Treatment of RMSF is with doxycycline 100 mg twice daily (or 3 mg/kg of body weight, whichever is higher) for at least 7 days, given orally for outpatients and intravenously for hospitalized patients. Doxycycline should be used even in children (at a dose of 4.4 mg/kg per day divided into BID doses), as the risk of tooth staining has been shown to be quite low for short-term therapy. This regimen will cover other tick-borne illnesses such as Lyme disease and ehrlichiosis, as well as RMSF. Chloramphenicol (at a dose of 50 to 75 mg per kg per day divided into four doses) is an alternative choice for pregnant women and patients with documented allergy to doxycycline, but is reportedly less effective [55]. Treatment should be continued until the patient has been afebrile for 2 to 3 days.

Case fatality rates range from 0.6% to 9%, with worse prognosis in older patients. Untreated RMSF has a mortality of 25%, whereas patients receiving appropriate treatment within 5 days of symptom onset have a mortality of 5% [52].

Disseminated Herpes Simplex Virus Infection

Herpes simplex virus (HSV), a member of the human herpes virus family, is a common cause of dermatologic disease. HSV-1 and HSV-2 have seroprevalence rates as high as 80% and 25% of U.S. adults respectively [56].

Infection is spread by close physical contact of mucous membranes or open skin with infected fluids or skin that is actively shedding virus. After initial infection, the virus remains latent in the dorsal root ganglion. Reactivation may be triggered by stress, illness, trauma (such as from intubation), intense UV exposure, and pregnancy. Grouped vesicles on an erythematous base, often with associated pain or pruritus, appear with reactivation. Rupture of vesicles leaves characteristic punched-out ulcers with scalloped edges [56,57].

Infection in immunocompetent patients is self-limited [58]. Immunocompromised patients (HIV, malignancy, medications, or pregnancy) have more frequent, more severe reactivations and there is an increased risk of disseminated cutaneous and visceral disease [56,58]. Reactivation of genital HSV in immunocompromised and pregnant individuals is associated with an increased risk of visceral dissemination and high mortality. Patients with disrupted skin secondary to eczema, TEN, burns or other conditions, are at risk for disseminated cutaneous disease known as Kaposi's varicelliform eruption or eczema herpeticum [56].

Patients with vesicular eruptions should be examined carefully for clustered lesions or erosions suspicious of HSV. A high index of suspicion is essential. The differential diagnosis includes herpes zoster, varicella, contact dermatitis, bullous impetigo, and other causes of vesiculation of the skin. Confirmatory tests include Tzanck smear, direct fluorescent antibody (DFA), viral culture, PCR, and ELISA. All studies are most sensitive when performed on vesicles less than 48 hours old. DFA and culture should be performed together to increase sensitivity from approximately 50% for each alone, to almost 80% [59]. PCR is the most sensitive test, but it is not always available.

Although there are no controlled studies for treatment of disseminated disease and no evidence that treatment decreases mortality, intravenous acyclovir at 8 to 10 mg per kg every 8 hours for 7 to 10 days is generally employed [57]. The dose is adjusted for patients with renal insufficiency. Alternatives for acyclovir-resistant cases include foscarnet, vidarabine, and cidofovir [58]. Secondary bacterial infection may complicate the course of HSV infection and should be treated with appropriate antibiotic therapy.

Disseminated Herpes Zoster

Varicella zoster virus (VZV) causes both chicken pox (varicella), representing a primary infection, and shingles (zoster), a manifestation of reactivated latent infection. After initial exposure, the virus remains dormant in the dorsal root ganglion [60] or in cranial nerve root ganglia [61]. Medications, aging, malignancy, bone marrow transplant, HIV, and poor nutrition can affect immune status and thereby increase the risk of reactivation. Incidence is approximately 5 per 1,000 per year, with no sex predilection, but there is significantly higher occurrence in at-risk populations and the elderly. A vaccine that is 50% to 64% effective against zoster is now in clinical use, but is not universally administered [60].

Upon reactivation, VZV tracks along sensory nerves to affect a particular dermatome, most commonly the thoracic dermatome. A prodrome of pain, pruritus, and paresthesia in the affected dermatome is noted by up to half of the patients. This is followed by an eruption of erythematous macules and/or papules. Over 24 hours, the lesions begin to vesiculate, and over the next 48 to 72 hours, crust over. Pain is the most common symptom, present in 90% to 95% of patients. Prior to onset of skin lesions, involvement of the thoracic dermatome may be mistaken for acute coronary syndrome.

Immunocompromised hosts may have atypical presentations with unusual lesion morphology, distribution, greater ulceration, and dissemination. Disseminated disease, defined as more than 20 lesions outside the primary dermatome, may present with multiple contiguous or non-contiguous dermatomes. Visceral dissemination can involve the lung, liver, and brain [61], but even in immunocompromised hosts, visceral disease is a low likelihood [60]. Cases of VZV reactivation and visceral dissemination without cutaneous lesions have been rarely reported [60,62].

Uveitis, keratitis, corneal ulcers, and blindness may result from reactivation along the ophthalmic division of the trigeminal nerve. Myelitis or encephalitis may result in weakness and altered mental status. Rarely, motor nerves may be involved with resulting weakness [60].

Differential diagnosis includes HSV infections, bullous drug eruption, contact dermatitis, and erythema multiforme. Tzanck smear, direct fluorescent antibody, or viral culture should be performed if the diagnosis is in question. However, treatment should not be delayed pending results. Patients should be treated if they present within 1 week of onset of their lesions or if they still have any lesions that have not crusted over [61].

Oral acyclovir or valacyclovir is appropriate for healthy individuals who can take oral treatment and for uncomplicated cases in immunocompromised patients. The dosing regimen is 1 g of valacyclovir or 500 mg of famciclovir every 8 hours, or acyclovir 800 mg 5 times a day, with dose adjustment for renal insufficiency. The duration of treatment is 7 to 10 days. IV acyclovir is the treatment of choice in immunocompromised patients with ophthalmic, disseminated, or HIV-associated disease or those with significant comorbidities [60,61]. Acyclovir resistance is more prevalent in immunocompromised populations and should be suspected if new lesions are forming on acyclovir or a related drug (famciclovir, valacyclovir). Viral sensitivities should be checked in this setting. Resistant strains are treated with foscarnet, 180 mg per kg per day divided into two or three doses and renally adjusted [61]. CNS, ophthalmologic, or atypical cutaneous presentations should trigger neurology, ophthalmology, and dermatology consultation [60,61].

Disseminated Candidiasis

Systemic candidiasis may occur as candidemia or as an infection involving a single or multiple organs. It is the fourth most common cause of bloodstream infection in hospitalized patients, with *C. albicans* and *C. glabrata* comprising 70% to 80% of these cases [63]. Immunosuppression and granulocytopenia are important risk factors for candidemia. Patients at high risk include those with hematologic malignancies, those undergoing chemotherapy, and organ and stem cell transplant recipients. Other risk factors for systemic candidiasis include ICU stay, presence of a central venous catheter, parenteral nutrition, broad-spectrum antibiotics, severe trauma, burns, hemodialysis, abdominal surgery, and GI perforation.

Skin lesions are present in up to 35% of patients with systemic candidiasis [63,64]. The eruption appears as pink or violaceous, firm papules or nodules most commonly on the trunk and extremities, but can also involve the face [64]. The lesions are often purpuric, which may be due to concurrent thrombocytopenia or vascular damage from the candida [64]. Other presentations include hemorrhagic or necrotic lesions, pustules, and abscesses. The eyes, kidney, liver, heart, and meninges may also be affected by hematogenous spread of the organism.

Blood cultures are positive in only 50% to 60% of patients with disseminated candidiasis; therefore, biopsy of a skin lesion is a more sensitive approach in early diagnosis and should be submitted for both pathology and tissue culture. Histopathology demonstrates aggregates of hyphae and spores in the dermis. The 1–3 D-glucan detection assay, which was approved by the FDA in 2004, measures the level of glucan in the fungal cell wall and therefore detects fungi, including candida, with a high degree of sensitivity and specificity.

Treatment requires extended courses of a systemic antifungal, usually fluconazole, caspofungin, or less commonly amphotericin B. Intravenous micafungin is a newer agent for invasive candidiases, which was well tolerated in clinical trials [65]. Intravenous catheters should also be removed and replaced, as should other potential sources of infection. With a mortality rate of 30% to 40%, systemic candidiasis causes more fatalities than any other systemic mycosis [63].

BLISTERING DISEASES

Pemphigus vulgaris, paraneoplastic pemphigus, and bullous pemphigoid are autoimmune blistering disorders characterized by autoantibodies directed at cell–cell adhesion molecules or components of the basement membrane zone.

Pemphigus Vulgaris

Pemphigus vulgaris is a rare but potentially fatal bullous disorder that affects the skin and mucous membranes. The worldwide incidence is 0.76 to 5 per million population. However, the incidence is much higher in those of Jewish ancestry [66]. Pemphigus typically affects middle-aged or older individuals. Pemphigus is caused by autoantibodies against the desmosomal proteins, desmoglein 1 and 3, which are required to maintain cellular adhesion between keratinocytes in the epidermis.

Virtually all patients with pemphigus develop painful oral erosions, which are usually the presenting signs. Hoarseness and dysphagia may be a sign of pharyngeal and esophageal involvement, respectively. Cutaneous lesions develop in more than half of the patients, usually after the onset of oral erosions. Vesicles or bullae in pemphigus are fragile and rupture easily since blistering occurs within the epidermis. Consequently, it is more likely to encounter erosions rather than intact blisters on the skin. Blistering may be induced by rubbing intact, normal appearing skin near areas of blistering, a phenomenon known as the Nikolsky sign. Extensive loss of epidermal barrier function in pemphigus may be complicated further by secondary systemic bacterial infection and fluid loss.

TABLE 195.2

SUMMARY OF RECOMMENDATIONS BASED UPON RANDOMIZED CONTROLLED CLINICAL TRIALS FOR PEMPHIGUS VULGARIS

Intervention	Year	Study	No. of Patients	Findings	Reference
Oral prednisolone, high dose (120 mg/d) versus low dose (60 mg/d) regimens	1990	Prospective, randomized trial over 5 y	22	High dose regimen had no long-term benefit over low dose regimen in terms of frequency of relapse or incidence of complications	Ratnam et al. [67]
Adjuvant oral dexamethasone pulse therapy (300 mg pulses 3 d/mo) versus placebo in conjunction with conventional oral prednisolone (80 mg/d) and azathioprine sodium (3 mg/d)	2006	Multicenter, randomized, placebo-controlled trial	20	No benefit of oral dexamethasone pulse therapy given in addition to conventional treatment	Mentink et al. [68]
Comparison of four treatment regimens for pemphigus vulgaris: prednisolone alone, prednisolone plus azathioprine, prednisolone plus mycophenolate mofetil, and prednisolone plus intravenous cyclophosphamide pulse therapy	2007	Randomized, controlled open-label trial over 1 y	120 (30 pts/arm)	Efficacy of prednisolone is enhanced when combined with cytotoxic agent. Azathioprine was found to be the most efficacious cytotoxic drug to reduce steroid, followed by cyclophosphamide and mycophenolate mofetil.	Chams-Davatchi et al. [69]
Comparison of oral methylprednisolone plus azathioprine or mycophenolate mofetil	2006	Prospective, multicenter, randomized, non-blinded trial	33	Azathioprine and mycophenolate mofetil have similar efficacy, corticosteroid-sparing effects and safety profiles as adjuvant treatments.	Beissert S et al. [70]
High dose intravenous immunoglobulin (IVIG) over 5 consecutive days in patients relatively resistant to systemic steroids	2009	Multicenter, randomized, placebo-controlled, double-blind trial	61 (includes pemphigus foliaceus)	IVIG (400 mg/kg/day for 5 days) is safe and effective for relatively steroid resistant patients.	Amagai M et al. [71]
Dapsone versus placebo in patients already on conventional systemic steroids	2008	Multicenter, randomized, placebo-controlled, double-blind trial	19	"Trend to efficacy" of dapsone but not statistically significant.	Werth et al. [72]
Cyclosporine as adjuvant to systemic corticosteroids	2000	Concurrently randomized trial	29	Cyclosporine ineffective as adjuvant to corticosteroids.	Ioannides D et al. [73]

For patients with only oral disease, the differential diagnosis includes oral HSV, aphthous ulcers, oral lichen planus, and systemic lupus erythematosus. With cutaneous disease, further consideration should be given to bullous impetigo, bullous drug eruptions, and other autoimmune blistering disorders. Drug-induced pemphigus has been associated with the use of various medications, in particular penicillamine and captopril [66].

Diagnosis of pemphigus is made by routine histology, which demonstrates loss of cell–cell adhesion of keratinocytes (acantholysis) and retained attachment of basal cells to the basement membrane along the dermal-epidermal junction. Immunofluorescence of perilesional tissue shows intercellular deposits of IgG. Serum sent for indirect immunofluorescence or ELISA assays will demonstrate circulating antibodies, and titers in pemphigus usually correlate with disease activity [66].

Standard treatment of pemphigus is oral prednisone at 1 mg per kg per day. Studies of corticosteroid-sparing agents for pemphigus, including azathioprine, mycophenolate mofetil, cyclosporine, cyclophosphamide, and IVIG, are reviewed in Table 195.2 [67–73]. Plasmapheresis and rituximab have also been reported to be effective in case series. However, based on a Cochrane review [74], the optimal therapeutic strategy has not been established. Most patients require maintenance treatment for sustained remission. Prior to treatment with oral corticosteroids, most patients died within 5 years of disease onset. Current mortality rate is about 5% to 15%, mostly due to complications from immunosuppressive therapy such as sepsis [66].

Paraneoplastic Pemphigus

Paraneoplastic pemphigus is a variant of pemphigus associated with benign or malignant neoplasms. Most commonly associated conditions include non-Hodgkin's lymphoma, chronic lymphocytic leukemia, Castleman's disease, thymoma,

sarcoma, and Waldenstrom's macroglobulinemia. Autoantibodies in paraneoplastic pemphigus are directed against a variety of proteins including desmogleins 1 and 3, Bullous Pemphigoid Antigen 230, as well as the plakin family of proteins [75].

The disease usually presents with a recalcitrant stomatitis involving the mouth and characteristically, the lips. Other mucous membranes, including the eyes, genitalia, nasopharynx, and esophagus, may be involved. Cutaneous lesions are polymorphic and may resemble pemphigus vulgaris, bullous pemphigoid, erythema multiforme, or lichen planus. Some patients develop bronchiolitis obliterans, which may be fatal as a result of respiratory failure [75].

Two thirds of patients diagnosed with paraneoplastic pemphigus have a known underlying neoplasm. In the other third, mucocutaneous disease precedes the diagnosis of an associated neoplasm, and these patients must be carefully followed. Severe, intractable stomatitis is a clue in differentiating paraneoplastic pemphigus from other bullous disorders.

Disease associated with benign neoplasms such as thymoma or Castleman's disease may improve or clear completely with treatment of the underlying condition. The course of disease and prognosis in malignancy-associated paraneoplastic pemphigus is poor. The stomatitis is often refractory to treatment with corticosteroids and immunosuppressants [75].

Bullous Pemphigoid

Bullous pemphigoid (BP) is a chronic subepidermal blistering disorder that usually affects the elderly. It has an incidence of 6 to 7 cases per million. It is usually not life-threatening but often requires long-term use of immunosuppressive agents, which can lead to morbidity and mortality.

Subepidermal blisters in BP result from autoantibodies directed against the hemidesmosomal proteins BP180 and BP230, which are located at the epidermal-dermal junction. BP may be induced by medications, the most common of which are penicillamine and furosemide. Other reported associations include captopril, bumetanide, phenacetin, amoxicillin, ciprofloxacin, potassium iodide, and gold [76].

BP has a variety of clinical manifestations, including a nonbullous prodromal phase characterized by severe pruritus, either alone or associated with excoriated eczematous or urticarial lesions. The bullous phase is characterized by tense vesicles and bullae on normal or erythematous skin. Unlike pemphigus, numerous blisters in bullous pemphigoid are found intact. The lesions are frequently symmetric and are most commonly found in flexural areas on the limbs, the lower trunk, and abdomen. The oral mucosa is involved in 10% to 30% of patients [76].

The differential diagnosis includes pemphigus, bullous lupus erythematosus, dermatitis herpetiformis, bullous erythema multiforme, cicatricial pemphigoid, linear IgA dermatosis, and epidermolysis bullosa acquisita. Diagnosis is made by skin biopsy from the edge of a blister, which shows a subepidermal blister with an eosinophil-rich dermal inflammatory infiltrate. Direct immunofluorescence of perilesional skin shows linear deposits of IgG and/or C3 along the basement membrane zone. Indirect immunofluorescence will detect circulating autoantibodies in 60% to 80% of patients [76].

Bullous pemphigoid has a tendency toward remission and can be controlled more easily than pemphigus. Treatment with high-potency topical corticosteroids may be effective with fewer side effects than the usually employed therapy with oral corticosteroids. Other immunosuppressive agents such as azathioprine, mycophenolate mofetil, cyclophosphamide, and methotrexate may be added for recalcitrant cases or for steroid sparing. The combination of nicotinamide and minocycline or tetracycline has been successful in small case series. Dapsone, IVIG, plasmapheresis, and extracorporeal photopheresis have all been reported to be effective as well.

VASCULAR DISORDERS

Cutaneous Vasculitis

Vasculitis is defined by inflammation of the blood vessel wall and may involve any sized vessel. Since this subject is covered in more depth in Chapter 196, the present discussion will focus on cutaneous findings. Vasculitis may be limited to the skin, or there may be multiorgan involvement involving most commonly the kidneys, the gastrointestinal tract, and/or the joints. It is important to recognize that skin involvement may be a sign of more serious internal organ involvement. The pathogenesis involves immune complex deposition in the affected vessel walls leading subsequent activation of complement. Vasculitis may primary, or secondary to infections (15% to 20%), medications (10% to 15%), malignancy (2% to 5%), or inflammatory disorders including connective tissue disease, inflammatory bowel disease, and others (15% to 20%) [77]. Commonly associated infections include *Streptococcal* and other bacterial acute respiratory infections, bacterial endocarditis, gonococcemia, chronic meningococcemia, hepatitis B and C, HIV, CMV, and mycobacteria. Implicated medications include antibiotics, allopurinol, thiazide diuretics, hydantoins, propylthiouracil, NSAIDs, and anti-TNF agents. Malignancies associated with vasculitis include lymphoproliferative, hematologic, and solid organ cancers. Among connective tissue diseases, systemic lupus erythematosus and rheumatoid arthritis are most likely to be complicated by cutaneous and systemic vasculitis. The underlying etiology may remain unidentified in up to 50% of patients [77].

Vasculitis affecting the skin may be a clue to involvement of other organs. Recognition of cutaneous morphologies associated with vasculitis allows for early recognition and classification of disease, timely workup and diagnosis, and prompt treatment. Cutaneous findings in vasculitis correlate with the size of vessels involved.

Cutaneous small vessel vasculitis includes Henoch-Schonlein purpura, urticarial vasculitis, septic vasculitis, and essential mixed cryoglobulinemia in which HCV may precipitate an immune response. The morphologic hallmark of small vessel vasculitis in the skin is palpable purpura. Red to purple, nonblanching macules and papules are concentrated over dependent areas of the skin such as the ankles and lower legs (Fig. 195.6), or over pressure areas such as the buttocks. There may be significant associated edema. Other morphologies include urticarial lesions, which are less evanescent than typical hives. The patient may have associated constitutional symptoms and arthralgias. Although most cases of cutaneous small vessel leukocytoclastic vasculitis affect only the skin, further consideration should be given to involvement of the renal, gastrointestinal, and central nervous system vasculature. The eruption typically resolves over weeks with hyperpigmentation. It is important to monitor for systemic disease, even after the cutaneous signs have resolved.

Polyarteritis nodosa, Wegener's granulomatosis, and Churg-Strauss syndrome are conditions in which there is inflammation of small and medium sized arteries. Mucocutaneous findings may be found in Churg-Strauss syndrome (55%) and Wegener's granulomatosis (40%). These conditions may present with painful subcutaneous nodules that often ulcerate, typically on the dependant areas such as the lower legs. Other mucocutaneous findings may include a necrotizing livedo reticularis, digital ischemia with gangrene, and oral ulcers. Palpable purpura, splinter hemorrhages, and pustules may also be

FIGURE 195.6. Vasculitis. Nonblanching, red to purple papules and plaques over the legs associated with edema.

present when there is concomitant small vessel disease. There may be associated constitutional symptoms, myalgias, and arthralgias. Peripheral sensorimotor neuropathy, cardiomyopathy or myocardial infarction, gastrointestinal symptoms and intestinal infarction, seizures, hemiplegia, and necrosis of major organs may also result from inflammation of larger vessels.

Disorders with large vessel vasculitis are usually diagnosed when bruits, asymmetric pulses, claudication, or neurologic deficits are present. Some patients also have cutaneous findings that serve as clues to underlying pathology. In giant cell arteritis (GCA), the temporal artery is tender, swollen, indurated, or pulseless. The tongue may be tender, atrophic, swollen, or cyanotic. Rarely, patients with GCA may have tender nodules overlying other superficial arteries. In less than 20% of cases of Takayasu's arteritis, erythema nodosum-like nodules or pyoderma gangrenosum like ulcers may be present. Cutaneous findings, although present in 80% of patients, are nonspecific in Kawasaki's disease, a syndrome associated with coronary artery aneurysms in 12% of affected children. The eruption of Kawasaki's disease is polymorphous, and patients may present with macules, papules, wheals, targetoid plaques, papulovesicles, pustules, or a scarlatiniform eruption most commonly on the abdomen, groin, perineum, and buttocks. There is often desquamation of the fingertips and mucous membrane involvement may include conjunctival injection, dryness of the lips, erythema of the mouth, and prominent tongue papillae (strawberry tongue). Most patients have enlarged cervical lymph nodes and high fever.

Histopathologic evaluation is important for diagnosis and early lesions are most revealing on biopsy. Thus, timely consultation of the dermatology service is important. Along with determining size of vessel disease, microscopic evaluation of tissue vessels distinguishes inflammatory from noninflammatory vessel disease. Furthermore, immunofluorescence studies of sampled tissue may help confirm a diagnosis of IgA vasculitis associated with Henoch-Schonlein purpura.

It is important to consider coagulopathies and other occlusive vascular diseases in the differential diagnosis of vasculitis since the management of noninflammatory vessel disease differs from that of vasculitis. Purpura, livedo reticularis, ulcers, and necrosis are manifestations of coagulopathies such as immune thrombocytopenic purpura (ITP), thrombotic thrombocytopenic purpura (TTP), drug-induced thrombocytopenia, inherited platelet dysfunction, warfarin and heparin necrosis, disseminated intravascular coagulation (DIC), gammopathies, protein C and S deficiencies, and the antiphospholipid syndrome. In bland occlusive disorders in which vessels may be occluded by fibrin, cryoglobulins, or emboli, the purpura may be palpable as in leukocytoclastic vasculitis, so the clinical distinction is not always apparent.

Treatment is directed at the underlying etiology and preventing the progression of inflammation. It is always important to evaluate and treat any underlying cause, whether it is infection, malignancy, or drug. With early intervention, morbidity and mortality from vasculitis may be reduced. For disease limited to the skin, supportive care with rest, leg elevation, and analgesics is usually sufficient. NSAIDs, colchicine, dapsone, or prednisone are helpful for patients with recalcitrant or progressive skin disease. Severe intractable skin disease or involvement of organs other than the skin requires immunosuppressive therapy with high dose prednisone 1 to 2 mg per kg per day, sometimes with steroid sparing support from methotrexate, cyclosporine, azathioprine, or cyclophosphamide [77].

Purpura Fulminans

Purpura fulminans (PF) is characterized by extensive purpura and necrosis of the skin associated with fever, DIC, sepsis, and hypotension. PF is seen mostly in three clinical settings: acute infections, inherited or acquired coagulopathies, and idiopathic. Meningococcemia, in which 3% of cases develop PF, is the most commonly associated infection. Varicella and pneumococcal sepsis are less frequently associated and rare or isolated reports include *H. influenza* [78] and other organisms. Asplenism is a risk factor for infection associated with PF. PF in the newborn period is usually due to an inherited coagulopathy and results in high mortality. PF has also been reported in association with acquired coagulopathies seen in inflammatory bowel disease [79,80]. Idiopathic disease is the mildest variant [81–83].

The pathophysiology of PF depends on the underlying trigger. The common endpoint is that of extensive microvascular thrombosis that affects cutaneous and visceral blood supply. In meningococcemia, endotoxin results in release of cytokines and activation of coagulation pathways, and infection is associated with substantially decreased levels of protein C [81].

Initially in PF, there is pain and erythema in affected areas. Irregular areas of blue–black discoloration develop within the center of erythematous patches, and lesional skin becomes indurated. There is progression to hemorrhagic vesicles and bullae, and finally to tissue necrosis. Lesions associated with infection tend to involve distal parts first and spread proximally, while idiopathic and coagulopathy-associated disease may remain localized to the lower extremities. Idiopathic PF usually affects only the skin; however, other forms may result in widespread necrosis with multiorgan failure. Disease complications include scarring, secondary infection, digital or limb necrosis, and autoamputation [81–83].

Differential diagnosis of PF includes Henoch-Schonlein purpura and post-infectious thrombocytopenic purpura, although these are both associated with milder disease than seen in PF. The presence of DIC helps distinguish PF from other causes of cutaneous necrosis [82].

Early recognition of disease and underlying trigger is essential in this rapidly progressive condition. Appropriate antimicrobials are instituted for infection. Supportive care includes aggressive fluid resuscitation, electrolyte monitoring, and replacement of blood products. If deficient, protein C and antithrombin III may be replaced. Other treatment options include fresh frozen plasma, heparin, plasmapheresis, topical nitroglycerin (for local vasodilation), and recombinant tissue plasminogen activator [82]. Surgical consultation may be necessary for debridement and grafting.

Antiphospholipid Antibody Syndrome

Antiphospholipid antibody syndrome (APS) is characterized by a hypercoagulable state with venous or arterial thrombosis, recurrent fetal loss, thrombocytopenia, and elevated titers of the antiphospholipid antibodies (anticardiolipin antibodies, lupus anticoagulant, anti-β-2 glycoprotein I antibodies). Up to 2% of the normal population exhibits detectable titers of these antibodies and 0.2% have elevated titers. APS may be primary, or it may be seen in conjunction with systemic lupus erythematosus, malignancy, drugs, infection, or hematologic disease [84–86].

Cutaneous manifestations in APS, although highly variable, are common and often the presenting sign of disease. Therefore, recognition of these findings is essential for early diagnosis and prompt evaluation for more extensive disease. Skin lesions are thought to be a direct result of arterial or venous occlusion and subsequent ischemia. The most common finding is livedo reticularis or livedo racemosa, seen in up to 40% of patients, and up to 70% of patients who have systemic lupus. These present as a netlike pattern of dusky erythema often found on the upper or lower extremities; they are thought to be more common in cases with underlying arterial disease and are less often seen in veno-occlusive disease [87]. Other associated findings include cyanotic macules, ecchymoses and purpura, ulcerations of the ears, face, and legs, porcelain-white scars (atrophie blanche) at the ankles, thrombophlebitis, Raynaud's phenomenon, digital ischemia, and gangrene. Any major organ systems can be affected by thrombosis [84–86].

The differential diagnosis of APS includes other disorders with associated livedo reticularis and cutaneous necrosis including vasculitis, warfarin-induced skin necrosis (WISN), cholesterol emboli, and cryoglobulinemia. Similar to other vaso-occlusive disorders, APS shows bland thrombosis of small dermal vessels. APS is distinguished from other noninflammatory vaso-occlusive disorders by the presence of elevated antiphospholipid antibody titers [84,86]. Although cutaneous findings are common, they are not among the diagnostic criteria for APS, which require positive antibodies on two occasions at least 6 weeks apart in addition to a history of vascular thrombosis or pregnancy complications [88].

Both treatment and prophylaxis consist of anticoagulation. Some advocate the use of aspirin in those without a history of thrombosis or with superficial venous thrombosis only. Otherwise, long-term warfarin anticoagulation with an INR goal of 3 to 4 is recommended. Immunosuppressive agents and immunotherapy (plasmapheresis, intravenous immunoglobulin, cyclophosphamide) may help reduce antibody levels, but is likely to rebound once treatment is discontinued [84,86].

Warfarin-Induced Skin Necrosis

Warfarin-induced skin necrosis (WISN) is seen in 0.01% to 0.1% of individuals on warfarin, 3 to 10 days after starting therapy. Women are affected four times more frequently than men, and are most often middle-aged and obese. Three quarters of patients with WISN are being treated for deep venous thrombosis or pulmonary embolism. Atrial fibrillation, valve replacement, and arterial occlusion are disorders in which anticoagulation with warfarin less commonly results in WISN [89].

Although the pathophysiology of WISN is not understood completely, the generally accepted mechanism involves the imbalance between intrinsic procoagulant and anticoagulant factors created early on during warfarin therapy. Due to their short half-lives, anticoagulant protein C and factor VII are depleted before procoagulant factors II, IX, and X, and this results in an initial hypercoagulability that is thought to trigger onset of WISN [89]. Most individuals on warfarin do not experience this complication, and therefore additional risk factors are likely required to induce necrosis. Protein C and S deficiency, activated protein C resistance, Factor V Leiden, antithrombin III deficiency, or prothrombin gene mutations, and heparin-induced thrombocytopenia may be contributory. Protein C deficiency, either inherited or acquired, is a significant risk factor [89], and has been implicated in more than 50% of cases of WISN. High loading doses of warfarin and inadequate overlap with heparin therapy are also thought to increase risk of early WISN. There are rare reports of cases occurring up to years after the onset of warfarin therapy, and delayed-onset WISN may be related to poor compliance with warfarin, broken up courses of interacting medications, or changing liver synthetic function [89].

WISN generally occurs 3 to 10 days after initiation of therapy. Patients experience pressure or pain in the involved area of skin. Poorly demarcated, indurated erythema develops asymmetrically over fatty areas such as the breast, buttock, thighs, and lower abdomen. Induration progresses over 24 to 72 hours to edema with a *peau d'orange* surface, blue–black discoloration, and hemorrhagic bullae. Localized or widespread full thickness skin necrosis ensues. Histology of involved skin shows noninflammatory thrombosis and fibrin deposition in small dermal vessels with necrosis of the dermis and subcutaneous fat [89].

Differential diagnosis of WISN includes necrotizing fasciitis, APS, DIC or purpura fulminans, calciphylaxis, gangrene, embolic disease, cellulitis, and pyoderma gangrenosum. Recent initiation of warfarin should raise suspicion of WISN.

Screening for hypercoagulable states before anticoagulation is neither predictive of WISN risk nor cost-effective. Low initial loading doses and gradual increases in warfarin levels may decrease risk of WISN. WISN is treated by discontinuation of warfarin, administration of FFP and vitamin K to reverse its effects, and anticoagulation with heparin. Small lesions may be treated conservatively. Extensive involvement may necessitate debridement, grafting, and in extreme cases, amputation. Deep tissue necrosis, secondary infection, and multiorgan failure are more likely with more widespread disease. Even with treatment, the mortality rate is 15% within 3 months of onset. Prior episodes of WISN are not predictive of future occurrences. In most patients with WISN, future warfarin therapy may be reinstituted with caution, avoiding loading doses and overlapping with heparin initially [89].

Cryoglobulinemia

Cryoglobulinemia (CG) is characterized by precipitation of immunoglobulins from serum in cold temperatures. It is classified into three subtypes. Type I CG constitutes 5% to 25% of cases and presents with monoclonal immunoglobulinemia. It is associated with underlying hematologic disease such as multiple myeloma or Waldenstrom's macroglobulinemia. Types II and III CG are the mixed cryoglobulinemias. Type II constitutes 40% to 60% of cases and is associated with a mixture of polyclonal and monoclonal immunoglobulins. It generally occurs in patients with persistent viral infections such as hepatitis C and HIV. Type III CG represents 40% to 50% of cases. It is associated with a polyclonal immunoglobulinemia and with connective tissue disorders.

Two distinct syndromes are seen with CG depending on the subtype. In type I disease, monoclonal cryoglobulins result in hyperviscosity of blood, which may manifest on the skin as livedo reticularis or Raynaud's phenomenon. Cryoglobulins precipitate in cold and result in vascular occlusion or immune

complex-mediated vasculitis which may cause digital ischemia and purpura, respectively.

The mixed cryoglobulinemias are seen in association with infectious and inflammatory diseases. These underlying conditions are thought to trigger B cell hyperactivation, which promotes production of cryoglobulins. Meltzer's triad of palpable purpura, arthralgia, and myalgia may be apparent in 25% to 30% of patients. Other findings include fatigue, neuropathy (70% to 80%), and cutaneous vasculitis. The course in these patients fluctuates. Organ systems other than the skin may be involved as well. The kidneys may be affected in any of the three forms. Bone marrow may be involved in Type I disease, while the peripheral nervous system may be affected in Types II and III.

Diagnosis is based on clinical signs and symptoms and elevated serum cryoglobulin levels. Blood samples should be collected into prewarmed vials and maintained at 37 °C to prevent precipitation of cryoglobulins. While involved skin characteristically shows noninflammatory occlusion of dermal vessels by immunoglobulin precipitates, leukocytoclastic vasculitis may be apparent in up to 50% of cases.

Treatment of mild disease is supportive in nature and otherwise focused on any underlying disease process. For more severe disease, options include immunosuppressive agents, plasmapheresis, rituximab, and radiation or chemotherapy to treat associated hematologic malignancy.

Cryoglobulinemia itself does not typically worsen clinical outcomes of associated disease. Morbidity and mortality are attributed to associated diseases, and death is often due to cardiac disease or infection [90].

Embolic Diseases

Embolization of cholesterol or atheromatous material, fat, or tumor may result in striking systemic and cutaneous findings. Cholesterol embolization is typically a result of interventional vascular procedures such as left heart catheterization or angiograms, and can also be associated with cardiac surgery, thrombolysis, and aortic dissection. Less frequently, patients with severe and extensive atherosclerotic disease may experience spontaneous embolization, or emboli triggered by coughing or straining. Showers of cholesterol and atherosclerotic material travel distally and lodge in small arteries of the CNS, lungs, GI tract, kidneys, and skin. Presenting signs and symptoms of embolic disease include mental status changes, pulmonary edema, heme positive stools, and acute renal failure. Cutaneous findings are striking when apparent and include livedo reticularis, a coarse netlike pattern of violaceous erythema evident on the lower extremities and abdomen (Fig. 195.7). The erythema may be more prominent when the patient is standing compared to the supine position. Tender blue discoloration, petechiae, ecchymoses, ulceration, and gangrene of the feet and toes may eventuate. Pedal pulses are generally intact but bruits may be audible over the femoral artery and abdominal aorta. Calf tenderness is variable. Similar findings on the arm and hands may result from aortic embolization to the upper extremities [91–93].

Fat embolization, seen most commonly after fractures of the long bones or following surgical procedures, is a less common source of embolic disease that presents with the classic triad of pulmonary, neurologic, and cutaneous symptoms. It has rarely been reported following liposuction. Petechiae distributed on the upper body (head, neck, chest, and subconjunctiva) are thought to be pathognomonic and are seen about 50% of the time [94]. Emboli from atrial myxoma, a benign cardiac hamartoma, may result in cyanosis, ecchymoses, splinter hemorrhages, and tender violaceous lesions of the digits [95].

FIGURE 195.7. Cholesterol emboli. Purpuric plaques involving the toes represent areas of necrosis. Note the livedoid (reticulated) pattern on the sole of the foot, an earlier sign of vascular occlusion.

The diagnosis of emboli should be highly suspected in any patient with characteristic skin findings, acute onset end-organ failure, and a recent invasive vascular procedure. Biopsy of the affected organ will show occlusion of vessels with needle-shaped clefts representing cholesterol crystals. Skin is the most accessible and easiest tissue to sample. Atrial myxoma is evident on echocardiogram, and sampling of affected skin will demonstrate the embolized myxomatous material. Laboratory parameters such as BUN, creatinine, CBC and ESR, presence of hematuria, and heme positive stools will be reflective of the organs involved. Treatments include surgical removal or bypass of emboli, amputation of gangrenous digits, and anticoagulation if disease is not thrombolytic-induced [92,95].

Calciphylaxis

Calciphylaxis, or calcific uremic arteriolopathy, is a rare but serious disorder involving calcification of cutaneous arteries and resultant tissue necrosis, usually in the setting of end-stage renal disease (ESRD) and dialysis. Other risk factors include hyperparathyroidism, obesity, white race, female sex, liver disease, malignancy, hypercoagulability, and use of corticosteroids or vitamin D [96]. An elevated calcium phosphate product is not a prerequisite for calciphylaxis, nor is there a correlation between the degree of elevation of calcium, phosphate, or parathyroid hormone levels and the likelihood of developing calciphylaxis. Among patients with ESRD, 1% to 4% develop this disorder.

Calciphylaxis presents with the acute onset of intensely painful indurated purpuric to necrotic skin lesions on a background of livedo reticularis, erythematous papules, plaques, and subcutaneous nodules. Lesions are most common on the thighs, buttocks, and lower abdomen, but may even occur on the digits.

The differential diagnosis of calciphylaxis includes vasculitis, warfarin necrosis, atheroemboli, cryoglobulinemia, APS, protein C or S deficiency, polyarteritis nodosa, and disseminated intravascular coagulation. A deep incisional skin biopsy is usually diagnostic. Calcification is seen in the subcutaneous fat, especially in the medial layer of arterioles, associated with endovascular fibrosis, thrombosis, and necrosis of the subcutaneous fat and overlying skin. Vasculitis is not seen. Laboratory studies addressing causes of hypercoagulability can be helpful as can plain radiographs or technetium 99 bone scans showing vascular calcification.

Treatment of calciphylaxis is controversial and no controlled studies have been performed. Most sources recommend normalization of calcium and phosphorus levels using diet, binding agents, low-calcium dialysis, and sometimes parathyroidectomy [97]. Good wound care and pain control are important. Precipitating factors such as intravenous infusions, oral calcium supplements, or corticosteroids should be avoided or discontinued. Recent studies suggest that use of cinacalcet (30 to 60 mg daily) or sodium thiosulfate (25 gm IV given three times weekly after hemodialysis) may be useful [98]. Overall mortality in calciphylaxis is 80% [97].

CONNECTIVE TISSUE DISORDERS

Systemic Lupus Erythematosus (SLE)

Lupus erythematosus may involve the skin in many forms. Patients with the acute form of cutaneous lupus erythematosus are most likely to have systemic disease, which may be encountered in an ICU setting.

Approximately 80% of patients with SLE have cutaneous manifestations that, although they appear in a multitude of ways, are helpful in identifying affected patients. In fact, 4 of the 11 American Rheumatism Association criteria for diagnosing SLE are cutaneous findings (malar rash, photosensitivity, discoid rash, and oral ulceration). The most characteristic eruption is a transient facial erythema involving the malar area and the bridge of the nose that follows sun exposure (Fig. 195.8). The redness, which may be accompanied by edema, lasts between hours and several weeks before resolving without scarring. This "butterfly" rash may be an indicator of internal disease as it may be associated with anti-dsDNA antibody and lupus nephritis [99].

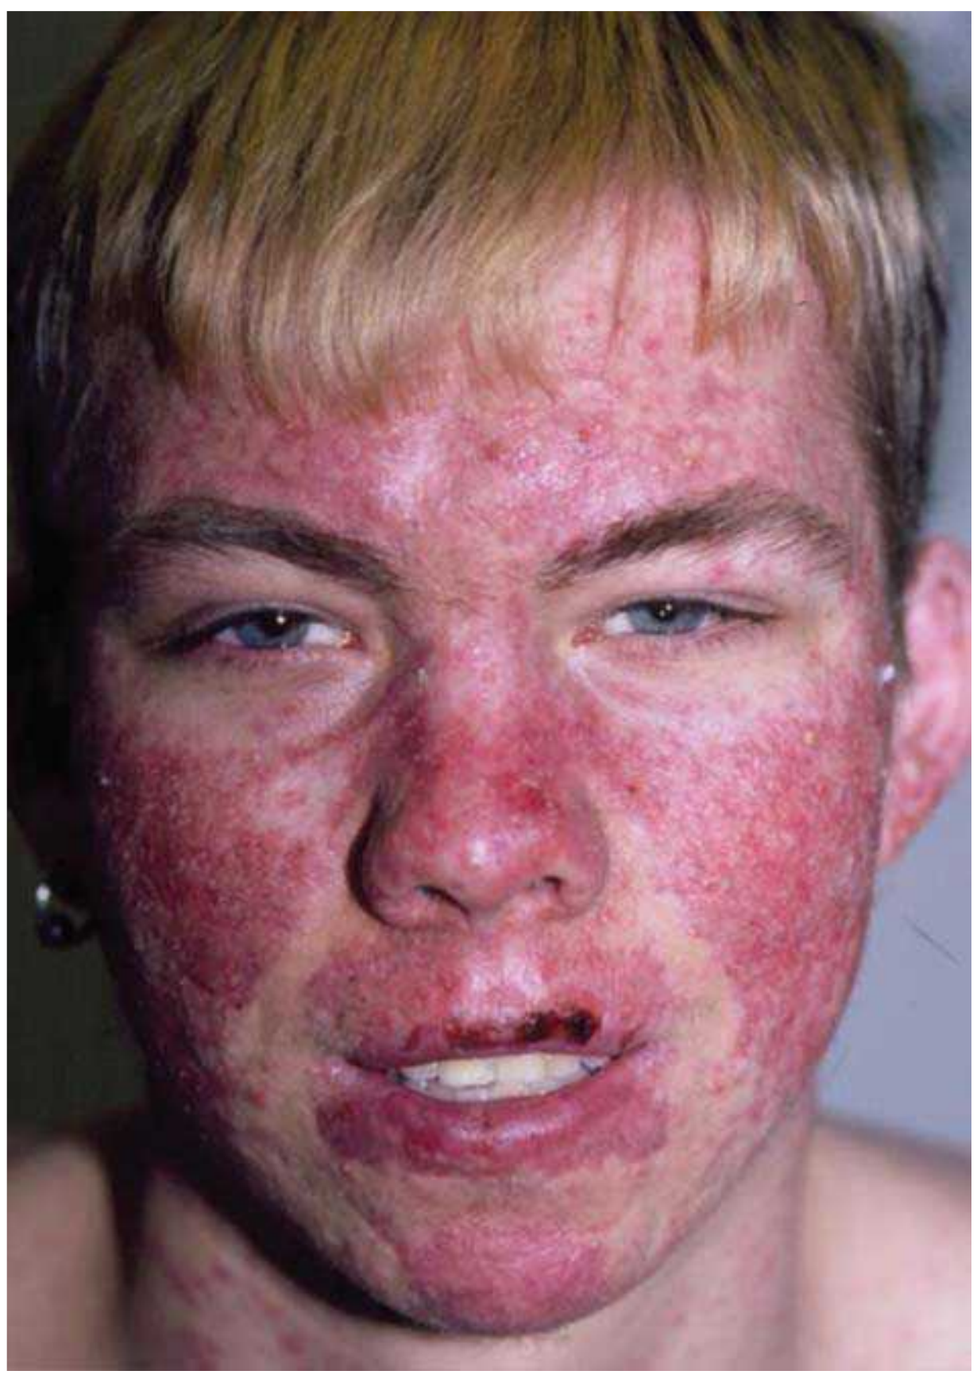

FIGURE 195.8. Cutaneous lupus erythematosus. Marked erythema and telangiectasia involving the malar and other areas of the face.

Erythema and poikiloderma (hyperpigmentation, hypopigmentation, telangiectasia, and atrophy) also occurs over other sun-exposed surfaces such as the V neck area of the chest as well as the back. On the hands, this erythema characteristically spares the knuckles. Tense bullae, also triggered or worsened by sun exposure, may appear in a similar distribution. Mucous membrane lesions occur in about 20% to 30% of patients with SLE. Petechiae or shallow ulcerations may be noted on the hard palate and may accompany malar erythema. Gingival, nasal, and vaginal ulcerations may also be seen.

Scalp hair shedding occurs diffusely and is not associated with scarring. Fragile hairs on the periphery of the scalp break and appear short. Hair shedding may also result from telogen effluvium associated with a chronic illness. Patients with SLE are also more likely to have alopecia areata [99], which typically manifests as oval patches of scalp alopecia.

Vascular lesions, although not specific for SLE, occur in 50% of patients and are highly suggestive of connective tissue disease. The presence of Raynaud's phenomenon, persistent palmar erythema, periungual telangiectasias, purplish plaques over the tips of fingers and toes with cold exposure, and persistent erythema over the palms, soles, elbows, knees, or buttocks should prompt a search for systemic disease.

Vasculitis involving postcapillary venules in the skin manifests as palpable purpura or hemorrhagic wheals. Nodules that ulcerate along the course of arteries reflect deeper, larger vessel involvement. Vascular thrombosis as a consequence of an associated APS causes punched out ulcers that typically appear over malleolar and pretibial surfaces. The presence of livedo reticularis, thrombosis, and cutaneous infarction also warrants consideration of a prothrombotic state.

Less common cutaneous findings in SLE include a symmetric eruption of erythematous papules on the extremities, which demonstrate palisaded granulomatous inflammation with or without vasculitis on light microscopy. Calcinosis cutis, rarely present in SLE, presents as reddish or violaceous firm plaques or nodules on the head, trunk, or extremities.

Other connective tissue diseases should be considered in the differential diagnosis of the acute lupus syndrome. Eruptions of lupus localized to the head and neck may be difficult to differentiate from rosacea, dermatomyositis, drug induced photosensitivity, and sunburn. Drug eruptions or exanthems appear similar when lupus manifests diffusely on the skin.

Treatment of cutaneous lupus is difficult. Strict sun protection along with topical corticosteroids and calcineurin inhibitors are a mainstay of treatment. Antimalarial drugs with or without corticosteroids or steroid-sparing immunosuppressives may be required for systemic or severe skin disease.

Dermatomyositis

Dermatomyositis is a rare disease characterized by a proximal muscle myositis with skin changes. It has a bimodal age distribution and is more common in female and black patients. Initial cutaneous manifestations include swelling of the face and eyelids with a characteristic violaceous erythema. These changes become more widespread with erythema and telangiectasia spreading to the neck and sun-exposed area of the chest, to the back in a shawl distribution, as well as to the scalp, elbows, and knees. These eruptions are usually photosensitive, and pruritus or burning is a common complaint. Gottron's sign, which consists of scaly reddish papules over the knuckle, is considered pathognomonic of dermatomyositis. Hands may take on the appearance of mechanics' hands with hyperpigmentation, scaling, fissuring of the fingertips, ragged cuticles, and enlarged

proximal nail fold capillaries. Intermittent malaise, anorexia, weight loss, and arthralgias are often apparent at this stage. Cutaneous disease usually precedes myositis by months. Juvenile dermatomyositis is relatively rare, and has a better prognosis, but requires aggressive treatment to prevent calcinosis of affected skin. Dermatomyositis may be drug-induced, with hydroxyurea being the most common culprit [100].

Aggressive treatment at this early stage allows for better disease control with lower immunosuppression. Early treatment also reduces the development of disfiguring calcium deposition in the skin and muscle. Initial treatment of skin disease is sunscreen with topical corticosteroids or calcineurin inhibitors, but resistant skin disease may require methotrexate or antimalarials. With evident myositis, therapy requires the use of prednisone (0.5 to 1.5 mg/kg/d tapered slowly over 1 to 2 years) and the addition of a steroid-sparing immunosuppressive such as azathioprine or methotrexate. It is important to also consider the coexistence of other connective tissue diseases such as scleroderma, systemic lupus erythematosus, and rheumatoid arthritis in a patient with dermatomyositis. With appropriate and timely therapy, patients may become disease-free and off therapy within 2 to 4 years. Patients should be surveyed for an occult visceral malignancy which is associated with dermatomyositis in up to 25% of adult cases. Poor prognostic factors include malignancy, older age, initiating therapy after 24 months of muscle weakness, extensive cutaneous lesions, dysphagia, and cardiac or pulmonary issues [101]. A discussion of myositis and systemic disease associated with dermatomyositis is detailed in Chapter 193.

DERMATOLOGIC ISSUES RELATED TO BONE MARROW TRANSPLANTATION

Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) occurs in 30% to 80% of hematopoietic cell transplant recipients and is regarded as the primary cause of morbidity and mortality in these patients [102]. Although it is typically a complication of bone marrow and hematopoietic stem cell transplantations, GVHD may also occur in the setting of unirradiated blood product infusion, solid organ transplantation, and maternal–fetal transfusions [103]. Risk factors for GVHD include unrelated donor, HLA mismatch, older age of recipient, female donor with a male recipient, and suboptimal dosing of immunosuppressive drugs. Patients who develop GVHD appear to be at a reduced risk of recurrence of their malignancy, probably due to graft-versus-leukemia or graft-versus-malignancy reactions.

GVHD can occur when immunologically competent donor T cells are transferred to a host that is incapable of rejecting them. The pathogenesis is incompletely understood, but the mediators include donor CD4+ and CD8+ T cells, NK cells, host dendritic cells, macrophages, major and minor histocompatibility antigens on immune and epithelial cells, and cytokines including TNF-α, and IFN-γ [102].

GVHD can be divided into acute and chronic forms, with the acute form developing within the first 100 days after transplantation and the chronic form developing after about day 100.

Acute GVHD

Acute GVHD occurs in 25% to 40% of patients receiving transplants from HLA matched siblings, and it increases to 60% to 80% with 1 HLA mismatch [103]. There is decreased survival from acute GVHD after allogeneic bone marrow transplant. Acute GVHD is classified into four grades based on the extent of skin involvement, serum bilirubin level, and the amount of diarrhea per 24 hours. Skin findings begin with painful or pruritic erythematous macules on the palms, soles, and ears and evolve into a diffuse morbilliform eruption which is often folliculocentric. In severe cases, there may be progression with bullae formation, erythroderma, and skin necrosis. There have been rare reports of acquired ichthyosis as a manifestation of acute GVHD [104]. The differential diagnosis of acute GVHD includes drug eruptions, viral exanthems, and the eruption of lymphocyte recovery. Mucous membrane lesions may be difficult to distinguish from mucositis caused by chemotherapy.

Histopathology of involved skin classically shows an interface dermatitis and apoptotic keratinocytes. However, the utility of a skin biopsy in diagnosing GVHD is controversial. In a small case series, the presence of eosinophils in biopsy specimens was not a reliable marker favoring drug hypersensitivity reaction over GVHD [105]. In three bone marrow transplant recipients with acute skin eruptions, biopsy led to an initial diagnosis of drug eruption, and immunosuppressive therapy was delayed until additional features of GVHD appeared, resulting in considerable morbidity and two deaths.

Chronic GVHD

Chronic GVHD occurs in 30% to 60% of patients and is more common in hematopoietic stem cell transplants compared to bone marrow transplants [102]. A patient's risk of developing chronic GVHD is 11 times higher with a prior history of acute GVHD, but 20% to 30% of patients can develop chronic GVHD without prior acute GVHD [103].

There are two forms of chronic cutaneous GVHD, lichenoid and sclerodermoid. The lichenoid variant is characterized by erythematous and violaceous papules and plaques, often distributed on flexural surfaces that resemble lichen planus. The sclerodermoid form presents with sclerotic, indurated white to yellow plaques that involve the dermis. The process may extend to fascia and result in significant tightening of skin and joint contractures. Lichen sclerosis and eosinophilic fasciitis can also be presentations of the sclerodermoid variant of chronic GVHD [106]. The oral mucosa is often involved and may demonstrate redness and atrophy of mucosal surfaces, lacy white reticulations of buccal mucosa, and ulcerations. Xerostomia is frequently present as well.

COMMON DERMATOLOGIC CONDITIONS COEXISTING IN ICU PATIENTS

Abscess

A cutaneous abscess is a painful, fluctuant, walled-off collection of pus found within the skin. A furuncle represents an abscess associated with a hair follicle and a carbuncle is a collection of multiple furuncles. Abscesses and furuncles are typically caused by *S. aureus*. Patients may carry *S. aureus* in their nares or have Staphylococcal folliculitis as preceding conditions. The clinical presentation consists of a small red papule that evolves into a tender, erythematous deep-seated nodule that may become fluctuant with time. The surrounding area may be warm to the touch if there is an associated cellulitis. The differential diagnosis includes an inflamed epidermal inclusion cyst and an insect bite. Conservative treatment consists of application of warm wet compresses. Incision and drainage may also be performed with culture of contents. As MRSA is becoming increasingly common, lesions that recur or do not

respond to conservative treatment may necessitate appropriate antibiotic treatment based on culture results.

Folliculitis

Folliculitis is a very common disorder characterized by inflammation or irritation of hair follicles. Although cultures are usually negative, Staphylococci, Pseudomonas, or Malassezia furfur are commonly causative. Herpes virus and dermatophytes are less commonly implicated. Folliculitis presents as papules or pustules on an erythematous base with a centrally extruding hair. The lesions may be pruritic and are most often found on the face, scalp, thighs, axillae, and inguinal area. Pseudomonal folliculitis may be more inflammatory and localized to a distribution that would be covered by a bathing suit. Pityrosporum folliculitis may be localized to the upper back and chest and be extremely pruritic. A follicular papulopustular eruption on the face, chest, and upper back has been associated with EGF-R inhibitors and correlates with a positive response to chemotherapy [107]. Diagnostic tools include a potassium hydroxide preparation, Gram stain, and bacterial, fungal, and viral cultures. Treatment is directed at the underlying etiology. Most cases will respond to appropriate topical and/or oral antibiotics (most commonly anti-staphylococcal). Pityrosporum folliculitis requires topical or oral antifungals and Pseudomonal folliculitis may require fluoroquinolones. The prognosis is generally good, but some patients experience recurrent disease [107].

Steroid Acne

Administration of either topical or systemic corticosteroids can lead to the abrupt appearance of an acneiform eruption. In a prospective study of 51 patients receiving intravenous corticosteroids in the setting of acute spinal cord injury, one subject (2%) developed steroid acne [108]. Lesions of steroid acne are usually monomorphic inflammatory papules and pustules that appear on the chest and back. The eruption resolves within weeks of discontinuing the corticosteroids.

Peripheral Edema

Peripheral edema, which is commonly seen in the elderly and hospitalized patients, occurs when capillary hydrostatic pressure and filtration exceeds the lymphatic drainage rate. Common causes of edema include heart failure, renal failure, nephrotic syndrome, cirrhosis, venous thrombosis, or medications, particularly calcium channel blockers. Acute exacerbations of chronic edema may cause edema blisters which present as asymptomatic, noninflammatory tense vesicles and bullae with clear fluid, usually on the distal lower extremities. Edema blisters can be distinguished from other blistering disorders by clinical history and physical examination. If needed, a biopsy for routine histopathology and immunofluorescence may help exclude other blistering disorders. Acute peripheral edema may also produce local dermal edema, leading to induration of the skin and dimpling, known as *peau d'orange*.

Stasis Dermatitis

Stasis dermatitis occurs in the setting of venous hypertension due to valvular incompetence. Risk factors include conditions that exacerbate lower extremity edema such as obesity, congestive heart failure, cirrhotic liver disease, and chronic renal insufficiency. Typically, there is reddish mottling and a yellowish or brown discoloration of the medial lower legs, corresponding to the location of major communicating veins. There may be an eczematous component as well that often results from contact sensitization to topical medicaments applied to the legs. There are often other signs of venous hypertension, including edema, varicose veins, and venous leg ulcers. Over years, the legs may develop lipodermatosclerosis, which occurs when adipose tissue becomes indurated and adherent to fascia, and lower legs take on the appearance of an inverted wine bottle.

The diagnosis is evident in the right clinical context. However, asteatotic eczema, contact dermatitis, and cellulitis may also be considered in the differential. Relief of itching is attained through the regular application of emollients and the use of class IV or V topical steroids. Long-term management involves improving venous return through various measures such as leg elevation above the level of the heart, elastic compression, and exercises to strengthen calf muscles. Care should be taken to avoid trauma to the leg that would facilitate ulcer formation. In severe cases, ligation of incompetent communicating veins may be necessary.

Pressure Ulcers

Pressure ulcers are areas of ischemic soft tissue necrosis resulting from prolonged pressure, shearing force, or friction anywhere on the body. Sites that are most frequently involved include skin overlying bony prominences of the sacrum, ischial tuberosities, heels, greater trochanters, and lateral malleoli. Nonblanching erythema of skin overlying a bony prominence may signify impending ulceration. Other early indicators include warmth, edema, or induration of skin. Initial ulcers appear punched out. Ulceration may occur as partial thickness skin loss, full thickness skin loss involving subcutaneous tissue, or full thickness skin loss extending to muscle, tendon, or bone. Associated pain may be severe and should be managed aggressively. Treatment involves relief of pressure, which may be accomplished through frequent position changes and supportive surfaces such as air, liquid, or foam cushions. Local wound care includes cleansing with normal saline, debridement, and occlusive hydrocolloid dressings to optimize healing. Operative repair is necessary in some cases. Wounds should be monitored for local infection and treated accordingly. Sepsis and osteomyelitis may further complicate ulceration.

Psoriasis

In its most common form (chronic plaque psoriasis), psoriasis presents as chronic well-demarcated erythematous plaques with adherent silvery scale, most commonly over the elbows, knees, and scalp. In guttate psoriasis, there are smaller psoriatic papules and plaques diffusely over the body, and this is often triggered by streptococcal infections. Sudden onset of pustules that coalesce to form "lakes of pus" at the edges of psoriatic plaques associated with fever typifies the more generalized form of pustular psoriasis (Fig. 195.9). Hypocalcemia and pregnancy may be triggering factors in pustular psoriasis. In erythrodermic psoriasis, there is bright red erythema involving $\geq 90\%$ of the skin. These patients are itchy and also complain of chills from the extensive heat loss due to dilatation of cutaneous vessels. In both pustular and erythrodermic forms, patients are generally toxic and may have associated acute respiratory distress syndrome, congestive heart failure, pneumonia, or viral hepatitis (see "Exfoliative Erythroderma" section).

There is a newly recognized association of psoriasis, particularly severe disease, with increased risk of cardiovascular, cerebrovascular, and peripheral vascular disease [109,110].

FIGURE 195.9. Pustular psoriasis. Large pustules coalescing to form "lakes of pus" over an area of well-demarcated erythema of the palm.

Treatment of routine cases is with topical corticosteroids and the vitamin D derivative, calcipotriene (Dovonex), whereas more severe cases require ultraviolet phototherapy, methotrexate, systemic retinoids, or TNF-α blocking agents.

Atopic Dermatitis

Atopic dermatitis is characterized by eczematous skin changes and typically involves flexor surfaces in adults, although any body area may be involved. Atopic dermatitis, asthma, and hayfever constitute the atopic triad. The disease is most common in young children in whom the tendency for atopic dermatitis is to gradually improve with age; however, in a minority of patients, disease persists into or manifests in adulthood. In the most severe cases, eczematous dermatitis may evolve into erythroderma (see "Exfoliative Erythroderma" section). Other complications of this disease include secondary bacterial infection (impetigo) or herpetic infection, a condition known as eczema herpeticum. Treatment of atopic dermatitis includes topical corticosteroids, emollients, oral antihistamines, antibiotics as needed, and management of coexisting asthma and allergies.

Contact Dermatitis

Contact dermatitis occurs when direct contact with a substance triggers an inflammatory response in the skin. Irritant contact dermatitis, which accounts for 80% of contact cases, occurs when a chemical directly induces damage to the skin. Common irritants include soap, water, and solvents. The remaining cases represent an immunologically mediated, delayed (Type IV) hypersensitivity reaction. Causes of allergic contact dermatitis in hospitalized patients include adhesives, topical medications, frequently topical antibiotics, preservatives, fragrances, metals, and rubber components.

Acute contact dermatitis, whether irritant or allergic in nature, presents with pruritic papules and weepy vesicles on an erythematous base, initially localized to the area of contact. Chronic lesions are erythematous plaques of thickened skin with accentuated skin markings, scale, and occasionally fissuring. The differential diagnosis may vary depending on the location of the eruption, but generally includes atopic dermatitis, seborrheic dermatitis, stasis dermatitis, and tinea.

History and physical examination are usually sufficient to make the diagnosis. Patch testing may be useful in identifying potentially relevant contact allergens. Treatment involves avoidance of the offending agents. For mild to moderate cases, topical steroids and bland emollients are used. For extensive and severe cases, a 2- to 3-week tapering course of oral prednisone, along with an oral antihistamine to relieve pruritus, is appropriate. For lesions that are oozing and crusting, wet-to-dry or aluminum acetate compresses may be helpful.

Seborrheic Dermatitis

Seborrheic dermatitis is a very common, usually asymptomatic, scaly eruption of the oil-gland bearing skin of the scalp, face, and trunk. It may present in mild cases as common dandruff and in severe cases as a florid erythematous scaling eruption involving the scalp, eyebrows, eyelids, paranasal folds, chest, and axillae. Seborrheic dermatitis typically occurs in perfectly healthy individuals, but is usually most severe in immunocompromised patients, such as those infected with HIV, and in patients with neuropsychiatric disorders. An acute severe presentation should prompt testing for HIV. *Malassezia* yeasts are frequently seen at high levels on the skin of patients with seborrheic dermatitis, but their pathogenic role is unclear. Nonetheless, treatment with antifungals is quite effective.

Diagnosis of seborrheic dermatitis is clinical. The differential diagnosis includes psoriasis, tinea capitis, rosacea, and atopic or contact dermatitis.

Treatment is with antidandruff shampoos containing selenium sulfide, zinc pyrithione or ketoconazole, and topical antifungals (ketoconazole cream, etc.) or mild corticosteroids (hydrocortisone cream). If the patient is not bothered by this rash, it need not be treated.

Transient Acantholytic Dermatosis (Grover's Disease)

Transient acantholytic dermatosis (TAD) is a common eruption consisting of discrete variably pruritic red to brown nonfollicular scaly keratotic papules of the upper trunk seen typically in middle-aged white men, more often in the wintertime. TAD is often seen in bedbound patients and is associated with malignancies. Like miliaria, TAD is often associated with heat and excessive sweating; however, its histopathology, clinical appearance, and treatment are different. Lesions of TAD are more keratotic and scaly than those of miliaria, and histopathology reveals epidermal acantholysis rather than spongiosis. TAD may also be confused with folliculitis, which consists of follicular nonscaly papules and pustules. Treatment of TAD consists of mitigation of heat and sweating, application of midstrength topical corticosteroids (such as triamcinolone cream

FIGURE 195.10. Miliaria rubra. Tiny nonfollicular inflammatory papules and pustules.

0.1%) twice daily for up to 2 weeks, topical lotions containing pramoxine or menthol, and oral antihistamines (such as hydroxyzine 10 to 25 mg every 6 hours as needed). In severe cases, oral retinoids such as isotretinoin (0.5 to 1 mg per kg daily) may be used. The condition usually remits slowly over weeks to months but can recur.

Miliaria

Miliaria is a common skin eruption in hospitalized patients, caused by blockage of eccrine sweat ducts that occurs with fever and excessive sweating. It occurs in three main forms: miliaria crystallina, which presents as tiny clear asymptomatic superficial vesicles on the trunk, head, and neck; miliaria rubra, which presents as uniform, small pruritic erythematous papules on the trunk, neck, and flexural extremities (Fig. 195.10); and miliaria profunda, which presents as firm, flesh-colored asymptomatic nonfollicular papules or pustules on the trunk and extremities of patients who have had repeated episodes of miliaria rubra. It is important to be able to recognize miliaria to distinguish it from more medically significant entities such as disseminated herpes simplex, varicella, or candidiasis. The distribution of miliaria in areas where the skin is occluded and where excessive sweating occurs is helpful for the diagnosis. Miliaria crystallina does not need to be treated, as it is self-limited and asymptomatic. Miliaria rubra may be treated by decreasing the heat and humidity of the patient's environment. Some reports state that oral ascorbic acid and topical lanolin can be helpful, but no controlled trials have been done [111].

Tinea Corporis

Tinea corporis is a common, superficial fungal infection found on the skin excluding the palms, soles, scalp, and groin. *Trichophyton rubrum* is the most common causative organism, although any dermatophyte may be responsible. Tinea corporis presents as one or multiple annular lesions with erythematous scaly borders that exhibit centrifugal spread and leave a central clearing. Other clinical presentations include Tinea profunda, which exhibits a granulomatous or verrucous appearance due to an excessive host inflammatory response, and Majocchi's granuloma, which presents as follicular-based pustules or papules. The differential diagnosis includes nummular eczema, subacute cutaneous lupus erythematosus, and granuloma annulare. The diagnosis is easily confirmed by potassium hydroxide examination of scale or fungal cultures. Limited disease may be treated with topical agents such as naftifine 1% cream, terbinafine 1% cream, or clotrimazole 1% cream applied twice daily for 2 to 4 weeks. More extensive or recalcitrant disease may require systemic treatment such as itraconazole 100 mg daily or terbinafine 250 mg daily for 2 weeks. Prognosis is excellent with 70% to 100% cure after treatment, but recurrence is common [112].

Scabies

Scabies is a common, extremely pruritic dermatosis caused by infestation with the mite, *Sarcoptes scabiei*. It spreads from person-to-person through direct skin contact, although it can rarely spread through fomites such as bedding or towels. Scabies should be considered in the differential diagnosis of any patient with severe generalized itching, especially if they have had contact with residential institutions such as nursing homes, where it may be epidemic.

Patients with scabies present with severe generalized pruritus, sparing the head and neck, which is worst at night. The pathognomonic lesions are linear burrows (Fig. 195.11), most often found on the hands and feet, especially in the web spaces. Papules, pustules, vesicles, and nodules may also occur, the last being especially common in children. Scabies has a predilection for the hands, feet, wrists, axillae, abdomen, buttocks, and genitalia. Immunocompromised and neurologically impaired patients may present with the crusted or "Norwegian" variant of scabies, in which the skin is markedly thickened and crusted. These crusts are filled with thousands of mites and the patients are highly infectious.

Definitive diagnosis of scabies is made by observing skin scrapings microscopically for mites, eggs, or mite feces. First line treatment of scabies is with topical 5% permethrin cream applied from neck down and left on overnight, with special attention to the genitalia, web spaces, and under the fingernails. All household members or suspected contacts should be treated simultaneously. All bedding, clothing, and towels are then laundered. The application is repeated after 1 week. When topical treatment is impractical, oral ivermectin may be given as a single dose of 200 µg/kg of body weight, repeated in 1 week. Itching usually resolves within 6 weeks of adequate treatment [113].

CHAPTER 196 ■ VASCULITIS IN THE INTENSIVE CARE UNIT

PAUL F. DELLARIPA AND DONOUGH HOWARD

The vasculitides are a group of disorders characterized by the presence of destructive inflammation in vessel walls [1–4]. The possibility of systemic vasculitis should be considered in a patient with systemic complaints and dysfunction of multiple organ systems, frequently in the context of constitutional symptoms such as fever, malaise, and weight loss (Table 196.1). Patients hospitalized in the intensive care unit (ICU) may present with symptoms related to the clinical features associated with a specific vasculitis but may also present with a known diagnosis of vasculitis and complications of treatment, most notably infection.

Vasculitic syndromes typically are classified by the size of vessel involved. Though there may be overlap in the vessel size, diseases may affect predominately large vessels (Takayasu's arteritis), medium-size arteries (such as polyarteritis nodosa and central nervous system [CNS] vasculitis), and small vessels (Wegener's granulomatosis, microscopic polyangiitis, Churg-Strauss syndrome, cryoglobulinemia, and drug-induced vasculitis). These particular vasculitides will be the focus of this chapter. For a more general discussion of vasculitis, other references are noted [1–4].

Disorders not discussed but that may simulate presentation of vasculitis include embolism due to endocarditis, cardiac myxoma, hypercoagulable states including the antiphospholipid antibody syndrome, hyperviscosity syndromes, chronic ergotism, radiation arteriopathy, and, less commonly, Ehlers–Danlos syndrome, neurofibromatosis, Sweet's syndrome, pseudoxanthoma elasticum, and Köhlmeier–Danlos diseases [5,6].

POLYARTERITIS NODOSA

Polyarteritis nodosa (PAN) is a systemic necrotizing arteritis involving predominately medium-size vessels, although sometimes affecting smaller vessels. Vasculitic lesions characteristically occur at the bifurcations or branches of vessels and are often segmental. Almost any organ can be involved, but frequently the skin, peripheral nerves, kidneys, gastrointestinal (GI) tract, and joints are the principal organs affected [7].

Clinical manifestations vary from mild localized disease to multisystem organ failure. Patients generally complain of malaise, weight loss, fevers, abdominal or lower-extremity pain, myalgias, or arthralgias. Clinical parameters include hypertension and azotemia with proteinuria but rarely glomerulonephritis. Peripheral neuropathy occurs in up to 60% of cases, usually involving a mixed sensorimotor and mononeuritis multiplex [8]. Sudden-onset paresthesias associated with motor deficits are common manifestations. CNS involvement, including seizures, focal events, and altered mental status, are less common [9]. Musculoskeletal symptoms including arthralgias (50%), and less frequently, arthritis can occur [7]. Vasculitis of skeletal muscles may cause severe myalgias, and muscle biopsy can be useful diagnostically [10]. Abdominal pain may have a variety of causes, including intestinal angina, mesenteric thrombosis, and localized gallbladder or liver disease. Acute GI bleeding, perforation, and infarction are rare but are associated with a high mortality if the diagnosis is not established promptly [11]. Cardiac involvement, observed in nearly 60% of autopsy series, is often clinically silent and includes congestive heart failure, pericarditis, myocardial infarctions, and conduction abnormalities [12,13]. Cutaneous lesions include nonspecific palpable purpura, livedo reticularis, tender nodular lesions, digital infarcts, and ulcers [14]. Arteritis of the eye, testes, pancreas, ovaries, breasts, and involvement of the temporal arteries may develop rarely.

The pathogenesis of polyarteritis is unknown. Hepatitis B surface antigen has been found in a minority of patients with PAN. The presence of circulating immune complexes of hepatitis B surface antigen and deposition of surface antigen and immunoglobulin in vessel walls has suggested that immune mechanisms may play a role in some forms of polyarteritis [15,16]. Hepatitis C has rarely been associated with PAN [17]. Pathologically, fibrinoid necrosis and pleomorphic cellular infiltration, predominantly with lymphocytes, macrophages, and varying degrees of polymorphonuclear leukocytes involve the entire wall of small and medium muscular arteries. Thromboses and aneurysms can be found in lesions [18].

The diagnosis of PAN focuses on the most frequent areas of involvement, namely, nerve, skin, and GI systems. Laboratory parameters usually include elevated sedimentation rate, elevated C-reactive protein (CRP), and thrombocytosis. Antineutrophil cytoplasmic antibody (ANCA), antinuclear antibody (ANA), and rheumatoid factor are not typically present in PAN. Mesenteric angiography often shows evidence of aneurysms including the renal, hepatic, and mesenteric arteries, and areas of arterial stenosis alternating with normal or dilated vessels [18]. Sural nerve biopsies are easily accessible sources of nerve tissue when a mononeuritis is present, although the location of biopsy may be guided by electromyography.

Although there is no consensus for treatment of PAN, administration of corticosteroids at 1 mg per kg per day orally is indicated in nearly all cases. In fulminant disease, daily intravenous (IV) methylprednisolone, 1 g per day for 3 days, is reasonable followed by daily oral or intravenous corticosteroids. In the presence of GI involvement, intravenous dosing may need to be continued especially in life-threatening cases. The use of a second drug is guided by the severity of presentation and if there is failure to respond to steroids alone. A severity of illness scoring system (the Five Factor Score) has been developed based on five different parameters, namely, proteinuria more than 1 g per day, azotemia, GI involvement, cardiomyopathy, and CNS involvement. The presence of two or more of these factors portends a mortality of nearly 50% [7]. A review of long-term follow-up of these patients suggests that those with more severe illness as defined with one of the above factors have a higher survival rate when treated with cyclophosphamide [19]. Cyclophosphamide may be given orally, usually 2 mg per kg per day, though adjustment should be made for renal failure (Table 196.2). If the oral route is not feasible, then intravenous dosing of 500 to 1,000 mg per m^2 monthly is

TABLE 196.1

NOTABLE PHYSICAL SIGNS, SYMPTOMS, AND LABORATORY FEATURES OF DIFFERENT VASCULITIC SYNDROMES

Constitutional Symptoms (WG, MPA, CSS, BS, TA, PAN, GCA)	Pulmonary infiltrates/nodules (WG, MPA, CSS)
Sinusitis/epistaxis (WG, MPA, CSS)	Pulmonary hemorrhage (WG, MPA, rarely CSS, BS, Cryo)
Cough, hemoptysis (WG, MPA, CSS, rarely Cryo)	Subglottic stenosis (WG)
Otitis/hearing loss (WG)	Cardiac involvement (CSS, PAN, WG, TA)
Ocular involvement (WG, BS, GCA, TA)	Mononeuritis (WG, PAN, MPA, Cryo)
Cutaneous lesions (WG, PAN, MPA, Cryo, CSS, BS)	Glomerulonephritis (WG, MPA, rarely Cryo)
Claudication (TA, GCA)	Hypertension (PAN, TA)
Arthritis/arthralgia (WG, CSS, MPA, Cryo, PAN)	ANCA positivity (WG, MPA, CSS)
Abdominal pain/GI bleeding (PAN, CSS, BS, MPA)	Angiographic abnormalities (PAN, TA)

ANCA, antineutrophil cytoplasmic antibody; BS, Behcet's syndrome; Cryo, cryoglobulinemia; CSS, Churg-Strauss syndrome; GCA, giant cell arteritis; MPA, microscopic polyangiitis; PAN, polyarteritis nodosa; TA, Takayasu's arteritis; WG, Wegener's granulomatosis.

appropriate (see Table 196.3). Plasmapheresis (PE) in combination with antiviral therapy is indicated in hepatitis B-associated PAN, though PE does not improve outcome in non–hepatitis B virus PAN [29,30].

A variety of drugs, viral infections, connective tissue diseases such as rheumatoid arthritis, and underlying malignancies may cause a necrotizing angiitis that may be indistinguishable from polyarteritis [31–36].

MICROSCOPIC POLYANGIITIS

Microscopic polyangiitis is a necrotizing vasculitis that involves small vessels, including arterioles, capillaries, and venules. As noted previously, cases of microscopic polyangiitis previously classified as part of the PAN classification were distinguished mainly by the presence of segmental necrotizing glomerulonephritis. Clinical presentations may involve concomitant capillaritis with or without alveolar hemorrhage and rapidly progressive glomerulonephritis, the so-called pulmonary renal syndrome, although more indolent and slower presentations have been described. Glomerulonephritis occurs in nearly all cases, and pulmonary involvement ranging from cough and dyspnea to frank hemoptysis occurs in up to 30% of cases. Neuropathy and cutaneous vasculitis occur in up to 50% of cases [14,35,36].

Pathologically, renal lesions show segmental necrosis, minimal immune or pauci-immune deposition, and crescent formation. In the lung, there is edema of the alveolar wall, neutrophilic invasion, type II epithelial cell hyperplasia, and a paucity of immune deposits. These findings may not be histologically different from those found in patients with Wegener's granulomatosis, and clinically the two entities may be difficult to distinguish. ANCA is found in about 75% of cases, mostly specific for myeloperoxidase (MPO), though occasionally ANCA proteinase 3 (PR3) has been described [36].

Diagnosis is typically made with a biopsy of lung, kidney, skin, or nerve in conjunction with a positive ANCA result. Treatment is similar as described for Wegener's granulomatosis, with corticosteroids at 1 mg per kg per day oral or intravenous methylprednisolone, and cyclophosphamide orally or intravenously [36]. Recent studies comparing rituximab with cyclophosphamide therapy for initial remission induction suggest similar efficacy and toxicities, while rituximab maybe more effective for relapsing disease [27,28]. PE may have a role in the treatment of severe renal disease with evidence suggesting a lower reduced frequency of dialysis, but no mortality benefit [21]. There are no prospective data available regarding the efficacy of PE in diffuse alveolar hemorrhage (DAH), although retrospective data suggest a benefit [37]. In the face of DAH and severe respiratory failure in the setting of a systemic vasculitis, PE in addition to corticosteroids and cyclophosphamide is reasonable as long as every effort has been made to exclude infection. In relapsing disease, intravenous immunoglobulin may be of benefit [20].

TABLE 196.2

DOSAGE ADJUSTMENTS OF ORAL CYCLOPHOSPHAMIDE WITH RENAL IMPAIRMENT

Creatinine clearance (mL/min)	Oral cyclophosphamide dose (mg/kg/d)
> 100	2.0
50–99	1.5
25–49	1.2
15–24	1.0
< 15 or on dialysis	0.8

From WGET Research Group: Design of the Wegener's Granulomatosis Etanercept Trial (WGET). *Control Clin Trials* 23(4):450–468, 2002, with permission.

CHURG-STRAUSS SYNDROME

Churg-Strauss syndrome (CSS) is characterized by the presence of eosinophilic infiltrates and granulomas in the respiratory tract and necrotizing vasculitis in the setting of asthma and peripheral eosinophilia. Typically, patients have a preceding history of asthma and allergic rhinitis and then develop constitutional symptoms of fatigue and weight loss followed by systemic symptoms such as mononeuritis, cardiomyopathy, pulmonary infiltrates, or abdominal pain [14]. Pulmonary disease includes fleeting or diffuse infiltrates and nodular lesions,

TABLE 196.3

RANDOMIZED TRIALS IN THE TREATMENT OF VASCULITIS

Study	Types of vasculitis	Study design	Results	Comment
Gayraud et al. [19]	PAN, MPA, CSS	Meta-analysis of randomized trials	Survival benefits of CYC in addition to CS with FFS ≥ 2	Meta-analysis of four different prospective trials; mixed patient population
Jayne et al. [20]	WG, MPA	Prospective double-blinded placebo controlled, using IVIG in patients with persistent disease activity	Reduced disease activity in IVIG treated group	Short-term follow-up (3 mo)
Gaskin and Jayne [21]	WG, MPA all with renal failure	Randomized controlled trial using either plasmapheresis or pulse CS in addition to standard CS/CYC	Lower rate of dialysis dependence in plasmapheresis treated group	1 year follow-up data only
De Groot et al. [22]	WG, MPA	Prospective, randomized, unblinded comparing MTX to CYC in both induction and maintenance of remission in nonrenal AAV	No difference in the number of patients achieving remission, but higher rates of relapse noted in the MTX treated group	MTX may still maintain remission if initial induction is with CYC
Jayne et al. [23]	WG, MPA	Prospective, randomized, unblinded comparing CYC and AZA in remission maintenance	Relapse rate was not significantly different between the two groups; no difference in AEs	Supports standard of care of changing to AZA once remission induced with CYC
WGET [24]	WG	Prospective, randomized, double-blinded, placebo-controlled trial looking at maintenance of remission with the addition of etanercept or placebo to standard treatment	No increase in remission–maintenance noted in the etanercept group; possible increased malignancy rate in the etanercept group	Shows no role for TNF inhibitors in the maintenance of remission
deGroot K et al. [25]	ANCA associated vasculitis	Prospective randomized controlled trial using oral or IV CYC for induction of remission	No difference in time to remission or proportion of patients who achieved remission	Total dose of CYC less in IV group. Study not powered to detect differences in relapse rates amongst the two groups.
Pagnoux C et al. [26]	WG, MP	Prospective, open label, multicenter trial using either methotrexate or azathioprine as maintenance therapy after remission achieved with CYC and CS.	Relapse rates similar in both groups and AE were similar in both groups.	
Jones RB, et al. [27]	WG, MP: nephritis only	Prospective, open label, multicenter, parallel trial comparing RTX to standard intravenous CYC for induction therapy	Sustained remission rates were similar in both groups and adverse events in both groups were similar	12 month follow-up; small number (44 pts) Patients in RTX group also received IV CYC 15 mg/kg with first and third infusions
Stone, et al. [28]	WG, MP	Randomized, double-blinded, double-dummy multicenter trial comparing RTX to oral CYC for induction therapy	RTX is equivalent to oral CTX in remission induction; no difference in adverse events; RTX may be superior to CYC in relapsing disease	6 months follow-up only and data on maintenance of remission with AZA not available yet 197 patients total

AAV, ANCA-associated vasculitis; AEs, adverse events; AZA, azathioprine; CS, corticosteroid; CSS, Churg-Strauss syndrome; CYC, cyclophosphamide; IVIG, intravenous immunoglobulin; MPA, microscopic polyangiitis; MTX, methotrexate; PAN, polyarteritis; RTX, rituximab; TNF, tumor necrosis factor; WG, Wegener's granulomatosis; WGET, Wegener's granulomatosis etanercept trial.

and peripheral infiltrates occur in up to 75% of patients [38]. The diagnosis of eosinophilic pneumonia may be suggested in the context of peripheral infiltrates and peripheral eosinophilia. Rarely alveolar hemorrhage may occur. Peripheral neuropathy occurs in up to 75% of patients with CSS, whereas renal involvement is much less common than in microscopic polyangiitis and Wegener's granulomatosis. Other sources of morbidity and mortality include GI involvement with bleeding and bowel perforation, cardiac involvement causing arrhythmias, myocarditis, pericarditis, and congestive heart failure [38,39]. The etiology of CSS is unknown. ANCA is positive in approximately 38% to 60% of cases, mostly myeloperoxidase [40–42]. As mentioned earlier, the presence of more than one of the five prognostic factors (i.e., proteinuria ≥ 1 g, azotemia, GI involvement, cardiomyopathy, and CNS involvement) has been associated with a higher mortality and should guide the choice of treatment, suggesting corticosteroids as mentioned above for limited disease and addition of cyclophosphamide in the setting of severe disease [19].

CRYOGLOBULINEMIC VASCULITIS

Cryoglobulins are immunoglobulins that precipitate below 37°C. There are three types: Type I, seen in myeloproliferative disorders; type II, or mixed essential cryoglobulins; and type III, mixed polyclonal. Types II and III are most closely associated with hepatitis C infection. Typical involvement includes cutaneous vasculitis, arthritis, and peripheral neuropathy. Abnormal liver enzymes suggest hepatitis C infection; complement levels, especially C4, are decreased [43,44]. Infrequently, cryoglobulinemic vasculitis may be life threatening with severe renal, GI, and pulmonary involvement including alveolar hemorrhage [45,46]. Therapy in severe cases consists of corticosteroids and cyclophosphamide with careful attention to the potential risk of increased hepatitis C replication. In severe cases involving progressive glomerulonephritis, PE or cryofiltration may be of additional benefit [47–49]. The use of rituximab combined with pegylated interferon and ribavirin may be useful in refractory cases [50].

WEGENER'S GRANULOMATOSIS

Wegener's granulomatosis is a disease of unknown etiology characterized by granulomatous vasculitis of the upper and lower respiratory tract, segmental necrotizing glomerulonephritis, and systemic vasculitis of small blood vessels [51]. A subset of patients may have disease isolated to the upper respiratory tract or have less severe organ involvement and are referred to as having "limited" Wegener's granulomatosis. Although the disease may affect individuals of a wide range of ages, the disease most commonly affects persons in their fourth or fifth decades of life with a slight predominance for men over women [52,53]. Patients most frequently require intensive care treatment for severe pneumonitis, glomerulonephritis, stroke, myocardial infarction, multiorgan system dysfunction secondary to necrotizing vasculitis, and infection due to immunosuppression and anatomic abnormalities secondary to the granulomatous inflammation.

The etiology of Wegener's granulomatosis is unknown. Possible infectious etiologic associations with *Staphylococcus aureus* have been proposed but are as yet unproven [54]. ANCA is present in more than 90% of patients with systemic Wegener's granulomatosis, and in 70% to 80% with active limited disease. In Wegener's granulomatosis, the pattern noted on immunofluorescence is C-ANCA or cytoplasmic staining, and the specific antigen in most cases is the PR3 antigen, although in 10% of cases or more, there may be a P-ANCA or perinuclear staining with MPO (myeloperoxidase) as the specific antigen [55]. Correlation of ANCA titers with clinical remission is controversial, with the most recent data suggesting that relapse is unlikely in treated patients with negative titers, whereas those with rising or recurrently positive titers have a higher risk of relapse, although the timing of relapse is not predictable [56,57]. There is also increasing evidence of the pathogenicity of ANCA in the vasculitic component of Wegener's granulomatosis [58].

Pathologically, the vessels involved in Wegener's granulomatosis include small arteries and veins; these vessels are often adjacent to granuloma. The pathology of vasculitis includes fibrinoid necrosis with inflammatory mononuclear cell infiltrates of vessel walls, focal destruction of the elastic lamina, and narrowing or obliteration of vessel lumens. Granulomatous lesions are characterized by areas of central necrosis surrounded by epithelial fibroblasts and scattered multinucleated giant cells [59]. Granulomatous vasculitis may involve the lung, skin, CNS, peripheral nerves, heart, and other organs.

Most patients (approximately 85% to 90%) present with symptoms referable to the upper respiratory tract, including sinusitis, nasal obstruction, rhinitis, otitis, hearing loss, ear pain, gingival inflammation, epistaxis, sore throat, laryngitis, and nasal septal deformity. Fever, in addition to being caused by the underlying disease, may be due to suppurative otitis or *S. aureus* sinusitis [60]. Granulomatous vasculitis of the upper respiratory tract may lead to damage of nasal cartilage, resulting in the "saddle-nose" deformity, sore throat, and oral and nasal mucosal ulcers [61]. In addition, chondritis of the nose or ear may develop [62]. Laryngeal involvement may result in severe narrowing of the upper respiratory tract [63,64]. Approximately 10% of patients present with only nonspecific constitutional symptoms such as arthralgias, myalgias, fever, and weight loss. Unusual manifestations of Wegener's granulomatosis include distinctive punched-out ulcerative skin lesions appearing as pyoderma gangrenosum [65] and painless subcutaneous nodules occurring in approximately 2% to 5%.

Although only one third of patients present with symptomatic lung involvement (including cough, sputum production, dyspnea, chest pain, hemoptysis, and even life-threatening pulmonary hemorrhage), lower respiratory tract disease is found in almost all patients after evaluation. The characteristic chest radiographic findings are multiple, nodular, bilateral cavitary infiltrates, but infiltrates without sharp margins occur more frequently than distinct nodules. Cavitation may occur in distinct nodules and in infiltrates with less-defined borders. Nodules may have thick or thin walls. Infiltrates may involve the lower or upper lobes. In approximately 50% of patients, the infiltrates are bilateral. Infiltrates may be transient [64,66]. Less common chest radiographic abnormalities include paratracheal masses, large cavitary lesions, a miliary pattern, massive pleural effusion, calcified nodule, and masses between the trachea and esophagus [67]. Computed tomography (CT) of the chest may reveal pulmonary lesions not well demonstrated on plain radiographs.

Wegener's granulomatosis may also be associated with inflammation and subsequent scarring/stenosis of the subglottic region, in about 25% of patients [68]. This complication is distinctly more common in younger adult and pediatric populations and may sometimes be difficult to differentiate from relapsing polychondritis where tracheal and subglottic inflammation is the major presenting feature.

Although renal manifestations are often asymptomatic, urinalysis reveals renal involvement in approximately 80% of patients at presentation. The typical renal lesion is segmental necrotizing glomerulonephritis. Functional renal impairment may progress rapidly if appropriate therapy is not instituted promptly [69,70].

The vasculitis of Wegener's granulomatosis may cause a variety of other clinical manifestations, including arthralgias and less commonly arthritis, most frequently affecting the knees [71,72]; perinephric hematoma; renal artery aneurysms;

ureteral obstruction [73]; a variety of cutaneous lesions, including ulcers, papules, vesicles, and subcutaneous nodules [66]; episcleritis; conjunctivitis; scleritis; uveitis; optic nerve vasculitis [74]; mononeuritis multiplex or polyneuritis; cranial nerve dysfunction; meningitis [75]; cerebral infarction [76]; subarachnoid hemorrhage; abdominal pain; intestinal perforation; and diarrhea [77].

Typically, diagnosis is based on the clinical findings of upper and lower respiratory tract noninfectious inflammation [78] with glomerulonephritis and positive anti-PR3 antibodies and rarely MPO antibodies. In cases with more limited involvement or where ANCA titers are negative or show the less typical MPO specificity, tissue diagnosis may be necessary.

Recent advances in the treatment of Wegener's granulomatosis have led to the development of a biphasic approach with an initial remission–induction phase using a combination of cyclophosphamide and corticosteroids for 3 to 6 months followed by a remission–maintenance phase using a less toxic immunosuppressive agent, usually methotrexate or azathioprine, for a further 12 to 24 months [79].

Initial treatment with corticosteroid is generally given as prednisone 1 mg per kg per day orally. In the critically ill ICU patient with severe systemic involvement, pulse corticosteroid with IV methylprednisolone 1 g per day for 3 days is advocated, transitioning to prednisone 1 mg per kg per day orally or its IV equivalent. Prednisone therapy is maintained at 60 mg for 1 month and then weaned to 20 mg over 2 to 3 months and then to zero over 6 months.

Cyclophosphamide can be administered as monthly intravenous boluses or as a daily oral dose. Both approaches have shown similar rates of remission–induction at 6 months, 78% with daily oral treatment versus 89% with monthly IV boluses [25]. However, relapse rates were much higher in the monthly IV group, 52% compared with 18% in the daily oral group. In the clinically ill patient, initial treatment with an IV bolus of cyclophosphamide 500 to 1,000 mg per m^2 body surface area is recommended followed by transitioning to daily oral cyclophosphamide 2 mg per kg 4 weeks later. Oral or intravenous doses need to be adjusted for renal impairment. Table 196.2 outlines renal adjustments in oral cyclophosphamide doses. Table 196.3 outlines a standard protocol for the use of IV cyclophosphamide.

Cyclophosphamide therapy is associated with significant morbidity and with patients or their proxy needs to be counseled prior to consent for treatment. There is overall a 2.4-fold increase in malignancy with 11-fold increase in the risk of leukemia or lymphoma and a significant increased risk of bladder cancer occurring in 1% to 3% of Wegener's granulomatosis patients treated with cyclophosphamide [80]. Hemorrhage cystitis has been reported in 12% to 43% of patients treated for Wegener's granulomatosis. In one NIH study, 57% of women of childbearing years became infertile [80]. Opportunistic infection, particularly with *Pneumocystis jiroveci*, was reported in 6% of patients in initial trials with combination cyclophosphamide and corticosteroids and it is now the standard of care for patients to be prophylactically treated with double strength trimethoprim/sulfamethoxazole, 3 times weekly.

Due to these significant morbidities with cyclophosphamide, two recent randomized trials explore the efficacy and safety of rituximab versus cyclophosphamide (one study with intravenous dosing and the second with oral dosing) as induction therapy for ANCA-associated vasculitis. The results in both studies suggest equivalency in inducing remission but also similar adverse event profile [27,28]. Thus, rituximab represents an alternative in induction therapy for patients with ANCA associated vasculitis. The precise role of rituximab in rapidly progressive vasculitis in the critically ill patient is unknown as this was not the focus of the two prospective trials utilizing this agent.

Once remission has been achieved over the first 3 to 6 months, the aim of ongoing therapy is to maintain remission using a less toxic immunosuppressive agent and monitoring the patient closely for signs of relapse. Typical remission–maintenance agents are methotrexate 15 to 25 mg per week orally or subcutaneously or azathioprine 1.5 mg per kg per day orally. Both drugs have been shown to have similar efficacy and side effect profiles in this setting [26]. Mycophenolate mofetil has also shown promise both in remission induction and maintenance [81].

A prospective placebo controlled trial in the use of the tumor necrosis factor inhibitor etanercept as a remission–maintenance agent showed no added efficacy over standard therapy [24]. Treatment of relapsing disease with rituximab may be more effective than repeat cyclophosphamide [28]. Other treatment considerations include management of concomitant upper and lower respiratory tract infections, which are common and difficult to diagnose when superimposed on inflammatory disease.

As mentioned earlier, Wegener's granulomatosis is specifically associated with subglottic stenosis. Optimal treatment of this is best achieved with localized treatment, with bronchoscopic mechanical dilatation, and transbronchial corticosteroid injection of the involved area [82].

DRUG-INDUCED VASCULITIS

Cases of vasculitis associated with the use of certain drugs, vaccines, and toxins have long been recognized. Previously these were described as hypersensitivity reactions causing small vessel vasculitis [83]. More recent work in drug-induced vasculitis has broadened the group to include a large variety of small- and medium-vessel syndromes. There are no specific pathological or clinical features that distinguish this group from other forms of vasculitis. Cases ranging from self-limiting cutaneous involvement to severe multiorgan failure have been reported. Diagnosis is based simply on the development of vasculitis where a causal drug/agent can be identified, which in most cases leads to resolution of the vasculitis after drug discontinuation. There is great variation in the length of drug exposure before symptoms develop, with many reports of years of exposure before the apparent sudden onset of vasculitis.

The most commonly reported medications causing drug-induced vasculitis include, propylthiouracil, allopurinol, hydralazine, cefaclor, minocycline, d-penicillamine, phenytoin, isotretinoin, and methotrexate with colony stimulating factors [84], quinolone antibiotics, and leukotriene inhibitors more recently added to the list [85]. Other cases have been reported following vaccination, particularly hepatitis B [86] and influenza [87].

The pathophysiology of drug-induced vasculitis appears to be varied. Recently, cases of drug-induced vasculitis have been shown to be associated with temporary production of ANCA antibodies, typically against the MPO antigen and most notable with propylthiouracil and allopurinol [88]. Antibody titers also decrease in these cases following the discontinuation of medication, supporting its causal role [89].

Drug-induced vasculitis can involve medium or small vessels and therefore can present with a variety of clinical features depending on the site and size of vessel involved. Drug-induced vasculitis can present with clinical manifestations similar to any other systemic vasculitis, and there are no clinical findings specific to the syndrome. Skin involvement is common, most commonly in the form of palpable purpura. Although 33% of patients have no symptoms associated with the lesions, 40% complain of burning or pain. Bowel and nervous system involvement is also well recognized along with arthralgias and myalgias. Renal involvement is present in 40% of cases.

Treatment involves the withdrawal of potential causative medications. With mild skin involvement alone, no specific treatment is advocated. Where skin breakdown occurs, skin lesions are very symptomatic, or if internal organ involvement is identified, treatment with corticosteroids is beneficial. In rare cases, particularly those associated with ANCA production, other immunosuppressive agents may be necessary but usually only for short periods of time.

CENTRAL NERVOUS SYSTEM VASCULITIS

CNS vasculitis is a rare condition that can present as a primary form confined to the CNS, known as primary angiitis of the CNS (PACNS) or as a secondary form associated with a systemic vasculitis or other systemic illness. Although many of the systemic vasculitides and rheumatologic diseases can result in CNS involvement and are discussed briefly in other sections, this section focuses on the CNS manifestations of PACNS. Other secondary causes of CNS vasculitis and syndromes mimicking CNS vasculitis include sarcoidosis, antiphospholipid antibody syndrome, lymphoma, atrial myxoma, atheroemboli, reversible vasoconstrictive syndrome, Lyme disease, HIV infection, herpes zoster, tuberculosis, and drugs including cocaine, methamphetamines, ergotamine, pseudoephedrine, and heroin [90].

The clinical presentation associated with PACNS is broad and includes subacute memory loss, acute encephalopathy, and other cognitive and behavioral changes. Seizures, cranial nerve abnormalities, focal deficits involving the cerebrum, cerebellum, and brainstem, spinal cord lesions, meningismus, headache, auditory and vestibular disturbances, intracranial or subarachnoid hemorrhage, and reduced visual acuity or blindness due to retinal and optic nerve vasculitis have been described [91,92]. Frequently, patients have hypertension that aggravates their underlying disease or raises questions about their primary diagnosis. Disease manifestations may develop precipitously but often can present with a long prodrome over months involving subtle mental status changes and cognitive dysfunction [91,92]. The disease has a predilection for the small and medium vessels, especially of the leptomeninges and appears more common in men.

The diagnostic approach to CNS vasculitis includes a careful, frequently repeated neurologic examination, laboratory studies including cultures, viral and bacterial serologies, ANCA, cryoglobulins, antinuclear antibodies, antiphospholipid antibodies, and complement levels, which may help to establish secondary causes of CNS vasculitis related to infections, connective tissue disorders, and systemic vasculitides. CSF abnormalities seen in PACNS, including elevated protein levels and elevated cell counts, mostly lymphocytes, occurs in 80% of patients [92]. Angiographic changes showing alternating areas of stenosis and ectasia are suggestive of the disease but can be seen with other diagnoses including vasospasm and infection. In biopsy proven cases of PACNS, angiography is normal in 40% of cases [92,93]. Magnetic resonance imaging (MRI) can additionally be suggestive of ischemic lesions due to vasculitis if lesions are seen in different vascular distributions, although this finding is not specific for PACNS. A negative MRI and normal CSF make CNS vasculitis less likely, although cases of PACNS have been described with a negative MRI [94,95]. In most cases, unless angiography is highly suggestive in the correct clinical context, pathologic confirmation is necessary. Biopsy of the leptomeninges and other areas guided by previous imaging is necessary to rule out other diagnoses including infection, malignancy, and sarcoidosis, among other diagnoses. In PACNS, the inflammatory infiltrate is predominately mononuclear cells, but neutrophils, plasma cells, and histiocytes are also noted [96].

Treatment of PACNS involves corticosteroids (CS) as the initial treatment of choice, ranging from doses of 1 mg per kg per day orally to 1 g intravenously daily for 3 days followed by oral CS. Cyclophosphamide is used in most cases although absolute recommendations are limited by a lack of prospective trials [97].

There are other vasculitic syndromes that can cause similar presentations, as discussed above, although they typically will present with CNS manifestations in the context of other systemic features such as fever, weight loss, peripheral neuropathy, glomerulonephritis, arthritis, or other organ involvement. PAN, Wegener's granulomatosis, and Churg-Strauss syndrome can all present with CNS involvement including seizure, cranial nerve deficit, cerebral vascular events, and subarachnoid hemorrhage [98–101].

OTHER VASCULITIDES

Takayasu's arteritis is a large vessel vasculitis that affects the aortic arch and branches, affecting mainly women up to the age of 50. Patients typically present with constitutional symptoms of fatigue, weight loss, elevated erythrocyte sedimentation rate, and evidence of limb claudication and bruits. Patients can present with stroke due to inflammation and subsequent stenosis of the extracranial vessels [102]. Behcet's disease is characterized by aphthous stomatitis, genital ulcers, and can sometimes present with vasculitis that can affect various-sized blood vessels. Meningoencephalitis, seizure, intracranial hemorrhage, and cerebral vascular events have been reported [103]. Connective tissue disease such as systemic lupus erythematosus (SLE), rheumatoid arthritis, and Sjögren syndrome can all be associated with a variety of CNS manifestations including stroke, seizure, encephalopathy, and aseptic meningitis [104–106].

CHOLESTEROL EMBOLISM

Cholesterol crystal embolization can produce a clinical picture very similar to that of a systemic vasculitis [107,108] with the gradual onset of peripheral skin lesions, typically blue toe or livedo reticularis [109], with worsening renal function [110]. Bowel ischemia, acute confusional states [111], and retinal embolization may also be present.

The syndrome occurs due to the release of cholesterol crystals from eroded atherosclerotic plaques. It occurs most frequently following percutaneous endovascular interventions [112,113], but spontaneous episodes or those following anticoagulant [114] or thrombolytic therapy [115] have also been reported.

The chronology of impaired renal function after angiography may help distinguish radiocontrast dye-induced renal failure from renal failure due to atheromatous microemboli. Renal failure caused by radiocontrast dye tends to appear soon after the study, reaches maximal severity within 7 to 10 days, and then improves, with renal function returning to baseline over several weeks. In contrast, renal failure due to atheromatous microemboli to the kidney generally develops over 1 to 4 weeks or even over several months after the angiographic procedure and may not be reversible.

To establish the diagnosis of atheromatous emboli, one must have a high degree of suspicion based on the clinical presentation, history, physical findings, and laboratory results. The diagnosis is confirmed by the demonstration on histologic samples of biopsied skin, muscle, and kidney or amputated tissue of the characteristic biconvex needle-shaped clefts representing the "ghosts" of the cholesterol crystals within arteries and arterioles that are dissolved during routine histologic preparation [116]. With special histologic preparation, the cholesterol

crystals display birefringence when viewed with a polarized light microscope.

Treatment of atheromatous emboli consists of controlling pain and blood pressure, and measures to increase local blood flow with topical glyceryl trinitrate (2% Nitrol) ointment, sympathetic blockade, calcium channel blockers to reduce vasospasm, and perhaps pentoxifylline to improve the rheostatic properties of red blood cells. Newer vasodilator agents such as iloprost and phosphodiesterase inhibitors are also being tried [117,118]. There are also case reports of improvements in cholesterol emboli-associated renal disease with statins [119]. Corticosteroid therapy has also been reported to be helpful in several case reports [120]. There are, however, no controlled trials in the use of any of these agents.

A number of modalities are ineffective for the treatment of atheromatous emboli, including the use of antiplatelet drugs and low-molecular-weight dextran. The use of heparin and warfarin is controversial. The general consensus, however, is that these drugs are contraindicated, because by preventing the formation of an organized thrombus over ulcerated atheromatous plaques, anticoagulants may allow continued breakdown and embolization of material [121]. In cases of chronic distal embolization from abdominal aortic aneurysm, surgical repair or endovascular stent-graft repair usually leads to definitive resolution [122].

TREATMENT STRATEGIES IN UNDIFFERENTIATED RHEUMATIC DISEASES PRESENTING WITH CRITICAL ILLNESS AND RELAPSE OR WORSENING KNOWN RHEUMATIC DISEASE

In certain circumstances, patients present to the hospital or ICU with overwhelming respiratory failure or hemodynamic instability without a previously defined rheumatic disorder. For example, patients with undiagnosed SLE or vasculitis may present with respiratory failure, alveolar hemorrhage, and rapidly progressive renal failure but no specific historical clues or previous serologic data supporting any particular diagnosis, and the results of laboratory and tissue evaluation biopsy may not yet be available. In this situation, one cannot be certain whether the underlying process is an immune complex–mediated disease, such as SLE, Goodpasture's syndrome, or cryoglobulinemia, or a pauci-immune process such as Wegener's granulomatosis or microscopic polyangiitis. The appropriate laboratory evaluation would include an ANCA, ANA, anti-glomerular basement membrane antibody, and cryoglobulins prior to initiating therapy. Initial therapy might include PE, which may transiently remove autoantibodies, cytokines, and complement associated with the inflammatory process, in addition to high-dose methylprednisolone, 1 g intravenously per day for 3 days, and then initiation of intravenous or oral cyclophosphamide [123,124]. The benefit of intravenous immunoglobulin in relapsing or life-threatening vasculitis is not well understood due to a paucity of controlled trials [125,126].

In the face of known rheumatic disease treatment failure, caution must be exercised to exclude infectious sources that may mimic worsening of the underlying disease process. Especially in patients on chronic or high-dose corticosteroids and or cyclophosphamide, particular attention must be paid to exclude opportunistic infections such as *P. jiroveci* and fungal infections such as *Aspergillus* while deciding whether disease activity is escalating and becoming unresponsive to therapy. Once infection has been thoroughly excluded, one can consider either higher doses of a standard or novel immunosuppressive agent or addition of other therapies such as immunoglobulin or PE.

Due to the rarity of systemic vasculitis, there have previously been few prospective clinical trials evaluating accepted treatments. In recent years due to establishment of several investigator consortiums, multicenter prospective studies are now beginning to be performed. The more important of these studies are summarized in Table 196.3.

SECTION XVII ■ PSYCHIATRIC ISSUES IN INTENSIVE CARE

JOHN QUERQUES

CHAPTER 197 ■ DIAGNOSIS AND TREATMENT OF AGITATION AND DELIRIUM IN THE INTENSIVE CARE UNIT PATIENT

JASON P. CAPLAN

> . . . patients are attacked with insomnolency, so that the disease is not concocted; they become sorrowful, peevish, and delirious; there are flashes of light in their eyes, and noises in their ears; their extremities are cold, their urine unconcocted; the sputa thin, saltish, tinged with an intense color and smell; sweats about the neck, and anxiety; respiration, interrupted in the expulsion of the air, frequent and very large; expression of the eyelids dreadful; dangerous deliquia [syncope]; tossing of the bed-clothes from the breast; the hands trembling, and sometimes the lower lip agitated. These symptoms, appearing at the commencement, are indicative of strong delirium, and patients so affected generally die, or if they escape, it is with a deposit, hemorrhage from the nose, or the expectoration of thick matter, and not otherwise. Neither do I perceive that physicians are skilled in such things as these; how they ought to know such diseases as are connected with debility, and which are further weakened by abstinence from food, and those aggravated by some other irritation; those by pain, and from the acute nature of the disease, and what affections and various forms thereof our constitution and habit engender, although the knowledge or ignorance of such things brings safety or death to the patient.
>
> *Hippocrates, 400 B.C.*

In *On Regimen in Acute Diseases*, Hippocrates identified agitation as a harbinger of severe illness and poor outcome [1]. His admonition that physicians understand the causes and treatments of agitation remains vital today, for the safety not only of patients but also of hospital staff attending to them. Nowhere is this more pertinent than in the intensive care unit (ICU) and its finely balanced environment of invasive and often delicate treatment modalities, interference with which is rarely as easily corrected as is "tossing of the bed-clothes." The sudden pulling of precisely placed central lines, intraaortic balloon pumps, or endotracheal tubes can carry profound consequences for patients and those responsible for their care.

The term "ICU psychosis" has unfortunately entered common medical parlance in reference to agitation and confusion in the ICU patient [2]. This misnomer is inaccurate for several reasons. Classifying agitation as psychosis is usually diagnostically incorrect; moreover, drawing an etiologic connection between the patient's geography and the development of agitation is nonsensical. Historically, sensory deprivation and interruption of normal sleep patterns alone were thought to result in behavioral disturbances in the ICU, but modern research has not confirmed this relationship [2]. The causal attribution of mental status changes to the environment of the ICU is dangerous because it obviates the need for further diagnostic inquiry that could reveal a previously unidentified pathologic process. As with all new symptoms, careful diagnosis is the first step toward effective treatment.

This chapter reviews the causes, presentations, and treatments of common causes of agitation in the ICU patient, focusing on delirium.

DELIRIUM

Perhaps the most common cause of agitation in the general hospital as a whole, and the ICU in particular, delirium is a neuropsychiatric manifestation of a systemic disturbance (Table 197.1) [3]. As such, the paramount task in its treatment is the identification of its underlying cause(s).

Epidemiology

Prospective studies of all patients admitted to the ICU regardless of pathology have found incidence rates of delirium of 31% on admission [4] and 82% when limited to the population requiring intubation and mechanical ventilation [5].

A diagnosis of delirium exacts a profound toll on both the immediate and long-term well-being of patients and the economic resources required for their care. One study of mechanically ventilated patients in the ICU demonstrated significant increases in length of hospital stay and 6-month mortality, even after adjustment for age, severity of illness, comorbidities, coma, and medication exposure [5]. Another study of patients—limited to those who did not require mechanical ventilation—found that a diagnosis of delirium independently predicted longer hospital stay, even after correction for relevant covariates [6]. When framed in fiscal terms, delirium has been associated with 39% higher ICU costs and 31% higher hospital costs overall [7]. Delirium predicts greater hospital costs across multiple domains, including professional, technical, consultative, and nursing [8].

Disruptive behavior poses a grave risk of acute injury to the delirious ICU patient because of the extensive use of invasive technology in the ICU. This hazard has been specifically studied in patients who extubate themselves. Restlessness and agitation—two of the most frequent concomitants of delirium—independently predict self-extubation, which results in laryngeal and vocal cord trauma, emesis, aspiration, cardiac arrhythmia, respiratory arrest, and death [9].

Etiology

An exhaustive review of conditions that may precipitate delirium would likely cover the breadth of medical and surgical practice. Given the near limitless number of possible etiologies,

TABLE 197.1

DIAGNOSTIC CRITERIA FOR DELIRIUM

Alteration of consciousness and attention
Change in cognition (e.g., memory deficit, disorientation, language or perceptual disturbance) that is not due to dementia
Development over hours to days
Fluctuation during the course of the day
Precipitation by a medical condition or its treatment

when searching for a possible cause of delirium, it often proves useful to scan the clinical data searching for broad categories of pathology. The mnemonic "I WATCH DEATH" (Table 197.2) lists the processes most commonly related to delirium; the mnemonic "WWHHHHIMPS" (Table 197.3) aids recall of immediately life-threatening causes.

With complicated conditions requiring interventions on multiple fronts, patients in the ICU are often subjected to polypharmacy. A review of the patient's medication list with an eye toward certain categories of medications frequently causative of, or contributory to, delirium is warranted (Table 197.4). Particular offenders include anticholinergics, antihistamines, corticosteroids, opioids, and benzodiazepines [10,11].

Pathology

Alertness is subserved by the ascending reticular activating system (RAS) and its bilateral thalamic projections; attention is mediated by neocortical and limbic inputs to this system [12]. Structural or neurochemical interference with these pathways could theoretically result in the deficits in alertness and attention that are the hallmarks of delirium. Because the primary neurotransmitter of the RAS is acetylcholine, the relative deficit of cholinergic reserve in the elderly (e.g., due to microvascular disease or due to atrophy) may be the neural basis of the heightened risk of delirium in the geriatric population. Medications with anticholinergic activity are likely to disrupt this system's functioning even further.

In the setting of impaired oxidative metabolism, dopaminergic neurons have been found to release excess amounts of dopamine; its subsequent reuptake and extracellular metabolism are also disrupted. Because, at high levels, dopamine is theorized to facilitate the excitatory effects of glutamate [13], this dopaminergic hypothesis constitutes a proposed mechanism for the agitation seen in delirium. In fact, oxidative dysfunction predicts increased risk of delirium [14].

Risk Factors and Detection

Risk factors for delirium can be divided into three broad categories: properties of the illness (acute physiologic), preexisting properties of the patient (chronic physiologic), and properties of the environment (iatrogenic) (Table 197.5) [15].

The majority of patients suffering from delirium present with the hypoactive subtype. Withdrawn and psychomotorically retarded, the patient with hypoactive delirium is frequently thought by caretakers and family to be depressed. Although these patients cause little disruption to the ICU environment and provoke less acute distress in their treaters, they are no less subject to the adverse outcomes of an altered sensorium. Although the immediate threat to safety may be less apparent in these cases, hypoactive delirium can rapidly and unpredictably evolve into acute agitation as a result of unchecked, upsetting delusions. Moreover, the subjective experience of hypoactive delirium is as intense and distressing as the agitated variety [16].

Two delirium screening scales have been validated for use by nonpsychiatric personnel in the ICU. The Confusion Assessment Method for the ICU (CAM-ICU) features a four-domain assessment that can be administered in less than 1 minute [17]. Both sensitivity and specificity are >90%, and it has been translated into several languages. The Intensive Care Delirium Screening Checklist (ICDSC) features eight items, each scored present or absent. Sensitivity and specificity of the ICDSC are

TABLE 197.4

COMMON ICU DRUGS ASSOCIATED WITH DELIRIUM

- Antiarrhythmics
  - Disopyramide
  - Lidocaine
  - Mexiletine
  - Procainamide
  - Quinidine
  - Tocainide
- Antibiotics
  - Aminoglycosides
  - Amodiaquine
  - Amphotericin
  - Cephalosporins
  - Fluoroquinolones
  - Gentamicin
  - Isoniazid
  - Metronidazole
  - Rifampin
  - Sulfonamides

99% and 64%, respectively [18]. The minimal time required to complete either of these scales allows for scoring several times daily, which is an important feature, given the waxing and waning nature of delirium. Both scales are available at www.icudelirium.org. Careful screening and early detection can limit the sequelae of delirium and forestall the additional consequences attendant to the evolution of hypoactive delirium into agitation.

Diagnostic Evaluation

In ambiguous cases of delirium, an electroencephalogram (EEG) may provide objective data to aid diagnosis. Although the association of delirium and EEG changes was first described in the 1940s, no objective test since has demonstrated better performance in accurately detecting delirium. In their classic studies, Engel and Romano described three landmark electrographic findings in delirious patients: generalized slowing, consistency of this slowing despite wide-ranging underlying conditions, and resumption of a normal rhythm with treatment [19]. For all presentations of delirium, generalized slowing in the delta-theta range (delta: 0 to 4 Hz, theta: 4 to 8 Hz), poor organization of the background rhythm, and loss of reactive changes to eye opening and closing are considered diagnostic [20]. Recent studies have estimated the sensitivity of EEG in the diagnosis of delirium to be approximately 75%, with false–negative results likely a result of slowing not sizable enough to drop the patient's baseline rhythm from one range to the next.

EEG may also prove helpful in discerning the etiology of a delirium, since delirium tremens (DTs) as a result of alcohol or sedative–hypnotic withdrawal is associated with low-voltage fast activity superimposed on slow waves, while sedative–hypnotic toxicity is associated with fast beta activity (> 12 Hz) [20]. EEG may also detect previously undiagnosed deliriogenic conditions, including nonconvulsive status epilepticus, complex partial seizures, or cerebral lesions that may act as seizure foci.

Once delirium is confirmed, the search for an underlying medical cause should commence. A careful step-by-step approach can help prune a near-endless list of possible etiologies. Although no evidence-based protocol of diagnostic studies most likely to identify a culprit exists, broad-based, relatively inexpensive, and noninvasive laboratory testing can often be informative (Table 197.6).

In most circumstances, psychiatric consultation is beneficial to the patient and the consultee. A consultation psychiatrist's familiarity with delirium and its causes and treatments usually speeds diagnosis and intervention. Delay in psychiatric consultation predicts lengthier hospitalization [21].

Pharmacologic Management

The definitive treatment of delirium is the identification and treatment of the underlying cause(s). In addition, numerous interventions may reduce its potentially harmful sequelae.

Cholinergic Agents

Given the hypocholinergic/hyperdopaminergic neurophysiological model of delirium, the intuitive goals of pharmacologic treatment are to increase cholinergic and decrease dopaminergic activities. By reversibly inhibiting metabolism of acetylcholine, the cholinesterase inhibitor physostigmine has been shown to reverse delirium resulting from multiple etiologies, but its clinical utility is limited by a brief duration of efficacy and a narrow therapeutic window. Therefore, physostigmine is usually used only when delirium is known (or highly suspected) to be caused by anticholinergic toxicity, for which it is considered the agent of choice [22].

Some small studies and case series of dementia-treating cholinesterase inhibitors have demonstrated possible deliriioprotective effects [23,24], but these agents' utility in the acute setting is hampered by their long half-lives and subsequent extended interval before therapeutic serum levels are reached. Two randomized, double-blind, placebo-controlled trials failed to demonstrate any benefit of donepezil in either preventing or treating postoperative delirium [25,26]. An additional randomized, placebo-controlled trial of rivastigmine for delirium prevention also failed to demonstrate any such benefit [27].

TABLE 197.5

RISK FACTORS FOR DELIRIUM

Properties of illness (acute physiologic)	Properties of patient (chronic physiologic)	Properties of environment/treatment (iatrogenic)
Hyper- or hyponatremia	Age > 70 y	Administration of psychoactive medication
Hyper- or hypoglycemia	Transfer from a nursing home	Tube feeding
Hyper- or hypothyroidism	History of depression	Bladder catheter
Hyper- or hypothermia	History of dementia	Rectal catheter
BUN/creatinine ratio ≥ 18	History of stroke	Central venous catheter
Renal failure (creatinine > 2 mg/dL)	History of seizure	Physical restraints
Liver disease (bilirubin > 20 mg/dL)	Alcohol abuse within 1 mo	
Cardiogenic shock	Drug overdose or illicit use within 1 wk	
Septic shock	History of congestive heart failure	
Hypoxia	Human immunodeficiency virus infection	
	Malnutrition

Haloperidol

As dopamine receptor antagonists, neuroleptics are theoretically suited to the task of dampening dopaminergic activity. Through decades of clinical experience and published data, haloperidol, a butyrophenone neuroleptic, has shown itself to be the agent of choice in the treatment of acute delirium [28,29]. It is ideal for use in the ICU since it can be administered by the oral, intramuscular (IM), or intravenous (IV) route. Although the U.S. Food and Drug Administration (FDA) has not approved the IV administration of haloperidol, FDA regulations permit the use of any approved drug for a non-approved indication or by an unsanctioned route in the context of innovative therapy. IV administration is preferable to the oral and IM routes for multiple reasons, including improved absorption; limitation of pain as a consequence of injection; minimization of apprehension on the part of the patient; and reduction in extrapyramidal side effects (EPS), including acute dystonia, parkinsonism, and akathisia [30]. Although there is no standard dosing regimen for the use of IV haloperidol, treatment is usually initiated with a bolus dose ranging from 0.5 mg (in the elderly) to 10 mg (for severe agitation). A 30-minute interval should be observed between doses to gauge the effect of the previously administered dose. If the initial dose does not achieve the desired effect, then the next dose can be effectively doubled until appropriate sedation is achieved (i.e., 1 mg, 2 mg, 5 mg, 10 mg, and so on). Although a randomized, double-blind comparison trial did not support the use of benzodiazepines alone for the management of delirium (except when due to alcohol or sedative–hypnotic withdrawal), IV lorazepam in doses of 1 or 2 mg can be coadministered with haloperidol to achieve more rapid sedation [31]. The combination of haloperidol and lorazepam has been shown to allow for lower total doses of each drug [32] and to minimize EPS further [33].

Complete absence of agitation should be targeted, and the regimen should be adjusted to achieve this goal. Once agitation is effectively quelled, haloperidol can be given 2 or 3 times daily, with additional doses provided as needed for breakthrough agitation. The total dose can be gradually decreased; it is usually wise to wean the evening dose last to provide some prophylaxis of "sundowning."

Side Effects of Haloperidol. As with all pharmacologic interventions, the use of haloperidol is not without risk. Neurologic sequelae—EPS, seizures, neuroleptic malignant syndrome, and tardive dyskinesia—have all been associated with the chronic

use of haloperidol. In practice, however, these are rare and are minimized by IV administration [30]. Of these neurologic symptoms, akathisia is often most problematic in the setting of delirium since the sense of having to be in motion at all times is noxious, tiring, and likely to exacerbate agitation. Treatment with β-blockade is often effective. In clinical practice, haloperidol's reported lowering of the seizure threshold appears negligible [34].

Hypotension, a rare complication, is easily detected by routine monitoring in the ICU. Haloperidol has been shown in some cases to prolong the QT interval, resulting in increased risk for torsade de pointes and possible death [35,36]. An electrocardiogram should be ordered to measure the baseline corrected QT (QTc) interval, and serum potassium, magnesium, and calcium levels should be checked and monitored [28]. Once treatment begins, a QTc > 500 milliseconds or an increase > 25% from baseline may warrant telemetry, cardiologic consultation, and reduction or discontinuation of haloperidol. In these cases, it is advisable to calculate the QTc manually, since the automated reading may overestimate the value and result in the needless interruption of necessary treatment. The minimization of other drugs with the potential to prolong the QTc should also be considered to allow the ongoing effective treatment of delirium. Other antipsychotics, including the newer agents, have also been associated with QT prolongation [37].

Other Dopamine Receptor Antagonists

Droperidol, the other member of the butyrophenone family of neuroleptics, had been used extensively for the treatment of delirium, but its use was constrained by the 2001 FDA-mandated black-box warning regarding QT prolongation, torsade de pointes, and death [38].

Phenothiazines, the other major class of so-called conventional or first-generation neuroleptic medications (e.g., chlorpromazine, fluphenazine, thioridazine, mesoridazine, perphenazine, and trifluoperazine), are poorly suited to the treatment of delirium due to sedation, anticholinergic effects, and α-adrenergic blockade.

With the exception of clozapine, all of the so-called atypical or second-generation neuroleptic agents (i.e., risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole) have been studied in the treatment of delirium [39–42]. Single case reports, case series, retrospective analyses, and open-label studies have found these medications to be safe, well tolerated, and effective.

Quetiapine may have a niche role in the treatment of delirium in patients with Parkinson's disease or Lewy body dementia, since its action at various subtypes of dopamine receptors is less likely to exacerbate these disorders [43]. The strict regulation of clozapine due to the risk of agranulocytosis effectively precludes its use in delirium.

In 2005, the FDA required that a black-box warning be placed on all atypical neuroleptics indicating an increased risk of death when used to treat behavioral problems in elderly patients with dementia and, in 2008, broadened this warning to encompass conventional neuroleptics. In addition, risperidone, olanzapine, and aripiprazole carry warnings regarding a potential increased risk of cerebrovascular events in elderly patients with dementia-related psychosis. The benefits of neuroleptics in treating delirium often outweigh their risks.

Randomized, Controlled Trials of Dopamine Receptor Antagonists in Delirium

To date, there have been five randomized, controlled trials investigating neuroleptics in the management of acute delirium, and two randomized, double-blind, placebo-controlled trials of a neuroleptic for the prophylaxis of delirium (Table 197.7) [31,44–49]. Of the five treatment studies, four demonstrated clinical improvement in delirium with the use of neuroleptics (specifically haloperidol, chlorpromazine, risperidone, olanzapine, and quetiapine). The remaining study by Girard and colleagues used only presence or absence of delirium as a measure

TABLE 197.7

RANDOMIZED, CONTROLLED TRIALS OF NEUROLEPTIC AGENTS IN DELIRIUM

Study	Response examined	Oral agents compared	Total number of patients	Results
Breitbart et al. [31]	Treatment	Haloperidol Chlorpromazine Lorazepam	30	Both neuroleptics significantly improved delirium. No improvement was seen with lorazepam. The lorazepam arm was terminated early due to adverse effects.
Han et al. [44]	Treatment	Haloperidol Risperidone	24	No significant difference was found in efficacy or response rate between haloperidol and risperidone.
Skrobik et al. [45]	Treatment	Haloperidol Olanzapine	73	Clinical improvement was similar for both agents. Haloperidol was associated with extrapyramidal side effects not seen with olanzapine.
Devlin et al. [46]	Treatment	Quetiapine Placebo	36	Scheduled quetiapine resulted in more rapid resolution of delirium, reduced agitation, and improved rates of transfer to home or a rehabilitation facility. Both groups received as-needed intravenous haloperidol.
Girard et al. [47]	Treatment	Haloperidol Ziprasidone Placebo	101	All patients were mechanically ventilated. Neither neuroleptic significantly decreased duration of delirium.
Kalisvaart et al. [48]	Prophylaxis	Haloperidol Placebo	430	Low-dose haloperidol did not reduce the incidence of postoperative delirium. It decreased severity and duration of delirium and length of stay.
Prakanrattana et al. [49]	Prophylaxis	Risperidone Placebo	126	Single-dose risperidone following cardiac surgery significantly reduced the incidence of postoperative delirium.

of clinical status [47]. Since the definitive treatment of delirium requires identification and treatment of the underlying cause, it may not be reasonable to expect that a neuroleptic will completely eradicate all symptoms of a delirium to the point that it is undetectable. Rather, neuroleptics are intended to manage the symptoms of delirium and to reduce the likelihood of further harm to the patient or ICU staff.

Dexmedetomidine

Dexmedetomidine is a selective α_2-adrenergic receptor agonist used as a sedative and analgesic in the ICU. A number of randomized, controlled trials have demonstrated a significantly lower incidence of delirium when ICU patients were sedated with dexmedetomidine compared with midazolam, lorazepam, or propofol [50–52]. An additional study comparing dexmedetomidine with morphine found a comparable incidence but a shorter duration of delirium with dexmedetomidine [53]. A randomized, open-label trial comparing dexmedetomidine infusion with IV haloperidol for the management of delirious intubated patients demonstrated significantly shortened time to extubation and length of ICU stay with dexmedetomidine [54]. Despite the relatively high cost of the drug, two studies have demonstrated it to be cost-effective due to the offset of time spent ventilated, time in the ICU, and the sparing of other expensive sedating agents [52,55].

Prevention

When possible, patient education limits distress from the experience of delirium. If a patient is to undergo a procedure that carries a high risk of delirium, or has multiple risk factors for delirium, preemptively informing the patient of the risk of delirium, describing its clinical course, and emphasizing it may be experientially distressing but that it is not uncommon or permanent have proven helpful in limiting the emotional dysregulation that may lead to behavioral problems later in the course. Similarly, education of the patient's family and reduction of their distress can result in an environment that is more reassuring to the patient and less likely to foment paranoia.

Environmental cues in the ICU can prove invaluable in helping the patient maintain a sense of temporal continuity, thus reducing disorientation. Maintenance of a regular sleep–wake cycle is vital, with lighting cues adjusted to simulate night and day as closely as possible. Noise should be limited at night, although in a busy ICU this may not always be tenable. Televisions should be turned off, and noises from monitors, pumps, and pagers adjusted to a reasonable minimum.

Efforts should be made to orient the patient with a clock, a calendar, and a clearly visible sign indicating the name of the hospital. Measures to increase the familiarity of the milieu with photographs, items from home, and visits from family members can also limit disorientation and distress. Because some patients may be unwilling to report the presence of perceptual disturbances because of fear or shame, frequent reassurance that such phenomena are not a sign of going "crazy" can prevent a frightened patient from acting injudiciously.

One randomized, double-blind, placebo-controlled study examined the use of haloperidol started preoperatively in elderly patients undergoing hip surgery as prophylaxis against postoperative delirium [48]. Results indicated that, while there was no statistically significant decrease in the incidence of delirium, there were significant decreases in severity and duration of delirium and in the length of hospital stay. Another study examined the administration of a single dose of risperidone after cardiac surgery and demonstrated a significant decrease in the incidence of delirium [49].

OTHER CAUSES OF AGITATION

Dementia is a predisposing risk factor for the development of delirium. The demented patient, however, is also at risk of becoming agitated in the ICU as a result of unfamiliar surroundings and possible delusional beliefs. Behavioral measures should be employed to help the patient orient to the milieu. In cases of acute agitation, haloperidol is the treatment of choice; however, in cases of Lewy body dementia, quetiapine is less likely to exacerbate parkinsonian symptoms.

Similarly, the patient with preexisting schizophrenia may have difficulty in understanding and adapting to an ICU stay. Preemptive behavioral measures should be taken to make the ICU as familiar and comfortable as possible.

TABLE 197.8

DIFFERENTIAL DIAGNOSIS OF AGITATION

	Delirium	Dementia	Depression	Schizophrenia
Onset	Acute	Insidious[a]	Variable	Variable
Course	Fluctuating	Progressive[b]	Variable	Variable
Reversibility	Usually	Not usually	Usually	Not usually
Level of consciousness	Impaired	Unimpaired until late stages	Unimpaired	Unimpaired[c]
Attention and memory	Both poor	Poor memory without marked inattention	Attention usually intact, memory intact	Poor attention, memory intact
Hallucinations	Usually visual but can occur in any sensory modality	Visual or auditory	Usually auditory	Usually auditory
Delusions	Fleeting, fragmented, usually persecutory	Paranoid, often fixed	Complex and mood-congruent	Frequent, complex, systematized, and often paranoid

[a]Except when due to strokes, when the onset is acute.
[b]Lewy body dementia often presents with a waxing and waning course imposed on an overall progressive decline. Vascular dementia follows a stepwise pattern, worsening with each successive stroke.
[c]Except when complicated by catatonia.
Adapted from Trzepacz PT, Meagher DJ: Delirium, in Levenson JL (ed): *The American Psychiatric Publishing Textbook of Psychosomatic Medicine.* Washington, DC, American Psychiatric Publishing, 2005, pp 91–130.

Inadequately controlled pain, panic-like anxiety, and a sense of hopelessness resulting from depression can also present with agitation. Anxiety and depression are discussed in Chapters 198 and 199, respectively. Once the trigger for agitation is understood, the appropriate course of treatment is often relatively straightforward. Table 197.8 compares and contrasts several diagnostic traits characteristic of different causes of agitation.

Various substance-withdrawal syndromes may present with agitation and delirium. These often require specific treatment (usually featuring replacement of the dependence-inducing agent and gradual taper) and are covered in Chapter 145.

NONPHARMACOLOGIC TREATMENT OF AGITATION

Despite all efforts to curtail agitated or disruptive behavior, some patients may ultimately require physical intervention to prevent injury to themselves or hospital staff. Interventions range from relatively unobtrusive (e.g., use of mitts to prevent interference with equipment or constant observation to minimize wandering) to more restrictive (e.g., soft limb restraints, Posey vests, four-point locked leather restraints) [28]. Most states and individual institutions have protocols governing the application and documentation of such procedures. Since the application of physical restraints can, in itself, be disquieting to the patient, such intervention should be accompanied by the administration of sedating medication.

LONG-TERM SEQUELAE

Patients diagnosed with delirium are at greater risk for a multitude of neuropsychiatric sequelae long after their discharge from the hospital. Multiple studies have demonstrated increased risk of longstanding cognitive impairment in delirious patients when compared to matched controls [56–58]; one study reported that a diagnosis of delirium resulted in an almost doubled risk of cognitive impairment at 2 years [59]. A review of the available literature by Jackson and colleagues concluded that the presence of delirium (regardless of severity or duration) predicts a greater risk of long-term cognitive impairment, including the development of dementia [60]. Post-traumatic stress disorder (PTSD) has been reported in up to 44% of patients admitted to the ICU [61]. While PTSD may result from the experience of actual physical experiences in the ICU, it has also been reported to occur as the sole result of frightening, hallucinatory, or delusional symptoms experienced in the context of delirium [62]. PTSD is fully discussed in Chapter 198.

CONCLUSION

Agitation in the ICU patient jeopardizes the immediate safety of the patient and may signify a potentially unidentified pathologic process. Delirium is the most frequent cause of agitation and is associated with poorer outcomes across multiple facets of patient care. Careful evaluation of possible causes of delirium is vital, since its only definitive cure is identification and treatment of the responsible underlying condition. Management may involve both pharmacologic and environmental measures, with manipulation of the dopaminergic and cholinergic axes, the primary targets of pharmacologic intervention.

Agitation may also be a symptom of other psychiatric disorders. Preexisting diagnoses of dementia, depression, or psychosis do not rule out the presence of delirium; however, active delirium does rule out the possibility of being able to diagnose a new dementia, depression, or psychosis. Given this level of diagnostic primacy and its manifold associated deleterious sequelae, delirium should be at the cornerstone of any investigation of agitation in the ICU.

CHAPTER 198 ■ DIAGNOSIS AND TREATMENT OF ANXIETY IN THE INTENSIVE CARE UNIT PATIENT

SHELLEY A. HOLMER AND ROBERT M. TIGHE

Anxiety is a normal, adaptive biological response to threat. It occurs when a person feels helpless and apprehensive about an uncertain future due to a perceived inability to predict or control a desired outcome. In contrast, *pathologic anxiety* is normal anxiety run amok. It occurs spontaneously or amid usually benign circumstances, is excessive in intensity or duration, and impairs functioning and behavior. Anxiety manifests in a variety of ways, resulting in physical, affective, behavioral, and cognitive symptoms and signs (Table 198.1).

Patients admitted to the intensive care unit (ICU) commonly experience anxiety in response to pain, invasive procedures, an unfamiliar setting, and the fear of death. In moderation, anxiety

TABLE 198.1

SYMPTOMS AND SIGNS OF ANXIETY

Physical	Behavioral
Tachycardia	Restlessness
Tachypnea	Agitation
Hypertension	Compulsiveness
Diaphoresis	Avoidance
Light-headedness	Noncompliance with diagnostic or therapeutic interventions
Tremulousness	Fidgetiness
Affective	Cognitive
Uneasiness	Apprehension
Edginess	Worry
Nervousness	Fear of emotional or bodily damage
Fright	Denial
Panic	Obsessiveness
Terror	Preoccupation with harm
	Thoughts about death

can promote healthful behaviors, just as pain can lead to protection from future injury. In excess, however, anxiety can complicate diagnosis, interfere with treatment, and contribute to poor outcomes by increasing both morbidity and mortality. Anxiety can complicate the clinical picture, as symptoms and signs of many medical problems overlap with those of anxiety (e.g., chest pain, palpitations, tachycardia, diaphoresis, tremulousness). Overwrought patients may refuse tests or procedures they fear will cause pain or will lead to bad news. Patients with phobias of blood, needles, and confined spaces (e.g., as in computed tomography and magnetic resonance imaging machines) may forego necessary interventions. Pathologic anxiety may contribute to the need for ICU admission in the first place.

This chapter reviews the physiologic concomitants of anxiety, medical causes of anxiety, critical medical conditions particularly affected by anxiety, anxiety disorders specific to the ICU setting, and the treatment of anxiety.

PHYSIOLOGIC EXPRESSIONS OF ANXIETY

The physiologic expressions of anxiety are myriad. By activating the *fight or flight response*, anxiety recruits the entire autonomic nervous system to respond to an unknown enemy. Multiple organ systems—endocrine, gastrointestinal, musculoskeletal, immune, cardiovascular, and respiratory—are involved [1]. Anxiety increases blood levels of cortisol, prolactin, and growth hormone [2]. A disquieted patient has enhanced gastric motility and gastric secretions, vasoconstriction of the splanchnic and cutaneous circulations, and vasodilation of striated muscle groups [3]. Anxiety also has direct effects on the immune system: a reduction in the chemotaxis of lymphocytes and neutrophils, a decrease in the phagocytic ability of neutrophils, and an increase in plasma levels of tumor necrosis factor α and superoxide anion [4]. This suggests a complex physiologic effect of anxiety in the critically ill population.

The organ systems adversely affected by anxiety of most concern to the intensivist are the cardiovascular and respiratory systems. Anxiety affects the cardiovascular system by altering normal autonomic tone, manifested as increases in heart rate, blood pressure, cardiac output, and cardiac irritability [1]. The stress of simply being hospitalized augments urinary excretion of catecholamines, which represents activation of the sympathetic nervous system and contributes to cardiac arrhythmias [5]. In the fight or flight response, augmentation of cardiac output prevents cardiovascular collapse, but, in heart failure and myocardial infarction (MI), excessive cardiac output can be detrimental. Anxiety increases respiratory rate, tidal volume, and airway resistance [6] and can induce hyperventilation and syncope. These data suggest that anxiety, while exacting a psychological toll, also significantly alters cardiorespiratory physiology, especially in the critical care setting.

MEDICAL CAUSES OF ANXIETY

Because failure to identify and treat *organic* (i.e., *medical* or *secondary*) causes of anxiety can result in increased morbidity and mortality, the distinction between organic and *functional* (i.e., *psychiatric* or *primary*) causes is vitally important. The presence of an organic cause is suggested when anxiety occurs autonomously in the absence of an apparent psychologically charged situation or of a discrete physical event (e.g., acute pain or tachyarrhythmia). However, in any given patient, determination of what constitutes an appropriate or sufficient psychological precipitant for anxiety is difficult. Life history, cultural background, and prior behavioral conditioning are often unknown to clinicians in the fast-paced ICU setting. Therefore, when anxiety is present and no clear psychological or medical cause is obvious, a thorough search for an organic cause is indicated.

Anxiety is a symptom of hundreds of medical conditions; Table 198.2 provides a list of conditions common in the ICU. Two syndromes that are particularly difficult to distinguish from primary anxiety are delirium and substance withdrawal.

Delirium

Treating delirious patients solely with anxiolytics (e.g., benzodiazepines) can exacerbate their confusion, so it is important to distinguish delirium from anxiety by doing a brief cognitive examination. In delirium, performance of tasks of attention, orientation, memory, and language is often impaired; rarely does an anxious patient have these deficits. By definition, delirium always has a medical cause; therefore, determination of its cause, rather than simply treating its symptoms, is vital. Recognition and management of delirium are discussed in Chapter 197.

TABLE 198.2

COMMON MEDICAL CAUSES OF ANXIETY

Neurologic	Respiratory
Delirium	Respiratory failure
Substance withdrawal syndromes	Asthma
Complex partial seizures	Hypoxia
Traumatic brain injury	Hyperventilation
Pain	Pneumothorax
	Pulmonary edema
Cardiac	Pulmonary embolism
Acute myocardial infarction	Toxic
Shock	Illicit drug intoxication
Paroxysmal tachycardia	Anticholinergic intoxication
	Prednisone
Metabolic	Isoniazid
Hypoglycemia	Caffeine
Hyperthyroidism	
Pheochromocytoma	
Cushing's syndrome	
Addison's disease	

Substance Withdrawal Syndromes

Because withdrawal from central nervous system depressants (e.g., opioids, benzodiazepines, alcohol) can be life-threatening, it should always be high on the differential diagnosis of anxiety. This diagnosis can be missed because patients either underreport their substance use or are unable to communicate. Patients can also withdraw from sedatives and opioids prescribed during a lengthy period of mechanical ventilation. Recognition and treatment of withdrawal syndromes are discussed in Chapter 145.

SCENARIOS IN WHICH ANXIETY SIGNIFICANTLY AFFECTS OUTCOMES OF MEDICAL ILLNESS

Acute Myocardial Infarction

As heart disease remains the leading cause of mortality in the United States, *acute coronary syndrome* is a common reason for admission to the coronary care unit (CCU). Prevention and treatment have focused on awareness and alteration of traditional risk factors (e.g., hyperlipidemia, hypertension, family history). A developing literature supports consideration of psychosocial factors as well, most frequently, anxiety, depression, and personality traits [7–11].

Anxiety is a frequent occurrence in the CCU, both related to MI itself and as a premorbid condition contributing to the development of MI [12]. In the general hospital, anxiety has been noted to occur in 24% to 31% of patients after MI [13]. The stress of being cared for in an ICU, particularly the relinquishing of control and privacy, in addition to dealing with a potentially life-threatening disease, contribute to anxiety in this setting [9]. Anxiety in the CCU after MI rapidly rises and peaks within the first 12 hours; declines, though persists, during the next 36 hours; and then increases again as patients face transfer out of the CCU and ultimately discharge from the hospital [14]. Physicians and nurses often under-recognize anxiety and underestimate its severity after MI [15]. Anxiolysis should be an early consideration in post-MI patients.

Physiologically, anxiety-disordered patients have decreased heart rate variability, which may result in an alteration in cardiac autonomic tone [16,17], either by heightened sympathetic stimulation or diminished vagal control [7]. Enhanced sympathetic stimulation is associated with arrhythmias [18], and reduced vagal control is linked with impairment in the baroreflex control of the heart; both perturbations are associated with sudden death [19]. These physiologic changes may explain why anxiety—especially phobic anxiety—enhances risk for sudden death [20,21]. In addition, elevated anxiety is associated with poor implementation of important risk-reducing recommendations after MI, particularly stress reduction, greater socialization, smoking cessation, and adherence to carrying supplies [22].

Two groups demonstrated that anxiety, independent of depressive symptoms, was associated with in-hospital complications after acute MI, including recurrent ischemia, reinfarction, congestive heart failure, and ventricular arrhythmias [9,10]. Further trials are required to determine the nature of this relationship; whether the effect of anxiety is "dose"-dependent; and whether effective anxiety treatment improves cardiac outcomes acutely.

Several studies have looked at the correlation between anxiety and post-MI outcomes in the long term. Some [12,23,24], but not all [25–28], prospective trials demonstrated that high levels of anxiety predicted cardiac events (unstable angina, reinfarction) and/or mortality. Meyer et al. [11] showed that anxiety predicted greater mortality in post-MI patients only if left ventricular function was reduced. These reports suggest that the data for hard cardiac endpoints over the long term remain unclear.

Weaning from Mechanical Ventilation

Respiratory failure and consequent need for mechanical ventilation are common causes of admission to the ICU. Nearly three fourths of patients resume spontaneous, unassisted breathing with little difficulty [29]. However, patients who require prolonged mechanical ventilation have longer hospital stays, face higher morbidity and mortality, and require lengthier rehabilitation. Therefore, the goal is to wean patients as soon as possible.

The experience of shortness of breath has been well associated with anxiety and is one of the most commonly reported symptoms in panic disorder. In fact, anxiety and panic have been shown to lead to hyperventilation, which, when performed voluntarily, induces panic attacks and mediates a wide variety of psychosomatic symptoms [6]. Chronic hyperventilation due to anxiety and panic leads to hypocapnia and slowed recovery from changes in respiratory status. The integral connection between anxiety and respiratory physiology suggests anxiety may contribute to respiratory failure.

Given the limitations of communication and easy fatigability in patients with critical illness, the evaluation of anxiety in this setting remains difficult. Nearly 60% of patients on a ventilator may experience moderate levels of anxiety. The highest levels occur in patients intubated for primary respiratory disorders (e.g., chronic obstructive pulmonary disease [COPD]) and in those on prolonged (> 22 days) artificial ventilation, the very groups who are most at risk for difficulty weaning from mechanical ventilation [30].

Although the physiologic measures used to determine readiness to wean from the ventilator are well known and several of them have been studied closely in clinical trials, information about the effect of the patient's psychological state, specifically anxiety, on weaning from the ventilator is scant. Anxiety may cause shortness of breath and a fear of death or abandonment, especially as ventilatory support is withdrawn. This can stimulate the sympathetic nervous system; cause bronchoconstriction; and increase airway resistance, work of breathing, and oxygen demand. This cascade can become a perpetuating cycle of anxiety, muscle fatigue, and thus weaning failure [31].

Anxiety should be considered in all patients during the weaning process, especially those who are intubated for primary respiratory causes and for a prolonged period. Given the paucity of data regarding the effect of anxiety on ventilator weaning, no clear treatment guidelines exist; however, it is well appreciated that weaning should be approached from a multidisciplinary standpoint. Treatment includes pharmacologic, environmental, and educational approaches, and is enhanced when both patient and nursing staff are involved in the decision to wean and in the process of weaning.

Because anxiety and respiratory distress due to fatiguing respiratory muscles can produce similar cardiorespiratory manifestations, it is important to try to distinguish between these two syndromes. Only if one is convinced that anxiety is the cause should one consider pharmacotherapy for anxiety because pharmacotherapy with benzodiazepines can potentially prolong weaning due to central pump fatigue from respiratory depression (see Chapter 60 on Mechanical Ventilation Part III: Discontinuation). Although this class of medications is associated with respiratory depression and altered level of consciousness, benzodiazepines can be quite effective when used judiciously in the correct setting. Neuroleptics are less associated

with respiratory depression and may be more beneficial than benzodiazepines, especially for patients whose weaning failure is due to fear or to delirious agitation.

More recent evidence suggests a role for dexmedetomidine, an α_2-adrenergic receptor agonist, which causes a rapid onset of sedation and analgesia but not respiratory depression [32–34]. The lack of respiratory-depressant effects allows patients to be extubated while remaining on dexmedetomidine, whereas benzodiazepines require discontinuation or reduction prior to extubation. Though not specifically studied in anxious patients, dexmedetomidine demonstrates adequate sedation and decreased time on the ventilator, suggesting that it may be a useful agent in the anxious patient attempting to wean from the ventilator.

Nursing support is critical in successful weaning. Staffing should remain as consistent as possible with an individual patient, and during active weaning, a 1:1 nurse-to-patient ratio should be maintained. Weaning is more successful when patients are aware of their environment and engaged in discussions of the plan and process of weaning. Patients should be told and reminded that weaning without extubation does not represent a failure but is part of the process. Music therapy has been associated with decreased anxiety levels in ICU patients and may facilitate weaning [35].

Asthma

Up to 8.9% of adults in the United States have been diagnosed with asthma; of those, 3.4% have experienced an episode in the preceding 12 months [34]. In a multicenter study in 2000, 10% of 29,430 admissions for asthma were to the ICU and 2.1% of these patients were intubated [36]. Despite the advent of inhaled corticosteroids in 1972, there continues to be a population of patients with brittle or near-fatal asthma that follows a poor clinical course even with aggressive use of anti-inflammatory agents. This has re-heightened attention to psychological factors (e.g., anxiety, depression, and denial) as a possible focus of intervention in these patients.

Anxiety has a strong association with asthma, particularly in severe cases admitted to the hospital. Anxiety-spectrum disorders have been identified among individuals suffering near-fatal asthma attacks, and patients who deny the disease process are more likely to develop near-fatal asthma attacks [37,38]. A prospective study of children with asthma identified a relationship between stressful life events and new asthma attacks both immediately and 5 to 7 weeks after a stressful event [39]. Despite this, there appears to be no difference in anxiety or other psychological parameters in adults with severe, life-threatening asthma compared to asthma patients requiring hospital admission [40]. Due to the retrospective reporting in many of these studies, however, a causal relationship between anxiety and asthma cannot be confirmed; moreover, whether the association is due to a direct physiologic impact on airway resistance or reflects a comorbid disease process is not known [41]. Despite the lack of answers, it is clear that asthmatic patients suffer from higher rates of anxiety. For this reason, anxiolysis in ICU patients admitted for asthma exacerbations may need to be considered.

ANXIETY DISORDERS SPECIFIC TO THE INTENSIVE CARE UNIT

Patients with a variety of anxiety disorders present to the ICU. Symptoms associated with these conditions can be exacerbated by the acute medical or surgical problem that led to the ICU admission. In addition, medications used to treat a preexisting anxiety disorder may be discontinued on admission, or their bioavailability may be altered by interactions with newly prescribed medications. Both discontinuation and pharmacokinetic changes may significantly worsen preexisting primary anxiety disorders. In addition to exacerbating established psychiatric illnesses, the experience of the ICU can lead to new, longstanding anxiety disorders [42]. Anxiety disorders particularly relevant in the ICU include acute stress disorder (ASD), posttraumatic stress disorder (PTSD), and panic disorder.

Acute and Posttraumatic Stress Disorders

The experience of treatment in the ICU—which includes frightening confusion, painful invasive procedures, and fear of death—can be traumatic for many patients. Often, especially in the surgical ICU, patients are admitted due to a traumatic event (e.g., motor vehicle accident, severe burn, and assault). These circumstances predispose patients to the development of ASD and PTSD.

Diagnosis of both ASD and PTSD requires clinically significant distress following an experience of threatened death or serious injury, which engenders intense fear, helplessness, or horror in the traumatized person. That event is then re-experienced through dreams, intrusive memories, flashbacks, or intense distress when exposed to reminders of the event. Other characteristic symptoms include emotional numbing, anhedonia, amnesia, restricted affect, and symptoms of autonomic arousal (e.g., irritability, hypervigilance, and exaggerated startle response). For a diagnosis of ASD, these symptoms must occur within the first month after the trauma; if symptoms persist beyond 1 month, a diagnosis of PTSD should be considered.

Some patients develop syndromes consistent with both ASD and PTSD consequent to events that occur in the ICU. The prevalence of PTSD in ICU patients has been widely studied. A systematic review of the literature found the median point prevalence of clinically significant PTSD symptoms to be 22% (range 8% to 51%), significantly higher than the 3.5% prevalence of PTSD in the general population [43,44]. The risk of developing ASD and PTSD is presumed to be even higher in patients who are admitted to the ICU after a trauma.

There is a burgeoning literature about the prevention of PTSD related to critical care. Several studies have attempted to identify risk factors for developing ICU-related PTSD; the most robust risks are: preexisting anxiety and depression, greater ICU benzodiazepine administration, and memories of in-ICU frightening experiences, nightmares, and delusions [43]. The positive correlation between benzodiazepines and PTSD symptoms may be due to the need for higher doses of these medications in patients with preexisting psychiatric conditions. However, benzodiazepines are likely an independent risk factor for PTSD because they often result in delirium and prolonged sedation, both of which may spawn frightening agitation and delusions and necessitate physical restraint. When patients with ICU-associated PTSD report the content of their intrusive memories and nightmares, they are commonly false memories laid down during periods of delirium or sedation. These false memories fill in memory gaps such that true memories of the ICU stay become interwoven with fragments of dreams, delusions, and hallucinations [45]. Isoflurane may have an advantage over midazolam for sedation in reducing memories of delusions and hallucinations [46]. Studies indicate that false memories of the ICU stay are correlated with higher rates of PTSD and worse health-related quality of life [47–49]. Therefore, interventions that target delirium, disorientation, and faulty reality testing may prevent the development of PTSD. Though the provision of a self-help rehabilitation manual did not reduce anxiety or PTSD symptoms compared to usual care, patients who read a daily-event log recorded for them during their critical care

TABLE 198.3

SYMPTOMS OF A PANIC ATTACK

Neurologic	Respiratory
Feeling dizzy, unsteady, light-headed, or faint	Dyspnea
Feeling unreal or detached from oneself	Sensation of smothering
Fear of losing control, going crazy, or dying	Feeling of choking
Paresthesias	Gastrointestinal
Cardiovascular	Nausea
Palpitations	Abdominal distress
Pounding heart	Miscellaneous
Tachycardia	Diaphoresis

admission had less anxiety compared to patients who did not read such a diary [50,51].

Even in the absence of delirium, prolonged sedation may contribute to the development of PTSD. Studies comparing daily sedation withdrawal to continuous sedation and light versus deep sedation showed fewer PTSD symptoms with sedation withdrawal and light sedation [52,53].

Studies of psychopharmacologic intervention for the prevention of PTSD have yielded mixed results. Several studies have demonstrated a decrease in the prevalence of PTSD in critically ill patients treated with stress doses of corticosteroids, which are thought to have an effect on traumatic-memory retrieval [54–57]. There is also evidence that treatment with β-receptor antagonists may protect against the development of PTSD, perhaps by blocking catecholamines, which enhance memory of emotionally arousing experiences [58–61]. However, this benefit was not seen in a randomized, controlled trial of critically ill patients [62]. Further research is necessary before prophylactic treatment with either corticosteroids or β-blockers becomes a standard intervention.

In the ICU, acute trauma should be treated with supportive reassurance and symptom-targeted medications. Clinicians should identify and treat delirium, make efforts to reduce unnecessary sedation, and help orient patients to what is happening around them. A recent study identified other modifiable predictors of PTSD: memories about pain, lack of control, and inability to express needs [63]. These can be addressed with appropriate pain assessment and management, allowing patients more choices in their care, and helping patients to communicate (e.g., using Passy-Muir valves in tracheostomized patients). Psychiatric consultation can be useful for both acute management and recommendations for outpatient treatment, especially in patients with preexisting psychiatric illnesses.

Panic Disorder

Panic disorder is one of the most common psychiatric disorders in patients who are high users of medical services. The risk for development of panic disorder is higher in patients with mitral valve prolapse, asthma, COPD, and migraine [64]. As defined

TABLE 198.4

SOME INTRAVENOUS MEDICATIONS FOR THE TREATMENT OF ANXIETY

Drug	Typical dose	Onset (min)	Drug interactions	Side effects
Lorazepam	0.04 mg/kg	5–15	Fewer drug interactions than other benzodiazepines	Respiratory depression, mixed in propylene glycol solution, venous irritation
Diazepam	0.1–0.2 mg/kg	1–3	Effects increased by cimetidine, erythromycin, isoniazid, ketoconazole, metoprolol, propranolol, valproate Effects decreased by rifampin and theophylline	Respiratory depression, mixed in propylene glycol solution, venous irritation
Midazolam	0.025–0.35 mg/kg	1–3	Same as diazepam	Respiratory depression, accumulates with prolonged (> 48 h) use, excessive sedation
Propofol	0.25–1 mg/kg (loading dose) then 1–6 mg/kg (continuous infusion)	< 1	Minimal	Respiratory depression, vasodilation particularly with bolus dosing and in hemodynamically unstable patients
Haloperidol	1–5 mg	20–30	Effects decreased by rifampin Medications that widen QT interval	QT interval prolongation, neuroleptic malignant syndrome, EPS (less with IV than with oral use)
Dexmedetomidine	Initial recommended dose: 0.8 μg/kg/h titrated to a dose between 0.2 and 1.4 μg/kg/h	6	Minimal but has the potential to augment bradycardia induced by vagal stimuli or negative chronotropic drugs and may increase the effects of vasodilators	Hypotension, bradycardia

EPS, extrapyramidal symptoms; IV, intravenous.
Adapted from Marino PL (ed): *The ICU Book*. 2nd ed. Baltimore, Lippincott Williams & Wilkins, 1998; and Eisendrath SJ, Shim JJ: Management of psychiatric problems in critically ill patients. *Am J Med* 119:22, 2006.

by the *Diagnostic and Statistical Manual of Mental Disorders* [65], a panic attack is a discrete period of fear or discomfort that develops suddenly, reaches a peak within 10 minutes, and is associated with the symptoms listed in Table 198.3. Panic disorder consists of recurrent panic attacks accompanied by persistent fear of having additional attacks, worry about the implications and consequences of the episodes, and a significant change in behavior related to the attacks. Many panic-disordered patients are hypervigilant to internal bodily stimuli, and some fear that their attacks indicate the presence of an undiagnosed, life-threatening illness. These concerns are assuaged only when the panic disorder is accurately diagnosed and effectively treated.

Risks for developing panic attacks include separation, disruption of important relationships, and medical illness—all endemic in the ICU. Timely diagnosis and treatment of panic disorder can circumvent unnecessary medical procedures and decrease morbidity and mortality. Additionally, the physiologic consequences of panic may exacerbate symptoms of preexisting medical conditions and lead to more frequent medical hospitalizations. However, because its presentation is similar to that of several medical conditions (e.g., MI, stroke, gastrointestinal conditions, respiratory compromise), especially in the ICU, panic disorder must be considered a diagnosis of exclusion. Treatment for panic disorder includes psychotherapy and medication. Cognitive-behavioral techniques (e.g., psychoeducation, anxiety management skills, cognitive reframing, and exposure to somatic cues) have been well studied. Benzodiazepines and antidepressants—specifically the selective serotonin reuptake inhibitors (SSRIs)—are the standard of care for the psychopharmacological management of panic disorder.

TREATMENT OF ANXIETY IN THE INTENSIVE CARE UNIT

Treatments for anxiety in the ICU include both nonpharmacologic and pharmacologic options. Additionally, the stress placed on medical and nursing staff attending to anxious patients in an emotionally charged treatment setting must be acknowledged and addressed to improve the overall care of anxious patients in the ICU. This topic is reviewed in Chapter 202.

Nonpharmacologic methods that have been explored include education, environmental manipulation, muscle relaxation, and music therapy. The data supporting these practices are limited and equivocal. Nonetheless, these therapeutic modalities have been useful in clinical practice.

TABLE 198.5

RANDOMIZED TRIALS OF ANXIETY TREATMENTS IN CRITICALLY ILL PATIENTS

Study	Enrollment	Intervention	Results
Sackey et al. [46]	40 mechanically ventilated ICU patients	Isoflurane vs. midazolam	Trend toward fewer memories of delusions/hallucinations in the isoflurane group. No differences between groups in memories of feelings or factual events or in anxiety, depression, and well-being scores.
Jones et al. [50]	126 ICU patients	Self-help rehabilitation manual vs. routine follow-up	Trend toward a lower rate of depression in intervention group. No differences in anxiety and PTSD symptoms between groups.
Knowles et al. [51]	36 ICU patients	Prospective diary reviewed postdischarge vs. standard of care	Improvement in both depression and anxiety symptoms in experimental group.
Kress et al. [52]	32 mechanically ventilated ICU patients	Daily sedation withdrawal vs. continuous sedation	Fewer PTSD symptoms in daily sedation withdrawal group.
Treggiari et al. [53]	137 mechanically ventilated ICU patients	Light vs. deep sedation	Fewer symptoms in the light sedation group at 4 weeks. No differences in anxiety and depression between groups.
Schelling et al. [55]	91 patients undergoing cardiac surgery, 48 followed up in 6 months	High-dose corticosteroids perioperatively vs. standard care	Reduced PTSD symptoms in the steroid group. No difference in traumatic memories between groups.
Weis et al. [56]	36 patients undergoing cardiac surgery	Stress-dose hydrocortisone vs. placebo	Reduced incidence of chronic stress symptoms and better health-related QoL in steroid group. No difference in traumatic memories between groups.
Schelling et al. [57]	20 patients with septic shock	Stress-dose hydrocortisone vs. placebo	Lower incidence of PTSD in intervention group. No difference in traumatic memories between groups.
Stein et al. [62]	48 patients admitted to a surgical trauma center	Propranolol vs. gabapentin vs. placebo	No differences in PTSD symptoms, depression, or ASD at 1, 4, and 8 months after injury.
Ziemann et al. [66]	41 CAD patients admitted to a CCU	Individualized contact with nurse vs. usual care	Significantly less anxiety, depression, and hostility in the experimental group.
Corbett et al. [67]	89 mechanically ventilated patients after nonemergent CABG	Propofol vs. dexmedetomidine	No differences in pain, anxiety, and sleep/rest between groups.

ASD, acute stress disorder; CABG, coronary artery bypass grafting; CAD, coronary artery disease; CCU, coronary care unit; ICU, intensive care unit; PTSD, posttraumatic stress disorder; QoL, quality of life.

Patients should be made aware of their clinical situation and oriented to their environment. Provision of ambient light, a clock, and a calendar promotes accurate orientation and a normal sleep–wake cycle. In addition, to foster a sense of control and mastery of their situation, patients should be made an integral part of decision-making. In a randomized, controlled trial of 41 CCU patients, those who were given choices about family visits, daily hygiene schedule, physical activity, and their room environment enjoyed significant improvement in anxiety and depression measures after 48 hours [66]. Muscle relaxation has been used with some success in weaning patients from ventilators. In limited studies, relaxed, nonpercussion music decreased anxious symptoms and associated physiologic measures. These methods should be considered adjunctive to pharmacotherapy and may help reduce the need for medications.

Benzodiazepines represent the standard for anxiolysis in the ICU; of these, lorazepam is the most widely used. Available in an intravenous formulation, it undergoes little hepatic metabolism, has no active metabolites, and is more appropriate for use in patients with liver disease or with poor liver function. Lorazepam is also useful for long-term sedation in ventilated patients as it is not associated with heart block (as is propofol) or with wide body storage (as is midazolam). However, lorazepam is mixed with propylene glycol, and prolonged use of high doses can precipitate an osmolar-gap acidosis.

Another agent of recent interest and increasingly used in the ICU is dexmedetomidine, which inhibits the central and peripheral effects of norepinephrine and epinephrine, resulting in sedation and analgesia. While dexmedetomidine may cause bradycardia and hypotension, trial data suggest that clinically significant adverse hemodynamic changes are rare [33,34]. Dexmedetomidine and propofol performed equally in pain and anxiety reduction and sleep/rest promotion [67].

Other agents that may prove useful in the anxious patient are SSRIs, neuroleptic agents, and propofol. SSRIs have been shown to decrease the sense of dyspnea in anxious patients with COPD [68]. Neuroleptics are beneficial in patients who are fearful, delirious, or so anxious that they are nearly psychotic [69]. Use of neuroleptic agents is discussed in Chapter 197. Propofol continues to be the most commonly used medication for sedation in the ICU but is impractical for routine anxiolysis given its significant respiratory-depressant effects [70]. Table 198.4 contrasts various agents commonly used to quell anxiety in critically ill patients. Table 198.5 presents a summary of randomized trials of anxiety treatments in critically ill patients.

CONCLUSION

Ubiquitous in the ICU, anxiety has a broad range of physiologic and psychological consequences. Although it can be difficult to diagnose in the acutely ill, current evidence suggests that identification and treatment of anxiety enhance patient comfort and compliance and improve morbidity and mortality. Therefore, anxiety should be routinely assessed in critically ill patients. Psychiatric consultation should be considered whenever anxiety complicates the clinical course.

CHAPTER 199 ■ DIAGNOSIS AND TREATMENT OF DEPRESSION IN THE INTENSIVE CARE UNIT PATIENT

EDITH S. GERINGER, JOHN QUERQUES, MEGHAN S. KOLODZIEJ, TUESDAY E. BURNS AND THEODORE A. STERN

Intense emotions are evoked routinely in intensive care units (ICUs), where life-and-death decisions occur daily. In the ICU, depression can be a psychological reaction to an acute medical illness, a manifestation of a primary affective disorder, a mood disorder associated with a specific organic disease or its treatment, or a result of the confusing overlap of somatic symptoms of depression and symptoms of medical illnesses.

In this chapter, the term depression refers not to being transiently sad, discouraged, disappointed, despondent, or grief-stricken but refers to major depressive disorder (MDD), defined in the 4th edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) [1] as a syndrome of distinct and persistent dysphoria associated with neurovegetative changes and functional impairment. Varied in presentation,

course, and response to treatment, depressive disorders remain a pathophysiological enigma, despite centuries of recognition and more recent investigation of their possible genetic, neurochemical, neuroanatomic, endocrine, and immune underpinnings [2,3].

Many physicians believe that depression is appropriate in the ICU because severe illness devastates a person's life. However, we believe that while being dispirited may be an understandable response to critical illness, having a depressive disorder is not; therefore, it is always important to treat the latter. In fact, compelling evidence shows that untreated depression increases morbidity and mortality from cardiac and neurologic conditions and has detrimental effects on other—perhaps all—organ systems.

In this chapter, we focus on the links between depressive and medical conditions and the diagnosis, evaluation, and treatment of depression in critically ill patients.

LINKS BETWEEN DEPRESSION AND MEDICAL CONDITIONS

Cardiovascular Disease

That depression is associated with the development and the progression of coronary heart disease (CHD), and with worse prognosis in CHD patients, is well established [4]. Not proven thus far is that treatment of depression can improve or prevent these outcomes. After two trials—the Enhancing Recovery in Coronary Heart Disease Patients (ENRICHD) study [5] and the Myocardial Infarction and Depression–Intervention Trial (MIND–IT) [6]—failed to show this, attention turned to isolating those attributes of a depressive episode that portend greater risk. Secondary analyses of these and other trials have examined symptom type, episode onset before or after an index event [7,8], recurrence [9,10], treatment responsiveness [11], and persistence of the cardiotoxic effects of depression [12]. For example, some studies suggested that worse cardiac outcomes are associated with somatic/affective symptoms (e.g., insomnia, fatigability, and diminished libido) more than with cognitive/affective symptoms (e.g., pessimism, self-dislike, and suicidal ideas) [13–15].

Possible explanations for the greater rates of cardiac death among patients diagnosed with depression include hypothalamic–pituitary–adrenal axis hyperactivity, elevation in inflammatory markers (e.g., interleukin 6, tumor necrosis factor α), diminished heart rate variability, decreased parasympathetic tone, increased sympathetic tone, and enhanced platelet activation causing more avid platelet aggregation and plaque formation [16]. Interestingly, sertraline decreases platelet and endothelial activation in depressed patients after an acute coronary syndrome (ACS) [17,18]. The Heart and Soul Study, a prospective cohort study of 1,017 patients with stable CHD, found that behavioral factors, especially physical inactivity, were most responsible for the greater rate of adverse cardiac events in patients with depressive symptoms [19].

Cerebrovascular Disease

As with cardiovascular disease, there appear to be bidirectional links between cerebrovascular disease and depressive illness. The Caerphilly Study of 2,201 men found that psychological distress predicted fatal stroke but not nonfatal stroke or transient ischemic attack (TIA) [20]. The Framingham Heart Study of 4,120 men and women found that depressive symptoms were a risk factor for stroke or TIA before, but not after, age 65 [21].

Poststroke depression (PSD) has been extensively studied during the past 3 decades. Robinson [22] pooled the available data and found the mean prevalence of poststroke affective illness to be 19.3% for major depression and 18.5% for minor depression. Risk factors for the development of PSD include stroke severity, extent of physical disability, presence of cognitive impairment, and poor social support [23].

In the early 1980s, Robinson et al. [24,25] reported that the severity of PSD correlated with the proximity of the lesion to the frontal pole in the left, but not the right, hemisphere. This finding has been replicated by some [26,27], but not all [28], researchers; this localization may hold only during the first few months after stroke [29].

DIAGNOSIS OF DEPRESSION

Important questions for the intensivist are "What is depression?" and "What does a patient experiencing depression look like in the ICU?" To qualify for a diagnosis of MDD according to the DSM-IV, a patient must have five of the nine symptoms listed in Table 199.1, one of which must be either depressed mood or anhedonia, most of the day, nearly every day, for at least 2 weeks. The mnemonic—SIG: E CAPS (where SIG [abbreviation for the Latin, *signa*] refers to the instructions on a prescription, E refers to energy, and CAPS refers to capsules)—is a helpful guide to remember the eight neurovegetative symptoms associated with depressed mood. The mnemonic—ABCs of depression—portrays more richly the myriad affective, behavioral, and cognitive aspects of the condition (Table 199.2). Each symptom should be asked about, and questions about suicide should be raised directly. If a patient has thoughts of suicide, he or she should be asked whether there is a specific plan; the physician should then make a judgment about the likelihood of the patient's acting on the plan. If an active plan for suicide exists, psychiatric consultation is imperative (see Chapter 200).

Four of the nine diagnostic criteria (i.e., insomnia, fatigue or loss of energy, diminished ability to think or concentrate, and anorexia or weight loss) are difficult to attribute exclusively to depression in the medically ill patient. However, in terminally ill cancer patients, Chochinov et al. [30] found that inclusion of these somatic symptoms in the diagnostic criteria did not artifactually increase rates of diagnosis, as long as the cardinal symptoms of depressed mood and anhedonia were held to the strict requirement of presence most of the day, nearly every day, for at least 2 weeks.

TABLE 199.2

ABCs OF DEPRESSION—AFFECTIVE, BEHAVIORAL, AND COGNITIVE FEATURES

Affective	Behavioral	Cognitive
Depressed mood	Crying	Suicidal thinking
"Blue" mood	Increased or decreased sleep	Thoughts of death
Sadness	Increased or decreased appetite	Somatic preoccupation
Blunted affect	Decreased energy	Guilty rumination
Hopelessness	Psychomotor agitation or retardation	Confusion
Emptiness	Increased or intractable pain	Decreased concentration
Irritability	Deliberate self-injury	
Anger	Impulsivity	
Decreased interest	Poor eye contact	
	Noncompliance	

Patients Who are Unable to Speak

It may be particularly difficult to diagnose depression in a patient who is being mechanically ventilated or who has aphasia. However, much can be learned about a patient even when he or she is mute. It is important to watch facial expressions, observe hand gestures and other body language, and read lips. An individual who averts his or her eyes from the examiner's gaze may be demoralized, discouraged, or depressed. Slow, sighing respirations may indicate depression rather than respiratory insufficiency. The astute clinician can also watch vital-sign monitor screens, looking for changes that can signify intense affect.

Does the patient respond to the mention of a favorite hobby or a grandchild with a smile or with tears? Is the patient's affect labile or consistent with the content of the discussion? Emotional lability is not usually an indicator of MDD; instead, it suggests frontal lobe dysfunction. One can probe for affect by joking and observing the patient's reaction.

A patient who can move his or her arms can be asked to write, draw, or point to a letter or a picture board. One simple screening test that can be used is human figure drawing (i.e., having the patient draw a picture of a person and another of what the patient thinks is wrong with the person). Typically, drawings by depressed patients convey their sense of dejection or a disordered understanding of their dilemma.

TABLE 199.3

METHODS OF ASSESSING DEPRESSION IN SENSORIALLY COMPROMISED PATIENTS

- Watch facial expressions and gestures
- Write questions
- Have patients write answers
- Use letter or picture board
- Observe whether facial expressions are consistent with content of discussion
- Observe rate of change of affect
- Ask about and observe neurovegetative features of depression
- Ask about known sources of the patient's enjoyment (e.g., favorite hobby, grandchildren, sports) and observe whether the patient takes pleasure in these things
- Joke with the patient or tell a funny story and observe the patient's reaction
- Ask the patient to draw a picture of himself or herself and what is wrong, then assess the pictures for a sense of demoralization or hopelessness
- Make a fist and ask the patient, "What would you do if you had one of these?", and assess emotions in response to this maneuver

Some tracheostomized patients may have the oxygenation status, control of respiratory muscles, and ability to manage secretions sufficient to use a Passy-Muir valve, which permits exhaled air to pass the larynx and thus allows the patient to speak. Alternatively, electronic voice-output communication aids may be used. These devices pair prerecorded messages or synthesized speech with labeled icons; patients communicate messages by touching buttons on display screens or on touch-sensitive keyboards. Speech pathologists have knowledge of and access to such technology. Methods of assessing depression in sensorially compromised patients are summarized in Table 199.3.

DIFFERENTIAL DIAGNOSIS OF DEPRESSION

Causes Related to Medical Conditions

A variety of medical illnesses can cause affective disorders, contribute to their occurrence, and worsen their severity (Table 199.4). Clues that depression is due to a medical illness include

TABLE 199.4

MEDICAL CONDITIONS ASSOCIATED WITH DEPRESSIVE SYMPTOMS

- Cardiovascular
  - Cardiac tumors
  - Congestive heart failure
  - Hypertensive encephalopathy
- Collagen-vascular
  - Polyarteritis nodosa
  - Systemic lupus erythematosus
- Endocrine
  - Diabetes mellitus
  - Hyper- or hypoadrenalism
  - Hyper- or hypoparathyroidism
  - Hyper- or hypothyroidism
- Infectious
  - Hepatitis
  - Human immunodeficiency virus
  - Mononucleosis
  - Influenza
- Metabolic
  - Acid–base problems
  - Hypokalemia
  - Hyper- or hyponatremia
  - Renal failure
- Neoplastic
  - Carcinoid
  - Pancreatic carcinoma
- Neurologic
  - Brain tumor
  - Multiple sclerosis
  - Parkinson's disease (especially with on/off phenomenon)
  - Temporal lobe epilepsy
  - Stroke
  - Subcortical dementia
- Nutritional
  - Vitamin B_{12} deficiency
  - Wernicke's encephalopathy

older age at onset of symptoms, lower incidence of a family history of depression, and changes in personality and cognition. A thorough history (including a review of systems), physical (including neurologic) examination, and laboratory testing can distinguish between primary (i.e., due to a psychiatric condition) and secondary (i.e., due to a medical condition) causes of depression. For secondary causes, treatment of the underlying illness is usually more effective than is the use of psychotropic medications.

Perhaps the most important differential diagnosis to consider in a patient who appears to have MDD is hypoactive delirium. The key feature that distinguishes it from depression is inattention (i.e., an inability to focus and sustain alertness on a given stimulus and to resist distraction by other stimuli). Delirium is discussed in Chapter 197.

Causes Related to Medical Treatments

The pharmacologic agents most often responsible for depression in the ICU are antihypertensives, beta-blockers, antiarrhythmics, and steroids (Table 199.5). Some medications may cause depression only after several weeks or even months of continuous use. If a drug regimen or a dosage increase appears to be temporally related to the patient's depression, the dose should be lowered or the medication eliminated entirely. If the medication cannot be stopped without serious risk to the patient, the depression should be treated.

Steroids

Depression, mania, psychosis, and delirium are frequent side effects of corticosteroid therapy. Mood symptoms are dose-dependent and usually occur within the first 2 weeks of therapy, although they can arise on the first day. A practical rule of thumb holds that neuropsychiatric adverse effects are common with prednisone ≥80 mg per day (or equivalent), uncommon ≤30 mg per day, and not uncommon in between. Although it has been suggested that women are more likely to develop steroid-induced adverse effects, the apparent increased frequency may be due to the higher prevalence of rheumatologic diseases in women. Corticosteroid-induced mood disorders are generally reversible with dosage reduction or discontinuation of the medication.

TABLE 199.5

DRUGS ASSOCIATED WITH DEPRESSIVE SYMPTOMS

Acyclovir (especially at high doses)
Alcohol
Amphetamine-like drugs (withdrawal): fenfluramine, phenmetrazine, phenylpropanolamine
Anabolic steroids: methandrostenolone, methyltestosterone
Anticonvulsants (at high doses or plasma levels): carbamazepine, phenytoin, primidone
Antihypertensives: clonidine, hydralazine, methyldopa, reserpine, thiazides
Asparaginase
Baclofen
Barbiturates
Benzodiazepines: alprazolam, clonazepam, clorazepate, diazepam, lorazepam, triazolam
Beta-blockers: atenolol, betaxolol, propranolol, timolol
Bromides
Bromocriptine
Cimetidine
Cocaine (withdrawal)
Oral contraceptives
Corticosteroids
Cycloserine
Dapsone
Digitalis (at high doses or in elderly patients)
Diltiazem
Disopyramide
Ethionamide
Halothane (postoperatively)
Heavy metals
Histamine-2 receptor antagonists: cimetidine, ranitidine
Interferon α
Isoniazid
Isotretinoin
Levodopa (especially in the elderly)
Mefloquine
Metoclopramide
Metrizamide
Metronidazole
Nalidixic acid
Narcotics: meperidine, methadone, morphine, pentazocine, propoxyphene
Nifedipine
Nonsteroidal anti-inflammatory drugs
Norfloxacin
Phenylephrine
Prazosin
Procaine derivatives: lidocaine, penicillin G procaine, procainamide
Thyroid hormones
Trimethoprim-sulfamethoxazole

LABORATORY EVALUATION OF DEPRESSION

Although the clinical interview and mental status examination are the most important components of psychiatric diagnosis, the use of laboratory tests is essential to exclude organic causes of depression. Although there is no consensus on the laboratory tests necessary in a patient with new-onset mood disorder, Table 199.6 lists those tests that should be considered. Thyroid-stimulating hormone is not on this list because many critically ill patients have abnormal thyroid biochemical profiles but do not have intrinsic thyroid disease. Syphilis and hypovitaminosis are rarely the sole causes of depression; tests for these conditions should be ordered only when there is a specific indication for them. Neuroimaging, electroencephalography, and cerebrospinal fluid analysis are relatively indicated in patients with new-onset psychiatric symptoms, altered cognition, new neurologic symptoms, seizures, and fever. The more of these features a patient has, the more important these additional tests become.

TREATMENT OF DEPRESSION

Patients who meet the criteria for MDD are usually treated with a somatic therapy (including pharmacotherapy and electroconvulsive therapy [ECT]), alone or in combination with psychotherapy (Table 199.7). In critical care units, somatic therapies are the most widely used treatments for depression. Pharmacotherapy may be used in critical care units also for patients who have an adjustment disorder with depressed mood, particularly when these patients have several neurovegetative symptoms. A patient who is neither eating nor sleeping and who lacks the energy to participate in his or her rehabilitation may be helped considerably by antidepressants, especially psychostimulants.

Each type of pharmacotherapy has its own indications and contraindications, but general rules are available when

selecting an antidepressant [31,32]. The most common rule is to choose a medication with a side-effect profile that best fits a patient's needs. For instance, a patient who is having trouble sleeping will benefit from a sedating antidepressant. Conversely, a patient who has severe psychomotor retardation may benefit from a more stimulating antidepressant. With the exception of the psychostimulants, all antidepressants require approximately 4 to 6 weeks until full antidepressant effects are noted, although some response can occur in 1 to 2 weeks. Obviously, in critical care units, quicker effects are generally needed. Stimulants and ECT work more quickly, usually within several days. Patients with depression may also manifest considerable anxiety and may be helped by the use of an anxiolytic while awaiting response to an antidepressant. Psychotically depressed patients (with delusions or hallucinations) may need antipsychotics for control of symptoms.

Psychostimulants

Psychostimulants have been used to treat depressive symptoms since their development in the 1930s, but they fell into disrepute when they became known as drugs of abuse in the 1950s and 1960s. Since then, there have been numerous reports on the use of stimulants in the treatment of depressed patients, particularly apathetic and geriatric patients; recently, there has been a renewed interest in the use of psychostimulants in depressed, medically ill patients who are intolerant of other medications

TABLE 199.7

COMPARATIVE PROPERTIES OF SOME ANTIDEPRESSANTS

[33]. Thought to be particularly effective in patients with cancer and stroke, their rapid onset is of great use in any setting, including the ICU, where speed of recovery is crucial. For example, they are valuable in patients who are difficult to wean from mechanical ventilation [34].

The psychostimulants most commonly used are dextroamphetamine (Dexedrine) and methylphenidate (Ritalin). Both appear to work through the direct neuronal release of dopamine and norepinephrine; dextroamphetamine blocks catecholamine reuptake and weakly inhibits monoamine oxidase. Both of these psychostimulants are predominantly excreted by the kidneys, although dextroamphetamine also undergoes a complex biotransformation.

The usual effects of stimulants are to increase motor behavior, increase arousal, and decrease appetite; however, in patients who are anorexic on the basis of depression, appetite is paradoxically increased, likely through dopaminergic stimulation of the nucleus accumbens. Their antidepressant effect is usually evident in the first 2 days of treatment, if not earlier. In a review of 66 patients hospitalized on medical-surgical wards at Massachusetts General Hospital, 93% achieved maximum benefit within 2 days of use [35,36]. Stimulants do not show anticholinergic effects or cause orthostatic hypotension. They can increase heart rate and blood pressure and can cause coronary spasm and cardiac arrhythmias; however, these effects are rare (even with preexisting cardiac abnormalities) at the low doses (5 to 20 mg/day) usually used for the treatment of depression [35]. In fact, stimulants have been used safely and effectively in a broad spectrum of patients, including those with critical illness, and have shown little potential for abuse or dependence. Contraindications to stimulant use include the concurrent use of α-methyldopa (which becomes a sympathoamine when metabolized), monoamine oxidase inhibitors (MAOIs), and bronchodilators; and pregnancy, seizures, delirium, psychosis, significant hypertension, and active angina [37].

Psychostimulants should be the first consideration in treating depression in critically ill patients. Patients are started on 5 mg of methylphenidate or 2.5 to 5 mg of dextroamphetamine in the morning. The dose is increased by 5 mg per day (for methylphenidate) or 2.5 to 5 mg per day (for dextroamphetamine) until a therapeutic effect is detected or until a maximum dose of 20 mg has been reached. Heart rate and blood pressure should be monitored as closely as necessary. Stimulants are usually given for at least 1 to 2 weeks after depressive symptoms have fully remitted. In most cases, after stimulants are stopped, depression does not recur.

Stimulants taken in overdose may cause seizures, coma, hallucinations, paranoia, hyperthermia, hypertension, cardiac arrhythmias, angina, and circulatory collapse. The major treatment for overdose is to acidify the urine (which enhances renal excretion) and to use supportive measures for all other abnormalities.

Modafinil (Provigil)—a wakefulness-promoting medication approved for narcolepsy, shift work sleep disorder, and obstructive sleep apnea/hypopnea syndrome—may be a beneficial alternative to the psychostimulants.

Selective Serotonin Reuptake Inhibitors

The SSRIs are a class of antidepressants that causes a potent and selective blockade of serotonin reuptake. Since the introduction of fluoxetine (Prozac) in 1987, SSRIs have become the most widely prescribed class of antidepressants. Other SSRIs include sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox), citalopram (Celexa), and escitalopram (Lexapro). They are far less anticholinergic, antihistaminergic, and anti-α_1-adrenergic than the older tricyclic antidepressants (TCAs) and, therefore, are associated with far fewer side effects. They also have fewer cardiovascular effects and do not commonly cause orthostatic hypotension.

Pharmacokinetics

SSRIs are well absorbed from the gastrointestinal tract, and absorption is generally unaffected by food and antacids. They have a large volume of distribution and are highly protein-bound. They are extensively metabolized in the liver, where they are oxidized, methylated, and conjugated. The elimination half-lives of sertraline, paroxetine, fluvoxamine, and citalopram are approximately 1 day (although sertraline has a mildly active metabolite with a half-life of 66 hours); this allows once-a-day dosing. Fluoxetine has a half-life of 2 to 3 days and a highly active metabolite (norfluoxetine) with a mean half-life of 6.1 days. Fluoxetine takes a much longer time to reach steady state and, more importantly for drug overdoses, can take weeks to months to be fully cleared. Elimination half-lives are dose-dependent (i.e., higher doses and lengthier usage are associated with higher plasma levels and longer half-lives). SSRIs show wide interindividual variation in pharmacokinetics and do not yet have a clearly established dose-response curve.

Metabolic Impairment

Fluoxetine, sertraline, fluvoxamine, and citalopram are unaffected by renal dysfunction [38,39]. Paroxetine, although minimally excreted in the urine (like other SSRIs), shows increased plasma concentrations in the setting of renal disease [38]. Fluoxetine, sertraline, paroxetine, and citalopram doses should be reduced by at least half in patients with liver disease [38]. Fluvoxamine has been used in patients with cirrhosis and hepatic encephalopathy without adverse effects [40]. The hepatic clearance, not the plasma concentration, of fluvoxamine is affected by cirrhosis. Therefore, the dosage frequency, rather than the total dosage, should be altered [40]. In elderly individuals, fluoxetine does not have altered pharmacokinetics; in contrast, sertraline and paroxetine have increased plasma levels and slower clearance. Although citalopram has a 30% longer half-life in the elderly, the frequency and severity of side effects are not higher in this group [41].

Side Effects

SSRIs can cause tremulousness, agitation, irritability, insomnia, anorexia, nausea, vomiting, diarrhea, excess sweating, and sexual dysfunction (i.e., decreased libido, erectile and orgasmic dysfunction). The syndrome of inappropriate antidiuretic hormone is an uncommon adverse effect reported with all of the SSRIs; especially in critically ill patients, other causes of hyponatremia should be sought before attributing the metabolic derangement to the SSRI. The SSRIs do not typically cause clinically significant changes in heart rate, blood pressure, or the electrocardiogram (ECG). Overdoses of SSRIs are discussed in Chapter 124.

Theoretically, SSRIs can cause angina or myocardial infarction (MI) due to the direct vasoconstrictive effects of serotonin on damaged myocardium. When fluoxetine therapy is initiated, serum serotonin levels rise for the first 2 weeks and then return to baseline. This mechanism has been implicated in 3 cardiac deaths that occurred 10 days after initiation of fluoxetine [42]. This theoretical concern should extend to other SSRIs as well.

Drug–Drug Interactions

The SSRIs are extensively metabolized by the cytochrome P450 system. All of them also inhibit various isoenzymes in this system and consequently raise the plasma levels of other drugs metabolized by those isoenzymes; sertraline, citalopram, and escitalopram do this the least. The interactions most likely to

occur in an ICU are listed in Table 199.8. Attention to drug dosage can mitigate the harmful effects of these interactions.

Drug Discontinuation

The usually mild symptoms of the SSRI discontinuation syndrome (e.g., headache, dizziness, myalgias, and nausea) are generally eclipsed by more pressing issues in critically ill patients.

Atypical Antidepressants

Bupropion

A monocyclic ketone antidepressant, bupropion (Wellbutrin) blocks norepinephrine and dopamine reuptake. As such, it can be activating and used in place of psychostimulants for patients who cannot tolerate these agents or in whom they are contraindicated. Its major side effects are agitation, insomnia, tremulousness, nausea, vomiting, and diarrhea. The immediate-release formulation is associated with an increased risk of seizures, but this risk in the sustained-release (SR) and extended-release (XL) preparations is comparable to that associated with other antidepressants. It carries a low risk of cardiac toxicity, though, in overdose, sinus tachycardia and intraventricular conduction delays have been reported [43]. Bupropion has gained widespread use as an aid to smoking cessation.

Mirtazapine

Mirtazapine (Remeron) is an analog of the tetracyclic antidepressant, mianserin. As an antagonist at presynaptic and postsynaptic α_2-adrenergic receptors and at postsynaptic 5-HT_2 and 5-HT_3 receptors, it enhances both norepinephrine and serotonin transmission. It has few anticholinergic and anti-α_1-adrenergic effects. Mirtazapine is a potent histamine blocker and can cause significant sedation, an increase in appetite, and weight gain—a side-effect profile that is often exploited to advantage in medically ill patients. Mirtazapine is devoid of significant effects on the cytochrome P450 system, making it less apt to cause drug–drug interactions.

Venlafaxine

Venlafaxine (Effexor) is a selective serotonin and norepinephrine reuptake inhibitor (SNRI). It is very similar to the SSRIs in most clinical and pharmacologic aspects. It has few anti-α_1-adrenergic, anticholinergic, and antihistaminergic side effects. Venlafaxine has a 6- to 8-hour half-life and must be given 2 to 3 times daily, but an extended-release preparation (Effexor XR) allows once-daily dosing. It causes a dose-dependent increase in systolic and diastolic blood pressure (up to 7.5 mm Hg), occurring in approximately 7% of patients taking daily doses between 200 and 300 mg and in up to 13% of patients taking > 300 mg [44]. The major active metabolite of venlafaxine, desvenlafaxine, is now available as a primary compound (Pristiq); its advantages over its parent compound are uncertain.

Duloxetine

Another SNRI, duloxetine (Cymbalta) is indicated for MDD, generalized anxiety disorder, diabetic neuropathy, and fibromyalgia. Its half-life is 12 hours, and it can be given once or twice daily. Like venlafaxine, it has little effect on α_1-adrenergic, cholinergic, and histaminergic receptors. Any therapeutic advantage over venlafaxine, particularly in critically ill patients, has yet to be demonstrated.

Trazodone

A triazolopyridine derivative, trazodone (Desyrel) is an atypical antidepressant usually used as a sleep aid. It has a more

benign cardiac profile than the TCAs and rarely causes cardiac dysrhythmias. The most common cardiovascular effect of trazodone is orthostatic hypotension. Priapism is a rare adverse event.

Tricyclic Antidepressants

TCAs work by blocking reuptake of norepinephrine and serotonin at presynaptic sites. The most common side effects of TCAs are sedation, orthostatic hypotension, and anticholinergic effects (including confusion, blurred vision, dry mouth, constipation, and urinary hesitancy or retention). The tertiary-amine parent compounds, amitriptyline (Elavil) and imipramine (Tofranil), are more apt to produce these adverse effects than are their respective secondary-amine metabolites, nortriptyline (Pamelor) and desipramine (Norpramin).

Because of this extensive side-effect profile, including adverse effects on cardiac conduction and cardiac rhythm, the TCAs have largely been eclipsed in recent times by the SSRIs and other newer agents, which are safer and better tolerated. For example, in a head-to-head comparison of nortriptyline and fluoxetine in patients with cardiac disease, patients taking nortriptyline had 5 times the incidence of adverse cardiac effects compared to those in the fluoxetine group (20% vs. 4%) [45]. TCAs are relatively contraindicated in patients with cardiac disease and are not recommended in the acute post-MI period. In fact, some data even suggest that TCAs may precipitate arrhythmias and sudden death in cohorts other than just the post-MI population [46].

As a result, it is relatively unusual to see a patient on a TCA at an antidepressant dose in the ICU and highly unusual to start a TCA in an ICU patient. TCAs are still used with some regularity for neuropathic pain syndromes; when used in this situation, doses are much lower than those used in depression treatment. Overdoses with TCAs may be treated in the ICU and are discussed in Chapter 123.

Monoamine Oxidase Inhibitors

The MAOIs (isocarboxazid [Marplan], phenelzine [Nardil], tranylcypromine [Parnate]) work by blocking the oxidative deamination of biogenic amines (e.g., norepinephrine, serotonin) and have been used for the treatment of depression since the 1950s. MAOIs may cause a profound hypertensive crisis when a patient taking MAOIs also takes a sympathomimetic medication (e.g., reserpine, guanethidine, pseudoephedrine, and ephedrine) or ingests tyramine-containing foods (e.g., aged cheeses, pickled foods, and yeast extracts). Coadministration with opioids, particularly meperidine, also may lead to hypertensive crises and to elevated blood levels of meperidine and its neurotoxic metabolite, normeperidine. The use of beta-blockers with MAOIs may lead to unopposed α-adrenergic activity and also cause severe hypertension. For these reasons, similar to TCAs, MAOIs are infrequently used in recent times, even by psychiatrists, and it would be highly unusual to begin an MAOI in an ICU patient. Overdoses with MAOIs may be treated in the ICU and are discussed in Chapter 123.

Pharmacologic Treatment of Depression in Heart Disease

Several studies have examined the effect of antidepressant treatment on psychiatric or cardiovascular outcome or both in patients with CHD. These include the Sertraline Antidepressant Heart Attack Randomized Trial (SADHART), ENRICHD, MIND–IT, and the Canadian Cardiac Randomized Evaluation of Antidepressant and Psychotherapy Efficacy (CREATE) trial. The basic details and findings of these landmark studies, as well as two other randomized trials [47,48], are summarized in Table 199.9.

In SADHART, response to sertraline was independently predicted by each of the following factors: (a) onset of the current depressive episode before the ACS, (b) a history of MDD, and (c) greater severity of depression [49]. Moreover, in the cohort with recurrent MDD, quality of life and several functional status scores were significantly improved in the sertraline group [50]. SADHART was designed to evaluate only the safety and efficacy of sertraline, not its effect on cardiac outcomes. Nevertheless, the number of severe cardiac events (e.g., death, MI, congestive heart failure [CHF], recurrent angina, stroke) was lower in patients treated with sertraline (14.5%) compared with those receiving placebo (22.4%) [51]. After a median follow-up of almost 7 years, baseline MDD severity and persistence of depression despite active or placebo treatment in the 6 months immediately after ACS independently predicted more than a doubling of mortality risk [7].

ENRICHD was the first trial of the effect of depression treatment on mortality and reinfarction in post-MI patients [5]. The differential improvement in depression between the intervention and the usual-care groups was only modest and was short-lived. Most notably, the intervention yielded no cardiac benefit. This negative result may have occurred because many of the patients in the usual-care arm received antidepressant medication, thus potentially obscuring any between-group differences. In fact, a secondary analysis found that patients exposed to SSRIs had a lower risk of death or recurrent MI and of all-cause mortality compared to patients who did not take SSRIs [52]. In addition, patients with mild, transient depressions likely to have improved on their own were included in the study, and the treatment duration of 6 months may have been too short to discern a salutary effect.

Thus Carney et al. [53] undertook a subgroup analysis of patients with full (rather than modified) criteria for MDD or minor depression, a baseline Beck Depression Inventory (BDI) score ≥ 10, and a history of at least one episode of MDD and completed the follow-up evaluation 6 months after enrollment (i.e., those patients who completed the intervention). While the difference in the mean change in BDI score from baseline to 6 months between groups was higher in this narrowed sample than in the entire cohort, this enhanced improvement did not translate into a survival benefit. While patients who responded to the intervention experienced a reduction in mortality, the authors recommended caution in evaluating this finding as it was based on small numbers.

MIND–IT examined the effects of antidepressant treatment on cardiac prognosis and on the long-term course of depression [6]. The active treatment arm included three possibilities: randomization to mirtazapine or placebo, open treatment with citalopram, or treatment at the discretion of the treating psychiatrist. Those randomized to mirtazapine or placebo were given the option to switch to unblinded citalopram if there was no response after 8 weeks. Similar to ENRICHD, no significant differences between active treatment and usual care were found in depressive or cardiac outcome. In a separate analysis of just the patients who received mirtazapine, this agent yielded a therapeutic advantage over placebo [54]. In a three-way comparison of responders and nonresponders to either antidepressant (mirtazapine or citalopram) and patients who received no treatment, responders had the least cardiac events, followed by the untreated patients and then the nonresponders, leading the authors to suggest that persistence of depression may be the crucial "cardiotoxic" attribute of depressive illness, for which treatment resistance may be a marker [55].

TABLE 199.9

RANDOMIZED, CONTROLLED TRIALS OF DEPRESSION PHARMACOTHERAPY IN PATIENTS WITH CARDIOVASCULAR DISEASE

Study	Enrollment	Intervention	Results
Berkman et al. [5]	2,481 patients with modified[a] DSM-IV major or minor depression and/or low perceived social support within 28 d after MI	Intervention (CBT ± sertraline 50–200 mg/d or other medication) vs. usual care for 6 mo	The intervention yielded a significant, though modest, improvement in depression and in social support after 6 mo. This effect was insignificant for depression after 30 mo and for social support after 42 mo. There was no significant difference between groups in death or nonfatal MI, all-cause mortality, cardiac mortality, or recurrent nonfatal MI after an average follow-up of 29 mo.
van Melle et al. [6]	331 patients with ICD-10 depression 3–12 mo after MI	Intervention (mirtazapine, citalopram, or nonpharmacological treatment) vs. usual care for 6 mo	There was no difference between groups in mean BDI scores, presence of depression, and incidence of cardiac events at 18 mo.
Roose et al. [47]	81 patients with MDD and stable ischemic heart disease	Paroxetine 20–30 mg/d vs. nortriptyline for 6 wk	61% of the patients on paroxetine improved compared to 55% of those on nortriptyline. Those on SSRI had fewer adverse cardiac events.
Strik et al. [48]	54 patients with MDD 3–12 mo after a first MI	Fluoxetine vs. placebo	The response rate in the fluoxetine group was significantly greater at week 25, especially in patients with mild depression. There was no decrease in cardiac function in the fluoxetine group.
Glassman et al. [51]	369 patients with MDD and ACS (either MI or unstable angina)	Sertraline 50–200 mg/d vs. placebo for 24 wk	Sertraline had no significant effect on mean LVEF, increase in PVCs, QTc prolongation, and other cardiac measures. In cohorts with recurrent or severe MDD, depression scores were significantly lower in the sertraline group.
Honig et al. [54]	91 patients with DSM-IV depression 3–12 mo after MI	Mirtazapine vs. placebo for 24 wk	Mirtazapine was superior to placebo on two of three depression scales at 8 and 24 wk. There was no assessment of effect on cardiac outcomes.
Lespérance et al. [56]	284 patients with DSM-IV MDD and CAD	Twelve weekly sessions of IPT with CM vs. CM alone, and citalopram 20–40 mg/d vs. placebo for 12 wk	The addition of IPT to clinical management conferred no therapeutic advantage. Citalopram was significantly more effective than placebo in reducing depression.

[a] Symptoms of ≥ 7 days' duration if there was ≥ 1 prior depressive episode, 14 days if not.
ACS, acute coronary syndrome; BDI, Beck Depression Inventory; CBT, cognitive-behavioral therapy; CM, clinical management; DSM-IV, *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition; ICD-10, *International Classification of Diseases*, 10th edition; IPT, interpersonal therapy; LVEF, left ventricular ejection fraction; MDD, major depressive disorder; MI, myocardial infarction; PVCs, premature ventricular contractions; QTc, QT interval corrected for heart rate; SSRI, selective serotonin reuptake inhibitor.

CREATE, the first and only study designed to evaluate paired psychological and pharmacological interventions for depression treatment in CHD patients, failed to show a therapeutic advantage for interpersonal therapy, a manualized, short-term therapy focused on loss, grief, life transitions, interpersonal conflicts, and social isolation [56]. It demonstrated, however, that citalopram is an effective antidepressant in this population.

Several additional studies in this area are currently underway. The Safety and Efficacy of Sertraline for Depression in Patients with CHF (SADHART–CHF) study will evaluate the effects of 12 weeks of sertraline compared to placebo on depression and cardiac prognosis in approximately 500 patients with MDD and chronic systolic heart failure [57]. The Bypassing the Blues (BtB) study will randomize 450 patients after coronary artery bypass grafting (CABG) to either an 8-month nurse-delivered telephone-based collaborative care intervention or usual care and evaluate the effect on mood, cardiac morbidity, health-related quality of life, and other outcomes [58]. The first study of the prevention of depression in CHD patients, the Depression in Coronary Artery Disease (DECARD) trial will randomize 240 patients with ACS, but without depression, to 1 year of escitalopram or placebo [59].

Pharmacologic Treatment of Depression in Stroke

Table 199.10 summarizes findings from the randomized, controlled trials of depression treatment and prophylaxis in patients with cerebrovascular disease [60–79]. In a randomized, double-blind, placebo-controlled study of poststroke patients, nortriptyline was more effective than fluoxetine or placebo

TABLE 199.10

RANDOMIZED, CONTROLLED TRIALS OF DEPRESSION PHARMACOTHERAPY IN PATIENTS WITH CEREBROVASCULAR DISEASE

Study	Enrollment	Intervention	Results
Lauritzen et al. [60]	20 poststroke patients with depression	Imipramine and mianserin[a] vs. desipramine and mianserin for 6 wk	The imipramine arm was superior to the desipramine arm.
Rampello et al. [61]	31 patients with "retarded" depression within 12 mo after CVA	Reboxetine[b] 4 mg twice daily vs. placebo for 16 wk	Reboxetine showed good efficacy, safety, and tolerability. There was a significant difference in change in HDRS and BDI scores between groups.
Robinson et al. [62]	159 patients with MDD 10 d to 3 mo after CVA	Nefiracetam[c] 600 or 900 mg/d vs. placebo	Both arms showed response rates > 70% and remission rates > 40%. Patients in the top quintile of HDRS scores showed a significant effect with 900 mg compared to 600 mg or placebo.
Robinson et al. [63]	104 poststroke patients with and without depression	Nortriptyline 25–100 mg/d, fluoxetine 10–40 mg/d, or placebo for 12 wk	Nortriptyline resulted in a significantly higher response than fluoxetine or placebo in reversing depression, reducing anxiety, and improving functional status. Neither active treatment improved cognitive or social functioning in depressed or nondepressed patients.
Wiart et al. [64]	31 poststroke patients with MDD	Fluoxetine 20 mg/d vs. placebo for 6 wk	Fluoxetine produced a significant improvement in depression but not in motor, cognitive, or functional scores.
Fruehwald et al. [65]	50 poststroke patients with depression	Fluoxetine 20 mg/d vs. placebo for 3 mo	Both groups showed significant improvement, with no between-group difference, after 1 mo. At 18 mo, the fluoxetine group had significantly less depression.
Choi-Kwon et al. [66]	152 patients 3–28 mo after CVA with depression, emotional incontinence, or anger proneness	Fluoxetine 20 mg/d vs. placebo for 3 mo	Fluoxetine produced significantly higher scores in the mental health, general health, and social functioning domains of QOL after 12 mo.
Li et al. [67]	150 poststroke patients with moderate to severe depression	FEWP[d] vs. fluoxetine vs. placebo for 8 wk	The active arms showed a higher clinical response than placebo, but no difference between FEWP and fluoxetine was discernible at the end of the study.
Choi-Kwon et al. [68]	152 poststroke patients with depression, emotional incontinence, or anger proneness	Fluoxetine 20 mg/d vs. placebo for 3 mo	Fluoxetine significantly improved emotional incontinence and anger proneness but not depression.
Andersen et al. [69]	66 patients with depression 2–52 wk after CVA	Citalopram 10–40 mg/d vs. placebo for 3 and 6 wk	Citalopram yielded greater improvement than placebo.
Rampello et al. [70]	74 poststroke patients with depression	Citalopram 20 mg/d vs. reboxetine 4 mg/d for 16 wk	Both agents showed good safety and tolerability. Citalopram showed a greater effect on anxious depression, reboxetine on retarded depression.
Cravello et al. [71]	50 poststroke patients with depression	Venlafaxine SR 75–150 mg/d vs. fluoxetine 20–40 mg/d for 8 wk	Both agents yielded similar improvement in depressive symptoms. Venlafaxine showed more improvement on an alexithymia scale.
Grade et al. [72]	21 poststroke patients admitted to a rehabilitation facility	Methylphenidate 5–30 mg/d vs. placebo for 3 wk	Methylphenidate yielded lower HDRS and Zung[e] scores.
Murray et al. [73]	123 poststroke patients with MDD or minor depression	Sertraline 50–100 mg/d vs. placebo for 26 wk	Both groups improved substantially. There was no difference in depression between groups and significantly less emotional distress and better QOL in the treatment group.
Narushima et al. [74]	48 poststroke patients who were not depressed at baseline	Nortriptyline 25–100 mg/d, fluoxetine 10–40 mg/d, or placebo for 12 wk for prophylaxis	Significantly fewer depressive episodes occurred in the treatment groups. However, more nortriptyline-treated patients developed depression in the 6 months after treatment was stopped compared to the other two groups.
Robinson et al. [75]	176 patients without depression within 3 mo after CVA	Escitalopram vs. placebo vs. problem-solving therapy for 1 y for prophylaxis	Patients who received either escitalopram or therapy were significantly less likely to develop depression. In an intention-to-treat analysis, escitalopram, but not therapy, was significantly superior to placebo in depression prevention.

(*continued*)

TABLE 199.10

CONTINUED

Study	Enrollment	Intervention	Results
Niedermaier et al. [76]	70 poststroke patients who were not depressed	Mirtazapine 30 mg/d vs. placebo for 1 y for prophylaxis and treatment	Significantly fewer patients in the treatment group developed depression. Fifteen out of 16 patients who developed depression were treated effectively with mirtazapine.
Rasmussen et al. [77]	137 poststroke patients who were not depressed at baseline	Sertraline 50–150 mg/d vs. placebo for 1 y for prophylaxis	Significantly fewer patients in the sertraline group developed depression compared to the placebo group.
Almeida et al. [78]	111 patients without depression < 2 wk after CVA	Sertraline 50 mg/d vs. placebo for 24 wk for prophylaxis	There was no significant difference in development of depressive symptoms.
Palomäki et al. [79]	100 patients with acute ischemic CVA	Mianserin 60 mg/d vs. placebo for 1 y as prophylaxis	Prevalence of depression did not differ between groups. No difference in stroke outcome or functional outcome was found.

[a] An antagonist at α_2-adrenergic pre- and postsynaptic receptors and 5-HT_2 receptors, similar to mirtazapine, available in Europe.
[b] A norepinephrine reuptake inhibitor available in Europe.
[c] A so-called cognitive enhancer used in patients with Alzheimer's disease.
[d] A Chinese herbal antidepressant.
[e] A depression rating scale.
CVA, cerebrovascular accident; FEWP, Free and Easy Wanderer Plus; HDRS, Hamilton Depression Rating Scale; MDD, major depressive disorder; PSD, poststroke depression; QOL, quality of life; SR, sustained release.

in reversing depression, reducing anxiety, and improving performance of daily activities [63]. Treatment with either antidepressant significantly increased the survival of depressed patients and, interestingly, nondepressed patients as well [80]. Other studies [64–67], although not all [68], found that fluoxetine was more effective than placebo for PSD. Citalopram [69,70], venlafaxine [71], and methylphenidate [72] also have been beneficial. Recently, Jorge et al. [81] found that poststroke patients who received escitalopram showed more improvement in global cognitive functioning than did patients who received placebo or problem-solving therapy. Moreover, this effect was independent of the antidepressant effect of the SSRI. Fluoxetine and sertraline may be more effective for emotional incontinence and anger proneness after stroke than for depression [68,73]. Nortriptyline [74], fluoxetine [74], escitalopram [75], and mirtazapine [76] were effective in preventing PSD; sertraline had mixed results [77,78], and mianserin was ineffective [79].

Electroconvulsive Therapy

ECT is a safe and effective treatment that may be used in cases of severe or delusional depression or when more conventional therapies cannot be used or are ineffective or intolerable to patients. Found to be particularly helpful in the depressive states accompanying stroke, Parkinson's disease, and dementia, ECT has become part of the standard of care for treatment of severe depression in the medically ill [82]. ECT is also used to treat catatonia.

There are no absolute contraindications to ECT, but patients with unstable cerebro- or cardiovascular disease or increased intracranial pressure warrant closer scrutiny [83–85]. The decision to proceed with ECT or not is made after a careful weighing of the risks of the treatment itself on any underlying physical morbidity against the risks of ongoing untreated depressive illness. This calculation is best done by a psychiatrist experienced in ECT in consultation with an anesthesiologist and other specialists. The latest research in this area has examined the memory impairment associated with ECT and the relationship of lead placement (e.g., bifrontal, bitemporal, and unilateral) to cognitive function [86–89].

Psychological Management

Although pharmacologic treatments are the mainstay of treatment for depression in the ICU, psychological remedies are also important. Patients often benefit from information, clarification, reassurance, and support. Psychological therapies are most useful in cases of adjustment disorder with depressed mood, often as an adjunct to pharmacologic interventions. Evidence has shown that brief psychotherapy at the bedside can give way to increased resilience and hope [90].

When patients come to the ICU, they are often terrified about the outcome of the illness that brings them there. They frequently believe that the illness, no matter how well controlled in the ICU, will continue to be life-threatening after discharge. Some patients believe that their illness will necessitate a radical change in lifestyle. For example, many cardiac patients secretly believe that having had an MI means they will never be able to have sex again. One way to help patients with such concerns is to ask specific questions about how they believe their illness will affect daily life in the future. In this way, one will hear the patient's specific fears and be able to educate the patient about the real effects of the illness. Another example is the patient who is physically weak after an MI and thinks he or she is a cardiac cripple. The patient does not understand that the physical debility is the result of muscle wasting from prolonged bed rest. Education often reassures patients.

Another way to help patients cope with depression in the ICU involves learning about a patient's premorbid activities. Because patients in the ICU feel stripped of their identities and are demoralized, showing interest in who they are and what is important to them can remind them that they are respected and have lives outside the hospital. Families also can be helped to have realistic expectations. Strategies to help patients and families cope effectively in the ICU are discussed in Chapter 201.

CONCLUSION

Treatment of depression in ICUs is multifaceted. Many difficulties are involved in treating depression. Nevertheless, aggressive treatment of depression in the ICU can drastically improve a patient's sense of well-being and transform a demoralized, hopeless patient into an active participant in treatment. In this chapter, we have outlined the recognition, differential diagnosis, and treatment of depression in ICUs. We strongly advocate that depression be treated as a serious illness; although a depressed mood is sometimes understandable, a depressive disorder is never appropriate.

CHAPTER 200 ■ MANAGING THE SUICIDAL PATIENT IN THE INTENSIVE CARE UNIT

SAORI A. MURAKAMI AND HOA THI LAM

The assessment of the suicidal patient is a significant challenge for any intensive care team. Even when a psychiatrist is consulted to conduct an expert assessment of risk and to assist with the formulation of a treatment plan, the intensivist's ability to evaluate, manage, and safeguard the patient's safety is essential. The evaluation and management of a patient—whether contemplating suicide or recovering from a suicide attempt—require an understanding of risk factors, protective factors, the interplay among these various elements, and the relationship between staff and patient. In addition, the primary medical team should be aware of the necessity for ongoing psychiatric care during and after the stabilization of acute medical issues.

This chapter reviews the epidemiology of suicide, risk and protective factors, parasuicide, and intervention and

management strategies for suicidal patients in the intensive care unit (ICU).

EPIDEMIOLOGY OF SUICIDE

Suicide is the 11th leading cause of death in the United States (8th in men, 16th in women) [1]. In 2006, suicide was responsible for 33,300 deaths, with higher rates among whites, youths, and individuals more than 65 years of age [2]. Although no recent national estimates of the number of admissions to ICUs due to suicide attempts are available, in 2008, 376,306 people presented to an emergency department for treatment of self-harm, and 163,489 people were hospitalized due to self-inflicted injuries [1].

RISK AND PROTECTIVE FACTORS

Although appraisals of suicide risk are incapable of absolute predictions of suicidal behavior, careful history-taking, detailed examination, and astute clinical judgment allow a comprehensive understanding and evaluation of risk factors, protective factors, and the interplay among them (Table 200.1).

The first set of factors is sociodemographic, including age, gender, race, marital status, and religion. In general, men are more likely to complete suicide, whereas women are more likely to make attempts [1,3,4]. White men are more likely to attempt suicide than nonwhites; among nonwhite populations, rates vary [1,3]. Suicide rates increase in two particular age distributions: late adolescence to young adulthood and older than age 65 [1,2,5]. In general, the suicide rate is greatest among divorced and widowed people, followed by single individuals, and married people [5]. The combination of age, gender, and marital status also plays a role; young widowed men have a particularly high rate of suicide [5].

Some evidence suggests that religious beliefs and the strength of one's religious convictions protect against suicide; however, for some, religion may increase suicide risk. For example, an individual who believes he will be reunited with his lost loved ones when he himself dies may be comforted by the idea of dying. Thus, the various meanings religion can have in different people's lives mandate careful exploration with the patient of the role of religion in death and suicide [5,6].

Psychiatric illness contributes significantly to the risk for suicide. Retrospective studies have identified one or more psychiatric disorders in individuals who have completed suicide or presented following a suicide attempt [7,8]. In addition, conditions often comorbid with psychiatric illnesses (e.g., substance use disorders) increase the risk for suicide. The presence of a past history of suicide attempts, suicidal thinking, self-injurious behavior, impulsivity, assaultiveness, and trauma (physical or emotional) is an important component of risk assessment. Whether a patient is in active outpatient psychiatric treatment—and compliant with it—is also critical. Psychological factors—coping skills, tolerance of emotions, personality traits, insight, and judgment—figure prominently in the estimation of how a patient handles stress.

The presence of a physical illness contributes to the risk for suicide, with the number of physical illnesses increasing the risk for suicide in a linear fashion [9]. Suicide risk is greater in patients with neurologic disorders (e.g., Huntington's chorea, organic brain syndromes, multiple sclerosis, spinal cord injuries), and suicide attempts are more common in patients with epilepsy [5,10,11]. In addition, head trauma is associated with an enhanced risk for suicide, particularly when behavioral or cognitive sequelae result. Executive function deficits due to delirium, dementia, or mental retardation also contribute to the risk for suicide. Other illnesses of significance are listed in Table 200.1 [5,12].

TABLE 200.1

RISK AND PROTECTIVE FACTORS FOR SUICIDE

Sociodemographic factors
Age
Gender
Race
Marital status
Religion
Psychiatric history and present psychiatric conditions
Psychiatric disorders
Substance abuse/dependence
History of suicide attempts
History of self-injurious behavior
History of homicidal or assaultive behavior
Impulsivity
History of physical or emotional trauma
Psychiatric treatment, both outpatient and inpatient
History of treatment adherence
Psychological factors
Medical history and present medical conditions
Neurologic disorders
Head trauma, with or without cognitive and behavioral sequelae
Executive function deficits
Malignancies
Human immunodeficiency virus infection
Acquired immune deficiency syndrome
Peptic ulcer disease
Chronic inflammatory diseases
Hemodialysis-treated chronic renal failure
Heart disease
Chronic pulmonary disease
Family history
Psychiatric illness
Substance abuse/dependence
History of completed suicide
Psychosocial stressors
Family life
Work life
Relationships
Finances
Recent real or perceived loss

Adapted from American Psychiatric Association: Practice Guideline for the Assessment and Treatment of Patients with Suicidal Behaviors. Arlington, VA, American Psychiatric Association, 2003. Available at: www.psych.org/psych_pract/treatg/pg/Practice%20Guidelines8904/SuicidalBehaviors.pdf. Accessed January 2, 2010.

Psychosocial stressors—including states of family life, work life, relationships, finances, and losses—are important considerations when assessing risk. A family history of psychiatric disturbances, substance use, or completed suicide may indicate potential genetic vulnerabilities in management of these stressors and response to interventions.

Protective factors include the presence of supports (e.g., family, friends, faith) and the absence of risk factors.

Risk and protective factors must be understood on a case-by-case basis [13–15]. Despite the significance of each factor, the weight to attribute to each element must be individualized, as the interaction among these features defines each patient's unique risk. For example, a 70-year-old unmarried white man with an incurable malignancy may be protected from suicide

by his religion's prohibition against it and by his three grandchildren's frequent visits.

PARASUICIDE

Some physicians may differentiate "genuine" suicide attempts (in which the person's aim was to kill himself) from parasuicide, a term introduced by Kreitman meaning "a non-fatal act in which the individual deliberately causes self-injury or ingests a substance in excess of any prescribed or generally recognized therapeutic dosage" [16]. Often, parasuicide is not a failed attempt to kill oneself per se, but could be either a maladaptive way to cope with emotions or an effort to elicit a specific reaction from someone else, whether an emotional response (e.g., feeling hurt or sorry) or a behavioral one (e.g., forestalling abandonment or providing nurturance). As such, a physician may be tempted to construe parasuicide as less concerning than an authentic attempt to end one's life. However, these individuals require equal attention and caution because parasuicide often recurs; when repeated often enough, such behavior may prove lethal, even if death is unintended. Furthermore, parasuicide may leave the person subsequently suicidal [17,18]. For example, a man who commits parasuicide in an attempt to keep his wife from divorcing him may feel genuinely suicidal if his wife ends up leaving him.

TREATMENT OF THE SUICIDAL PATIENT

Nonpharmacologic Interventions

A patient's verbalization of intent to harm himself or herself poses a unique challenge for the ICU physician. Although such utterances can be variously motivated and belie different intentions, any such statement should be taken seriously and viewed as the patient's request for help and support. Suicidal statements may take the form of explicit declaration or implicit action (e.g., refusal to eat or to cooperate with care). The suicidal act can be impulsive or deliberate. Because accurate prediction of which statements will result in action is impossible, the ICU team must institute effective precautions whenever a patient avows suicide.

The ICU team should implement close monitoring, in the form of constant observation by a one-to-one sitter or more frequent checks of the patient. Physical restraint of a patient at ongoing risk may be necessary when constant observation is not possible [12]. Staff should be aware of potential means by which patients may harm themselves. Any opportunity of jumping from windows or of hanging should be minimized, if not eliminated. All material that a person may use to harm himself or herself (e.g., razors, scissors, needles, glass, medications, and eating utensils) must be removed and any personal belongings searched for these items. Staff should also be aware of items brought in by visitors. The team should review medications and consider decreasing or discontinuing medications that may heighten impulsivity or disinhibition. Estimations of safety should be made at least daily.

The primary team must also identify and address among themselves any negative feelings they have about the patient. Emotional reactions to dealing with psychological problems in the ICU can include helplessness, insecurity, fear, anxiety, guilt, and sympathy. People who repeatedly attempt suicide or whose motives have been deemed "manipulative" can engender frustration, anger, and exhaustion with demands for constant attention, thereby creating distance between the patient and the treatment team. It is important to understand these feelings and to prevent them from hampering patient care and clouding recognition of a potentially unsafe patient. For example, patients with borderline personality disorder can "split" the staff (i.e., behave well for one subset of the staff and badly for another) [19]. Regular communication among staff members and between the staff and the patient can minimize splitting and prevent team members from feeling defensive or apologetic in the face of a critical and demanding patient.

An empathic approach that seeks to understand what the patient feels can prevent these emotions from instigating countertherapeutic responses. Even if a "suicide attempt" is an effort to elicit a particular response from others (rather than a genuine attempt to end one's life), the desperation required to put one's life at risk is nonetheless sobering. For people whose intent was to die, waking up from an unsuccessful suicide attempt can be accompanied by despair, shame, guilt, fear, anger, a sense of inferiority, and ambivalence about having survived [20]. The physical discomfort of the life-sustaining measures employed in the ICU only compounds such patients' pain.

Medications

The question of whether and when to restart psychiatric medications following a suicide attempt can be a difficult one, particularly if the person attempted to kill himself or herself by overdose on these agents. The decision to resume outpatient medicines must be guided first and foremost by accurate psychiatric diagnosis. They should not be restarted reflexively just because they had been prescribed previously; they should be ordered only if the patient has a bona fide psychiatric condition. Psychiatric consultation can be beneficial when the diagnosis is uncertain.

The next consideration is the patient's physical condition and the medications' effects on organs that the suicidal act may have compromised. Medications that are potentially toxic to impaired organs should not be restarted. Attention should also be paid to the patient's level of arousal and the risks for seizures and arrhythmias because psychiatric medications may enhance these risks.

Anxiety is a potent risk factor for suicide and should be treated to prevent recurrence of suicidal behavior and intensification of suicidal thinking. Benzodiazepines can be particularly helpful in quelling anxiety, whereas neuroleptic medications—both conventional and atypical—are preferred when anxiety escalates into outright fear. For full discussions of the use of neuroleptic agents and benzodiazepines in the ICU, see Chapters 197 and 198, respectively.

Psychiatric Consultation

Psychiatric consultation is strongly recommended whenever a patient's safety is questionable. The consultant will address psychiatric diagnosis, suicide risk, medications, and disposition. Consultation can also be helpful in understanding the psychological dynamics between patient and staff. The patient who may be thinking about, or at risk of, self-harm but has not articulated a specific thought may also benefit from expert consultation; elderly patients often do not report suicidal thoughts to caretakers [21,22].

When requesting a consultation, it is helpful to provide the consultant with as many details of the suicide attempt as possible (e.g., method, number of pills in cases of ingestion, likelihood of rescue). The exact words used by a patient who makes a suicidal comment, as well as the context in which the statement was made, are critically important and should be included in the consultation request. Basic elements of the patient's mental status (e.g., level of wakefulness, affect, presence of psychosis,

and ongoing suicidal thinking) should be determined and relayed to the psychiatrist.

Clear documentation from the nursing staff and physicians will help the consultant follow the patient's course and identify points of intervention. The existence of a suicide note can be of particular help in the assessment of suicide and in intervention planning [23]. However, whether to keep the suicide note in the permanent medical record is not clear. The suicide note can be of help to subsequent treaters; yet, in deference to the patient's privacy, a brief and general discussion of the note's existence and content may be all that is necessary for the medical record. The resolution of this matter should be made in consultation with the psychiatrist.

Disposition

When medically and surgically stable, patients face two options for discharge—home or psychiatric facility. Patients who may benefit from or require continued treatment in a psychiatric facility are those whose risk factors outweigh their protective factors. This decision is usually made with the psychiatric consultant, who will also assist with placement, prior authorization (which is required by some insurance plans), and the handling of any legal matters (e.g., if the patient is unwilling to be hospitalized psychiatrically and thus requires involuntary commitment).

CONCLUSION

Suicide is a tragic consequence of mental and physical illness that represents a relatively small number of ICU admissions. Nonetheless, the care of a patient who is suicidal or has just attempted suicide requires attention to a number of details not usually considered in the management of a typical ICU patient. The ICU team must be cognizant of their emotional reactions to the patient and of patient–staff dynamics, vigilant for potentially dangerous objects in the physical environment, and knowledgeable about specific interventions, including constant observation of the potentially self-harming patient. Psychiatric consultation can be helpful in managing important aspects of care for this patient population, from diagnosis and safety assessment to medication management and disposition.

CHAPTER 201 ■ PROBLEMATIC BEHAVIORS OF PATIENTS, FAMILY, AND STAFF IN THE INTENSIVE CARE UNIT

CRAIGAN T. USHER

The ear says more
Than any tongue.

W.S. Graham, "The Hill of Intrusion"

Whether a patient being treated in the intensive care unit (ICU), a supportive family member, or a physician or other healthcare professional working there, it is clear that the ICU is a stressful environment [1–5]. Problematic communication among patients, their families, and the hospital staff can hinder the restoration and maintenance of basic life functions that are the hallmark of intensive care. Occasionally, such difficult patient–staff or family–staff interactions stem from problems with care providers themselves. Depression, anxiety, overwork, sleep deprivation, longstanding interpersonal rigidity, and the cumulative effects of stress may cause some physicians and nurses to fail to address adequately the emotional needs of their patients and patients' families [6–8]. In other instances, patients and families become overwhelmingly stressed, their judgment and interpersonal skills rent asunder by longing, shame, rage, and despair. Such patients and family members may then act in ways that are irritating or even dangerous.

This chapter presents approaches to problematic patient conduct in the ICU, details common patterns of exasperating behavior in critically ill patients, provides practical ways of dealing with them empathically, and outlines some effective modes of communication with families of patients in the ICU. Above all, this chapter emphasizes that listening to patients and family members, paying special attention to the psychological needs underlying problematic behavior, and attempting to meet those needs make better patient–doctor/family–doctor relationships possible.

APPROACH TO PROBLEMATIC BEHAVIORS

Critically ill patients can behave in disruptive ways that jeopardize ICU activity and treatments. Some patients become childlike, cry or whimper, turn away from care providers, and refuse examinations or procedures. A number of patients grow demanding of nurses' and physicians' attention; they hurl insults when providers are not as attentive as they would like. Others may be violent, threatening staff, even punching and kicking caretakers.

Before deciding how to approach the disruptive patient, one must first answer the questions "Do I feel safe?" and "Is the patient safe?" ICU personnel learn to override their fears as they perform procedures that demand brisk, decisive action. Unfortunately, such denial occasionally leads to failure to heed an internal alarm regarding patient behavior, resulting in injury to patients and staff. Hence, it is key to "tune-in" to this sense of peril when acute danger to a patient or others exists and then to administer calming medications, summon security personnel, and apply physical restraints if necessary [9]. Physical confrontation with a non-delirious patient can sometimes be avoided by calling security personnel expeditiously, as merely seeing several officers, patients recognize the seriousness with which staff is approaching their threats or actions—and then relax.

For example, emerging from delirium after a near-lethal toxic ingestion, an impetuous adolescent threatened to "beat up" staff if not permitted to leave the ICU immediately. When hospital security arrived and the physician informed the young patient he would have to wait, the teenager quickly sat back in bed. Asked by the psychiatric consultant why he had calmed, the young man explained: "When it was just the nurses and doctor, I thought I could take them. But I knew I wasn't going anywhere when the police arrived. So I chilled."

Once the safety of the patient, other patients, and staff is ensured, examination of underlying causes of a patient's taxing behavior follows. As irritability and emotional lability are the final common pathway of myriad medical and psychiatric conditions and of normal emotional responses, precise determination of the cause of a patient's disruptive behavior is often vexing. Asking and answering the questions listed in Table 201.1 can be helpful in narrowing the vast differential diagnosis.

Delirium is a common source of troublesome patient behavior in the ICU. Patients who are hallucinating or harboring persecutory delusions that ICU staff is torturing them can be immensely problematic. Due to its potentially lethal nature [10], delirium should be ruled out first as the driving force behind a patient's disruptiveness. A full discussion of delirium is provided in Chapter 197.

After delirium has been excluded, it is important to look for major psychiatric illnesses, which are frequently exacerbated by the chaos, vulnerability, and prolonged inner tension associated with being treated in the ICU [11]. The intensivist should discern if the patient has a history of psychotic disorder, affective illness, or anxiety disorder and, in the absence of contraindications, should order any medications that have been effective in treating these conditions in the past. As part of this psychiatric workup, a substance-use history is also imperative; data from collateral sources may be necessary to confirm the patient's report. At any step in the process of assessing the roots of patients' problematic behaviors, psychiatric consultation may be useful in establishing and confirming diagnoses and in guiding treatment.

While gathering data about psychiatric conditions and substance use, common sources of patient stress in the ICU (e.g., pain, sleeplessness, and isolation) should be eliminated, as much as possible. Biancofiore et al. showed that liver transplant recipients and patients who underwent major abdominal surgery identified "being unable to sleep, being in pain, having tubes in nose/mouth, missing husband/wife, and

TABLE 201.1

KEY QUESTIONS ABOUT BEHAVIORAL PROBLEMS IN THE INTENSIVE CARE UNIT

Safety
Is the patient's behavior dangerous? If so, how can I keep the patient and others safe?

Delirium
Is the patient delirious? If so, am I effectively treating the underlying causes of delirium?

Psychiatric illness
Does the patient have an anxiety, mood, or psychotic disorder or other psychiatric illness? If so, am I providing adequate treatment for these conditions?

Intoxication and withdrawal
Is the patient intoxicated with or withdrawing from alcohol or other substance? Am I addressing the untoward effects of withdrawal?

Psychosocial stressors
Can I reduce pain, sleeplessness, isolation, and other stressors related to being in the ICU?

Personality problems
What is the patient's predominant mode of coping? How can I best manage this patient's uniquely taxing coping strategies?

seeing family and friends only a few minutes a day as the major stressors" [12]. Provision of adequate analgesia, effective sleep aids, anxiolytic agents, and uninterrupted interaction with significant others often substantially curtails problematic behaviors.

COMMON PATTERNS OF PROBLEMATIC BEHAVIOR

Critical illness leads many patients to feel lonely, dependent, or anxious about the prospect of death; traumatic memories may be reawakened as well. To keep these unpleasurable feelings and recollections at bay, ICU patients deploy a broad array of psychological defenses. Some patients' patterns of defense—that is, their personalities—are quite adaptive, even at times of stress. Other patients are devoid of the healthy emotional protoplasm, reliable social supports, and ample psychological armamentarium required to deal well with adversity. Such patients may be said to suffer from *psychosocial insufficiency*. Through denial, devaluation, passive-aggressiveness, and other primitive defenses [13], these patients are prone to wreak havoc in the ICU.

Psychosocially insufficient patients fall into two categories: (a) those with personality disorders who were difficult to deal with even before becoming critically ill and (b) those who have simply regressed and use primitive coping mechanisms that, outside the ICU, would be less apparent. Because the focus in the ICU is on the "here and now," distinguishing between these two categories is unnecessary. More important is recognition of pathologic personality styles [14] that frequently engender loathing in ICU personnel and require limit-setting, validation, and a commitment on the part of the physician to have a different, less unpleasant type of relationship with the patient (Table 201.2).

The Dependent Patient

Dependent patients demand assistance in nearly every aspect of their ICU experience. Through urgent requests for

TABLE 201.2

COMMON PROBLEMATIC COPING STYLES OF PATIENTS AND FAMILY MEMBERS IN THE INTENSIVE CARE UNIT

Personality type	Core deficit	Characteristic behavior	Suggested response
Dependent	Hypersensitive to abandonment, inadequacy, and aloneness	Craves attention Demands special care Childlike Cries easily and complains of abandonment and inadequate care	Schedule examination and rounding times Anticipate nursing staff changes, physician care shifts, transfer to floor Validate patient's plight and offer to help within reason
Narcissistic	Hypersensitive to loss of control and stature Defended against looking weak	Denies severity of illness Shows bravado Critical of ICU staff and care	Acknowledge patient's stature Enlist patient as active partner in care and decision-making
Obsessive	Hyperaware of loss of control Defended against looking weak	Excessive focus on medical facts and minutiae Restricted affect Not apt to "show emotional cards"	Schedule patient and family meetings Have a set amount of information to share with patient and family Provide factual explanations of data Avoid emotional commentary or inquiry
Dramatic	Difficulty feeling cared for or thought of except within emotionally extreme exchanges	Engaging and charming to some staff, denigrating and caustic to others May have multiple allergies and phobias May "fire" some staff and take exception to rules	Acknowledge patient's positive attributes Validate patient's plight and offer to help within reason Set limits as a team

Adapted from Kahana RJ, Bibring GL: Personality types in medical management, in Zinberg NE (ed): *Psychiatry and Medical Practice in a General Hospital*. New York, International Universities Press, 1965, p 108.

spoon-feeding, bedpan assistance, pillow adjustment, analgesia, and better food, among sundry other entreaties, dependent patients drive nurses and house officers to distraction. Yet, when examined through a sympathetic lens, one finds that dependent patients are incredibly fearful and leverage demands for care to keep their nurses and doctors in sight, thus reducing their anxiety. In this way, demanding patients are like the infant who, unable to hold onto the mental image of his mother, wails when she leaves the room. These patients are hypersensitive to aloneness. To mitigate these fears, nurses and doctors should keep such patients informed (e.g., when they plan to return, when rounds will take place, and when family will visit).

Still, for many dependent patients, basic information of this sort is insufficient to quiet their incessant demands for instant anxiety reduction. In these situations, validation of these patients' feelings, communication that their requests are understood, and explanation that the staff is unable to provide everything these patients want are key. These tasks are often accomplished through "I wish" statements. For example, a particularly dependent and anxious patient in a busy ICU pled for her ICU team to stay in the room. Respecting that the patient felt she needed more security than she was experiencing, the team leader responded: "While I wish we could stay here longer to explore your questions and provide further reassurance, unfortunately we need to complete rounds. However, I will return at noon to check on you." By validating the patient's needs, acknowledging her personal limitations, and providing reassurance about the time of return, this physician better met the patient's dependency needs.

The Narcissistic Patient

Being critically ill in the ICU can lead the most psychologically healthy person to feel infantilized; hence, for most patients, regaining a sense of control is extremely important. For some patients, however, this need to regain control takes the form of entitled demands and scathing critique. These patients often admonish nurses ("You're not doing that the right way!"), belittle their doctors (e.g., calling young house staff "Doogie Howser"), and name-drop ("Dr. Smith is an expert cardiologist I play golf with, and he would never allow that").

With such patients, it is best to appeal to, rather than to confront, their narcissism. When the narcissistic patient looks around the ICU, all he sees are his inadequacy, inability, and incapacity. The intravenous pump reminds him he cannot feed himself, the ventilator brings to mind that he cannot breathe unaided, and the bedside commode or bedpan becomes a glaring reminder of his inability to move about nimbly. By using words that remind the patient that, despite his infirmities, he is still a valuable person, one then "joins" the patient and incurs less wrath and invective. Such "joining" can be done by respectfully calling patients "Mr.," "Ms.," and "Dr.," as appropriate. It is also helpful to ask them about their lives outside the hospital, promoting the notion that they are not frail and infantile but able-bodied adults endowed with personal agency despite their current debility.

The narcissistic patient, with his sense of specialness and need for excessive admiration, appreciates any control he can be afforded. Even if this means controlling the light switch, choosing the hour the physical therapist will arrive, or using patient-controlled analgesia, the narcissistic patient revels in being a partner in his care. Finally, avoidance of power struggles and sharing of dilemmas are key to working with these patients effectively. For example, an astute medical intern said to a "very important person" (VIP) in the ICU: "While I realize the catheter is completely uncomfortable, if I were to remove it right now, it is likely I would have to replace it tomorrow. I can do this if you'd like—it is your decision—but I am concerned that this would cause you even greater pain." Knowing he had a choice, the VIP felt greater self-agency and was thus able to defer to the doctor's educated opinion, electing to leave the catheter in for the time being.

The Obsessive Patient

The obsessive patient is rules-based and acts much like an early school-age child clinging to the rules of a board game. Following the obsessive mantra "a place for everything and everything in its place" [15], the obsessive patient wants to know what his radiograph shows before it is even taken. His day can rise and fall on laboratory minutiae. Like the narcissistic patient, the obsessive individual feels his control slipping away at times of illness. However, rather than acting in a haughty manner to deny that illness is stripping him of his control, the obsessive patient attempts to attain mastery over his condition through excessive focus on detail. A master of "losing the forest for the trees," the obsessive patient gets mired in the fine points. He asks questions incessantly and wants to manage his own treatment. For example, one obsessive patient with myasthenia gravis espied an "L" next to her hematocrit and demanded to know why she was not being transfused when her hematocrit was 32.3%. When her nurse sat down at her bedside and provided a synopsis of her laboratory results and the team's rationale for management, the patient was soothed. For all patients, but particularly for obsessive ones, it is helpful to: (a) have in mind a set amount of information that the team wants to share with the patient, thus allowing the patient the mastery over illness he or she craves but without overwhelming him or her; (b) announce a regular time when nurses and physicians will share a progress report; and (c) use scientific/deductive reasoning to explain each step in treatment.

The Dramatic Patient

With intense difficulty identifying their own affective state and the thoughts and feelings of others [16], extremely dramatic patients or family members, many of whom may suffer from borderline personality disorder, make erroneous assumptions about their caregivers' intentions. Based on little data, such patients sense that they are loved and appreciated by some, while loathed and apt to be mistreated or abandoned by others. The dramatic patient or family member thus idealizes and praises some staff members while alienating others with toxic devaluation and belligerence. Even the most mindful, well-meaning, intelligent physician or nurse can find himself or herself suddenly on the wrong side of this idealization/devaluation "split." Validating patients' feelings but not necessarily their beliefs can be helpful. For example, one family member berated a physician: "You must hate our family!" The physician responded: "I am surprised to hear you say that, because I am not aware of having bad feelings toward you or your family. I wonder what gives you that impression." The family member then explained that the doctor seemed to turn away from the family when he passed by the visitors' lounge and "did not do nearly enough family meetings." Now understanding that this person required more information and dialogue than he customarily provided, the physician agreed to have more frequent meetings and made a concerted effort to acknowledge the family's presence when passing them, and thus enjoyed a more positive working relationship with this family member.

When clinicians who have had completely different experiences with a dramatic patient or family member confer, they are at odds over how to handle the dramatic individual's demands. This discord creates tremendous tension among treatment team members and can be relieved when clinicians acknowledge they

TABLE 201.3

PRINCIPLES OF ESTABLISHING LIMITS AND NEGOTIATING CONFLICTS IN THE INTENSIVE CARE UNIT

Acknowledge the patient's real struggles.

Explain limits in a clear and concise manner. Avoid jargon such as, "You are demonstrating unsafe behavior, sir. This is a nonsmoking environment," and simply offer, "You can't smoke while you're in the unit."

Before speaking with the patient, know what areas, if any, are flexible and make concessions to the patient in those areas.

Determine consequences for transgressing limits in advance.

Avoid long, drawn-out arguments as they are rarely, if ever, useful. Leaving the patient's bedside to cool down, thinking of a new strategy, or consulting a colleague is better than acting impulsively.

Adapted from Winnick JA, Wool CA, Geringer ES, et al: Problematic behavior of patients, family, and staff in the intensive care unit, in Irwin RS, Rippe JM (eds): *Irwin and Rippe's Intensive Care Medicine*. 5th ed. Philadelphia, Lippincott Williams & Wilkins, 2003, p 2192.

have had divergent emotional experiences with a patient. Once this "split" is named, the team can then strategize how best to set limits (Table 201.3).

COMMUNICATION WITH FAMILIES

Almost always for better, but occasionally for worse, family members are not mere visitors to the ICU [17]. Families play an integral role in encouraging and comforting critically ill patients and informing distant loved ones of patients' progress or problems. With the exception of those patients who, prior to hospitalization, expressed their preferences for medical care, relatives are also responsible for learning about a patient's diagnosis and prognosis and making decisions for critically ill patients who lack the capacity to make medical choices for themselves.

It can be difficult to function in these roles, as the experience of having a family member in the ICU takes a psychological toll. One study revealed that 69% of family members of intensive care patients suffered depressive symptoms and 35% had anxious symptoms [2]. Azoulay and colleagues reported that up to one third of family members suffered posttraumatic stress symptoms 3 months after their family member was discharged from the ICU [3].

Adequate communication between ICU staff and patients' family members is central to reducing family stress and dissatisfaction [18,19], decreasing conflict around end-of-life decisions [20], limiting futile interventions [21], and reducing strife between families and ICU staff [22]. Some general principles of communication with families in the ICU include providing clear and concise medical information, scheduling and keeping appointment times to meet with families, respecting the uniqueness of the family and the patient, attending to special aspects of the patient's and family's life story, and providing early diagnostic and prognostic information, even if this means saying, "I'm not sure" [23,24] (Table 201.4).

Even with good communication, problems arise. Occasionally, before the physician can provide information regarding prognosis, family members will foreclose discussion and disagree with the doctor or other family members about how much workup or end-of-life treatment to pursue. Some special situations related to the emotional life of family members bear examination in further detail. These include the guilty family member, the family member compelled to preserve the dignity or "fighter status" of the patient, and the vindictive family member. Physician interventions or "conversational reframes" in these situations are aimed not at coercion but at enhancement of doctor–family and family–family conversation about how best to proceed with a critically ill family member's care.

TABLE 201.4

CORE PRINCIPLES OF COMMUNICATION WITH FAMILIES IN THE INTENSIVE CARE UNIT

*C*lear
Provide family members with clear, concise descriptions of the patient's condition. Avoid jargon. Ask if you have adequately addressed the family's questions and concerns.

*O*n time
Schedule appointments for family conferences or treatment updates and try, as best as possible, to be on time. Send a representative if you must.

*R*espect the patient's uniqueness
These appointments are as much about what you say as how well you listen. Pay close attention to people's names and what makes the patient special.

*E*arly diagnosis and prognosis
Even if it means saying, "I'm not sure," try to inform the family early in the ICU stay.

Occasionally, a sibling, parent, or child of an ICU patient who has played little role in the ailing family member's life attempts to rectify this estrangement by coming to the rescue at the 11th hour. To assuage their guilt, these family members demand that "everything" be done for their relative, to the point of pushing for futile assessments and treatments. Reframing the dilemma for these family members, giving them a sense of authority, and explaining how they can be helpful can shift the family–staff dialogue. For example, one intensivist told a particularly guilt-ridden son whose mother had suffered a severe stroke: "I know you've had to be away for several years and not been able to play a day-to-day role in your mother's care. However, this is a really big opportunity to help support your dying mother and your struggling sister. You can help your sister and the rest of your family come to a well thought-out decision about your mother's care." By suggesting how this young man could help in the here and now and indirectly addressing his guilt, the physician altered this concerned son's attitude.

When dealing with end-of-life care, some family members will demand that everything be done because they do not want their loved one to seem weak. "But he's a fighter," some relatives protest. In these situations, one should listen closely to why it is important that the patient's status as a "fighter" be maintained. Once this information is obtained, the ICU staff member might illustrate how the patient remains a fighter even as heroic measures are scaled back. For example, a 78-year-old World War II naval veteran was admitted to the ICU with a massive myocardial infarction from which a meaningful recovery was extremely unlikely. The patient's daughter touted the fact that her father had made it through polio, the Pacific campaign, and a kidney transplant, and refused even to discuss withdrawing ventilator support. Wed to the picture of her father as a warrior, this loving daughter asserted, "He's made it this far and he'll keep fighting." When the intensivist told the daughter he understood her father had made it through these

trying illnesses and battles, detailed the extent of her father's myocardial damage, and emphasized that it took a "remarkably massive" heart attack to bring him down, the daughter's vision of her father as a "fighter till the end" was affirmed. She was then more amenable to discussing end-of-life care and relaxed her terse "do everything" commands.

Some family members may be angry with the patient. Wasserman studied responses provided by relatives of patients who had attempted suicide and found that a family's request for "do not resuscitate" orders sometimes reflected anger toward the patient [25]. Eliciting these feelings during a family meeting may help family members to acknowledge the hostile origins of their decisions and to feel they have acted less impulsively and more thoughtfully about how to proceed with a loved one's care.

Communication between ICU staff and a patient's family may be disrupted when a family member does not want to make decisions on behalf of a loved one or suffers symptoms of anxiety, depression, or other psychiatric illness [26]. Such family members may derive great benefit from consultation with the ICU's social worker or an outpatient psychiatrist. When discussions over care reach a standstill and interventions spur little movement, referral to an ethics consultant or committee (particularly with regard to end-of-life care) or patient-rights advocate (regarding a family member's grievance) may help resolve the conflict.

CONCLUSION

Physicians, nurses, and other members of the critical care team are often confronted with patients and families whom they find taxing or even dangerous. Establishment of safety, exclusion of causes of disruptive behavior amenable to medical intervention, examination of the patient's and family member's predominant defense mechanisms, and attempts to address the patient's or family member's psychological needs better can improve such difficult interactions. Patients with personality problems often respond to validation of their distress and to limit-setting, entailing a description of how they are expected to act and what they can expect from their caregivers. Family members and loved ones play a crucial role in critical care; ensuring that they are part of the ICU team involves providing clear diagnostic information early on, conveying respect for the uniqueness of patients and their families, and providing regular, scheduled updates.

CHAPTER 202 ■ RECOGNITION AND MANAGEMENT OF STAFF STRESS IN THE INTENSIVE CARE UNIT

GUY MAYTAL

Intensive-care settings reveal humanity at its best and at its worst. This is as true for the staff as it is for the patients. We who serve in intensive care settings in a true sense risk our own lives in these settings—our feelings, our self-esteem, our self-respect. By risking these daily we grow; by avoiding the risk we must face the dehumanization of ourselves or of our patients.

Cassem and Hackett [1]

The intensive care unit (ICU) is a structurally, functionally, and socially complex entity with its own culture, personnel, protocols, and problems [2,3]. Today, such units are routinely filled to capacity with complicated patients suffering from multiple life-threatening illnesses. As technology has advanced, patients with once-terminal illnesses are surviving longer, raising ever more complicated ethical issues [4].

For patients and their families, time spent in an ICU can lead to physical and psychological trauma [5–7]. The overall "hostile" environment of the ICU—with its multiple, complicated devices, lack of patient comforts, lack of privacy, and elevated ambient noise—contributes to negative psychological outcomes for patients [8].

This same environment also affects ICU staff. The psychological pressures on ICU personnel are myriad: increasingly sophisticated technological advances, overwhelming amounts of data, burdensome demands on caretakers, long hours, nursing shortages, and trying ethical issues. Staff may not be prepared to handle their emotional reactions to these challenges while simultaneously tending to the technical and clinical aspects of intensive care.

This chapter reviews the general concepts of stress and burnout, the tensions associated with training and working as a physician or a nurse in an intensive care setting, and strategies for managing staff stress in the ICU.

STRESS

The physiologic, cognitive, and affective facets of stress are based on the seminal early work of Selye [9] on the *general adaptation syndrome*. Selye defined stress as the nonspecific result of any demand on the body, and observed that different organisms and biological systems respond to stress in a stereotyped and predictable three-part pattern. The initial alarm reaction (characterized by activation of the sympathetic nervous system and various hormonal, immunologic, and psychological responses) is followed by the stage of resistance, during which the organism establishes a temporary homeostasis by marshalling various reserves to adapt to the new situation. However, the body's ability to adapt is finite, and, with continued exposure to the stressor, its reserves become depleted and the organism enters a stage of exhaustion.

Researchers in biology and sociology have expanded this work to encompass processes ranging from individual cellular responses to stress, to the reactions of individuals and social systems to external and internal stressors. The study of occupational stress (i.e., stress due to one's work situation) has grown substantially since the 1960s, expanding to professions ranging from factory work to nursing. Research during the past four decades has consistently demonstrated the significant adverse impact of excessive occupational stress on physical health, mental health, and decision-making. Regardless of the field, low job satisfaction is often predicted by a small number of factors: little participation in decision-making, ambiguity about job security, poor use of skills, and lack of clarity about role. These stressors are consistent with the *demand–control model* of the effects of job demands on worker's well-being. This model predicts that the fewer demands and more control a worker has on the job, the less stress he will experience [10,11]. For example, an analysis from the Swedish National Registry of 958,000 people found that hospitalization rates for myocardial infarction (MI) were higher among men and women with high-demand, low-control jobs [11].

Other well-recognized occupational stressors include noise-related stress, dangerousness of the work environment, nonstandard work hours, and excessive fatigue [10]. Of these stressors, work overload and a poor social environment at work are the most significant determinants of work-related health problems. Cross-sectional associations between work overload and health complaints are consistently reported [12,13]. Furthermore, work overload and overall low job satisfaction are strongly associated with the development of psychiatric (particularly affective) problems. A meta-analysis of job satisfaction and health outcomes examined 485 studies (267,995 individuals) and concluded that poor job satisfaction was strongly associated with the development of depressive and other affective illnesses [14].

In addition to physical and mental health, decision making also can be adversely affected by high levels of stress. Awareness of one's limited knowledge and problem-solving capabilities, fear that bad outcomes will occur regardless of which choice is made, worry about making a fool of oneself, and fear of loss of self-esteem if the decision is wrong can force decision-makers to come to "premature closure." Fearing a negative assessment of their sense of helplessness, otherwise rational decision-makers foreclose the decisional dilemma before a search for, and an unbiased assimilation of, all relevant information and generation and careful appraisal of all alternatives can be completed [15].

Such premature closure can lead to incorrect or even harmful decisions [15]. For example, in their classic study of patients with acute MI, Hackett and Cassem [16] noted that the majority of patients experiencing what they thought might be an MI delayed calling for help for 4 to 5 hours. In an effort to avoid

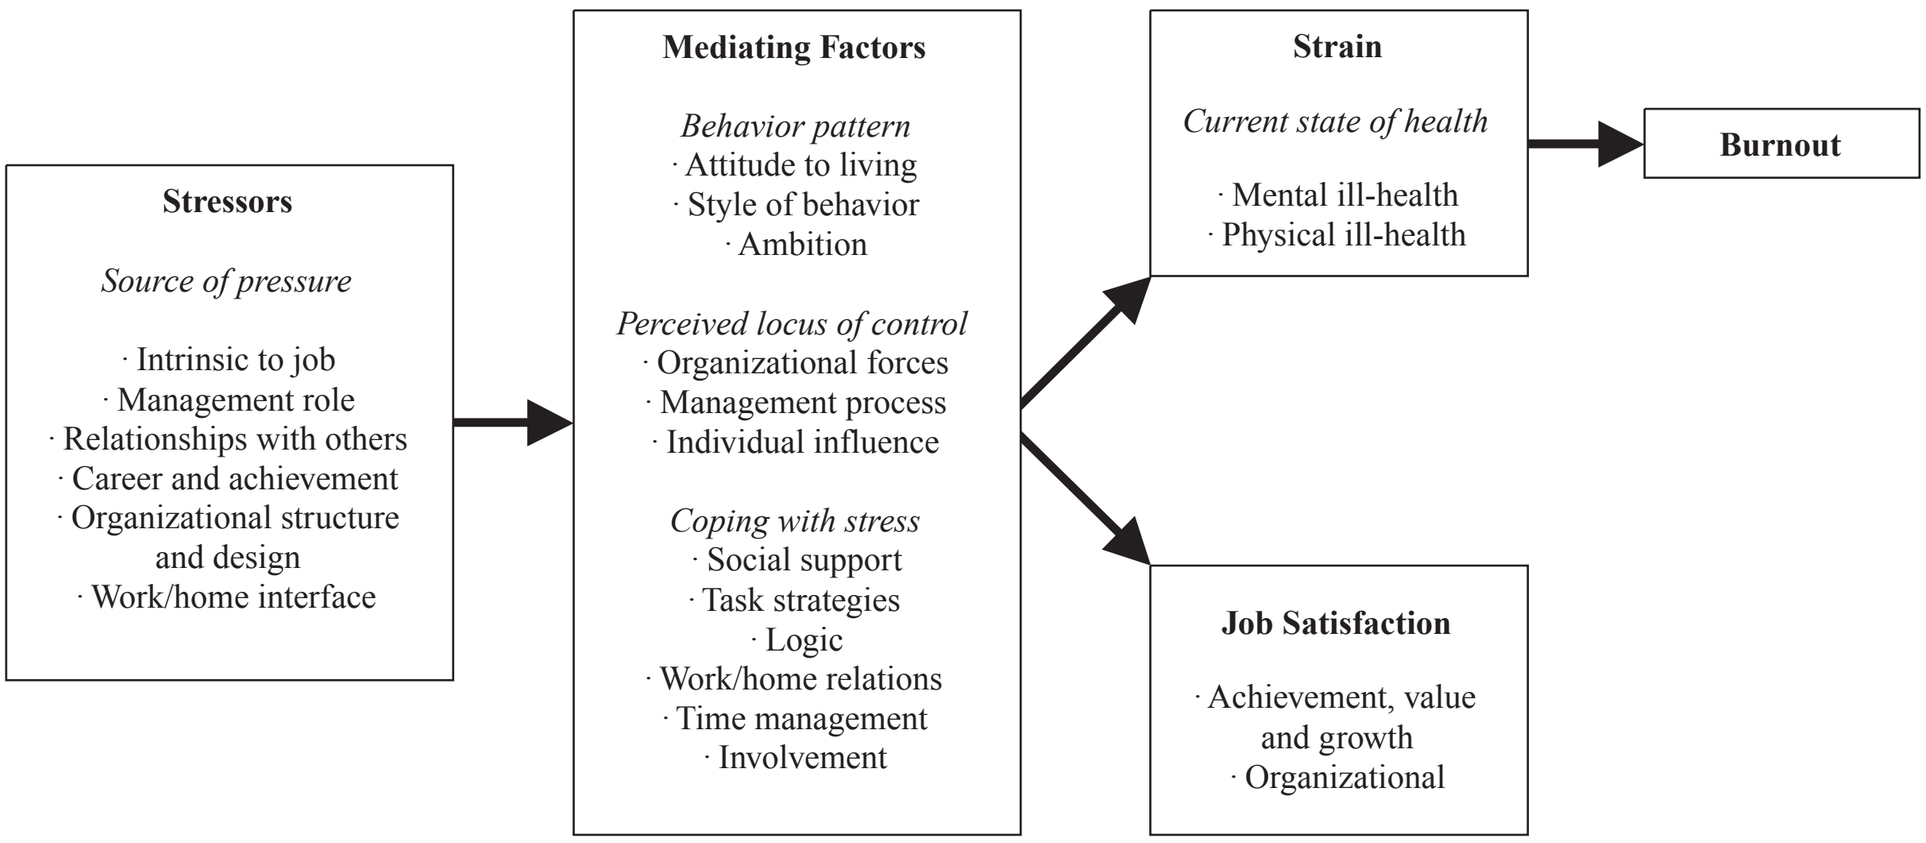

FIGURE 202.1. Stress–strain model of occupational stress. [Adapted from Cooper CL, Sloan SJ, Williams S: *Occupational Stress Indicator: Management Guide*. Windsor, UK, NFER-Nelson, 1988.]

the anxiety of a potentially devastating diagnosis and its implications, these patients came to premature closure and made potentially deleterious decisions about when to seek medical attention [17].

In a work environment, including the ICU, stressors (both work- and nonwork-related, both internal and external) affect each individual in a unique manner as mediated by a variety of factors. The interaction between stressors and mediating factors leads the individual to experience either strain or job satisfaction (Fig. 202.1) [18]. When this interaction leads to strain that is chronic or particularly intense (or both), burnout occurs.

BURNOUT SYNDROME

Coined by the clinical psychologist Herbert Freudenberger [19] in 1974, *burnout syndrome* has been viewed as a behavioral or a psychological condition as well as a process or a syndrome [20]. Research during the past 2 decades (especially by Maslach and colleagues) has narrowed the current definition to encompass the spheres of emotional exhaustion, depersonalization (i.e., negative or cynical attitudes regarding work), and the absence of personal accomplishment—particularly among individuals who do "people work" (Table 202.1) [21]. While emotional exhaustion is the key component of the syndrome, people with all three symptoms experience the greatest degree of burnout [22]. Ultimately, this definition describes a process whereby highly motivated and committed individuals lose their spirit, their motivation for creativity, and, in the ICU, their belief in their ability to help people [23,24].

Burnout varies in intensity and duration, although it often has an insidious onset [25]. Even if an individual's experience of burnout does not reach consciousness initially, it may affect others, burdening the system with another source of stress.

Many have argued that the cause of burnout lies in our need to believe that our lives are meaningful and that what we do is useful and important [23]. Work takes on a central role in providing some people with this sense of meaning in their lives. When individuals who derive such meaning from work think they have failed in their jobs, they may experience burnout. Burnout tends to afflict people who enter their professions with high motivation and idealism; it is particularly common in occupations often seen as "callings" [26]. In a supportive environment, highly motivated individuals reach their goals and achieve success, which leads to a sense of meaningfulness that itself increases the original motivation. However, in an unsupportive environment, these individuals cannot accomplish what they set out to do and consequently fail. For people who expect a sense of meaningfulness from work, such failure often leads to burnout.

Everyone experiences stress, but only those who start their careers with high levels of idealism, motivation, and commitment are at risk for burning out: "You cannot burn out unless you were 'on fire' initially" [23]. Burnout occurs almost exclusively in individuals who work with people, arising from the emotional stress that such interactions engender. ICU staff tend to be idealistic, committed, and driven—the very attributes which render them susceptible to burnout. In assessing and managing burnout, attention should be paid to the impact of job-related stressors and their ramifications, as well as the individual's personality style. The character trait of hardiness (i.e., initiative, willingness to take risks, ability to face uncertainty,

TABLE 202.1
THREE COMPONENTS OF BURNOUT

Emotional exhaustion	Reduced energy and job enthusiasm Emotional and cognitive distancing from the job
Depersonalization	Cynicism Lack of engagement and distancing from patients Treatment of patients as inanimate, unfeeling objects
Absence of personal accomplishment	A significantly diminished sense of efficacy, effectiveness, involvement, commitment, engagement, and capacity to innovate, change, and improve

Adapted from McManus IC, Keeling A, Paice E: Stress, burnout and doctors' attitudes to work are determined by personality and learning style: a twelve year longitudinal study of UK medical graduates. *BMC Med* 2:29, 2004.

and assertiveness in attaining and manipulating external rewards) has been shown to protect healthcare professionals (particularly nurses) from burnout in multiple stressful settings [27].

For the individual, burnout is characterized by physical, emotional, and attitudinal symptoms. Physical symptoms are nonspecific and include chronic fatigue, headaches, insomnia, weight changes, and worsening of chronic medical conditions. Burnout can lead to increased consumption of tobacco, alcohol, and illicit drugs. Emotional symptoms include despair, hopelessness, and depression. Relationships can become disrupted and the ability to work can be compromised [21].

On an organizational level, cynical attitudes toward work, colleagues, and patients can isolate coworkers and precipitate staff conflicts. At some hospitals, job dissatisfaction and burnout have led to absenteeism, accelerated staff turnover, and severe staff shortages, which may limit the number of ICU beds available for patient admissions [28].

STRESS AND BURNOUT IN HEALTHCARE PROFESSIONALS

Stress is a common aspect of medical practice for physicians, nurses, and trainees. Not surprisingly, studies over the past several decades have reported a high prevalence rate of burnout in healthcare professionals. Rates of burnout among physicians range from 25% to 60%, depending on working conditions and medical specialty [29–34]; burnout can develop at any stage of a physician's career. Nurses also experience high levels of burnout. Studies in nurses indicate rates of 35% to 50%, depending on working conditions, clinical setting, and level of autonomy experienced [22]. Multiple factors have been associated with burnout in healthcare professionals, but the best characterized include: heavy workload, stressful work environments (e.g., ICUs), severity of patients' illnesses, and conflicts with coworkers or patients [35,36].

Physicians who experience burnout suffer physical (e.g., anorexia, insomnia, tachycardia, and hypertension) and psychological (e.g., irritability, frustration, apathy, indecision, and depression) symptoms. Burnout leads to increased nurse distress, decreased patient satisfaction, increased mortality in the ICU, and substance abuse [37,38]. Furthermore, approximately 10% of physicians develop a substance-related disorder in their lifetimes; the risk of narcotic abuse in physicians is ten times that of the general population. Substance abuse often leads to sanctions and to loss of license and livelihood [39]. The primary risk factors for addiction in physicians include high stress levels, access to drugs, and chronic fatigue, all pronounced in ICU settings. Often shielded by a "code of silence" among fellow practitioners, impaired physicians often come to clinical attention in an advanced stage of addiction.

Just as concerning are the statistics on physician suicide. Male physicians are two times more likely to commit suicide than average Americans; female physicians are three times as likely [40]. Furthermore, physicians' personal relationships with spouses and children are damaged by burnout: "Being a physician is one of the few socially acceptable reasons for abandoning a family" [41].

STRESS AND ITS CONSEQUENCES IN PHYSICIAN TRAINING

During the past 20 years, the medical and sociological literatures have documented the impact that work-related stress has on physicians and on their ability to care for patients. Consequently, efforts have been made to understand the nature of stress and burnout in house officers, fellows, and staff physicians—particularly those who work in intensive care settings. Stress and burnout have been associated with deterioration of the physician–patient relationship and a diminution in both the quantity and the quality of care [37]. Therefore, burgeoning efforts have been directed to prevent stress and impairment and to improve the care of physicians suffering from stress or burnout [42–44].

Competitive, highly driven, and able to delay short-term gratification indefinitely, people attracted to medicine are more likely to have personalities that render them susceptible to the detrimental effects of stress and to burnout. As a rule, they are success-driven, tend to be "people-pleasers," and are unable to recognize their own limitations. Similarly, they do not often understand or attend to their own emotional and psychological health and, citing the need to be "strong," squelch their emotional reactions to stressful events [44].

Medical practice has changed dramatically over the past several decades, and many physicians who entered medicine to enhance their sense of control and mastery find themselves in a medical system that is increasingly out of their control [44]. Physicians have experienced a decline in status and autonomy alongside increased work pressures. Under closer scrutiny by regulatory agencies and insurance companies, physicians have had to contend with ever growing amounts of paperwork. Due to increased pressure to discharge patients, the acuity of patients in hospital settings has increased, "turnover" is more rapid, and interventions are more aggressive.

House officers, in particular, face a unique constellation of stressors. According to a review of the stresses of residency by Colford and McPhee [42], the stressors faced by house officers are varied, including those related to the nature and educational structure of residency, being a female resident, and perceptions about work. Among the most potent stressors are sleep deprivation, information overload, long work hours, and confrontation with chronic and fatal diseases. Others include financial debt (including from educational loans), personal relationships, and anxiety about malpractice. These researchers also found that alcohol and drug abuse was a significant problem in 7% to 10% of physicians. They cited studies verifying high levels of stress due to physicians' relationships, psychological problems (e.g., anxiety and depression), and professional dissatisfaction.

In recent years, more quantitative evaluations of the effects of stress and burnout on house officers have implicated residency-related stressors in contributing to psychiatric and physical impairment. Such stressors include overnight call, responsibility for four or five times as many patients at night as during daytime hours, lack of supervision while on call, the inability to complete a task without interruptions, and lack of substantive patient interactions [45–47].

In a longitudinal study that examined the impact of job stress on house officers, Tyssen and colleagues [45] followed 371 medical students from their last semester through the end of their internship. They found that 11% of these interns had mental health problems. Predictors of mental health problems included prior mental health problems, a high level of neuroticism, and experience of a serious negative life event during internship. Most important among these factors was perceived job stress. Furthermore, perceiving oneself as deficient in clinical skills or knowledge at the end of medical school was related to a mental health problem during internship. Importantly, gender, number of hours worked weekly, and lack of sleep were not linked to mental health problems.

In a similar study, Newbury-Birch and Kamali [46] examined the relationship among work-related stress, job satisfaction, and personality factors in 109 medical house officers. They found that 24% of the men and 38% of the women suffered from psychological stress. Levels of depression and

anxiety were significant among these house officers. The personality characteristic of neuroticism was a predisposing factor for stress and anxiety.

Shanafelt and colleagues [47] examined the relationship between burnout and self-reported patient care practices in a university-based internal medicine residency program. They found that 87 (76%) of the residents surveyed met criteria for burnout. Those residents who were burned out were much more likely to be depressed, have low career satisfaction, and report significantly more "suboptimal patient practices."

Stress and burnout are associated not only with work hours but with a variety of internal and external factors; quality of teamwork, personality characteristics, and trouble with the work/home interface all contribute to the development of stress and burnout in house officers. A 12-year longitudinal study of medical school graduates found that specific personality traits (e.g., high neuroticism, low extraversion, and low conscientiousness) measured while in medical school strongly predicted the development of stress, burnout, and job satisfaction as a staff physician [48].

Despite work-hour restrictions, house officers and fellows continue to shoulder stressful workloads that have a significant impact on their physiology and psychology [46]. Gopal and coworkers [48] studied a single cohort of residents before (2003) and after (2004) restrictions on work hours were implemented. Residents in 2004 had less burnout, emotional exhaustion, sleep deprivation, and depression. However, the residents did not perceive any significant changes in their quality of life, and their learner satisfaction was significantly reduced.

Parshuram and colleagues [49] prospectively studied 11 critical care fellows in Toronto, Canada, working within the Ontario guidelines limiting work hours and overnight call shifts. The researchers thoroughly examined the amount of work performed by the fellows (e.g., number of hours, admissions, procedures, pages). They also used Holter monitors to screen for arrhythmias, pedometers to measure distance walked, and urinalysis to evaluate hydration. The results showed that, despite work-hour restrictions, the fellows continued to work long shifts, with little sleep (average, 1.9 hours per night), frequent pages (average, 41 per shift), many admissions, and many procedures. Furthermore, they walked an average of 6.3 km per shift. More alarming was that abnormalities in heart rate and rhythm occurred in all participants. Ketonuria was found in 21% of the shifts during which it was measured, indicating dehydration and suggesting self-neglect.

STRESS AND BURNOUT AMONG INTENSIVISTS

Stress and burnout are not limited to house officers and fellows. Staff physicians—in particular those who work in ICUs—have a high prevalence of burnout syndrome. The protracted stress of working as a physician can lead to lower-quality patient care, disruptions in personal relationships, and even impairment of physical health [50]. Intensivists labor in an atmosphere of perpetual stress and often limited rewards. In addition, society often has unrealistic expectations of the physician not only as a professional but also as a spouse, parent, employer, and community member. Failure to live up to any of these can lead to a sense of failure [50]. A 2001 survey by the Canadian Medical Association found a significant decline in physician morale, due to volume of work, sleep deprivation, teaching and research demands, potential for litigation, and greater demands from the public [44].

In recent years, researchers have attempted to better quantify the way in which these stressors affect physicians who work in intensive care settings. Coomber and coworkers [38] surveyed all members of the Intensive Care Society in the United Kingdom (85% response rate, 758 respondents) to identify "distressed" doctors and to relate this state to "repeated and long-term exposure to job stressors." They found that nearly 30% of the physicians surveyed were distressed, 12% were depressed, and 3% had suicidal thoughts. These physicians reported that the most stressful aspects of their work were the feeling of being overstretched, the effect of work hours and stress on personal/family life, and the pressure to compromise standards when resources were limited. Other important stressors included perceiving a lack of peer recognition, feeling alone in making important decisions, and occasionally having too much responsibility.

In a recent survey of 978 French intensivists, Embriaco and colleagues [35] found that 46.5% had a high level of burnout syndrome. Risk factors included female sex, increased workload, and conflicts with coworkers. Similarly, in a survey of 6000 American physicians, female physicians were 60% more likely to report burnout than their male counterparts [51]. Furthermore, in the Embriaco study, workload (as measured by number of shifts per month and length of time from the last day off) was associated with higher rates of burnout. Lastly, conflicts with coworkers are associated with higher levels of burnout, while good relationships with nurses are a protective factor [35,36,52].

Given the high frequency of burnout in physician populations, the Academy of Professors of Medicine analyzed survey data from more than 4,000 physicians in the United States and the Netherlands and formulated a model to predict burnout. Their model (Fig. 202.2) lists factors specific to physicians that place them at risk for developing burnout, and suggests areas of intervention to help prevent the development of this burdensome and costly syndrome [37].

STRESS AND BURNOUT AMONG INTENSIVE CARE UNIT NURSES

Although nurses and physicians work in the same physical environment, nurses have unique working conditions, emphasize

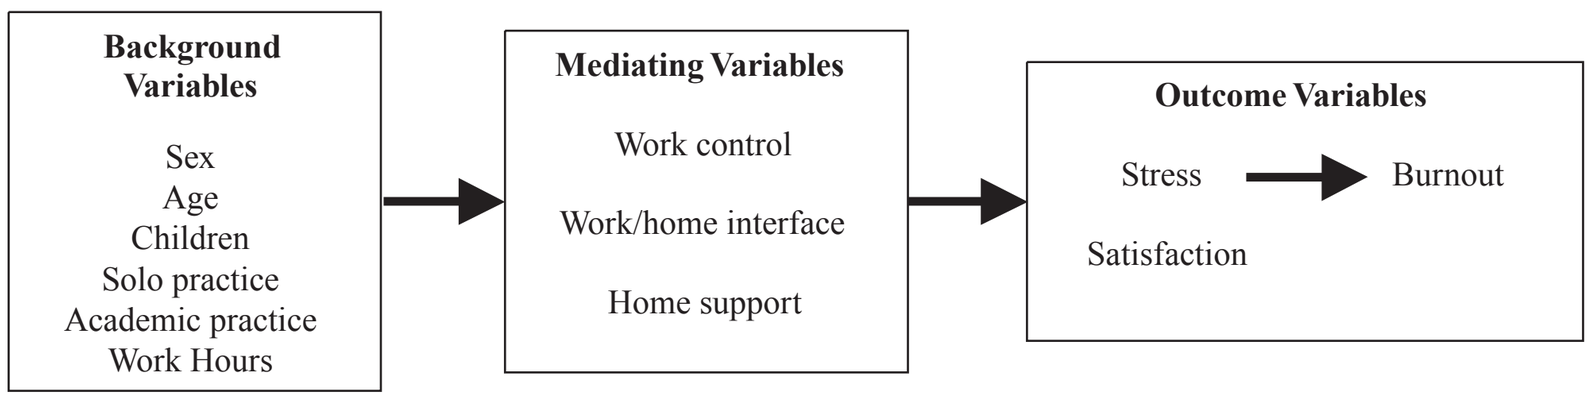

FIGURE 202.2. Model for predicting physician burnout. *Arrows* indicate a direct effect. [Adapted from Linzer M, Visser MR, Oort FJ, et al: Predicting and preventing physician burnout: results from the United States and the Netherlands. *Am J Med* 111:170, 2001.]

different aspects of clinical care, and experience different stresses. As one nurse stated in a study on burnout: "There is a mutual goal in your work as a nurse, no matter where you work, and that is to take care of the patient. Nursing is a job in which you are always under pressure. You are dealing with life and death issues on a daily basis. You can't come to work and say: I slept only five hours tonight and I'm tired. You have to be on full alert at all times. You work under incredible pressure with little rewards" [53].

Nurses usually work in the ICU indefinitely, compared to residents, and even critical care fellows and attendings, who rotate through different units in the hospital. Despite their relative permanence in the ICU, nurses do not generally accrue as much autonomy and stature as do physicians, which may lead to stress over career and organizational structure [54]. Poncet and colleagues [36] surveyed 2,392 French nurses working in 165 ICUs (mean time from graduation was 40 months and mean time working in the ICU was 36 months). Severe burnout was identified in 33% of the nurses surveyed. Four characteristics were independently associated with this outcome: younger age, organizational factors (e.g., less autonomy in scheduling days off), poor quality of working relationships, and factors related to end-of-life decisions. Other studies also have demonstrated that concerns surrounding ethical decisions are consistently the most important issues of ICU nurses [55]. In situations in which nurses attempt to reconcile their ideals regarding ethical dilemmas with the reality of their limited autonomy, stress can develop. Nurses with fewer workplace restrictions and thus greater autonomy have less anxiety and are more likely to advocate for their patients [56].

The personality trait of hardiness also can protect against stress and burnout among ICU nurses [57–59]. Aiming not merely at survival in the face of difficult circumstances but at the enrichment of life, hardiness consists of the triad of commitment (a sense of purpose expressed by becoming an active rather than a passive participant in life), control (the tendency to behave in a way that influences life events rather than to feel impotent in the face of adversity), and challenge (the belief that change, instead of stability, is normal and a stimulus to enhance maturity rather than a threat to security) [60]. Wright and colleagues [61] found a strong inverse relationship between hardiness and burnout in 31 intensive care nurses. Any interventions to reduce stress and burnout among nurses should include efforts to augment hardiness [62].

MANAGEMENT OF STAFF STRESS AND BURNOUT IN THE INTENSIVE CARE UNIT

Stress and burnout are common and deleterious to the ICU team. Therefore, preventing and ameliorating burnout syndrome in the ICU should be a priority. Ample descriptive reports of interventions to address stress and burnout in the ICU exist, but there are few outcome studies. Their general aim is to reduce stressors for staff, employing individual, interpersonal, and organizational strategies. The use of humor, support groups, and a system for outside referral are important in preventing and managing stress [45].

Individual strategies proposed to prevent burnout include relaxation training, time management, assertiveness training, team building, and meditation [21]. The aim of all such strategies is to enhance individuals' capacity to cope with the demands of their jobs [49,63]. For example, Isaksson Rø and colleagues studied the effectiveness of a 1-day individual session or a 1-week group intervention aimed to prevent burnout in 227 Norwegian physicians. They found that participants in either intervention had a significantly reduced level of emotional exhaustion as compared to physicians who did not participate [64].

Given that interpersonal conflict is a risk factor for severe burnout, improving the quality of relationships among doctors and nurses protects against burnout [35,36]. Groups and workshops have been reported as useful in managing stress [1,62,65,66]. Cassem and Hackett [1] described weekly and impromptu group meetings to explore ICU staff reactions to crises, to resolve conflict, and to discuss feelings, experiences, and knowledge. McCue and Sachs [62] described the effectiveness of a stress management workshop for medical and pediatric residents; it cost little, was positively received, and demonstrated significant short-term improvement in stress and burnout scores.

On the organizational level, reducing work hours and improving work organization is a first step toward burnout prevention [49]. Furthermore, ensuring adequate staffing, shared decision-making, active review of unit policies and procedures, freeing up time for patient care or research, bolstering administrative support, and allowing flexibility to curtail work/home conflict may help reduce stress and increase job satisfaction [37,67].

CONCLUSION

Recognizing and attending to staff stress in the ICU are necessary to ensure the continued effectiveness and well-being of each individual and of the unit as a whole. Left unaddressed, staff stress and burnout can exact a heavy price. As Civetta [68] wrote:

> We must accentuate the positive qualities of human capabilities that are beyond technological advancement. . . . A smile, a touch, confidence and security are still beyond our programming capabilities. . . . We must focus on our distinct human qualities of insight and caring. In this way, the popular view that intensive care is a depersonalizing environment can be replaced by the recognition that human beings are caring for human beings.

CHAPTER 203 ■ USE OF NURSING-SENSITIVE QUALITY INDICATORS

MARGARET LACCETTI AND CHERYL H. DUNNINGTON

INTRODUCTION

Nursing care does make a difference to the patient, to the families, to the healthcare team and in determining patient outcomes. Functions of nursing in the critical care environment include: ongoing assessment of the patient, therapeutic interaction with the family, facilitation of communication across multiple healthcare disciplines, and engaging in activities directly impacting the patient clinical outcome. A critical care nurse is a registered nurse who has been specially oriented and educated concerning the needs and acute physiology of a critically ill patient. Through the application of scientific knowledge, the critical care nurse reacts to the full range of human experiences, within the context of a caring relationship. One focus of nursing care in the ICU is the concept of quality. Quality includes the promotion of safe, efficient, and effective care based on scientific principles demonstrated through evidence that culminates in satisfaction for the patient, family, and the nurse.

The scope of practice for a nurse is determined by the level of formal education or preparation, area of clinical practice, competency validation, hospital or facility policy, and education or training as part of or required for a particular job. Scope of practice may also be mandated by the individual State Board of Nursing or through legislation. Critical care nurses receive more intensive orientation in preparation for patient care, and may be required to hold certifications in areas such as advanced life support. The American Association of Critical Care Nurses has developed a set of standards of care (Table 203.1) and defines the scope of practice for the critical care nurse, using the principles developed by the American Nurses Association (ANA) [1]. Utilization of these standards provides a framework for the delivery of comprehensive, high quality care.

CRITICAL CARE NURSES: PAST TO PRESENT

In 1854, Florence Nightingale was the first to identify the need to segregate the sickest patients needing the most intensive care in an area she referred to as her Monitoring Unit. Here, patients wounded in battle were able to receive nursing care with greater regularity, from women she had trained specifically. Through delivery of more consistent care from better trained nurses, she was able to demonstrate significantly decreased battlefield mortality, from 40% to 2% [2].

Caring for the most critically ill patients separate from other patients allows nurses to meet the complex needs of patients and families. This is accomplished through application of specific training and education with regard to disease process, treatment modalities, and the psychology of devastating injury or illness. Additionally, sequestering critically ill patients for care facilitates changes in nurse-to-patient ratio. A critical care nurse is commonly responsible for the nursing care of one or two patients.

Critical care nursing, as we know it today, emerged after World War II. The increase in medical specialization and improvement of technology influenced the development of this specialty [3]. The first intensive care or critical care units were established in the 1960s. Preparation to care for these patients resulted in development of curricula addressing nurses as well as intensivists, physicians specifically trained in critical care.

Nurses are the largest group of healthcare providers caring for patients daily in the critical care unit. As members of the healthcare team, nurses are responsible to provide nursing and medical interventions, as ordered, and evaluate the effect of those interventions on patients. An enormous part of the demand of patient care is the work of nurses, based on standards of care supported by appropriate resource allocation, enhanced nursing knowledge, accountability, and institutional policies and procedures. Clinical decision making is grounded in evidence-based practice that grows from the nurse's commitment to lifelong learning. Developing and implementing a plan of care allows interventions to be provided in a safe, systematic way, tailored to the condition of each individual patient. As a result of a holistic approach and long periods of time at the bedside in critical care, it is the nurse who gives voice to the patient and family, including them in planning for care. Communication and collaboration among healthcare professionals are essential in planning and delivering care, as well as in maintaining a healthy work environment, one that promotes safe, efficient, effective care for patients. Interdisciplinary communication and collaboration are critical to prevent errors and omissions in the plan of care. The American Association of Critical Care Nurses, in a 2005 study [4], described the consequences of poor communication behaviors among healthcare professionals. These consequences include medication errors, infections, falls, increasing complications of both disease and treatment, and death. Seven areas were specified to be contributing to poor outcome: broken rules, mistakes, lack of support, incompetence, poor teamwork, disrespect, and micromanagement. Participants in this study described a resistance to communicating with others regarding these areas. Only through promotion of enhanced communication can patient safety and improved outcomes be expected. The Joint Commission on Accreditation of Healthcare Organizations identifies poor communication as a primary factor in sentinel events [5]. The Institute of Medicine described communication as a contributor to the harm patients experience in the course of their care [6].

The result of poor nursing care in relation to poor patient outcomes has been evaluated. These poor outcomes result in higher overall cost, low rates of nursing job satisfaction,

TABLE 203.1

CRITICAL CARE NURSING: STANDARDS OF CARE

Assessment	The nurse caring for the critically ill patient collects all data that is pertinent to the patient. This data is collected from the patient, family, and other members of the healthcare team to develop a holistic view of the patient and their issues. Data collection is driven by the priorities of the patient's immediate condition and anticipated concerns for care. The critical care nurse uses analytical models and problem solving tools when collecting assessment data. All relevant data is documented and communicated to other healthcare providers.
Diagnosis	The critical care nurse uses the assessment data to develop diagnosis and care issues directly related to this individual patient. These diagnoses are prioritized according to the immediate needs of the patient.
Planning	The critical care nurse is sometimes seen as the coordinator of the plan of care for the individual patient. They take into account the patients' individualized needs and situation. This care plan is developed in conjunction with the patient, family, and other members of the healthcare team. The plan establishes priorities, provides continuity of care, and considers resources available.
Implementation	Once the plan of care has been developed, it is the responsibility of the critical care nurse to implement the care. The interventions are developed to promote comfort and reduce or prevent suffering.
Evaluation	The critical care nurse must evaluate all plans of care once they have been implemented. They must evaluate the effectiveness of interventions and check if the desired outcome was achieved.

decreased patient and family satisfaction, accreditation issues, and lower rates of reimbursement [7]. For example, cost per case will increase in medical patients with urinary tract infection and pressure ulcers and in surgical patients with urinary tract infection and pneumonia. Provision of safe, high quality patient care is motivated by both professional accountability and growing financial pressure. By evaluating the quality of patient care, opportunities for poor patient outcomes can be eliminated or prevented. Use of Nursing-Sensitive Quality Indicators (NSQI) provides an opportunity to evaluate and improve care in the critical care unit. Quality and Nurse sensitive indicators are defined as measures and indicators that reflect the impact of nursing actions on outcomes. Although the entire scope of nursing-sensitive indicators includes structure, process, and outcome of nursing, nursing-sensitive indicators in critical care are primarily outcome driven.

Nursing-sensitive quality indicators identify and allow measurement of structures of nurse-specific patient care, the processes by which this care is accomplished, and the outcomes of that care. They are performance measures that quantify the work of nursing and the outcomes of that work. These indicators are particularly useful in the critical care setting, where intensive nursing care directly influences patient safety and outcome. In addition to measurement, the use of NSQI promotes identification of best practice and accountability for practice, and points out gaps in research, education, and practice within the discipline of nursing and in interdisciplinary patient care. NSQI, as they measure nursing's impact on the quality of patient care, are instrumental in helping hospitals to reduce misdirection of nursing time to nonproductive or non-patient care tasks or activities. By allowing nurses to engage in the work of nursing, patient outcomes are improved, appropriate staffing decisions are made, and nurse job-satisfaction is enhanced [8].

The American Nurses Association (ANA) Nursing Safety and Quality Initiative began in 1994, aimed at the development of hospital quality indicators. Data from this initiative was stored in the National Database of Nursing Quality Indicators (NDNQI), at the Midwest Research Institute and University of Kansas School of Nursing in 1998. The initial outcome measures included nosocomial infection rate (bacteremia), rate of patient falls with injury, patient satisfaction with nursing care, patient satisfaction with pain management, patient satisfaction with educational information, and patient satisfaction with care. Process measures included maintenance of skin integrity. The NDNQI has developed nationally accepted measures to assess quality of nursing care, identifying and promoting best practice around specific indicators. The database provides members the transparency of quality outcomes, motivating nursing leaders to implement practice that can maintain or improve those outcomes. Current NDNQI indicators can be found in Table 203.2.

NSQI IN CRITICAL CARE NURSING PRACTICE

Infection is one complication critical care patients are particularly at risk for, as the result of invasive procedures, disease process, and exposure to multiple infective organisms. Specific NSQI address behaviors aimed at avoiding this risk. The most common potential infections in the ICU are catheter-associated urinary tract infection, central line related blood stream infection (BSI), and ventilator-associated pneumonia.

Urinary Tract Infections

Catheter-associated urinary tract infections (CAUTI) contribute to almost half of all nosocomial infections, resulting in increased hospital stays and cost of treatment. Placement of urinary catheters in the critically ill patient facilitates determination of urinary output. They are also essential in managing incontinence in the unresponsive or immobile patient, preventing moisture-related skin breakdown. However, an indwelling urinary catheter enhances the risk of UTI.

Urinary catheter care is a direct responsibility of nursing, including proper placement, assessment, maintenance of a closed system, use of aseptic technique when obtaining a urine sample, management of the collecting bag system, and appropriate delegation of tasks. The critical care nurse is well prepared to provide care as necessary for UTI prevention, as well as to delegate care tasks such as catheter hygiene, appropriately and safely to ancillary staff. It has been proposed that one important aspect of CAUTI prevention may include increases in the number of registered nurses (RN) at the bedside to provide patient care. In one study, a large and significant inverse relationship was found between full-time-equivalent RNs per adjusted inpatient day and urinary tract infections after major surgery [9].

Proper placement of a urinary catheter mandates that strict asepsis be maintained throughout insertion. Choice of an appropriately sized catheter is critical in proper placement. The

TABLE 203.2

NDNQI NURSING INDICATORS

Nursing hours per patient day	■ Registered nurse (RN) hours per patient day ■ Licensed practical/vocational nurses (LPN/LVN) hours per patient day ■ Unlicensed assistive (UAP) hours per patient day
Nursing turnover	
Nosocomial infections	
Patient falls	
Patient falls with injury	■ Injury level
Pressure ulcer rate	■ Community acquired ■ Hospital acquired ■ Unit acquired
Pediatric pain assessment, intervention, reassessment cycle	
Pediatric peripheral intravenous infiltration	
Psychiatric physical/sexual assault	
RN/education/certification	
RN survey	■ Job satisfaction scales ■ Practice environment scale
Restraints	
Staff mix	■ RN ■ LPN/LVN ■ UAP ■ Percent agency staff

NDNQI, National Database of Nursing Quality Indicator.

smallest possible catheter to promote bladder drainage reduces opportunities for infection by reducing damage to urethral mucosa during insertion.

Assessment of the patient with a urinary catheter should, at least, address the presence of adequate urinary production, as well as placement of the collecting bag at an appropriate place below the level of the patient's body. The catheter should be secured to the patient's thigh (or abdomen, in male patients only) with a catheter strap or anchoring system to prevent pulling and tugging. Pulling on the catheter can cause damage to the tissue in the urethra. Damage to this area can lead to a bladder infection. Use of skin prep under the anchoring system may help to prevent skin irritation and breakdown [10]. Care of the patient with a urinary catheter includes cleaning the catheter with soap and water or peri spray as part of daily hygiene and following a bowel movement, and avoiding powders and creams on or around the catheter or insertion area. CAUTI prevention is enhanced when the collection bag is emptied consistently prior to moving or ambulating the patient, and maintaining the drainage bag and tubing below the bladder level to facilitate urine flow and prevent backward flow into the bladder. It is important to never place the collecting bag on top of the patient when transferring him to or from a stretcher, as this allows backflow of urine to the patient.

Three main sites of potential infection in patients with a urinary catheter are: along the urethral wall (avoided by providing catheter care), at the junction between catheter and drainage bag if the system is opened (avoided by maintaining a closed system and not disconnecting the catheter from drainage bag), and at the drainage outlet (avoided with appropriate aseptic technique).

Through conscientious and evidence-based nursing care for the patient with an indwelling urinary catheter, it is possible to prevent CAUTI, thereby reducing the patient's risk of increased length of stay in the hospital, infection-related complications, and increased cost of patient care.

Blood Stream Infection

As the result of multiple invasive procedures that will occur in the care of a patient in the critical care unit, as well as conditions or treatments that may compromise the patient's ability to resist infection, the critically ill patient is at greater risk for nosocomial infection. Catheter-related BSIs are one example of an infectious complication that occurs in patients cared for in critical care units. These catheter-related BSIs are responsible for increased healthcare costs, longer critical care unit stays, longer hospital stays, and death.

A central venous line is a catheter that delivers fluids directly into the central circulation. Three primary functions of this catheter in critically ill patients are large volume fluid resuscitation, hemodynamic monitoring, and administration of hyperosmolar intravenous fluids, such as total parenteral nutrition. They may be an alternative when the patient has poor peripheral access, and specifically with multi-lumen catheters that allow for administration of complex medication regimens and solutions simultaneously. In critically ill patients, the advantages of central vascular access over peripheral access are many. Central access allows medications and solutions administered directly into central circulation, promoting rapid systemic distribution. Blood flow at the right atrium or superior vena cava is rapid, large volume, quickly diluting hyperosmolar solutions. The patient's peripheral vasculature is preserved intact for later access, when the patient is no longer a resident of the critical care unit.

Catheter-related BSIs are identified by positive blood culture with the catheter suspected as the infective site clinically or in

light of the microbiology. Through excellent nursing care, the critical care nurse is instrumental in preventing these infections from the process of insertion, attending to aseptic technique during dressing changes and catheter use, and by comprehensive assessment of the site and patient status, as long as the catheter remains in place.

Preventive measures essential for the nurse to facilitate at insertion of a central catheter include appropriate hand hygiene for aseptic procedures, full barrier precautions, and skin preparation with 2% chlorhexidine or the institutional policy driven choice. Use of gloves does not eliminate the need for hand washing.

Regular assessment of the insertion site for drainage, redness, oozing or swelling, and assessment of the dressing for integrity are part of comprehensive nursing care of the critically ill patient. Hub or injection cap contamination is another source of potential infection. Thorough cleansing with an antimicrobial is required prior to every access. Cleansing is mechanical, as well as chemical, and it is important to allow antimicrobial solutions to dry before accessing the port. All connectors should be regularly inspected for integrity, and antimicrobial disinfection should be used at connection sites whenever the closed system is broken. The nurse can also determine when it may be appropriate to remove a central catheter. If a central line is not being used, or the patient's condition or treatments support vascular access peripherally, removing the central catheter may be a good choice to reduce the patient's risk of catheter-related BSI [11].

Given the need for multiple opportunities to utilize vascular access in critically ill patients, multi-lumen catheters are the norm in critical care units. There is evidence that multi-lumen central venous catheters put patients at slightly higher risk of infection compared with single-lumen catheters. However, this increased risk is justified for the critically ill patient by the convenience and improved vascular access afforded by multi-lumen vascular catheters [12].

Finally, documentation is a nursing function vital to prevention, prompt identification, and treatment of catheter-related BSIs. Documentation is a primary form of communication between members of the healthcare team. It provides history and context to clinical findings. Nursing documentation of process and procedure during insertion or use of a central line, and routine assessment findings provide the basis for prevention and early intervention.

Ventilator-Associated Pneumonia

Ventilator-associated pneumonia (VAP) is the most common type of hospital-acquired infection, impacting approximately 9% to 27% of all mechanically ventilated patients [13]. VAP can increase the average length of stay for an ICU patient by 7 to 9 days. It may also increase mortality by up to 43% when the patient has an antibiotic resistant microbe [14]. This translates to an additional cost of $40,000 to each hospital stay and can be estimated to cost hospitals $1.2 billion per year. Approximately 50% of all antibiotic use in the hospital setting is for the treatment of VAP [15].

VAP is defined as a pneumonia that occurs 48 hours after mechanical intubation. The endotracheal tube provides a direct link for the bacteria to the lungs. Upper airway and oral secretions pool above the cuff on the endotracheal tube, forming a biofilm that can be dislodged into the lungs during routine nursing tasks such as suctioning, turning the patient, or repositioning the endotracheal tube. The body is unable to prevent entry of these bacteria into the lungs, enhancing the risk of pneumonia. Diagnosis of VAP is based upon radiographic findings, clinical, laboratory, and microbiology results. Symptoms to be considered in diagnosis include fever, elevated white count, and purulent sputum [16].

Nursing plays an integral role in the prevention of VAP. The CDC recommends that all patients receive a pneumococcal vaccine every 5 years, except those who received the vaccination over the age of 65 [17]. Critical care nurses are the front line against the prevention of VAP. It is the care that the bedside nurse provides that has the greatest impact. Things as basic as hand washing prior to patient contact will contribute to prevention.

Mouth care, a basic nursing intervention, is thought to decrease VAP by reducing the amount of bacteria in a patient's mouth. Mouth care is described as not only rinsing the mouth but also brushing the teeth, gums, and tongue to remove plaque. The use of pharmacological agents (such as chlorhexidine) has shown to decrease VAP in the cardiac surgery population, but these protocols remain untested in other patient populations [18].

The old habit of using saline lavages down the endotracheal tube prior to suctioning is related to an increase in the VAP rate. Rather than liquefying secretions, the saline lavage actually dislodges bacteria from the endotracheal tube and pushes the bacteria into the lungs [19].

Turning patients who are intubated on a routine basis not only improves pulmonary status, it also helps prevent pressure ulcers. The position of the patient is critical in VAP prevention; studies have shown that having the bed elevated to between 30 and 45 degrees prevents reflux and aspiration of stomach contents into the lungs [19]. It is imperative to not only have the patient at more than 30 degrees while in bed, but also during transport, or during CT scan or MRI, if it is possible to maintain the elevation of the head of the bed.

The use of standardized orders and clinical pathway guidelines are an important part of the prevention of VAP. All disciplines must be aware of the standards of care and practice to those standards.

Lastly, even in the busiest of ICU's, it is important that the patient's pneumococcal vaccine status be assessed and addressed.

Pressure Ulcers

Pressure ulcers are the direct result of decreased capillary perfusion to the skin and subcutaneous tissues as the result of compression. They range from areas of redness and irritation to frank tissue necrosis. Mortality is related to pressure ulcer development, particularly in elderly patients, with some studies describing rates of mortality as high as 60% in older persons within 1 year of hospital discharge [20]. More often, pressure ulcers occur with changes in health status, particularly as mobility, perfusion, and nutritional status are negatively affected. Pressure ulcers result in increased length of stay and increased hospital costs related to treatment. The Healthcare Cost and Utilization Project, in 2006, determined the average charge for pressure ulcer treatment per hospital stay to be $37,800 [21].

Multiple risk factors are associated with the development of pressure ulcers, including host-specific factors such as nutritional status and disease process and systemic factors such as preventive resources and workload of direct caregivers. Risk factor identification, preventive measures, and treatment of existing pressure ulcers to decrease exacerbation and progression and promote healing are all within the purview of the critical care nurse. Disease states putting the patient at risk to develop pressure ulcers include diabetes mellitus, cardiovascular and peripheral vascular disease, stroke, renal failure, sepsis, febrile illnesses, cancer, and hypotension. Patients who are hypovolemic are at risk because of decreased perfusion, as are

those who are malnourished. Illness states directly affect nutritional status by increasing metabolic need. Any physiologic process that impedes the microcirculation, whether locally or systematically increases the risk for pressure ulcer development. (Smoking is an important contributor to impairment of the microcirculation, so a current smoking history is a significant risk factor to add to the patient's risk profile.)

Previous history of pressure ulcer is a clinical risk indication. Any condition or treatment that impairs patient mobility directly enhances the patient risk, including use of physical restraints. Pressure ulcer development has been associated with low body mass index, where the boney prominences do not have the protective benefit of adipose tissue, and with obesity, where increased weight directly impedes capillary flow and perfusion. Both localized and generalized edema can also contribute to the risk of ulcer development. Incontinence, both urinary and fecal, and diuresis put the patient at risk of moisture-related ulcer development, as will poor hygiene. In the critical care area, the presence of multiple tubes, lines, and catheters also put the patient at risk by adding new areas of perfusion compression. Pressure ulcers form below the nostrils or behind the ears as a result of pressure from a nasal oxygen cannula or elsewhere, when IV tubing or urinary catheters lay under body parts. This short list of risk factors just begins to describe patients in critical care.

The work of the critical care nurse is in both prevention and treatment; the essential starting point is assessment. Preventive assessment includes identification of those patients at high risk to develop pressure ulcers by defining the risk factors present, so that preventive measures can be instituted to address as many of these factors as possible. A variety of tools have been developed for this purpose, with the Norton and Braden scales most popular in hospitals in the United States. Regardless of the tool chosen, the importance is to use it consistently for comprehensive risk assessment and to document and communicate both the findings from the scale or tool and the plans in place for prevention. Additionally, patients at risk must be assessed regularly for areas of redness, poor capillary refill or skin tears, all of which indicate the beginnings of pressure ulcer formation.

Prevention can be especially challenging for the nurse caring for the critically ill patient. Many of the risk factors identified may be directly related to either disease or treatment and may be difficult to modify. Therefore, the consequences of disease or treatment must be considered in the prevention plan. For example, the patient with low body mass index and protuberant boney prominences will be managed through frequent turning, positioning, and use of assistive devices to promote mobility or maintain positioning. Longer term interventions to address nutritional needs may or may not be possible for a particular patient at a particular time.

Considerations for preventive interventions include skin care, hygiene, support surfaces to reduce pressure distribution, nutrition and hydration, and mobility and mechanical loading. Although there is no current agreement on what preventive skin care exactly entails, bathing to promote good basic hygiene, particularly in cases of incontinence, and use of protective or barrier products in areas prone to moisture, friction, irritation, or compression are essential. Barrier skin products are essential to managing pressure ulcer prevention in the incontinent patient, as urine or stool can chemically promote skin breakdown in certain conditions, or complicate pressure ulcers through the potential for infection. The bathing process also promotes mobility, even if only passive mobility, repositioning during bathing and application of skin protection products, and an opportunity to assess for developing ulcers or areas of potential hazard, such as wrinkles or rolls in bedding or tubes and catheters in place underneath the patient's body. It is important to address dry skin as a risk but avoid traditional lotions or creams. They may promote moisture-associated ulcers, and may even promote bacterial growth.

Assessing for and addressing hydration issues are important in the critically ill patient. Hypovolemia or hypotension directly affects capillary perfusion, decreasing oxygen delivery to areas of compression, enhancing the risk for pressure ulcers at those points. Hypervolemia may result in edema, also increasing the risk of compression.

In critical care units, nurses are particularly apt to utilize 'special beds' to prevent skin breakdown. There are a variety of choices currently available, with much variation depending on the facility. However, the goals of any of these special surfaces are redistribution of weight or pressure, reducing incidence of compression and promoting capillary perfusion. As risk factors mount in preventive assessment, the more beneficial a specialized support surface becomes. Little research currently supports which is the best surface to use, and patients with different clinical conditions may have widely different needs. Drawbacks to use of special support surface beds, whether dynamic air or particle beds, or static surfaces such as foam, are expense, availability, and sometimes, ease of use for the nurse.

Enhanced mobility as prevention may include using assistive devices to promote patient-assisted mobility or the traditional nursing approach of frequent turning and positioning. Providing an over bed trapeze for the bedbound patient may give a patient who is strong enough the leverage assistance to be able to move about in bed more frequently. Even maintaining both upper side rails in a raised position when not directly caring for the patient may give him the opportunity to use those side rails as assistive devices in being able to move, sit up, or turn side to side.

For the patient unable to move himself in the bed, turning and positioning at least every 2 hours to reduce compression over potential areas of breakdown over time is essential. A sentinel study evaluating time between repositioning has added to the science of nursing in identifying the 2-hour window as being the most beneficial for most patients [22], but even Florence Nightingale described turning and repositioning her patients in the quest for optimal return to health. Turning and repositioning in a timely fashion can be a challenge in the critical care setting. The patient's clinical condition, as well as equipment used for treatment may impede options for positioning. Patients who are unconscious, paralyzed, or immobile for other reasons may be unable to remain in position once turned or moved. So, it becomes vital for the nurse to use mobility aids and positioning devices to effectively move the patient. Mobility devices may be as simple as using the draw sheet or more sophisticated, such as air driven hover devices or lifts. Although mobility aids protect the patient, just as importantly, they are designed to protect the nurse from injury while repositioning the patient. Once moved, wedges, pillows, splints, or other devices may be used to retain that position. Please be certain that those devices do not contribute to new areas of compression on their own.

With critically ill patients, the most carefully implemented prevention regimen may fail, or the patient who arrives in the critical care unit in a state of progressively declining health may already have one or several pressure ulcers. At that point, using agency procedures or clinical guidelines, cleaning, staging, consistent assessment and restaging as required. A variety of treatment measures including those interventions useful for prevention, are used to prevent exacerbation, stage advancement, and promote healing.

Specialized interventions may include debridement, whether surgically or mechanically, such as the use of a wet to dry dressing. Large ulcers may be treated using wound vacuum dressings to promote closure but retard abscess formation. As pressure ulcers are often particularly painful, assessment and pain

management is another essential part in managing pressure ulcers in the critical care unit.

Falls

More than one third of persons over the age of 65 fall every year, and half of these falls are recurrent. By 2020, the estimated cost related to falls and subsequent injuries is $34 billion dollars [23]. The Joint Commission has identified falls as high risk and requires all facilities to develop a fall prevention program. This initiative was instituted because of the increase of patient deaths due to falls (sentinel events): in 2008, the Joint Commission reported 60 sentinel events related to falls and this trend has been rising since 1996 [24].

While the ICU frequently treats patients post fall, it is important to monitor and prevent falls during their ICU stay. Every patient must be assessed for fall risk upon admission, at least daily and when there is a change in status. Multiple tools are available for assessing risk, such as Heinrich II and Morse scales. All tools consider age, comorbidities, fall history, physical limitations, cognitive impairment, and current medications [25,26]. The majority of all ICU patients classify as high risk.

It is the responsibility of the critical care nurse to identify those patients at risk for falling and institute measures to prevent falls. Based upon assessed needs of the patient, the bedside team needs to initiate measures to prevent falls that may include physical and psychosocial needs as well as environmental concerns.

Addressing physical needs includes provision of adequate pain management, intervention with sensory deficiencies such as sight or hearing, interventions preventing or alerting changes in position of rising from the bed or chair such as wedge cushions, lap belts, or tab (bed exit) alarms. Other interventions to meet physical needs may include repositioning for both safety and comfort, and adequately meeting toileting needs. Toileting includes instituting a schedule based on patient need, frequent offering of assistance, commode or bedpan, and teaching regarding urinary catheterization.

Providing for psychosocial needs includes management of anxiety, frequent reminders to request help before moving about, enlisting the aid of family members or sitters to alert staff-to-patient movement, or using distraction techniques to minimize the effects of the critical care environment.

Environmental issues that may add to the risk of falls in the critical care unit include noise and lightning as well as inconsistent patient observation. Initiatives to control noise, normalize lighting, promote quiet time or rest, or simply moving the patient closer to the nurses' station for more consistent observation may be useful interventions to reduce the risk of falling.

THE CHALLENGE OF FOCUSING ON ONE NSQI AS IT IMPACTS ON OTHERS

Use of NSQI in clinical practice is not just an exercise in measurement, but a true clinical tool in improving patient outcomes. Nurses do, indeed, influence patient care and patient outcomes. Even focus on a single NSQI promotes preventive or health promoting action in other areas of the patient's health, even on other measurable NSQI [27]. Focused nursing measures on prevention of catheter-related urinary tract infections may address issues such as incontinence, directly affecting risk for pressure ulcers. Helping the patient to increase or enhance mobility, finding ways to eliminate catheter need and enhance bladder emptying may also address mobility-associated risks for pressure ulcer formation. Conversely, interventions aimed at preventing VAP may confound or prohibit efforts intended to address another NSQI. For example, maintaining the head of the bed at a 45 degree angle as a preventive measure for ventilator-associated pneumonia may prevent efforts at early removal of indwelling urinary catheter, as the patient is unable to move and position effectively to promote use of a bed pan or urinal, thus putting the patient at greater risk for UTI. The critical care nurse's holistic approach to caring for the patient allows for consideration and balance in prevention and intervention to facilitate optimal patient outcomes through enhancing preventive measures to consider other interventions necessary.

CHAPTER 204 ■ ROLE OF THE ADVANCED PRACTICE NURSE IN CRITICAL CARE

THERESA R. MACFARLAN

INTRODUCTION

Advanced practice nurses (APNs) are registered nurses prepared at the master's or doctoral level. They function in a multitude of inpatient and outpatient settings across the health care continuum. APN roles include Clinical Nurse Specialist (CNS), Nurse Practitioner (NP), Certified Nurse–Anesthetist, and Nurse Midwife. Though their practice environments, patient populations, specialty knowledge-base and skill sets vary greatly, all APNs share core competencies of direct clinical practice, expert coaching and guidance, consultation, research, clinical and professional leadership, collaboration, and ethical decision-making [1]. CNSs and Acute Care Nurse Practitioners (ACNPs) possess education and expertise in areas that uniquely equip them to practice in the critical care environment. All APN roles require advanced nursing knowledge and skills; the roles are not the same as those held by physicians, although APN practice may be similar to physicians in many medical therapeutic realms [1]. When APNs begin to transfer new skills or interventions into their practice, they become nursing skills, informed by the clinical practice values of the nursing model: "*the advanced practice of nursing is not the junior practice of medicine* [1]."

This chapter describes the Acute Care CNS and ACNP roles, scope of practice, certification, credentialing, and reporting mechanisms. In addition, the science related to outcomes of APN practice and co-practice with other providers is discussed.

ROLE AND SCOPE OF PRACTICE

CNS—A CNS is an expert clinician in a specialized area of nursing practice. The specialty may be defined by a population (women), a setting (critical care unit), a disease or medical subspecialty (cardiovascular disease), a type of care (rehabilitation), or a type of problem (wounds) [1,2]. The CNS approaches the APN role through three spheres of influence: at the patient level in direct care, at the nurse level with staff development, and at the institution level providing oversight of care [1]. Staff education and system change responsibilities represent a large percentage of the CNS's role [1]. In each of the spheres of influence, the primary goal of the CNS is continuous improvement of patient outcomes and nursing care. Key elements of CNS practice are to create environments through mentoring and system changes that empower nurses to develop caring, evidence-based practices. The CNS is responsible and accountable for diagnosis and treatment of health-illness states, disease management, health promotion, and prevention of illness and risk behaviors among individuals, families, groups, and communities [3].

ACNP—Of the APN categories, nurse practitioners (NPs) have undergone the broadest expansion in practice arenas. Emerging from the primary care setting, NPs began to expand their role into specialty and subspecialty areas in response to population changes in health care. Preparing NPs for acute care practice began in the early 1990s as a response to the need for advanced level practitioners in the inpatient, acute and critical care settings. Only ACNPs have been educated and trained to manage critically ill patients in ICU settings, but NPs with other educational preparation (such as family, adult, or gerontology) may practice in other hospital areas. However, this use of other NPs in the acute care setting has been questioned, as their scope of practice (academic preparation and experience) does not always include acute care patient management [4].

Though both CNS and ACNP are targeted to a patient-centered approach to care for patient populations, the continuous on-unit presence of the ACNP at the bedside of patients often differentiates the role of the ACNP from the CNS role [1]. In a 2006 American Association of Critical Care Nurses (AACN) study of APN practice, ACNPs reported spending 74% of their practice time directed toward individual patient management, while CNSs divided their time between nursing personnel (36%), populations of patients (21%), and other disciplines, organizations, or systems (17%) [4]. The primary responsibilities of ACNPs involve activities related to direct management of patient care, accounting for 85% to 88% of time spent in the role [5]. Key elements of the ACNP role include conducting physical examinations and comprehensive health assessments, gathering patients' medical histories, ordering and interpreting the full spectrum of diagnostic tests and procedures, use of differential diagnoses to reach a medical diagnosis, prescribing medications, providing and evaluating the outcomes of interventions, conducting rounds, initiating transfers and consultations, and preparing patients for discharge [6,7]. ACNP care includes health promotion, disease prevention, health education, and counseling as well as the diagnosis and management of acute and chronic diseases [3].

CREDENTIALING

Credentialing is furnishing the documentation necessary to be authorized by a regulatory body or institution to engage in

certain activities and to use a certain title [1]. In all states, APN regulation for practice is based on basic nursing licensure, but many states have additional rules and regulations that delineate requirements and define and limit who can use a specific advanced practice nursing title [1,7]. Nurse practice acts are administered under the authority of state governments to assure public safety [7]. In 23 states, the board of nursing has sole authority over advanced practice nursing; in others, there is joint authority with the board of medicine, the board of pharmacy, or both [8]. Advanced practice nursing certification is national in scope, and it is a mandatory requirement for APNs to obtain and maintain credentialing in most states [9]. APNs must fulfill continuing education (CE) and practice requirements to successfully maintain their national certification, although requirements differ from specialty to specialty. Each advanced practice nursing certification entity clearly lays out the requirements and time frame for recertification. National certifications for most specialties last from 5 to 8 years, and require that the candidate retest unless established parameters are met [1].

Credentialing and licensure for prescriptive authority also occur at the state level. Pharmacology requirements vary from state to state, with most states requiring a core advanced pharmacotherapeutics course during the graduate APN educational program, and yearly continuing education credits to maintain prescriptive privileges [1].

The requirement for APN hospital privileges varies according to the nurse's practice. Many hospitals have different levels of hospital privileges, ranging from "full" privileges to modified privileges for specific functions [1]. A collaborative practice agreement exists between an APN and physician to define parameters of practice for the APN. Many states require this as part of APN licensure [8]. This agreement may take many forms, from a one-page written agreement defining consultation and referral patterns to a more specific prescribed protocol for specific functions based on state statues for APNs. These agreements should be written as broadly as possible to allow for practice variations and new innovations [1].

CERTIFICATION

CNS—Upon completion of an accredited graduate CNS program, certification by examination is available through the American Nurses Credentialing Center (ANCC), or through the certification boards of specialty organizations. The American Association of Critical Care Nurses (AACN) offers a Critical Care Nurse Specialist exam [2]. However, certification exams are not available for many CNS specialties. This is a major regulatory barrier for many CNS specialties in those states that require CNS certification for second licensure [1]. Creating a universal CNS certification examination is in the forefront of current efforts to address this problem. Some states allow prescriptive authority for CNSs.

ACNP—Upon completion of an accredited graduate ACNP program, a national certification exam is available through ANCC or AACN. National certification for acute care nurse practitioner practice began in 1995 [4]. For licensure, many states do not differentiate between NP specialties (such as family and acute care) [1]. ACNPs are granted full prescriptive authority, regulated by state statutory and regulatory bodies [1].

REPORTING MECHANISM

Reporting structures for APNs vary widely within health care organizations [1]. In organizations with many APNs, an APN may report to another APN. In the critical care setting, APNs may report to a nursing administrator responsible for critical care, to a physician, or both. This type of dual reporting may maximize support for the role and clarify role expectations [9]. As licensed independent providers, ACNPs in many institutions must obtain privileges through the credentialing committee. This process may require a designated physician supervisor/collaborator [1]. The degree of supervision needed may change as the APN becomes more experienced in the role.

FACTORS AFFECTING THE GROWTH OF THE ACNP IN CRITICAL CARE

Major factors that contributed to integrating ACNPs into the critical care arena occurred in the late 1990s as a result of a decrease in the number of medical residents and an increase in the acuity of the patient population. Strict guidelines have been placed on resident work hours by the Accreditation Council of Graduate Medical Education (ACGME) and the Residency Review Committee [10]. Instituted in 2003 [5], the 80-hour workweek restriction has especially challenged surgical residents who must balance operative and nonoperative care time in managing critically ill patients [10]. This has contributed to the almost impossible task of providing appropriate level 24-hour intensive care unit coverage by surgical house staff. In a national survey, Gordon et al. [10] found that the use of Physician Assistants (PAs) or NPs may be one effective strategy in allowing surgical residents to care more efficiently for critically ill patients under the new ACGME guidelines. Critical care units that employ ACNPs report being able to meet the ACGME standard for the 80-hour workweek for residency training programs [11]. ACNPs are uniquely equipped to bridge the gap between the nursing and medical models of care, providing seamless continuity of care to patients and their families.

EVIDENCE-BASED OUTCOMES DRIVEN CARE

Evidence-based practice for ACNPs can be described as using the best scientific evidence and clinical expertise to influence patient outcomes [12]. APNs should be adept in the search and critical review of published material, including familiarity with grading systems that indicate the strength of the evidence. Multiple clinical studies have demonstrated cost-containment, decreased days on mechanical ventilation, and decreased length of stay (LOS) as a result of direct APN involvement in managing patients in critical care units [13–20]. Cardiovascular (CV) surgeon and ACNP collaborative practice decreased the LOS for specific diagnosis-related group (DRGs) and decreased total cost for the episode of care when compared to CV surgeon alone. Cowan et al. (2005) [21] demonstrated that physician/NP collaboration focused on enhancing continuity, multidisciplinary team planning, discharge coordination and assessment after discharge, and reduced LOS and hospital costs without negatively affecting readmissions or mortality. In a study that compared outcomes in chronically critically ill patients admitted to a subacute Medical Intensive Care Unit (MICU) who were collaboratively managed by an ACNP/attending physician team or a team composed of fellows and an attending physician, no significant differences were reported in LOS, duration of mechanical ventilation, number of patients who had been weaned at discharge, and disposition [22]. After adding two ACNPs to their trauma service, one teaching hospital was able to obtain compliance with residency work hour limitations by decreasing the average number of hours worked per trauma resident per week from 86 to 79 hours, as well as decreasing

overall hospital LOS [23]. In the area of patient/family satisfaction, NPs have been shown to score higher than resident or attending physicians [24–31]. It has been shown that MD/NP collaboration can enhance continuity of care, multidisciplinary team planning, discharge coordination and assessment after discharge, reducing LOS and hospital costs without affecting readmissions or mortality [21].

COLLABORATIVE PROVIDERS

ACNPs and CNSs sometimes practice collaboratively with other providers in critical care, especially in teaching hospitals and university settings. Brief descriptions of physician assistants and intensivists are included to differentiate clinical roles.

Physician Assistant (PA)

The first formalized physician assistant program was implemented at Duke University in 1965 [32]. PA programs were first developed to augment the practice of primary care physicians, fill service gaps in underserved areas, and help control health care costs [33]. PAs emerged from a medical model of care, as compared to APNs whose identity and practice is shaped by the nursing model of care [34]. The PA role is rapidly expanding beyond primary care to specialty and inpatient practice, including critical care [4].

Intensivists

The Leapfrog Group (founded in November, 2000) recommendations emerged from the growing evidence supporting dedicated intensivist staffing in ICUs. A review of studies revealed that ICUs in which an intensivist manages or co-manages all patients, there were improved patient outcomes, including a reduction in hospitality mortality [35]. Leapfrog recommends at least 8 hour per day intensivist on-unit presence as one of four hospital safety standards supported by evidence-based research. ACNPs provide expert, collaborative care with the intensivists. The AACN has described the importance of effective communication in critical care practice as a core element for patient safety, seamless care, and healthy work environments [36].

CONCLUSION

The complexity of multilayered chronic diseases upon acute illness states, additional regulatory burden for documentation and outcome measurements, the explosion of information and medical technologies, and the astronomical cost of health care poses challenges unforeseen by our nursing predecessors. The enormous workforce and economic burden associated with long-stay ICU patients mandates innovative approaches for their care provision. Nursing practice continues to evolve, striving to keep pace with the needs of an increasingly complex and aging population. Nursing has always been a dynamic profession, evolving with the needs of the population and the capacities of health care systems' resources. Creative visioning and the passion to deliver skilled and compassionate care continue to drive nursing's capacity to meet health care needs. With the current health care crisis of unsustainable cost escalation, it is imperative that healthcare organizations deliver high quality care that is highly efficient and cost effective. Provision of intensive care is one of the largest and most costly aspects of health care in the United States [22]. We are entering a period of unprecedented growth in the number of individuals likely to need ICU services. With current levels of growth, the U.S. health care system will fall far short in the ability even to provide the current level of care, let alone increase the access for the critically ill to intensivists by the year 2020 [35,37]. APN-friendly cultures do not occur by chance, but are created when committed organizations and APNs share common vision and values. An APN friendly culture is one in which all professionals are valued and recognized as possessing unique contributing knowledge and skill-sets necessary to provide excellent, collaborative patient and family-centered care [38]. As we move forward into the uncertain health care climate of the future, ACNPs and CNSs can deliver cost-effective, competent, collaborative, and compassionate care to the growing critical care population.

CHAPTER 205 ■ INTERPROFESSIONAL COLLABORATION AMONG CRITICAL CARE TEAM MEMBERS

DEBRA GERARDI AND DORRIE K. FONTAINE

"In the ICU, nurses and physicians stand at a patient's bedside initially as strangers, thrown together by a combination of choice and circumstance. With each interaction, they assess one another's knowledge, openness to suggestion, and commitment to patient care. They learn each other's strengths and weaknesses and, over time, forge relationships that become the bedrock of effective collaboration. They communicate, negotiate, and compromise [1]."

INTERPROFESSIONAL COLLABORATION IN CRITICAL CARE

Collaboration among critical care professionals is essential to the provision of safe and effective care in the Intensive Care Unit (ICU). Outcomes associated with effective collaboration include patient safety, improved quality indicators, retention of healthcare providers, and patient and family satisfaction with care. In 1994, a joint position statement was issued by the Society of Critical Care Medicine (SCCM) and the American Association of Critical Care Nurses (AACN) promoting a multidisciplinary approach for managing and providing intensive care services as the preferred model of care [2]. Since that time, an increasing number of mandates and standards issued from national organizations reinforce interprofessional collaboration as a necessary component of care delivery in complex clinical environments.

This chapter describes the principles and importance of interprofessional collaboration, the integration of teamwork as a means of achieving collaborative outcomes, and strategies for cultivating environments in which collaborative delivery of safe patient care can flourish.

DEFINING COLLABORATION

Collaboration is the process of working together toward common goals through joint communication and joint decision-making [3]. Collaboration is both a process and a style that blends high levels of assertiveness and cooperation. Interprofessional collaboration is defined as the process in which different professional groups work together to positively impact health care and relies on negotiated agreements to bring the valued and unique contributions of experts to patient care. Interprofessional collaboration involves understanding what enables effective collaboration as well as understanding barriers to collaboration including: unhealthy power dynamics, poor communication patterns, lack of understanding of one's own and others' roles and responsibilities, and conflicts due to varied approaches to patient care that are inherent within diverse clinical teams [4]. Collaboration is vital, difficult, and learnable [5]. True collaboration is relational and requires skilled communication, trust, knowledge, shared responsibility, mutual respect, optimism, and coordination [6].

COLLABORATION AS A CORE COMPETENCY FOR HEALTH PROFESSIONALS

Health professionals are required to possess core competencies (knowledge, skills, and attitudes) associated with interprofessional collaboration including communication, negotiation, and conflict resolution as a component of academic training

and professional practice [7–9]. The Accreditation Council for Graduate Medical Education and the Association for American Medical Colleges include aspects of communication, coordination, and collaboration among the required physician competencies [10]. Explicit guidelines for collaboration are embedded in professional codes of ethics for nurses and physicians [11,12]. Understanding of and respect for the professional contributions of colleagues across the professions is a necessary precursor to effective collaboration. Slow progress is being made to incorporate these competencies into curricula across the health professions to better teach the concepts of collaboration that support patient safety and improved care coordination [9,13].

MANDATES FOR INTERPROFESSIONAL COLLABORATION

The need for improved interprofessional collaboration has been discussed for decades among professional associations—particularly among critical care associations. The past decade has seen a shift from discussion to concerted action, as multiple calls for improvement in care delivery from the Institute of Medicine (IOM) have emerged, resulting from data linking poor clinical outcomes to ineffective teamwork and inadequate care coordination [14–16]. There is substantial evidence that the leading contributors to medical errors and unsafe care are breakdowns in teamwork, communication, and the overriding culture of health care itself [17,18]. Hundreds of billions of dollars are wasted on medical errors and ineffective care coordination each year [19]. In addition to poor patient outcomes, ineffective collaboration has been linked to perceptions of hostile work environments [20], low morale, and job stress among health professionals [21], increased turnover of clinical staff [22], and moral distress [23]. As such, new mandates are emerging to focus attention within healthcare organizations on strategies for developing interprofessional collaboration as a component of safe patient care.

The National Quality Forum (NQF) added teamwork training and interventions to their 2006 consensus report, Safe Practices for Better Healthcare, which are now represented in the 2009 Report as Safe Practice #3—Teamwork Training and Skill Building [24]. The Joint Commission, through their Patient Safety Goals [25], their sentinel event alerts [17], and their accreditation standards, requires improved teamwork, collaboration, and conflict management across the healthcare organization. Calls for conversation and dialogue to begin to address the challenges to working together are growing [26–28]. With this increased interest comes a growing database of empirical evidence associated with teamwork, collaboration, and improved conflict management in the clinical setting. This culture shift creates a golden opportunity for researchers interested in elucidating the impact of professional subcultures, human factors, team training, and conflict dynamics on the effectiveness of interprofessional collaboration and its impact on clinical outcomes, quality of work environments, and the resilience of health professionals.

INTERPROFESSIONAL COLLABORATION—EMERGING RESEARCH

The complexity of delivering critical care services requires ongoing integration of skills and knowledge from multiple professions. Emerging research highlights several areas including: perceptions of health professionals; the impact of collaboration and teamwork on clinical outcomes, quality indicators, retention of health professionals, patient satisfaction, and the quality of the work environment; characteristics of effective teams; and the influence of conflict on team effectiveness. Much of the research is based on self-reports combined with only a few observational or controlled trials. Several key studies will be reported here that serve as the foundation for future strategies.

Perceptions of Health Professionals

Physicians and nurses often state the importance of collaboration, communication, and cooperation in delivery of clinical care. Until recently, however, there has been little evidence as to how each of the professions defines these key components of the practice environment. In a 2009 study, health professionals indicated understanding and appreciation of professional roles and responsibilities, and communicating effectively to be two core competencies necessary for patient-centered collaborative practice [29]. Studies where both physicians and nurses were queried about collaboration and communication in their specific units suggest that their perspectives are often far apart. Using the Safety Attitude Questionnaire, Sexton and colleagues found that nurses' and anesthesiologists' perceptions of teamwork in the operating room were significantly lower than that reported by surgeons in the same area [30]. One study measuring communication in four ICUs in the United Kingdom noted that, while a majority of senior physicians reported a highly positive open communication style between nurses and physicians, only one third of nurses reported the same [31]. Thomas et al. investigated critical care nurses and physicians' attitudes about teamwork in eight ICUs in six hospitals. Findings of the 320 subjects suggested that while over 70% of physicians viewed collaboration as very high, only one third of the nurses felt the same [32]. These studies indicate that the two professions experience the organizational climate very differently. This begs the question, what underlies these varying perceptions, given that those surveyed were working together in the same units?

A review of the various codes of ethics for the professions of nursing, pharmacy, medicine, occupational therapy, social work, physical therapy, respiratory care, and chaplaincy indicate that the levels of ethical responsibility associated with interprofessional practice fall into five categories: professional conduct (citizenship), acknowledgement of others, cooperation, collaboration, and conflict engagement. The categories reflect a progression in depth of professional engagement and they provide a glimpse into the perceptions each profession acquires regarding interprofessional practice [33]. The discrepancy highlighted in the studies above suggests that differing approaches found in the professional codes of ethics may impact the way in which each profession is defining and perceiving collaboration. This idea proves likely based on the results of a 2006 survey measuring teamwork among nurses and physicians in the OR (operating room) setting. Discussions with survey respondents indicated that, "nurses often described good collaboration as 'having their input respected,' whereas physicians often described good collaboration as having nurses, 'who anticipate their needs and follow instructions' [30]." Research into effective teamwork indicates that having shared mental models and a common language are key for working well together. A good starting point for enhancing collaboration is the joint development of shared models for collaboration that provide a common language for working together.

Impact on Quality, Safety, and Retention

Research that examines the impact of interprofessional teams on patient safety is limited. Most reports either are anecdotal

or include a limited description of the methods used to measure team effects [16]. A 2009 Cochrane review of clinical trials measuring the impact of interprofessional collaboration practice-based interventions designed to improve the work interactions or processes among various types of health professionals yielded five studies that fit the review criteria [4]. The five studies evaluated the effects of interprofessional rounds, interprofessional meetings, and an externally facilitated interprofessional audit. Three of the studies found that the interventions led to improvements in patient care, such as drug use, length of hospital stay and total hospital charges, while one study showed no impact, and one study showed mixed outcomes. The results of other studies suggest a positive correlation between interprofessional practice and clinical outcomes. Recent studies looking at the impact of teams in critical care and primary care have linked teamwork to increased survival to discharge, decreased readmission to the intensive care unit (ICU), fewer adverse events, shorter lengths of stay, and decreased mortality rates following surgical interventions [34]. Research assessing system failures in ORs and ICUs found that positive perceptions of team coordination among ICU staff were associated with lower error rates, that is, when the staff perceived timely transfer of information, role clarity, and awareness of team member activities [35]. Thomas et al. assessed the relationship between teamwork and noncompliance with neonatal resuscitation standards in 132 videotaped resuscitations and found a weak correlation between team behaviors (information sharing, inquiry, treatment planning, and leadership) and compliance [36]. There is also evidence that good team behaviors are linked to decreased turnover among nursing staff in the OR [30] and survey research has shown a link between high levels of cooperation between ICU nurses and physicians and reports of staff burnout [37]. Greater perceived relational coordination has been associated with patient perceptions of higher quality of care, less postoperative pain, greater postoperative functioning, and shorter length of stay [16].

The 2004 Institute of Medicine report, *Keeping Patients Safe*, addresses the work environment of nurses and its impact on patient safety. The report provides an extensive review of the literature on interprofessional collaboration in its *Appendix B: Interdisciplinary Collaboration, Team Functioning, and Patient Safety* [16]. Additional research is needed to differentiate the impact of team behaviors, organizational context, team composition, and team stability on clinical outcomes. In addition, the next phase of research should further elaborate strategies for cultivating team effectiveness [34].

Interprofessional Collaboration and End-of-Life Care

End-of-life care in the ICU is a complex and oftentimes an emotion-filled, process. Much work has been done to examine how to improve end-of-life care. In a 2005 special report from the Hastings Center, three areas were identified as needing greater attention to improve end-of-life care. The authors suggested a rethinking of assumptions related to (i) the end-of-life care delivery system, (ii) the approach to advance directives and surrogate decision making, and (iii) how to manage conflict and disagreement [38]. Each of these has implications for collaborative practice among ICU team members. Difficulties for clinicians in providing end-of-life care include: variability in practice, poor communication among providers, lack of consensus regarding plan of care, incomplete documentation, and differences of opinion regarding the definition of futility [39]. According to a statement released from the Consensus Conference in Critical Care, "The principles of shared end-of-life decision making between patients, family members, and clinicians can be achieved only through full participation of all ICU healthcare professionals in the communication and decision-making process [40]."

Critical care nurses have consistently described one of the greatest stressors in their work to be related to decision-making regarding futile treatment [41]. The most important factor enabling nurses to move from cure to comfort-oriented care is developing a consensus about the treatment plan. A survey of 864 critical care nurses revealed barriers to good end-of-life care as being disagreement about the direction of the dying patient's care, actions that prolonged a patient's suffering, and physicians who were evasive and avoided talking with patient's families [42]. When nurses believe that they are powerless to impact decisions related to a course of treatment they perceive to be unethical or harmful to the patient, it leads to moral distress [43]. According to the American Association of Critical Care Nurses, moral distress has a significant impact on the clinical work environment. Studies indicate that one in three nurses experiences moral distress and in one study, nearly half of the nurses surveyed left their unit, and for some their profession, as a result of moral distress [44]. Incorporation of shared goal setting, protocols for managing end of life care, collaborative decision-making processes, and interprofessional dialogue related to complex cases can alleviate some of the stress experienced by all clinicians in the critical care environment and improve care for patients and their families at a very difficult time in their lives.

STRATEGIES FOR ADVANCING INTERPROFESSIONAL COLLABORATION

There can be no assurance of safe, effective, quality care without collaboration that begins with a trusting, respectful relationship. Addressing what some consider these "soft" issues may in reality be the solution to many of the hardest challenges in critical care settings. In the complex environment of the ICU, the challenge to focus full attention on the patient experience and create systems of care where clear communication from respectful collaboration is the norm is crucial [45]. The history of critical care in the United States is replete with the concept of teams and reliance on expertise from many professionals—the hallmark of the ICU [46]. Relationship-centered care, where the primacy of relationship of patient and healthcare provider exists, cannot occur without skilled partnerships of all members of the healthcare team, especially physicians and nurses [47].

Given the broad impact of interprofessional collaboration and the growing application of teamwork to provision of critical care, it is important to better understand the current strategies for advancing collaborative practices and team effectiveness. Bronstein describes a model for interprofessional collaboration that includes: interdependence, professional activities (work structures and acts), flexibility in traditional roles, collective ownership of goals, and reflection on process (how well the team is working together) [48]. Reader et al. in a review of the literature linking teamwork to outcomes in intensive care generated a performance framework categorizing the various team behaviors that had an impact on clinical care. These behaviors can be categorized as: team communication, team leadership, team coordination, and team decision making [49]. Clarifying models for observing and evaluating collaborative practices provides a baseline for improving performance and elucidating what works. An overview of some of the emerging areas of interest associated with interprofessional collaboration is described below.

Attitudes and Attributes Indicative of Effective Interprofessional Practice

A blend of relational qualities, personal characteristics, skills, and activities constitute collaborative practice. The give and take between team members is in constant flux and resides within the context of the organizational environment. Team factors are divided into task, process, and relationship components. Processes include methods for communicating and sharing information, managing conflict, goal setting, and decision-making. Relationship factors include trust, respect, shared mental maps, status differentials, and attitudes toward teamwork [33]. Increasing emphasis on relational aspects of teamwork is emerging as principles from complexity science further define the necessary elements for high quality care in complex systems. In a study assessing factors that contribute to higher quality outcomes in complex primary care practices, Lanham et al. found trust, mindfulness, heedfulness, respectful interaction, diversity, social/task relatedness, and rich/lean communication to be important factors for the emergence of high-quality care. In addition, they determined that effective reflection, learning, and sense making were requisite behaviors among members of the clinical team [50].

Research indicates that attitudes toward teamwork impact the presence of collaborative practice [51]. Favorable attitudes toward team performance and collaborative patient management approaches maximized team outcomes [16]. There is a significant amount of literature addressing the relational aspects of trust and respect as components of collaborative practice [52]. The Society for Critical Care Medicine describes the attributes of interprofessional teams to be: trust and transparency, collaboration and communication, appreciation of complimentary roles for a shared purpose, leadership, action, and accountability [53].

Team Effectiveness

Collaborative patient-centered care is associated primarily with work in interprofessional teams [54]. In addition to the attitudes and attributes necessary for teamwork, there are specific skills and processes that enable a diverse collection of professionals to work in concert to provide care to critically ill patients. High functioning teams are characterized as having good communication, low levels of interpersonal conflict, high levels of collaboration, coordination, cooperation, and participation [34]. Team coordination is the concerted and synchronous performance of patient care tasks by team members. Coordination requires each team member to maintain an awareness of the work accomplished by the others on the team [49].

Collaboration, as an ongoing process, occurs across a continuum requiring a range of skills for engaging at various levels of depth and nuance. These skills include the capacity for self-reflection, the ability to communicate effectively across professional groups, the ability to give and receive feedback and engage in shared decision-making, consensus building, and the ability to engage in and resolve conflicts [33]. Work processes that support engagement across this continuum are essential as is effective team leadership.

A great deal of research has been conducted on teamwork and team behaviors. One model that has emerged as a foundation for addressing team performance is the Salas framework. This model specifies five core aspects of teamwork which include (i) team leadership (formal and informal), (ii) collective orientation (cohesiveness, common goals, and team success), (iii) mutual performance monitoring (awareness of others and understanding and appreciation of various roles), (iv) backup behavior (helping one another), and (v) adaptability (ability to adjust strategies and resources on the basis of situational assessment) [55]. These areas of teamwork are supplemented by three coordinating activities that include (i) establishing shared mental models, (ii) closed loop communication, and (iii) mutual trust. This model serves as the foundation for the evidence-based TeamSTEPPS training curriculum developed by the Department of Defense and the Agency for Healthcare Research and Quality (AHRQ) [56].

The construct of "team" has multiple definitions. In a recent literature review assessing the impact of teams on clinical and organizational effectiveness, team was defined as, "a collection of individuals who are interdependent in their tasks, who share responsibility for outcomes, who see themselves and who are seen by others as an intact social entity embedded in one or more larger social systems (for example, business unit or corporation), and who manage their relationships across organizational boundaries [34]." Impacting team effectiveness is the continuous morphing of team membership. The idea of team in a traditional work setting is much different in the clinical setting where shift changes, floating, locum tenens, trainee rotations, cross-covering, consultation, procedural specialists, and interdepartmental support staff all impact team configuration at any point in time. This dynamic creates challenges for communication and development of trust among team members. The forming and re-forming of the team requires establishment of relationships on an ongoing, quick-time basis [57]. Team dynamics and organizational complexity require clear communication among team members and effective methods for collaborative decision-making.

Team Communication and Decision Making

Physicians and nurses speak different languages, approach patient care from different frames of reference, and carry out their work very differently from each other (shift work vs. case-based work). The holistic model of nursing, with its emphasis on relational practice and sensitivity to patients' needs as primary, is a different framework from the scientific and objective model of medicine and its emphasis on disease process and diagnosis. As such communication difficulties are predictable. Schmitt identifies the key interprofessional communication patterns that contribute to errors in diagnosis and treatment as (i) counterproductive hierarchical communication; (ii) disjunctions in distribution of authority, responsibility, and accountability across disciplines; and (iii) issues of lack of respect and lack of clarity with regard to legal and ethical obligations across disciplines [58]. Additionally, nurses and physicians evaluate each other's competence in different ways. In a study reported by Schmalenberg et al., physicians tended to judge the competence of the nurses by the quality of the information given, particularly in emergency situations when the patient's condition had changed. Nurses tended to judge the competence of the physician by patient outcomes and the absence of complications, consultation with the nurse prior to writing orders, and the extent to which the physician listened and collaborated in determining the patient's plan of care [59,60]. The need for bridging these world views to ensure effective communication and decision-making is obvious. A look at communication patterns during patient care rounds demonstrates both the status differential between physicians and nurses and the differing perceptions of information sharing. In a 9-month study in which researchers observed 2,391 intensive care interactions, it was noted that nurses made only 12% of comments during rounds and only 10% of the team discussion was directed toward the nurses [61]. The observed nurses were asked their opinion by the medical staff only four times in the nine-month period, and

when interviewed, the nurses portrayed themselves as assertive during rounds. Physicians rely on the surveillance function of nurses who are present with the patient a larger portion of the time and they rely on timely reporting of information by the nurse to make critical treatment decisions.

Team communication is the ongoing sharing of information, ideas, and opinions among members of the team. Reader reviewed 35 studies on teamwork in the ICU and found that errors in patient care occurred most often when team communication failed, particularly after shift change and handoffs, with 37% of the observed errors associated with nurse/physician communication [49]. In a 2008 survey of over 5,000 critical care nurses, 40% of those responding rated communication with physicians as only fair or poor with close to 60% noting verbal abuse [62]. Pronovost and colleagues analyzed ICU adverse event and critical incident data and found that critical incidents were associated with reluctance among nursing staff to report observed errors and patient care issues, a lack of communication between physicians and nurses regarding changes in treatment, inaccurate transfer of information between ICU teams, and inadequate information transfer when new patients were admitted to the unit [63].

Such results have led to initiatives that help the various professions communicate more effectively with each other. These include the use of electronic medical records, practice protocols, procedural checklists designed together by the team, and the use of SBAR for reports from one clinician to another. SBAR, which stands for Situation-Background-Assessment-Recommendation is a script developed by the military as a means of communicating necessary information in a concise and uniform manner so that the receiver of the information can make prompt decisions in response [64]. These efforts help to reinforce the aspects of effective teamwork identified previously including shared mental models, collective orientation, and closed loop communication.

Team decision-making occurs as information and perceptions from the various team members are integrated. Decisions can be made together as the members confer or may be made by the team leader on behalf of the team [49]. Complex decision-making requires the integration of divergent viewpoints within the team that represent a rich array of perspectives, experience, and information. Negotiating through the differences to come to agreement regarding the plan of care is an essential skill for critical care teams. Doing so is dependent upon the relational factors previously described including trust and respect. Teams that adopt competitive, rather than collaborative approaches are not only less effective, but they also create environments in which there are lower levels of team member satisfaction [65]. When negotiations are cooperative, team members are better able to remain flexible and open to the ideas of others leading to more creative problem solving. When conflict levels are high and negotiations are competitive, cognitive flexibility decreases and defensive postures prevent effective collaboration. Team member support for team decisions is predicated on the perceived level of procedural fairness experienced during the decision-making process [16]. Those teams where senior members seek out and incorporate the perspectives and opinions of junior members are more likely to have members who remain engaged with the group, follow through on team decisions, and who continue to be cooperative in future negotiations.

Self-Reflection and Self-Correction

Effective critical care teams are capable of giving and receiving feedback among the various team members and they are able to self-correct, that is, adapt their actions to changes in the patient's condition or to changes in team performance [55]. Reflective practice enables clinicians to evaluate their own responses to situations and to identify areas that need attention. Reflective practice techniques have increasingly been integrated into the teaching of communication skills in medical schools to improve clinician–patient interactions [66]. Developing team practices that allow for self-reflection, observation, and evaluation of group process, and incorporation of what is learned into performance improvement activities, greatly enhances team effectiveness and develops improved trust as the team discovers what qualities and activities enable them to function effectively. Mechanisms for reflecting on performance include: use of team debriefs, case reviews, facilitated reflection with mentors or coaches, and informal conversations among team members.

Professional practice entails continuous learning and adaptation as feedback is received to improve performance and provide increasingly sophisticated care. Improving clinical abilities is just one aspect of self-corrective behavior. A more difficult component of professional practice is the giving and receiving of feedback among colleagues, particularly feedback related to professional conduct and team behaviors [45]. In the seminal 2005 study, *Silence Kills*, researchers sampled critical care staff and physicians in 13 ICUs nationwide. The researchers discovered that the majority of critical care staff and physicians surveyed had concerns about competence of some of their colleagues, had witnessed shortcuts and mistakes, and had experienced disrespect and insufficient team support with very few speaking up to address these concerns [67]. The reasons given by those surveyed for not speaking up include: fear of retaliation, lack of conflict skills, deference to authority, and the belief that nothing will come from speaking up. Avoidance of these difficult conversations led to elaborate workarounds, by physicians and nursing staff, which compromised patient care. In most cases, team members were aware of a colleague's poor performance, often for over a year, and they allowed it to continue rather than provide the necessary feedback needed for improving performance.

Failing to address clinical performance is not the only area of difficulty for health professionals. In July 2008, the Joint Commission released Sentinel Event Alert #40, *Behaviors that Undermine a Culture of Safety* [17]. The alert cites evidence of the correlation between intimidating and disruptive behaviors and the incidence of medical errors and preventable adverse events, patient satisfaction, costs of care, and retention of qualified personnel. The alert goes on to indicate that there is a history of tolerance and indifference to such behaviors and that failure to address these behaviors at both the individual and system levels contributes to unsafe care.

Increasingly, research indicates a large prevalence of unprofessional conduct that could contribute to patient harm. Such behavior also impacts the quality of the work environment. The results from Rosenstein's studies indicate that more than 90% of clinicians surveyed felt that disruptive behaviors invoked feelings of stress and frustration, with more than 80% feeling that disruptive behaviors caused a loss of concentration, reduced team collaboration, and impaired information transfer. In addition, more than 90% felt that disruptive behaviors contributed to poor communication and impaired nurse–physician relationships [68]. A 2009 study among experienced labor and delivery nurses indicates that despite their knowledge of proper clinical actions based on evidence and national practice standards in five high-risk scenarios, the nurses chose to delay or work around the physician when the physician was difficult to deal with. This was particularly true when the nurses believed that their manager or hospital administration would not back them up [69].

The findings of these studies add to the growing literature base that calls for a reexamination of what it means for nurses and physicians to authentically collaborate for patients

to receive expert coordinated care. Improving the capacity of clinicians across the professions to engage in conflict situations and give difficult feedback to colleagues is an essential step in improving the safety of patient care and the quality of clinical work environments [26]. Since January 2009, the Joint Commission has required accredited healthcare organizations to (i) develop a universal code of conduct, (ii) implement a process for dealing with lapses in professional conduct, and (iii) to develop and implement a conflict management process for addressing conflicts among the three top leadership groups (executives and senior management, medical staff, and the governing body) [70]. This increased focus on improving conflict management in the clinical setting is a powerful step in helping to cultivate conflict competent organizations.

Conflict Competence Among Team Members

In addition to managing day-to-day team processes, critical care teams must also manage the competing agendas that inherently exist in interprofessional teams [71]. Just as with perceptions of collaboration and communication, there are differing perspectives among physicians and nurses regarding the presence of conflict. "Studies indicate that physicians do not always recognize nurses' perspectives on conflict. In a study of conflict in intensive care units, nurses identified nearly twice as many conflicts as were identified by both the physician and the nurse [72]." Again, developing a shared mental model of conflict and developing the skills of team members to constructively engage with each other is crucial.

Health professionals identify high levels of conflict in the workplace and much of that conflict is with each other. In a 2009 survey sent to 13,000 physicians and nurses, nearly 98% of the survey respondents reported witnessing behavior problems between doctors and nurses in the past year, with 30% indicating they saw such behaviors weekly and 10% indicating daily occurrences [73]. Among ICU intensivists responding to a survey published in 2009, 70% reported conflict in the past week, with half of the incidents perceived as "severe" and those reporting indicated that the conflict was associated with increased job strain [21].

Physicians and nurses identify a desire for increased opportunities for training and open dialogue that focuses on teamwork and conflict engagement [74,75]. Expertise in conflict management ranges from novice to expert and incorporates capacity for addressing personal conflict, as well as skill in facilitating and mediating conflicts among others. Foundational to skill acquisition is the development of non-adversarial (dialogic) mindsets, cognitive roadmaps for approaching conflict, and expanded capacity for self-reflection and self-correction of ineffective behaviors [76]. Maine Medical Center in Portland, ME and the UMass Memorial Medical Center in Worcester, MA are examples of institutions that have invested in systematic communications training for healthcare providers, leading to sustained improvements in safety and quality [77].

Difficulties that can contribute to conflict within the team include role boundary issues, perceptions of unfair decision-making processes, autonomy versus team needs, feeling that one's contribution is not valued, miscommunication of information, and inappropriate use of hierarchy [78]. Not all conflict is bad and in fact conflict is often necessary for obtaining the best decisions in complex cases. Evidence of the impact of variable types of conflict indicates that some types of conflict (task-related) can improve social capital (trust) within the team and thereby improve coordination of patient care [79].

Conflict within the critical care team may be associated with serious medical errors. An analysis of a national survey of over 6,000 residents (multispecialty sample) indicated that just over 20% reported "serious conflict" with another staff member with nearly 10% of those conflicts being between the resident and nursing staff, and 10% being with another resident. Among those residents who reported no conflict with professional colleagues, 23.8% reported having made a serious medical error, and among those who reported conflict with two or more colleagues, the serious medical error rate was 51%. Further research is needed to determine the empirical association but the significant difference in error rates is enough to prompt further attention [80].

Developing conflict competence across the clinical team to better manage interpersonal conflict is a key aspect of effective team performance. Training and coaching can help to develop conflict engagement skills that enable productive conversations around difficult issues [76]. In addition, ensuring that team leaders and senior professionals model constructive conflict behaviors is even more powerful as a means of embedding conflict competence among team members. Assisting team members and team leaders by incorporating system-wide policies that address conflict and unprofessional conduct provides a starting place for difficult conversations to occur. In addition, embedding conflict experts within the organization whose job is to help facilitate or mediate disputes is another means of supporting safe patient care.

Team Training and Simulation

The growing emphasis on teamwork and interprofessional practice within academic training will have a positive impact on future generations of clinicians. However, there is a lack of team orientation and skills among practicing clinicians. To respond to this need, many organizations are implementing team training and simulation to help promote safe care and more effective clinical coordination, particularly in complex or high risk areas such as the OR, ICU, ED, and Labor and Delivery [81]. In 2007, the AHRQ launched a national effort to support team training to improve communication and teamwork skills among health professionals [56]. Known as TeamSTEPPS™, the program curriculum reflects more than 20 years of research and applied knowledge from other industries including aviation, nuclear power, and the military. Another approach for improving team skills is the use of high fidelity simulation in which clinical teams are given scenarios to enact within a highly sophisticated simulation environment, much as astronauts or pilots would do. The simulations are videotaped and the clinical scenario is adjusted during the training session to assess not only clinical knowledge but also team skills, leadership, and crisis management. Debriefs following the simulations provide for a discussion among team members as to what worked and what could be done to improve performance. Designing training programs that provide for interprofessional learning promotes collaboration and understanding of roles, concentrates the group's efforts toward the needs of patients, and promotes development of trust and respect within the team [82].

Organizational Supports for Interprofessional Collaboration

Even teams that have excellent skills in communication, decision-making, and clinical expertise need support from the organization in which they reside. Design of work processes, policies, and the broader culture of the organization all play a role in supporting effective collaborative practice. Intentionally developing team leaders and supporting them with mentors and

coaches is one means of organizational support [83]. Additionally, creating dyadic leadership models, or "productive pairs," in which there is co-leadership of the ICU by both a medical director and a nursing director, can provide direct support to the clinical teams and also provides a means for modeling interprofessional collaboration and setting a culture of collaboration within the unit. A joint task force from the American Association of Critical-Care Nurses (AACN) and the Society of Critical Care Medicine (SCCM) developed a collaborative practice leadership model in 1983 that resulted in 10 principles outlining the interdependent nature of the two professions in the critical care environment and also outlined the complimentary roles of the two leaders [84]. Such partnerships enable the leaders to more fully address the complex integration of competing demands that range from clinical operations to financial management, risk management, and professional development of new clinicians.

Broader efforts to embed effective interprofessional collaboration across the entire healthcare organization are also underway. The ANCC Magnet certification process specifically emphasizes effective collaboration practices and communication among the professions and those organizations seeking this coveted designation must demonstrate what they have done to ensure adequate mechanisms are in place [85]. Research evaluating nurse–physician relationships within Magnet hospitals has demonstrated better relationships and more collegial work climates than non-Magnet designated hospitals [28]. Hospitals celebrating their Magnet credential now number over 300 with many more seeking certifications.

An innovative model developed to support interprofessional collaboration across the medical center has been implemented by the University of Virginia and makes use of the social technology Appreciative Inquiry [86]. Initiated in 2005, the Center for Appreciative Practice has developed collaborative efforts by the Schools of Medicine, Nursing, and the Health System as a method of supporting ongoing efforts to identify what works best using an appreciative focus. This enables professionals to develop solutions together while enhancing their appreciation of the accomplishments and contributions of colleagues from other professional groups. Such innovative approaches are highly indicative of organizational cultures that fully support interprofessional collaboration and the impact it can have on improving patient care and the quality of work environments.

PERSONAL WELL-BEING AND RESILIENCE

Collaborative environments are not only good for patients, but they also support the well-being of the health professionals who provide care to the seriously ill. A growing area of research related to resilience and personal well-being emphasizes the importance of self-care and collegial support as a means of providing safe care and enabling health professionals to continue in their work for the duration of their career. In a study published in 2008, residents from nine separate residency programs indicated that personal well-being not only impacted the quality of their work, but that high levels of personal well-being resulted in greater patience and collegiality with other health professionals and that low levels of personal well-being contributed to increased interpersonal conflict with colleagues [87]. The residents cited the ability to talk with colleagues as one means of maintaining their sense of personal well-being. Surveys of ICU and OR physicians and nurses indicate that the majority of them seriously underestimate the effect of stress on their professional performance and the likelihood of making an error [16]. Increasingly, emphasis on interprofessional collaboration as a means of improving resilience will emerge as health professionals look for ways to decrease stress, better manage conflict, and effectively navigate the growing complexity of healthcare organizations.

CONCLUSION

There is a growing emphasis on interprofessional collaboration in critical care environments as a means of improving the safety and quality of patient care, to support the development of healthy work environments, and to further the resilience and well-being of health professionals. A great deal more research is needed to further these efforts. Training and academic preparation that reinforces team skills and an appreciation of the contributions of the various professions provides a first step in the promotion of effective collaboration. The development of new models for implementing clinical teamwork, joint leadership, and organization-wide supports will continue to shift the culture of health care toward one in which the various professions are working together, and not just side-by-side.

CHAPTER 206 ■ HEALTHY WORK ENVIRONMENTS: NECESSARY FOR PROVIDERS AND PATIENTS

KATHLEEN M. McCAULEY

Envision the following scenario: you are a recent graduate of your basic educational program or fellowship, have successfully passed your boards and certification examinations, are armed with superb references from your mentors and faculty, and have identified two job openings in which you can work with the leaders in your specialty. The locations are perfect, close enough to family and friends, and the salary is competitive. You have scheduled interviews at each site and are excited about the opportunities to launch your career and are ready to convince the interviewers that you are the perfect new addition to their team. Your mentors have coached you in competitive strategies to stand out from the other applicants. Given that both interviewers are eager to hire you, how will you choose?

In launching a new career or accepting a new position to further an established career, clinicians would be wise to consider the health of the work environment as important in their final decision. The responsibilities of succeeding in a complex healthcare provider role coupled with demands of personal lives, particularly when complicated by caring for children and/or aging parents, contribute to stress. An analysis of sources of stress for women physicians revealed that expectations at both work and home were key factors, but also that the quality of the work environment was important as well [1].

Results of an expanding body of research and anecdotal reports from a wide range of stakeholders argue that the health of the work environment is critical to both professional satisfaction and patient outcomes. In this chapter, the consequences of toxic work places and knowledge about characteristics of healthy work environments will be reviewed. Differing communication norms between physicians and nurses, inaccurate perceptions about the reality of the ways that team members contribute to critical patient care decisions, significant deficits in conflict management skills, and tolerance for disrespectful treatment of colleagues all contribute to unnecessary and dangerous tension in the workplace that can harm patients. This chapter presents strategies for creating healthy work places, including widespread adoption of national standards.

A sense of what constitutes a toxic versus healthy work environment was clarified by Heath and colleagues [2]. They conducted a series of focus groups with nurses, who were asked to consult with multiple colleagues prior to their discussion. Consensus emerged that toxic environments lack effective communication as well as trust. Hazing behaviors were reported in toxic environments that included withholding critical information, setting each other up to fail, and sometimes actual physical violence. When there is a lack of vision and leadership, arguments over conflicting values are common. In toxic environments, poor behavior is exhibited by all healthcare providers and these problematic behaviors extend to patients and families both as perpetrators and victims.

In times of documented shortages of key healthcare providers, work environments that drive talented clinicians from direct care roles require serious attention. In a study examining job satisfaction rates of nurses in the United States (U.S.), Canada, England, Scotland, and Germany, Aiken and colleagues found that with the exception of German nurses, job dissatisfaction was high, ranging from 33% to 41%. These dissatisfaction rates are much higher than those reported by other professional (10%) and general workers (15%). Of particular concern is the effect of the work environment on younger nurses since one out of three U.S. nurses in this study planned to leave the hospital job within the next year [3]. Factors contributing to job dissatisfaction included insufficient staff to deliver high quality care or simply to get the work done, inadequate support services, failure of administrators to listen to nurses' concerns, minimal opportunity to participate in policy decisions, lack of recognition of contributions, and poor opportunities for advancement [4]. Dr. Julie Sochalski, an expert in health policy who has conducted research on the shortage of nurses and consulted for the federal government about healthcare reform, argues that the current shortage cannot be remedied by enhanced recruitment alone. We must retain our best and brightest clinicians and it means that our work environments must be healed (J. Sochalski, personal communication, 2010).

Positive nurse–physician relationships coupled with adequate staffing and strong support from hospital administrators are associated with significantly lower rates of nurse burnout and with patients who were twice as likely to report higher levels of satisfaction with their care [5]. Conversely, in a study conducted in Switzerland, nurses caring for an average of eight patients daily felt that they needed to ration nursing care. Rationing was related to adverse patient outcomes such as medication errors, falls, avoidable critical incidents, and pressure

ulcers. Rationing included nurses' perceptions that they were unable to deliver needed nursing interventions such as feeding and hygiene, patient education and rehabilitation, monitoring, support and advocacy, and documentation of care and preventive functions such as appropriate hand washing. The Swiss investigators found that even low levels of rationing were associated with poor outcomes and yet they acknowledged that some rationing is inevitable. Further research is needed to identify a threshold in which truly unacceptable rationing occurs. It is likely that rationing of care, since it directly affects the patient, may be an important variable in understanding the influence of staffing and work environments on patient outcomes [6]. Burnout and dissatisfaction with rationing of care are clearly negative influences on a healthy work environment.

HEALTHY WORK ENVIRONMENT STANDARDS

In 2003, the Board of Directors of the American Association of Critical-Care Nurses (AACN) embarked on a strategic planning initiative to identify the three most pressing issues in which AACN's influence and voice could have the greatest impact on members. Consensus emerged that nurse staffing, healthy work environments, and end-of-life care were pivotal issues. Staffing and healthy work environments were seen as critical issues for nursing's largest specialty organization because of evidence that strong and supportive environments contribute to lower patient mortality rates [7]. Healthy work environments are those in which professionals work as team members, respect each other, and display caring for patients and families as well as each other. In these environments, effective collaboration provides opportunities for shared problem solving and emergence of shared mental models that support new solutions [2]. Professionals are empowered to practice according to the standards of their professions, including making decisions about their practice. They are led by leaders with the skills and power to design and implement a vision for superb practice. This was the vision that motivated the AACN Board of Directors to charge a work group, led by past president Connie Barden to develop healthy work environment standards [8]. These standards, listed in Table 206.1, were designed to give a strong message that immediate change in current practice settings was needed. Research identifying factors foundational to healthy work environments support AACN's decision to select these standards as the framework to drive widespread change.

TABLE 206.1

AACN STANDARDS FOR ESTABLISHING AND SUSTAINING HEALTHY WORK ENVIRONMENTS: A JOURNEY TO EXCELLENCE

Skilled Communication: Nurses must be as proficient in communication skills as they are in clinical skills
True Collaboration: Nurses must be relentless in pursuing and fostering true collaboration
Effective Decision Making: Nurses must be valued and committed partners in making policies, directing and evaluating clinical care, and leading organizational operations
Appropriate Staffing: Staffing must ensure effective match between patient needs and nurse competencies
Meaningful Recognition: Nurses must be recognized and should also recognize others for the value each brings to the work of the organization
Authentic Leadership: Nurse leaders must fully embrace the imperative of a healthy work environment, authentically live it, and engage others in its achievement

Adapted from American Association of Critical-Care Nurses: AACN Standards for establishing and sustaining healthy work environments: a journey to excellence. *Am J Crit Care* 14(3):187–197, 2005.

ENHANCING COMMUNICATION AND COLLABORATION: EFFECTIVE DECISION MAKING

There is evidence that nurses and physicians who work together differ significantly in their perceptions of collaborative decision making. In a large French study involving over 3,000 nurses and over 500 physicians, over 90% of the total sample agreed that decisions involving patients' end-of-life care should be made collaboratively. In practice, however, physicians were nearly twice as likely as nurses to report that nurses were involved in decision making (50% vs. 27%) and were significantly more satisfied with decision processes (73% vs. 33%, $p < 0.001$). These uneven perceptions were paralleled by strong differences in reports of physician consultation with nurses in the decision making process (79% vs. 31%, $p < 0.001$). Nurses were much more likely to feel that their presence in the meeting with the family was important. They valued being there more than the physicians valued their presence (56% vs. 36%, $p < 0.05$). The importance of these findings to clinical practice was evident in that significant linkages were found between satisfaction with decision making, perception of the unit's commitment to high ethical standards, and nurses' involvement in achieving these standards ($p < 0.0001$) [9]. Understanding that providers have disparate views of successful collaboration provides insight into potential root causes of communication problems both in day-to-day practice and when providers and patients face tough decisions. Efforts to achieve an ethical solution to practice dilemmas using processes that respect and value the input of the entire healthcare team are needed to achieve truly healthy work environments.

Effective communication has been shown to affect prevention of adverse outcomes. In particular, timeliness of nurse–physician communication was related to decreased incidence of pressure ulcers in a critical-care patient population, and conversely, when nurses perceived variability in communication with physicians, ventilator associated pneumonia (VAP) rates were higher [10]. Given the importance of preventing adverse events, it is reasonable to consider changes in care processes to foster clear and effective communication. System changes such as use of multidisciplinary rounds, appointment of a hospitalist medical director, and addition of a nurse practitioner (NP) to support the care interface between staff nurses and physicians are becoming more common, particularly in tertiary care hospitals. In a setting with these values in place, when care in that environment was compared with standard practice on a similar acute medical care unit, it was found that attending physicians and house staff perceived nurse collaboration to be significantly better but both the physicians and nurses rated collaboration with the NPs to be significantly better than with each other. No differences were found between nurses' perceived communication and collaboration with physicians on the model unit versus the standard practice unit. However, physicians on the model unit reported improved communication with each other. Improved patient outcomes included reduction in patient length of stay and care costs without reductions in quality of care or increased readmissions [11]. A possible explanation for the positive outcomes of physician/NP collaboration may lie in an appreciation of skills gained through NP versus MD education. It has been argued that NPs may be more adept at managing

patients through chronic care protocols in primary care. This is supported by their nursing background with its focus on patient education and use of communication skills [12]. Hence, the NP lives in both worlds and can easily translate and fill in gaps.

Why would physicians and nurses perceive care processes so differently? As was evident in Vazirani and colleagues' study [11], staff nurses may have difficulty being freed from direct care responsibilities to be able to participate in patient rounds or may be uncomfortable presenting their data and recommendations and thus avoid participation. Clear expectation for each provider's role in rounds, support for their participation through patient coverage, and providing adequate mentoring of young professionals in effective participation strategies are needed. Dialogue to ensure clarity about the characteristics of good collaboration and to develop respect and recognition of the value of each others' contributions are important steps in achieving benefits for patients and providers. Without this preparation, physicians may view improved collaboration to mean simply receiving accurate patient information and nurses following through on physician orders versus actual sharing in the decision making process. Addition of an NP to the team may serve as a bridge between nurses and physicians, improving the flow of information but may have the unintended effect of predisposing the nurses to communicate with the NP at times when they otherwise may call a physician [11].

Nurse–physician communication difficulty may have its roots in disparate educational systems. In their basic education, nurses are expected to present a broad, comprehensive picture of the patient's situation, in contrast to the targeted, specific problem focus that drives physician communication [13]. Nursing case summaries are graded highly if they thoroughly addressed the patient's physical health problems, including supporting pathophysiology, emotional and coping reactions, family and community support systems, and the interrelationships between all of these, resulting in a comprehensive nursing care plan that also integrates the nurse's support of the medical plan. Parsimonious, concise descriptions tend to be graded as missing key information and insights. Those training exercises, while designed to educate the nurses to view the patient holistically as a being with vast nursing needs beyond the medical illness, do not prepare them for a concise, problem-specific and action-driven health system, particularly as exists in critical-care settings. Thus, vastly different and ingrained way of thinking about patients' problems coupled with hierarchical power differentials can lead to pervasive dysfunctional norms of communication. Fear of reprisal or ridicule blocks interjection of critical information into the dialogue. Reliance on vague, imprecise communication styles may exclude critical information or urgency in message delivery. Leonard and colleagues [13] refer to this as the "hint and hope" model—one that holds a strong potential to harm patients.

Similarly, if a culture of perfection, personal failure, and blame exists rather than one of analysis of human and systems factors that contribute to errors, the tendency to bury errors and near misses rather than discuss them openly and correct root causes, further impede effective communication and harm patients [13]. Effective communication skills are needed. Given the authentic team leadership and implementation of skill building strategies, nurses can learn to participate effectively in interdisciplinary rounds, to summarize concisely changes in patients' conditions and to advocate for their needs, and to diffuse the inevitable conflicts that emerge among the healthcare team and with patients and families [14].

A widely used communication tool, SBAR (situation, background, assessment, recommendation) supports concise and organized communication between providers. It is a structure that guides a nurse's explanation of the situation, focusing on relevant background information, an assessment of what is happening and recommendations for corrective action. This technique has been criticized, however, for its failure to ensure that each provider fully understands the patient's problem and recommended action. Consequently, another tool gaining acceptance, STICC, adds a requirement for feedback and clarification of misunderstanding. With this tool, S describes the situation (Here's what I think we face), T is the task (This is what I think we should do), I refers to intent (This is why we should do it), C describes concern (What we should keep our eyes on), and C provides an opportunity to calibrate (Now let's talk; tell me what you don't understand, can't do, or if you see something I don't) [15]. Outcomes improve in settings in which nurses are empowered to state clearly that the patient requires immediate attention and can expect that this message will receive an immediate response, no matter the time of day or day of the week. While techniques such as SBAR and STICC improve the clarity of the message, the sense that "something isn't right" should be recognized as a call to action. Borrowing techniques in critical language from the airline industry such as the CUS system (I'm concerned, I'm uncomfortable, this is unsafe or I'm scared) provides a shorthand way of alerting colleagues that the problem is serious and demands attention. It is inevitable that false alarms will occur but a culture of effective communication and collaboration further supports strengthening nurses' assessment and communication skills [13].

STAFFING

An emerging body of research demonstrates strong connections between nurse staffing, particularly RN staffing, and patient outcomes. For surgical patients in acute care hospitals, increasing Registered Nurse (RN) care hours by 1 hour per day resulted in an 8.9% reduction in the patients' odds of developing pneumonia. The importance of the RN's role in care, as compared to less skilled nursing personnel, was further validated by a reduction in the risk of pneumonia by 9.5% when the proportion of RNs to overall nursing personnel increased by 10% [16]. Turnover of nursing staff has been shown to affect how a healthcare team learns from experiences with each other so that their abilities develop and they grow in behavioral skills and that, in turn, affects patient outcomes. Higher levels of workgroup learning were associated with higher patient satisfaction and fewer severe medication errors. Conversely, workgroup learning was found to be lower when turnover levels were moderate (3.31% to 4.5%) [17].

Evidence is also emerging that the educational level, skill set of the nurse, and quality of nurse–physician relationships make a difference. A 10% increase in the number of nurses prepared with a baccalaureate or higher degree resulted in a 5% decrease in both the likelihood that a surgical patient would die within 30 days of admission or that a failure to rescue event would occur [18]. These results occurred even after adjusting for patient characteristics such as comorbid conditions, hospital characteristics such as size, teaching status, and technology level, nurse staffing and experience, and the board certification status of the surgeon. Similarly, substituting unlicensed aids for RNs has been shown to reduce quality outcomes in a large study (18,142 patients) of patients with common cardiovascular and pulmonary diagnoses. The largest part of the variance in 30-day mortality rate was attributed to patient age and illnesses (44.2%). However, hospital and nursing factors accounted for an additional 36.9% of the variance. Lower 30-day patient mortality rate was found in settings with a higher proportion of baccalaureate nurses (OR, 0.81; 95% CI [0.68, 0.96]), presence of more RNs versus less skilled nursing personnel (OR, 0.83; 95% CI [0.73, 0.96]), and healthy nurse–physician relationships (OR, 0.74; 95% CI [0.60, 0.91]).

The use of temporary nurses was associated with a higher 30-day mortality rate (OR, 1.26; 95% CI [1.09, 1.47]) [19].

Nurses, however, perceive that staffing to deliver quality care involves more than simple nurse-to-patient ratios. In a study based on interviews conducted with 279 nurses from 14 Magnet Hospitals, nurses perceived staffing to be adequate when all providers worked as members of a team, collaboration was strong, and nurses possessed the knowledge, experience, and skills to meet patient needs. Empowerment to make autonomous clinical decision and control of their practice environment were crucial factors as were support strategies such as computerized documentation, order entry systems, and well trained, motivated, assistive personnel and support services. Patient acuity influenced staffing perceptions but these nurses perceived that high patient acuity was best handled when other positive work environment characteristics were present. Nurses valued administrators' recognition of the need to factor patient acuity into staffing allocations [20]. In a study of nearly 8,600 Canadian nurses, an analysis of nurses' perceptions about their work environment found a direct causal relationship between poor staffing and nurses' emotional burnout, and a direct positive relationship between the presence of a nursing model of care, one that values nurses' personal and professional ideals, and personal accomplishments [21].

The notion that perceived staffing adequacy is not as simple as nurse–patient ratios was addressed in a significant way by AACN and the AACN Certification Corporation when they charged a workgroup with developing and refining a new

TABLE 206.2

AACN'S SYNERGY MODEL FOR CLINICAL EXCELLENCE: PATIENT CHARACTERISTICS

- **Resiliency:** The patient's capacity to rebound or return to function using compensatory physiological and other coping mechanisms; a history of adapting to significant stressors; reserve capacity
- **Vulnerability:** Degree of susceptibility to real or potential stressors; affected by physiological capacity, coping ability, pre-illness health status; the person's ability to protect themselves from threats
- **Stability:** Capacity to maintain a steady state, maintain equilibrium; influenced by responsiveness to therapies
- **Complexity**: Interconnectedness of two or more systems; can be physiological, psychological, family interactions or environmental impact; with greater numbers of systems affected, complexity increases
- **Resource Availability**: Supports available to the patient by the family, community, and the patient himself/herself; resources are broadly defined: physical, emotional, fiscal, social, personal; in general, more resources are linked to better outcomes
- **Participation in Care**: Engagement by the patient and family in care processes; influenced by educational levels/health literacy, cultural background and resources
- **Participation in Decision Making:** Ability to comprehend and act on information and to contribute to decisions; influenced by cultural background, degree of physiologic function, beliefs and values
- **Predictability**: Accuracy in anticipating responses and course of illness; facilitates use of diagnostic indices and evidence-based pathways to plan care

Adapted from Hardin S, Kaplow R: *Synergy for Clinical Excellence. The AACN Synergy Model for Patient Care*. Sudbury, MA, Jones and Bartlett Publishers, 2005, pp 3–54.

TABLE 206.3

AACN'S SYNERGY MODEL FOR CLINICAL EXCELLENCE: NURSE COMPETENCIES

- **Clinical Judgment:** Nursing skill, clinical reasoning, and critical thinking abilities developed over time through education, practice, and attention to evidence-based care; ability to integrate patient-specific knowledge into care planning and delivery
- **Advocacy:** Serve as a moral agent, one who intervenes to support another who cannot voice her/his own rights and needs; helps to resolve ethical conflicts and clinical problems for patients and families
- **Caring Practices:** A large collection of nursing practices that provide a therapeutic, supportive, and compassionate environment that promotes healing and prevents unnecessary suffering; applies to patients, families, and staff
- **Collaboration:** Cooperative engagement among all members of healthcare team, along with patients and families to achieve optimal and realistic patient goals
- **Systems Thinking:** Ability to see the real causes of problems; knowledge and skills to manage the environment and resources for the betterment of the patient, family, and health care team, within and across health and non-healthcare systems
- **Response to Diversity:** Recognition, appreciation, and incorporation of differences among racial, ethnic, marginal, and vulnerable populations to support individuality, cultural attributes, spirituality, family, and lifestyle preferences into the provision of care.
- **Clinical Inquiry:** Persistent process of questioning and evaluating practice to ensure that practice is informed by current research and experiential learning
- **Facilitator of Learning:** Recognition of patient and family needs for knowledge and skill development and use of standardized and patient appropriate materials and creative strategies to ensure that patients and families are prepared to handle their healthcare needs; valuing and promoting life-long learning among all members of the team.

Adapted from Hardin S, Kaplow R: *Synergy for Clinical Excellence. The AACN Synergy Model for Patient Care*. Sudbury, MA, Jones and Bartlett Publishers, 2005, pp 57–107.

paradigm for clinical practice. Initially designed as a framework to guide development of a conceptually redefined certification examination, the model became a driving force to articulate nurses' contribution in achieving AACN's vision—*a healthcare system driven by the needs of patients and families where acute and critical-care nurses make their optimal contribution* [22]. The Synergy Model for Clinical Excellence identifies patient characteristics and nurse competencies that, when matched appropriately, enable patient outcomes to be optimized [23]. Table 206.2 describes the patient characteristics and Table 206.3 identifies the competencies of the nurses caring for these patients.

RECOGNIZED POSITIVE WORK ENVIRONMENTS: MAGNET HOSPITALS AND BEACON UNITS

During the 1980s, nursing administrators noted that some hospitals continued to maintain adequate staffing even during nursing shortages. Subsequent research identified the positive practice environment characteristics of these hospitals and the

term "Magnet" was applied to them since they served as a magnet for nurses. The knowledge gained from this research was used by the American Nurses Association and its accrediting arm, the American Nurses Credentialing Center (ANCC), to develop a Magnet Recognition program to identify those hospitals with the quality indicators and standards of care that result in excellence in patient care and an exemplary practice environment for nurses. Of the prestigious *U.S. News & World Report* Honor Roll of top hospitals, 71% of medical centers and 90% of the Children's Hospitals achieving that designation are Magnet organizations [24].

In 2003, AACN launched the Beacon Award for Critical-Care Excellence. This highly competitive award recognizes individual critical care and progressive care units whose staff has achieved high levels of quality patient and family care and excellent care outcomes within a healthy work environment. The award recognizes outstanding outcomes in recruiting and retaining a staff that values ongoing education and training to sustain competent practice, research and evidence-based practice, strong leadership and commitment to organizational ethics, and a sustained healing environment [25]. While nurses tend to lead the movement to attain Beacon status, this honor cannot be achieved or sustained without significant interdisciplinary collaboration and authentic leadership to transform the practice environment.

The benefits of a healthy work environment and factors associated with sustaining it can be understood by examining work environment research conducted in Magnet institutions. For example, when work environment characteristics of 23 Magnet institutions were compared with 156 non-Magnet hospitals, Magnet designation was associated with significantly more decentralized decision making involving nurses, collegial nurse/physician relationships, adequate staffing, presence of nurse managers with good leadership skills, and a preceptor program for newly hired RNs. Without Magnet designation, only 17.3% of the hospitals scored well on practice environment measures and all scored lower on all characteristics than the ANCC Magnet hospitals [26]. Similarly, a survey of over 2300 nurses from 110 ICUs in 68 hospitals revealed that nurses in Magnet hospitals perceived their work environment to be significantly better than those in non-Magnet facilities [27].

In a study of over 4,000 nurses, Ulrich and colleagues [25] examined perceptions of work environments within agencies that had Magnet or Beacon status, were actively pursuing either status, or had neither status. Nurses in Magnet or Beacon agencies had significantly more positive appraisals of the work environment, greater current job satisfaction, a higher rated skill set of the nursing leadership team, and improved quality of care compared with non–Magnet/ Beacon agencies. They also rated quality of interdisciplinary team communication and collaboration more positively, as well as respect for RNs, organizational support for education and certification, and nursing career satisfaction. Shared governance structures were significantly more likely to be in place in Magnet or Beacon organizations. In many of the parameters measured, units and organizations on the journey to Magnet or Beacon fared significantly better than those groups not pursuing that designation [25].

Insight into factors that staff nurses, physicians, and nurse managers perceive to be most important in the work place may help colleagues understand differences in expectations and emphasis in effort. In a survey of all three groups working together in Magnet institutions, Schmalenberg and colleagues [20] found that physicians overwhelmingly viewed a competent nurse as a colleague who was able to make timely, correct, and independent decisions to support patients. These physicians reported that they rely on nurses who can quickly discern what patients need and implement the required care, particularly when physicians were unable to be physically present.

TABLE 206.4

SPECIFIC STRATEGIES TO IMPLEMENT HEALTHY WORK ENVIRONMENTS

1. Empower nurses to control practice through strong physician and team collaborative decision making and active participation in interdisciplinary rounds; teamwork becomes a core value.
2. Shared governance models included members from multiple departments and disciplines resulting in an "integrated" model that is far more efficient and empowering than single discipline "silo" governance models (p. 82).
3. Staffing structures that allow nurses the time to attend rounds and governance meetings. Governance structures that support nurses' input into decisions by administrators, physicians, and others.
4. Groups own the outcomes of decisions and care improvement efforts; a culture exists that appreciates individual and group contributions
5. Quality patient care is based on the best scientific evidence and is morally and ethically congruent with the patient's wishes and professional standards.
6. Safe care is the minimum but goals demanded excellent, high quality patient/family centered care.
7. Competence, ongoing education, personal accountability for evidence-based practice, and certification were valued and expected.
8. Camaraderie and a family orientation among team members resulted in a nurturing work environment where expression of concerns and feelings was the norm. Team members supported and filled in for each other without grumbling.
9. Respect, trust, and treating each other as equals and with dignity were valued. The same principles applied to interactions with patients and families.
10. Honesty and integrity as core values were reflected in communication; team members are reluctant to place blame, seeking instead root causes of problems. Willingness to acknowledge mistakes and short comings is valued.
11. Patient advocacy and clinical autonomy are supported by appropriate surveillance to prevent complications or rescue patients and a passion to get patients what they need.
12. Stewardship means that the team values the patient's and each other's time and energy; appropriately uses and conserves resources and delivers quality outcomes.
13. Active transmission of core values and unit norms to new members of the team happens because managers and team members develop and implement a conscious plan to ensure that the values and norms become entrenched in the culture of the team.

Adapted from Kramer M, Schmalenberg C, Maguire P, et al: Walk the talk: promoting control of nursing practice and a patient-centered culture. *Critical Care Nurse* 29(3):77–93, 2009.

These comments clearly demonstrated that competent nurses earned the trust and respect of physicians [14].

Nurse manager expectations were similar in that they valued the vigilance, advocacy, and persistence of competent nurses. While correctly interpreting what is happening and acting on it was critical in their view, they also valued nurses who demonstrated commitment to ongoing competence through education. The managers expected that nurses request increasingly challenging assignments, incorporate the latest evidence-based practice standards into care, and manage both complexity and volume of care responsibilities. Organizational skills of priority setting and multitasking are needed to manage the demands of busy units, but competent care demands complex thought processes and decision making skills while retaining empathy and concern for the individual patient [14]. Thus, managers' view of competence is much broader than that reported by physicians in this study. While physicians and staff nurses agreed on the importance of clinical knowledge and decision making and physicians welcomed and expected the input of competent nurses, they may have failed to comprehend the full range of nursing duties, particularly with a full caseload of acute and critically ill patients. Hence, the importance that nurses and nurse managers place on multitasking is understandable [14]. These findings support the notion that healthcare today is characterized by "complexity compression," a term that describes the challenges inherent in taking on additional responsibilities while simultaneously providing highly complex care in a condensed time frame [28]. For today's work environments to become healthy, recognizing that complexity compression affects all providers is a critical step. As our reliance on each others' expertise grows, our appreciation for the demands on each other and our support for each other must grow as well. Specific characteristics demonstrating achievement of a healthy work environment are described in Table 206.4.

TRANSFORMING WORK PLACES: AUTHENTIC LEADERSHIP

Achieving and sustaining the change described in these studies requires leaders with the skills to build teams and motivate staff to develop a broad set of competencies in communication, collaboration, decision making, as well as evidence-based practice. Individual as well as team competencies are needed to transform work places and sustain positive change. One strategy that was found to increase significantly collaborative communication, problem solving, and conflict management skills was a 24-hour program using a modular format that offered leadership and communication training to physician and nurse leaders in an organization. Strong engagement was reflected in attendance rates of over 90% of the sessions and positive evaluations about the usefulness of the learning. While this study involved a small sample, it demonstrates that investing in joint physician–nurse leadership competency development is effective [29].

Efforts to create healthy work environments through systems improvements and enhanced skills in communication, collaboration, and leadership are likely to have additional payoff in terms of patient outcomes and satisfaction. To turn our current silo-driven, fragmented health systems into centers of patient-focused care, we must ensure that sustained commitment to collaborative care is based on effective communication and is led by authentic leaders [30].

CONCLUSIONS AND NEXT STEPS

Let's return to where we began—the job interview scenario. Thriving in today's difficult practice world demands that we acquire a strong base in the evidence supporting clinical care. Colleagues who share that commitment will contribute to our growth in knowledge and clinical decision-making skills. Evidence is also growing that patient outcomes are not controlled only by the clinical decisions we make but by the environment where those decisions are implemented. Healthy workplaces promote collaborative decision making, leading to better informed decisions and avoidance of incomplete or inaccurate information that contributes to adverse events and poor outcomes. Therefore, gather as much information as you can about the practice climate, interprofessional relationships, and skills of the leadership team. Ask to speak with members of the disciplines you will be practicing with to understand the real level of collaboration that exists. Interview the managers and leaders you will be working with to ascertain their commitment to achieving a work environment where you will make your optimum contribution and thrive. Finally, be a force for a positive environment that supports each other as well as patients and families. The factors listed in Table 206.4 provide a start. We all have a stake in the process and the outcomes.

CHAPTER 207 ■ ICU NURSING IN THE TELEMEDICINE AGE

REBECCA J. ZAPATOCHNY RUFO, TERESA A. RINCON AND SHAWN CODY

INTRODUCTION

In the 1999 publication by the Institute of Medicine, *To Err Is Human*, the authors painted a grim picture of medical errors in hospitalized patients [1]. The report stated tens of thousands of patients each year suffer a preventable medical error. Errors can lead to death, physical impairment, increased length of stay, and cost increases amounting to billions of dollars. The Institute of Medicine (IOM) estimated that almost 100,000 American patients die yearly from medical errors making it the eighth leading cause of death in the United States.

Historically, Intensive Care Units (ICUs) are major sites for medical errors and complications. Patient safety experts cite outmoded systems of work as the reason for many of healthcare's errors and quality problems [2]. It is believed that redesigned systems will yield safer, better care. According to the Leapfrog Group, a healthcare advisory board for Fortune 500 companies [3], more than four million patients are admitted to the ICUs and approximately 500,000 die annually. They estimated that providing a dedicated, intensivist-based care model could save between 50,000 and 100,000 lives annually [4] and that mortality could be reduced by 15% to 20%.

Modern ICUs are complex and prone to errors [5]. In 1999, Doering described what she termed as threats to effective collaboration in the critical care setting [6]. These threats included the complexity of the environment and the increasing workloads of staff at the bedside. She suggested that the process of effective collaboration required a commitment of administrators and staff alike when both are facing competition for scarce resources. Effective communication and collaboration required time and nurturing from all involved. It should be built on a concept of trust and could not be rushed and is often the first thing to be omitted when outside forces pull caregivers in different directions.

AGING WORKFORCE

Long lengths of stay, higher rates of infection, and failure to rescue are patient care outcomes that have been linked with nurse staffing levels [7]. Concerns related to the implications of a projected nursing shortage has influenced interest in how staffing mix as well as sheer loss of numbers of critical care nurses could lead to an increase in errors in patient care. This led to the passing of the Nurse Reinvestment Act (NRA), Public Law 107–205 in 2002 by Congress. This legislation was aimed at stimulating the growth of the nursing profession [8].

The composition of the registered nurses (RNs) workforce was predicted to shift to the largest group of RNs being in the 50- to 60-year-old age group by 2010 and according to a recent study by Auerbach et al., RNs in their 50s will outnumber all other age groups in this profession by 2012 [9]. The demand for RNs is predicted to accelerate at the same time as the nation's eighty million baby boomers begin to reach the age of 65. By 2020, the gap between supply and demand of RNs is estimated at over 400,000 [10].

Although some progress has been made in recruitment and retention of nurses, the future projections still fall short of the goal of maintaining a supply and demand balance for this vital workforce. Discovering more innovative solutions to leverage nursing expertise and practice is needed. The Sixth report by the National Advisory Council on Nurse Education and Practice (NACNEP) recommended the use of simulation-based education as well as utilization of interactive Internet-based learning programs to enhance effectiveness of nursing education and critical thinking skills. Strategic use of technology to not replace the nursing workforce but to enhance skill mix and staffing as well as to prepare and support the novice nurse was also recommended [11]. Leveraging nursing practice and expertise through the use of technology is the essence of telenursing.

A task force was commissioned by the Robert Wood Johnson Foundation to publish a white paper in 2006 to identify

strategies and opportunities for retaining the experienced nursing workforce. This paper examined the effects of loss of knowledge that occurs when older experienced nurses leave the profession [12]. Leading experts are convinced that organizations suffer detrimental effects on productivity and performance with loss of older employees. Shifting the ratio of experienced nurses to less experienced nurses will have serious implications on quality and safety of patient care according to national experts [12]. If the emerging role development of the telemedicine team is fostered by internal driving forces of clinical competence, independent decision making, and strong interpersonal skills, then can telemedicine enable a new care delivery model that embraces empowerment through leveraging of critical resources?

What happens to nursing knowledge, if as projected, large numbers of experienced nurses leave the field all at once? Bleich et al. warns that the implications of loss of knowledge will be devastating to not only performance and productivity but the shift from "experienced to less experienced nurses will have serious implications for quality and safety of patient care" [13]. The authors go on to explain that more than just "rudimentary skills and routine know-how about common processes" are required, these nurses also have "deep-smarts," a "tacit knowledge" that is difficult but not impossible to articulate into formal language. It is a knowledge that is gained through the maturation process of being a nurse; a synthesis of learned knowledge, deep insight, and intuition that allows the experienced nurse to incorporate multiple assessment variables rapidly into an assessment and a plan of care. It is the "state of knowing" that could be lost as nurses leave the profession if we do not find innovative and creative solutions to maintain and leverage it.

IS TELEMEDICINE THE ANSWER?

According to leading experts, telemedicine may be leveraged to support a multidisciplinary intensivist-led team and incorporates re-engineering of workflow processes, outcome measurement, collaboration and professional role development to facilitate efforts to change behavior for improved patient quality [14]. Telemedicine is defined as the transmission of electronic data from one location to another to allow for remote evaluation of the data by a medical professional [15–17]. Data may include pictures, EKGs, radiology studies, or audio–video feeds. The remote medical professional then communicates back to the sending facility with an opinion using one of several means, including fax, audio, video, or other electronic means.

The concept of telemedicine has been around for several decades. Telemedicine in its current form can be found in the literature as far back as the 1950s [15]. The National Aeronautics and Space Administration monitored astronauts' heart rate and respirations while in space from a remote location or during test runs on the earth. NASA continued to monitor astronauts and to develop computer software over the ensuing years [15]. Several projects were funded by government agencies in the 1960s, 1970s, and 1980s to bring medical care to remote or hard to reach locations both nationally and internationally, often using microwave audio and video communication. Most of these early projects could not be sustained due primarily to the prohibitive cost of the microwave communication technology [16].

During the 1990s, the availability and transmission of digital radiological studies allowed the efficient reading of images remotely, allowing a single radiologist from a different location to interpret studies when an on-site radiologist was not available. Another use that gained favor around the same time was the use of psychiatric staff doing remote evaluations. Telemedicine has also allowed neurologists to remotely review studies and allow for real-time decision making in the treatment of acute stroke care [17]. This along with changes to the laws required for consults to allow for neurologists to bill for their remote services has greatly enhanced the care of these patients.

Today telemedicine is a significant component of the Department of Veterans Affairs strategic plan to care for veterans [18]. According to the American Psychiatric Association, "Telepsychiatry is currently one of the most effective ways to increase access to psychiatric care for individuals living in underserved areas" [19]. The Department of Health and Human Services, Health Resources and Services Administration (HRSA), supports the use of telehealth to meet the needs of underserved people [20].

Over the past 10 years the advancement of computer systems of relatively low cost and of faster transmission has greatly enhanced what data can be viewed from a remote location. The advent of clinical documentation systems at the bedside have further made the data readily available using electronic means. Over the past 35 years, research scientists have worked to develop computer systems to assist clinicians in making decisions related to patient care [21]. This coupled with high-resolution audio–video technologies have led to the emergence of telemedicine in the intensive care unit or tele-ICU care.

TELE-ICU STAFFING PATTERNS

A modern tele-ICU center is typically staffed by both clinical and nonclinical members. The fundamental component to the remote clinical team includes experienced critical care nurses and physicians specializing in Critical Care Medicine. Other board certified specialty physicians such as cardiothoracic, pulmonary medicine, cardiology, and trauma/surgery may serve as the tele-ICU physician. Affiliate practitioners such as Nurse Practitioners and Pharmacists are adjunctive team members in some tele-ICUs to leverage resources in patient monitoring, management, and performance improvement. Operational processes are supported by nonclinical staff in the tele-ICU center through timely, current data entry and by facilitation of communication between remote and onsite teams.

The number of clinical and nonclinical staff required for each program is dependent upon the volume of monitored beds and the off-site team's level of involvement with the bedside. At least one physician along with several nurses and nonclinical support consist of the core team members each shift. An additional physician or mid-level practitioner such as an advanced practice nurse may be needed to meet the demands of monitoring larger patient volumes. The tele-ICU care team composition is dependent on the type of service provided. There are specialty physicians providing consultative care models using telemedicine technology to support the care of critically ill patients. Some of these care modalities use telenursing support in their programs.

Tele-ICU staffing is impacted by several factors including the ratio of patients monitored per tele-ICU nurse. Typically, one tele-ICU nurse monitors approximately 35 to 50 patients. The ratio affects the number of nurses required each shift to staff the tele-ICU.

One consideration of staffing is the degree of integration and effort needed by the tele-ICU nurse to maintain timely data for monitoring and interventional purposes. Another consideration in managing this many patients is the degree of electronic documentation performed at the bedside versus the remote site. Fragmentation of documentation (paper, electronic, combination) impacts monitoring abilities of the tele-ICU nurse and demands greater oversight to maintain accuracy of data.

TELE-ICU NURSING

The ICU nurse is a key leader to clinical transformation and the re-engineering of care processes. Therefore, it would follow that the tele-ICU nurse would and should be an integral part of the tele-ICU team. What makes the tele-ICU nurse think differently than the bedside ICU nurse? How does the tele-ICU nurse use or draw upon innate cognitive abilities when processing information? Drawing from previous experience, training and knowledge the expert critical care nurse uses tacit knowledge to synthesize complex physiological information and care modalities into nursing diagnoses and recommendations for optimizing patient care. Information technologies (ITs) allow nurses to not only view information remotely but to observe pertinent data in an organized, real-time manner enhance the efficiency in which clinicians can amalgamate information.

TRANSITION FROM THE BEDSIDE

The tele-ICU nurse requires a transitioning process to fulfill role development. The transitioning period or role development may last several months past orientation. A fundamental aspect of this period is learning new responsibilities as a tele-ICU nurse versus an ICU nurse. Role development encompasses expanded functions as mentor, preceptor, educator, leader, and program advocacy. Unlike bedside care, the tele-ICU nurse must learn to transition from hands-on care to technology-driven care.

Conceptual development is important to understanding role transition of the tele-ICU nurse. Discussion of conceptual development of the tele-ICU nurse is limited to absent in the literature. Understanding what makes the tele-ICU nurse transition into an emerging new breed of caregiver is important to the future of nursing practice. A paradigm shift occurs in care delivery once the bedside ICU nurse transitions into a tele-ICU nurse. The shift in traditional care delivery of one to three ICU patients is now dozens of patients per shift. How does the tele-ICU nurse begin to conceptualize and synthesize from managing individual patients to whole populations of patients occur? Benner [22] identifies five stages of nursing development and the teaching/learning needs at each stage. These stages are congruent with the professional role development and transition period of the tele-ICU nurse. Unlike a new graduate nurse at the novice stage of professional bedside practice, the tele-ICU nurse possesses clinical experience but is new to the emerging role of the remote environment as well as to using IT to drive decision making and assessment practices. All nurses transition to some degree through these five stages of development regardless of their specialty area. The time spent in each developmental stage will vary with each nurse and the ability to adapt to the complexity of the new role.

The case could be made that these expert nurses should be physically present at the bedside caring for complex patients and providing face to face mentorship of novice nurses. How could taking more nursing expertise away from the bedside actually serve to enhance staff mix? Because of nurse supply and demand trends and predictions, finding alternative ways to leverage nursing expertise across the over 6,000 ICU in the nation will take a creative and innovative approach [23].

Expertise and knowledge working in isolation from caring can hinder execution of high level nurse practice. Therefore, it is imperative to include a balance of knowledge and caring in the development of the emerging discipline of virtual or tele-ICU nursing. Dr. Jean Watson's Theory of Human Caring contain 10 factors that are described by her as "those aspects of nursing that actually potentiate therapeutic healing processes and relationships; they affect the one caring and the one-being-cared-for" [24]. She describes the soul or spirit within human beings as "greater than the physical, mental, and emotional existence of a person at any given point in time." According to Watson, this inner spirit allows each individual to achieve a "higher degree of consciousness, an inner strength, and a power that can expand human capacities." The virtual nurse should possess a deep-rooted attribute of caring that extends to not only patients but also to the care providers at the bedside.

TELE-ICU COLLABORATION

The tele-ICU nurse needs to balance caring with power to meet the needs of the patient–family unit through negotiation and advocacy. The concept of power is frequently associated with negative connotations such as restricting freedom, authoritative leadership, and hierarchical status [25]. Power also is referenced to coercion and domination of others. Leaders may display various forms of power or a lack of power depending on the situation and degree of empowerment. Legitimate power is when one person relinquishing power to another individual. This power is associated with action and expertise. Power can be connected with knowledge, coercion or conditioned.

The empowered tele-ICU nurse exhibits effectual use of clinical knowledge and innovative technology. Virtual rounding is an example of empowerment and is a principle mechanism to immediately serve as a clinical resource for assessment, intervention, or mentoring. Nurses should conduct virtual patient and environmental rounds proactively to assess for potential sources of complications, errors and interventional effectiveness. Understanding the concepts of social presence can effectuate acceptance from caregivers at the bedside and mitigate interaction issues related to critical missing communication cues.

Empowerment inherent in organizations where individuals are encouraged to assume responsibility and act in line with organizational goals is an approach that allows staff to retain control over their work, where responsibility is delegated within the hierarchy and resources are readily available [26,27]. Hence, organizational development for a tele-ICU service should begin with a vision and strategy that empowers the remote team to work toward the best care practices within an integrated team model. If this is not present then virtual teams will struggle against entrenched loyalties and hierarchical power structures that are prohibitive to safe and collaborative patient care. Some examples of integrated team approaches with a tele-ICU team are the following:

- Decreased ventilator days [28])
- Implementation of evidence-based best practice strategies at system levels [29,30]
- Ability to provide real-time feedback or reports to guide clinician practice
- Improved compliance to best practice standards [31,32]
- Increased cost effectiveness of critical care
- Prevention of cardiac arrest and complication prevention/management [33–36]

The virtual presence of the tele-ICU nurse may further complicates effective communication due to the lack of direct person to person contact and inability to read the body language. For decades, the healthcare industry has known that ineffective communication has been a significant factor in adverse events in hospitals and in critical care. Inadequate communication was cited as one of the main findings of the 1999 IOM *To Err Is Human* publication [1]. A 2003 study examined the attitudes of critical care nurses and physicians regarding collaboration and teamwork [37]. The results described that physicians predominantly found collaboration to be satisfactory yet the nursing staff interviewed found collaboration lacking. It is thought that communication and collaboration throughout critical care among caregivers is not what it should be [38]. This

is important to keep in mind from a tele-ICU perspective as the camera and microphone may be viewed as intrusive. We are reminded of this in George Orwell's 1949 novel "1984" [39]. Written at the end of World War II, it described a fictional society run by The Party, and it's affect on the main character, Winston Smith. In the novel, all thoughts and actions are controlled by the party, through the use of spies, cameras, and microphones. The controlling Party, and its leader, Big Brother, are attempting to control everything in the people's lives, from where they work to how they think. This "1984" mentality of technology connecting everyone in the world could contribute to a reluctance of care providers and consumers in embracing telemedicine as sound method of care delivery. Understanding this mind-set is important as telemedicine care providers address the communication and collaboration barriers that can surface when using technology-enhanced care modalities.

The tele-ICU nurse is in a unique position to view variation or gaps in care across and within health systems. As the tele-ICU nurse finds these opportunities for improvement this along with Appreciative Intelligence (AI) creates "survival anxiety" which can influence or prompt change to occur [40]. This leads to unfreezing of prior perceptions of care delivery and with AI, tele-ICU nurses can then reframe situations for better negotiating or problem solving in more creative ways. They can use concepts of AI to enhance critical thinking and drive interventions in order to achieve patient safety goals. For example, the tele-ICU nurse has the potential to view continuous vital sign trending. The bedside vital sign data is processed through decision support software that identifies early trends in deterioration. When a vital sign alert is triggered the tele-ICU nurse evaluates the alert for potential patient deterioration, using an audio–video assessment, review of laboratory values, and other pertinent clinical data to assist in the critical thinking and assessment processes. The tele-ICU nurse rapidly processes these data using tacit knowledge which leads to decision making related to evidence-based practice.

COMPUTER-ENHANCED CARE

Social presence (SP) using computer-mediated communication (CMC) has been studied in education disciplines [41–43] and its learnings can be applied to the telemedicine arena. Communication mediums can determine how well people communicate but that individual perceptions often have a powerful influence on acceptance of these mediums. SP has been described as the state of being "real" in mediated communication and is based in telecommunication literature. Social presence relates to how a person is perceived as being real and being there or present in communication [42].

The aspects of SP influence how well communication occurs. Although the degree of saliency and the quality of the social medium can assist in influencing satisfaction of users in using technology as a vehicle of communication, individual perspectives have been shown to be a powerful dynamic [43]. Factors that influence the degree of social presence are: verbal or nonverbal cues, physical proximity, formality of dress, facial expressions, eye contact, humor, and personal topics of conversation. CMC is considered low in the order of social presence [44]. Given previous statistics that highlight the role of communication in errors that harm patients, understanding the impact of modes of communication is important to this discussion. Tele-ICU nurses should receive advanced training in communication techniques and nursing leadership should design communication algorithms that enhance collaboration and mitigate negative perceptions. Further research is needed in the area of telenursing and social presence.

Since the tele-ICU nurse can manage 35 to 50 patients per shift, thoughtful strategies must be employed to accomplish efficient, comprehensive rounding. Studer, a nationally recognized healthcare management thought leader identified nine steps to standardize rounding [45]. These nine steps are applicable in various settings where rounding is present.

1. Give staff a heads-up. The tele-ICU nurse should inform the bedside caregivers of their presence and purpose for rounding.
2. Prepare a scouting report. Understand specific issues or situations within each unit that may impact rounding such as staffing constraints, new nurses.
3. Make a personal connection. Identify a common connection with bedside caregivers to facilitate compassion and genuine personal concern.
4. Identify an issue or concern raised on a previous rounding episode. Demonstrates your follow through to resolve an issue or problem.
5. Remember five questions framed in a positive manner. Script five basic questions that are communicated in a positive and inviting approach for rounding purposes.
6. When an individual identifies a problem, assure him or her that you will do the best to resolve their concern(s). Develops the foundation for open and trusted relationships.
7. Record issues that arise in a rounding log. This will allow for accurate accountability of issues and needs of the bedside caregivers or patients.
8. Recognize and reward those who are identified a high performers. Extending words of thanks for superior work and positive interactions develops strong relationships.
9. Repeat process. The tele-ICU nurse gains repeated experience with rounding since this is an essential function of their role.

TELEMEDICINE AND EVIDENCED-BASED PRACTICE

An expert committee formed by the IOM found that "current care is insufficiently reliable in its use of the best science and best-known practices because it lacks IT systems that put that knowledge at the point of use and because it honors and protects unscientific variations in care based on local habits, unquestioned forms of autonomy, and insufficient curiosity" [46]. According to leading nursing experts the acquisition and implementation of evidence-based practice is lacking in nursing practice [47]. Data also suggests that social interaction and experience are the two most utilized sources of practice knowledge for nurses [48]. Nurses in the virtual environment should maintain a high level of competency through attainment of advance certifications in critical care. Given this, the tele-ICU nurse has a unique opportunity to maintain and disseminate a high level of evidence-based practice knowledge.

CONCLUSION

As discussed previously, the expert nurse can rapidly put together the whole patient picture integrating the patient's needs into timely and appropriate nursing interventions while others may be focused on the next task or a technical skill [49]. This ability to synthesize knowledge into appropriate decision-making skills can then facilitate effective support to the bedside nurse practice. Nurses make hundreds of decisions a day when caring for patients [50]. The tele-ICU nurse can serve as not only a sounding board for bedside nurses as they make these decisions they can use influence and negotiating skills to facilitate evidence-based care practices. Within this context the virtual clinicians function autonomously yet collaboratively with bedside caregivers in clinical decision-making. The autonomy

and independence of the virtual team is cultivated from years of professional experiences, personal attributes, hardiness, and exceptional tacit knowledge synthesis skills. In this virtual environment, nurses and physicians are challenged differently than at the bedside. Monitoring patient data and intervening without physical presence demand skillful communication and expertise in critical care.

Leveraging scarce critical care nursing expertise is just one of the benefits of tele-ICU care models. An expert nursing team can coach and mentor novice ICU nurses remotely, reinforcing care practices, assisting in establishing patient goals, and enhancing critical thinking and assessment skills. Experience is a prerequisite for becoming an expert, according to research that focused on critical care nurses and the learning process [51]. Experts have the ability to go beyond the tasks to read and respond to the global needs of the patient. This allows for the ability to avert potential catastrophe or "failure to rescue" [49,51]. Most sites report that nurses working in a tele-ICU have on average 10 to 15 years of experience in various fields of critical care nursing.

Multidisciplinary integration of the tele-ICU technology and care delivery method through empowerment contributes to organizational acceptance and utilization [52]. Widespread integration with nurses, physicians, respiratory therapists, dieticians, physical medicine, and other care givers will leverage clinical and technical expertise. Data transparency can be enhanced across disciplines with immediate availability of electronic clinical documentation tools within software applications.

Using standardized reporting metrics to evaluate severity adjusted mortality and length of stay as well as compliance with best practice standards is a benefit to centralized data collection. Quality assurance/improvement oversight can be enhanced and efficiency improved with technological tools and tele-ICU processes [53]. This can lead to development of system wide clinical risk reduction strategies that can in turn improve patient safety and quality. Tele-ICU systems allow providers to extract reports from the software application in real-time to evaluate and intervene on patients at multiple intervals each day.

Robust health IT systems employ clinical decision support tools to prompt the clinician to institute evidence-based best practices at the point of care. These systems can provide real-time feedback and reports to alert the physician/nurse to any gaps in care that need to be filled. These "smart" systems coupled with collaboration between on-site and tele-ICU teams empower clinicians to implement best care processes effectively and consistently [54,55].

SECTION XIX ■ CONTEMPORARY CHALLENGES IN THE INTENSIVE CARE UNIT

CRAIG M. LILLY

CHAPTER 208 ■ ICU ORGANIZATION AND MANAGEMENT

THOMAS L. HIGGINS AND JAY S. STEINGRUB

INTRODUCTION

Organization is the act of assembling elements into an orderly, functional whole. Management is the ongoing revision and renovation of that careful assembly to cope with change. The concept of "bedside management" is familiar to clinicians who titrate vasopressors or adjust ventilator settings; intensive care unit (ICU) management is itself a form of titration and continuous adjustment. ICU management extends beyond simply implementing policies and procedures, organizing service and teaching rounds, preparing budgets, and complying with regulations. The successful ICU manager must also innovate and facilitate change. Creativity is important, but perseverance may be more essential because of the ways a typical organization will resist change. Knowing how to navigate the obvious and subtle impediments to change is a key skill for the ICU manager.

The already staggering cost of health care continues to escalate, and now represents 16% of the gross domestic product (GDP) in the United States, with estimates that unchecked, it could double again to 31% of GDP in the next 25 years [1]. Hospital costs are roughly a third of total health care costs, and intensive care alone consumes between 4% and 10% of total healthcare costs, or 0.56% to 1.5% of GDP [2–4]. One-third of Medicare patients spend part of their hospital stay in the ICU or coronary care unit, at an average unit cost per day of $2,616 (in 2004 US dollars) [5]. Discrepancies exist between the Medicare Provider Analysis and Review File (MedPAR) and the Hospital Cost Report Information System (HCRIS), two federal databases used to assess inpatient and critical care costs in the Medicare population [6]. In fact, critical care days may have decreased by 4.5% between 1995 and 2000 based on HCRIS data, while an increase of 7.2% was seen using MedPAR data, which includes "post/intermediate" billing codes [6]. Nonetheless, the Center for Medicare and Medicaid Services continues to forecast a substantial increase in the rate of growth in volume and intensity of medical services as the leading edge of the "baby boom" generation enters retirement [7]. Physician and nursing shortages [8] and increasing costs will constrain growth of intensive care services, while consumer demand (fueled in part by easy internet access to information) and an aging population with chronic disease will exacerbate existing capacity issues. New, unpredictable risks (e.g., novel bacterial and viral threats, terrorism) require preparedness and the ability to ramp up critical care capacity in a crisis. Meanwhile, attention continues to be focused on preventable medical errors. This confluence of events implies that attention must be paid to the health and well-being of the ICU in addition to addressing the needs of individual patients [9].

The conceptual frameworks [10] and business skills for successful ICU leadership must somehow be acquired, whether in business school or on-the-job. Important characteristics of leaders include self-awareness, self-regulation, motivation, empathy, and social skill [11]. The American College of Physician Executives is one organization that provides information on how to prepare for and succeed in medical management [12]. A formal Masters of Business Administration (MBA) program will typically include courses on accounting, data analysis, ethics, financial analysis, human resource management, information systems, marketing, production/operations management, organizational behavior, organizational planning and strategy, quality improvement, team building, and leadership. Given the difficulty in compressing a multiyear MBA curriculum into a book chapter, we will focus on typical ICU organization patterns, human resource issues, the roles of the ICU director, methods for monitoring clinical ICU care, and ancillary management issues.

ICU ORGANIZATION

In broad terms, there are three common models for ICU organization:

- **Open Unit:** Any physician with privileges to admit patients to the hospital may admit and care for patients in the ICU. Patient care decisions are made by the admitting physician, often with the input of consultants. Admission and discharge (triage) decisions fall to the unit director only in event of a bed or staffing shortage. Intensivists may be available for consultation at the request of the attending physician. The major perceived benefit of this model is continuity of care, and it remains prevalent in the United States, particularly in smaller hospitals.
- **Closed Unit:** All patients entering the ICU are transferred to the care of an intensivist (critical care specialist) for the duration of the ICU stay. Depending on local custom, the admitting physician may remain closely involved or collaborate from a distance. Benefits of this model include documented reductions in mortality, rates of complications, and ICU and hospital length of stay. This model is more common in Europe and Australia, but is gaining acceptance in the United States, based on research findings and response to external pressure from the Leapfrog Group [13] and payers.
- **Transitional (Semiclosed) Unit:** Patients are referred for ICU admission to an intensivist, who reviews all admissions for appropriateness (gate-keeping). Final decisions regarding admission, discharge and triage rest with the physician unit director or his or her designee. Either automatically, or by specific consultation, the intensivist may participate in some or all of the patient's care in conjunction with the patient's attending physician of record. The intensivist's role may be limited to triage functions and emergency response, but more often encompasses hemodynamic, respiratory, fluid,

nutritional, and safety management. This model is seen in the transition phase between open and closed structures, and remains common in surgical practices where the attending surgeon addresses the specific operative aspects of a patient's care (e.g., wound care, transplant immunosuppressive regimens) while delegating resuscitation, physiologic monitoring, organ system support and ICU safety issues to the intensivist.

Pronovost et al. [14] conducted a systematic review of articles examining physician staffing patterns and clinical outcomes published through 2001. The model of care in each of 17 studies was classified as low intensity (no intensivist or elective consultation) or high intensity (mandatory critical care consultation or closed ICU). The high-intensity model was associated with lower ICU mortality (pooled mortality risk estimate 0.61) and lower hospital mortality (pooled mortality risk estimate 0.71). Although the literature overwhelmingly favors intensivist staffing models, a recent retrospective analysis of the Project IMPACT database by Levy et al. [15] demonstrated *higher* odds for hospital mortality in patients managed by critical care physicians. These counterintuitive findings have been challenged as being caused by unmeasured confounders including case mix differences [16] and the role of trainees and part-time academic faculty [17]. The higher risk-adjusted mortality in *teaching* hospitals where more invasive interventions are performed [18] may also counteract beneficial effects of full-time intensivists.

Case-control studies, where outcomes have been examined before and after implementing a closed model, offer additional insight into the value of intensivists. Patients admitted to closed units tend to be sicker [19,20], as might be expected with tighter triage criteria, although average severity scores are not necessarily higher in closed units [21]. Nursing confidence in physician clinical judgment improves [18], as a closed system allows the nurse to contact one managing physician rather than having to call the pulmonologist for ventilator changes, the nephrologist for fluid and electrolyte issues, and the cardiologist for arrhythmias. (Although, as Marik et al. [17] have pointed out, detrimental "parceling out" of care may occur in an academic setting even when full-time intensivists are present). These efficiencies are generally reflected in shorter ICU and hospital LOS [19]. The effect of dedicated intensivist staffing on ICU LOS remains significant after case-mix is adjusted for risk factors such as patient age, admission severity of illness, pre-ICU length of stay and percentage of patients requiring mechanical ventilation [22].

Staffing patterns, in terms of in-house, overnight coverage, also vary widely [23]. The benefits of around-the-clock (versus business hours) in-house intensivist coverage is uncertain, despite outcome differences documented as a function of ICU admission time and day of week [24–28]. At the hospital level, there is no statistically significant mortality difference based on time of admission for most (77%) diagnoses [29], including acute myocardial infarction, congestive heart failure, pneumonia, stroke, gastrointestinal bleeding, and many surgical conditions. Mortality was higher, though, in patients with ruptured abdominal aortic aneurysms, acute epiglottitis, and pulmonary embolus, when these patients presented on the weekend. This suggests that for at least some conditions, adverse effects occur because of decreased weekend staffing, lack of patient familiarity with cross-coverage, and perhaps less supervision. Around-the-clock intensivist coverage may reduce severity-adjusted mortality [30] but there is debate if the on-site physicians need to be intensivists, especially given the current shortage of specialists [31]. Introduction of continuous on-site intensivists improves processes of care and staff satisfaction, and decreases ICU complications and hospital length of stay [32].

Remote intensive care, using a telemedicine approach, has been proposed as a partial solution to the shortage of intensivists. Using intensivists and physician extenders to provide supplemental monitoring and management of ICU patients between noon and 7 AM, Breslow et al. were able to demonstrate reductions in hospital mortality (RR 0.73), ICU length of stay (3.63 vs. 4.35 days) and lower variable costs per case [33]. Given the critical care shortage of intensivists, tele–ICU systems can potentially permit these specialists to monitor more patients, and those patients who might not otherwise have access to an intensivist. Despite the shortage of data, Leapfrog Group and the University Health System Consortium have encouraged the application of tele-ICU [34]. Results from the first federally funded multicenter evaluation of tele-ICU of approximately 4,000 patients from before and after activation of a tele-ICU did not demonstrate any differences in adjusted hospital and ICU mortality, length of stay or ICU complications with telemedicine intervention [35]. Of interest, improved survival rates were observed in the sicker population while mortality for less severely ill patients was increased. A major limitation of this multicenter trial include limited authority delegated to the tele-ICU by the majority of attending physicians; that is choosing to limit the remote specialists to monitoring rather than direct intervention authority. In addition, the inability to share the ICU electronic medical records with the central facility could have potentially delayed implementation of tele-ICU orders. The mixed outcome benefit of telemedicine for the ICU noted in recent trials [36] may indicate that the actual mechanisms of implementing telemedicine in ICU may play a significant role as to its effectiveness. Understanding and identifying local hospital wide operations including ICU staffing levels, evaluation of standardized care processes if any and availability of computerized order entry capability may help identify which ICUs benefit from tele-ICU.

A hospital's approach to ICU organization will depend on its patient population, existing professional talent, physical facilities, and economies of scale. Reimbursement for critical care and evaluation/management services typically cannot cover the cost of a dedicated intensivist in smaller units. Triage functions and general management of the unit (as opposed to management of individual patients) cannot be billed to patients, and thus does not generate professional revenue. However, there is ample evidence that hospital investment in physician intensivist services is recouped with better patient flow (reducing the need for additional ICU beds) and lower utilization of pharmacy, laboratory, and radiology services. Simply having an intensive care physician round daily on postoperative patients shortens LOS, reduces complications and lowers total hospital cost in patients undergoing esophageal resection [37] or abdominal aortic surgery [38]. Organizational restructuring of a cardiothoracic unit with an attending physician dedicated to ICU care resulted in reduced pharmacy, radiology, and laboratory utilization, and a per-patient decrease in hospital costs of $2,285 [39]. Pronovost et al. developed a financial model for 6-, 12-, and 18-bed intensive care units for hospitals transitioning over a 1-year period to the Leapfrog Group ICU physician staffing standard. Cost savings ranged from $510,000 to $3.3 million, depending on bed size [40]. Their best-case scenario results could generate up to $13 million in annual savings, while a worst-case scenario imposed net costs of $1.3 million.

PHYSICIAN HUMAN RESOURCE ISSUES

Hiring full-time critical care specialists is already a challenge with the growing shortage of intensivists. Critical care work force needs have not been adequately addressed by public

policy [41]. Medicare payments often do not cover the costs of providing critical care [42,43]. Angus et al. predicted in 2000 that supply and demand of intensivists would remain in equilibrium until 2007, but that demand would subsequently grow, producing serious shortfalls by 2020 [44]. The Society of Critical Care Medicine conducted a survey of 731 critical care physicians in 2004. These respondents planned to retire at an average age of 62 years, and to change focus or reduce patient load beginning in their fifties [45]. Nearly 40% of the respondents were already over the age of 45. Their average workweek was 66 hours, with a typical shift of 10 to 12 hours, providing clinical care an average of 48 weeks per year. It is unclear that the next generation of intensivists will continue to work at this level of intensity, or that critical care will be a viable career choice when remuneration is better for specialties with shorter working hours and less stress.

Current Leapfrog Group standards call for *in-house* intensivist staffing for a minimum of 8 hours, 7 days per week [13,46] or ≥2,920 hours per year to cover one ICU, with requirements for off-hours coverage met by an intensivist on beeper call, with an FCCS-certified physician or physician extender immediately available in-house. Hospitalists with FCCS certification can also potentially provide off-hours ICU coverage. In a retrospective study of care provided during after-hours coverage of a pediatric intensive care unit, Tenner et al. found improved survival with hospitalists compared with housestaff [47].

It is helpful to consider the concept of a clinical full-time equivalent (FTE) to represent the amount of work done by one individual working only on direct patient-care tasks in the intensive unit. In reality, some ICU clinicians will also allocate professional time to research, administration, or education; choose to work part time, or spend part of their clinical time on the trauma team, in the pulmonary clinic, or administering anesthesia. A full-time physician working only in the ICU might have grant funding for 0.25 FTE, and another 0.25 stipend for administrative and educational activity, leaving 0.5 FTE for ICU clinical activity.

How many hours will one FTE work in a year? The SCCM respondents' reports annual work hours from less than 1,000 to more than 4,000, but most commonly 2,000 to 2,500 hours [44]. Since attractive jobs currently offer at least 4 weeks vacation, about 10 paid holidays and at least 5 days of meeting time, we'll consider annual work to be 45 weeks with 10-hour days, yielding 2,250 hours, in accord with the range reported in the SCCM survey. If in-house coverage for the ICU is around-the-clock, 365 days per year, with 30 minutes overlap at the beginning and end of 12-hour shifts, then annual hours to be covered are 9,490. Thus, 4.2 FTEs would be needed to cover the clinical workload. This workload might be met by five physicians, assuming each worked full time and 0.8 FTE was sufficient to attend to administrative and quality assurance activities. If coverage is only during the daytime (3,650 hours per year) fewer FTEs would be required; although on-call hours must still be staffed.

Staffing calculations must consider intensivist-to-patient staffing ratios, which are not well-defined. In England and Wales, where intensivists staff 80% of ICU's, the average six-bed general ICU has three consultants committed to the unit, and another three consultants participating in the on-call rotation [48]. A retrospective study from the Mayo Clinic [49] did not find differences in the severity-adjusted mortality rate at daytime intensivist-to-bed ratios between 1:7.5 and 1:15 although ICU length of stay increased at the higher extreme. Larger hospitals with closed units may take advantage of cross-coverage between units, providing daytime care at intensivist to patient ratios of 1:8 to 1:12; and increasing the ratio during off-hours when there are fewer acute interventions or procedures to be accomplished.

MULTIDISCIPLINARY MODELS: PHYSICIAN EXTENDERS

The enormous work force requirements and economic burdens of providing round-the-clock critical care staffing has led physician leaders, hospital administrators, and insurance companies to re-examine models of health care delivery. Some medical centers now employ physician extenders on the critical care team as a response to physician shortage at both the attending and house-staff level. Physician extender is a broad term covering mid-level health care providers such as nurse practitioners (NPs) and physician assistants (PAs). Physician assistants must complete an accredited education program, usually 2 years in duration, but often requiring prior college and health care experience. PAs must pass a national examination to obtain a license, and always work under a physician's supervision. A nurse practitioner is a registered nurse who has completed advanced training and must be licensed in the state where practicing. Following state licensure, NPs may seek national certification from professional nursing boards and/or pursue specialty certification. NPs have more latitude to practice independently.

Driving forces that have accelerated employment of the physician extenders include cutbacks in federal funding for residency training, identifiable patient care needs, and ACGME standards placing strict limits to the number of hours that medical trainees can participate in providing care. Physician extenders can provide safe and cost-effective care as part of a collaborative medical management team in acute care settings and they are well received by patients, nurses, physicians, and administrators. A limited number of studies suggest that introduction of NP/intensivist team-based care is beneficial to patient outcomes, financial outcomes, length of stay, and patient satisfaction [50]. An attending physician/NP team can safely manage former ICU patients admitted to a subacute unit therefore allowing the intensivist/fellow team time to care for higher acuity ICU patients [51]. Decreased overall length of stay and ICU length of stay, lower rates of UTI and skin breakdown, and a shorter time to mobilization have been documented after introduction of an NP team to neuroscience ICUs [52]. NP participation in weaning protocols for mechanical ventilation has been associated with greater reductions in mechanical ventilation days, ICU length of stay, and hospital length of stay when compared to pre-NP participation [53]. NPs and physicians in training had equivalent efficacies in performing required tasks but residents spend more time in nonunit activities (lectures, rounds) and NPs spend more time monitoring patients, talking to families, and collaborating with other health team members [54].

A team-oriented culture characterized by timely communication is associated with a shorter length of ICU stay, greater ability to accommodate the needs of patient families, and a higher quality of technical care [55]. Including PAs on house-staff-directed ICU teams does not appear to affect rates of occupancy, mortality, or complications [56].

Intensive care services are among the most urgent and costly aspects of healthcare in the United States, and national surveys indicate the need to accommodate about 50,000 patients a day [43]. Professional societies are projecting an inability to meet this demand with intensivists, so the role of physician extenders will need to be further examined as a major component of the healthcare delivery model for critically ill patients.

ROLE OF THE ICU DIRECTOR

The Joint Commission on Accreditation of Health Care Organizations (JCAHO) requires that an individual be designated as the ICU Director, but actual job descriptions vary. At one

extreme, the medical director may simply approve critical care policies and serve as a resource for questions that cannot be solved by nursing administration. He or she may triage only in times of high census, and may have very little role in the delivery of critical care, other than to his or her own patients. At the other extreme, the medical director may lead the team of intensivists that assumes total responsibility for all patients occupying ICU beds. Nonclinical duties may consume more work effort than clinical responsibilities when committee membership, administrative tasks, budget preparation, educational activities, and the business of running the ICU physician practice are included. When the medical director is heavily involved in day-to-day operations, ICU occupancy rates and number of patients misallocated to ICU beds decline [57]. ICU admission decisions are only part of the triage function. One in six patients experience ICU discharge issues (unexpected medical deterioration, level of care issues, administrative problems [58]) that demand executive resolution.

Larger hospitals typically have multiple intensive care units, each with its own director. The directors or designees may participate in a hospital-wide Critical Care Committee that sets overall policies and procedures. In some units, the medical director may delegate administrative tasks, quality improvement, education, and research to associate medical directors. Typically, the ICU director(s) will have a close working relationship with the nursing unit manager in each unit. Multidisciplinary units will involve interaction with other professionals (pharmacists, dieticians, social workers, clergy, utilization management specialists) and the medical director may have an overall coordinating role. Essential character traits of the successful ICU director include willingness to collaborate, ability to delegate, trust in colleagues, and excellent communication skills.

Tasks performed by the ICU Director can best be divided into strategic versus tactical (Table 208.1). Strategic tasks involve the "big picture": recognition of patterns and trends, setting priorities, considering alternatives, and implementing change. The ICU Director is often the champion for process improvement projects. Areas deserving of strategic consideration include cost containment, the overall culture of the ICU, quality improvement efforts, education of physicians, nurses and other health professionals, and coping with change driven by ICU, hospital and external factors [59]. Developing a strategic vision and communicating it well are essential roles. Yet, it is equally important to lead by example, particularly when it comes time to drive change, such as implementing electronic medical records or computerized physician order entry.

Tactical chores consist of the day-to-day, "hands-on" running of the unit. Leaving aside patient care, which in itself can fill the day, there are issues of personnel coordination, patient triage, bed allocation, and conflict resolution [60]. The ICU director is often granted by hospital policy the authority to intervene in any patient's care, and may be charged with evaluating issues and complaints that originate from family members, nursing staff, other physicians, or hospital administration. Tools to assist with the tactical aspects of patient care include checklists [61] and computerized systems. The danger is that tactical chores multiply to occupy all available time, leaving little time for strategic direction. Implementation of computerized order sets, therapist-directed protocols, and other "bundles" of care help to minimize the individual, routine tactical decisions, and leave more time for strategic thinking.

The difference between strategy and tactics reflects the difference between leading and managing. Applied to academic teaching rounds as an example, the residents or physician assistants should be patient managers responding to the information flow of physical exam findings, laboratory tests, and radiology reports. They collect and analyze this data, and develop a daily or even hourly plan. In contrast, the attending physician or fellow should not get lost in the details, but rather should be planning at a higher level exactly what broad changes and interventions will be required to get the patient recovered and discharged from the unit. It is difficult to concentrate on both tactics and strategy at the same time, which argues for dividing the effort with a team approach. The strategic leader should not be isolated from patient contact, however, for it is the experienced interpretation of clues and subtleties that define the expert [62].

The job responsibilities of the ICU Director (and by delegation, the triage physician of the day) create an inherent conflict of interest. A treating physician's fiduciary responsibility is to advocate for an individual patient's best interest. As the ICU manager, however, there is a responsibility to do the most good for the greatest number of patients. The essence of triage is to maximize benefits for the group, even at the expense of an individual. In times of bed shortages, the ethical principle of beneficence ("do good") conflicts with the ethical principle of social justice. For example, a 92-year-old patient has a cardiac arrest at home, and arrives intubated and ventilated in the emergency room with fixed pupils but slight respiratory effort. Although the outcome is uncertain, it certainly does not look promising. Should the last remaining ICU bed go to this patient who is unlikely to survive, if it means refusing a complex hospital transfer, canceling an operating room procedure, or denying ICU admission to a septic patient on a regular nursing floor? These ethical issues are discussed elsewhere in this text, but it is essential for the ICU director to recognize these conflicts and preemptively construct ICU and hospital policy to address how such conflicts are to be handled.

TABLE 208.1

STRATEGIC VERSUS TACTICAL DUTIES OF THE ICU DIRECTOR

Strategic	Tactical
Creating ICU vision and mission statement	Conflict resolution, communicating vision
Evaluating and improving quality of care	Implementing care "bundles" and protocols
Right-sizing physician workload	Hiring new staff; creating call schedule
Fostering interdisciplinary relationships	Interdisciplinary rounds. Joint conferences
Planning for the future	Budgeting; space and equipment needs
Delivering value	Specific cost-containment initiatives
Economic self-sufficiency of practice	Monthly review of financial statements
Professional development	Physician and nursing education
Efficient resource management	Bed triage: written policies
Exploiting advanced technology	Implementing electronic medical records

BUDGET AND PROFESSIONAL REIMBURSEMENT ISSUES

The ICU director may be responsible for managing the budget of the entire critical care unit, including the nursing and respiratory therapy components, but if so, will usually have administrative assistance. More typically, the division chief in an academic ICU or the director of a practice group will be

particularly concerned with revenue from physician professional activity. Particular attention must be paid to actual revenue received since the net collected will always be less than gross professional billing, a problem that is increasingly worse with the current system for physician payment based on the Medicare sustainable growth rate [63].

In the United States, critical care revenue is generated by billing critical care codes (CPT code 99291 and 99292) when the patient qualifies for time-based bedside critical care, or otherwise for Evaluation and Management Codes (typically CPT code 99232–33 for subsequent hospital care, and 99251–53 inpatient consultation) [64,65]. Various procedures have specific codes, and each code is associated with relative value units (RVU) that form the basis for eventual payment. Further information on CPT coding is available on the AMA Web site [66] and through the American College of Chest Physicians [67], among other sources. The relationship between total RVU and CPT codes change over time. For example, insertion of a pulmonary artery catheter generated 3.79 total facility RVU in 2006, but only 3.08 RVU in 2009. On the other hand, CPT 99291 (Critical Care, first hour) was worth 5.99 RVU in 2009, up from 5.48 in 2006. Despite the 9% increase in RVU for this code, however, reimbursement only increased a little over 1%. Critical care physicians must constantly monitor the coding and reimbursement landscape. As of January 1, 2010, the Center for Medicare and Medicaid services (CMS) eliminated all inpatient and outpatient consultation codes. It is anticipated that other insurance carriers may adopt these changes going forward, but as of this writing, consultation codes are still valid for most non-CMS claims. In the interim, providers (or their billing offices) have to pay careful attention to how claims are submitted, depending on a patient's insurance status. Demonstration projects are already underway to move away from RVU piece-work to a global, or bundled, payment system [68].

The connection between RVU generation and effort in the ICU setting in any case is tenuous at best, in part due to the difficulty in documenting and billing the multitude of small tasks accomplished over the course of the day. The bulk of billable services may occur during the normal business day. Thirty-one to seventy-four minutes of bedside attention to one patient will justify a single CPT 99291 code. Additional services rendered to that patient throughout a 24-hour period would have to exceed 74 total minutes to additionally bill CPT 99292. As a result, off-hours interventions may generate less income than what it costs to staff those hours, although revenue will depend on the number of patients seen, their severity of illness, and the reimbursement rate for a particular locale. In many institutions, revenue received may be 50% or less of what was actually billed, owing to indigent patients and contractual agreements with insurers. Thus, under systems of reimbursement used in the United States, it may not be possible for a critical care physician group to be self-funding on patient care revenue alone especially when providing extended hours of in-house coverage.

The ICU director plays an increasingly important role in managing the business aspects of the critical care practice. It is helpful to have a tracking system to ensure that each physician is submitting his or her patient care charges in a timely manner, and that the billing service is properly submitting and capturing these charges. On a monthly basis, patient care volume, charges submitted and relative value units (RVU) should be reviewed and compared with budgeted amounts. Individual physician performance by billing code should be tracked, not only for productivity, but also to ensure that codes are being used appropriately and in line with the practice's usual profile. It would be unusual for all patients to qualify for critical care codes; some percentage of patients may only qualify for E&M billing, with or without additional procedures. Periodic internal audits help confirm physician compliance with Medicare and insurer billing rules; it is easier and less costly to identify and rectify any issues internally. The alternative may be an external audit, where any errors detected in a small sample of charts will be applied proportionately over a multiyear period to demand a large retrospective repayment for billing errors. A provision in the 2009 American Recovery and Reinvestment Act of 2009 mandates annual fraud and abuse training for health care providers.

The Centers for Medicare and Medicaid Services (CMS) have recently implemented a Recovery Audit Contractor (RAC) program to review billing and identify over- and underpayment [69]. Four regional auditing firms will be paid on a contingency basis to review medical record documentation, especially the diagnostic specificity of admitting and discharge diagnoses, listings of comorbidities, and evidence of medical necessity as patients transition from care environments (operating room, recovery room, emergency department, inpatient vs. observation status). Service level is likely to drive reimbursement more than patient location. The coding of diagnosis-related groups (DRGs) will come under particular scrutiny. DRGs likely to trigger review include many common ICU conditions including sepsis (versus infection alone); acute respiratory failure (versus acute systolic or diastolic heart failure), pneumonia, chest pain, and stroke (versus transient ischemic attack).

ICU directors are frequently asked to represent the ICU on multiple hospital committees, particularly pharmacy and therapeutics, informatics oversight, quality improvement, peer-review, and technology assessment. Depending on the hospital's structure, the ICU director may report to the chair of Medicine, Surgery, or Anesthesia (or all three!) and frequently interact with Emergency Medicine, Obstetrics, Radiology, Laboratory Medicine, Clinical Engineering, Information Systems, Risk Management, and Nursing. A "virtual" critical care department can monitor and manage all critical care activities, while retaining a traditional academic reporting structure [70]. Responsibilities of the ICU director include developing a team performance framework for the unit [71], and addressing the physical, emotional and professional elements that create an attractive and rewarding ICU work environment [9]. These communication and collaboration activities take time, and, not surprisingly, administrative and other non-patient care activities may consume 50% or more of the ICU Director's work hours. Since this time is not revenue generating, these activities must be supported by other means such as a hospital stipend.

MONITORING CLINICAL CARE

Good structure (attributes of the setting in which care occurs) facilitates good process (what is actually done), which promotes good outcome (or results) [72]. Although the JCAHO historically focused on structural elements such as medical staff organization, available equipment, and human resources, emphasis has now shifted to analysis of process and outcome. Performance variables (appropriateness and effectiveness of care) may offer advantages over outcome variables for ICU evaluation, but are less well developed [73]. Most benchmarking currently takes place by outcome assessment, commonly using mortality and resource utilization as endpoints. Because patients present with different levels of disease and physiologic reserve, raw outcome measures such as mortality must be adjusted for severity of illness [74]. For the ICU, tools include the Acute Physiology and Chronic Health Evaluation (APACHE) system [75–77], and the Mortality Probability Models (MPM) [78,79]; the Simplified Acute Physiology Score (SAPS) [80,81], and the Intensive Care National Audit and Research Centre (ICNARC) model [82]. These systems are based on large

databases, report acceptable discrimination and calibration, and have been extensively examined in the peer-reviewed literature. However, only a minority of hospitals (about 10% of acute care hospitals in the United States) consistently collect this type of data. Although APACHE and MPM are generally used in North America, SAPS in Europe, and ICNARC in Great Britain, models can be employed in any location as long as the model is recalibrated for the local environment [83].

ICU severity models facilitate comparisons between intensive care units, and are most useful for retrospective analysis of performance, with limited but improving utility for real-time management. (APACHE, for example, offers a "bed-board" that displays both current severity of illness and daily predictions for mortality, discharge, and next-day resource utilization but unless this is interfaced to the electronic medical record, updates depend on coordinators entering updated information.) Project IMPACT (which uses the MPM prediction model) and the APACHE system each carefully define data elements and outcomes to be collected, and thus facilitate comparison of local outcomes with national data. APACHE provides the ability to run local comparison reports on an ad hoc basis; comparison reports from Project IMPACT are centrally generated on a quarterly schedule. APACHE, SAPS, and MPM have all recently transitioned from models based on 1990's data to updated versions that reflect changes and improvement in medical practice over the past 15 years [76,78,80].

An APACHE IV score comprises the Acute Physiology Score ("APS," see later), age, and chronic health items. The APS is generated by summing point values based on physiologic derangement in 17 variables and then adding points for age and chronic health status [76]. The APS is interpreted in light of the main patient diagnosis, patient location, and duration of hospital stay prior to admission to the ICU. Mechanical ventilation during the first ICU day and emergency surgical status also influence an individual's predicted mortality. Although the error bars around the mortality estimate are modestly large for any individual patient, the APACHE system has been shown to be quite reliable at assessing outcome for groups of patients [76]. APACHE IV is also useful for assessing ICU length of stay in groups of patients even though utility is limited for individuals [84].

Project IMPACT, developed by the Society of Critical Care Medicine, began collecting data in 1996 and providing benchmarking with the MPM-II model, SAPS-II, and APACHE II. Beginning in 2007, Project IMPACT transitioned to the updated MPM-III model [85]. Project IMPACT data collectors must pass a certification examination to access the data entry module. The MPM-III model has been prospectively validated using recent Project IMPACT data from 55,459 patients at 103 participating ICU's in North America [86]. As of this writing, plans are underway to consolidate the APACHE system and Project IMPACT into a single critical care information system that will take advantage of the ease and immediacy of the MPM score (generated on admission) with the more detailed, disease-specific predictions of the APACHE system at 24 hours and beyond.

Specialized scoring systems are more appropriate for pediatric [87], trauma [88,89], or cardiac surgical units [90]. Pediatric scoring (e.g., PRISM) differs from adult scoring due to expected differences in normal physiologic ranges. Cardiac surgical systems downplay acute physiology, which is deliberately controlled by the operating room team, and emphasize variables such as left ventricular function, IABP use, and cardiopulmonary bypass (CPB) time that might not be available or clinically relevant in other patient groups. Performance of the general severity models deteriorates when case-mix in an ICU becomes skewed [91]. APACHE-IV accommodates case-mix differences by including disease-specific coefficients. MPM-III provides sub-group models for use when an individual ICU's case-mix is skewed from average [92], although the general model is essentially as good as specialized models for identifying outliers.

The primary clinical limitation of all outcome-adjustment models is that they apply to analysis of outcome in groups of patients, but not when making individual therapeutic decisions. At best, the prognostic estimates for an individual patient may be used in a probabilistic manner to predict bed or other resource utilization, but could be inaccurate if applied as a prediction for application or denial of individual medical therapy, because of the uncertainty of individual estimates. A patient's risk will change over time, making it problematic, for example, to use the admission severity score to determine eligibility for later therapy [42]. In fact, ICU physicians discriminate between survivors and non-survivors more accurately than scoring systems, at least in the initial 24 hours of care [93].

Groups of patients can be compared by generating predicted mortality rates with APACHE, ICNARC, MPM, or SAPS as a tool, and comparing the prediction with actual results. The ratio of observed mortality to predicted mortality is called standardized mortality ratio (SMR), and an ICU with a SMR close to 1.0 would be exhibiting expected performance based on their case-mix of patients. SMRs significantly greater than 1 indicate a higher than expected mortality whereas SMRs less than 1 suggest outcomes better than expected. The sample size and distribution of patient acuities will determine exactly how far from 1.0 (in either direction) the SMR becomes significant.

Events and therapy prior to ICU admission that alter physiology at admission creates a "lead time" bias which has a measurable effect on outcome [75,94]. Because the SMR will be affected by differing use of postacute facilities and the percentage of patients with DNR orders, it may not always be valid in interhospital comparisons, unless applied to similar types of hospitals with similar policies [95].

Both clinical performance and cost-effectiveness should be considered when defining high-quality ICU care [96]. Rapoport and Teres initially described a method, since updated [97] that graphically displays both severity-adjusted clinical outcome and cost-effectiveness, using weighted hospital days as a proxy for cost. With this method, normalized severity-adjusted mortality is displayed on the *x* axis, and normalized weighted hospital days on the *y* axis (Fig. 208.1). Standard deviations of the normalized scale are displayed relative to the group mean at the origin (0,0). Units performing significantly better than predicted for both dimensions of care will chart in the right upper quadrant of the graph.

CRITICAL CARE OUTREACH SERVICE AND EARLY WARNING SYSTEMS

Illness is commonly heralded by a constellation of quantifiable changes in physiologic and biochemical measurements. Abnormal values of selected physiologic measurements are useful as an objective indication of a patient's risk level (as with severity scores) but may also be used "real-time" to predict subsequent clinical deterioration on hospital wards. In theory, if hospital staff were to identify and provide intervention to these patients at an earlier stage, outcomes could improve, in terms of reduced intensive care admissions and length of stay. Critical Care outreach services include the employment of a Rapid Response Team (RRT) and/or an Early Warning System (EWS) to identify and provide intervention to potentially deteriorating hospitalized patients. The fundamental concept behind the evolution of Critical Care Outreach Programs is that significant vital sign abnormalities occur in many patients in the hours prior to acute cardiorespiratory events [98,99]

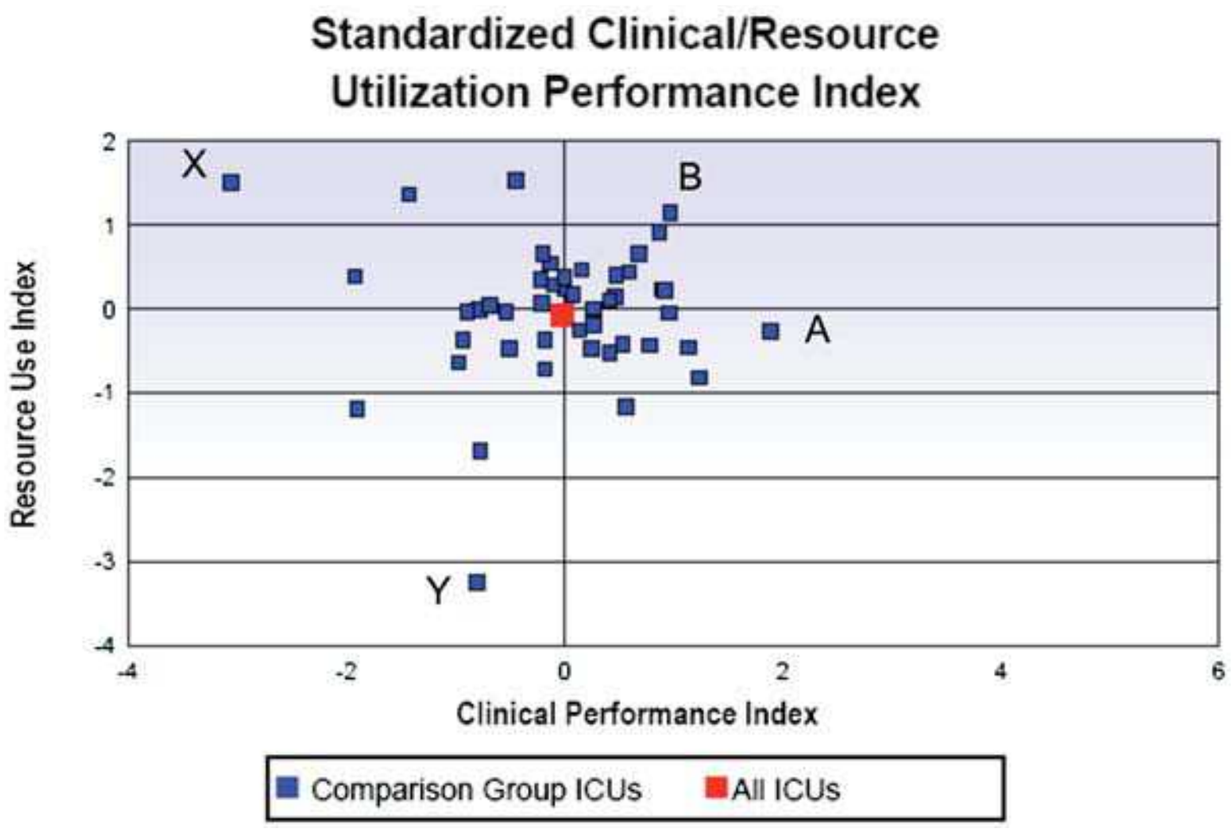

FIGURE 208.1. Standardized Clinical/Resource Utilization Performance Index. Hospital A has superior risk-adjusted mortality, while hospital B has superior risk-adjusted length-of-stay. Both hospitals are in the desirable right upper quadrant. Hospital X has a short length of stay, but coupled with risk-adjusted mortality that is worse than predicted. Hospital Y has length-of-stay issues while remaining within the expected severity-adjusted mortality range.

Analysis postimplementation of a RRT model of care (also called Medical Emergency Team or MET) on hospital wards demonstrates 17% to 50% fewer cardiorespiratory arrests [97,98,100]. The composition of a RRT/MET varies by hospital but frequently includes an ICU nurse and/or physician, a hospitalist, and a respiratory therapist. The Institute for Healthcare Improvement has recommended that hospitals establish RRTs as one of the six strategies of the 100,000 Lives Campaign [101]. Though the purpose of the RRT is to reduce preventable deaths [102], evidence supporting their effectiveness remains controversial [103–105]. Clinical trial results have suffered from methodologic limitations, varying staffing models, and limited number of randomized control trials. A recent trial could not document reductions in hospital-wide code rates or mortality but did demonstrate fewer cardiorespiratory arrests outside the ICU [106]. It is possible that the RRT involvement may propel end-of-life discussions in patients on the wards that might otherwise not have taken place. Further comprehensive investigations of the expanding RRT model will require better data on hospital characteristics, assessment of patient–family satisfaction, assessment of end-of-life issues, and nursing and physician satisfaction on the wards.

EWS incorporate technology to provide earlier identification of patients at risk of clinical deterioration on general hospital wards [107,108]. Although clinicians generally excel at detecting acute change, incremental changes in vital signs may not be clinically apparent, but become obvious using tracking software. A "track and trigger" EWS is designed to secure the timely presence of skilled clinical assistance by the bedside of patients exhibiting physiologic signs compatible with impending critical illness [109]. Although RRT responses might be triggered by a single dramatic physiologic vital sign change, EWS responds to simultaneous multiple parameters using patterns of subtle alterations in vital signs to identify patients at risk [110]. An automated EWS score is calculated from a handful of traditional physiologic parameters (mental status, heart rate, blood pressure, respiratory rate, temperature, urine output) recorded with traditional bedside or electronic charting [111]. Several readings over time may be more informative than isolated recordings. Newer bedside physiologic monitors (for example, Philips MP Series with ProtocolWatch) [112] can automate this process without requiring a full electronic medical record. Although recent data indicates that EWS integrating information from multiple physiologic variables is better at detecting physiologic instability [113], the diversity and methodologic limitations of most studies to date limit the ability to interpret the effectiveness of EWS application in hospitals.

Failure to identify clinical emergencies may be becoming more frequent as sick patients cannot always be accommodated in critical care units. High-quality multicenter research will be needed to determine the most appropriate triggers for activation of the EWS and/or RRTs and the effect of these interventions on patient outcomes. Because EWS and RRT deployment will affect ICU resource utilization, ICU leaders need to be involved in planning, implementing, and maintaining these systems.

OPERATIONAL ISSUES

Nursing staffing levels are now subject to public scrutiny, and literature supports a link between staffing levels and patient outcome. Excessive nursing workload has been shown to correlate with increased mortality [114], longer hospital length of stay and increased complications [60], and the spread of resistant bacterial organisms in the ICU [115]. Adverse events have been reported to occur in about 20% of critically ill patients, with roughly half reportedly being preventable [116]. The most common cause of an adverse event is failure to carry out intended treatment correctly, often because of miscommunication or poor coordination of care [117]. Some hospitals have explored crew resource management training, adapted from the aviation industry, to improve team collaboration and coordination, and ultimately improve patient safety. The medical director, in conjunction with the nurse manager and other professionals, will play a major role in defining and maintaining the organizational culture of the ICU. Disruptive physician behavior adversely affects nursing retention [118] and occasionally will require the intervention of the medical director, perhaps with the assistance of the hospital's Physician Health or Medical Staff Health committee. Effective teamwork is essential, and team leadership is vital in promoting team interaction and coordination [70].

Interdisciplinary communication is fostered by a number of formal and informal efforts. At a basic level, the format for daily ICU rounds should encourage all members of the team to contribute information, ask questions, and make suggestions for the direction of care. Formal multidisciplinary rounds, often held weekly, are useful when discussing the needs of long-term patients in the ICU, and offer an opportunity to step back from acute physiologic concerns to collect additional insight from allied health professional, social service and clergy. Conferences, journal club, lectures, and research projects offer opportunities for beneficial interdisciplinary interaction. Some hospitals have

established a Critical Care Practice Committee (CCPC), composed of physician and nursing representatives from each intensive care unit, the emergency department, and the postanesthesia recovery unit. Members of this committee may also include representatives from Pharmacy, Central Supply, Clinical Engineering, Respiratory Therapy, and Purchasing. A hospital-wide CCPC facilitates standardization of policies and procedures [69,119], implementation of care bundles, decisions on supplies to be stocked, maintenance of "Code" carts, and quality improvement initiatives relevant to the membership [120].

Patient families deserve special consideration; especially since the family is likely to notice and appreciate the operational efficiencies and communication style that reflects the ICUs culture. A multicenter evaluation of a scoring system for family satisfaction [121] identifies the key components for family satisfaction as assurance (the need to feel hope for a desired outcome), proximity (the need for personal contact and to be physically and emotionally near the patient), information (which should be consistent, realistic and timely), personal comfort, and support (resources, support systems and ventilation). Written materials (booklets, information sheets) can help meet family informational needs, especially with older, better educated relatives [122].

SUMMARY

Economic considerations continue to drive the agenda in hospitals and intensive care units, and with the wave of "baby boomers" reaching retirement, increasing incidence of obesity, diabetes and vascular disease in the population, and sporadic emergence of new threats, such as pandemic threats like the H1N1 strain of the Influenza A virus, we can expect further change. With a sicker, more chronically ill population, hospitals have become places for the hyper-acutely ill, with much of recovery and recuperation outsourced to other facilities. Thus, intensive care will continue to consume an ever-greater proportion of total hospital costs, even as this growth becomes constrained by economics, bed shortages, and most importantly, insufficient numbers of nurses and physicians specializing in critical care. In many hospitals, what was once the province of the ICU has migrated to step-down and specialty units, leaving the ICU populated by the sickest of the sick. The advent of hospitalists and rapid response teams are but two manifestations of this continuing evolution in how care is delivered. These changes have forced a re-evaluation of ICU organizational practices (increasing the value of "closed" units), human resource needs, a more management oriented role for the ICU director, and critical care management approaches that involve professionals from more than one ICU. Benchmarking critical care outcome becomes essential in managing the increasingly complex world of the ICU, and we are on the threshold of having computerized real-time systems to automate some of the tactical decisions that occupy too much professional time. Telemedicine, increased automation, use of physician extenders and protocol supported care are all potential solutions to the impending crisis in critical care delivery. Continued change emphasizes the need for clinically and managerially competent physicians to organize and manage the increasingly complex world of critical care.

CHAPTER 209 ■ CRITICAL CARE INFORMATION SYSTEMS: STRUCTURE, FUNCTION, AND FUTURE

WILLIAM F. BRIA, JOSEPH J. FRASSICA, RICHARD KREMSDORF, M. MICHAEL SHABOT AND VIOLET L. SHAFFER

INTRODUCTION

In over five decades since the first implementation of the electronic health record (EHR) in the United States, there have been both the rise, definition, and establishment of critical care medicine as a specialty and important force in health care both in research and practice.

Although technology has played an essential role in the very creation of the specialty (e.g., ventilators, cardiovascular monitoring), the implementation of the EHR in U.S. hospitals, and, as per available data sources, in intensive care units (ICUs), remains at a meager 1.5% [1].

With the American Recovery and Reinvestment Act (ARRA), the HITECH section promises to stimulate "meaningful use" of information technology (IT) in U.S. hospitals. This is the greatest single transformation ever undertaken of the information infrastructure of U.S. health care.

This chapter reviews a number of key components of IT in the modern U.S. ICU. The reader is introduced to some of the most important innovative technologies that have been brought to bear on the safe, effective, and efficient delivery of critical care medicine.

General information on the electronic medical record, departmental information systems, and coding and billing information systems has been extensively documented elsewhere and we assume a working knowledge of these basic components of the modern healthcare information infrastructure. Instead, we concern ourselves with the ICU-specific IT of greatest interest to the practicing critical care physician.

In this chapter, we address (i) telemedicine in the ICU, (ii) clinical decision support systems, and (iii) outcomes' prediction information systems.

TELEMEDICINE AND THE INTENSIVE CARE UNIT

According to the Military Health System Web site, telemedicine may be defined as "an umbrella term that encompasses various technologies as part of a coherent health service information

resource management program [2]. Telemedicine is the capture, display, storage and retrieval of medical images and data towards the creation of a computerized patient record and managed care. Advantages include: move information, not patients or providers; enter data ONCE in a health care network; network quality specialty health care to isolated locations; and build from hands-on experience."

Critical care information systems (CCIS) have largely overcome the technical barriers to their implementation. While there are enormous amounts of data available and opportunities to enhance the delivery of critical care, it remains challenging to marshal those resources in ways that meet the needs of both hands-on caregivers and overall delivery system efficiency and quality.

There are two large categories in which clinical information systems technology can be deployed and each is enhanced by the use of the other approaches. These are (i) single-patient–focused tools and (ii) multiple-patient–focused tools.

Single-Patient–Focused Tools

The most mature implementation of critical care clinical information systems consists of tools which meet the needs of the hands-on caregivers. Historically, massive amounts of data documenting an ICU patient's clinical status and treatment have been recorded on large double-sided paper flow sheets, which are plagued with problems of legibility, inaccurate calculations, and use restricted to a single person at a time. By replacing this document with computer screens, each customized to a specific purpose, these problems have been essentially solved.

Going beyond simple replacement of paper documents provides an opportunity to present information such that patterns are more easily recognized. For example, correlation of measures of physiologic status, clinical status (such as urinary output and body weight), and administration of medications can facilitate clinical analysis by juxtaposing interdependent variables. Less obviously, trends over longer periods of time can be easily displayed while these could only be laboriously drawn by hand.

Optimal use of clinical information systems should also guide the hands-on caregivers to provide care using evidence-based protocols. Simply creating a place to document the position of head of the bed underscores that this is important issue to be managed in prevention of ventilator-associated pneumonia (VAP). Explanatory information can also be provided on a just-in-time basis to encourage protocol compliance. Computer provider order entry prompts and order sets can also facilitate standardization of care.

Simply collecting and displaying information electronically, while an advance over a paper record, vastly underutilizes the capability of the computer system. The data are being gathered in a computable form and consequently are subject to continuous analysis, enabling detection of patterns that could signify clinical decompensation. Vastly larger datasets than can be retained and analyzed in the human brain can be evaluated and, furthermore, it can be done continuously on all monitored patients, simultaneously. Such an early warning system could trigger evaluation that might otherwise be delayed.

Finally, computable information that describes in detail both the patient's status and treatment can be used to analyze compliance with protocols for optimal care, resource utilization, and outcomes. Monitoring on a near real-time basis provides timely feedback and is an opportunity to intervene to improve ongoing care.

Once all of these capabilities are available and used by the hands-on caregiving team, their individual capabilities can be optimized. Nonetheless, the realities of the critical care environment are such that patients may be critically ill and yet not be in a setting where their care needs can be expeditiously met. For example, a patient might be in a distant hospital where intensivist coverage is not available. Or, even in a sophisticated medical center, patients may decompensate outside the ICU and, indeed, even in the ICU after hours, an intensivist might not be physically available to respond.

Two technological approaches to dealing with this problem have developed, each dependent on a suitably trained intensivist sitting at a remotely located computer that is equipped with a microphone and speaker and a high-bandwidth Internet connection. Each approach also has one or more high-resolution cameras which can be controlled by a remote physician and means to communicate with caregivers and patients and family who are in the patient's room. Medical devices such as stethoscopes can sometimes be connected as well.

Connectivity to additional clinical information systems varies according to institutional capabilities. For example, some systems have as many as eight monitors arrayed such that the remote physician can see the real-time electrocardiogram tracing, access the institution's image archiving and communication systems, and review all elements of a comprehensive clinical information system, simultaneous with viewing and talking with the patient. Without question, availability of this full suite of technological capabilities allows a comprehensive evaluation of the patient that far surpasses the limited verbal interaction between the bedside caregiver and a physician connecting by telephone. It is now well documented that such interactions can provide for more timely and therapeutically appropriate interventions [3]. Nonetheless, such evaluations are still limited in that hands-on physician diagnostic and therapeutic maneuvers are not available when the physician is remote. It has been documented that remote proctoring of a procedure being performed by a house officer who is in the hospital is a practical alternative when immediate interventions are required. Furthermore, even in the case where the physician or patient will need to travel to the point of care, useful temporizing measures may be deployed.

A form of technology that is particularly well suited for the interaction with an individual patient is a mobile robot, offering what is referred to as "robotic telepresence." One form of this device can actually be driven remotely by the physician from its storage location to the patient's location in the appropriately equipped facility. Using wireless connectivity, the robot establishes a similar connection to that which exists in rooms that have been specifically hardwired for these capabilities. Because of the costs of connectivity, institutions frequently limit fixed installations to ICUs. Nonetheless, it is clear that patients in other patient care locations can decompensate and care may be needed elsewhere. Such robots provide a lower cost means to provide similar capabilities and could be used to augment the expertise of rapid response teams.

Interactions may be initiated by the caregiving staff from any care location. In such circumstances acceptance has been generally very favorable. Nurses feel that there are trained physicians who are awake and available in the middle of the night and can be provided with all of the information needed to provide care. As a consequence, nurses may be more confident that the patients are receiving quality care. A limitation is that the remote physician may have less of an appreciation for the patient's clinical course than a physician who has seen the patient daily. However, in some ICUs, the physician on call at night at home and using the robot may be the same person who rounded on the patient that day. Interaction between remote and primary treating physicians remains an essential element of care.

Multiple-Patient–Focused Tools

In institutions where multiple ICUs have been equipped with cameras in each room and connectivity to clinical information systems and other clinical data sources has been established, a

team is established at a central monitoring location which may be distant from the ICUs and hospital(s), frequently off campus in less-expensive commercial office space. Analysis of signals from bedside monitors and other devices as well as the results of laboratory tests alert off-site providers to perform patient assessments. Alternatively, bedside providers can request evaluation and off-site management. Interventions, including the ordering of diagnostic tests, medications or consultations, or the manipulation of life support devices can be done by off-site providers or by on-site providers. Thus, a single patient interaction may be initiated by the remote physician as well as by hands-on caregivers. Like any team endeavor, effectiveness is determined in part by communication timeliness and dynamics of trust and responsibility among the bedside and off-site team members.

The primary responsibilities of the remote monitoring team are identification of unfavorable trends and to intervene to enhance best practice adherence, perform care plan reviews for patients admitted after day time hours and provide ICU pharmacist [4] review of after hours provider medications orders which provides an additional safety net for patients in the ICU [3,4]. Bedside caregivers have the potential to be overwhelmed by the need to care for multiple patients, and the requirement to deal with the mechanics of providing care may interfere with always maintaining perspective on the patient's course.

Information systems that power the central monitoring station have been equipped with series of rules that evaluate clinical information as it is being gathered at the bedside and returned from the laboratory. By correlating this data, alerts can be fired to draw the attention of the remote monitoring team. The team then has the clinical information available to judge whether this is a new or serious development which then prompts interactions with the bedside caregiving team. Such tools may also be available to the bedside caregiving team; however, their many clinical duties can often result in a delayed response. Furthermore, many bedside clinical information systems are much less sophisticated in this area than are the systems designed for use in monitoring a population of patients.

An important capability is the opportunity to perform virtual rounds on the sickest patients. The acuity status is used to identify which patients might most benefit from closer observation. In this way, the remote physician can perform virtual rounds at intervals to judge the effect of medications which may have been administered to determine if physiologic responses are improving or deteriorating. This surveillance can be an important complement to bedside care.

An essential element for the success of remote monitoring of critically ill patients is the effective collaboration between the hands-on caregivers in the central monitoring team. The bedside critical care multidisciplinary team that is responsible for the patient and sees the patient and family on an ongoing basis is best positioned to establish the daily plan of care for each patient. The role of the off-site team members is to keep the patient on the intended trajectory and to communicate with the bedside providers when the patent's course has deviated from that path. In ICUs where full-time 24-hour day coverage is not available, which is the vast majority of ICUs, physician interaction that may be necessary to ensure that the goals of care are achieved may be sporadic and untimely. The remote team serves as a surrogate for the bedside team at times when they are not able to attend to the patient. In recent years, evidence has accumulated that ongoing availability of intensivist is associated with improved outcomes. If there are an insufficient number of trained intensivists to cover the ICUs that exist, such remote monitoring is being used to increase the availability of trained staff.

It has also been established that implementing certain protocols for care of critically ill patients is associated with better outcomes in the management of sepsis and the avoidance of VAP. Nonetheless, it has proven challenging not only to achieve initial compliance with such protocols, but even more difficult to maintain compliance at a high level. An additional role played by a central monitoring team is to identify when patients who are eligible for a protocol are not receiving such care.

To the extent that the remote monitoring team functions completely independently from the on-site caregivers, there is opportunity for miscommunication and compromise of trust. Indeed, bedside caregivers have been reported to feel threatened by the sense of someone looking over their shoulders all the time and the primary treating physicians could resent intrusions that alter the plan of care set out by them [5]. A substantial investment in relationship building and acceptance by all members of the on-site and remote teams of the importance of minimizing medical errors is thought to be associated with larger improvements in outcomes.

In the fall of 2009, a new technological sea change is that the Blackberry and Apple iPhone are beginning to not only take over the previous place of the medical pager, but, due to their ubiquitous access to high-speed Internet, provide the means to deliver high-resolution bedside monitoring device (BMDI) data, as well as complete access to the electronic medical record from any location at any time. Although telemedicine has enabled new healthcare structures, as mentioned earlier, these new technologies delivered to the individual practitioner are likely to transform medicine just as has happened in the business world [6].

ANALYSIS OF DELIVERY SYSTEM PERFORMANCE WITH REAL-TIME FEEDBACK

Clinical Decision Support

Clinical decision support (CDS) has been defined as a system that uses two or more items of patient data to generate case-specific advice [7]. In practical terms, CDS includes a wide range of functions, including predefined rules, alerts, reminders, workflow, and collaboration tools—and associated content—for improved medical decision making. CDS is often intended to facilitate the introduction of and conformance to evolving evidence-based medical protocols and standards of care while enabling appropriate individual physician discretion (such as during order entry). Rules are, at their core, built on IF/THEN logic statements that allow a tremendous amount of flexibility and power to be added to systems within critical care and across the hospital or integrated health system.

Over the past decade, the business end (e.g., the user experience) of CDS has been the alert box. A growing number of studies are beginning to reveal the critical limitation of alerts that, by design, interrupt the clinician's workflow, in particular, during order entry [8,9]. The primary reason for this limitation lies in CDS systems designed mainly to alert post hoc after the clinician has requested a particular item (e.g., drug dosage, test).

CDS has the potential to provide special value in settings like the ICU due to the density of data assailing the busy critical care physician and the ability of computers to combine, synthesize, and correlate these data and then create more complex rules and information interpretation displays [10]. Studies have demonstrated that critical care rounds may challenge the physician with 20 times more data elements than the human brain can simultaneously process [11]. In the past, we have relied on the team approach to cope with this onslaught. In the current practice reality of competing priorities of intensivist time, numerous handoffs among providers, the need for IT to take more of a facilitation role for the ICU physician and

nurse is substantial. The next emerging developments in CCIS are likely to be in both the areas of visual design and complex rules and algorithms to predict and inform clinicians about patient circumstances by multiple means. This is discussed, along with emerging techniques for ICU performance management and related metrics, in a later section of this chapter.

Stepwise Plan of Implementation of a Critical Care Information System

The following steps enable the physician, in combination with other stakeholders such as nurses and pharmacists, to evaluate, select, and obtain maximal benefits from CCIS systems, with the assistance of a professionally certified and experienced project manager (typically from the IT department). It is the project manager who coordinates overall project planning, ensures that the required technical resources will be available on time, and monitors tasks and milestones among the project team. Technical needs such as interfaces to other IT systems and to medical devices, hardware, power, physical space, network access, and system security are necessary parts of this coordinated planning in addition to software delivery and configuration.

1. Goal setting: Considerations for valued, realistic goals. Experience has shown that the most important goal for achieving successful CCIS implementation is improvement in the quality of patient care. An ICU team is well versed in the concept of change, usually in the context of changes in patient condition. However, deploying and leveraging a CCIS implementation is a different kind of change. It should enable and will require reengineering of certain processes and a reduction in productivity during transition should be anticipated. An ICU team is not expected to tolerate delays in patient care, and needs to plan carefully and set realistic expectations around workflow issues that typically occur in the context of the learning curve necessary to use a new CCIS. With the goal of improved quality of patient care as the guiding light, the sequence of introduction of CCIS and the speed of implementation can be considered. An improved structure of order sets that have the support of virtually all clinicians and that interface with other department's systems (e.g., laboratory, pharmacy, radiology) is key [12].
2. CCIS users must have understanding and input into CCIS design before implementation. The history of CCIS implementation has shown that physicians are the most likely group to be surprised by CCIS structure and function. Reasons include lack of physician attendance at planning meetings, and therefore little direct input in CCIS planning and configuration, due to physician perception of systems as being solely clerical. The importance of involving clinically influential physician leaders in a successful CCIS process has been shown in the literature [21]. The chief medical informatics officer (CMIO), serving as a bridge between physicians and IT through design, training, support, and enhancement, improves clinical IT deployments. Note that about 7% of CMIOs come from the ranks of intensive care medicine, according to recent survey data [13].
3. Preemptive workflow and practice reengineering. The knowledge base necessary for a successful CCIS implementation is not limited to learning about the system itself. More important is the timely recognition that the workflow changes engendered by implementation can be both tolerated and supportive of the central goal of improved patient care.
4. Minimize changes to base system before implementation. This step is really a caveat of step 2. Yes, users should have some time to learn the out-of-the-box system and suggest changes before implementation, but that has to be balanced with the actual experience of the "shake-down cruise" period with the new system during the daily operations of the ICU. Veteran computer analysts of many CCIS implementations will attest to the frequency of changes of some components of a system back to factory specs after a few weeks or months of use. Nothing can replace time and experience in using a system in the actual ICU environment to truly recognize what would or would not be a helpful modification.
5. Establish implementation milestones. Implementation of a complex system should be phased in gradually, with each step building on the foundation of the previous component. Starting with results reporting, to computerized physician order entry (CPOE), then to decision support, workflow is increasingly affected and the changes take time to be absorbed effectively. This process is necessary to avoid any adverse impact on the all-important central goal of improved patient care.
6. Establish a backup/back-out plan for each milestone. It needs to be recognized that a successful implementation may require some temporary delays for extra training or system reconfiguration. Daily clinical operations of the ICU must always be paramount.
7. CCIS should be viewed as a system of patient-centered reminders, not an attempt to control providers. CCIS systems should be a helpful aid in optimizing patient care; for example, memory aids and consistent care reminders can be helpful. Components that may be perceived as attempting to control user behavior are not well accepted, and systems have been rejected on these grounds [14].

Critical Care Specific Technologies

Concurrent Process Monitoring

On the most basic level, CCIS put an end to juggling the awkwardly large flow sheet. Like CPOE, they eliminate the confusion and potential errors that can result from illegible handwriting and from fluid contamination, including the familiar coffee spill. The truly significant contributions CCIS makes to patient safety are in the areas of care processes and medical decision making. First among these is the ease of access to data. Access to a paper record can be problematic in the ICU, where multiple clinicians need to assess the patient's clinical condition and response to treatment. Electronic records allow multiple caregivers to view the data at the same time, without waiting to access the one-and-only paper chart. Clinicians not in the ICU can check on a patient's status without physically having to be in the unit, allowing them to be consulted at the very moment their expertise is needed. When timeliness is critical, access is a critical enabler.

The impact of access on patient safety is enhanced when clinicians have confidence that the data provided are accurate and timely. By automating calculations, CCIS ensures that measures such as input/output are computed correctly, and provides multiple measures, including those too time-consuming to compute routinely on paper such as hemodynamic calculations incorporating many variables. In addition, CCIS can automatically acquire data directly from monitoring equipment and ventilators, eliminating delays and errors in data gathering.

Unlike the paper flow sheet, with its fixed format, CCIS offer multiple displays of data. Each display provides a problem-oriented view suitable for analysis of the issue at hand. Constrained to one view of the data, physicians using paper-based systems on occasion resort to duplicate data entry, a practice nurses are trained to disallow. By contrast, CCIS allows

the clinician to select from multiple displays, each providing a problem-oriented view suitable for analysis of the issue at hand.

CCIS further supports the clinician by easing trend recognition. Specific displays establish the correlation of events in time, offsetting the possibility that it might be less apparent on the computer screen than on the paper flow sheet. Other displays provide multi-day views, which are critical for measures like fluid balance and fever curves, surpassing the paper flow sheet's view of only one day at a time. The displays on CCIS integrate multiple data elements that stand in isolation on the existing flow sheet. By combining vital signs, laboratory results, ventilator settings, medication drips, and medication administration, CCIS enables clinicians to address the complicated clinical scenarios characteristic of critically ill patients in ICUs. This integrated record also assures attention to details that can be lost in a frenetic setting; for example, by issuing a warning that a medication is overdue or being dosed earlier than appropriate per orders.

In the ICU and throughout the hospital, specialized tools can address "failure to rescue," which has been identified by the Agency for Healthcare Research and Quality (AHRQ) as accounting for the majority of patient-safety Medicare deaths. These tools provide proactive clinical surveillance; they interpret patient data (which are collected by the CCIS) and act as early warning systems.

In failure to rescue, the patient experiences clinical decompensation over a period of hours, without intervention by caregivers. This error of omission occurs for any of several reasons. The changes in the patient's condition may be subtle; for example, a physiologic value may be decreased, but not alarmingly so unless viewed as part of a trend. In other cases, changes may not be appreciated for what they signify. Clinicians may lack the necessary expertise to discern such changes or may be overwhelmed with other tasks. Indeed, according to the AHRQ, there is strong evidence that level of staffing and the nursing skill-mix are both factors in this failure.

Delays in detecting changes are of grave concern for a simple reason: the earlier the intervention, the greater the likelihood for a better clinical outcome. Intervening at the first signs of decompensation may make it possible to avert cardiorespiratory renal failure or address a more treatable complication. For example, stabilizing a patient whose heart rate is reaching dangerous levels (less than 40, more than 130 beats per minute) is more likely to succeed and less likely to involve additional complications than resuscitating a patient in a state of cardiac arrest.

There are warnings, if caregivers are able to recognize critical data among the numerous data elements on every patient. Studies of clinical instability suggest that patients experience symptoms in advance of critical events like cardiac arrest. In one study, 70% showed evidence of respiratory deterioration within 8 hours of arrest; in another, 66% of patients showed abnormal signs and symptoms within 6 hours [15].

Proactive clinical surveillance systems highlight trends and out-of-bounds values and conditions for further scrutiny. They provide displays—"dashboards"—that integrate different data elements to optimize evaluation of clinical problems. An additional feature offers severity scoring for the purpose of early detection of decompensation, issuing modified early warning scores to alert clinicians to problems as they develop.

These dashboards function both inside and outside the ICU to identify patients whose conditions are worsening, putting them in critical condition. Depending on their resources, hospitals may respond in several different ways.

In many hospitals, ICUs are staffed with nurse specialists and have high nurse-to-patient ratios. Yet most hospitals in the United States do not have a full-time intensivist on staff, ready to step in when a patient decompensates in the ICU or in another unit elsewhere in the hospital. In some instances, physicians in other specialties who practice in the ICU choose not to have an intensivist on staff, even if their hospital has the financial resources to recruit one. Nationally, there are more ICUs than intensivists. In 2001, staffing every ICU sufficiently would have required 35,000 to 40,000 intensivists, and there were less than 10,000 of these specialists.

Outside critical care areas, nurse-to-patient ratios are typically lower. Moreover, general medical/surgical areas are staffed by nurses who are not trained in the care of the critically ill. When a patient decompensates, the nurse is less likely to recognize this has happened, and the patient is less likely to receive appropriate interventions. Failure to recognize and respond quickly to patients with deteriorating conditions not only results in cardiac arrests and death, but is also associated with serious complications and prolongation of hospital length of stay. For patients and professionals in these units, the dashboards provided by hospital-wide proactive clinical surveillance systems improve safety, if in fact there is a mechanism for responding.

One approach is to create what the Institute for Healthcare Improvement [16] calls a rapid response team (RRT), also known as medical emergency team. The RRT consists of clinicians and nurses with critical care expertise that can be called anywhere in the hospital if a patient experiences acute change(s) in physiologic conditions; for example, in respiratory rate (more than 8 or less than 28 per minute), systolic blood pressure (less than 90), oxygenation, and neurologic status. As structured by the Institute for Healthcare Improvement, the program is contingent on a nurse to request help.

Whether or not a hospital has RRTs, a computerized surveillance system could function to alert clinicians that a patient is decompensating. Studies show a 50% reduction in non-ICU cardiac arrests, reduced postoperative emergency ICU transfers (58%) and deaths (37%), and reduction in arrest prior to ICU transfer (4% vs. 30%). With RRTs, one 750-bed community hospital reported a 23% decrease in their overall code rate per 1,000 discharges, a 44% decrease in codes occurring outside their ICU, and a 48% increase in the percentage of coded patients surviving at discharge.

Whether or not a hospital has RRTs, surveillance systems function to alert clinicians that a patient is decompensating. In either situation, the decision may be made to move the patient to critical care. Survival in the ICU is enhanced if patients are brought to the ICU in less critical condition and are less likely to experience severe complications. Moving patients into the ICU reduces the incidence of codes in areas outside the ICU that are less skilled at responding to them. Effective patient triage, management of potentially seriously ill patients prior to development of progressive physiologic deterioration, and reduction of unanticipated ICU admissions may also result in savings that can neutralize the cost of maintaining an RRT.

Another capability provided by CCIS that has the potential to improve patient safety includes concurrent process monitoring. This relies on details of care that define how a process is being implemented. When data are captured electronically and stored as discrete data elements, they can become available for analysis. When analyses are concurrent (e.g., done as care is delivered), they allow managers and caregivers to have visibility into global processes of care. In the ICU, concurrent process monitoring allows evaluation of whether a particular practice is actually being implemented and whether it is affecting outcomes, such as elevation of the head of the bed to reduce the likelihood of VAP.

Historically, organizations are good at creating policies and procedures, but much less effective in deploying them. Although it is easy to sit in a conference room and discuss them, it is harder to get people to follow them. If data are extracted

and tabulated manually, it is laborious to figure out whether a particular practice is being implemented and the reporting is done long after the events being studied have occurred. In such cases, caregivers may believe "It used to be that bad, but now we're better." With more retrospective analysis, the same pattern repeats.

In contrast, concurrent process analyses allow the implementation of evidence-based practices by identifying and reinforcing practice patterns as they occur. Moreover, concurrent monitoring takes advantage of data already being gathered in the course of care, eliminating the need for duplicate data entry or chart abstraction.

Critical Care Decision Support Systems

The ICU is routinely acknowledged by hospital executives as a high-cost, high-risk hospital center. Intensive care and the role of intensive care-trained professional have been far less well appreciated as the service that often is the difference between effective and profitable hospital care for seriously ill patients. Ironically, despite great challenges of data collection and a general lack of payer and care-delivery organization support, ICU researchers have been among the real pioneers in trying to understand how to impact the effectiveness and efficiency of ICU and overall hospital care. As clinical automation and the resulting routine and standardized data collection are becoming more common, it is likely that these important methods for measuring, comparing, and improving care will find their way into mainstream medical practice.

ICU PERFORMANCE MANAGEMENT

Since the Institute of Medicine published its 1999 "expose" on patient safety [17], the ICU has received increased national attention as an important target for medical error reduction and improved quality. Both the Leapfrog Group collaborative of large employers and the Joint Commission accreditation organization have focused on developing national ICU performance measurement metrics [18]. IT can be used to more easily gather patient, process, and outcomes data and facilitate improvement. Performance measures are typically categorized as structural (how care is organized), process (what is done), or outcomes (including medical/functional, such as death or the ability to perform specific functions of daily life); experiential, which covers both patients/families and providers; and financial, which includes both cost/resource use and profitability perspectives.

Structure and process measures are used on the presumption that their variance causes a specific significant variance in one or more outcomes. Examples of popular structural ICU measurable processes are intensivist coverage [19] and appropriate levels of nurse staffing. Head-of-bed elevation in mechanically ventilated patients to prevent nosocomial pneumonia and associated increased mortality is an example of a contemporary measurable process [12].

One of the most significant challenges in quality improvement efforts is the lack of trust or alignment that can exist among clinicians, hospital administrators, insurance companies, and government over the motivation behind measurement. Clinicians believe that the purpose of measurement should be to understand and improve—while they too often, and too often rightly, assume payers' and overseers' plan to use metrics only to judge and to penalize—not to reward superior performance or improve patient care but only to drive down cost.

Given this environment, without standardized measures of meaningful medical outcomes that are defined, understood, and accepted by the relevant clinical community, making significant progress is difficult. Business intelligence systems, including performance dashboard techniques, that combine clinical data from computer-based patient records with financial data for analysis and reporting are predicted to be an area of increased interest. As this evolution occurs, critical care leaders will want to assure that their unique information needs are met in these systems and that appropriate attention is given to elements like risk adjustment and critical care-specific process analysis. Niche ICU analytic systems such as the Virtual Pediatric Intensive Care Unit (PICU) Performance System/National Association of Children's Hospitals and Related Institutions, the Vermont-Oxford Network for neonatal intensive care, and Cerner Corporation's Acute Physiology, Age, Chronic Health Evaluation (APACHE) prognostic, concurrent, and retrospective decision support system focused on adult ICU units are also available [20].

RISK-ADJUSTMENT MODELS FOR COMPARING INTENSIVE CARE OUTCOMES

Risk adjustment, severity adjustment, or case-mix adjustment are terms used to describe mathematical models derived from large datasets of a particular population whose purpose is to represent the relative risks individual patients bring at the entry point to care process. Patient risk factors of course impact what care processes and resources are required to produce similar outcomes and what the best realistically achievable outcomes are. Modeling research needs to define three elements: (a) the binary or continuous outcome variable(s) to be modeled (e.g., lived/died, length of stay), (b) the beginning and end points in time (e.g., at admission to the ICU, at discharge from the hospital, at 100 days), and (c) the specific risk factors to be included (e.g., age/gestational age, weight/birth weight, diagnosis, physiology). Because most hospital patient records are still paper-based, the most viable data source developing risk adjustment has been those using administrative (claims) data, examples being APR-DRGs (all patient refined diagnosis-related groups) and disease staging. Model developers juggle the collection cost versus the desirability of capturing specific data, but unequivocally more detailed patient data than that included in claims is required to adequately represent patient-risk variance in the ICU population. Model developers also struggle with defining reasonable end points for capturing outcomes. They also need to consider and factor in relationships among institutions and settings, potentially "gaming of the system." A report card that inadequately adjusts for patient risk might harm hospitals and physicians who take on the highest risk patients, or encourage entities to transfer dying patients to reduce their mortality [20]. As an example, a recent analysis of several Pennsylvania hospitals pointed out a facility with higher reported stroke mortality rates, in part because it kept more terminal stroke patients in the hospital rather than discharging them to home or hospice [22]. As Iezonni [23] notes, "developing risk adjusters de novo is complicated and often frustrating." Risk models for adult, pediatric, and neonatal ICU populations have been sufficiently vetted and have sufficiently evolved to serve as the foundation for nationally standardized outcomes measurement in an increasingly automated hospital environment. Risk models need to be reevaluated periodically to assure that they remain consistent with current patient factor, care process improvements, and outcomes' experience. They should also be evaluated for their appropriateness in geographies not included in their modeling datasets.

There are multiple risk-adjustment models in current use. Representative examples of ICU risk-adjustment models based primarily on U.S. patient data include

1. APACHE IV (Acute Physiology, Age, Chronic Health Evaluation, 4th version) [24,25]
2. PRISM (Pediatric Risk of Mortality) [26]
3. SNAP/SNAPPE (Score for Neonatal Acute Physiology) [27]
4. Neonatal Risk Models of the Vermont-Oxford Network

EVALUATING RISK-ADJUSTED OUTCOMES INFORMATION

Because risk-adjusted assessments are based on mathematical models, taking an objective approach to understanding the causes of variance data is logical. For example, there are four main causes of variance, and sequentially evaluating them helps clinicians gain familiarity with the models and acceptance of variance between actual and predicted results. These models include (i) data randomness (small sample), (ii) existence of patient risk factors not incorporated or (iii) adequately weighted in the particular model, and (iv) variance likely attributable to differences in care.

Emerging Trends: Predictive Modeling and Data Visualization

Predictive analytics enable an organization to estimate or anticipate the risk of future events, and are used increasingly in other industries, such as for predicting consumer behavior. In health care, these techniques are often applied for planning demand for healthcare services and facilities, for identification of at-risk populations, and for actuarial projection of healthcare utilization or life span.

Clinical decision support systems in the future will take more advantage of larger databases of increasingly granular patient data to drive pattern recognition engines that will help clinicians predict physiologic deterioration progressively earlier in its course. Examples of predictive models in use today include the individual patient predictions components of the APACHE IV ICU models referenced previously [25], and the Northern New England Cardiovascular Disease Study Group's preoperative mortality risk and cerebrovascular accident and risk of vascular complication models [28]. Not intended to replace but to support physician judgment, such predictive models have to date focused on evaluating the appropriateness of ICU admission and readiness for discharge, assessing patient progress and effectiveness of current therapies, building care team consensus around prognosis and care strategies, identifying patients for palliative care assessments, and improving

communications and setting realistic expectations with patients and families. Additional efforts now underway include a database being developed at the Mayo Clinic that incorporates clinical patient data along with genomic data. The expectation is that powerful prediction models will result from analysis of this large-scale aggregated patient history, outcomes, and genomic dataset [29].

Another large-scale database is currently being collected and analyzed by a collaborative of industrial, medical, and academic partners (MIT, Philips Medical Systems, and the Beth Israel Deaconess Medical Center) [30]. To date analysis of this dataset (MIMIC II) has resulted in several prediction models that provide a rudimentary "early warning system" for several specific types of physiologic deterioration. One such model consists of a rule set that, when applied to near real-time patient physiologic data, is capable of predicting hemodynamic deterioration hours before its occurrence [31]. Early warning alerts from advanced clinical decision support systems hold the promise of improving response times to patient events. Although it seems to logically follow that such early identification of physiologic deterioration would allow earlier intervention and prevention of patient crises, the effects of these interventions on patient outcomes are yet to be studied.

It is important to note that the use of individual patient risk prediction for concurrent or prospective decision support has been challenging to incorporate into physicians' workflow, and has struggled to obtain widespread physician acceptance.

ADVANCES IN DATA VISUALIZATION TECHNIQUES

Although many organizations have successfully applied performance metrics, severity scores, and predictive risk models for improved quality and decision making, data collection/calculation and integrated display is likely to expand more in the next decade than in all previous ones. Designers have much work to do to accomplish meaningful display of the most important patient, process, alerting, and predictive information without overloading the clinician's ability to absorb and respond. Two examples of the application of modern data visualization techniques are represented in Figures 209.1 and 209.2. Figure 209.1 illustrates a comprehensive ICU performance management dashboard, as used by the Memorial Hermann Healthcare System in Houston, Texas. Note the integration of different categories of metrics, such as census, occupancy, glycemic control, infection prevention bundle compliance, medication and ventilator utilization, financial data, and patient outcomes. This is a fully automated monthly report that is electronically distributed to ICU and executive management across the health system. Figure 209.2 displays a comprehensive real-time ICU hospital-acquired infection (HAI) dashboard, including HAI rates and detailed bundle compliance results for prevention of catheter-related blood stream infection and VAP. This is a live intranet web display that is

updated constantly. Both reports are widely available within the Memorial Hermann system and have helped drive performance excellence.

Most importantly, to taking advantage of these new possibilities, though, is that senior medical executives, ICU directors, and clinicians must "own" responsibility for localizing and embracing performance metrics and the advancing base of evidence-based decision support being made available.

In conclusion, the modern CCIS is a dynamic information instrument, extending the capabilities of the intensive care physician and staff in ways that would be considered science fiction only a generation ago. The rapid adoption of these new information tools is now anticipated, as the complexity of medical care, particularly in the ICU setting, becomes increasingly demanding and evidence-based decision making moves from a goal to an expectation of acute medical care.

CHAPTER 210 ■ DEFINING AND MEASURING PATIENT SAFETY IN THE CRITICAL CARE UNIT

ALAN M. FEIN, STEVEN Y. CHANG, SARA L. MERWIN, DAVID OST AND JOHN E. HEFFNER

Patient safety has become a major concern of the general public, policy makers, and local, state, and national government. Frequent news coverage has been devoted to individuals who were victims of serious medical errors. In the 1999 publication of the Institute of Medicine, *To Err Is Human: Building a Safer Health Care System* [1], the risks of medical care were highlighted, particularly the nearly 100,000 deaths per year that could be attributed to medical errors. A general sense of the importance of a safety culture in the intensive care unit (ICU) is increasing, as suggested by the multiple reports and publications in the lay and scientific media devoted to this topic [2].

The high-risk environment of the ICU benefits from integrated and coordinated systems that identify patient safety problems and report them to providers so they can improve

their performance. To maintain high-quality care, critical care teams need to know not only what to do but also how they are doing and what they need to do to improve their structure, processes, and outcomes of care. Donabedian [3] first described these three domains—structure, process, and outcome—as necessary elements for measuring the quality of health care. They also serve as a conceptual framework for measuring patient safety in the ICU.

On a broad scale, ICU patient safety-reporting systems identify trends and patterns allowing health care organizations, governmental agencies, and private accreditation organizations to monitor the quality and safety of health care delivery, which facilitates public reporting of data and increases transparency [4]. Patient safety-reporting systems also have the potential to create large data repositories that inform the development of strategies that reduce the risk of preventable medical incidents [5,6].

Effective reporting systems require definitions and methods that are standardized throughout the community of providers, so that information can be shared and meaningful comparisons can be made. In the 2003 report, *Patient Safety: Achieving a New Standard of Care,* the Institute of Medicine (IOM) emphasized the importance of standardizing and better managing information on patient safety to improve outcomes of care [5]. A critical element of this standardization is the development of a common taxonomy of patient safety terms. In the absence of standardized terminology, health care providers have no way to know what events to capture and how to describe those events in consolidated reports [7]. Also, fragmented approaches for defining and classifying near misses, adverse events, and other patient safety concepts prevent aggregation of data in formats that allow analysis and summary reporting [1,8]. To date, governmental and private sector accrediting bodies have not coordinated their efforts to develop actionable, integrated, validated, and reliable systems to measure and report medical errors and patient safety [9].

SAFETY LESSONS FROM OTHER INDUSTRIES

Safety and error prevention in the health care setting compares unfavorably with that in aviation, banking, chemical manufacturing, and military services in peacetime. Lessons from these industries are now being applied to the health care industry. Approaches to safety in these industries are characterized by well-defined strategies to protect workers and customers. Technology-based approaches are part of this strategy, but organizational and psychologic aspects are contributing factors as well. For example, developing a culture of safety has been identified as one important method of improving safety. The aviation industry has focused on the importance of teamwork in reinforcing a safety culture.

Although technical, organizational, and psychologic interventions are effective, it is also worth noting the limits of the existing method. Persistence of fatalities in aviation and auto transportation suggest that safety efforts may be counterbalanced by other competing risk factors such as high volumes, greater complexity of the product, cost-pressure, and rapidly changing designs. This is particularly relevant to health care because the population is changing (higher number of increasingly older and higher-risk patients) and the technology is changing at a very rapid rate [10].

Thus, there is probably an upper limit in terms of cost-effective health care safety that can be reached, but has not been attained. Health services are being encouraged by the IOM report to aim for an error rate of less than 3.4 per million, that is, "six-sigma quality." The discipline of anesthesiology in particular has made substantial contributions through its development of a safety culture and equipment-manufacturing standardization that resulted in a reduction in anesthesia-related deaths to 4.4 per million, that is, "five-sigma standard."

To achieve this standard in the ICU, there must be a precise definition of the terms needed to study patient safety, their methods of measurement, how these can be applied to the special problems of ICU organization, physician training, and development of a culture of safety, and finally how these concepts apply to governmental regulations.

DEFINITIONS

The basic terms in common use to define concepts of patient safety are listed in Table 210.1 and show the working definitions that have entered into the lexicon of the patient safety industry [11]. Health care quality is defined by the IOM as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge" [12]. This definition conforms to two (process and outcome) of the three constructs (structure, process, and outcome) proposed by Donabedian [3] to be necessary for measuring the quality of health care. The IOM has also listed several attributes of quality care that define quality care as being safe, patient-centered, timely, effective, efficient, and equitable [13]. Thus, patient safety is one domain within the broader concept of quality.

Patient safety has been variously defined by the Agency for Health Care Research and Quality (AHRQ) as "the absence of the potential for, or the occurrence of, healthcare associated injury to patients created by avoiding medical errors as well as taking action to prevent errors from causing injury" [14] and "freedom from accidental or preventable injuries produced by medical care" [15].

Within this context of safety, medical errors are defined as "mistakes made in the process of care that result in or have the potential to result in harm to patients. Mistakes include the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim. These can be the result of an action that is taken (error of commission) or an action that is not taken (error of omission)" [14]. Errors of commission (e.g., ordering an incorrect drug dose) as compared with errors of omission (e.g., failure to order heparin for venous thromboembolism prophylaxis) are more readily noted. Errors are further classified as *active* or *latent* [16,17]. Active errors occur at the interface between a human provider and a care-delivery system (e.g., mechanical ventilator, intravenous pump) and typically involve readily apparent actions (e.g., adjusting a dial incorrectly). Latent errors define a less obvious failure of a health care organization or structure that contributed to errors or allowed the errors to harm patients. An example of a latent error would be understaffing of nurses in an ICU. Other typologies include domains that ascribe characteristics of preventability, seriousness and whether the error was intercepted before affecting a patient [18] (Table 210.1).

Errors have also been classified as *slips* or *mistakes*. Slips are failures of automatic behaviors, or lapses in concentration (e.g., forgetting to perform a routine task due to a lapse in memory) and often occur from fatigue or distractions in the workplace. Mistakes represent incorrect choices, such as choosing the wrong drug for a clinical condition, and typically result from inexperience or lack of knowledge or training. The remedies for these two types of errors differ, with slips being more responsive to removing distractions from the workplace or automating monotonous tasks and mistakes respond to increased training or supervision.

Incidents are defined as unexpected or unanticipated events or circumstances not consistent with the routine care of a particular patient, which could have or did lead to an unintended

TABLE 210.1

GENERAL TERMS USED IN PATIENT SAFETY

Quality: The degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge

Patient safety: The absence of the potential for, or the occurrence of, health care-associated injury to patients created by avoiding medical errors as well as taking action to prevent errors from causing injury. Freedom from accidental or preventable injuries produced by medical care

Medical errors: Mistakes made in the process of care that result in or have the potential to result in harm to patients. Mistakes include the failure of a planned action to be completed as intended or the use of a wrong plan to achieve an aim. These can be the result of an action that is taken (error of commission) or an action that is not taken (error of omission)

Active errors: Errors that occur at the interface between a human provider and a care-delivery system (e.g., mechanical ventilator, intravenous pump) and typically involve readily apparent actions (e.g., adjusting a dial incorrectly).

Latent errors: Less obvious failures of a health care organization or structure that contributed to errors or allowed the errors to harm patients. An example of a latent error would be understaffing of nurses in an intensive care unit.

Serious medical errors: A medical error that causes harm (or injury) or has the potential to cause harm. Includes preventable adverse events, intercepted serious errors, and nonintercepted serious errors. Does not include trivial errors with little or no potential for harm or nonpreventable adverse events.

Intercepted serious error: A serious medical error that is caught before reaching the patient

Nonintercepted serious error: A serious medical error that is not caught and therefore reaches the patient but because of good fortune or because the patient had sufficient reserves to buffer the error, it did not cause clinically detectable harm

Nonpreventable adverse event: Unavoidable injury due to appropriate medical care

Preventable adverse event: Injury due to a nonintercepted serious error in medical care.

Slips: Failures of automatic behaviors, or lapses in concentration (e.g., forgetting to perform a routine task due to a lapse in memory) and often occur from fatigue or distractions in the workplace.

Mistakes: Incorrect choices, such as choosing the wrong drug, a clinical condition and typically result from inexperience or lack of knowledge or training.

Incident: An event or circumstance that could have, or did lead to, unintended and/or unnecessary harm to a person.

Harm: Death, injury, suffering, dissatisfaction, or disability experienced by a person.

Near miss: Any incident that could potentially lead to patient harm.

Adverse event: Any injury due to medical management, rather than the underlying disease.

Adapted from references [11,12,14–18].

or unnecessary harm to a person, or a complaint, loss, or damage. Adverse events are different, and are defined as an "untoward and usually unanticipated outcome that occurs in association with health care" [14] or more broadly stated by the IOM as "an injury resulting from a medical intervention" [1]. The Critical Care Safety Study defines adverse events as "Any injury due to medical management, rather than the underlying disease [18]. Describing an event as an adverse event does not imply poor-quality care or that an error occurred. An adverse event only indicates that an undesirable outcome resulted from a medical intervention rather than an underlying disease process [19]. As an example, if proper procedures are followed for central line placement but the patient develops a pneumothorax, this would constitute an adverse event even though all the elements of quality care were met.

Most existing typologies of definition related to patient safety pertain to medical interventions. Errors of diagnosis are emerging as relatively uninvestigated but equally important causes of unsafe patient management in the ICU [20].

MEASUREMENT OF SAFETY IN THE INTENSIVE CARE UNIT

The science of measuring and reporting patient safety remains immature and can be viewed from the perspective of whether the measure identifies a structure, process, or outcome related to safety. Different methods of measurement focus on one or more of these elements and may be more or less efficient at identifying safety risks in one or more of these domains. The primary methods of measurement include incident reporting, targeted monitoring, use of discharge data sets, process of care measurement, trigger tools, ICU audits, and direct observation [18].

Incident Reporting

In terms of collecting safety measurement data, traditional methods based on incident reporting of specific adverse events have been largely ineffective for several reasons [21]. First, reports have been generated in a punitive environment that focuses on the provider who committed an error rather than systems of care and discourages self-reporting of errors [5]. Second, each report of an error represents a "numerator" value that does not give insight into the denominator pool of patients at risk for similar errors. In the absence of these values, the incidence of errors and the overall safety of an ICU cannot be assessed. Third, definitions of errors used in incident-reporting systems vary, which impedes data synthesis, analysis, collaborative work, and evaluation of the impact of changes in health care delivery [22]. And fourth, appropriate functional data spanning the domains of structure, process, and outcome are not collected, which impedes the ability to "deconstruct" an error to understand its root causes and patient impact.

Recent advances to incident reporting have enhanced the detection and analysis of errors. Internet-based systems allow anonymous reporting of errors to encourage providers who have either committed an error or have knowledge of an error to enter related information into a central data repository. Institutional commitment to a "culture of safety" has a motivational effect on error reporting because health care providers note the impact that a reported error can generate in terms of improved quality of care. This culture requires several essential process elements to enhance error reporting: A team (a) convenes to develop preventative solutions to a reported error, (b) generates plans to improve the care, and (c) has a method for implementing and measuring the impact of their plan [23]. The Intensive Care Unit Safety Reporting System (ICUSRS) is

an anonymous reporting system that focuses on "systems factors" rather than "person factors" and provides expert analysis with feedback and guidance to improve processes of care and prevent error recurrences [11,24]. The University Health Systems Consortium's Safety Net reporting system can generate consolidated reports with application to the ICU [24].

However, problems remain with incident reporting in terms of the taxonomy used to describe errors and adverse events. The Joint Commission (JC) published a patient safety event taxonomy and classification schema for near misses, errors, and adverse events [11]. The taxonomy was designed to conform to an analytical framework and common word usages to promote its use and the understanding of its output. Data entered allows classification of a patient safety event within five complementary primary groups: *impact*—the outcome or effects of medical error and systems failure, commonly referred to as harm to the patient; *type*—the implied or visible processes that were faulty or failed; *domain*—the characteristics of the setting in which an incident occurred and the type of individuals involved; *cause*—the factors and agents that led to an incident; and *prevention and mitigation*—the measures taken or proposed to reduce incidence and effects of adverse occurrences.

The ICUSRS reporting platform similarly uses a framework for evaluating factors that contribute to an incident [11]. Both the JC and ICUSRS systems recognize that errors are multifactorial and therefore include multiple variables along the three domains of structure, process, and outcomes, such as caregiver performance, systems of care, resource availability, functioning of teams, and the environment of care. These systems describe events with a multidimensional taxonomy to allow the comprehensive description and full deconstruction of errors to determine their root causes [9]. However, even if taxonomy issues of incidence reporting are improved, the problem of determining the true incidence rate remains. A comprehensively described and deconstructed incident only gives insight into the numerator; it does not provide information on the number of patients at risk and does not allow determination of true incidence rates.

Targeted Monitoring

A complementary approach to incident reporting is targeted monitoring. ICUs can measure their patient safety outcomes by monitoring a specific indicator, such as the incidence of *Clostridium difficile* infection in the ICU or ventilator-associated pneumonia. In so doing, ICUs are challenged to define their denominators and select indicators that can be readily detected and counted to provide an accurate numerator. The denominator is especially difficult to determine because the measurement has major impact on interpretation [11]; for instance, *C. difficile* infection rates can be described per ICU patient, patient ICU days, or at-risk patient ICU days. The numerator data are equally challenging because of the time and expense of chart extraction needed for their collection. If the characteristics of the patient population change over time, then these factors must be accounted for as well. For example, if the patient population changes or new services such as transplant are offered by a given hospital, then the patient mix will change and adjusted hazard rates will be needed. Thus, for this approach to work, a multidisciplinary team that includes people with ICU training, organizational skills, database management, and epidemiology are needed.

Discharge Data

Discharge data represents a potential source of information to allow the retrospective collection of quality and safety indicators to profile ICU performance [25–27]. Recently, AHRQ has developed empiric measures of quality and safety from multistate discharge data in a redesign of the original Healthcare Cost and Utilization Project Quality Indicators [28]. The Patient Safety Indicators are relevant to ICU safety of care. Although most of these indicators relate to surgical patients, newer indicators are being designed to measure the safety of care for medical patients with critical illnesses, such as myocardial infarction, stroke, and congestive heart failure.

Although this method is powerful and can be quite useful, it is important to also recognize its limitations. Discharge data analysis gives insight into outcomes, but little information on structure or process. Large datasets such as these also have limited data quality for clinically relevant covariates, so controlling for confounders is difficult. Because all of the clinically relevant covariates are not included, the problem of residual confounding is always a problem and caution should be exercised when interpreting results. Making interinstitutional comparisons is therefore difficult, and even when trending data over time, results must be analyzed with caution. When patient populations and their problems are relatively homogenous and stable over time, this is a good system (e.g., surgical patients). When there is marked heterogeneity in terms of clinical problems and rapid changes in process of care over time, this approach will have difficulty. Having said this, discharge datasets can be an important tool for hypothesis generation so that ICU leaders can then launch more systematic studies into particular problems.

Process of Care Measurement

Safety can also be measured through determination of the proportion of patients who receive certain processes of care that have a strong evidentiary base for improving clinical outcomes. However, it may be difficult to isolate and to ascertain the contributory effect of influential factors, that is, adherence to best practice by the caregiving team, the role of complications, or level of care. Physicians and other clinicians often have a stronger sense of accountability toward a process measure than an outcome measure because the process measure can be more strongly linked to a particular care provider or team [29]. Also, physicians may believe that outcomes can be overly influenced by severity of disease and prove resistant to quality improvement efforts. To serve as an accurate measure of safety and to influence quality improvement, process measures must have a causal relationship with the outcome they are intended to represent.

Examples of process measures include approaches for ordering therapy in the ICU. Medication errors and adverse drug events occur commonly in the ICU [30] and can be limited by the use of formatted drug-ordering forms [31]. Computerized physician order entry for drugs has the potential to decrease the rate of serious medication errors [32] and to improve clinical outcomes when applied to antibiotic prescribing [33]. Additional care processes that should be in place to support patient safety can be constructed by reviewing evidence-based clinical practice guidelines [34], such as standardizing orders for ventilator management in the ICU [35].

Process of care measurement is often very effective for certain types of problems, like computerized order entry, but it is important to recognize some of the limitations and difficulties inherent in the system when applied to more complex problems. When strong evidence-based clinical practice guidelines are available, this is a feasible strategy, but often this is not the case. In addition, properly identifying those patients eligible for a particular protocol in the appropriate time period is critical. Examples include the use of thrombolytics for myocardial infarction and stroke, as well as recombinant activated protein C

for sepsis. Determining the numerator for such process of care measures is fairly easy (who actually received the drug), but determining the denominator can be more difficult and can be costly because of the time and expense needed for data collection (e.g., reviewing every chart in the emergency department of a patient presenting with angina or suspected myocardial infarction). In addition, chart abstraction in such cases usually requires a high level of expert judgment, which makes it even more difficult. Thus, process of care measurement, because of cost and time considerations, may be a suitable approach to improving safety for those problems in which there is a strong-evidence base and in which the costs of identifying the patient population (both numerator and denominator) are sustainable and warranted by the value of information obtained.

Intensive Care Unit Audits

An audit of the existing structure of an ICU can also measure patient safety. Evidence supports improved outcomes in ICUs staffed by sufficient numbers of board-certified intensivists [36,37]. Additional structure measures of safety include the presence of resources to establish ongoing competency of medical staff and residents [38], adequate nurse staffing and skill sets [39,40], and appropriate technology resources, such as smart pumps and bar coding [41]. And, most importantly, the presence of a culture of safety represents a central structure within an ICU for promoting safety. Such a culture emerges from the presence of leaders who are committed to safety and staff who understand that errors are inevitable, acknowledge that errors are to be reported, dedicate time to learn about new risks and hazards, support teamwork and open communication, and upgrade procedures and implement safeguards on a continuing basis [16]. Organizational characteristics of safe programs with low accident rates include successful safety programs with strong management commitment, safety training as part of new employee's training, frequent open contacts between workers and management, general environmental control and good housekeeping, a stable workforce, and positive reinforcement for good safety practices. Surveys exist that allow ICU directors to assess the status of their units' culture of safety [42–45]. Pronovost and Sexton [44] recommend measuring the entire hospital annually with the full Safety Attitudes Questionnaire, which has construct validity and sufficient reliability for measuring the single construct of safety culture. Once measured, the culture of safety can be improved with focused interventions for any low-scoring hospital areas, such as an ICU.

Trigger Tools

Trigger tools refer to techniques used to detect organizational signals for adverse events. For instance, orders for flumazenil may identify patients who were given an overdose of a benzodiazepine drug. The flumazenil order therefore would serve as a trigger to perform a chart review. A trigger or set of triggers can be used to identify medical records for retrospective review to assess organizational safety or used in "real time" as a tool to identify a specific patient at risk for an adverse outcome. Trigger tools for the ICU have been shown to be practical approaches to enhance detection of adverse events in critically ill patients [46].

INTENSIVE CARE UNIT ORGANIZATION

Because patient safety and quality of care are intricately related, it is vital that intensive care medicine be effective and efficient at delivering safe, high-quality care at a low cost, especially as between 0.66% and 1% of the gross domestic product in the United States is spent on critical care services [47–49]. As with any critical activity, the organization and structure of services affect its delivery [50].

The Committee on Manpower for Pulmonary and Critical Care Societies was sponsored by the American Thoracic Society, the American College of Chest Physicians, and the Society of Critical Care Medicine to make supply–demand projections about pulmonary and critical care services and physicians [51]. It was estimated that by 2020 there would be a deficit of pulmonologists equal to 35% of demand and that by 2030 the deficit would be equal to 46% of demand. The calculated shortfalls for intensivists were 22% and 35% for 2020 and 2030, respectively.

Given these shortages in physician personnel resources, it is imperative that ICUs optimize their organization and utilization of personnel. Thus, several issues regarding organization and staffing of the ICU are relevant (see Chapter 208). Current controversies in this area include whether around-the-clock intensivist staffing are required for quality care, whether closed or open ICU formats are better, and whether regional intensive care centers are necessary.

Intensivist Staffing

Twenty-four hours a day, 7 days a week (24/7) attending intensivist coverage was available in only 6% of American ICUs in a 1991 survey, and such coverage was available in 72% of European ICUs in the European Prevalence of Infection in Intensive Care survey [52,53]. Given the discordance in around-the-clock coverage across the Atlantic Ocean, there is surprisingly little evidence to support the benefit of 24/7 coverage of ICUs by senior intensivists. In fact, many academic institutions in the United States offer 24/7 coverage by dedicated house staff and other physician extenders with critical care attending backup, either by pager or mobile phone, without any temporal changes in mortality or utilization of resources [54].

There has been much speculation regarding the benefits of continuous, on-site attending physician coverage in the ICU [55–58]. Hypothesized benefits might include decreased mortality, decreased length of stay, decreased global costs (although ICU costs might be higher), decreased complications, improved nutritional management, efficient admission and discharge policies, improved reimbursement, and improved ICU team functioning. Within the context of patient safety, improved staffing ratios would presumably tend to reduce latent errors and mistakes. A single, retrospective pre- and postintervention study examining 24/7 intensivist coverage in the United Kingdom did show a decline in mortality with institution of continuous, on-site attending coverage [59]. Others studies have continued to support the benefits of intensivist involvement in critical care, even in ICUs where control was maintained by primary care physicians. Intensivist involvement also has been demonstrated to improve outcome in settings involving surgery of the abdominal aortic and esophagus, pediatric critical care and combat injuries. On balance, however, there are little data supporting the hypothesis that attending intensivists need to be on-site on a continuous basis to provide cost-effective quality care. In fact, a multicenter retrospective analysis suggested that there was a higher mortality rate when critically ill patients were managed by intensivists [60]. Although issues of confounding and controlling for these factors are always at issue in retrospective analysis, this study (Project Impact) has only reinforced the need to further study optimal staffing and training for critical care personnel.

Higher staffing ratios, whether nursing or physician, should theoretically eventually improve quality of care; for example, 1:1 patient-to-nurse ratios and continuously available on-site physicians from all specialties. The real issue centers around the

incremental costs and benefits of improved staffing ratios compared with the current ratios (generally, 2:1 patients-to-nurse and variable attending coverage). We can restate the question as, given the finite and constrained resources we have, what is the optimal physician staffing ratio and organization for ICUs from a societal cost-effectiveness perspective? Currently, there are insufficient data to answer this question and indeed the "correct" answer is probably contingent on many other factors, including societal values, economic resources, physician manpower considerations, nursing costs and availability, nurse training, availability of house staff, house staff training, organizational culture, technology costs, and legal considerations.

As an example, if resident and fellow house staff are available, ICU nurses have advanced training and good organization, the number of patients in the ICU is small, and the clinical population has relatively straightforward problems, then in-house, 24/7 intensivist coverage is less likely to be cost-effective compared to intensivist backup (on-call). However, if ICU size goes up, complexity of patient problems increase, house staff training for ICU-related problems goes down, and there is a high amount of nursing staff turnover, which limits their expertise, then 24/7 intensivist coverage may have more benefits. The interaction of many of these variables makes study of this field complex because multiple variables have an impact on each other as well as an impact on safety and outcomes, but the issues of patient safety and the potentially high costs of instituting 24/7 coverage warrant further prospective studies.

ICU Models

The 24/7 intensivist staffing variable is a critical element of several variables determining ICU safety as it impacts errors of omission and recognition and can reduce critical mistakes. However, in addition to the actual number and availability of intensivists, how they are organized is equally and possibly even more important if cost-effective quality care is to be delivered.

One aspect of organization that can impact care is whether an ICU uses an open or closed model. Much evidence suggests that in an open ICU, intensivist consultation should be required for critically ill patients [61]. More ideally, however, critical care services should be delivered in closed units with dedicated intensivist staffing with administrative structures that allow for rapid implementation of protocols that have been proven to be beneficial to patients [54,62,63]. It might even be possible that a closed ICU functions efficiently without implementation of protocols as suggested by a nonblinded study [64,65]. Closed units also allow for strong leadership coupled with a multidisciplinary team approach to patient care, which might allow for effective and efficient delivery of services in the manner envisioned by the Society for Critical Care Medicine [50,66,67].

From a patient safety perspective, strong evidence-based protocols offer many potential advantages. They can help to minimize both slips and mistakes. For instance, daily assessment of patients to determine if they should undergo weaning from mechanical ventilation is important, but in the busy ICU environment, this can easily be overlooked. The liberation of patients from mechanical ventilation via protocols has been studied by Ely et al. (1996 and 1999) [63,68]. In a randomized, controlled trial of 300 intubated adult patients, Ely et al. [68] showed that early identification of patients capable of spontaneous breathing via daily screening by other physicians, respiratory therapists, and nurses could decrease the duration of mechanical ventilation by 1.5 days when compared to patients in whom their attending physicians made decisions about extubation on an individual basis, despite the fact that the intervention (e.g., daily screening) group was more ill. In a subsequent study, Ely et al. [63] showed a respiratory therapist-directed weaning protocol *without direct physician supervision* could be instituted in the ICUs of their university medical center with modest degrees of success. This would constitute one example in which protocols, disseminated through a closed ICU organization, can improve safety by limiting slips.

Other management strategies, such as sedation and ventilator management of ARDS/ALI are well suited for development of protocols and may further limit mistakes, such as over- or undersedation in the ICU [69,70] and enhance use of lower tidal volume ventilation. Nurse-driven protocols with specific sedation targets and daily lightening of sedation have been shown to impact duration of mechanical ventilation.

Intuitively, it seems that protocols would be easier to institute using a closed ICU organizational structure rather than an open structure. Protocol development, dissemination, and implementation are all facilitated by having a stable, smaller number of physician providers rather than having many providers with varying practice patterns. In addition, development and implementation of protocols allows for process of care measures to be built into the system, so that the measurement of safety in the ICU can be achieved in a more cost-effective manner.

Regional Intensive Care Unit Centers and Telemedicine

The Leapfrog group (http://www.leapfroggroup.org) is a consortium "made up of more than 170 companies and organizations that buy health care." The consortium's overarching objectives are to improve the quality, safety, and affordability of health care, including the way critical care medicine is practiced. What distinguishes Leapfrog from other quality-improvement organizations is its tremendous economic clout. Their current recommendations for ICU organization are that (a) ICUs should be managed or co-managed by intensivists who are dedicated to the unit and who are physically present during daytime hours, and that at other times, (b) the intensivists can return pages within 5 minutes, and (c) that the intensivists can either reach the ICU or can arrange for physician extenders to be on-site within 5 minutes. Whether or not one agrees with these recommendations (often misinterpreted as requiring on-site 24/7 intensivist coverage), many hospitals are attempting to adhere to the standards set forth by the Leapfrog group. Their recommendations for ICU staffing and practice are primarily based on "common sense and rational extrapolation of the data"[71]. Because *there are not* and will not be enough pulmonologists and intensivists to staff all hospitals in the fashion suggested by the Leapfrog group [51], there will need to be alternative acceptable schemes for the delivery of critical care services.

One potential solution is the regionalization of intensive care services in a hub-and-spoke pattern similar to airports [67,72]. In 1994, the American College of Critical Care Medicine challenged the medical community to study the regionalization of ICUs [36]. Since then, however, only a few studies have directly examined the issue of transferring adult critically ill patients from community hospitals to larger tertiary care centers [73,74]. In a retrospective, case-controlled study, Rogers et al. [73] showed that trauma patients could be safely stabilized at smaller, outlying community hospitals prior to transfer to a level I trauma center. Similarly, Surgenor et al. [74] showed in a prospective fashion that interhospital transfers of patients requiring high-level critical care were as safe as intrahospital transfers. Both of these studies hint at the feasibility of safely regionalizing critical care services as one method for partially dealing with the likely shortage of physicians trained and dedicated to critical care medicine [51]. In addition, higher volume centers have been demonstrated to have improved outcomes in patients with sepsis and respiratory failure requiring mechanical ventilation, thereby reinforcing the case for transfer to regional centers of critical care excellence.

However, even if transfers can be accomplished safely, it is not clear that regionalization can deal with the significant shortages projected. Regionalization of high-level services may allow some economies of scale to be recognized, but it is unlikely that these benefits could fully offset the shortages projected.

Another increasingly used model involves telemedicine [75]. In this paradigm, one or several ICUs are electronically linked to a central and remote site where intensivists monitor critically ill patients. For instance, ICUs (patient rooms and nursing stations) can be linked to the remote site via cameras, speakers, and microphones. The hospital computer and data system, order-entry system, ICU and telemetry monitors, digital radiography, and any other required information systems can be linked remotely to intensivists. This allows for oversight of ICU activities without actually requiring that critical care physicians be physically on-site. Procedures can then be performed by on-site physician extenders while the ICU nurses can carry out orders. The patients' primary physicians or daytime intensivists can then choose to be involved to varying degrees during off-hours.

Two studies have been published examining the feasibility of ICU telemedicine and the associated patient outcomes [76,77]. Rosenfeld et al. [77], compared a single prospective intervention arm to two retrospective baseline arms (one arm to exclude seasonal variations and the second to account for temporal changes in outcome) of surgical ICU patients, and found that severity-adjusted ICU mortality, severity-adjusted hospital mortality, ICU length of stay, and complication rates all decreased by a statistically significant amount while concurrently lowering costs. Breslow et al. [76] demonstrated similar benefits when linking multiple ICUs to a remote monitoring site using commercially available equipment. Nonetheless, another study of the effectiveness of telemedicine failed to conclusively demonstrate improved outcomes or length of stay [78].

In a previously well staffed critical care system, the addition of an supplementary layer of telemedicine monitoring improved hospital and ICU mortality and length of stay. Adherence to critical care "best practices" was also improved [79].

PHYSICIAN TRAINING AND DEVELOPMENT OF A CULTURE OF SAFETY

It is during residency training that physicians acquire not only their clinical knowledge, but also their familiarity with system-based practice attitudes toward patient safety. Because development of a culture of safety is one of the key elements to solving patient safety issues, the training of residents is central to developing long-term solutions to patient-safety problems. However, the ICU experience can be one in which residents themselves become a safety issue. Residents need to acquire the body of knowledge, skills, and experience necessary to function as attending physicians, and as part of this training they need to develop a culture of safety. Yet, lack of supervision, experience, and resident fatigue can adversely affect patient safety, especially in the ICU setting. It is thus useful to separate the issues of safety into those related to proper resident training, which affects the culture of safety in the long term, and those related to resident performance, which impacts patient safety in the short term.

Teaching a Culture of Safety

Poor outcomes related to resident errors have been documented by up to 45% of house officers queried, with nearly one third of the incidents associated with patients' death [80]. Resident cross-coverage and hand-offs also increases the risk of medical errors. The harried work environment and heavy workloads add to the risk of medical mishaps. It is within this context that residents are also acquiring their attitudes and the habits that determine their culture of patient safety. There is typically limited integration of safety practice into work routines [81]. To address these issues, governmental, local, and educational organizations have focused on how patient safety can be integrated into the continuum of medical education. Only a small proportion of clerkships and directors of clerkships, in the medical student setting, have patients' safety content as part of course curricula. Limited exposure of medical students to quality management, quality improvement, and organizational problem solving, has prompted curriculum guidelines that require residents to develop competency in six areas, including; patient care, medical knowledge, patient-based learning, personal and group communication skills, professionalism, and system-based practice [81,82]. Patient-based learning and system-based practice are the areas most relevant to patient safety and the development of a culture of safety.

The traditional morbidity and mortality conference in medical school-teaching hospitals has been an important training forum, for discussion of adverse events and errors as well as inculcating a safety culture. Data show that Internal medicine conferences were longer than surgery conferences and allowed more time for listening to invited speakers but had less time in audience discussion. Problematic cases in medicine were less often attributed to root causes. There was less frequent acknowledgement of specific errors in the medical cases compared with those in surgery [83].

Resident and Trainee Performance

Optimal resident and trainee performance requires adequate rest, supervision, and sufficient training to perform increasingly complex problem-solving tasks. Each of these areas can contribute to safety as they represent potentially latent medical errors (errors due to the design of the educational system as well as the health care delivery system).

Preparing for work by getting sufficient sleep and enhancing alertness is a recognized responsibility of the clinician. Despite this seemingly obvious axiom, extended work hours and extreme fatigue among trainees are long-standing traditions in medical education and have often been the hallmarks of "excellence" in educational programs. Prolonged work hours and being on call was exceedingly common, with workweeks of 120 hours and on-call shifts of 48 hours not unusual. However, resulting fatigue has been associated with altered moods, depression, anxiety, confusion, and anger, and, most recently, impairment in clinical performance [84,85]. Among documented impairments were decreased technical dexterity, impaired clinical reasoning, and inability to learn and accommodate new information. In a recent study of medical house staff in which work was limited to 16 and fewer consecutive hours, trainees slept more and had less than half the rate of attention failures compared to traditional "long" schedules. Interns working extended shifts of 24 to 30 hours had greater attention failures and performance associated with significantly more medical errors compared to those scheduled to work only 16 consecutive hours [86,87]. These findings have been observed across medical specialties with prolonged shifts associated with decreased attention, vigilance, and simulated driving performance similar to blood alcohol level of up to 0.05%. In addition, the odds of having a motor vehicle crash were significantly increased after prolonged work shifts. Extended shifts increased the amount of risk of any motor vehicle crash and falling asleep at the wheel [88]. Although preliminary studies have demonstrated significant improvement in mortality in common hospital

diagnoses (acute myocardial infarction, congestive heart failure and gastrointestinal bleeding) in the first 2 years following these reform measures, cost estimates for these reforms have been estimated at $1.7 billion [89,90].

An assumption that improved work schedules will lead to improved patient outcomes has led to significant regulatory intervention to limit trainee work schedules. Following the 1984 Libby Zion case, New York State, adopted regulations that limit resident work hours to 80 hours per week, and with increased supervision [91]. The Accreditation Council for Graduate Medical Education (ACGME) has set standards for work hours and time off, although these vary among the specialties. The Association of American Medical Colleges issued duty hour regulations in July 2003. The purpose of these rules was to limit the number of weekly work hours, continuous hours, call frequency and set a minimum time between on call and insuring days off in between [92]. Direct federal regulation of work hours and duty periods for house staff has been introduced to the United States Congress [88], but federal policy also requires ACGME certification. In addition to regulating trainees, other proposed JC standards for 2008 may include recommendations to set limits on physician and nurse work schedules to reduce fatigue and thereby the frequency of medical errors.

Even when trainees have sufficient rest, they still require adequate training and supervision. The question becomes how to acquire sufficient experience while minimizing patient risks. Previous paradigms of critical care education have emphasized knowledge acquisition over performance. The critical care unit poses unique educational obstacles. Limitations of current training practices include difficulty in procuring cadavers, and tissues. There are ethical and financial barriers to utilization of animals. "Real" patients are increasingly reluctant to be used as a training tool. Critical care procedures are often dangerous and extremely difficult to learn and teach. Because of the learning curve, patients may be harmed, and the phrase "see one, do one, teach one" may no longer be relevant to modern practice.

One option that is being increasingly used in the ICU is simulation. Simulation is the imitation or representation of a potential situation in an experimental setting. It can be used to train physicians in the cognitive, procedural, and problem-solving aspects of critical care. Simulation has been increasingly used as an effective tool for training in medical settings [85]. First pioneered by Edward Leap, who designed a flight simulator for pilots in the 1920s, simulators are used today by all commercial airlines, by astronauts, the military, and the nuclear power industry. Medical simulators today frequently incorporate computers and virtual reality, but it is important to recognize that simulation training does not necessarily imply use of a computer. Simulators have traditionally focused on cardiopulmonary resuscitation models and normal/abnormal heart sounds, but many forms of simulation training are becoming available. Other simulators relevant to the ICU include mechanical models of the airway to teach basic bronchoscopy as well as newer bronchoscopy simulators with virtual reality augmentation [93]. The type of simulator (computer driven, mechanical, or a combination) depends upon the task being learned. For critical care, tasks can be broadly grouped into cognitive tasks (e.g., knowledge of physiologic responses to ventilator changes, analysis of cardiac rhythms in ACLS), mechanical-procedural tasks (e.g., bag-valve mask ventilation [94], intubation [95,96], bronchoscopy [93], central line placement [97]), and team performance tasks (e.g., respiratory failure using the Anesthesia Crisis Resource Management (ACRM) course [98], ACLS [99]). Simulation has been applied to all three areas. The incremental benefit of simulation training as compared with standard teaching methods on real-life performance has been demonstrated in only a few studies [93,97,100]. However, there is a much larger body of evidence in which surrogate outcomes (not real-life performance per se) have been used to demonstrate the positive effects of simulation training. Surrogate outcomes in these cases have included measures of student confidence [97] or performance on a model [94–96,99]. On balance, while the current evidence base is still incomplete with only a few randomized trials documenting superior real-life performance after simulation training, it reasonable to conclude that simulation training will play an increasingly important role in critical care education. The advantages hypothesized for simulation include safety, efficiency, and availability. Intricate elements of difficult procedures and potential complications as well as the response to equipment malfunction can be selectively and repeatedly rehearsed. The ability to provide immediate feedback and train teams is also enhanced. Employing simulation models may positively impact direct and indirect costs associated with training and educating personnel through reduced use of operating rooms and may potentially reduce malpractice claims. It is anticipated that as the expense of such equipment diminishes, simulators will be increasingly adopted in medical school curriculums and residency training.

The Agency for Health Care Quality and Research has made development of simulation devices and protocols an important priority. At the present time, there is only limited clinical evidence supporting the efficacy of simulators on improving patient-based outcomes such as length of stay and mortality.

REGULATION AND GOVERNMENT IMPACT ON PATIENT SAFETY

The role of government and nongovernmental regulation has increased during the past decade and taken on an international scope. As the public has become more aware of the need for patient safety and quality improvement within health care, there have been many new regulatory and reimbursement initiatives originating from the public sector (federal and state governments and agencies [e.g., www.ahrq.com]), state and county health departments, purchasers, and nongovernmental organizations (e.g., JC, ACGME), and international organizations (e.g., World Health Organization [WHO]). The hypothesis that significant mortality can be attributed to medical error has facilitated the implementation of rules and guidelines. Regulatory efforts encompass rules and regulations but also accreditation of organizations, certification of providers, and reimbursement programs based on patient safety processes and outcomes. Purchasers, led by the Centers for Medicare and Medicaid Services have adopted pay-for-performance reimbursement models [101] and nonreimbursement strategies for complications of care-related to specific "never events" [102]. A new area of interest pertains to appropriate levels of regulatory oversight for patient safety research that ensures patient protection yet fosters the acquisition of new knowledge necessary to improve patient care in the ICU [103].

Many regulatory initiatives are likely to improve outcomes, but others overlap thereby presenting a risk for causing confusion and malaise in health care providers as they attempt to comply with conflicting rules, mandates, and guidelines, and may actually become impediments to patient safety. Two trends include greater collaboration in developing safety efforts between relevant organizations and emergence of international partnerships of regulatory organizations. These efforts may result in improved harmonization of standards and regulations.

In regard to physician-related accreditation and certification, the ACGME has included patient safety concerns in its resident program accreditation process both in mandating duty hour limitations and requiring the inclusion of patient safety in educational curricula. The American Board of Medical

Specialties requires evidence of practice improvement efforts for maintenance of certification. Some of the required modules include patient safety domains. Regarding organizational-level regulations, the JC publishes annually an update of its national patient safety goals in support of their standards for accreditation, which include ICU-related processes of care [104]. In 2005, the JC and Joint Commission International were designated by the World Health Organization (WHO) as the first members of the WHO Collaborating Centre for Patient Safety Solutions. The Collaborating Centre has organized an international network to identify, evaluate, adapt, and disseminate patient safety solutions (http://www.ccforpatientsafety.org/WHO-Collaborating-Centre-for-Patient-Safety-Solutions-continued/). This effort demonstrates the international intent to create linkages with key organizations and individuals with expertise in patient safety, which include accrediting bodies, national patient safety agencies, professional societies, and others.

Independent, not-for-profit organizations, such as the Institute for Healthcare Improvement (IHI), develop programs to accelerate improvement by promoting cultures for change, stimulating promising concepts for improving quality and safety, and assisting health care organizations to implement these new concepts. The IHI has had considerable influence on regulatory organizations with respect to adoption of IHI initiatives, such as ventilator bundles, central line bundles, sepsis bundles, intensivist staffing models, and rapid response teams (http://www.ihi.org/IHI/Topics/CriticalCare/IntensiveCare/Changes/IntensiveCareChangesIndex.htm). Because of the emphasis on rapid promotion of promising new interventions, such organizations have occasionally endorsed interventions prematurely, such as tight glycemic control, ahead of supporting evidence.

Other proposed areas of regulation include minimum nursing staffing ratios to meet workload demands [105] for Medicare-participating hospitals and limitations of excessive work hours for nurses and residents. Hospitals have also been required to implement specific improvements and to develop a program for quality assessment. The IHI has also suggested that a patient safety officer needs to be an important component of all large health care organizations [106].

Safety has become a major concern in the high-risk environment of the ICU. Integrated and coordinated systems that identify patient safety problems and report them back to providers so they can improve their performance and so that they can improve "their structure, processes and outcomes of care" are being implemented. ICU reporting systems identify trends and patterns that facilitate health care improvement and reduction of preventable medical incidents. Because safety and error prevention in the health care setting compares unfavorably with those of other industries, a major thrust has been to adopt strategies and technologies that have proved successful in other settings and to apply them to the ICU. Common definitions of health care-related safety concepts and systems for safety monitoring and reporting will improve individual and group capability to improve patient safety. Approaches that have been implemented to some extent in the ICU community include incident reporting, targeted monitoring of process of care and discharges, trigger tools and ICU audits. Integration of electronic ICU patient data, such as hospital admissions information, laboratory results, progress notes, imaging and authentication data, with non-ICU patient data across a hospital computerized medical record is a prerequisite for promoting patient safety. ICU organization and staffing models also impact safety in the ICU and continue to be studied [107] along with team-training efforts [108] and programs in critical care telemedicine. Hospital design with placement of the ICU adjacent to emergency departments and surgical suites to facilitate rapid transfer of unstable patients will come under increased review. Although regulation by public sector agencies will impact the safety of the critical care environment, developing a culture of safety through graduate and postgraduate medical education will also be a major part of an ongoing program of quality improvement.

CHAPTER 211 ■ MEDICAL ETHICS, END OF LIFE CARE, AND CLINICAL RESEARCH IN THE INTENSIVE CARE UNIT

MARK TIDSWELL, PAUL G. JODKA AND JAY S. STEINGRUB

Scientific knowledge and technology dominate the intensive care unit (ICU) environment and the practice of critical care medicine. Caring for the critically ill person challenges our ability to apply knowledge in the best interest of the individual. The critical care physician is confronted by complex medical decisions, life-and-death circumstances, and a person who is frequently unable to communicate. This makes it difficult to intimately understand their moral values and wishes at the time when these values are most meaningful. Moral issues are inescapable in the course of critical care and occur so frequently that resolving some issues becomes a matter of routine. Deciding what we should do for the welfare of our patients is guided not only by scientific knowledge, but also by understanding numerous other complex and evolving attributes of the physician–patient relationship including: moral responsibilities to patients, legal obligations, and the role of the patient in decision making. This chapter provides an overview of current practice of guiding patients or families in making decisions about critical care, withdrawing life-sustaining treatments, and participating in clinical research.

Moral obligations of physicians to their patients have been recognized for millennia, and are described in the Hippocratic Oath (400 BC), the Oath and Prayer of Maimonides (1783), Nuremberg code (1947), The Belmont Report for protection of human subjects in research (1979), and contemporary guidelines and codes for physicians [1–3]. Whereas ancient and traditional descriptions of physician responsibilities emphasized trust, compassion, fairness, caring, and acting in the best interest of patients, contemporary conceptions of the patient-physician relationship emphasize the patient's individualism, or autonomy in decision making. This change in emphasis appears to have evolved along with social, political, and judicial prominence of respect for individuals along with a growing social mistrust of commercialized medical care and clinical research during the past 40 years. Humane care based on a foundation of trust remains the responsibility of the physician, particularly in the ICU where patients may have lost their ability to advocate and to be self-governing due to their illness, fear of dying, and limited understanding the scientific basis of their treatment.

Ethics is a branch of philosophy that concerns the analysis of moral obligations, values, and choices. Ethics involves deliberation and reasoning about the best course of action and results in a clearly delineated path to a decision. Critical care physicians apply ethical reasoning to make moral decisions with patients in the ICU. The ethical questions that confront physicians are practical, not theoretical, and the answers lead to decisions about the best choices in the care of patients.

PRINCIPLES OF BIOETHICS

Medical ethics is a one branch of bioethics. The ethical framework generally used for medical decision making is reasoning from ethical principles [4–6] (Table 211.1). The oldest principles are *beneficence* and *nonmaleficence*, and other principles have been described in recent decades. *Justice*, or fairness, implies that patients will be given the treatment that is indicated for their condition without regard to social, economic, ethnic, or other attributes. Unfortunately, there may be times when resources such as ICU beds or mechanical ventilators are limited and ICU physicians may need to work with hospital administration and the community to clarify how care may be rationed [7]. At the time this chapter was written, a global influenza pandemic was predicted [8,9]. *Patient autonomy* has, in recent years, become foremost among ethical principles. This emphasis on the importance of individual choice has been

TABLE 211.1

PRINCIPLES OF BIOETHICS

Beneficence: physicians act in the best interests of the patient
Nonmaleficence: physicians exercise caution when providing treatment
Justice: physicians allocate resources fairly
Autonomy: physician and patient deliberate about patient goals when deciding on medical therapy or research participation

influenced by numerous social changes and increasing distrust of the corporations and medical centers. Several highly publicized instances of inappropriate medical research in the United States during 1960 to 1980 led to legislation and policies defining the place of informed consent in research and in medical care. Autonomy is the foundation for the practice of informed consent for medical research and clinical care. Autonomy is exercised by patients but must be enabled by physicians and is based on an assumption that the competent informed person can weigh risks and benefits and make a decision that balances their medical needs and personal values. Autonomy requires that the patient or surrogate is able to deliberate about personal goals and act under their own direction (self-governance). The joint participation of physician and patient in "shared decision making" is recommended [10,11]. Unfortunately, it is usually not possible for ICU patients to share decision making due to the nature of their illness and life support devices. The physician plays a role by acknowledging the importance of autonomy and ensuring that a surrogate is identified as a decision maker.

Acknowledging the importance of autonomy emphasizes the role of the individual patient in decision making. To make decisions, the patient or surrogate must have information about the possible risks and benefits of an intervention. The ICU physician must provide information about the diagnosis and prognosis of the critical illness that will be used in a decision of consent or refusal. The competent and informed patient has the ability to consent to, or refuse, medical interventions or research. Because autonomy means that a person has ability to make decisions on all aspects of their life, the autonomous person may choose to not only oppose the advice of physicians, family, and friends, but may also choose to act contrary to their own previously expressed wishes and can change their mind. If a person lacks autonomy then their ability to speak for themselves can be protected by referring to a substitute such as previously expressed wishes or a surrogate decision maker.

Patient autonomy alone is not sufficient to describe the patient–physician relationship and the physician remains obligated to their own moral responsibilities and to acknowledging the values of the patient. In practice, the principles already described represent different values that must be considered and balanced against each other when reasoning toward a treatment decision by asking the question: how much potential benefit at how much risk is acceptable to this critically ill person? Beyond these generally accepted principles there are many other perspectives that may influence decision making, such as religious authority, the importance of relationships, the rights of the patient, or the value of patient care to society. It is possible that patients, families, or ICU staff will appeal to other ethical perspectives when reasoning toward a treatment decision, and while the patient is free to reason from their own ethical value system to guide their choices, the four principles are the standard guiding principles for the ICU physician.

DETERMINING DECISION-MAKING CAPACITY

To exercise autonomy, a patient must have the capacity to make a choice. Determining whether a patient has capacity occurs daily in the ICU and the critical care physician should be adept at this assessment. Physicians use criteria listed in Table 211.2 [12,13] and also must comply with local hospital policy and state law when determining decision-making capacity. Decision making capacity is decision specific; that is, patients may have the capacity to make some decisions but not other decisions. Capacity is determined one decision at a time by a physician (in contrast to competency that is determined by the courts).

All of the criteria listed in Table 211.2 must be present, or the patient lacks capacity. When the critically ill person is unable to make decisions, the physician must document lack of capacity and plans for making decisions. Historically, physicians and/or a capable family member made decisions. Currently, patients are likely to use advance directives or assign surrogate decision makers to make medical decisions should they become incapacitated. Patients with terminal disease can address situations where death is imminent and there is no hope of recovery by preparing advanced directives, or living wills. Advance directives are also useful for patients who indicate that they would refuse life support under any circumstance. However, in many cases, the circumstances of a patient's critical illness may be unanticipated, prognosis may be unknown, and written directives may be ambiguous. In the absence of a clear advanced directive, surrogate decision makers provide a "substituted judgment" for the incapacitated patient based on their knowledge of the patient's values and previous statements made by the patient. Surrogates are most often relatives of the patient either through legal authorization by the patient prior to their illness, or as permitted by state laws. To fulfill the role, a surrogate must disregard their own values and represent the values of the patient. An incapacitated patient can accept or refuse therapy through a surrogate. Refusal of therapy has been legally guaranteed to patients for decades, and the results of landmark cases of permanently incapacitated patients in persistent vegetative states refusing therapy through surrogates can be extended to ICU patients. Cases such as *Quinlan* (1976), *Cruzan* v. *Missouri* (1990), and *Schiavo* (2003–2005) led to laws that permit refusal of therapy through a surrogate. In many states, surrogates are required to now bring forward "clear and convincing evidence" in verbal statements from the patient prior to incapacitation to justify refusal of therapy [14–17].

PHYSICIAN RESPONSIBILITY FOR THE INCAPACITATED PATIENT

Physicians identify lack of capacity and confirm the need for a surrogate decision maker. Physicians may have discussed with the patient their understanding of, and wishes for, life support prior to critical illness. But, although obligated to act in the best

TABLE 211.2

CRITERIA FOR DECISION-MAKING CAPACITY

1. The patient communicates a choice
2. The patient understands the relevant information
3. The patient understands the situation and consequences
4. The patient manipulates the information rationally

interest of patients, there is a limit to the authority of physicians and they cannot make value decisions without taking into account the wishes of the patient. Physicians may have limited information about the values of a patient, they may have a very different set of personal values, or may have financial conflicts of interest with patient wishes [4]. Physicians cannot function as a patient surrogate to make decisions, but, in the capacity as treating physician, can refuse to perform procedures or provide care that they believe are unnecessary or non-beneficial [18–21]. Usually patients or surrogates can be dissuaded from unnecessary care by engaging in a thorough discussion of the appropriate care, reasons for refusing care, and offering a second opinion. Physicians are not compelled to perform services that violate their own moral values and can arrange for another physician to care for the patient. When patient wishes are known or communicated through a surrogate, the physician should attempt to carry these out, and obtain consent for procedures. Although some procedures can be justified without consent in the absence of previously expressed wishes on an emergency and life-saving basis, unless there is a justification physicians risk the charges of battery or negligence if procedures or other interventions are provided without consent or after refusal of consent [5,22,23].

Remarkably, surveys of ICU physicians have found that decision making practice varies greatly and often does not involve the patient. Some physicians report that they continue life support even when there is little hope of benefit from intensive care. The results of the SUPPORT study indicated that physicians did not consistently document or write a DNR order for patients that did not wish to have cardiopulmonary resuscitation (CPR) [24]. A survey in 1999 of ICU physicians from 16 European countries indicated that 73% of ICU's frequently admitted patients with no hope of survival. DNR orders were followed only 58% of the time. Yet, on the other hand, many physicians withheld therapy for patients who had no prospect of meaningful life, or deliberately administered large doses of drugs until death ensued. Only 41% of physicians surveyed felt ethical issues should involve patient and/or family [25].

Many patients with terminal illnesses will come to the ICU for resuscitation or monitoring prior to their deaths. CPR has little likelihood of improving survival of patients with terminal illnesses, and is usually regarded as nonbeneficial. Such a procedure with a low likelihood of success can be regarded as not in the best interest of the patient. This differs from medical futility, since futile care is defined as having no physiological rationale or care to which the patient has already failed to respond [4,18]. The term "futile" carries an important meaning and should be used carefully and accurately. When death is imminent and treatment has failed, then withholding futile care is supported by legal precedent. However, when death is not imminent, physicians may not be able to predict outcome. In one study, daily surveys of ICU staff found that physicians and nurses were unable to predict survival and quality of life 6 months after ICU. Nurses were incorrect in 58% of 45 patients and physicians were incorrect in 27% of 26 patients. Only one of the survivors about whom physicians believed care was futile reported poor quality of life 6 months after ICU [26]. A larger study that investigated determinants of withdrawal of mechanical ventilation found that physician's prediction of low likelihood of survival (< 10%) was a factor associated with withdrawal of mechanical ventilation and/or death [27]. In this study 3.6% of patients survived to hospital discharge after withdrawal of mechanical ventilation. A decision to withdraw support in this study was associated significantly with physician's perception of the patient's preferences about the use of life support. The ICU physician needs to know the precise hospital and legal definitions for "futility" and avoid invoking the term in cases where care is perceived as carrying a low likelihood of success or sustaining an unacceptable quality of life that is better termed nonbeneficial. If there is a plan to withhold support or procedures, for example, CPR, and the procedure is not strictly futile, then information should be provided about the procedure and rationale should be explained to the patient/surrogate [20,21,28].

ETHICS COMMITTEES

Ethics committees or ethics consultants provide an additional resource for resolving ethical conflicts. The committee is an objective "third party" not previously involved in disputes of the case. Committees review the medical and ethical and psychosocial aspects of the case and provide an ethical analysis. Committees can also provide social and emotional support to families and may be able to discuss and explain the ethical issues for longer periods of time than physicians and nurses. Since most ethics consultants are employed by the hospital, families may perceive a bias in favor of physicians or an attempt to protect the interests of the hospital. However, ethics consultants are usually well received by both physicians and patients/surrogates [28,29]. In addition to resolving conflicts, ethics consultations are associated with decrease in the duration of ICU length of stay and use of life-prolonging treatments for patients who ultimately do not survive [29].

COMMUNICATION WITH PATIENTS AND SURROGATES

Numerous studies and ICU practice guidelines over the past decade emphasize the importance of effective communication with, and support of, families of critically ill patients. Communication about plans for patient care most often takes place between physicians and family members, rather than between physicians and patients [30]. Discussions with families frequently occur when physicians have decided that continuation of care will be ineffective, but interviews with families indicate that more than half of family and patient representatives do not fully understand the prognosis and treatment plan [31]. To facilitate shared decision making, in which physician and family jointly reach a decision, communication must be more effective and needs to begin early during the ICU stay [10,11].

Physicians are more likely to achieve effective communication when meetings begin earlier in the course of care. In one study, proactive, formal, multidisciplinary meetings were held within 72 hours of ICU admission for patients with clinical features including a predicted ICU stay longer than 5 days, or predicted mortality greater than 25%. In these meetings the medical facts, the patient's perspectives on death dying and critical care, the care plan and the criteria for determining success of the care plan, were discussed. Intensive communication decreased ICU length of stay and allowed earlier access to palliative care [32]. Consistent proactive communication with families for updates on progress and encouragement to use advanced support when appropriate is recommended [10,11]. Improved communication can also be facilitated by using a private place for discussion, listening, empathic statements, acknowledging family emotions, focus on patient values and treatment wishes, clear explanation of the principle of surrogate decision making, assurance that the patient will not suffer, and support for the decisions made by the family [32–37]. A simplified mnemonic for important elements of effective physician–family communication is VALUE (Value and appreciate what is said by family members, Acknowledge the family members' emotions, Listen, Understand who the patient is as a person, Elicit questions from the family members) [39].

Families of ICU patients suffer and may develop long-term mental health issues related to the trauma of witnessing the ICU treatment or end-of-life care of a loved one. Symptoms can include posttraumatic stress disorder (PTSD), anxiety, and depression [33,40]. It is now clear that physicians have an opportunity to lessen the suffering of the family members through effective communication with families about prognosis and care of ICU patients. In one multicenter trial [38], proactive end-of-life conferences with relatives of patients dying in French ICUs resulted in better long-term psychological outcomes in the family members when compared with customary end-of-life conferences. The proactive communication intervention followed detailed guidelines [41], physicians focused on achieving the elements of effective communication summarized by the mnemonic VALUE, and family members received a brochure on bereavement. Physician–family conferences were longer (median 30 minutes vs. 20 minutes) and relatives spent more time talking (median 14 minutes vs. 5 minutes) in the intervention group. Relatives that participated in the proactive intervention had lower prevalence of PTSD symptoms, depression, and anxiety when interviewed 90 days later [38].

Ethical reasoning is part of shared decision making about ICU care for individual patients usually conducted together with a patient surrogate. Family conferences are important for facilitating care of the incapacitated ICU patient and are a forum for providing accurate prognostic information; whether the prognosis is that the patient is expected to survive or, at the other extreme, unlikely to benefit from critical care [32,42]. When a decision is made to forgo life-sustaining treatments and change to end-of-life care, effective communication serves the best interests of the patient and can improve the psychological well being of the surviving relatives.

Discussions that prepare families for the death of a patient or to discuss withdrawal of life support are an increasingly important part of a critical care physician's practice [30,43–45]. Interviews with surrogate decision makers suggest that accurate and timely prognostic information is preferred [46]. There was, however, no clear preference among surrogates (with surrogates divided for and against) about whether it was appropriate for physicians to make a recommendation about withdrawing life support [47]. Surrogate perceptions of communication and end-of-life care can be improved [48,49] and quality improvement can be assessed by means of several survey tools or outcome measures [50–52].

Among the ethical principles described in the preceding section, autonomy is emphasized in the United States. In contrast, this may not always be the case in European countries, where regional and national practices regarding the role of families in decision making, and legal and medical opinions about withholding or withdrawing life support, vary widely [25,53–57].

END-OF-LIFE CARE IN THE INTENSIVE CARE UNIT

Death remains a common occurrence in ICUs, with an estimate suggesting that as many as one in five Americans die during an episode of care that included an ICU admission [58]. Data from North America as well as Europe suggest that the percentage of patients dying following a decision to withdraw or withhold life-sustaining treatments is substantial, and increasing. Thus, critical care clinicians are effectively "managing" the process of death and dying in ICUs with increasing frequency [43,53,59–61]. A number of problems and challenges have been described in ICU end-of-life care, including the inability to predict outcomes for individual patients early in their ICU course, the difficulty in assessing patient preferences with the attendant challenges of surrogate decision making, communication problems between families and ICU staff, as well as concerns regarding the adequacy of symptom management for dying patients [24,43,59,62,63]. Wide variability in physician preferences and practices regarding withdrawal of life-sustaining therapies has been described [27,64,65].

A number of recommendations and guidelines to enhance care-delivery for dying ICU patients [45,66–73] are currently being incorporated into instruction in end-of-life skill to a broad range of trainees in and residency and fellowship training programs [74]. Quality indicators for end-of-life care in ICUs include domains of care focusing on patient and family-centered decision making, communication, continuity of care, emotional, practical, and spiritual support for patients and families, symptom management, as well as the creation of support systems for ICU clinicians. Ideally, the future of end-of-life care in the ICU will incorporate a range of validated palliative care-derived principles and allow for the development of a more robust evidence-based structure for the provision of such care.

End-of-Life Decision Making

General principles regarding the ethical framework surrounding decision making in the ICU setting are outlined in prior sections of this chapter. In the United States, there is substantive consensus, as well as legal support, for several ethical principles of particular relevance to ICU practice. These are (i) a distinction can be drawn between acts of killing, and allowing patients to die; (ii) withholding and withdrawing life-sustaining treatments can be considered equivalent; and (iii) the "doctrine of double effect" permits assertive symptom treatment with medications at the end-of-life even if death might be inadvertently hastened (an unintended, albeit foreseen potential consequence of such medication use) [43,75–79].

Patient- and family-centered care is increasingly being viewed as an ideal model for patient care in ICUs, and this naturally extends into the arena of end-of-life decision making as well [43,80,81]. Involving patients' families and surrogates in this process is of obvious importance, given the high percentage of ICU patients lacking decisional capacity [82,83]. A number of factors may influence physicians' attitudes and recommendations regarding end-of-life questions, but most importantly, clinicians must integrate their patients' views and values into a given care plan to establish goals of treatment that meet the needs of patients and families, in addition to being clinically realistic. Communication between all parties involved in a given case is the means to achieve this goal. Effective communication with clinicians is of great importance to family members, and in fact, families may rate a given caregiver's communication skills as equally or more important than their clinical skills [84,85]. Yet, despite the importance assigned by families of critically ill patients to communication issues, data suggest that ICU caregivers frequently fall short of family expectations in this regard [31,74,84–86].

A variety of strategies for improving end-of-life communication have been evaluated, and there is an evolving set of recommendations for the conduct of clinician-family conferences in the ICU [34,36,38,43]. In general, clinicians should focus on spending more time listening to families during conferences, acknowledge and address families' emotions, as well as encourage questions from family members. The use of the mnemonic VALUE during family meetings has been examined as a tool for the conduct of these meetings, and there is data suggesting that such structured approaches to communication not only facilitate real-time communication, but also reduce psychological morbidity of ICU patients' families [38].

The largest issue for all parties involved is ultimately the *content* and *focus* of these discussions, namely, how best to

meet the needs of a given patient. For families, the acute onset of life-threatening critical illness may be a singular, unprecedented event, whereas ICU staffs encounter death and dying on an almost routine basis. Therefore, it is of particular importance to consider communication an ongoing, dynamic process with a timeline that will vary from case to case, as families grapple with the need to fathom the patient's wishes (if not explicitly known) in addition to dealing with their own responses to a given situation. Clearly, there is no universal "blueprint" to delineate how to best guide patients, families, or surrogates through the process of decision making in the ICU, as every individual case has unique aspects. Conflict may arise at any point in a patient's care, and it may occur among members of the care team, among family members, or between the clinicians and family members. Timely, open, and honest communication may be the best strategy to avoid or ameliorate such conflicts, although on occasion outside agents may need to be engaged for mediation (e.g., ethics committees).

Changing Treatment Goals at the End of Life

The perspective that intensive care and palliative care are incompatible with each other is being replaced by the opinion that the need for restorative and palliative care coexists along the illness trajectory, with varying emphasis being placed on one versus the other as treatment goals are re-defined [80,87,88]. Once a decision has been made to forgo further curative treatment endeavors, any treatment or intervention ought to be scrutinized regarding its potential to advance the goal of maximizing comfort [89,90]. In general terms, the needs for pain relief, freedom from anxiety and agitation, relief of dyspnea, and the provision of spiritual support, if desired, become the predominant focus of care [90,91]. Ideally, clinicians should explore individual circumstances and adjust their approach on a case-by-case basis as needed.

Withdrawal of Life-Sustaining Treatments: Practical Considerations

Prior to the withdrawal of life-sustaining treatments, clinicians must inform the patient (if interactive) and the patient's family/surrogates about what to expect during this process. They need to be reassured that the patient's comfort will determine medication administration and the tempo with which the withdrawal process occurs. Family members and friends must have as much access to the patient as needed, and can be encouraged to participate in caregiving to an extent commensurate with their abilities and desires. The ICU staff should attempt to modify the patient's immediate environment to create as peaceful a setting as possible. Any unnecessary equipment, monitors, tubes, drains, and lines should be removed. The withdrawal of mechanical ventilation is unique in that its abrupt cessation can potentially cause suffering. Interventions such as pacemakers, defibrillators, vasopressors, intravenous fluids and nutrition, renal replacement therapy, as well as any medications that do not further the goal of maximizing comfort should therefore be discontinued prior to ventilator withdrawal. The cessation of artificial nutrition and hydration at times raises concerns for clinicians and families alike, potentially for a multitude of reasons [92]. Thirst, for example, may be a concern that can be managed without enteral or parenteral hydration by ice chips or other methods moistening the mouth [93]. Despite such concerns, there is little evidence to suggest that the maintenance of artificial nutrition and hydration contributes to a dying patient's comfort, and it may in fact be associated with complications (e.g., feeding tube malfunction, unintentional dislodgement, nausea) [93–95].

As these initial steps are taken, the patient must be closely observed for any signs of distress, such as grimacing, tachycardia, hypertension, accessory muscle use, sweating, and restlessness. Such symptoms can be treated with opioids (for relief of pain and dyspnea) and sedatives (e.g., benzodiazepines), often in combination. Clinical practice guidelines for the use of sedatives and analgesics in critically ill patients have been devised, applying to patients who are expected to recover, as well as those who are dying [91,96]. Clearly, the situation of the dying patient differs from that of the patient for whom curative therapies continue, but some common themes remain. Systematic symptom assessment with documentation and individualized medication administration is of utmost importance. Once the patient is comfortable, ventilator support can be withdrawn. This can occur either by immediate extubation of the patient, or through a process of gradual reduction in ventilator settings. Either approach is acceptable, assuming that clinicians use anticipatory medication dosing appropriate to the change in level of patient comfort that is predicted in response to a given intervention. In actual practice, a range of physician preferences has been reported [97]. Whether or not to ultimately extubate the patient (if the weaning approach is employed) depends on a variety of factors, including the patient's and/or family/surrogates preferences and airway considerations (e.g., edema, volume of secretions), among others.

Systematic investigation of clinical practice and patient preferences has improved the care of ICU patients. The studies cited above have our enhanced ethical reasoning and decision making for patients during all phases of their ICU care.

AN ETHICAL GUIDE TO RESEARCH

Clinical research involving critically ill persons is necessary and poses important ethical challenges. Significant research efforts in critical care medicine have enabled clinicians to improve outcomes and quality of life of those lives saved. Although the ICU remains the ideal environment to evaluate the effects of novel therapeutic agents and cutting-edge technologies, clinical research in this setting raises considerable ethical challenges. We continue to apply ethical principles to support the risks, benefits, and possible burdens of research protocols, yet many legal and ethical aspects of critical care research remain ambiguous. Ethical issues elicited by research require an acceptable balance of benefit and risk, the requirement for clinical equipoise, and the requisite for a valid informed consent process [98]. Nonetheless, concerns about the clarification of the boundary edge between research and clinical care continue to exist, with ethicists debating approaches that may help subjects better recognize the distinction between research and treatment [99]. This failure to understand which parts of ICU activity is research constitutes the *therapeutic misconception* [100] and may result in an overestimate of research benefits and an underestimate of risks. The next section discusses contemporary issues challenges encompassing research and medical ethics in the ICU.

ETHICAL PRINCIPLES APPLIED TO RESEARCH

Research involving critically ill persons is governed by ethical principles. In response to flagrant exploitation during human experimentation in the course of the World War II, The Nuremburg Code set standards for medical experimentation

on humans, establishing that voluntary consent of the human subject is absolutely essential. Subsequently, the Declaration of Helsinki asserted a voluntary consent requirement, and further affirmed that participants in research must possess the right to self-determination (choose to participate) and the right to make informed decisions regarding participation in research, both initially and during the course of the research [101]. The Belmont Report in 1979 articulated the boundaries between research and clinical practice, and identified the principles of autonomy, beneficence, and justice as the ethical underpinnings of ethical research [1]. Defining the boundaries between research and practice, the Belmont Report stated that *practice* refers to interventions intended to better the well-being of a patient and that these interventions have a likely expectation of success, whereas the term *research* was defined as activity designed to test a hypothesis, allow conclusions to be made, and therefore contributes to generalized knowledge. Three basic principles were described, including respect for persons (autonomy), beneficence, and justice. Applying these principles into practice and at the same time adhering to federal regulations, researchers must execute these concepts in an unbiased fashion and with proper clinical judgment to protect the interests of the research subject and assure the integrity of a study.

Autonomy

The informed consent process is an application of the principles of autonomy, with features highlighting disclosure, comprehension, voluntariness, and competence in making a decision to participate in research. The first principle, autonomy, or the right to render independent decisions, requires that the researcher discuss the trial fully in terms that the subject or their designee will understand the process of informed consent and will protect those persons unable to make an informed decision [82]. During these discussions, study risks, procedures, benefits, alternative treatment options, and study-related questions are reviewed. The informed consent process should document understanding and agreement to study participation by a subject who is competent and independent. Ongoing communication with the subject or their designee during the trial is necessary to maintain informed consent and avoid potential conflicts.

Beneficence

Beneficence in research differs from beneficence in clinical care since the actual benefits of research procedures are frequently unknown. Many participants in research trials remain unaware of study design implications, including the possibility of random assignment to a placebo control or comparison group. Although some subjects may participate in research to promote societal benefits, most enroll to achieve direct benefits [102]. Potential study participants may believe they will receive the treatment that is best for them rather than what is best for science. This perception of benefit could inadvertently induce subjects to enroll in research. Consequently, the investigator must attempt to challenge the "therapeutic misconception," the mistaken belief that the research will directly benefit the subject, which draws subjects to research trials. To do so, the investigator must clearly define benefits (if any) and risks, and the study must be monitored for occurrence of anticipated and unexpected risks.

One commonly accepted ethical requirement of randomized controlled trials is uncertainty or equipoise about the interventions being compared. Clinical equipoise [103] ensures a genuine parity in terms of benefit, harm, and uncertainty between therapeutic interventions that subjects would receive as part of clinical practice and the associated potential risks of nontherapeutic interventions (research) of a clinical trial [104]. Investigators should always inform subjects or their surrogates of the difference between an established therapeutic intervention and a nontherapeutic research intervention.

Justice

The principle of justice in research deals with who should receive the benefits of research and who bears the burden. These risks and benefits should be shared equally among all eligible patients in our society. Recruitment of both underserved and underrepresented groups assure each participant's ethical participation in research trials as well as securing the practical objectives of recruiting and retaining a wide range of study participants so as to ensure that the results from clinical trials are generalizable to larger populations. It is the investigator's responsibility to ensure that each subject fully comprehends the study, inclusive of any man, woman, or minority that speaks or reads a language other than English.

Informed Consent for Intensive Care Unit Research

Informed consent is an essential prerequisite for most human trials and is a process for patients and the research staff to come to a common understanding about the uncertainties of the research trial. The five elements of informed consent [82] require the following:

1. The person consenting must be competent in making medical decisions.
2. The information relevant to the person and his or her situation must be disclosed.
3. The person consenting must be able to understand the information.
4. Consent must be voluntary and free from undue influence or coercion.
5. The person must authorize treatment in a clinical investigation.

Because patients are frequently unable to give their own consent, and ICU research is often complex and unfamiliar, it is more difficult to fulfill the five elements of consent for research on ICU patients than for most other groups of patients. Legal experts and ethicists have continually emphasized the importance of transmitting information to potentially participating subjects during the entire process of consent. This process also requires several evaluations including the assessment of the decision-making capacity and competence of the prospective research volunteer. The ability of individuals to incorporate the information needed for providing effective informed consent must be established by assessment for decision-making capacity [105]. The decision making capacity doctrine refers to determination that the potential participating subject has the following abilities:

1. Possesses a comprehensive understanding of the study objectives relevant to the decision to volunteer;
2. Has the ability to weigh the possible risks and benefits of the study and alternative options to participating in a study;
3. Reasoning ability to incorporate the information with personal priorities, values, and consequences;
4. Awareness of their (subject's) right to withdraw from a trial at any time.

Decision-making capacity is generally interpreted to be task specific. That is, a prospective subject may make an informed

decision about participating in a trial involving a simple procedure, but not a more complex process. As an illustration, though a potential subject for a trial may be judged legally incompetent to manage their financial affairs, they may maintain sufficient decision-making capacity to make meaningful decisions about participating in a clinical study or choice of medical treatment. A variety of assessment scales (i.e., mini mental state exam) may be employed to determine decisional capacity; formal and less formal assessments are allowable and the relevancy of the exam will depend on the specific research protocol to be done [106]. When prospective participants are temporarily incompetent or lack decision-making capacity due to serious illnesses, either the subject cannot be enrolled or a designated surrogate can provide consent.

A barrier to enrolling ICU patients in research studies is the information that must be provided to obtain consent. Studies of the consent process show that patients and surrogates frequently fail to understand consent documents, and many cannot distinguish between research and routine care [107]. At the center of the issue is a fundamental conflict between two components of informed consent: full disclosure of relevant information, and understanding of the information by the prospective participant of the study. With the scientific language and complexity of clinical trial methodology, it is highly likely that most participants with insufficient skills will have difficulty totally understanding the study's objective(s) and the consent form. Moreover, when developing an informed consent document that enhances readability, simplification of the document may unintentionally render it ambiguous or perhaps too appealing. Though informed consent documentation is essential to obtain, time spent in conversation with prospective study subjects to assist the subject in better understanding the research project is vital. Informed consent is not only a brief discussion to obtain a signed document, but is a process that continues throughout the clinical trial. Consequently, improving the consent process is an important challenge to the immediate future of critical care research.

SURROGATE CONSENT

Federal regulations for the protection of human subjects defined under the "common rule" state that "no institution may involve a human being as a subject in research unless the investigator has obtained the legally effective informed consent from the subject or the subject's legally authorized representative" [108]. The term *legally authorized representative* (LAR) may be interpreted specifically to mean a court-appointed guardian, or more broadly to mean individuals who are authorized under state law or rules of the institution to serve as a proxy decision maker for clinical decisions. Consequently, all research trials must require that surrogate consent be obtained from the subject's legally authorized representative/surrogate decision maker in conditions of critical illnesses in which potentially effective therapies or research interventions need to be initiated within a specific time frame and that documentation of the presence of cognitive impairment, lack of capacity, or serious life-threatening diseases and/or conditions of the prospective subject exists. Currently, most institutional review boards (IRBs) in the United States with laws that sanction surrogate consent for overall medical treatment permit family members to serve as LAR for research. Surrogate consent for participation in a research study should be employed to the extent that it is consistent with the intent of the Common Rule 45 CFR 46, (Subpart A) and all other federal and state laws pertaining to the protection of human subjects participating in research [109].

One approach to recruit patients in studies, while simultaneously preserving sound ethical research and patient autonomy, is to include employing a consent option [110], whereby surrogate consent is initially obtained to enroll a patient in a trial, and the consent process is repeated (continuing consent) when the subject regains competence. This consent option allows a patient to refuse continuing participation but can preserve important collected data.

Some acute care research can proceed under a waiver of informed consent for interventions that may be medically necessary or require emergency treatment. In 1996, federal regulations established a policy for a waiver of informed consent for a limited class of research in human subjects who require emergency therapy and due to the subject's medical condition and the unavailability of a LAR, no legally effective informed consent can be obtained. This amendment (21 CFR 50.24) [111] permits a waiver of informed consent so that the patient may become a subject in a random assignment emergency research project that may include a placebo arm. Under the terms of the waiver, consent would be waived in certain life-threatening circumstances, including: the person requiring emergent action to save his or her life; the person is not capable to provide informed consent as a result of the condition; a surrogate is not readily available to obtain consent within the clinical trial window; the available therapies are unproven for this life-threatening condition; or the collection of scientific evidence is appropriate and necessary to evaluate safety and effectiveness of a particular intervention. A recent survey indicated that a majority of those surveyed concur with the potential benefit of allowing subjects to participate in an emergency research study without prior consent. Yet approximately 30% of persons would not be willing to choose to participate in emergency research or provide consent for their family members despite knowledge about the process [112].

INSTITUTIONAL REVIEW BOARD

Local review boards (IRB) at each institution in the United States represent one essential component of the multiple protections for research subjects. IRBs are overseen by the Office for Human Research Protections (OHRP), the agency responsible for evaluating local IRB compliance with federal regulations for protection of human research subjects, and by the Food and Drug Administration [113]. IRBs assure that research protocols are conducted ethically, that the research question is potentially beneficial and scientifically sound, and that risks to the subjects are minimized. In practice, much of the focus of an IRB review is the adequacy and accuracy of the information provided in the informed consent document to permit potential subjects to understand risks and procedures in a research study.

Individual IRBs have latitude to interpret and apply the federal regulations. The process of approving research protocols differs among institutions and may be attributable to state and local practice (laws, institutional polices, professional, and community standards). Variability in approving IRB research proposals can also be due to differences in the interpretation of the federal regulations [114]. It may be necessary for the OHRP to clarify regulations if IRB decisions deviate from the original intent of federal regulations. Review of multicenter clinical trials by a central IRB is another method to reduce unwarranted variations among IRBs and to also address ambiguities of the federal regulations.

QUALITY IMPROVEMENT INITIATIVE OR RESEARCH?

In recent years, quality improvement (QI) initiatives have become more interventional and are often tied to

cost-containment efforts. Review of the federal definitions of research related to typical QI activity suggest that much QI activity should be categorized as research because it may not benefit the patient and may represent a potential burden or risk. Without informed consent, much QI activity could be considered a violation of the principles of the Belmont Report. The purpose of QI activity is generalizable knowledge, but defining when this is research is difficult. Casarett et al. [115] suggest that a QI intervention is appropriately called research if the research subjects need protection as the patients involved in the project are not expected to benefit from the knowledge gained and are subjected to additional risks beyond usual clinical practice. Bellin and Dubler [116] concluded that studies using a control group are considered research; projects that carry minimal risk (data collection) are more readily characterized as not research, whereas riskier projects require independent review. Generally speaking, quality improvement initiatives are not anticipated to have any application beyond the specific organization in which they are conducted. If the goal of the project is to evaluate the accomplishments of an established program and information acquired from the evaluation improves a local program, the activity should not be deemed as research activity. On the contrary, when a quality improvement project involving human participants is testing a newly modified or untested intervention or program to establish its effectiveness and is applicable elsewhere, whether in published form or not, this activity would be considered human participant research and subject to IRB review. QI research has recently been addressed by the OHRP in response to a quality improvement research project seeking at reducing catheter-related infections in 103 ICUs at 67 Michigan hospitals [117]. The initial OHRP conclusion that the initiative constituted human subjects research requiring IRB review was based on the doctrine that informed consent was necessary for quality improvement research involving multiple centers. Given that informed consent for this study evaluating a protocol designed to routinely implement five evidence-based procedures could not have been obtained, does the absence of consent violate any important infringement of patient autonomy? A further review by the OHRP concluded that the initiative was being used solely for "clinical purposes and was not considered medical research or experimentation" [118]. In this specific case, the quality improvement interventions were not experimental but rather safe and demonstrated compliance with evidence-based procedures. Accordingly, patients were not rendered to be at greater risk than that provided by routine clinical care. Further discussions are warranted to reach consensus on the ethical and regulatory viewpoint to waive informed consent for low-risk research where the logistical situation may not allow for consent to be obtained, and consent would not necessarily offer significant protection for subjects.

HEALTH INSURANCE PORTABILITY AND ACCOUNTABILITY ACT

The Health Insurance Portability and Accountability Act (HIPAA) regulations established a federal minimum on the protection of patient privacy [119]. HIPAA regulations mandate appropriate confidentiality safeguards for medical records research without subject authorization. Recent proliferation of electronic health records and computerized research of these records have raised concerns about privacy of health information. Some argue that informed consent should not be required for research of databases because of the potential benefits to society, the minimal risks to the patients involved, and the impracticability of obtaining consent from all patients. One approach is to acquire a limited dataset, omitting information that might permit patient identification. An IRB may authorize a waiver of consent under specific regulations including when a study intervention is minimal risk (e.g., collection of routine data) and does not alter routine care. The rationale for study without consent is that the research involves minimal risk to the subject and these patients would consent if they could be informed, the waiver will not adversely affect the subject's rights and welfare, the research could not be performed without a waiver, or the subjects will eventually be provided with additional relevant information after participation. In our publicly funded health system, patients have a social obligation to allow their de-identified health care data to be used without their consent so that the health care system can be monitored and benefit all. For certain data registry subcomponents such as collection and storage of biological samples and direct patient interviews, consent should be obtained. Some critics suggest that the HIPAA regulations or restrictive interpretation of these regulations will lead to further barriers to clinical research, diminish the volume of research, and discourage institutions from making medical records available for research. In one national survey, HIPAA, researchers reported that privacy rules have added significant costs and delays to the conduct of research in the United States and negatively influenced the conduct of clinical research [120].

SUMMARY

Decision making about goals of critical care, end-of-life care, and participating in clinical research is influenced by a long history of ethical reasoning, legal judgments, and clinical considerations. The evolving practice of shared decision making for critically ill persons is being shaped by our understanding societal values and the impact of ICU care on patients and their families.

CHAPTER 212 ■ ASSESSING THE VALUE AND IMPACT OF CRITICAL CARE IN AN ERA OF LIMITED RESOURCES: OUTCOMES RESEARCH IN THE INTENSIVE CARE UNIT

ANDREW F. SHORR, WILLIAM L. JACKSON JR AND DEREK C. ANGUS

During the last three decades, critical care has matured to a distinct medical specialty. Sepsis, respiratory failure, and the care of the complicated postoperative patient are now perceived as the purview of the intensivist. Concomitant with this evolution in critical care medicine has been a growing focus on health care outcomes. This emphasis on the end points and effects of medical care generally and critical care specifically reflects the realization that critically ill subjects face a high risk of death and that many interventions applied in the intensive care unit (ICU) are expensive. Some older studies estimate that nearly 1% of the gross national product of the United States is consumed in the ICU and, relative to days spent on hospital wards, others suggest that ICU costs are nearly three times greater [1,2]. Whether it is mechanical ventilation (MV), extensive nursing care, or acute dialysis, many of the technologies and medications used in the ICU are associated with substantial economic costs. In addition, many often perceive that ICU interventions only delay mortality rather than prevent mortality, or that mortality reduction in the ICU comes only at the price of significant morbidity. Thus, there is increasing pressure to carefully evaluate and to understand the results of ICU care. This pressure becomes even more evident when one considers that ICU outcomes must be evaluated from both patient and societal perspectives. In other words, the emphasis on outcomes in the ICU reflects an underlying question about value.

Outcomes research reflects a systematic effort to address these issues and concerns. According to a recent position statement on outcomes research in critical care, "Outcomes research is employed to formulate clinical practice guidelines, to evaluate the quality of care, and to inform health policy decisions" [3]. Like clinical critical care, outcomes research draws on many different tools and expertise in multiple disciplines. More than only an issue of economics, outcomes research requires expertise in psychology and anthropology (to understand patient and physician behavior), epidemiology (to identify disease patterns and burdens), and health services research (to appreciate process) [3]. Use of a term like *outcomes*, though, presupposes a question: Outcomes for whom? At the bedside, the clinician or the investigator focuses on pathophysiology of a sole patient. Outcomes research addresses broader issues. Rather than being either centered on a particular disease or a physiologic measure, outcomes research deals with the overall results of care for the patient, for the family, and for society. Also in distinction to traditional clinical research, outcomes research has clear policy aspects as well; it attempts to facilitate debates about competing plans for resource allocation, research priorities, and national health policy. As an example, a randomized clinical trial deals with issues of efficacy (Does intervention "*x*" in a controlled environment have an independent impact?) and outcomes research is more concerned with effectiveness (What are the implications of intervention "*x*" applied outside a controlled setting and in the "real world" for the patient and society?). Traditional clinical research, moreover, often employs experimental approaches, and observational methods are routinely used in outcomes research. In short, outcomes research attempts to use methods from the social sciences to augment the understanding of health care as opposed to using only methods from conventional "hard" sciences. As a recent summary regarding outcomes research in sepsis indicated, the outcomes researcher seeks to answer a question separate from traditional research [4]. The clinical investigator essentially asks, "Does this work?" and outcomes researchers deal with the concern, "Does it help?" [4].

Readers should note that outcomes research is now a key component of the biomedical enterprise. It is no longer seen as an option or an add-on. It fits with mechanistic and clinical work in building the triumvirate of information needed to translate research findings into clinical practice. The absence of outcomes studies can lead to the failure to adopt what otherwise might be useful interventions.

METHODS IN OUTCOMES RESEARCH

Outcomes research relies on multiple methods for exploring patient-centered concerns. Generally, researchers employ both qualitative and quantitative methods [3]. Qualitative approaches are only occasionally used but can offer insight into complex processes that do not easily lend themselves to standard hypothesis testing. As such, qualitative work often results in the generation of important hypotheses for more formal testing. Quantitative methods are more standard in outcomes research in critical care and have two general aspects. First, they use some tool to measure a particular outcome (e.g., mortality, quality of life, functional status, cost). Second, quantitative techniques then seek to compare the outcome of interest between at least two alternatives. Unlike the controlled environment of the bench laboratory or even the randomized controlled trial (RCT), outcomes research is necessarily exposed to multiple potential confounders that can and do affect the primary measure of interest. Because critical care outcomes research remains patient-centered, it is important to acknowledge that these subjects bring with them complexities that may alter their mortality, quality of life, and function. Moreover, the impact of these preceding factors may affect a researcher's end point of interest in ways that have little to do with the

intervention under study. Similarly, after any intervention in the ICU, many post-ICU variables come into play that might affect the results of an outcomes study.

To address these complexities requires adoption of various techniques, all of which must be rigorous and reproducible. Therefore, outcomes research relies on more than simply RCTs. RCTs are well suited for deciding if specific interventions or agents can alter an easily ascertainable end point such as mortality. For example, use of large sample sizes combined with both block randomization techniques and protocols for patient care help to ensure that the potential confounders previously noted are minimized and, in turn, allows one to explore questions such as how low tidal volume MV affects mortality at day 28. But if the policy or research query deals with the functional status or total cost of care for survivors of acute respiratory distress syndrome (ARDS) more than a year after their hospital discharge, one may require additional approaches other than an RCT. In any event, critical care outcomes research begins by defining a particular question. The investigator can subsequently determine which approach is most appropriate.

In fact, sometimes outcomes research requires entirely separate study designs and major modifications to traditional models of clinical research. In other cases, more traditional models of investigation can be expanded to incorporate outcomes measures. This generally requires building these measures into the trial during the study inception phase. Therefore, outcomes research can be seen as an extension and complement to standard research practices. In other areas of medicine, such as rheumatology, patient-centered measures such as quality of life have come to serve as the primary end point in clinical studies.

Observational Studies

Of the various types of observational studies (e.g., case series, case-control, cross-sectional, and cohort), two are particularly important in critical care outcomes. A cross-sectional design has the advantage of looking at one precise time or over a short period of time at a specific disease or practice. This snapshot-in-time approach can provide important insight into both epidemiology and health services research. For example, a recent 1-day international survey of respiratory failure in the ICU demonstrated the burden of this disease relative to other diseases treated in the ICU and also documented the wide range in practice style with respect to the use of MV [5]. The Sepsis Occurrence in Acutely Ill Patients (SOAP) study, a European sepsis registry using an essentially cross-sectional design (it covered a set 2-week period) confirmed the burden of sepsis in the ICU and underscored the variability in the use of various medical therapies in the care of these patients [6]. Hence, these cross-sectional analyses generated important information about the current state of affairs and therefore provided a potential benchmark for use in future comparisons.

In addition, cohort studies are valuable components in outcomes research. With this strategy, subjects are selected based on some common characteristic (e.g., a diagnosis, a risk factor) and then observed [7]. Thus, cohort analyses have the advantage of being prospective. Cohort studies also specify a set starting time for the observation (e.g., time zero) from which observations proceed forward. Researchers can then look at the interplay of certain predefined risk factors or interventions and the characteristics that defined the cohorts to see how these affect the outcome. Often a cohort design is used to either describe the natural history of a disease or to assess quality of life. Although theoretically straightforward, cohort studies pose important challenges to the researcher. Selection bias and the inherent heterogeneity of critically ill patients can confound efforts to create a homogeneous cohort. Similarly, one needs to ensure means for capturing multiple potential exposure variables and acknowledge that the interaction between risk factors, exposures, and time is complex.

As Needham et al. [7] and Dowdy et al. [8] indicate in a recent review of methodologic issues associated with cohort studies, this study design has three key components: subjects, outcomes and exposures, and time. Subjects must be carefully identified, but the cohort study gives the researcher flexibility to define the population as sharing particular characteristics, such as common diagnoses, or risk factors. Alternatively, cohorts can be developed such that two groups emerge: individuals exposed to a particular event or variable and those not exposed. As a result, one can, using this technique, begin to draw conclusions about causal relationships. Generally, because the cohort shares some common time of designation (e.g., time zero) by observing the population one can evaluate the strength of the relationship between the given exposure and the outcome. Unlike the rigidity of an RCT, in which randomization works to ensure study groups are similar except for the intervention in question, a cohort design provides the researcher the chance to explore multiple exposures simultaneously, and how they interact with each other. To the point, in an RCT of a novel treatment for sepsis, any differences seen in outcomes should be a function of the particular intervention experimentally introduced. The ICU organization, pre-ICU care, and posthospital events should not affect the outcome because randomization should ensure that the impact of these variables is equalized between the active and comparator groups.

The purpose of a cohort study is to enhance the RCT by providing information that cannot, by definition, be gleaned from the RCT. Expanded adoption of cohort studies can also facilitate better understanding of natural history by shifting the focus back to a time prior to ICU admission. Without some initial work with adopting a cohort approach, we cannot hope to address significant questions relating to what determines which patients get admitted to the ICU, who most likely benefits from ICU care, and the outcomes for those never admitted to the ICU.

INTERVENTIONS AND END POINTS IN CRITICAL CARE OUTCOMES RESEARCH

Unlike traditional biomedical research, which looks at either novel technologic interventions (new drugs, new devices) or perhaps management strategies, the interventions studied in outcomes research are more diverse. Certain clinical measures have significant outcomes implications for the patient and society. However, managerial and organizational changes may be equally important. The issue of management and organization of critical care services is particularly acute at present, given current (and conflicting) data suggesting that the model of ICU administration affects both mortality and cost [9,10]. The question of organization and management is broader than simply whether one uses a closed, full-time intensivist model or a more traditional open ICU model. Under the rubric of organization and management are questions of nurse-to-patient ratios, the role for respiratory therapy, and the value of a dedicated critical care pharmacy group. Measuring how these types of potential features of the ICU work and whether they help patients and society is perhaps as important a question as if a new molecule for sepsis alters mortality. Issues of management and organization can provide feedback to affect the conduct of traditional research. Whether it is studies of resuscitation strategies or rapid response teams, these types of interventions

include service, delivery, and organizational aspects. If any one of these components of the trial collapses, the entire venture may be jeopardized.

Mortality

With respect to end points, mortality remains the center of investigative efforts because it has tangible meaning to the patient, to health care institutions, and to society. When outcomes research addresses mortality, it tries to do it in an appropriate context. In other words, the question of mortality begs the question of when? Is the appropriate timeframe survival to ICU discharge or to hospital discharge? Are these time points too myopic? Altering long-term mortality (e.g., 2 years after ICU admission) would be an admirable goal. Historically, 28-day all-cause mortality has served as the primary end point for trials in critical care. However, after some period of time it seems reasonable to postulate that occurrences and interventions in the ICU diminish in their impact while the patient's age [11] and health state prior to his or her ICU admission [3] become the main drivers of outcomes. Thus, the issue revolves around the timeframe chosen for measurement and its likely mechanistic link to the intervention under evaluation [12].

It is important to be cautious, though, since one can artificially alter ICU mortality by early use of certain interventions (e.g., tracheotomy in order to facilitate transfer to a chronic ventilator care facility). Likewise, decisions about when to suggest withdrawal of care can alter the apparent timing of death in the ICU. The central limitation is that with all time-dependent end points, there can be confounding by multiple factors. As the recent American Thoracic Society position statement on outcomes research appropriately observes, "The 'correct' mortality endpoint depends on the specific research question, the mechanisms and timing of the disease and/or treatment under study, and the study design" [3]. In addition, if a disease state is not associated with significant mortality, use of this measure may simply fail to capture the value of a particular intervention. Finally, mortality as the sole end point of any research ignores the entire concern about morbidity and the tradeoff between mortality and morbidity. Similarly, it fails to address the quality of life of the survivor.

Mortality, moreover, has limitations as a tool for comparing outcomes across different ICUs. Although recorded and tracked nearly uniformly in ICUs throughout the world, ICU mortality is a relatively uninformative measure of ICU performance. Extensive variability exists in not only the types of patients admitted to different ICUs but also in admission and discharge policies [12]. Some ICUs serve as major referral centers for and receive multiple transfers from other hospitals. These patients tend to be sicker or in need of specialized care. Hence, the mortality rates of the ICUs that send these persons elsewhere may be artificially low compared to the ICUs that accept such high-risk cases. Similarly, ICUs with intermediate-care facilities can transition individuals out of the ICU at different rates than ICUs lacking access to these resources. This fact can alter apparent ICU mortality rates because one might essentially be able to transition patients receiving comfort care only out of the ICU so that when they die the death is not captured as an ICU-related event.

One could correct for these possible variables by employing a definition of ICU mortality (for benchmarking performance) that removed transfers from both the numerator and denominator of the crude mortality rate. Adjusting for differences for availability of "stepdown" wards can be made by limiting comparisons to like-sized hospitals. However, even these efforts would be insufficient for purposes of performance and quality assessments because issues of case-mix remain unaddressed. Case-mix as a concept tries to capture that different ICUs admit different types of patients with differing severity of illnesses. It is important to note that case-mix as a concept describes more than differences in disease severity [13]. Case-mix adjusting tries to balance issues with underlying diagnosis, comorbidity, age, and severity of illness [13]. To illustrate the breadth of the aspects related to case-mix one need only consider an ICU that cared for only postoperative cardiothoracic patients should report low mortality rates and an ICU that admitted mainly immunocompromised persons would certainly describe different outcomes, even after one adjusted for severity of illness. As a corollary, comparing mortality between similar types of ICUs that admit similar types of patients, after controlling for disease severity, can prove helpful [13].

Severity of Illness Tools

To address disease severity, multiple tools exist. They differ with respect to the variables they measure, when they measure these variables, and if they try to describe ICU mortality or hospital mortality. The Acute Physiology and Chronic Health Evaluation (APACHE) score is commonly used in the United States and the Simplified Acute Physiology Score (SAPS) system is more regularly employed in Europe [14–16]. Severity of illness scores have been developed for application in specific types of patients (e.g., pediatrics, trauma) and others try to deal with a broader range of subjects. Other modeling systems include the Sequential Organ Failure Assessment (SOFA) score and the Multiple Organ Dysfunction Score [17,18]. A major limitation of all scoring systems is that they are developed and validated on large patient populations. Therefore, predicted mortality estimates for individual patients cannot and should not be translated into decisions at the bedside as to whether, based solely on predicted mortality, one should withhold or offer aggressive care.

Another concern with severity of illness tools as they relate to mortality is that some were initially created many years ago. Over time, new interventions and technologies have altered patient care and morality. Hence, older iterations of certain models may not longer apply and no longer have adequate calibration to be informative. Like many scales, they require recalibration. As an example, the APACHE system is now on its fourth revision, and with APACHE II versus APACHE IV, there are significant differences in terms of the explanatory power [19]. Nonetheless, in critical care research many have adopted the APACHE II and III approach as its equations are published. Researchers and administrators need therefore be cautious when assuming that similar scores computed by an older rubric necessarily translate into similar predicted mortalities among populations or across ICUs. APACHE generally functions by exploring historical cohorts of patients and creating prediction scores based on this "control" population. Alternatively one can also use the acuity measures used in these instruments to derive from predictions that are specific for the population of interest or under study.

Calculations of the actual scores for patients can also be prone to error. Several studies document significant interobserver variability among even trained researchers as to the calculation of severity of illness scores [20]. With APACHE II, one project revealed that the interrater agreement was strikingly poor ($\kappa = 0.20$) [21]. The main sources of variability appeared to be in assessment of the Glasgow Coma Score but variability was evident even in the determination of the blood pressure. Changes in practice can also have unpredicted effects on severity of illness scores. Nearly all scoring systems rest on measurement of physiologic parameters such as blood pressure, platelet count, and hemoglobin. The more extreme the actual value from the "normal" range, the greater the negative impact of this factor on the individual's composite

severity of illness score. As an example, a low hemoglobin is associated with more APACHE II points than a normal hemoglobin. Clinicians, though, may now be more tolerant of lower hemoglobins than they were when APACHE II was created. In fact, a restrictive transfusion strategy that necessarily allows the hemoglobin to drift lower may improve outcomes [22]. Consequently, APACHE II scores may be rising in ICU patients over time, reflecting this change in practice because physicians are not transfusing as frequently. This increase in APACHE II-predicted mortality when actual mortality might improve because of a change in clinical practice based on a large randomized trial underscores a significant assumption and limitation of severity of illness scoring classifications.

Severity of Illness and Performance Assessment

Mortality prediction equations can also result in calculation of a standardized mortality ratio (SMR) [13]. This ratio compares observed mortality to predicted mortality. Conceptually, the SMR can be calculated irrespective of the severity of illness system used to determine the predicted mortality. Ratios greater than 1 suggest excess mortality and those less than 1 imply enhanced survivorship. Implicitly, an SMR greater than 1 indicates an ICU with inferior outcomes after adjusting for severity of illness case mix. Alternatively, though, differences in SMR can reflect more than quality. First, scoring systems may be generally imprecise (see previous discussion) and may not capture some aspects of disease severity or other case-mix issues. Second, the SMR can be affected by the quality of data collection and by the sample size. There is also discordance in the published literature exploring if and how well the SMR correlates with other markers of ICU quality. Some investigators suggest the SMR sufficiently captures aspects of quality and others conclude that the relationship between other markers of quality and the SMR is less clear [13]. It is likely that no one SMR calculation method accurately reflects quality. Therefore, as policy makers, third-party payers, and patients demand simple report cards that allegedly capture quality, it is important that the intensivist resist the urge to simply publish SMRs without references to case-mix. Some more recent scoring systems address this (i.e., APACHE IV) but still may be imprecise as they derive from historical cohorts. We need to encourage the use of multiple measures beyond the SMR to describe qualitative differences in ICUs.

Nevertheless, the SMR can be used over time to assess interventions within an ICU or group of relatively homogenous ICUs [13]. Although one may not be able to conclude that SMR differences across institutions reflect true differences in quality and performance, when used as a benchmarking tool the SMR can be insightful. If one ICU has historical data about its case-mix and performance, it can then track over time how the SMR varies in response to interventions. Conversely, an increasing SMR can suggest the presence of some change in practice or structure that is adversely affecting mortality. By identifying these trends and investigating them, ICU staff can elucidate potentially harmful changes that have transpired and attempt to address them.

Organ Failures

One effort to move beyond mortality as the primary outcome measure in critical care has been the evolution of the concept of organ failure-free days [3]. The free-day paradigm recognizes that reducing mortality in the ICU may not always reduce morbidity. In fact, reductions in mortality may only increase morbidity by keeping alive for several additional days patients who otherwise would have died but then, nonetheless, succumb to the acute illness. From a different vantage, some interventions may appear attractive on a superficial level because they decrease the duration of either MV or vasopressor support. However, a shorter duration of MV in one population may only reflect a higher death rate in that cohort. In other words, there is a competing impact of mortality in the assessment of such time-to-event (e.g., liberation from MV) phenomena.

These two facts promoted the development of the failure-free day paradigm. As a consensus conference on sepsis stated, this concept evolved out of a need to evaluate "the net effects of therapy" and to try to "integrate mortality with morbidity" [3]. Failure-free days are computed so that each day alive free of the organ failure in question is counted during the specified observation period. If a patient dies before the study termination or requires support beyond this time point, he or she is assigned 0 failure-free days. Historically, failure-free days are measured up to day 28 following the start of an investigation. The 28-day cutpoint, however, is arbitrary and reflects that most trials in critical care use the 28-day mark as the final date for ascertaining vital status. One could follow subjects out further if there were a biologically plausible reason to believe that the intervention under analysis could have an impact to that time point. As an example, if one were interested in MV-free days accrued during the 28 days following a patient's enrollment in a study and the patient died on day 7, he or she would be credited with no ventilation-free days. If the individual required 7 days of ventilation and was alive at day 28, he or she would have earned 21 MV-free days. If remaining on the ventilator for all 28 days, no ventilator-free days would accrue.

The failure-free day approach has the potential advantage of capturing morbidity that transpires outside the ICU, such as the need for continued dialysis, as it is organ system-specific rather than defined purely based on the subject's location of care. It can further account for shifts in a patient's clinical status that might not be measured accurately if a researcher only recorded mortality. A patient with chronic obstructive pulmonary disease, for instance, might require 2 days of ventilatory support initially, be liberated from MV, but then several days later deteriorate and need to be placed back on ventilatory support. This waxing and waning in clinical status can potentially be accurately described from an outcomes perspective with the use of ventilator-free days.

Is it appropriate to pool death with requiring 28 days of MV but still surviving? The fundamental struggle in this question illustrates why organ failure-free days can only be used as an adjunct to other measures of outcomes in critical care. It is certainly not clear that organ failures correlate with meaningful clinical outcomes or if surviving 28 days on a ventilator with a respiratory organ failure is comparable with death. On the other hand, the concept of organ failure-free days allows one to examine if and how a novel approach or therapy might accelerate recovery. In turn, it lays the foundation for the use of pooled end points in clinical trials in critical care. If mortality remains the only primary end point for studies in critical care, then investigators may fail to pursue options that may prove valuable in other ways. The organ failure-free day concept also allows one to capture the effect of interventions on markers of resource utilization and cost. Differences in the use of ventilation, dialysis, and vasopressors have important implications for patients. Simultaneously, because of the costs associated with these interventions, decreasing organ failures and morbidity has ramifications for health care institutions, third-party payers, and policy makers. Future work in this area may in fact move beyond organ failure and try to develop metrics that incorporate this with mortality into a form of quality-adjusted survival measure.

Health Status

From the patient's perspective, surviving the ICU raises many issues. Most patients will require some additional time for further recovery along with the potential need for rehabilitation. Moreover, some physical impairment persists after ICU care, and this impairment can affect functional status, mental health, and quality of life. Globally, each of these concepts (functional state, mental health, quality of life) all attempt to capture the concept of health status. The need for adequate assessments of health status is made more acute given the limitations evident if one has only a sole focus on mortality.

Readers should note that, although the concepts are intertwined, functional status (either physical or mental) is distinct from quality of life [23]. Functional status depicts the subject's capacities and quality of life attempts to gauge an individual's satisfaction and state of well-being. As a result of this subtle distinction, someone who has a major functional limitation may rate his or her quality of life as high while another patient with relatively minor limitations might describe his or her quality of life as poor. Moreover, quality of life essentially relies on using the individual as his or her own control. Persons necessarily rate their quality of life relative to what they perceive it was prior to needing ICU therapy. Functional status, on the other hand, generally measures capabilities relative to a fixed scale of performance that is set irrespective of what the person's prior functional status might have been. As such, functional status tends to be more objective. Quality of life, alternatively, is influenced by a person's values, perceptions, and preferences [24]. Quality of life also is measured in a social context. Assessing an ARDS survivor's lung function provides no insight into how having physical limitations after surviving ARDS alters one's interactions with their family and friends.

Functional status captures physiologic assessments of impairment along with global and mental/neuropsychologic performance. Early outcomes studies in critical care and functional status explored the long-term pulmonary complications of ARDS [25]. Researchers examined how gas exchange and radiographs varied over time in ARDS survivors. Other investigators have used general measures of functional status to describe survivors of ICU care [25]. Often-used tools for this include the 6-minute walk test and the activities of daily living (ADL) system. ADL assessments as a tool have the advantage of being widely familiar to clinicians and easy to implement. Some, though, question their applicability to critical care outcomes [23]. ADLs may be of limited value because they were developed specifically for the elderly. Young survivors of critical illness may recover to a state of function beyond what the ADLs can possibly capture. The information that does exist indicates that severe functional impairment results following ICU care and that it may resolve slowly. For example, Herridge et al. [26], in a prospective observational analysis of ARDS survivors, noted that only 50% had returned to work by 1 year and many reported persistent limitations in their ADLs.

Evaluation of cognitive impairment complements appraisals of functional status. Again, because of the difficulty in assembling cohorts of critical care survivors, the heterogeneity of these patients, and the lack of validated tests appropriate for ICU survivors, limited information exists regarding this as an outcome parameter. In a comprehensive review of this issue, Hopkins and Brett [27] reported that at 1 year nearly a third of ARDS patients had cognitive limitations. A more recent study of a cohort of 51 ICU subjects suggested that 35% of these subjects scored at or below a level similar to the lowest fifth percentile of a normal population [28]. However, over time, 95% had experienced significant improvements in cognitive function [28].

The implications of persistent cognitive impairment are significant because they may portend difficulties with future employment and return to work. Hence, improved evaluations of cognitive recovery after critical illness in clinical trials, and the time course of that recovery, may help identify interventions that can have major implications for our patients. Again, if not incorporated into outcomes research, one cannot determine if and how what we do affects this variable. Likewise, it seems that different approaches to care in the ICU can alter neuropsychologic recovery from critical illness. Specifically, posttraumatic stress disorder (PTSD) is an emerging concern in outcomes research. The incidence of PTSD following an ICU course is unknown, but some survivors report disturbing memories and meet the clinical criteria for PTSD. Outcomes researchers have linked the development of PTSD to previous delusional memories while hospitalized, suggesting that our approach to sedation during the acute phase of a subject's illness can affect the rates of PTSD [29]. Confirming this, Kress et al. [30] observed that the incidence of PTSD approached 33% in persons randomized to standard sedation practices in the ICU and there was no PTSD in those allocated to a strategy relying on a daily interruption of sedation.

Quality of Life

In distinction to functional parameters such as the 6-minute walk distance or even cognitive function, estimating quality of life posses several unique challenges. Determining both the validity and reliability of quality-of-life measures, for example, is difficult. In addition, quality-of-life evaluations represent an intersection of clinical science with social science because many of the tools for rating quality of life rely on psychometrics for their theoretical foundations. Furthermore, the results of quality-of-life determinations can be affected by who is asking the questions and how they are asked. Research documents clearly that a patient and his spouse may score the patient's quality of life differently.

In general, quality-of-life tests attempt to score this on some form of a scale, which may be either continuous or categorical. The survey tool itself is often composed of select items that ask about certain aspects of life, functionality, quality, and so forth [24]. Items that inquire about certain, specific categories or aspects of quality of life are considered to fall within the same domain. Examples of domains routinely used to classify quality of life include pain and impairment, functional status, social role, satisfaction, and death. In reporting the results of quality-of-life testing, both aggregate scores and scores within a certain domain may be reported. The aggregate score often gives a sense of the overall health-related quality of life. Breaking out scores across the various dimensions can presents a profile of how an illness impacts quality of life. In addition, two distinct types of quality-of-life data are regularly collected: health profiles and utility measures [31]. The former generates information regarding the impact of disease and therapies for it on a unique patient. Utility measures, on the other hand, represent the preferences of groups of individuals who share certain common characteristics, such as exposure to like treatments or similar underlying disease states.

Quality-of-life scales may be either generic or disease-specific. Generic scales, such as the Sickness Impact Profile (SIP) or the Short-Form 36 (SF-36), have been developed in large diverse populations so that normal values exist [31]. Using these types of instruments allows comparisons across multiple disease states and various populations. Disease-specific instruments, such as the St. George's Respiratory Disease Questionnaire, may be better calibrated to detect changes over time as they focus on only one disease state or organ system [31]. These disease-specific measures are also focused on aspects of

TABLE 212.1

EXAMPLES OF QUALITY-OF-LIFE MEASURES

Name	Goal	Description	Concepts assessed
Sickness Impact Profile (SIP)	To asses health-related dysfunction	136 items in 12 domains	Physical, psychosocial, other (e.g., sleep, rest)
Short-Form 36 (SF-36)	Survey of general health status	36 items in 8 domains and a summary score	Physical, mental
Nottingham Health Profile	To determine perceived physical, social, and emotional health	Initial part of 38 items and second section of 7 items	Physical mobility, energy, pain, social isolation, emotional
EuroQuol	To measure health state and to determine preferences for 14 hypothetical health states	5 items measured at 3 levels	Physical and mental functioning

Adapted from Chaboyer W, Elliot D: Health-related quality of life in ICU survivors: review of the literature. *Intensive Crit Care Nurs* 16:88, 2000.

quality of life that may be of most concern to that specific group of patients. In other words, there is a tradeoff among rubrics between generalizability and resolution. Therefore, understanding critical care outcomes and ICU care's impact on quality of life necessitates studies using both approaches. Examples of various quality-of-life measures are shown in Table 212.1.

Despite using differing tools, examination of different types of patient cohorts, and issues with follow up evaluation, most quality-of-life research indicates that this is substantially impaired initially in ICU survivors. For example, Tian and Miranda [32] evaluated more than 3,500 ICU patients 1 year after initial admission. Employing the SIP, they observed that scores were substantially reduced among survivors. The main source of the impairment in quality-of-life assessment arose in the area of physical functioning. Interestingly, there was no correlation between the extent of the limitation in quality of life and either severity of illness at ICU admission or the duration of stay in the ICU. Others have confirmed this observation that severity of illness does not explain the limited quality of life reported by some persons. In a cohort of elderly survivors of prolonged MV, Chelluri et al. [33] observed that initial severity of illness as measured by the APACHE III score failed to explain both subsequent functional limitations and lower quality-of-life scores during the year following ICU discharge. Using the SF-36 rather than the SIP, Heyland et al. [34] concentrated on sepsis survivors. Compared to the general U.S. population, scores were significantly lower in nearly all domains. Both physical functioning and social functioning were rated at approximately two-thirds the level noted in a general U.S. sample. However, when analyzed against a cohort of subjects with chronic disease such as either chronic obstructive pulmonary disease or congestive heart failure, the self-reported quality of life of sepsis survivors was similar.

More recent studies have explored how quality of life changes over time after ICU discharge. Most surveys of quality of life represent cross-sectional efforts measuring this at only one time point and therefore provide little information about rates of change in quality of life or how pre-ICU quality of life affects quality of life after discharge. Addressing these limitations, Cuthbertson and coworkers [35] prospectively followed 300 consecutive patients admitted to their ICU. They measured quality of life using two different tools at 3, 6, and 12 months after ICU discharge. At 3 months, quality of life was substantially reduced compared to the subjects' premorbid states. During the ensuing year, quality of life improved and approached the pre-ICU level. Unfortunately, at 1 year, the quality of life of survivors still remained lower than that reported for a general population. Among 109 persons with ARDS, Herridge et al. [26] reported similar patterns in the recovery of quality of life. During 12 months, scores on the SF-36 for physical functioning doubled and those for social functioning rose by 75%.

Several general themes appear in the quality-of-life literature relating to ICU care. First, quality of life is substantially impaired in ICU survivors, but this improves with time after ICU discharge. Second, despite changes in quality of life, this may not return to preadmission levels and the time course of any recovery may be slow. Third, it is unclear what factors contribute to the quality of life of ICU survivors and how interventions in the ICU can affect subsequent quality of life.

Hence, many issues remain unresolved in this area of critical care outcomes research. Plaguing efforts to better comprehend this important patient-centered measure are multiple methodologic issues. As one systematic review of quality-of-life studies concluded: "There is no agreement as to the optimal instrument and [that] differences between studies preclude meaningful comparisons or pooling of results" [36]. These concerns explain why there has been a paucity of work in this area and why one group of investigators observed that fewer than 2% of all articles dealing with general critical care published from 1992 to 1995 dealt with this topic [37]. Despite all these concerns, an expert panel on surviving sepsis endorsed the SF-36 as best suited for outcomes research in critical care [4].

ECONOMIC OUTCOMES

A final aspect of critical care outcomes deals with economic and financial issues. The ICU remains a major focus for concerns relating to cost. Part of this arises from the fact that many expensive technologies are applied in the ICU. Simultaneously, ICU bed days are disproportionately expensive compared with costs related to general ward bed days. Adding to increased cost, sensitivity is a growing demand for ICU care. With the aging of the population, the need for critical care resources will escalate. For example, during the next three decades, the incidence of severe sepsis and septic shock has been projected to rise by 30% [38].

Relative to the entire U.S. economy, it was estimated that, approximately two decades ago, ICU costs accounted for nearly 1% of the nation's gross national product [1]. In a similar analysis, total critical care costs by the year 2000 had nearly tripled from 1984 and now exceeded $55.5 billion annually [39]. As a function of the national economy, however, the proportion of the gross domestic product devoted to the ICU had decreased to 0.56% [39]. Despite this relative fall in the resources consumed by critical care, which essentially reflects the growth of the U.S. economy, the ICU now accounts for one in

seven dollars spent on hospital care in the United States [39]. On a per-day basis, the most recent analyses indicate that costs for the initial day of MV in the ICU exceed $10,000 and fall to $4,000 per day by ICU day 3 when most subjects are clinically stable [2]. In short, from any perspective, whether societal or local, critical care remains exceedingly expensive.

As a result of this economic pressure, patients, physicians, third-party payers, and policy makers are all demanding improved efficiency and optimization of resource allocation. In the United Kingdom, formal cost analyses have become the purview of regulatory agencies, and recommendations from these authorities influence the adoption of new therapies. In the United States, legislation to require formal economic analyses for the approval of new pharmaceuticals is under consideration. Critical care practitioners, therefore, require an appreciation of economics and finance in order to advocate for their patients and the resources they need to care for the critically ill.

A Primer on Economic Analysis

Economic analysis represents a means for understanding and appreciating value in order to facilitate the efficient allocation of scare resources in light of competing claims for those resources. In many scenarios, the criteria employed to determine how to spend limited dollars may not be evident or may be filled with assumptions and bias. The essential goal of economic analysis is to make explicit both the means and criteria used for decision-making. Reflecting the growing significance of economic issues, multiple formal position statements now exist describing both the means to conduct and the implications of financial studies in health care [40,41].

There are several basic varieties of economic analysis in health care: cost-minimization, cost–benefit, cost-effectiveness, and cost-utility. Cost-minimization presupposes that the outcome of interest is fixed and competing approaches are equally efficacious. The main issue, therefore, is which alternative costs less. In critical care, though, few interventions achieve similar results, so a more complex means for comparing options is required. When both costs and outcomes differ, it is necessary to assign the distinct options a value in some common schema (such as dollars). After converting potential results of interventions into dollars, one can proceed with cost–benefit analysis. Cost–benefit analysis is rarely used in health care because many end points are not easily converted into dollar values (e.g., the dollar value of a life) and because cost–benefit approaches may inadvertently assign more value to those who have higher earning potential. Cost-effectiveness acknowledges the limitations of cost–benefit and thus leaves the outcome (or denominator) in clinical terms such that one is now comparing costs per common measure of effectiveness. Often-used examples of this in critical care explore costs per year of life saved or per ICU days avoided. Cost-utility analysis builds on cost-effectiveness analysis by adjusting the clinical outcome for the quality that results from the intervention.

The standard denominator for these types of studies is the quality-adjusted life-year (QALY). The QALY concept acknowledges that a year of life spent in a long-term ventilator facility is not viewed by the patient as being of the same quality as a year lived being fully functional. Although arbitrary, most consider cost-effective interventions that yield a price per QALY saved of between $50,000 and $100,000.

One source of confusion and controversy in economic analysis is estimation of costs. Given the market structure of health care, charges rarely reflect cost. In fact, formal means exist to convert charges to cost based on published cost-to-charge ratios. Analytically, costs can be computed through microcosting, in which the unique costs for each component of care are determined and then summed. Costs can also be estimated based on average bed-day costs. Both approaches have limitations: Microcosting may underestimate the fixed costs associated with care delivery and a bed-day approach assumes that costs remain similar despite the intensity of care the patient requires.

Any conversation about cost, though, has an underlying central question: Cost to whom? This issue of perspective is key in all economic analyses. Some intervention may appear cost-effective to an institution because it shifts costs to a third-party payer. For the payer, though, the intervention will be seen as less than optimal. To address this fact, formal recommendations for the conduct of cost-effectiveness analyses encourage adoption of a societal perspective [40,41]. Utilization of a common societal perspective can also facilitate comparisons across alternatives. However, in critical care, a societal perspective poses specific challenges. As one review notes: "The societal perspective forces consideration of outcomes and costs not usually considered in critical care studies and a time horizon longer than most critical care studies" [13,41].

Uncertainty represents a final aspect of cost-effectiveness and outcomes that merits mention. All estimates for any study's inputs are bracketed by assumptions and uncertainty. The issue then becomes how one's conclusions are affected by this inherent uncertainty. If the costs of an ICU day are half what one assumes, does it alter the outcome of an analysis? Determining the impact of this uncertainty is best done through sensitivity analysis. Sensitivity analysis is a tool for varying a model's inputs across a range of assumptions and seeing if and how the results vary in response to this. If introducing such variability fails to affect the conclusions, one can be more confident as to the strength of the outcomes.

Disease-Specific Costs

Multiple studies in the last several years have attempted to gauge the costs of various diseases commonly encountered in the ICU. These reports help provide estimates of disease-state costs, which can be then used for cost-effectiveness analyses of preventive interventions or be relied on for budget planning.

With respect to nosocomial infection, Warren et al. [42] calculated the attributable cost of a catheter-related blood stream infection (CRBSI) to be nearly $12,000 per event. Their study prospectively followed a cohort of critically ill subjects and compared those developing CRBSIs to those not suffering this complication. In addition, they controlled for multiple potential confounders such as severity of illness, use of MV, and need for dialysis. Blot et al. [43], in a retrospective case-controlled study in Europe, reached similar conclusions. They reported that a CRBSI significantly prolonged the duration of MV and ICU length of stay and resulted in net excess costs totaling € 14,000 [43]. Reflecting these high costs, multiple preventive strategies have been shown to be cost-effective. In an analysis of a multifaceted educational intervention emphasizing the pathogenesis, implications, and prevention of CRBSI, researchers from Washington University demonstrated that their efforts saved approximately $500,000 during the course of a year [44]. Likewise, use of chlorhexidine rather than povidone, adherence to the need for full barrier drapes, and adoption of antibiotic-impregnated catheters have been shown to yield net savings despite their initially high acquisition costs.

Ventilator-associated pneumonia also represents a common and costly ICU-acquired infection. Rello and coworkers [45] observed that the costs of this disease exceeded $40,000 per case. This analysis, though, was limited because it was a retrospective assessment of a large administrative database such that the definition of pneumonia employed might have led to selection bias. Alternatively, Warren et al. [46], in a prospective study of a community ICU, suggested that the costs of

ventilator-associated pneumonia were similar to those reported by Rello et al. Hence, two distinct studies using different approaches reached similar conclusions.

For non-ICU acquired processes, community-acquired pneumonia (CAP) represents a major driver of national health care expenditures by the U.S. government. Describing outcomes in a cohort of patients with severe CAP, Angus et al. [47] suggested that persons with CAP needing ICU care generated total hospital costs in excess of $21,000. Strikingly, this amount was more than 3 times greater than the costs for inpatient CAP not needing ICU admission. From a societal perspective, Kaplan et al. [48] reviewed data from Medicare and calculated that national ICU costs for CAP surpassed $2.1 billion. The financial implications of sepsis are also staggering. Multiple reports document hospital costs per case at approximately $30,000 to $40,000 [49,50]. Costs in Europe seen somewhat lower than those noted in the United States. For example, Adrie et al. [51] prospectively recorded costs for sepsis in six French ICUs. The mean cost of severe sepsis equaled € 22,800. They further described that sepsis costs varied based on whether the infection was community-acquired or evolved while the subject was hospitalized. In attempting to determine cost drivers in sepsis, Burchardi and Schneider [52] reviewed multiple costing reports and concluded that direct costs account for only 20% to 30% of overall costs in sepsis.

Cost-Effectiveness Studies in Critical Care

Coincident with the growing interest in cost-containment in critical care has been a rise in the number of formal cost-effectiveness analyses published in this field. Examples of such analyses have explored multiple resource-intense processes such as the use of MV in ARDS, reliance on renal replacement therapies (RRT) for acute renal failure in the ICU, and drotrecogin alfa (activated) (APC) for severe sepsis.

In ARDS, Hamel et al. [53] used information from the Study to Understand the Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT) to investigate the value of MV. They estimated that ventilatory support was a cost-effective strategy overall, but that the cost-effectiveness ratio varied from $29,000 per QALY saved to $110,000 per QALY based on the subject's initial risk of death. Their analysis was insensitive to patient age as the cost-effectiveness ratio in subjects younger than 65 years was $32,000 versus $46,000 per QALY in those older than 75 years. One strength of this analysis was its close follow-up of patients, and thus the ability to more precisely account for postdischarge health care utilization.

Also using similar techniques, Korkeila et al. [54] investigated RRT. They tracked patients needing RRT and calculated that the costs per 6-month survivor were $80,000. In a comparable study to the one by Hamel et al., the SUPPORT investigators reported that the cost per QALY saved by initiating dialysis and continuing aggressive care was $128,000 [55]. Again, underlying prognosis, not surprisingly, affected the cost-effectiveness ratio. In the best prognosis group, cost per QALY approached $68,000. In the worse prognosis group, it measured $274,000 per QALY saved. The authors concluded that, except in those with exceedingly good prognoses, this approach was not cost-effective. Readers should note that these cost estimates are from nearly a decade ago, and if updated to reflect health care inflation would only reinforce the impression that acute RRT has substantial financial implications for society.

Finally, much emphasis has been placed on estimating the cost-effectiveness of APC because of its acquisition costs. Different groups of researchers have approached this issue from differing national perspectives (e.g., Canada vs. Europe vs. United States) [56–58]. Using data from their own ICU and results from the pivotal clinical trial for APC, Manns et al. [56] concluded that the cost per year of life gained with APC in severe sepsis was $28,000. APC was more cost-effective in persons at higher risk of death as determined by the APACHE II score ($25,000 per year of life gained). Even in older patients with more severe sepsis, APC was cost-effective. Looking at QALYs as a more traditional end point, Angus et al. [57] reached similar results. They computed that APC therapy yielded a cost of $49,000 per QALY gained. This ratio improved further if therapy was restricted to those at higher risk of death ($27,000 per QALY) [57]. Their analysis was most sensitive to the likely duration of survival with the cost-effectiveness of APC deteriorating to more than $100,000 QALY if survivors lived less than 4.6 years. Cost-effectiveness studies conducted from both UK and German perspectives have confirmed the findings of these two analyses [58,59].

Although not a definitive review of the many cost-effectiveness analyses performed in critical care outcomes research, these three examples illustrate that this approach can be used successfully to inform both professional and policy dialogue. They also help to demonstrate the value of ICU care despite its seemingly expensive implications for third-party payers and national governments. Uniformly, these reports illustrate that it is possible to measure proxies for cost rather easily and hence should become routine in the conduct of clinical research. Cost researchers, alternatively, need to be cautious as the time period they choose to study (e.g., short term, intermediate term, and long term) can affect their results and conclusions. Short-term costs may be saved with a novel intervention. Over the longer term, though, what might have appeared attractive economically could result in major costs to society.

CONCLUSION

Outcomes research remains an emerging field in critical care. As appreciation of patient-centered issues expands along with improved understanding of the diseases treated in the ICU, the need for more extensive and refined outcomes research will grow. Outcomes research, fortunately, encompasses a wide area of interest, and patient-centered outcomes can now be better folded into end points of clinical trials. Although methodologic issues continue to exist and further refinement in analytic techniques is required, the practicing intensivist needs to grasp the issues central to outcomes research.

LAWRENCE C. MOHR JR

CHAPTER 213 ■ BIOLOGICAL AGENTS OF MASS DESTRUCTION

ANGELINE A. LAZARUS, ASHA DEVEREAUX AND LAWRENCE C. MOHR JR

OVERVIEW

The use of biological agents in warfare has been recorded throughout history. The first reported biological attack occurred in 1346 when the Tartar army used catapults to throw plague-infected corpses into the city of Kaffa. During the French and Indian War, British forces supplied blankets laden with smallpox to Native Americans supportive of the French. This caused a widespread epidemic of smallpox, leading to the surrender of Fort Carillon by Native American defenders and subsequent outbreaks of smallpox among tribes in the Ohio region [1]. In World War II, a Japanese plane reportedly dispersed rice and fleas infected with the plague organism over the city of Chu Hsien, China. An epidemic of bubonic plague developed in the Chu Hsien region shortly after this event [1].

In 1972, the United States and 161 other nations signed the Convention on the Prohibition of the Development and Stockpiling of Biological and Toxin Weapons. This international treaty prohibits the production of biological weapons and mandates the destruction of existing stockpiles. However, in 1979, there was an accidental release of aerosolized anthrax from the Institute of Microbiology and Virology at Sverdlovsk in the former Soviet Union. This resulted in an outbreak of inhalational anthrax and at least 66 deaths among the local civilian population [1].

In 1999, the Centers for Disease Control and Prevention (CDC) was designated as the lead agency in the United States for planning the public health response to a bioterrorism attack. Several reports published about that same time indicated that the risk of biological terrorism was increasing and that the use of biological agents, as both large-scale and small-scale weapons, was being actively explored by many nations and terrorist groups [2–6]. The concern expressed in these reports was realized after the attack on the World Trade Center in the fall of 2001, and when 22 cases of anthrax occurred in the United States as a result of anthrax spores being sent through the U.S. mail. There were 5 deaths among the 22 patients with anthrax [7,8]. These attacks demonstrated significant vulnerabilities of the United States to bioterrorism and the need for healthcare providers to be prepared to deal with bioterrorism attacks in their respective communities.

In 2002, the CDC published the *Public Health Assessment of Potential Biological Terrorism Agents* [9]. In this publication, potential bioterrorism agents were placed in one of three categories for the planning of public health preparedness. The agents in each category are summarized in Table 213.1. *Category A* agents have the greatest potential for the production of mass casualties and a major adverse public health impact. *Category B* agents have some potential for large-scale dissemination and mass casualties, but would be expected to cause less illness and death than Category A agents. *Category C* agents are those that do not pose a high bioterrorism threat at the present time, but could emerge as a future threat. This chapter focuses on Category A agents that have the greatest ability to cause mass casualties and significant loss of life. The Category B agent, ricin, is also discussed because of its unique potential to be used as a clandestine agent of terrorism.

SMALLPOX

The last case of endemic smallpox occurred in Somalia in 1977. In 1980, the World Health Organization (WHO) declared that the disease was eradicated. However, in recent years there has been renewed concern about the variola virus, the causative agent of smallpox, primarily due to the potential of the variola virus to be used as a biological weapon of mass destruction and the possibility for such a weapon to cause a major smallpox epidemic among infected populations. As a result of this concern, the WHO has restricted the number of laboratories officially authorized to serve as repositories for the variola virus to two: the CDC in Atlanta, Georgia, and the Vektor Institute in Novosibirsk, Russia [10].

Although smallpox has been officially declared to be eradicated, there is a possibility for its reemergence. In the nineteenth century, a major epidemic of smallpox appeared in the icy Sakha Republic in Russia, resulting in significant mortality. In the event of unusual thawing or flooding in that region, there is concern that infected corpses might be a potential source for the reemergence of smallpox. Although no live variola viruses have been isolated in the Sakha region, there is historical evidence of smallpox virus survival in interred and exhumed individuals from the eighteenth century [11].

With the increasing concern of bioterrorism and the possibility for the variola virus to be weaponized, the U.S. Military began smallpox vaccination of its troops on December 13, 2002 [12]. Much has been learned regarding the indications, contraindications, and efficacy of the vaccine since this mass immunization process began. Considerable thought has also been given to the dire consequences of a smallpox attack and the preparations necessary to manage a large-scale epidemic resulting from such an attack [13]. This section focuses on those aspects of smallpox infection that are most relevant to the critical care physician.

Virology

The causative agent of smallpox, the variola virus, is a member of the *Poxviridae* family, subfamily *Chordopoxvirinae*, and genus *Orthopoxvirus*. This genus also includes vaccinia (used in the smallpox vaccine), monkeypox virus, camelpox, and cowpox. The variola virus, like other members of the *Poxviridae* family, is a large, enveloped, DNA virus. *Poxviridae* viruses

TABLE 213.1

BIOTERRORISM AGENTS AND THREAT CATEGORIES

Category A	Category B	Category C
Bacillus anthracis (anthrax)	*Coxiella burnetii* (Q fever)	Nipah virus
Yersinia pestis (plague)	*Brucella* species (brucellosis)	Hantavirus
Variola major (smallpox)	*Burkholderia mallei* (Glanders)	Tickborne hemorrhagic fever viruses
Clostridium botulinum (botulism)	Ricin	Tickborne encephalitis viruses
Francisella tularensis (tularemia)	*Clostridium perfringens* Epsilon toxin	Yellow fever
Viral hemorrhagic fevers	Staphylococcal enterotoxin B	Multidrug-resistant tuberculosis

Adapted from Rotz LD, Khan AS, Lillibridge SR, et al: Public health assessment of potential biological terrorism agents. *Emerg Infect Dis* 8:225, 2002.

are the only viruses that can replicate in the cytoplasm of cells without involvement of the cell nucleus. The variola virus has a brick-shaped morphology, measures 260 by 150 nm, and has one of the largest viral genomes known. Its large genome makes it difficult to genetically engineer or synthesize the virus in the laboratory. Humans are the only known reservoir for the variola virus, although monkeys are susceptible to infection [14]. The variola virus is very stable and maintains infectivity for long periods of time outside the human host [15]. There are two strains of variola, variola major and variola minor. Variola major is more virulent with a mortality rate between 20% and 50% in infected individuals. Variola minor causes a similar illness, but the mortality is less than 1% [16].

Transmission and Pathogenesis

Transmission of variola occurs from person to person by respiratory droplet nuclei dispersion. Transmission is enhanced by infected individuals who have a cough. Although infrequent, infection has also been known to occur following contact with infected clothing, bedding, or other contaminated fomites [17,18].

Following inhalation, the variola virus seeds the mucus membranes of the upper and lower respiratory tract and then migrates to regional lymph nodes, where viral replication occurs. Viral replication in regional lymph nodes leads to viremia, which results in systemic dissemination of the virus to other organs including the liver, spleen, skin, lung, brain, and bone marrow, where it continues to replicate. Clinical symptoms typically develop after an incubation period of 7 to 17 days.

Clinical Manifestations

Following the initial infection period of 1 to 4 days in which viremia occurs, the clinical manifestations of smallpox appear in a series of distinct phases [18]. These phases that are uniquely characteristic of smallpox are summarized here.

Incubation Phase

The incubation phase of smallpox lasts for 7 to 17 days after infection. During this phase, the virus replicates in regional lymph nodes of the upper and lower respiratory tract. During the incubation phase, infected individuals will most likely be asymptomatic but may have minimal symptoms, such as low-grade temperature elevation or a mild, erythematous rash. Smallpox is not contagious during the incubation phase.

Prodrome Phase

Approximately 7 to 17 days after exposure and initial infection, viremia develops and the variola virus spreads systematically to mucous membranes of the oropharynx, lungs, liver, spleen, bone marrow, and dermal layer of skin. The prodrome phase is characterized by the abrupt onset of high fever (greater than 40°C), headache, nausea, vomiting, and backache. These symptoms are sometimes accompanied by abdominal pain and delirium [19]. These prodromal symptoms typically last for 2 to 4 days. Smallpox may be contagious during the prodrome phase.

Eruption Phase

The eruption phase occurs 2 to 4 days after the onset of prodromal symptoms. Enanthema of the tongue, mouth, and oropharynx precedes the eruption phase by about 1 day. The eruption phase usually begins as small, red maculopapular lesions approximately 2 to 3 mm in diameter. The lesions first appear on the face, hands, and forearms. Lower extremity lesions appear shortly thereafter. The fever usually fades as the skin lesions appear. Symptoms of the prodrome phase may continue and patients can appear very ill. During the next 2 days, the skin lesions become distinctly papular and spread centrally to the trunk. Lesions also appear on the mucous membranes of the oropharynx, and oropharyngeal sections become highly infectious. Smallpox is most contagious during the eruption phase. Healthcare workers, family members, and other close contacts are at greatest risk of contracting smallpox from an infected individual during this phase.

Vesicular Phase

In 2 to 3 days after the eruption of skin lesions, the papular lesions begin to appear vesicular. The vesicles are filled with a thick, opaque fluid and typically range from 2 to 5 mm in diameter. The vesicles are most abundant on the face and extremities. The vesicular phase usually lasts for 2 to 3 days. Humoral antibodies become detectable during this period. Smallpox is contagious during the vesicular phase.

Pustular Phase

The vesicular lesions become pustules approximately 4 to 7 days after the onset of rash. The pustules are sharply raised, firm to the touch, and may have a depressed center and become umbilicated after several days. The pustular phase lasts for 5 to 8 days. Smallpox is contagious during the pustular phase.

Crust Phase

The umbilicated pustules eventually desiccate and become crusted scabs. During this time, there may be a fever spike that may indicate the presence of a superimposed bacterial infection. The crust phase lasts for 5 to 7 days. The crusts contain virus particles and smallpox remains contagious during this phase.

Desquamation Phase

Approximately 2 weeks after the eruption of the rash, desquamation begins. During this phase, the crusts separate from the skin and begin to fall off. Crusts on the palms and soles persist the longest and typically desquamate last. Virus particles are found in the fallen-off crusts and patients are infectious until all crusts separate and fall off. The desquamation phase typically lasts for several weeks. After the crusts fall off the skin, lesions heal and form depressed, depigmented scars.

There are several important characteristics of the smallpox skin lesions that can help to distinguish smallpox from varicella infections (chickenpox). The sequential appearance of the various types of skin lesions described previously is one important characteristic. The distribution of the skin lesions is also characteristic. Smallpox lesions appear first on the face and hands, then on the upper and lower extremities and, over the course of approximately 1 week, eventually spread to the trunk. In all phases of smallpox, there is a predominance of skin lesions on the face and extremities. Another important characteristic of smallpox is that skin lesions are mostly of the same type and same stage of development throughout each clinical phase. The synchronous and centrifugal nature of the smallpox skin lesions is the hallmark of this disease. In contrast, the skin lesions associated with varicella infections are greatest on the trunk, spare the hands and soles, and are at multiple stages at any given time, with papules, vesicles, and crusts all present simultaneously [18].

The mortality rate from the usual variety of smallpox is 3% in vaccinated individuals and 30% in those who are unvaccinated [20]. Death from smallpox is presumed to be secondary to a systemic inflammatory response syndrome caused by overwhelming quantities of immune complexes and soluble variola antigen. Smallpox-associated systemic inflammatory response syndrome results in severe hypotension that usually occurs in the second week of illness. Respiratory complications, including pneumonia and bronchitis, are common [18]. Due to fever and fluid shifts during the vesicular stage of the rash, severe intravascular volume and electrolyte imbalance may occur, which can lead to the development of renal failure. Encephalitis (less than 1% affected) and bacteremia may arise, with the risk of each increasing with the severity of the disease and contributing to mortality. Osteomyelitis, arthritis, and orchitis are other rare manifestations.

There are two atypical manifestations of smallpox that have very high mortality rates [17]. Hemorrhagic smallpox occurs in less than 3% of infected individuals. The hemorrhagic form is characterized by a short incubation period and an erythematous skin eruption that later becomes petechial and hemorrhagic, similar to the lesions seen in meningococcemia. Most individuals with the hemorrhagic form of smallpox die in 5 to 6 days after onset of the rash. The malignant form, or "flat smallpox," is characterized by a fine-grained, reddish, nonpustular, and confluent rash, occasionally with hemorrhage. The malignant form occurs in 2% to 5% of infected individuals. Patients with the malignant form have severe systemic illness and most die within several days. Pulmonary edema occurs frequently in both hemorrhagic and malignant smallpox and contributes to the high mortality rates [20].

The primary long-term sequela of smallpox is the "pockmarks" that affect the skin. These are pitted lesions that permanently scar the face due to infection of sebaceous glands. Panophthalmitis, viral keratitis, and corneal ulcers can cause permanent blindness in 1% of infected individuals. Infection with smallpox results in lifelong immunity [20].

Diagnosis

The differential diagnosis of papulovesicular lesions that can be confused with smallpox includes chickenpox (varicella), shingles (varicella-zoster), disseminated herpes simplex, monkeypox, drug eruptions, generalized vaccinia, eczema vaccinatum, impetigo, bullous pemphigoid, erythema multiforme, molluscum contagiosum, and secondary syphilis. Severe chickenpox (varicella) is the most common eruption that can be confused with smallpox. Table 213.2 delineates clinical features that can help to distinguish chickenpox from smallpox.

Confirmation of smallpox can be performed by the analysis of skin scrapings, vesicular fluid, and oropharyngeal swabs. Specimens should be collected using respiratory and contact isolation procedures, ideally by previously vaccinated personnel. Specimen collection techniques and guidelines are available from public health departments, the CDC, and the WHO [18]. If smallpox is suspected, the local public health department should be notified immediately. Public health departments can provide valuable assistance in collecting specimens and getting them to an appropriate laboratory for analysis. The brick-shaped variola virus is distinguished from varicella-zoster by electron microscopy. However, polymerase chain reaction (PCR) assays are the mainstay of diagnosis at the present time. Serologic testing is not useful in differentiating the variola virus from other orthopoxviruses. Laboratory specimens

TABLE 213.2

DISTINGUISHING CLINICAL FEATURES IN SMALLPOX AND CHICKENPOX

Feature	Smallpox	Chickenpox
Prodrome	2–4 days of high fever, headache backache, vomiting, abdominal pain	Absent-to-mild, 1 day
Rash	Starts in oral mucosa, spreads to face, and expands centripetally	Starts on trunk and expands centrifugally
Palms/soles	Common	Rare
Timing	Lesions appear and progress at same time	Lesions occur in crops; lesions at varied stages of maturation
Pain	May be painful	Often pruritic
Depth	Pitting and deep scars	Superficial; does not scar

should only be manipulated and processed at laboratories with Biosafety Level 4 facilities [17]. Again, local public health departments can assist in getting specimens to an appropriate laboratory.

Infection Control

Although the primary transmission of smallpox is via respiratory droplet nuclei, infected clothing and bedding can also transmit disease [11]. Individuals with smallpox are most infectious within the first 7 to 10 days of the rash, but the disease is contagious until all crusted lesions have fallen off [17]. Secondary cases occur in family members or healthcare workers who are exposed to an infectious individual. If a new outbreak were to occur, it is anticipated that the rate of transmission may be as high as 10 new cases for every infected person. All individuals who have direct contact with the index case should be quarantined for 17 days in respiratory isolation. Home quarantine will be necessary in mass casualty situations. Healthcare workers caring for infected individuals should be vaccinated and use strict airborne and contact isolation procedures. Infected patients should be placed in respiratory isolation and managed in a negative-pressure isolation room, if possible. Patients should remain isolated until all crusted lesions have fallen off. Patients should also be vaccinated if the disease is in the early stage. If performed early, vaccination may significantly decrease the severity of smallpox symptoms [18].

Treatment

There is no U.S. Food and Drug Administration (FDA)-approved drug for the treatment of smallpox. At the present time, treatment is primarily supportive. Supportive care includes maintaining general hygiene, appropriate antibacterial therapy for secondary skin infections, daily eye irrigation for severe cases, and ensuring that the patient receives adequate nutrition and hydration. Topical treatment with idoxuridine can be considered for the treatment of corneal lesions.

Animal studies have suggested that cidofovir has activity against orthopoxviruses, including variola. Cidofovir given at the time of, or immediately following, exposure has the potential to prevent cowpox, vaccinia, and monkeypox. Aerosolized cidofovir has been shown to protect mice against intranasal challenge with the cowpox virus [21]. Additional animal studies are being conducted with other antiviral agents. A new class of potent antipoxviral drugs (ST-246 and lipid-soluble cidofovir CMX001) has been developed and stockpiled [22]. It has been demonstrated that vaccinia immune globulin decreases pulmonary viral loads and pneumonitis in animals with vaccinia or cowpox. However, there is no evidence that the use of vaccinia immune globulin offers any survival or therapeutic benefit in patients infected with smallpox.

Immunization

Smallpox eradication was possible due to a successful worldwide vaccination program with live vaccine viruses. Vaccination continues to be the mainstay of smallpox prevention. First-generation live virus vaccines (Dryvax, APSV, Lancy-Vaxina, L-IVP) were administered by puncturing the skin of the upper arm with a bifurcated needle to induce a robust humoral immunity. Many side effects, reactions, and contraindications resulted from the use of these vaccines. Second-generation vaccines produced in the last 5 to 10 years still contain replication-competent viruses produced in tissue culture and elicit an immunity level similar to first-generation vaccines. A lyophilized preparation of live vaccinia virus (Dryvax, Wyeth Laboratories, Lancaster, PA) that contains polymyxin B, streptomycin, tetracycline, and neomycin was used in the 2004–2005 U.S. vaccination program. Third-generation vaccine formulations have utilized attenuated vaccinia strains (LC16m8, MVA, NYVAC, DVVL) with the hope of an improved safety profile [23]. There has been considerable discussion regarding the efficacy of pre-exposure mass vaccination to protect the public against smallpox in the event of a bioterrorism attack. At the present time, the CDC recommends voluntary vaccination for those likely to be exposed to smallpox and "ring vaccination" in the event of a smallpox outbreak [24,25].

Within 1 week of primary vaccination, the Jennerian pustule develops a gray-white loculated pustule with central umbilication. This marks a "major reaction" and implies successful vaccination. The Jennerian pustule will then crust and darken and remain for approximately 3 weeks following immunization. Successful revaccination is marked by mild induration at the inoculation site. A repeat vaccination attempt is suggested for any equivocal responses. Due to the shortage of vaccine supply in early 2002, dilution studies showed that the vaccinia virus diluted to a titer as low as $10^{7.0}$ plaque-forming units (pfu) per mL (approximately 10,000 pfu per dose) will result in vesicle formation in 97% of inoculated individuals [26]. Dilutions to a titer of $10^{6.5}$ pfu per millimeter were only effective in 70% of those immunized. Lower doses decrease success to as low as 15% [27]. A successful primary vaccination offers full immunity for 5 to 10 years in 95% of those immunized. Successful revaccination is likely to be effective for 10 to 20 years.

The WHO and CDC instructions for the administration of smallpox vaccine are as follows [17,18,28]:

- *Site of vaccination*: Outer aspect of upper arm over the insertion of the deltoid muscle.
- *Preparation of skin*: None, unless the site is obviously dirty. Use water to cleanse the site because the use of a disinfectant can kill the virus.
- *Withdrawal of vaccine from the ampule*: A cool, sterile bifurcated needle is inserted into the reconstituted vaccine ampule. A droplet is sufficient for vaccination and is contained within the fork of the needle. Never dip the same needle back into the ampule to avoid contamination.
- *Application*: The needle is held at 90 degrees perpendicular to the skin; the needle then touches the skin to release the droplet. For primary vaccination, three strokes are made in a 5-mm area. For revaccination, 15 up/down, perpendicular strokes of the needle are rapidly made in the area of 5 mm diameter (through the drop of vaccine deposited on the skin). The strokes should be sufficiently vigorous so that a trace of blood appears at the site. If blood does not appear, the procedure (three strokes) should be repeated with the same needle.
- *Dressing*: Although the WHO does not recommend a dressing, the CDC recommends a loose sterile gauze dressing covered by a semipermeable dressing to prevent transmission of the virus. Absorb the excess blood and vaccine with gauze, and dispose the gauze in a biohazard receptacle.
- *Unused Vaccine*: Unused vaccine is good for 90 days after reconstitution and should be refrigerated without any special light precautions.

The most common adverse reactions following smallpox vaccination are tenderness and erythema at the injection site and secondary bacterial infections. Fever, malaise, local lymphadenopathy, erythema multiforme, Stevens–Johnson syndrome, urticaria, exanthems, contact dermatitis, and erythematous papules have been reported [29]. Inadvertent autoinoculation of another body site, generalized vaccinia (vesicles or pustules appearing on normal skin distant from the vaccination site), eczema vaccinatum, vaccinia keratitis, and progressive vaccinia

have been reported in primary vaccinations. Postvaccinia encephalitis is a very rare complication. Myopericarditis was reported in 200 cases from the recent military vaccination program, at a rate of 117 cases per million vaccinees [12,30]. The cause of postvaccination myopericarditis is not well understood but is probably immunologically mediated and not from direct viral infection of the myocardium. As a result, the CDC has recommended that routine vaccination should not be given to anyone with known previous cardiac disease or three or more risk factors for coronary artery disease [18,31]. The reported rate of cardiac mortality is 1.1 deaths per million primary vaccines. A review of approximately 39,000 people vaccinated against smallpox (36% primary vaccinations and 64% revaccinations) reported the following adverse reactions: encephalitis in 1 individual, myopericarditis in 21 individuals, generalized vaccinia in 2 individuals, inadvertent inoculation in 7 individuals, and ocular vaccinia in 3 individuals [32].

Contraindications to smallpox vaccination are infants less than 1 year of age, immune suppression, eczema, exfoliative skin conditions, pemphigus, cardiac disease as previously described, allergy to any component of the vaccine, and pregnant or breastfeeding women. Individuals who are taking, or have taken, high-dose corticosteroids should not be vaccinated within 1 month of completing corticosteroid therapy. Although testing for human immunodeficiency virus (HIV) is not mandatory prior to smallpox vaccination, the Advisory Committee on Immunization Practices has recommended that HIV testing be readily available to all individuals considering smallpox vaccination [25]. Individuals with a contraindication to vaccination should avoid people who have been recently vaccinated, due to possible transmission of vaccinia from viral shedding at the vaccination site. A small number of deaths (12/68) in the 1960s were attributed to unvaccinated persons exposed to recently vaccinated friends or family members [33].

Healthcare workers must be aware of the possibility for the nosocomial transmission of vaccinia during the hospitalization of a recently vaccinated patient. Nosocomial infection can result in mortality up to 11%. Direct carriage of the virus on the hands, nasal mucosa, fomites, contaminated equipment, and laundry has been implicated in the transmission of vaccinia [34]. Risk of the nosocomial transmission can be mitigated by several simple precautions. Semipermeable dressings should be applied to the site of a recent vaccination and changed frequently if there is evidence of the accumulation of purulent material. Gloves should be worn during dressing changes and meticulous handwashing with antimicrobial soap should be performed by all healthcare providers, both before and after contact with a recently vaccinated patient. Contaminated dressings should be disposed of in a biohazard container. Care should be taken to avoid contact of the vaccination site with material or equipment that could transmit the virus to other individuals. Clothing, towels, and other cloth materials that have contact with the site can be decontaminated by routine laundering with hot water. If at all possible, healthcare workers who are responsible for dressing changes should be vaccinated against smallpox, but nonvaccinated individuals are acceptable as long as appropriate precautions are observed [25]. Sexual transmission of vaccinia virus from a recently immunized active duty military member to a civilian has been recently reported following immunization [34].

Treatment of adverse effects following smallpox vaccination include supportive therapy; administration of vaccinia immune globulin; cidofovir; and an antiviral ophthalmic ointment, such as trifluridine or vidarabine, for eye involvement. Vaccinia immune globulin is available from the CDC, although the supply is limited. Cidofovir is available at no cost from the CDC under investigational use if a patient fails to respond to vaccinia immune globulin, the patient is near death, or all inventories of vaccinia immune globulin are depleted. The dose of cidofovir is 5 mg per kg, given intravenously, during 60 minutes as a single dose [18].

Due to the adverse effects of vaccinia, the federal government contracted with Acambis (Cambridge, England) and Baxter Healthcare (Cambridge, MA) to purchase a cell culture-derived smallpox vaccine that has demonstrated 94% efficacy in phase II clinical trials. Further research on the development of safer smallpox vaccines is currently in progress. In August 2007, the ACAM2000 vaccine was licensed by the FDA for administration to people at high risk of smallpox or other orthopoxvirus diseases. Over 200 million doses of the vaccine have been purchased by the U.S. Strategic National Stockpile (covers approximately 62% of the population), but it is not available for commercial use. Clinical trials show similar efficacy and side effects profile to the Dryvax vaccination, but ACAM200 cannot be diluted [18,22].

In the event of an international release of variola virus, the priority of vaccination is as follows [24,25,35]:

- *Group 1*: Individuals directly exposed to the release.
- *Group 2*: Individuals with face-to-face household contact with a directly exposed individual.
- *Group 3*: Personnel directly involved in the evaluation, care, or transport of infected patients.
- *Group 4*: Laboratory personnel responsible for handling and processing specimens, and others who may be exposed to infectious materials.

ANTHRAX

In the fall of 2001, 22 cases of anthrax with 5 deaths occurred in the United States as a result of anthrax spores in envelopes sent through the U.S. mail. Early recognition and treatment of anthrax by astute clinicians was responsible for preventing additional deaths [7,8]. Anthrax is thought to be the most likely biological agent to be used in a bioterrorism attack. Identification of a single case should prompt notification of local, state, and national public health authorities [36]. The CDC has rapid response teams with specialized expertise, training, and equipment that can be deployed immediately to assist local authorities in the event of a bioterrorism attack [8]. Cases of anthrax in animals have been reported to occur sporadically in North America. In 2006, an outbreak was reported in Canada that affected over 900 animals. Two cases of cutaneous anthrax and one case of inhalational anthrax in humans were reported in the United States from occupational exposure associated with drum making using animal hides from West Africa [37].

Microbiology

Bacillus anthracis (from the Greek word for coal, *anthrakis*) is a large, Gram-positive, aerobic, spore-forming, nonmotile bacillus. *B. anthracis* is found in the soil of many regions of the world, where it exists in the endospore form. Its virulence is determined by two plasmids. One plasmid involves the synthesis of a poly-D-glutamic acid capsule that inhibits phagocytosis of vegetative bacilli and the other contains genes for the synthesis of exotoxins. The exotoxins are known as *protective antigen, edema factor*, and *lethal factor*. The *protective antigen* is a binding protein that is necessary for entry into the host cell and combines with both edema factor and lethal factor to produce "edema toxin" and "lethal toxin" [38]. Edema toxin converts adenosine triphosphate to cyclic adenosine monophosphate (cAMP), resulting in high intracellular cAMP levels that impair water homeostasis and thereby cause cellular edema. Lethal toxin stimulates the overproduction of cytokines, primarily tumor necrosis factor-α and interleukin-1-β that cause

macrophage lysis. The sudden release of inflammatory mediators appears to be responsible for the marked clinical toxicity of the bacteremic form of anthrax.

Clinical Manifestations

There are three forms of anthrax infection. The clinical characteristics of each form are determined by the route of entry of the anthrax spores. *Cutaneous anthrax* is the most common naturally occurring form, comprising approximately 95% of cases reported. Spores enter the body through breaks in the skin and begin low-level germination within days, resulting in soft tissue or mucosal edema and localized necrosis. Initially, a painless, pruritic macule appears, followed by vesiculation, ulceration, and a black, "coal-like" painless eschar, from which anthrax gets its name. The eschar sloughs within 2 to 3 weeks of onset [39]. Abscess formation occurs only with superinfection. Endospores phagocytosed by macrophages are often transported to regional lymph nodes causing painful lymphadenopathy and lymphangitis. Infrequently, cutaneous anthrax may spread hematogenously with significant morbidity and death in a small number of individuals. Cutaneous anthrax has been reported to cause microangiopathic hemolytic anemia, renal dysfunction, and coagulopathy [40].

Gastrointestinal and *oropharyngeal anthrax* usually occur following the ingestion of contaminated meat. This is a rare manifestation of anthrax, with most cases occurring in Africa. Mucosal ulcers, edema, and regional lymphadenopathy are initial manifestations. In the oropharyngeal form, pseudomembranes are seen in the oropharynx and upper airway obstruction can develop. In the gastrointestinal form, a necrotizing infection progresses from the esophagus to the cecum. Fever, nausea, vomiting, abdominal pain, gastrointestinal bleeding, and bloody diarrhea are typical symptoms. Anemia, electrolyte abnormalities, and hypovolemic shock may follow. Massive ascites that is occasionally purulent has been reported. Death results from intestinal perforation or septicemia [20].

The third form of anthrax infection is *inhalational anthrax*. Anthrax spores are 1 to 1.5 μm in size and easily deposit in the alveoli following inhalation. There, the endospores are phagocytosed by the pulmonary macrophages and transported via lymphatics to the mediastinal lymph nodes, where they may remain dormant as "vegetative cells" for approximately 10 to 60 days or longer. Once germination in the lymph nodes is complete, bacterial replication occurs. The replicating bacteria release edema and lethal toxins that produce a hemorrhagic mediastinitis.

In some patients, the initial symptoms are relatively mild and nonspecific, resembling an upper respiratory tract infection. Fever, chills, fatigue, nonproductive cough, nausea, dyspnea, chest pain, and myalgias are common presenting complaints (Table 213.3) [36,37]. These symptoms typically last for 2 to 3 days and then progress to a more severe, fulminant illness. However, some patients present with fulminant illness without any prodromal symptoms. Dyspnea and shock characterize the fulminant phase of inhalational anthrax. The number of spores inhaled, age of the patient, and the underlying immune status most likely affect the clinical course of the disease [41]. Chest radiographs show mediastinal widening and pleural effusions that may be massive (Fig. 213.1). *B. anthracis* bacilli, bacillary fragments, and anthrax antigens can be identified by immunohistochemistry testing of the pleural fluid [42]. Although parenchymal infiltrates are not prominent, a focal hemorrhagic necrotizing pneumonitis, resembling the Ghon complex of tuberculosis, was noted in 11 of 42 autopsy patients from the accidental release of anthrax in Sverdlovsk, USSR, in 1979. Almost 50% of patients with inhalational anthrax develop hemorrhagic meningitis as a result of the hematogenous spread of *B. anthracis*. Massive bacteremia, with up to 10^7 to 10^8 bacteria per mL of blood, causes overwhelming septic shock and death within hours after the onset of symptoms. According to the Defense Intelligence Agency, the lethal dose to kill 50% of persons exposed (LD_{50}) to weapons-grade anthrax is 2,500 to 55,000 spores [43]. However, as few as one to three spores may be sufficient to cause infection [36].

TABLE 213.3

CLINICAL FEATURES OF INHALATIONAL ANTHRAX (U.S. OUTBREAK 2001, n = 10)

Feature	Incidence (%)
Fever and chills	100
Fatigue, malaise, lethargy	100
Cough	90
Nausea/vomiting	90
Dyspnea	80
Sweats-drenching	70
Chest discomfort	70
Myalgias	50
Headache	50
Confusion	40
Abdominal pain	30
Sore throat	20
Rhinorrhea	10

Diagnosis

A high index of suspicion is necessary to make the diagnosis of anthrax when patients present with a severe flulike illnesses. Laboratory findings from the U.S. outbreak in 2001 showed that patients had a mild neutrophil-predominant leukocytosis,

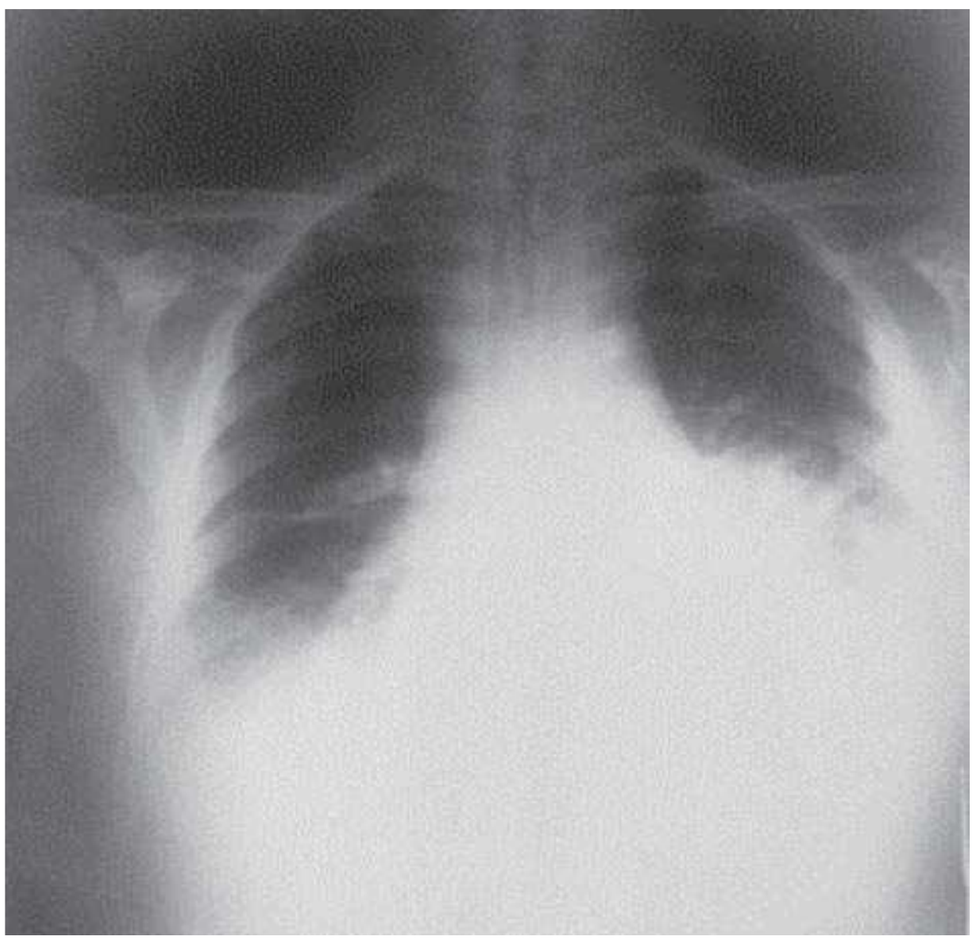

FIGURE 213.1. Chest radiograph from a patient with anthrax showing mediastinal widening and a pleural effusion. [From the CDC Web site: http://www.bt.cdc.gov/agent/anthrax/anthrax-images/inhalational.asp.]

in the range of 7,500 to 13,300 per µL. Peak white blood cell count during illness ranged from 11,900 to 49,600 per mm^3. Elevated transaminases, hyponatremia, and hypoxemia were also noted [7,37,41,43]. One hundred percent of these patients had an abnormal chest radiograph with mediastinal widening, pleural effusions, consolidation, and infiltrates predominating. The presence of mediastinal widening that may require computed tomography scanning to elucidate should be considered diagnostic of anthrax until proven otherwise [44–46]. Hemorrhagic necrotizing lymphadenitis and mediastinitis are pathognomonic of anthrax, but these are autopsy findings of these conditions [19]. *B. anthracis* is easily cultured from blood, cerebral spinal fluid, ascites, and vesicular fluid with standard microbiology techniques. The laboratory should be notified when the diagnosis of anthrax is being considered, as many hospital laboratories will not further characterize *Bacillus* species unless requested. Biosafety Level 2 conditions apply for workers handling specimens because most clinical specimens have spores in the vegetative state that are not easily transmitted [36]. The presence of large Gram-positive rods in short chains that are positive on India ink staining is considered presumptive of *B. anthracis*, until the results of cultures and other confirmatory tests are obtained. Confirmatory testing can be performed by the CDC Laboratory Response Network. Rapid detection tests based on immunohistochemistry, and PCR techniques are available via the Laboratory Response Network [37]. Nasal swabs are not recommended because they are not reliable for making the diagnosis of anthrax. Following the 2001 anthrax attack, there were negative nasal swab results in patients with fatal inhalational anthrax [43]. In June 2004, the FDA approved the Anthrax Quick ELISA test (Immunetics, Inc., Boston, MA) that detects antibodies to the protective antigen of *B. anthracis* exotoxin. The test can be completed in less than 1 hour and is available to hospital and commercial laboratories by the manufacturer [37].

Treatment

Due to the fulminant course of inhalational anthrax, prompt initiation of therapy is essential for survival. Ciprofloxacin (400 mg) or doxycycline (100 mg) given intravenously every 12 hours with one to two other antibiotics that have predicted efficacy against anthrax is currently recommended. Additional antibiotics that are effective against anthrax include rifampin, vancomycin, imipenem, chloramphenicol, penicillin, ampicillin, clindamycin, and clarithromycin. Two survivors of anthrax during the U.S. outbreak received parenteral ciprofloxacin, clindamycin, and rifampin. The addition of clindamycin may attenuate toxin production [44]. There are limited data regarding treatment of pregnant women for anthrax. However, the limited information that is available suggests that the use of ciprofloxacin during pregnancy is unlikely to be associated with a high risk for structural birth defects [47]. Therefore, ciprofloxacin should be given to pregnant women for the treatment of inhalational anthrax unless otherwise contraindicated. Doxycycline is relatively contraindicated in pregnancy and should only be considered if ciprofloxacin is unavailable or absolutely contraindicated. Therapy with ciprofloxacin or doxycycline should continue for 60 days. Patients can be switched to oral therapy with ciprofloxacin (500 mg twice daily) or doxycycline (100 mg twice daily) after fulminant symptoms have resolved and they are stable. The use of systemic corticosteroids has been suggested for meningitis, severe edema, and airway compromise. Parenteral ciprofloxacin and another antibiotic with good central nervous system penetration, such as rifampin, should be part of the initial treatment regimen for anthrax meningitis. Cutaneous anthrax with systemic involvement, significant edema, and lesions of the head and neck should be treated similarly. Uncomplicated cutaneous anthrax can be treated with oral ciprofloxacin or doxycycline for 7 to 10 days, but, due to the possibility of concomitant inhalational exposure, a 60-day course is recommended [36,37].

A review of anthrax cases in adults from 1900 to 2004 noted that fulminant inhalational anthrax is often fatal despite advances in medical care. Early diagnosis and initiation of therapy during the prodromal phase improved survival and are pivotal for decreasing mortality in inhalational anthrax [48]. Similarly, a review of anthrax cases in children from 1900 to 2005 shows that early diagnosis and treatment of all forms of anthrax are critical for improved survival in children [49].

Prophylaxis

All patients exposed to anthrax should receive prophylaxis with oral ciprofloxacin (500 mg twice daily), levofloxacin (500 mg daily), or doxycycline (100 mg twice daily) for 60 days, regardless of laboratory test results. Nasal swabs can confirm exposure to anthrax, but cannot exclude it. High-dose penicillin or ampicillin may be an acceptable alternative for 60 days in patients who are allergic or intolerant to the recommended antibiotics [36,37]. More than 5,000 people received postexposure prophylaxis following the 2001 U.S. outbreak, but only about half completed the 60-day course. The main reasons for discontinuing therapy were gastrointestinal or neurologic side effects (75%) or a low perceived risk (25%).

The anthrax vaccine (AVA-Biothrax) manufactured by BioPort Corporation in Lansing, Michigan, is the only licensed human anthrax vaccine in the United States. The vaccine consists of supernatant material from cultures of a toxigenic, nonencapsulated strain of *B. anthracis*. A six-dose series has been used by the U.S. Military. The anthrax vaccine is not available to the general public at the present time. Although efficacy data are limited to goat hair mill workers from the 1950s to 1974, fully vaccinated individuals did not contract anthrax as compared to those who did not participate in the vaccine program [50]. Approximately 95% of vaccinated individuals seroconvert after the third dose of vaccine. Data regarding vaccine safety from more than 1 million doses administered to members of the U.S. Military reveal that the adverse events were without any significant pattern or association. The vaccine is generally considered to be safe by the FDA [50]. A review by the U.S. Army Medical Research Institute of Infectious Diseases reported a 1% (101/10,722) incidence of systemic symptoms, most commonly headache. Local or injection site reactions occurred in 3.6% [36]. A study comparing four subcutaneous injections of anthrax vaccine adsorbed (AVA) with three and four intramuscular injections of AVA showed similar immunoprotection at 7 months with less adverse effects at the injection site. Following an aerosolized *B. anthracis* attack, postexposure prophylactic vaccination and antibiotic therapy remain the most effective and least expensive strategies [51].

TULAREMIA

Tularemia is a zoonosis found in a wide range of animals, primarily small mammals such as rodents and rabbits. In 1922, tularemia was reported to cause fatal illness in humans [52]. In the late 1920s, tularemia was recognized as a threat to laboratory workers. Tularemia is caused by *Francisella tularensis*, an intracellular, nonspore-forming, aerobic Gram-negative coccobacillus. In the mid-twentieth century, both the United States and the former Soviet Union developed biological weapons that could disperse *F. tularensis* [53]. Biological weapons have now been banned and are no longer in production. However, there is concern that *F. tularensis* could be used as an agent

of bioterrorism. In a 1970 report, the WHO estimated that 50 kg of aerosolized *F. tularensis* dispersed over a metropolitan area of 5 million people could cause 19,000 deaths and 250,000 incapacitating illnesses [19,54]. The impact of such an attack would probably linger for several weeks to months due to disease relapses [54].

Microbiology

F. tularensis is a nonsporulating, nonmotile, Gram-negative coccobacillus. It is a hardy organism, which makes it well suited for use as an agent of bioterrorism. It can survive in moist soil, water, and animal carcasses for many weeks. However, chlorination of water prevents its spread through water contamination. *F. tularensis* can be aerosolized and inhalation of aerosolized organisms poses a threat to those exposed. The most common isolate, and the most virulent form, is *F. tularensis* biovar *tularensis* (Group A). Inoculation or inhalation of as few as 10 organisms may cause clinical disease [55–57]. *F. tularensis* biovar *palaearctica* is found mostly outside of the United States, most notably in Europe. Transmission of *F. tularensis* to humans occurs predominantly through tick and fleabites, handling of infected animals, ingestion of contaminated food and water, and inhalation of the aerosolized organism. There is no human-to-human transmission of *F. tularensis*. As a biological weapon, the organism would most likely be dispersed as an aerosol and cause mass casualties from an acute febrile illness that may progress to severe pneumonia [19].

Epidemiology

Tularemia occurs worldwide but is rare in Africa, Central, South America, and the United Kingdom, with highest incidence in Russia and Scandinavian countries [57–59]. In the United States, tularemia cases are reported most often from the south central and western states (Arkansas, Illinois, Missouri, Oklahoma, Tennessee, Texas, Utah, Virginia, and Wyoming). The predominant mode of transmission to humans in the United States is by tick bites, and most cases are reported in spring and summer. Hunters and trappers exposed to animal reservoirs are at high risk for exposure [57–59]. In Europe and Japan, mosquito bites and the handling of infected animals appear to cause the disease. A large outbreak of tularemia in 2003 along with small summer outbreaks between 1995 and 2005 in Sweden suggests environmental sources clustering around recreational areas [60]. Tularemia epidemics may have a seasonal presentation. *F. tularensis* var *tularensis*, often seen in summer, is tick-borne, while *F. palaearctica*, seen in fall and winter, is commonly transmitted from contaminated water, rodents, or aquatic animals. An outbreak of tularemia in Martha's Vineyard, Massachusetts, during the summer of 2000 was associated with lawn mowing and brush cutting [61,62]. A waterborne outbreak resulting in 21 cases of oropharyngeal and 5 cases of glandular tularemia was reported in Georgia [63].

Pathogenesis

F. tularensis enters the human host via the eye, respiratory tract, gastrointestinal tract, or a break in the skin. The virulence of the organism depends on its ability to replicate within the macrophage. On entering the macrophage, the organism proliferates. This is followed by apoptosis of the macrophage and the release of a larger number of organisms, leading to involvement of the local lymph nodes and bacteremia. Once bacteremia develops, *F. tularensis* infects the lungs, pleura, spleen, liver, and kidney. The host defense against *F. tularensis* is reported to be T-cell independent in the first 3 days and T-cell dependent after 3 days of infection. Initially, a focal suppurative necrosis with polymorphonuclear cells, macrophages, epithelioid cells, and lymphocytes are noted. The predominant protective mechanism in containing the disease comes from cell-mediated immunity. On histopathology, granulomas with necrosis may be seen in infected organs. Following inhalational exposure, hemorrhagic airway inflammation progressing to bronchopneumonia, pleuritis, and pleural effusion have been reported [55–57]. The mucosal immunopathogenesis of *F. tularensis* in animal models has shown that the antibodies may provide both prophylactic and therapeutic protection against pulmonary infection when there is active cell-mediated immunity [64].

Clinical Features

The clinical manifestations of tularemia depend on the site of entry, exposure dose, virulence of the organism, and host immune factors. Hematogenous spread may occur from any of the initial clinical presentations. Tularemia can have various clinical presentations that have been classified as primary pneumonic, typhoidal, ulceroglandular, oculoglandular, oropharyngeal, and septic. The *ulceroglandular form* is the most common naturally occurring form of tularemia. After an incubation period of 3 to 6 days (range, 1 to 25 days) following a vector bite or animal contact, patients present with symptoms of high fevers (85%), chills (52%), headache (45%), cough (38%), and myalgias (31%). They may also have malaise, chest pain, abdominal pain, nausea, vomiting, and diarrhea. A pulse-temperature dissociation is often seen. At the site of inoculation, a tender papule develops that later becomes a pustule and ulcerates. Lymph nodes draining the inoculation site become enlarged and painful (85%). Infected lymph nodes may become suppurative, ulcerate, and remain enlarged for a long period of time. Exudative pharyngitis and tonsillitis may develop following ingestion of contaminated food or inhalation of the aerosolized organism. Pharyngeal ulceration and regional lymphadenopathy may be present. A systemic disease caused by *F. tularensis* without lymph node enlargement and presenting with fever, diarrhea, dehydration, hypotension, and meningismus is referred to as the *typhoidal form*. The *pneumonic form* of tularemia may occur as a primary pleuropneumonia following the inhalation of aerosolized organisms. The pneumonic form may also occur as a result of hematogenous spread from other sites of infection or following oropharyngeal tularemia. After an inhalational exposure, constitutional symptoms, such as fever and chills, typically precede the onset of respiratory symptoms. The respiratory symptoms include a dry or minimally productive cough, pleuritic chest pain, shortness of breath, and hemoptysis. Pleural effusions, either unilateral or bilateral, can occur. Pneumonic tularemia can rapidly progress to respiratory failure with acute respiratory distress syndrome, multiorgan failure, disseminated intravascular coagulation, rhabdomyolysis, renal failure, and hepatitis [55–57,65]. Rarely, peritonitis, pericarditis, appendicitis, osteomyelitis, erythema nodosum, and meningitis have been reported to occur in tularemia. It has been reported that delays in diagnosis and failure to institute prompt aminoglycoside therapy results in higher morbidity [66]. The mortality rate of untreated tularemic pneumonia is 60%, but with proper antibiotic therapy the mortality rate is significantly reduced to 1% to 2.5% [55,56].

Laboratory and Radiographic Findings

A high index of suspicion is needed in order to make an early diagnosis of tularemia. Lack of response to conventional treatment for skin ulcers or community-acquired pneumonia, along

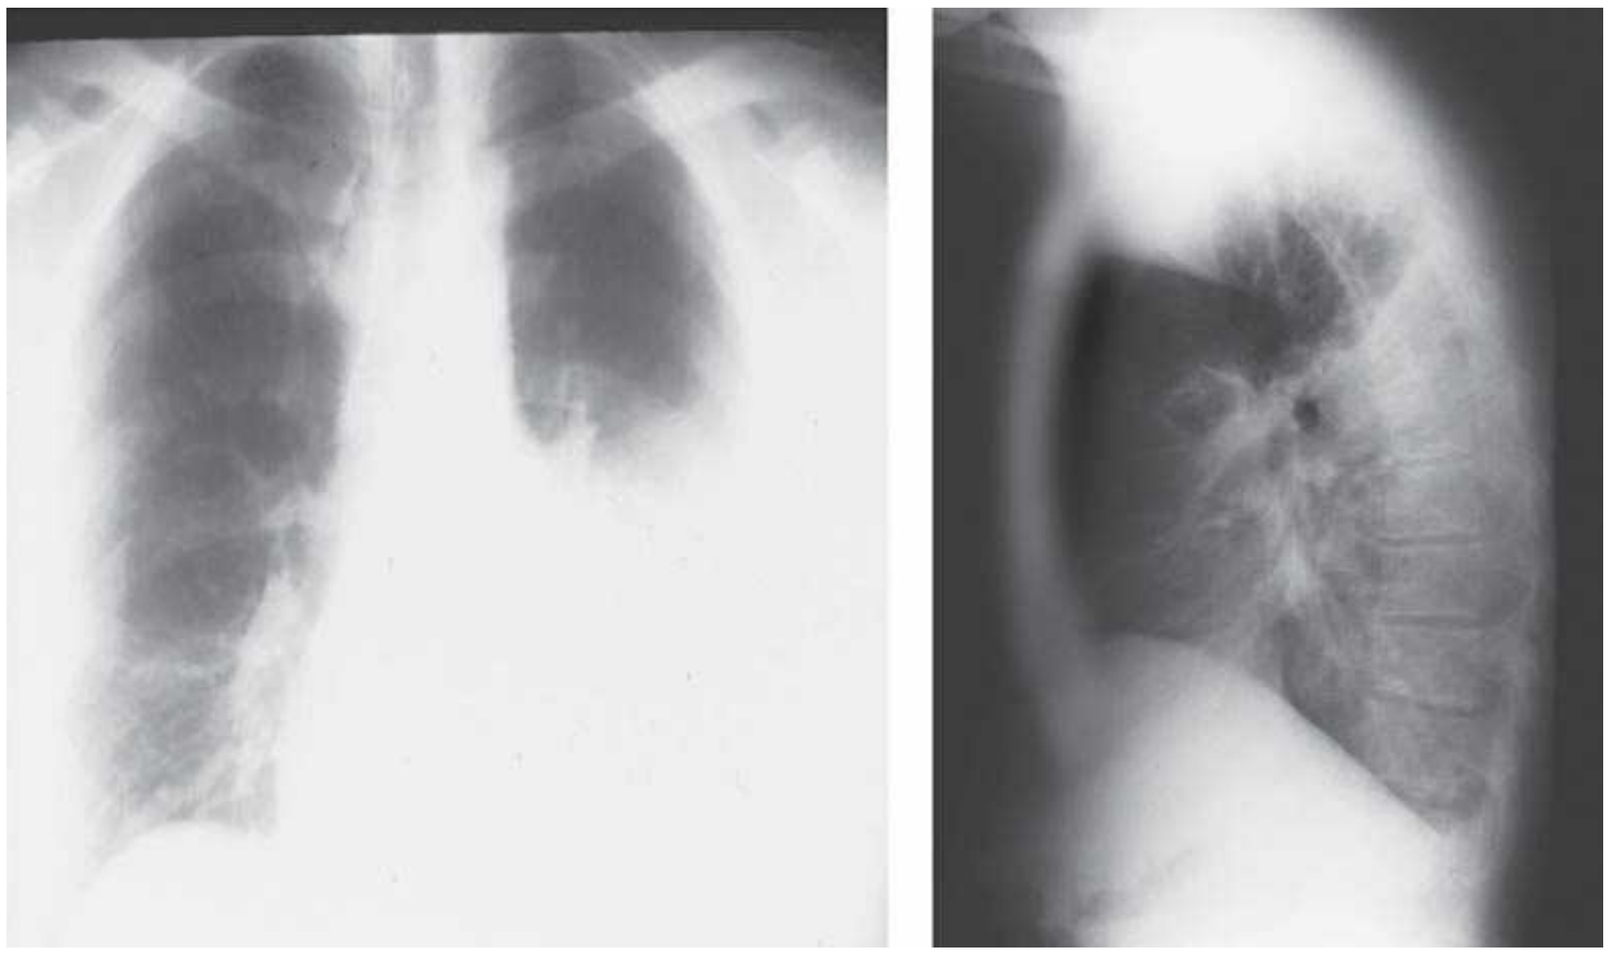

FIGURE 213.2. Chest radiograph from a 27-year-old man who contracted tularemic pneumonia after skinning a rabbit that he had hunted. [Courtesy of Angeline A. Lazarus, MD.]

with a history of exposure to animals, may alert the clinician to think of tularemia. Routine laboratory tests, such as a complete blood count and serum chemistry panels, are generally nondiagnostic. A complete blood count may show a leukocytosis with a normal differential or mild lymphocytosis. Mild elevations of lactic dehydrogenase, transaminases, and alkaline phosphatase may be seen on a serum chemistry panel. If rhabdomyolysis is present, an elevated serum creatine kinase concentration and urine myoglobin may be seen. Sterile pyuria has been reported. Mild abnormalities in cerebrospinal fluid cell counts, protein, and glucose have also been reported [54,56,65].

Tularemia can present with multiple abnormalities on a chest radiograph (Fig. 213.2). A report of the chest radiographic findings in 50 patients who had a confirmed diagnosis of tularemia showed the following abnormalities: patchy airspace opacities (74%, unilateral in 54%); hilar adenopathy (32%, unilateral in 22%); pleural effusion (30%, unilateral in 20%); unilateral lobar or segmental opacities (18%); cavitation (16%); oval opacities (8%); and cardiomegaly with a pulmonary edema pattern (6%). Rare findings such as apical infiltrates, empyema with bronchopleural fistula, miliary pattern, residual cyst, and residual calcification occurring in less than 5% of patients were also reported [67].

Diagnosis

It is possible to isolate *F. tularensis* from sputum, blood, and other body fluids, but the organism can be difficult to culture. Culture media must contain cysteine or sulfhydryl compounds for *F. tularensis* to grow. Notification of laboratory personnel that tularemia is suspected can be helpful in enhancing the yield of culture. Notification of laboratory personnel will also help to ensure that they observe appropriate biosafety procedures when manipulating specimens. Routine diagnostic procedures can be performed in Biosafety Level 2 conditions. Examination of cultures in which *F. tularensis* is suspected should be done in a biological safety cabinet. Manipulation of cultures and other procedures that might produce aerosols or droplets should be conducted under Biosafety Level 3 conditions [56].

Examination of secretions and biopsy specimens with direct fluorescent antibody or immunochemical stains may help to identify the organism. The diagnosis is often made through serologic testing using enzyme-linked immunosorbent assay (ELISA). Serologic titers may not be elevated early in the course of disease. A fourfold rise is typically seen during the course of illness. A single tularemia antibody titer of 1:160 or greater is supportive of the diagnosis [55,56,65]. The combined use of ELISA and confirmatory Western blot analysis was found to be the most suitable approach to the serological diagnosis of tularemia [67,68]. Other diagnostic methods include antigen detection assays and PCR [68–70]. A multitarget real-time TaqMan PCR assay (Applied Biosystems, Foster City, CA) has been reported to have high sensitivity and specificity for the diagnosis of tularemia and may be a valuable tool for the analysis of clinical specimens and field samples following a bioterrorism attack [71].

Treatment

The antibiotic of choice for the treatment of tularemia is streptomycin, 1 g, given intramuscularly (IM) twice daily. Gentamicin, 5 mg per kg, given IM or intravenously (IV) once daily, can be used instead of streptomycin. For children, the preferred antibiotics are streptomycin, 15 mg per kg, given IM twice daily (not to exceed 2 g per day) or gentamicin, 2.5 mg per kg, given IM or IV thrice daily. Alternate choices for adults are doxycycline, 100 mg, given IV twice daily; chloramphenicol, 15 mg per kg, given IV four times daily; or ciprofloxacin, 400 mg, given IV twice daily. For children, alternate choices are doxycycline, 100 mg, given IV twice daily if the child weighs 45 kg or more, and doxycycline, 2.2 mg per kg, given IV twice daily for children weighing less than 45 kg. Chloramphenicol and ciprofloxacin can also be used as alternate antibiotics in children. The ciprofloxacin dose in children should not exceed 1 g per day. Gentamicin is preferred over streptomycin for treatment during pregnancy. Chloramphenicol should not be given to pregnant patients. Treatment with streptomycin, gentamicin, or ciprofloxacin should be continued for 10 days. Treatment with doxycycline or chloramphenicol should be continued for 14 to 21 days. Patients beginning treatment with

doxycycline, chloramphenicol, or ciprofloxacin can be switched to oral antibiotics when clinically appropriate. β-Lactams and macrolides are not recommended for treatment of tularemia [56,72].

In a mass casualty setting caused by tularemia, the preferred antibiotic for adults and pregnant women is doxycycline, 100 mg, taken orally twice daily, or ciprofloxacin 500 mg, taken orally twice daily. For children, the preferred choices are doxycycline, 100 mg, taken orally twice daily if the child weighs 45 kg or more; doxycycline, 2.2 mg per kg, taken orally twice daily if the child weighs less than 45 kg; or ciprofloxacin, 15 mg per kg, taken orally twice daily and not to exceed 1 g per day. It is recommended that therapy be continued for 3 to 14 days. In immunosuppressed patients, either streptomycin or gentamicin is the preferred antibiotic in mass casualty situations [56,57].

Prophylaxis

Individuals exposed to *F. tularensis* may be protected against systemic infection if they receive prophylactic antibiotics during the incubation period. For postexposure prophylaxis, either doxycycline, 100 mg, taken orally twice daily, or ciprofloxacin, 500 mg, taken orally twice daily for 14 days, is recommended. Both doxycycline and ciprofloxacin can be taken by pregnant women for postexposure prophylaxis, but ciprofloxacin is preferred. Postexposure prophylaxis for children is the same as treatment during mass casualty situations [56,57].

Immunization

In Russia, a live attenuated vaccine has been used to offer protection to those living in tularemia-endemic areas. In the United States, a live attenuated vaccine has been given to laboratory personnel working with *F. tularensis*. The currently available vaccine does not offer total protection against inhalational exposure to *F. tularensis*. Therefore, vaccination is not recommended for postexposure prophylaxis. The intranasal administration of an attenuated live vaccine has been shown to provide protection against intranasal infection with *F. tularensis* biovar A in mice. The use of such a vaccine in humans requires further investigation [55,56,73,74].

PLAGUE

Plague is a zoonotic infection, primarily seen in rodents and rabbits. Humans are infected as an accidental host. Historically, three pandemics with bubonic plague occurred in the sixth, fourteenth, and nineteenth centuries, killing millions of people in Europe, Africa, and Central and Southern Asia. The fourteenth century pandemic became known as the "Black Death." This pandemic reportedly took the lives of more than 40 million people [75]. In recent years, the highly contagious nature of plague has raised concern about its possible use as an agent of bioterrorism.

Microbiology

Plague is caused by *Yersinia pestis*, a Gram-negative, nonmotile coccobacillus of the family *Enterobacteriaceae*. *Yersinia pestis* has a bipolar staining pattern with Wright–Giemsa or Wayson stain that gives a "safety pin" appearance to the stained organism (Fig. 213.3). From recent genetic studies of *Yersinia pestis*, it appears that there are three biovars and that the original organism has undergone chromosomal rearrangements over the years, leading to new ribotypes of the biovars. Three plasmids of *Yersinia pestis* have been identified as the source of virulence factors. Virulence factors include plasminogen activator, lipopolysaccharide endotoxin, V antigen, F1 antigen, and W antigen. These virulence factors confer antiphagocytic activity, cytotoxicity, and facilitate use of host nutrients to escape other host defense mechanisms [76–81]. The lipopolysaccharide endotoxin is responsible for the systemic inflammatory response, acute respiratory distress syndrome, and multiorgan failure [77,82].

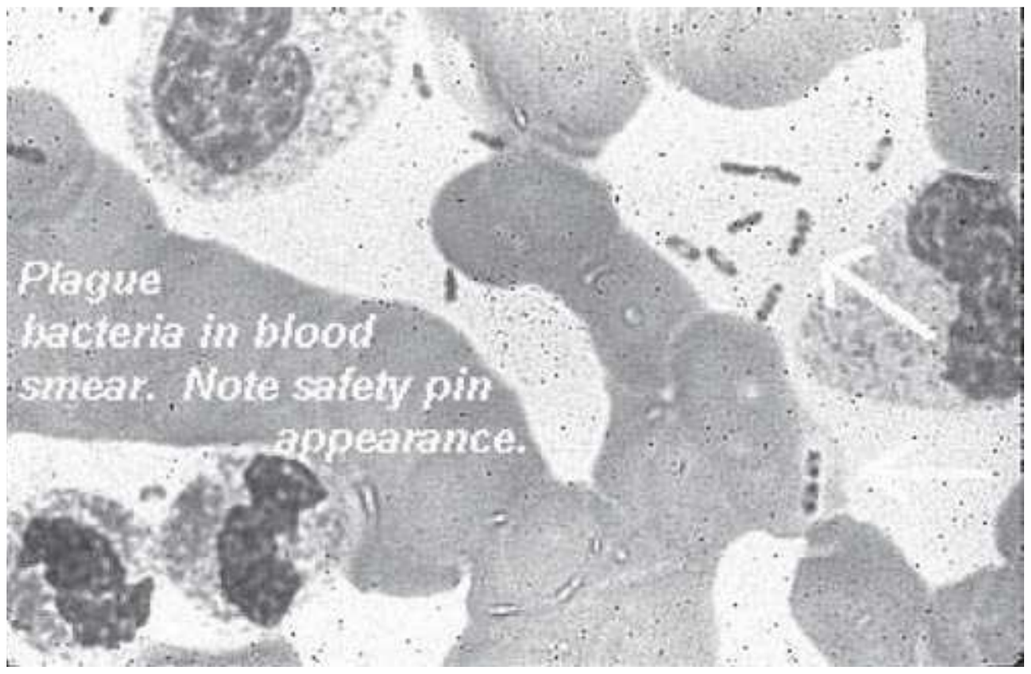

FIGURE 213.3. Wright–Giemsa stain of *Yersinia pestis* showing the characteristic bipolar staining pattern that gives a "safety pin" appearance to the organism. [From the CDC Web site: http://www.cdc.gov/ncidod/dvbid/plague/p1.htm.]

Plague is naturally transmitted by the bite of a plague-infected flea. Rodents, particularly rats and squirrels, are the natural reservoirs that transmit *Yersinia pestis* to fleas. After ingestion of blood from an infected animal, bacteria multiply in the digestive tract of the flea. Hundreds of bacteria are then regurgitated into the next animal or human victim of the plague-infected flea. Plague can be transmitted by all species of fleas; protection against fleabites is an important preventive measure in endemic areas and during epidemics. In the United States, the most common vector for the transmission of plague to humans is the *Diamanus montanus* flea. The most important reservoirs in the United States include ground squirrels, rock squirrels, and the prairie dog. Transmission to humans also occurs by direct contact with infected live or dead animals, inhalation of respiratory droplets from patients with pneumonic plague, or from direct contact with infected body fluids or tissue [76–78,82,83].

Plague as a Bioweapon

The use of plague as an intentional agent of warfare first occurred in 1346 with the Tartars catapulting the plague-infected corpses of their troops to the Christian Genoese troops during the siege of Kaffa. Since that time, plague has been used by the military forces of Russia against Sweden, and Japan against China. The biowarfare program of United States had plague in its arsenal before destroying biological weapons in the early 1970s. The CDC has classified plague as a Category A threat agent. Aerosolized droplets of *Yersinia pestis* could be used as a biowarfare agent, resulting in the highly fatal pneumonic form of plague [76,77,84]. Plague is contagious from person to person and can result in a greater number of casualties than those initially exposed and infected. The WHO estimates that 50 kg of *Yersinia pestis* aerosolized over a population of 5 million people may result in 150,000 infections and 36,000 deaths [53]. Intentional dispersion of *Yersinia pestis* as an aerosol will lead to pneumonic plague, while the release of infected fleas will usually result in bubonic or septicemic plague [53,76,77,84].

Epidemiology

Plague has been reported worldwide, with most human cases occurring in the developing countries of Africa and Asia. The WHO reports global occurrence of 1,000 to 3,000 cases per year. More than 90% of plague cases reported in the United States come from the states of Arizona, New Mexico, California, and Colorado, with rare cases from Texas. The majority of cases occur in spring and summer, when people come in contact with rodents and fleas while outdoors. In endemic areas of the United States, there is a higher incidence of plague among Native Americans compared to non-Native Americans [76,77,85–88]. In Uganda, 127 clinical cases of plague (88% bubonic, 12% pneumonic) were identified in 2006. Of these, 28 patients (22%) died and 11 of these had pneumonic plague. In one family, four members died of pneumonic plague [89]. Two small outbreaks of oropharyngeal plague were reported from the Middle East from the eating of raw camel liver and meat [90,91]. The WHO reported an outbreak of plague in the Democratic Republic of the Congo, consisting of 130 cases of pneumonic plague, 61 of which were fatal [92]. Smaller outbreaks of plague continue to occur throughout the world [93]. Recent studies have suggested that the Black Death pandemic probably led to mutations in the chemokine receptor CCR5. These mutations may confer immunity to certain individuals against plague and other infections, such as HIV-1 [94].

Pathogenesis

The common forms of naturally acquired human plague are *bubonic, septicemic*, and *primary pneumonic* forms. The bubonic and septicemic forms are the most common presentations. After entering the body through a fleabite, bacteria migrate via cutaneous lymphatics to the regional lymph nodes and are subjected to phagocytosis. If not killed by host defense systems, the bacteria proliferate within the macrophages with the aid of fraction I, an envelope antigen of *Yersinia pestis*. Other virulence factors secreted by the bacteria facilitate extracellular spread and resistance to destruction. The initial infection in lymph nodes causes lymphadenitis and local swelling that is referred to as the "bubo"; hence, the name "bubonic plague." Most buboes develop in the groin, axilla, or neck. Virulence factors perpetuate the progression of disease, leading to septicemia and the infection of other organs. Endotoxins released by *Yersinia pestis* result in the septic state and increased resistance to host defenses [76–82].

Inhalation of infected droplets of *Yersinia pestis* results in primary pneumonic plague. The primary pneumonic form is rapid in onset with an incubation period of 1 to 6 days (mean, 2 to 4 days). Presenting features are fevers, chills, cough, and blood-tinged sputum. Following inhalation into the lungs, *Yersinia pestis* organisms are engulfed by macrophages and transported to the lymphatic system and regional lymph nodes. This is followed by transient bacteremia that results in the seeding of other organs such as the spleen, liver, skin, and mucous membranes. Secondary pneumonic plague occurs as sequelae of bubonic or primary septicemic plague. Primary septicemic plague occurs when there is direct entry of *Yersinia pestis* bacilli into the bloodstream. The early recognition of primary septicemic plague is difficult because it resembles other febrile illnesses with septicemia. Other rare forms of plague are *plague meningitis* and *plague pharyngitis*. Plague meningitis occurs following the hematogenous spread of *Yersinia pestis* bacilli to the meninges. Plague pharyngitis may occur following the ingestion or inhalation of *Yersinia pestis* bacilli. Both plague meningitis and plague pharyngitis cause cervical lymphadenitis [76,78].

FIGURE 213.4. Bubonic plague with the characteristic bubo. [From CDC Web site: http://www.cdc.gov/ncidod/dvbid/plague/diagnosis.]

Clinical Presentation

The incubation period and clinical manifestations of plague vary according to mode of transmission. Of the plague cases seen in the United States, 85% are bubonic plague, 10% to 15% are primary septicemic plague, and less than 1% are primary pneumonic plague. Bubonic plague may progress to septicemic or pneumonic plague in 23% and 9% of cases, respectively. The clinical presentation of plague in children is similar to that of adults. There are little data regarding unique manifestations of plague in pregnant women [76,77,82,89,95,96].

Bubonic Plague

Following the bite of an infected flea, fever, chills, and headache will develop in 1 to 8 days. Nausea, vomiting, malaise, altered mentation, cough, abdominal pain, and chest pain may also be present. Patients then develop lymphadenitis, buboes (Fig. 213.4), and severe pain. Based on site of inoculation, palpable, regional buboes appear in the groin, axillae, or cervical regions, with erythema of the overlying skin. These enlarged lymph nodes are necrotic and contain dense concentrations of *Yersinia pestis* bacilli [76,77,95].

Septicemic Plague

A minority of patients exposed to *Yersinia pestis* develop septicemic plague, either as a primary form (without buboes) or secondary to the hematogenous spread of bubonic or primary pneumonic plague. The clinical features are similar to those of Gram-negative sepsis, with fever, chills, nausea, vomiting, and hypotension. Abdominal pain from hepatosplenomegaly, acral cyanosis, disseminated intravascular coagulation, and purpura has been reported. Severe anxiety and confusion may occur. Endotoxin released from *Yersinia pestis* may produce severe hypotension, oliguria, anuria, and acute respiratory distress syndrome. Gangrenous changes of the fingers, toes, and nose may occur. As a result of these manifestations, septicemic plague has been called the Black Death. Without treatment, the mortality rate of septicemic plague is 100% [75–77,87–89].

Pneumonic Plague

Primary pneumonic plague occurs by inhaling respiratory droplets from infected humans or animals and is characterized

by a severe, rapidly progressive pneumonia with septicemic features that is rapidly fatal if not treated within 24 hours. Plague is highly contagious by the airborne route. Following an incubation period of 1 to 6 days, there is a rapid onset of fever, dyspnea, chest pain, and cough that may be productive of bloody, watery, or purulent sputum. Tachycardia, cyanosis, nausea, vomiting, diarrhea, and abdominal pain may occur. Intra-alveolar edema and congestion are commonly seen. Buboes are generally absent, but may develop in the cervical area. Acute respiratory failure requiring mechanical ventilation may occur. Strict respiratory isolation should be observed because pneumonic plague is highly contagious [76,77,97–99]. Chest radiographs show bilateral alveolar opacities (89%) and pleural effusions (55%). Cavitations may occur [98]. Alveolar opacities in secondary pneumonic plague may have a nodular appearance. Mediastinal adenopathy is very rare in primary pneumonic plague but hilar node enlargement is often present. This can help to distinguish primary pneumonic plague from anthrax if bioterrorism is suspected and a causative agent has not been identified [100,101]. Without prompt treatment, the mortality rate of primary pneumonic plague is 100% [75].

Secondary pneumonic plague occurs in approximately 12% of individuals with bubonic plague or primary septicemic plague. It develops as a result of the hematogenous spread of *Yersinia pestis* bacilli to the lungs. It typically presents as a severe bronchopneumonia. Common symptoms include cough, dyspnea, chest pain, and hemoptysis. Chest radiographs typically show bilateral, patchy alveolar infiltrates that may progress to consolidation. In contrast to primary pneumonic plague, mediastinal, cervical, and hilar adenopathy may occur [76,100,101]. A chest radiograph from a patient with secondary pneumonic plague is shown in Figure 213.5.

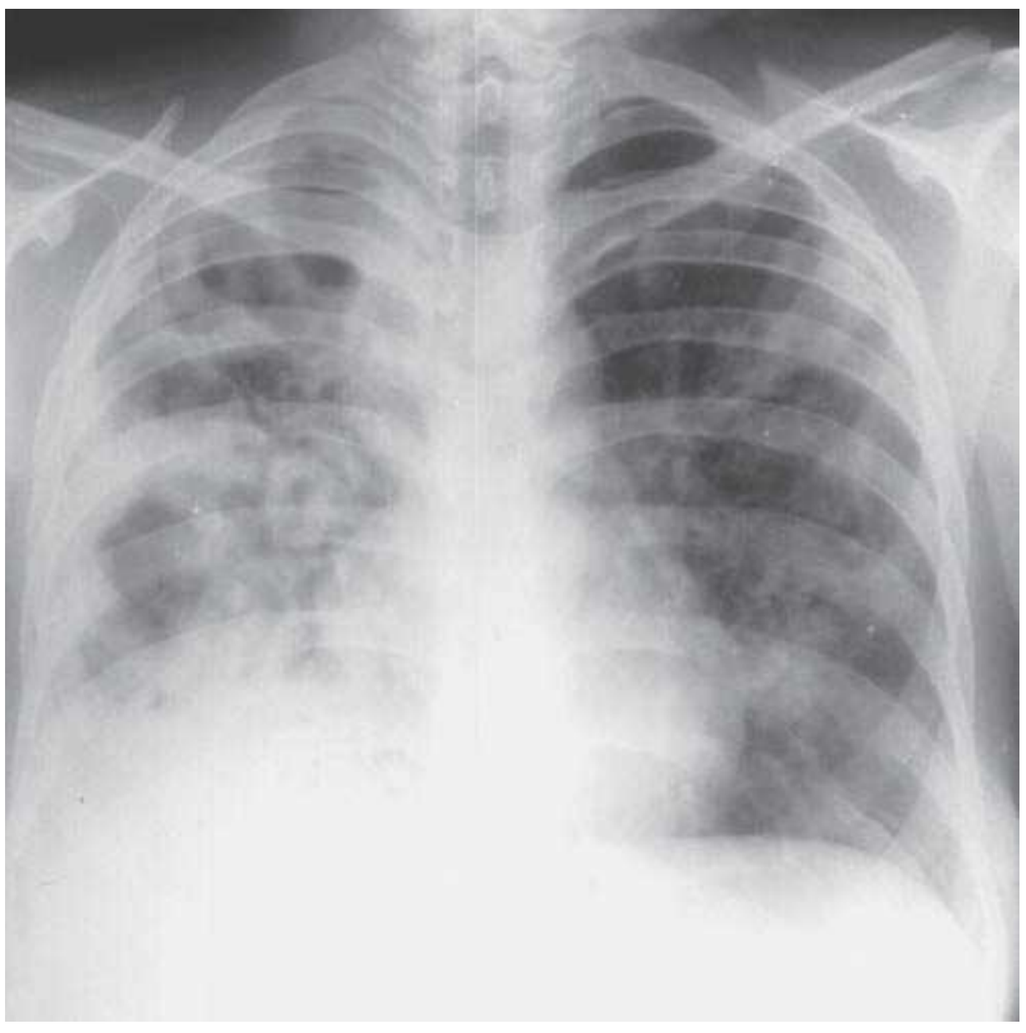

FIGURE 213.5. A 38-year-old man from Himachal Pradesh was admitted with complaints of fever, cough, hemoptysis, and dyspnea. There is endemicity of pneumonic plague where the patient came from due to the prevalent custom of hunting wild rats and rodents. Sputum examination was positive for *Yersinia pestis*. The patient was successfully treated with antibiotics. [Chest radiograph courtesy of Sanjay Jain, MD, Department of Internal Medicine, and Surinder K. Jindal, MD, Professor of Medicine, Postgraduate Institute of Medical Education and Research, Chandigarh, India.]

Diagnosis

The diagnosis of septicemic and pneumonic plague is challenging when buboes are not present. A high index of suspicion is critical in making an early diagnosis so that appropriate therapy can be started as soon as possible. The presence of Gram-negative rods in bloody sputum of an immunocompetent host should suggest pneumonic plague. In the event of multiple, simultaneous cases of rapidly progressive pneumonia, pneumonic plague should be considered in the differential diagnosis. For suspected bubonic plague, the differential diagnosis includes tularemia, cat scratch disease, suppurative adenitis, scrub typhus, tuberculosis, chancroid, and lymphogranuloma venereum [76,77].

Laboratory Diagnosis

A mild-to-moderate leukocytosis with neutrophil predominance and toxic granulations are seen in all forms of plague. In severe cases, elevated transaminases, azotemia, and coagulopathy with disseminated intravascular coagulation are often seen. The sputum is usually purulent, often blood-tinged, and contains *Yersinia pestis* bacilli. A Gram's stain of sputum, blood, or lymph node aspirate may show Gram-negative coccobacilli. Identification of the organism may be difficult by Gram's stain alone because an improperly decolorized specimen can cause *Yersinia pestis* to resemble a Gram-positive diplococcus as a result of its bipolarity. Microscopic examination of a sputum specimen prepared with Wright–Giemsa stain will show the characteristic bipolar staining pattern more clearly (Fig. 213.3). Cultures may be positive for *Yersinia pestis* within 24 to 48 hours. Misidentification of *Yersinia pestis* may occur with automated bacterial identification devices [76,77]. Rapid diagnostic tests such as immunoglobulin-M immunoassay, direct fluorescent antibody testing, and PCR are available in certain laboratories. Direct fluorescent antibody staining for *Yersinia pestis* (Fig. 213.6) and dipstick antigen detection tests are highly specific and are available at some centers [76,77,102–105]. A rapid diagnostic test using monoclonal antibodies to the F1 antigen has recently been field-tested in Madagascar and was shown to be comparable in specificity and sensitivity to detection by ELISA in both bubonic and pneumonic plague. This rapid diagnostic test shows promise for the early on-site diagnosis of

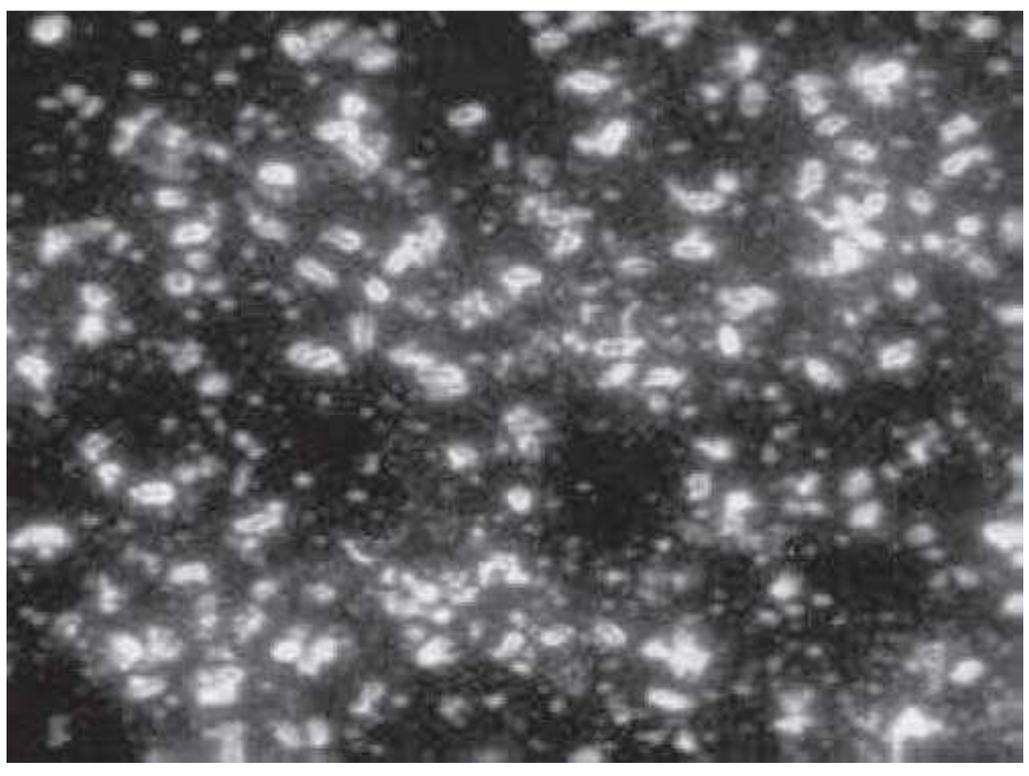

FIGURE 213.6. Fluorescence antibody positivity for *Yersinia pestis* is seen as bright, intense green staining around the bacterial cell. [From CDC Web site: http://www.cdc.gov/ncidod/dvbid/plague/bacterium.htm.]

plague [103]. Additional tests for detection and confirmation that are available through the Laboratory Response Network include PCR assays, molecular-based subtyping, and immunohistochemistry on formalin-fixed tissues [77].

The CDC recommends that plague should be suspected in persons with symptoms of fever and lymphadenopathy if they reside in, or have recently traveled to, a plague-endemic area and if Gram-negative and/or bipolar-staining coccobacilli are seen on a smear taken from affected tissues or other specimens. The diagnosis of plague should be presumed if immunofluorescence staining of smear or material is positive for the presence of *Yersinia pestis* F1 antigen and/or a single serum specimen shows the anti-F1 antigen in a titer of greater than 1:10 by agglutination. In order to confirm the diagnosis of plague, the CDC recommends that one or more of the following criteria be met: isolation of *Yersinia pestis* from a clinical specimen, a single *Yersinia pestis* antibody titer of more than 1:128 dilution, or a fourfold rise in paired sera antibody titer to *Yersinia pestis* F1 antigen. Antibody susceptibility testing should be done at a reference laboratory because there are no standardized procedures for such testing [76,77,105]. Plague as a bioterrorism agent should be suspected when multiple cases of severe and rapidly progressive pneumonic plague cases are seen with fulminant systemic symptoms and hemoptysis.

Treatment

Traditionally, streptomycin or gentamicin has been the mainstay of therapy for *Yersinia pestis*. Other acceptable antibiotics are ciprofloxacin, tetracycline, doxycycline, and chloramphenicol [75–77,82,83,106–109]. The recommendations of the Working Group on Civilian Biodefense for treatment of adult patients with plague in a small, contained casualty setting is streptomycin 1 g IM, given twice daily; gentamicin, 5 mg per kg IM or IV, once daily; or a 2 mg per kg loading dose of gentamicin followed by 1.7 mg per kg IM or IV thrice daily. The dosing of aminoglycosides must include adjustment for renal function. Alternate choices include doxycycline, 100 mg IV, given twice daily or 200 mg IV given once daily; ciprofloxacin, 400 mg IV, given twice daily; or chloramphenicol, 25 mg per kg IV, given four times daily. For pregnant women with plague, the treatment of choice is adult dosing with gentamicin, as described previously. Alternative choices for pregnant women include ciprofloxacin or doxycycline with dosing similar to that of other adults. It should be noted that doxycycline is relatively contraindicated in pregnancy and should only be given to pregnant women if other antibiotics are unavailable or contraindicate. For children, the preferred antibiotics are streptomycin, 15 mg per kg IM, given twice daily (maximum dose of 2 g per day), or gentamicin, 2.5 mg per kg IM or IV, given thrice daily. Alternate antibiotics for children include doxycycline at the adult dose if the child weighs more than 45 kg; doxycycline, 2.2 mg per kg IV, given twice daily if the child weighs under 45 kg; ciprofloxacin, 15 mg per kg IV, given twice daily; or chloramphenicol, 25 mg per kg IV, given four times daily. The duration of treatment is 10 days. For breastfeeding mothers and infants, treatment with gentamicin is recommended. Alternate therapy with fluoroquinolones can be used in either setting. The treatment of immunosuppressed individuals is similar to that of immunocompetent individuals [76,77].

Mass Casualty Treatment and Prophylaxis

In a mass casualty situation from the intentional release of plague, the urgency to initiate prompt treatment of infected individuals, as well as prophylaxis for those exposed but uninfected, may cause a significant stress on healthcare capabilities. The ability to administer parenteral streptomycin or gentamicin will be limited. The Working Group on Civilian Biodefense recommends the use of ciprofloxacin, 500 mg, taken orally twice daily or doxycycline, 100 mg, taken orally twice daily for adults and pregnant women, both for treatment and postexposure prophylaxis. The alternate choice is chloramphenicol, 25 mg per kg, taken orally four times daily. For children, the preferred choices are the adult dose of doxycycline if the child weighs more than 45 kg and 2.2 mg per kg orally twice daily for child weighing less than 45 kg. Children may also be given ciprofloxacin, 20 mg per kg, orally twice daily, or chloramphenicol, 25 mg per kg, orally four times daily. For breastfeeding mothers and infants, treatment with doxycycline is recommended. The duration of treatment is 7 days. All individuals who come within 2 m of a patient with pneumonic plague should receive postexposure prophylaxis. These recommendations are consensus-based for treating plague following an intentional release or bioterrorism attack and may not reflect the FDA-approved use or indications [76,77].

Immunization

Vaccination with a killed, whole-cell vaccine against plague was available in the United States until 1999 for those at high risk for exposure, such as military personnel, those working in endemic areas, and laboratory personnel working with *Yersinia pestis*. The vaccine was not effective against pneumonic plague, and adequate protection in a biowarfare setting is doubtful. Several studies of newer vaccines against plague are ongoing. Vaccines using F1 capsular antigen of doxycycline, 100 mg, taken orally twice daily *pestis* and monoclonal antibodies specific to the F1 and V antigens have shown promising results against pneumonic plague in animal models. Phase I studies with recombinant F1 and V antigens are underway. However, there is no approved vaccine for use against plague available in the United States at the present time [77,110–112].

Infection Control

Patients suspected of plague should be isolated and antibiotic therapy should be instituted promptly. Universal exposure precautions, respiratory isolation using CDC droplet precautions, and special handling of blood and discharge from buboes must be followed. In cases of pneumonic plague, strictly enforced respiratory isolation in addition to the use of masks, gloves, gowns, and eye protection must be continued for the first few days of antibiotic therapy. Following 2 to 4 days of therapy with appropriate antibiotics, patients with both nonpneumonic plague and pneumonic plague may be removed from isolation [113–115]. Laboratory workers should be warned of potential plague infection because cases of laboratory-acquired plague have been reported [98].

Preventive Measures

For naturally occurring cases, the primary preventive measure for plague is rodent and flea control. In endemic areas, the use of insect repellant, the wearing of gloves while handling wild animals, and avoiding rodent burrows will reduce exposure to *Yersinia pestis* [113,114].

BOTULINUM TOXIN

Botulinum is an extremely potent toxin produced by *Clostridium botulinum*, an anaerobic, spore-forming bacterium that is present in the soil. Unlike botulinum toxin that is inactivated by

temperatures above 85°C for 5 minutes, *Clostridium* spores can survive temperatures of 105°C for up to 4 hours, but are readily destroyed by chlorine. Spores may remain viable for over 30 years in a dry state and are resistant to ultraviolet light exposure [116,117]. The botulinum toxin produced by *Clostridium botulinum* is the most poisonous substance known. It can cause a serious, life-threatening paralytic illness in exposed individuals, is easily produced in a laboratory, and can be easily transported. In view of these properties, botulinum toxin has been identified as a major bioterrorism threat [116,118]. It has been designated as a Category A bioterrorism threat by the CDC [10]. There are reports that several countries may have stockpiled or are developing botulinum toxin for use as a bioweapon [116,118]. The general features and management of botulism are presented in Chapters 88 and 175, but the implications of botulism as a bioterrorist weapon are discussed here.

Botulinum Toxin as an Agent of Bioterrorism

There are three forms of naturally occurring botulism: *Foodborne botulism, wound botulism*, and *intestinal (infant and adult) botulism*. All forms of botulism can produce a serious paralytic illness that can lead to respiratory failure and death.

Botulinum toxin solution is a colorless, odorless, tasteless liquid that is easily inactivated by heating at a temperature greater than 85°C for 5 minutes. There are seven different antigenic types that are named botulinum A, B, C, D, E, F, and G. Given its extreme potency, botulinum toxin can produce devastating effects and mass casualties if intentionally dispersed by aerosol or used to contaminate the water supply. One gram of botulinum toxin has the capacity to kill more than 1 million persons if aerosolized [117,118]. Botulinum toxin types A, B, E, and F have been associated with naturally occurring foodborne botulism. Types C and D botulinum toxin cause natural disease in birds and cattle. Type G botulinum toxin is found in South America, but it has not been associated with foodborne botulism. Inhalational challenge studies with aerosolized botulinum toxin in monkeys have demonstrated the development of illness following exposure to types C, D, and G. Researchers suspect that humans are also susceptible to these types [118–120].

The intentional use of botulinum toxin can be either inhalational or foodborne. In the 1930s, the Japanese reportedly executed a number of Manchurian prisoners by feeding them cultures of *Clostridium botulinum*. During World War II, there was concern that Germany had weaponized botulinum toxin for use as a biowarfare agent. This led to the production of more than 1 million doses of botulinum toxoid vaccine for allied forces in Europe, but the vaccine was never given. Botulinum toxin was produced by the United States for use as a bioweapon from World War II to the early 1970s when the bioweapon program was terminated. Following the 1972 Convention on the Prohibition of the Development and Stockpiling of Biological and Toxin Weapons, both the former Soviet Union and Iraq continued to develop botulinum toxin as a biowarfare agent. After the 1991 Persian Gulf War, Iraq admitted to U.N. weapons inspectors that it had produced and stockpiled biological weapons containing botulinum toxin. It has been reported that several countries may continue to produce or stockpile botulinum toxin for use as a bioweapon [118].

At the present time, there is considerable concern about the potential use of botulinum toxin as an agent of bioterrorism. Contamination of either a food or a beverage source that can retain the potency of botulinum toxin can result in mass casualties, serious illness among affected individuals, the overwhelming of hospitals, enormous stress on intensive care units, and significant anxiety among the general population [117,118]. It has been estimated that 1 g of botulinum toxin added to milk that is commercially distributed and consumed by 568,000 individuals can result in 100,000 cases of botulism [121]. It has also been estimated that 1 g of aerosolized botulinum toxin could potentially kill more than 1 million people [118]. The dispersion of aerosolized botulinum toxin in the unsuccessful terrorist attacks in Japan during the early 1990s suggests that botulinum toxin could be used in future bioterrorism attacks.

Pathogenesis

Following exposure by inhalation or ingestion, the toxin is activated, enters the circulation, and the heavy chain of the toxin gets bound to the neuronal membrane on the presynaptic side of the neuromuscular junction. The toxin then enters the neuronal cell, after which the light chain of the toxin cleaves the synaptic proteins that form the synaptic fusion complex. Disruption of the synaptic fusion complex prevents release of acetylcholine release into the synaptic cleft. Without acetylcholine, the affected muscle becomes paralyzed. Muscle paralysis can last for several months. Death from botulism is caused by failure of the respiratory muscles to contract. The central nervous system is unaffected as botulism toxin does not cross the blood–brain barrier. A prospective, observational cohort study of 91 botulism patients in Thailand showed that those individuals presenting with dyspnea, moderate-to-severe ptosis, and papillary changes were likely to progress to respiratory failure, while a long incubation period before symptoms appeared was associated with a more favorable prognosis [122].

Treatment

The treatment of botulism includes supportive care, mechanical ventilation if necessary, and the administration of botulinum antitoxin. In an outbreak following an intentional release, the healthcare demands may overwhelm current capabilities, especially with regard to the availability of mechanical ventilators and critical care providers. At present, there is an ongoing U.S. government effort to stockpile mechanical ventilators that can be deployed in the event of a mass casualty.

Rega et al. suggest an algorithm to assess the severity of botulism cases that may be helpful in mass casualty situations [123]. Specific therapy for botulism involves the administration of botulinum antitoxin. Early suspicion of botulism and the prompt administration of botulinum antitoxin can reduce nerve damage and disease severity. However, any muscle paralysis existing prior to antitoxin administration will not be reversed. The goal of antitoxin therapy is to prevent further paralysis by neutralizing unbound botulinum toxin in the circulation. If the type of botulinum toxin is known, a type-specific antitoxin can be given. If the toxin type is not known, the trivalent antitoxin containing neutralizing antibodies against botulinum toxin types A, B, and E should be given. Botulinum antitoxin is available from the CDC through state and local health departments. If another type of toxin is intentionally dispersed during a bioterrorism attack, consideration may be given for the use of an investigational heptavalent antitoxin (ABCDEFG) that is in the possession of the U.S. Army. Physicians should review the package insert prior to administering the antitoxin to familiarize themselves with the dose, dilution, and mode of administration. A new heptavalent botulinum antitoxin (HBAT) approved by the FDA replaced the former botulinum antitoxin in 2010. This heptavalent antitoxin contains equine-derived antibody to all the seven botulinum toxins from A to G. If a case of botulism is suspected, prompt diagnosis is

essential. If botulism is confirmed, the CDC will provide the new heptavalent antitoxin and detailed instructions for its intravenous administration [124]. Additional doses of botulinum antitoxin will be needed if multiple cases of botulism occur after an intentional release. Following the initial administration of botulinum antitoxin, patients should be carefully assessed for refractory problems, such as rapidly progressing paralysis, severe airway obstruction, or overwhelming respiratory tract secretions, which may indicate the need for an additional dose. Hypersensitivity reactions to botulinum antitoxin may occur. These include anaphylaxis, serum sickness, chills, fever, dyspnea, cutaneous erythema, and edema of the tongue. The incidence of hypersensitivity with the recommended one-vial dose is about 1%. A small dose can be given initially to screen for hypersensitivity, but this would be impractical in a mass casualty situation [116–118,125–127].

Prophylaxis

In the United States, a pentavalent botulinum toxoid is available from the CDC for the immunization of laboratory workers who may be exposed to botulinum toxin and for the protection of military personnel in the event of a biowarfare attack. It may be obtained on an investigational basis for others at high risk for botulinum toxin exposure. Botulinum toxoid, 0.5 mL, is given subcutaneously at 0, 2, and 12 weeks, followed by a booster dose at 1 year. Adequate immunity against botulinum toxin is assessed by measuring antitoxin titers. In one study, an adequate response was noted in 91% of those immunized against toxin A and 78% of those immunized against toxin B. In an animal study, the intranasal administration of botulinum toxin in mice, with and without prechallenge immunization with pentavalent toxoid, showed intra-alveolar hemorrhage and interstitial edema in both groups, but the immunized mice were protected from lethality and nervous system changes in comparison to nonimmunized mice [128].

Mass immunization of the public with botulinum toxoid is not recommended and is not currently available. It takes several months to attain acquired immunity following the administration of botulinum toxoid and, therefore, it is not effective for postexposure prophylaxis. Recent evidence suggests that a recombinant oligoclonal antibody may have efficacy in preventing and treating botulism. Animal studies have shown promise for using the heavy chain of the botulinum toxin molecule as an inhalational agent for the treatment of botulism [116–118,125,128].

RICIN

Ricin is a potent toxin that belongs to the broad family of ribosome-inhibiting proteins and is easily extracted from seeds contained in the bean of the castor plant, *Ricinis communis*. "Ricinus" is the Latin word for tick and the plant was given this name for the resemblance of castor bean seeds to engorged ticks [129]. The castor plant, a native plant of Africa, is a common outdoor plant in warm climates and is also used for ornamental purposes. Castor bean seeds, castor oil, and the castor plant itself have been used for many centuries for their medicinal (laxative and purgative), lubricant, and decorative properties. Castor bean seeds contain high concentrations of ricin. Ingestion of as few as three seeds can be fatal. Ricin is an immunotoxin, allergen, and toxic enzyme that inhibits protein synthesis. As a result of its biochemical properties, ricin has antitumor effects and has undergone phase I and phase II clinical trials as a chemotherapeutic agent. Ricin can be inactivated by heating to 175°F for 10 minutes. It can be produced in liquid, crystalline, or dry powder forms. Both the liquid and powder forms have the potential to be aerosolized [130,131].

Toxicology

Ricin is an enzyme consisting of two sulfide-linked polypeptide chains, A and B. The A-chain enters the cytosol of a cell, inactivates the 28S ribosomal subunits, inhibits protein synthesis, and causes cell death. The B-chain binds to the cell surface at galactose-containing sites and facilitates entry of the A-chain into the cell [132,133]. Most of the data regarding the toxicity of ricin come from animal experiments. Both the toxicity and the lethality of ricin depend on the exposure dose and the route of administration. In experiments using mice, the LD_{50} and time of death are 3 to 5 µg per kg and 60 hours by inhalation, 5 µg per kg and 90 hours by intravenous injection, and 20 mg per kg and 85 hours by intragastric administration. The lethal doses of ricin in humans have been calculated to be approximately 5 to 10 µg per kg by inhalation and 1 to 10 µg per kg by injection [134–137]. On exposure to lethal doses of ricin by inhalation, rats develop a necrotizing tracheobronchitis and pneumonia with parenchymal inflammation and pulmonary edema. These pathologic changes lead to alveolar flooding and hypoxemia. Immunohistochemical stains show that ricin binds to bronchiolar cells, macrophages, and alveolar lining cells. In nonhuman primates, inhalation of ricin leads to death within 48 hours of exposure, and autopsy shows diffuse necrosis of airways, severe pulmonary edema, severe fibrinopurulent pneumonia, and mediastinal lymphadenitis [135]. Animal data show that the Kupffer cells are the primary targets of ricin-induced injury to the liver [134]. Ricin toxicity is not contagious to other individuals.

Ricin as an Agent of Bioterrorism

The high toxicity, relative ease of production, ease of dissemination, and stability of ricin in ambient conditions make it a potential agent of bioterrorism. Ricin can be dispersed as an aerosol or as a contaminant of food and beverages for the purpose of causing multiple casualties. Most experts agree that it would be logistically difficult to use ricin for the production of large-scale mass casualties because it would take a very large amount to do so [138]. However, ricin may be an ideal agent for small-scale bioterrorism attacks against high-value targets. Dozens of people could be killed in such attacks and the psychological impact on a community could be enormous.

There have been several reports of the use or intended use of ricin in terrorist activities. In 1978, a Bulgarian diplomat, Georgi Markov, was killed in London by a ricin-containing pellet fired from an umbrella-based weapon [139,140]. In January 2003, British authorities arrested 10 individuals from North Africa who were residing in a London apartment where ricin was found [140]. In October 2003, ricin was identified in an envelope at a Greenville, South Carolina, post office [140–142]. In November 2003, an envelope addressed to the White House was reportedly intercepted by the Secret Service and was found to contain ricin [140]. In February 2004, ricin was reportedly detected in the Dirksen Senate Office Building [140]. These events highlight the need for critical care providers to be familiar with the recognition and management of ricin poisoning.

Ricin Toxicity in Humans

The pathologic changes and clinical symptoms caused by ricin exposure depend on the exposure dose and the route of

exposure. The clinical effects of ricin in humans have been described following cases of castor seed ingestion and parenteral use in chemotherapeutic clinical trials. There are limited clinical data regarding ricin toxicity via inhalational route in humans. The clinical findings observed in animal models after the oral or parenteral administration of ricin appear to correlate with the clinical findings of humans exposed to oral or parenteral ricin. Therefore, the findings from animals following inhalational exposure are presumed to be similar to those that would be experienced by humans following ricin inhalation. Leukocytosis appears to be a constant finding, regardless of the route of exposure. Ricin toxicity by any route of exposure can produce hallucinations and seizures.

Gastrointestinal Route

The ingestion of castor seeds can cause human illness that ranges from mild to severe, based on the amount of ricin ingested. Compared to other routes of ricin exposure, the gastrointestinal route is the least toxic. A review of 751 cases of castor seed ingestion reported symptoms consisting of nausea, vomiting, and abdominal cramping within a few hours after ingestion, followed by diarrhea that may become bloody and lead to both dehydration and volume depletion. Patients developed hypotension, severe fluid and electrolyte loss, tachypnea, tachycardia, and sweating. There were case fatality rates of 8.1% for untreated individuals and 0.4% for treated individuals. Death occurred approximately 72 hours after exposure. In addition, sore throat, dilation of the pupils, altered mental status, hallucinations, and seizures were noted in some patients. On autopsy, hepatic necrosis, renal necrosis, necrosis of the gastrointestinal mucosa with local hemorrhage, and mesenteric lymph node necrosis were found. The hepatic and renal damage may be secondary to vascular collapse rather than the result of direct toxin injury [131,143–146].

Parenteral Route

In cases of ricin toxicity produced by parenteral administration, pain at the site of injection, fatigue, malaise, headache, rigors, and fever were noted in the first 24 hours. Patients also showed local necrotic lymphadenopathy. Ricin, when used as a chemotherapeutic agent at a dose of 18 to 20 µg per kg, caused nausea, vomiting, myalgia, and fatigue [131]. More serious adverse effects may include pulmonary edema, hypoalbuminemia, cardiac failure, hypotension, hypovolemic shock, acute hepatorenal failure, gastrointestinal bleeding, thrombocytopenia, and bleeding diathesis [131–133,143,147–149].

Inhalational Route

Patients with inhalational exposure of ricin may develop symptoms within 3 to 24 hours. The only information regarding human exposure to the inhalational form comes from exposure to castor seed dust. Reported symptoms from dust inhalation include itchy eyes, nasal and bronchial congestion, urticaria, chest tightness, and wheezing. Severe bronchospasm has been reported [131]. In an accidental exposure, ricin caused fever, chest tightness, dyspnea, cough, nausea, and arthralgias in 4 to 8 hours. These symptoms are suggestive of an allergic syndrome. Based on animal data following high-dose inhalational exposures, one may expect humans to develop cough, dyspnea, chest pain, cardiac dysfunction, cyanosis, arthralgias, airway necrosis, alveolitis, high permeability pulmonary edema, adult respiratory distress syndrome, and acute respiratory failure. The mortality rate in animals is high following ricin inhalation and usually occurs within 36 to 72 hours. It appears that ricin causes endothelial cell damage with fluid and protein leak with edema [131–133,143].

Ricin as an Allergen

Allergic responses of types I and IV have been reported following dermal exposure to castor seeds and castor seed dust. A case report describes an anaphylactic-type reaction in a woman when one of the seeds from her castor-bean necklace disintegrated in her fingers. The woman experienced rhinitis, sneezing, periorbital edema, and facial urticaria requiring a subcutaneous injection of epinephrine [150–152]. Urticaria has been reported following the inhalation of castor seed dust [150]. Although the incidence of ricin-associated allergic reactions is unknown, they may be relatively frequent among exposed individuals because of the immunogenic properties of the ricin molecule.

Diagnosis

The diagnosis of ricin toxicity is challenging. The differential diagnosis includes exposure to staphylococcal enterotoxin, phosgene, oxides of nitrogen, and organohalides. If a bioterrorism attack is suspected, anthrax, plague, and tularemia should also be considered. Ricin intoxication by the inhalational route can be confirmed by ELISA analysis of nasal mucosal swabs taken within 24 hours of exposure. Specific ricin antigen testing or immunochemical staining of serum and respiratory secretions can also be performed. Because ricin is an immunogenic toxin, a significant increase in the antiricin antibody titer 2 weeks after exposure may also be helpful in confirming the diagnosis. It is recommended that acute and convalescent antibody titers be obtained in all individuals suspected of ricin intoxication. However, antiricin antibodies are rapidly metabolized and excreted, so the absence of a significant increase in titer does not exclude the diagnosis [131,153,154].

Neutrophilic leukocytosis is usually present in peripheral blood. Pleural effusions and bilateral alveolar infiltrates, indicative of pulmonary edema, may be seen on chest radiographs. Arterial blood gases should be monitored to assess oxygenation, the adequacy of ventilation, and acid–base status. Myocardial ischemia, cardiac dysrhythmias, and cardiac conduction abnormalities may occur. Therefore, an electrocardiogram and cardiac biomarkers should be obtained. An echocardiogram may be helpful in assessing myocardial contractility if heart failure is suspected [131,155].

Treatment

The management of ricin intoxication is largely supportive, regardless of the route of exposure [130,132,133]. All patients suspected of ricin intoxication should be decontaminated by removing all clothing and washing the skin with soap and water. Careful attention to fluid and electrolyte balance is essential, especially in patients with pulmonary edema. Vasopressors may be needed for the management of severe hypotension. If ricin ingestion has occurred, gastric lavage may be helpful in removing ricin from the gastrointestinal tract. If the patient is alert, activated charcoal can be given. Blood transfusion with packed red blood cells may be needed if severe anemia is caused by bloody diarrhea. If inhalation is the route of exposure, careful airway management is essential. Bronchospasm should be treated with a nebulized bronchodilator. Patients with severe pulmonary edema will require intubation and mechanical ventilation. Oxygen should be administered at a concentration sufficient to keep the arterial oxygen tension (PaO_2) greater than 60 mm Hg. Myocardial infarction, myocardial ischemia, cardiac dysrhythmias, and cardiac conduction abnormalities should be treated as appropriate. A temporary pacemaker may

be required for severe conduction abnormalities, such as complete heart block. Mild allergic reactions can be treated with an antihistamine. Epinephrine should be given for anaphylaxis. A nonsteroidal anti-inflammatory drug can be given for arthralgias and myalgias [131].

There is no specific antitoxin for ricin. Animal studies have shown that active immunization or passive prophylaxis can be effective against the parenteral or intraperitoneal administration of ricin if administered within a few hours following exposure. One animal study showed that the administration of aerosolized antiricin antibody can offer protection against the effects of ricin inhalation. The intratracheal administration of ricin toxoid led to reduction in lung inflammation in another animal study. There are no clinical trials or reports regarding the use of these agents in humans; therefore, their therapeutic efficacy in the clinical setting is unknown [130–133,146].

Most patients with ricin intoxication should survive the acute effects if appropriate supportive care is given promptly after exposure. However, because the clinical effects of ricin intoxication are dose-related, individuals exposed to high concentrations may die from cardiopulmonary arrest in spite of the best supportive care.

Immunization

Animal studies have shown that rats immunized against ricin with formalin-treated toxoids administered subcutaneously survived acute inhalation challenges with lethal doses of ricin [137,156,157]. Another animal study showed that the immunization of mice with an oral ricin-toxoid vaccine encapsulated in polymeric microspheres offered protection against inhalational exposure to ricin [158]. Several studies using a rat model have shown that antibody-mediated immunity to ricin following ricin-toxoid vaccination offered protection against lethal doses of ricin. There are also animal data that indicate that secretory antibodies are important in preventing injury to the lung after an aerosol challenge with ricin. Although ricin-toxoid vaccines have been shown to be protective in animal models, they may not be clinically useful in humans due to safety concerns. Researchers are working on the development of a vaccine against ricin that can be given to humans prior to exposure. The future use of such a vaccine in humans will depend on its safety profile and its efficacy in stimulating protective antibodies against ricin, especially in the mucosal layers of the respiratory and intestinal tracts [131,159–162].

CHAPTER 214 ■ CHEMICAL AGENTS OF MASS DESTRUCTION

JAMES GEILING AND LAWRENCE C. MOHR JR

If supposedly civilized nations confined their warfare to attacks on the enemy's troops, the matter of defense against warfare chemicals would be purely a military problem, and therefore beyond the scope of this study. But such is far from the case. In these days of total warfare, the civilians, including women and children, are subject to attack at all times.

Colonel Edgar Erskine Hume, Medical Corps, U.S. Army, 1943 [1]

Chemical agents of terror have moved to the forefront of concern for healthcare providers as weapons of mass destruction (WMD) have become readily available to both domestic and international terrorists. Critical care physicians must be familiar with these agents, their impact on patients, and the potential dangers these compounds can cause to healthcare workers.

Although terrorists have traditionally focused their efforts on the use of conventional explosives, chemical agents have emerged as attractive weapons of terrorism for a variety of reasons:

- Raw materials for their production are readily available throughout the world.
- Raw materials are inexpensive.
- A chemical weapon of mass destruction can be produced with relatively small amounts of raw materials.
- They may be odorless, colorless, and tasteless.
- They are poorly detected.
- They do not destroy infrastructure.
- They possess a latency period between the time of exposure and the development of clinical symptoms.
- Their use produces a mass media response [2].

Hospital-based physicians normally, at some time in their medical career, study the skills and procedures needed to treat mass casualties. The focus, however, has traditionally centered on large numbers of casualties presenting to the emergency department as a result of multisystem trauma, such as that sustained in an explosion, airplane crash, or natural disaster. The event of September 11, 2001, and subsequent terrorist threats have changed the nature of physician training and preparation requirements. The scope of preparation now requires knowledge of the mass care of victims following a WMD event. This chapter focuses on the recognition and management of patients exposed to common chemical agents of mass destruction.

HISTORY

Chemical agents of mass destruction are gaseous, liquid, or solid substances that are employed against a population because of their direct toxic effects. Virtually any toxic substance can be used as an agent of mass destruction. However, those that have been successfully weaponized are characterized by ease of production, ease of handling during weapon assembly, dispersion properties, and ability to cause injury and death in relatively low concentrations [3].

Although the first reported use of chemical agents dates back to 1000 BC, when Chinese forces used arsenical smokes, the use of chemical agents in warfare began in earnest during World War I when German forces seeking a breakout from the stalemate of trench warfare released 150 tons of chlorine gas from 6,000 cylinders on the afternoon of April 15, 1915, near Ypres, Belgium. The chlorine gas resulted in 800 deaths and caused the retreat of 15,000 Allied troops, largely because of the psychological terror produced by the gas attack.

The next major use of chemical weapons took place more than 2 years later, on July 12, 1917, again near Ypres. On that date, German forces attacked Allied troops with artillery shells containing sulfur mustard. This attack resulted in 20,000 casualties. Although many casualties had debilitating injuries, less than 5% of the troops died as a result of the chemical attack. Persistent and nonvolatile, sulfur mustard caused a host of new problems for Allied forces, including a latency period before the effects appeared and the need for men, and their horses, to wear protective overgarments [4].

The Geneva Convention of 1925 banned the use of chemical warfare agents because of the physical and psychological trauma they imposed on their victims.

Nerve agents appeared in the 1930s when the German industrial chemist, Dr. Gerhard Schrader, began research into the development of stronger insecticides, the first two of which were tabun and sarin. German forces stockpiled these for use in World War II, but never used them.

Chemical agents were used sporadically in the second half of the twentieth century. The United States used defoliants and riot-controlled agents in Vietnam. Iraq used mustard, tabun, and eventually sarin against Iran in the Iran–Iraq war of the 1980s. Later in the 1980s, reports implicated Iraq in the use of cyanide against the Kurdish population in northern Iraq [5].

The most recent publicized use of chemical agents took place in Japan when the Aum Shinrikyo religious cult released sarin gas on two occasions. The first took place on June 27, 1994, in Matsumoto and resulted in 600 persons exposed, 58 admitted to the hospital, and 7 deaths [6]. The more famous and larger event took place the following year, on March 20, 1995, when the cult released sarin gas in the Tokyo subway system during rush hour. The subway system attack resulted in the deaths of 11 commuters and the medical evaluation of approximately 5,000 individuals [7].

In 1997 the Chemical Weapons Convention (CWC) went into effect as an international treaty that bans the use, development, production, acquisition, transfer, stockpiling, and retention of chemical weapons by signatory nations. At the time of this writing, the CWC was ratified by 175 nations, including the United States. The CWC is administered by the Organization for the Prohibition of Chemical Weapons, which conducts regular inspections and monitors compliance with provisions of the treaty [8].

DETECTION AND DECONTAMINATION

Initial steps in the management of chemical agent casualties include detection of the chemical agent used in the attack and the decontamination of casualties. Detailed discussions on detection and decontamination are beyond the scope of this chapter. However, hospital-based critical care physicians should understand basic concepts of these topics to better care for their patients and protect themselves and their facilities from potential harm.

The most important tool in detecting the use of these agents is accurate and timely intelligence from military or law enforcement agencies. Unfortunately, hospitals are not usually in the information-sharing and decision-making circles with these groups. As a result, initial awareness of a chemical agent attack typically occurs with the first patient presenting to the emergency department. Hospitals and physicians can improve their preparedness for the management of chemical agent casualties by actively participating in disaster-planning activities in their respective communities.

Various types of sensing devices can be used for the detection of chemical agents in the environment. At the present time, all commercially available detection equipment uses point source technology; that is, proximity to the substance is required. The handheld Chemical Agent Monitor uses ion mobility spectrometry to detect mustard and nerve agents. Chemical agent detection papers, such as the M8 and M9 papers (Anachemia, Lachine, Quebec, Canada), can be used to detect mustard and nerve agents. The M256 Detection Kit (Anachemia, Lachine, Quebec, Canada) can detect mustard, nerve agents, phosgene, and cyanide. Standoff capability, that is, detecting agents from as far away as 5 km, has been developed to detect contaminated areas without being exposed [9]. Newer chemical agent detection technologies will continue to evolve in response to the terrorism threat. These can only help ensure hospitals and providers have quicker, more accurate information to meet the needs of victims.

Ideally, the decontamination of chemical agent casualties should be accomplished by first responders or hazardous material personnel prior to evacuation or transport to a medical facility. Unfortunately, most disaster victims bypass emergency medical system transport and arrive unannounced at the closest hospital. As a result, hospitals must be prepared to decontaminate chemical agent casualties prior to admission. Facilities and protocols to decontaminate such casualties should be developed by all hospitals. Such processes are needed to protect the victims from further exposure and to prevent the spread of chemical agents within the hospital and among healthcare providers. Critical care physicians, nurses, and support personnel may be called on to help develop decontamination protocols and assist in the decontamination process. It is imperative that all individuals designated to serve on decontamination teams be thoroughly trained in the procedures, precautions, and protective clothing required in the decontamination process. Attempting to provide help in a contaminated environment without prior training puts the healthcare provider at risk of being exposed to a chemical agent and could impede the delivery of effective medical care for the victims of a chemical attack.

The sarin gas release in Tokyo provides a clear example of the need for preparation and training prior to a chemical attack. Of the 1,364 emergency personnel who responded to the attack, 135 (9.9%) became symptomatic and required medical support themselves. None of the first responders wore protective clothing or face masks and off-gassing of the chemical agent from clothing of victims played a significant role in their complaints. These effects were evident among hospital staff as well first responders. It was reported that 23% of the staff at the hospital that received the patients also experienced symptoms [10].

The Occupational Safety and Health Administration (OSHA) mandates that all healthcare providers be trained to perform their duties without jeopardizing the health and safety of themselves or coworkers. It provides guidance for the use of personal protective equipment and requires that written plans be developed for hospitals to train teams in the use of personal protective equipment to receive contaminated victims [11]. Most medical facilities prepare their decontamination teams to operate in OSHA personal protective equipment Level C; that is, full-face mask with an air-purifying canister respirator and chemical-resistant clothing.

In most situations, effective chemical decontamination can be performed by carefully removing the victim's clothing and thoroughly washing the victim with soap and water. It has been reported that removing contaminated clothing alone can eliminate 85% to 90% of chemical contaminants [12]. Recently developed for the military and soon to be used by first responders is Reactive Skin Decontamination Lotion (RSDL) (O'Dell Engineering Ltd/E-Z-EM Canada Inc., Canada). It is not used for prophylactic protection or total body decontamination, but, if applied early following exposure, is effective in neutralizing chemical warfare agents and T2 mycotoxins [13]. However, in exposures associated with trauma, RSDL may interfere with normal wound healing [14]. EasyDECON (Envirofoam Technologies, Huntsville, Alabama) can be used to decontaminate exposed environmental surfaces. Normally employed as a foam, it effectively neutralizes a variety of chemical agents including nerve gases and mustard [15]. Finally, medical facilities must consider environmental variables such as wind direction, wind velocity, temperature, and water runoff when setting up decontamination areas. These environmental considerations are important in protecting patients and employees from exposure to chemical agents, as well as minimizing the risk of contaminating buildings and equipment during the patient decontamination process.

CLASSIFICATION OF CHEMICAL AGENTS

Chemical agents are normally classified into broad categories based on their mechanisms of action and physiologic effects. The most common classification scheme divides them into the following categories:

- Nerve agents
- Vesicants
- Cyanide agents or "blood" agents
- Pulmonary agents or "choking" agents
- Nonlethal incapacitating agents

Nerve Agents

Because they are the most toxic, nerve agents are the most feared of chemical agents. All nerve agents are organophosphorus compounds, which inhibit butyrylcholinesterase in the plasma, acetylcholinesterase in the red blood cell (RBC), and acetylcholinesterase at cholinergic receptor sites in the central and peripheral nervous systems. The chemical bond between nerve agent molecules and acetylcholinesterase is irreversible; thus, acetylcholinesterase activity returns only with new acetylcholinesterase synthesis or RBC turnover (1% per day) [16]. The decrease in acetylcholinesterase activity results in the accumulation of acetylcholine at both muscarinic and nicotinic

receptors in the central nervous system and neuromuscular junctions of the peripheral nervous system. Cholinergic overstimulation resulting from the accumulation of excess acetylcholine in the central and peripheral nervous systems is responsible for the clinical manifestations of nerve agent toxicity [17].

After an acute exposure to nerve agents, RBC acetylcholinesterase reflects nervous system acetylcholinesterase activity better than the activity of butyrylcholinesterase in the plasma. The measurement of RBC acetylcholinesterase activity is principally a research tool at the present time, and it is not useful in the management of mass casualties from nerve agent exposure. However, its measurement in blood samples collected from victims of a chemical attack may be useful in forensic investigations.

Several different nerve agents currently exist, each characterized by a unique molecular structure that irreversibly inhibits acetylcholinesterase. Compounds that were originally developed in Germany have been designated as the "G" series of nerves agents. The "V" series of agents are better absorbed through the skin than the "G" agents and are so designated because they are more "venomous." The most common nerve agents include:

- GA (tabun): ethyl N,N-dimethylphosphoramidocyanidate
- GB (sarin): isopropyl methyl phosphonofluoridate
- GD (soman): pinacolyl methyl phosphonofluoridate
- GF: O-cyclohexyl-methylphosphonofluoridate
- VX: O-ethyl S-(2-(diisopropylaminoethyl) methyl phosphonothiolate

The "G" agents are volatile, whereas VX is a persistent, oily substance with better percutaneous absorption. Each of these agents can be dispersed through a variety of weapons and munitions.

Inhalation of nerve gas is the most effective means of producing clinical effects, although it can also be ingested. High doses of persistent nerve agents, such as VX, can be absorbed through the skin. The clinical effects of nerve agent toxicity occur as a result of acetylcholine accumulating at both nicotinic sites (autonomic ganglia and skeletal muscle) as well as muscarinic sites (including postganglionic parasympathetic fibers, glands, and pulmonary and gastrointestinal smooth muscles). Nicotinic receptors appear to be most sensitive to the effects of nerve agents, with inactivation of acetylcholinesterase in autonomic ganglia and the neuromuscular junction of skeletal muscle responsible for many symptoms and signs of nerve agent exposure. The typical clinical manifestations of nerve agent toxicity are similar to those produced by organophosphate insecticides, although nerve agents are up to 1,000 times more toxic [17].

The basic clinical syndrome produced by nerve agents can be remembered by the acronym "SLUDGE": salivation, lacrimation, urination, defecation, gastric distress, and emesis. Alternatively, "DUMBELS" (diarrhea, urination, miosis, bradycardia/bronchorrhea/bronchospasm, emesis, lacrimation, salivation/secretion/sweating) provides a more detailed tool to remember the muscarinic signs and symptoms [18]. Specific signs and symptoms in various organ systems depend on the dose of nerve agent received. Inhalation of a nerve agent usually produces immediate effects that occur within seconds to minutes after exposure. Dermal absorption usually produces delayed effects that can develop at any time between 10 minutes and 18 hours after skin exposure, depending on the dose. Common signs and symptoms in each organ system are summarized here.

Inhalation of a nerve agent typically results in the development of rhinorrhea, bronchorrhea, and bronchoconstriction soon after exposure. Dyspnea and chest tightness are common early symptoms. Coughing and wheezing may occur. The volume of airway secretions, the magnitude of bronchoconstriction, and the severity of airway symptoms all increase with higher exposure doses. High-dose or prolonged exposure may result in diaphragmatic weakness and centrally mediated apnea, which can result in ventilatory failure [16,17].

Although vagally mediated bradycardia is the expected heart rate response from cholinergic overstimulation of muscarinic receptors, this is commonly overridden by tachycardia resulting from nicotinic-mediated adrenergic stimulation and hypoxia. First-, second-, and third-degree heart block may occur [16,17]. Prolongation of the QTc interval can precipitate Torsade de pointes that has a poor prognosis [19]. Although hypertension may occur as a result of nicotinic-mediated adrenergic stimulation, blood pressure usually remains normal. A decline in blood pressure is typically a sign of impending death [4].

Muscarinic and nicotinic stimulation of the peripheral nervous system typically results in muscle fasciculations and profuse sweating, respectively. Muscle weakness and muscle paralysis may occur following high-dose exposures. Seizures can develop suddenly. The seizures may resolve spontaneously, but can be prolonged with status epilepticus [16,17]. Smaller-exposure doses typically result in nonspecific neurologic findings including an inability to concentrate, insomnia, irritability, and depression. A variety of psychological and behavioral changes, ranging from mild confusion to severe anxiety, can also occur [15]. Hallucinations or complete disorientation do not appear. Mild exposure also may result in a slight decline in memory function, as observed in first responders in the Tokyo sarin gas release of 1995 [20]. In the decade since that event, those exposed continue to have mild cerebellar effects and principally posttraumatic stress disorder [21].

Direct contact of the eyes with nerve agent vapor causes miosis that is usually associated with intense ocular pain. Patients also complain of blurred or dim vision and typically have injected conjunctivae with significant lacrimation.

Nausea and vomiting may be among the first signs of nerve agent toxicity. Abdominal cramping and diarrhea may also occur [16,17].

Unfortunately, few of the clinical signs or symptoms listed here may appear following exposure to a high dose of nerve agent. This is due to the fact that the range of exposure of doses, which produce clinical symptoms, is only slightly less than those which cause death. Therefore, central nervous system collapse with seizures, loss of consciousness, and central apnea may be the first signs of nerve agent toxicity following a high-dose exposure [16].

Management of all nerve agent casualties begins with the traditional "ABCs" of resuscitation: airway, breathing, and circulation support. Contaminated patients should be managed in the following order:

- Airway management
- Breathing support
- Circulation and hemorrhage control
- Antidote administration
- Decontamination
- Wound dressing
- Evacuation to a noncontaminated treatment location [22]

Ventilatory failure is the primary cause of death following nerve agent exposure [23]. As a result, airway management and breathing support are extremely important in the management of nerve agent casualties. The nausea and vomiting that these patients typically experience must be considered in their airway management. In this regard, all patients should be considered to have a full stomach. Endotracheal intubation and assisted ventilation are required for the management of ventilatory failure. High airway resistance necessitating the need of pressures up to 50 to 70 cm of water may complicate ventilatory support [17]. Because of high airway pressures, if a cuffed endotracheal tube cannot be placed, a double-lumen Combitube (Tyco

Healthcare, Pleasanton, CA) is preferable to a laryngeal mask airway [24]. Once an effective airway has been established, ventilatory assistance can be provided by manual ventilation using a bag-valve device or by mechanical ventilation. Nebulized ipratropium can be used for the treatment of bronchospasm that may, in turn, result in decreased airway resistance [16]. Frequent suctioning is necessary to remove the copious airway secretions associated with nerve agent exposure. The use of depolarizing neuromuscular blocking agents during ventilatory assistance should be avoided [25].

The principal antidote for nerve agents is atropine. Atropine is an anticholinergic drug that blocks acetylcholine receptor sites. As a result, atropine blocks the pathophysiologic effects of the excess acetylcholine that accumulates as a result of nerve gas exposure; it is most effective at muscarinic sites. Atropine is primarily used for the purpose of drying up the copious airway secretions that patients develop following nerve agent exposure. The standard adult dosing regimen is 2 mg, administered intramuscularly, every 5 to 10 minutes, titrated to the patient's secretions. The recommended pediatric dose is 0.05 mg per kg, with a minimum dose of 0.1 mg, administered intravenously every 2 to 5 minutes, titrated to effect [17,23]. In severe cases, adult patients may require 10 to 20 mg of atropine in the first hour to control secretions. The administration of atropine to a hypoxemic patient could precipitate the development of ventricular fibrillation. Therefore, oxygen should be administered and hypoxemia corrected before atropine is given [22,26]. Miosis will not respond to parenteral atropine. Topical tropicamide is effective for the treatment of miosis and the relief of ocular pain [23]. Atropine alone may not be an effective treatment for terminating seizures or reversing ventilatory failure [17,26]. Bulk atropine is available for reconstitution and may be required in the setting of mass nerve agent casualties.

Pralidoxime chloride is the other major antidote for nerve agents. It functions by "prying off" the nerve agent molecule from acetylcholinesterase, thereby rendering the enzyme active again. Unfortunately, it must be given early, before the agent–enzyme bond matures or "ages," that occurs in as little as 2 minutes for soman but takes 3 to 4 hours for sarin. Once the agent–enzyme bond completely ages, the bond is irreversible and pralidoxime chloride has no therapeutic effect. Pralidoxime chloride is only effective at nicotinic sites and, therefore, helps to increase muscle strength. The standard adult dose is 15 to 25 mg per kg or 1 g, given intravenously (in 100 to 250 mL of 0.9% saline) during 20 to 30 minutes. The initial dose may be followed by an infusion of 200 to 500 mg per hour, if necessary. Higher dosing with a 2 g load followed by 1 g per hour for 48 hours has been shown to significantly decrease atropine requirements and the duration of mechanical ventilation in patients poisoned by organophosphate pesticides [27]. Severe hypertension is a potential side effect of pralidoxime chloride, and this can be rapidly reversed by a 5-mg intravenous infusion of phentolamine. The recommended pediatric dose is 15 to 25 mg per kg administered intravenously during 30 to 40 minutes [23].

Atropine and pralidoxime chloride come packaged as two autoinjectors in commercially available kits, called MARK-I Nerve Agent Antidote Kits (Meridian Medical Technologies, Columbia, MD). Each kit contains one AtroPen Auto-Injector containing 2 mg of atropine and one pralidoxime chloride Auto-Injector containing 600 mg of pralidoxime chloride. The same company also now produces DuoDote^{TM}, a single autoinjector 2.1 mg of atropine and 600 mg of pralidoxime chloride [28].

Historically, diazepam has been the anticonvulsant recommended for the management of seizures associated with nerve agent exposure. In the hospital setting, diazepam may be given intravenously. The adult intravenous dose is 5 to 10 mg every 10 to 20 minutes until seizures resolve, but not to exceed 30 mg in an 8-hour period. The pediatric dose is 15 to 25 mg per kg [23]. Autoinjectors that contain 10 mg of diazepam are available for use in the field (Meridian Medical Technologies). In both hospital and prehospital settings, healthcare providers must carefully monitor patients for signs of ventilatory failure following the administration of diazepam. Lorazepam and midazolam that are typically used in a critical care environment are also effective in controlling seizures following nerve agent exposure [29,30].

Decontamination is a key step in the treatment of nerve agent casualties because minimizing exposure to the agent decreases the severity of toxic effects. Removal of all clothing, rinsing the eyes with water or normal saline for 10 minutes, and washing the entire body once with soap and water should suffice. Decontamination should be conducted as soon as possible after ventilatory and circulatory support has been initiated and antidotes have been administered. Rapid decontamination is especially important for nerve agents that can be absorbed through the skin. It is important for healthcare providers to wear protective clothing and face masks prior to and during contamination of nerve agent casualties [10,16].

Vesicants

The two principal vesicants or "blister agents" are sulfur mustard and lewisite. This section focuses on the more notable sulfur mustard (bis-[2-chloroethyl] sulfide) that is commonly referred to as *mustard*. Lewisite has similar health effects except for the immediacy of its action in comparison to mustard, which has a latency period. It normally takes several hours between contact with mustard and the onset of signs and symptoms, with the specific latency period depending on the exposure dose. In general, the higher the exposure dose, the shorter the latency period. Mustard is an oily liquid that ranges from clear to pale yellow to dark brown in color. It classically smells like onion, garlic, or mustard, which is allegedly how it got its name. At temperate conditions, it is a persistent liquid that volatilizes slowly. At temperatures greater than 100°F, however, mustard evaporates and mustard vapor becomes a major hazard. As a weapon, mustard will most likely be employed as a contact agent [31].

On entering living cells, mustard alkylates and cross-links DNA that causes DNA strand breaks and eventually leads to cell death. Mustard damages any skin that it contacts, resulting in vesicle or bullae formation within 4 to 24 hours after exposure. Vesicle formation typically peaks within several days after contact with the skin; of note, the bullae fluid is not toxic and therefore not a threat to providers. As the most sensitive organ to low dosage exposures, contact with the eyes may result in painful irritation, conjunctivitis, blepharospasm, and corneal opacity related to edema and pannus formation. Blindness can occur if the corneal pannus is severe and covers the visual axis. Eyelid burns may be first or second degree. Mild-to-severe airway damage can occur following mustard inhalation. The extent and severity of airway damage is dose-dependent, with lower doses primarily affecting the upper airways and higher doses affecting both upper and lower airways. At all doses, the proximal and upper airways are affected more than lower airways. High inhalational doses can cause severe inflammation, inflammatory exudate, necrosis of mucous membranes, mucosal sloughing, and pseudomembrane formation. Sloughed mucosal tissue and pseudomembranes can cause obstruction of the lower airways and serve as a nidus for respiratory tract infections, principally *Pseudomonas*. Other pulmonary problems include asthma, laryngospasm, acute bronchitis, chronic bronchitis, bronchiectasis, tracheobronchial stenosis, pulmonary fibrosis, and bronchiolitis obliterans [32,33]. Hypoxia and hypercarbia may occur as a result of ventilation-perfusion

mismatching caused by airway mucosal sloughing and hyperreactive or bronchitic airways. Severe gastrointestinal side effects and bone marrow suppression can occur following ingestion of high doses of mustard. Leukopenia with a cell count less than 200 cells per mm^3 portends a poor prognosis. Sepsis may occur as a result of leukopenia and the breakdown of skin, respiratory epithelium, and gastrointestinal mucosa [34].

Decontamination is a critical component in the management of mustard casualties. Indeed, decontamination within 1 to 2 minutes after exposure is the most effective means of reducing serious skin and tissue damage from mustard. Because of its persistence, removal of mustard from casualties must occur before admission to a medical treatment facility so healthcare workers do not become contaminated. In general, the medical care of mustard casualties is supportive. Areas of denuded skin should be treated like burns and liberally covered with silver sulfadiazine ointment [12]. Calamine lotion may soothe mild burning and itching in erythematous areas of skin. Nonsteroidal anti-inflammatory drugs may help to mitigate pain associated with cutaneous inflammation. Cooling the skin to 15° C and applying deferoxamine or zinc oxide may also be beneficial [35]. Skin healing following mustard exposure takes longer than skin healing following thermal burns. Some patients may require skin grafts and reconstructive surgery.

Respiratory care is mostly supportive. Bronchodilators may be helpful for the treatment of asthma-like symptoms related to hyperreactive airways. Corticosteroids may also be helpful, but should be used with caution because of the risk of superinfection. Intubation and ventilatory support may be necessary for the management of severe laryngospasm or respiratory failure following high doses of inhaled mustard. Bronchoscopy may be necessary to remove pseudomembrane fragments from the airway. Chronic, progressive tracheobronchial stenosis has been reported following mustard inhalation, and may require periodic bronchoscopy with bougienage and laser photoresection to maintain airway patency [36].

For systemic toxicity, early treatment with nonsteroidal anti-inflammatory agents may be useful. Thiosulfate decreases toxicity in animals; also in animal models, granulocyte colony stimulating factor has been shown to reduce the duration of neutropenia by approximately half [37].

In summary, acute mortality is relatively low, but morbidity is high following exposure to mustard. The severity and duration of illness and injuries following mustard exposure are directly related to the exposure dose and routes of exposure. Because of the persistence of mustard, decontamination is critically important in the management of mustard casualties and for protecting healthcare workers from being exposed. Victims of mustard exposure will consume significant healthcare resources in the management of their acute care needs and some will require prolonged periods of treatment and rehabilitation for chronic sequelae.

Cyanide

Cyanide can exist either as gas or as a colorless, volatile liquid that easily vaporizes. In both physical states, it typically has the smell of bitter almonds, although 40% to 60% of the population is unable to detect this odor. It is a chemical asphyxiant of the type that is historically classified as a "blood" agent. Cyanide can be used as an agent of mass destruction in two chemical forms: hydrogen cyanide and cyanogen chloride. Although very lethal in high doses, the volatility of cyanide makes it difficult to weaponize and it ranks among the least lethal of the common chemical agents of mass destruction. Cyanide produces its pathologic effects by binding to iron-containing sites on cytochrome a_3 in the mitochondria that inhibits the enzyme's activity. The binding of cyanide to cytochrome a_3 can occur very rapidly. Cytochrome a_3 is a key enzyme in the cytochrome oxidase system involved in aerobic metabolism within the mitochondria of cells. Inhibition of cytochrome a_3 by cyanide effectively stops cellular respiration and forces affected cells into anaerobic metabolism. Cyanide also has an increased affinity for the ferric ion in methemoglobin that is a property exploited for treatment of cyanide poisoning [38].

The clinical manifestations of cyanide poisoning result from the inability of cells to extract and use oxygen. The onset of signs and symptoms occurs rapidly following inhalation (within 15 seconds), whereas a delayed response of up to 30 minutes follows ingestion. Metabolic acidosis develops as a consequence of increased lactate production from anaerobic metabolism. Compensatory mechanisms to increase oxygen delivery to tissues include tachycardia and increased minute ventilation, which are the earliest clinical signs. Dyspnea may occur as a result of the hyperpnea. Other signs include agitation, anxiety, vertigo, headache, muscle weakness, and trembling. Diaphoresis and flushing sometimes occur. Seizures have been reported. Dilated, unresponsive pupils and coma are late signs of cyanide poisoning and portend a poor prognosis. Without treatment, cyanide victims eventually develop apnea and cardiac dysrhythmias, followed by death from cardiac arrest [38].

Both the administration of specific antidotes and supportive care should be given as soon as possible after exposure to cyanide. Sodium nitrite and sodium thiosulfate are the traditional antidotes used to treat cyanide poisoning. This treatment's objectives focus on detoxifying and excreting the cyanide, as well as on preventing its reentry into the cell. One ampule containing 300 mg of sodium nitrite in 10 mL of diluent (30 mg per mL) is administered intravenously for 2 to 4 minutes to form methemoglobin. The pediatric dose of sodium nitrite is 0.33 mL per kg of a 3% solution given intravenously for 2 to 4 minutes, not to exceed 10 mL. Cyanide binds more effectively and preferentially to the ferric ion site on methemoglobin in comparison to cytochrome a_3. Therefore, the methemoglobin generated by sodium nitrite removes cyanide from cytochrome a_3-binding sites and frees the enzyme to once again participate in the processes of cellular respiration and aerobic metabolism. Following sodium nitrite administration, 12.5 g of sodium thiosulfate in 50 mL of diluent is administered intravenously at a rate of 3 to 5 mL per minute. The pediatric dose of sodium thiosulfate is 412.5 mg per kg (1.65 mL per kg), given intravenously at a rate of 3 to 5 mL per minute. Sodium thiosulfate acts as substrate for rhodanese, converting the cyanide to thiocyanate that is then excreted in the urine. Sodium nitrite and sodium thiosulfate are very effective antidotes for the treatment of cyanide poisoning if they are given before the cessation of cardiac activity [38,39].

A specific challenge in managing these patients is in the prehospital environment, specifically in hypoxia environments such as fires or smoke, inhalation where decreased oxygen-carrying capacity can be exacerbated by the induction of methemoglobinemia. Hydroxocobalamin, a precursor of vitamin B_{12}, provides an alternative treatment option for both pre- and in-hospital management. Cyanokit® (Dey L.P., Napa CA., www.cyanokit.com) contains two vials of 2.5 g of lyophilized hydroxocobalamin that is reconstituted in 100 cc saline for administration. The standard initial adult dose is 5 g infused over 15 minutes with an additional 5 g given depending on the patient's condition. Hydroxocobalamin binds with cyanide to form cyanocobalamin that is then excreted in the urine. It is well tolerated with no known major toxicities. Of note, the red molecule results in red mucous membranes, skin, and urine [40]. A major impediment to widespread use of this modality is its cost which is over twice as expensive as the sodium nitrite/sodium thiosulfate kit [41].

Supportive care for cyanide poisoning includes the administration of oxygen that has been shown to be effective in managing hypoxia, even though the poor cellular uptake and

utilization of oxygen found in cyanide toxicity would suggest supplemental oxygen to be of little efficacy. Hyperbaric oxygen may also be beneficial in select severely ill patients, though this therapy would be difficult to institute in a mass casualty setting [12]. Ventilatory support should be provided as needed. Consideration should be given to the administration of sodium bicarbonate for the treatment of severe lactic acidosis in patients who are unconscious or hemodynamically unstable. The recommended dose of sodium bicarbonate intravenously is 1 to 2 mg per kg intravenously, for both adults and children. Arterial blood gas analysis is used to guide the need for repeat doses of sodium bicarbonate to ensure that a metabolic alkalosis does not develop. In most cases of cyanide poisoning, appropriate supportive care in conjunction with the administration of sodium nitrite and sodium thiosulfate or hydroxocobalamin before cardiac arrest occurs can result in a complete recovery over a period of several days [38,40,42].

Pulmonary or "Choking" Agents

Pulmonary or "choking" agents cause acute lung injury after inhalation. The acute lung injury produced by these agents typically results in the development of pulmonary edema. Phosgene and chlorine are the two most common chemical agents in this category. Both were used as chemical warfare agents in World War I. Their effects relate, in part, to their water solubility. Highly water-soluble gases like ammonia, hydrogen chloride, and sulfur dioxide affect primarily the eyes and upper airway mucous membranes. Chlorine, a moderately water-soluble gas, affects the upper airway less but also damages the lower airway. Finally, slightly water-soluble gases like phosgene affect primarily the lower airways.

Phosgene is a colorless gas at room temperature, but becomes a volatile liquid on cooling or compression. The gaseous form has an odor of green corn or freshly mown hay. The gas is denser than air and accumulates in low-lying areas. On exposure to water, phosgene hydrolyzes to form carbon dioxide and hydrochloric acid. These hydrolyzation products may cause phosgene gas to appear as a white cloud when it comes into contact with water vapor in the air [43].

Initial symptoms of phosgene poisoning are primarily related to inflammatory irritation of the eyes and mucous membranes of the oronasopharynx. The irritation is caused by the hydrochloric acid that is formed when phosgene reacts with tissue water. Initial symptoms occur shortly after exposure and include burning sensation in eyes, conjunctival erythema, increased lacrimation, soreness of the throat and nasal membranes, rhinorrhea, coughing, choking, and tightness in the chest. Nausea, occasional vomiting, and headache have also been reported to occur shortly after phosgene exposure. These may be the only symptoms that occur following a low-concentration exposure. However, a life-threatening illness, characterized by noncardiogenic pulmonary edema and respiratory failure, can develop after exposure to higher concentrations.

Inhaled phosgene causes the formation of hydrochloric acid in the airways and alveoli that causes direct inflammatory injury to epithelial cells and endothelial cells of pulmonary capillaries. In addition, phosgene causes an acylation reaction with amino, hydroxyl, and sulfhydryl groups on cellular macromolecules, resulting in oxidative injury to lung tissues. It also stimulates the synthesis of lipoxygenase-derived leukotrienes that results in the chemotactic attraction of neutrophils and their accumulation in the lung. In the lung, the damaged alveolar-capillary membrane leads to pulmonary edema. This effect only occurs through direct inhalation.

As noted earlier, inhaled phosgene affects primarily the lower respiratory tract, causing diffuse bronchoalveolar injury, bronchospasm, and noncardiogenic pulmonary edema. Exertion tends to decrease the latency period between phosgene inhalation and the development of pulmonary symptoms, as well as exacerbate pulmonary symptoms once they occur. Phosgene-produced pulmonary edema may begin as early as 2 to 6 hours after inhalation. Although the pulmonary edema may appear to be mild at first, it can become extensive and life threatening. Normal pulmonary lymphatic drainage may be overwhelmed by increasing pulmonary edema that leads to the development of the acute respiratory distress syndrome (ARDS) in some individuals. The onset of ARDS may be delayed for up to 48 hours after phosgene inhalation [44].

Chlorine is a greenish-yellow, noncombustible gas at room temperature and normal atmospheric pressure. It is heavier than air and gravitates to low-lying areas if released in the environment. Chlorine has a strong, pungent odor similar to bleach that is usually detectable by smell, even in low concentrations. It is a highly reactive element and, like phosgene, forms hydrochloric acid on contact with water [43].

Initial symptoms of chlorine exposure are similar to the initial symptoms following exposure to phosgene. Again, these symptoms are caused by irritation produced by the hydrochloric acid that is formed when chlorine comes into contact with tissue water. Initial symptoms occur within minutes after exposure and include burning of the eyes, redness of the conjunctivae, increased lacrimation, soreness of the throat and nasal membranes, rhinorrhea, coughing, choking, and tightness in the chest. Burning and blistering of the skin can occur shortly after contact of chlorine with exposed areas [45].

Inhalation of chlorine, even in low concentrations, causes immediate coughing and choking that can be severe. The coughing and choking tend to prevent some of the inhaled chlorine from reaching the peripheral airways and lung tissue. Thus, inhaled chlorine typically affects the upper airway primarily, causing laryngeal edema, laryngospasm, and bronchospasm. Hoarseness and aphonia may occur. Dyspnea is the first sign of upper airway involvement, followed by copious secretions, productive cough, and chest tightness. Wheezing typically occurs with bronchospasm. Individuals with a history of asthma or airway hyperactivity may have particularly severe bronchospasm. Severe bronchospasm may cause mediastinal and subcutaneous emphysema secondary to air trapping. Inhalation of high concentrations of chlorine may produce laryngospasm that is severe enough to cause sudden death [43].

Noncardiogenic pulmonary edema can occur within 2 to 4 hours following the inhalation of chlorine, especially in high concentrations [46]. Frothy sputum and rales may be the first clinical signs of pulmonary edema. Radiographic signs of pulmonary edema typically lag behind the development of clinical symptoms [47]. The development of ARDS with hypoxemic respiratory failure may eventually occur. The fluid losses associated with severe pulmonary edema and ARDS can be so profound that hypovolemic shock develops.

Management of individuals exposed to inhaled phosgene and chlorine is essentially the same. There is no specific antidote for either agent and treatment is supportive. In all cases, the patient must be removed from the contaminated environment and contaminated clothing as soon as possible. Decontamination should be performed by washing the patient with soap and copious amounts of water for 3 to 5 minutes. The eyes should be flushed with normal saline. Exertion should be minimized during transport and hospitalization.

Aggressive bronchodilator therapy with a nebulized β_2 agonist is the mainstay of therapy for bronchospasm. Nebulized ipratropium may be added if the β_2 agonist alone is ineffective. Systemic corticosteroids may be useful in the treatment of severe bronchospasm, particularly in individuals who have a history of asthma or airway hyperreactivity. Animal studies have shown that inhaled corticosteroids improve oxygenation and attenuate the development of acute lung injury, especially when

given in conjunction with an inhaled bronchodilator [48]; this has not, however, been validated in humans. Thus, although systemic corticosteroids are recommended for life-threatening situations, there is no definitive clinical evidence for their efficacy in reducing the severity of acute lung injury or pulmonary edema.

Bacterial superinfection of the airways can lead to the development of severe tracheobronchitis and pneumonia 3 to 5 days after toxic irritant exposure. The presence of persistent fever, elevated white blood, or the production of thick, purulent sputum should prompt the physician to obtain cultures of sputum, blood, and any pleural fluid that is evident on chest radiograph. Empiric antibiotics should be given in accordance with the guidelines for intensive care unit patients with community-acquired pneumonia. The antibiotic regimen should be adjusted on the basis of the culture and antibiotic sensitivity results [43].

Intubation and mechanical ventilation may be required for severe bronchospasm, laryngospasm, and pulmonary edema. They are usually required for the management of ARDS and respiratory failure. Given the rapidity with which these problems can develop, preparations for intubation and mechanical ventilation should take place during the latency period, before serious respiratory problems develop. Nasotracheal intubation should not be performed because of nasal inflammation. Orotracheal intubation under direct visualization of the airways is the recommended technique. During mechanical ventilation, an appropriate amount of positive end-expiratory pressure, typically in the range of 5 to 10 cm H_2O, and inverse ratio ventilation may be helpful in improving oxygenation in patients with pulmonary edema or ARDS (see Chapters 47 and 58). In animal models, protective ventilation strategies with 6 mL per kg tidal volumes improve oxygenation, decrease shunt fraction, and improve mortality [49].

Careful attention must be given to fluid balance and the administration of intravenous fluids in patients with pulmonary edema and ARDS. Vasopressors may be required for the treatment of hypovolemic shock. Both ibuprofen and acetylcysteine aerosol have demonstrated some efficacy in preventing phosgene-induced lung injury in animal models, although there are no human clinical trials regarding their use [50,51].

Pulmonary edema that appears within 4 hours after phosgene or chlorine exposure is a poor prognostic sign. Some individuals may develop the reactive airways dysfunction syndrome (RADS) following phosgene or chlorine inhalation [52,53]. This disorder is characterized by chronic, nonspecific airway hyperreactivity that persists after the patient has recovered from the effects of an acute exposure. Patients who develop RADS should receive prompt treatment with oral prednisone (40 to 80 mg daily for 10 to 15 days) followed by treatment with a high dose of an inhaled corticosteroid, such as beclomethasone (2,000 µg per day). RADS patients should be followed closely with serial methacholine bronchial challenge testing, and the dose of oral corticosteroid should be tapered in accordance with improvements in airway hyperresponsiveness. It may take years for some individuals with RADS to show significant improvement in airway hyperresponsiveness [54]. However, most individuals who survive phosgene or chlorine exposure will recover completely with no long-term effects [43].

Nonlethal Incapacitating Agents

Chemical agents that cause temporary incapacitation are commonly classified as nonlethal agents. These chemical agents, although potentially lethal in high concentrations, are typically employed in doses that cause temporary injury or confusion to individuals or groups of individuals. They are commonly used to incapacitate unruly groups in military or riot control situations. However, they could be used in a terrorist attack. In this regard, they could be used alone, they could be used prior to an attack with conventional weapons, or they could be used in conjunction with other chemical, biological, or radiological agents of mass destruction.

The most common incapacitating agent is BZ (QNB; 3-quinuclidinyl benzilate), a competitive inhibitor of acetylcholine at postsynaptic and postjunctional muscarinic receptors. BZ is a stable, odorless, persistent crystalline solid. It is usually dispersed as a fine solid powder, although it can be dissolved in a liquid substrate and dispersed as a liquid aerosol. Both the powder and aerosolized forms can be readily ingested or inhaled. Ingestion and inhalation of BZ particles that are 1 µm in size result in bioavailabilities that are approximately 80% and 50% of a parental dose, respectively [55].

The clinical effects of BZ are similar to those of atropine, although BZ is approximately 25 times more potent and has a much longer duration of action. Symptoms of BZ exposure include mydriasis, blurred vision, dry mouth, indistinct speech, dry skin, increased deep tendon reflexes, poor coordination, decreased level of concentration, illusions, and short-term memory deficits. The most prominent central nervous system effects of BZ are related to so-called "anticholinergic delirium." The delirium typically occurs after high-dose BZ exposure and has been described as a "walking dream." This syndrome is characterized by periods of staring, unintelligible muttering, occasional shouting, and bizarre hallucinations. The degree of delirium can fluctuate frequently from minute to minute, with periods of lucidity and appropriate responses interspersed among periods of severely altered mental status [4,55].

The intensity and duration of anticholinergic symptoms associated with BZ exposure are dose-dependent, with higher doses causing more severe symptoms and a longer duration of effect. Incapacitating symptoms typically appear within 1 hour after exposure, peak at approximately 8 hours after exposure, and subside gradually during the next 48 to 72 hours. All individuals exposed to BZ should be decontaminated by washing the entire body with soap and water. Medical therapy is mostly supportive, to include control of the patient for the prevention of accidents, removal of dangerous objects from the patient's environment to prevent self-inflicted harm during delirium, moist swabs or hard candy for dryness of the mouth, keeping the room temperature at 75°F or below to prevent the development of hyperthermia, and the use of topical antibiotics and sterile dressings for abrasions of dry, parched skin. Severe signs and symptoms of BZ exposure can be treated with physostigmine. Physostigmine temporarily raises acetylcholine concentrations by binding reversibly to anticholinesterase on postsynaptic or postjunctional membranes. Physostigmine can be administered either intravenously or intramuscularly. The recommended intravenous dose is 30 µg per kg by slow infusion at a rate of 1 mg per minute. The recommended intramuscular dose is 45 µg per kg in adults and 20 µg per kg in children. The patient should be evaluated every hour for improvement in signs and symptoms, with physostigmine readministered periodically at a dose and time interval that is titrated to the severity of clinical signs. Physostigmine can cause a precipitous decrease in heart rate and patients should be carefully monitored during its administration. It should not be administered to any patient with cardiopulmonary instability, hypoxemia, electrolyte imbalance, or acid–base disturbances that predispose to cardiac dysrhythmias and seizures. It is recommended that an intravenous test dose of 1 mg be administered to adults if the diagnosis of BZ exposure is in doubt. If slight improvement is noted and there are no adverse effects within 1 hour, the full dose can be given [4,55].

Riot control agents are intended to produce unpleasant but nonpersistent medical effects. They are sometimes referred to as

irritants. The two riot control agents most commonly used are 2-chloro-1-phenylethanone (CN or MACE; MACE Security International, Bennington, VT) and 2-chlorobenzalmalononitrile (CS or tear gas). Another product used for riot control or security is oleoresin capsaicin (OC or pepper spray). All riot control agents cause significant irritation to the eyes, upper airways, and skin. In addition to burning of the eyes and increased lacrimation, exposed individuals may experience temporary blepharospasm with transient blindness. Upper airway symptoms include rhinorrhea, sneezing, salivation, and tightness of the chest. Exposed individuals with preexisting reactive airway disease may develop bronchospasm, which can progress to respiratory failure [56]. Because riot control agents are dispersed as a solid powder, decontamination consists of getting the victims into fresh air, removing their clothing, and irrigating their eyes and mucous membranes with normal saline. Treatment is nonspecific and supportive. Most symptoms resolve in 15 to 30 minutes. Episodes of acute bronchospasm in susceptible individuals should be treated with a short-acting β_2 agonist administered by nebulizer [57].

Finally, a variety of other readily available compounds can be aerosolized and need to be considered as potential incapacitating agents. Nausea-producing agents such as diphenylaminearsine (DM or "adamsite") can produce incapacitating gastrointestinal symptoms. Psychedelic drugs, such as 3,4-methylenedioxymethamphetamine and phencyclidine, are easily obtained and could be used as aerosolized incapacitating agents. In October 2002, carfentanil, a potent aerosolized derivative of fentanyl, was probably employed in combination with halothane in an attempt by Russian authorities to release more than 800 hostages held by terrorists in Moscow's Dubrovka Theater. Unfortunately, 127 hostages in the theater died and more than 650 were hospitalized after being exposed to the chemicals that were used in the rescue attempt [58]. This is a good example of how readily available pharmaceutical agents can be used to incapacitate, or even kill, a large number of individuals.

SUMMARY

Chemical agents pose a significant threat to populations throughout the world, whether accidentally released from an industrial or transportation accident, or released intentionally as part of a crime or terrorist event. Regardless of the cause of release, they have the potential to produce a large number of casualties in a short period of time. However, the terminology *weapons of mass destruction* does not entirely reflect the impact that a terrorist attack with such agents could have on the general population. Even a relatively small number of casualties from a terrorist attack would be likely to cause significant psychological trauma, resulting in anxiety and behavioral changes among large numbers of "worried well." Such psychological trauma could significantly disrupt normal business and community activities for a long period of time. Instilling widespread fear and anxiety in the general population is a primary goal of terrorism and, unfortunately, the use of chemical agents is an efficient method of achieving that goal.

Critical care providers must be prepared to deal with the recognition, decontamination, transport, medical treatment, and psychological trauma of casualties resulting from chemical agents. They must also be prepared to protect themselves and colleagues from contamination with chemical agents during the course of patient care. Training in the medical management of chemical agent casualties and planning for mass casualty situations are essential to ensure that the best possible care is provided to the victims of a chemical exposure or chemical attack.

CHAPTER 215 ■ THE MANAGEMENT OF ACUTE RADIATION CASUALTIES

LAWRENCE C. MOHR JR

INTRODUCTION

It has been stated by the nation's political and military leadership that it is not a matter of "if" but "when" another terrorist attack will occur within the continental United States. Such future attacks could include the use of a radiological dispersion device, commonly called a "dirty bomb," an attack on a nuclear power plant or the detonation of a nuclear weapon. Indeed, a nuclear attack by a group of rogue terrorists is the single greatest risk to our homeland security. The objective of this chapter is to become familiar with the medical consequences of a radiological or nuclear attack and the management of casualties that could result from such an attack. It is to help you to think about the "unthinkable."

RADIOLOGICAL WEAPONS OF TERRORISM

Radiological dispersion devices, or "dirty bombs," consist of radioactive materials that are placed around a high explosive charge. The radioactive material is released and dispersed by detonation of the high explosive charge. Dirty bombs are easy to make and raw materials are readily available throughout the world. It is important to note that dirty bombs are not nuclear weapons and are not weapons of mass destruction. Their adverse health effects depend on the type and amount of explosive used, the type and amount of radioactive material used, and atmospheric conditions at the time of detonation. Most injuries from a dirty bomb will come from the blast effects of the conventional explosion [1,2]. Acute radiation health effects are very unlikely. Delayed health effects, such as the development of cancer, are also unlikely. The risk of developing cancer following a dirty bomb attack is related to the radiation exposure dose and to the amount of internal radiation that results from the inhalation, ingestion, and absorption of radioactive material through the skin or open wounds. Long-term psychological trauma is likely to occur among some members of a population who have been exposed to radioactive material from a dirty bomb [2,3].

A nuclear explosion results from nuclear fission or from thermonuclear fusion, in which a tremendous amount of energy is suddenly released in the form of heat, blast, and radiation. Human injury is caused by exposure to a combination of these three forms of energy following a nuclear detonation. The radiation exposure from a nuclear explosion can be very intense and lead to a life-threatening acute radiation syndrome, radiation burns, thermal burns, and blast injuries. Such radiation exposure can also result in the development of various types of cancer and leukemia over a period of many years if an individual survives the short-term initial effects of a nuclear explosion [4–6].

The life-threatening acute radiation syndrome may develop in some radiation-exposed individuals following a nuclear explosion. The acute radiation syndrome consists of a continuum of complex and unique medical sub-syndromes that involve the hematopoietic, gastrointestinal, and central nervous systems in a dose-related fashion. Patients who develop any of the acute radiation sub-syndromes require prompt assessment and critical care management in order to minimize loss of life. It is essential that any physician who may be called upon to treat patients following a nuclear explosion be familiar with the diagnosis and management of these unique sub-syndromes [7]. The acute radiation syndrome and its associated sub-syndromes are discussed in detail later in the chapter.

BASIC RADIATION PHYSICS

In order to understand the medical aspects of radiation exposure, it is important to review some basic principles of radiation physics. *Radiation* is defined, simply, as energy that is transmitted through space. The transmitted energy may be in the form of high-speed particles or electromagnetic waves. There are two general types of radiation: ionizing radiation and nonionizing radiation. Ionizing radiation has enough energy, so that when it interacts with an atom, it can remove tightly bound electrons from their orbits and cause the atom to become charged. Nonionizing radiation, on the other hand, does not have enough energy to remove electrons from their orbits. Ionizing radiation is more harmful to humans than nonionizing radiation and is the type of radiation that would be expected to be released in a radiological or nuclear attack.

Ionizing radiation can take four forms: alpha, beta, gamma, and neutron radiation. Alpha radiation consists of the emission of a helium nucleus from a parent nucleus, such as ^{235}Uranium; it is a particle that has an atomic mass of four and a charge of plus one. Beta radiation is the emission of a small negatively charged particle from a parent nucleus, such as ^{40}Potassium. Beta particles have a mass that is almost undetectable and a charge of minus one, similar to that of an electron. Gamma radiation is the emission of high-energy electromagnetic waves from a parent nucleus, such as ^{60}Cobalt. Gamma rays have no mass, no charge, and frequently accompany the emission of alpha or beta particles. Neutrons are very high-energy particles that are emitted from parent nuclei, such as ^{235}Uranium and ^{239}Plutonium during a nuclear chain reaction. Nuclear chain reactions can be controlled, such as the kind found in a nuclear reactor, or they can be uncontrolled, such as the type that causes a nuclear explosion. Neutrons are very damaging to human cells and tissues [8,9].

Each specific type of ionizing radiation has a different penetrating distance with respect to inert material and human tissues. Alpha particles will not penetrate paper or human skin. Indeed, you can safely hold an alpha-emitter, such as ^{240}Plutonium, in your hand as long as you do not have any breaks in the skin. However, if alpha particles are ingested, inhaled, or internalized through a break in the skin, they can do

a tremendous amount of internal damage to human cells and tissues [8,9].

Beta radiation will penetrate paper, thin layers of skin, and the conjunctiva of the eye, but will not penetrate thin layers of plastic or aluminum foil. Beta particles travel relatively short distances and will be stopped by most clothing. As with alpha particles, beta radiation is more damaging to human tissues if inhaled or ingested [8,9].

Gamma rays can travel significant distances and are a highly penetrating type of ionizing radiation. They readily penetrate skin and clothing. Gamma radiation can cause considerable damage to human cells and tissues after penetration. Several inches of lead or several feet of concrete are required to stop gamma rays [8,9].

Neutrons are high-energy nuclear particles that have no charge. Neutron radiation easily penetrates skin and clothing and can cause significant damage to internal tissues and organs. Neutrons primarily cause biological damage by colliding with other particles. They transfer the most energy when they collide with particles that are about the same size, especially protons. These high-energy, subatomic collisions result in the dislodgement of both protons and tightly bound electrons from atoms that are bombarded by neutrons, with ionization of atoms in surrounding cells and tissues. Neutron radiation is extremely harmful to humans. It is not stopped by plastic, glass, or lead; it can only be stopped by several feet of concrete [8,9].

Ionizing radiation causes damage to human cells and tissues through two biological mechanisms: (i) direct high-energy damage to DNA molecules and (ii) the generation of free radicals, which secondarily damage DNA molecules by superoxide radicals generated from ionized water. The fate of irradiated human cells is dependent on the dose of radiation exposure. Low-dose exposures are characterized by DNA and cellular repair. Moderate-dose exposures are characterized by permanently damaged DNA and significantly altered cells, which may be eliminated by apoptosis, or reproduce abnormally and eventually lead to the development of cancer. High-dose radiation exposures typically result in cell death, which causes several serious, acute radiation syndromes that can result in death of the organism [10,11].

Human radiation exposure can be categorized as either external or internal. External exposure, which involves exposure to the skin, may be either whole body or partial body depending on the surface area exposed to radiation. Internal exposure may occur from the inhalation, ingestion, or transdermal penetration of radioactive material. Combined radiation injuries may also occur in cases where radiation exposure and trauma occur concurrently. In combined radiation injuries, radioactive material is introduced through open wounds [8].

RADIATION DOSES

There are two units of radiation dose that physicians must be familiar with: the Rad and the Gray. It is not essential for physicians to understand the physics that underlie the determination of these doses, but it is important for them to know that these are the units which are used to express the amount of radiation that is absorbed by human tissues. The Rad is the traditional unit of **r**adiation **a**bsorbed **d**ose. One Rad is defined as 100 ergs per g. The Gray (abbreviated Gy) is the newer Standard International unit of radiation exposure. One Gy is equal to 100 Rads, which is defined as 1 J per kg. One hundred centi-Gray (100 cGy) are equal to 1 Gray [12].

Radiation doses can be measured by several techniques. A radiac meter is an instrument that directly measures radiation dose using a Geiger–Müller tube or similar device. There are many different types of radiac meters, each of which may be more sensitive to specific types of radiation, such as alpha, gamma, or neutrons, than to other types of radiation. It is important, therefore, to know both the capabilities and limitations of any radiac meter that one uses to determine radiation doses. Most radiac meters in use today are highly portable and will accurately measure alpha, beta, gamma, and neutron radiation. The measurement of the lymphocyte count between 24 and 48 hours after exposure can provide a useful biological estimate of radiation dose, especially in the clinical setting [13]. The dose range in Gy and the estimated lethality associated with each dose range is illustrated in Table 215.1.

TABLE 215.1

LYMPHOCYTE COUNT BETWEEN 24 AND 48 HOURS AFTER RADIATION EXPOSURE, ESTIMATED DOSE RANGE (Gy), AND ESTIMATED LETHALITY (%)

Lymphocyte count (× 1,000/mm^2)	Dose range (Gy)	Lethality (%)
3.0	0–0.25	—
1.2–2.0	1–2	< 5
0.4–1.2	2.0–3.5	< 50
0.1–0.4	3.5–5.5	50–99
0–0.1	> 5.5	99–100

From Walden TL, Farzaneh MS. Biological assessment of radiation damage, in Walker RI,, Cerveny TJ (eds): *Medical Consequences of Nuclear Warfare,* in Zajtchuk R Bellamy RF (eds): *Textbook of Military Medicine, Part I: Warfare, Weaponry and the Casualty*. Washington, *DC, United States Department of the Army, Office of the Surgeon General and Borden Institute*, 1996, p 87. Available at: http://www.usuhs.mil/afrri/outreach/pdf/tmm/chapter6/chapter6.pdf.

Chromosomal aberrations and translocations in lymphocytes can provide a useful estimate of both the type of radiation that one has been exposed to as well as the radiation dose [14]. This method requires considerable expertise in fluorescent in situ hybridization techniques as well as expertise in the interpretation of the chromosomal abnormalities. As a result, the analysis of chromosomal aberrations is primarily used as a research tool at the present time.

OVERVIEW OF RADIATION CASUALTIES

Radiation casualties consist of two general types: an acute radiation syndrome and delayed illnesses that may occur many years after radiation exposure. Acute radiation syndrome is a life-threatening condition consisting of a continuum of dose-related sub-syndromes that occur shortly after a high-dose radiation exposure, such as may occur following the detonation of a nuclear weapon. Delayed illnesses include leukemia, lymphoma, and various solid tumors, which may occur later in life following radiation exposure doses that are lower than those needed to produce acute radiation illness. In general, the higher the radiation dose, the more severe the acute effects of radiation exposure, the greater the probability of delayed illnesses, and the higher the mortality rate [4,7,15].

In considering the human dose-response to radiation exposure, a measurement known as the $LD_{50/60}$ is commonly used. The $LD_{50/60}$ is the radiation dose that causes a 50% mortality rate in an exposed population within 60 days following exposure. For whole-body radiation exposure, the $LD_{50/60}$, with no treatment, is 3 to 4 Gy. Therefore, 50% of a population that receives a radiation dose of 3 to 4 Gy will die within 60 days unless they receive treatment. With appropriate treatment and

supportive care following radiation exposure, the $LD_{50/60}$ is 4 to 5 Gy [7,12].

ACUTE RADIATION SYNDROME AND SUB-SYNDROMES

Acute radiation syndrome is a continuum of dose-related organ system sub-syndromes that develop after an acute radiation exposure of greater than 1 Gy. There are three main sub-syndromes that occur: the hematopoietic sub-syndrome, the gastrointestinal sub-syndrome, and the central nervous system sub-syndrome. Each of these sub-syndromes occurs in a dose-related fashion. The hematopoietic sub-syndrome occurs with radiation exposures greater than 1 Gy. The gastrointestinal sub-syndrome occurs in addition to the hematopoietic sub-syndrome at radiation exposures greater than 6 Gy. The central nervous system sub-syndrome occurs in addition to the hematopoietic and gastrointestinal sub-syndromes at radiation exposures greater than or equal to 20 Gy.

All acute radiation sub-syndromes begin with a *prodromal phase* that lasts for 2 to 6 days. This phase is characterized by nausea, vomiting diarrhea, and fatigue. The higher the radiation dose, the more rapid the onset, and the more severe the symptoms of the prodromal phase. After 2 to 6 days of the prodromal phase, the patient enters a *latent phase*, in which he or she appears to recover and is totally asymptomatic. The latent phase lasts for several days to 1 month, with the time period inversely proportional to the radiation exposure dose, that is, the higher the dose, the shorter the latent period. After the asymptomatic latent period, the patient enters the *manifest illness phase*. This phase of acute radiation illness lasts from several days to several weeks and is characterized by the manifestation of the hematopoietic, gastrointestinal, and central nervous system sub-syndromes, according to the exposure dose that the patient received [16].

Some individuals may develop a radiation-associated multiple organ dysfunction syndrome in association with the organ-specific clinical syndromes mentioned in the previous paragraph. Multiple organ system dysfunction typically occurs in the manifest illness phase, but may also occur early after a sublethal radiation exposure. Patients with hematopoietic, gastrointestinal, central nervous system, and multiple organ dysfunction syndromes will require management in an intensive care unit [17,18].

The Hematopoietic Sub-Syndrome

The hematopoietic sub-syndrome typically occurs with a radiation dose of greater than 1 Gy. It is characterized by bone marrow suppression resulting from the radiation-induced destruction of hematopoietic stems cells within the bone marrow. Hematopoietic stem cell destruction results in pancytopenia, which is characterized by a progressive decrease in lymphocytes, neutrophils, and platelets in the peripheral blood. Both the magnitude and the time course of the pancytopenia are related to the radiation dose. In general, the higher the radiation dose, the more profound and the quicker the pancytopenia occurs [7,16].

Lymphocytic stem cells are exquisitely sensitive to radiation and circulating lymphocytes decrease rapidly following radiation exposure and remain low for a long period of time. Erythrocytic stem cells, on the other hand, seem to be more resistant to radiation than lymphocytic, neutrophilic, and thrombocytic stem cells. Therefore, the red blood cell count and hemoglobin concentration typically do not decrease to the same extent as lymphocytes, neutrophils, and platelets following radiation exposure. Hematological effects that occur in the manifest illness phase of the hematopoietic sub-syndrome following radiation exposures of 1 Gy and 3 Gy are depicted in Figure 215.1.

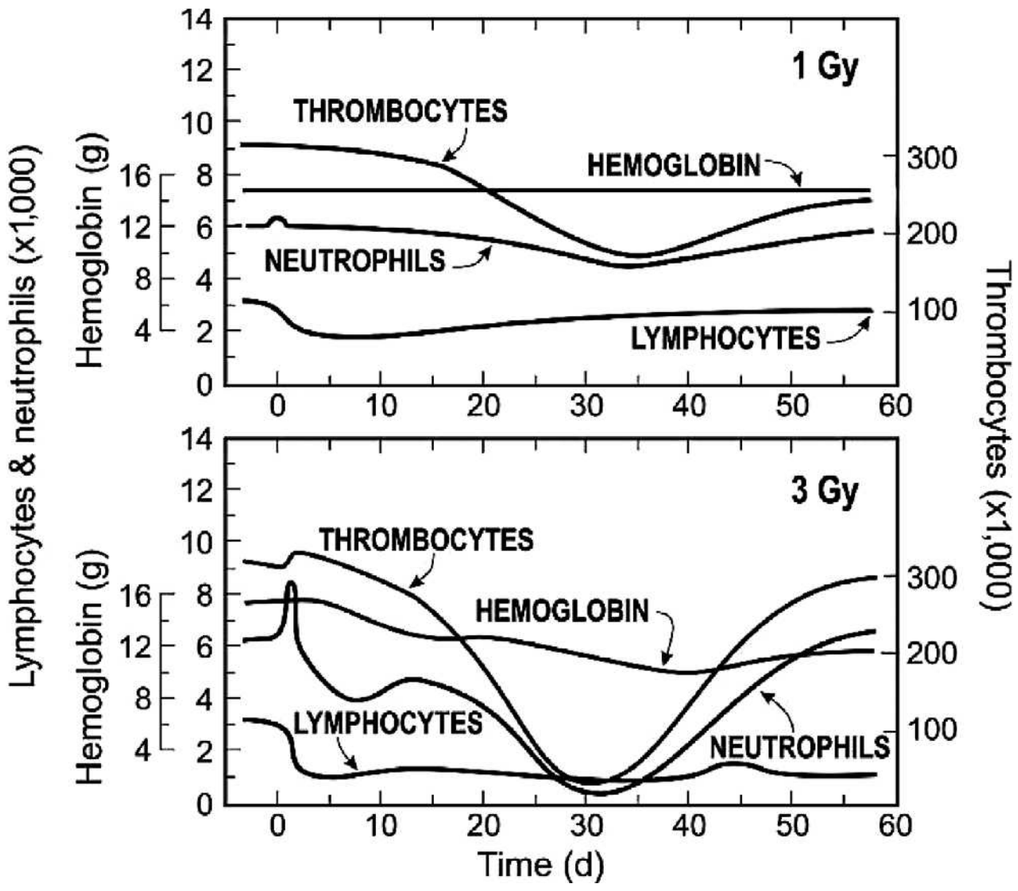

FIGURE 215.1. Hematological effects in the manifest illness phase of the hematopoietic sub-syndrome following radiation exposures of 1 and 3 Gy, respectively. [From Cerveny TJ, McVitte TJ, Young RW: Acute radiation syndrome in humans, in Walker RI, Cerveny TJ (eds): *Medical Consequences of Nuclear Warfare*, in Zajtchuk R, Bellamy RF (eds): *Textbook of Military Medicine, Part I: Warfare, Weaponry and the Casualty*. Washington, DC, United States Department of the Army, Office of the Surgeon General and Borden Institute, 1996, p 19. Available at: http://www.usuhs.mil/afrri/outreach/pdf/tmm/chapter2/chapter2.pdf. Accessed April 14, 2010.

As seen in Figure 215.1, the hematological effects of acute radiation exposure are dependent on the radiation dose. A radiation exposure of 3 Gy or more results in significant hematological effects than a radiation exposure of 1 Gy. Lymphocytes will decrease very rapidly following a radiation exposure of 3 Gy, and they will stay low for a relatively long period of time. Typically, it takes about 90 days before lymphocytes begin to recover from a 3 Gy radiation exposure. Neutrophils, after an initial period of intravascular demargination, will also begin to decline fairly rapidly following a 3 Gy exposure. Neutrophils do not fall as rapidly as lymphocytes, but between 3 and 5 days following exposure, such patients will be significantly neutropenic. Platelets also decrease steadily following a 3 Gy exposure and patients will become significantly thrombocytopenic at 2 to 3 weeks. Both platelets and neutrophils will reach a nadir, with values close to zero, at about 30 days following a 3 Gy exposure. Platelets and neutrophils then recover gradually during the next 30 days. Lymphocytes remain low for a long period of time, however, and typically do not begin to recover for at least 90 days following a 3 Gy exposure. Thus, there is a period of about a month following a 3 Gy exposure when patients will be significantly lymphopenic, neutropenic, and thrombocytopenic. Such patients are susceptible to developing serious infections and serious bleeding problems during that time [7].

The Gastrointestinal Sub-Syndrome

The gastrointestinal sub-syndrome typically occurs following a radiation dose of greater than 6 Gy. It develops as a result of radiation damage to intestinal epithelial cells. The loss of

epithelial cells results in denudation of the intestinal mucosa. Following the asymptomatic latent phase, patients will develop a manifest illness phase characterized by fever, vomiting, and severe diarrhea. Malabsorption, severe fluid losses, and severe electrolyte derangements will follow. Most patients will have severe pancytopenia as a result of a coexisting hematopoietic sub-syndrome. Sepsis and opportunistic infections commonly occur. The resulting sepsis can be very severe, and typically involves enteric organisms that migrate into the systemic circulation through damaged and denuded gastrointestinal mucosa. Approximately 10 days after the onset of the manifest illness phase, these patients typically develop fulminate bloody diarrhea that usually results in shock and subsequent death [7,16,19].

The Central Nervous System Sub-Syndrome

The central nervous system sub-syndrome is seen with radiation doses greater than or equal to 20 Gy, although cognitive dysfunction can be seen with radiation doses greater than 10 Gy. The latent period is very short, lasting from several hours to 3 days. Following the asymptomatic latent period, patients typically develop nausea, vomiting, diarrhea, and confusion. Microvascular leaks in the cerebral circulation result in cerebral edema. Elevated intracranial pressure and cerebral anoxia may develop rapidly. Mental status changes develop early in the manifest illness phase and the patient eventually becomes comatose. Seizures and burning dysesthesia may occur. Patients typically die within hours after onset of the manifest illness phase of the central nervous system sub-syndrome [1,7,20,21].

Multiple Organ Dysfunction Syndrome

As mentioned previously, some patients may develop multiple organ system dysfunction following exposure to ionizing radiation. This was first reported following a 1999 nuclear accident in Japan [22–24]. Idiopathic pneumonia syndrome, acute respiratory distress syndrome, diffuse alveolar hemorrhage, fluid and electrolyte abnormalities, bacteremia, and acute renal insufficiency may occur [17]. The specific causes of radiation-associated multiple organ system dysfunction are unknown. Similarly, there is no well-defined dose–effect relationship that has been associated with its development. However, there are several clues to possible pathogenic mechanisms. It is known that whole body radiation exposure causes severe inflammation, which is probably mediated by the generation of reactive oxygen species and cytokines [25–27]. Increased permeability of blood vessels has also been observed shortly after radiation exposure [22,25]. Furthermore, hemorrhagic shock, the inability to increase oxygen consumption with adequate oxygen delivery, and sepsis, all of which may occur following radiation exposure, have been associated with multiple organ system dysfunction [25,28,29]. From a clinical perspective, it is important to understand that all of these phenomena may contribute to the unpredictable and rapid development of multiple organ system dysfunction in some patients following acute radiation exposure. Such patients will require prompt supportive care and treatment in an intensive care unit in order to maximize the potential for survival [17].

Prognosis

The prognosis of patients who develop acute radiation sub-syndromes depends on the radiation dose to which they were acutely exposed. Patients who are exposed to 1 to 2 Gy will probably survive. Survival is possible in patients who are exposed to doses of 2 to 5.5 Gy, but many of these patients will require prompt treatment and intensive care in order to survive. Survival is possible, but improbable, in patients who are exposed to doses of 5.5 to 10 Gy. Even with the most aggressive treatment, survival is extremely rare following exposure doses above 10 Gy and impossible following doses greater than 20 Gy [30].

Management

All patients should receive basic supportive care following acute radiation exposure. This consists of fluid and electrolyte balance, antiemetic agents to manage vomiting, antidiarrheal agents to manage diarrhea, proton pump inhibitors for gastrointestinal ulcer prophylaxis, pain management, psychological support, and pastoral care if death is likely. In patients with any of the acute radiation sub-syndromes, it is important not to instrument the gastrointestinal tract, since this could result in perforations that precipitate fulminate bleeding or sepsis [31,32].

Cytokine therapy with a colony-stimulating factor should be given to certain patients in order to stimulate neutrophil production in the bone marrow [30]. If there are less than 100 casualties, cytokines should be given to patients with no other injuries who have had a radiation exposure of 3 to 10 Gy. If patients in this category have multiple injuries or burns, they should receive cytokine therapy if they received a radiation dose of 2 to 6 Gy. If, on the other hand, the number of casualties is greater than 100, cytokines should be given to patients with no other injuries who have had a radiation exposure dose of 3 to 7 Gy and to patients with multiple injuries or burns who have had an exposure dose of 2 to 6 Gy [30–32].

Various types of granulocyte colony-stimulating factor (G-CSF) can be given: G-CSF (Filgrastim), pegylated G-CSF (Pegfilgrastim), or GM-CSF (Sargramostim). These are all commercially available preparations and they are all effective. The recommended doses of the various cytokines for the treatment of acute radiation sub-syndromes in adults are summarized in Table 215.2.

There are also guidelines for the use of antibiotics following acute radiation exposure [26–28]. If the total number of casualties is 100 or less, patients with no other injuries should be given antibiotics if they have been exposed to a radiation dose of 2 to 10 Gy. Patients in this category with multiple injuries or burns should be given antibiotics if they have received a radiation exposure dose of 2 to 6 Gy. In a mass casualty situation, in which there are more than 100 casualties, patients with no other injuries should be given antibiotics if they received a radiation exposure of 2 to 7 Gy. Patients in a mass casualty situation who have multiple injuries or burns should be given antibiotics if they received a radiation exposure dose of 2 to 6 Gy [30–32].

The specific antibiotic regimen used in the management of an acute radiation sub-syndrome should depend on the antibiotic susceptibilities of any specific organisms that are able to be isolated from blood or tissue cultures. It is generally recommended that a fluoroquinolone with streptococcal coverage be used, along with acyclovir or one of its congeners for viral coverage, and fluconazole for the coverage of fungi and candida. Once culture results are obtained, specific antibiotic treatment should be given according to the sensitivities of any organisms that are isolated. Antibiotics should be continued until the absolute neutrophil count is greater than 0.5×10^9 cells per L, until they are no longer effective, or for the duration indicated for specific organisms that have been isolated [30–32].

Blood transfusions are indicated for patients with an acute radiation sub-syndrome who have severe bone marrow damage or who require concurrent trauma resuscitation. The purpose

TABLE 215.2

RECOMMENDED DOSES OF CYTOKINES

Cytokine	Adults	Children	Pregnant women[a]	Precautions
G-CSF or filgrastim	Subcutaneous administration of 5 µg/kg of body weight per day, continued until ANC > 1.0×10^2 cells/L	Subcutaneous administration of 5 µg/kg/d, continued until ANC > 1.0×10^2 cells/L	Class C (same as adults)	Sickle-cell hemoglobinopathies, significant coronary artery disease, ARDS; consider discontinuation if pulmonary infiltrates develop at neutrophil recovery
Pegylated G-CSF or pegfilgrastim	1 subcutaneous dose, 6 mg	For adolesoents > 45 kg, 1 subcutaneous dose, 6 mg	Class C (same as adults)	Sickle-cell hemoglobinopathies, significant coronary artery disease, ARDS
GM-CSF or sargramostim	Subcutaneous administration of 250 µg/m^2/d, continued until ANC > 1.0×10^2 cells/L	Subcutaneous administration of 250 µg/m^2/d, continued until ANC > 1.0×10^2 cells/L	Class C (same as adults)	Sickle-cell hemoglobinopathies, significant coronary artery disease, ARDS; consider discontinuation if pulmonary infiltrates develop at neutrophil recovery

[a]Express in biodosimetry must be consulted. Any pregnant patient with exposure to radiation should be evaluated by a health physicist and maternal-fetal specialist for an assessment of risk to the fetus. Class C refers to U.S. Food and Drug Administration Pregnancy Category C which indicates that studies have shown animal, terarogenic, or embryocidal effects, but there are no adeqate controlled studies in women; or no studies are available in animals or pregnant women.
ANC, absolute neutrophil count; ARDS, acute respiratory distress syndrome; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.

of blood transfusions in such patients is to provide erythrocytes for the improvement of oxygen-carrying capacity, blood volume to improve hemodynamic parameters, and platelets to help prevent bleeding. Cytokines, not blood transfusions, are used to increase absolute neutrophil counts, according to the criteria and doses previously discussed. All cellular products in the blood to be transfused should be leukoreduced and irradiated to 25 Gy in order to prevent a graft versus host reaction. Leukoreduction also helps to protect against platelet alloimmunization and the development of cytomegalovirus infections [17,30].

Stem cell bone marrow transplantation should be considered for certain patients with acute radiation illness. Allogenic stem cell transplantation is indicated for individuals who have a radiation exposure dose of 7 to 10 Gy. If a patient is fortunate enough to have a stored autograft bone marrow specimen or a syngenetic donor, preferably an identical twin, stem cell transplantation should be considered if they have had radiation exposure doses of 4 to 10 Gy [30,31].

ACUTE RADIATION ILLNESS AND TRAUMA

The blast from a nuclear detonation can produce powerful, high-pressure winds that have greater velocities than the most powerful hurricane winds. These winds can extend miles from the point of detonation. They can cause large numbers of seriously injured casualties from missiles caused by flying debris or from individuals being blown against objects in the environment.

The combination of an acute radiation syndrome and trauma presents some special challenges to the physician. There is a significant increase in mortality among patients who have this combination of illness and injury and such patients require prompt medical and surgical care in order to survive. They should receive the standard treatment for acute radiation syndromes, as described earlier. They are also very susceptible to operative and postoperative infections as a result of decreased neutrophil and lymphocyte counts and require 2 to 3 months for the bone marrow to recover after acute radiation exposure. This greatly complicates the management of such patients, especially those with multiple, serious injuries. Most importantly, if a patient with a combination of an acute radiation syndrome and trauma requires surgery, the operation should be performed within 48 hours after the initial radiation exposure. If surgery is not performed in this "window of opportunity" following acute radiation exposure, it may have to be postponed for up to 2 to 3 months [31,33]. Therefore, all radiation-exposed patients with life-threatening traumatic injuries should be transported to a surgical care facility and receive emergency surgery as soon as possible within the 48-hour "window."

ACUTE RADIATION DERMATITIS

An acute radiation dermatitis may occur in conjunction with acute radiation illness. The symptoms and signs of acute radiation dermatitis typically appear several days *after* an acute radiation exposure. Although acute radiation dermatitis is essentially a radiation burn, it is different from the thermal burns that may occur *immediately* after exposure of the skin to a nuclear explosion. In this regard, radiation burns and thermal burns are different. Exposure of the skin to radiation causes loss of the epidermal layer at radiation doses greater than 2 Gy. This leads to erythema and blisters. Loss of the dermis occurs at radiation exposure doses of greater than 10 Gy, and this results in the development of skin ulcers. Skin ulcerations that result from radiation doses greater than 10 Gy heal very slowly over a period of many months, if they heal at all. Chronic skin ulcers in patients with acute radiation illness predispose these patients to the development of serious infections. Such ulcers should be debrided early in their development to help prevent infection. Topical antibiotics, such as mafenide acetate or silver sulfadiazine, should be applied prophylactically. However, since these topical antibiotics can cause neutropenia, they should be used judiciously with careful monitoring of the absolute

neutrophil count in severely neutropenic patients. Although no studies have been conducted on the efficacy of skin grafting in radiation burn patients, it is recommended that an attempt should be made to graft full-thickness burns and ulcers [33,34].

INTERNAL CONTAMINATION

In the assessment of patients with acute radiation exposure, it is important to ascertain whether or not they have experienced any internal contamination. Internal radiation contamination can occur by the inhalation, ingestion, or the transdermal penetration of radioactive material. It can occur via a variety of portals, such as the nose, the mouth, a wound, or, with a large enough dose, by the penetration of gamma rays or neutrons directly through intact skin. Internal organs commonly affected by internal radiation contamination are the thyroid, the lung, the liver, adipose tissue, and bone. These are the areas where radioactive isotopes tend to accumulate within the human body. Leukemia and various types of cancers can develop in these organs many years after an acute radiation exposure with internal contamination.

Assessment of Potential Internal Radiation Contamination

The patient history is crucial to determining whether or not they may have experienced internal contamination. Any history which suggests that a patient may have inhaled, ingested, or internalized radioactive material through open wounds should prompt further evaluation for internal contamination. This assessment should attempt to identify both the radiation dose received and, if possible, the specific isotopes that cause the internal contamination. An initial survey of the patient should be performed with a radiac meter, especially around the mouth, nose, and wounds, to give some idea of the extent of any possible internal exposure. The diction of radioactive isotopes on nasal swabs can be very helpful to determine whether or not a patient has been exposed internally. If it is suspected that a person has inhaled a significant amount of radioactive material, bronchoalveolar lavage can be considered for the purposes of identifying inhaled radioactive isotopes as well as for removing residual radioisotopes from the lungs. Bronchoalveolar lavage has been shown to be effective in removing inhaled radioactive isotopes from the lungs of animals. The collection of stool and urine samples can be very helpful in determining both the type and the amount of internal radiation that an individual might have received. Chest and whole-body radiation counts can also be helpful in determining the extent of any internal radiation contamination. Unfortunately, however, most medical institutions do not have the capability to do either chest or whole-body radiation counts. The analysis of nasal swabs, stool samples, and urine samples are the most practical methods of determining the type and extent of internal radiation contamination by hospital-based physicians [35,36].

Treatment of Internal Radiation Contamination

Patients who have experienced internal radiation contamination should be promptly treated in order to reduce the absorbed radiation dose and prevent the development of future health problems. The goals of treatment are to reduce absorption and enhance elimination of the internal radionuclide contaminant. There are three main categories of agents that are used to treat internal radiation contamination: purgative agents, blocking agents, and chelation agents. Specific agents are used to treat internal contamination by specific radioactive isotopes. Such treatment is most effective when given as soon as possible after the radiation exposure. Gastric lavage can be used to empty the stomach completely after the potential ingestion of radionuclides. If promptly performed, it could decrease the concentration of radionuclides in the gastrointestinal tract. This could result in a decrease of the absorbed radiation dose. In deciding whether or not to treat a patient for internal radiation contamination, the physician may need to act on preliminary information and may have to treat potentially exposed individuals empirically, based on the information that is available [35,36].

Purgative Agents

Purgative agents help to remove radionuclides from the gastrointestinal tract. The most common purgatives are laxatives and enemas, which are helpful in reducing the residence time of radionuclides in the colon. Prussian blue (ferric ferrocyanide) is an ion exchange resin that binds ^{137}cesium in the gastrointestinal tract and facilitates its secretion. Patients who have experienced internal ^{137}cesium contaminate should be treated with oral Prussian blue (3 g, three times daily) for at least 3 weeks. Aluminum phosphate binds ^{90}strontium in the gastrointestinal tract. A single, 100 mL oral dose of aluminum phosphate gel will reduce the gastrointestinal absorption of ^{90}strontium by 85%. Oral aluminum phosphate should be used if internal contamination with ^{90}strontium is expected [35,36].

Blocking Agents

Blocking agents block both the uptake and bioavailability of internal radionuclide contaminants. The most important blocking agent is potassium iodide, which is used for the treatment of internal contamination with $^{125/131}$iodine. Potassium iodide blocks the uptake of radioactive iodine by increasing the uptake of nonradioactive isotope. Since the thyroid gland is very sensitive to the effects of internal contamination with $^{125/131}$iodine, potassium iodine should be given as soon as possible after radioactive iodine exposure. It is recommended that patients take 300 mg of potassium iodide per day for 7 to 14 days following a potential $^{125/131}$iodine exposure. Potassium iodide can also be taken prophylactically if there is sufficient warning of a potential $^{125/131}$iodine exposure. The standard prophylactic regimen is a single 130 mg dose of potassium iodide [35,36].

Chelation Agents

Chelation agents are the mainstay of treatment for internal radiation contamination. Chelation agents are substances that bind strongly with certain metals to form a stable, soluble complex that can be excreted by the kidneys. Diethylenetriaminepentaacetic acid (DTPA) is the most effective and commonly recommended chelation agent for the treatment of internal radiation contamination. DTPA complexes are very stable and water soluble and are unlikely to release bound radionuclides prior to renal excretion. DTPA chelation therapy is especially effective for the treatment of internal radiation contamination with ^{241}americium, ^{60}cobalt, and ^{239}plutonium. DTPA is administered as an intravenous solution of 1 g dissolved in 250 mL of saline or 5% glucose, infused over 1 hour per day for up to 5 days. DTPA can be used for the treatment of all internal radiation contaminants except $^{238-235}$uranium. The use of DTPA is contraindicated for treatment of $^{238-235}$uranium contamination because of an increased risk of renal damage. It is

TABLE 215.3

AGENTS USED TO TREAT COMMON INTERNAL RADIATION CONTAMINANTS

Radionuclide	Primary toxicity	Treatment	Agent category	Route
^{241}Americium	Bone, liver	DTPA	Chelation	IV infusion
^{137}Cesium	Total body	Prussian blue	Purgative	Oral
^{60}Cobalt	Total body	DTPA	Chelation	IV infusion
$^{125/131}$Iodine	Thyroid	Potassium iodide blocking	Oral	
^{239}Plutonium	Bone, lung	DTPA	Chelation	IV infusion
^{210}Polonium	Lung, kidney	Dimercaprol	Chelation	IM injection
^{90}Strontium	Bone	Aluminum phosphate	Purgative	Oral
$^{238-235}$Uranium	Kidney	$NaHCO_3$ and diuretic	Chelation	Oral

recommended that internal contamination with $^{238-235}$uranium be treated with oral sodium bicarbonate, with the dose regulated to maintain an alkaline urine pH. Excretion of $^{238-235}$uranium can be enhanced with the addition of a diuretic, such as furosemide [35,36].

Dimercaprol is a chelation agent that is particularly useful for the treatment of internal contamination with ^{210}polonium. Dimercaprol has been used for many years as an effective chelation agent for mercury poisoning. For ^{210}polonium contamination, 5 mg per kg of dimercaprol should be given initially, followed by 2.5 mg per kg two times daily for 10 days. Dimercaprol should be given by deep intramuscular injection only; it should not be given intravenously. Dimercaprol is very nephrotoxic and should always be used with caution. It is recommended that oral sodium bicarbonate be given to maintain an alkaline urine pH, which decreases the risk of nephrotoxicity by preventing the dissociation of the dimercaprol-^{210}polonium complex in the urine. Serum creatinine and urine pH should be carefully monitored during treatment with dimercaprol [35,36].

Need for Rapid Treatment

In order to be most effective, treatment for internal contamination should begin within hours after the radiation exposure. Early information on the history of a radiation exposure incident may or may not identify the major isotopes involved. Patients will likely present with no clinical symptoms other than conventional trauma. Therefore, critical decisions regarding the initial, empirical treatment of potential internal radiation contamination may have to be based on the historical information that is provided. It is imperative that physicians who could be involved in the management of radiation casualties be familiar with the agents used for treatment of the most likely internal radiation contaminants. These agents are summarized in Table 215.3.

DECONTAMINATION

In order to prevent contamination of other patients and medical staff, radiation casualties must be decontaminated prior to admission to a hospital. However, life-saving emergency medical care should be performed as soon as possible and before decontamination takes place. Therefore, a special emergency treatment area, where potentially contaminated patients can be treated and stabilized, will have to be set up outside the hospital. Once a patient has been stabilized, decontamination can occur in another specially designated area that is also outside the hospital. It is recommended that the designated decontamination area be at least 50 yards downwind from the hospital or other treatment area.

All healthcare workers should protect themselves with scrubs, gowns, masks, double gloves, and shoe covers during the treatment and decontamination of radiation casualties. These measures provide sufficient protection from any radioactive isotopes that could be contaminating a patient. It is recommended that healthcare workers continue to observe these measures after decontamination of a radiation casualty, since it is possible that the decontamination could be incomplete and residual radioactive material could remain on the patient. Similarly, it is best to assume that every patient in close proximity to a radiation-exposure event is contaminated, even if no radiation is detected by a radiac meter. Such patients should be decontaminated as usual and members of the decontamination team and medical treatment staff should wear protective clothing.

The decontamination process is quite simple. All of the patient's clothing must be removed and discarded into a clearly labeled and secure container, so that it does not further contaminate people and surroundings after removal. If the clothing needs to be cut off the patient, the scissors should be washed with soap and water between each cut to avoid spreading contamination on subsequent cuts. After all clothing has been removed, the patient is thoroughly washed with soap and water. This simple soap-and-water process has been shown to be effective in removing more than 95% of residual radioactive material from radiation-exposed patients [37].

Once a radiation-exposed patient has been stabilized and decontaminated, he or she should be admitted to the hospital or other treatment facility for definitive care. Again, it is best to assume that hospitalized radiation-exposed patients may still be contaminated, even after the decontamination process has been completed. Thus, it is recommended that all radiation casualties be admitted to specially designated areas of the hospital and that the staff in these areas wear appropriate protective clothing, as described earlier.

Patients exposed to potentially life-threatening doses of radiation will require critical care management during the manifest illness phase of an acute radiation sub-syndrome. In order to reduce the potential of radioactive contamination, it is recommended that such patients be cared for in specially designated areas of intensive care units or in a designated hospital area that has been converted to an intensive care unit for the management of radiation casualties.

CHAPTER 216 ■ PLANNING AND ORGANIZATION FOR EMERGENCY MASS CRITICAL CARE

JAMES GEILING, ROBERT M. GOUGELET AND LAWRENCE C. MOHR JR

HOSPITAL AND COMMUNITY DISASTER RESPONSE

The Importance of Hospitals in Disaster Response

Hospitals and their critical care units play important roles in a community's response to a disaster, whether the disaster is sudden in nature, such as an explosion, or a more prolonged event, such as pandemic influenza. First of all, hospitals are the major source of a community's medical care and provide rapid access to health care. Most likely, the first response of an individual with a disaster-related medical problem will be to go to the closest hospital. Similarly, emergency medical system ambulances will routinely transport critically ill or injured patients to the nearest hospital. Second, hospitals are capable of managing critically ill or injured patients in a timely manner if adequate staff and resources are available. Third, it is especially difficult to provide critical care outside of the hospital setting during a disaster. For example, it may be possible to provide medical care in a building of opportunity, such as a school gymnasium, for low-acuity patients. However, providing critical care in such a setting would require significant amounts of medical equipment, supplies, and specially trained staff. It would be logistically difficult, costly, and time consuming to move critical care resources to a nonhospital facility during a disaster. Finally, hospitals which are accredited by the Joint Commission or other accrediting agencies must meet specific requirements for disaster preparedness. These requirements include continuity-of-operations plans, an internal operations center with an incident command structure, and the planning and conduct of disaster response exercises in coordination with the neighboring community.

In summary, the hospital is the major healthcare asset in disaster response and is likely to be the only facility where critical care is provided. In order to maintain its capability to respond to the most critical patients during a disaster, the hospital must be part of a community-based healthcare response system that can be efficiently mobilized during a catastrophic event.

The large numbers of patients requiring care immediately after a disaster, the continued flow of patients during a prolonged disaster, or the loss of hospital infrastructure as a result of a disaster, all have the potential to overwhelm available resources at any hospital. Thus, it is possible that there will be limits to the number of patients that can be cared for and the level of care that can be provided by a hospital during a catastrophic event.

Surge capacity generally refers to the ability to manage a sudden or prolonged increase in numbers of patients that would otherwise severely challenge or exceed the present capacity of the facility. Medical surge capacity may be defined, more technically, as "the quantifiable amount of community or regional resources and services available for providing medical care in emergencies that overwhelm the normal medical infrastructure" [1]. To provide adequate surge capacity and maintain medical system resiliency during disasters, hospitals and communities must have medical preparedness plans, as well as carefully planned command and control systems that will efficiently manage the medical response.

Local Community Medical Response

Incident Command Systems

In the United States, both hospitals and community governments are required to adhere to the requirements of the National Incident Management System, which is managed by the Federal Emergency Management Agency [2]. This includes the requirement that both hospitals and communities have an Incident Command System (ICS) [3]. The currently used ICS model for disaster response is a modular system that follows the basic principles of organizational leadership, with one person in charge of a command section that supervises the activities of 3 to 7 subsections. Most ICS structures have five principal components:

1. *Leadership*—This is the command section, chaired by the leader of the response effort (the incident commander). The incident commander is supported by special staff, such as public affairs, public safety, legal counsel, etc.
2. *Operations*—This section oversees and coordinates the immediate response and ongoing operational activities. This tends to be the most active section during a disaster.
3. *Planning*—This section assesses the potential for future events, develops contingency plans for future events, and plans timelines for the deployment of critical resources. These planning activities permit the operations branch to focus on managing the response to active events.
4. *Logistics*—This section focuses on the logistical support that every event requires, including equipment, personnel, supplies, and infrastructure support.
5. *Finance*—This section accounts for and manages all money that is spent during responding to a disaster. While immediate costs and purchases during a disaster tend to be supported by affected communities and hospitals, accurate purchasing records, inventory records, personnel costs, and transportation costs must be carefully managed in order to recoup costs after the event.

The Hospital Incident Command System (HICS) manages the response within the hospital and coordinates the hospital's efforts with the overall community response. The HICS is led by an incident commander within the hospital. The hospital's incident commander and the community incident commander

communicate with each other directly through telephone, radio, computer, or via liaison personnel. The organization and leadership of the HICS is usually different than organizational structure and leadership of day-to-day hospital operations [4]. What works for managing the daily business of a hospital oftentimes does not work well for managing the response to a crisis. Therefore, hospitals, and their intensive care units (ICUs), must assign personnel to specific HICS positions as part of their disaster preparedness planning. Each individual assigned to an HICS position has specific duties that must be performed prior to, during, and following the disaster response. It is imperative that all HICS personnel be fully trained for the duties they are required to perform.

Modular Emergency Medical Systems

The Modular Emergency Medical System, or MEMS, is a community emergency medical care system consisting of temporary facilities that can be quickly set up to supplement hospital care during a disaster. This system provides a conceptual framework for managing a surge in patients who require screening, triage, antibiotic treatment, immunizations, prophylaxis, or noncritical inpatient care. The MEMS helps hospitals to maximize their critical care capacity during a disaster by providing temporary, alternate facilities that can care for noncritical patients in their respective communities.

The major MEMS components are Neighborhood Emergency Help Centers (NEHC) and Acute Care Centers (ACC). Both types of centers can provide screening and triage. The NEHC provides routine, nonurgent outpatient care. The ACC can provide inpatient care to acutely ill noncritical patients. The ACC can receive patients directly from the incident, or be a facility to which hospitals can offload stable inpatients in order to free up hospital critical care bed space during overwhelming events. Local or regional authorities can open an NEHC or an ACC under two scenarios: (i) when a federal public health incident or a federal disaster is declared or (ii) when the state governor has issued a state of emergency. Both types of temporary facilities will operate under the command and control of the local community ICS with support from a Regional Multiagency Command [5].

How Does Critical Care Fit into the MEMS Plan?

The hospital is only place where critical care can be provided immediately after a disaster. Therefore, the community's medical surge plan must address how to protect the hospital from being overwhelmed with patients during a disaster. A carefully executed MEMS plan allows hospitals to offload stable patients to an ACC. This will help to prevent the hospital from being overwhelmed during a disaster and allow the hospital to expand its critical care capabilities by utilizing non-ICU hospital beds for critical care, if necessary.

Refining Surge Capacity

Hick and colleagues suggest a classification for surge capacity that may aid hospitals and communities in their planning for a major disaster [6]. They categorize surge capacity into three levels:

- *Conventional capacity*—This level would be implemented in major mass-casualty incidents that trigger activation of the hospital emergency operations plan. The resources used (spaces, staff, and supplies) would be consistent with the hospital's usual care levels.
- *Contingency capacity*—This level would be used temporarily during a major mass casualty incident, or on a longer-term basis during a disaster whose medical demands exceeded community resources. The resources would require adaptations to medical care spaces, staffing constraints, and supply shortages, but without significant impact on the medical care that is delivered.
- *Crisis capacity*—This level would be implemented in catastrophic situations that result in a significant impact on standard of medical care that can be provided. Severe limitations of space, staff, and supplies would not allow hospitals to provide the usual standard of medical care. If surge capacity reaches the crisis level, resources would be allocated in a way that facilitates the best possible medical care with the limited resources that are available.

It is recommended that hospitals and their critical care units develop disaster preparedness plans that contain specific criteria for each level of surge capacity. It is important to note that the same disaster event might have very different effects on different hospitals, depending on the institution's size. For example, an eight-victim automobile crash may require a conventional level of surge capacity for a large hospital that has a level 1 trauma center, but could require a contingency or crisis level of surge capacity for a small community hospital.

CRITICAL CARE IN DISASTERS

Current Status

From 2002 to 2007, the Hospital Preparedness Program of the U.S. Department of Health and Human Services spent $2.2 billion to support medical preparedness goals, which included improvement of hospital surge capabilities [7]. However, in 2008 the U.S. General Accounting Office reported that many states are still not adequately prepared to respond effectively to a catastrophic event, such as pandemic influenza, in which medical resources could become overwhelmed and there would be a need to change the way medical care is provided by altering or adjusting the care pathways [8]. During a major disaster, nothing will challenge hospitals more than attempting to provide high-quality critical care with limited resources.

Traditionally, most hospitals have focused their disaster planning on trauma care capabilities. However, the advent of severe acute respiratory syndrome (SARS) and the risk of an H1N1 influenza pandemic have caused hospitals to consider their overall critical care capability, to include medical critical care, as an important component of disaster response plans. For example, it is estimated that without adequate critical care resources during the 2003 SARS outbreak in Toronto, the case fatality rate would have been approximately 20%, compared to the 6.5% case fatality rate that actually occurred [9]. These data highlight the importance of including the overall critical care capabilities of hospitals in disaster planning efforts, not just the capabilities for trauma care.

At present, it is estimated that the average daily occupancy rate of critical care beds in the United States is 65%. This suggests that some hospitals may have the capability to expand critical care services during a disaster, assuming that staff and supplies are available [10]. However, even with normal excess capacity, there does not appear to be a sufficient number of critical care beds to meet the demands of a pandemic that might affect the entire nation at the same time. It is estimated that critically ill patients who are not cared for in an ICU have a threefold mortality rate compared with those who are cared for in an ICU [11]. Thus, if critical care capabilities become overwhelmed by large numbers of critically ill or injured patients during a disaster, high mortality rates are likely to occur.

Surging Assets to Optimize Critical Care Capability

In planning for surge capacity during disasters, hospitals need to prepare for events that have a sudden impact and are of relatively short duration, such as transportation accidents,

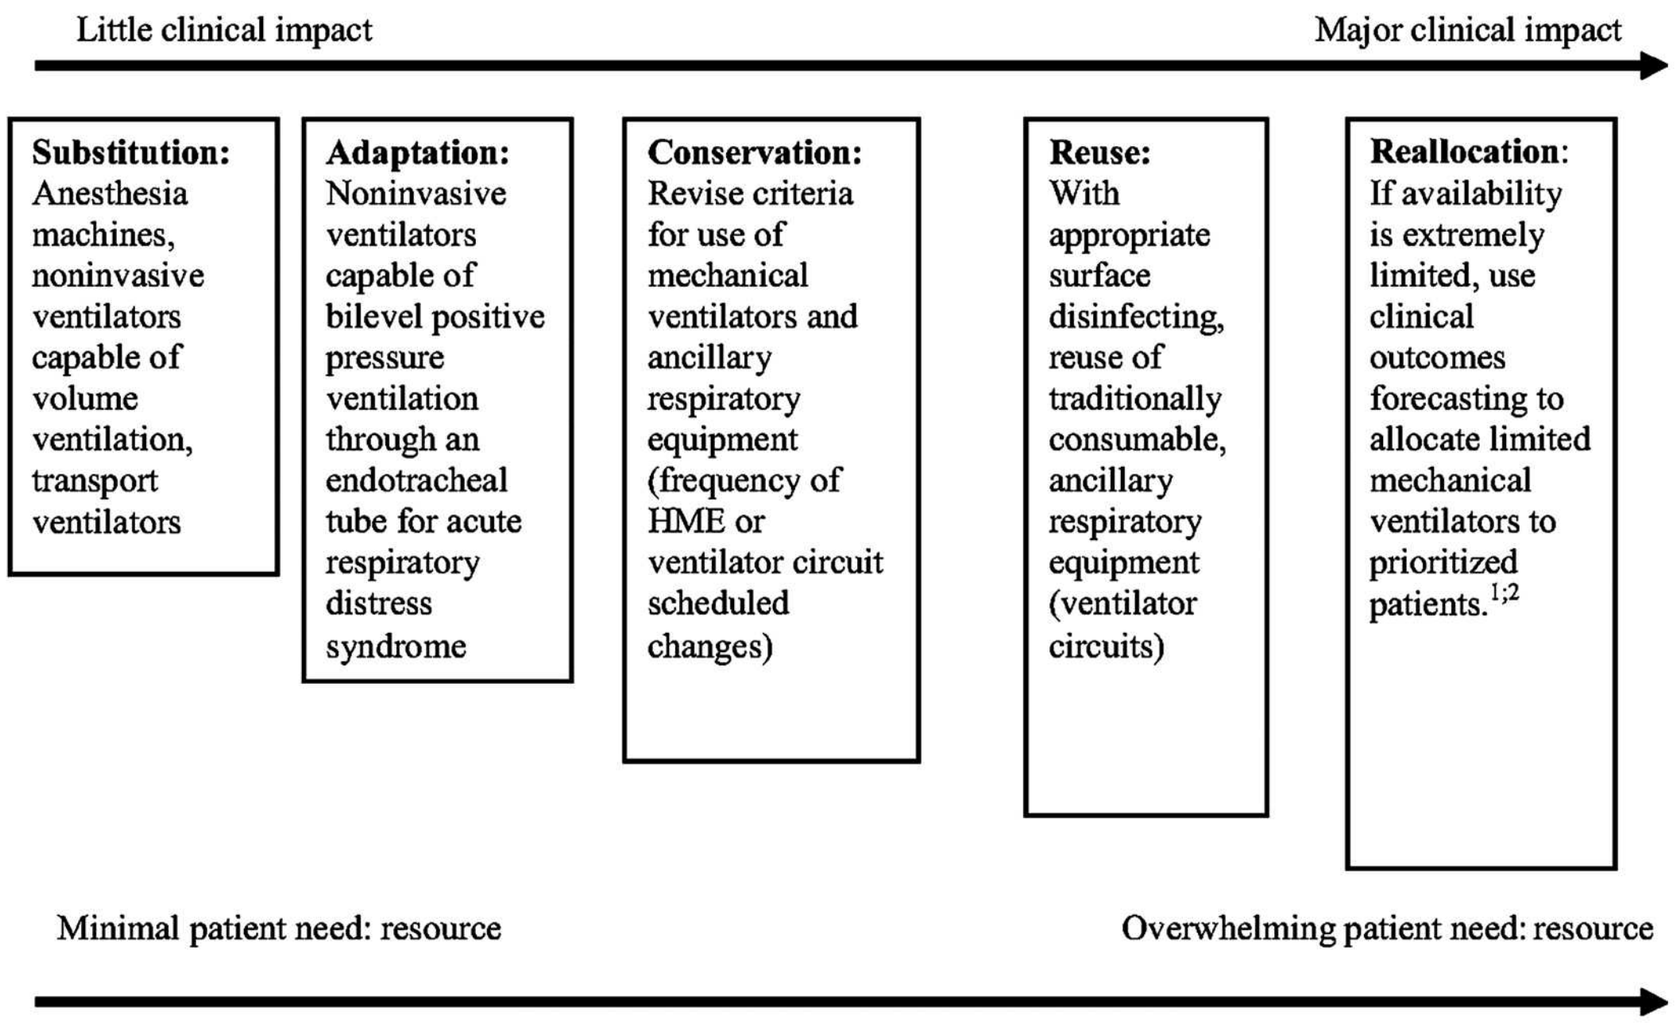

FIGURE 216.1. Stepwise modifications in resource use to maintain positive-pressure ventilation. HME, heat and moisture exchanger. [From Rubinson L, Hick JL, Hanfling DG, et al: Definitive care for the critically ill during a disaster: a framework for optimizing critical care surge capacity. *Chest* 133:18S–31S, 2008.]

explosions, bombings, as well as more prolonged events, such as earthquakes, hurricanes, and influenza pandemics [12,13].

A common rubric for the planning of critical care surge capacity places critical care resources into three categories: "*stuff*"—the medical supplies and equipment necessary for providing critical care; "*staff*"—the availability of trained critical care providers and support personnel; and "*space*"—the physical space within the hospital that can be used to provide critical care to a large number of critically ill or injured patients [14]. In all disaster situations, the effective utilization of critical care surge capacity will ultimately depend on the training and effectiveness of the hospital and community incident command systems which must execute surge capacity plans [15].

Stuff

Patients requiring care beyond the levels available on medical-surgical wards are generally admitted to ICUs because of monitoring needs, the need for intensive-care nursing, or the need for treatment with special equipment. The provision of mechanical ventilation is the most common requirement needed to manage critically ill patients with respiratory compromise. The main challenge in providing this important therapeutic modality during a disaster is the availability of mechanical ventilators.

The United States has approximately 62,000 full-feature ventilators or 20 of these per 100,000 residents (52 pediatric full-feature ventilators per 100,000 children under age 14). Approximately 100,000 ventilators that are less than full-feature are also available [16]. In any disaster with a large number of critically ill patients, it is likely that the availability of mechanical ventilators will rapidly decrease. Thus, in preparing to provide mechanical ventilation to a large number of critically ill disaster casualties, planners need to consider other options, such as anesthesia machines or noninvasive positive-pressure ventilation. Although these alternatives are not ideal for infection control, and their use may be limited by a lack of skilled respiratory therapists, they may be the best available options in a major disaster [17,18,19]. A systematic stepwise approach for providing positive-pressure ventilator support as resources become progressively scarce during a disaster is illustrated in Figure 216.1.

In considering the use of mechanical ventilators during a disaster, it is recommended that emergency response personnel should not rely on ventilators that operate on high-pressure medical gas. This is because such devices typically require a large amount of oxygen, which is likely to be in short supply during a prolonged event, especially if there are large numbers of casualties with respiratory problems. The most common form of hospital oxygen is liquid oxygen. The technical difficulties involved in supplying, storing, generating, and concentrating this kind of oxygen make it virtually impossible to increase supplies to a level that will meet the high demand caused by a large number of critically ill patients [20]. Finally, both mechanical ventilator and oxygen vendors may have multiple contracts with different hospitals within a region; such contract duplication could result in major shortages if all hospitals in a region require increased support simultaneously.

In order to support the need for additional mechanical ventilators during a disaster, both the United States and Canada have prepositioned stockpiles of sophisticated transport ventilators throughout their respective countries. The United States has at least 4,600 prepositioned ventilators at the present time [21]. Three types of transport ventilators are currently available in the United States stockpiles: Impact 754, Pulmonetic Systems LTV-1200, and Puritan Bennett LP-10 [22]. Access to these ventilators during a disaster would be provided by the federal government through a formal request from an affected state [23]. In addition, many states and regions are developing their own mechanical ventilator stockpiles along with plans for distributing the stockpiled ventilators to affected areas during a disaster.

The provision of critical care during a disaster will also require that a large quantity of supplies and pharmaceuticals be on hand and readily available to critical care providers. In 2005, during the Hurricane Katrina disaster in New Orleans, the lack of available supplies, pharmaceuticals, and operational equipment forced the dedicated providers at Charity Hospital

to improvise critical care practices and deviate from the usual standards of care prior to final evacuation of the hospital [24]. This unfortunate incident illustrates the importance of carefully planning for the increase in supplies, pharmaceuticals, and infrastructure that will be needed to provide critical care during a prolonged disaster. The Task Force for Mass Critical Care convened in 2007 by the American College of Chest Physicians (hereafter referred to as "the Task Force") recommends that hospitals should be prepared to triple their normal daily critical care capacity for 10 days without external assistance [25].

Staff

A significant challenge in maintaining critical care capability during a disaster will be the availability of a sufficient number of trained personnel. Shortages of intensivists, critical care nurses, respiratory therapists, critical care pharmacists, or other specially trained personnel may be a limiting factor in caring for large numbers of critically ill patients. Such limitations could be especially problematic in settings such as pandemic influenza, where providers might be ill, or might choose not to work because of personal safety fears or the need to care for ill family members [26]. Lastly, many critical care providers also play important emergency response roles in their communities; this is especially prevalent in nonurban settings. Such "dual-hat" responsibilities could impact the availability of critical care providers in hospitals during a major disaster.

In reviewing critical care staffing requirements during a disaster, the Task Force endorsed previously published recommendations on the surging of staff [14]. In short, the most experienced providers should perform direct patient care, if feasible. Those providers not normally operating in critical care settings should be cross-trained, or retrained, on essential bedside skills in the ICU as part of a hospital's disaster preparedness program. Finally, systematic procedures (such as protocols) should be instituted and understood by all critical care providers, in order to standardize processes, maximize good outcomes, and maximize safety to patients and staff during a disaster.

While intensivists are the most highly trained critical care physicians and should provide direct patient care to the extent feasible, in surge conditions they will need to focus part of their effort on supervising cross-trained physicians from other specialties. In such a situation, intensivists should only provide direct care for patients who require complex treatment or procedures. Nonintensivist physicians who are skilled in proving hands-on care, such as hospitalists, inpatient pediatricians, general surgeons, or anesthesiologists, could be assigned six patients each. Intensivists could supervise 4 to 8 such providers, thereby extending their critical care expertise to almost 50 patients. Similarly, critical care nurses understand the need for matching nursing staff with patient acuity. ICU charge nurses could, therefore, match several non-ICU nurses to appropriate patients within a "pod" of patients that are overseen by an ICU nurse, leaving only the most complex patients under the sole care of other ICU nurses. Another approach could be to assign specific bedside care procedures to non-ICU nurses (bathing, vital signs, catheter management, medication delivery, etc.), thereby permitting ICU nurses to oversee the provision of specific critical nursing care to several patients. Respiratory therapists usually provide care to four to six ICU patients, in accordance with the American Association for Respiratory Care Uniform Reporting Manual. Surge requirements may mandate a higher ratio of patients per therapist, ICU therapists supervising outpatient or non-ICU therapists, or even ICU therapists directing non-therapists in basic respiratory care. Finally, oncology, outpatient, radiation, or other non-ICU pharmacists may similarly be asked to support critical care operations under the tutelage of critical care pharmacists. Variants of these options already occur, for example, during off hours, or during brief surges such as mass casualty setting. Training for, rehearsing and streamlining such processes will become necessary for prolonged events that will severely strain staff resources during a major disaster [20].

Space

ICUs are highly sophisticated areas where complex equipment requirements are married with highly skilled and specialized staff in order to maximize patient outcomes. However, during a major disaster space limitations may require that critical care be provided in other areas of a hospital [27,28]. If it becomes necessary to provide critical care outside of an ICU during a major disaster, it should be provided in those areas of a hospital that are most analogous to an ICU.

In the initial phases of a surge requirement, hospitals should be able to accommodate small increases in critically ill patients with minimal impact, assuming that "stuff" and "staff" are available and the hospital is not at maximum capacity. Stable ICU patients requiring minimal care or monitoring can be transferred to step-down units, telemetry areas, postanesthesia care units, surgical centers, or other ambulatory care settings, as appropriate. In this event, the hospital bed space should be decompressed by transferring stable ward patients to home care, to skilled nursing facilities, or to alternate community facilities such as an ACC. As an emergency mass critical care event progresses, formal critical care space will need to expand into other areas of the hospital, with the hospital continuing to make room for critically ill patients by transferring the most stable inpatients elsewhere.

An alternative to expanding internal ICU capability is for communities to develop and deploy "field" ICUs. Critical care has been provided in such settings before, and can be especially relevant and appropriate when hospitals have been physically destroyed or incapacitated [29–31]. However, because of the logistical requirements for specialized equipment, infection control support, and the relocation of trained personnel, critical care should only be provided in "field" settings as a last resort. In most major disaster situations, such facilities can be best used for the management of noncritically ill patients who are transferred from hospitals in order to free up space for the management of the critically ill. The Task Force recommends using alternate sites, or buildings of convenience, for critical care only if a region's medical facilities are physically destroyed or rendered unsafe to occupy [20].

RESOURCE ALLOCATION AND TRIAGE DURING TIMES OF OVERWHELMING DEMAND

The Greatest Good for the Greatest Number of Victims

The goal of surging critical care resources during a disaster is to provide the greatest good for the greatest number of event victims. Critical care providers and institutions should strive to manage resources within their own facility and region with the goal of providing usual critical care practices to the extent possible. However, in a major disaster, as resources become increasingly limited, healthcare providers and leaders must have a plan in place to change the focus of critical care from the needs of the individual to the needs of the population as a whole. This requires a defined triage plan to be developed, communicated, and implemented fairly.

Ethical and Legal Principles

Utilitarian principles guide the theory of the "greatest good for the greatest number." In times of overwhelming resource constraints, limited capabilities should be targeted to those with the greatest likelihood of benefitting from the care. Those who are unlikely to recover or improve with the available care are not abandoned, but are provided with appropriate palliative care. This fundamental principle guides the implementation of a mass-casualty triage system during major disasters [32].

The Task Force supports the concept that if surge measures do not meet demand, then individual autonomy will be limited. It mandates a fair and just rationing of resources, based on objective information and decision-making, in order to benefit the population as a whole, rather than individual patients. Such a shift in healthcare priorities requires active community involvement and an open, transparent decision-making processes. Ideally, plans for the fair and just rationing of critical care resources during periods of overwhelming demand should be developed prior to the disaster. "Procedural justice" requires absolute conformity to the agreed-upon process, which itself must be repeatedly reevaluated and validated through ongoing, real-time epidemiological investigation [33].

Importantly, in order to implement such processes, providers must feel secure in their legal protection. Hence, providers must be legally protected from local and state law if there is a need to deviate from the usual standards of care during periods of scarce resources. The need for such legal protection was poignantly highlighted in New Orleans during the Hurricane Katrina disaster, as palliative care was provided to some patients as evacuation attempts were repeatedly delayed and hospital capabilities were overwhelmed [34]. Several states have begun efforts to address this important issue [35,36]. The Task Force recommends that uniformly accepted, predetermined algorithms be developed for triaging critically ill patients during a disaster, with adherence to these algorithms being sufficient to provide necessary legal protection to providers and other decision makers [33].

Critical Care Triage

Triage processes have been well described for the prehospital and emergency department mass-casualty events, such as the use of START (Simple Triage and Rapid Treatment) cards [37]. However, ICU triage processes and procedures have not been well studied or validated in overwhelming critical care disasters. The Task Force recommends that planning for the triage of critically ill patients during a major disaster should include well-defined "triggers" that promptly alert hospital and community leadership to the fact that critical care resources are being overwhelmed and there is a need to direct the use of a triage process. Such triggers would include a lack of critical equipment or medical supplies, inadequate critical care spaces, inadequate staff, and inadequate capability to transfer noncritically ill patients to other facilities.

Once the requirement to triage care has been directed, critical care providers must determine which patients should receive critical care and which patients should not. This process needs to be carefully planned and evaluated with community

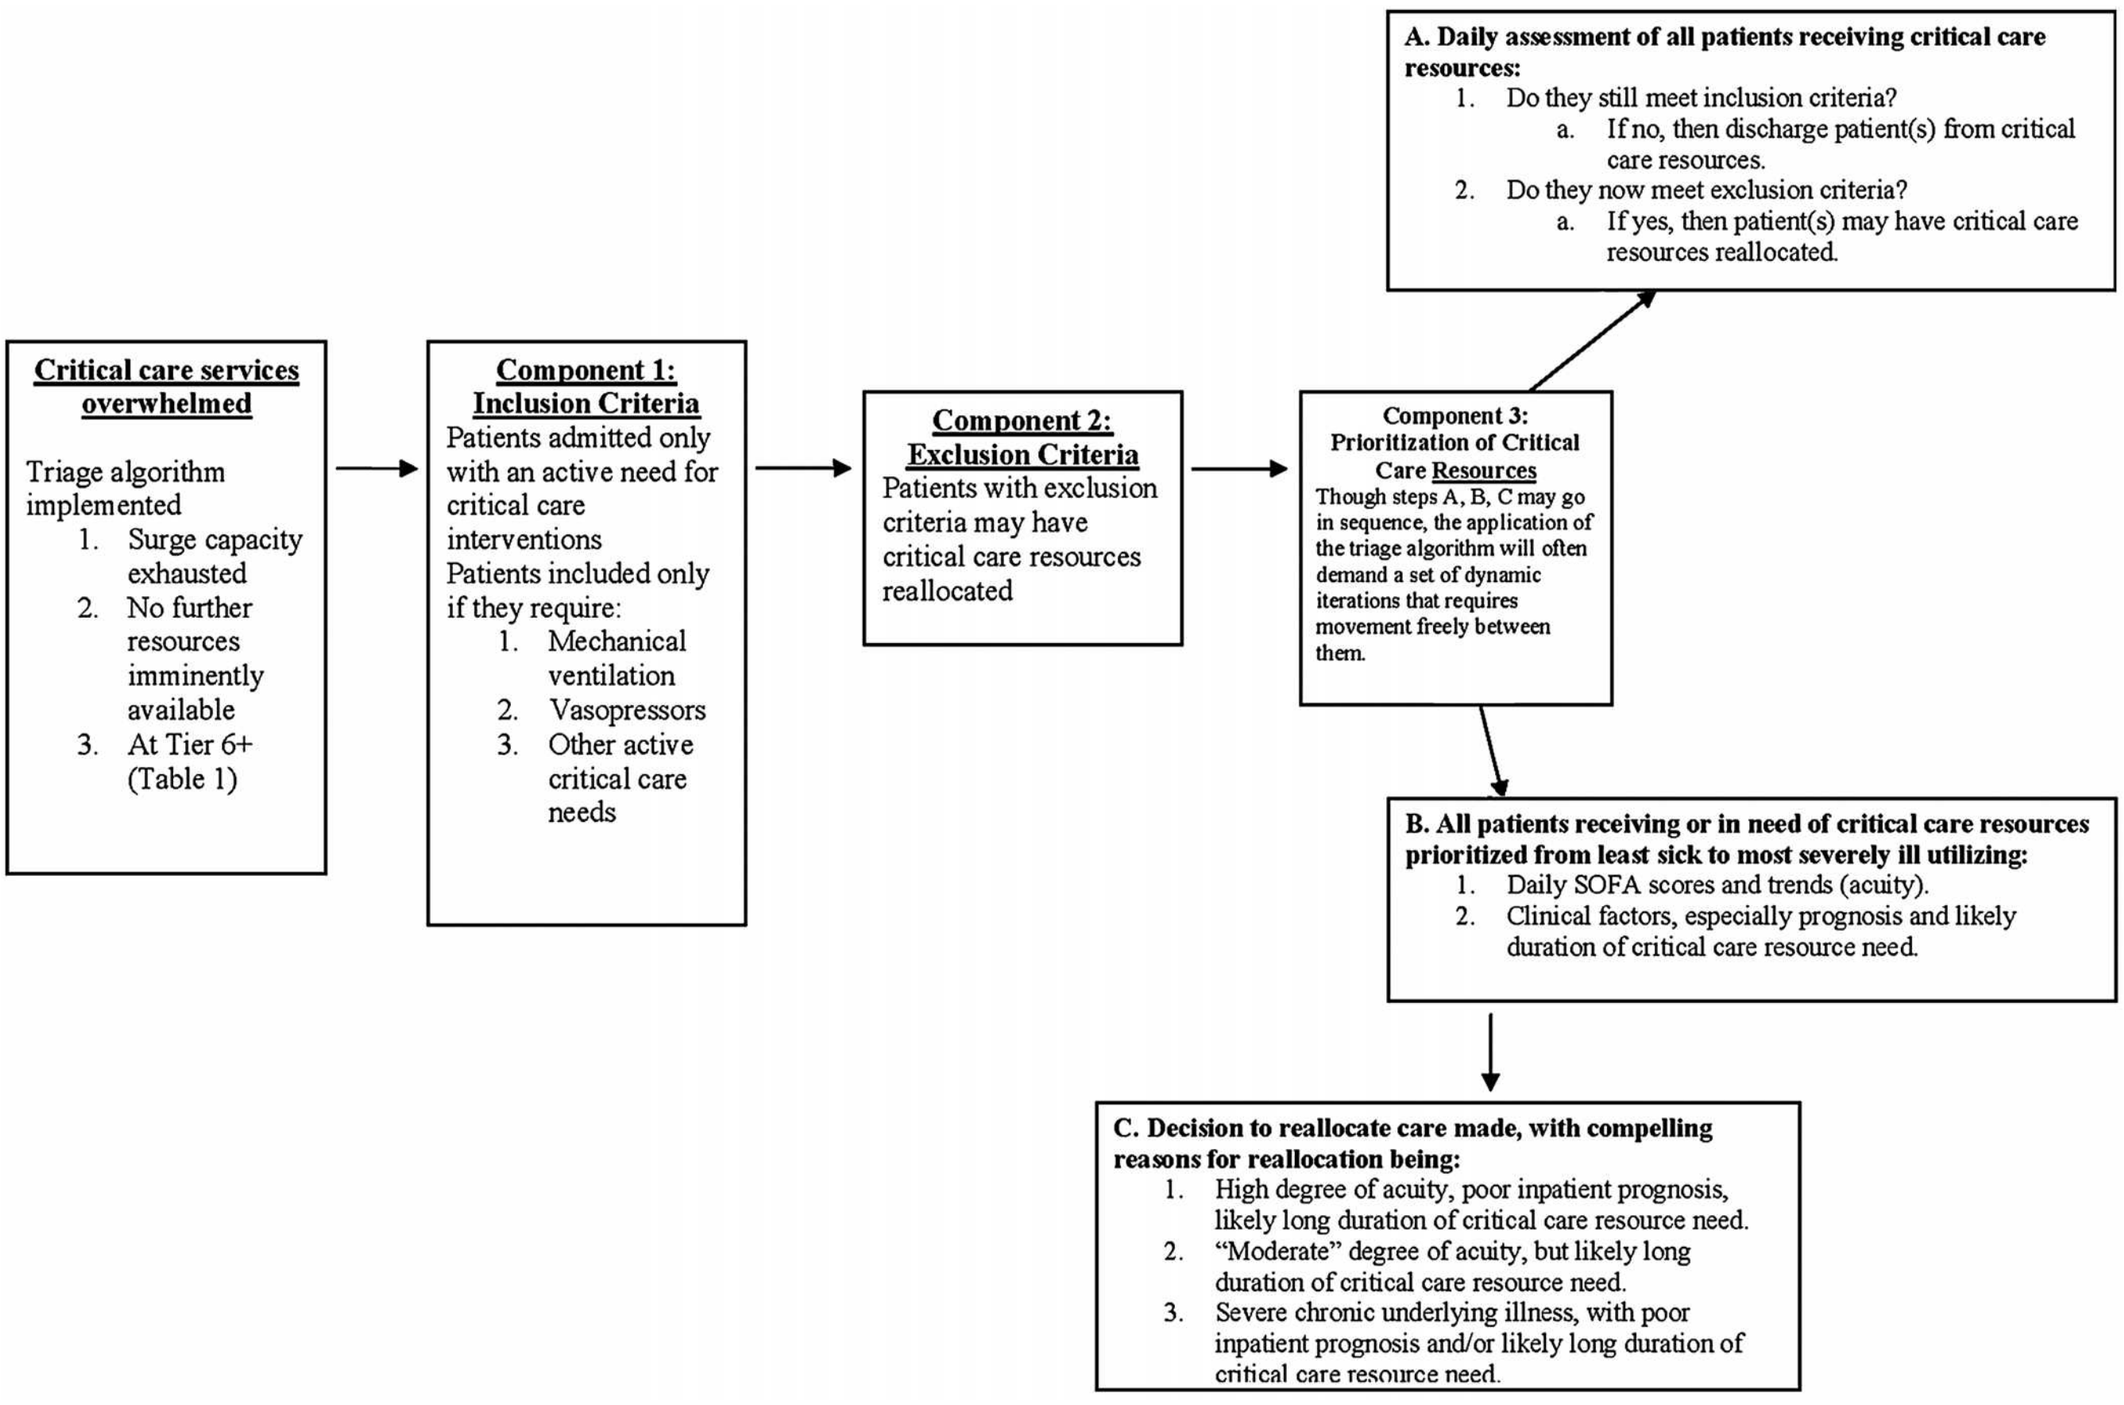

FIGURE 216.2. Critical care triage algorithm. [From Devereaux AV, Dichter JR, Christian MD, et al: Definitive care for the critically ill during a disaster: a framework for allocation of scarce resources in mass critical care. *Chest* 133:51S–66S, 2008.]

involvement prior to a catastrophic event. If, for example, a healthcare system or region proposes to exclude critical care to the very elderly during a major disaster, then community representatives from the elderly population would need to be included in such decisions. That is, the elderly would participate in advance planning with providers on how to triage the elderly in future mass-casualty emergencies.

Several severity-of-illness models have been developed for the ICU setting that may be applied to the triage process. However, all have similar limitations in that they have not been rigorously evaluated in emergency mass critical-care scenarios. The Task Force and other groups have advocated the use of the Sequential Organ Failure Assessment (SOFA) score because of its demonstrated effectiveness in the ongoing assessment of critically ill patients and the ease with which it can be calculated with minimal laboratory requirements [33,38].

The Task Force recommends that hospitals establish a critical care triage team for the effective and ethical triage of critically ill patients. It recommends that the triage team consist of a small group of experienced providers to include an intensivist, a critical care nurse, a respiratory therapist or pharmacist, and a hospital administrator. This group, operating independently from the bedside clinicians, would gather periodic SOFA scores to determine the severity of illness and document improvement, stability, or deterioration of critically ill patients over time. The Task Force recommends that patients with high SOFA scores (> 11) not be offered critical care. Similarly, patients who deteriorate or fail to improve over time would have their critical care resources reallocated to other patients (Fig. 216.2). The availability of an experienced critical care triage team has the advantage of removing the burden of triage decisions from busy clinicians who are providing critical care at the bedside. In the HICS, the critical care triage team should operate under the command of the Hospital Operations Section Chief.

In order to assure compliance and integrity of the triage process, the Task Force recommends that a review committee be established to oversee triage plans and operations. This committee, distinct from the triage team, would:

- Work with regional planners and maintain situational awareness in the community and state, regarding the ongoing use and need of triage protocols;
- Review the implementation of the local triage protocol, to ensure compliance and integrity of triage operations;
- Serve as a forum for appeals by patients, families, and staff regarding the accurate and ethical implementation of the triage tool; and
- Participate in the real-time epidemiological evaluation of the catastrophic event, to help public health and other officials determine the ongoing validity of the SOFA score as a triage tool for critically ill patients.

SUMMARY

Preparing ICUs for disasters requires a methodical approach within a defined organizational structure in order to optimize care for large numbers of critically ill patients. Ideally, hospitals are the optimal setting to provide critical care for severely ill and injured patients. During major disasters, hospitals should coordinate with community medical response systems to offload patients with minor injuries or illnesses so that hospital resources can be focused on the care of critically ill patients.

Predisaster planning and training are essential for mitigating the adverse effects of an overwhelming disaster on hospitals and their communities. Carefully developed plans for surging critical care "stuff, staff, and space" will facilitate continuation of usual critical care processes for as long as possible. However, if surge procedures fail to meet the critical care demands of an overwhelming patient influx, processes to triage and alter the usual standards of critical care must be implemented. The planning concepts and guidelines outlined in this chapter can help guide critical care practitioners to care for their patients under the challenging conditions of a catastrophic disaster.

APPENDIX

JOSEPH J. FRASSICA

CALCULATIONS COMMONLY USED IN CRITICAL CARE

JOSEPH J. FRASSICA

TABLE OF CONTENTS

ABBREVIATIONS USED IN THE APPENDIX

A	Alveolar	atm	Atmosphere
D	Dead	BSA	Body surface area
E	Expiration	cap	Capillary
I	Inspiration	cr	Creatinine
P	Pressure	dyn	Dynamic
$\dot{Q}$	Net liquid flow	is	Interstitium
R	Respiratory quotient	st	Static
T	Tidal	ICP	Intracranial pressure
V	Volume	a	Arterial
Δ	Change	d	Distribution
H	Viscosity	l	Length
Π	Oncotic pressure	r	Radius
Σ	Permeability	t	Time
		$\bar{v}$	Mixed venous

FAHRENHEIT AND CELSIUS TEMPERATURE CONVERSIONS

°C	°F	°C	°F
45	113.0	32	89.6
44	111.2	31	87.8
43	109.4	30	86.0
42	107.6	29	84.2
41	105.8	28	82.4
40	104.0	27	80.6
39	102.2	26	78.8
38	100.4	25	77.0
37	98.6	24	75.2
36	96.8	23	73.4
35	95.0	22	71.6
34	93.2	21	69.8
33	91.4	20	68.0

DOSAGE AND ACTION OF COMMON INTRAVENOUS VASOACTIVE DRUGS

	Dosage	α	β_1	β_2
Dopamine	1–2 µg/kg/min	+	+	0
	2–10 µg/kg/min	++	+++	0
	10–30 µg/kg/min	+++	++	0
Dobutamine	2–30 µg/kg/min	+	+++	++
Norepinephrine	0.05–1 mg/kg/min titrate to effect	+++	++	+
Epinephrine	0.1–1.0 mg/kg/min	++	+++	+++
Isoproterenol	2–10 µg/min	0	+++	+++
Phenylephrine	0.1–0.5 mg/kg/min	+++	0	0
Milrinone	(Loading dose 50 mg/kg over 10–15 min)			
	0.375–0.75 mg/kg/min	—	—	—
Labetolol	2 mg/min; max dose 300 mg	—	—	—
Esmolol	50–300 mg/kg/min	—	—	—

HEMODYNAMIC CALCULATIONS

MEAN BLOOD PRESSURE (mm Hg)

$$= \overline{BP}$$

$$= \frac{\text{Systolic BP} + (2 \times \text{Diastolic BP})}{3}$$

$$= \text{Diastolic BP} + \frac{1}{3}(\text{Systolic BP} - \text{Diastolic BP})$$

Normal values: 85–95 mm Hg

THE FICK EQUATION FOR CARDIAC INDEX (L/min/m^2)

$$= \text{CI}$$

$$= \frac{\text{CO}}{\text{BSA}}$$

$$= \frac{\text{Oxygen consumption}}{\text{Arterial } O_2 \text{ contemt} - \text{Venous } O_2 \text{ content}}$$

$$= \frac{10 \times \dot{V}O_2\,(\text{mL/min/m}^2)}{\text{Hgb (g/dl)} \times 1.39}$$

$$\times (\text{Arterial \% saturation} - \text{Venous \% saturation})$$

Normal values: 2.5–4.2 L/min/m^2

STROKE INDEX (mL/beat/m^2)

$$= \frac{\text{CI (L/min/m}^2) \times 1{,}000}{\text{Heart rate (beats/min)}}$$

Normal values: 33–47 mL/beat/m^2

SYSTEMIC VASCULAR RESISTANCE (dyne/sec/cm^5)

$$= \text{SVR}$$

$$= \frac{80 \times (\text{Arterial } \overline{\text{BP}} - \text{Right atrial } \overline{\text{BP}})}{\text{CO (L/min)}}$$

Normal values: 770–1,500 dyne/sec/cm^5

PULMONARY VASCULAR RESISTANCE (dyne/sec/cm^5)

$$= \text{PVR}$$

$$= \frac{80 \times (\text{Pulmonary artery } \overline{\text{BP}} - \text{Pulmonary capillary wedge pressure})}{\text{CO (L/min)}}$$

Normal values: 20–120 dyne/sec/cm^5

TOTAL PULMONARY RESISTANCE (dyne/sec/cm^5)

$$= \text{TPR}$$

$$= \frac{80 \times \text{Pulmonary artery } \overline{\text{BP}}}{\text{CO (L/min)}}$$

CAPILLARY FLUID FILTRATION

$$= \dot{Q}_f$$

$$= k(P_{cap} - P_{is}) - k\sigma(\pi_{cap} - \pi_{is})$$

NUTRITIONAL CALCULATIONS

BODY MASS INDEX

$$= \text{BMI}$$

$$= \frac{\text{Weight (kg)}}{(\text{Height [cm]})^2}$$

CALORIC CONTENT OF FOODS

Food type	kcal/g	Range
Carbohydrate	3.4	3.4–4.1
Protein	4.0	3.3–4.7
Fat	9.1	9.1–9.5

RESPIRATORY QUOTIENT

$$= \frac{CO_2 \text{ production (mL/min)}}{O_2 \text{ consumption (mL/min)}}$$

$$= \frac{\dot{V}_{CO_2}}{\dot{V}_{O_2}}$$

RELATIONSHIP OF FUEL BURNED TO RESPIRATORY QUOTIENT

Fuel	*R*
Ketones	< 0.6
Fat	0.7
Carbohydrate	1.0
Lipogenesis	> 1.0

NITROGEN BALANCE

$$= \text{Nitrogen consumed} - \text{Nitrogen excreted}$$

$$= \frac{\text{Protein calories (kcal/day)}}{25} - \text{Urine nitrogen (g/day)} - 5\ (\text{g/day})$$

HARRIS–BENEDICT EQUATION OF RESTING ENERGY EXPENDITURE (kcal/day)

$$\text{Males} = 66 + (13.7 \times \text{Weight [kg]}) + (5 \times \text{Height [cm]}) - (6.8 \times \text{Age})$$

$$\text{Females} = 655 + (9.6 \times \text{Weight [kg]}) + (1.8 \times \text{Height [cm]}) - (4.7 \times \text{Age})$$

WEIR EQUATION (MODIFIED) OF ENERGY EXPENDITURE (kcal/day)

$$= (3.94 \times \dot{V}_{O_2}\,[\text{mL/min}]) + (1.11 \times \dot{V}_{CO_2}\,[\text{mL/min}])$$

TYPICAL DRUG DOSAGES FOR RAPID SEQUENCE INTUBATION

Muscle relaxants	
Rocuronium	0.6–1.2 mg/kg
Succinylcholine	1 mg/kg
Vecuronium	0.1–0.20 mg/kg
Sedatives	
Etomidate	0.3–0.4 mg/kg
Ketamine	1–2 mg/kg
Propofol	1–2 mg/kg
Thiopental	3–4 mg/kg

PULMONARY CALCULATIONS

TIDAL VOLUME

$= V_T$
$=$ Dead space + Alveolar space
$= V_D + V_A$

ALVEOLAR GAS EQUATION

$$PAO_2 = PIO_2 - \frac{PaCO_2}{R}$$
$$= FIO_2(P_{atm} - P_{H_2O}) - \frac{PaCO_2}{R}$$
$$= 150 - \frac{PaCO_2}{R} \text{(room air, sea level)}$$

ALVEOLAR ARTERIOLAR GRADIENT

$= A - a$ gradient
$= PAO_2 - PaO_2$

Normal values (upright): 2.5 + (0.21 × age)

ALVEOLAR VENTILATION (L/min)

$= \dot{V}_E$
$$= k\frac{\dot{V}CO_2}{PaCO_2}$$
$$= \frac{0.863 \times \dot{V}_{CO_2}(\text{mL/min})}{Pa_{CO_2}(1 - V_D/V_T)}$$

Normal values: 4–6 L/min

BOHR EQUATION OF DEAD SPACE

$$V_D/V_T = \frac{PACO_2 - PECO_2}{PACO_2}$$

Normal values: 0.2–0.3

PHYSIOLOGIC DEAD SPACE

$$V_D/V_T = \frac{PaCO_2 - PECO_2}{PaCO_2}$$

Normal values: 0.2–0.3

OXYGEN DISSOLVED IN BLOOD (mL/dL)

$= Do_2$
$= 0.003\,(\text{mL}\,O_2/\text{dL}) \times PaO_2\,(\text{mm Hg})$

OXYGEN CAPACITY OF HEMOGLOBIN (mL O_2/dL)

$= 1.39\,(\text{mL}\,O_2) \times \text{Hgb}\,(\text{g/dL})$

Normal values: 17–24 mL/dL

OXYGEN CONTENT OF THE BLOOD (mL/dL)

$= Co_2$
$= D_{O_2} + (1.39 \times \text{Hgb}\,[\text{g/dL}] \times [\%\ \text{Hgb saturated with}\ O_2])$
$= D_{O_2} + (1.39 \times \text{Hgb}\,[\text{g/dL}] \times S_{O_2})$

Normal values: 17.5–23.5 mL/dL

PERCENTAGE OF SATURATION OF HEMOGLOBIN WITH OXYGEN

$= SO_2$
$$= 100 \times \frac{CO_2 - DO_2}{1.39 \times \text{Hgb}\,(\text{g/dL})}$$

Normal values: > 95%

PHYSIOLOGIC SHUNT

$= \dot{Q}_S/\dot{Q}_T$
$$= \frac{C_{capo_2} - C_{O_2}}{C_{capo_2} - C_{\bar{v}O_2}}$$
$$= \frac{1.39 \times \text{Hgb}\,(\text{g/dL}) + 0.003 \times PaO_2 - CaO_2}{1.39 \times \text{Hgb}\,(\text{g/dL}) + 0.003 \times PaO_2 - C\bar{v}O_2}$$

Normal values: < 5%

COMPLIANCE

$= \Delta V/\Delta P\,(\text{mL/cm}\,H_2O)$

On Mechanical Ventilation

$$\text{Static compliance} = C_{st} = \frac{V_T}{P_{plateau} - P_{end\,exp}}$$

$$\text{Dynamic effective complicance} = C_{dyn} = \frac{V_T}{P_{peak} - P_{end\ exp}}$$

During Spontaneous Breathing

$$\text{Compliance of the lung} = C_L = \frac{V_T}{P_{alveolus} - P_{pleura}}$$

$$\text{Compliance of the chest wall} = CW_{cw} = \frac{V_T}{P_{pleura} - P_{atm}}$$

$$\text{Compliance of the respiratory system} = C_{rs} = \frac{V_T}{P_{alveolus} - P_{atm}}$$

Normal values: C_{st} > 60 mL/cm H_2O; C_{dyn} > 60 mL/cm H_2O
C_L > 200 mL/cm H_2O; C_{rs} > 100 mL/cm H_2O

RESISTANCE—OHM'S LAW

$$= \Delta P/\text{flow} = \Delta P/\dot{Q}$$

Normal values: airway resistance of the lung at functional residual capacity (FRC) = 2 cm H_2O/L/sec

WORK-OF-BREATHING

$$W_{\text{Thorax}} = \int_{t_1}^{t_2} (P_{\text{aw}} - P_{\text{atm}})\dot{V}\,dt$$

$$W_{\text{Lung}} = \int_{t_1}^{t_2} (P_{\text{aw}} - P_{\text{es}})\dot{V}\,dt$$

$$W_{\text{Chest wall}} = \int_{t_1}^{t_2} (P_{\text{es}} - P_{\text{atm}})\dot{V}\,dt$$

Normal values: W_{thorax} = 0.5 kg-M/min

LAPLACE'S LAW OF SURFACE TENSION OF A SPHERE

$$P = 2T/r$$

POISEUILLE'S LAW OF LAMINAR FLOW

$$\dot{V} = \frac{P\pi r^4}{8\eta l}$$

COMPOSITION AND PROPERTIES OF COMMON INTRAVENOUS SOLUTIONS

Solution	Na^+	Cl^-	K^+	Ca^+	Lactate	Kcal/L	mOsm/L
D5W	0	0	0	0	0	170	252
D10W	0	0	0	0	0	240	505
D50W	0	0	0	0	0	1,700	2,530
1/2 NS	77	77	0	0	0	0	154
NS	154	154	0	0	0	0	308
3% NaCl	513	513	0	0	0	0	1,026
Ringer's lactate	130	109	4	3	28	0	308
20% mannitol	0	0	0	0	0	0	1,098

ELECTROLYTE AND RENAL CALCULATIONS

ANION GAP

$$= [Na^+] - [Cl^-] - [HCO_3^-]$$

Normal values: 9–13 mEq/L

EXPECTED ANION GAP IN HYPOALBUMINEMIA

$$= 3 \times (\text{albumin [g/dL]})$$

CALCULATED SERUM OSMOLALITY

$$= 2[Na^+] + \frac{[\text{Glucose}]}{18} + \frac{[\text{BUN}]}{2.8}$$

Normal values: 275–290 mOsm/kg

OSMOLAR GAP

= Serum osmolality measured − Serum osmolality calculated

Normal values: 0–5 mOsm/kg

Na^+ AND GLUCOSE

$[Na^+]$ decreases 1.6 mEq/L for each 100 mg/dL increase in [glucose]

TOTAL CALCIUM AND ALBUMIN

Corrected calcium (mg/dL) = Measured total calcium (mg/dL) + 0.8(4.0 − serum albumin)

GLOMERULAR FILTRATION RATE = GFR

$$\text{Measured} = \text{Creatinine clearance} = \frac{U_{\text{Creat}}V}{P_{\text{Creat}}}$$

$$= \frac{[\text{Creatinine}]_{\text{urine}}\ (\text{g/dL}) \times \dfrac{\text{Urine volume (mL/day)}}{1{,}440\ (\text{minute/day})}}{[\text{Creatinine}]_{\text{plasma}}\ (\text{mg/dL})}$$

$$\text{Estimated for males} = \frac{(140 - \text{Age}) \times (\text{Lean body weight [kg]})}{P_{\text{Creat}} \times 72}$$

Estimated for females = 0.85 × Male estimate

Normal values: 74–160 mL/min

WATER DEFICIT IN HYPERNATREMIA (L)

$$= 0.6 \times (\text{Body weight [kg]}) \times \left(\frac{[Na^+]}{140} - 1\right)$$

WATER EXCESS IN HYPONATREMIA (L)

$$= 0.6 \times (\text{Body weight [kg]}) \times \left(1 - \frac{[Na^+]}{140}\right)$$

FRACTIONAL EXCRETION OF SODIUM

$$= F_E\,Na$$

$$= \frac{\text{Excreted } Na^+}{\text{Filtered } Na^+} \times 100$$

$$= \frac{U_{Na^+} \times V}{\text{GFR}} \times [Na^+] \times 100$$

$$= \frac{U_{Na^+}/[Na^+]}{U_{\text{Creat}}/[\text{Creat}]}$$

ACID–BASE FORMULAS

HENDERSON–HASSELBALCH EQUATION

$$\text{pH} = pK + \log\frac{[HCO_3^-]}{0.03 \times PaCO_2}$$

HENDERSON'S EQUATION FOR CONCENTRATION OF H^+

$$[H^+](\text{nM/L}) = 24 \times \frac{PaCO_2}{[HCO_3^-]}$$

METABOLIC ACIDOSIS

Bicarbonate deficit (mEq/L) = 0.5 × (Body weight [kg]) × (24 − $[HCO_3^-]$)

Expected PCO_2 = 1.5 × $[HCO_3^-]$ + 8 ± 2

METABOLIC ALKALOSIS

Bicarbonate excess = 0.4 × (Body weight [kg]) × ($[HCO_3^-]$ − 24)

RESPIRATORY ACIDOSIS

$$\text{Acute: } \frac{\Delta H^+}{\Delta PaCO_2} = 0.8$$

$$\text{Chronic: } \frac{\Delta H^+}{\Delta PaCO_2} = 0.3$$

NEUROLOGIC CALCULATIONS

GLASGOW COMA SCALE (3–15)

= Eyes (1 − 4) + Motor (1 − 6) + Verbal (1 − 5)

Normal value: 15

TABLE A.1

SPECIFIC COMPONENTS OF THE GLASGOW COMA SCALE

Eye opening	
Spontaneous	4
To speech	3
To pain	2
Nil	1
Motor response	
Obeys commands	6
Localizes	5
Withdraws	4
Exhibits abnormal flexion	3
Exhibits abnormal extension	2
Nil	1
Verbal response	
Oriented	5
Confused, conversant	4
Uses inappropriate words	3
Uses incomprehensible sounds	2
Nil	1

CEREBRAL PERFUSION PRESSURE (mm Hg)

= $\overline{BP}$ − ICP

BODY SURFACE AREA FORMULA AND NOMOGRAM

BODY SURFACE AREA (BSA)

= (Height [cm])$^{0.718}$ × (Weight [kg])$^{0.427}$ × 74.49

See Figure A.1 for the nomogram for calculating BSA.

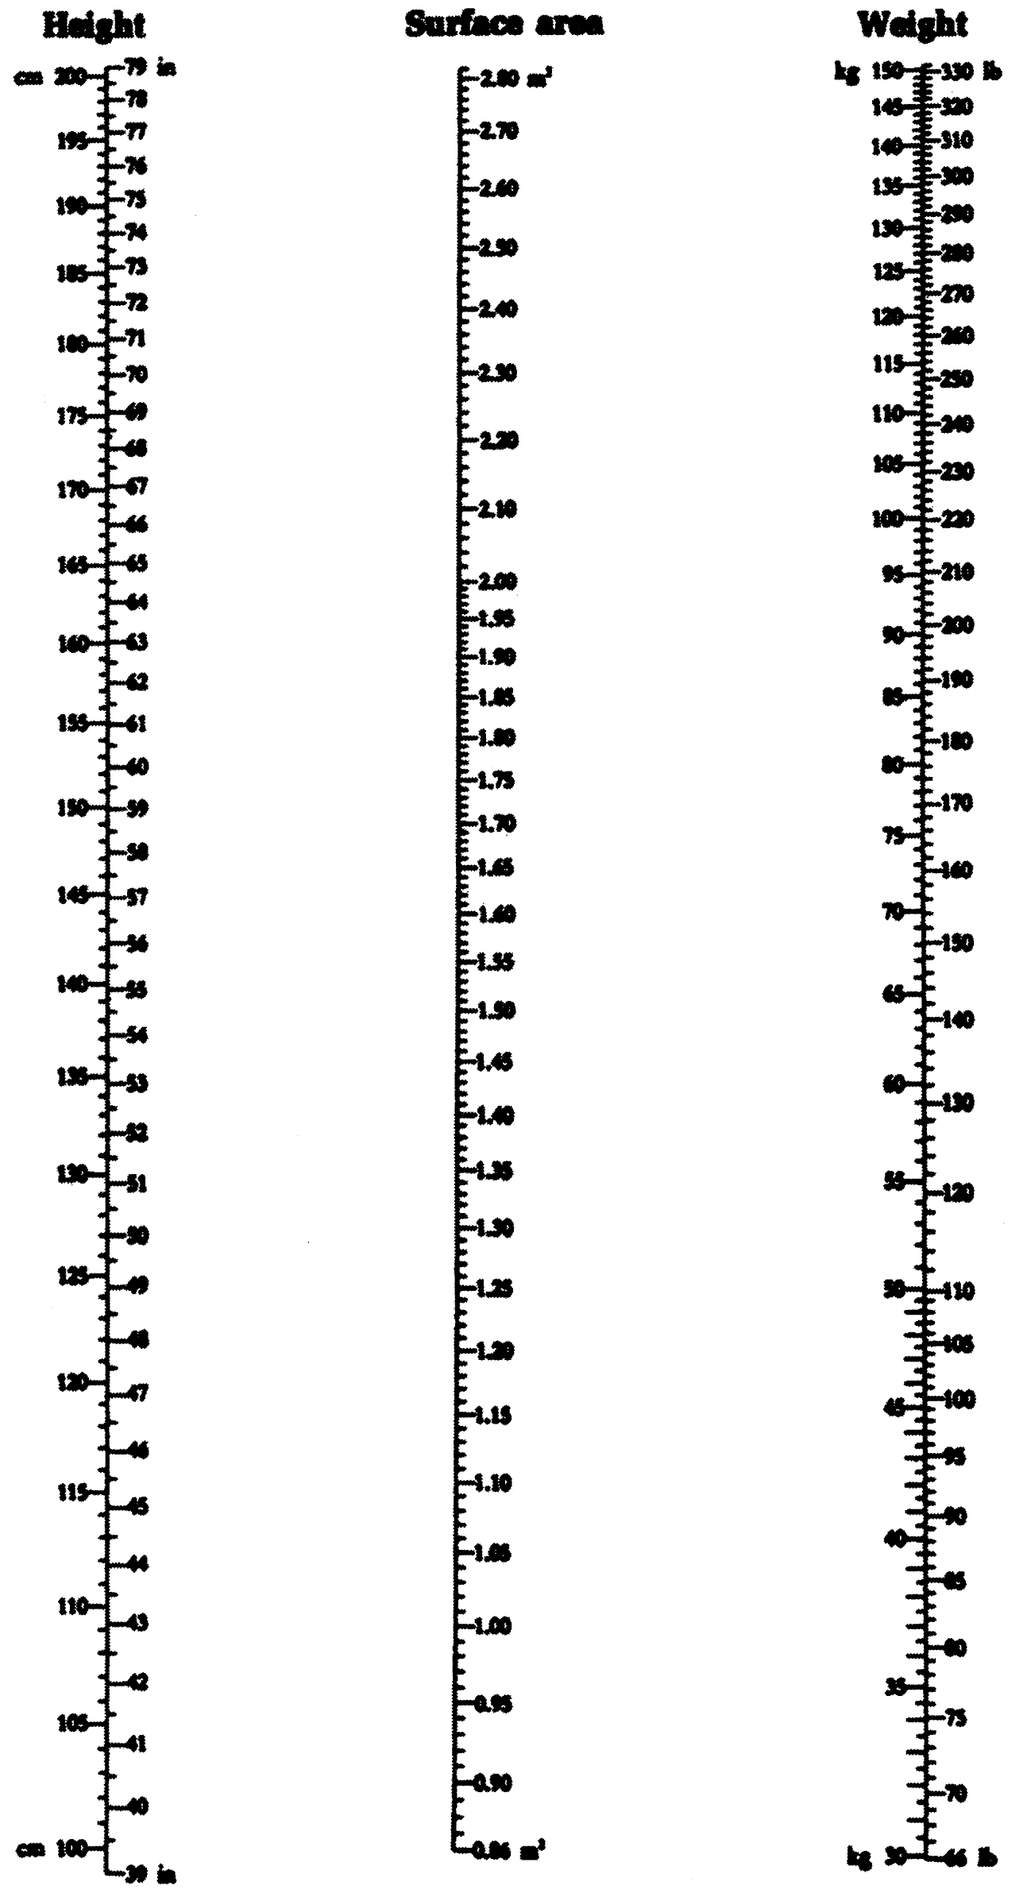

FIGURE A.1. Nomogram for calculation of body surface area (BSA) in square meters by height and weight.

PHARMACOLOGIC CALCULATIONS

DRUG CLEARANCE

= $V_d \times K_{el}$

DRUG HALF-LIFE

= $t_{1/2}$

$$= \frac{0.693}{K_{el}}$$

DRUG ELIMINATION CONSTANT

= K_{el}

$$= \frac{\ln\left(\frac{[\text{Peak}]}{[\text{Trough}]}\right)}{t_{peak} - t_{trough}}$$

DRUG LOADING DOSE

$$= V_d \times [\text{Target peak}]$$

DRUG DOSING INTERVAL

$$= \frac{-1}{K_{el}} \times \ln\left(\frac{\text{Desired trough}}{\text{Desired peak}}\right) + \text{Infusion time (hours)}$$

See ICU Acuity Scoring for the calculation of APACHE scores.

ICU ACUITY SCORING

SAPS II Score [1,2]

Type of admission		Points
	Scheduled surgery	0
	Unscheduled surgery	8
	Medical	6
Chronic diseases	None	0
	Metastatic carcinoma	9
	Hematologic malignancy	10
	AIDS	17
Age	< 40	0
	40–59	7
	60–69	12
	70–74	15
	75–79	16
	≥ 80	18
Temperature	< 39°C	0
	> 39°C	3
Heart rate	< 40	11
	40–69	2
	70–119	0
	120–159	4
	≥ 160	7
Systolic blood pressure	< 70 mm Hg	13
	70–99	5
	100–199	0
	≥ 200	2
Urine output	< 500 cc/24 h	11
	500–999 cc/24 h	4
	> 1,000 cc/24 h	0
Glasgow Coma Score	< 6	26
	6–8	13
	9–10	7
	11–13	5
	14–15	0
Serum urea or BUN	< 10	0
	10–29.9	6
	≥ 30	10
Serum sodium	> 146 mEq/L	1
	125–144 mEq/L	0
	< 125 mEq/L	5
Serum potassium	< 3 mEq/L	3
	3–4.9 mEq/L	0
	> 5 mEq/L	3
WBC	< 1,000/mm^3	12
	1,000–19,000/mm^3	0
	> 20,000/mm^3	3

(*continued*)

CONTINUED

Type of admission		Points
HCO_3^-	< 15 mEq/L	6
	15–19 mEq/L	3
	≥ 20	0
Bilirubin	< 4 mg/dL	0
	4–5.9 mg/dL	4
	≥ 6	9
PaO_2/FIO_2 (if ventilated or CPAP)	< 100	11
	100–199	9
	≥ 200	6

SAPS II, Simplified Acute Physiology Score II.

APACHE IV VARIABLES (NON-CABG PATIENTS) [3]

Age **Chronic Health Issues on Admission** *Use the one with the highest point value that is present* *Nonoperative and emergency surgery patients only* *otherwise = 0*	**Points**
AIDS	23
Hepatic failure	16
Lymphoma	13
Metastatic cancer	11
Leukemia/multiple myeloma	10
Immunosuppression	10
Cirrhosis	4
None/not available	0

Acute Physiology Score	
P_aO_2/FIO_2 ratio (or $P(A–a)O_2$ for intubated patients with $FIO_2 >= 0.5$	
Ventilated anytime during day 1	Y/N
ICU admission information	
Admit to ICU from floor	
Transfer to ICU from other hospital	
Admit to ICU from OR/PACU	
Emergency surgery	Y/N
Pre-ICU length of stay (# of days between ICU and hospital admission)	
Admitting diagnosis (see Diagnosis Tables)	
If DX is acute MI is the patient on thrombolytic therapy?	Y/N
Unable to obtain GCS (due to meds, anesthesia or sedation)	Y/N
GCS	

Acute Physiology Score (APS Score)

Pulse (beats/min) *Select heart rate furthest from 75*	
≤ 39	8
40–49	5
50–99	0
100–109	1
110–119	5
120–139	7
140–154	13
≥ 155	17

Mean blood pressure (MAP)
Select MAP furthest from 90

≤ 39	23
40–59	15
60–69	7
70–79	6
80–99	0
100–119	4
120–129	7
130–139	9
≥ 140	10

Temperature (degrees centigrade)
Select core temperature furthest from 38
Add 1 degree centigrade to axillary temps prior to selecting worst value

≤ 32.9	20
33–33.4	16
33.5–33.9	13
34–34.9	8
35–35.9	2
36–39.9	0
≥ 40	4

Respiratory rate (breaths/min)
Select respiratory rate furthest from 19
For patients on mechanical ventilation no points are given for respiratory rates of 6–12

≤ 5	17
6–11	8
12–13	7
14–24	0
25–34	6
35–39	9
40–49	11
≥ 50	18

PaO_2 (mm Hg)
Use only for nonintubated patients or intubated patients with FIO_2 < 0.5 (50%)

≤ 49	15
50–69	5
70–79	2
≥ 80	0

OR

A-aDO_2
Only use A-aDO_2 for intubated patients with FIO_2 ≥ 0.5 (50%)
Do not use PaO_2 weights for these patients

< 100	0
100–249	7
250–349	9
350–499	11
≤ 500	14

Hematocrit (%)
Select hematocrit furthest from 45.5

≤ 40.9	3
41–49	0
≥ 50	3

WBC (cu/mm)
Select WBC furthest from 11.5

< 1.0	19
1.0–2.9	5
3.0–19.9	0
20–24.9	1
≥ 25	5

Creatinine without ARF (mg/dL)
Select creatinine furthest from 1

≤ 0.4	3
0.5–1.4	0
1.5–1.94	4
≥ 1.95	7

OR

Creatinine with ARF (mg/dL)
Acute renal failure (ARF) is defined as creatinine ≥ 1.5 mg/dL as creatinine ≥ 1.5 mg/dL and urine output < 410 cc/d and no chronic dialysis

0–1.4	0
≥ 1.5	10

Urine Output (cc/day)
Total for day

≤ 399	15
400–599	8
600–899	7
900–1,499	5
1,500–1,999	4
2,000–3,999	0
≥ 4,000	1

BUN (mg/dL)
Select highest BUN

≤ 16.9	0
17–19	2
20–39	7
40–79	11
≥ 80	12

Sodium (mEq/L)
Select sodium furthest from 145.5

≤ 119	3
120–134	2
135–154	0
≥ 155	4

Albumin (g/dL)
Select albumin furthest from 3.5

≤ 1.9	11
2–2.4	6
2.5–4.4	0
≥ 4.5	4

Bilirubin (mg/dL)
Select highest bilirubin furthest from 0

≤ 1.9	0
2–2.9	5
3–4.9	6
5–7.9	8
≥ 8	16

Glucose (mg/dL)
Select glucose furthest from 130
Glucose ≤ 39 mg/dL is lower weight than 40–59

≤ 39	8
40–59	9
60–199	0
200–349	3
≥ 350	5

Neurological Abnormalities Score (see matrix)
Acid–Base Abnormalities Score (see matrix)

APACHE IV Score Calculator available at: http://www.cerner.com/public/filedownload.asp?LibraryID=40394. Accessed July 26, 2010.
Note: Mortality prediction calculations based on the APACHE IV are different for the day of ICU admission and subsequent days.

MPM0 III VARIABLES [4]

Category	Variable
Physiology	
	Coma or deep stupor at admission not due to drug overdose
	Heart rate > 150 beats/min
	Systolic blood pressure ≤ 90 mm Hg
Chronic diagnoses	
	Chronic renal compromise or insufficiency
	Cirrhosis
	Metastatic malignant neoplasm
Acute diagnoses	
	Acute renal failure
	Cardiac dysrhythmia
	Cerebrovascular accident
	Gastrointestinal bleeding
	Intracranial mass effect
Other variables	
	CPR within 24 hours prior to admission
	Mechanical ventilation within one hour of admission
	Medical or unscheduled surgery admission
	Full code status
	Age (years)

MPM_0-III variables are collected at the time of ICU admission or within 1 hour of admission.
Calculator available at: http://www.cerner.com/public/filedownload.asp?LibraryID=25783. Last accessed July 26, 2010.

TABLE A.2

APACHE IV NONOPERATIVE DIAGNOSES [3]

Diagnostic group
Cardiovascular diagnoses
- AMI
- Anterior
- Inferior/lateral
- Non-Q
- Other
- Cardiac arrest
- Cardiogenic shock
- Cardiomyopathy
- Congestive heart failure
- Chest pain, rule out AMI
- Hypertension
- Hypovolemia/dehydration (not shock)
- Hemorrhage (not related to GI bleeding)
- Aortic aneurysm
- Peripheral vascular disease
- Rhythm disturbance
- Sepsis (by infection site)
- Cutaneous
- Gastrointestinal
- Pulmonary

(*continued*)

TABLE A.2

CONTINUED

- Urinary tract
- Other location
- Unknown location
- Cardiac drug toxicity
- Unstable angina
- Cardiovascular, other

Respiratory diagnoses
- Airway obstruction
- Asthma
- Aspiration pneumonia
- Bacterial pneumonia
- Viral pneumonia
- Parasitic/fungal pneumonia
- COPD (emphysema/bronchitis)
- Pleural effusion
- Pulmonary edema (noncardiac)
- Pulmonary embolism
- Respiratory arrest
- Respiratory cancer (oral, larynx, lung, trachea)
- Restrictive lung disease (fibrosis, sarcoidosis)
- Respiratory disease, other

GI diagnoses
- GI bleeding, upper
- GI bleeding lower/diverticulitis
- GI bleeding, varices
- GI inflammatory disease
- Neoplasm
- Obstruction
- Perforation
- Vascular insufficiency
- Hepatic failure
- Intra/retroperitoneal hemorrhage
- Pancreatitis
- Gastrointestinal, other

Neurologic diagnoses
- Intracerebral hemorrhage
- Neurologic neoplasm
- Neurologic infection
- Neuromuscular disease
- Drug overdose
- Subdural/epidural hematoma
- Subarachnoid hemorrhage, intracranial aneurysm
- Seizures (no structural disease)
- Stroke
- Neurologic, other

Trauma diagnoses
- Trauma involving the head
- Head trauma with either chest, abdomen, pelvis, or spine injury
- Head trauma with extremity or facial trauma
- Head trauma only
- Head trauma with multiple other injuries
- Trauma, chest and spine trauma
- Trauma, spine only
- Multiple trauma (excluding head trauma)

Metabolic/endocrine diagnoses
- Acid–base, electrolyte disorder
- Diabetic ketoacidosis
- Hyperglycemic hyperosmolar nonketotic coma
- Metabolic/endocrine, other

Hematologic diagnoses
- Coagulopathy, neutropenia, thrombocytopenia, pancytopenia
- Hematologic, other

Genitourinary diagnoses
- Renal, other

Miscellaneous diagnoses
- General, other

TABLE A.3

APACHE IV SURGICAL DIAGNOSES [3]

Diagnostic group

Cardiovascular surgery
- Valvular heart surgery
- CABG with double or redo valve surgery
- CABG with single valve surgery
- Aortic aneurysm, elective repair
- Aortic aneurysm, rupture
- Aortic aneurysm, dissection
- Femoral–popliteal bypass graft
- Aortoiliac, aortofemoral bypass graft
- Peripheral ischemia (embolectomy, thrombectomy, dilation)
- Carotid endarterectomy
- Cardiovascular surgery, other

Respiratory surgery
- Thoracotomy, malignancy
- Neoplasm, mouth, larynx
- Thoracotomy, lung biopsy, pleural disease
- Thoracotomy, respiratory infection
- Respiratory surgery, other

GI surgery
- GI malignancy
- GI bleeding
- Fistula, abscess
- Cholecystitis, cholangitis
- GI inflammation
- GI obstruction
- GI perforation
- GI, vascular ischemia
- Liver transplant
- GI surgery, other

Neurologic surgery
- Craniotomy or transsphenoidal procedure for neoplasm
- Intracranial hemorrhage
- Subarachnoid hemorrhage (aneurysm, arteriovenous malformation)
- Subdural/epidural hematoma
- Laminectomy, fusion, spinal cord surgery
- Neurologic surgery, other

Trauma surgery
- Head trauma only
- Multiple trauma sites including the head
- Surgery for extremity trauma
- Multiple trauma (excluding the head)

Genitourinary surgery
- Renal/bladder/prostate neoplasm
- Renal transplant
- Hysterectomy
- Genitourinary surgery, other

Miscellaneous surgery
- Amputation (nontraumatic)

NORMAL VALUES OF EXPIRATORY PEAK FLOW [5]

There is a wide variability in peak expiratory flows due to individual differences. Values also vary slightly depending on the peak flow meter used.

TABLE A.4

NORMAL VALUES OF EXPIRATORY PEAK FLOW FOR MEN

	Height				
Age (y)	**60 Inches**	**65 Inches**	**70 Inches**	**75 Inches**	**80 Inches**
20	554	602	649	693	740
25	543	590	636	679	725
30	532	577	622	664	710
35	521	565	609	651	695
40	509	552	596	636	680
45	498	540	583	622	665
50	486	527	569	607	649
55	475	515	556	593	634
60	463	502	542	578	618
65	452	490	529	564	603
70	440	477	515	550	587

TABLE A.5

NORMAL VALUES OF EXPIRATORY PEAK FLOW FOR WOMEN

	Height				
Age (y)	55 Inches	60 Inches	65 Inches	70 Inches	75 Inches
20	390	423	460	496	529
25	385	418	454	490	523
30	380	413	448	483	516
35	375	408	442	476	509
40	370	402	436	470	502
45	365	397	430	464	495
50	360	391	424	457	488
55	355	386	418	451	482
60	350	380	412	445	475
65	345	375	406	439	468
70	340	369	400	432	461

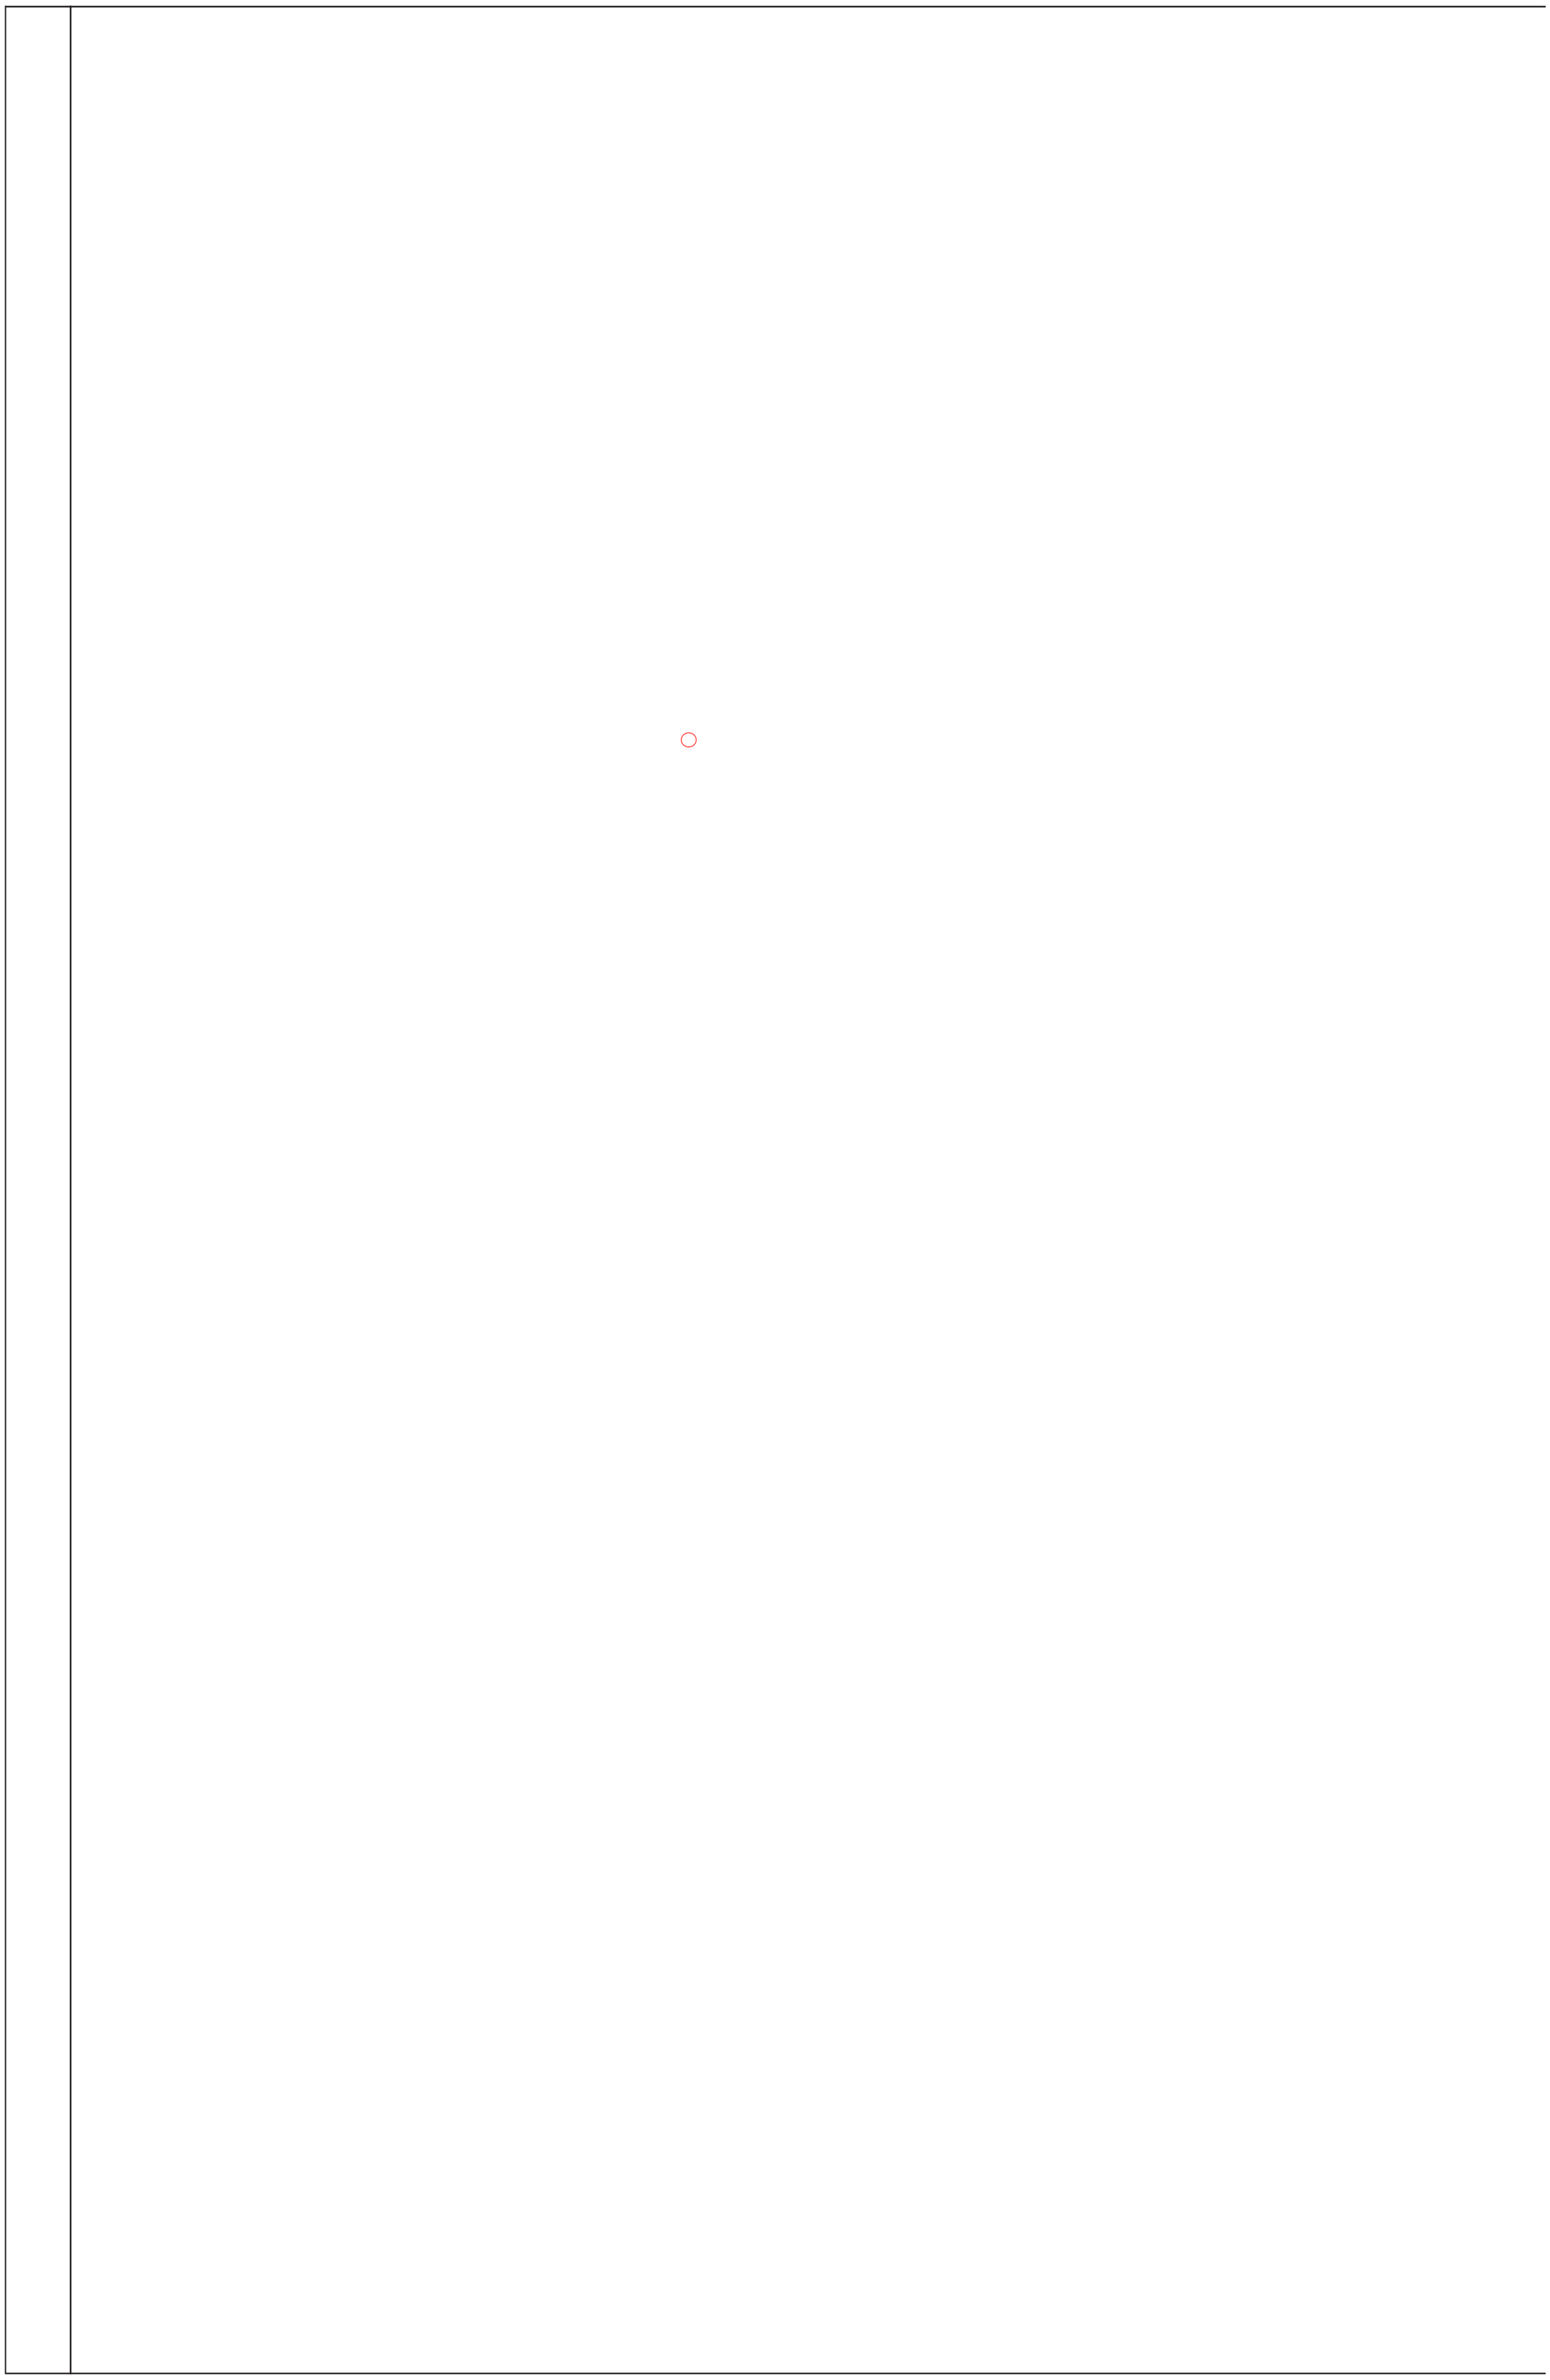
2250



D50W = dextrose 50% water; D25W = dextrose 25% water; D10W = dextrose 10% water; h = hours; IM = intramuscular; IV = intravenous; LR = Lactated Ringer's; max = maximum; NS = normal saline; RaVR = terminal R wave in lead aVR; R/SaVR = R-wave/S-wave ratio in lead aVR; wks = weeks.

Box I. Digoxin antibody dosing calculator.

$$\text{Number of vials} = \frac{\text{Digoxin body burden to be neutralized in ng/mL (nmol/L} \times 1.28) \times \text{weight (kg)} \times \text{volume of distribution (Vd)}}{1{,}000 \times 0.6\ \text{mg/vial}}$$

V_d: Adults 8 L/kg

Box II. Polyethylene glycol solution (PEG) whole bowel irrigation.
Insert nasogastric/oral tube and administer PEG solution at 2 L/h for 5 h and clear rectal effluent is evident; doubtful patients would be cooperative or tolerate oral PEG.

INDEX

Note: Page numbers followed by *f* and *t* indicates figure and table respectively.
