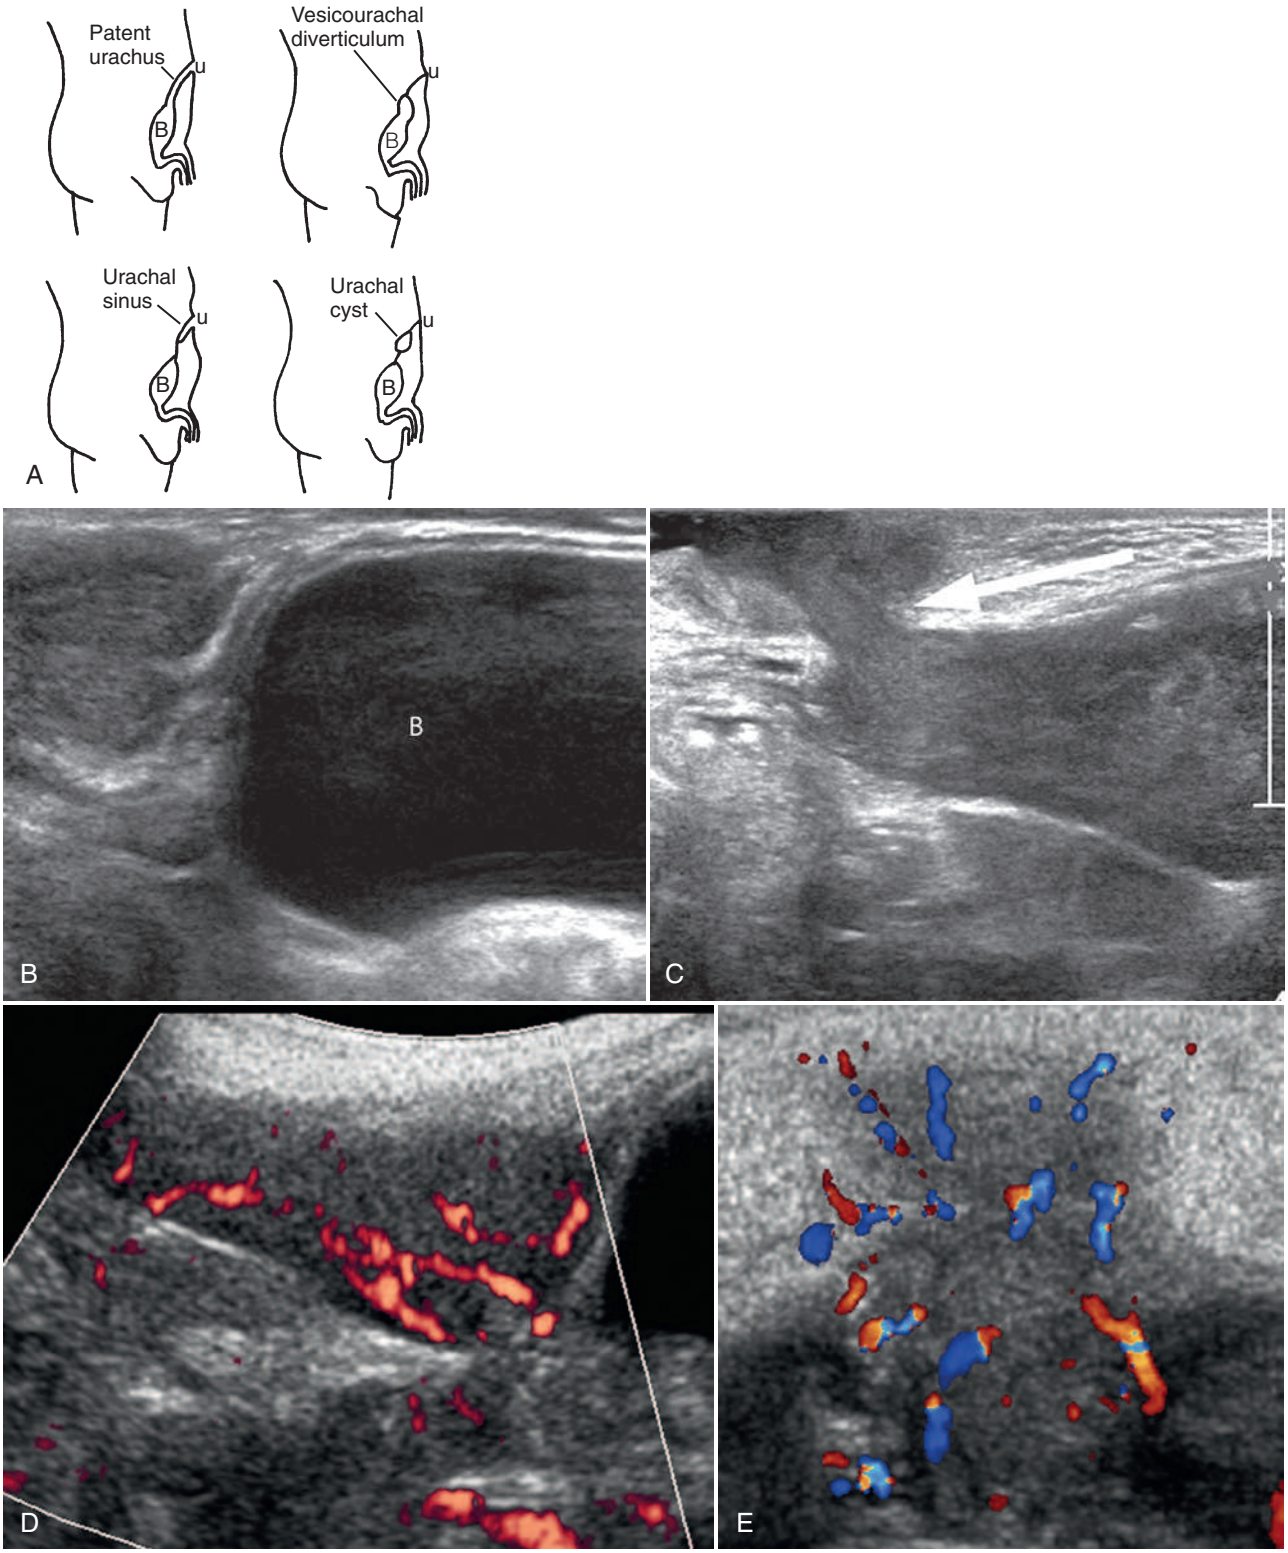

FIG. 54.62 Urachal Abnormalities. (A) Patent urachus (urachal lumen communicates with both umbilicus and bladder); **vesicourachal diverticulum** (urachal lumen communicates only with bladder); **urachal sinus** (urachal lumen communicates only with umbilicus); and **urachal cyst** (does not communicate with bladder or umbilicus). **(B)-(D) Infected urachal cyst.** Eight-year-old boy with lower abdominal pain, fever, and inflammation around the umbilicus with occasional drainage. **(B)** Sagittal image of the supravesicular region shows a tubular hypoechoic urachal cyst extending from the bladder *(B)* dome superiorly. **(C)** Just superior to image in **(B)**, the urachal cyst is seen extending to the umbilicus *(arrow).* **(D)** Power Doppler image shows hyperemia. **(E)** Transverse color Doppler shows hyperemia extends thru umbilicus into subcutaneous fat which is hyperechogenic. FIG. 54.64 Prostatic Utricle in 4-Year-Old True Hermaphrodite. This child was reared as a boy after external genitalia reconstruction. Sagittal view of the bladder reveals a fluid-filled, tubular utricle posterior to the bladder base.

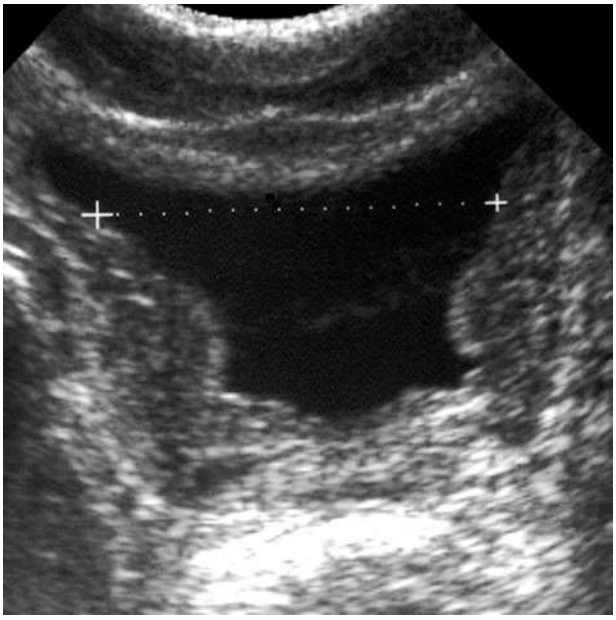

FIG. 54.65 Viral Cystitis in 11-Year-Old Boy With Frequency, Hematuria, and Dysuria. Transverse sonogram shows lobulated thickening *(cursors)* of the bladder wall.

muscle. Anechoic spaces caused by necrosis and hemorrhage are occasionally seen (Fig. 54.68). Calcification is uncommon. Bladder lesions originate in the submucosa, infiltrate the bladder wall, and produce polypoid projections into the lumen (sarcoma botryoides). Tumors arising in the prostate cause concentric or asymmetrical enlargement of the prostate and often infiltrate the bladder neck, posterior urethra, and perirectal tissues (Fig. 54.69). Regional and retroperitoneal lymph node metastases are common. Rarely, leiomyosarcoma may arise from the bladder wall and is more likely to have calcifications.

Benign tumors of the lower urinary tract are extremely rare and include **transitional cell papilloma** (**neurofibroma, fibroma, hemangioma,** and **leiomyoma**).[219,220] Neurofibromatosis can be invasive, with diffuse involvement of the pelvic organs.[221] **Pheochromocytoma** of the bladder is a rare tumor that probably arises in the paraganglia of the visceral (autonomic) nervous system and is located submucosally either in the dome or in the posterior wall close to the trigone. In children, 2% of bladder pheochromocytomas are malignant. Pheochromocytomas can be seen in the context of familial syndromes or diseases, which include neurofibromatosis, **von Hippel–Lindau disease, Sturge-Weber syndrome, tuberous sclerosis, multiple endocrine neoplasia type A** (medullary thyroid carcinoma and hyperparathyroidism), and **multiple endocrine neoplasia type IIB** (medullary thyroid carcinoma, mucosal neuromas, and pheochromocytoma). Pheochromocytomas of the bladder may cause headache, blurred vision, diaphoresis, palpitations, intermittent hypertension (70%), and hematuria (6%). Any of these symptoms

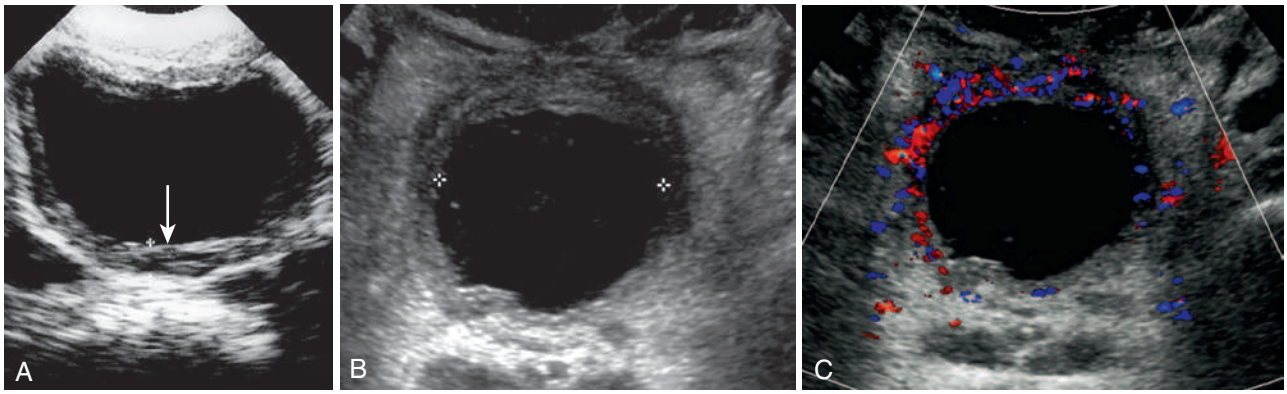

FIG. 54.66 Cystitis. (A) Chronic bacterial cystitis. Transverse sonogram demonstrates bladder wall thickening *(arrow)*. **(B)** and **(C)** Cyclophosphamide (Cytoxan) cystitis in child after bone marrow transplant. The bladder wall is thickened and hyperemic. Debris is noted within the bladder lumen.

(**B** and **E** with permission from Rosenberg HK, Eggli KD, Zerin JM, et al. Benign cystitis in children mimicking rhabdomyosarcoma. J Ultrasound Med. 1994;13[12]:921-932.[217])

may be seen with micturition.[222] Benign polyps in the male urethra can arise from a stalk near the verumontanum and cause urinary tract obstruction.

Trauma

Trauma to the lower urinary tract in children is most often caused by blunt trauma. Foreign bodies and complications of surgery are less frequent causes. The bladder in children is in a more intraabdominal position than in adults, and therefore bladder rupture is usually intraperitoneal. **Spontaneous bladder rupture** is rare in children and is seen primarily in neonates with urinary ascites secondary to urethral obstruction or neurogenic bladder.

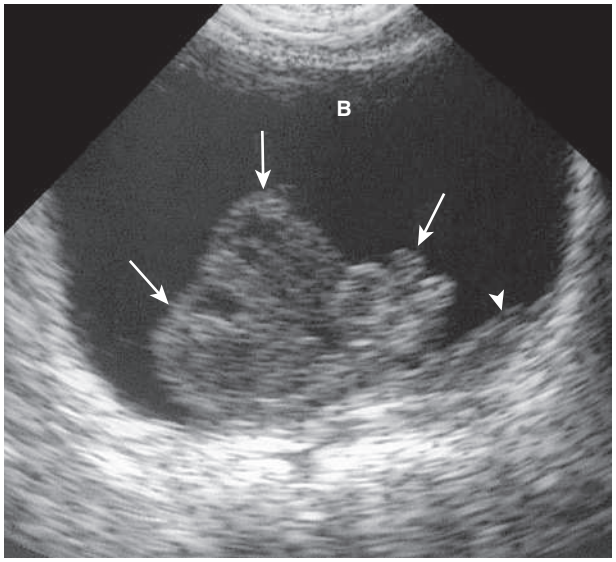

FIG. 54.68 Rhabdomyosarcoma of Bladder Wall. Large, complex, polypoidlike mass *(arrows)* arises from base of the bladder *(B)* in this 9-year-old boy with painless hematuria. Asymmetrical bladder wall thickening was noted posterolaterally on patient's left *(arrowhead)*.

Preexisting abnormalities of the vesical wall, such as tumors, stones, tuberculosis, diverticula, and surgical scars, can predispose a child to spontaneous rupture of the bladder.[223] Sonography can demonstrate urinary ascites in cases of intraperitoneal rupture or a loculated fluid collection **(urinoma)** in the retropubic or perivesical space in extraperitoneal rupture.

Postoperative Bladder

Sonography has assumed an important role in the evaluation of the postoperative bladder. **Ureteral reimplantation** is a common surgical procedure for the correction of persistent vesicoureteral reflux. The reimplanted ureteral segment is submucosal and contiguous to the bladder mucosa. Sonograms reveal an echogenic, fixed, tubular, submucosal structure without acoustic shadowing at or just above the trigone. Occasionally the reimplanted ureter appears only as an area of focal thickening of the posterior bladder wall.[224] Sonography is also useful for the demonstration of the echogenic mound present after treatment with Deflux (dextranomer–hyaluronic acid copolymer) as a first-line treatment for high-grade vesicoureteral reflux[225] (Fig. 54.70).

Bladder augmentation is now a widely accepted surgical procedure for the reconstruction of small-capacity bladders caused by exstrophy, neurogenic bladder, or tumor. Segments of bowel, usually the sigmoid, cecum, or ileum or the ileocecal segment, are anastomosed to the bladder to increase the size of the urinary reservoir. Sonography of the augmented bladder reveals a thick or irregularly shaped bladder wall (Fig. 54.71). Pseudomasses within the bladder lumen, representing bowel folds, mucous collections, or bowel that was surgically intussuscepted into the reconstructed bladder to prevent reflux, are a common finding. Fine debris and linear strands often float within the urine and probably represent mucus. Active peristalsis within the bowel segment can be identified on real-time imaging. Complications of bladder reconstructive surgery can be detected on ultrasound and include enterocystic **anastomotic strictures, ureteral reflux**

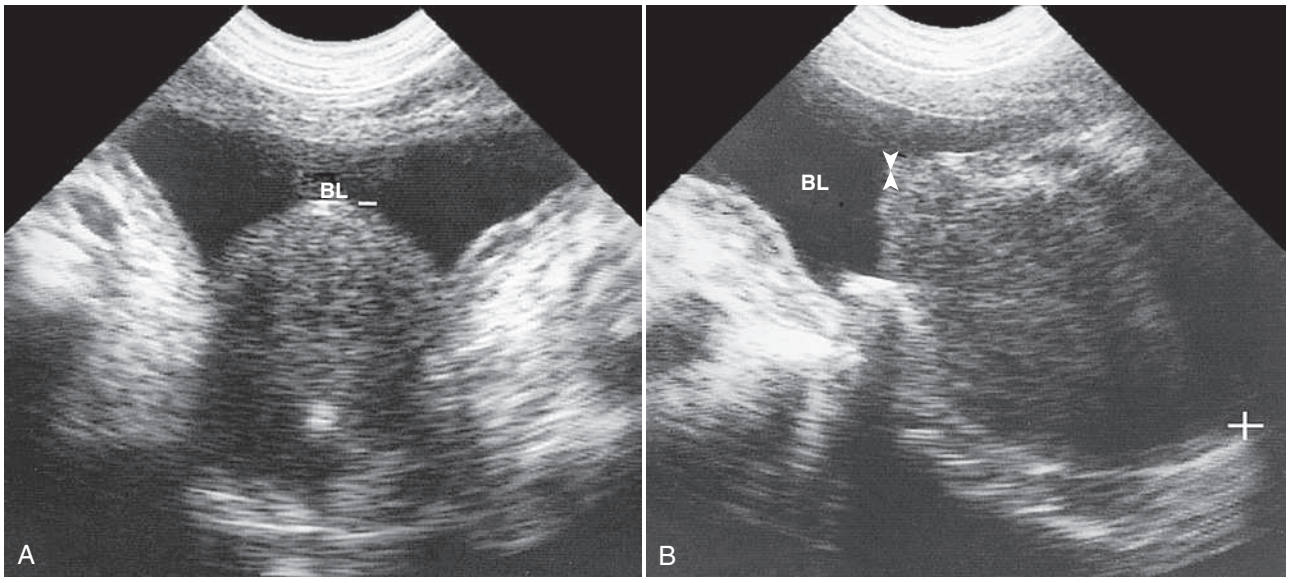

FIG. 54.69 Prostatic Rhabdomyosarcoma With Bladder Invasion in 11-Month-Old Boy With Pelvic Pain. (A) and **(B)** Transverse and sagittal sonograms of the pelvis demonstrate a large, solid mass arising inferior to the bladder neck *(BL)* invading the bladder base.

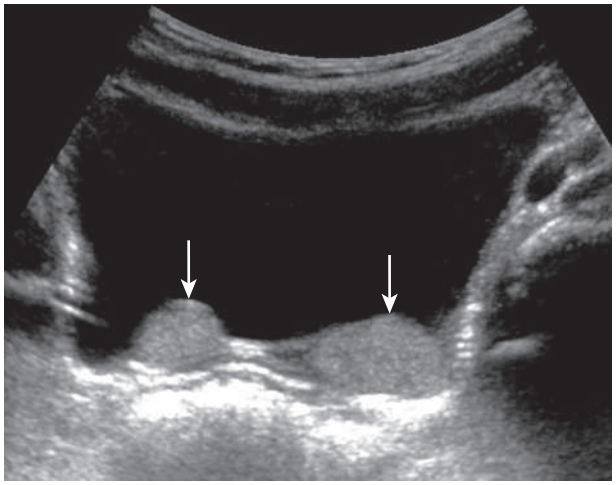

FIG. 54.70 Bilateral Injections of Deflux Into Ureterovesical Junctions. This 2-year-old girl had a history of recurrent urinary tract infection and bilateral vesicoureteral reflux. Note the round, brightly hyperechoic mounds of Deflux *(arrows)* at the trigones bilaterally.

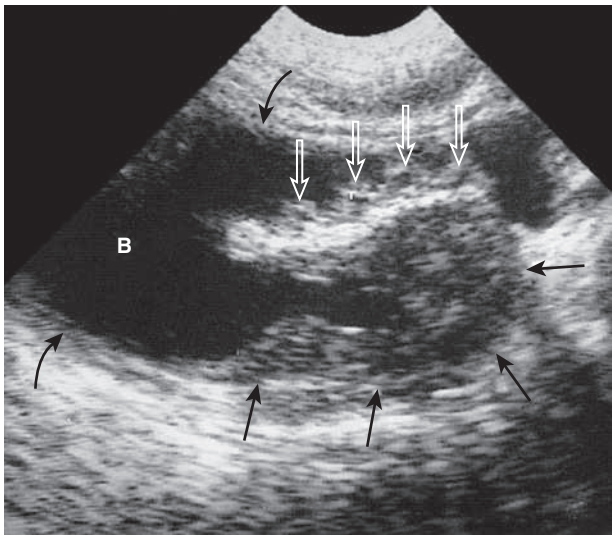

FIG. 54.71 Augmented Bladder. Transverse view of the bladder *(B)* shows the thick wall of the anatomic bladder *(straight black arrows)* and the large augmentation *(curved arrows); open arrows,* haustral markings.

or obstruction, calculi, extravasation, abscess, urinoma, hematoma, and large amounts of residual urine after voiding.[226,227]

PRESACRAL MASSES

The presacral space is a potential space between the perirectal fascia and the fibrous coverings of the anterior sacrum. A lesion in the presacral space can usually be identified on routine sonography through a distended bladder. To confirm the origin of the mass, a water enema can be performed to identify the rectosigmoid colon in relation to the lesion. Additional scans through the buttocks are often helpful to determine the true extent of the tumor.

Presacral Masses in Children

SOLID
Sacrococcygeal teratoma
Neuroblastoma
Rhabdomyosarcoma
Fibroma
Lipoma
Leiomyoma
Lymphoma
Hemangioendothelioma
Sacral bone tumors

CYSTIC
Abscess
Rectal duplication
Hematoma
Lymphocele
Neurenteric cyst
Sacral osteomyelitis
Ulcerative colitis
Anterior meningocele

Sacrococcygeal teratoma is the most common presacral neoplasm in the pediatric age group. About 50% are noted at birth, with a 4:1 female-to-male incidence. Sacrococcygeal teratoma arises from multipotential cells in Hensen nodes that migrate caudally and come to lie within the coccyx. Radiographic evidence of bony abnormalities of the sacrum or coccyx may be present (Fig. 54.72). There is a 75% incidence of associated congenital anomalies, most often involving the musculoskeletal system. Some sacrococcygeal teratomas are familial, with autosomal dominant inheritance. These teratomas have a high frequency of twins.[228]

Sacrococcygeal teratomas can be benign or malignant. Tumors detected before age 2 months are most likely benign. Those detected after 2 months have a 50% to 90% incidence of malignancy. Malignancy is more common in boys and in lesions that are predominantly solid. Cystic lesions are more likely benign. All teratomas have a malignant potential, regardless of their texture, location, or size. Recurrence of a benign teratoma after incomplete surgical removal leads to increased risk of malignant transformation; therefore the coccyx must be removed completely at surgery to prevent recurrence. Sacrococcygeal teratomas can be divided into the following four types, based on their location:

Type I: Predominantly external
Type II: External with a substantial intrapelvic component
Type III: Small external mass with predominant intrapelvic portion
Type IV: Entirely presacral with no external component

Type I lesions are usually benign and appear at birth. Types II, III, and IV have a higher incidence of malignancy, probably because the large intrapelvic component goes unrecognized and

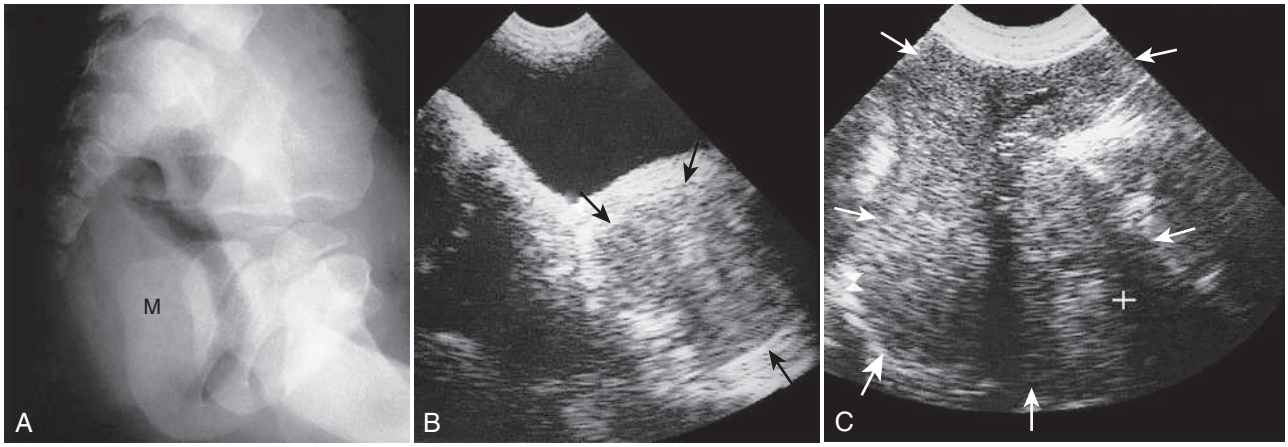

FIG. 54.72 Sacrococcygeal Teratoma in 2-Year-Old Boy With Palpable Mass at Base of Spine. (A) Lateral radiograph of the pelvis shows lack of coccygeal ossification and large, retrorectal, soft tissue mass *(M)* with anterior displacement of the rectum. **(B)** Sagittal ultrasound shows a solid mass *(arrows)* deep in the pelvis posteroinferior to the bladder. **(C)** Transverse ultrasound over the base of the spine posteriorly shows a primarily solid mass *(arrows)* with one small cystic area extending deep into the pelvis.

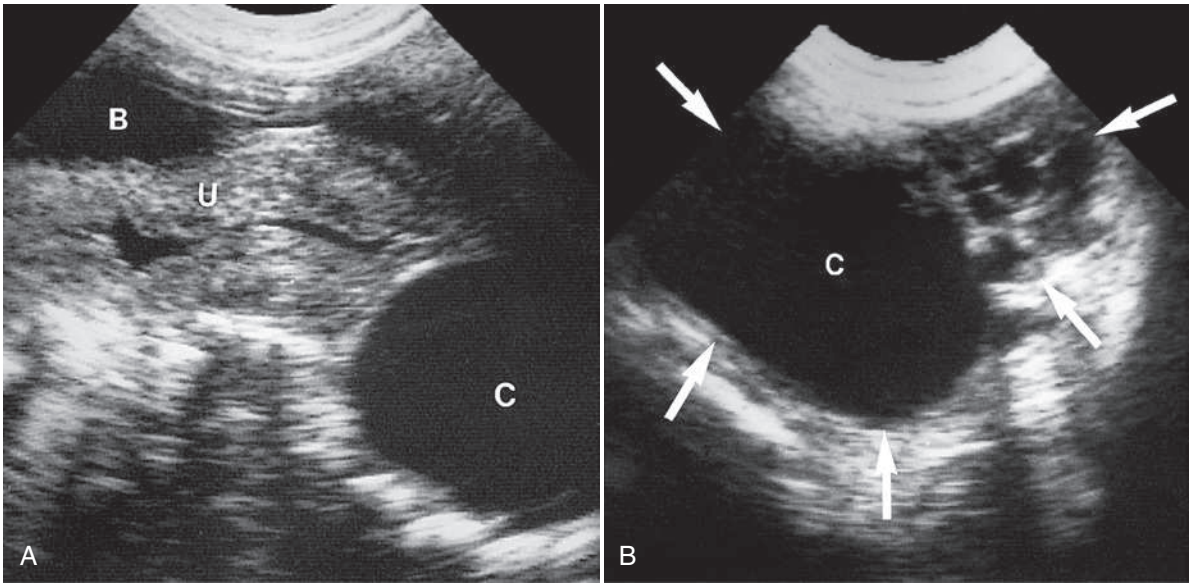

FIG. 54.73 Sacrococcygeal Teratoma in Newborn Girl With Buttock Mass. (A) Sagittal sonogram demonstrates a large, cystic mass *(C),* deep in the pelvis, posteroinferior to the uterus *(U).* The small amount of fluid noted in the endometrial canal is secondary to residual material hormonal stimulation. *B,* Bladder. **(B)** Transverse image over the base of the spine posteriorly demonstrates a complex mass *(arrows)* with a predominantly large cystic *(C)* component.

undetected for longer periods than the large, exophytic masses.[49,228] Malignant teratomas are usually **endodermal sinus tumors.**

There is a wide spectrum of ultrasound appearances of sacrococcygeal teratomas, ranging from purely cystic to mixed or purely solid (Figs. 54.73 and 54.74). Calcifications, seen in one-third of cases, can be amorphous, punctate, or spiculated and suggest the lesion is benign. Fat within the tumor appears as bright areas of heterogeneous echogenicity. Large tumors may displace and compress the bladder anteriorly and superiorly, causing urinary retention and hydronephrosis.

Neuroblastoma and other neurogenic tumors can arise in the presacral space in children. Five percent of neuroblastomas arise in the pelvis. Because of their midline location, they are considered stage III tumors. Pelvic neuroblastoma has a better prognosis than intraabdominal neuroblastoma. The pelvic lesions have a similar sonographic appearance to the adrenal lesions. They are solid, echogenic, heterogeneous masses with a 70% incidence of calcification. Areas of cystic necrosis and hemorrhage are uncommon[229,230] (see Fig. 54.74).

Rhabdomyosarcoma arising from the pelvic musculature can manifest as a solid presacral mass. It is usually an infiltrating tumor with poorly defined margins. Anechoic spaces within a predominantly solid mass suggest areas of necrosis and hemorrhage. Calcification is rare.[229] Ultrasound is an excellent method for identifying and staging rhabdomyosarcoma arising from the genitourinary tract. However, computed tomography (CT) and MRI provide more complete information for those tumors arising from the pelvic side walls. Other predominantly **solid presacral**

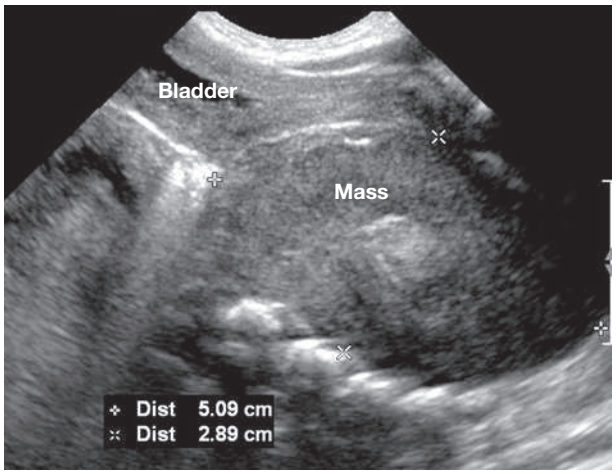

FIG. 54.74 Neuroblastoma. Full-term male baby with a prenatal diagnosis of a large (5 × 3 × 4 cm), solid, deep, pelvic mass that contains a central, nonshadowing calcification. The mass flattens the urinary bladder while displacing it anteriorly.

masses to be considered in the differential diagnosis include fibroma, lipoma, leiomyoma (and their malignant counterparts), lymphoma, hemangioendothelioma, and metastatic disease. **Sacral bone tumors,** such as Ewing sarcoma, osteosarcoma, chondrosarcoma, giant cell tumor, and aneurysmal bone cyst, may also appear as presacral masses. Chordomas of the sacrococcygeal region are rare in children.

Cystic presacral lesions, in addition to sacrococcygeal teratomas, can be detected on sonography. These include abscess, rectal duplication, hematoma, lymphocele, neurenteric cyst, sacral osteomyelitis, and ulcerative colitis. An anterior sacral meningocele also manifests as a cystic presacral mass. It represents herniation of the meninges through an anterior defect in the sacrum. The sacrum usually has a scimitar- or sickle-shaped configuration. A solid mural nodule within the cystic meningocele represents glial or lipomatous tissue.

CHAPTER 55

The Pediatric Hip and Other Musculoskeletal Ultrasound Applications

Leslie E. Grissom and H. Theodore Harcke

SUMMARY OF KEY POINTS

- Ultrasound is the preferred technique in the diagnosis and management of development dysplasia of the hip (DDH).
- DDH is multifactorial: the highest risk factor is female breech delivery.
- The two basic methods, morphologic and dynamic, share the need for recognition of critical anatomic landmarks of the hip. The dynamic technique emphasizes stability.
- The American Institute of Ultrasound in Medicine Practice Parameter standard examination includes assessment of hip position, stability, and morphology.
- In the United States, general screening of infants for DDH is by physical examination. Ultrasound is recommended for infants with abnormal physical examination findings or risk factors.
- Radiographs may be used for assessment of bony acetabular development after 4 to 6 months of age.
- Congenital and other musculoskeletal abnormalities of the developing bones can be assessed with ultrasound because of the superior visualization of cartilage.
- Sonography can serve as a screening tool for diagnosis of musculoskeletal infection and trauma.

CHAPTER OUTLINE

DEVELOPMENT DYSPLASIA OF THE HIP
Clinical Overview

Infection
Noninfectious Inflammation
Trauma
Popliteal Cysts
SUMMARY

Ultrasound has been widely used in the diagnosis and management of **development dysplasia of the hip** (DDH), although many other applications for sonography of the pediatric musculoskeletal system have been developed. Ultrasound is ideally suited to the evaluation of the immature skeleton and associated soft tissues because of visualization of the cartilage found in large amounts in developing bones and because of the lack of ionizing radiation. Other advantages include the ability to perform dynamic evaluations and to examine children without sedation. With some applications, including DDH, sonography may replace other imaging studies; in other cases, sonography complements radiography to aid in the diagnosis. In this chapter, we review the use of ultrasound in DDH and also describe briefly its use in other musculoskeletal conditions. Ultrasound of the pediatric spine is discussed in Chapter 49; fetal spine sonography is discussed in Chapter 35; and musculoskeletal ultrasound in nonpediatric patients is reviewed in Chapters 23 and 24.

DEVELOPMENT DYSPLASIA OF THE HIP

Clinical Overview

Development dysplasia of the hip (DDH), formerly called "congenital dislocation of the hip," usually manifests in the first year of life. The **incidence of DDH** varies throughout the world.

In whites, overt dislocation is reported to be 1.5 to 1.7 per 1000 live births.[1,2] When lesser degrees of abnormality such as subluxation are included, as many as 10 infants per 1000 live births may show some features of the disorder.[3] Early detection of an abnormality in the infant hip is the key to successful management. If treatment is begun at a young age, most of the sequelae that occur when DDH goes unrecognized until walking age can be prevented. Clinical screening programs have been instituted, and primary care physicians are taught to evaluate the hips as part of the newborn physical examination. Historically, infants with abnormal clinical examination findings were referred for plain radiographic film examinations. Ultrasound has now become the preferred technique for diagnosis and management of DDH in the first 6 months of life.[4] Hip sonography offers clear advantages over other imaging techniques in DDH. At the early age of initial diagnosis in the first 6 months of life, the femoral head and acetabulum consist of cartilage components that are clearly identified by ultrasound. Real-time sonography allows assessment of the hip in multiple planes, both at rest and with movement. Ultrasound can replace radiographic studies and reduce radiation exposure to the young infant.

The **cause of DDH** is multifactorial, with both physiologic and mechanical factors playing a role. Maternal-fetal interaction influences the development of hip problems in both categories. Maternal estrogens and hormones that affect pelvic relaxation just before delivery are believed to lead to temporary laxity of the hip capsule in the perinatal period. Most fetuses are exposed to extrinsic forces in the later weeks of pregnancy because of their increasing size and the diminishing volume of amniotic fluid. It is theorized that these forces, although gentle, can lead to deformation if persistently applied.[5] An increased incidence of DDH is reported in infants born in the breech position, in infants with a positive family history of DDH, in firstborns, and in pregnancy with oligohydramnios. Infants with skull-molding deformities, congenital torticollis, and foot deformities are also at increased risk for DDH.[6] Current reviews of risk have focused on female breech delivery as the highest risk for DDH, and imaging is recommended for these infants in published guidelines from the major U.S. societies.[7-9] There is some evidence of familial acetabular dysplasia,[10] although this is not considered a cause in most cases.

Risk Factors for Development Dysplasia of the Hip (DDH)

Family history of DDH
Firstborn child
Oligohydramnios
Breech delivery (female breech is the highest DDH risk category)
Skull-molding deformities
Congenital torticollis
Foot deformities

The mechanism of a typical dislocation is thought to be a gradual migration of the femoral head from the acetabulum because of the loose, elastic joint capsule. In the newborn period, the femoral head usually dislocates in a lateral and posterosuperior position relative to the acetabulum. The displaced femoral head can usually be reduced, and the joint components typically do not have any major deformity. When dislocation is not recognized in early infancy, the muscles tighten and limit movement. The acetabulum becomes dysplastic because it lacks the stimulus of the femoral head. Ligamentous structures stretch, and fibrofatty tissue occupies the acetabulum. Thus it becomes impossible to return the femoral head to the acetabulum with simple manipulation; a pseudoacetabulum may form along the inferior ilium laterally where the dislocated femoral head rests.

Sonography is most often used for evaluation of an infant with an abnormal physical examination or a DDH risk factor, such as positive family history, breech delivery, foot deformity, or torticollis. Many reports attest to greater efficacy of sonography compared with the clinical and radiographic examination.[11-15]

The routine screening of all newborn infant hips with ultrasound has been a controversial issue. Based on a comparison between clinical and sonographic screening with sonography, Tonnis and colleagues[11] concluded that all newborns should be screened for DDH with ultrasound because it detects more pathologic joints than the clinical examination. In some European countries, routine screening has been tried on a regional basis. Critics of **newborn screening programs** note the high number of infants undergoing treatment or requiring follow-up studies (whether for minor instability or immaturity in acetabular development), but it is also recognized that studying only infants at risk will not eliminate late cases of DDH.[16,17]

The current consensus in the United States is that the net benefits of universal sonographic screening are not clearly established. This opinion is based on the fact that there is a high rate of spontaneous resolution of neonatal hip instability and dysplasia and lack of evidence that intervention affects outcomes for the population.[18] The American Academy of Pediatrics (AAP) has published guidelines for pediatric examinations for the diagnosis of DDH.[7] Screening by clinical examination is recommended, and ultrasound is reserved for infants having abnormal examination findings or risk factors.[19-22] If a frankly dislocated hip is present, referral to orthopedic specialists is appropriate. When the abnormal physical examination findings suggest less severe hip instability shortly after birth, sonography should not be done until at least 3 to 4 weeks of age because hip instability may resolve on its own. Experience has indicated that many infants younger than 30 days have hip laxity that becomes normal after a few weeks without treatment. This is not a new observation; the phenomenon was recognized clinically by Barlow.[1] It identifies, however, a group of infants who need follow-up. Not all infants' hips become normal, and these patients require continued observation.[11]

Newborns with a risk factor for DDH should be checked at 4 to 6 weeks. This avoids multiple examinations in cases of transient neonatal instability and immaturity related to maternal hormones.

Indications for Hip Ultrasound

- Abnormal findings on physical or imaging examination of the hip
- Monitoring of patients with development dysplasia of the hip (DDH) treated with a Pavlik harness or other splint device
- Any family history of DDH
- Breech presentation regardless of gender
- Oligohydramnios and other uterine causes of postural molding
- Neuromuscular conditions

Dynamic Sonographic Technique: Normal and Pathologic Anatomy

History

The first in-depth use of sonography was performed by Graf,[23] an Austrian orthopedic surgeon. Scanning was performed from the lateral approach with the femur in its anatomic position. Graf's method, which keyed on acetabular morphology, established ultrasound's ability to distinguish the cartilage, bone, and soft tissue structures that compose the immature hip joint. When real-time sonographic equipment became available, sonographers experimented with different approaches to the hip[24] and the use of dynamic assessment. Both approaches recognize the need for critical landmarks of the femur and acetabulum. The dynamic technique, as proposed by Harcke and colleagues, mirrored the physical examination.[25]

Although two basic assessment strategies evolved, morphologic and dynamic, the two methods have common features,[25,26] in addition to stressing positional relationships and stability and assessment of critical acetabular landmarks. This formed the basis for an examination drawing on elements from both techniques,[26,27] which has become part of the practice parameter recommended by the American College of Radiology (ACR), the American Institute of Ultrasound in Medicine (AIUM), Society of Pediatric Radiology (SPR), and Society of Radiologists in Ultrasound (SRU).[8]

Technical Factors

Hip sonography should be performed with real-time linear array transducers. One should use the highest frequency transducer that provides adequate penetration of the soft tissues to the depth required. For infants up to 6 months of age, the 15-8 MHz broadband digital transducer is successful. A lower-frequency transducer may be required for infants older than 6 months.

Standard scanning is performed from the lateral or posterolateral aspect of the hip, moving the hip from the neutral position at rest to a position in which the hip is flexed. With the hip flexed, the femur is moved through a range of abduction and adduction, with stress views performed in the flexed position. One aspect of hip sonography relevant to dynamic examinations is the shift of the transducer between the examiner's hands when examining the right and left hip. The infant is lying supine with the feet toward the sonographer. When examining the left hip, the sonographer grasps the infant's left leg with the left hand, and the transducer is held in the right hand. When the right hip is examined, we recommend that the sonographer hold the transducer in the left hand and use the right hand to manipulate the infant's right leg. Although some sonographers find this awkward at first, ambidexterity in this context is easily mastered. We found that this technique makes it possible to perform the stress maneuver more reliably and better maintain the planes of interest.

For a satisfactory examination, the infant should be relaxed. Infants can be fed before or during the examination. Toys and other devices to attract the infant's attention are helpful and can be used as sonography is being performed. A parent can hold the infant's arms or head and can talk to the infant. There is no need for sedation. The upper body may remain clothed. Our standard practice is to leave the infant diapered and expose only the side of the hip being examined (strongly recommended for boys).

The **anatomy** is considered in orthogonal views. It is our routine practice to record images in each of these views for permanent records. This standardizes the examination and, in our institution, provides a guideline for the technologist who performs the initial examination. In describing views, we use a

Minimum Standard Examination for Development Dysplasia of the Hip (DDH) According to Guidelines From the American College of Radiology (ACR), American Institute of Ultrasound in Medicine (AIUM), Society for Pediatric Radiology (SPR), and Society of Radiologists in Ultrasound (SRU)

- The minimum standard is two orthogonal planes: a coronal view in the standard plane at rest (in flexion or extension) and a transverse view of the flexed hip with and without stress. This enables an assessment of hip position, stability,[4] and morphology when the study is correctly performed and interpreted. It should be noted that additional views and maneuvers can be obtained and that these may enhance the confidence of the examiner.
- Morphology is assessed at rest. The stress maneuvers follow those prescribed in the clinical examination of the hip and assess femoral stability.
- The attempts to dislocate the femoral head or reduce a displaced head are analogous to the Barlow and Ortolani tests used in the clinical examination. It is acceptable to perform the standard examination with the infant in a supine or lateral position.[8]

[a]Modified from ACR-AIUM-SPR-SRU practice parameter for the performance of the ultrasound examination for detection and assessment of developmental dysplasia of the hip. American College of Radiology. 2013. Available from: https://www.acr.org/~/media/ACR/Documents/PGTS/guidelines/US_Hip_Dysplasia.pdf. Accessed 2/21/2017.[8]

two-word combination that indicates the plane of the transducer with respect to the body (coronal or transverse) and the position of the hips (neutral or flexed).

It is the objective of the dynamic hip assessment to determine the position and stability of the femoral head, as well as the development of the acetabulum. With a normally positioned hip, the femoral head is congruently positioned within the acetabulum. Mild displacement, such as when the head is in contact with part of the acetabulum or is displaced but partly covered, is referred to as **subluxation.** The **dislocated hip** has no contact with or coverage by the acetabulum. A change in position of the femur may change the relationship of the femoral head and acetabulum. A hip that is subluxated in the neutral or rest position may seat itself with flexion and abduction. A dislocated hip may improve its position and partially reduce to a subluxated position. This is, in fact, a principle of treatment.

The **stability of the hip** is determined through motion and the application of stress. The stress maneuvers are the imaging counterparts of the clinical Barlow and Ortolani maneuvers, which are the basis for the clinical detection of a hip abnormality. The **Barlow test** determines whether the hip can be dislocated. The hip is flexed and the thigh brought into the adducted position. The gentle push posteriorly can demonstrate instability by causing the femoral head to move out of the acetabulum.[1] The **Ortolani test** determines whether the dislocated hip can be reduced. As the flexed, dislocated hip is abducted into a frog-leg position, the examiner feels a vibration or "clunk" that results when the femoral head returns to the acetabulum.[28] The **normal hip** is always seated at rest, with motion, and during the application of stress. The lax hip is normally positioned at rest and shows mild subluxation with stress. It must, however, invariably remain within the confines of the acetabulum. The subluxated hip is displaced laterally at rest and is loose; it may be dislocatable with stress and reducible with flexion and abduction. The **dislocated hip** may be able to be returned to the acetabulum with traction and abduction. This hip is distinguished from the most severe form of DDH, in which the femoral head is dislocated and cannot be reduced.

At birth, the proximal femur and much of the acetabulum are composed of cartilage. On sonographic examination, cartilage is hypoechoic compared with soft tissue, so it is easy to distinguish. A few scattered specular echoes can be visualized within the cartilage when high-frequency transducers are used and technique adjustments are optimally set. The **acetabulum** is composed of both bone and cartilage. At birth, the bony ossification centers in the ilium, ischium, and pubis are separated by the **triradiate cartilage,** which has a Y configuration. A cartilaginous acetabular rim (the **labrum**) extends outward from the acetabulum to form the cup that normally contains the femoral head. Most of the acetabular cartilage has an echogenicity similar to the femoral head. It is still possible to determine the joint line, which distinguishes the cartilaginous acetabulum from the femoral head, by simply rotating the femur. More pronounced movement of the hip often creates echoes within the joint space, probably as a result of the formation of microbubbles. At the lateral margin of the **labrum,** the hyaline cartilage changes to fibrocartilage, and this shows increased echogenicity. The echogenic hip capsule, composed of fibrous tissue, borders the femoral head laterally. The bony components of the hip reflect all of the sound beam from their surface. This creates a bright linear or curvilinear appearance on the sonogram, indicating the contour of the osseous surfaces in that plane.

Radiographically, the ossification center of the femoral head is recognized between the second and eighth months of life. It is typically seen earlier in females than in males, and there is a wide normal variation for the time of appearance. Although some asymmetry between the left and right hips can be normal, both in time of appearance and in size, delayed appearance and development are associated with DDH. Hip sonograms reflect the development of the ossification center and can be used to document the development of the center.[29] The ossification center can be found with ultrasound several weeks before it is visible radiographically. Initially, a confluence of blood vessels produces increased echoes within the cartilage. This precedes actual ossification. As ossification begins, the calcium content is insufficient to produce a visible radiographic density; however, the sound waves are reflected. With maturation, the size of the ossification center increases. In early development, the echoes from the center have a punctate appearance, whereas later in the first year of life, the growth in size gives it a curvilinear margin. As the normal infant approaches 1 year of age, the size of the ossification center precludes accurate determination of medial acetabular landmarks.

Sonography of the hip is practical only up to 8 months of age, unless there is delayed ossification of the femoral head. Between 4 months and 6 months, radiography becomes more reliable. Usually by 1 year of age, the femoral ossification center is large enough to prevent good sonographic visualization of the acetabulum.[9] The presence and size of the ossific nucleus can be evaluated in all views.

Coronal/Neutral View

The **coronal/neutral view,** which forms the basis for the morphologic technique, is performed from the lateral aspect of the joint with the plane of the ultrasound beam oriented coronally with respect to the hip joint. The femur is maintained with a physiologic amount of flexion. The coronal/neutral view is performed with the patient supine. The transducer is placed on the lateral aspect of the hip, and the hip is scanned until a standard plane of section is obtained (Fig. 55.1). The plane must precisely demonstrate the midportion of the acetabulum, with the straight iliac line superiorly and the inferior tip of the os ilium seen medially within the acetabulum. The echogenic tip of the labrum should also be visualized. The alpha and beta angles, if measured, relate to fixed points on the bony and cartilaginous components of the acetabulum[30] (see Fig. 55.1), and the exact plane must be obtained for the measurements to be reliable. The similarity can be noted between the appearance of the acetabulum in this coronal/neutral view and in the coronal/flexion view (Fig. 55.2). The difference is that the bony shaft (metaphysis) of the femoral neck is visualized below the femoral head in the coronal/neutral projection. In the coronal/flexion view, the femoral shaft is not in the plane of examination because the femur is flexed. A stability test can be performed in the coronal/neutral view

by gently pushing and pulling the infant's leg. This helps to verify deformity of the acetabulum and to identify craniodorsal movement of the femoral head under pressure. Zieger and colleagues[31] proposed a further adaptation of this view, advocating flexion and adduction of the hip to identify lateral displacement when instability is present. This is similar to the coronal/flexion stress view.

In the normal coronal/neutral view, the femoral head is resting against the bony acetabulum. The acetabular roof should have a concave configuration and cover at least half the femoral head. The cartilage of the acetabular roof is hypoechoic and extends lateral to the acetabular lip, terminating in the labrum, which is composed of fibrocartilage and is echogenic (see Fig. 55.1C). When a hip becomes subluxated or dislocated, the femoral head gradually migrates laterally and superiorly, with progressively decreased coverage of the femoral head (see Fig. 55.1E). In hip dysplasia, the acetabular roof is irregular and angled, and the labrum is deflected superiorly and becomes echogenic and thickened. When the hip is frankly dislocated, the labrum may be deformed. Echogenic soft tissue is interposed between the femoral head and the bony acetabulum. A combination of deformed labrum, fibrofatty tissue (pulvinar), and thickened ligamentum teres prevents the hip from being reduced.

The acetabulum can be assessed visually or with measurements, noting the depth and angulation of the acetabular roof, as well as the appearance of the labrum (see Fig. 55.1F). This can be seen in both coronal/neutral and coronal/flexion views and should be described in the report. Morin and colleagues[32,33] correlated coverage of the femoral head by the bony acetabulum with measurements of the acetabular angle. This assessment relates acetabular depth (d) to the diameter of the femoral head (D) and is expressed as percent ($d/D \times 100$) coverage of the femoral head. These data showed that normal radiographic measurements always had a femoral head coverage that exceeded 56%, and that clearly abnormal radiographic measurements had coverage of less than 40%.[33] This information should be used with caution because there are intermediate values for which sonographic and radiographic measurements do not correlate. We have also noted cases in which sonography showed the acetabulum to be better developed than it appeared radiographically, and vice versa.[34] This discrepancy occurs because the radiograph is a two-dimensional projection of the three-dimensional pelvis, and selected sonographic images illustrate a single coronal slice that may not match the projection.

Classification of hip joints may also be based on the measurement of the alpha and beta angles (see Fig. 55.1D-F). The alpha angle measures the inclination of the osseous acetabular roof with respect to the lateral margin of the iliac bone (baseline). The beta angle is formed by the baseline iliac bone and the inclination of the anterior cartilaginous acetabular roof, for which the tip of the labrum is its key landmark. Ultrasound units may contain software that facilitates measurement of these angles. Four basic hip types have been proposed on the basis of alpha and beta measurements.[30] Most of these subtypes have been subdivided, and small changes in angular measurements can result in a change in category. The reproducibility of angular measurements and subtypes has been a point of considerable discussion. In Europe, classification by measurement has been based on large numbers of infants examined. Some examiners have experienced problems with the use of measurements,[31,32,34-36] but those who adhere strictly to the technique find acceptable reproducibility.[11,37,38]

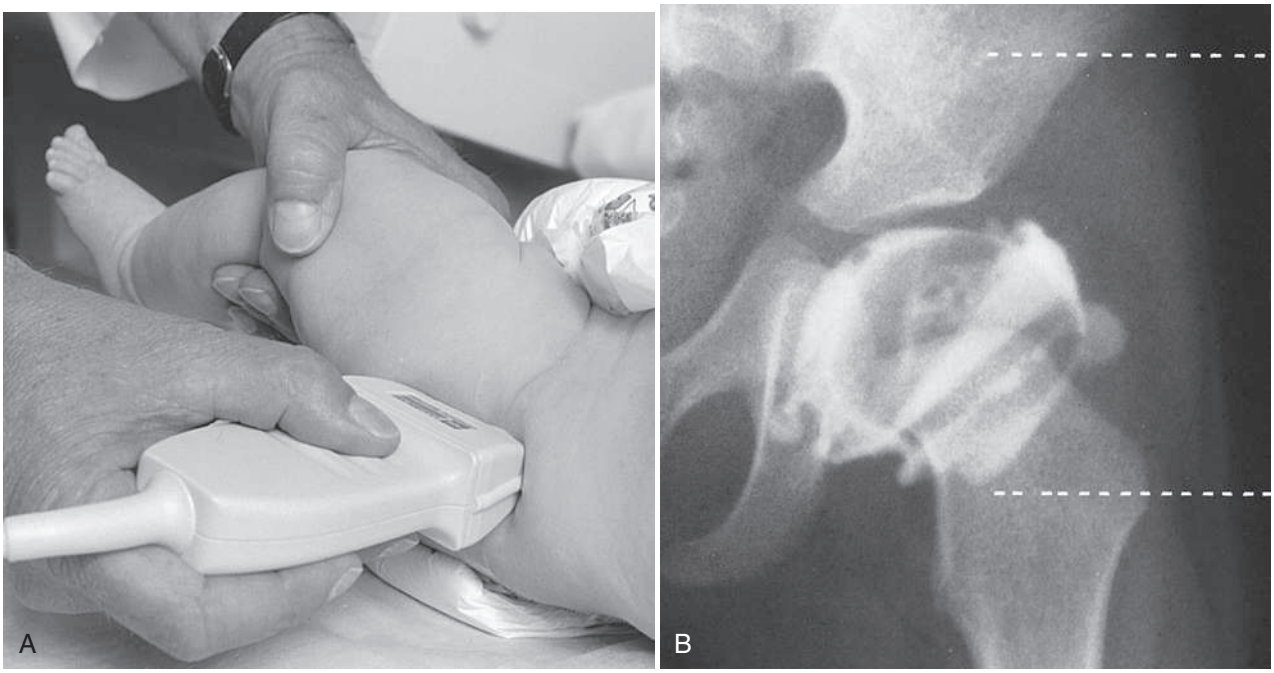

FIG. 55.1 Coronal/Neutral Hip View. (A) Linear array transducer is placed coronal and lateral with respect to the hip. The femur is in "physiologic neutral" for the infant (slight hip flexion). **(B)** Scan area *(dotted lines)* on arthrogram.

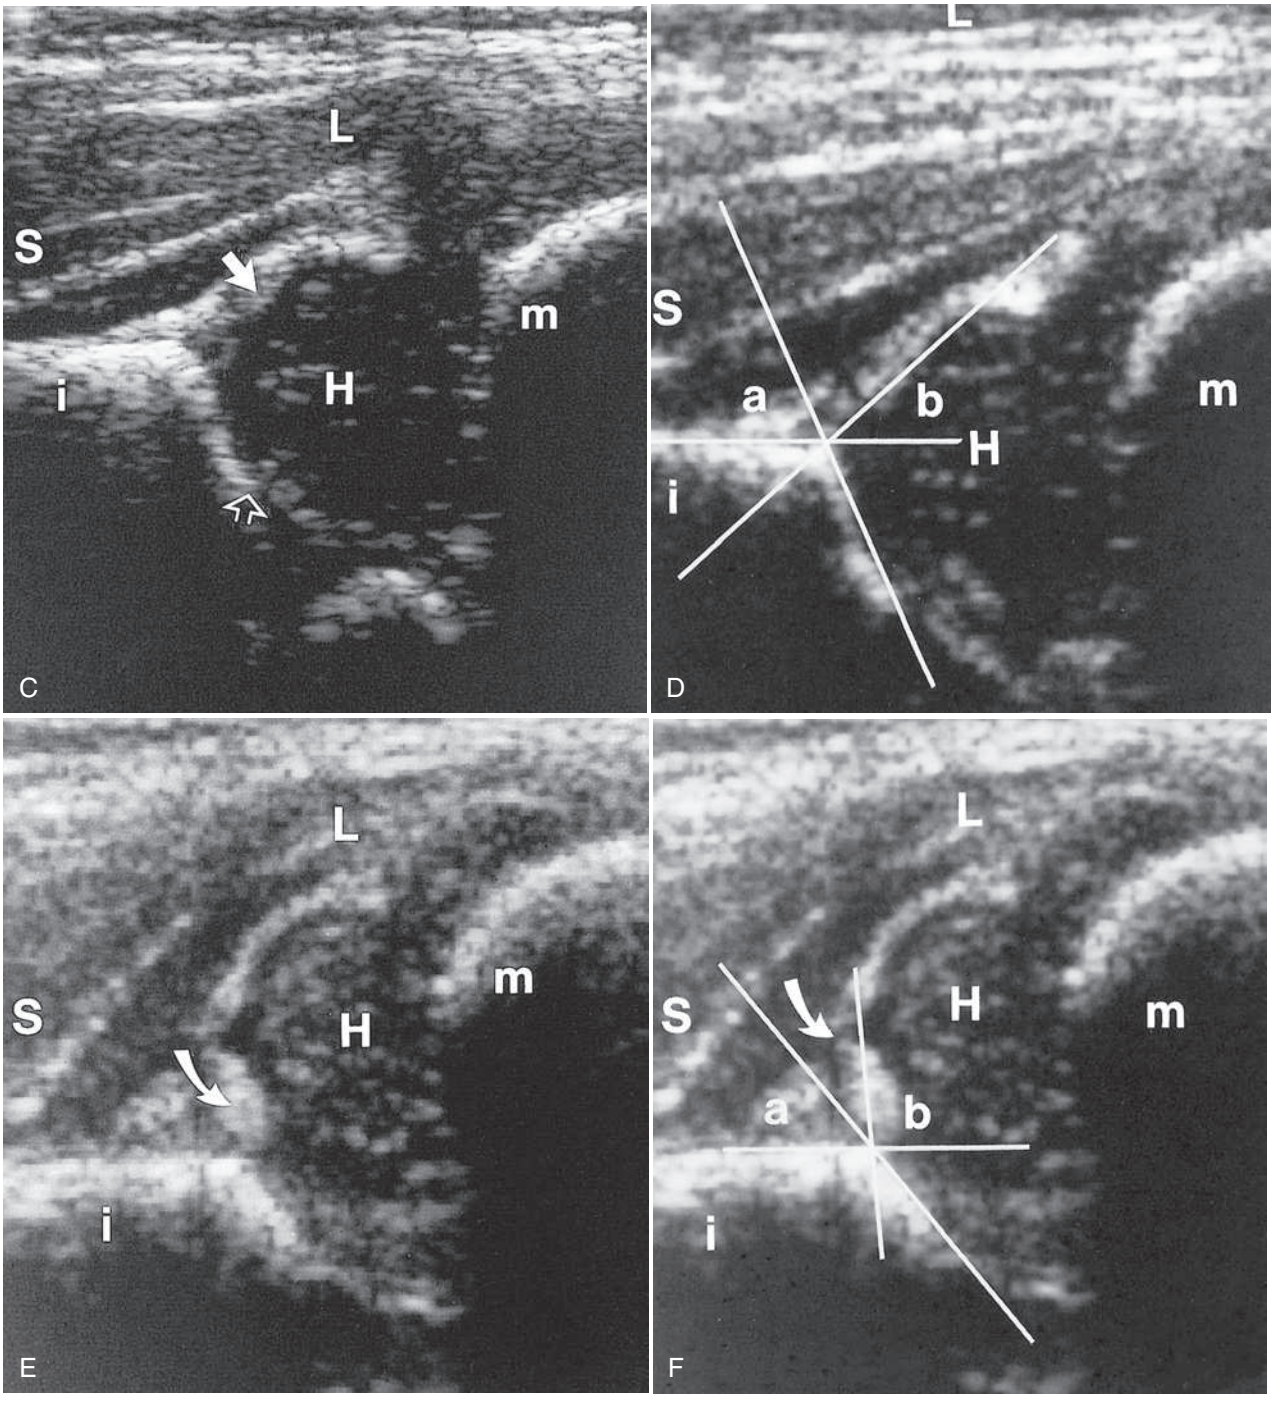

FIG. 55.1, cont'd **(C) Normal hip** sonogram shows sonolucent femoral head *(H)* resting against the bony acetabulum. Coronal/Flexion View

In the **coronal/flexion view** the transducer is maintained in a coronal plane with respect to the acetabulum (Fig. 55.2A) while the hip is moved to a 90-degree angle of flexion. During the assessment in this view, the transducer is moved in an anteroposterior direction with respect to the body to visualize the entire hip. Anterior to the femoral head, the curvilinear margin of the bony femoral shaft is identified. In the midportion of the acetabulum, the normally positioned femoral head is surrounded by echoes from the bony acetabular components (see Fig. 55.2B). Superiorly, the lateral margin of the iliac bone is seen, and the transducer position must be adjusted so the iliac bone becomes a straight horizontal line on the monitor. This landmark (**iliac**

bone line: flat and straight) is a key to accurately visualizing the midacetabulum and to obtaining the maximum depth of the acetabulum. When the transducer is positioned too anteriorly, the iliac line is inclined laterally; and if positioned too posteriorly, the iliac line exhibits concavity. When the plane is not correctly selected, it could be falsely concluded that the acetabulum is maldeveloped. A **normal hip** gives the appearance of a "ball on a spoon" in the midacetabulum. The femoral head represents the ball, the acetabulum forms the bowl of the spoon, and the iliac line is the handle. When the transducer is moved posteriorly and the scan plane is over the posterior margin of the acetabulum, the posterior limb of the triradiate cartilage, also known as the "posterior lip," becomes an easily recognized landmark. The bone above and below the cartilage notch is flat, and the normally

positioned femoral head is not visualized (Videos 55.1 and 55.2).

In **subluxation,** the femoral head is displaced laterally, posteriorly, or both, with respect to the acetabulum. Soft tissue echoes are seen between the femoral head and the bony reflections from the medial acetabulum. In **dislocation,** the femoral head is completely out of the acetabulum (see Fig. 55.2C). With superior dislocations, the femoral head may rest against the iliac bone. In posterior dislocations, the femoral head is seen lateral to the posterior lip. The acetabulum is usually not visualized in a dislocation because the bony shaft of the femur blocks the view.

Dynamic examination in the coronal/flexion view has two components. The first is performed over the posterior lip using a push-and-pull maneuver (see Fig. 55.2D-E). In the normal hip the femoral head is never seen over the posterior lip of the acetabulum. When there is instability, a portion of the femoral head appears over the posterior lip of the triradiate cartilage as the femur is pushed. With a pull, the head disappears from the plane. In a dislocated hip, the femoral head may be located over the posterior lip and may or may not move out of the plane with traction. The second component of the dynamic examination is performed over the midacetabulum. The Barlow-type maneuver is performed with **adduction** and gentle pushing against the knee. In the normal hip the femoral head will remain in place against the acetabulum. With subluxation or dislocation, the head will migrate laterally and posteriorly, and there will be echogenic soft tissue between the femoral head and the acetabulum (Videos 55.3, 55.4, and 55.5).

Transverse/Flexion View

Transition from the coronal/flexion view to the **transverse/flexion view** is accomplished by rotating the transducer 90 degrees and moving the transducer posteriorly so it is in a posterolateral position over the hip joint. The orientation of the scan plane is parallel to the flexed femoral shaft (Fig. 55.3A). The plane of the transducer and the landmarks are demonstrated on a computed tomography (CT) scan of a patient in a spica cast with a normal left and dislocated right hip (see Fig. 55.3B). Sonographically, the bony shaft and metaphysis of the femur give bright reflected echoes anteriorly, adjacent to the sonolucent femoral head. The echoes from the bony acetabulum appear posterior to the femoral head, and in the normal hip, a **U-shaped configuration** is produced by the metaphysis and the ischium (see Fig. 55.3C). The relationship of the femoral head and acetabulum is observed while the flexed hip is moved from maximum adduction to wide abduction. The sonogram changes its appearance in abduction and adduction. The deep, U-shaped configuration is produced with maximum abduction, whereas in adduction, a shallower, V-shaped appearance is observed. It is important to have the transducer positioned posterolaterally over the hip to see the medial acetabulum. When the transducer is not posterior enough, the view of the acetabulum is blocked by the femoral metaphysis, and the hip can appear falsely displaced. In adduction, the hip is stressed with a gentle posterior push (a **Barlow test**). In the normal hip, the femoral head will remain deeply in the acetabulum in contact with the ischium with stress. In **subluxation,** the hip will be normally positioned or mildly displaced at rest, and there will be increased lateral displacement from the medial acetabulum with stress, but the femoral head will remain in contact with a portion of the ischium. With **frank dislocation,** the hip will be laterally and posteriorly displaced to the extent that the femoral head has no contact with the acetabulum, and the normal U-shaped configuration cannot be obtained (see Fig. 55.3D). The process of dislocation and reduction is able to be visualized in unstable hips in the transverse/flexion view. With abduction, the dislocated hip may be reduced, representing the sonographic counterpart of the Ortolani maneuver. With adduction, the subluxated hip may be dislocatable, corresponding to the Barlow maneuver (Videos 55.6, 55.7, and 55.8).

Alternative Views

A **transverse/neutral view** is still used in our examination protocol, but this view has not been included in published guidelines. The transducer is directed horizontally into the acetabulum from the lateral aspect of the hip; the leg is in physiologic neutral position. The plane of interest is one that passes through the femoral head into the acetabulum at the center of the triradiate cartilage.[26] The position of the head with respect to the triradiate cartilage is evident and can confirm findings on the coronal/neutral view.

A number of **anterior views** have been described, and sonographers experienced in their use have indicated success with these views.[12,24] The anterior approach of Dahlstrom and colleagues[13] is performed with the patient supine and the hips flexed and abducted. The transducer is placed anterior to the hip joint and is centered over the femoral head with the plane of the sound beam parallel to the femoral neck (Fig. 55.4A-B). A Barlow or push maneuver can be performed to detect instability. **Complete dislocation** is considered to be present when femoral head displacement exceeds 50% of its diameter (see Fig. 55.4C). The image produced in a normal hip is an axial section through the acetabulum and a longitudinal section through the femoral head and neck.[11] The anterior view is particularly useful in rigid abduction splints and casts in which the posterior aspect of the hip is covered.

Evaluation of the Infant at Risk

We examine each hip in multiple views and report our findings with an emphasis on position and stability. Femoral head position is described as normal, subluxated, or dislocated. Dislocations are easy to determine, and we have had no difficulty with their identification. Sometimes it can be problematic to decide whether an abnormal hip that is widely displaced should be called "subluxated" or "dislocated." Stability testing is reported as normal, lax, subluxatable, dislocatable (for subluxated hips), and reducible or irreducible (for dislocated hips). When stress maneuvers are performed, it is important that the infant be relaxed; otherwise, inconsistency may be found between the sonographic and clinical examination findings and in serial ultrasound studies.

The acetabulum is assessed visually and is described as normal, immature, or dysplastic. More important are the development of the cartilaginous labrum and its coverage of the femoral head. Situations in which the bony component is steeply angled but the cartilage is well developed and covers the femoral head should

be noted. Deformity and increased echogenicity of the cartilage are indications of more severe acetabular dysplasia.

Evaluation During Treatment

The usefulness of **sonography in the follow-up of infants with DDH,** whether for observation of resolving abnormality or in conjunction with a defined treatment regimen, is widely accepted. Currently, sonography is routinely used to follow borderline cases, particularly in very young infants, before a commitment is made to a treatment regimen. When treatment is indicated, ultrasound is typically used to monitor hip position during treatment. Dynamic splints, such as the Pavlik harness, hold the hip in a flexed abducted position. These restraints and similar devices are popular, and ultrasound has been tested as a way of monitoring hip position for infants in splint devices.[34,39,40] The sonographic examination in these patients is limited to the transverse/flexion and coronal/flexion views. The stress portion of the examination should not be performed unless requested. Typically, stress is not used until the conclusion of treatment, when weaning from the harness is instituted.

One of the problems with follow-up sonography has been its reliability in morphologic assessment of the bony acetabulum. Reports of discrepancies between the sonographic appearance of the bony acetabulum and the radiographic appearance indicate inexact correlation.[34] This may result from observer variation and the nature of the ultrasound measurements. The American Academy of Orthopaedic Surgeons (AAOS) guideline states that at 4 to 6 months of age it is appropriate to shift to the radiograph when following a patient.[41] We have chosen to include the pelvic radiograph as a baseline toward the end of the treatment protocol. The older the infant, the more we tend to consider radiography, particularly when the ossification centers are large. After successful treatment, continued monitoring of acetabular development by periodic radiographs is prudent. Residual acetabular dysplasia is reported in a small number of patients.[42]

At one time, we performed ultrasound in severe cases of DDH after casting through a window cut in the cast posteriorly. Now, cross-sectional imaging with CT or magnetic resonance imaging (MRI) is done after casting. The localizer CT film enables the technologist to select the appropriate level to assess hip position with attention to keeping the radiation dose low. MRI is increasingly used and gives no ionizing radiation, although its high cost and limited availability are disadvantages.[43] Our MRI protocols include T2-weighted images in axial and coronal planes.[44] Vascularity of the femoral head after reduction can be evaluated by adding contrast to the examination.[45]

Avascular necrosis of the femoral head is a recognized complication of DDH treatment devices. Both color and power Doppler ultrasound have been used to assess the vascularity of the femoral head during treatment. Because of the microvascular architecture in the cartilage canals, power Doppler sonography is thought to have the best potential. Normal hips show a radial pattern of flow from the center of the unossified head. The central collection of vessels is the precursor of the ossification center and is seen before the center is apparent on radiographs. Bearcroft and colleagues[46] reported that diminished flow can be demonstrated when the hip is placed in wide abduction, compressing the medial circumflex artery. This may correlate with development of avascular necrosis, and thus assessment of flow has been proposed as an aid in determining a safe abduction position for treatment. The examination is technically difficult and currently performed primarily in the research arena. Magnetic resonance imaging has become the preferred method for diagnosis of avascular necrosis.[45]

OTHER PEDIATRIC MUSCULOSKELETAL ULTRASOUND APPLICATIONS

In pediatric musculoskeletal sonography, knowledge of the normal appearance of cartilage, soft tissues, and developing osseous structures is essential. Use of a high-frequency linear transducer is advised, and comparison to the contralateral unaffected side is recommended. The focal zones should be over the area of interest with the appropriate depth, and gain should be optimized for the tissues scanned.[47] This section reviews ultrasound use in the diagnosis and management of congenital musculoskeletal abnormalities, including foot deformities, teratologic hip, congenital limb deformities, congenital nonhip dislocations, and brachial plexus injury. It also describes sonographic findings in other conditions such inflammation and trauma specific to children. Tumors and sports injuries are discussed in other musculoskeletal ultrasound chapters (see Chapters 23 and 24).

Nondevelopmental Dysplasia Hip Abnormalities

Painful Hip and Hip Joint Effusion

A variety of conditions cause hip pain in pediatric patients, including transient synovitis, osteomyelitis, Perthes disease, slipped capital femoral epiphysis, fracture, and arthritis. Although radiography is performed initially and is often diagnostic, the plain radiographic film often is normal in the presence of small joint effusions. Sonography can be used to determine if an effusion is present and to guide arthrocentesis. Several large studies of sonographic hip joint effusion detection have been reported. They show the technique to be easy to master and rapidly performed. The results have been highly sensitive in the detection of effusion, with as little as 1 mm of fluid recognized experimentally. False-negative results have been reported in infants younger than 1 year,[48] probably because the femoral neck has not developed and the capsule is small. Fluid tends to surround the femoral head instead.

Although hip sonography is sensitive in the detection of effusion, its place in the workup of the painful hip varies from center to center. In one large series, although ultrasound facilitated early diagnosis or prompted further investigation in some patients, it altered the therapy or outcomes in only 1% of the patients.[49] Clinicians use a number of physical signs (oral temperature, weight bearing) and laboratory findings (white blood cell count, C-reactive protein, erythrocyte sedimentation rate) to distinguish septic arthritis from transient synovitis in children.[47,50,51] They employ these parameters when making the decision to perform joint aspiration or seek additional imaging.

At our institution, the workup of the painful hip is individualized, and we find hip sonography to be helpful in certain circumstances. When the clinical picture is unclear, the presence or absence of an effusion can guide the clinician in the diagnosis and the need for further evaluation. For example, in the patient with clinical and laboratory signs of transient synovitis, hip sonography may be used to demonstrate an effusion; however, the patient does not usually undergo joint aspiration. In a patient with hip pain and signs of sepsis, MRI may be performed, regardless of the results of hip ultrasound, to exclude osteomyelitis and other soft tissue infection sites. MRI provides a more detailed evaluation of localized disease beyond the hip joint.

The patient is examined in the supine position with the hips in the neutral position with as little flexion as possible. A high-frequency linear transducer is recommended. The hip is scanned in a sagittal, oblique plane along the long axis of the femoral neck (Fig. 55.5). The brightly echogenic anterior cortex of the femoral head and neck with the intervening echolucent physis is seen; the anterior margin of the bony acetabulum is visualized superiorly. The anterior recess of the joint capsule parallels the femoral neck in this area, with the outer margin forming an echogenic line anterior to the cortex of the femoral neck and extending over the femoral head. The iliopsoas muscle is superficial to the capsule.

In the normal hip, the joint capsule has a concave contour and the thickness of the capsule from the outer margin to the cortex of the femoral neck measures 2 to 5 mm. When there is joint effusion, the anterior recess of the capsule becomes distended with a convex outer margin, and fluid is seen between the anterior and posterior layers of the capsule.[52] There is increased thickness of the abnormal joint capsule of at least 2 mm compared with the normal contralateral capsule.[53-55] The use of measurements alone is problematic when both hips are abnormal, although this occurs infrequently.

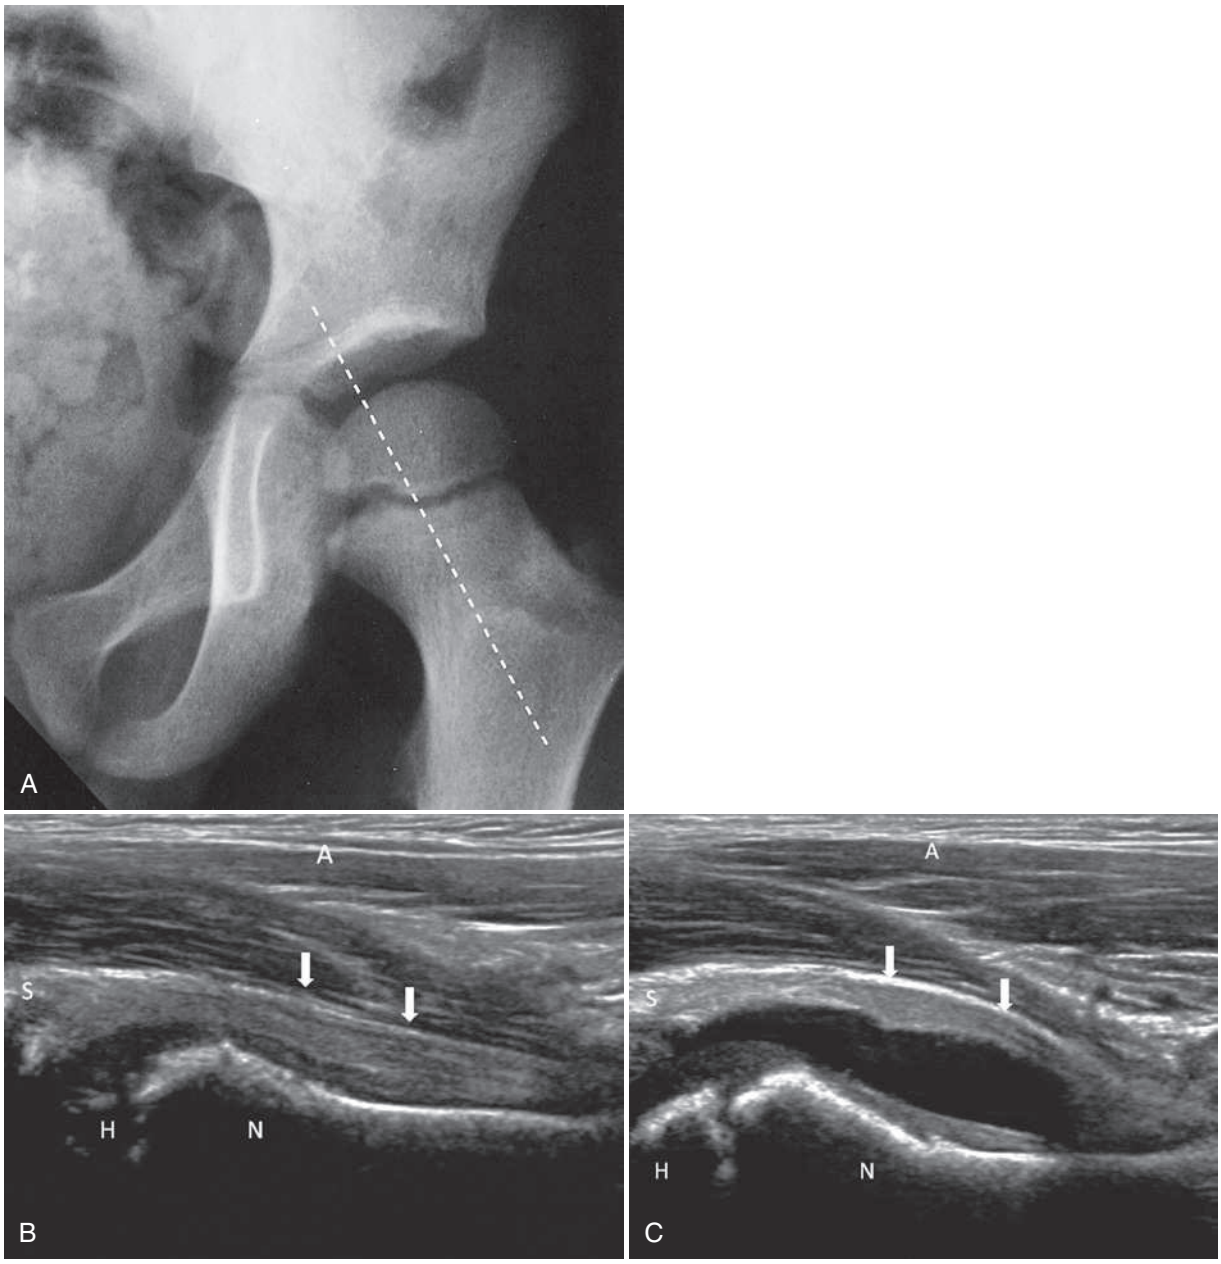

FIG. 55.5 Hip Joint Transient Synovitis. (A) Transducer position parallels femoral neck. Scan plane is shown by dashed line. **(B)** Normal hip sonogram shows joint capsule *(arrows)* following contours of femoral head *(H)* and neck *(N)*. **(C)** Hip effusion sonogram shows bulging joint capsule *(arrows)* with hypoechoic fluid in anterior recess extending along femoral neck *(N)* and cephalad over femoral head. *A,* Anterior; *S,* superior.

Fluid of varying echogenicity is visible within the capsule. The echoes are created by inflammatory debris or hemorrhage.[54] Zieger and colleagues[48] concluded that if the fluid is anechoic, the diagnosis of septic arthritis can be excluded. Other investigators have found the character of the fluid to be nonspecific,[49,53] describing echoes (probably representing hemorrhage) in the fluid in transient synovitis and anechoic fluid in cases of septic arthritis. Color Doppler sonography has also been used in an attempt to distinguish between infectious and noninfectious effusions, but the technique has proved to be unreliable.[56]

When fluid is detected, arthrocentesis can be performed using sonographic guidance; a saline lavage can be used if fluid cannot be withdrawn. Although the procedure requires patient cooperation, it is relatively easy to perform and avoids the ionizing radiation required in fluoroscopic arthrocentesis. Some clinicians use arthrocentesis therapeutically in Perthes disease, which can be recognized by fragmentation of the femoral head and thickened articular cartilage.[57] Sonograms to check for effusion may show other pathology, such as slippage of the head in **slipped capital femoral epiphysis** and cortical disruption in fracture or osteomyelitis, but these findings are better evaluated radiographically.

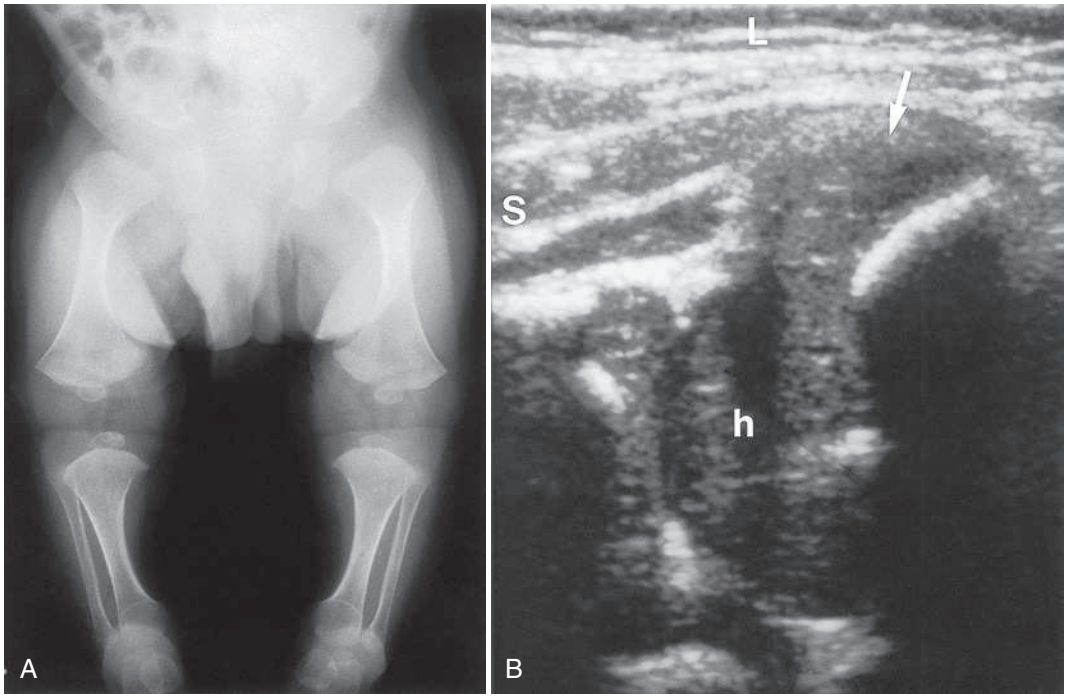

FIG. 55.6 Atypical Hip. (A) Radiograph of a 4-month-old infant with **Kniest dysplasia** shows shortening of the long bones and bulbous ends of the bones. **(B)** Coronal/neutral sonogram shows increased echogenicity of the cartilage and coxa vara with elevation of the greater trochanter *(arrow)* and narrowing of the acoustic window of the hip joint. *h,* Femoral head; *L,* lateral; *S,* superior.

Soft tissue swelling and other soft tissue abnormalities outside the joint capsule have also been diagnosed.

Teratologic Hip Dislocation

Teratologic hip dislocation is considered a different entity from DDH. Teratologic hips are dislocated earlier in utero than DDH and are seen in patients with various syndromes and neuromuscular diseases such as **arthrogryposis, Larsen syndrome,** and **chromosomal abnormalities.** Sonographic examination is the same as for DDH, but the planes of interrogation may require adjustment if there are contractures. Sonographic findings at rest resemble frank dislocation in DDH, but teratologic dislocation is more severe with contractures and limited movement. The acetabulum is small, typically obscured by the proximal femur, and the femoral head is distorted from chronic dislocation.[58,59]

Atypical Hips

Other patients with "atypical hips" include those with **skeletal dysplasias, congenital myopathy,** or **congenital coxa vara.** These patients have displacement of the hips, acetabular dysplasia, and coxa vara. There is delayed ossification of the bones, allowing examination at a later age, but the cartilage and soft tissues often show abnormal increased echogenicity, which obscures the osseous anatomy. With coxa vara, there is narrowing of the sonographic window, and the cartilage of the greater trochanter is elevated. The greater trochanter can be mistaken for a dislocated femoral head, so careful scanning is required. Adduction of the femur during scanning can widen the sonographic window and allow visualization of the normally located femoral head[60-63] (e.g., Kniest dysplasia) (Fig. 55.6).

Congenital Foot Deformities

Club Foot

The treatment of **equinovarus deformity** has dramatically improved with the development of the Ponseti technique of serial casting followed by limited surgery when necessary,[64] and similar changes have occurred with treatment of vertical talus. Imaging of foot anomalies has traditionally been radiographic, but ultrasound is now recognized as an accurate alternative for examination of both unossified and ossified tarsal bones at rest and with movement to assess alignment before and after treatment.

In clubfoot, there is medial displacement of the navicular and anterior displacement of the medial malleolus in relation to the talus with narrowing of the space between the bones.[65] The most commonly used sonographic measurement is the distance between the medial malleolus and the navicular (MMN), measured at rest and with abduction in the medial coronal plane. The measurement is lower than normal in clubfoot, and there is decreased movement with abduction. Other views and measurements include the calcaneocuboid (CC) joint, the length of the talus (TL), the talonavicular joint, the posterior sagittal view for measurement of the tibiocalcaneal distance, and the navicular morphology.[66-69] Normal measurements have been established for some of the views (MMN, CC, TL) for comparison.[70]

Vertical Talus

Congenital vertical talus is a less common anomaly of the foot, frequently occurring in patients with neuromuscular or genetic abnormalities in which there is dorsal dislocation of the navicular

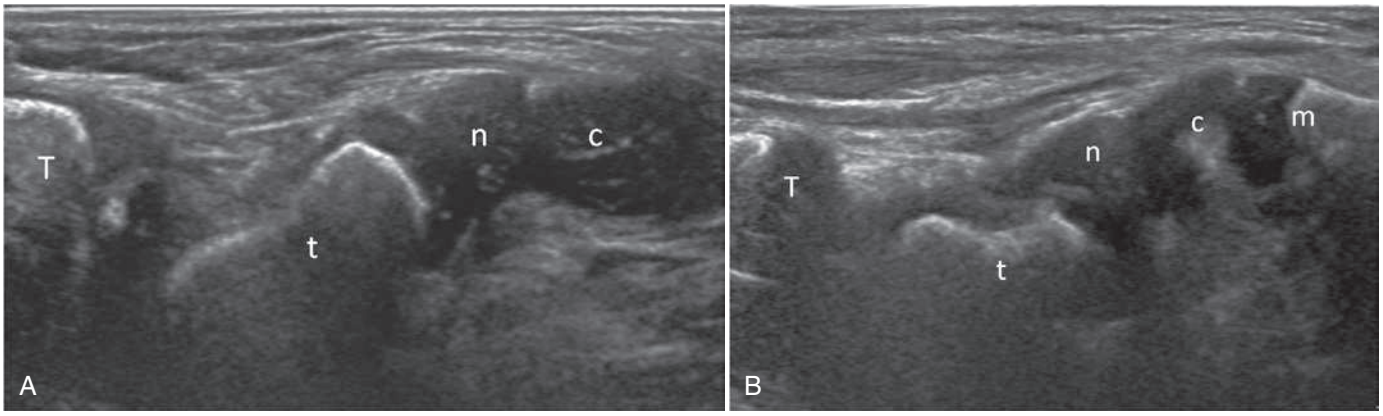

FIG. 55.7 Normal Foot Compared With Congenital Vertical Talus. (A) Sagittal view of the dorsum of the normal foot. The tibia *(T)* is visible proximally, and the talus *(t),* navicular *(n),* and cuneiform *(c)* in a line distally. **(B) Congenital vertical talus.** Sagittal view of the dorsum of the foot. The navicular *(n)* is displaced dorsally and superiorly overlying the head of the talus *(t).* The cuneiform *(c)* and metatarsal *(m)* distally are aligned with the navicular. The tibia *(T)* is visible superiorly.

bone with respect to the plantarflexed (vertical) talus, and it is not reducible. Oblique talus is similar in that the talus is more vertical than normal, and there is dorsal displacement of the navicular in dorsiflexion, reducible in plantarflexion. In the infant with unossified navicular and small talus, it can be difficult to determine the alignment of the joint radiographically, but with ultrasound the joint is easily seen when scanning in the sagittal plane dorsally. Normally, the navicular is located at the head of the talus in a straight line with the first metatarsal. In congenital vertical talus and oblique talus at rest, the navicular is dorsally displaced, projecting anterior to the head of the talus. With plantar flexion, the alignment will not change in vertical talus but corrects with oblique talus.[71] Some investigators use serial manipulation to correct vertical talus,[72] and ultrasound can be used to confirm improving alignment in these patients (Fig. 55.7). Other foot deformities that can be evaluated sonographically include skewfoot and metatarsus adductus.[66]

Congenital Limb Deformities

Proximal Focal Femoral Deficiency

Proximal focal femoral deficiency (PFFD) is a rare congenital anomaly with variable hypoplasia or absence of the proximal femur, usually unilateral and most often isolated. Prenatal diagnosis focuses on the diagnosis of a short femur based on routine femur measurements. If both femurs are short, it suggests skeletal dysplasia. After birth, ultrasound can be used to determine the subtype of PFFD, and thus the treatment, based on what cartilaginous components are present before they are ossified. Scanning includes the standard views of the hip with additional longitudinal and transverse views of the proximal femur. If there is a cartilaginous femoral head, it is essential to determine if it is connected to the proximal femur (Fig. 55.8). This is a difficult examination because of flexion contractures, the small size of the structures, and patient movement, but it can be helpful until the patient can undergo definitive MRI.[73-75]

Tibial Hemimelia

Tibial hemimelia is a rare defect in which there is hypoplasia or aplasia of the tibia, often associated with other congenital anomalies. As in PFFD, evaluation of cartilaginous and soft tissue components is important in the determination of surgical treatment and prognosis, and sonography can be used for this before ossification, scanning anteriorly in longitudinal and transverse planes with flexion and extension of the knee. The osseous defect in the tibia may be proximal or distal, and there may be a substantial cartilaginous component that can be seen sonographically.[76,77] The presence and function of the quadriceps tendon and the extensor mechanism are key; when the mechanism is intact, the cartilaginous patella will be visible overlying the intercondylar notch of the distal femur, and the patellar tendon will extend from the lower pole of the patella to the proximal tibia. The presence of an intact quadriceps mechanism allows reconstructive surgery and preservation of the knee joint, often with below-knee amputation and use of a prosthesis. The absence of the quadriceps mechanism may lead to disarticulation of the knee and use of a prosthesis without the benefit of knee extension.[76,78]

Congenital Nonhip Dislocations

Elbow and Knee Dislocations

Elbow and knee dislocations are rare, usually occurring secondary to malposition in utero and various syndromes, especially **arthrogryposis** and **Larsen syndrome.** Radial head dislocation can also be isolated. Diagnosis of **knee dislocation** can be problematic radiographically because of the large amount of cartilage making up the joints, and ultrasound is an easy way to diagnose displacement or dislocation, scanning anteriorly in longitudinal and transverse planes (Fig. 55.9). Circumferential scanning may be helpful when the orientation of the joint is uncertain. Comparison views of the contralateral side can be used for confirmation, but dislocation is often bilateral. Dynamic

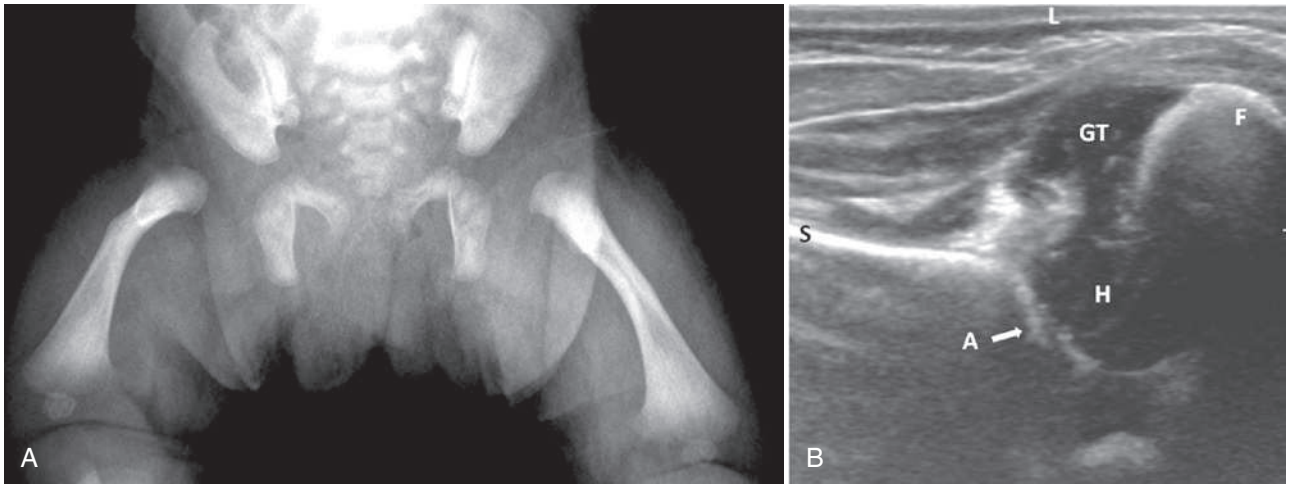

FIG. 55.8 Proximal Femoral Focal Deficiency (PFFD). (A) Pelvic radiograph shows PFFD on the right with a hypoplastic bowed right femur. Right hip appears laterally displaced. Left side normal. **(B)** Coronal/neutral sonogram of the right hip shows coxa vara with elevation of the greater trochanter. Femoral head seated. *A,* Acetabular roof; *F,* femur; *GT,* greater trochanter; *H,* femoral head; *L,* lateral; *S,* superior.

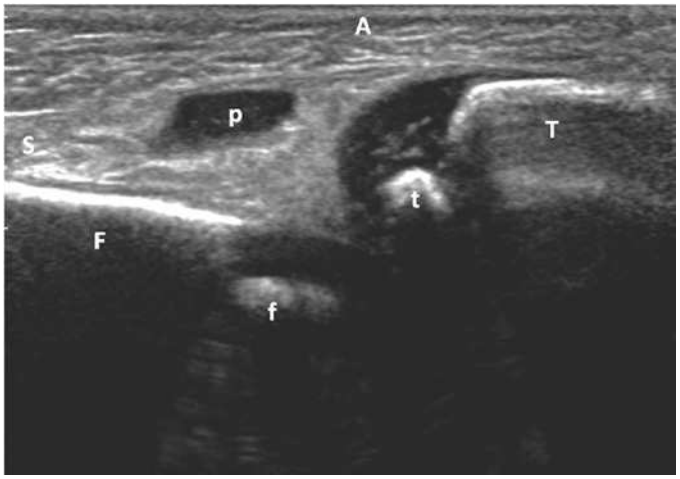

FIG. 55.9 Knee Dislocation With Anterior Displacement of the Tibia. Anterior longitudinal view in extension. *A,* Anterior; *f,* distal femoral epiphysis; *F,* femur; *p,* patella; *S,* superior; *t,* proximal tibial epiphysis; *T,* tibia.

sonography can be used to determine optimal position for reduction, splinting, and physical therapy.[79-81]

Patellar Dislocation

Congenital patellar dislocation is a rare anomaly of variable severity characterized by flexion contracture, genu valgum, and external rotation of the tibia. When suspected, diagnosis is easily made with ultrasound, scanning in sagittal and transverse planes anteriorly with the knee partially flexed. The patella normally lies in the intercondylar notch of the femur; the quadriceps muscle is visible superiorly and the patellar tendon inferiorly extending from the lower pole to the tibial tuberosity. In dislocation the patella may be elevated and/or laterally displaced, and it may be small, requiring more extensive search of the thigh. The patellar tendon may be thin and may appear "stretched," and the quadriceps muscle may be thin. Early diagnosis and treatment can lead to improved joint function[82] (Figs. 55.10 and 55.11).

Brachial Plexus Injury

Brachial plexus injury due to shoulder dystocia, also called **Erb palsy,** is the most common indication for shoulder ultrasound in the infant. Advanced imaging such as CT or MRI is reserved for older children in whom abnormalities persist. Brachial plexus birth injury manifests with weakness of the arm, limited external rotation, and in some cases progressive posterior displacement of the humeral head. It is relatively common, with an incidence of 3.8 per 1000 births. Although many cases resolve spontaneously, 7.3% of patients with birth injury progress to develop shoulder dislocation in the first year of life.[83] When symptoms persist, it is important to monitor the condition so that appropriate treatment can be initiated before there is substantial deformity of the osseous structures and soft tissues.[84]

We scan the shoulder in infants by using multiple views,[85] for conditions such as fracture, infection, or masses (Fig. 55.12). However, the most commonly used protocol for evaluation of brachial plexus injury is posterior scanning of the glenohumeral joint, first described by Hunter and colleagues[86] The technique was subsequently refined, adding dynamic scanning with internal and external rotation of the arm to elicit instability and reduction.[87] Martinoli and colleagues developed a technique for direct visualization of the brachial plexus in the neck.[88]

The patient is examined lying on the side or seated, supported by the parent, and the glenohumeral joint is scanned posteriorly in the transverse plane at rest and with maximum internal and external rotation. The humeral head rests on the cartilage of the glenoid with the triangular labrum extending posteriorly from the lip of the glenoid. The glenoid has a well-defined bony margin with approximately 90 degrees of angulation with respect to the posterior aspect of the scapula, similar in appearance to the coronal/flexion view of the infant hip. The humeral head normally protrudes beyond a line drawn parallel to the scapula; the degree

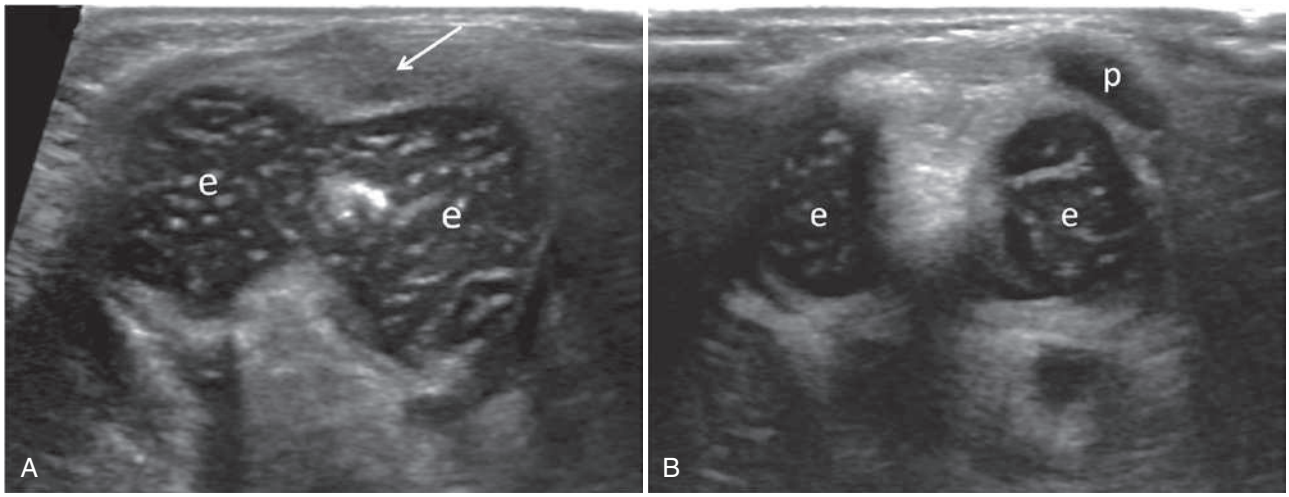

FIG. 55.10 Lateral Dislocation of the Patella. (A) Transverse ultrasound of the knee shows the cartilage of the femoral epiphysis *(e)* and empty intercondylar notch *(arrow).* **(B)** More inferior image shows cartilaginous femoral condyles *(e)* and laterally dislocated patellar cartilage *(p).*

The femur *(f)* and the tibia *(t)* are normally aligned with a very thin hypoechoic band anteriorly representing a dysplastic patellar tendon *(arrow).* The patella is not visible. **(C)** Sagittal magnetic resonance imaging demonstrates the superiorly dislocated patella and very thin patellar tendon.

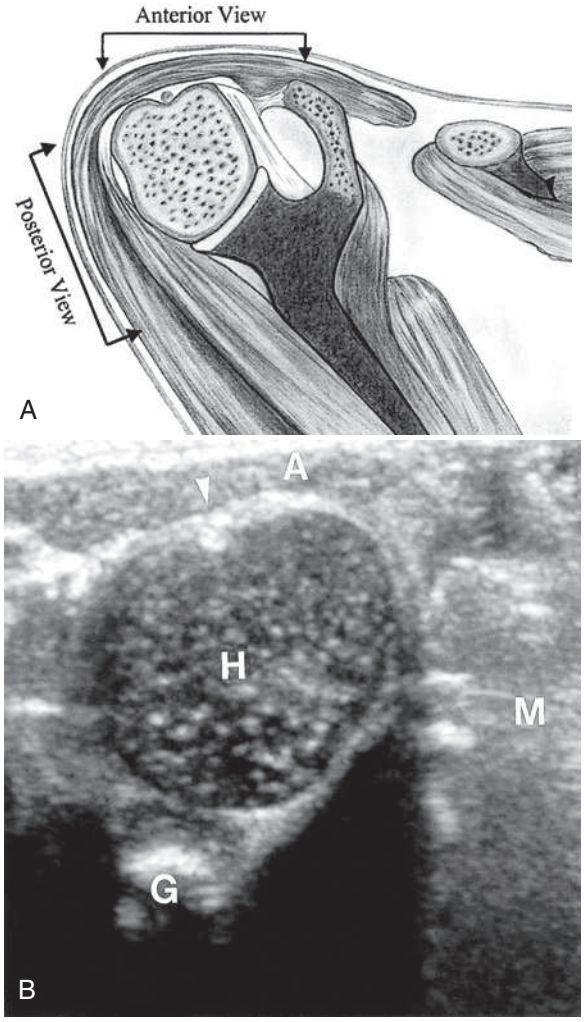

FIG. 55.12 Normal Neonatal Shoulder. (A) Illustration of anterior and posterior axial planes of interrogation of the shoulder. **(B)** Anterior axial image. Cartilaginous humeral head *(H)* anteriorly rests on glenoid *(G)* posteriorly. Biceps tendon *(arrowhead)* can be seen in the bicipital groove. *M,* Medial. (**A** reproduced with permission from Grissom LE, Harcke HT. Infant shoulder sonography: technique, anatomy, and pathology. Pediatr Radiol. 2001;31[12]:863-868.[85])

of protrusion is measured between the scapular line and a line connecting the osseous lip of the glenoid and the posterior margin of the humeral head cartilage as the alpha angle, normally less than 30 degrees.[89] The subluxated shoulder shows increased protrusion, deflection of the labrum, and deformity of the glenoid, which becomes irregular and angled, and the dislocated shoulder is not in contact with the glenoid surface. With internal rotation the position may worsen, and with external rotation the shoulder position may improve. This examination is technically challenging because of patient movement and agitation, but with experience it can be accomplished quickly and reproducibly.[87,90] One of the difficulties is determining the correct plane and angulation of interrogation. Repeat examination is recommended at 1, 3, 6, and 12 months of age, during which time there can be increasing displacement of the humeral head[90] (Fig. 55.13).

Inflammation

Infection

Ultrasound is increasingly used to evaluate pediatric patients for infection of the soft tissues,[91] often to supplement other modalities. Cellulitis (infection of subcutaneous soft tissues) and pyomyositis (infection of skeletal muscle) may be hematogenous or may originate from a puncture wound. Sonographically, there is heterogeneous soft tissue thickening and increased echogenicity in the affected area, and there may be regional adenopathy. If there is a puncture wound, foreign material or air may be present. Comparison with the contralateral unaffected side is helpful to make the diagnosis. The inflammatory process can progress to abscess formation or necrosis. Although inflammatory debris within the abscess may be hypoechoic, it can also be isoechoic or even hyperechoic and difficult to appreciate.[92] Color and power Doppler may also assist in the diagnosis in that the rim of the abscess will demonstrate increased flow, and the debris within the cavity should be avascular.[93] If the fluid is mobile, motion may cause color or power signal on Doppler sonography, but spectral analysis will not reveal any true vascularity. Sonographic guidance can be used to biopsy or drain an abscess.[94] A recent hematoma, early myositis ossificans, or a necrotic mass can have a similar appearance to an abscess, and the best way to distinguish infection from these entities is by clinical history and laboratory tests. In myositis ossificans and hematoma, after calcification has developed, the echo pattern changes, and being mistaken for abscesses becomes unlikely.

Septic arthritis can be an isolated abnormality or can be secondary to infection in the adjacent soft tissues or bone. Fluid is visible in the joint, and debris may or may not be seen within it. When joint fluid is anechoic or hypoechoic, it may be difficult to distinguish from the cartilage that caps the ends of the bones forming the joint. In addition, if there is debris in the fluid, it may be difficult to detect the septic effusion, similar to the soft tissue abscess (Fig. 55.14). Movement of the joint will show the cartilage-fluid interface clearly. Application of pressure to the tissue around a joint will cause joint fluid to shift, making the fluid easier to recognize. Pressure along the sides of the knee, for example, can force fluid into the suprapatellar bursa, thereby confirming an effusion. Color or power Doppler sonography may help because there is typically hyperemia in the capsule with infection.[95] The absence of hyperemia does not exclude septic arthritis.[56] As with hip effusions, sonography can be used to aspirate from the joints.[96]

Lyme disease, caused by the spirochete *Borrelia burgdorferi* and spread by deer ticks, can result in arthritis. This usually occurs in the subacute or chronic phase of the infection and is characterized by relapsing effusions, particularly in the knee joint. There may be synovial thickening, and cartilage loss is seen late in the course. This can be confused with juvenile rheumatoid arthritis, and the diagnosis should be considered in patients with oligoarticular joint effusions.[97]

Osteomyelitis typically occurs in the metaphyses of the long bones. The earliest sonographic sign is deep soft tissue swelling. Later signs are fluid along the cortex of the bone or, subperiosteally, fluid in the adjacent joint (either sterile or septic),

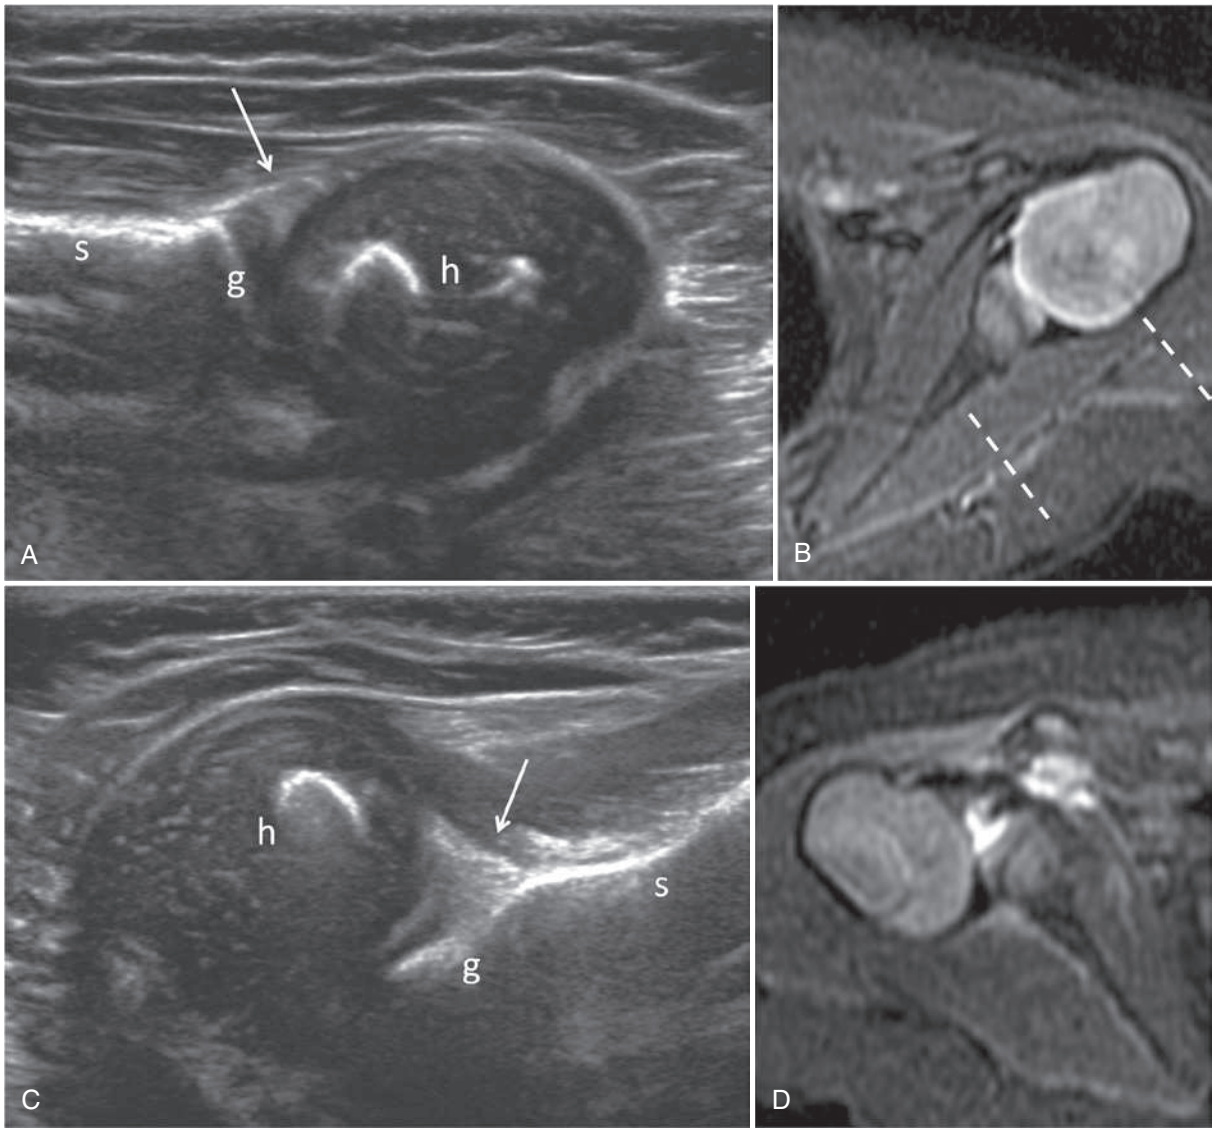

FIG. 55.13 Normal and Dislocated Shoulder. (A) Normal shoulder posterior axial sonogram. The humeral head *(h)* projects only minimally beyond the margin of the scapula. and cortical disruption (Fig. 55.15). Color and power Doppler sonography show increased flow at the margin of the elevated periosteum in advanced infection.[98-100] Osteomyelitis often spreads hematogenously in pediatric patients, so when it is detected in one location, examination of any other symptomatic areas is recommended. Some investigators examine all the extremities in this situation, particularly in infants who are difficult to assess clinically. Negative ultrasound findings do not exclude osteomyelitis.

Cat-scratch fever is caused by a gram-negative bacillus and is characterized by fever and regional, sometimes suppurative, adenopathy occurring proximal to the affected area—for example, in the groin related to scratches on the leg or in the epitrochlear area from scratches on the upper extremity. These infected nodes are highly vascular[101-103] (Fig. 55.16). Patients with cat-scratch disease may also develop hypoechoic hepatic and splenic lesions.[104]

Noninfectious Inflammation

Sonography has been used to evaluate and to monitor the effects of treatment in pediatric patients with arthritis. Synovitis and effusion are often seen, and there is increased Doppler signal in the inflamed, thickened synovium. The cartilage can also be examined for decreased thickness, increased echogenicity, and erosive changes.[105-107] Baker cysts occur in these patients, most often in the knee, and must be differentiated from a mass or deep venous thrombosis.

Trauma

Radiographs are the initial diagnostic modality used in evaluation of trauma, but sonography is a useful problem-solving tool when symptoms are present and radiographs are unrevealing. This applies to abnormalities such as growth plate fracture, soft tissue injury, and retained nonopaque foreign body.

Sonography is an excellent means to detect a fracture through the growth plate, particularly in the infant in whom the epiphyses

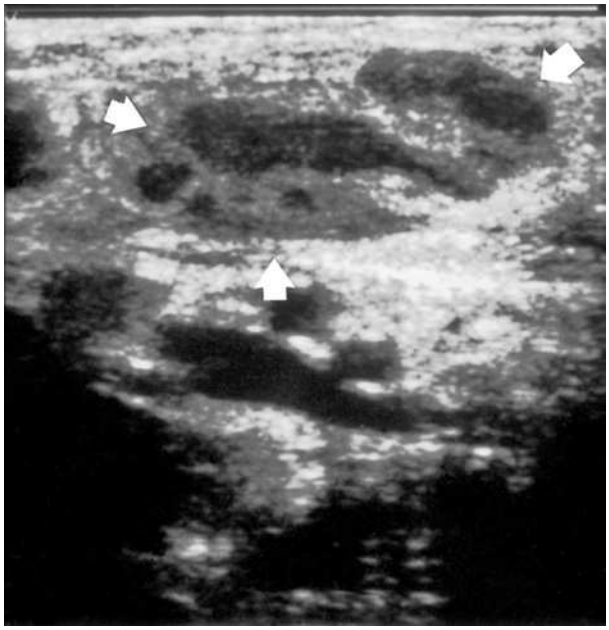

FIG. 55.16 Cat-Scratch Disease. Enlarged inguinal lymph nodes *(arrows)* with increased vascularity *(gray areas).*

are not ossified. When searching for a fracture, it is important to study the bone from all possible angles. In the extremities, this may mean 360-degree visualization. By careful examination of the affected area and comparison with the contralateral normal side, one can confirm fracture findings and assessment alignment. An avulsion or metaphyseal fracture may be detected that is not seen radiographically. This can be especially useful in **nonaccidental trauma** (Fig. 55.17). The joint can be examined to differentiate fracture from dislocation and to diagnose secondary effusion. Care must be taken to distinguish fluid from cartilage because both are hypoechoic. Passive motion and compression help to eliminate confusion. With fracture, there is virtually

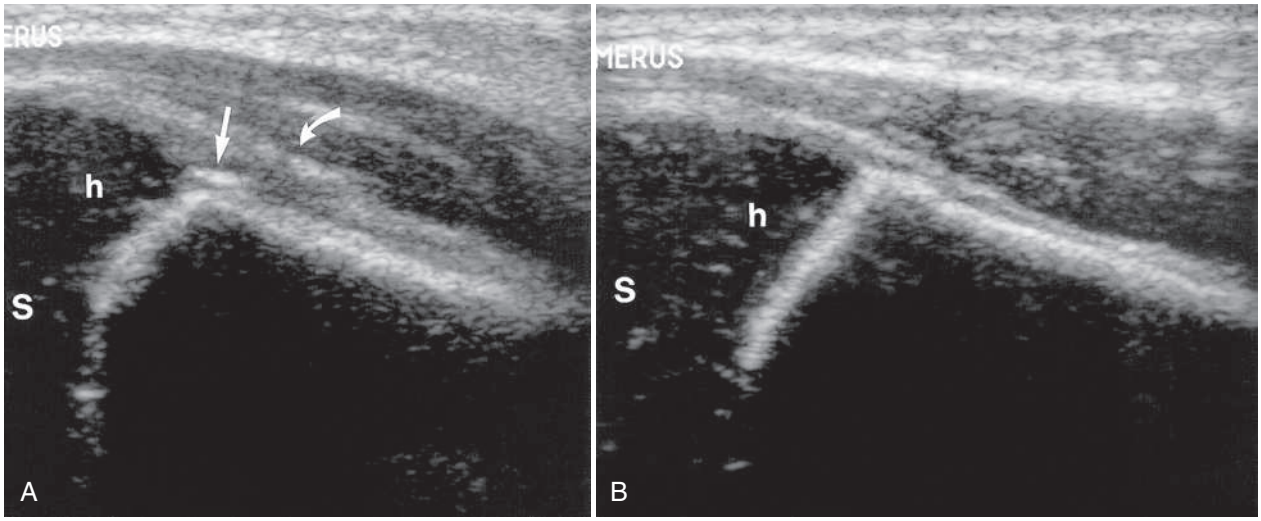

FIG. 55.17 Infant With Nonaccidental Trauma. Longitudinal sonogram of shoulder. **(A)** Metaphyseal fracture fragment *(straight arrow)* and soft tissue swelling *(curved arrow)* not detected on radiograph. **(B)** Normal side for comparison. *H,* Humeral head; *S,* superior.

always associated soft tissue abnormality, although this may be subtle and localized. The soft tissue planes become thickened by edema, and a small fluid collection may be present. Hematoma is initially hyperechoic with disruption of normal soft tissue planes, and later more complex as it organizes and resorbs. If myositis ossificans develops, it will gradually ossify, starting peripherally, but the early appearance will be identical.[108-110]

Ultrasound is also useful in evaluation of soft tissue structures such as tendons, ligaments, and muscles, and this is described in the other musculoskeletal chapters (see Chapters 23 and 24). In the pediatric population, sonography can be used to diagnose and grade Osgood-Schlatter disease.[111,112] Ultrasound can also be used for examination for foreign bodies.

Popliteal Cysts

Popliteal cysts often manifest in pediatric patients as a painless "swelling" or "soft tissue mass" behind the knee joint. Ultrasound is used to confirm the cystic nature of the mass. The cysts arise from the gastrocnemius-semimembranosus bursa lined with synovial fluid. They are deemed idiopathic, and although many practitioners think they are posttraumatic, a trauma history is rarely elicited, and associated intraarticular pathology is rare. Popliteal cysts are considered to be different from those found in childhood arthritis. These cysts are usually oval with a few septations but no solid tissue, located posteromedially in the popliteal fossa. Popliteal cysts can persist for years but do not rupture or become symptomatic. The natural history is spontaneous regression, so typically no treatment is recommended.[113-115] Whenever a cyst is seen in the area of a joint, ganglion cyst should also be considered.

SUMMARY

Although DDH was the first and continues to be the most common single indication for musculoskeletal ultrasound in pediatric patients, many other uses have been explored and developed. The ability to differentiate soft tissue structures from cartilage makes ultrasound especially helpful in infants. In this age of increasing concern regarding radiation, sonography has become an attractive alternative in the evaluation of the musculoskeletal system.

CHAPTER 56

Pediatric Interventional Sonography

Neil Johnson and Allison Aguado

SUMMARY OF KEY POINTS

- Understanding of the different needs of the parents and the child being treated is essential for pediatric interventions.
- Multimodality interventional suites allow for procedural guidance with varied modalities at different points during the procedure.
- Although needle guides may be used, they add to the expense of the procedure. Therefore we typically advocate for a single-operator freehand technique with needle entry point chosen after careful consideration of the anatomy and important structures such as ribs, large vessels, diaphragm, and bowel.
- Many needles and devices are available, and each practitioner should select and become very familiar with a limited selection of these devices.
- Few children younger than 12 years will cooperate during an invasive procedure, and a thorough familiarity with pediatric sedation is necessary, together with skilled personnel and adequate resuscitation facilities.
- In general, it is the external covering of an organ or muscle, the pleura, the peritoneum, the perimysium, or the deep fascia that registers pain sensation. Therefore local anesthesia is particularly important in these deep areas.
- Procedures such as abscess drainage, peripherally inserted central catheter (PICC) lines, pleural drainage, percutaneous cholangiography, targeted organ lesion biopsy, and musculoskeletal procedures can all benefit from ultrasound guidance.

NOTE FROM THE AUTHORS

GENERAL PRINCIPLES

The Patient

Unlike many adult patients, most pediatric patients are medically robust, without multiple comorbidities such as superimposed coronary, peripheral vascular, or cerebral disease. The smaller the patient, the more appropriate is the use of ultrasound for interventional procedure guidance of at least the initial access phase of an interventional procedure. Physicians whose practice includes mostly adults often regard a baby as a fragile, dangerous

patient. On the contrary, children tolerate levels of pH, creatinine, Po_2, and sedation that might cause major complications in adults. The pediatric patient is often quite unconcerned with the details of the disease and treatment, and all but the sickest patients simply want to leave the imaging department with the greatest amount of play and the least amount of anxiety and discomfort possible. Conversely, the parents are often more difficult to manage than the child. Understanding of the different needs of the parents and the child is essential from the beginning of the interaction.

Personnel and Equipment

Adequate equipment and experienced assistants are essential for successful and safe pediatric intervention. Although most interventional radiologists should be able to perform basic ultrasound-guided procedures on children, some cases are not appropriate for the inexperienced or occasional operator. A commitment to careful, graded learning, including the use of training phantoms, is needed, as is a good knowledge of regional anatomy or the willingness to learn and review the relevant anatomy before attempting challenging procedures.

By its nature, the timing of interventional practice is not always predictable or convenient, and it is common for the general ultrasound department to resent calls for borrowing ultrasound equipment on short notice. Despite the inconvenience, the interventionist should insist on the best technical ultrasound equipment available. The ideal situation is to have dedicated interventional ultrasound equipment housed in the interventional suite. Some major pediatric radiology departments have moved the interventional suite to the operating room environment. This integration of interventional radiology services within the operating room environment has generally resulted in increased cooperation between interventional radiologists and surgeons, especially involving intraoperative ultrasound assistance during traditional surgical procedures.

GUIDANCE METHODS

Computed tomography (CT) is necessary for some procedures, especially for procedures involving bone, but in most other cases, ultrasound-guided access with either ultrasound or fluoroscopic monitoring of wire and catheter placement is ideal (Table 56.1). Ultrasound can be used in the CT suite to complement a predominantly CT-guided procedure. Radiation dose to children undergoing CT procedures has recently aroused significant controversy, so ultrasound can be used to lower the need for CT.[1]

Multimodality Interventional Suites

The recent availability of cone-beam CT software installed on advanced angiography equipment with virtual three-dimensional (3-D) guidance enables combined complex interventional procedures involving ultrasound guided access, CT-like 3D imaging, live guidance graticules superimposed over 3-D images, and conventional fluoroscopy, all in the same interventional radiology suite.[2]

TABLE 56.1 Computed Tomography (CT) Versus Ultrasound for Interventional Procedures

	CT	Ultrasound
Ionizing radiation	Radiation dose to pediatric patients is an important current issue in pediatric imaging, particularly for interventional procedures, when more than one scan may be needed	None
Scan plane	Typically limited to initial axial images (especially difficult near the diaphragm)	Unlimited, except by bone or gas
Resolution	Excellent, although lack of fat in children can limit visualization	Excellent except for membranes in fluid collections
Convenience	More difficult to schedule	High
Cost	High	Intermediate
Monitoring	By repeat scan; no real-time ability; recovery from kinked wires difficult	Real time
Gas and bowel	Excellent, especially with contrast	Poor

Magnetic resonance imaging (MRI) guidance in pediatrics is uncommon. An example of multimodality guidance is shown in Fig. 56.1.

ULTRASOUND TECHNIQUES

Equipment and Transducers

A selection of transducers is essential. Small patient size and lack of subcutaneous fat in most children allow use of high-frequency transducers. Procedures performed around ribs, such as thoracentesis, are best done with small-footprint sector transducers. Vascular access procedures are best performed with a linear high-frequency transducer. Color Doppler is useful for localization of major blood vessels. Transducers with good near-field resolution are used for superficial lesions and for initial accurate placement of local anesthetic on the peritoneum, deep fascia, or organ capsule.

One Operator Versus Two

It is common for inexperienced operators to require a technologist or another radiologist to perform the ultrasound scanning. This should be vigorously discouraged. Although large, simple fluid

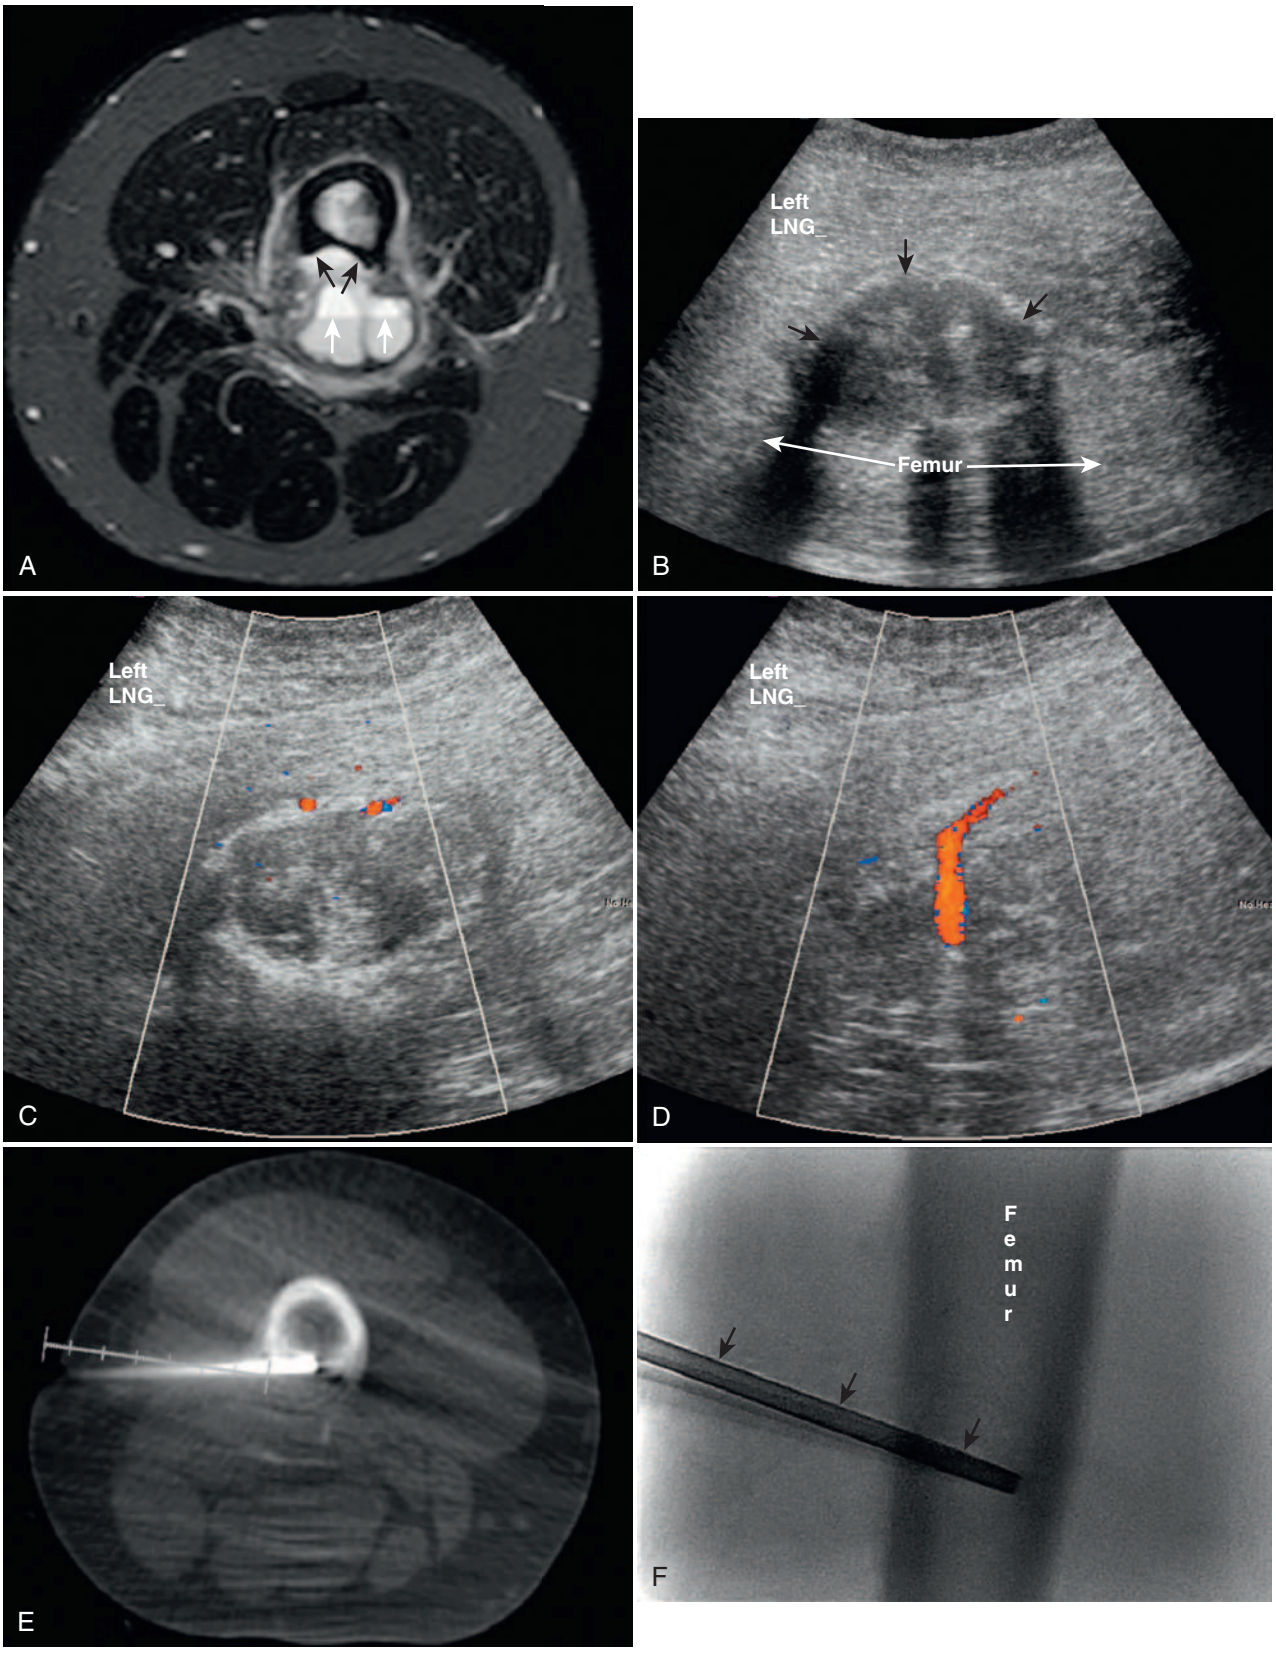

FIG. 56.1 Multimodality Interventional Procedure Guidance. Biopsy of posterior femur cortical aneurysmal bone cyst in a 15-year-old with 3 months of left thigh pain initially treated as a knee sports injury. **(A)** Transverse short-tau inversion recovery (STIR) magnetic resonance image mid left femur. Black arrows show eroded posterior bone cortex. White arrows show fluid-fluid levels. **(B)** Longitudinal ultrasound showing the soft tissue component of the lesion *(black arrows)*. **(C)** Color Doppler showed little internal blood flow, but **(D)** moderate-size peripheral arterial vessels were identified and avoided during the biopsy. **(E)** Axial cone-beam computed tomography scan showing initial guidance graticule and bone biopsy device entering the posterior bone cortex to obtain initial soft tissue samples for frozen section analysis to minimize the risk of more aggressive biopsy of a malignant lesion. Frozen section revealed a benign lesion. **(F)** Conventional fluoroscopy then allowed further sampling from all quadrants of the lesion.

collections can be drained this way, the necessary skills for accurate needle placement in small organs or near critical structures will never be learned. A single practitioner using an ultrasound transducer in one hand and the access needle or other device in the other hand is far superior to the "where's my needle now?"–type verbal communication required when there are two operators.

Freehand Versus Mechanical Guides

Most ultrasound equipment manufacturers supply well-designed mechanical guides that attach to a transducer and allow a predictable needle path to be visualized. These guides are useful for keeping the needle in the plane of the ultrasound beam and can be used for lesions with a simple approach path or a wide access window. Most devices require a disposable sterile kit when the device is used, adding to the cost of the procedure. Special needle guides are useful for the initial puncture for transrectal abscess drainage,[3] although many practitioners use simple freehand ultrasound guidance imaging of the rectal puncture needle using an anterior view through the filled bladder.

Freehand guidance is more difficult to learn but allows much more flexibility of approach. When the needle can be positioned 45 to 90 degrees to the beam, even fine, 30-gauge needles are easily visible. Freehand guidance allows the operator to choose the most advantageous transducer geometry and to steer the needle or biopsy device around other structures on the way to the lesion. Accurate placement of local anesthetic on the peritoneum, pleura, and other sensitive structures is made easier by freehand technique.

Color Doppler Ultrasound

Color Doppler has been advocated for visualization of the moving needle during interventional procedures, but our experience has been that the potential for better visualization of the needle tip is outweighed by the degradation of the gray-scale image and flash artifacts when color Doppler is active. Various needle tracking devices are available to enhance the visualization of the needle, but with the exception of the Yueh (Cook, Bloomington, IN) and Skater (InterV, Stenlose, Denmark) type sheathed access devices, which have very small holes in the catheter tip, these devices all add complexity and expense and are generally unnecessary if accurate ultrasound technique is learned.

FREEHAND TECHNIQUE

Freehand technique requires that the transducer be held in one hand and the needle or biopsy device in the other. The interventional physician needs to be able to use either hand as the needle or operating hand. For example, a biopsy specimen of the liver might be obtained by placing the transducer on the anterior abdominal wall using the right hand and making the needle approach from the patient's right lateral position, parallel to the table, using the left hand. A left-sided biopsy would best be performed by using the left hand for the transducer and the right hand for the needle approach from the left flank. With some practice and some simple rules, it is not difficult to use the nondominant hand as the needle hand.

Initial Needle Placement and Localization

The most important technique to learn in freehand sonography is needle localization. These rules work equally well for a needle entry site near the transducer or one at a distance (Fig. 56.2). The entry point is chosen after careful consideration of the anatomy and important structures such as ribs, large vessels, diaphragm, and bowel. Indentation of the entry site using a finger to compress the skin (Fig. 56.3) allows the exact entry site to be assessed. Once the entry site is chosen, a last check can be made by placing the transducer exactly over the marked entry point for a "needle's-eye view" to ensure that there will be no surprises such as the internal mammary artery during mediastinal biopsy or inferior epigastric artery during paracentesis or abdominal abscess drainage, which may be overlooked unless specifically localized. Once the entry path has been chosen and after proper application of local anesthetic, the needle or biopsy device is

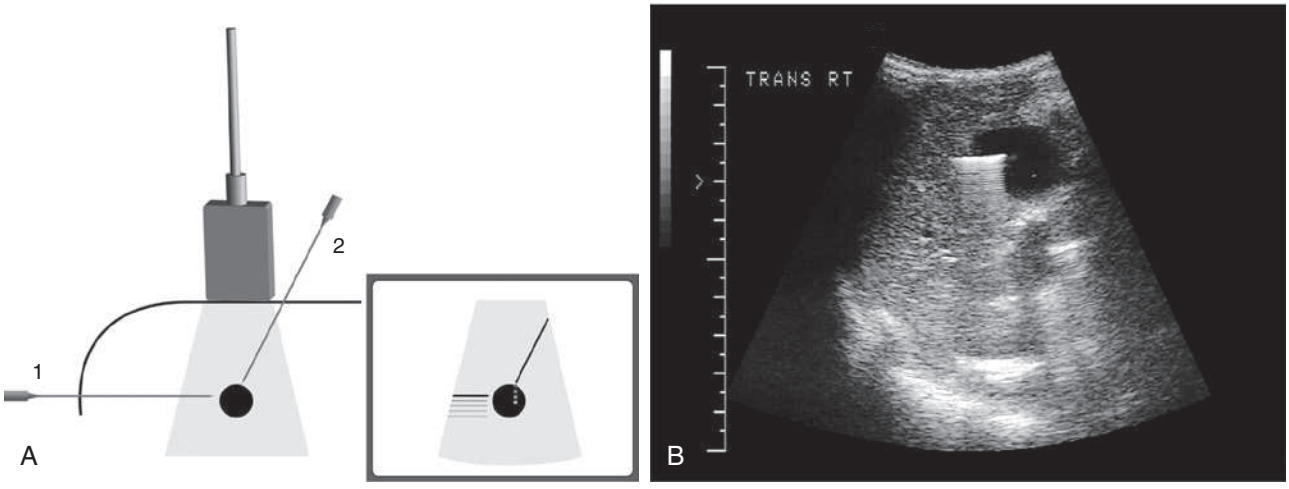

FIG. 56.2 Common Approaches. (A) The most common entry sites are either *(1)* lateral (parallel to the transducer face) or *(2)* adjacent to the transducer. **(B)** When the needle is parallel to the transducer face, a prominent reverberation artifact is seen, or a "comet-tail" artifact is seen when the needle is not parallel. The needle can be more difficult to locate in position 2.

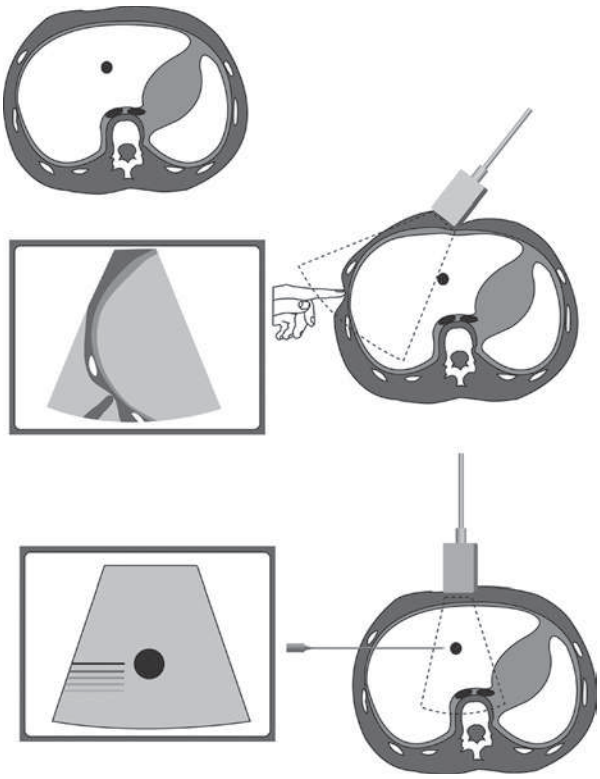

FIG. 56.3 Locating the Entry Site Laterally. The exact point of entry can be tested by rotating the transducer toward the body wall and palpating potential entry sites with a finger that is readily visible on the ultrasound real-time images.

placed through the skin toward the target. The needle and transducer need to be precisely in the same plane. This can be checked by looking directly down onto the top of the transducer and needle just before the initial placement is made (Fig. 56.4). The depth of the target should be measured and remembered before needle placement.

The needle should be initially advanced about one-half of the distance to the target under direct ultrasound monitoring. If necessary, the preplanned distance of insertion can be marked on the needle with a Steri-Strip. Inexperienced operators often have an uncontrollable urge to keep pushing the needle, hoping that it will magically make the needle visible. Radiologists who usually work with adults may not appreciate the short insertion distances required in small children and babies.

Locating the Needle After Insertion

With experience, it is possible to keep the needle visible starting from the moment of insertion, but if not, the needle must be localized before any further advancement is made. Check that the transducer and needle are parallel to each other by looking down the cable of the transducer with one eye closed. If the two are not parallel, adjust the position of the transducer, not the needle. Once the transducer and needle are parallel, keep the transducer in that plane and move the transducer a few millimeters back and forth strictly in the plane of the needle (Fig. 56.5). It is often useful to anchor the transducer hand on the patient by placing the fourth and fifth digits or the hypothenar border of

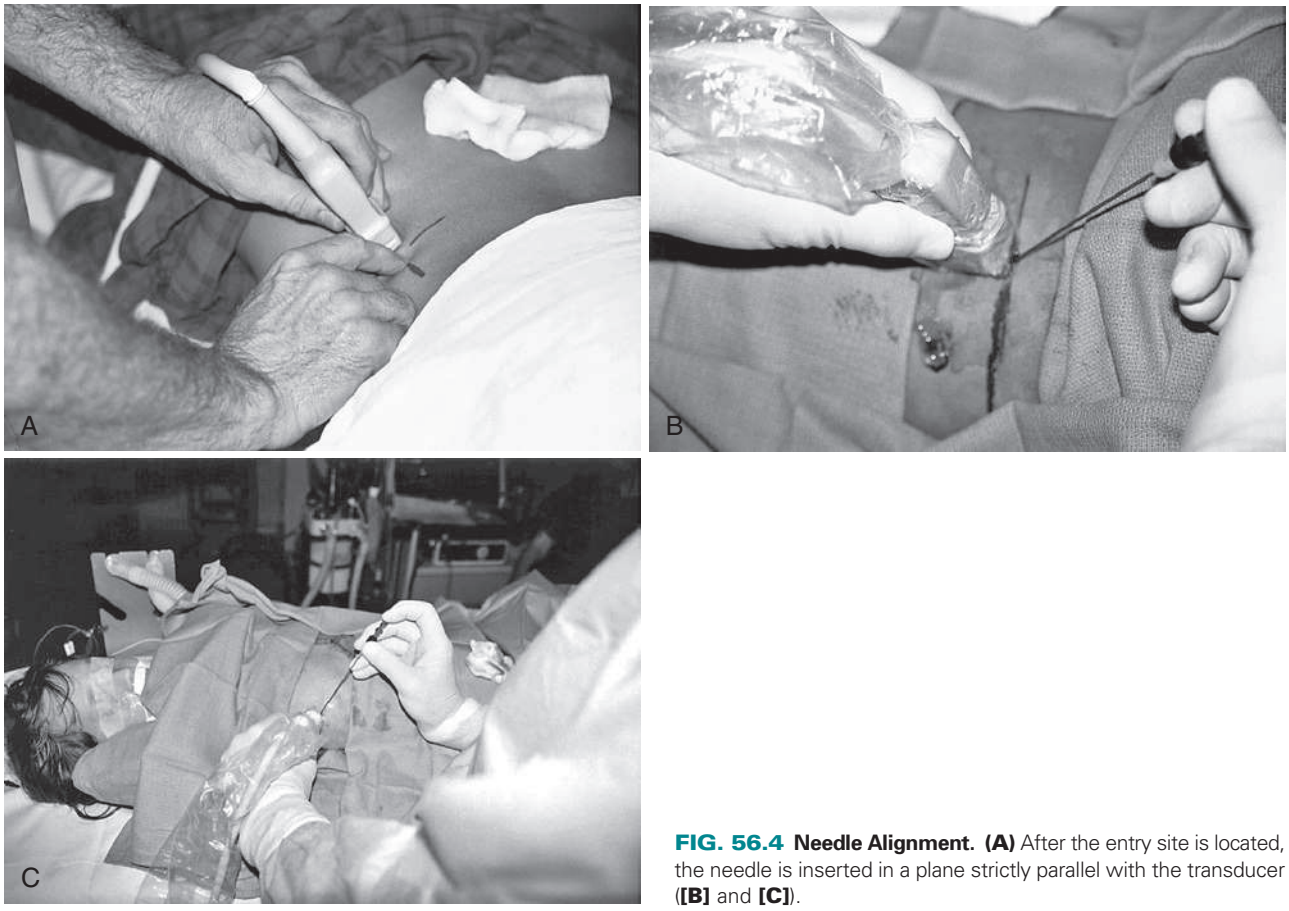

FIG. 56.4 Needle Alignment. (A) After the entry site is located, the needle is inserted in a plane strictly parallel with the transducer (**[B]** and **[C]**).

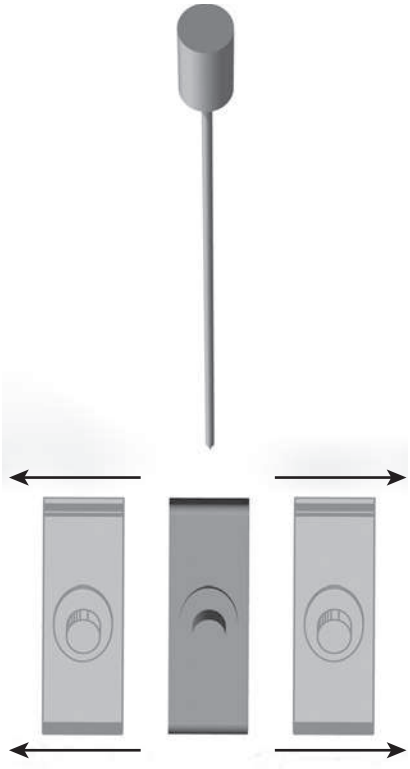

FIG. 56.5 Transducer Motion. After the needle is inserted, if the needle is no longer visible on the ultrasound image, the transducer is translated backward and forward in the plane of the needle, without rotating the transducer, until the needle is localized. The actual amount of movement required is much less than shown in this diagram; typically, it is only a few millimeters.

the transducer-holding hand firmly on the patient's skin, using the thumb and the second and third digits to hold and move the transducer. It is important not to jab the needle in and out aggressively or to try to move the needle and transducer in complex directions or angles all at once in a hopeful, and usually ineffective, attempt to localize the needle tip.

If the whole length of the needle is not visible, it may be at an angle oblique to the plane of the transducer, resulting in an erroneous impression of the position of the needle's tip (Fig. 56.6). Usually, only a few degrees of transducer rotation are required to obtain an image of the whole of the needle shaft.

The localization of the needle after initial placement must be a thoughtful and purposeful process that involves moving the transducer back and forth ("translation"), then adjusting and rotating its position in small increments until the whole length of the needle is visible.

If the needle is visible and the target is visible and the needle is pointing at the target, the needle is simply advanced toward the target. The needle may need a short sharp jab to enter the target, particularly if the target is a normal structure such as the gallbladder, a renal calyx, or a bile duct. The organs and tissue planes of children are soft and compliant (ballotable) and can sometimes "float" away from the needle tip as it is advanced, but the short jab required to puncture such organs or structures must always be made under control and with a purpose. Conditions such as some collagen disorders and prune belly syndrome cause even greater difficulties in initial organ or structure puncture.

The most common problem is that either the needle is not pointing at the target or the target is no longer visible in the scan plane.

Correcting the Needle Angle

If the needle and target are visible in the one image, but the needle angle is incorrect, do not attempt to radically change the angle of the needle while it is deep in an organ. Doing so, especially with a rigid biopsy needle, may result in significant bleeding and other complications. Instead, the needle is partly withdrawn until it is subcutaneous, the angle is adjusted, and the device is reinserted under direct ultrasound monitoring as before (Fig. 56.7).

If the transducer is not vertical, it is sometimes difficult to decide which way to adjust the needle's angle. The following simple rule will always work. Consider the position of the transducer cable and move the needle in relation to it (Fig. 56.7D-E). It is important, however, to know which side of the transducer belongs to which side of the ultrasound monitor screen. One should always test the orientation of the image before beginning a procedure by running a finger over the transducer face and noting where the finger appears on the screen. Otherwise the image of the needle is expected on one side of the screen but is actually on the other side of the screen where it is not noticed and is well on its way toward the aorta or some other significant structure.

Correcting the Off-Target Needle

If the needle is visible but the target is not, move the transducer parallel to the plane of the needle, first one way and then the other, until the target is reestablished. Remember which way the transducer needed to be moved to reimage the target, then withdraw the needle to the skin, move the skin entry site in the same direction by moving the needle tip in the subcutaneous tissues, and advance the needle once again into the patient.

Training Aids for Freehand Sonographic Intervention

These techniques can be practiced on various phantoms. The most readily available and practical practice phantom consists of a turkey breast and various materials, such as beef kidney, olives, cocktail onions, or artificial cysts made by tying off the finger of a surgical glove that has been filled with water. These materials are placed in the plane between the pectoralis major and minor muscles while the turkey breast is under water.[4-6]

NEEDLES, WIRES, CATHETERS, AND BIOPSY DEVICES

Many needles and devices are available, and each practitioner should select and become very familiar with a limited selection of these devices.

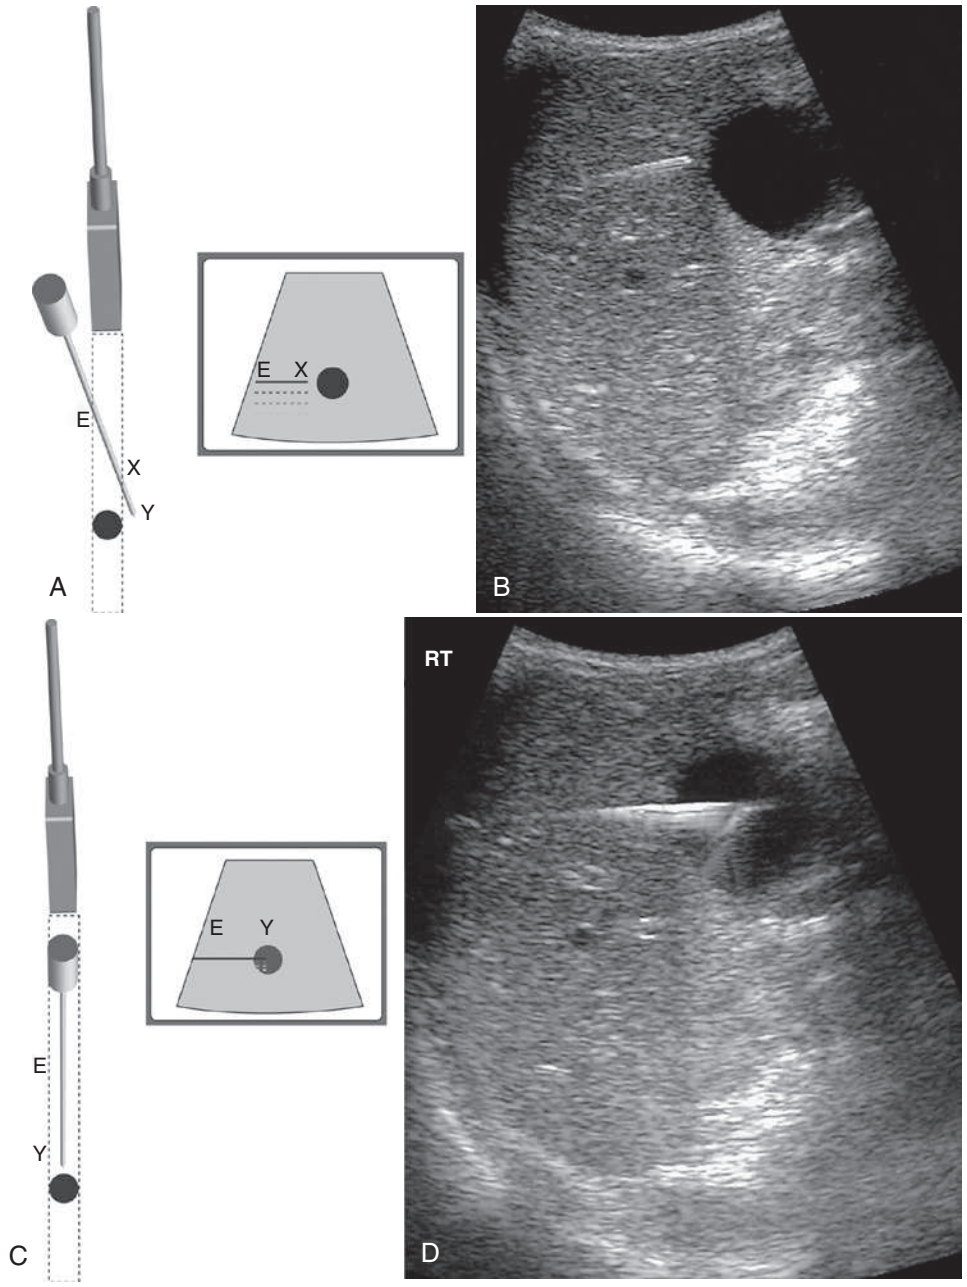

FIG. 56.6 Off-Plane Needle Position. (A) This off-plane position results in a shortened view *(E-X)* of the needle and a false sense of needle tip position at point *X,* whereas the real position of the tip is at point *Y.* **(B)** Off-plane view of part of the shaft of the needle during gallbladder puncture. **(C)** With needle in the exact plane of the transducer, the whole of the needle *(E-Y)* is visible. **(D)** It is now clear that the needle tip is actually in the gallbladder. Normally, the tip is accurately localized before puncture of the gallbladder. These images were obtained for illustration purposes, after successful gallbladder puncture.

Chiba Needles

Chiba needles are a class of relatively safe, very useful, flexible, small-diameter (usually 22-gauge) needles used for diagnostic contrast studies or for initial puncture of a target, especially if the target is near a vital structure. If the procedure involves subsequent placement of a guidewire or catheter, only a thin guide (typically 0.018 inch) can be placed through the needle. This is a relative disadvantage because a dilator will have to be placed over the 0.018-inch wire, and the thin wires are subject to kinking, especially when the dilator meets the deep fascia or capsule of an organ. We have found the Aprima Access set (Cook, Bloomington, IN) (formerly Neff set) to be especially useful and easy to use.

Drainage Catheters

Modern commercial catheters are of high quality, and usually a general purpose or locking loop catheter will suffice. For thick pus or old blood, a large-caliber catheter may need to be placed.

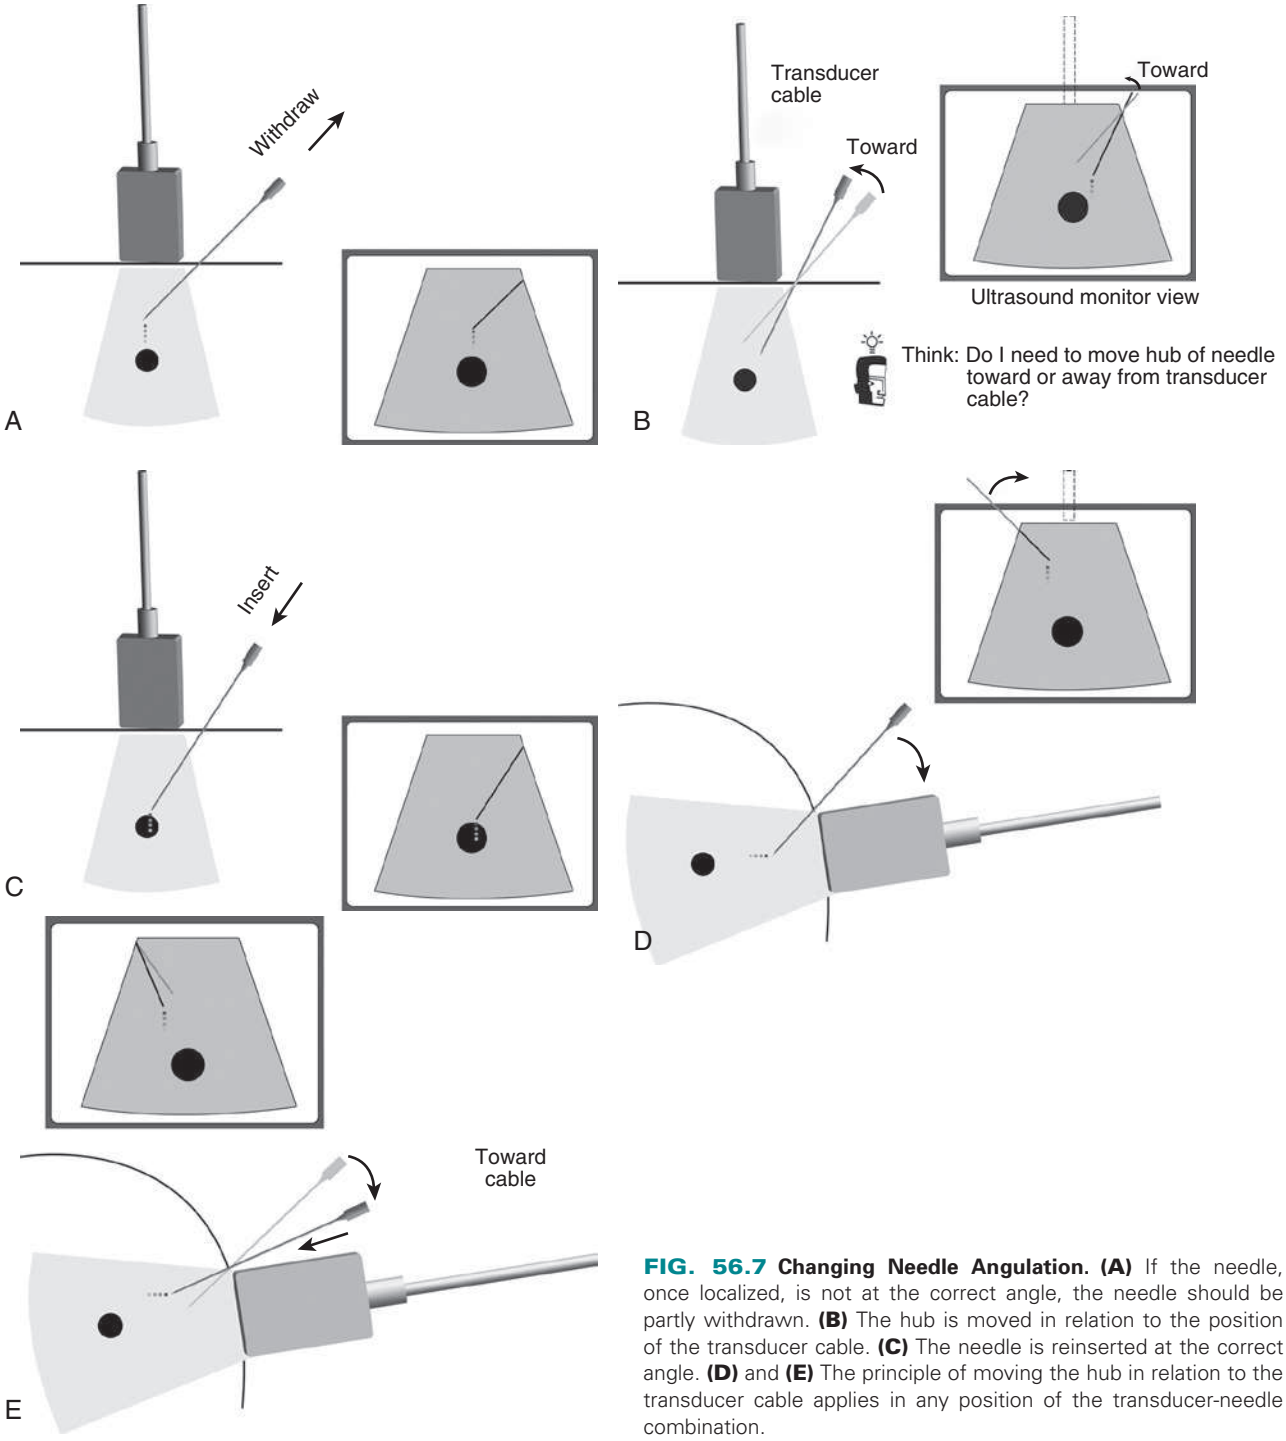

FIG. 56.7 Changing Needle Angulation. (A) If the needle, once localized, is not at the correct angle, the needle should be partly withdrawn. **(B)** The hub is moved in relation to the position of the transducer cable. **(C)** The needle is reinserted at the correct angle. **(D)** and **(E)** The principle of moving the hub in relation to the transducer cable applies in any position of the transducer-needle combination.

Initial Puncture Device

Most drainage catheters need to be placed over at least a 0.035-inch-diameter guidewire. An initial puncture with a small-caliber needle and placement of a 0.018-inch wire requires an exchange maneuver, and each passage of a wire or dilator adds to the time and complexity of the procedure, increasing the risk of losing position or kinking the wire, especially with most 0.018-inch wires, which are not robust.

Various prepackaged exchange sets are available commercially. Some sets (i.e., micropuncture, Aprima Access set) have a dilator/sheath that is placed over the 0.018-inch wire and then the dilator is removed, leaving the larger sheath in place, which allows placement of the 0.035-inch wire. These systems are used for some biliary procedures or where vital structures are very close to the target.

The Yueh needle (Cook, Bloomington, IN) is a needle/sheath device with small holes drilled in the end of the catheter, making

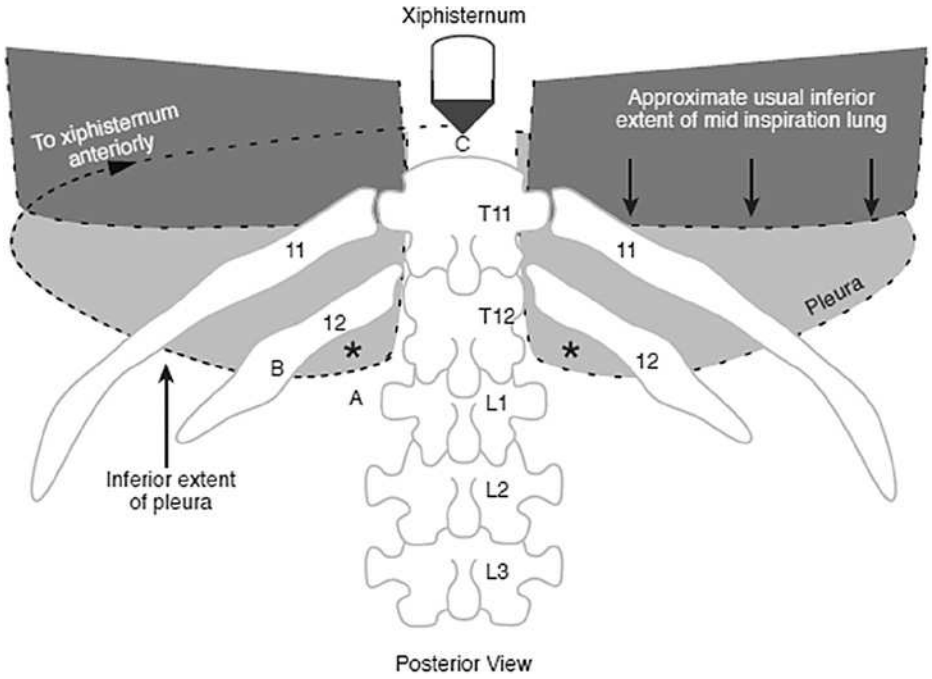

FIG. 56.8 The Surface Anatomy of the Diaphragm—Posterior View. The pleural space normally extends inferior to the 12th rib medially (position *A*), and superior to the lateral third of the 12th rib (position *B*). A line drawn from position *B* to the xiphoid process of the sternum (the xiphisternum) (position *C*) will map out the surface markings of the peripheral attachment of both the normal and the pathologically elevated diaphragm. Even if the dome of the diaphragm is grossly elevated by a pathologic process, the peripheral attachment remains unchanged.

it more conspicuous during ultrasound guidance. The holes also aid in aspiration of fluid.

Biopsy Devices

Aspiration cytology is not widely used in children because there is a much more diverse group of potential lesions in children than in adults. Many of the pediatric tumors depend partly on cellular arrangement for diagnosis, and pediatric pathologists are generally uncomfortable with making important diagnoses based on cytology specimens alone. Automated suction-core or slotted needle instruments are most often used.

Although it may seem logical that small-diameter devices should be used in children, in general, 16- to 18-gauge needles are most commonly used in order to obtain sufficient material for pathology examination. The larger needles may seem more dangerous, but if they are placed and monitored under ultrasound guidance, the risk is minimized.

ANATOMY

Diaphragm

A thorough knowledge of regional anatomy is essential. If a procedure is to take place in an unfamiliar area, there is always time to look up the anatomy in a text before proceeding. The surface anatomy of the diaphragm must be thoroughly understood (Fig. 56.8). It is important to remember that even if the apex of the diaphragm is grossly elevated by a mass or a subphrenic fluid collection, the diaphragm is still attached to the chest wall in the same relative position as it was at birth. If the pleural space is to be avoided, one must still enter a subphrenic collection below the peripheral attachment of the diaphragm. The diaphragm generally passes posteriorly across the junction of the middle and outer thirds of the 12th or last palpable rib posteriorly. From this point, a line drawn around the chest to the xiphoid process of the sternum (xiphisternum) will trace out the peripheral attachment of the diaphragm. It is important to be aware that the pleural space extends inferior to the medial third of the 12th rib (see Fig. 56.8).

Colon or Bowel

The colon lies just anterior to the kidneys and may be inadvertently punctured when entering from the posterior-lateral position during percutaneous nephrostomy. A nondistended colon may not be easily detectable by ultrasound, and one must be careful to avoid placing a nephrostomy too laterally or too anteriorly. If there is any doubt, a contrast enema can be performed and the position of the colon can be localized by fluoroscopy before or during the procedure. If available, cross-sectional imaging should be referenced before the procedure.

SEDATION

Few children younger than 12 years will cooperate during an invasive procedure, and a thorough familiarity with pediatric sedation is necessary, together with skilled personnel and adequate resuscitation facilities. It is better to perform a procedure using general anesthesia than to attempt the procedure without adequate sedation. If the child is uncomfortable or moving excessively,

the sedation should be increased, help should be obtained, or the procedure should be terminated.

Our previous sedation protocol has been published,[7] although we no longer manage our own sedation, preferring to use the anesthesia service that is readily available in our interventional suite. The anesthesiologists have been very flexible in accommodating our needs. Details of radiologist-supervised sedation are beyond the scope of this chapter. Specific publications should be consulted and adequate training acquired before performing deep sedation in children. A well-organized and experienced team that performs sedation regularly, with appropriate guidelines and limits, is more important than which particular drugs are used.

LOCAL ANESTHETIC TECHNIQUE

The most commonly used agent is lidocaine (Abbott Laboratories, Chicago, IL) 1% solution. The usual maximum adult dose for local anesthesia is 4.5 mg/kg (0.45 mL/kg of 1% solution). A maximum dose of 3 to 4 mg/kg (0.3-0.4 mL/kg of 1% solution) for children older than 3 years is noted in the product insert dosage recommendations, but there is no recommendation for younger children. We routinely use 3 to 4 mg/kg for all but extremely premature babies. Lidocaine is chemically stable only in a slightly acidic solution, so lidocaine is often combined with sodium bicarbonate 8.4% solution in a ratio of 10:1 immediately before injection. This effectively neutralizes the pH and reduces the sensation of stinging as the local anesthetic is injected. Liberal use of topical local anesthetic creams is also useful, but they must be applied 20 minutes before the procedure, and the entry site for a procedure is not always known in advance.

It is a common error to inject the local anesthetic and then immediately commence the procedure. All clinically useful local anesthetics work by diffusing across the lipid myelin and nerve cell membrane and block the sodium channel from the intracellular side of the sodium channel. It is therefore not surprising that lidocaine needs 5 to 8 minutes to achieve full effect. We usually place the local anesthetic, at least in the deep subcutaneous tissues, before gowning and gloving and preparing equipment. This allows time for the anesthetic to achieve maximal effect. Dentists are well aware of the time needed for maximal local anesthetic effect (they would lose their business if they did not practice good local anesthetic technique), but for obscure reasons, many physicians seem unaware of the need for waiting to achieve good local anesthetic effect.

The pain and stretch receptors are mostly in the epidermal layer. Discomfort associated with local anesthetic administration arises mostly from the rapid stretching of the epidermal sensors, before the local anesthetic agent has had time to block the axons. Thus the common practice of "raising a wheal" in the epidermis is contraindicated. Use of 30-gauge or smaller needles for initial slow deep subcutaneous injection minimizes the discomfort and often allows initial injection without the patient being aware of the skin puncture. Initial local anesthetic application to the deep subcutaneous layers allows the local anesthetic agent to first block the axons of the pain and other epidermal sensory nerve endings. Once this has been achieved, later local anesthetic application to the epidermis is usually painless. Care must be taken to exclude air from the syringe and needle before injecting the local anesthetic because even the amount of residual air in a 30-gauge needle, injected subcutaneously, may seriously degrade the ultrasound image.

Ultrasound-Guided Deep Local Anesthetic Administration

One of the keys to successful percutaneous procedures in children is adequate local anesthetic control of deep sensation. Many practitioners anesthetize only the skin and subcutaneous tissues and are then surprised when the patient moves or complains vigorously as a dilator is passing through the peritoneum, deep fascia, or the capsule of the organ. The solution is to place the majority of the local anesthetic on the peritoneum, fascia, or capsule. In general, it is the external covering of an organ or muscle, the pleura, the peritoneum, the perimysium, or the deep fascia that registers pain sensation. Subcutaneous fat, organs, and the muscle belly have very few nerve endings. Deep local anesthetic application is best achieved by using sonographic guidance. Surprisingly, even 30-gauge needles can be easily identified close to the skin with high-quality 7-or 10-MHz transducers. The focal zone must be adjusted appropriately, but with optimal conditions the local anesthetic can be deposited where it will have the most effect. This reduces the depth of sedation required and allows some procedures to be completed faster and without general anesthesia when it would otherwise have been required (Fig. 56.9).

ANTIBIOTICS

Antibiotics are routinely needed only when draining an infected collection or when the patient is immunosuppressed. We usually use periprocedural antibiotics for liver and renal transplant patients. The choice of antibiotics is individualized after consultation with the referring service, and they are usually given intravenously at the time of sedation or anesthesia induction. The basis for timing and duration of antibiotic prophylaxis of interventional radiology procedure is derived from the surgical literature. There is greatest suppression of infection when antibiotics are administered before inoculation. The likelihood of postprocedure infection increases with lengthening delay between the initiation of antibiotic prophylaxis and the procedure.[8] If a procedure is likely to be prolonged (i.e., >2 hours), a supplemental dose of antibiotics should be considered, depending on the half-life of the agent being administered.[9,10]

THE TYPICAL PROCEDURE

Prior Consultation and Prior Studies

It is important to review previous imaging or interventional radiology studies before the procedure. One should know what difficulties were encountered the previous time, or if there was a contrast reaction at a previous scan. Picture archiving and communications systems (PACSs) with integrated radiology

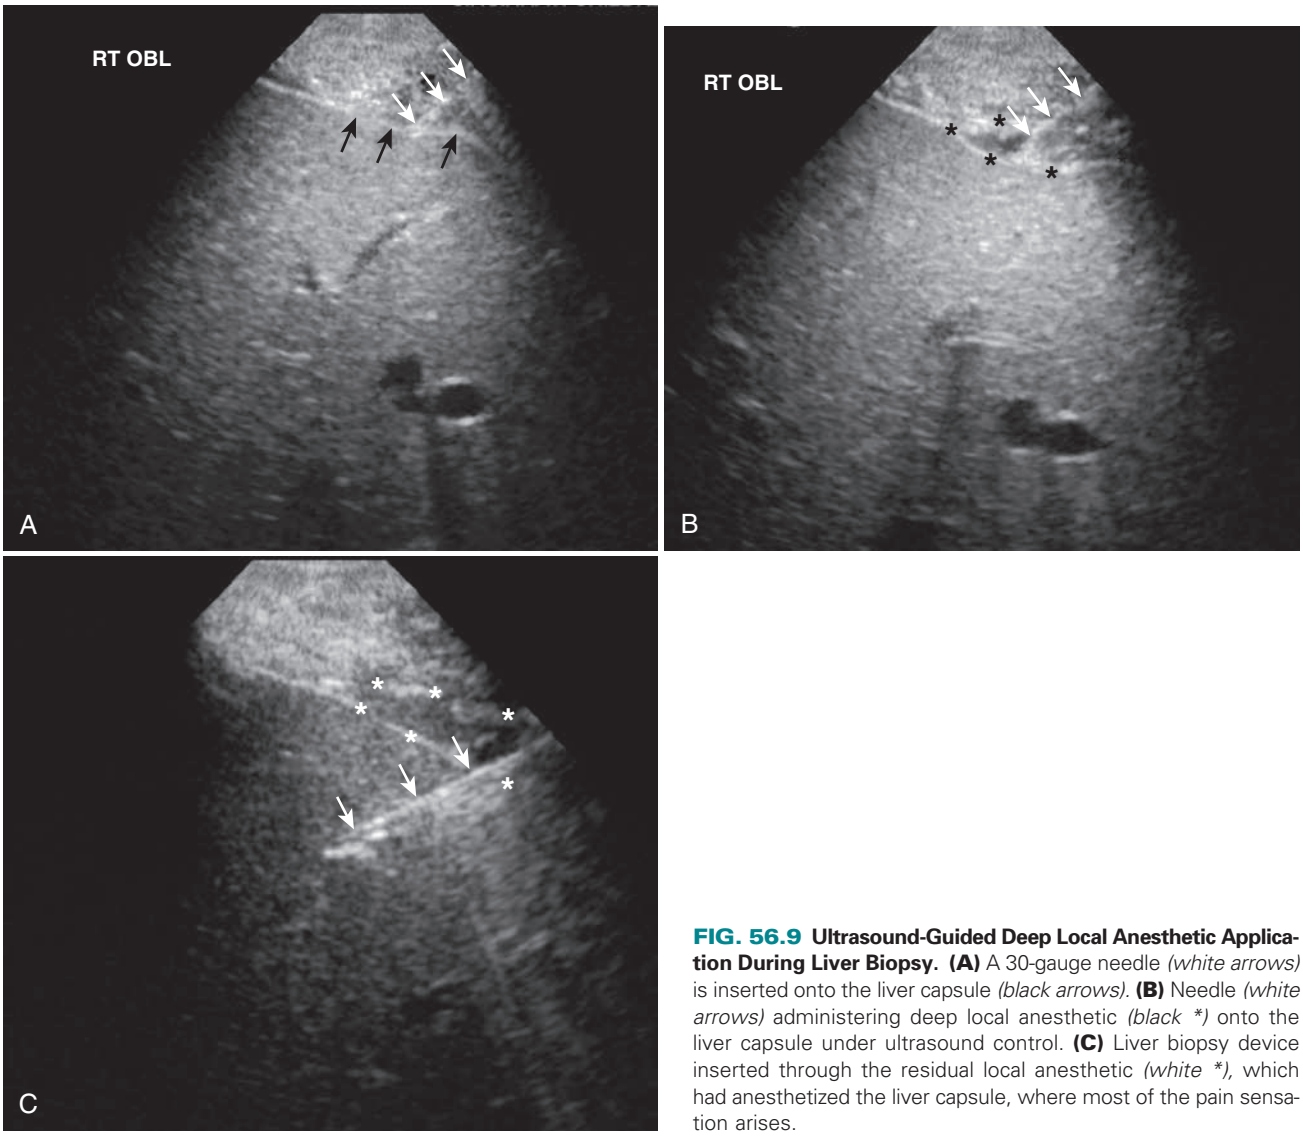

FIG. 56.9 Ultrasound-Guided Deep Local Anesthetic Application During Liver Biopsy. (A) A 30-gauge needle *(white arrows)* is inserted onto the liver capsule *(black arrows)*. **(B)** Needle *(white arrows)* administering deep local anesthetic *(black *)* onto the liver capsule under ultrasound control. **(C)** Liver biopsy device inserted through the residual local anesthetic *(white *)*, which had anesthetized the liver capsule, where most of the pain sensation arises.

reports and other clinical data make this easy. The interventional radiologist is responsible for having a clear understanding of the clinical reasons for the procedure and the expected benefits. At times, it is the duty of the interventional radiologist to insist on, or convene, a combined-care conference before undertaking a major procedure. This can be the greatest contribution a radiologist can make to the medical care of the child.

Coagulation Studies

Hematologic management in the patient undergoing percutaneous image-guided intervention is complex because of the wide range of procedures and equally wide range of patient demographics and comorbidities. Coagulation studies are indicated for most intraabdominal, chest wall, or retroperitoneal abscess drainage or biopsy procedures, which carry a moderate risk of bleeding; it should also be noted that renal biopsy carries a significant bleeding risk.[11] The management guidelines recommend correcting the international normalized ratio (INR) to below 1.5.[12] A platelet count is usually obtained in oncology patients; underlying malignancy appears to be an independent risk factor for bleeding after liver biopsy.[13] Caution should be exercised when the platelet count is below 50,000, and it is important to remember that platelet function may be affected by some chemotherapy, by nonsteroidal antiinflammatory agents, by uremia, and by other medical conditions. Patients with Wilms tumor may rarely have an undiagnosed transient acquired von Willebrand syndrome. Caution should be exercised if the skin incision continues to bleed vigorously for more than a minute or so. It is better to cancel a procedure and do a full coagulation workup than to continue and cause a major hemorrhage.

Aims and Expectations

Anticipation of problems is good practice, not a sign of weakness. No procedure should be undertaken without a clear understanding

of the aims, the expected benefit, and a reasonably detailed plan for completing the task. If an abscess is difficult to localize by ultrasound (e.g., in the psoas muscle in a large adolescent), then a transfer to the CT suite should be considered. Fluoroscopy after initial ultrasound-guided access allows a kinked wire to be withdrawn into the dilator and replaced or advanced into the abscess. CT is essential in some areas, notably pelvic abscesses requiring transgluteal drainage,[14] although transgluteal drainage of pelvic abscess has been almost exclusively replaced by ultrasound-guided transrectal catheter drainage at our institution.

A well-thought-out alternate plan is important, especially in complex procedures, such as renal stone removal or ureteric stent placement. What happens if the patient moves or the wire is dislodged? A second safety wire tucked up in an upper-pole calyx is always good insurance in complex renal procedures. Expect the unexpected, and the procedure will usually go as planned.

Initial Ultrasound Scan Should Occur Before Sedation

Understand the individual patient's anatomy before sedation or general anesthesia. Spending enough time to consider the most effective approach and the adjacent anatomy is as important as proper needle placement. It is less-than-perfect technique to pass a needle through the colon when a little time and care would have avoided the problem. The radiologist should have a good three-dimensional understanding of the patient's regional anatomy before commencing a procedure.

Pus

Pus is the liquefied products of inflammation. "Liquefied" is the most important word for the interventional radiologist. Unlike CT, which generates a static image, real-time ultrasound allows exploration of the liquidity and therefore of the drainability of a lesion. Urinomas are notoriously echogenic when first examined, but if the operator vigorously prods the collection with the ultrasound probe, the free-flowing nature of the collection becomes apparent and it can be drained by a simple 8-French catheter, rather than by the large-caliber sump catheter one may have thought would be needed.

Catheter Fixation May Be Difficult in Infants

Catheters are objects of wonder for small children and babies and are great chewing material if left in the grasp of tiny hands. Often, when a catheter "just falls out by itself," there has been some lapse in care on the part of professional staff. Either the catheter was not properly secured in the first place or a health care practitioner forgot to undo the safety pin when taking the child to the bathroom.

Some methods of fixation include standard sutures, sutures secured to the catheter by waterproof tape, or various commercial skin fixation devices. If the catheter is sutured in place, the suture must be placed deeply in the subcutaneous tissues. In babies and infants, the catheter is hidden out of reach, if possible, and secured with transparent plastic adhesive film. The joint between the catheter shaft and the hub of a drainage catheter is its weakest point, so we routinely affix the hub to the skin with adhesive tape or film, and train the patient's nurses to always retape this hub when performing routine catheter care.

Postprocedure Care and Follow-Up

Apart from bad communication skills, the quickest way to destroy an interventional referral pattern is to ignore the patient or the referring physician or surgeon once the patient has left the radiology department. The interventional radiologist is responsible for accepting the patient, for being satisfied that the procedure is justified and likely to be of significant benefit to the patient, and for follow-up, both in the immediate postprocedure period and for the long term. Leaving a pager number in the medical notes may result in a few trivial calls, but overall it will benefit the patient and increase referrals and satisfaction. If a complication occurs, either deal with it or consult another service, but do the consultation personally.

Be cautious of blood loss in children after liver or other biopsy. A hematocrit before and 2 hours after biopsy is a prudent precaution. Blood loss is typically slow and self-limiting, but if bleeding persists, often the only objective signs are pain and a rising pulse rate. Children who are experiencing blood loss notoriously maintain blood pressure and brain perfusion until very late and then suddenly deteriorate.

SPECIFIC PROCEDURES

Abscess Drainage

When entering an abscess cavity, a pus sample is usually obtained for culture, but the cavity should not be aspirated completely before placement of the catheter. Once the catheter is in position, simple aspiration with ultrasound monitoring for completeness is all that is required. Flushing with large volumes of saline or performing a contrast study could result in intravasation of infected material through the raw granulation tissue that always lines these abscesses. Contrast studies and flushing can be done later, once the cavity is healing, although we rarely do any postprocedure study for the majority of uncomplicated abscess drainages. During initial aspiration, it is not uncommon to get blood return near the end of aspiration. This is probably blood arising from the granulation tissue, and at times it can be alarming in amount. If active aspiration is ceased, the bleeding usually stops. The catheter should be left in place until the aspirate is straw colored and less than a few milliliters per day.

Transrectal Drainage

Deep pelvic abscesses can be drained by means of surgery or by a catheter inserted under ultrasound control.[15] The ultrasound-guided method is particularly appropriate for high collections that are beyond the reach of surgeons, but at our institution,

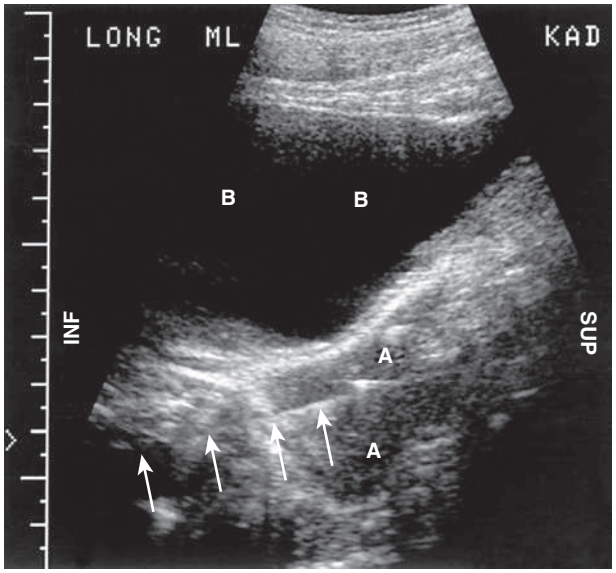

FIG. 56.10 Ultrasound-Guided Transrectal Abscess Drainage. The needle *(arrows)* has been inserted through the rectum and has punctured the high pelvic abscess *(A)* under ultrasound guidance. The bladder *(B)* is anterior to the abscess.

ultrasound-guided transrectal abscess drainage has substantially replaced the surgical procedure (Fig. 56.10). The catheter can either be withdrawn after complete aspiration of the cavity or left in place and secured to the leg with tape.[3]

Peripherally Inserted Central Catheter Lines

Peripherally inserted central catheters (PICCs) are a useful way of obtaining safe central access for short- to medium-term use.[16] The catheters range from 2 French to 5 French in size, and various commercial units are available, with insertion sets containing either a peel-away cannula similar to an intravenous catheter or a peel-away Seldinger-style sheath.

After insertion of the sheath into a peripheral vein (arm, leg, or scalp), the catheter is placed through the sheath and positioned in the central veins. Visual access to the arm veins is often easy in the older individual, but the veins of corpulent babies and infants can be notoriously difficult to identify and cannulate. Ultrasound guidance in these patients has become an essential skill for the PICC line service, and most PICC line nurses can successfully be taught the technique. In infants, the technique of ultrasound guidance for venous access is different from previously described parallel techniques. Because of beam-width issues, it is best to monitor the needle position by constantly adjusting the transverse or axial position of the transducer in a sweeping manner (Figs. 56.11 and 56.12, Video 56.1). The veins are usually so small that monitoring the needle position with the transducer in the plane of the needle and vein usually results in malpositioning of the needle because of the width of the ultrasound beam.

In older patients with larger veins, scanning in the plane of the vein can be useful, and safe passage of the guidewire can be observed (Fig. 56.13).

Central Venous Access

Placement of long-term central venous access devices is one of the most common vascular interventional procedures. Central venous access is used in infectious disease, dialysis, transplant, and oncology patients. The preferred vein is the right internal jugular vein (RIJV); it is large, is close to the skin, and provides a short, straight route to the superior vena cava. The RIJV should be used whenever possible for dialysis catheters or in renal failure patients to avoid compromise of the subclavian veins and the left brachiocephalic vein, which are important for the success of upper arm surgical dialysis access.[17] The RIJV also avoids the risk of pneumothorax and reduces the rate of symptomatic central venous stenoses when compared with the subclavian vein.[18,19] Use of the RIJV also avoids catheter pinch-off syndrome, seen exclusively in subclavian venous access, which is subject to repetitive trauma in the costoclavicular space and can result in catheter fracture.[20] When compared with the nonimage-guided surgical landmark technique (e.g., carotid artery, sternocleidomastoid muscle), the use of ultrasound has been reported to improve successful RIJV catheterization and achieves access with fewer attempts, a reduced incidence of carotid artery punctures, and increased success rate and a decreased duration of procedure.[21-25]

Ultrasound guidance allows accurate oblique access to the jugular vein, enabling a smoother curve to the tunneled part of the central catheter, which minimizes the risk of kinking or pinch-off obstruction of the catheter.

Pleural and Peritoneal Drainage

Ultrasound-guided diagnostic aspiration of pleural fluid is a common and useful procedure. Simple catheter drainage of parapneumonic complex fluid collection or empyema can result in complete cure if performed early enough, but the pleura has a remarkable ability to thicken and produce fibrin. These infected collections often loculate and become difficult to drain using a simple catheter technique. CT scanning does not usually show the loculations, and therefore referring clinicians often believe that the parapneumonic fluid should be easy to drain. The administration of thrombolytics, typically tissue plasminogen activator (tPA), through the pleural tube in order to change the physical characteristics of the thick fluid[26,27] is now a routine procedure. Any chest tube for empyema drainage must be monitored frequently by radiography, ultrasound, or occasionally postprocedure CT, to ensure that loculation has not recurred (Fig. 56.14).

Peritoneal fluid drainage for diagnostic and/or therapeutic reasons is usually not difficult and can often be achieved at the bedside with minimal or no sedation and good local anesthetic technique. When accessing the fluid via the lower quadrants, care must be taken to accurately localize and mark the position of the inferior epigastric vessels, which can cause substantial and difficult-to-control bleeding into the peritoneal fluid if injured during an otherwise "simple" aspiration procedure. Occasionally, debris obstructs the draining catheter and needs to be dislodged, either by vigorous movement of the needle and catheter or by

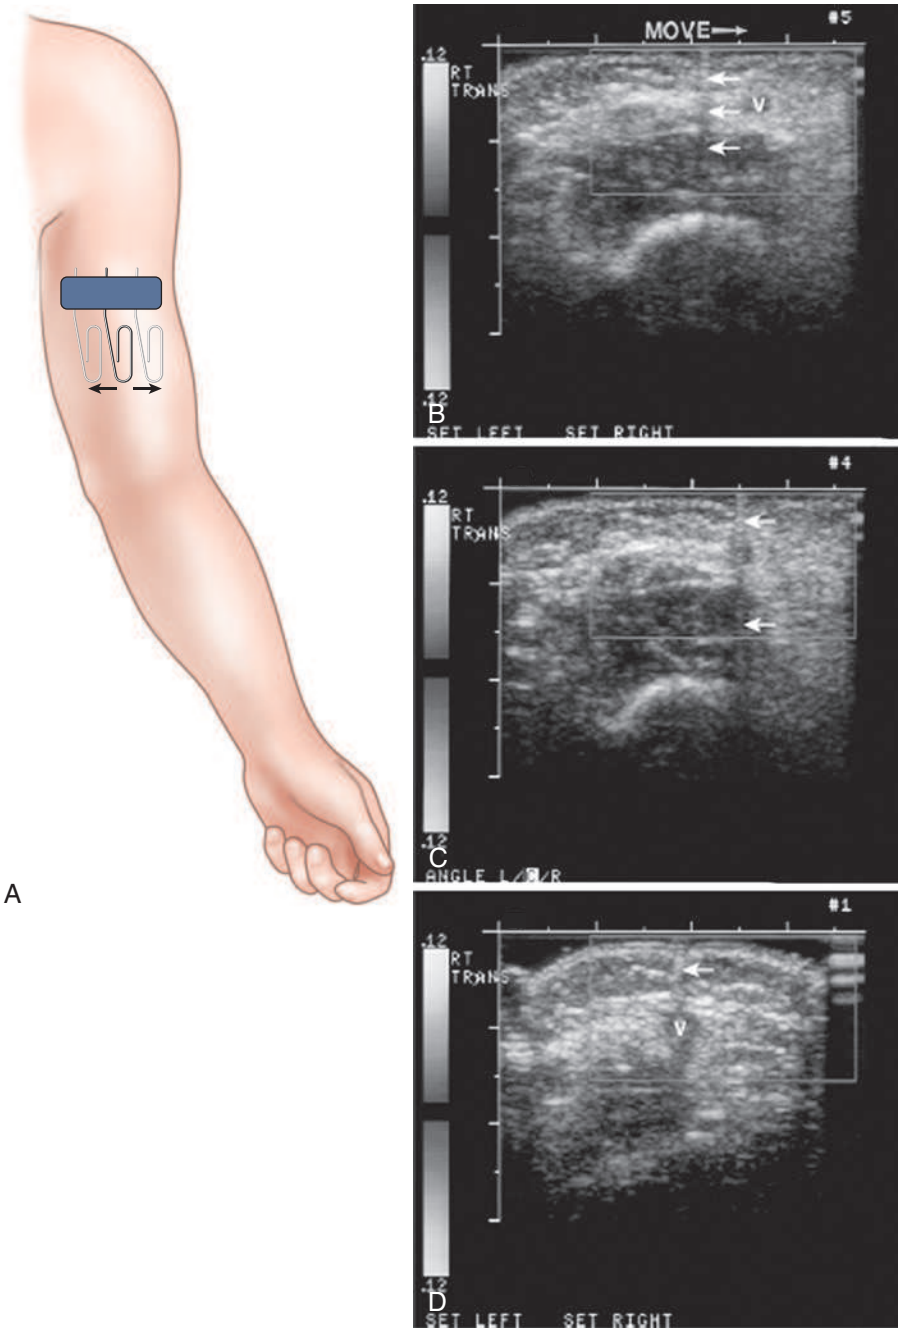

FIG. 56.11 Technique for Locating Exact Position of a Deep Vein Prior to Peripherally Inserted Central Catheter (PICC) Line Placement. **(A)** With the transducer held transverse to the direction of the target vein, a partly unfolded paper clip, placed between the skin and the transducer face, is moved backward and forward (**[B]** and **[C]**) to locate the vein for accurate application of subcutaneous local anesthetic. The transducer is held transverse to the needle path to avoid beam-width errors. The thin paperclip artifact *(arrows)* localizes the vein *(V)*. Note that with a tourniquet in place, especially in a small baby **([B]-[D]),** color Doppler sonography may show no flow. A tight tourniquet in a baby can obstruct even arterial flow, resulting in erroneous placement of an intraarterial PICC line, a very dangerous event, if unrecognized.

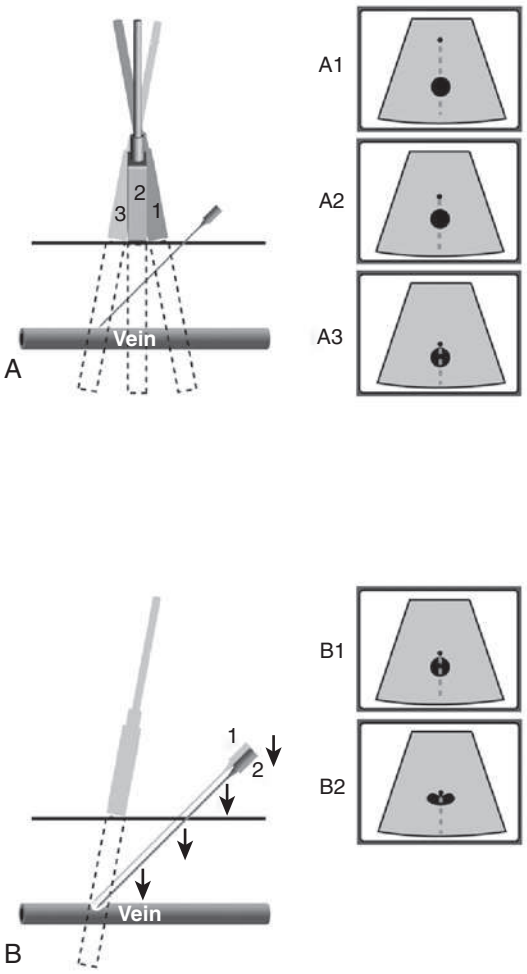

FIG. 56.12 Localizing the Needle Tip Near the Vein. (A) As the needle is advanced toward the vein, the transducer is used in transverse orientation and rocked back and forth *(A1-A3)* to sequentially track the tip of the needle as it is advanced toward the vein. In the illustration, the needle is depicted only as it is about to enter the vein (position *3*). **(B)** Trapping and puncturing the vein. The needle can easily slip to the side of the vein if it is simply advanced, especially when attempting to puncture a deep brachial vein. The loose soft tissue surrounding deep veins allows the vein to slide out of the way of the needle. When the tip of the needle is positioned correctly, adjacent to the anterior wall of the vein *(B1)*, gentle downward movement of the needle, without trying to puncture the vein, will "trap" the vein with the needle tip *(B2)*. Once the vein is trapped, a quick thrust will puncture both walls. Careful withdrawal usually results in venous blood return through the needle, allowing successful peripherally inserted central catheter (PICC) line placement.

passage of a guidewire to dislodge the obstructing debris (Video 56.2, Video 56.3).

Percutaneous Cholangiography and Drainage

Percutaneous transhepatic cholangiography can be successfully performed in children with or without duct dilation. Ultrasound is used to guide the Chiba needle toward the bile ducts, which lie in the portal tracts. The optimal diagnostic puncture site is at the junction of the middle and peripheral thirds of the duct, well away from the central portal veins and hepatic artery. If the ducts are dilated, the needle can be guided directly into the duct with the usual ultrasound techniques. Puncture should be made at a site and at an angle that will allow conversion of the track to a catheter drain should the diagnostic study reveal bile duct stenosis or complete obstruction, especially in liver transplant patients. Initial puncture of minimally dilated bile ducts in pediatric liver transplant patients is one of the most technically demanding ultrasound-guided procedures (Fig. 56.15).

Mediastinal Mass Biopsy

Lymphoma is a common childhood malignancy often manifesting with a mediastinal mass. In many cases, cervical, abdominal or axillary lymphadenopathy is seen at presentation enabling histologic diagnosis by surgical lymph node biopsy. In some cases, however, the patient has respiratory difficulty as a result of tracheal compression and there are no convenient enlarged lymph nodes available for biopsy. Many of these patients are unable to lie flat without respiratory distress. The mediastinal mass can enlarge very rapidly, such that a child who could lie flat for the initial CT scan cannot lie flat a few hours later. In these cases, ultrasound-guided mediastinal biopsy is often the safest option. Emergency radiotherapy and steroid administration can also be used to shrink the mass, but these maneuvers can result in inability to subtype the cells of the lymphoma, which is becoming more important for treatment decisions and prognosis.

These patients are managed in the operating room in a semi-erect position and need to be supervised and sedated by experienced anesthesia staff. We typically use copious local anesthesia and only minimal intravenous sedation, avoiding intubation if at all possible.

Doppler ultrasound is used to locate and avoid the internal mammary artery and vein. The mass is usually approached through a paramanubrial intercostal space under direct ultrasound guidance using a small-footprint sector probe. The great vessels and lung must be clearly visualized before biopsy. Multiple samples can be obtained with remarkably low risk of complication (Fig. 56.16).

Appendiceal Abscess Drainage

Initial ultrasound-guided drainage of an appendix-associated abscess is a well-documented procedure. Occasionally a secondary abscess occurs after interval endoscopic surgery for removal of the appendix, usually caused by a retained or unrecognized fecalith. Ultrasound guidance can also be used to drain these recurrent abscesses. In one case, we were able to precisely target the retained fecalith, drain the abscess, and then remove the fecalith by a second interventional procedure using an Amplatz biliary sheath (Cook, Bloomington, IN) and Fogarty balloon retrieval of the fecalith through the sheath (Fig. 56.17, Video 56.4).

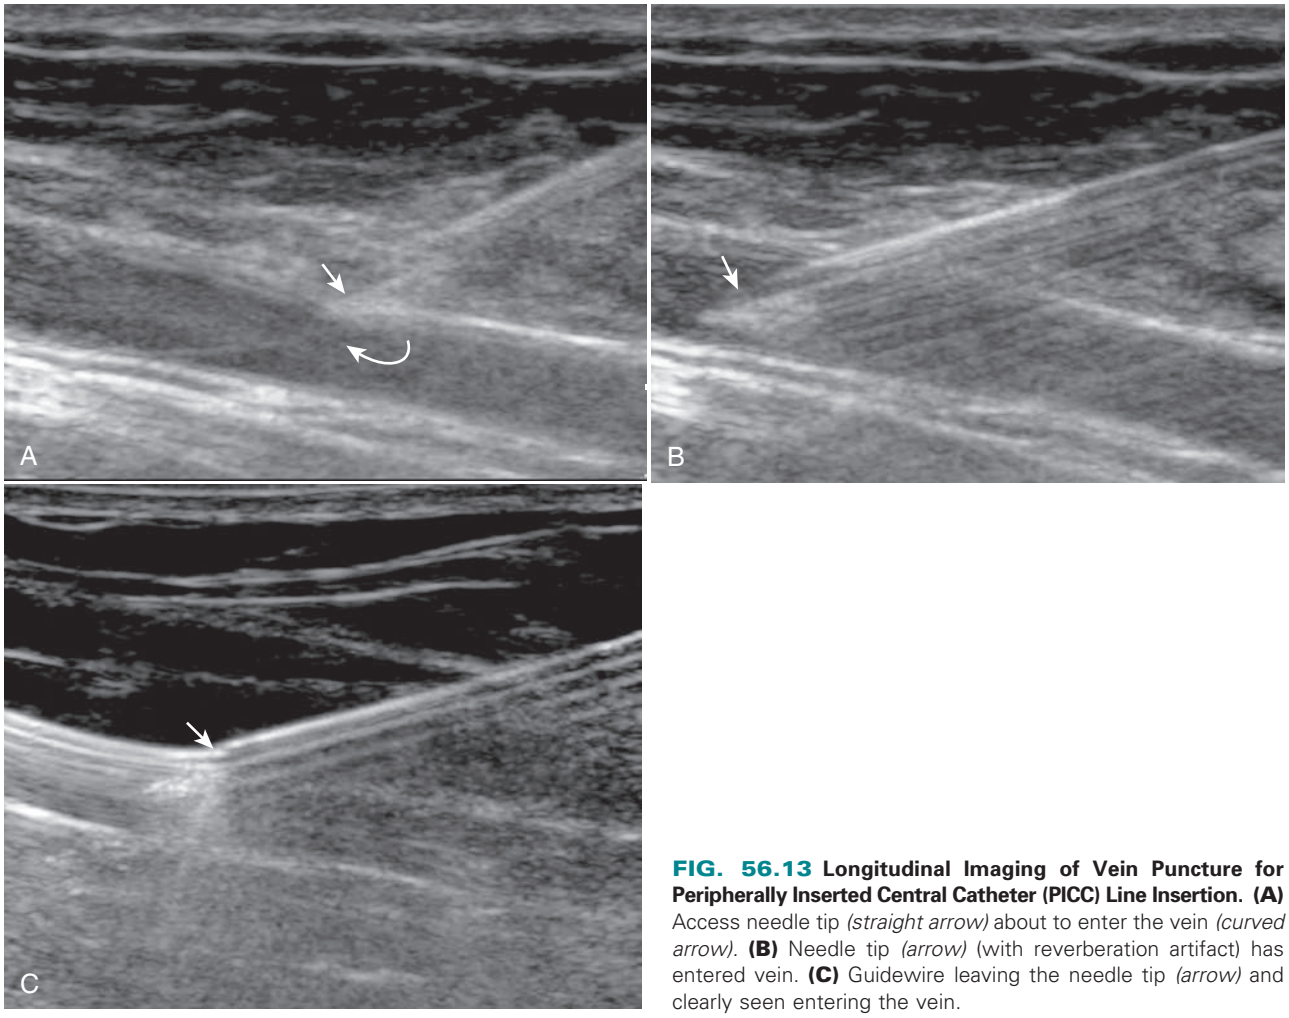

FIG. 56.13 Longitudinal Imaging of Vein Puncture for Peripherally Inserted Central Catheter (PICC) Line Insertion. (A) Access needle tip *(straight arrow)* about to enter the vein *(curved arrow)*. **(B)** Needle tip *(arrow)* (with reverberation artifact) has entered vein. **(C)** Guidewire leaving the needle tip *(arrow)* and clearly seen entering the vein.

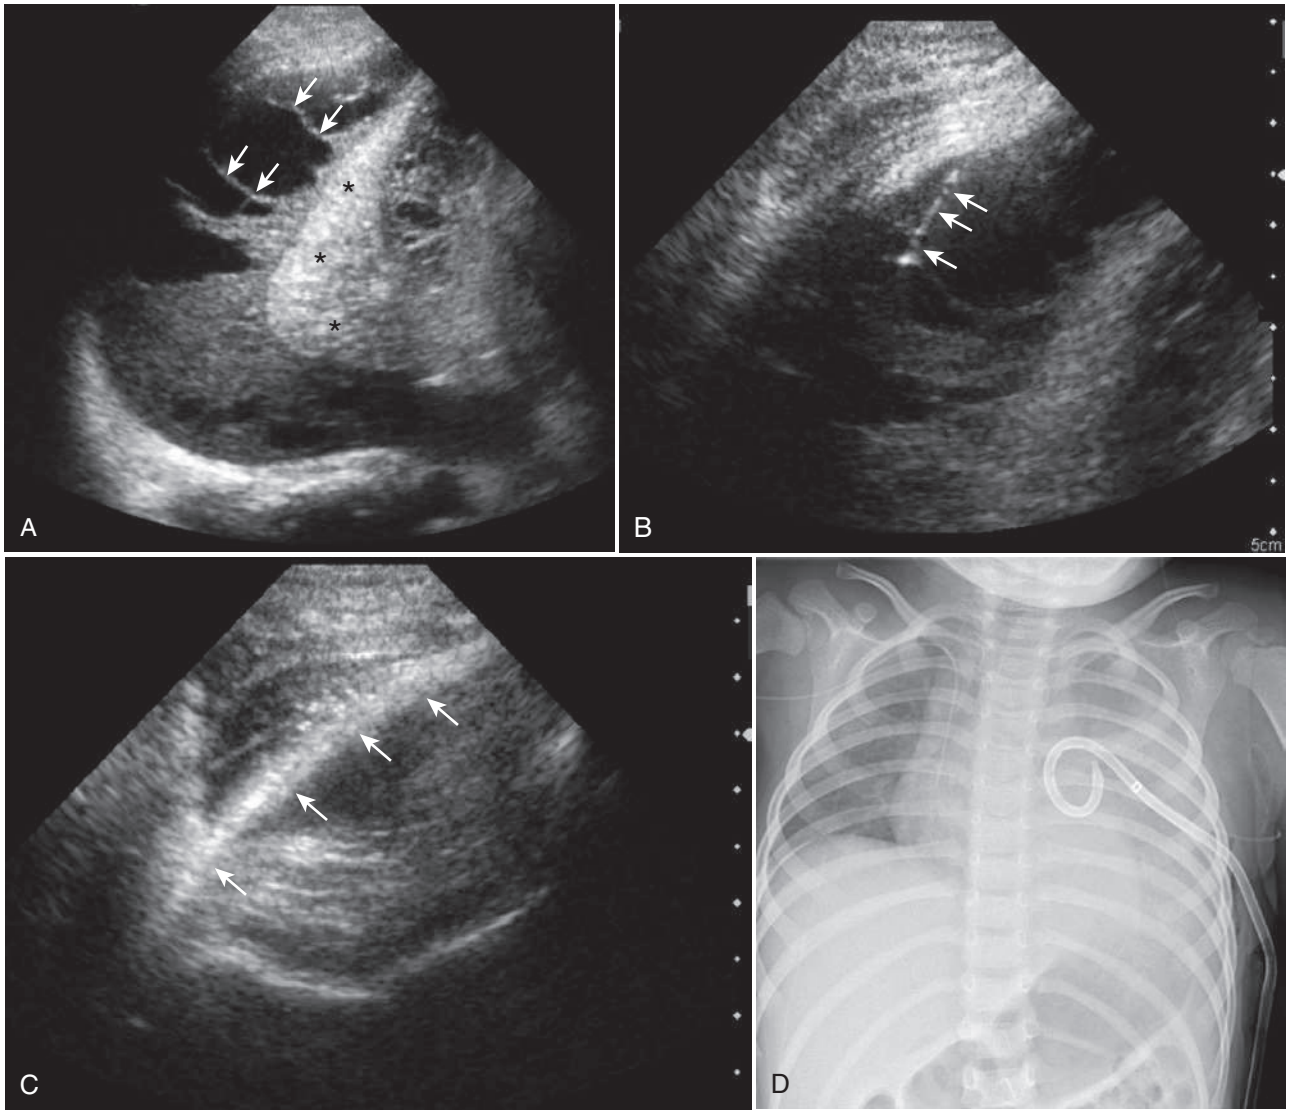

FIG. 56.14 Ultrasound Guidance for Treatment of Loculated Chest Empyema. (A) Semisolid extrapleural inflammatory material with septae *(arrows)* compressing the airless adjacent left lung *(black *).* **(B)** Access needle *(arrows)* entering the empyema. **(C)** Left chest tube *(arrows)* inserted for drainage and for installation of tissue plasminogen activator (tPA), a very successful combined treatment of this condition formerly treated by thoracotomy. **(D)** Radiograph showing left chest tube position.

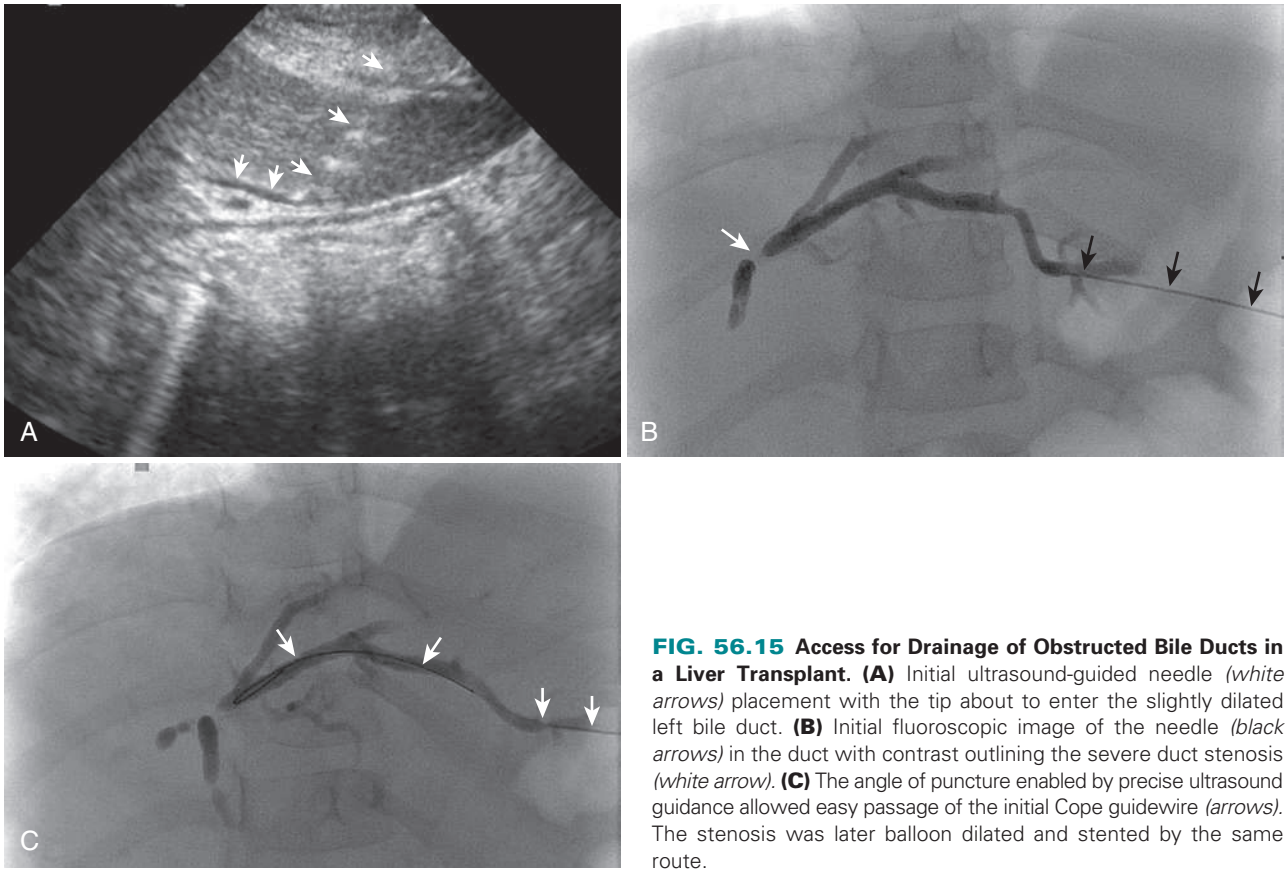

FIG. 56.15 Access for Drainage of Obstructed Bile Ducts in a Liver Transplant. (A) Initial ultrasound-guided needle *(white arrows)* placement with the tip about to enter the slightly dilated left bile duct. **(B)** Initial fluoroscopic image of the needle *(black arrows)* in the duct with contrast outlining the severe duct stenosis *(white arrow)*. **(C)** The angle of puncture enabled by precise ultrasound guidance allowed easy passage of the initial Cope guidewire *(arrows)*. The stenosis was later balloon dilated and stented by the same route.

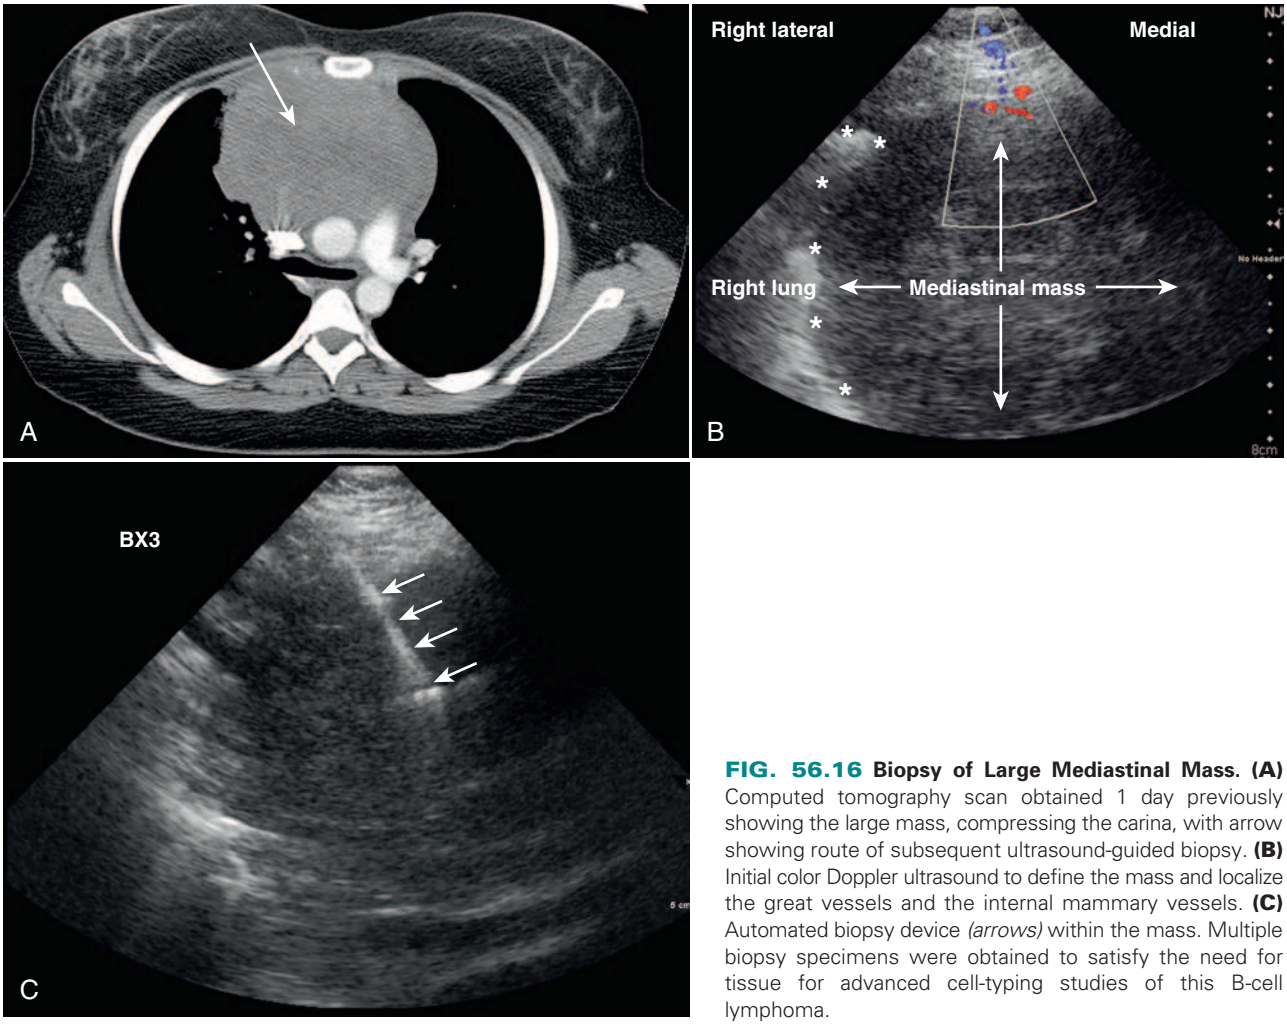

FIG. 56.16 Biopsy of Large Mediastinal Mass. (A) Computed tomography scan obtained 1 day previously showing the large mass, compressing the carina, with arrow showing route of subsequent ultrasound-guided biopsy. **(B)** Initial color Doppler ultrasound to define the mass and localize the great vessels and the internal mammary vessels. **(C)** Automated biopsy device *(arrows)* within the mass. Multiple biopsy specimens were obtained to satisfy the need for tissue for advanced cell-typing studies of this B-cell lymphoma.

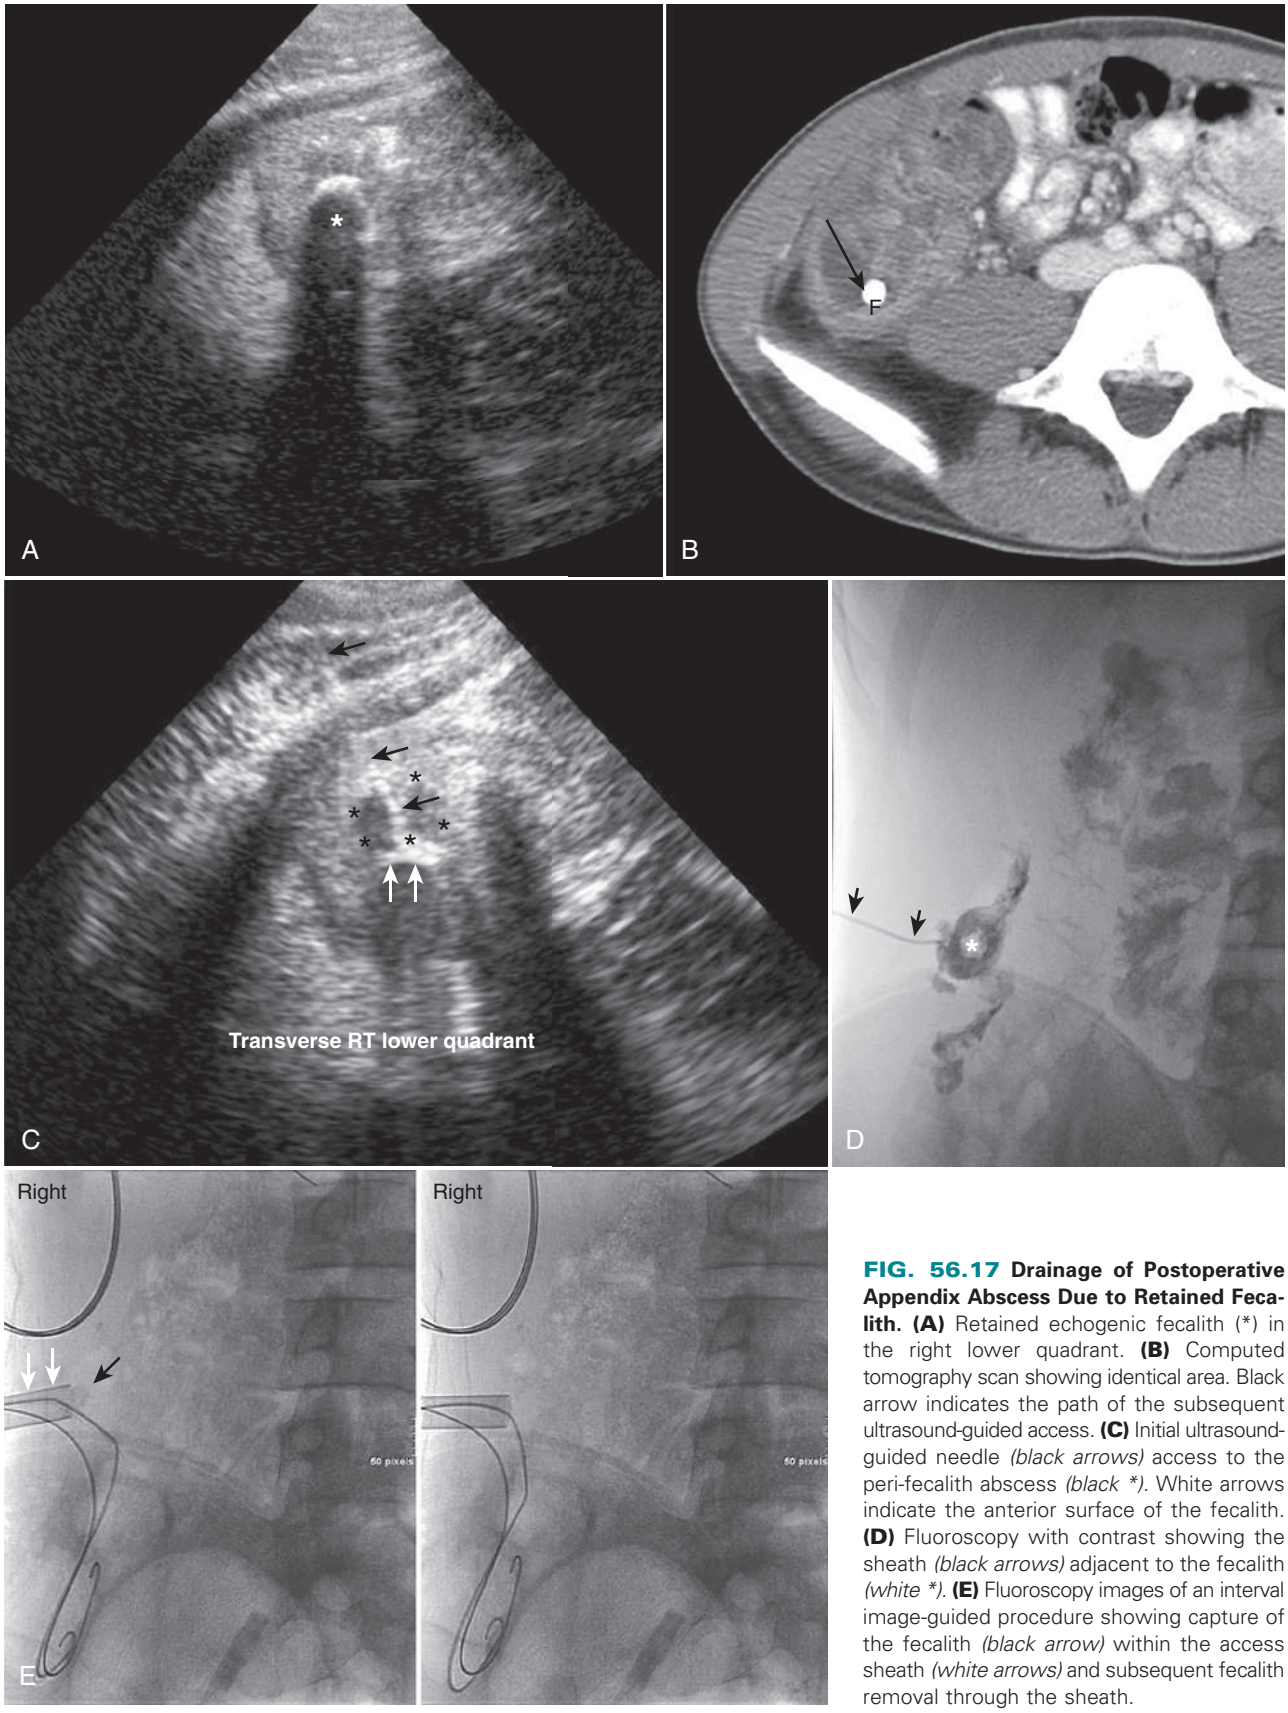

FIG. 56.17 Drainage of Postoperative Appendix Abscess Due to Retained Fecalith. (A) Retained echogenic fecalith (*) in the right lower quadrant. **(B)** Computed tomography scan showing identical area. Black arrow indicates the path of the subsequent ultrasound-guided access. **(C)** Initial ultrasound-guided needle *(black arrows)* access to the peri-fecalith abscess *(black *)*. White arrows indicate the anterior surface of the fecalith. **(D)** Fluoroscopy with contrast showing the sheath *(black arrows)* adjacent to the fecalith *(white *)*. **(E)** Fluoroscopy images of an interval image-guided procedure showing capture of the fecalith *(black arrow)* within the access sheath *(white arrows)* and subsequent fecalith removal through the sheath.

Targeted Organ Lesion Biopsy

Ultrasound-guided nontarget-organ biopsy such as for suspected liver or kidney abnormality is a well-established procedure. Targeted intraorgan lesion biopsy is more demanding. Each case must be assessed on its merits, but caution should be exercised for lesions close to the diaphragm or major intraorgan or extraorgan vasculature. Figs. 56.18 and 56.19 illustrate two such targeted lesion biopsies.

Musculoskeletal Procedures

Whereas CT or cone-beam CT is the usual guidance modality for deep bone procedures, ultrasound can be useful for certain periosteal or cartilage-related lesions (see Fig. 56.1; Fig. 56.20, Video 56.5, Video 56.6, and Video 56.7).

Steroid injection for local treatment of specific joints in diseases such as juvenile rheumatoid arthritis can be achieved by nonimage-guided access in large joints such as the knee, but increasingly, rheumatologists are referring patients for image-guided steroid injection for smaller or technically difficult joints such as the subtalar, temporomandibular, or interphalangeal joints. Ultrasound guidance can be used for accurate access to these small joints.[28,29] Ultrasound-guided steroid injection of tendon sheaths is a valuable procedure (Fig. 56.21, Video 56.8).

Some deep foreign bodies can be removed under ultrasound guidance (Fig. 56.22). It is important that the ultrasound-guided procedure be done before the wound is opened and probed in the emergency room or operating room. Otherwise, air degrades the ability of ultrasound to visualize the foreign body and the case must be cancelled and rescheduled.

Head and Neck Lesions

Certain vascular and lymphatic malformations are amenable to ultrasound-guided access and treatment, usually by sclerosing agents.[30] Orbital lymphatic malformations are difficult to treat surgically but respond well to percutaneous ultrasound-guided sclerosis (Fig. 56.23).

Ranulas are rare lesions consisting of saliva-containing cysts most commonly due to trauma or obstruction of the sublingual duct. The sublingual duct secretes saliva continuously, whereas the submandibular and parotid duct secrete only with oral stimuli such as eating, and therefore the sublingual gland is more prone to formation of ranula. Plunging ranula can be treated successfully by ultrasound and fluoroscopically guided sclerosis (Fig. 56.24).

NOTE FROM THE AUTHORS

The authors dedicate this chapter to the memory of Dr. William (Bill) Shiels. Dr. Shiels was an interventional ultrasound innovator, an extreme enthusiast, and co-author of this chapter in the fourth edition. He pioneered many new and innovative techniques in pediatric interventional radiology, often involving ultrasound guidance and monitoring. He established a popular system of training phantoms and established and maintained active leadership of the annual "hands-on" sessions at the RSNA for many years. He inspired many young pediatric interventionalists and taught us all. He will be remembered by all who came into contact with this unique and inspiring person. Thank you, Bill.

APPENDIX

Ultrasound Artifacts: A Virtual Chapter

Korosh Khalili, Hojun Yu, Alexander Jesurum, and Deborah Levine

SUMMARY OF KEY POINTS

- Artifacts are common in ultrasound imaging.
- Knowledge of artifacts can aid in diagnosis.
- Understanding ultrasound physics allows for correction of artifacts that distort the visualized anatomy.

CHAPTER OUTLINE

ASSUMPTIONS IN GRAY-SCALE IMAGING
Velocity of Sound
Attenuation of Sound
Path of Sound
Beam Profile
PROPAGATION VELOCITY ARTIFACT
ATTENUATION ERRORS
Shadowing
Increased Through Transmission
PATH OF SOUND-RELATED ARTIFACTS
Mirror Image Artifact
Comet-Tail Artifact
Refraction
Anisotropy
Reverberation Artifact
GAS-RELATED ARTIFACTS
Reverberation Artifact
Ring-Down Artifact
Dirty Shadowing Artifact
BEAM PROFILE–RELATED ARTIFACTS
Side Lobe and Grating Lobe Artifacts
Partial Volume Averaging
DOPPLER IMAGING ARTIFACTS
Loss or Distortion of Doppler Information
Artifactual Vascular Flow
Tissue Vibration Artifact
Aliasing and Velocity Scale Errors
Spectral Broadening
Blooming Artifact
Twinkle Artifact
Acknowledgment

Almost all ultrasound images contain artifacts. Many of these artifacts go unrecognized because they are contained within (and contribute to) the background noise. However, when artifacts substantially alter the signal, they become recognizable on images. Certain artifacts distort the images and must be recognized in order to improve image quality or prevent a false diagnosis. Other artifacts add useful data and thus are important for understanding the composition, anatomy, and pathology of the image being visualized. We hope you enjoy this virtual chapter, which encompasses animated illustrations of how artifacts are produced as well as multiple examples of images and videos from the text.

ASSUMPTIONS IN GRAY-SCALE IMAGING

Several assumptions about the propagation of sound waves are made when ultrasound equipment maps echoes onto the image.[1] When one or more of these assumptions prove invalid, artifacts result.

Velocity of Sound

The speed of sound throughout the tissues is assumed to be uniform at 1540 m/sec. When the waves travel through tissues that substantially alter sound velocity, propagation velocity artifacts occur.

Attenuation of Sound

Sound waves normally become fainter—that is, their intensity decreases—as they travel through tissues. The equipment assumes that this attenuation of intensity occurs at a constant rate. If the waves travel through tissues that either do not attenuate as much or attenuate more than the adjacent tissues, attenuation errors such as increased through transmission or shadowing arise.

Path of Sound

In creating the image, the equipment assumes that the generated sound wave travels from the surface of the probe in a straight line, is reflected off a reflector only once, and returns directly back to the probe at the same angle exactly to the point from which it left the probe. If the sound waves undergo more than one reflection, then artifacts such as mirror image, reverberation,

or comet-tail occur. And if the direction of the beam or its echo is altered, refraction or anisotropy artifact may be produced.

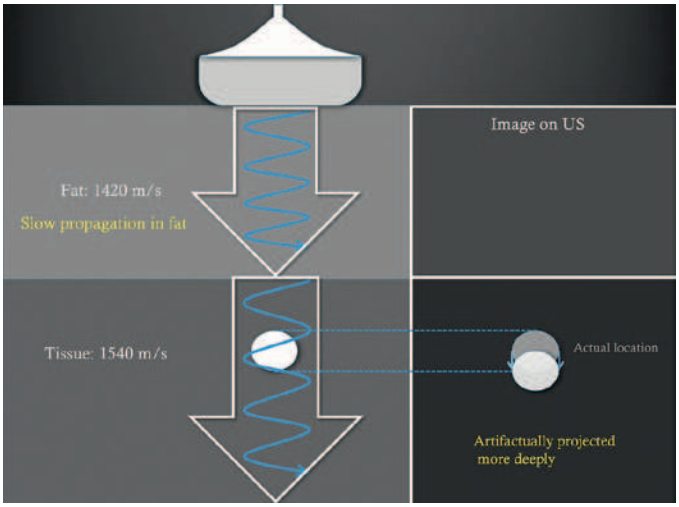
Beam Profile

An assumption is made that the sound beam generated by the transducer is a narrow line. When the beam is not sufficiency narrow in the imaging plane or in the elevation plane (i.e., along the short axis of the transducer), side lobe or grating lobe or partial volume averaging artifacts may occur.

PROPAGATION VELOCITY ARTIFACT

Ultrasound image processing assumes that the speed of sound in tissue is a constant 1540 m/sec. However, when a sufficiently large structure composed of tissue that propagates speed at a different velocity is encountered, then propagation velocity artifact can occur.[1] In the case of a fatty lesion, the slower speed of propagation (approximately 1450 m/sec) means that the echo will take longer to return to the transducer; thus the lesion is displayed deeper in the image than its true location. Some newer ultrasound machines with multibeam (spatial compounding) features and improved signal processing can minimize this artifact.

Click here to see an explanatory video of **propagation velocity artifact** (Video A.1).



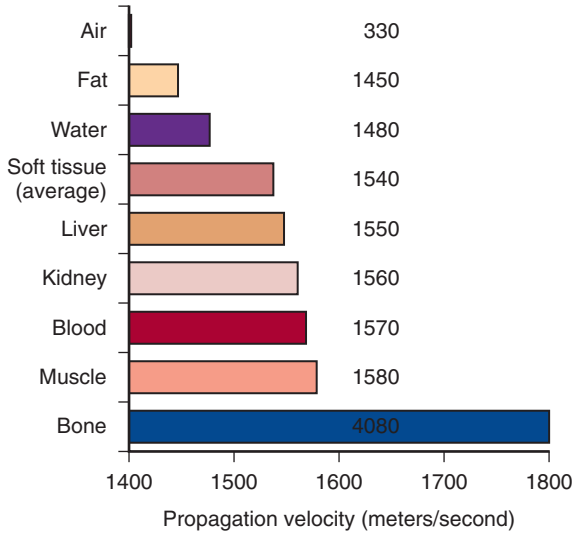


FIG. A.1 Propagation Velocity. Propagation velocity of different body tissues.[2] (See Chapter 1, Fig. 1.2.)

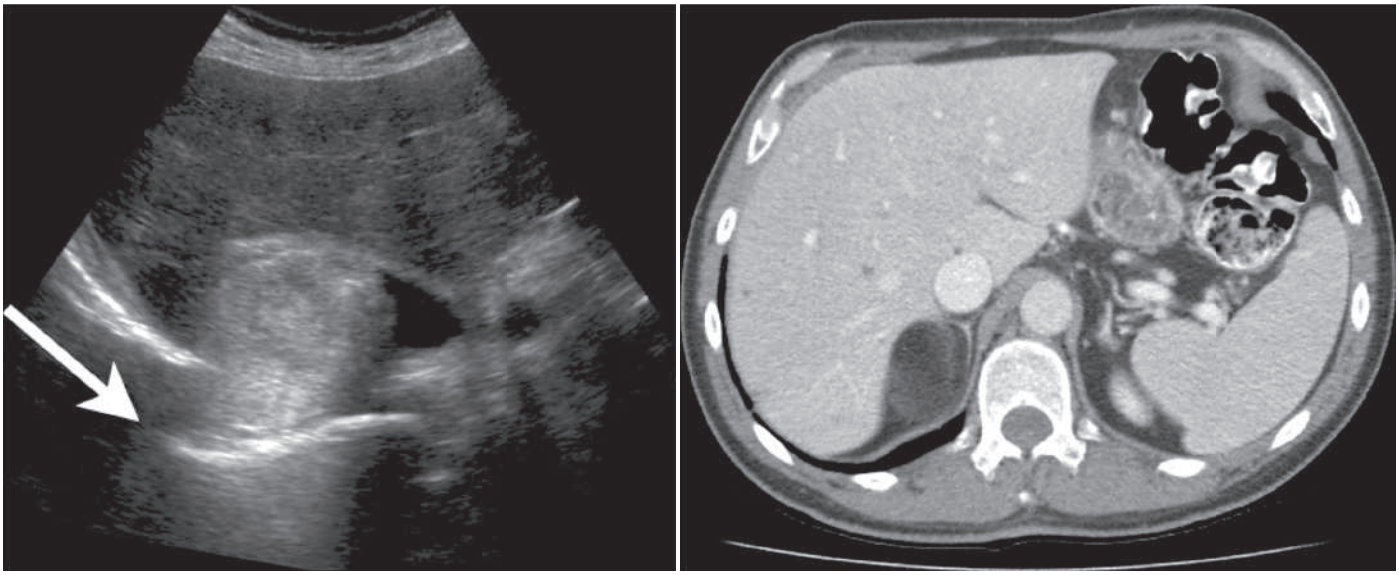

FIG. A.2 Propagation Velocity. When sound passes through a fatty mass, in this case a myelolipoma, its speed slows down to 1450 m/sec. Because the ultrasound scanner assumes that sound is being propagated at the average velocity of 1540 m/sec, the delay in echo return is interpreted as indicating a deeper target. Therefore the final image shows a **misregistration artifact** in which the diaphragm *(arrow)* is shown in a deeper position than expected in this patient with a right adrenal myelolipoma. The computed tomography image depicts the myelolipoma, confirming its fatty nature.

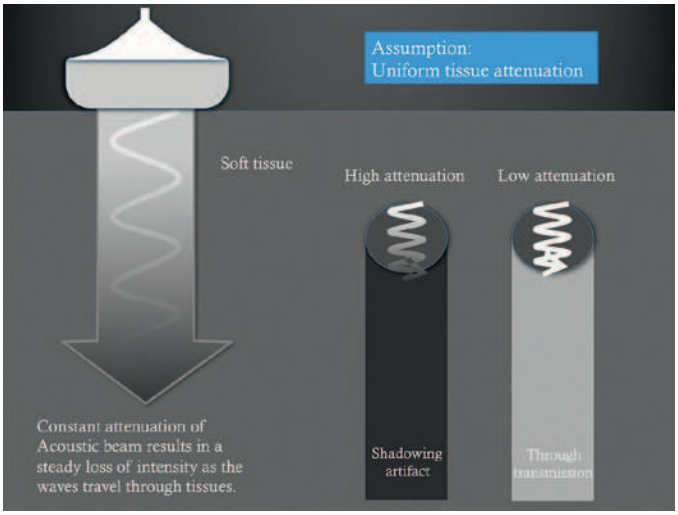
ATTENUATION ERRORS

When the ultrasound beam encounters a focal lesion that attenuates the sound to a greater or lesser extent than the surrounding tissues, the intensity of the beam deep to the lesion will be either weaker (shadowing) or stronger (increased through transmission) than in the surrounding tissues.

Click here to see an explanatory video of **attenuation-related artifacts** (Video A.2).



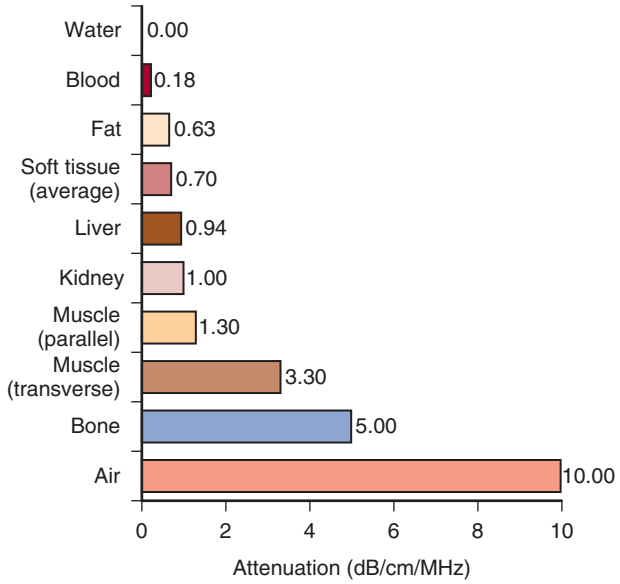


FIG. A.3 As sound passes through tissue, it loses energy through the transfer of energy to tissue by heating, reflection, and scattering. Attenuation is determined by the insonating frequency and the nature of the attenuating medium. Attenuation values for normal tissues show considerable variation. Attenuation also increases in proportion to insonating frequency, resulting in less penetration at higher frequencies.[2] (See Chapter 1, Fig. 1.9.)

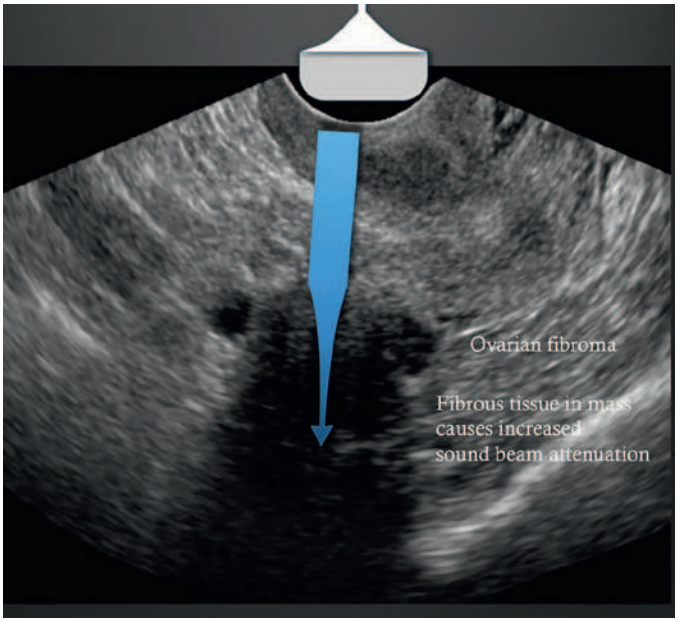
Shadowing

Shadowing results when there is a marked reduction in the intensity of the ultrasound deep to a strong reflector, attenuator, or refractor. Clean dark shadows will be seen behind calcified objects when the focal zone is at or just below the structure.

Click here to see an explanatory video of **shadowing** (Video A.3).



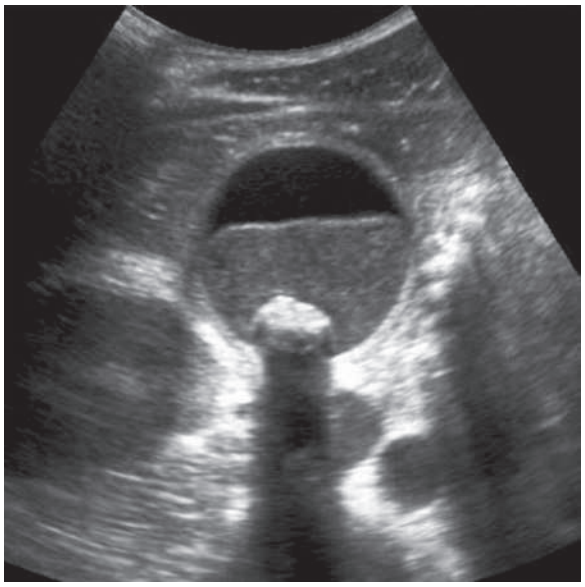


FIG. A.4 Gallstone With Shadowing. Note the dark, well-defined shadow.[3] (See Chapter 6, Fig. 6.39C.)

FIG. A.5 Shadowing From Hernia Repair Mesh.

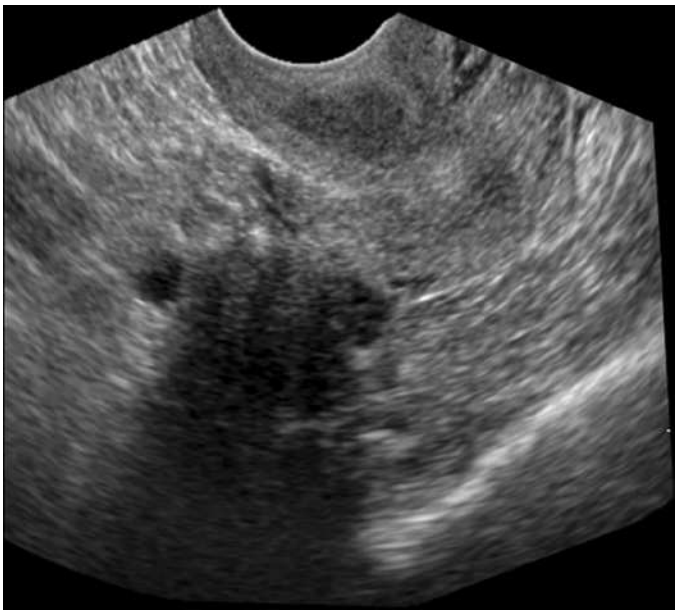

FIG. A.6 Shadowing From Ovarian Fibroma. This is a slightly less "clean" shadow since the fibroma is not as dense as a calcified stone.

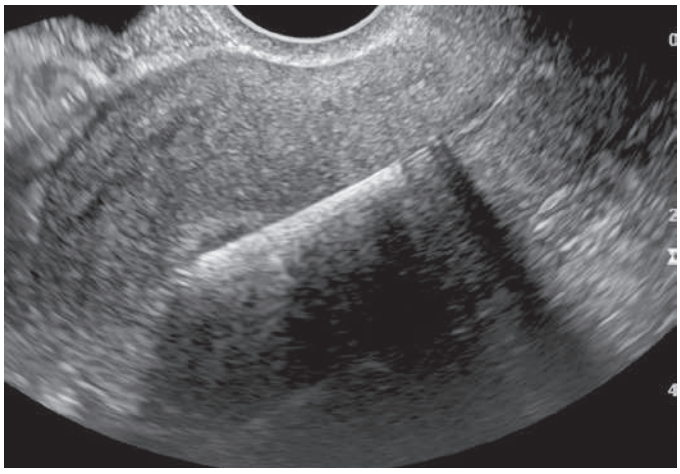

FIG. A.7 Shadowing From an Intrauterine Device.[4] (See Chapter 15, Fig. 15.25A.)

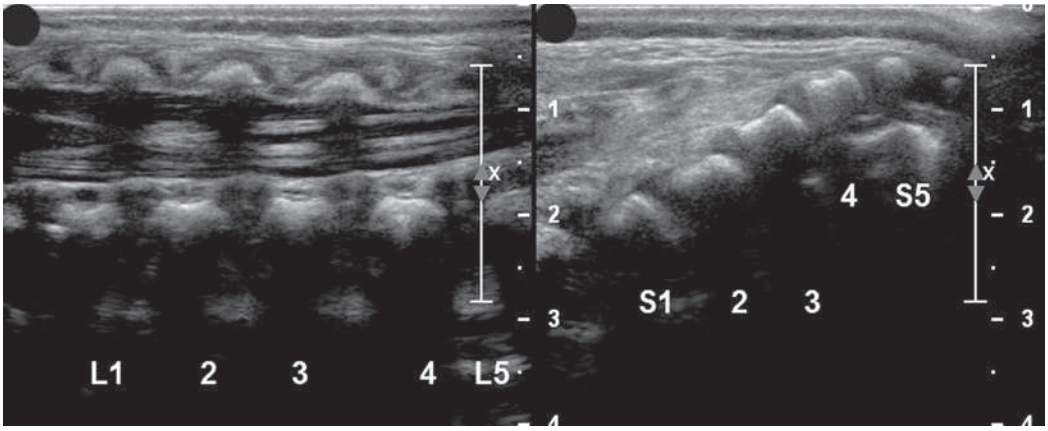

FIG. A.8 Shadowing. Coned down view of distal neonatal spine shows **shadowing** from vertebral bodies that interrupt the linear appearance of the nerve roots.[5] (See Chapter 49, Fig. 49.3.)

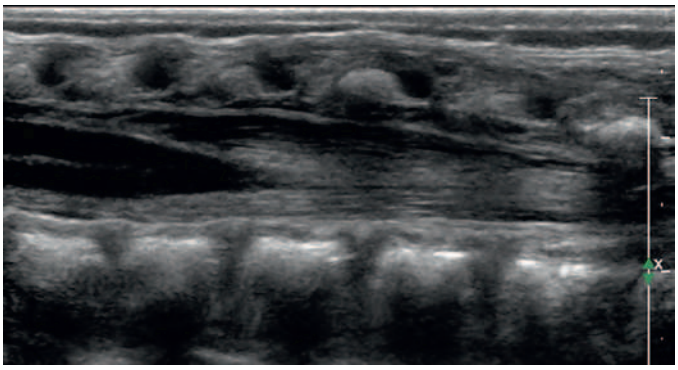
Click here to see real-time cine clip of showing in region of cauda equina (Video A.4).[5]



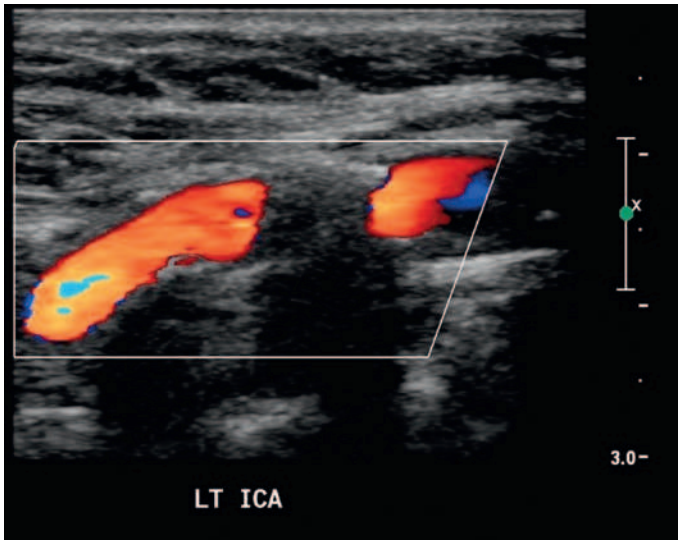


FIG. A.9 Shadowing. Shadowing from dense plaque prevents assessment of color flow in that region. Note that there must be flow present because similar color is visualized before and after the shadow.[6] (See Chapter 26, Fig. 26.8.)

Edge shadowing is caused by excessive refraction and commonly occurs from the edges vessels, cystic structures, and bones.

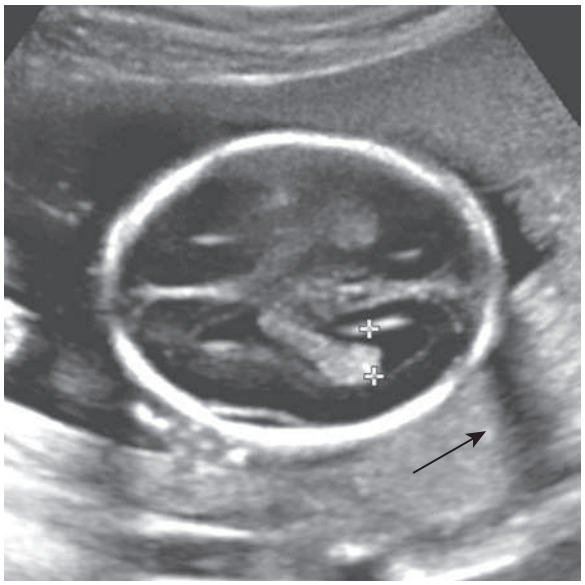

FIG. A.10 Edge Shadowing. Note the **edge shadowing** artifact behind the posterior aspect of the fetal skull. The beam bends at curved surface and loses intensity, producing a shadow *(arrow)*.[7] (See Chapter 34, Fig. 34.3.)

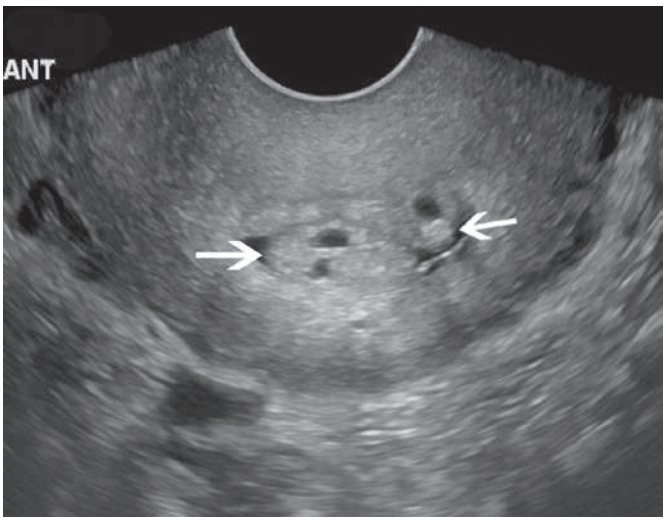

FIG. A.11 Edge Shadowing 2. Endometrial polyp shows both **through transmission** behind the cystic spaces and **edge shadowing** at the margins of the cysts.[4] (See Chapter 15, Fig. 15.14B.)

Increased Through Transmission

Increased through transmission occurs when an object (such as a cyst) attenuates the sound waves less than the surrounding tissues.

Click here to an explanatory video of **increased through transmission** (Video A.5).

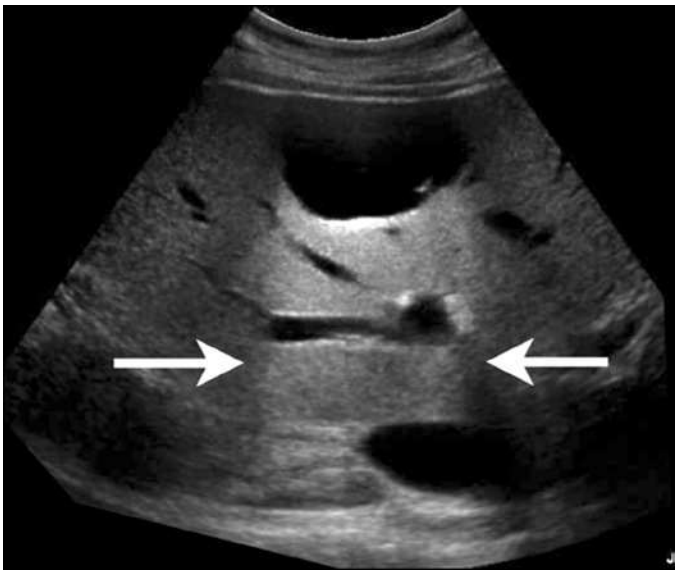

FIG. A.13 Increased Through Transmission. The hepatic parenchyma distal to the cysts is falsely displayed as increased in echogenicity *(arrows)* secondary to increased through-transmission artifact.

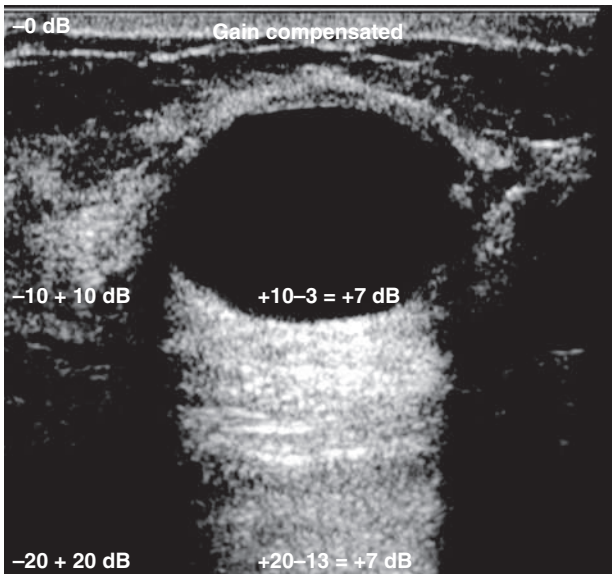

FIG. A.12 Increased Through Transmission. The cyst attenuates 7 dB less than the normal tissue, and time gain curve correction for normal tissue results in overamplification of the signals deep to the cyst, producing **increased through transmission** of these tissues.[2] (See Chapter 1, Fig. 1.31C.)

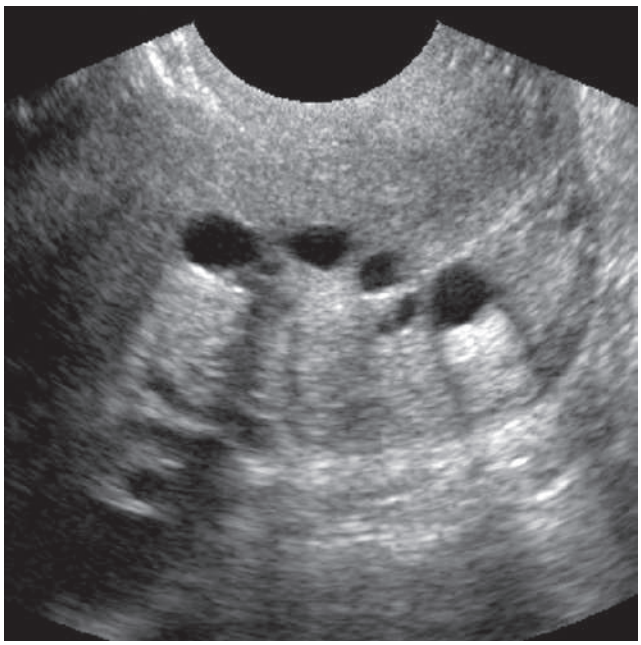

FIG. A.14 Increased Through Transmission. Nabothian cysts show both **increased through transmission** behind the cysts and **edge shadowing** at the margins of the cysts.[4] (See Chapter 15, Fig. 15.7C.)

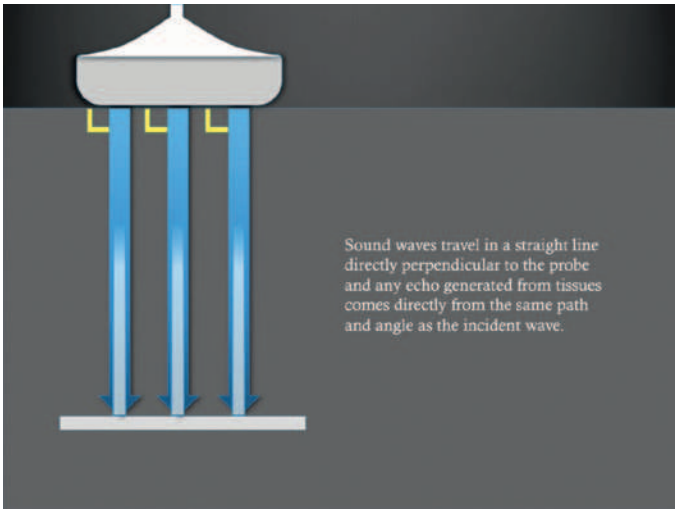
PATH OF SOUND-RELATED ARTIFACTS

In mapping a returning echo onto the generated image, an assumption is made that it originated from the same part of the transducer from which it was produced. Also, an assumption is made that the echo is the result of a single reflection. The depth of the reflector is calculated based on the time it took for the sound wave to travel from the transducer to the reflector and back, assuming a single reflection. When these assumptions do not hold, various types of artifacts occur.

Click here to see an explanatory video of **path of sound assumption** (Video A.6).



Mirror Image Artifact

A mirror image artifact is created when the primary beam encounters a highly reflective surface that acts like a mirror. The reflected echoes then encounter other reflectors and bounce back onto the mirror before being directed to the transducer. The result is artifactually inverted projection of the reflectors deeper to the surface of the mirror. The image is displayed deeper because of the longer path of the reflected sound. If the mirror image artifact causes confusion, it can be decreased or eliminated by moving the transducer to center it on the region of interest and/or placing the focal zone at the level of interest in the real structure.

Click here to see an explanatory video of **mirror image artifact** (Video A.7).

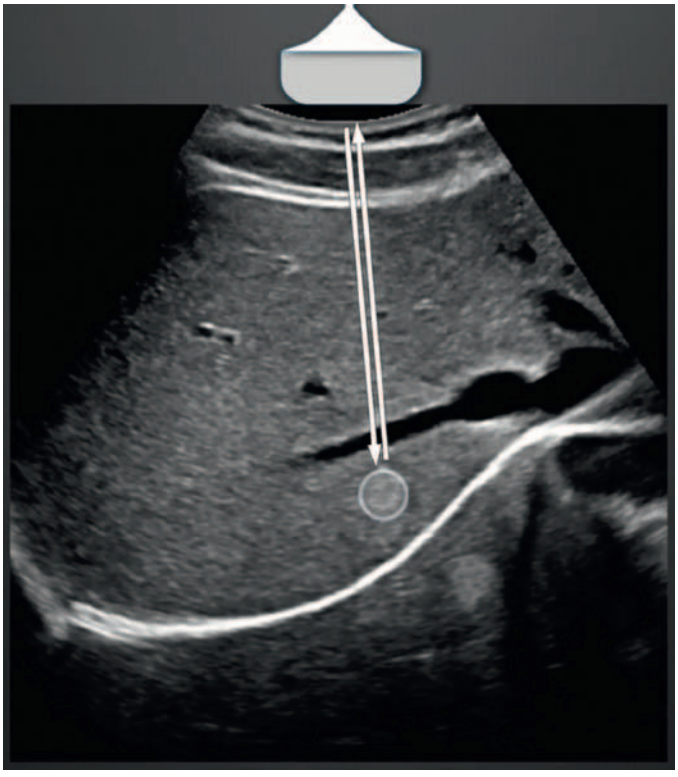


FIG. A.15 Mirror Image. Picture of reflection in water—similar to mirror image artifact.

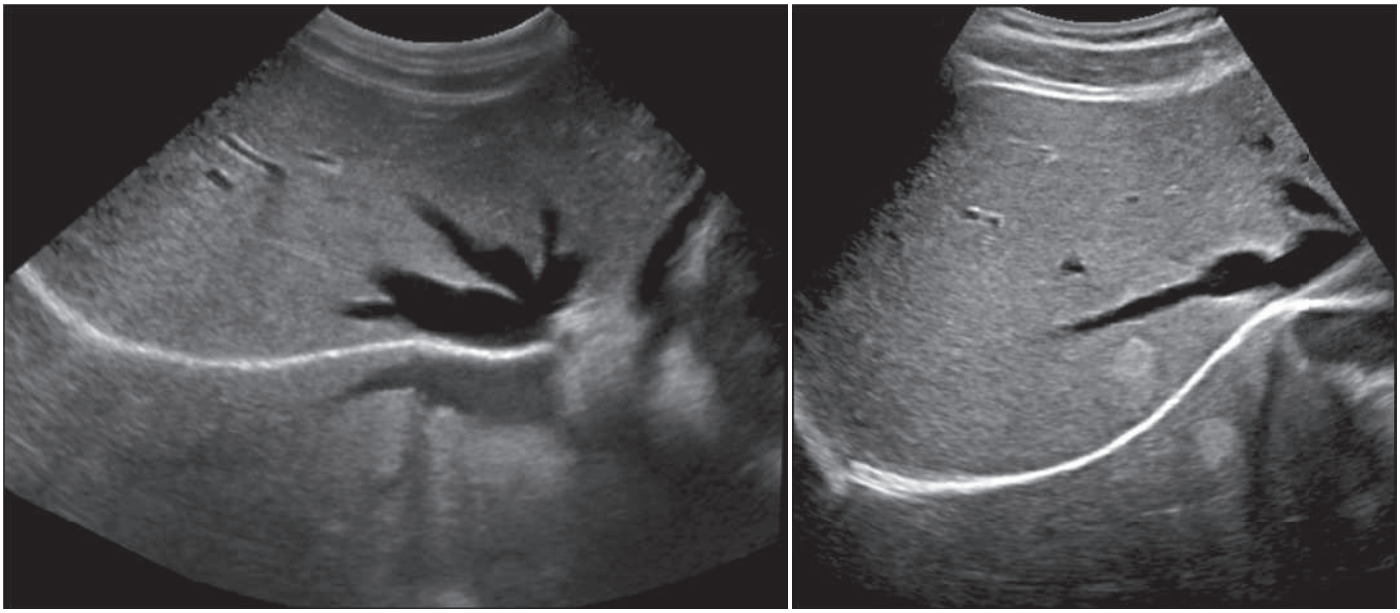

FIG. A.16 Mirror Image Artifact. Soft tissue–gas interfaces, such as the diaphragm, are excellent reflectors of the sound beam owing to the large difference in the acoustic impedance between the two materials. Therefore hepatic structures are frequently seen mirrored beyond the diaphragm onto the lungs. These two figures show liver parenchyma, hepatic veins in part A, and a hepatic hemangioma in part B all inversely projected onto lung.

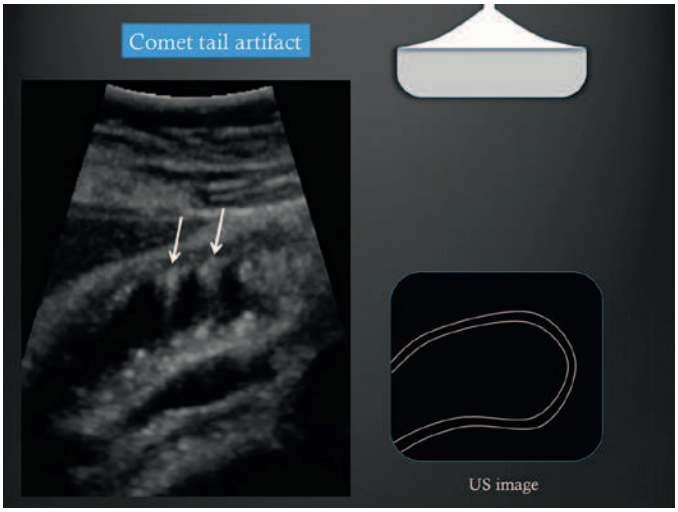
Comet-Tail Artifact

Comet-tail artifact is a type of reverberation artifact.[8] The repetitive reflections occur within very small structures, such as tiny cysts in the case of von Meyenburg complexes and tiny crypts in the wall of the gallbladder in the case of adenomyomatosis. Accordingly, the reverberated echoes may not be individually visible. The tapered, comet-tail appearance is due to the decreasing amplitude of each reverberation as a result of beam attenuation.

Click here to see the explanatory video of **comet-tail artifact** in adenomyomatosis (Video A.8).



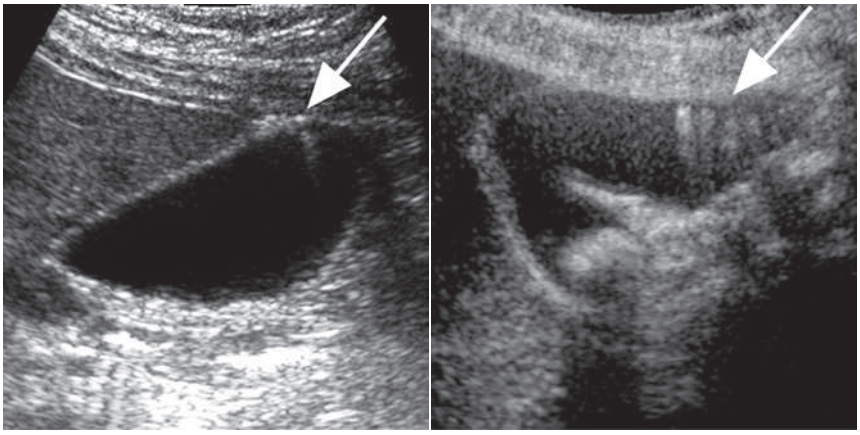


FIG. A.17 Comet-Tail Artifact in Association With Adenomyomatosis. This is felt to be due to cholesterol crystals within the prominent Rokitansky-Aschoff sinuses.[3] (See Chapter 6, Fig. 6.45.)

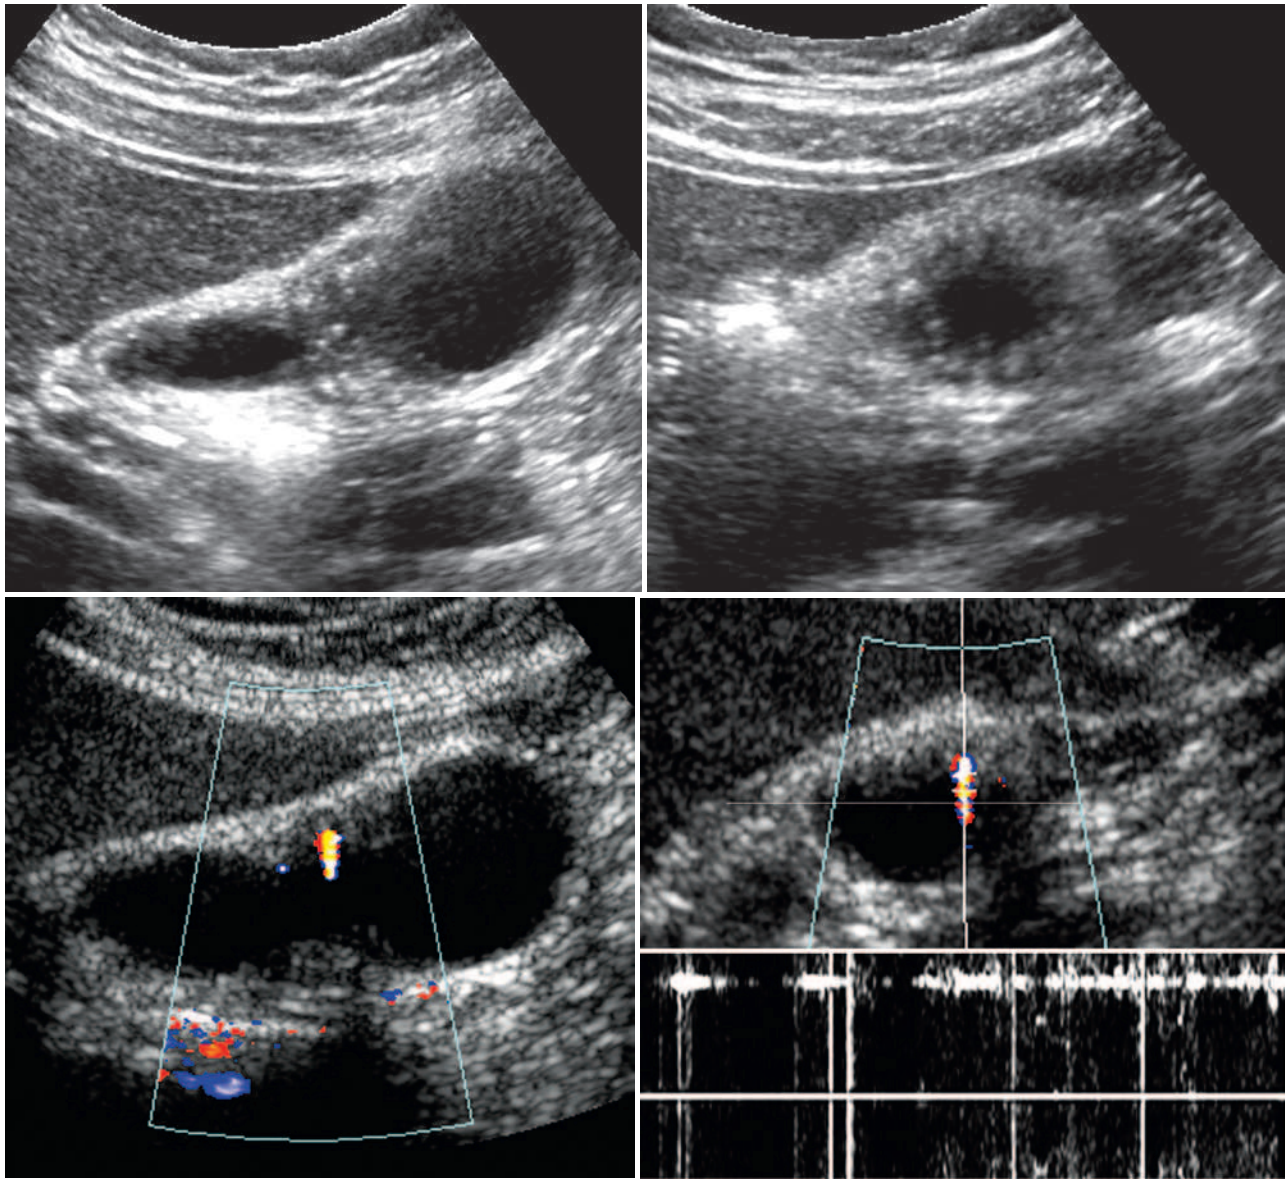

FIG. A.18 Comet-Tail Artifact. On color and spectral Doppler this can look like a twinkle artifact, but it is a color representation of the comet-tail. (See section on color Doppler artifacts for description of the twinkling.[3]) (See Chapter 6, Fig. 6.46.)

FIG. A.19 Adenomyomatosis and Comet-Tail Artifact.

Click here to see real time scanning of **comet-tail artifact** in adenomyomatosis (Video A.9).

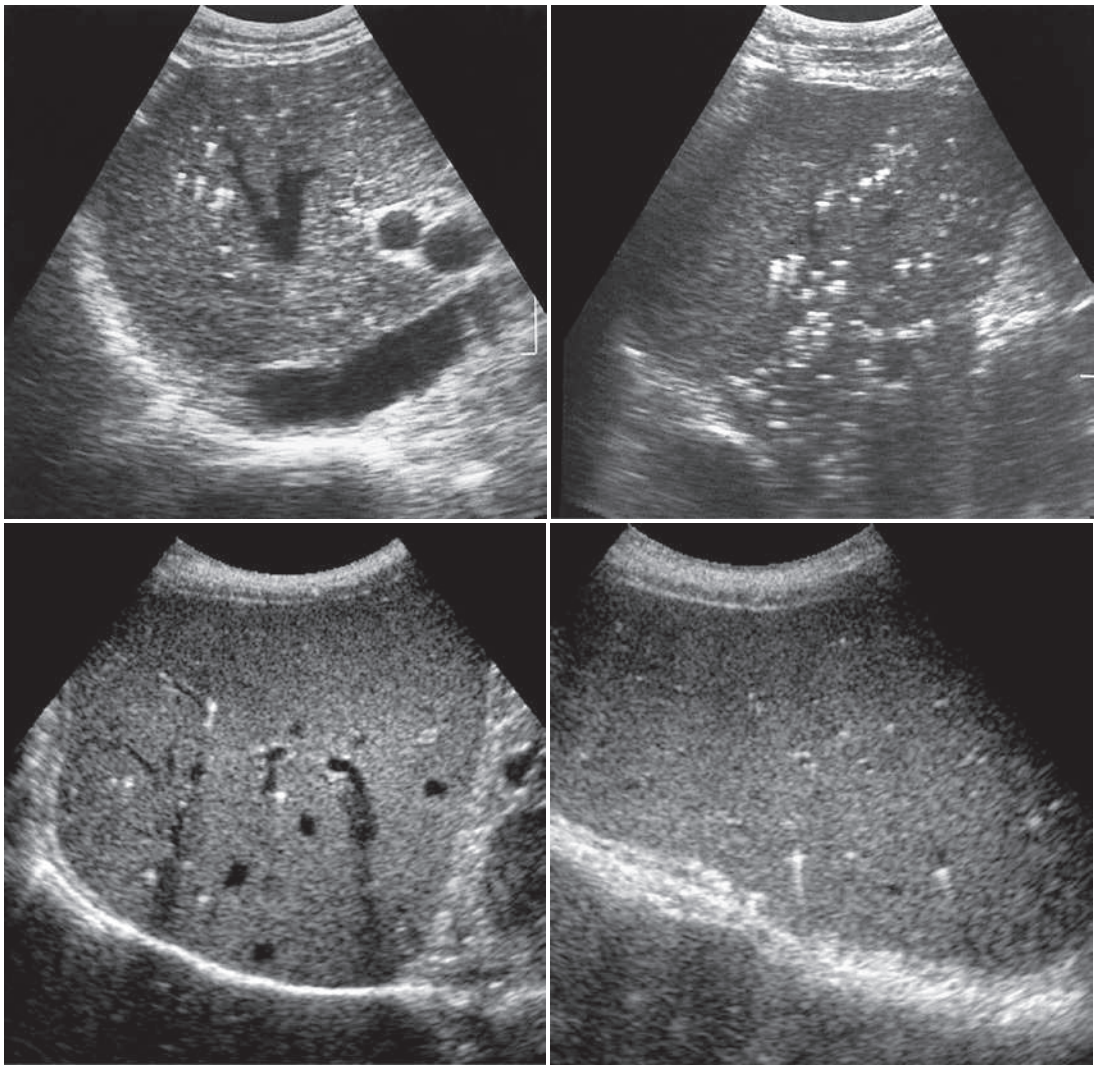

FIG. A.20 Comet-Tail Artifact Behind von Meyenburg Complex in Two Patients.[9] (See Chapter 4, Fig. 4.16.)

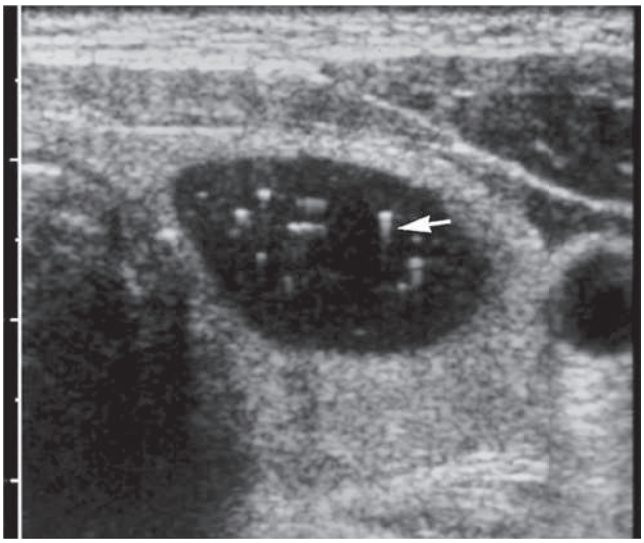

FIG. A.21 Colloid Cyst in Thyroid Gland With Characteristic Comet-Tail Artifact *(Arrow).* [10] (See Chapter 19, Fig. 19.10A.)

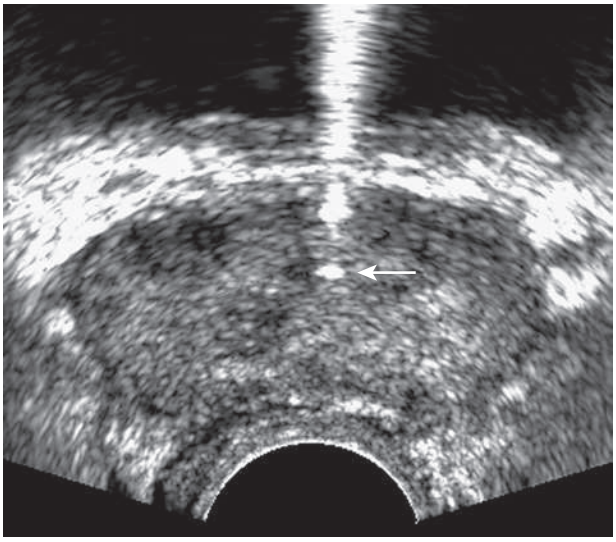

FIG. A.22 Strong Comet-Tail Artifact Due to Fiducial Marker in Patient With Prostate Cancer. [11] (See Chapter 10, Fig. 10.13.)

Refraction

As sound moves between tissues with different propagation velocities, such as from muscle to fat, it changes its direction at their interface as a result of refraction. The physical properties of refraction are explained by Snell's law, as demonstrated in Figs. A.23[12] and A.24. The change in the direction of the sound waves results in violation of the assumption made by the ultrasound equipment that the incident and reflected waves travel in a straight line. Therefore, with refraction, structures insonated by the bent path of sound waves are artifactually translated to appear as if the sound waves had traveled along a straight path. If refraction is suspected, it can be minimized by increasing the scan angle so that sound waves travel perpendicular to the interface.

Click here to see an explanatory video of **refraction** from the anterior abdominal wall (Video A.10).

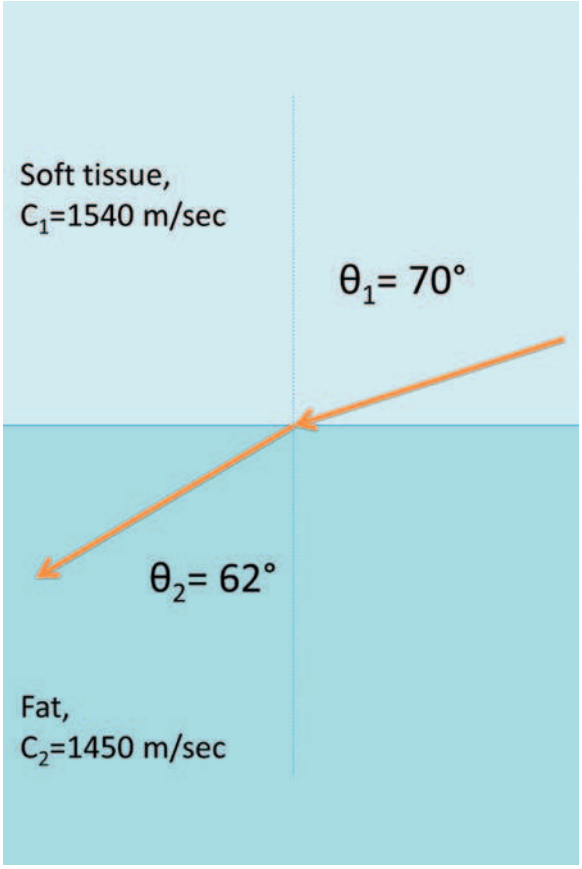

FIG. A.23 Refraction. Refraction can be due to tissues with different propagation velocities. When sound passes from soft tissue with propagation velocity (C_1) of 1540 m/sec to fat with a propagation velocity (C_2) of 1450 m/sec, there is a change in the direction of the sound wave because of refraction. The degree of change is related to the ratio of the propagating velocities of the media forming the interface ($\sin\theta_1/\sin\theta_2 = C_1/C_2$)[2]. Note that when the incident angle is changed to zero degrees—that is, the incident beam is perpendicular to the interface ($\theta_1 = 0°$)—the artifact disappears.

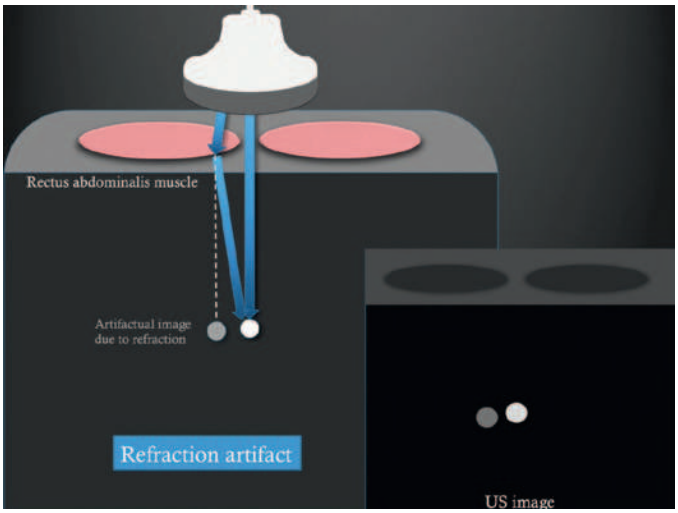

FIG. A.24 Refraction. Image of a straw in water. Refraction has occurred owing to the difference between air and water, causing an offset in the appearance of the straw. Note also how the straw appears larger in the water because of distortion of the image.

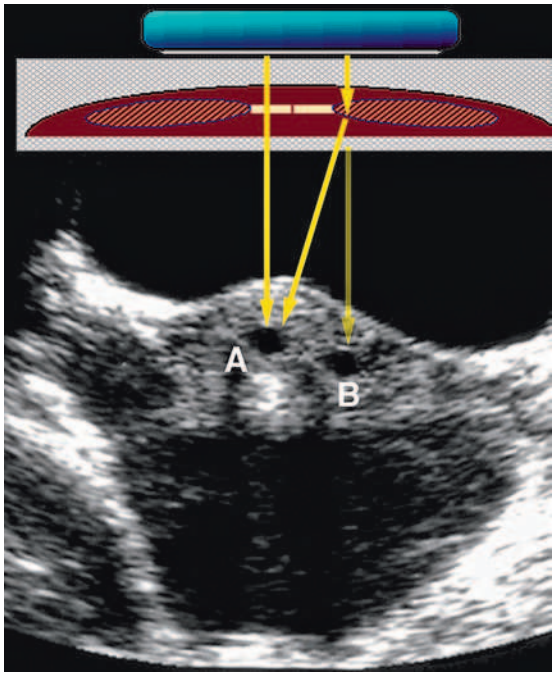

FIG. A.25 Refraction. This figure shows what appears to be a second gestational sac due to refraction artifact. This is sometimes called **"ghosting."**[2] (See Chapter 1, Fig. 1.8.)

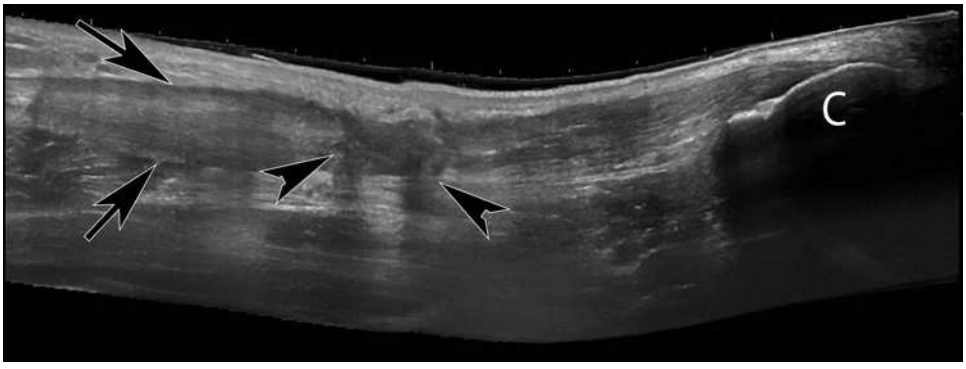

FIG. A.26 Refraction. A panoramic view of the Achilles tendon demonstrates a rupture within the midportion of the tendon. The proximal aspect of the tendon is chronically thickened and hypoechoic *(arrows)*. **Refraction artifact** *(arrowheads)* is caused by the interfaces between the ruptured tendon edges and hemorrhage. *C,* Calcaneus.[13] (See Chapter 23, Fig. 23.11.)

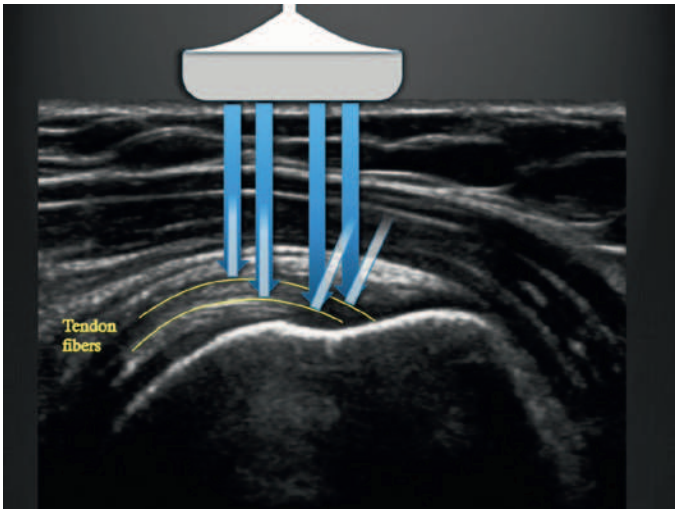
Anisotropy

Anisotropy is an artifact caused by structures that are composed of bundles of highly reflective fibers running parallel to each other, such as tendons and ligaments. If the sound beam hits the tendon or ligament fibers perpendicular to their length, it is reflected directly back, resulting in an echogenic appearance. But if the angle of insonation is not perpendicular to the tendon fibers, the beam is reflected away from the transducer, leading to the generation of an image with artifactual hypoechogenicity within the tendon.

Click here to see an explanatory video of **anisotropy** (Video A.11).



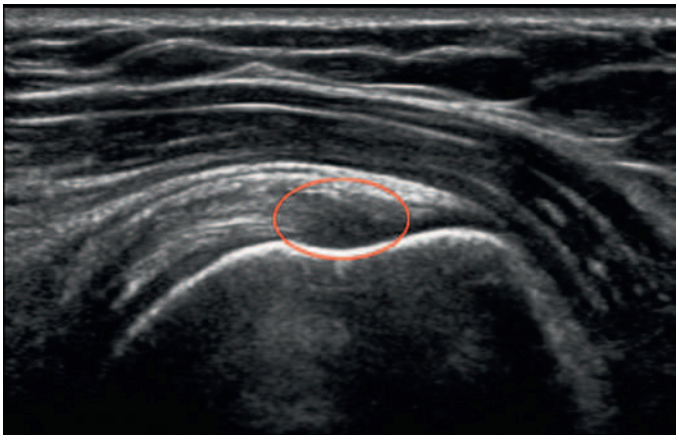


FIG. A.27 Anisotropy. The insertion of supraspinatus tendon artifactually appears hypoechoic due to anisotropy.

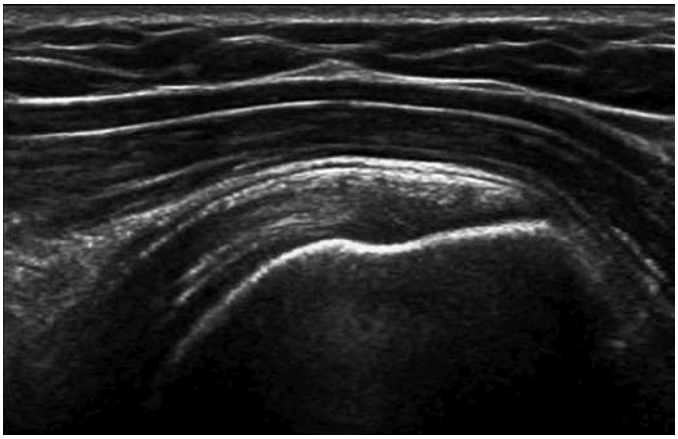
Click here for video of real-time scanning of **anisotropy** at supraspinatus insertion (Video A.12).



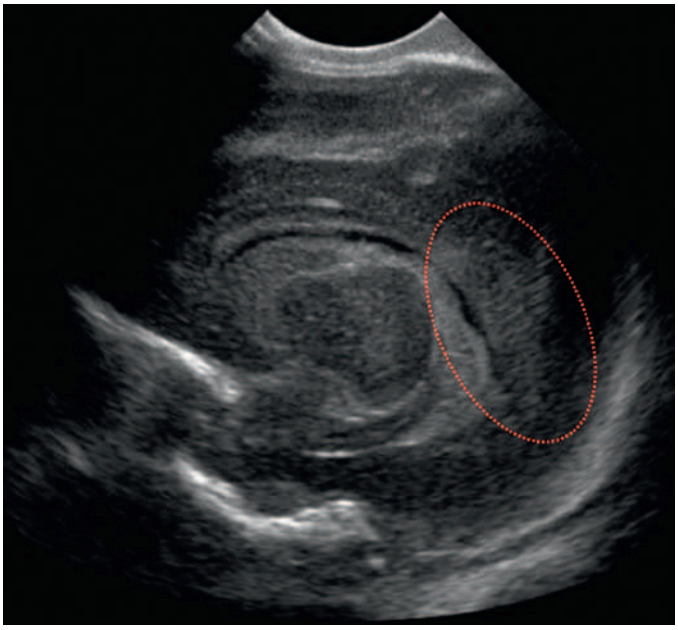


FIG. A.28 Anisotropy. The peritrigonal region of the white matter *(ellipse)* appears relatively echogenic, also called "peritrigonal blush." This **anisotropic effect** artifact occurs because in the trigone region, the parallel white matter fibers run perpendicular to the incident sound beam, causing increased reflection.[14] The artifact is visible only in the region of the trigone when the anterior fontanelle is used as a scanning window.

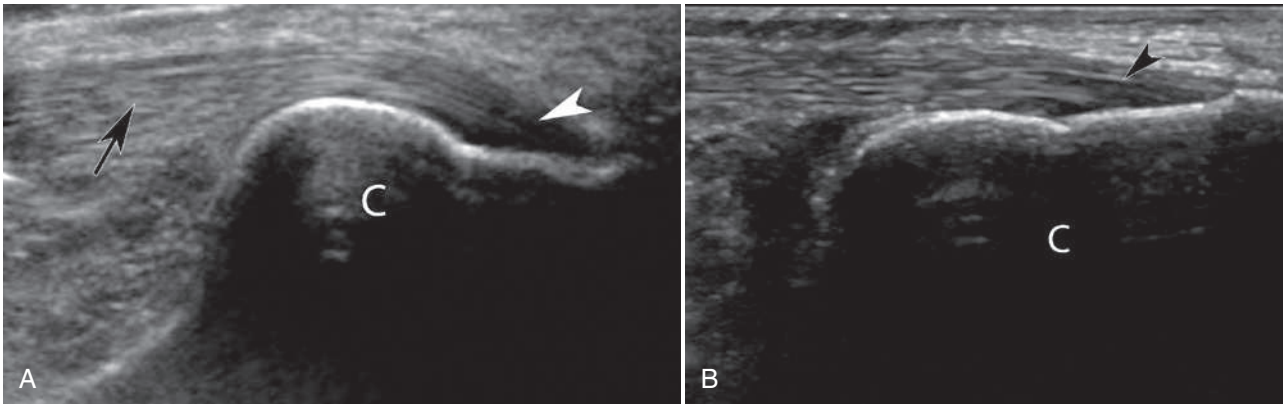

FIG. A.29 Anisotropy. (A) In this long-axis scan of the Achilles insertion on the calcaneus, the proximal portion of the imaged tendon demonstrates a normal fibrillar appearance *(arrow),* whereas the distal tendon insertion is hypoechoic *(arrowhead). C,* Calcaneus.[13] (See Chapter 23, Fig. 23.8.)

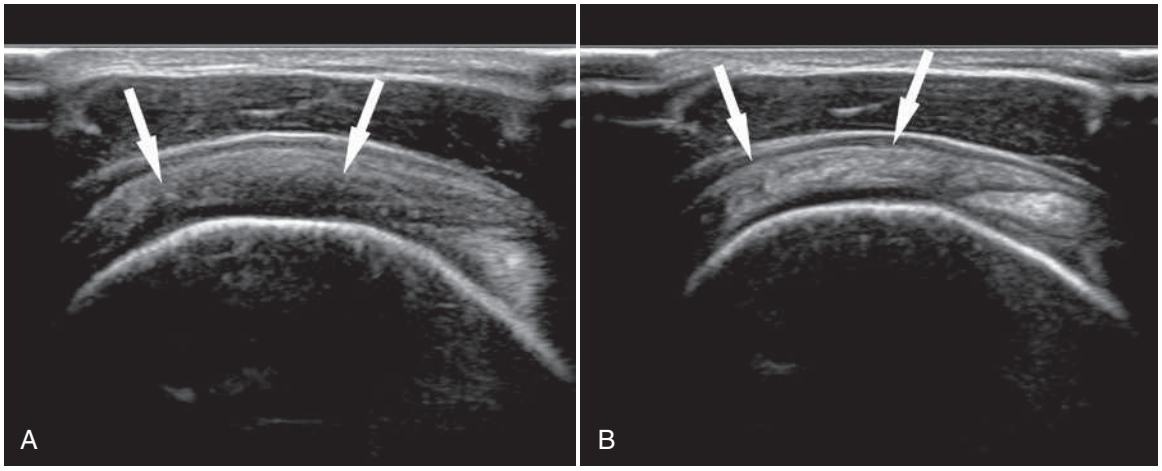

FIG. A.30 Anisotropy. Short-axis images of the supraspinatus tendon. **(A)** Artifactual hypoechogenicity of the supraspinatus tendon *(arrows)* may simulate tendinosis or tear. **(B)** Correction of angle of insonation to be perpendicular to the tendon permits visualization of the normal intact tendon.[15] (See Chapter 24, Fig. 24.30.)

Reverberation Artifact

Reverberation artifact occurs when a strong reflector runs perpendicular to the direction of the beam (i.e., parallel to the probe surface), usually close to the skin surface.[1] The sound waves may then get partially "trapped" between the reflector and skin, reverberating back and forth and causing the appearance of multiple regular lines when some of the waves eventually reach the probe. Often the reflectors are the skin and subcutaneous fascia (see Fig. A.31). Reverberation artifact is angle dependent, so moving the transducer slightly will cause a decrease in or elimination of the artifact. Reverberation can be helpful during biopsies, to see a needle. If it is distracting, try changing the angle of insonation, using a different window, or decreasing the gain.

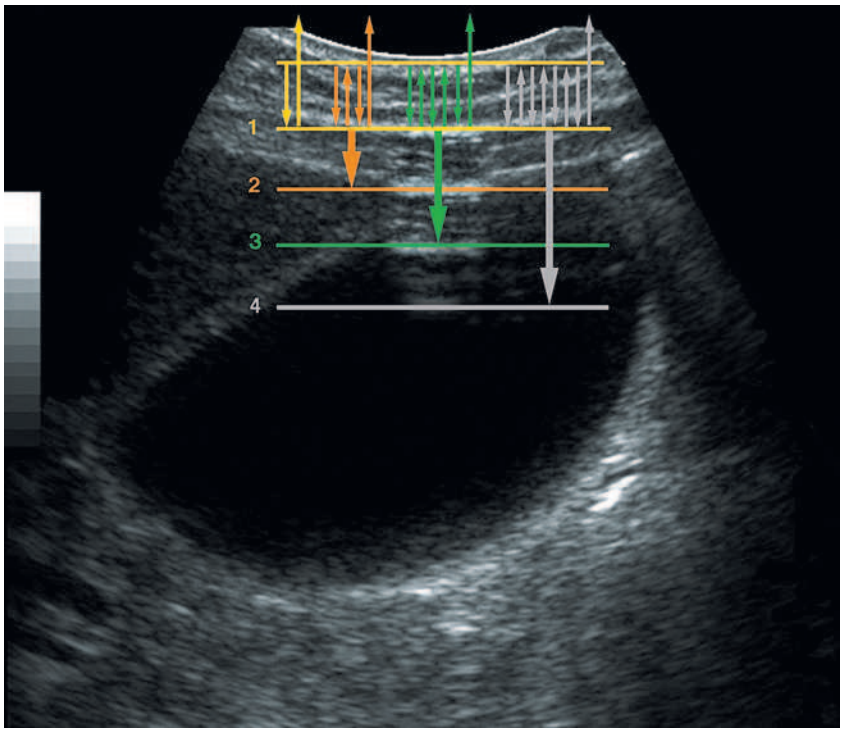

FIG. A.31 Reverberation Artifact. Reverberation artifacts arise when the ultrasound signal reflects repeatedly between highly reflective interfaces near the transducer, resulting in delayed echo return to the transducer. This appears in the image as a series of regularly spaced echoes at increasing depth.[2] (See Chapter 1, Fig. 1.27.)

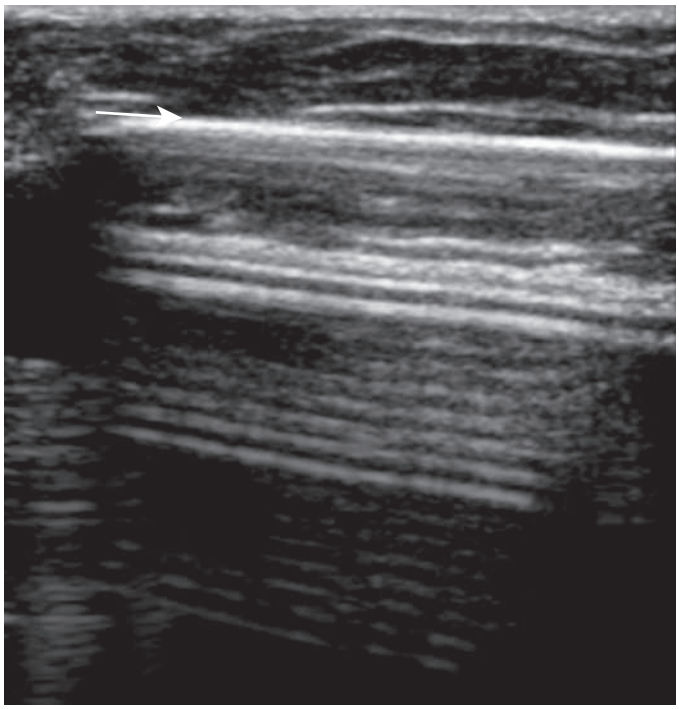

FIG. A.32 Mirror Image and Reverberation Artifacts Behind a Pacemaker. The highly reflective and mirrorlike surface of the pacemaker *(arrow)* results in repeated bouncing of sound wave among the probe surface, pacemaker, and skin.

For reverberation due to gas, see next section.

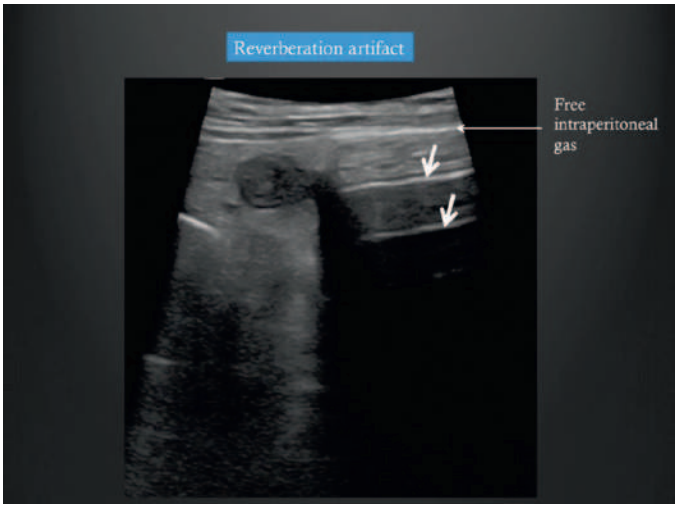
GAS-RELATED ARTIFACTS

Several physical properties of gases lead to unique artifacts in ultrasound that help identify gas but also may hinder visualization of other organs. These properties include the very dissimilar acoustic impedance of gas compared with soft tissues, making them highly reflective surfaces. The varied and ever-changing shape of gas in the body, including foam, leads to variability of its appearance even in the same field. The very low density of gases makes them quite compressible, and they can undergo resonant oscillation in response to sound waves, leading to amplification of echoes. These properties result in three distinct artifacts, which can be present at the same time: **reverberation, ring-down,** and **dirty shadowing.**[16]

Reverberation Artifact

The physical pressure of the probe on the soft tissues, such as the abdominal wall, flattens their shape in the near field, making them perpendicular to the surface of the probe and the incident sound beam. Because gases conform to the shape of their containers, they too will form a linear and perpendicular interface to the incident sound beam, especially when in the form of a large bubble. The highly reflective gas interface will act like a mirror, resulting in reverberation artifacts.

Click here to see an explanatory video of **reverberation artifact due to gas** (Video A.13).



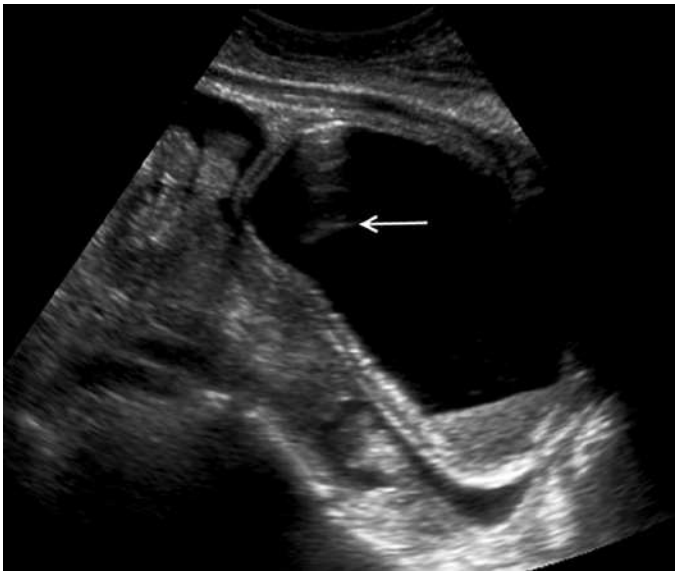


FIG. A.33 Reverberation Artifact. Small amount of gas within the bladder is recognizable by the reverberation artifact *(arrow)*.

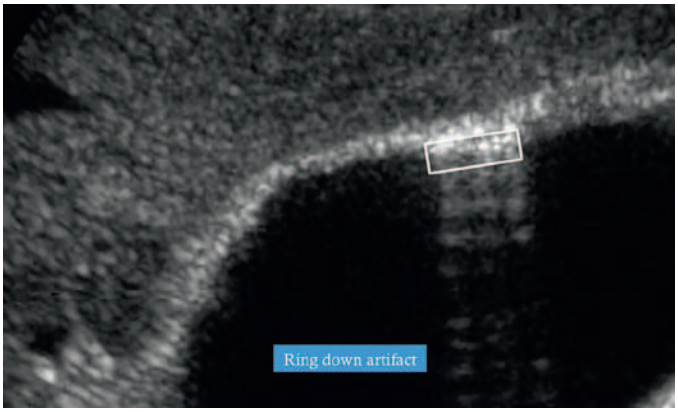
Ring-Down Artifact

Ring-down artifact occurs when the ultrasound waves cause oscillation within fluid trapped by a tetrahedron of gas bubbles.[17] These oscillations create a continuous sound wave that is transmitted back to the transducer. What will be seen is a line or series of parallel bands extending posterior to a gas collection. Although this has the appearance of reverberation artifact, it actually has a different mechanism.

Click here to see an explanatory video of **ring-down artifact** (Video A.14).



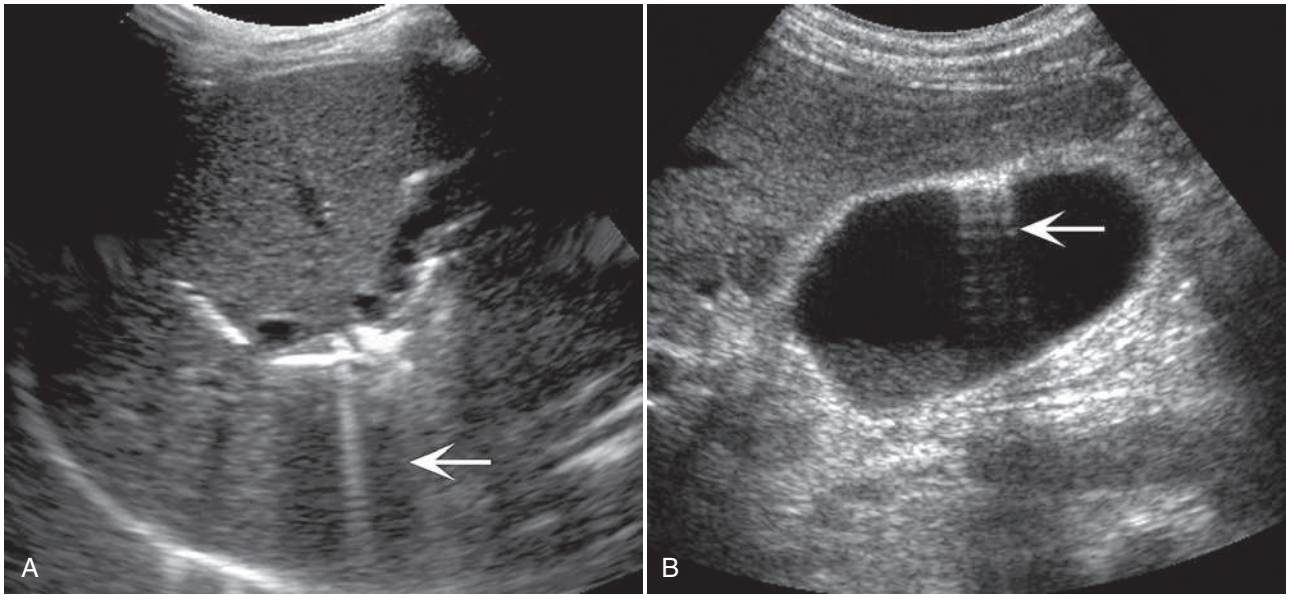


FIG. A.34 Ring-Down Artifact. Pneumobilia causing **ring-down artifact** in the biliary tree **(A)** and gallbladder **(B).**[3] (See Chapter 6, Fig. 6.13.)

Click here to see a video clip of **ring-down artifact** in peripheral ducts of the liver (Video A.15).

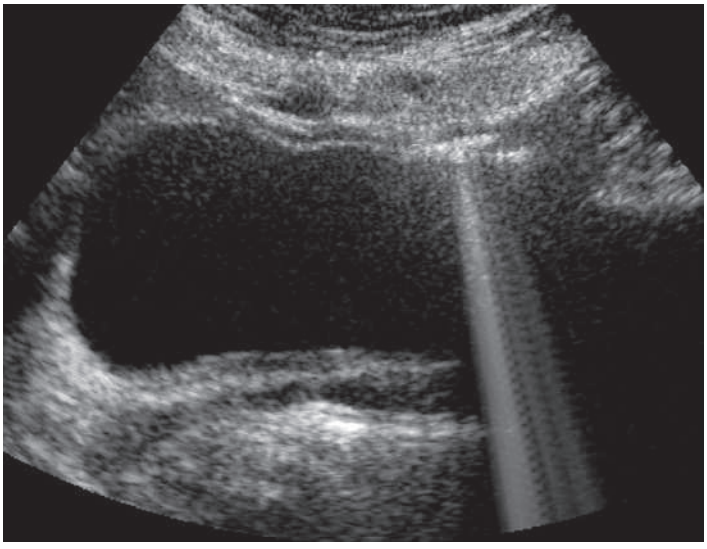

FIG. A.35 Ring-Down Artifact. Iatrogenic air in the bladder introduced at cystoscopy appears as a nondependent bright region with **ring-down artifact.**[18] (See Chapter 9, Fig. 9.36.)

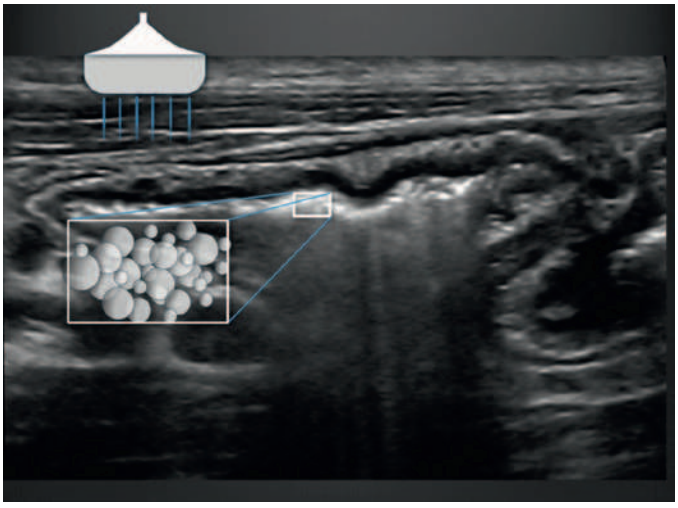
Dirty Shadowing Artifact

Dirty shadowing results from a combination of reflection, reverberation, and ring-down artifacts arising from multiple variably sized bubbles in foam.[16]

Click here to see an explanatory video of **dirty shadowing** artifact (Video A.16).



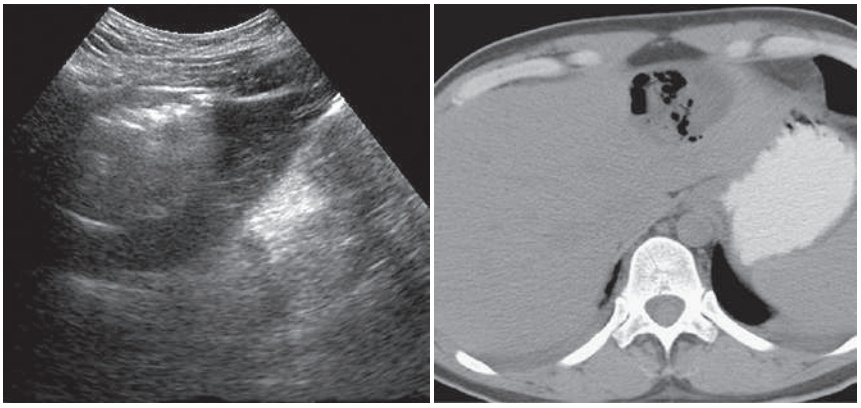


FIG. A.36 Dirty Shadowing. Sonographic image of the liver shows gas in liver mass with reverberation artifact filling the cavity. See comparison computed tomography scan.[9] (See Fig. 4.19.)

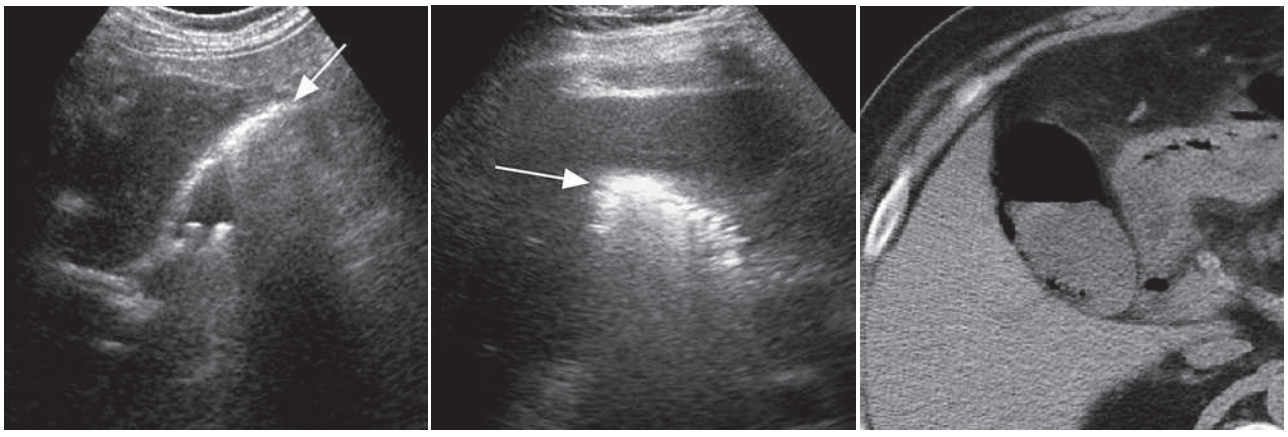

FIG. A.37 Dirty Shadowing Posterior to Emphysematous Cholecystitis.[3] (See Chapter 6, Fig. 6.40.)

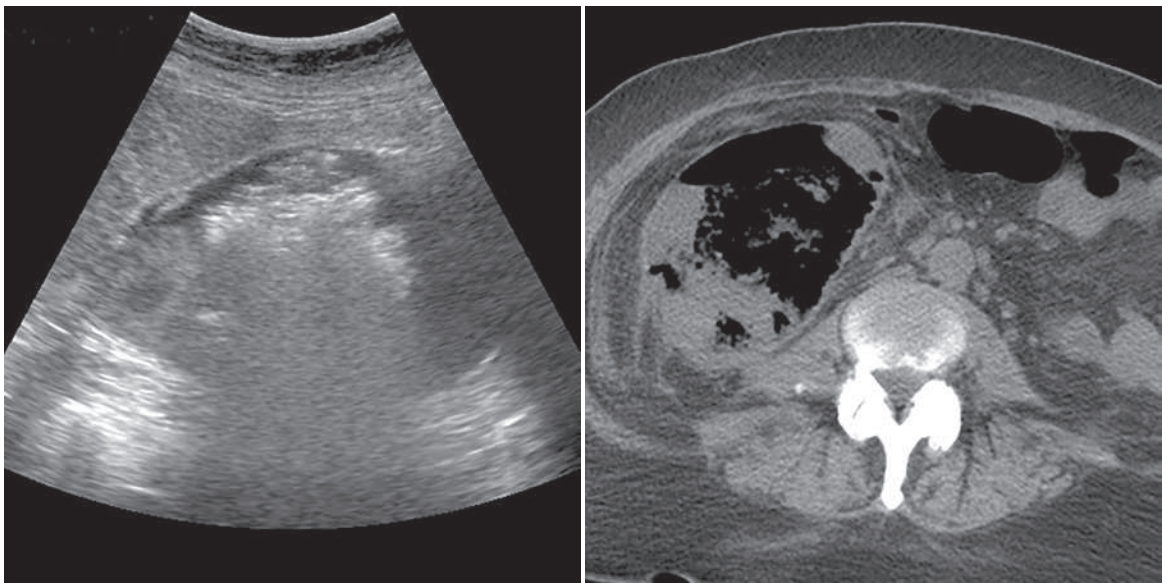

FIG. A.38 Dirty Shadowing in the Kidney Due to Emphysematous Pyelonephritis.[18] (See Chapter 9, Fig. 9.22.)

BEAM PROFILE–RELATED ARTIFACTS

Frequently echoes are seen within what should be an anechoic structure. This can occur as a result of side lobe or grating lobe artifacts in which information from the side of the image projects centrally, or because of partial volume averaging (owing to the thickness of the ultrasound beam (resolution in the Z plane).

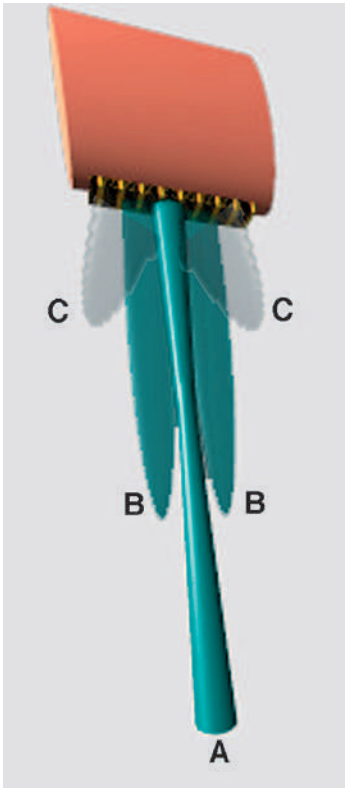

FIG. A.39 The ultrasound beam is not a narrow straight line but has a complex profile that varies depending on the type and shape of the transducer. Although most of the energy generated by a transducer is emitted in a beam along the central axis of the transducer *(A)*, some energy is also emitted at the periphery of the primary beam (*B* and *C*). These are called "side lobes" *(B)* or "grating lobes" *(C)* and are lower in intensity than the primary beam. Side lobes or grating lobes may interact with strong reflectors that lie outside of the scan plane and produce artifacts that are displayed in the ultrasound image.[2] They are more evident when the misplaced echoes overlap an expected anechoic structure. (See Chapter 1, Fig. 1.28.)

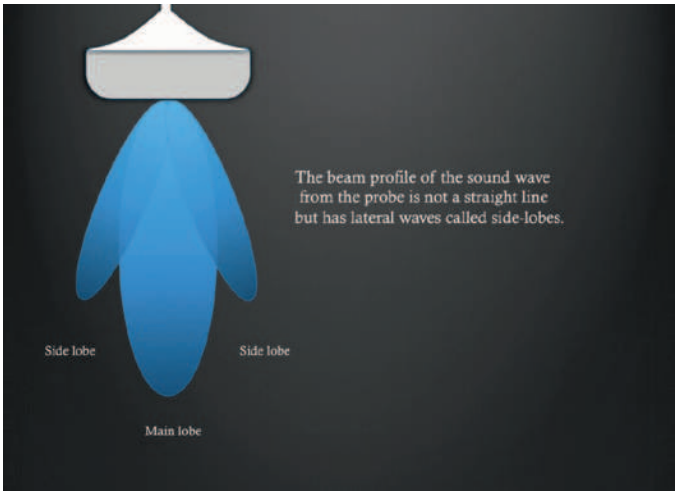
Side Lobe and Grating Lobe Artifacts

Click here to see an explanatory video of **side lobe artifact** (Video A.17).



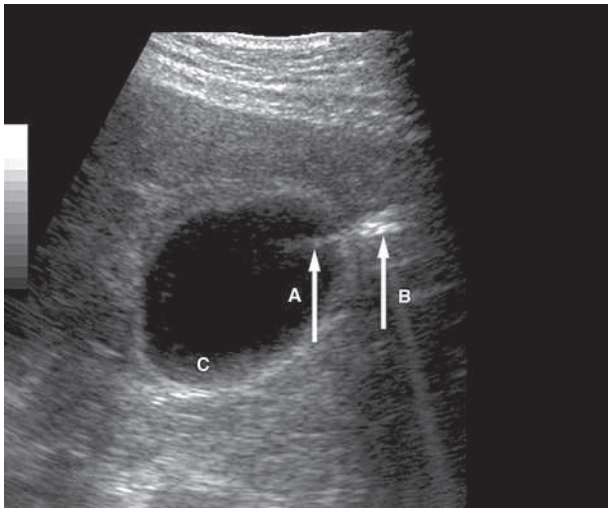


FIG. A.40 Side or Grating Lobe 1. Transverse image of the gallbladder reveals a bright internal echo *(A)* that suggests a band or septum within the gallbladder. This is a side lobe artifact related to the presence of a strong out-of-plane reflector *(B)* medial to the gallbladder. The low-level echoes in the dependent portion of the gallbladder *(C)* are also artifactual and are caused by the same phenomenon. Side lobe and slice thickness artifacts are of clinical importance because they may create the impression of debris in fluid-filled structures.[2] (See Chapter 1, Fig. 1.29.)

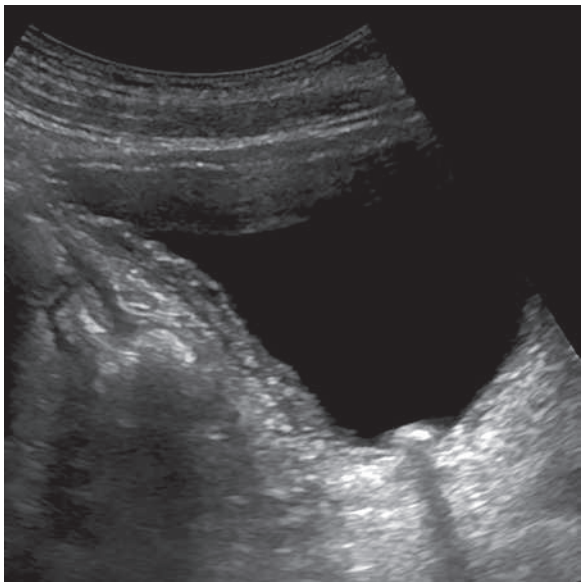

FIG. A.41 Side or Grating Lobe. In this patient with a ureterovesical junction stone there are echoes seen in the nondependent portion of the bladder. These are due to **grating lobe artifact,** wherein off-axis signal projects into the field of view.[18] Note also the **shadowing** behind the bladder stone.[18] (See Chapter 9, Fig. 9.43.)

Partial Volume Averaging

The ultrasound beam not only has a complex shape in the imaging plane but also has a real profile in the third dimension, called the "elevation plane" or "Z plane." The ultrasound image appears as a flat two-dimensional image, but the brightness of each pixel is representative of the average sum of all the echoes received within the thickness of the beam in the elevation plane. This results in echoes being projected in structures that should be anechoic.

Click here to see an explanatory video of **partial volume averaging** (Video A.18).

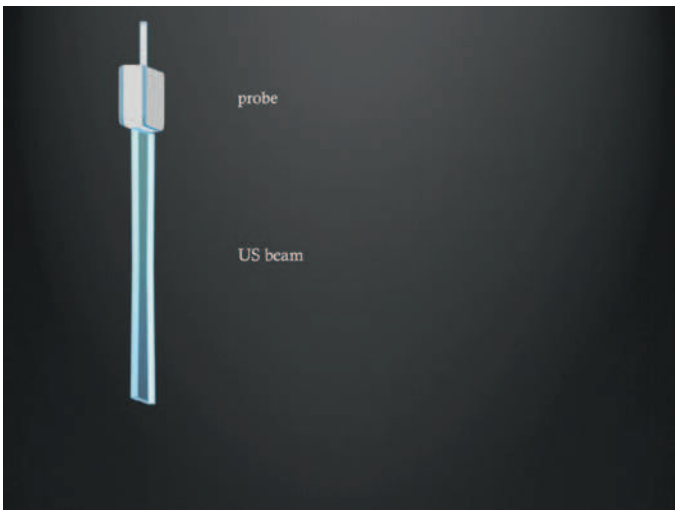

FIG. A.42 Partial Volume Averaging. The bladder wall is indistinct in region of this image. It is unclear if there are masses or if this is due to **grating lobe artifact** or **partial volume artifact** or both. Moving the patient or transducer to avoid bowel gas and putting the focal zone in the region in question should aid in evaluation. For the area closer to the patient's anterior abdominal wall, a higher-frequency transducer might be helpful.[18] (See Chapter 9, Fig. 9.57.)

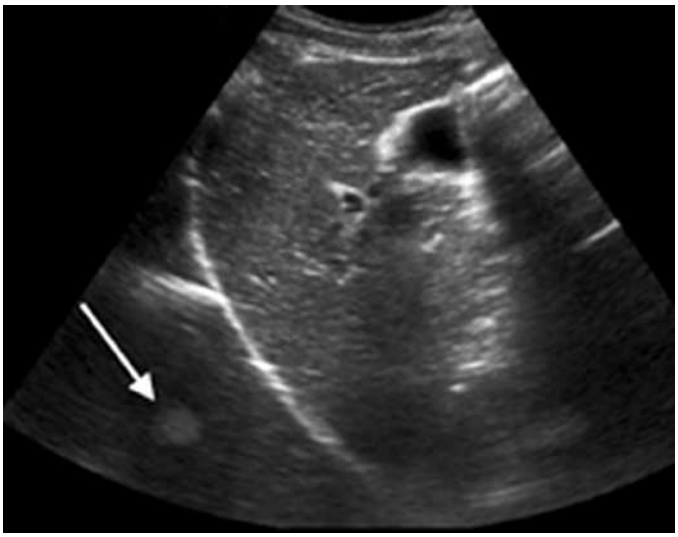

FIG. A.43 Partial Volume Averaging. A radiofrequency ablation zone present in the liver just outside the scanning plane is depicted onto the lungs through both partial volume averaging and mirror image artifacts.

DOPPLER IMAGING ARTIFACTS

The appearance of color Doppler signal is affected by several variables including color-write priority, gray-scale gain, and pulse repetition frequency. If the color gain is too low, flow might not be visualized. If the gain is too high, artifactual flow may be seen in adjacent soft tissues, and thrombus within the vessel might be missed.

Loss or Distortion of Doppler Information

Incorrect gain, wall-filter, and velocity scale can all lead to loss or distortion of Doppler signal. A rule of thumb for gain adjustment in Doppler imaging is to turn up the color gain until noise is encountered and then back off just until the noise clears from the image. In estimating frequency, the rule of thumb is to use a Doppler angle less than 60 degrees (but not 0). Wall filters eliminate low-frequency noise, but a high setting can lead to loss of signal. In general, wall filters should be kept at the lowest practical level, typically in the range of 50 to 100 Hz.

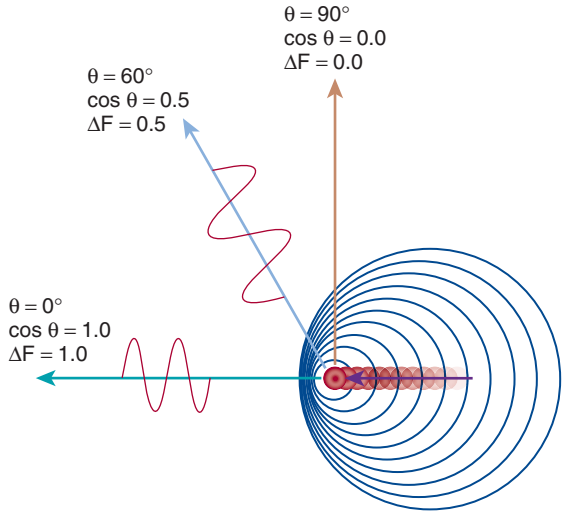

FIG. A.44 Effect of Doppler Angle on Frequency Shift. At an angle of 60 degrees, the detected frequency shift detected by the transducer is only 50% of the shift detected at an angle of 0 degrees. At 90 degrees, there is no relative movement of the target toward or away from the transducer, and no frequency shift is detected. The detected Doppler frequency shift is reduced in proportion to the cosine of the Doppler angle. Because the cosine of the angle changes rapidly at angles above 60 degrees, the use of Doppler angles of less than 60 degrees is recommended in making velocity estimates.[2] (See Chapter 1, Fig. 1.35.)

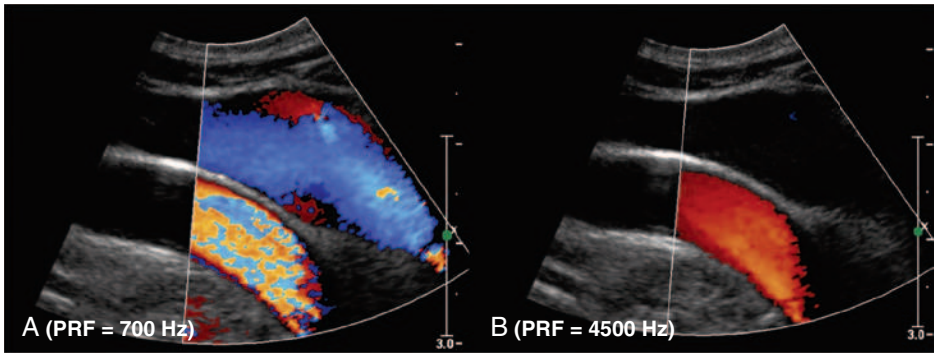

FIG. A.45 Artifactual Lack of Flow. Color Doppler image of a carotid artery and jugular vein. In **(A),** the pulse repetition frequency *(PRF)* is 700 Hz and there is aliasing in the carotid artery, but slow flow in the jugular vein is seen. In **(B),** the PRF is 4500 Hz, eliminating aliasing in the artery but also suppressing the display of the low Doppler frequencies in the internal jugular vein.[2] (See Chapter 1, Fig. 1.43.)

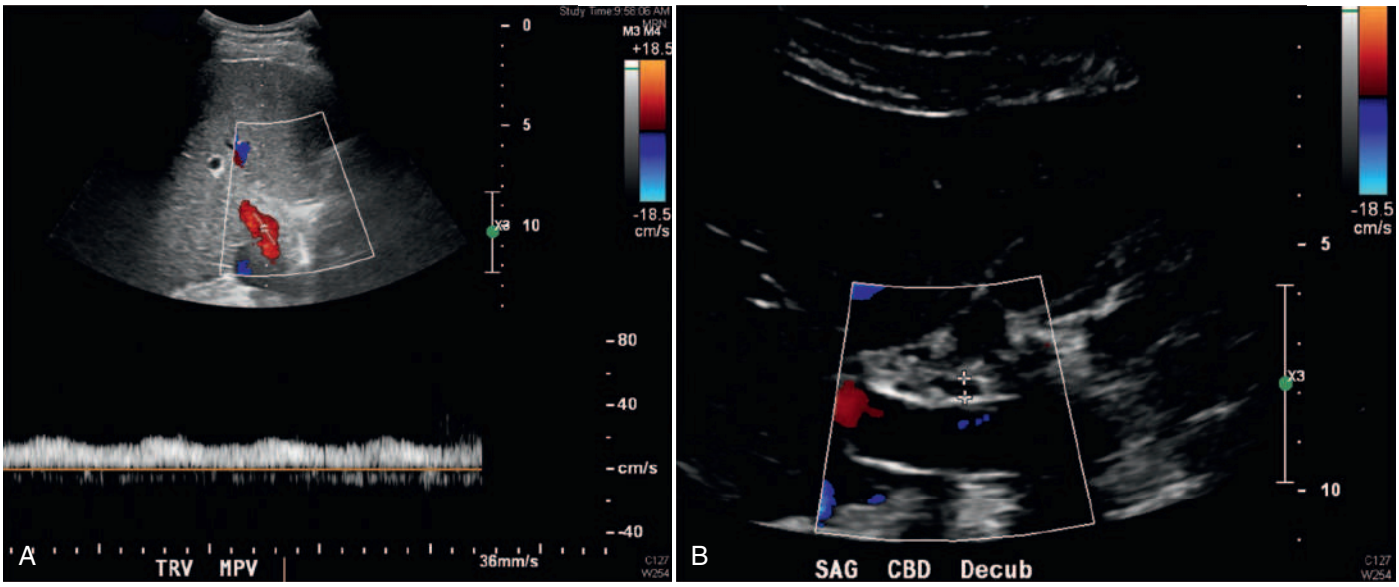

FIG. A.46 Artifactual Lack of Flow. (A) Color Doppler image shows flow in the portal vein. **(B)** When a color image is taken to assess the common duct, no flow is visible in the portal vein. Note the difference in overall gain in image **B.**

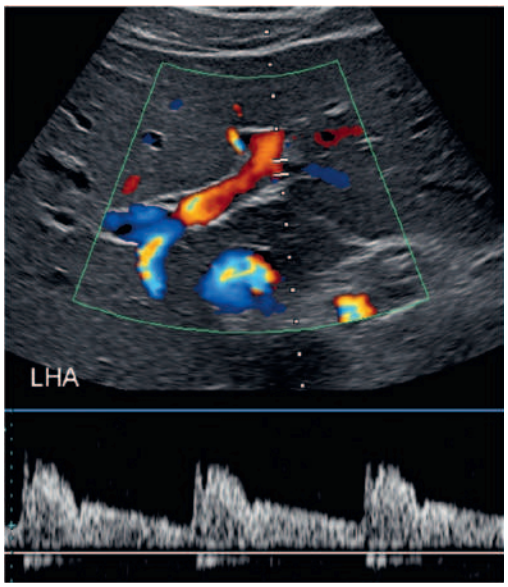

FIG. A.47 Color Direction. Shown in color is a portion of the portal venous system. Note how the flow direction appears to change in the region of branching, but this is merely a result of the orientation of flow with respect to the mid transducer. Note the aliasing in the posterior branch of the right portal vein. This is due to the curve of the vein and change in Doppler angle.[19] (See Chapter 51, Fig. 51.22.)

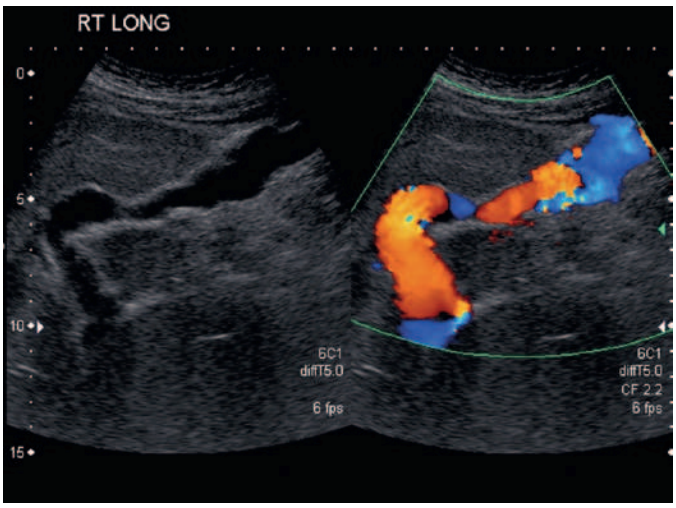

FIG. A.48 Color Direction as Shown in Recanalized Umbilical Vein. Flow on color Doppler will sometimes appear to change direction, but the flow needs to be assessed with respect to the transducer in order to determine if it is in the appropriate direction or not. In this example, transverse paramedian gray-scale and color Doppler sonograms show left lobe of liver in a child with cirrhosis and portal hypertension.[19] The recanalized umbilical vein is always flowing in relatively the same direction out of the liver, but at times, due to tortuosity, appears to change flow direction. Note that the flow changes from red (toward the transducer) to blue (away from the midpoint of the transducer), but at each interface there is a black region where the Doppler angle is 90. (See Chapter 51, Fig. 51.28.)

Artifactual Vascular Flow

The Doppler effect (shift) is not specific to vascular flow and occurs with movement of any reflector toward or away from the ultrasound beam. Fluid or solid tissue motion can mimic vascular flow. Transmitted pulsations, especially close to the heart or major arteries, can therefore result in artifactual appearance of flow within thrombosed veins or avascular areas. Artifactual vascular flow can also be visualized if the color gain is too high or the color-write priority is too high.

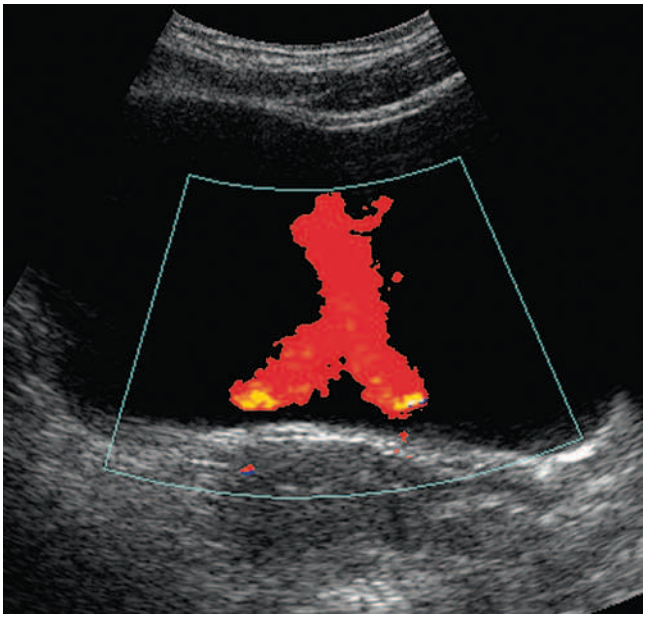

FIG. A.49 Artifactual Vascular Flow. Color Doppler jets in the bladder use color motion to indicate that there is flow from each ureteral orifice.[18] (See Chapter 9, Fig. 9.42A.)

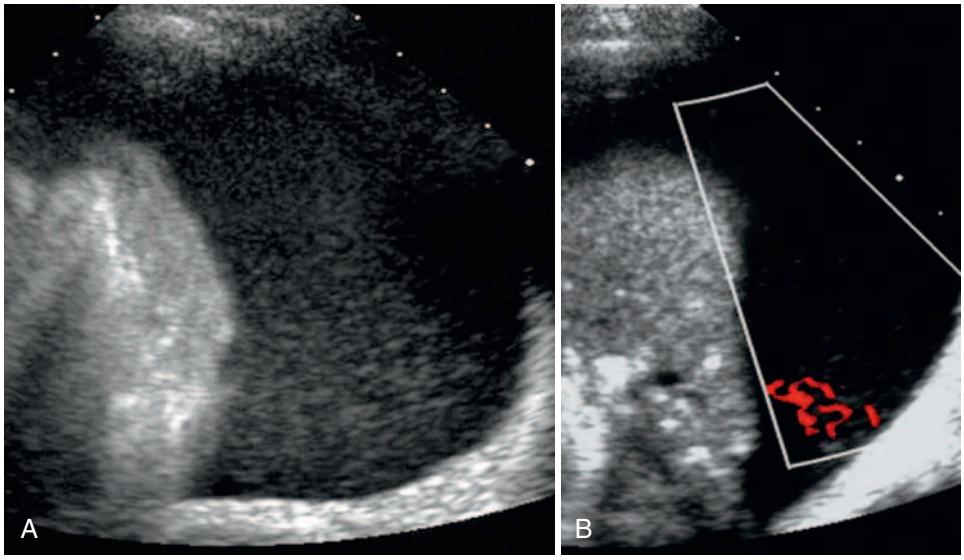

FIG. A.50 Artifactual Vascular Flow. Color flow Doppler signal in pleural fluid with debris. **(A)** Gray-scale sonogram shows left pleural fluid with much debris. **(B)** Color flow Doppler signal.[20] (See Chapter 50, Fig. 50.14.)

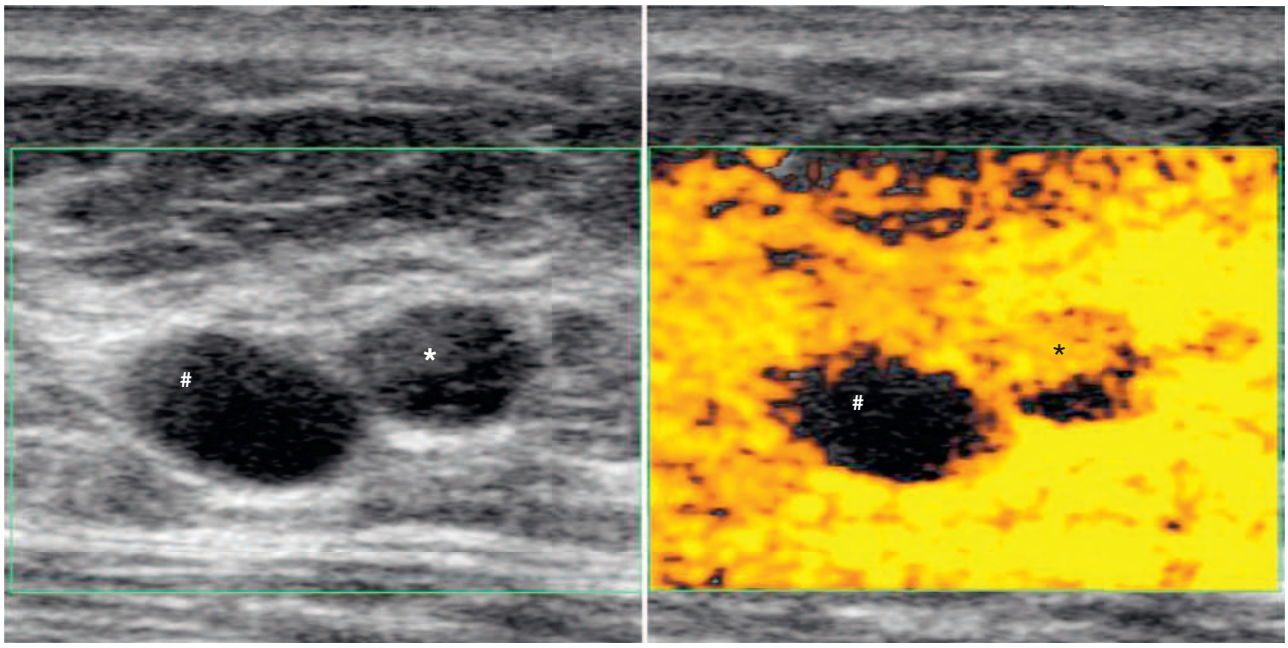

FIG. A.51 Artifactual Vascular Flow. Power Doppler ultrasound **vocal fremitus** can be used to distinguish a mural nodule from a fat-fluid level. The lipid layer is not attached to the cyst wall, so the fremitus artifact will not pass through it. On the other hand, true papillary lesions that are attached to the cyst wall will vibrate and transmit the fremitus artifact on power Doppler; having the patient hum in a deep voice creates a color artifact on power Doppler ultrasound.[21] (See Chapter 21, Fig. 21.26.)

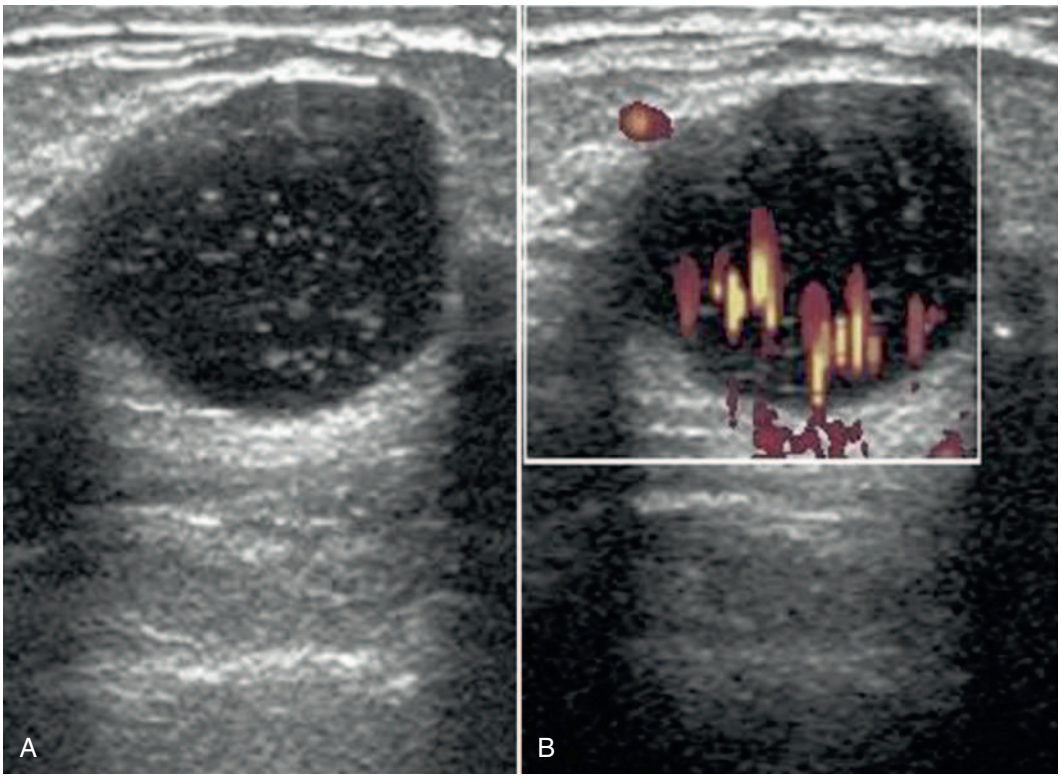

FIG. A.52 Color Streaking Artifact. (A) This complicated cyst contains floating punctate echoes that move posteriorly while being scanned, creating a scintillating appearance on gray-scale sonography. **(B)** Power Doppler ultrasound pushes the echoes posteriorly faster and with more energy than does the gray-scale beam. The echoes move fast enough that color persistence creates the appearance of **"color streaking"** artifact.[21] (See Chapter 21, Fig. 21.21.)

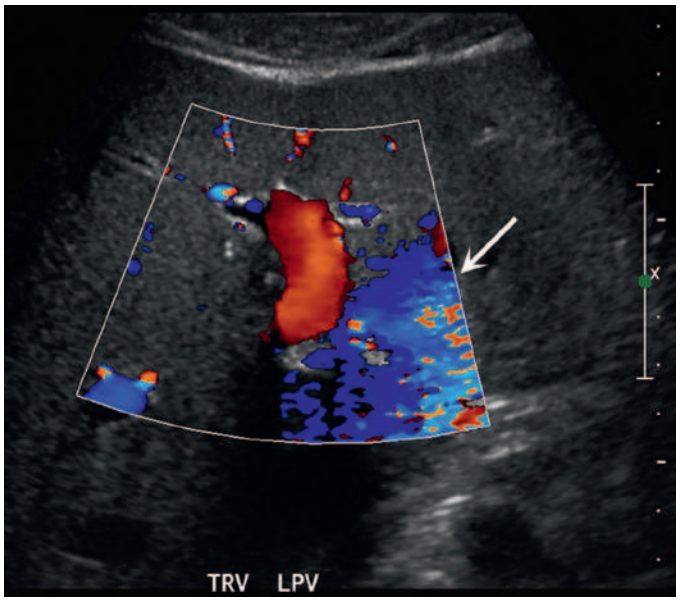

FIG. A.53 Flash Artifact From Pulsation. In this image of the left portal vein, note how transmitted pulsation from the heart causes artifactual flow in the adjacent liver owing to motion.

Tissue Vibration Artifact

Tissue vibration artifact consists of color pixels erroneously placed in the adjacent soft tissue by the ultrasound scanner because of the transmitted vibration from a region of marked turbulence. It is commonly seen with shunts, tight stenoses of large arteries, and especially arteriovenous fistulas. If tissue vibration artifact is seen, a search should be made for an arteriovenous fistula.

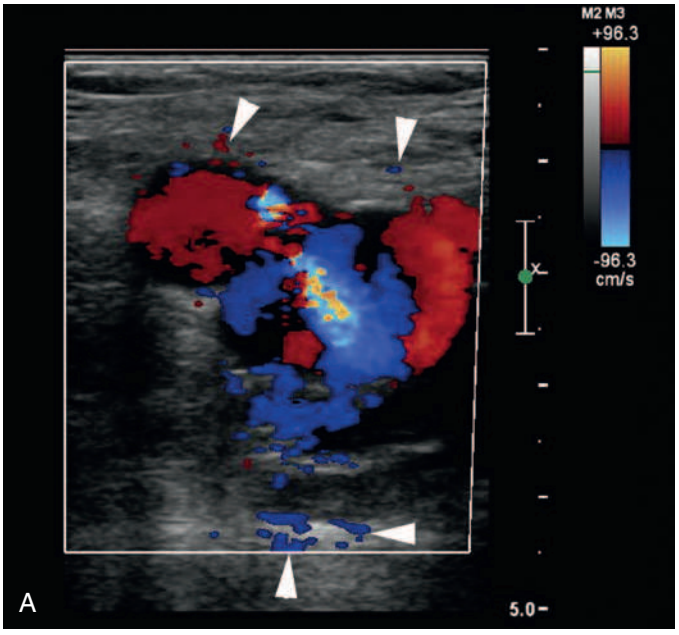

FIG. A.54 Tissue Vibration Artifact From Common Femoral Artery to Common Femoral Vein Arteriovenous Fistula. Turbulent flow through the fistula may affect surrounding tissues, causing a tissue vibration artifact, which may be the first clue that an arteriovenous fistula (AVF) is present. **Common femoral artery to common femoral vein AVF. (A)** Color Doppler shows common femoral artery to common femoral vein AVF. Note the adjacent tissue vibration artifact *(arrowheads)*. (See Chapter 27, Fig. 27.14.)

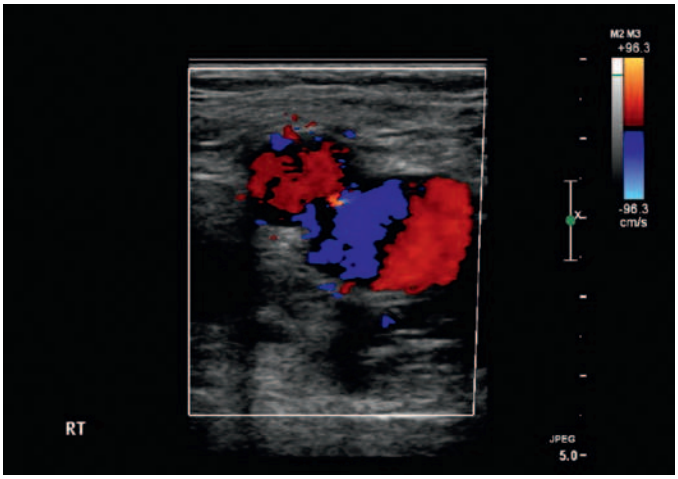
Click here to see the video of **tissue vibration** (Video A.19).



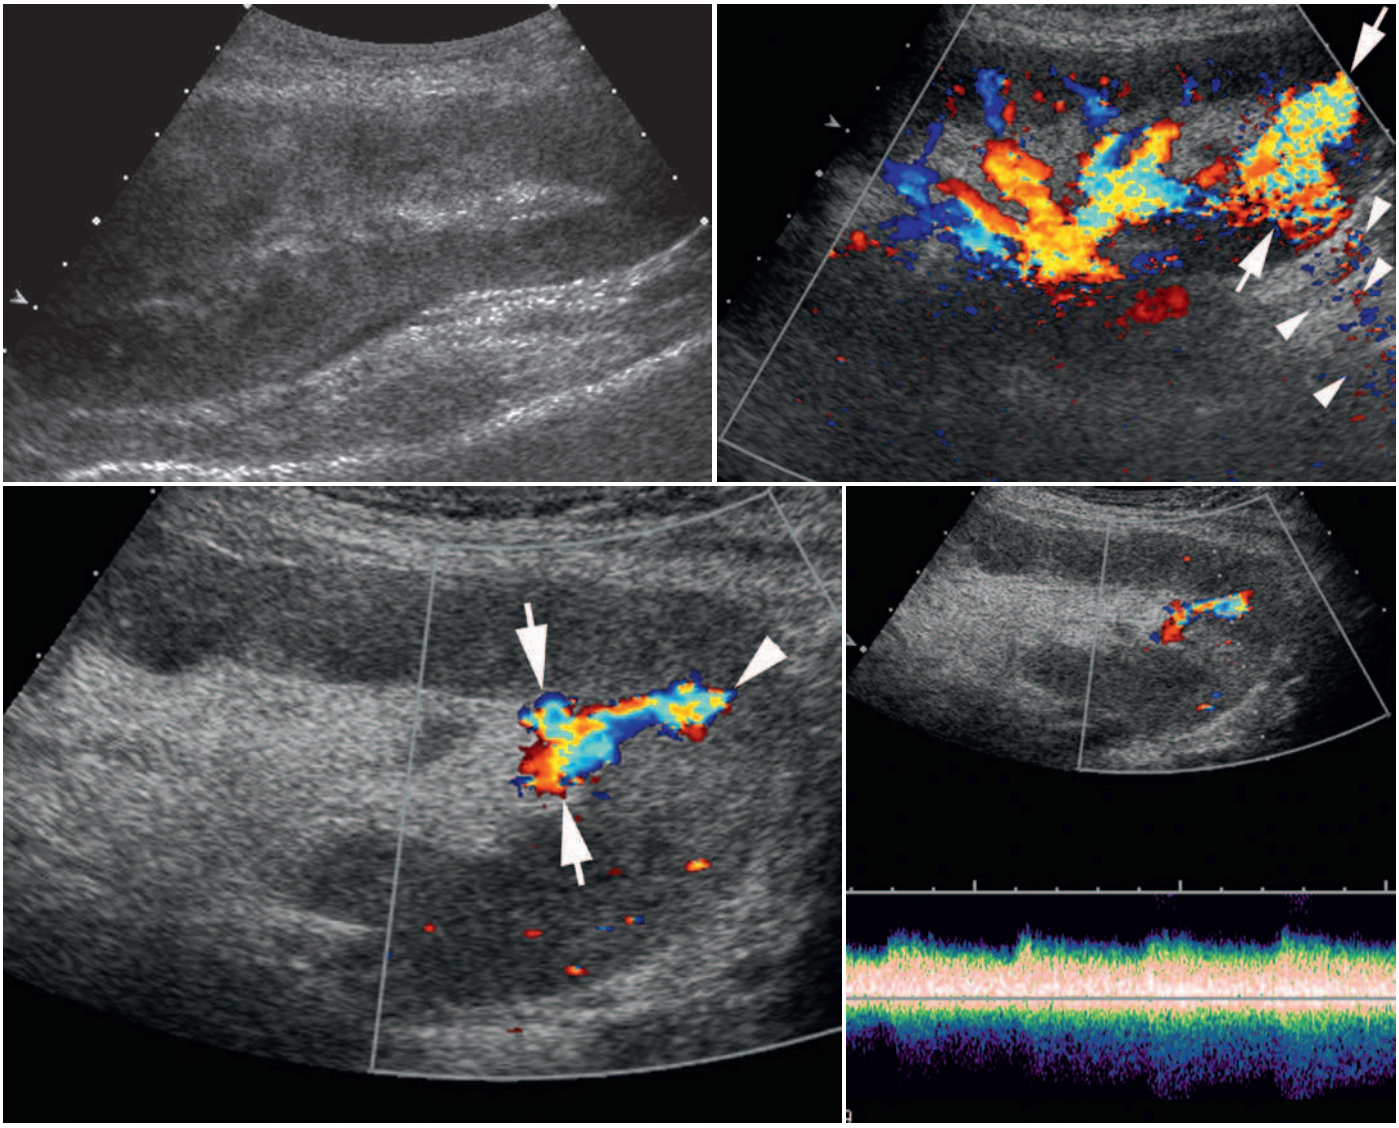


FIG. A.55 Tissue Vibration Artifact. Postbiopsy arteriovenous fistula. Color Doppler image shows markedly increased lower-pole blood flow *(arrows)* with adjacent soft tissue color artifact related to tissue vibration *(arrowheads)*.[22] (See Chapter 52, Fig. 52.49.)

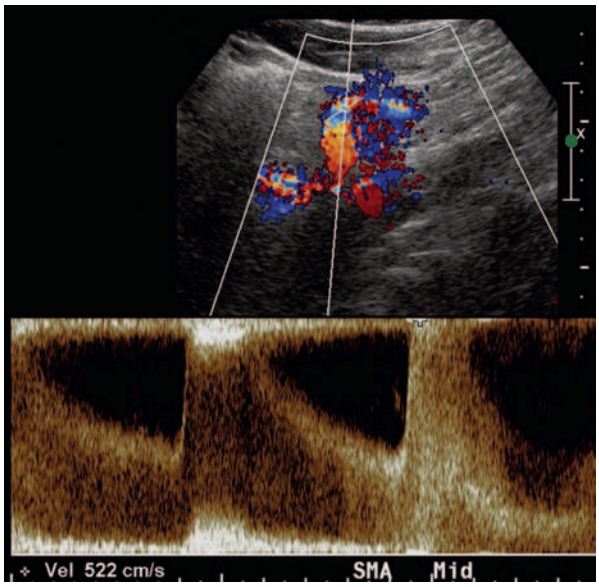

FIG. A.56 Tissue Vibration Artifact. Spectral waveform at site of superior mesenteric artery stenosis shows very high systolic velocity, and diastolic velocities of greater than 500 cm/sec. Color portion of the image shows **color bruit** consisting of color outside the vessel near the stenosis site. Color bruit is believed to be caused by tissue vibration.[23] (See Chapter 12, Fig. 12.27A.)

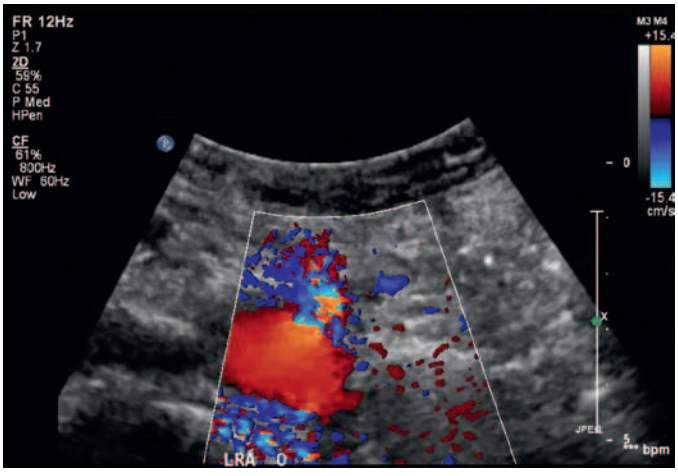
Click for video showing **tissue vibration artifact** in patient with **stenotic superior mesenteric artery with color bruit** (Video A.20). (See also Video 12.11.)



Aliasing and Velocity Scale Errors

Aliasing is an artifact due to undersampling of Doppler signal, resulting in incorrect estimation of flow velocity. To measure the Doppler frequency shift appropriately by pulsed Doppler, at least two samples from the cycle are required (Nyquist limit). If the pulse repetition frequency is less than twice the maximum frequency shift produced by movement of the target, aliasing results. The Doppler signal wraps around either the spectrum (spectral Doppler) or the color scale (color Doppler). The most common methods for correcting for aliasing are to shift the baseline down or up, or increase the pulse repetition frequency (or velocity scale). A lower-frequency transducer can also be used to help in correcting for aliasing. As angulation approaches 90 degrees, directional ambiguity can occur, suggesting bidirectional flow. Errors in Doppler angle correction can also lead to misleading assessments of flow velocity.

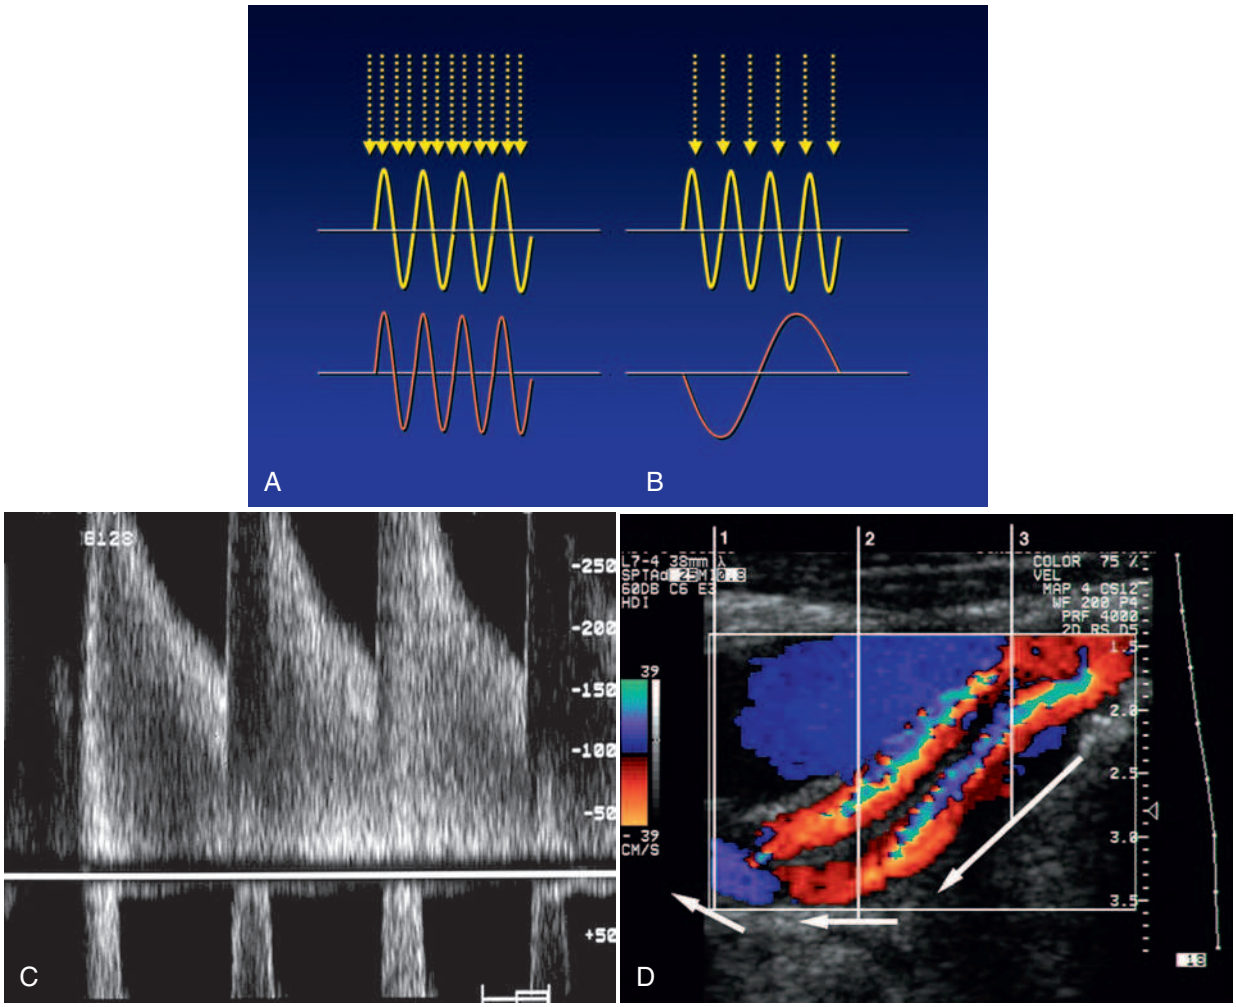


FIG. A.57 Aliasing. Pulse repetition frequency (PRF) determines the sampling rate of a given Doppler frequency. **(A)** If PRF *(arrows)* is sufficient, the sampled waveform *(orange curve)* will accurately estimate the frequency being sampled *(yellow curve)*. **(B)** If PRF is less than half the frequency being measured, **undersampling** will result in a lower-frequency shift being displayed *(orange curve)*. **(C) Aliasing** appears in the spectral display as a "wraparound" of the higher frequencies to display below the baseline. **(D)** In color Doppler display, aliasing results in a wraparound of the frequency color map from one flow direction to the opposite direction.[2] Unlike a true direction of flow change, with aliasing there will be no transition of unsaturated color. (See Chapter 1, Fig. 1.46.)

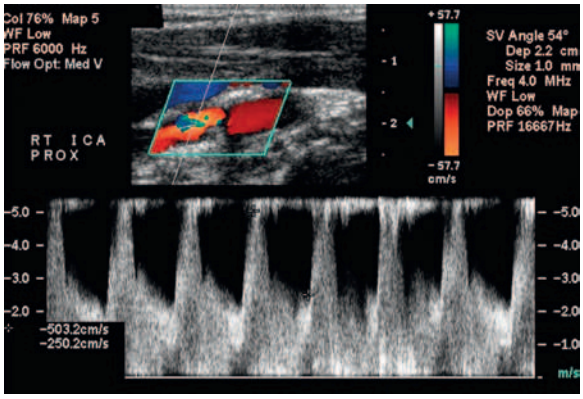

FIG. A.58 Aliasing. Note that aliasing prevents precise calculation of the maximum systolic velocity. However, because it is greater than 500 cm/sec, the precise number is not needed. The aliasing in the image allows for easier identification of the region of highest velocity for placement of the spectral Doppler gate.[6] (See Chapter 26, Fig. 26.20.)

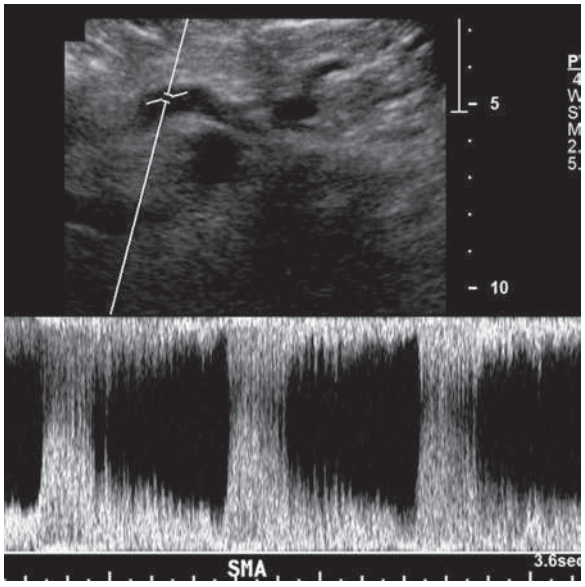

FIG. A.59 Aliasing in Superior Mesenteric Artery (*SMA*) Due to High-Velocity Flow.[23] (See Chapter 12, Fig. 12.28.)

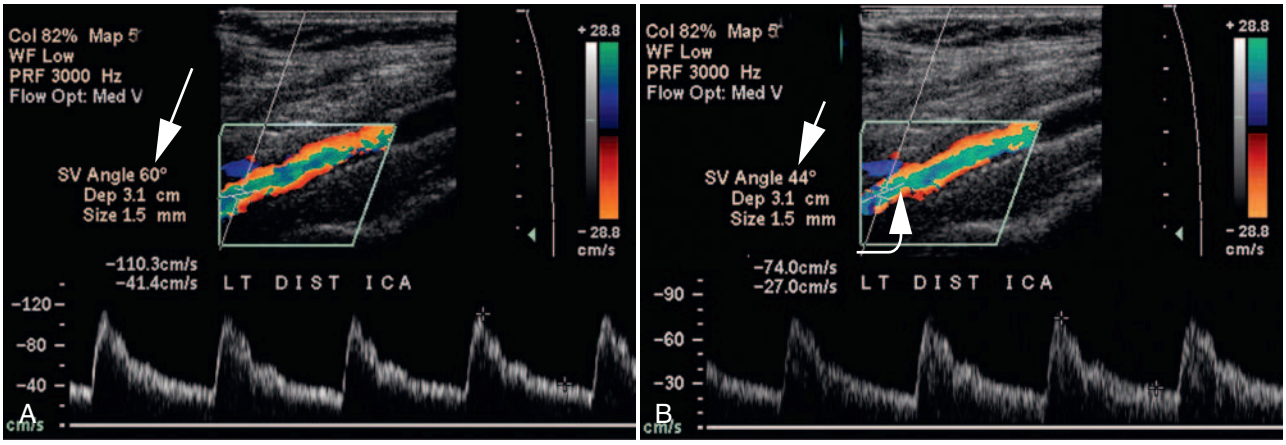

FIG. A.60 Aliasing Due to Doppler Angle Theta Changes. (A) Velocity obtained in the distal internal carotid artery with angle theta of 60 degrees is higher than that obtained at 44 degrees *(arrow)*. **(B)** However, the sample angle does not parallel the vessel wall at 60 degrees. Note central color aliasing in the region of highest velocity *(curved arrow)*.[6] (See Chapter 26, Fig. 26.16.)

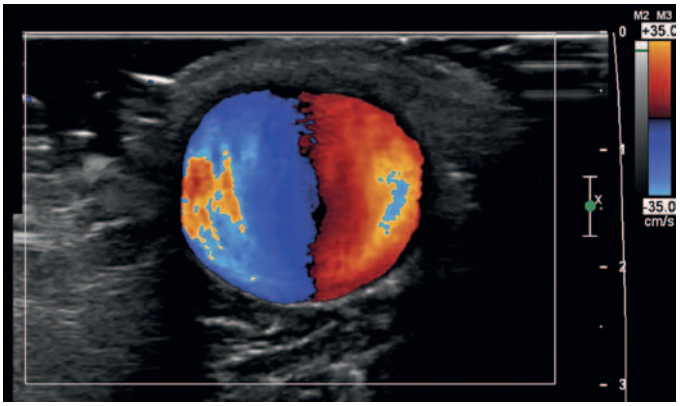

FIG. A.61 Aliasing in Pseudoaneurysm. Note the swirling flow in a pseudoaneurysm, resulting in a yin-yang appearance.[24] At the midline border of red and blue, there is a black line where the Doppler angle is 90 degrees. Here the flow is perpendicular to the sound beam, and so it is not detected. At 3 and 9 o'clock positions, there is aliasing within the blue and red areas. Here the Doppler angle is zero degrees with the flow directly toward and away from the transducer, thus appearing with maximal velocity. As the velocity exceeds the selected 35-cm/sec Doppler velocity range, aliasing results with artifactual opposite direction color signal. (See Chapter 27, Fig. 27.63.)

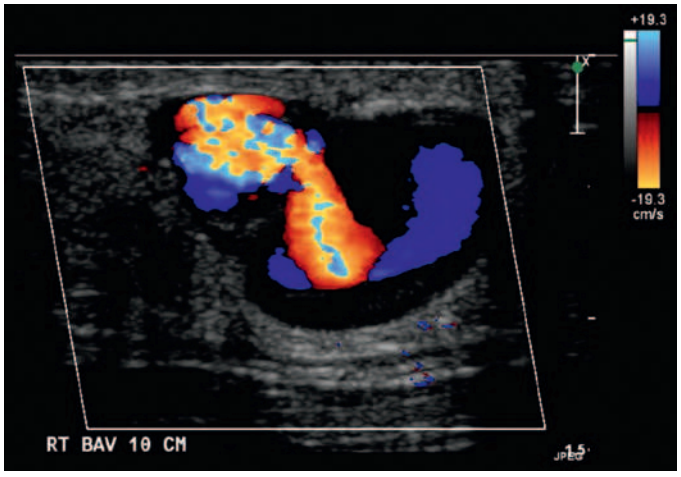
Click here to see the pseudoaneurysm video clip showing even more dramatic aliasing in the femoral artery (Video A.21).[24] (See also Chapter 27, Video 27.5.)



Spectral Broadening

Spectral broadening occurs when there are multiple different velocities of flow within a vessel. This can be a sign of stenosis. However, artifactual spectral broadening can occur owing to improper positioning of the sample volume near the vessel wall, use of an excessively large sample volume, or excessive system gain.

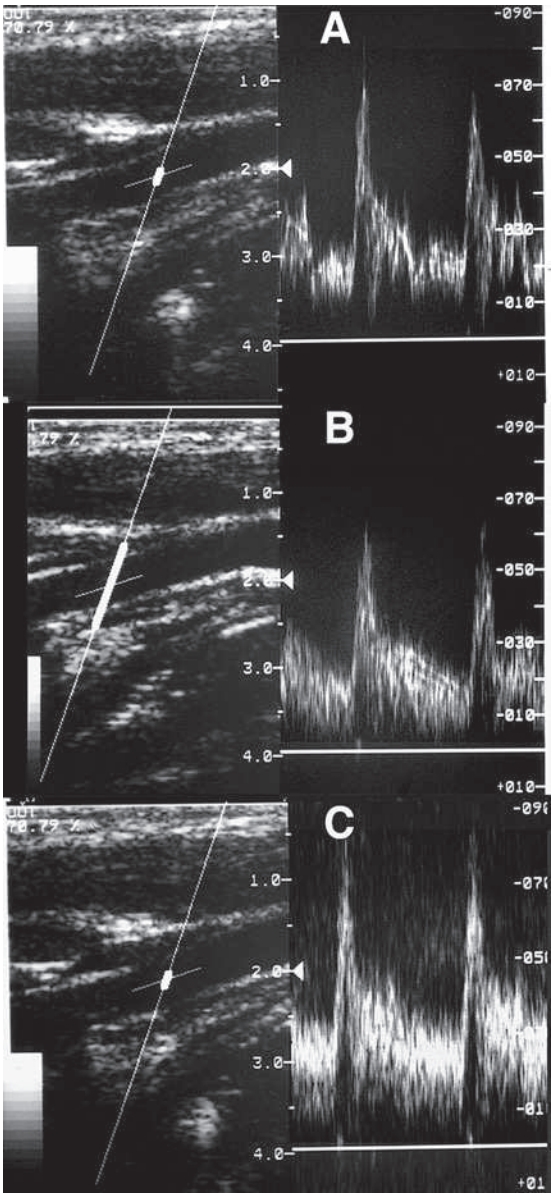


FIG. A.62 Spectral Broadening. The range of velocities detected at a given time in the pulse cycle is reflected in the Doppler spectrum as spectral broadening. **(A) Normal spectrum.** Spectral broadening may arise from turbulent flow in association with vessel stenosis. **(B** and **C) Artifactual spectral broadening** may be produced by improper positioning of the sample volume near the vessel wall, use of an excessively large **sample volume (B), or excessive system gain (C).**[2] (See Chapter 1, Fig. 1.45.)

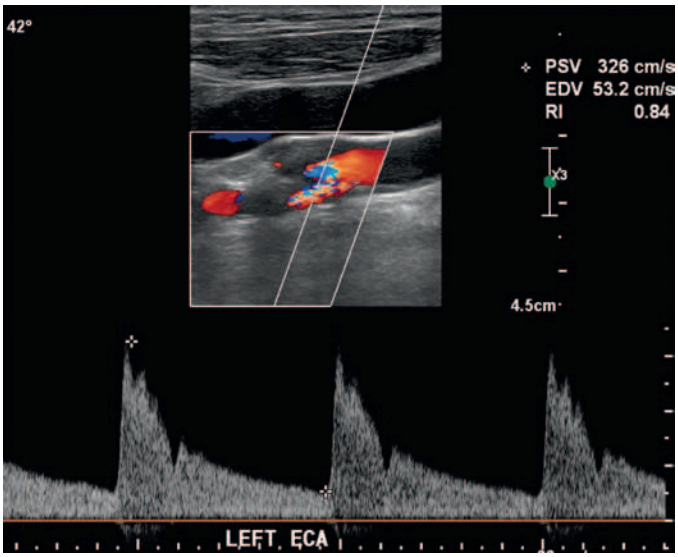

FIG. A.63 Spectral Broadening. True spectral broadening due to ECA stenosis.[6] (See Chapter 26, Fig. 26.18.)

Blooming Artifact

Blooming artifact occurs when color reaches beyond the vessel wall, making the vessels look larger than expected. It is gain dependent in that lowering the gain will decrease blooming. It is also wall filter and color-overwrite dependent, in that increasing the wall filter will decrease the artifact.

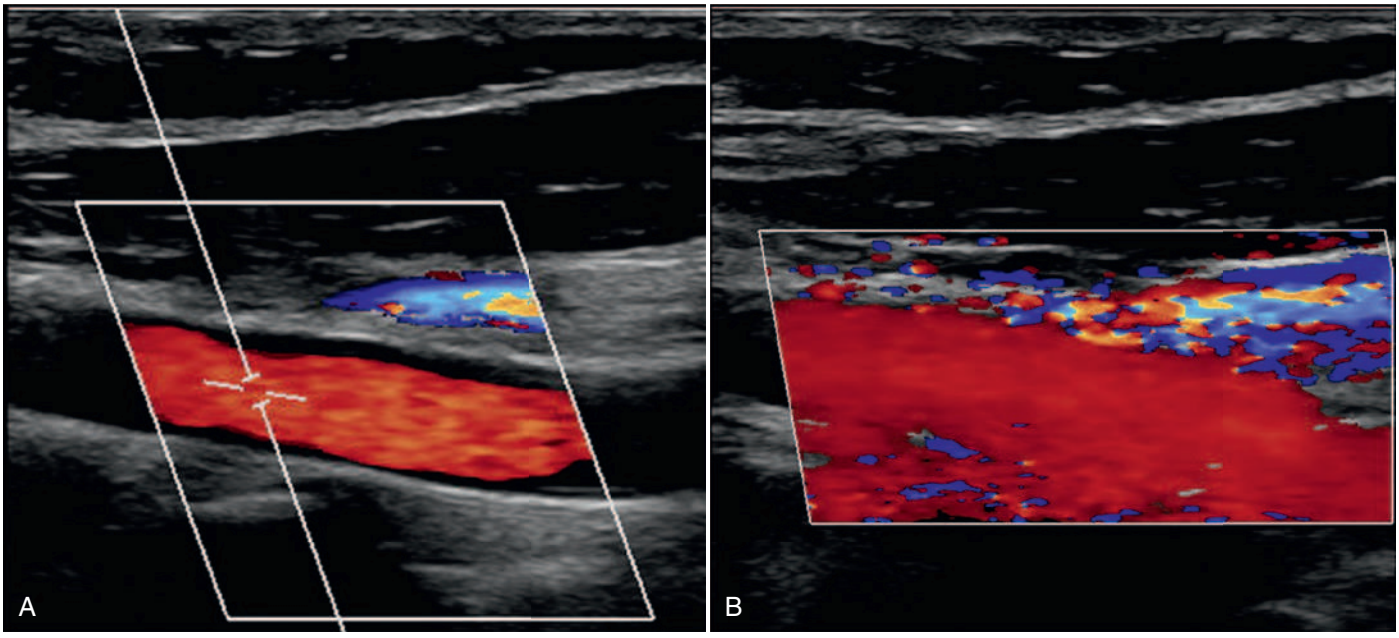

FIG. A.64 Blooming Artifact. Two images of the same carotid artery. In **(A)** the gain and wall filter are appropriate to show the flow centrally in the vessel. In **(B)** the gain and wall filter have been changed (in a manner beyond what would be used in clinical imaging) to demonstrate how these can make the vessel "bloom" and appear larger.

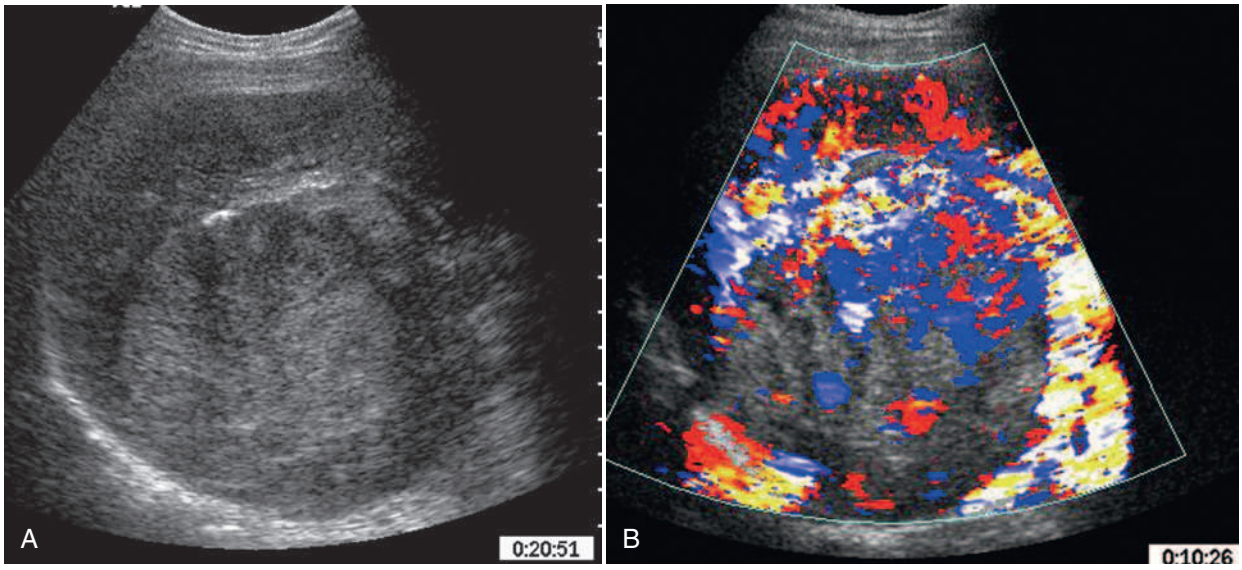

FIG. A.65 Blooming artifact due to use of contrast and tissue motion. **(A)** Use of contrast material creates color Doppler artifacts owing to blooming and tissue motion. **(B)** Contrast-specific imaging shows blood vessels not seen with Doppler.[25] (See Chapter 3, Fig. 3.7.)

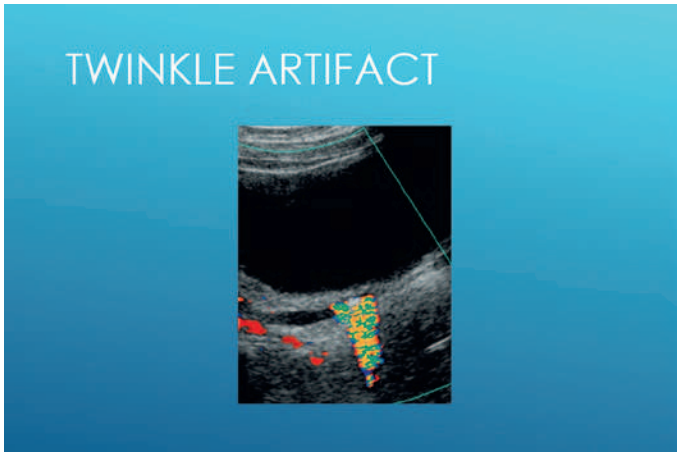
Twinkle Artifact

Twinkle artifact is the artifactual depiction of color signal on crystalline materials in the body. It appears as discrete foci of alternating colors with or without an associated color comet-tail artifact. The appearance of twinkle artifact is highly dependent on machine settings and is likely generated by a narrow-band, intrinsic machine noise called "phase (or clock) jitter." This, along with a strongly reflecting, rough surface such as a renal stone, results in a high-amplitude, broadband signal appearing as random motion on color Doppler sonography. The twinkle artifact is quite useful clinically because it can aid in the detection of small stones, calcifications, and other crystalline material within the body.

View the PowerPoint illustration of **twinkle artifact** here (Video A.22).



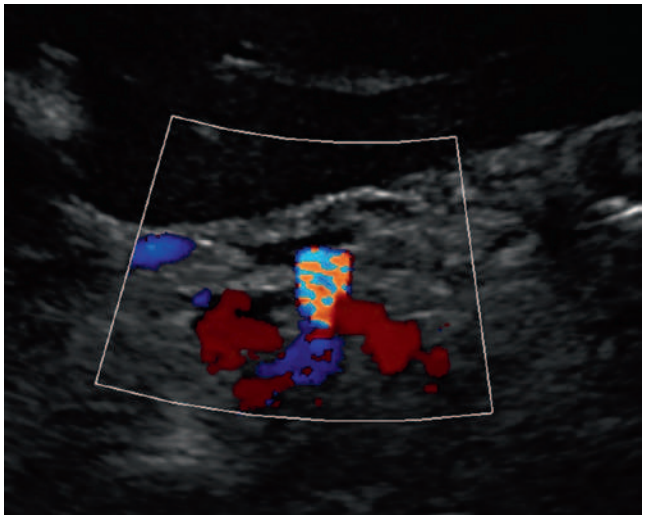


FIG. A.66 Twinkle Artifact Posterior to Pancreatic Duct Stone.[26] (See Chapter 7, Fig. 7.48D.)

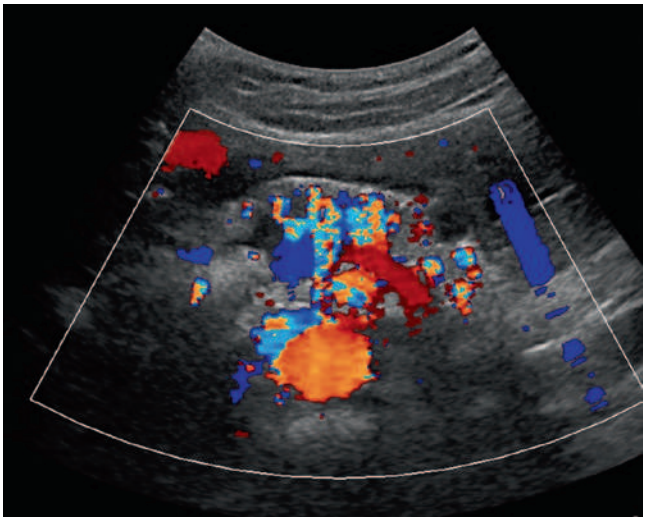

FIG. A.67 Calcifications in Chronic Pancreatitis With Twinkle Artifact.[26] (See Chapter 7, Fig. 7.49B.)

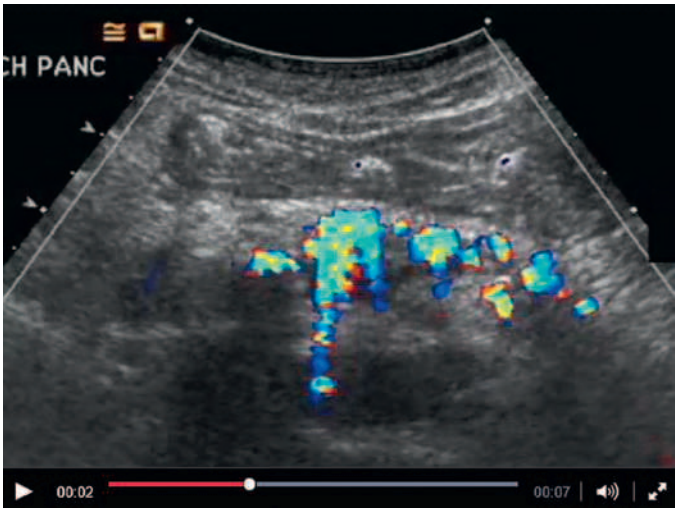
Click here for associated cine clip (Video A.23).[26] (See also Chapter 7, Video 7.5.)



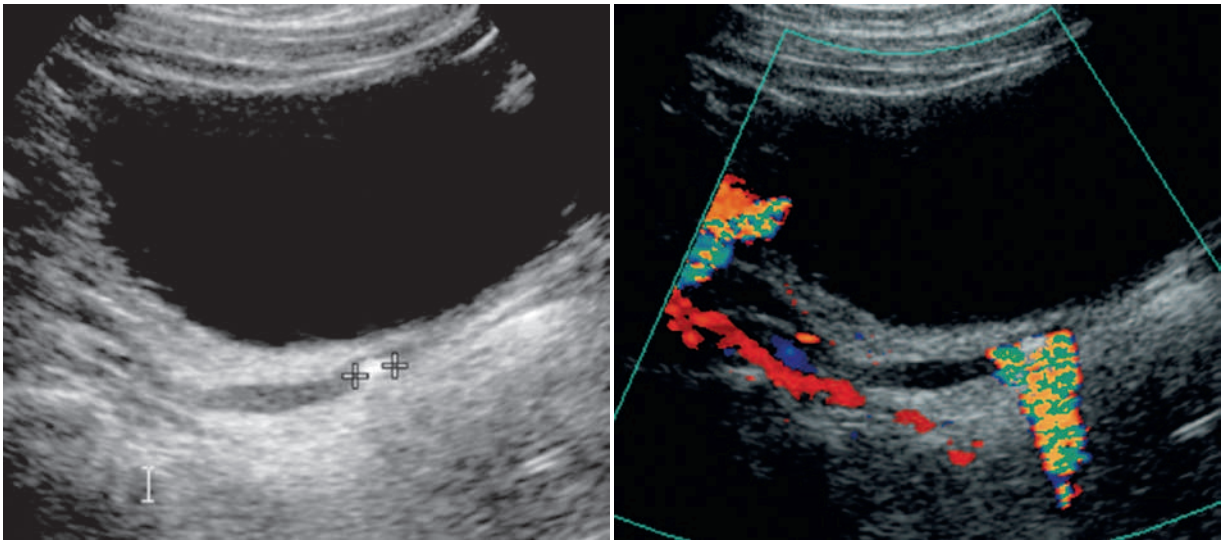


FIG. A.68 Twinkle Behind Distal Ureterovesical Junction Stone.[27] (See Chapter 54, Fig. 54.61.)

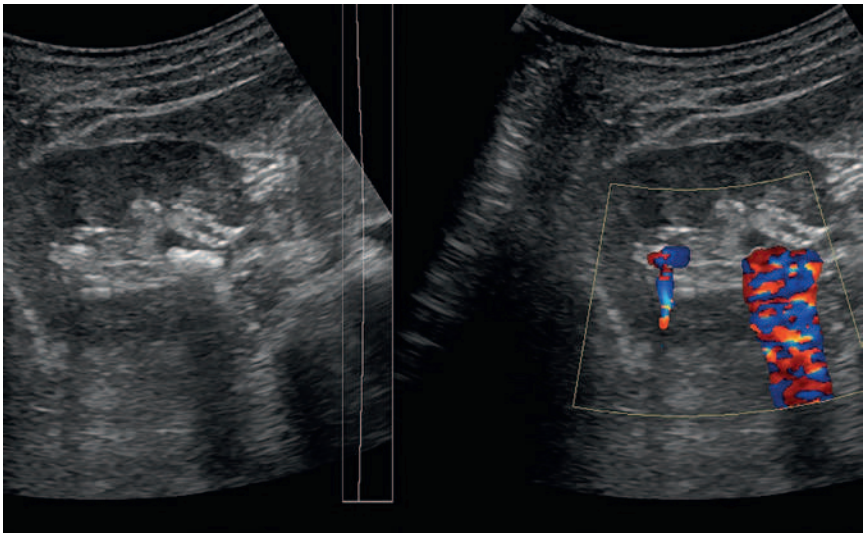

FIG. A.69 Twinkle Behind a Kidney Stone.[18] (See Chapter 9, Fig. 9.38.)

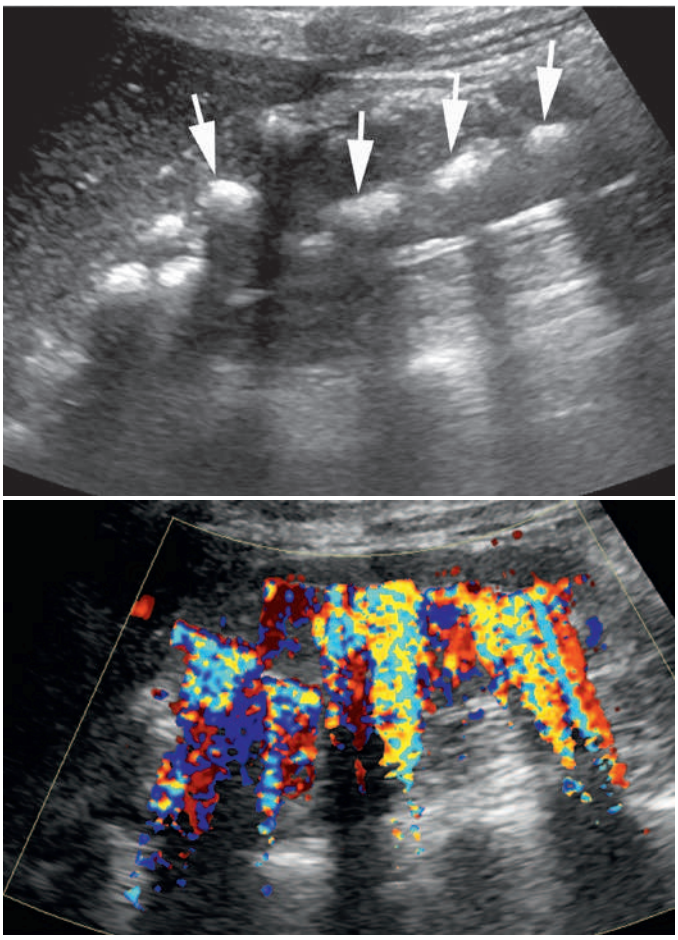

FIG. A.70 Twinkle Behind Multiple Kidney Stones.[22] (See Chapter 52, Fig. 52.37.)

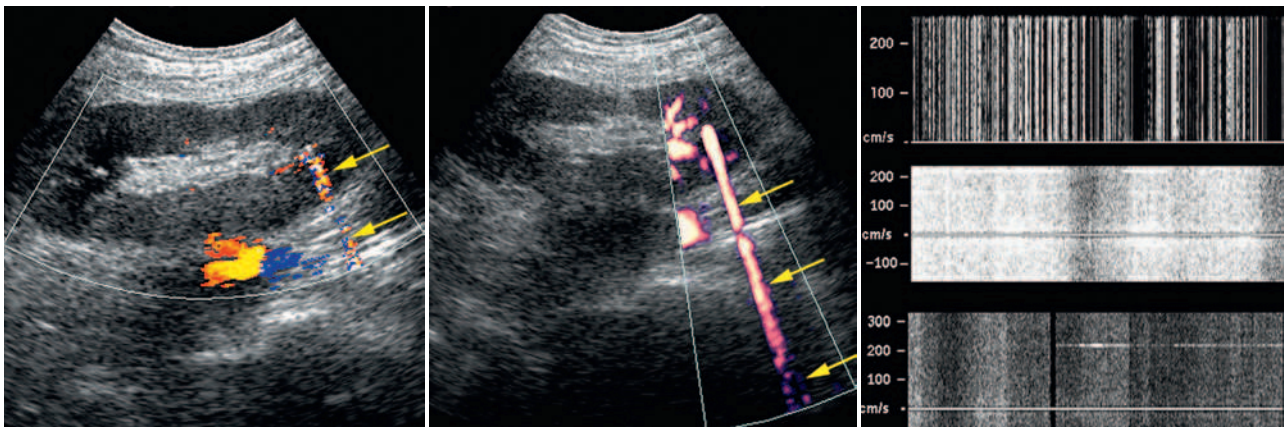

FIG. A.71 Appearances of Twinkle Artifact on Color, Power, and Pulsed Wave Doppler. Note how the spectral Doppler tracing of a twinkle artifact shows lines going through the tracing, which allow distinction from true blood flow.[28] (See Chapter 18, Fig. 18.52.)

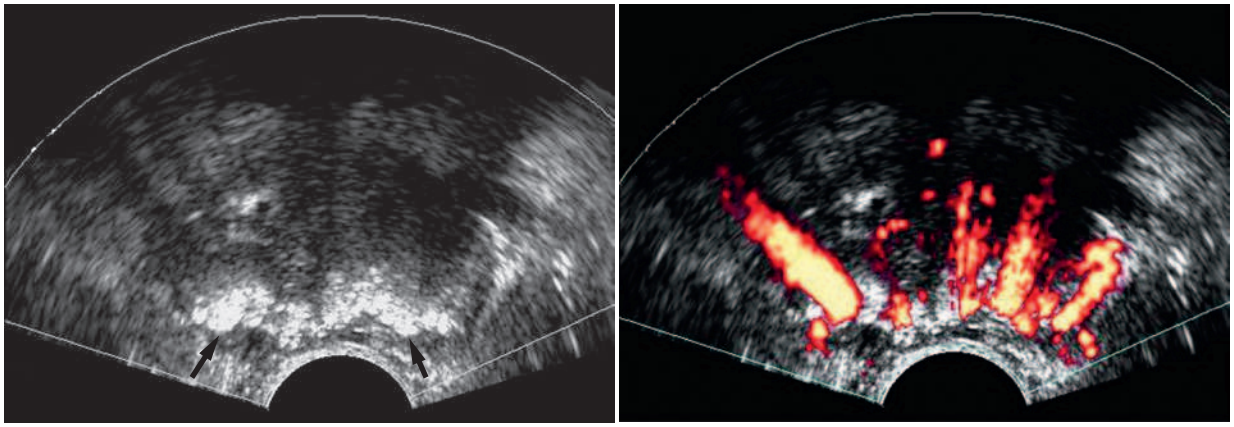

FIG. A.72 Power Doppler Image of Twinkle Behind Prostatic Calcifications.[11] (See Chapter 10, Fig. 10.7.)

Acknowledgment

Most of the images in this virtual chapter were obtained from chapters in the fifth edition of Diagnostic Ultrasound. We thank the authors for the use of their work.

Abdominal wall, fetal, 1322–1330
  amniotic band syndrome and, 1330, 1330*f*
  bladder exstrophy and, 1326, 1328*f*
  body stalk anomaly and, 1329
  cloacal exstrophy and, 1328–1329, 1329*f*
  ectopia cordis and, 1329, 1329*f*
  embryology of, 1322, 1323*f*
  gastroschisis and, 1322–1325
    associated conditions of, 1324–1325
    epidemiology of, 1322–1323
    management of, 1325
    pathogenesis of, 1323
    prenatal diagnosis of, 1323–1324, 1324*f*
  maternal serum alpha-fetoprotein and defects of, 1322
  omphalocele and, 1325–1326, 1326*f*
    associated conditions with, 1325, 1327*f*
    epidemiology of, 1325
    management of, 1325–1326
    prenatal diagnosis of, 1325, 1327*f*
  pentalogy of Cantrell and, 1329
Abductor tendon, injection for, 905–907, 907*f*
Ablation. *See also* Ethanol ablation
  adrenal, 428
  endometrial, 551–552, 552*f*
Abscess(es)
  abdominal, drainage of, 612
  adrenal, bacterial, 423
  amebic liver, 613
  appendiceal, pediatric, 1871*f*
    hemorrhagic ovarian cyst differentiated from, 1877
  branchial sinus, type IV, 1643–1645, 1645*f*, 1651, 1653*f*
  breast, 803–804, 803*f*–804*f*
  cellulitis leading to, 874, 874*f*
  complicated lymphadenitis with, in children, 1634, 1658–1660
  costochondral junction, pediatric, aspiration and drainage of, 1963*f*
  in Crohn disease, 275–276, 278*f*–279*f*
  empyemas differentiated from, pediatric, 1725, 1726*f*
  enteric, 612
Abscess(es) *(Continued)*
  gastrointestinal, 592
  hydatid, 613
  of kidneys
    acute pyelonephritis and, 325, 325*f*
    drainage of, 617, 618*f*
    pediatric, complicating acute pyelonephritis, 1792–1793
    transplantation complications with, 651, 656*f*
  liver
    drainage of pyogenic, 612–613, 614*f*–615*f*
    after liver transplantation, 638–639, 646*f*
    pyogenic, 85–86, 87*f*
  liver, pediatric, 1746–1748
    parasitic, 1747–1748
    pyogenic, 1746–1747, 1751*f*
  lung, pediatric, 1711, 1713*f*
  pancreatic, acute pancreatitis complications with, 230
  parenchymal, pediatric renal transplantation and, 1812
  parotid, pediatric, 1632–1633, 1633*f*
  pediatric drainage of, interventional sonography for, 1953
    transrectal, 1953–1954, 1954*f*
  pelvic, 283, 591
    drainage of, 612, 613*f*
  percutaneous needle biopsy complications with, 609, 610*f*
  perforated appendicitis and, pediatric, 1857, 1861*f*
  perianal, perianal inflammatory disease and, 305–306
  perinephric
    acute pyelonephritis and, 325
    pediatric renal transplantation and, 1812
    after renal transplantation, 664–665
  perinephric fluid collections and, 1809
  peritonitis and, 517, 520*f*
  prostate, 389, 390*f*, 392
  splenic, 148, 151*f*
    drainage of, 617
    pediatric, 1769
  stitch, after herniorrhaphy, 494–496, 495*f*
  subphrenic, 1716
  testicular, 831–832, 831*f*
  tubo-ovarian, in pelvic inflammatory disease, 588–589, 588*f*

volume of, 1339–1340
Amniotic fluid index (AFI), 1339
method for obtaining, 1340
values for, in normal pregnancy, 1341*t*
A-mode ultrasound, 9
Amplitude
evaluation of, power Doppler in, 935
modulation imaging, 64, 65*f*
Ampulla, 565
Amputations, from amniotic band sequence, 1401, 1403*f*
Amyand hernias, 472–473, 473*f*
Amyloidosis, renal failure in, 372
Anabolic steroid therapy, hepatic adenomas and, 1746
Anal atresia, 1311
Anal canal, endosonography of, 302–307, 304*f*–307*f*, 306*b*
Anal dimple, 1311–1312, 1311*f*
fetal cloacal exstrophy and, 1328
Analgesia, TRUS-guided biopsy and, 407
Anaplastic carcinoma, of thyroid gland, 707–708, 708*b*, 709*f*
Anasarca, fetal, in hydrops, 1417, 1420*f*
Anastomotic pseudoaneurysms, 438
Anastomotic strictures, bladder augmentation and, 1912–1913
Anderson-Carr-Randall theory of stone progression, 339, 1798–1799
Androblastoma, 585
Androgens, secretion of, 417
Anechoic cysts, 331

Anemia
  fetal, hydrops from, 1431
  pediatric, Fanconi, 1746
Anencephaly, 1218
  CDH and, 1263
  detection of, early, 1018–1019, 1019*f*
  embryonic, 1077
  in fetal brain, 1179, 1180*f*
  temperature increase in utero and, 1037
  thickened NT and, 1096*f*
Anesthetics
  local, for pediatric interventional sonography, 1951, 1952*f*
  for musculoskeletal injections, 901
Aneuploidy. *See also* Trisomy 21
  background risk for, 1088, 1089*f*
  definition of, 1088
  fetal echogenic bowel and, 1315–1316, 1315*f*
  fetal gastroschisis and, 1324–1325
  fetal liver calcifications and, 1316–1318
  hand and foot abnormalities in, 1404, 1406*f*
  identification of, fluorescent in situ hybridization in, 1433–1434
  pyelectasis as marker for, 1355
  risk of, NT in assessing for, 1018–1019, 1019*f*, 1049
  screening for, first-trimester, 1089–1097
    with cell-free DNA, 1107
    combined, 1090–1091
    contingent, 1091
    cystic hygroma in, 1093, 1093*f*
    integrated, 1091
    in multifetal pregnancy, 1091
    nasal bone in, 1093–1095, 1094*b*, 1094*f*
    NT in trisomy 13 and 18, 1093
    NT in trisomy 21 and, 1089, 1090*f*
    NT measurement technique and, 1091–1093, 1092*b*
    reversed flow in ductus venosus in, 1095, 1095*f*
    sequential, 1091
    serum biochemical markers in, 1089–1090
    thickened NT in congenital heart defects and, 1095–1097, 1096*f*
    tricuspid regurgitation in, 1095
  skeletal findings with, 1407–1409
Aneurysm(s). *See also* Abdominal aortic aneurysm
  abdominal aortic, 433–439
  atrial septal, 1295
  in AVF for hemodialysis, 1003, 1005*f*
  carotid flow disturbances in, 928
  common carotid artery, 947–948
  hepatic artery, after liver transplantation, 1768, 1769*f*–1770*f*
  of peripheral arteries
    lower extremity, 971–972, 972*f*
    upper extremity, 976
  portal vein, 103–104
    after liver transplantation, 1768, 1769*f*–1770*f*
  renal artery, 369, 369*f*, 451
  in synthetic arteriovenous graft for hemodialysis, 1003
  umbilical artery, 1483
  vein of Galen, 1204, 1206*f*
    arachnoid cysts differentiated from, 1192–1193
    cavum veli interpositi cysts differentiated from, 1170
    in neonatal/infant brain, duplex Doppler sonography of, 1583–1584, 1585*f*–1586*f*
  ventricular, congenital, 1294
Angiogenesis, in yolk sac wall, 1057
Angiography, in carotid stenosis diagnosis, 916
Angiomas, littoral cell, splenic, 153–156, 156*f*
Angiomyolipomas
  of liver, 117–118, 119*f*
  renal, 351–352, 351*f*–352*f*
    pediatric, 1820, 1822*f*
Angiosarcoma
  hepatic, 123
  splenic lesions in, 153, 155*f*
Angle of incidence, 5
Angle of insonation, 4
Angle of refraction, 5
Angle theta
  consistent, in carotid spectral analysis, 926–927
  Doppler
    definition of, 926
    measurement of, 926–927, 926*f*
  increasing, to overcome aliasing, 939
Angular margins, in breast sonography, 788–789, 790*f*
Aniridia, sporadic, Wilms tumor screening with, 1818
Anisospondyly, in dyssegmental dysplasia, 1399
Anisotropic effect, in HPS sonography, 1838, 1838*b*, 1839*f*
Anisotropic effect artifact, 1517
Anisotropy
  shoulder ultrasound and, 895, 895*f*
  tendon, 859, 860*f*, 899
Ankle, injection of, 901
  superficial peritendinous and periarticular, 902–904, 903*f*–904*f*
Annular constricting lesions, 261–264, 263*f*
Annular pancreas, fetal, 1320, 1321*f*
Anomalous pulmonary venous return (APVR), 1280, 1282*f*, 1290, 1291*f*
  total compared to partial, 1290
Anophthalmia, 1140, 1145*f*
Anorchidism, 1890
Anorectal malformations, fetal, 1310–1312, 1311*f*
Anterior cerebral artery (ACA)
  of infant, RI in, 1576, 1577*t*
  of infant, RI in, fontanelle compression in hydrocephalus and, 1582, 1584*f*
  stenosis of, SCD and, 1607*f*
  TCD sonography for collateral flow in, 1610, 1611*f*
  as transtemporal approach landmark, 1592, 1593*f*–1594*f*
Antibiotic prophylaxis, TRUS-guided biopsy and, 407, 408*f*
Antibiotics, for pediatric interventional sonography, 1951
Anticoagulants, deficiency of physiologic, dural sinus thrombosis from, 1205–1206
Antley-Bixler syndrome, craniosynostosis in, 1136–1138
Antral dyskinesia, 1836–1838
Antral foveolar hyperplasia, prostaglandin-induced, 1839–1840
Antral web, pediatric, 1839, 1840*f*
Anus
  ectopic, pediatric, 1847–1848, 1850*f*
  imperforate, 1310–1311
    block vertebrae with, 1689, 1692*f*
    high, pediatric, risk of spinal dysraphism with, 1689
    pediatric, 1847–1848, 1850*f*
Aorta
  coarctation of, 1291, 1292*f*
    fetal, hydrops from, 1423–1424
    hypoplastic left heart syndrome with, 1287
  fetal, continuity of, 1278*f*
  small, in Turner syndrome, 1106*f*, 1107
Aortic arch
  fetal, 1275, 1279*f*
  pediatric, cervical, 1658
Aortic balloon pump, carotid flow waveforms and, 936–937, 936*f*
Aortic coarctation, renal artery stenosis and, 447, 449*f*
Aortic root, fetal, diameter of, 1277*f*
Aortic stenosis, 1292
  carotid flow waveforms and, 936–937
  fetal, hydrops from, 1423–1424
Aortic valve, lesions of, carotid flow waveforms and, 936–937
Aortoenteric fistulas, 438
Apert syndrome
  craniosynostosis in, 1136–1138
  midface hypoplasia in, 1148
Aplasia
  pulmonary, 1245–1246
  of thyroid gland, 694, 694*f*
Apnea, sleep, pediatric TCD sonography for, 1611
Aponeurosis, torn, in spigelian hernia, 483–484, 487*f*
Appendices epiploicae, torsion of, 290
Appendicitis
  acute
    clinical misdiagnosis of, 283–285
    pathophysiology of, 283
    right lower quadrant pain from, 282–285
    sonographic diagnosis of, 283, 283*b*
    symptoms of, 283
    transvaginal ultrasound for diagnosis of, 283, 285*f*
  Crohn, 285, 287*f*
  focally inflamed fat in, 521
  pediatric, 1855–1860
    acute, 1857, 1859*f*
    Meckel diverticulum resembling, 1858–1860, 1862*f*
    normal appearance of, 1857, 1858*f*
    perforated, 1857, 1857*b*, 1861*f*
    sonographic signs of, 1857*b*
Appendicolith, 283
Appendix. *See also* Appendicitis
  inflammation of, 282–285
  mucocele of, 299, 299*f*
  pediatric
    abscess of, 1871*f*, 1877
    abscess of, drainage of, 1956, 1960*f*
    gangrenous, 1857, 1861*f*
    normal, 1857, 1858*f*
  perforations of, 283–285, 285*b*, 286*f*
Appendix epididymis, pediatric, 1897, 1897*f*
Appendix testis, 820–821, 820*f*
  pediatric, 1897
"Apple peel" jejunal atresia, 1310
Aprosencephaly, 1186
APVR. *See* Anomalous pulmonary venous return
Aqueduct of Sylvius
  in rhombencephalosynapsis, 1192
  stenosis of
    obstructive hydrocephalus from, 1538, 1540*f*
    VM and, 1177, 1177*f*
Arachnoid cyst(s)
  cavum veli interpositi cysts differentiated from, 1170
  corpus callosum agenesis and, 1526–1528
  fetal brain and, 1192–1193, 1193*f*
  of neonatal/infant brain, 1563–1565, 1565*b*
  spinal canal and, pediatric, 1695–1697, 1696*f*
Arachnoid granulations, 1177
Arcuate arteries, calcifications of, 531–532, 533*f*
Arcuate uterus, 534, 536–538, 536*f*–537*f*
Area cerebrovasculosa, in anencephaly, 1179
Area membranacea, 1189
Areflexia, detrusor, 372–374, 373*f*
ARFI. *See* Acoustic radiation force imaging
ARPKD. *See* Autosomal recessive polycystic kidney disease

Arrays, transducer, 11–12
Arrhenoblastoma, 585
  pediatric, 1880
Arrhythmia(s)
  early pregnancy loss and, 1069
  Ebstein anomaly with, 1286
  fetal heart, 1295–1297
    bradycardia as, 1297, 1297*f*
    CHD and, 1270–1273
    congenital heart block as, 1297, 1297*f*
    hydrops from, 1424, 1425*f*
    PACs and PVCs as, 1295–1296
    tachycardia as, 1296–1297, 1296*f*
Arsenic, 123
Arterial venous (AV) anastomoses, 1125, 1125*f*
Arterial/arterial (AA) anastomoses, 1125, 1125*f*
Arteriomegaly, 440
Arteriovenous fistulas (AVFs)
  arteries supplying, spectral broadening in, 927–928
  of common femoral artery, 974*f*
  dural, TCD sonography assessing, 1614
  hemodialysis and
    aneurysms near, 1003, 1005*f*
    arm and leg swelling with, 1006, 1009*f*
    hematomas near, 1002–1003, 1005*f*
    maturation of, evaluating, 1003
    occlusion of, 1006
    palpable focal masses near, 1002–1003
    placement of, 996, 997*f*
    pseudoaneurysms near, 1003, 1005*f*
    stenoses associated with, 1003–1006, 1007*f*–1008*f*
    ultrasound evaluation of, 1000–1006, 1002*f*–1003*f*
  of lower extremity peripheral arteries, 973–974, 974*f*
  after pancreas transplantation, 678, 680*f*
  pediatric, of neck, 1658
  renal, 366–367
    percutaneous needle biopsy of, 606, 607*f*
  renal biopsies and, Doppler assessment of, 1809, 1810*f*
  traumatic, 973
Arteriovenous graft, synthetic, hemodialysis and
  arm and leg swelling with, 1006, 1009*f*
  hematomas near, 1002–1003
  occlusion of, 1006, 1010*f*
  palpable focal masses near, 1002–1003
  placement of, 996, 997*f*
  ultrasound evaluation of, 1002, 1004*f*
Arteriovenous malformations (AVMs)
  arteries supplying, spectral broadening in, 927–928
  cerebral, pediatric, TCD sonography detecting, 1614, 1615*f*
  fetal hydrops from, 1430–1431
  of lower extremity peripheral arteries, 973
  pediatric, of neck, 1657–1658, 1659*f*
  pial, 1204–1205
  postpartum recognition of, 556, 556*f*
  renal, 366–367, 367*f*
    renal transplantation complications from, 661–664, 667*f*–670*f*
    twinkling artifacts mimicking, 662–664, 668*f*
Arteriovenous shunting, in fetal sacrococcygeal teratoma, 1238–1239
Arteritis
  alloimmune, after pancreas transplantation, 677
  of common carotid artery, 944–946, 947*f*
  Takayasu, aortic stenosis in, 444
Artery(ies). *See specific arteries*

sonographic appearance of, 1380*f*
thanatophoric dysplasia differentiated from, 1388–1389
Camptodactyly, fetal, 1404–1405, 1406*f*
Campylobacter, 1852
Canal of Nuck
cyst or hydrocele of, simulating groin hernia, 499–500, 501*f*
delayed closure of, indirect inguinal hernia from, 476–477, 477*f*
Canalization, in spine embryology, 1672, 1673*f*
Candida albicans
genitourinary tract infections from, 330–331, 331*f*
neonatal urinary tract infection from, 1794, 1795*f*
Candidiasis
hepatic, 86–87, 88*f*
hepatosplenic, splenic abscesses in, 150–152, 154*f*
neonatal, 1794, 1795*f*
Capillary malformations, tethered cord and, 1679
Capsular arteries, 821
Caput medusae, 1752
Carcinoid tumor, renal, 355–356
Carcinoma(s). *See also* Breast(s), solid nodules of; Ductal carcinoma in Situ; Hepatocellular carcinoma; Papillary carcinoma; Renal cell carcinoma; Transitional cell carcinoma
acinic cell, parotid gland, pediatric, 1638, 1639*f*
acoustic shadowing caused by, 791–792, 793*f*
adenoid cystic, salivary gland, pediatric, 1638
adrenal, pediatric, 1827, 1827*f*
adrenocortical, 424–425, 426*f*
of bladder
squamous cell, 348
transitional cell, 347–348, 350*f*
cervical, 542, 543*f*
hematometra in, 547*f*, 549
choriocarcinoma, testicular, 824, 825*f*
circumscribed, 786
clear cell, 581, 582*f*
colon, 261–264, 263*f*–264*f*
pediatric, 1880

Carcinoma(s) *(Continued)*
embryonal, 823, 825*f*
ovarian, 1880
pediatric, testicular, 1899
endometrial, 544, 548–551, 550*f*
polycystic ovarian disease and, 1877–1878
esophageal, staging of, endosonography in, 301
fallopian tube, 589
gallbladder, 206–207, 206*f*
gastric, endosonographic identification of, 301
mucoepidermoid, salivary gland, pediatric, 1638
of parathyroid glands
adenomas differentiated from, 735–736, 738*f*
primary hyperparathyroidism from, 734
primary peritoneal serous papillary, 511–513, 515*f*
prostate, transrectal sonography of, 302, 302*f*
rectal, staging of, endosonography in, 301–302, 301*f*–304*f*
spiculated, 786
TDLU, 789–790, 792*f*
of thyroid gland, 695
anaplastic, 707–708, 708*b*, 709*f*
follicular, 701, 701*b*, 706*f*–707*f*, 1648
incidence of, 722, 722*f*–723*f*
medullary, 701–707, 707*f*–708*f*, 1648
nodular disease and, 698–708
papillary, 698–701, 701*f*–705*f*, 713, 1648, 1649*f*
vaginal, pediatric, 1883
Carcinomatosis, peritoneal, 510–511, 510*f*–515*f*
Cardiac output, reduced, carotid flow waveforms and, 935*f*, 936–937
Cardioembolic stroke, 915–916
Cardiomyopathy(ies)
carotid flow waveforms and, 936–937, 936*f*
fetal, 1295*f*
adrenal glands and, 1353–1354
hydrops from, 1425
Cardiopulmonary bypass
partial, in neonatal/infant brain, duplex Doppler sonography and, 1578–1579, 1579*f*
pediatric TCD sonography in, 1621–1622
Cardiosplenic syndrome, 1292–1293, 1293*b*
Cardiovascular disease, 432–433
Carney complex, 826
Carney triad, pheochromocytomas with, 1826
Caroli disease
of biliary tree, 171, 171*f*
pediatric, 1735
bile duct dilation in, 1736–1737, 1736*f*
Carotid artery(ies). *See also* Plaque(s), carotid
anatomy of, 916, 917*f*
arthrosclerotic disease of, plaque characterization in, 919
color Doppler evaluation for stenosis of, 932–935
advantages and pitfalls of, 934–935, 934*b*, 934*f*
bruit from, 933, 934*f*
optimal settings in, low-flow vessel evaluation, 933–934, 933*b*, 934*f*

Congenital heart disease (CHD)
chromosomal anomalies in, 1270
extracardiac malformations in, 1270
fetal arrhythmia and, 1270–1273
hydrops and, 1270
IVF and, 1270–1273
MCDA twins and, 1270–1273
risk factors associated with, 1270, 1271*t*–1272*t*
recurrence, in offspring, 1273*t*
recurrence, in siblings, 1273*t*
Congenital high airway obstruction (CHAOS), 1248*t*, 1253–1255, 1254*f*
hydrops from, 1426
Congenital hypothyroidism, 694
pediatric ovarian cysts and, 1875
Congenital infantile myofibromatosis, 1664, 1665*f*
Congenital lobar emphysema, 1246
Congenital lobar overinflation (CLO), 1246, 1251–1252, 1253*f*
Congenital malformations, obstetric sonography and, 1041
Congenital myopathy, atypical hips and, 1932
Congenital nephrotic syndrome, CKD and, 1796–1798
Congenital pulmonary airway malformation (CPAM)
classification of, 1248
differential diagnosis of, 1248*t*
fetal, 1246–1252
hydrops development and, 1248–1249, 1426, 1427*f*
pediatric, 1715–1716, 1717*f*
pleuropulmonary blastoma differentiated from, 1252–1253
sonographic diagnosis of, 1248, 1249*f*
volume ratio of, 1248, 1250
Congestive heart failure
gallbladder wall thickening and, 199*f*
neonatal/infant, 1566
Conglomerate masses, Crohn disease and, 269
Conjoined tendon insufficiency
direct inguinal hernia and, 479–481, 483*f*–484*f*
sports hernia and, 485–486, 489*f*
Conjoined twins, 1115–1116
complications with, 1129–1130, 1130*f*
Conn syndrome, adrenal adenomas in, 419
Connatal cysts, 1566
Connective tissue, dense fibrous, homogeneous plaque and, 920–921
Conradi-Hünermann syndrome, 1399
Constrictive amniotic bands, 1182–1183
Continuous ambulatory peritoneal dialysis, 521
Continuous wave (CW) devices, 8
Continuous wave Doppler, 24, 25*f*
Continuous wave probes, with duplex pulsed Doppler, 939
Continuous wave ultrasound, 36
Contraceptive devices, intrauterine, 529, 552–554, 553*f*
Contraceptives, oral, hepatic adenomas and, 1746
Contrast, speckle effect on, 13–15, 14*f*
Contrast agents, 41–42. *See also* Blood pool contrast agents
acoustic cavitation and, 43, 44*b*
avoidance of, in obstetric sonography, 1038
blood pool, 55–56
disruption-replenishment imaging and, 66–67, 67*f*
echo enhancing, 57*f*
harmonic imaging with, 58–64
in hydrosonovaginography, 1870–1871, 1871*f*
intermittent harmonic power Doppler imaging and, 66, 66*f*
intermittent imaging with, 64–67, 66*f*
intravenous Doppler, 1749–1750
intravenous ultrasound, 1746
microbubbles as, 53–54, 54*f*
behavior of, incident pressure and, 56–58, 57*t*
disruption of, 64–67, 66*f*
FNH characterization with, 106, 106*f*, 108*t*, 109*f*
future of technology for, 68–69, 69*f*–70*f*
HCC characterization with, 106, 106*f*
hemangioma characterization with, 106, 106*f*–107*f*, 108*t*
inertial cavitation and, 67–68
lesional enhancement with, 105, 106*f*–107*f*, 109*f*
liver mass characterization with, 105–106, 106*f*–107*f*, 108*t*, 109*f*–110*f*
MI and, 58, 58*b*, 105
need for, 56–58, 57*f*
regulation of, 68
safety of, 67–68
in musculoskeletal interventions, 898
nonlinear echoes and, 58–64
amplitude and phase modulation imaging and, 64, 65*f*
harmonic B-mode imaging and, 60
harmonic spectral and power Doppler and, 60–61, 60*f*–62*f*
plane-wave contrast imaging and, 64
pulse inversion Doppler imaging and, 63–64
pulse inversion imaging and, 62–63, 62*f*–63*f*
temporal maximum intensity projection imaging and, 64, 65*f*
tissue harmonic imaging and, 61–62
perfluorocarbons in, 56
for liver mass detection, 107, 111*f*
requirements for, 54–56

Contrast agents *(Continued)*
triggered imaging and, 65
types of, 54–56
in water enema technique, 1870–1871, 1871*f*
Contrast effect, of steroid anesthetic mixture, 899, 899*f*
Contrast pulse sequence (CPS), 64
Contrast-enhanced ultrasound (CEUS)
adenoma diagnosis with, 116–117, 117*f*
backscatter increased with, 107, 111*f*
for breast lesions, 773–774
cavernous hemangioma characterization with, 111, 113*f*
for Crohn disease, 269, 273*f*
Crohn disease identification with, pediatric, 1853, 1854*f*
in fatty liver diagnosis, 91–92
FNH diagnosis with, 113–115, 115*f*
gut wall and, 261
HCC detection with, 120–122, 123*f*
Hilar cholangiocarcinoma assessment with, 188, 191*f*
liver metastases diagnosis with, 128–129, 130*f*
for pancreas, 251
for pancreas transplantation, 676
for prostate cancer, 406
for thyroid gland assessment, 692, 714–715
Contrast-to-noise ratio, spatial compounding and, 13–15, 15*f*
Conus medullaris
determining position of, 1677, 1679*f*
fetal, location of, 1218–1221, 1221*f*, 1673, 1673*f*
low and tethered, caudal agenesis type II and, 1689
Conus septum, TOF and, 1288
Cooper ligaments, 761, 761*f*–763*f*
Copy number variants (CNVs), 1088
Coracoacromial ligament, 878–879
Coracobrachialis muscle, 878–879
Coracoclavicular ligaments, 878–879
Coracohumeral ligament, 878–879
Coracoid process, 878–879, 879*f*
Cordocentesis, 1434, 1434*f*
Cornelia de Lange syndrome, microcephaly in, 1194
Cornua
hematometra and, 551–552
"Cornual pregnancy", 1073
Coronary bypass graft, radial artery evaluation for, 977–978, 980*f*
Corpora amylacea, 387
Corpora quadrigemina, 1518
Corpus callosum
agenesis of
in Chiari II malformation, 1526, 1528*f*
fetal brain and, 1199–1201, 1202*f*, 1203*b*
neonatal/infant neural tube closure disorders and, 1526–1528, 1529*b*, 1530*f*–1533*f*
periventricular nodular heterotopia and, 1199*f*
VM and, 1177
dysgenesis of, fetal brain and, 1199–1201, 1203*b*
lipoma of, 1529, 1533*f*
in rhombencephalosynapsis, 1192
thinning of, in PVL, 1552
Corpus luteum
angiogenesis of, 1063
cysts of, 570
pediatric, 1875
development of, 568
formation of, 1049
Corrected TGA, 1290, 1290*f*
Cortical development malformations, fetal brain and, 1193–1203
absence of septi pellucidi as, 1201–1203
cerebrohepatorenal syndrome as, 1196
chondrodysplasia punctata as, 1196
Cortical development malformations, fetal brain and *(Continued)*
classification of, 1194*b*
corpus callosum agenesis/dysgenesis as, 1199–1201, 1202*f*, 1203*b*
focal changes in, 1196
hemimegalencephaly as, 1195
heterotopia as, 1196, 1199*f*
intracranial calcifications as, 1195*f*, 1203, 1204*f*
lissencephaly as, 1195–1196, 1196*f*–1197*f*
macrocephaly as, 1194–1195
megalencephaly as, 1194–1195
microcephaly as, 1194, 1195*f*
polymicrogyria as, 1196, 1198*f*
schizencephaly as, 1196, 1199*f*
SOD as, 1201–1203, 1203*f*
TSC and, 1198, 1200*f*
Cortical nephrocalcinosis, 339
pediatric, 1798, 1798*b*, 1798*f*
Corticosteroids, for musculoskeletal injections, 900
Cortisol, secretion of, 417
Couinaud anatomy, of liver, 76–77, 77*t*, 78*f*
Coxa vara, congenital, atypical hips and, 1932
Coxsackie virus, 1203–1204
Coxsackie virus infection, fetal hydrops from, 1431
Coxsackievirus B, endocardial fibroelastosis from, 1294
CPAM. *See* Congenital pulmonary airway malformation
CP/CPPPS. *See* Chronic prostatitis/chronic pelvic pain syndrome
CPS. *See* Contrast pulse sequence
Cranial Bone Thermal Index (TIC), 39–40
Cranial hairy tuft, diastematomyelia and, 1689
Cranial neuropore, in spine embryology, 1217
Craniocervical junction, in pediatric spine, 1674, 1675*f*
Cranioectodermal dysplasia, 1395
Craniolacunia, in Chiari II malformation, 1526
Craniopharyngioma, intracranial, fetal, 1208
Craniorachischisis, 1179, 1218
Cranioschisis, definition of, 1225*t*
Craniosynostosis
with cloverleaf-shaped skull deformity, 1137*f*–1138*f*
cranial contour indicating, 1382
intracranial compliance in, evaluation of, 1581–1582
metopic, 1137*f*
syndromes associated with, 1136–1139, 1137*f*–1138*f*
Cranium, in skeletal dysplasias, 1382
Crass position, for shoulder ultrasound
modified, 881, 883*f*–884*f*
original, 881, 883*f*
Creeping fat, Crohn disease and, 269, 271*f*
Cremasteric (external spermatic) artery, 821, 821*f*
Cremasteric reflex, 846
CREST. *See* Carotid Revascularization Endarterectomy Versus Stenting Trial
CRL. *See* Crown-rump length
Crohn disease
anatomy affected by, 268
appendicitis associated with, 285, 287*f*, 1862*f*
CEUS for, 269, 273*f*
classic features of, 269
color Doppler ultrasound for, 268*t*, 269, 272*f*
complications of, 269–276
fistula formation as, 276, 279*f*–280*f*
incomplete mechanical bowel obstruction as, 274, 276*f*
inflammatory masses as, 275–276, 278*f*–279*f*
localized perforation with phlegmon as, 274–275, 277*f*
perianal inflammation as, 276, 281*f*, 305–306
strictures as, 269–274, 275*f*–276*f*
Crohn disease *(Continued)*
conglomerate masses and, 269
creeping fat and, 269, 271*f*
diagnosis of, 267–268
gastrointestinal tract and, 266–269
gut wall thickening and, 269, 270*f*–271*f*
hyperemia and, 269, 272*f*–273*f*
intramural sinus tract in, 269, 274*f*
lymphadenopathy in, 269, 272*f*
management of, 266–267
mucosal abnormalities and, 269, 274*f*
pediatric, 1853, 1854*f*
sonographic assessment of, 268, 268*b*, 268*t*
transperineal scanning in, 276
Crossed-fused ectopia, 318, 318*f*
pediatric, 1784–1785, 1785*f*
Crouzon syndrome
craniosynostosis in, 1136–1138
midface hypoplasia in, 1148
Crown-rump length (CRL), 1054
accurate, criteria for, 1092, 1092*b*
early pregnancy failure and, no heartbeat and, 1063, 1064*f*
embryos with less than 7 mm, and no heartbeat, 1064
in gestational age determination, 1445, 1446*f*, 1446*t*
in gestational age estimation, 1062
gestational sac with small MSD in relationship to, early pregnancy failure and, 1066, 1067*f*
NT compared to, 1089, 1090*f*
Cryptorchid testes, 823
Cryptorchidism
testicular microlithiasis and, 1904
testis and, 851, 851*f*
pediatric, 826
Crystalline form, of injectable steroids, 900
CT. *See* Computed tomography
Cubital tunnel, 865–866
Cul-de-sac

disease of
acquired cystic, 340, 364, 364*f*
cystic, 356–365
end-stage, reflux nephropathy and, 327, 327*f*
localized, 362–364, 363*f*
medullary, 359
neoplasm-related, 364–365
polycystic, 359–361, 361*f*–362*f*
renal cell carcinoma and acquired cystic, 340
ectopia and, 318, 318*f*
failure of, chronic, transplantation for, 641
glomerulonephritis of, 370, 371*f*
growth of, congenital anomalies related to, 317–318
hemangiopericytoma of, 356
hematomas of, 365–366
horseshoe, 159–160, 318, 319*f*
fetal, 1345–1346, 1345*f*, 1362
pediatric, 1784, 1785*f*
hypoplasia of, 317
intrathoracic, pediatric, 1716
lacerations of, 365–366, 366*f*
leiomyomas of, 355–356
leukemia involving, 353–354
lymphomas of, 333, 352–353, 353*b*
maternal, IUGR and, 1455
medullary sponge, 339, 340*f*, 359
pediatric, 1799
metastases to, 354, 355*f*
multicystic dysplastic, 361, 362*f*
multilocular cystic nephroma and, 361–362, 363*f*
oncocytoma of, 348–351
parenchyma of, calcification of, 339–340, 340*f*
pelvic, 318, 318*f*
identification of, 592
percutaneous needle biopsy of, 605–606, 606*f*–607*f*
"putty", 330
sarcomas of, 356
shattered, 365–366
sonographic technique for, 314
squamous cell carcinoma of, 348
supernumerary, 319
thoracic, 318
transitional cell carcinoma of, 346–347, 346*f*–349*f*
trauma to, 365–366, 366*f*
tumors of, rare, 355–356
vascular abnormalities of, 366–369
renal vascular Doppler ultrasound and, 366
Kidneys, fetal
agenesis of
bilateral, 1342–1344, 1343*f*–1344*f*, 1344*b*
unilateral, 1344
VUR with, 1360
cystic disease of, 1346–1352
ADPKD and, 1350, 1350*f*
ARPKD and, 1348–1350, 1349*f*
Kidneys, fetal *(Continued)*
bilateral reniform enlargement of, 1348, 1349*f*
HNF1β mutations in, 1350–1351
MCDK as, 1346–1347, 1346*f*–1347*f*
Meckel-Gruber syndrome and, 1351, 1351*f*
obstructive cystic renal dysplasia as, 1347–1348, 1347*f*–1348*f*
syndromes associated with, 1350–1351, 1351*f*
duplex, VUR with, 1360
ectopic, 1344–1345, 1344*f*–1345*f*
embryology of, 1336–1338, 1337*f*
horseshoe, 1345–1346, 1345*f*
megalourethra and, 1362
hyperechogenic, 1351–1352, 1352*f*
length of, at 14-42 weeks' gestation, 1338–1339, 1339*t*
lobation in, 317, 1781, 1781*f*
lobes of, formation of, 1781, 1781*f*
normal sonographic appearance of, 1342*f*
pelvic, 1344–1345, 1344*f*
postnatal function of
fetal urinalysis in prediction of, 1365, 1365*t*
poor, antenatal predictors of, 1364*b*
routine sonographic view of, 1026*f*
sonographic appearance of, 1338–1339, 1338*f*
tumors of, 1352–1353, 1353*f*
Kidneys, pediatric. *See also* Hydronephrosis, pediatric, causes of; Nephrocalcinosis; Urinary tract, pediatric
abscess of, complicating acute pyelonephritis, 1792–1793
absence of, 1784, 1784*f*
biopsies of, Doppler assessment of, 1809, 1810*f*–1811*f*
"cake", 1785
crossed-fused ectopia, 1784–1785, 1785*f*
cystic disease of, 1812–1818
ADPKD and, 1814–1815, 1815*f*
ARPKD and, 1812–1813, 1814*f*
MCDK and, 1815, 1816*f*
medullary cystic kidney disease and, 1816, 1817*f*
nephronophthisis and, 1815–1816, 1816*f*
cysts of, congenital, 1816–1818
dialysis and acquired, 1816–1818, 1817*f*
after liver transplantation, 1816–1818
in TSC, 1816, 1817*f*
in VHL disease, 1816
Doppler ultrasound for, 1778
dysplastic, 1798, 1798*f*
focal scarring of, from acute pyelonephritis, 1792, 1793*f*
horseshoe, 1784, 1785*f*
hydronephrosis and, 1785–1791
length of
age, height, weight compared to, 1776–1778, 1777*f*
by age, with single functioning kidney, 1779*t*
birth weight and gestational age compared to, 1776–1778, 1780*f*
normal measurements of, 1776–1778, 1777*f*
position for visualizing, 1776*f*
reference values for, according to age and gender, 1776–1778, 1778*t*
medical diseases of, 1794–1798
acute kidney injury as, 1795–1796, 1796*b*, 1797*f*
chronic kidney disease as, 1796–1798, 1797*t*, 1798*f*
normal anatomy of, 1781–1783, 1781*f*–1782*f*
normal term, 1781–1783
"pancake", 1785
pelvic, 1908
premature, normal, 1781–1783
renal duplication and, 1783–1784, 1784*f*

Kidneys, pediatric *(Continued)*

acute pancreatitis complicated by, 230, 231*f*
chronic pancreatitis and, 232–233, 234*f*–235*f*
Splenogonadal fusion, 833
paratesticular, 1904
Splenomegaly
causes of, 145, 146*t*
complications of, 146
diagnosis of, 145–146
fetal, 1320
massive, 145, 146*t*
portal hypertension as cause of, 145, 147*f*
in sickle cell disease, 157
sonographic appearance of, 143*f*–144*f*
Splenorenal ligament, 139–141, 140*f*
Splenorenal shunts, in portal hypertension, pediatric, 1757, 1759*f*
Splenosis, posttraumatic, 160–161
Splenunculi, 158–159, 160*f*
Split cord malformation
fetal, 1234–1235
pediatric, 1688–1689, 1688*f*
Split liver graft, from deceased donor, 625
Split-screen imaging, for breast assessment, 769, 769*f*
Sports hernias, 484–488, 488*f*–489*f*
SPTA. *See* Spatial peak temporal average
Squamous cell carcinoma (SCC), 348
Staghorn calculus
tyrosinemia and, 1799, 1800*f*
in xanthogranulomatous pyelonephritis, 328, 329*f*
Standard sonographic examination, 1019
Standoff pad, in breast tumor imaging, 767, 767*f*
Steatosis
diffuse, 91, 92*f*
in inborn errors of metabolism, 1738
pediatric, 1740, 1740*f*, 1741*b*
Stein-Leventhal syndrome, 573
pediatric, 1877–1878, 1879*f*
Stener lesion, 864, 864*f*
Stenotic disease, of abdominal aorta, 441–445, 445*f*
Stensen duct, pediatric, 1630
Stent graft, 438
Stepladder sign, in intracapsular breast implant rupture, 804–805, 805*f*
Sternocleidomastoid muscle, 692*f*, 694
Sternohyoid muscle, 692*f*, 694
Sternum, defect of, pentalogy of Cantrell and, 1329
Steroids
anabolic, therapy with, hepatic adenomas and, 1746
injectable, for musculoskeletal interventions, 900–901
injection of, interventional sonography for, pediatric, 1961, 1964*f*
Stickler syndrome, clefts of secondary palate in, 1153
Stippled epiphyses, 1399
Stitch abscess, after herniorrhaphy, 494–496, 495*f*
Stomach, fetal, 1306–1308
absent or small, 1306, 1306*b*
esophageal atresia and, 1305–1306, 1305*f*
dilated, 1307, 1308*f*
intraluminal gastric masses in, 1308, 1309*f*
midline, 1307, 1308*f*–1309*f*
normal, 1307*f*
right-sided, 1307, 1308*f*–1309*f*
Stomach, pediatric, 1833–1840
anatomy of, 1834–1835, 1835*f*–1836*f*
antrum distention in, HPS pitfalls and, 1838, 1839*f*
Stomach, pediatric *(Continued)*
artifact of empty, 1838, 1839*f*
bezoars and, 1840, 1841*f*
gastric diaphragm and, 1839, 1840*f*
gastric ulcers and, 1839–1840, 1840*f*
gastritis and, 1839–1840, 1840*f*
HPS and, 1835–1838, 1835*b*, 1837*f*–1838*f*
pitfalls in diagnosis of, 1838, 1838*b*, 1839*f*
pylorospasm and minimal muscular, 1836–1838, 1838*f*
optimal measurements of, 1834*b*
sonographic technique for, 1833–1835
Stomodeum, 1133–1134
Strain elastography, 16, 17*f*, 772
Strain modulus, 15–16
Strangulated hernias. *See* Hernia(s), strangulated
Strawberry-shaped skull, 1136, 1137*f*
Streaming, 35
Streptococcal meningitis, group B, neonatal/infant, 1560, 1561*f*–1562*f*
Stress maneuvers, for hip stability determination, 1923
Strictures in, in Crohn disease, 269–274, 275*f*–276*f*
String sign, occluded carotid artery distinguished from, 939
Stroke
cardioembolic, 915–916
from carotid artery stenosis, 915–916
in neonatal/infant brain, duplex Doppler sonography and, 1580–1581, 1584*f*
SCD and
cerebrovascular disease indicators with, 1601*f*–1603*f*
risk categories for, 1599–1604, 1605*t*, 1606–1607
screening for, 1598
velocity indications of, 1605–1607
Stromal cell tumors, ovarian, pediatric, 1879
Stromal tumors, gastrointestinal, 264, 265*f*
pediatric, 1862
Struma ovarii, 584
Sturge-Weber syndrome
facial hemangiomas in, 1154
pheochromocytomas with, 1910–1912
TCD sonography assessing, 1614
Subacromial impingement, of shoulder, 877–879, 882–883
Subacromial spurs, 878–879
Subacromial-subdeltoid bursa, 879
appearance of, normal, 889, 891*f*
rotator cuff tears and, 888–889, 892*f*
thickening of, 889–891, 892*f*
with ganglion, 889–891, 892*f*
Subacute granulomatous thyroiditis, 724, 724*f*
Subamniotic hematomas, of placenta, 1474
Subarachnoid hemorrhages, neonatal/infant brain and, 1550, 1550*f*
Subarachnoid spaces, neonatal/infant
development of, 1520–1521
fluid collections in, duplex Doppler sonography of, 1585, 1588*f*
Subchorionic cysts
maternal floor infarction with, 1474, 1476*f*
placental, 1474, 1477*f*
Subchorionic hematoma, 1474
placental abruption differentiated from, 1471, 1474*f*
Subchorionic hemorrhage
early pregnancy failure and, 1069, 1069*f*
fetal echogenic bowel and, 1315*f*
Subclavian artery, 975
stenosis of, 976, 978*f*–979*f*
Subclavian steal phenomenon, 952–954, 953*b*, 953*f*–954*f*, 976, 979*f*
Subclavian vein
anatomy of, 990–991, 990*f*
stenosis of, sever, 1006, 1009*f*
ultrasound examination for, 991, 991*f*
Subcutaneous edema, fetal, in hydrops, 1417, 1419*f*–1420*f*
Subdural effusions, neonatal/infant, duplex Doppler imaging of, 1585, 1588*f*
Subdural hematomas, neonatal/infant, 1557, 1558*f*
Subdural hemorrhage, fetal, bilateral, 1207*f*
Subependymal cysts, 1543–1544
of neonatal/infant brain, 1566, 1567*f*
Subependymal hemorrhage, neonatal/infant brain and, 1543–1544, 1543*f*–1544*f*
Subfascial hematomas, cesarean sections and, 556–557, 557*f*
Subglottic stenosis or atresia, CHAOS and, 1253
Sublingual gland, pediatric, anatomy of, 1631, 1631*f*
Subluxation, 1923, 1927
Submandibular glands, pediatric
anatomy of, 1630–1631, 1631*f*
pleomorphic adenoma of, 1638*f*
sialolithiasis of, 1633, 1633*f*
Submandibular space, pediatric, 1630–1631, 1631*f*
cystic lesions of, 1639–1640, 1640*b*
Submandibular window, for TCD sonography, 1592–1593
Subphrenic abscess, 1716
Subplacental hematoma, 1471, 1474*f*
Subscapular fossa, 878–879
Subscapularis tendon
anatomy of, normal, 878–879, 879*f*
ultrasound evaluation of, 880, 882*f*
Subtrochanteric femur, absence of, 1400
Subvalvular aortic stenosis, 1292
Succenturiate lobes, of placenta, 1480–1481, 1481*f*
"Sugar icing", 868*f*
Sulcation disorders, of neonatal/infant brain, 1536–1537
Sulcus(i), of brain
development of, 1167
neonatal/infant
development of, 1520–1521, 1520*f*–1521*f*
effacement of, in diffuse cerebral edema, 1553, 1554*f*
normal sonographic appearance of, 1169, 1171*f*
radial arrangement of, in corpus callosum agenesis, 1528, 1532*f*
Sulfur colloid scanning, FNH and, 115
"Sunburst sign," in corpus callosum agenesis, 1528, 1532*f*
Superb microvascular imaging (SMI), 1746
basic technique of, 1749–1750, 1752*f*
Superficial fascia, pediatric, 1628, 1629*f*
Superficial peritendinous and periarticular injections, 902–904
for foot and ankle, 902–904, 903*f*–904*f*
for hand and wrist, 904, 905*f*
Superficial venous insufficiency, 981–982
Superior mesenteric artery (SMA)
pancreatic body and, 211, 211*f*
small bowel obstruction and, 1308
Superior mesenteric vein (SMV), 211, 211*f*
Superior vena cava (SVC)
anatomy of, 991
catheter position for, pediatric, 1716–1721, 1722*f*
stenosis, with PICC line, 993*f*
thrombosis of, pediatric, 1721, 1721*b*, 1722*f*
ultrasound examination of, 991–992, 992*f*
Supernumerary glands, 733
Supernumerary kidneys, 319
Supernumerary testes, 838–839, 841*f*

Superoanteromedial ridge, 416–417
Supraclavicular lymphadenopathy, pediatric, 1658
Suprahyoid space, pediatric
  anatomy of, 1628–1640, 1629*f*
  cystic lesions of, 1639–1640, 1640*b*, 1640*f*–1641*f*
  masticator space of, pathology of, 1640, 1641*f*
  salivary glands in, 1629–1639
    anatomy of, 1630–1631
Supraspinatus fossa, 878–879
Supraspinatus tendon
  anatomy of, 878–879
  calcific tendinitis of, 891–892, 892*f*
  postoperative, 888, 891*f*
  tendinosis of, 886*f*
  ultrasound evaluation of, 881–883, 883*f*–884*f*
Supratentorial tumors, neonatal/infant brain and, 1562
Supraventricular tachycardia (SVTs)
  with Ebstein anomaly, 1286–1287
  fetal, 1296–1297, 1296*f*
    hydrops from, 1424, 1425*f*
Surface epithelial inclusion cysts, 569, 573
Surface epithelial-stromal tumors, 579–582, 580*f*–582*f*
SURUSS. *See* Serum, Urine and Ultrasound Screening Study
Surveillance
  of AAA, 435–437
    CT in, 437
    sonographic technique for, 436–437, 436*f*–437*f*
  active, for prostate cancer, 401
Suspensory (infundibulopelvic) ligament, 564–565
Sutures, cranial, premature fusion of, 1136–1139, 1138*b*, 1138*f*–1139*f*
SVC. *See* Superior vena cava
SVTs. *See* Supraventricular tachycardia
SWE. *See* Shear wave elastography
Swyer syndrome, 1887
Sylvian fissure, neonatal/infant, development of, 1514*f*–1515*f*, 1520–1521
Syncytiotrophoblast, 1049, 1051–1052, 1052*f*, 1466*f*
Syndactyly
  fetal, 1406, 1406*f*
  of fingers, in triploidy, 1105*f*, 1406
Synechia, amniotic band sequence and, 1401
Synovitis, 867, 869
  hip joint, pediatric, 1931*f*
Syntelencephaly, 1187, 1189, 1535–1536
Synthetic arteriovenous graft. *See* Arteriovenous graft, synthetic
Syphilis, 1203–1204
  fetal hydrops from, 1431–1432
Syringocele, 1683–1684
Syrinx, 1681
System setup, obstetric sonography and, 1035–1036, 1035*f*–1037*f*
Systemic lupus erythematosus, maternal, fetal AVB from, 1297
Systolic velocity, cerebral, factors changing, 1612*t*
Systolic-to-diastolic ratio (S/D ratio), 27, 27*f*

T

"T" sign, in monochorionicity, 1119, 1119*t*, 1121*f*
Tachyarrhythmias, fetal, hydrops from, 1424
Tachycardia
  fetal, 1296–1297, 1296*f*
  neonatal/infant, intracranial RI and, 1576
  supraventricular
    with Ebstein anomaly, 1286–1287
    fetal, 1296–1297, 1296*f*
    fetal, hydrops from, 1424, 1425*f*
  ventricular, 1296
Tactile sensation, in obstetric sonography, 1038
Tailgut cysts, 297, 298*f*
Takayasu arteritis
  aortic stenosis in, 444
  of common carotid artery, 944–946, 947*f*
Talipes equinovarus, fetal, 1406*f*, 1407
  campomelic dysplasia and, 1395
Talipomanus, fetal, 1407
TAMM. *See* Time-averaged mean of maximum velocity

nonseminomatous germ cell, 822*b*, 823–824, 825*f*
pediatric, 1899–1902
regressed germ cell, 824–825, 825*f*–826*f*
Sertoli cell, 826, 827*f*
sex cord-stromal, 825–826, 827*f*
stromal, 822, 822*b*
teratocarcinomas as, 1899
teratomas as, 823–824, 825*f*, 1899
yolk sac, 823–824, 825*f*
undescended, 851, 851*f*
dysplastic gonads and, 1899
in prune belly syndrome, 1361–1362
right, pediatric, 1890, 1890*f*
Testosterone, Leydig cells and secretion of, 819
Tethered cord, 1674
in diastematomyelia, 1236*f*
fetal cloacal exstrophy and, 1328
pediatric, 1678–1679, 1681*f*
spina bifida occulta and, 1226
Tetralogy of Fallot (TOF), 1288, 1288*f*
Tetraphocomelia, Roberts syndrome and, 1401
TGA. *See* Transposition of great arteries
TGC. *See* Time gain compensation
Thalamostriate vessels, mineralization of, 1203, 1204*f*
Thalamus
fetal, normal sonographic appearance of, 1168
neonatal/infant, sagittal imaging of, 1515, 1517*f*
vasculopathy of, neonatal/infant brain and, 1556–1557
α-Thalassemia, nonimmune hydrops from, 1423, 1431
Thanatophoric dysplasia
bowing of long bones in, 1381–1382
campomelic dysplasia differentiated from, 1388–1389
cloverleaf-shaped skull and, 1136, 1137*f*, 1389*f*
craniosynostosis in, 1136–1138, 1137*f*
diagnosis of, 1376–1377
homozygous achondroplasia differentiated from, 1389, 1389*f*
lethal skeletal dysplasia and, 1387–1390
megalencephaly associated with, 1194–1195
platyspondyly in, 1388–1389, 1390*f*
sonographic appearance of, 1380*f*
type 1, 1388–1389
type 2, 1388–1389, 1389*f*
Thanatophoric skeletal dysplasia, cortical malformations and, 1193–1194
Theca externa, 1049
Theca lutein cysts, 570, 572
pediatric, 1875
Thecomas, ovarian, 585
Thelarche, pseudoprecocious puberty and, 1888
Thermal effects, in ultrasound, 31. *See also* Bioeffects, thermal
obstetric, 1036–1038
Thermal index (TI), 38–40, 38*b*
for bone, in late pregnancy, 1039
obstetric sonography duration as function of, 1035–1036, 1036*f*, 1042*t*
for soft tissue, in early pregnancy, 1039
tissue model of
with bone at focus, 39
with bone at surface, 39–40
homogeneous, 39
Thigh graft, hemodialysis and, preoperative mapping for, 1000, 1001*f*

precocious puberty and, 1887–1888
pregnancy and, 1884–1885
stenotic, vaginal obstruction from, 1881
Peutz-Jeghers syndrome and watery discharge of, 544
Vaginal fornix, 528–529
Vaginal pessary, cervical incompetence and, 1507
Vaginal progesterone, 17α-OHPC compared to, 1507
Vaginal septum, 538
transverse, vaginal obstruction from, 1881
Vaginitis, pediatric, 1887

Vallecula
cysts, pediatric, 1640, 1641*f*
neonatal/infant, in mastoid fontanelle imaging, 1517–1518, 1519*f*
Valproic acid, NTDs from, 1218
Valsalva maneuver, 471, 992
for dynamic ultrasound of hernias
femoral, 472*f*, 483
inguinal, 473, 474*f*
Valve leaflet morphology, 1285*f*
Valvular aortic stenosis, 1292
Varicella
fetal brain and, 1203–1204
fetal hydrops from, 1432
Varices
gallbladder wall, in chronic pancreatitis, 233, 235*f*
gastric mural, in chronic pancreatitis, 233, 235*f*
gastrointestinal, endosonographic identification of, 301
round ligament, simulating groin hernias, 500, 501*f*
Varicocele(s)
idiopathic, 837–838
pediatric, 1902–1903, 1903*f*
scrotal, 837–838, 838*f*–839*f*
Vas aberrans of Haller, 1897*f*
inferior, 820–821
Vas deferens, 819–820
absence of, 394
calcification of, 392
cysts of, 842*f*
Vasa aberrantia, 820–821
Vasa previa, 1480, 1485–1487, 1488*f*–1489*f*
Vascular abnormalities, in liver. *See* Liver, vascular abnormalities in
Vascular anomalies, of neck, pediatric, 1654–1655, 1655*b*
malformations, 1655–1658, 1655*b*, 1657*f*, 1659*f*
tumors, 1655, 1655*b*, 1656*f*
Vascular malformations
fetal, 1204–1208, 1206*f*
dural sinus thrombosis as, 1205–1206, 1206*f*
hydranencephaly as, 1208, 1208*f*
intracranial hemorrhage as, 1206, 1207*f*
pediatric
in masticator space, 1640, 1641*f*
in neck, 1655–1658, 1655*b*, 1657*f*, 1659*f*
Vasculitis
acute, gut edema and, 295, 297*f*
autoimmune, Henoch-Schönlein purpura and, 1853
mesenteric ischemia from, 453
renal artery stenosis and, 447
Vasectomy, epididymis changes following, 841, 843*f*
Vasodilation, 27
Vasospasm, 950
pediatric, TCD sonography for, 1608–1610, 1609*f*, 1610*t*
VATER syndrome
fetal renal anomalies in, 1341
spina bifida and, 1226
Vein mapping
before hemodialysis, 996–1000
upper extremity, 996–998, 998*f*–1000*f*
of lower extremity peripheral veins, 989–990
Vein of Galen
aneurysms of, 1204, 1206*f*
arachnoid cysts differentiated from, 1192–1193
in neonatal/infant brain, duplex Doppler sonography of, 1583–1584, 1585*f*–1586*f*
cavum veli interpositi cysts differentiated from aneurysm of, 1170

Vein of Galen *(Continued)*
malformations of, neonatal/infant brain and, 1566, 1567*f*
Vein of Markowski, 1180
fetal brain and, 1204
Velamentous umbilical cord insertion, 1484–1485, 1486*f*
multifetal pregnancy and, 1119, 1122*f*
Velocardiofacial syndrome, clefts of secondary palate in, 1153
Velocity
arterial stenosis and, 969, 970*f*
diastolic, end, in assessing degree of carotid stenosis, 930
in Doppler spectral analysis of carotid artery, 925
stroke and SCD indications with, 1605–1607
systolic
cerebral, factors changing, 1612*t*
peak, in determining carotid stenosis, 929–930
TCD sonography evaluation of, 1593, 1595–1596
time-averaged mean of maximum, 1593, 1605–1606
time-averaged peak, 1593
Velocity range, in obstetric Doppler sonography, 1036
Velocity ratios, in carotid artery stenosis evaluation, 937
Venography
in IJV, 955–956
wedge hepatic, 1764
Veno-occlusive disease, hepatic, 103
Venous drainage, in pancreas transplantation, 672
Venous insufficiency
deep, causes of, 989, 990*f*
superficial, 981–982
Venous malformations, pediatric
of neck, 1657
of salivary gland, 1636
Venous occlusive disease, hepatic, small-vessel, 1762–1763
Venous venous (VV) anastomoses, 1125, 1125*f*
Ventilation, mechanical, in neonatal/infant brain, 1578, 1579*f*
Ventral hernias, 488–494
Ventral induction errors, fetal brain and, 1186–1203
arachnoid cysts as, 1192–1193, 1193*f*
in cerebellum, 1189–1192
Dandy-Walker malformation as, 1190, 1190*f*
HPE as, 1186–1189, 1187*b*, 1188*f*, 1189*b*
mega-cisterna magna as, 1192, 1193*f*
in posterior fossa, 1189–1192
rhombencephalosynapsis as, 1192
vermis hypoplasia or dysplasia as, 1190–1192, 1192*f*
Ventricle(s)
cardiac
double-outlet right, fetal, 1288–1289, 1289*f*
echogenic foci, significance of, 1294, 1294*f*
hypoplastic left, fetal, 1292
hypoplastic right, fetal, 1287, 1287*f*
neonatal/infant, left, dysfunction of, intracranial RI and, 1576
cerebral, fetal, sonographic view of, 1024*f*
fourth
cisterna magna clot of, 1546*f*
trapped, in intraventricular hemorrhage, 1545–1547
Ventricle(s) *(Continued)*
lateral, neonatal/infant
coarctation of, 1566
in coronal imaging, 1513–1515, 1514*f*–1515*f*
in sagittal imaging, 1515–1517, 1517*f*
measurement technique for, 1174–1176, 1175*f*
medial wall of, separation of choroid from, in VM evaluation, 1176, 1176*f*
persistent terminal, pediatric, 1685
third
in corpus callosum agenesis, 1528, 1531*f*
fetal, normal sonographic appearance of, 1168
Ventricular aneurysms, congenital, 1294
Ventricular diverticula, 1294
Ventricular septal defects (VSDs), 1270, 1281–1284, 1283*f*–1284*f*
with spina bifida, 1233
in trisomy 21, 1098*f*, 1101
Ventricular tachycardia, fetal, 1296
Ventriculitis
chemical, 1206
in intraventricular hemorrhage, 1545–1547
neonatal/infant brain and, 1560, 1563*f*
Ventriculoarterial discordance, in TGA, 1289
Ventriculomegaly (VM)
CDH and, 1263
conditions associated with, 1178*b*
fetal brain and, 1174–1178
hydrocephalus differentiated from, 1611–1612
isolated, 1176
IUFD and, 1124*f*
marked, 1176, 1177*f*
measurement technique for, 1174–1176, 1175*f*
mild, 1176, 1177*f*
neonatal/infant hydranencephaly compared to, 1538*f*
pathogenesis of, 1177–1178

Wormian bones, 1139, 1139*b*, 1139*f*
Wrist, injection of, 901
superficial peritendinous and periarticular, 904, 905*f*

X

Xanthogranulomatous cholecystitis, 202
Xanthogranulomatous pyelonephritis (XGP), 328, 329*f*, 348
X-linked hydrocephalus, 1177
X-linked NTDs, 1226

Y

Yersinia, 1852–1853, 1852*f*
"Yin-yang" pattern, in renal biopsy pseudoaneurysms, 1809, 1811*f*
Yolk sac tumors, 585, 823–824, 825*f*
Yolk sac(s)
angiogenesis wall of, 1057
assessment of, 1016, 1016*b*
calcification of, 1067, 1068*f*
diameter of, measurement, 1017*f*
echogenic material in, 1067–1068
embryo in, 1058*f*
hematopoiesis in, 1057
identification of, in gestational age determination, 1445, 1445*f*, 1446*t*
MSD and, 1057
normal sonographic appearance of, 1057, 1058*f*
number of, amnionicity and, 1117
in nutrient transfer, 1057
primary, formation of, 1051, 1052*f*
secondary, formation of, 1051, 1053*f*
size and shape of, in early pregnancy failure, 1067–1068, 1068*f*
transvaginal ultrasound for identification of, 1057
Yolk stalk, 1059

Z

Zellweger syndrome, 1196, 1399
subependymal cysts from, 1566
Zero baseline, shifting, to overcome aliasing, 939
Zika virus, 1194, 1203–1204
congenital, neonatal/infant brain and, 1560
Zona fasciculata, 417
Zona glomerulosa, 417
Zona reticularis, 417
Zuckerkandl fascia, 314
Zygosity, in multifetal pregnancy, 1115–1116, 1116*f*
Zygote, formation of, 1051, 1051*f*

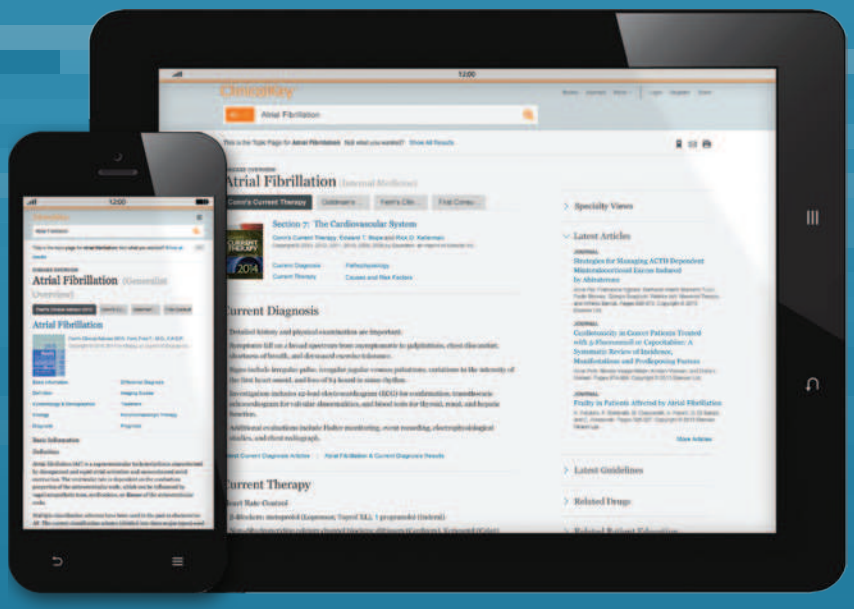
ClinicalKey®

Fast answers and trusted evidence



Drive better outcomes with a clinical search engine that makes it easier to find and apply relevant knowledge.

Fast
Anticipates your query, recognizing concepts and offering shortcuts

Complete
Draws relevant answers from a wide range of current, comprehensive content across 30+ medical and surgical specialties

Convenient
Accessible at the patient's bedside or on the go, making it easy to discover, share, and apply content anywhere

Trusted
Content from Elsevier, the name healthcare professionals worldwide rely on
