DEDICATION

To Our Families

Diane, Rachel, Sara, Catherine, Rebecca, John, Andrew K. Andrew M. and Adam;
Stephanie, Hart, Jaelin, Devon, and Jamie

CONTRIBUTORS

Cynthia K. Aaron, MD, FACMT, FACEP
Professor of Emergency Medicine and Pediatrics
Program Director, Medical Toxicology
Department of Emergency Medicine
Wayne State University School of Medicine
Detroit Medical Center
Regional Poison Center at Children's Hospital of Michigan
Detroit, MI

Wissam Abouzgheib, MD, FCCP
Attending Physician
Department of Pulmonary and Critical Care
Sparks Health System
Fort Smith, AR

Gregory A. Abrahamian, MD
Associate Professor of Surgery
Department of Surgery
University of Texas Health Science Center at San Antonio
San Antonio, TX

Konstantin Abramov, MD
Assistant Professor of Medicine
Division of Renal Medicine
UMass Memorial Medical Center
Worcester, MA

Christopher D. Adams, PharmD, BCPS
Clinical Pharmacist
Department of Pharmacy Services
Brigham and Women's Hospital
Boston, MA

Suresh Agarwal, MD, FACS, FCCM
Chief, Surgical Critical Care
Associate Professor of Surgery
Boston Medical Center
Boston, MA

Lauren Alberta-Wszolek, MD
Assistant Professor of Medicine
Division of Dermatology
University of Massachusetts Medical School
Worcester, MA

Alfred Aleguas Jr, PharmD, DABAT
Managing Director
Northern Ohio Poison Center
Rainbow Babies & Children's Hospital
Cleveland, OH

Satya Allaparthi, MD
Fellow in Robotic and Laparoscopic Urology
Department of Urology/Surgery
UMass Memorial Medical Center
Worcester, MA

Gilman B. Allen, MD
Assistant Professor
Director, Medical Intensive Care Unit
Department of Medicine
Division of Pulmonary and Critical Care Medicine
University of Vermont
Fletcher Allen Health Care
Burlington, VT

Luis F. Angel, MD
Associate Professor of Medicine
Department of Medicine
University of Texas Health Sciences Center at San Antonio
San Antonio, TX

Kevin E. Anger, PharmD, BCPS
Clinical Pharmacy Specialist in Critical Care
Department of Pharmacy Services
Brigham and Women's Hospital
Boston, MA

Derek C. Angus, MD, MPH
Professor and Vice Chair for Research
Department of Critical Care Medicine
University of Pittsburgh Medical Center
Pittsburgh, PA

Neil Aronin, MD
Professor of Medicine and Cell Biology
Chief of Endocrinology and Metabolism
Department of Medicine
University of Massachusetts Medical School
Worcester, MA

Samuel J. Asirvatham, MD, FACC, FHRS
Professor of Medicine and Pediatrics
Division of Cardiovascular Diseases
Mayo Clinic College of Medicine
Rochester, MN

Seth M. Arum, MD, FACE
Assistant Professor of Medicine
Department of Endocrinology
UMass Memorial Medical Center
Worcester, MA

Philip J. Ayvazian, MD
Assistant Professor
Department of Urology
UMass Memorial Medical Center
Worcester, MA

Riad Azar, MD
Associate Professor of Medicine
Department of Internal Medicine
Division of Gastroenterology
Washington University School of Medicine
Barnes Jewish Hospital
St. Louis, MO

Ruben J. Azocar, MD
Associate Professor and Residency Program Director
Department of Anesthesiology
Boston University Medical Center
Boston, MA

Ednan K. Bajwa, MD, MPH
Associate Director, Medical ICU
Department of Pulmonary and Critical Care
Massachusetts General Hospital
Boston, MA

K.C. Balaji, MD
Professor, Department of Surgery
Division of Urology
UMass Memorial Medical Center
Worcester, MA

Jerry P. Balikian, MD, FACR
Professor and Vice Chair of Radiology
Department of Radiology
University of Massachusetts Medical School
Worcester, MA

Ian M. Ball, MD, DABEM, FRCPC
Assistant Professor
Program in Critical Care Medicine and
Departments of Clinical Pharmacology/Toxicology
and Emergency Medicine
Queen's University Kingston
Ontario, Canada

Meyer S. Balter, MD, FRCPC
Professor
Department of Medicine
University of Toronto
Director, Asthma Education Clinic
Mount Sinai Hospital
Toronto, Ontario, Canada

Gisela I. Banauch, MD, MS
Assistant Professor of Medicine Division of Pulmonary,
Allergy, Critical Care and Sleep Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Daniel T. Baran, MD
Region Medical Director
Merck
Adjunct Professor of Medicine, Cell Biology, and Orthopedics
UMass Memorial Medical Center
Worcester, MA

Stephen L. Barnes, MD, FACS
Associate Professor and Chief, Division of Acute
Care Surgery
Department of Surgery
University of Missouri
Columbia, MO

Suzanne J. Baron, MD
Cardiology Fellow
Department of Cardiology
Massachusetts General Hospital
Boston, MA

Thaddeus C. Bartter, MD, FCCP
Professor of Medicine
Department of Medicine
Division of Pulmonary and Critical Care
University of Arkansas for the Medical Sciences
Little Rock, AR

Amit Basu, MD
Assistant Professor of Surgery and Attending Physician
Department of Surgery
University of Pittsburgh Medical Center
Thomas E Starzl Transplantation Institute
Pittsburgh, PA

Kenneth L. Baughman, MD (DECEASED)

Richard C. Becker, MD
Professor of Medicine
Department of Medicine
Duke University School of Medicine
Durham, NC

Robert W. Belknap, MD
Assistant Professor of Medicine
Division of Infectious Diseases
Denver Health and Hospital Authority
University of Colorado
Denver, CO

Isabelita R. Bella, MD
Associate Professor of Clinical Neurology
Department of Neurology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Andrew C. Bernard, MD
Associate Professor of Surgery
Department of Surgery
University of Kentucky Healthcare
Lexington, KY

Megan Bernstein, MD
Resident
Department of Dermatology
University of Massachusetts Medical School
Worcester, MA

Mary T. Bessesen, MD
Associate Professor of Medicine
Department of Medicine
University of Colorado at Denver
Department of Veterans Affairs Medical Center—Denver
Denver, CO

Michael C. Beuhler, MD
Medical Director
Department of Emergency Medicine
Carolinas Poison Center
Charlotte, NC

Bonnie J. Bidinger, MD
Assistant Professor of Medicine
Department of Internal Medicine
Division of Rheumatology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Steven B. Bird, MD
Associate Professor
Department of Emergency Medicine
Division of Medical Toxicology
University of Massachusetts Medical School
Worcester, MA

Bruce R. Bistrian, MD, PhD
Professor of Medicine
Harvard Medical School
Department of Medicine
Beth Israel Deaconess Medical Center
Boston, MA

Robert M. Black, MD
Professor of Clinical Medicine
UMass Medical School
Chief, Nephrology
Division of Renal Medicine
St. Vincent Hospital
Worcester, MA

Ernest F.J. Block, MD, MBA, FACS, FCCM
Professor of Surgery, University of Central Florida
Department of Acute Care Surgery
Holmes Regional Medical Center
Melbourne, FL

Jeremiah Boles, MD
Hematology/Oncology Fellow
Department of Medicine
Division of Hematology/Oncology
University of North Carolina at Chapel Hill
Chapel Hill, NC

Naomi F. Botkin, MD
Assistant Professor of Medicine
Division of Cardiovascular Medicine
UMass Memorial Medical Center
Worcester, MA

Suzanne F. Bradley, MD
Professor
Department of Internal Medicine
Division of Infectious Diseases and Geriatric Medicine
Veterans Affairs Ann Arbor
University of Michigan Healthcare Systems
Ann Arbor, MI

William F. Bria, MD
Chief Medical Information Officer
Department of Medical Affairs
Shriners Hospital for Children
Tampa, FL

Veronica Brito, MD
Pulmonary and Critical Care Medicine Fellow
Department of Medicine
Winthrop-University Hospital
Mineola, NY

Traci L. Buescher, RN
Department of Heart Rhythm Services
Mayo Clinic
Rochester, MN

Keith K. Burkhart, MD, FACMT, FAACT, FACEP
Senior Advisor for Medical Toxicology
FDA Center for Drug Evaluation and Research
Office of New Drugs
Silver Spring, MD

Michael J. Burns, MD, FACEP, FACMT
Chief of Emergency Medicine
Saint Vincent Hospital
Worcester, MA
Division of Medical Toxicology
Department of Emergency Medicine
Beth Israel Deaconess Medical Center
Boston, MA

Tuesday E. Burns, MD
Assistant Professor of Psychiatry
Department of Psychiatry
Eastern Virginia Medical School
Norfolk, VA

Scott W. Byram, MD
Assistant Professor of Anesthesiology
Department of Anesthesiology
Loyola University Medical Center
Maywood, IL

Brian T. Callahan, MD
Interventional Radiology Fellow
Department of Radiology
Harvard Medical School
Beth Israel Deaconess Medical Center
Boston, MA

Christine Campbell-Reardon, MD
Associate Professor of Medicine
Department of Pulmonary and Critical Care Medicine
Boston University School of Medicine
Boston Medical Center
Boston, MA

Christopher P. Cannon, MD
TIMI Study Group
Cardiovascular Division
Brigham and Women's Hospital
Associate Professor of Medicine, Harvard Medical School
Boston, MA

Jason P. Caplan, MD
Chief of Psychiatry
Department of Psychiatry
Creighton University School of Medicine at St. Joseph's Hospital and Medical Center
Phoenix, AZ

Raphael A. Carandang, MD
Assistant Professor
University of Massachusetts Medical School
Department of Neurology and Surgical Intensive Care
UMass Memorial Medical Center
Worcester, MA

Paul A. Carpenter, MD
Associate Professor
Clinical Research Division
Fred Hutchinson Cancer Research Center
Seattle, WA

Karen C. Carroll, MD
Professor Pathology and Medicine
Department of Pathology
Division of Medical Microbiology
Johns Hopkins Hospital
Baltimore, MD

David A. Chad, MD
Associate Professor of Neurology
Harvard Medical School
Department of Neurology
Massachusetts General Hospital
Neuromuscular Diagnostic Center
Boston, MA

Eugene Chang, MD
Martin Boyer Professor of Medicine
Department of Medicine, Section of Gastroenterology
University of Chicago
Chicago, IL

Steven Y. Chang, MD, PhD
Assistant Professor of Medicine
Division of Pulmonary & Critical Care Medicine
Director of the Medical Intensive Care Unit
University of Medicine & Dentistry of New Jersey—
New Jersey Medical School
Newark, NJ

Michael L. Cheatham, MD, FACS, FCCM
Director, Surgical Intensive Care Units
Department of Surgical Education
Orlando Regional Medical Center
Orlando, FL

Sarah H. Cheeseman, MD
Professor of Medicine, Pediatrics, Microbiology and
Molecular Genetics
University of Massachusetts Medical School
Division of Infectious Diseases
UMass Memorial Medical Center
Worcester, MA

Annabel A. Chen-Tournoux, MD
Cardiology Fellow
Department of Medicine
Division of Cardiology
Massachusetts General Hospital
Boston, MA

William K. Chiang, MD
Chief of Service and Associate Professor of Emergency
Medicine
Department of Emergency
Bellevue Hospital Center
New York, NY

Victor G. Cimino, MD, FACS
Associate Professor
Department of Surgery
Loyola University Medical Center
Maywood, IL

Mary Dawn T. Co, MD
Assistant Professor of Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Shawn Cody, MSN, MBA, RN
Associate Chief Nursing Officer for Critical Care
UMass Memorial Medical Center
Worcester, MA

Felipe B. Collares, MD, MSc
Interventional Radiologist
Department of Radiology
Beth Israel Deaconess Medical Center
Instructor in Radiology
Harvard Medical School
Boston, MA

Bryan R. Collier, MD
Assistant Professor of Surgery
Division of Trauma & Surgical Critical Care
Vanderbilt University Medical Center
Nashville, TN

Nancy A. Collop, MD
Professor of Medicine
Department of Medicine
Emory University
Atlanta, GA

John B. Cone, MD, FACS, FCCM
Professor of Surgery
Norma & Nolie Mumey Chair in General Surgery
Department of Surgery
University of Hospital of Arkansas
Little Rock, AR

Sara E. Cosgrove, MD
Associate Professor of Medicine
Division of Infectious Disease
Johns Hopkins Medical Institutions
Baltimore, MD

Filippo Cremonini, MD, PhD
Attending Physician
Department of Gastroenterology
Beth Israel Deaconess Medical Center
Harvard Medical School
Boston, MA

Jonathan F. Critchlow, MD
Assistant Professor of Surgery
Harvard University
Beth Israel Deaconess Medical Center
Boston, MA

Ruy J. Cruz Jr, MD, PhD
Assistant Professor of Surgery
Department of Surgery
University of Pittsburgh Medical Center
Pittsburgh, PA

Frederick J. Curley, MD
Associate Professor of Medicine
University of Massachusetts Medical School
Lung, Allergy & Sleep Specialists
Hopedale, MA

Armagan Dagal, MD, FRCA
Assistant Professor
Department of Anesthesiology and Pain Medicine
University of Washington, Harborview Medical Center
Seattle, WA

Seth T. Dahlberg, MD
Associate Professor of Medicine and Radiology
Department of Medicine and Radiology
University of Massachusetts Medical School
Division of Cardiology
UMass Memorial Medical Center
Worcester, MA

Frank F. Daly, MBBS
Clinical Toxicologist and Emergency Physician
Department of Emergency Medicine
Royal Perth Hospital
Western Australia, Australia

Jennifer S. Daly, MD
Professor of Medicine
Clinical Chief, Infectious Diseases and Immunology
Department of Medicine
University of Massachusetts Medical School
Worcester, MA

Lloyd E. Damon, MD
Professor of Clinical Medicine
Department of Medicine
University of California, San Francisco
San Francisco, CA

Raul E. Davaro, MD
Associate Professor, Clinical Medicine
Department of Medicine
University of Massachusetts Medical School
Worcester, MA

Wellington J. Davis III, MD
Assistant Professor of Surgery and Pediatrics
Section of Plastic and Reconstructive Surgery
St. Christopher's Hospital for Children
Philadelphia, PA

Ronald J. DeBellis, PharmD, FCCP
Professor and Chair
Department of Pharmacy Practice
Albany College of Pharmacy and Health Sciences—Vermont
Colchester, VT

G. William Dec, MD
Chief, Cardiology Division
Massachusetts General Hospital
Department of Cardiology
Boston, MA

Paul F. Dellaripa, MD
Assistant Professor of Medicine
Harvard Medical School
Division of Rheumatology
Brigham and Women's Hospital
Boston, MA

Gregory J. Della Rocca, MD, PhD, FACS
Assistant Professor
Co-Director, Orthopaedic Trauma Service
Department of Orthopaedic Surgery
University of Missouri
Columbia, MO

Thomas G. DeLoughery, MD, FACP
Professor of Medicine, Pathology and Pediatrics
Department of Hematology
Oregon Health and Science University
Portland, OR

Mario De Pinto, MD
Assistant Professor
Department of Anesthesiology
University of Washington
Harborview Medical Center
Seattle, WA

Mark Dershwitz, MD, PhD
Professor and Vice Chair of Anesthesiology
Professor of Biochemistry & Molecular Pharmacology
UMass Memorial Medical Center
Worcester, MA

Akshay S. Desai, MD
Instructor in Medicine
Harvard Medical School
Associate Physician
Cardiovascular Division
Department of Medicine
Brigham and Women's Hospital
Boston, MA

Asha Devereaux, MD, MPH
Pulmonary Physician
Sharp Coronado Hospital
Coronado, CA

Christopher R. DeWitt, MD
Medical Toxicologist and Emergency Physician
Department of Emergency and British Columbia Poison Center
Saint Paul's Hospital
University of British Columbia
Vancouver, BC

Peter Doelken, MD
Associate Professor
Department of Medicine
Division of Pulmonary, Critical Care, Allergy & Sleep Medicine
Medical University of South Carolina
Charleston, SC

Robert P. Dowsett, FACEM
Senior Staff Specialist
Department of Emergency Medicine
Westmead Hospital
Wentworthville, NSW, Australia

David A. Drachman, MD
Professor of Neurology
Chairman Emeritus
Department of Neurology
University of Massachusetts Medical School
Worcester, MA

Director of Trauma
Vice-Chair of Surgery
Stamford Hospital
Stamford, CT

Steven B. Edelstein, MD
Professor of Anesthesiology
Vice-Chairman Education & Compliance
Department of Anesthesiology
Loyola University Medical Center
Loyola University Stritch School of Medicine
Maywood, IL

W. Thomas Edwards, PhD, MD
Director, Fellowship in Pain Medicine
Associate Professor of Anesthesiology
Department of Anesthesiology
University of Washington
Harborview Medical Center
Seattle, WA

Richard T. Ellison III, MD
Professor of Medicine, Molecular Genetics and Microbiology
University of Massachusetts Medical School
Department of Medicine
Division of Infectious Diseases and Immunology
UMass Memorial Medical Center
Worcester, MA

Ashkan Emadi, MD, PhD
Adjunct Faculty
Division of Adult Hematology
Department of Internal Medicine
Johns Hopkins Hospital
Johns Hopkins University
Baltimore, MD

Charles H. Emerson, MD
Professor Emeritus of Medicine
Department of Medicine
UMass Memorial Medical Center
Worcester, MA

Timothy A. Emhoff, MD
Chief, Trauma, Surgical Critical Care
Department of Surgery
UMass Memorial Medical Center
Worcester, MA

Jennifer L. Englund, MD
Medical Toxicology Fellow
Department of Emergency Medicine
Division of Medical Toxicology
University of Massachusetts Medical School
Worcester, MA

Robert M. Esterl Jr, MD
Professor of Surgery
Department of Surgery
University of Texas Health Science Center at San Antonio
San Antonio, TX

Salomao Faintuch, MD, MSc
Instructor in Radiology
Harvard Medical School
Department of Interventional Radiology
Beth Israel Deaconess Medical Center
Boston, MA

Pang-Yen Fan, MD
Associate Professor of Medicine
Division of Renal Medicine
University of Massachusetts Medical School
Medical Director, Renal Transplant Program
UMass Memorial Medical Center
Worcester, MA

James C. Fang, MD
Professor of Medicine
Cardiovascular Division
Case Western Reserve University
Cleveland, OH

John Fanikos, RPh, MBA
Assistant Director of Pharmacy
Department of Pharmacy
Brigham and Women's Hospital
Boston, MA

Harrison W. Farber, MD
Professor of Medicine
Department of Pulmonary Center
Boston University School of Medicine
Boston, MA

Khaldoun Faris, MD
Associate Director of Surgical Intensive Care Unit
Department of Anesthesiology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Alan P. Farwell, MD
Associate Professor of Medicine
Director, Endocrine Clinics
Department of Endocrinology, Diabetes and Nutrition
Boston University School of Medicine
Boston Medical Center
Boston, MA

Alan M. Fein, MD, FACP, FCCP, FCCM
Clinical Professor of Medicine
Chief of Pulmonary, Sleep and Critical Care Medicine
Hofstra North Shore—LIJ School of Medicine
ProHEALTH Care Associates, LLP
Lake Success, NY

Philip Fidler, MD, FACS
Associate Director, Burn Center
Department of Surgery
Washington Hospital Center
Washington, DC

Michael A. Fifer, MD
Director, Cardiac Catheterization Laboratory
Division of Cardiology
Department of Medicine
Massachusetts General Hospital
Boston, MA

Robert W. Finberg, MD
Professor and Chair, Department of Medicine
University of Massachusetts Medical School
Department of Medicine
UMass Memorial Medical Center
Worcester, MA

Kimberly A. Fisher, MD
Assistant Professor of Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Marc Fisher, MD
Professor of Neurology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Patrick F. Fogarty, MD
Director, Penn Comprehensive Hemophilia and Thrombosis Program
Department of Medicine
University of Pennsylvania
Philadelphia, PA

Dorrie K. Fontaine, PhD, RN, FAAN
Dean and Professor
School of Nursing
University of Virginia
Charlottesville, VA

Nancy M. Fontneau, MD
Associate Professor of Clinical Neurology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Marsha D. Ford, MD
Director, Carolinas Poison Center
Department of Emergency Medicine
Carolinas Medical Center
Charlotte, NC

Professor of Medicine
Dartmouth Medical School
Hanover, NH;
Chief, Medical Service
VA Medical Center
White River Junction, VT

Debra Gerardi, RN, MPH, JD
CEO
EHCCO, LLC
Principal, Debra Gerardi and Associates
Half Moon Bay, CA

Edith S. Geringer, MD
Psychiatrist
Department of Psychiatry
Massachusetts General Hospital
Boston, MA

Terry Gernsheimer, MD
Medical Director of Transfusion
Seattle Cancer Care Alliance and University of Washington Medical Center
Professor of Medicine
Division of Hematology
Puget Sound Blood Center
Department of Medical Education
Seattle, WA

John G. Gianopoulos, MD
System Chair of Maternal/Fetal Medicine
Department of OB/GYN
Cook County Health and Hospital System
Chicago, IL

Michael M. Givertz, MD
Associate Professor of Medicine
Harvard Medical School
Medical Director, Heart Transplant and Circulatory Assist Program
Cardiovascular Division
Brigham and Women's Hospital
Boston, MA

Richard H. Glew, MD
Professor of Medicine, Molecular Genetics and Microbiology
Vice Chair, Medicine—Undergraduate Medical Education and Faculty Affairs
Department of Medicine
UMass Memorial Medical Center
Worcester, MA

Dori Goldberg, MD
Assistant Professor of Medicine
Division of Dermatology
Department of Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Andrew J. Goodwin, MD
Clinical and Research Fellow
Department of Pulmonary and Critical Care
Brigham and Women's Hospital
Boston, MA

Kim L. Goring, MMBS
Assistant Professor of Medicine
Department of Internal Medicine
Division of Pulmonary, Critical Care and Sleep Medicine
Howard University Hospital
Washington, DC

Robert M. Gougelet, MD
Assistant Professor of Medicine (Emergency Medicine)
Director, New England Center of Emergency Preparedness
Department of Emergency Medicine
Dartmouth Hitchcock Medical Center
Lebanon, NH

Andis Graudins, MBBS, PhD, FACEM, FACMT
Professor of Emergency Medicine Research and Clinical Toxicology
Faculty of Medicine Nursing and Health Sciences
Monash University
Department of Emergency Medicine
Monash Medical Centre
Clayton, Victoria, Australia

Barth A. Green, MD
Professor and Chairman
Department of Neurological Surgery
Jackson Memorial/University of Miami
Miami, FL

Damian J. Green, MD
Research Associate
Clinical Research Division
Fred Hutchinson Cancer Research Center
Seattle, WA

Bruce Greenberg, MD
Assistant Professor
Department of Medicine
University of Massachusetts Medical School
Worcester, MA

Bonnie C. Greenwood, PharmD, BCPS
Staff Development and Perioperative Services Manager
Department of Pharmacy
Brigham and Women's Hospital
Boston, MA

Ronald F. Grossman, MD
Professor of Medicine
University of Toronto
Credit Valley Hospital
Mississauga, Ontario, Canada

Professor of Medicine
Department of Anesthesia and Surgery
Interim Chair
Department of Medicine
Baystate Medical Center
Springfield, MA

Nicholas Hill, MD
Chief
Department of Pulmonary, Critical Care and Sleep Division
Tufts Medical Center
Boston, MA

John B. Holcomb, MD, FACS
Vice Chair and Professor
Department of Surgery
Memorial Hermann Hospital
Houston, TX

Judd E. Hollander, MD
Professor, Clinical Research Director
Department of Emergency Medicine
Hospital of the University of Pennsylvania
Philadelphia, PA

Helen M. Hollingsworth, MD
Associate Professor of Medicine
Department of Pulmonary Allergy and Critical
Care Medicine
Boston Medical Center
Boston, MA

Shelley A. Holmer, MD
Clinical Associate
Department of Psychiatry
Duke University Medical Center
Durham, NC

Donough Howard, MD
Consultant Rheumatologist
Hermitage Medical Clinic
Dublin, Ireland

Michael D. Howell, MD, MPH
Director, Critical Care Quality
Beth Israel Deaconess Medical Center
Boston, MA

Rolf D. Hubmayr, MD
Professor
Department of Medicine and Physiology
Mayo Clinic
Rochester, MN

Abhinav Humar, MD
Professor of Surgery
Division Chief, Transplant Surgery
Department of Surgery
University of Pittsburgh
Pittsburgh, PA

Thomas L. Husted, MD
Assistant Professor of Surgery
Department of Surgery
University of Cincinnati
Cincinnati, OH

Richard S. Irwin, MD, Master FCCP
Professor of Medicine and Nursing
University of Massachusetts
Chair, Critical Care
UMass Memorial Medical Center
Worcester, MA

John M. Iskander
Fellow in Gastroenterology
Division of Gastroenterology
St. Louis, MO

Eric M. Isselbacher, MD
Professor of Medicine
Harvard Medical School
Co-Director, Thoracic Aortic Center
Massachusetts General Hospital
Boston, MA

Rao R. Ivatury, MD
Chair
Department of Surgery
Division of Trauma, Critical Care, Emergency Surgery
Virginia Commonwealth University
Richmond, VA

William L. Jackson Jr, MD, MBA
Medical Director, Adult Critical Care
Inova Health System
Falls Church, VA

Eric W. Jacobson, MD
Associate Professor of Medicine
University of Massachusetts Medical School
Senior Vice President, Clinical Research and Regulatory Affairs
Chief Medical Officer
Synta Pharmaceuticals Corp.
Lexington, MA

Donald H. Jenkins, MD, FACS
Trauma Director
Associate Professor of Surgery
Division of Trauma, Critical Care and Emergency General Surgery
Mayo Clinic
Rochester, MN

Jing Ji, MD
Neurology Resident
Department of Neurology
University of Massachusetts Medical School
Worcester, MA

Tun Jie, MD, MS
Assistant Professor of Surgery
Department of Surgery
University of Arizona, College of Medicine
Tucson, AZ

Thanjira Jiranantakan, MD
Preventive and Social Medicine Department
Siriraj Hospital Faculty of Medicine
Mahidol University, Thailand
Medical Toxicology Fellow
Department of Clinical Pharmacology and Medical Toxicology
San Francisco General Hospital, University of California
The California Poison Control System—San Francisco Division
San Francisco, CA

Paul G. Jodka, MD
Assistant Professor of Medicine and Anesthesiology
Tufts University School of Medicine
Adult Critical Care Division
Baystate Medical Center
Springfield, MA

Scott B. Johnson, MD, FACS, FCCP
Associate Professor
Chief of General Thoracic Surgery
Department of Cardiothoracic Surgery
University of Texas Health Science Center, San Antonio
San Antonio, TX

Professor of Medicine
Director of Pancreatic and Biliary Endoscopy
Washington University School of Medicine
Division of Gastroenterology
St. Louis, MO

Bryan S. Judge, MD
Associate Program Director
Assistant Professor
Spectrum Health
Grand Rapids MERC/Michigan State University Program in Emergency Medicine
Grand Rapids, MI

Eias E. Jweied, MD, PhD
Cardiovascular/Thoracic Surgeon
Department of Cardiothoracic and Vascular Surgical Associates, S.C.
Advocate Christ Medical Center
Oak Lawn, IL

Marc J. Kahn, MD
Professor of Medicine
SR. Associate Dean
Department of Medicine
Tulane University School of Medicine
New Orleans, LA

Raja Kandaswamy, MD
Axline Professor of Surgery
Director of the University of Florida Institute of Transplantation
Department of Surgery
Shands Hospital—University of Florida Gainesville
Gainesville, FL

Abhishek Katiyar, MD
Medical and Toxicology and Emergency Medicine
Department of Emergency Medicine
UIC/Advocate Christ Hospital
Oak Lawn, IL

Carol A. Kauffman, MD
Professor Internal Medicine
University of Michigan Medical School
Chief, Infectious Diseases
Veterans Affairs Ann Arbor Healthcare System
Ann Arbor, MI

Christoph R. Kaufmann, MD, MPH
Professor of Surgery, East Tennessee State University
Department of Trauma and Emergency Surgery
Johnson City Medical Center
Johnson City, TN

Shubjeet Kaur, MD
Clinical Professor and Vice Chair
Department of Anesthesiology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Glenn Kershaw, MD
Associate Professor of Clinical Medicine
Division of Renal Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Mark A. Kirk, MD
Medical Toxicology Fellowship Director
Department of Emergency Medicine
University of Virginia
Charlottesville, VA

Meghan S. Kolodziej, MD
Instructor in Psychiatry
Department of Psychiatry
Brigham and Women's Hospital
Boston, MA

Scott E. Kopec, MD
Assistant Professor of Medicine
Division of Pulmonary, Allergy and Critical Care Medicine
UMass Memorial Medical Center
University of Massachusetts Medical School
Worcester, MA

Bruce A. Koplan, MD
Assistant Professor of Medicine
Harvard Medical School
Cardiac Arrhythmia Service
Department of Cardiac Arrhythmia
Brigham and Women's Hospital
Boston, MA

Richard Kremsdorf, MD
Clinical Professor of Medicine, Voluntary
University of California, San Diego School of Medicine
President
Five Rights Consulting, Inc.
San Diego, CA

Stephen J. Krinzman, MD
Assistant Professor of Medicine
Division of Pulmonary, Allergy, and Critical Care Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Gowri Kularatna, MD
Fellow in Gastroenterology
Washington University School of Medicine/Barnes Jewish Hospital
Division of Gastroenterology
St. Louis, MO

Sonal Kumar, MD
Internal Medicine Resident
Department of Internal Medicine
Barnes Jewish Hospital
St. Louis, MO

Margaret Laccetti, PhD, RN, AOCN, ACHPN
Director, Nursing Professional Development
UMass Memorial Medical Center
Worcester MA

Hoa Thi Lam, BS
Research Assistant
Department of Child Psychiatry
Massachusetts General Hospital
Boston, MA

Robert A. Lancy, MD, MBA
Chief of Cardiac Surgery
Department of Cardiac Surgery
Bassett Medical Center
Cooperstown, NY

Angeline A. Lazarus, MD
Professor of Medicine
Department of Pulmonary Medicine
Division of Pulmonary
National Naval Medical Center
Bethesda, MD

Jason Lee-Llacer, MD
Fellow
Department of Critical Care Medicine and Anesthesia
George Washington University
Washington, DC

Anthony J. Lembo, MD
Associate Professor of Medicine
Department of Medicine
Beth Israel Deaconess Med Center
Boston, MA

James A. de Lemos, MD
CCU and Cardiology Fellowship Director
Department of Cardiology/Medicine
The University of Texas Southwestern Medical Center
Dallas, TX

Adam B. Lerner, MD
Director, Cardiac Anesthesia
Department of Anesthesia and Critical Care
Beth Israel Deaconess Medical Center
Boston, MA

Phillip A. Letourneau, MD
Research Fellow/General Surgery Resident
Department of Surgery
University of Texas Medical School at Houston
Houston, TX

Howard B. Levene, MD, PhD
Assistant Professor of Neurological Surgery
Department of Neurosurgery
University of Miami Hospital
Miami, FL

Nikki A. Levin, MD, PhD
Associate Professor of Medicine
Division of Dermatology
University of Massachusetts Medical School
Worcester, MA

Stephanie M. Levine, MD
Professor of Medicine
Department of Medicine
University of Texas Health Science Center at San Antonio
San Antonio, TX

William J. Lewander, MD
Professor and Associate Vice Chair of Pediatric Emergency Medicine
The Warren Alpert Medical School of Brown University
Department of Emergency Medicine
Rhode Island Hospital
Providence, RI

Daniel H. Libraty, MD
Associate Professor
Department of Medicine/Infectious Diseases
University of Massachusetts Medical School
Worcester, MA

Craig M. Lilly, MD
Professor of Medicine, Anesthesiology and Surgery
Department of Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Sonia Lin, PharmD, BCPS
Clinical Pharmacy Specialist
Department of Pharmacy
University of Colorado Hospital
Aurora, CO

Christopher H. Linden, MD
Professor, Department of Emergency Medicine
Division of Medical Toxicology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Michael Linenberger, MD, FACP
Professor, Division of Hematology
Department of Medicine
University of Washington
Associate Member, Clinical Research Division
Fred Hutchinson Cancer Research Center
Seattle Cancer Care Alliance
Seattle, WA

Mark S. Link, MD
Professor of Medicine
Department of Cardiac Electrophysiology
Tufts Medical Center
Boston, MA

Carol F. Lippa, MD
Professor of Neurology
Department of Neurology
Drexel University College of Medicine
Philadelphia, PA

Alan Lisbon, MD
Associate Professor, Anaesthesia, Harvard Medical School
Department of Anaesthesia, Critical Care and Pain Medicine
Beth Israel Deaconess Medical Center
Boston, MA

Mauricio Lisker-Melman, MD
Professor of Medicine
Director, Hepatology Program
Department of Internal Medicine
Division of Gastroenterology
Washington University School of Medicine
Barnes-Jewish Hospital
St. Louis, MO

N. Scott Litofsky, MD, FACS
Professor and Chief
Director of Neuro-Oncology and Radiosurgery
Division of Neurological Surgery
University of Missouri School of Medicine
Columbia, MO

Afroza Liton, MD
Fellow
Department of Infectious Disease
University of Massachusetts
UMass Memorial Medical Center
Worcester, MA

Frederic F. Little, MD
Assistant Professor of Medicine
Pulmonary Center and Department of Pulmonary, Allergy, and Critical Care Medicine
Boston University School of Medicine
Attending Physician
Boston Medical Center
Boston, MA

Nancy Y.N. Liu, MD
Associate Professor of Clinical Medicine
Department of Medicine
Division of Rheumatology
University of Massachusetts Medical School
Worcester, MA

Randall R. Long, MD, PhD
Cheshire Medical Center/Dartmouth Hitchcock Keene
Keene, NH

Robert B. Love, MD, FACS
Professor and Vice Chairman
Department of Thoracic and Cardiothoracic
Loyola University Medical Center
Maywood, IL

Matthew W. Lube, MD
Assistant Professor of Surgery and Surgical Clerkship Director
University of Central Florida College of Medicine
Associate Director of Medical Education
Department of Surgical Education
Orlando Regional Medical Center
Orlando, FL

Fred A. Luchette, MD, MSc
The Ambrose and Gladys Bowyer Professor of Surgery
Stritch School of Medicine
Medical Director, General Surgery III Service
Department of Surgery
Maywood, IL

Alice D. Ma, MD
Associate Professor of Medicine
Department of Medicine
Division Hematology/Oncology
University of North Carolina
Chapel Hill, NC

Theresa R. (Roxie) Macfarlan, RN, MSN, CCRN, ACNP-BC
Advanced Practice Nurse 2
Department of Thoracic-Cardiovascular Postoperative Intensive Care Unit
University of Virginia Health System
Charlottesville, VA

J. Mark Madison, MD
Professor of Medicine and Physiology
Chief, Division of Pulmonary, Allergy and Critical Care Medicine
UMass Memorial Medical Center
University of Massachusetts Medical School
Worcester, MA

Ajai K. Malhotra, MBBS, MD, MS, DNB, FRCS
Associate Professor and Vice Chair
Associate Medical Director, Level 1 Trauma Center
Department of Surgery
Division of Trauma, Critical Care and Emergency General Surgery
Virginia Commonwealth University Medical Center
Richmond, VA

Atul Malhotra, MD
Associate Professor of Medicine
Department of Medicine
Brigham and Women's Hospital
Boston, MA

Samir Malkani, MD
Clinical Associate Professor of Medicine
Division of Diabetes
Department of Medicine
UMass Memorial Medical Center
Worcester, MA

Avinash V. Mantravadi, MD
Resident Physician
Department of Otolaryngology—Head and Neck Surgery
Loyola University Medical Center
Maywood, IL

Paul E. Marik, MD, FCCM, FCCP
Professor of Medicine
Department of Pulmonary and Critical Care Medicine
Eastern Virginia Medical School and Norfolk General Hospital
Eastern Virginia Medical School Internal Medicine
Norfolk, VA

William L. Marshall, MD
Associate Professor of Medicine
Department of Medicine
UMass Memorial Medical Center
Worcester, MA

Arthur J. Matas, MD
Professor of Surgery
Department of Surgery
University of Minnesota
Minneapolis, MN

Paul H. Mayo, MD
Professor of Clinical Medicine
Hofstra Northshore—LIJ School of Medicine
Long Island Jewish Medical Center
New Hyde Park, NY

Guy Maytal, MD
Director of Urgent Care and Primary Care Psychiatry
Department of Psychiatry
Massachusetts General Hospital
Boston, MA

Melanie Maytin, MD
Instructor in Medicine
Department of Cardiovascular Medicine
Brigham and Women's Hospital
Boston, MA

Kathleen M. McCauley, PhD, RN, ACNS-BC, FAAN, FAHA
Associate Dean for Academic Programs
Class of 1965 25th Reunion Term Professor of Cardiovascular Nursing
Cardiovascular Clinical Specialist
University of Pennsylvania School of Nursing
Hospital of the University of Pennsylvania
Philadelphia, PA

Sara L. Merwin, MPH
Assistant Professor of Medicine
Department of Medicine
Hofstra North Shore—LIJ School of Medicine
North Shore University Hospital
Manhasset, NY

Marco Mielcarek, MD
Assistant Professor
University of Washington
Assistant Member
Department of Medical Oncology
Fred Hutchinson Cancer Research Center
Seattle, WA

Ross Milner, MD
Associate Professor of Surgery
Chief, Division of Vascular Surgery and Endovascular Therapy
Department of Vascular Surgery
Loyola University Medical Center
Maywood, IL

Ann L. Mitchell, MD
Associate Professor of Clinical Neurology
Department of Neurology
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Lawrence C. Mohr Jr, MD, ScD, FACP, FCCP
Professor of Medicine, Biometry and Epidemiology
Director, Environmental Biosciences Program
Medical University of South Carolina
Charleston, SC

Takki Momin, MD
Vascular Surgery Fellow
Department of Vascular Surgery
Georgetown University/Washington Hospital Center
Washington, DC

Jahan Montague, MD
Assistant Professor of Medicine
Department of Nephrology
UMass Memorial Medical Center
Worcester, MA

Bruce Montgomery, MD
Associate Professor
Department of Medicine, Oncology
University of Washington
VA Puget Sound HCS
Seattle, WA

Majaz Moonis, MD, MRCP(1), DM, FRCP (Edin)
Professor of Neurology
Director, Stroke Services
Director, Vascular Fellowship Program
UMass Memorial Medical Center
Worcester, MA

John P. Mordes, MD
Professor of Medicine
Department of Medicine/Endocrinology
UMass Memorial Medical Center
University of Massachusetts Medical School
Worcester, MA

David A. Morrow, MD, MPH
Director, Samuel A. Levine Cardiac Unit
Department of Cardiovascular Medicine
Brigham and Women's Hospital
Harvard Medical School
Boston, MA

James B. Mowry, PharmD, DABAT, FAACT
Director, Indiana Poison Center
Department of Emergency Medicine and Trauma Center
Methodist Hospital, Indiana University Health
Indianapolis, IN

Saori A. Murakami, MD
Psychiatrist
Massachusetts General Hospital, McLean Hospital
Boston, MA

Michael C. Muzinich, MD
Neurosurgical Resident
Department of Neurological Surgery
University Hospital and Clinics
Columbia, MO

John G. Myers, MD
Associate Professor
Department of Surgery
University of Texas Health Science Center, San Antonio
San Antonio, TX

Shashidhara Nanjundaswamy, MD, MBBS, MRCP, DM
Assistant Professor
Department of Neurology
University of Massachusetts Medical School
Worcester, MA

Lena M. Napolitano, MD, FACS, FCCP, FCCM
Professor of Surgery
Department of Surgery
University of Michigan
Ann Arbor, MI

Jaishree Narayanan, MD, PhD
Associate Professor Clinical Neurology
Department of Neurology
UMass Memorial Medical Center
Worcester, MA

Theresa A. Nester, MD
Associate Medical Director
Puget Sound Blood Center
Department of Laboratory Medicine
University of Washington Medical Center
Puget Sound Blood Center
Seattle, WA

Michael S. Niederman, MD
Professor of Medicine
SUNY at Stony Brook
Chairman, Department of Medicine
Winthrop-University Hospital
Mineola, NY

Dominic J. Nompleggi, MD, PhD
Associate Professor of Medicine and Surgery
University of Massachusetts Medical School
Chief, Division of Gastroenterology
Director, Adult Nutrition Support Service
UMass Memorial Medical Center
Worcester, MA

Sean E. Nork, MD
Associate Professor
Department of Orthopaedics & Sports Medicine
Harborview Medical Center, University of Washington
Seattle, WA

Robert L. Norris, MD, FACEP
Associate Professor
Department of Surgery
Chief, Division of Emergency Medicine
Stanford University Medical Center
Palo Alto, CA

Richard A. Oeckler, MD, PhD
Assistant Professor of Medicine and Physiology
Department of Pulmonary and Critical Care Medicine
Mayo Clinic
Rochester, MN

Patrick T. O'Gara, MD
Executive Medical Director of the Carl J. and Ruth Shapiro Cardiovascular Center
Associate Professor
Harvard Medical School
Director, Clinical Cardiology
Brigham and Women's Hospital
Boston, MA

Paulo J. Oliveira, MD, FCCP
Director, Advanced Bronchoscopic and Pleural Procedures
Assistant Professor of Medicine
Division of Pulmonary, Allergy and Critical Care Medicine
UMass Memorial Medical Center
Worcester, MA

Kent R. Olson, MD, FACEP, FAACT, FACMT
Medical Director, San Francisco Division
California Poison Control System
Clinical Professor of Medicine and Pharmacy
University of California, San Francisco
San Francisco, CA

Steven M. Opal, MD
Professor of Medicine
Warren Alpert Medical School of Brown University
Memorial Hospital of Rhode Island
Division of Infectious Disease
Pawtucket, RI

Achikam Oren-Grinberg, MD, MS
Director of Critical Care Echocardiography
Department of Anesthesia, Critical Care & Pain Medicine
Beth Israel Deaconess Medical Center
Boston, MA

David Ost, MD, MPH
Associate Professor
Department of Pulmonary Medicine
The University of Texas M.D. Anderson Cancer Center
Houston, TX

Mickey M. Ott, MD
Assistant Professor in Surgery
Division of Trauma & Surgical Critical Care
Vanderbilt University Medical Center
Nashville, TN

John A. Paraskos, MD
Professor of Medicine
Department of Medicine
University of Massachusetts Medical School
UMass Memorial Medical Center
Worcester, MA

Polly E. Parsons, MD
Professor and Chair of Medicine
Department of Medicine
University of Vermont College of Medicine
Fletcher Allen Health Care
Burlington, VT

Laura Santos Pavia, MD
Resident in Anesthesiology
Boston Medical Center
Boston University School of Medicine
Boston, MA

Marie T. Pavini, MD, FCCP
Intensivist
Department of Intensive Care Unit

PREFACE

It is with great pleasure that we present the seventh edition of *Irwin and Rippe's Intensive Care Medicine*. As with previous editions, the editorial challenge that we faced with the seventh edition was to continue to ensure that the textbook evolved as the field has evolved and improved to meet the varied and rigorous demands placed on it by the diverse group of specialty physicians and nonphysicians practicing in the adult intensive care environment without losing strengths that have made previous editions so useful and popular. We hope and believe that the seventh edition of *Irwin and Rippe's Intensive Care Medicine* has risen to meet these challenges.

Over the past 27 years since the publication of the first edition of our textbook, dramatic changes have occurred in virtually every area of critical care, and these are reflected in the evolution of our textbook. While our textbook initially focused primarily on medical intensive care, it now provides an interdisciplinary emphasis on anesthesia, surgery, trauma, and neurointensive care as well as medical intensive care with strong collaboration across all these disciplines. With this edition, a critical care nursing-centric section has been added. This reflects the reality that intensive care medicine has inevitably become more interdisciplinary and collaborative.

The seventh edition is approximately the same length as the previous edition. To make this happen, we challenged every section editor and author to carefully balance edited materials emphasizing new evidence-based as well as state-of-the-art information by discarding outdated information. All of our section editors and chapter authors have done a superb job meeting this challenge. All chapters in every section have been updated with recent references and other materials that reflect current information, techniques, and principles. New chapters have been added to reflect emerging areas of interest. As stated earlier, an entirely new section has been added on "Nursing Issues in the ICU" that was ably coedited by Dorrie Fontaine and Shawn Cody. This section was meant to focus on issues related to collaboration, healthy work environments, and the expanding roles of nurses not the specifics of nursing care that have been brilliantly covered in textbooks of ICU nursing; and Dorrie and Shawn have admirably succeeded in this regard. Another new section on "Critical Care Consequences of Weapons (or Agents) of Mass Destruction" reflects the changing realities of our world and has been ably edited by Larry Mohr.

Evidenced-based medicine continues to play an ever more prominent role in all branches of medicine including critical care. With this in mind, we have asked every chapter author to make recommendations that specifically reflect recent trials with a particular emphasis on randomized prospective controlled trials. Authors have summarized such evidence, when the data have allowed, with helpful tables.

In medical intensive care, important changes and advances have occurred since the publication of the sixth edition. These include managing our ICUs according to the following guiding principles: (i) making our ICUs safer for our patients; (ii) decreasing variability by following clinical practice guidelines based upon the best available evidence to ensure better outcomes for our patients; and (iii) doing more with less to decrease the cost of caring for our patients. While these principles have always been espoused, it has become clear that we must more consistently follow them. With respect to specific issues, the day-to-day use of ultrasonography by critical care specialists is a very recent change and this is reflected in the liberal use of ultrasonographic images throughout the book and a new chapter entitled Interventional Ultrasound; these are prominently featured in the procedure and monitoring chapters. Moreover, there is an imperative to increasingly utilize information technology in the everyday practice of intensive care medicine. This not only includes using electronic medical records, computer physician order entry, and clinical decision support tools but also tele-ICU. All of these issues are covered in the section entitled "Contemporary Challenges in the Intensive Care Unit" edited by Craig Lilly.

In coronary care, rapid advances in techniques and interventions continue to occur. These changes are reflected in the "Cardiovascular Problems and Coronary Care" section of the seventh edition. It is interesting to see how cardiovascular intensive care has dramatically changed since the publication of our first few editions, as the advances in cardiology and cardiac surgery became known from the large, multicenter, randomized controlled clinical trials. We welcome Akshay Desai who has joined Patrick O'Gara as co-section editor for this section.

Equally important advances have occurred in surgical critical care, including new therapies and techniques in a variety of conditions treated in this environment. Our "Surgical Problems in the Intensive Care Unit" section remains a great strength of this book. Fred Luchette did his usual magnificent job on this edition. We recognize Arthur Trask and Stephen Barnes who have done an admirable job of updating the "Shock and Trauma" section of the textbook as well.

While our textbook has been updated and broadened to include new understandings, information and techniques, our goal has been to maintain the practical, clinically oriented approach that readers have come to expect from previous editions. Our editorial focus remains on clinically relevant studies and information that readers have found so useful in the previous six editions.

As in the past, our textbook opens with a detailed section on commonly performed "Procedures and Techniques in the Intensive Care Unit." This section, along with the "Minimally Invasive Monitoring" section, has also been simultaneously published as a smaller book entitled "Procedures, Techniques, and Minimally Invasive Monitoring in Intensive Care Medicine. All chapters in these sections have been updated with new figures and descriptions of techniques which have been added to reflect changes since the sixth edition of the textbook. We are indebted that section editors Stephen Heard and Alan Lisbon who have done a superb job on these sections.

The "Pharmacology, Overdoses, and Poisoning" section, consisting of 29 chapters, remains a great strength of this book and essentially represents a textbook on these topics embedded into our larger book. In this edition, we welcome new section editors Luke Yip and Kennon Heard who have joined Steven Bird as section editors for this outstanding and comprehensive section.

Because intensive care cannot be divorced from public policy, we continue to emphasize this with a major section of our textbook entitled "Contemporary Challenges in the Intensive Care Unit." This section includes not only more ethical and legal issues but also issues related to ICU organization and management, economics, safety, and information technology. With this edition, we welcome Craig Lilly, who has done an outstanding job on this section.

Our team of section editors continue to do a wonderful job coordinating large bodies of information that comprise the core of modern intensive care. Many of our section editors have been with us for one or more editions. Richard Ellison III (Infectious Disease), Neil Aronin (Endocrinology), Stephanie Levine (Transplantation), Dominic Nompleggi (Metabolism/Nutrition), Mark Madison (Pulmonary), John Querques (Psychiatry), and Joseph Frassica (Appendix, Calculations Commonly used in Critical Care) all fall into this category and have done their usual, excellent job. A new table on Antidotes has been added to the Appendix based on the efforts of Luke Yip, Jeremy Helphenstine, Jerry Thomas, and Ian Ball.

Some new section editors have joined us for the seventh edition and done great work. In addition to the individuals that we have already mentioned, we would like to specifically acknowledge the excellent efforts by the following new section editors or co-section editors: Pang-Yen Fan (Renal), Dominic Nompleggi (Gastrointestinal Problems), Patrick Fogarty (Hematologic Problems), David Paydarfar (Neurologic Problems), David Harlan (Endocrine Problems), and Nancy Liu (Rheumatologic, Immunologic and Dermatologic Problems).

As with previous editions, our emphasis remains on clinical management. Discussions of basic pathophysiology are also included and guided and supplemented by extensive references to help clinicians and researchers who wish to pursue more in-depth knowledge of these important areas. When therapies reflect institutional or individual bias or are considered controversial, we have attempted to indicate this.

We hope and believe that the outstanding efforts of many people over the past 4 years have continued to result in an evidence-based and state-of-the-art and comprehensive textbook that will elucidate the important principles in intensive care and will continue to guide and support the best efforts of practitioners in this challenging environment in their ongoing efforts to diagnosis and treat complicated diseases and relieve human suffering.

Richard S. Irwin, MD, Master FCCP
James M. Rippe, MD

ACKNOWLEDGMENTS

Numerous outstanding individuals have made significant contributions to all phases of writing and production of this textbook and deserve special recognition and thanks. First and foremost is our managing editor, Elizabeth Grady. Beth literally lives and breathes this textbook as it works its way through the production cycle every 4 years. She is the guiding and organizing force behind this textbook. It would simply not be possible without Beth's incredible organizational skills, good humor, and enormous energy. She has guided this book through six editions—this book is as much hers as it is ours.

Our administrative assistants, office assistant, and clinical coordinators, Carol Moreau, Debra Adamonis, Karen Barrell, Mary Garabedian, and Cynthia French have helped us continue to coordinate and manage our complex professional and personal lives and create room for the substantial amount of time required to write and edit. Our section editors have devoted enormous skill, time, and resources to every edition of this textbook. We have very much appreciated their deep commitment to this book and to advancing the field of intensive care medicine.

Our editors at Lippincott Williams & Wilkins including Brian Brown, executive editor, have been a source of great help and encouragement. As with the last edition, Nicole Dernoski continues to be extremely helpful and accommodating in supervising and coordinating all phases of production in an outstanding way.

Lastly, we are grateful to Indu Jawwad and her staff for the outstanding job they have done copyediting the manuscript for this edition.

Our families support our efforts with unfailing encouragement and love. To them, and the many others who have helped in ways too numerous to count, we are deeply grateful.

Richard S. Irwin, MD, Master FCCP
James M. Rippe, MD

CHAPTER 108 ■ DISORDERS OF HEMOSTASIS IN CRITICALLY ILL PATIENTS

JEREMIAH BOLES AND ALICE D. MA

Disorders of hemostasis are common in critically ill patients. This chapter will review hemostasis, pathophysiology of commonly encountered congenital and acquired bleeding disorders along with their associated symptoms, laboratory findings, and management.

REVIEW OF NORMAL HEMOSTASIS

Hemostasis can be broken into a series of steps occurring in overlapping sequence. Primary hemostasis refers to the interactions between the platelet and the injured vessel wall, culminating in the formation of a platelet plug. The humoral phase of clotting, or secondary hemostasis, encompasses a series of enzymatic reactions, resulting in a hemostatic fibrin plug. Finally, fibrinolysis and wound repair occur. Each of these steps is carefully regulated, and perturbations can predispose to either hemorrhage or thrombosis. Depending on the nature of the defect, the hemorrhagic or thrombotic tendency can be either profound or subtle.

Primary hemostasis begins at the site of vascular injury, with platelets adhering to the subendothelium, utilizing interactions between molecules such as collagen and von Willebrand factor (vWF) in the vessel wall with glycoprotein (GP) receptors on the platelet surface. Upon exposure to agonists present at a wounded vessel, signal transduction leads to platelet activation. Via a process known as inside-out signaling, the platelet membrane integrin $\alpha_{2b}\beta_3$ (also known as GP IIbIIIa) undergoes a conformational change to be able to bind fibrinogen, which cross-links adjacent platelets, leading to platelet aggregation. Secretion of granular contents is also triggered by outside signals, potentiating further platelet activation (Fig. 108.1). Lastly, the surface of the platelet changes to serve as an adequate scaffold for the series of biochemical reactions resulting in thrombin generation.

Following platelet activation, a series of enzymatic reactions take place on phospholipid surfaces, culminating in the formation of a stable fibrin clot. Several models have attempted to make sense of these reactions. The cascade model was developed by two groups nearly simultaneously [1,2] and explained the extrinsic, intrinsic, and common pathways leading to fibrin formation (Fig. 108.2). While the cascade model accounts for the physiologic reactions underlying the prothrombin time (PT) and the activated partial thromboplastin time (aPTT), it fails to explain completely the bleeding diathesis seen in individuals deficient in factors XI, IX, and VIII, as well as the lack of bleeding in those deficient only in contact factors. A cell-based model of hemostasis has been developed to address these deficiencies. In this model, upon vascular injury, the membrane of a tissue factor (TF)-bearing cell such as an activated monocyte or fibroblast serves as a platform for generation of a small amount of thrombin and FIXa, which then serves to activate platelets and cleave FVIII from vWF. Newly formed FVIIIa participates in the tenase complex on the surface of activated platelets to form FXa that interacts with the FVa generated on the platelet surface to form the prothrombinase complex. This complex generates a large burst of thrombin which is sufficient to cleave fibrinogen, activate FXIII, and activate the thrombin activatable fibrinolysis inhibitor (TAFI), thus allowing for formation of a stable fibrin clot (Fig. 108.2).

Fibrinolysis leads to clot dissolution once wound healing has occurred, in order to restore normal blood flow. Plasminogen is activated to plasmin by the action of either tissue plasminogen activator (t-PA) or urokinase plasminogen activator (u-PA). Plasmin degrades fibrin and fibrinogen and can thus dissolve both formed clot as well as its soluble precursor. Plasmin is inhibited by a number of inhibitors, of which α_2-plasmin inhibitor is the most significant. Plasminogen activation is also inhibited by a number of molecules; chief among them is plasminogen activator inhibitor-1 (PAI-1). Lastly, cellular receptors act to localize and potentiate or clear plasmin and plasminogen activators (see Chapter 111 for further discussion).

APPROACH TO THE BLEEDING PATIENT

Physicians in the intensive care unit (ICU) often encounter bleeding patients and it can be difficult to identify which of these patients require further evaluation. Patients who experience bleeding that is excessive, spontaneous, or delayed following surgery or tissue injury require further investigation, which must begin with a thorough clinical history. A bleeding history should assess a patient's exposure and response to all hemostatic challenges in the past such as trauma, surgery, and childbirth. Characterization of menses in females also may be revealing. Several bleeding assessment tools have been developed and are useful in the evaluation for an underlying coagulopathy, particularly von Willebrand disease (vWD) [3]. This history should also identify coexisting medical conditions such as liver, kidney, or thyroid disorders. A careful medication history is also important, including use of all over-the-counter medications which may contain aspirin, as well as any herbal preparations. Also of cardinal importance is an evaluation for a family history of abnormal bleeding. An inherited or congenital bleeding disorder is suggested by abnormal bleeding with onset shortly after birth and persistence throughout life. It is further supported by a family history with a consistent genetic pattern. However, it is important to note that a negative family history does not exclude a congenital bleeding disorder. For instance, approximately one third of all cases of hemophilia A arise from spontaneous mutations. Many of the rare coagulation disorders, including deficiency of factors II, V, VII, X,

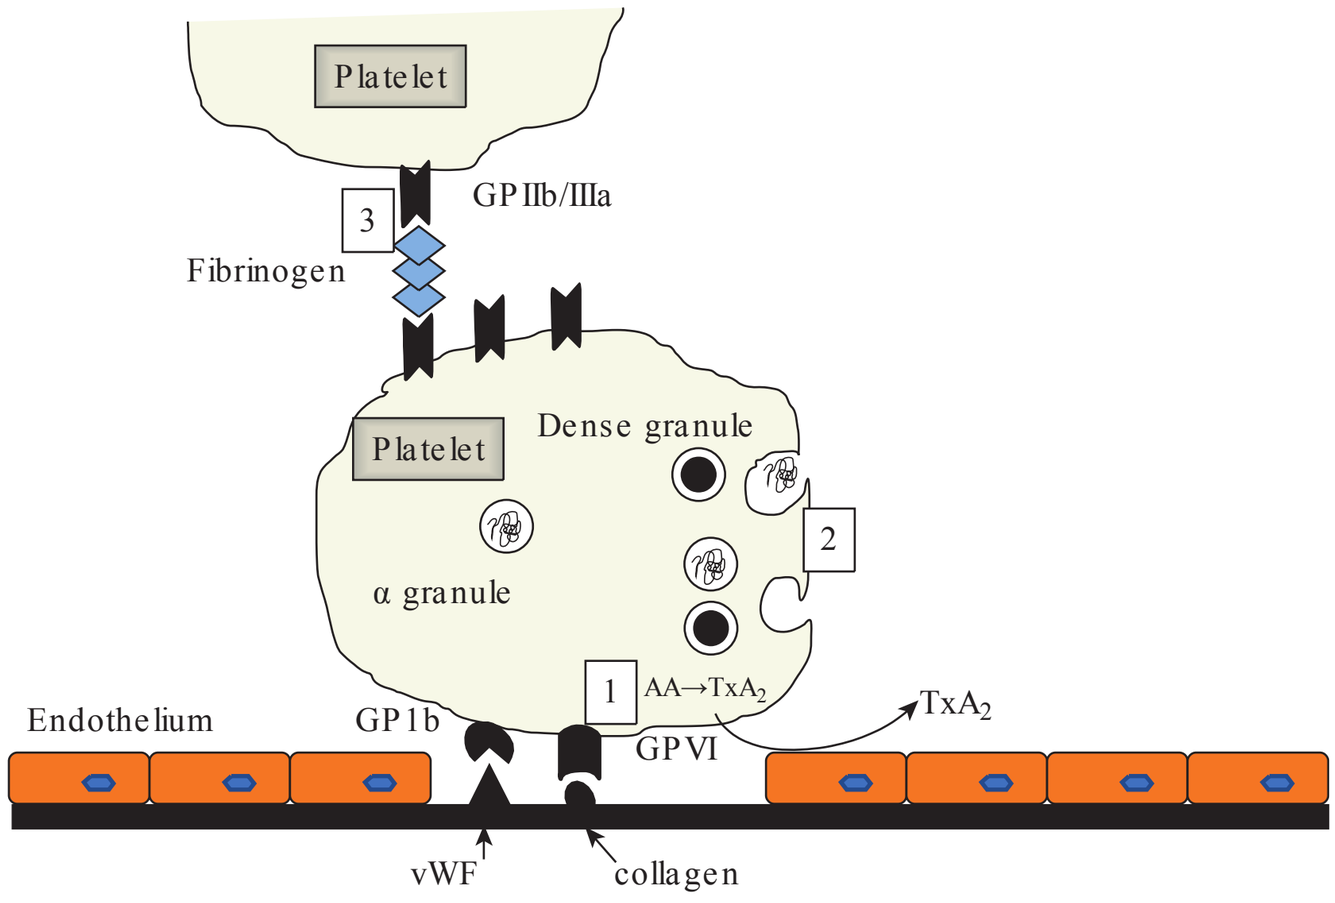

FIGURE 108.1. Primary hemostasis. (1) Exposure of subendothelium at sites of vascular disruption results in platelet adhesion via GPIb and GP VI with exposed von Willebrand factor (vWF) and collagen, respectively. Following platelet adhesion TxA_2 is produced and released which promotes vasoconstriction and platelet aggregation. (2) Platelet adhesion also results in fusion of cytoplasmic granules to the plasma membrane. Release of alpha and dense granules activates nearby platelets. (3) Platelet activation results in exposure of GPIIb/IIIa on the platelet surface allowing fibrinogen to cross bridge platelets resulting in a platelet plug.

as well as vWD type 2 N, among others, are inherited in an autosomal recessive fashion, and the parents of the patient may be entirely asymptomatic.

A bleeding history should also ascertain past sites/mechanisms of bleeding. Surgical bleeding in patients with an underlying hemorrhagic condition is typically described as "diffuse oozing," without the readily identifiable bleeding source seen with a surgical mishap such as a severed vessel. Patients with platelet disorders typically manifest mucocutaneous bleeding such as gingival bleeding and epistaxis as well as menorrhagia, petechiae, and ecchymoses. Platelet defects impact primary hemostasis and therefore the bleeding in these disorders is often immediate following surgery or trauma, whereas delayed bleeding is more classically associated with coagulation disorders. Patients with coagulation defects typically present with hemorrhages into soft tissues such as muscles and joints.

A physical examination should pay particular attention to the skin, joints, mucosal surfaces, and liver and spleen size.

LABORATORY ASSAYS OF PRIMARY AND SECONDARY HEMOSTASIS

While the history and physical examination can increase suspicion for the presence of a bleeding disorder, laboratory confirmation is required for precise diagnosis and treatment.

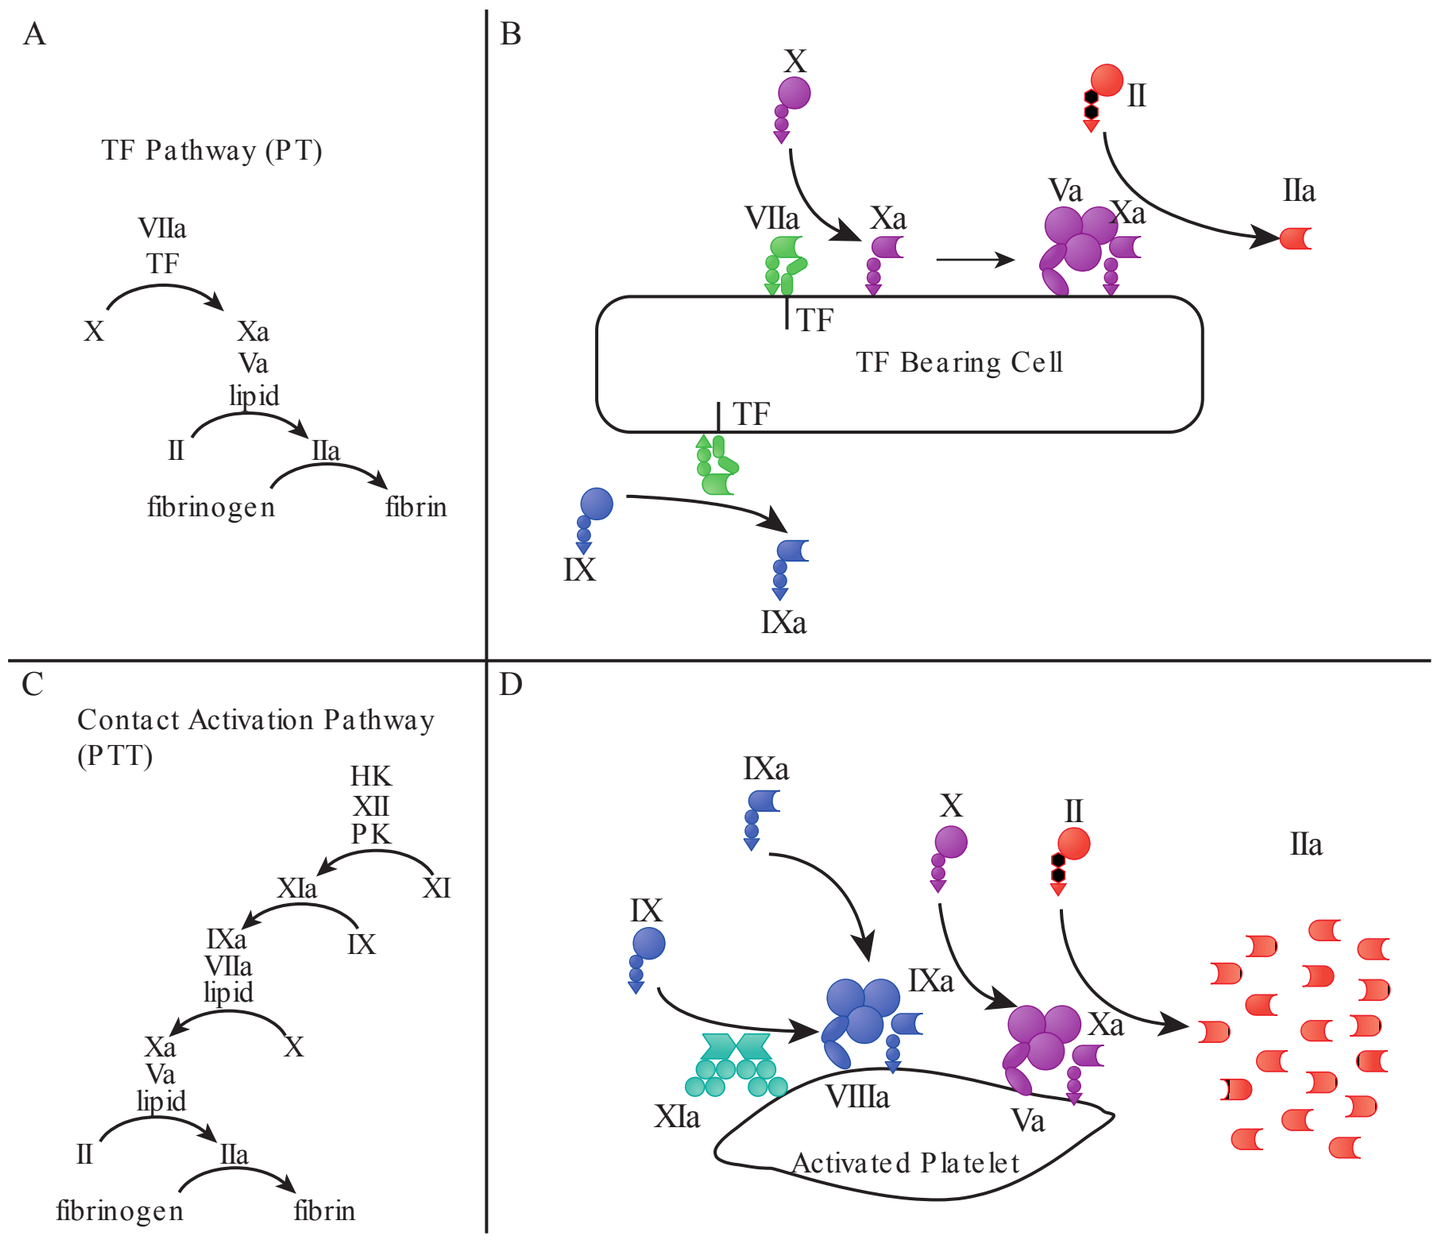

FIGURE 108.2. Secondary hemostasis. **A:** Tissue factor (TF) pathway cascade model of coagulation—basis for prothrombin time (PT) laboratory assay. **B:** Circulating FVIIa binds TF on a TF-bearing cell. TF/FVIIa along with calcium (Ca) and phospholipid (lipid) form the "extrinsic tenase" complex and converts FX to FXa. FXa combines with FVa, calcium, and phospholipid, "prothrombinase" complex, to activate FII to FIIa which in turn converts fibrinogen into fibrin. **C:** Contact activation pathway model of coagulation—basis for partial thromboplastin time (PTT) laboratory assay. **D:** On an activated platelet surface, FXIa activates FIXa. FIXa is also formed on the surface of a TF-bearing cell (B). FIXa, along with FVIIIa, Ca, and lipid, constitute the "intrinsic tenase" complex. This complex converts FX to FXa with subsequent FIIIa generation through the prothrombinase complex. (Courtesy of Dougald Monroe.)

Laboratory evaluation is particularly crucial in individuals who are suspected of having a bleeding disorder but in whom prior bleeding is absent, such as those with mild congenital bleeding disorders who never previously underwent a sufficient hemostatic challenge, or those with acquired hemorrhagic disorders.

Initial Evaluation of Primary Hemostasis—Platelet Function

An assessment of a patient's platelet count is fundamental in evaluating primary hemostasis. This is typically part of a complete blood count (CBC). Reduced platelet counts, or thrombocytopenia, may be seen in a large number of acquired and congenital conditions. Evaluation and management of thrombocytopenia is further discussed in Chapter 109.

An evaluation of the peripheral smear is also cardinal in any evaluation of a bleeding patient. It allows one to assess platelet size and morphology, presence of platelet clumping (pseudothrombocytopenia), leukocyte inclusions, and red cell fragments, among other aberrancies, which may further direct workup and treatment.

Traditionally, platelet function was evaluated by bleeding time (BT). However, many institutions have discontinued using this test given the difficulty in standardization. Furthermore, the BT has been shown to be an inadequate predictor of bleeding, particularly in preoperative risk assessment [4]. More recently, automated tests have been developed to assess platelet function. The most widely used is the platelet function analyzer (PFA-100®). This assay measures the time required (closure time) for flowing whole, citrated blood to occlude an aperture in a membrane impregnated with a combination of either collagen and epinephrine or collagen and adenosine diphosphate (ADP). Closure time is affected by platelet count, hematocrit, platelet function, and vWF [5]. The PFA-100® appears to assess platelet function with greater sensitivity and reproducibility than the BT; however, a recent position statement from the Platelet Physiology Subcommittee of the Scientific and Standardization Committee of the International Society of Thrombosis and Hemostasis noted that although the PFA-100® is abnormal in some platelet disorders, it was not felt to have sufficient sensitivity or specificity to be used as a screening tool for platelet disorders [6].

Evaluation of Secondary Hemostasis—Coagulation

The PT and the aPTT are assays performed on citrated plasma, which require enzymatic generation of thrombin on a phospholipid surface. Prolongation of the PT and the aPTT can be seen in individuals with either deficiencies of, or inhibitors to, humoral clotting factors, though not all patients with prolongations of these assays will have bleeding diatheses (Table 108.1).

The PT measures the time needed for formation of an insoluble fibrin clot once citrated plasma has been recalcified and thromboplastin has been added, indicating activity of factors VII, V, X, and II and fibrinogen. It commonly is used to monitor anticoagulation with vitamin K antagonists such as warfarin. Since thromboplastin from various sources and different lots can affect the rates of clotting reactions, the International Normalized Ratio (INR) measurement was developed

TABLE 108.1

LABORATORY TEST ABNORMALITIES IN COMMON ACQUIRED AND CONGENITAL BLEEDING DISORDERS

	Acquired bleeding disorders	Congenital bleeding disorders
PT elevated, aPTT wnl	Liver disease DIC Vitamin K deficiency Vitamin K antagonists (e.g., warfarin)	FVII deficiency
PT wnl, aPTT elevated	Heparin Lupus inhibitor Acquired FVIII inhibitor	Hemophilia A and B FXI deficiency Severe vWD
Both PT and aPTT elevated	Heparin overdose Warfarin overdose FVI inhibitors FX inhibitors Severe DIC Severe vitamin K deficiency Severe liver disease Direct thrombin inhibitors	Afibrinogenemia Hypo- or dysfibrino-genemia Prothrombin deficiency FV deficiency Combined deficiency of FV and FVIII
Both PT and aPTT wnl	LMWH therapy Fondaparinux therapy Antiplatelet agents Acquired vWD Scurvy Acquired thrombocytopenia	vWD FXIII deficiency Congenital platelet dysfunction Congenital thrombocytopenia Collagen disorders (e.g., Ehlers–Danlos syndrome)

wnl, within normal limits; DIC, disseminated intravascular coagulation; LMWH, low-molecular-weight heparin; PT, prothrombin time; PTT; partial thromboplastin time; vWD, von Willebrand disease.

to avoid some of this variability in PT measurement. Each batch of thromboplastin reagent has assigned to it a numerical International Sensitivity Index (ISI) value, which is used in the formula:

$$INR = (PT_{patient} / PT_{normal\ mean})^{ISI}$$

The INR is less predictive of bleeding in patients with liver disease, and can be inaccurate in patients with lupus anticoagulants that are strong enough to affect the PT.

The aPTT tests the activity of factors XII, XI, IX, VIII, X, V, and II, and fibrinogen, high-molecular-weight kininogen (HMWK), and plasma prekallikrein (PK) [7]. Citrated plasma is recalcified, and phospholipids (to provide a scaffold for the clotting reactions) and an activator of the intrinsic system such as kaolin, celite, or silica are added. The reagents used show variable sensitivities to inhibitors such as lupus anticoagulants and heparin, and to deficiencies (if any) in involved clotting factors, and normal ranges will vary from laboratory to laboratory. aPTT values that are vastly different from one laboratory to another should prompt suspicion of a lupus anticoagulant.

The Thrombin Clotting Time and Reptilase Time

The thrombin clotting time (TCT) or thrombin time (TT) measures the time needed for clot formation once thrombin is added to citrated plasma. Thrombin enzymatically cleaves fibrinopeptides A and B from the α- and β-chains of fibrinogen, allowing for polymerization into fibrin. The TT is prolonged in the presence of any thrombin inhibitor such as heparin, lepirudin, or argatroban; by low levels of fibrinogen or structurally abnormal fibrinogen (dysfibrinogens); and by elevated levels of fibrinogen or fibrin degradation products, which can serve as nonspecific inhibitors of the reaction. Patients with paraproteins can have a prolonged TT because of the inhibitory effect of the paraprotein on fibrin polymerization.

Reptilase is snake venom from *Bothrops atrox* which also enzymatically cleaves fibrinogen. Reptilase cleaves only fibrinopeptide A from the α-chain of fibrinogen, but fibrin polymerization still occurs. Reptilase time (RT) is not affected by heparin but may be more sensitive than the TT to the presence of a dysfibrinogenemia.

Mixing Studies

Mixing studies are used to evaluate prolongations of the aPTT (less commonly the PT or the TT) and are useful in making the distinction between an inhibitor and a clotting factor deficiency. The patient's plasma is mixed 1:1 with normal control plasma, and the assay is repeated (with or without prolonged incubation at 37°C). Correction of the clotting test signifies factor deficiency, since the normal plasma will supply the deficient factor. Incomplete correction of the clotting test after mixing suggests the presence of an inhibitor, since an inhibitor will prolong clotting in normal plasma. Incomplete correction can sometimes be seen with nonspecific inhibitors such as lupus anticoagulants, elevated fibrin split products, or a paraprotein. Less commonly, deficiencies of multiple clotting factors can lead to incomplete correction of the mixing study, since the mixing study was designed to correct deficiency of a single factor.

Tests of specific factor activity levels as well as evaluation for vWD will be discussed in the following sections.

CONGENITAL DISORDERS OF HEMOSTASIS

Due to a requirement for specialized management, all cases of suspected or proven congenital hemostatic defects require consultation with a hematologist upon admission to the critical care setting.

Von Willebrand Disease

It has been estimated that lower-than-reference levels of vWF occur in 1% of the population worldwide and therefore vWD is the most common congenital bleeding disorder [8]. However, only a fraction of the aforementioned individuals are symptomatic (approximately 5% of those with low levels) [9]. vWD is inherited in an autosomal manner with the more common type I disease being autosomal dominant.

vWD constitutes a quantitative or qualitative deficiency in vWF, and is divided into three subtypes according to the pathophysiology. Types 1 and 3 are the result of a partial (type 1) or virtually a complete (type 3) quantitative deficiency of vWF, while type 2 is a qualitative defect in vWF. Type 1 vWD represents the most common subtype accounting for approximately 70% of patients, while type 2 accounts for 15% to 20% and type 3 for only 2% to 5% of vWD patients [10].

Because bleeding symptoms in persons with vWD may be absent or overlooked until a major hemorrhage due to surgery or trauma has occurred, the diagnosis should be considered in an ICU patient with otherwise unexplained excessive bleeding, particularly if there is a significant family history including an autosomal pattern of inheritance. The most common historical bleeding symptoms include epistaxis, increased bleeding after dental extractions, and menorrhagia. A validated bleeding assessment tool has been developed to screen outpatients who may benefit from formal vWD laboratory testing [3], but its usefulness in the critical care setting has not been established.

A formal diagnosis of vWD should be based on three components: (a) a history of excessive bleeding, either spontaneous mucocutaneous and/or postsurgical, (b) a positive family history for excessive bleeding, and (c) confirmatory laboratory testing. Diagnostic tests for vWD, reviewed elsewhere [11], should be performed in a specialized laboratory and are summarized in Table 108.2.

The goals of treatment in vWD are to correct the quantitative or qualitative deficiencies in vWF, platelets, and FVIII. Treatment options include desmopressin (DDAVP), vWF-containing concentrates, and/or antifibrinolytics. See Tables 108.3 and 108.4 for general treatment guidelines.

In normal volunteers, DDAVP increases plasma levels of FVIII, vWF, and tissue plasminogen activator [12]. It may be given IV or SQ [13]. When given intravenously, the FVIII and vWF levels are usually increased three- to fivefold above basal levels within 30 minutes. vWD patients should undergo a DDAVP trial to gauge their individual response since there is considerable interindividual variability. Dosing of DDAVP for vWD is generally recommended at 0.3 μg per kg (IV or SQ), or 300 μg intranasally, which can be repeated at intervals of 12 to 24 hours. Tachyphylaxis (due to depletion of FVIII/vWF from repeated endothelial exocytosis into plasma) following repeated dosing is expected; DDAVP given as a second dose is 30% less effective than the first dose [14]. For this reason, and due to the risk of hyponatremia (which can lead to seizures), serial dosing should be limited to two to three doses in a 72-hour period with concurrent free water restriction and monitoring of serum sodium levels. DDAVP is most effective in type 1 vWD. It is relatively contraindicated in type 2B vWD because of the transient induction of thrombocytopenia [15]. Patients

with type 3 vWD are usually unresponsive to DDAVP. Certain hemophilia treatment centers caution against use of DDAVP in patients with coronary artery disease, since this agent may also activate platelets.

Antifibrinolytic agents (epsilon aminocaproic acid and tranexamic acid) can be used alone or as adjunctive treatment in vWD patients with mucosal bleeding. These drugs inhibit fibrinolysis by inhibiting plasminogen activation, thereby promoting clot stability. They are contraindicated in the setting of gross hematuria as resultant ureteral obstruction by insoluble clot has been described. Given a concern for thrombosis, antifibrinolytics should be avoided in patients with

TABLE 108.3

DOSING GUIDELINES FOR VON WILLEBRAND DISEASE (vWD) TREATMENT

Medication	Dose	Comments
DDAVP	Nasal spray: 300 µg (1 spray in each nostril) If weight < 50 kg 150 µg (1 spray in 1 nostril) IV: 0.3 µg/kg (not to exceed 20–25 µg)	Most useful in type 1 vWD, ineffective in type 3. Requires challenge to document efficacy. Relatively contraindicated in type 2B as may exacerbate thrombocytopenia May repeat dose in 12 h and/or 24 h. Tachyphylaxis occurs with repeat dosing. Due to risk of hyponatremia, if dosing serially, limit doses to no more than 2–3 in a 72-h period, fluid restrict, and follow serum sodium levels. Avoid in patients with coronary disease.
Antifibrinolytic agents: epsilon-aminocaproic acid (EACA)	50 mg/kg PO up to q 6h (lower doses may be effective) or 1 g/h IV continuous infusion Do not exceed 24 g/24 h	Especially useful for mucocutaneous bleeding, especially for dental procedures May be used as adjunctive treatment (DDAVP, factor concentrates)
Tranexamic acid	25 mg/kg q 8 h (not yet available in the United States)	Avoid in upper urinary tract bleeding
vWF-containing FVIII concentrates (e.g., Humate-P, Alphanate)	60–80 RCoF U/kg as an initial dose, then 40–60 u/kg IV every 12 h (see Table 108.4)	FVIII activity levels are often used in the monitoring of response to vWF-containing products as real-time vWF activity measures are not always available Dosed in RCoF units. Individual product is labeled with ratio of RCoF units:FVIII

DDAVP, desmopressin; vWD, von Willebrand disease; vWF, von Willebrand factor; RCoF, ristocetin cofactor.

TABLE 108.4

SUGGESTED INITIAL DOSING OF vWF CONCENTRATES FOR PREVENTION OR MANAGEMENT OF BLEEDING

	Major surgery/bleeding
Loading dose[a]	60–80 RCoF U/kg
Maintenance dose	40–60 RCoF U/kg, typically every 12 h initially
Monitoring	vWF:RCo and FVIII trough and peak, at least daily
Therapeutic goal	Trough vWF:RCo and FVIII > 50 IU/dL for 7–14 d
Safety parameter	Do not exceed vWF:RCo 200 IU/dL or FVIII 250–300 IU/dL
May alternate with DDAVP for latter part of treatment	
	Minor surgery/bleeding
Loading dose[a]	30–60 U/kg
Maintenance dose	20–40 U/kg every 12–48 h
Monitoring	vWF:RCo and FVIII trough and peak, at least once
Therapeutic goal	Trough vWF:RCo and FVIII > 50 IU/dL for 3–5 d
Safety parameter	Do not exceed vWF:RCo 200 IU/dL or FVIII 250–300 IU/dL
May alternate with DDAVP for latter part of treatment	

[a]Loading dose is in vWF:RCo IU/dL.

prothrombotic conditions, disseminated intravascular coagulation (DIC), or when receiving prothrombin complex concentrates (PCCs).

vWF factor-containing FVIII concentrates are appropriate for patients with severe vWD or in situations when other therapies (including DDAVP) are ineffective and are preferred to cryoprecipitate, which contains vWF, but has not undergone viral inactivation. When used in the treatment of vWD, they are dosed in ristocetin cofactor (RCoF) units, as opposed to FVIII units (Table 108.4). Limited data suggest a role for rFVIIa in patients with type 3 vWD who have developed alloantibodies to vWF [16].

The National Heart Lung and Blood Institute has recently published guidelines for the diagnosis, evaluation, and management of vWD [17].

Hemophilia

The hemophilias are congenital bleeding disorders characterized by X-linked inheritance and result in a deficiency of FVIII (hemophilia A) or FIX (hemophilia B). In the United States, they have a combined incidence of 1 in 5,000 male births. Hemophilia A is more common than hemophilia B and accounts for approximately 80% of cases. Since hemophilia is an X-linked disorder, all daughters of affected males are obligate carriers and all sons are healthy. Females may rarely manifest bleeding symptoms if they (a) are the homozygous offspring from a carrier mother and affected father, (b) have a high degree of lyonization, or (c) are a carrier with concomitant Turner's syndrome (XO).

The clinical phenotype of hemophilia patients depends on the residual level of circulating procoagulant protein (FVIII or FIX). It is possible to differentiate three degrees of clinical severity: (a) mild hemophilia (5% to 50% factor activity) in which bleeding is prolonged but typically only occurs following trauma or surgery, (b) moderate hemophilia (1% to 5% factor activity) in which prolonged bleeding follows minor trauma, and (c) severe hemophilia (< 1% factor activity) where patients experience spontaneous hemorrhage into joints (hemarthrosis) and muscles.

In severe and moderate hemophilia, the PT is normal and the aPTT is prolonged. However, the PTT may be normal in patients with mild hemophilia whose residual factor activity is > 20%. If the aPTT is prolonged, it should correct with a mixing study, since hemophilia is a factor deficiency syndrome. Specific factor assays should be performed to confirm a diagnosis of hemophilia A or B.

The management of most cases of hemophilia, thanks to the availability of replacement clotting factor concentrates, occurs in the outpatient setting, but individuals who previously have escaped diagnosis (mild or moderate hemophilia) or who have sustained major trauma or complications from a bleeding episode (compartment syndrome) may present to critical care. If not previously diagnosed, hemophilia should be suspected in male patients who have a personal history of bleeding into joints or muscles, a history of excessive bleeding upon surgical challenge, and/or a positive sex-linked family history of bleeding.

Hemarthrosis, a hallmark of hemophilia, accounts for approximately 85% of all bleeding events in severe hemophilia and most commonly involves the ankles, knees, and elbows [18]. Intramuscular hematomas in persons with hemophilia may expand to the point where blood flow is compromised to surrounding neurovascular structures resulting in tissue gangrene and compartment syndrome; the condition requires surgery and aggressive clotting factor replacement therapy [19] (Table 108.5). Gastrointestinal bleeding is uncommon in hemophilia. However, patients with an underlying structural lesion may present with hematemesis, hematochezia, or melena. Hemophilia patients who present with evidence for gastrointestinal bleeding should have a complete endoscopic evaluation to assess for and treat any underlying lesion. Approximately 90% of persons with severe hemophilia will develop hematuria during their life, although the condition is typically painless, benign, and unassociated with a structural lesion. As discussed earlier, antifibrinolytic agents are contraindicated in patients with genitourinary bleeding.

TABLE 108.5

RECOMMENDED HEMOSTATIC LEVELS IN HEMOPHILIA[a]

Clinical situation	Hemophilia target factor activity (%)[a]
Mild hemorrhage (joint, muscle)	30–40
Mucosal hemorrhage (oral, dental)	30–40 with EACA
Major hemorrhage	> 50
Life-threatening hemorrhage or perioperative management (major and orthopedic procedures)	100

[a]Minimum recommended goal factor activity levels.
EACA, epsilon-aminocaproic acid.

Hemorrhage into head and neck structures is a medical emergency in persons with hemophilia. Retropharyngeal hematoma, which may occur spontaneously or following dental or surgical procedures, may present with inability to control saliva, neck swelling, and pain. If untreated, it may result in airway compromise and in some cases may require tracheostomy. Hemorrhage into the central nervous system is a severe and potentially fatal (albeit rare) complication of hemophilia. Intracranial hemorrhage (ICH) may occur spontaneously in severe hemophilia or as the result of trauma. Prompt recognition of ICH is paramount and factor replacement therapy should be given immediately while the diagnostic workup is underway (Table 108.5).

The approach to treating major bleeding episodes in hemophilia A and B is similar. The clinical scenario dictates the target factor activity level (Table 108.5). For example, an ICH requires a target activity level of 100% initially, while levels of 30% to 40% may be sufficient for minor bleeds such as uncomplicated hemarthrosis. Prior to completion of the diagnostic (radiologic or otherwise) workup, clotting factor concentrate should be administered immediately to a person with hemophilia and a suspected life- or limb threatening bleed. Plasma-derived and recombinant factor concentrates [20] contain much higher concentrations of the desired factor compared to fresh frozen plasma (FFP) or cryoprecipitate. If possible, avoidance of FFP or cryoprecipitate is advised to avoid volume overload, transfusion-related lung injury (TRALI), and potential viral transmission (see Chapter 114).

DDAVP may be used instead of factor concentrate in selected patients with mild hemophilia A who have minor bleeding or a requirement for an enhanced FVIII activity level prior to a short-lived bleeding challenge. Any mild hemophilia A patient should undergo a DDAVP trial to gauge his or her individual response in lieu of assuming efficacy of the agent. FVIII levels in plasma increase two- to six-fold following administration. For mild hemophilia A, the recommended dose is 0.3 µg per kg (IV or SQ) or 300 µg intranasally; as previously discussed, tachyphylaxis and hyponatremia may develop after serial dosing.

Antifibrinolytic agents are a useful adjunctive treatment in hemophilia patients with mucosal bleeding. However, hemophilic patients with hematuria, DIC, receiving a PCC, or other prothrombotic conditions should not be treated with antifibrinolytics.

One of the most significant complications of hemophilia treatment is the development of an inhibitor. Inhibitors are alloantibodies against exogenously administered clotting factor that neutralize the factor. The development of a new inhibitor is more common in hemophilia A than in hemophilia B [21], in severe hemophilia, and among previously untreated patients (as opposed to adults who typically have been extensively exposed to clotting factor concentrate).

Inhibitors, if present at high titer, neutralize exogenous factor rendering factor concentrates ineffective. Therefore, an inhibitor should be suspected when administration of factor concentrate at a dose previously sufficient to achieve hemostasis, or improve bleeding, fails to do so. Once suspected, a Bethesda assay should be performed to document the titer of the inhibitor (reported in Bethesda units, BU). Of the two goals of treatment in patients with inhibitors, namely, to achieve adequate hemostasis and to eradicate the inhibitor, only the former is typically relevant to the critical care setting. Bleeding should be treated with bypassing agents, typically an activated prothrombin complex concentrate (aPCC) or rFVIIa [22]. If the titer is < 5 BU, high doses of FVIII or FIX may be given as initial treatment in cases of life- or limb-threatening bleeding episodes. In patients with a long-standing inhibitor, however, the anamnestic response negates factor activity after 5 to 7 days, at which point bypassing agents become necessary.

RARE CONGENITAL COAGULATION DISORDERS

Less Common Coagulation Factor Deficiencies

The hemophilias and vWD represent approximately 85% of congenital bleeding disorders. The remaining disorders will be briefly discussed next.

Disorders of Fibrinogen

Congenital fibrinogen disorders result from a quantitative (afibrinogenemia) or qualitative (dysfibrinogenemia) defect in fibrinogen synthesis. Congenital afibrinogenemia has a variable bleeding phenotype with the majority of patients experiencing moderate bleeding [23]. Afflicted individuals present typically in the neonatal period with umbilical stump bleeding or bleeding following circumcision [23]. Patients may also experience hemarthrosis, intramuscular hemorrhage, spontaneous abortion, mucosal surface bleeds, ICH, or spontaneous splenic rupture [24]. Heterozygotes are typically asymptomatic. The clinical phenotype in patients with congenital dysfibrinogenemia is variable and includes (a) asymptomatic (55%), (b) hemorrhagic (25%), (c) thrombotic (10% to 20%), or (d) a combination of both hemorrhagic and thrombotic complications (1% to 2%) [25]. Treatment of congenital fibrinogen disorders should be individualized given the clinical variability. In general, replacement therapy in the form of fibrinogen concentrates, cryoprecipitate, or (not recommended) FFP should be given to patients with a hemorrhagic presentation to achieve a goal fibrinogen level of 50 to 100 mg per dL [26].

Prothrombin (FII) Deficiency

Congenital prothrombin deficiency is characterized by a concordant decrease in prothrombin antigen and activity [27]. Aprothrombinemia has not been reported. Patients with hypoprothrombinemia present with severe hemorrhage including ICH, mucocutaneous bleeding, hemarthrosis, spontaneous abortions, and significant postoperative bleeding. Heterozygotes are usually asymptomatic; however, they may experience

increased postoperative bleeding [28]. Prothrombin deficiency is treated with factor replacement in the form of FFP or PCC to a goal prothrombin level of 30% [29].

Factor V Deficiency

FV deficiency is associated with mucocutaneous bleeding and rarely with ICH [30]. There are mild, moderate, and severe deficiency states. Patients with severe deficiency usually present with umbilical stump and mucocutaneous bleeding. Older individuals may present with postoperative bleeding or menorrhagia. FV deficiency is treated with FFP to a goal activity level of 20% to 30%. Alpha granules in platelets contain FV and platelet transfusions have been used in the treatment of FV deficiency when patients have developed neutralizing inhibitors to FV with varying success [31]. Combined deficiency of FV and FVIII should always be considered in the differential diagnosis of patients who present with FV deficiency. This is discussed next [32].

Combined Factor V and VIII Deficiency

Combined FV and FVIII deficiency (F5F8D) is a rare disorder where patients have detectable, but low antigen and activity levels of both factors, typically in the 5% to 15% range. Patients present with increased bleeding following trauma or surgery. Patients are treated with a combination of FFP and FVIII concentrates.

Factor VII Deficiency

Patients with less than 1% FVII activity manifest a severe bleeding disorder, predominantly involving the mucous membranes, muscles, joints, and following surgery or trauma, while those with more than 5% have relatively mild symptoms. Factor VII activity correlates poorly with bleeding severity, but in general, only modest amounts of circulating FVII are required for adequate hemostasis, and bleeding is uncommon, even with surgery, in individuals with FVII activity levels > 15% to 20% [33,34]. In the United States, rFVIIa is used to treat FVII deficiency. Plasma-derived FVII concentrates are available in Europe to treat this disorder [35,36]. When rFVIIa and/or FVII concentrates are unavailable, PCC (depending on factor formulation) or FFP may be used.

Factor X Deficiency

In congenital FX deficiency, severity of bleeding appears to correlate with residual FX activity and may be quite severe. In a case series of Iranian patients with congenital FX deficiency, the most common symptoms were epistaxis, menorrhagia, and hemarthrosis [37]. FX deficiency is treated with PCCs.

Factor XI Deficiency

FXI deficiency, previously known as hemophilia C, is common amongst Ashkenazi Jews where the gene frequency is 8% to 9% [38]. The inheritance is autosomal rather than X linked as with hemophilia A and B. Severe FXI deficiency (< 15% to 20% FXI activity) occurs in homozygotes or compound heterozygotes. Heterozygous individuals have a partial FXI deficiency (20% to 70% FXI activity) [39]. Bleeding is unpredictable as some severe FXI deficiency patients are asymptomatic, while an analysis of 50 kindreds demonstrated that 30% to 50% of heterozygotes experienced significant bleeding [40].

Treatment for FXI deficiency includes FFP, antifibrinolytic agents [41], FXI concentrates (available in the United Kingdom and France) [42], and rFVIIa (not FDA approved for this purpose) [43]. There is concern of a prothrombotic potential associated with FXI concentrates as DIC and arterial thrombosis have been described in up to 10% of patients. Heparin has been added to these concentrates to reduce this thrombotic potential, but there is a general recommendation to maintain FXI levels at no greater than 70 IU per dL [44].

Factor XIII Deficiency

The most common presentation for FXIII-deficient patients is umbilical stump bleeding [45]. FXIII-deficient patients may also experience ICH, hemarthrosis, menorrhagia, and increased bleeding following surgery or trauma [46]. FXIII has a half-life of 8 to 12 days and levels required to maintain hemostasis are only in the range of 2% to 5%. Treatment includes FXIII concentrates, FFP, or cryoprecipitate. Given FXIII's long half-life, factor concentrates may be given once every several weeks as prophylactic therapy [47].

Vitamin K-Dependent Factor Deficiencies

Patients with combined deficiency of the vitamin K-dependent factors (FII, FVII, FIX, FX, proteins C and S) may present with umbilical stump bleeding or ICH [48]. Factor activity levels are variable and generally range from 1% to 30%. High doses of supplemental vitamin K may significantly improve or completely correct deficient factor activities. In acute bleeding episodes, patients may be treated with FFP or PCCs.

Congenital Qualitative Platelet Disorders

Defects in Platelet Adhesion

Bernard–Soulier syndrome (BSS) is a rare, autosomal recessive, severe bleeding disorder characterized by thrombocytopenia, giant platelets, and severe mucocutaneous bleeding [49]. Deficient platelet binding to subendothelial vWF is due to abnormalities (either qualitative or quantitative) in the GP Ib/IX/V complex. The mainstay of treatment in BSS is platelet transfusion during clinically significant hemorrhagic episodes. However, alloimmunization to transfused platelets is often encountered when patients develop neutralizing antibodies to GP Ib/IX/V on transfused platelets which renders those platelets useless. rFVIIa has been used to treat patients with these inhibitors and has proven successful in many cases [50].

Defects in Platelet Aggregation

Glanzmann thrombasthenia is a rare, autosomal recessive disorder characterized by absent platelet aggregation secondary to defective GP IIb/IIIa on the platelet surface. Affected patients present with severe to life-threatening mucocutaneous bleeding. Treatment includes platelet transfusion. However, many patients may become refractory as alloantibodies to transfused platelets form. rFVIIa has been used to treat bleeding in this disorder [51].

Disorders of Platelet Secretion: The Storage Pool Diseases

Platelets contain two types of intracellular granules, alpha and delta (or dense), which are required for an optimal secondary wave of platelet aggregation. The gray platelet syndrome is the most common alpha granule storage pool disease (SPD) and may predispose to early onset myelofibrosis, a

probable consequence of the impaired storage of growth factors such as PDGF [52]. Hermansky–Pudlak syndrome and Chediak–Higashi syndrome are SPDs affecting dense granules. The Hermansky–Pudlak syndrome is associated with oculocutaneous albinism and increased accumulation of an abnormal fat-protein compound, ceroid, in the reticuloendothelial system [53]. The Chediak–Higashi syndrome is characterized by oculocutaneous albinism, neurologic abnormalities, immune deficiency with a tendency to infections, and giant inclusions in the cytoplasm of platelets and leukocytes [54]. The primary treatment for clinically significant bleeding in patients with SPDs is platelet transfusion.

ACQUIRED COAGULATION DISORDERS

Anticoagulant Drugs

Use of anticoagulants in the critical care setting is ubiquitous. The pharmacology, monitoring, and appropriate reversal of anticoagulant drugs are reviewed in detail in Chapter 110.

Generally, patients on anticoagulants who develop clinically insignificant bleeding may be closely monitored while the drug is continued; appropriate therapeutic monitoring (e.g., INR, aPTT, anti-Xa) should also be obtained and followed closely. Major bleeding, except in rare instances, typically should prompt discontinuation of anticoagulant drugs. Consideration should also be given to holding subsequent doses or reducing doses based on laboratory or clinical evolution.

Heparins, Low-Molecular-Weight Heparins, and Fondaparinux

These agents, and management of associated bleeding complications, are discussed in Chapter 110.

Warfarin (Coumadin)

Given its widespread use, warfarin is a common cause of iatrogenic, serious bleeding that frequently requires critical care. Warfarin is an oral vitamin K antagonist that exerts its anticoagulant effects through inhibition of vitamin K-dependent γ carboxylation of the vitamin K-dependent factors (FII, FVII, FIX, and FX). γ carboxylation is required for these coagulation factors to become biologically active. Warfarin also inhibits γ carboxylation of the vitamin K-dependent regulatory proteins C and S. Treatment with warfarin reduces the biologically active levels of all these vitamin K-dependent factors, both pro- and anti-coagulant. However, the net effect at steady state is anticoagulation. Given the half-life of the independent factors affected by warfarin, patients may become relatively prothrombotic in the first several days after warfarin initiation as proteins C and S are the first to become significantly reduced. This is the rationale for "bridging" with unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH) for the first several days of warfarin administration to abrogate extension of existing thrombosis or development of new ones [55].

Warfarin is monitored via the PT and INR with a typical therapeutic range of 2.0 to 3.0 but this is patient and indication specific [55]. At supratherapeutic doses, the aPTT may also become prolonged.

When asymptomatic, supratherapeutic anticoagulation with warfarin does not generally require treatment beyond reducing the dose or holding warfarin for a period of time to allow for correction in the INR. Consideration may also be given to administering a small dose of vitamin K (1 to 5 mg) which will significantly lower the INR within 24 hours, depending on the INR and clinical scenario. If the patient is experiencing significant or life-threatening bleeding, reversal of anticoagulation is indicated and accomplished by replenishing the vitamin K-dependent factors. This can be achieved using either FFP or PCCs (Table 108.6).

TABLE 108.6

REVERSAL OF WARFARIN-INDUCED ANTICOAGULATION MANAGEMENT OF SUPRATHERAPEUTIC INR

Clinical situation	INR	Actions
No significant bleeding	< 5.0	■ Lower dose, or ■ Hold dose and restart at a lower dose once INR in desired range, or ■ Check INR in 24 h if INR only mildly prolonged
	5.0–9.0	■ Hold warfarin, repeat INR in 24 h ■ Give vitamin K_1 1–2.5 mg PO × 1 if at increased risk of bleeding ■ Check INR in 24 h—when INR in desired range, restart warfarin at adjusted dose
	≥ 9.0	■ Hold warfarin and give vitamin K_1 2.5–5 mg PO × 1 (may repeat in 24 h if INR not improved) ■ When INR in desired range, restart warfarin at adjusted dose
Serious or life-threatening bleeding	Any prolongation in INR due to warfarin administration	■ Hold warfarin ■ Give vitamin K_1 10 mg slow IV push (over 30 min); may repeat in 12–24 h ■ Give FFP, prothrombin complex concentrate (PCC), or rFVIIa for acute reversal ■ Monitor INR and repeat intervention as necessary

Adapted from Ansell J, Hirsh J, Hylek E, et al: Pharmacology and management of the vitamin K antagonists: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines (8th Edition). *Chest* [6, Suppl]:175s, 2008.

PCCs are plasma-derived products enriched in vitamin K-dependent factors. The typical dose is 25 to 50 U per kg depending on the degree of anticoagulation. There are two types of PCCs available, activated PCC (aPCC) and nonactivated (simply referred to as PCC). The activated form contains activated coagulation proteases that are used in the treatment of hemophilia with inhibitors. The nonactivated formulations were originally licensed for the treatment of hemophilia B, given their high FIX content. Furthermore, there are two types of nonactivated PCCs: 4-factor (FII, FVII, FIX, FX)–containing products and a 3-factor (FII, FIX, FX) product. While the 3-factor product does contain some FVII, it is at a low concentration (less than one-third that of FIX) and therefore is considered a 3-factor concentrate. If a 3-factor concentrate is used for warfarin reversal, rFVIIa may be required as adjunctive treatment to replenish FVII [55]. Notably, only 3-factor PCCs are currently available in the United States; however, a phase III clinical trial is currently enrolling to evaluate the efficacy and safety of a 4-factor PCC in reversal of oral vitamin K antagonist-induced bleeding. Both activated and nonactivated PCCs contain heparin and are therefore contraindicated in patients with heparin-induced thrombocytopenia [56]. As the effects of FFP, PCC, and rFVIIa are transient, 10 mg of parenteral vitamin K (IV over 30 minutes) should also be given to reverse the INR more durably [55]. When available, PCCs are preferred over FFP because they are concentrated into much smaller volumes, can be virally inactivated, and have a lower risk of TRALI (see Chapter 114). The pharmacodynamics of warfarin is discussed further in Chapter 110.

Superwarfarins

The superwarfarins are a group of pharmacologic compounds that are long-acting rat poisons. They have considerably longer half-lives than warfarin (weeks to months versus 1 to 2 days) and are considerably more potent. Superwarfarin poisoning has been associated with homicide and suicide attempts, accidental ingestion, and occupational exposure. Patients typically present with bleeding symptoms and laboratory findings similar to those of warfarin overdose; however, the PT/INR does not appropriately normalize with standard doses of vitamin K. An assay for each of the superwarfarins is necessary to confirm the diagnosis. Patients require high doses of vitamin K for prolonged periods to control bleeding risk. FFP or rFVIIa may be required in episodes of life-threatening bleeding [57].

Direct Thrombin Inhibitors (Argatroban, Lepirudin, Bivalirudin)

Reversal of anticoagulation due to direct thrombin inhibitors (DTIs) in cases of clinically significant bleeding is typically achieved through cessation of drug given a short half-life (< 1 hour). No specific antidote is available and supportive care is the standard. The pharmacodynamics of DTIs are discussed in greater detail in Chapter 110.

Vitamin K Deficiency

Vitamin K deficiency is a frequently encountered problem in hospitalized medical patients. It is particularly common in those with chronic malabsorption syndromes (e.g., cystic fibrosis), malnutrition, and those on broad-spectrum antibiotics [58]. Patients on warfarin and with vitamin K deficiency present with similar laboratory and physical findings, namely prolongation primarily of the PT as well as easy bruising or soft tissue bleeding. Vitamin K deficiency is managed by supplementation of vitamin K. If a patient has a malabsorptive syndrome, parenteral vitamin K is typically recommended.

Since vitamin K-dependent coagulation factors are synthesized in the liver, it can be difficult to distinguish between vitamin K deficiency and a coagulopathy of liver disease (decreased hepatic synthesis of coagulation factors). In clinical scenarios where underlying liver disease is present, it may be beneficial to evaluate coagulation factor levels, both vitamin K-dependent and independent (e.g., FII and FV, respectively). In this example, if both FII and FV levels are decreased, then the patient likely has hepatic synthetic dysfunction. If FV is normal and FII is decreased, then the patient likely has vitamin K deficiency.

Coagulopathy of Liver Disease

An unfortunate hallmark of liver disease is coagulopathy. It stands to reason that since all of the coagulation factors (except FVIII, which is also synthesized in extrahepatic endothelial cells) are made in the liver, end-stage liver disease (ESLD) is marked by multiple coagulation factor deficiencies [59,60]. However, increased extravascular redistribution and increased factor consumption also contribute. The degree of coagulation factor reduction as well as the number of factors reduced typically parallel the severity of liver disease [61]. Factors V and VII appear to be sensitive markers of hepatic synthetic dysfunction with FVII levels typically the most notably affected secondary to its short half-life [62]. A prolongation in the PT is therefore an early marker of liver disease. As hepatic dysfunction progresses and other coagulation factors in the common and contact activation pathway are decreased, the aPTT prolongs. In contrast, FVIII levels are typically elevated in compensated cirrhosis. This may be secondary to an increase in vWF that is seen in cirrhotics [60]. In addition, proteins required for FVIII clearance such as low-density lipoprotein receptor-related protein (LRP) are present in decreased amounts, thus raising FVIII levels. Patients with liver disease may have normal fibrinogen levels, given its long half-life, but they may develop an acquired dysfibrinogenemia associated with abnormal fibrinogen glycosylation that disrupts fibrin polymerization [63,64]. This may be reflected by a normal fibrinogen quantitative assay but an abnormal functional assay such as the TT or RT.

In addition to coagulation factor deficiency, a number of other variables associated with advanced liver disease may contribute to coagulopathy in this population. These include (a) vitamin K deficiency secondary to malnutrition, malabsorption/maldigestion from bile salt insufficiency, and altered intestinal motility [63]; (b) portal hypertension with resultant hypersplenism and secondary thrombocytopenia [65]; (c) decreased thrombopoietin (the principle regulator of platelet production) synthesis by hepatocytes with resultant thrombocytopenia [66]; (d) impaired platelet function as demonstrated by abnormal platelet function, as assessed by PFA-100® [66]; and (e) hyperfibrinolysis secondary to impaired synthesis of plasminogen activator inhibitors and decreased clearance of plasminogen activators (reviewed in reference [67]). Chronic, low-grade DIC may also contribute to coagulopathy (discussed later).

Despite evidence for a significant coagulopathy based on laboratory tests as well as evident petechiae, ecchymosis, purpura, and bleeding after invasive procedures, patients with ESLD rarely bleed spontaneously. It is much more common for them to present with hemorrhage as a result of an underlying anatomic lesion such as from an esophageal varix. There remains active debate as to the actual net degree of coagulopathy in these patients. For instance, Mannucci has argued that defects in platelet number and function may be balanced by increased levels of vWF. Furthermore, decreased levels of

coagulation factors and inhibitors of fibrinolysis are balanced by decreased levels of inhibitors of coagulation and profibrinolytic factors [68]. The end result is a potential rebalancing of hemostasis. The fact that the degree of PT and aPTT prolongation correlates poorly with bleeding after liver biopsy and other potentially hemorrhagic procedures supports this rebalancing notion [69,70]. Ultimately, a more comprehensive assessment of hemostasis is needed as PT and aPTT only assess thrombin generation in a closed system devoid of anticoagulant factors and do not address fibrinolysis at all.

Given that we lack a comprehensive hemostatic assessment tool, many physicians prefer to prophylactically give FFP or other hemostatic agents to patients with ESLD who are to undergo procedures or who have significantly abnormal coagulation laboratory values. Unfortunately, we have little data to support these measures. The current guidelines recommend FFP transfusions only when hemostasis is needed for bleeding or invasive procedures and the PT or aPTT is > 1.5 times normal (reviewed in reference [71]). FFP is generally given at a dose of 10 to 15 mL per kg repeated every 8 hours. Notably, despite repeated infusions of FFP, the PT may not completely correct and therefore clinical response should be monitored rather than relying on the PT as a measure of efficacy [72]. As discussed earlier, patients with ESLD may also develop hypofibrinogenemia or a dysfibrinogenemia. This should be suspected in a patient with a prolonged TT or RT or in a patient who continues to bleed despite FFP infusion. Cryoprecipitate may be required to treat hypo/dysfibrinogenemia as FFP typically does not sufficiently replace fibrinogen. Cryoprecipitate is typically given in doses of 10 pooled units. Patients should be transfused to a goal fibrinogen level of > 100 mg per dL. There are a number of human fibrinogen concentrates available in Europe, and in 2009 the Food and Drug Administration approved the first human fibrinogen concentrate in the United States. It is currently indicated for the treatment of patients with congenital afibrinogenemia and hypofibrinogenemia. Some authors have reported beneficial outcomes in patients given rFVIIa and PCCs in ESLD. However, there are currently no guidelines or randomized trials that address dosing or efficacy [63]. However, given the hypervolemia typical of patients with ESLD, multiple infusions of FFP may not be possible and treatment with PCCs may be considered to reduce volume overload as well as decrease the risk of TRALI. If a 3-factor PCC is used, adjunctive rFVIIa may be indicated [73].

Many have argued for controlled trials to evaluate the role of prophylactic hemostatic agents in this patient population as current practice typically involves using expert opinion and case series data [74].

Disseminated Intravascular Coagulation

DIC is a well-recognized syndrome characterized by both thrombotic and hemorrhagic complications in the setting of a number of defined disorders that are typically associated with systemic inflammation (Table 108.7) [75]. The pathogenesis of DIC is complex and is characterized by widespread activation of the TF coagulation pathway with a marked imbalance between procoagulant and anticoagulant processes resulting in unopposed thrombin generation and diffuse fibrin clot formation with subsequent microvascular occlusion and tissue hypoxia [76]. When severe, these changes may culminate in multiple organ dysfunction syndrome (MODS). The pathogenesis is further reviewed elsewhere [75,77].

The clinical presentation of DIC is variable and the majority of patients do not demonstrate a significant hemorrhagic phenotype [78]. A clinical suspicion for DIC is paramount in establishing its diagnosis. In addition to a compatible underlying condition (e.g., sepsis), abnormal laboratory studies consistent with increased thrombin generation and fibrinolysis (consumptive coagulopathy) are also required. A DIC screening panel is typically composed of PT, aPTT, platelet count, fibrinogen, and D-dimer. DIC is suggested when the laboratories demonstrate increased activation of coagulation (elevated PT/aPTT, decreased fibrinogen) as well as evidence of fibrinolysis (elevated D-dimer or fibrin degradation products). An elevation in PT is a very sensitive measure for DIC but has lower specificity since it may be normal, especially in chronic DIC [79]. Since fibrinogen is an acute phase reactant, it may be normal or even elevated in chronic DIC, thereby limiting its specificity in low-grade DIC. Elevation of D-dimer is a sensitive marker for DIC, in the range of 90% to 100% in one report; however, its specificity limits its utility as a single screening test [80].

The International Society on Thrombosis and Hemostasis established a subcommittee on DIC to develop and validate a scoring system to aid in the diagnosis of DIC. This system is based on platelet count, fibrin degradation products, PT, and fibrinogen level [81]. A prospective validation study demonstrated this scoring system to be 91% sensitive and 97% specific for the diagnosis of DIC, with higher scores correlated with higher 28-day mortality (Table 108.8) [82].

Identification and treatment of the underlying disorder remains the hallmark of treatment for DIC [78]. Treatment of DIC should be based on both the clinical presentation as well as the laboratory results [75]. Recommendations for the management of DIC are based on expert opinion given a lack of published, randomized data. In general, patients who experience

TABLE 108.7

DISORDERS ASSOCIATED WITH DISSEMINATED INTRAVASCULAR COAGULATION

Infection
Gram-negative or Gram-positive septicemia
Rickettsiae—especially Rocky Mountain spotted fever
Spirochetes
Fungi
Viruses—especially herpes
Protozoa—especially malaria
Tissue damage
Trauma
Crush injury
Burn
Heat stroke
Hemolytic transfusion reaction
Neoplasia
Metastatic carcinoma
Leukemia—especially acute promyelocytic leukemia
Chemotherapy
Obstetric disasters
Abruptio placentae
Retained dead fetus
Preeclampsia/eclampsia
Amniotic fluid embolism
Placenta previa, accreta, and percreta
Miscellaneous
Fat embolism
Shock
Cardiac arrest
Giant hemangioma (Kasabach–Merritt syndrome)
Vasculitis
Toxins (snake venom, brown recluse spider bite)
Near drowning—especially fresh water

TABLE 108.8

DIAGNOSTIC SCORE FOR DISSEMINATED INTRAVASCULAR COAGULATION

1. Underlying disorder associated with DIC—if yes → proceed, if no → do not proceed, search for alternative process
2. Obtain global coagulation tests: platelet count, PT, fibrinogen, D-dimer
3. Assign score based on laboratory tests
   a. Platelet count
      i. > 100 = 0, < 100 = 1, < 50 = 2
   b. D-dimer or fibrin degradation products

Adapted from Bakhtiara K, Meijers JC, de Jonge E, et al: Prospective validation of the International Society of Thrombosis and Haemostasis scoring system for disseminated intravascular coagulation. *Crit Care Med* 32(12):2416–2421, 2004.

significant bleeding or who require invasive procedures should be treated with FFP to replace coagulation factors. PCCs may also be considered when hypervolemia complicates FFP administration, but they may lack certain depleted factors such as FV. Furthermore, the literature discusses increased risk for thrombosis given trace amounts of activated factors contained in the preparations [83]. It is unclear if this risk is still present in today's products. Cryoprecipitate should be used to replace fibrinogen if the plasma level is < 100 g per dL. While there is no established threshold at which to transfuse platelets in DIC, in the setting of active bleeding or in anticipation of invasive procedures, platelet transfusions may be indicated.

In contrast to replacing coagulation factors, fibrinogen, and platelets, some investigators have evaluated the role of anticoagulants, namely UFH, in the treatment of DIC. This putative measure is based on the pathologic activation of coagulation-associated with DIC as well as the depletion of endogenous anticoagulants. Initial animal studies evaluating anticoagulants in DIC suggested a benefit [84]; however, subsequent human trials have yielded conflicting results [78,85,86]. To date there are no data from randomized, controlled trials to support the use of UFH in the management of DIC.

More recently, trials of recombinant anticoagulant proteins have been conducted in patients with sepsis-related DIC. Similar to UFH, early trials evaluating tissue factor pathway inhibitor (TFPI) were promising; however, a subsequent phase III trial did not demonstrate survival benefit [87,88]. Large trials evaluating the use of antithrombin concentrates to restore the anticoagulant pathway have also been disappointing [89]. Most recently, considerable attention has been directed toward activated protein C (APC) and sepsis/DIC. Animal models suggest a link between downregulation of the protein C/thrombomodulin system and endotoxin-induced DIC (reviewed in reference [90]). Recombinant human APC (drotrecogin alfa) has been demonstrated to improve mortality and organ function in septic patients. Furthermore, it appears that patients with the most severe sepsis (APACHE score > 25) received the largest benefit [91]. Drotrecogin alfa is not used in DIC unassociated with severe sepsis.

DIC is discussed in further detail in Chapter 109.

Trauma-Induced Coagulopathy

Trauma-induced coagulopathy includes the coagulopathy associated with the stresses of trauma as well as unintended consequences of its treatment. Historically it was felt that the coagulopathy associated with trauma was largely secondary to dilution of the coagulation system with volume and blood replacement. However, it is becoming increasingly apparent that this process is much more dynamic and complicated. Traumatic events requiring massive transfusion of blood lead to significant coagulopathy through a number of mechanisms that include (a) dilution of coagulation proteins and platelets from volume resuscitation, (b) consumptive coagulopathy and thrombocytopenia (through DIC associated with trauma), (c) acidemia which impairs function of the coagulation cascade, (d) hypothermia which impairs function of platelets and coagulation factors, and (e) electrolyte perturbations, particularly hypocalcemia which impairs the calcium-dependent coagulation processes [92]. Prompt attention is required to mitigate the coagulopathy associated with trauma and to rapidly correct it. Clinically, patients have a compatible history of massive trauma requiring aggressive resuscitation and typically have a prolongation of PT and aPTT that corrects on mixing study, as well as thrombocytopenia and often hypofibrinogenemia. Treatment is targeted at correcting or preventing the occurrence of the above listed mechanisms that have been associated with the development of trauma induced coagulopathy. Most guidelines recommend transfusion of red blood cells to a target hemoglobin of 7 to 10 g per dL to maintain rheology, FFP administration to a goal PT/aPTT of < 1.5 × upper limit of normal, platelet transfusion to keep platelets > 50×10^9/L (or > 100×10^9 in patients with brain injury), and fibrinogen > 100 mg per dL [93,94]. Notably, recent large animal models of dilutional coagulopathy suggest that treatment with PCC was as effective as FFP in correcting coagulopathy and warranted further investigation [95]. Some studies also suggest that rFVIIa may be beneficial (reviewed in reference [96]).

Acquired Hemophilia A

The most common antibodies that affect clotting factor activity with a resultant hemorrhagic phenotype are directed against FVIII. Acquired hemophilia A, or acquired FVIII deficiency, is a rare disorder with an estimated incidence of 1.0 per million that is caused by autoantibodies directed against a patient's endogenous FVIII, resulting in low FVIII activity levels [97]. Acquired hemophilia A is most commonly an idiopathic condition that occurs in the elderly but can also be associated with malignancy, drugs, autoimmune disorders, and the postpartum state.

Acquired hemophilia should be suspected in patients without a prior bleeding history who present later in life with significant, large ecchymoses, hematomas, mucosal, gastrointestinal bleeding, or who experience significant bleeding following surgery or trauma. Hemarthroses that are a hallmark of congenital hemophilia are not typical of acquired hemophilia.

Patients with acquired hemophilia present with bleeding symptoms and a prolonged aPTT in contrast to patients with a lupus anticoagulant who typically present with a prolonged aPTT and thrombotic complications [97]. Once acquired hemophilia is suspected based on clinical presentation and a prolonged aPTT, an incubated aPTT mixing study should be performed. Since FVIII inhibitors are commonly time and temperature dependent, the mixing study should be performed

at 37°C for 1 to 2 hours. In the case of an acquired FVIII inhibitor, the incubated aPTT will not completely correct into the normal range which indicates the presence of an inhibitor. A FVIII activity level may also be helpful to identify the inhibitor as FVIII specific. The strength of the inhibitor may be quantified in a Bethesda assay. The strength of the inhibitor has treatment implications.

Treatment goals of these patients are twofold: (a) control of bleeding and (b) eradication of the inhibitor. Bleeding in patients with low-titer inhibitors (< 5 BU) can often be treated with high doses of FVIII concentrates [98]. Bleeding in patients with high-titer inhibitors is treated with a FVIII inhibitor bypassing agent, such as an aPCC or rFVIIa [99]. Porcine FVIII was also an option for patients with a low-titer inhibitor since the inhibitor titer to porcine FVIII is only 5% to 10% of the titer against human FVIII [100]. Unfortunately, this product was removed from production in 2004 given concerns for porcine parvovirus contamination. Clinical trials are currently underway evaluating recombinant porcine FVIII. Inhibitor eradication typically involves immunosuppression, though spontaneous resolution of the inhibitor can occur [98]. There is an unfortunate relapse rate of approximately 20%; however, 70% of these patients can be brought back into a second remission [101].

ACQUIRED PLATELET DISORDERS/DYSFUNCTION

Medications

The antiplatelet effect of medications is the most common cause for acquired platelet dysfunction. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) are the most commonly used medications that affect platelet function (Table 108.9) [102]. Their predominant antiplatelet effect is achieved through the inhibition of platelet cyclooxygenase (COX-1) which in turn ultimately inhibits vasoconstriction and platelet aggregation [103]. Inhibition of COX-1 by aspirin is irreversible for the life of the platelet and is dose-dependent. There is an increased risk of bleeding in patients taking aspirin, and two recent meta-analyses have described an approximate 1% increase in absolute risk of bleeding in patients taking aspirin compared to placebo [104,105]. Notably, this bleeding risk does not appear to be dose dependent when the total daily dose is ≤325 mg per day but does increase with concomitant administration of other anticoagulants or antiplatelet agents [106,107]. The primary site of bleeding associated with aspirin is gastrointestinal. NSAIDs, on the other hand, reversibly inhibit COX-1 for the length of time that the medication remains metabolically active. Platelet function is not affected by the newer COX-2 specific inhibitors or acetaminophen.

Dipyridamole is a less frequently used antiplatelet drug with an unclear mechanism of action. It has historically been used for stroke prophylaxis. There does not appear to be a significant increase in bleeding risk for patients taking dipyridamole versus placebo in several randomized trials evaluating the efficacy of dipyridamole in stroke prevention [108].

Clopidogrel (Plavix) belongs to a class of antiplatelet agents known as the thienopyridines and is being used with increasing frequency in the treatment of cardio- and cerebrovascular disease. Thienopyridines are irreversible antagonists to the platelet P2Y12 receptor which inhibits ADP-mediated platelet aggregation. The thienopyridines, particularly ticlopidine (Ticlid), have been implicated in the development of thrombotic thrombocytopenic purpura (TTP) [109].

The GP IIb/IIIa antagonists are a group of antiplatelet agents that are primarily used during coronary procedures. These drugs impair aggregation by inhibiting the cross bridging of platelets by fibrinogen. This class is associated with an increased risk of bleeding, particularly at the puncture site for percutaneous coronary intervention. There does not appear to be an increased risk for intracerebral hemorrhage for patients receiving GP IIb/IIIa inhibitors versus heparin [110]. These agents are also associated with thrombocytopenia, often profound, that may result in significant bleeding complications [111].

Many other medications including large doses of penicillins, psychotropic drugs such as fluoxetine, dietary supplements such as fish oil, gingko, garlic, and cumin may impair platelet function, although not typically to a significant degree [102].

Laboratory testing to confirm an acquired platelet defect secondary to medication is rarely necessary as clinical history and medication record usually suffice. However, if needed for confirmation, platelet function testing may be useful. Treatment for drug-induced platelet dysfunction depends on the severity of bleeding as well as the medication involved. In most cases, minor bleeding may be addressed by withholding the medication. In more severe cases, platelet transfusion may be indicated depending on timing of the last dose as well as its specific platelet effect. In general, platelets have a life span on average of 7 to 10 days. As a result, the bone marrow replaces approximately 10% of the body's platelets each day. Therefore, if a medication irreversibly inhibits platelet function, platelet transfusion may be needed to reverse the antiplatelet effect until the bone marrow has sufficiently replenished the affected platelets. For most situations, a single platelet transfusion is sufficient to correct bleeding association with disordered platelets.

Acquired platelet dysfunction due to antiplatelet agents is discussed in further detail in Chapter 109.

TABLE 108.9

DRUGS THAT COMMONLY AFFECT PLATELET FUNCTION

- Analgesics
  - Aspirin
  - NSAIDs
- Cardiovascular medications
  - Dipyridamole
- P2Y12 receptor blockers—thienopyridines
  - Ticlid (ticlopidine)
  - Plavix (clopidogrel)
  - Effient (prasugrel)
- GP IIb/IIIa inhibitors
  - ReoPro (abciximab)
  - Aggrastat (tirofiban)
  - Integrilin (eptifibatide)
- Antibiotics
  - β-Lactam antibiotics—e.g., PCN, cephalosporins
- Psychotropic
  - Antidepressants (fluoxetine)
  - Phenothiazines
- Herbal supplements
  - Fish oil
  - Cumin
  - Garlic
  - *Ginkgo biloba*
  - Turmeric

Uremia

The multisystem organ dysfunction encountered in critically ill patients often includes acute kidney injury and subsequent uremia. Bleeding associated with uremia has long been recognized

and has historically been associated with a prolonged bleeding time. However, the degree of BT prolongation neither correlates with the degree of azotemia nor the severity of bleeding symptoms. The clinical manifestations of uremic bleeding are predominantly mucocutaneous though patients may present with epistaxis, gastrointestinal bleeding, hematuria, or increased bleeding following surgery or procedures [112].

Despite this long-recognized association between uremia and a bleeding diathesis, the exact pathophysiology remains poorly defined though impairment in platelet function appears integral [113]. There are data to suggest that this is a multifactorial process and includes an acquired platelet defect as well as impairment in platelet–endothelium interaction. Additional factors include vWF abnormalities, anemia which affects rheology, thrombocytopenia, uremic toxins, and increased nitrous oxide (NO) production [114]. The presence of a uremic toxin is supported by the improvement in platelet function in patients following dialysis. Notably, urea is unlikely to be the primary toxin as there is no positive correlation between blood urea nitrogen and bleeding risk [115]. NO is produced by endothelial cells and platelets and inhibits platelet aggregation. Plasma from uremic patients has increased NO and the addition of an NO synthesis inhibitor to uremic rats improved BT [116,117].

Treatment for uremic bleeding often includes aggressive dialysis which may correct the bleeding and has been suggested to prevent uremic bleeding. DDAVP has been recommended as the first-line therapy for uremic bleeding (2 to 4 μg per kg intranasally or 0.3 μg per kg by slow intravenous infusion); it improves platelet function in uremia, most likely due to release of FVIII and vWF [118]. If no improvement is noted after the first dose, further doses should not be given. If DDAVP is ineffective or contraindicated, cryoprecipitate may be given (10 units every 12 to 14 hours). Improvement in bleeding in response to cryoprecipitate is likely related to FVIII and vWF [119]. Correction of anemia to a goal hematocrit of 30% corrects the BT in many patients through improved rheology. This may be accomplished via red cell transfusions in the acute period or erythropoietin over prolonged periods. Erythropoietin may also have beneficial effects on platelet function [120]. Conjugated estrogens may improve uremic bleeding and appears to do so in a dose-dependent manner presumably by reducing NO production [121,122] (reviewed in reference [123]).

Hematologic Disorders

Abnormal platelet function is frequently noted in patients with a number of primary hematologic disorders, including myelodysplastic syndromes and myeloproliferative disorders. The bleeding diathesis occurs out of proportion to what would be expected in patients with similar quantitative platelet defects. In general, the mechanisms underlying the platelet dysfunction seen in these disorders are poorly understood but probably reflect the genetic and developmental abnormalities in stem cells that underlie these disorders. The severity of the predisposition to bleeding cannot be reliably predicted from the results of the bleeding time, platelet count, or in vitro platelet function tests.

The bleeding complications of the myeloproliferative disorders have been estimated in the literature to range from 1.7% to 37%, depending on the disorder and population screened [124]. The bleeding manifestations in both polycythemia vera (PV) and essential thrombocythemia (ET) involve the skin and mucous membranes and include menorrhagia, epistaxis, ecchymosis, and gastrointestinal bleeding. This pattern of bleeding suggests an underlying platelet or vWD defect. It has long been assumed that dysfunctional platelets derived from abnormal stem cells were responsible for increased bleeding with these disorders. Recently, however, there are increasing data to suggest that extreme thrombocytosis may paradoxically result in an acquired type 2 vWD which contributes to the bleeding diathesis [125]. Other conditions associated with acquired vWD include Heyde's syndrome, which is the association of tight aortic stenosis with gastrointestinal arteriovenous malformations. In this condition, the shear stress associated with the stenotic aortic valve consumes the high-molecular-weight multimers of vWF [126].

Treatment of the underlying disorder remains the mainstay though platelet transfusions may be needed for clinically significant bleeding. If acquired vWD is suspected, it should be confirmed through appropriate testing (to be discussed later) prior to initiating directed treatment. Treatment depends largely on the degree of defect and could include intravenous immune globulin, DDAVP, or vWF replacement [125].

OTHER ACQUIRED BLEEDING DISORDERS

Acquired vWD

Acquired vWD is a heterogenous disorder that is associated with a number of different disease states. Several distinct pathophysiological mechanisms are involved which include increased vWF clearance or proteolysis, vWF adsorption to cells with subsequent increased clearance, decreased synthesis, and antibody formation against vWF [127]. Lymphoproliferative and autoimmune disorders are most commonly associated with acquired vWD.

In general, mechanisms underlying acquired vWD are divided into immune- and nonimmune-mediated categories. Immune-mediated acquired vWD is suggested by mixing studies which show an inhibition of vWF in a functional assay. Proposed nonimmune mechanisms include (a) vWF being adsorbed onto cells (e.g., Wilm's tumor, platelets in myeloproliferative disorders, plasma cells in multiple myeloma, and Waldenström's macroglobulinemia), (b) increased proteolysis of HMW multimers at sites of high blood shear flow rates in patients with aortic stenosis, angiodysplasia, and congenital heart disease, (c) decreased synthesis in hypothyroidism, and (d) proteolysis by plasmin during increased periods of fibrinolysis such as with thrombolytic therapy and DIC. A diagnosis should be expected if a patient has a bleeding phenotype similar to a patient with vWD, a compatible underlying disorder, an absence of lifelong bleeding symptoms, and a negative family history [128]. Treatment for acquired vWD is aimed at correcting the underlying disorder if possible and while promoting hemostasis as one would in patients with congenital vWD (e.g., DDAVP, factor concentrates, antifibrinolytics).

Acquired FII (Prothrombin) Inhibitors

Clinically, patients with antiphospholipid antibodies most commonly have a thrombotic phenotype; however, rarely these patients may also have an antibody directed against prothrombin. This antibody binds to prothrombin and increases its clearance, which results in low FII activity levels and clinically significant bleeding. This disorder should be considered in a bleeding patient with evidence for prolongation in PT and PTT. The PT should correct with mixing, the PTT will not. Tests for the lupus inhibitor will be positive, and measurements of FII activity as well as FII antigen will be low. Treatment for acute hemorrhage involves FFP, typically at a dose of 15 to 20 mL per kg with a goal FII activity of > 30% [129]. PCCs may also be used.

Acquired FV Inhibitors

Acquired FV inhibitors are noted to occasionally occur following cardiac surgery after exposure to topical thrombin or fibrin-glue preparations. These preparations may be contaminated with bovine FV and antibodies may form which cross-react with human FV. A recent retrospective analysis of acquired FV patients noted that 68% of patients presented with bleeding events that most commonly manifested as mucocutaneous events [130]. Patients typically present with a significant prolongation in both the PT and PTT. This prolongation fails to correct in a mixing study. Inhibitor specificity to FV is demonstrated with a low FV activity. FFP is not recommended as a treatment since FV is present in such a low concentration that it is quickly neutralized by the inhibitor. PCCs are likewise felt to be unhelpful given their low FV content. Plasma exchange and platelet transfusions have been used successfully to control bleeding. It is thought that FV contained in the alpha granules of circulating platelets is protected from inhibition until the platelet becomes activated at the site of vessel damage. More recently, rFVIIa has been reported to successfully promote hemostasis in a small case series [131].

Acquired FX Deficiency

Acquired FX deficiency is associated with amyloidosis. It is thought that amyloid fibrils bind to FX and thereby remove it from circulation. Treatment of the underlying amyloidosis and/or splenectomy has been shown to improve the circulating FX level [132]. PCCs are the preferred treatment for acute bleeding episodes.

ACKNOWLEDGMENT

This work was supported in part by a grant from the National Hemophilia Foundation-Baxter Fellowship (JB).

CHAPTER 109 ■ THROMBOCYTOPENIA

THOMAS G. DELOUGHERY

Thrombocytopenia is common in the intensive care unit (ICU). Platelet counts below 100,000 per μL occur in 25% to 38% of ICU patients and counts fewer than 10,000 per μL occur in 2% to 3% [1–4]. A variety of disease processes can lead to thrombocytopenia, ranging from an epiphenomenon of the illnesses that lead to the ICU admission to a devastating complication of therapy (Table 109.1).

The immediate priorities in thrombocytopenic patients are to establish the validity and severity of the thrombocytopenia, evaluate for life-threatening processes such as heparin-induced thrombocytopenia or thrombotic thrombocytopenic purpura, and initiate therapy. In the critical care setting, therapeutic decisions often have to be made before a definitive cause of the thrombocytopenia is established.

INITIAL EVALUATION

The initial assessment should be rapid, focusing on whether the patient is bleeding or experiencing thrombosis; the underlying disorder(s) leading to ICU admission; current medications; and (if available) past medical history.

In the assessment of bleeding, one should detect whether the patient is suffering from "structural" aberrancies (e.g., bleeding from a gastric ulcer) or generalized bleeding, which may suggest a hemostatic defect such as may occur due to thrombocytopenia. One should inspect sites of instrumentation, such as IV sites or chest tube drainage, and the mucosa for bleeding. The fingertips and toes should be examined for evidence of emboli or ischemia.

TABLE 109.1

DIFFERENTIAL DIAGNOSIS OF THROMBOCYTOPENIA

Disseminated intravascular coagulation
Drug-induced thrombocytopenia
HELLP syndrome
Hemophagocytic syndrome
Heparin-induced thrombocytopenia
Liver disease
Posttransfusion purpura
Pseudothrombocytopenia
Thrombotic thrombocytopenia purpura

HELLP, hemolysis, elevated liver tests, and low platelets.

TABLE 109.2

LABORATORY TESTS IN EVALUATION OF THROMBOCYTOPENIA

Prothrombin time/INR Activated partial thromboplastin time D-dimer LDH Creatinine Bun Peripheral smear
LDH, lactate dehydrogenase level.

Exposure to medicines is a common cause of thrombocytopenia [5,6]. One should carefully review the record of current and recently administered medications and ask the patient (if possible) and family about medications (prescribed, over the counter, and herbal) [7,8] that the patient has recently taken.

Laboratory Testing

In the patient with thrombocytopenia, examination of the blood smear can quickly reveal whether pseudothrombocytopenia (artifactual platelet clumping) [9] is present and verify the degree of thrombocytopenia (Table 109.2). Although exceptions do exist, the magnitude of thrombocytopenia can be an aid in the differential diagnosis of low platelet counts (Table 109.3). Heparin-induced thrombocytopenia and thrombotic microangiopathy (including thrombotic thrombocytopenic purpura, TTP) often present with modest thrombocytopenia (50 to 100 × 10^9 per L). The smear should be carefully reviewed for presence of fragmented red cells (schistocytes). Laboratory assessment of liver function and renal function also should be assessed. A markedly elevated level of lactate dehydrogenase level (LDH) out of proportion to other liver function abnormalities characteristically occurs in TTP and hantavirus infection [10,11]. If there is any suspicion of HIT, all heparin should be stopped and alternative antithrombotic agents should be started [12,13]. Assessment of platelet function can be difficult and must be based largely on clinical judgment. The bleeding time or the platelet function assay (PFA) is rarely useful in the evaluation of a thrombocytopenic patient, because the low platelet count leads to prolongations in the test endpoint [14].

TABLE 109.3

TYPICAL PLATELET COUNTS IN VARIOUS DISEASE STATES

Moderate thrombocytopenia (50–100,000 per μL) Thrombotic thrombocytopenic purpura Heparin-induced thrombocytopenia Disseminated intravascular coagulation Hemophagocytic syndrome
Severe thrombocytopenia (< 20,000 per μL) Drug-induced thrombocytopenia Posttransfusion purpura Immune thrombocytopenia

Diagnostic Clues

The reason for the ICU admission is a very important indicator in evaluation of thrombocytopenia (Table 109.4) [15]. For example, thrombocytopenia in patients who present with sudden-onset multiorgan system failure may indicate TTP or sepsis. In long-term critical care patients, new-onset thrombocytopenia may be a manifestation of HIT, drug-induced thrombocytopenia, occult or established sepsis, or bacteremia [16].

IMMEDIATE THERAPY—PLATELET TRANSFUSION

Although platelet thresholds below which critically ill patients are at risk for severe bleeding are likely to vary among patients, clinical practice generally dictates that a platelet count above 10,000 per μL does not require platelet transfusion, as long as the patient is stable without signs of bleeding, is not receiving platelet inhibitors, has preserved renal function, does not require an invasive procedure, and does not have aggressive DIC [17]. If any of these is present, especially major or life-threatening hemorrhage (such as intracranial), then a threshold of greater than 50,000 per μL is reasonable [18,19]. An exception is thrombocytopenia due to thrombotic microangiopathy (TTP), wherein platelet transfusion is contraindicated unless perhaps the platelets are transfused slowly and plasma exchange already is underway. Platelet transfusions should comprise six to eight platelet concentrates or one single-donor plateletpheresis unit. Additional discussion regarding transfusion of blood products in critically ill patients is found in Chapter 114.

THROMBOCYTOPENIA

Heparin-Induced Thrombocytopenia

HIT occurs due to the formation of antibodies directed against the complex of heparin and platelet factor 4 [12,20]. This complex in a minority of cases binds to the Fcγ RIIA receptor, activating platelets and macrophages. The frequency of HIT is 1% to 5% when unfractionated heparin is used but less than 1% with low-molecular-weight heparin [21]. HIT is more common in women and more common in surgery patients than medical patients [22].

HIT should be suspected when there is a sudden onset of thrombocytopenia with either at least a 50% drop in the platelet count from baseline or the platelet count falling to less than 100 × 10^9/L in a patient receiving heparin in *any* form. HIT usually occurs at least 4 days after starting heparin but may occur suddenly in patients with recent (less than 3 months) exposure [23]. An often overlooked feature of HIT is recurrent thrombosis in a patient receiving heparin despite a normal platelet count [24]. Recently, a scoring system—the four Ts—has been validated in several critical care studies as a means of assessing the pretest probability of HIT [25,26] (Table 109.5).

Patients with very low scores are very unlikely to have HIT and can forgo PF4-heparin antibody testing and empiric therapy. A biphasic pattern of thrombocytopenia following cardiac surgery—namely, recovery from the postsurgical thrombocytopenia followed by recurrent thrombocytopenia—is strongly predictive for HIT [27].

The diagnosis of HIT can be challenging in the critical care patient who has multiple reasons for being thrombocytopenic.

TABLE 109.4

DIAGNOSTIC CLUES TO THROMBOCYTOPENIA

Clinical setting	Differential diagnosis
Cardiac surgery	Cardiopulmonary bypass, HIT, dilutional thrombocytopenia, TTP
Interventional cardiac procedure	Abciximab or other IIb/IIIa blockers, HIT
Sepsis syndrome	DIC, ehrlichiosis, sepsis hemophagocytic syndrome, drug-induced, misdiagnosed TTP, mechanical ventilation, pulmonary artery catheters
Pulmonary failure	DIC, H1N1, infection hantavirus pulmonary syndrome, mechanical ventilation, pulmonary artery catheters
Mental status changes/ seizures	TTP, ehrlichiosis
Renal failure	TTP, dengue, HIT, DIC
Cardiac failure	HIT, drug-induced, pulmonary artery catheter
Postsurgery	Dilutional, drug-induced, HIT, TTP
Pregnancy	HELLP syndrome, fatty liver of pregnancy, TTP/HUS
Acute liver failure	Splenic sequestration, HIT, drug-induced, DIC

DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver function tests, and low platelets; HIT, heparin-induced thrombocytopenia; TTP, thrombotic thrombocytopenic purpura.

In this situation, the laboratory assay for HIT may be helpful. Two levels of HIT testing exist. Increasingly, an ELISA assay that detects the presumed pathogenic antiheparin-platelet factor 4 antibodies is evaluated initially [13]. This test is very sensitive but in some populations not specific. For example, 25% to 50% of cardiac surgery patients will show positive results (presumably due to platelet activation in the bypass circuit) [28,29]. A negative test rules out HIT in all but the highest-risk patients.

A second type of test, a (functional) platelet aggregation assay, such as the serotonin release assay, comprises patient plasma, donor platelets, and heparin. If added heparin induces platelet aggregation, the test is considered to be positive. The test is technically demanding, but if performed carefully can be sensitive and specific [12,13,30]. One caveat is that early in the HIT disease process, the test can be negative but then turns positive 24 hours later as the antibody titer increases. Due to substantial frequency of false positivity of PF4-heparin ELISA among cardiovascular, dialysis, and vascular surgery patients, a diagnosis of HIT should be confirmed by a serotonin release assay, even if treatment for HIT already has been initiated.

The first step in therapy of HIT consists of stopping *all* heparin. Low-molecular-weight heparins cross-react with the HIT antibodies and therefore these agents are also contraindicated. Institution of warfarin therapy alone following a diagnosis of HIT has been associated with an increased risk of thromboses and is also contraindicated. Due to the high risk of thrombosis (53% in one study) [21] among HIT patients, antithrombotic therapy should be administered to all patients [12]. For immediate therapy of HIT patients, several antithrombotic agents are available [12,20,31] (Table 109.6).

Argatroban is a synthetic thrombin inhibitor with a short half-life of 40 to 50 minutes [12,32]. Dosing is 2 µg per kg per minute with the infusion adjusted to keep the aPTT 1.5 to 3 times normal. One advantage of argatroban is that it is not renally excreted and no dose adjustment is necessary in renal disease [33]. These characteristics make it the most useful agent for patients in the critical care unit. However, argatroban

TABLE 109.5

PREDICTION RULE FOR HEPARIN-INDUCED THROMBOCYTOPENIA

Points	2	1	0
Thrombocytopenia	> 50% fall from baseline and nadir 20–100 × 10^9/L	30%–50% fall or nadir 10–19 × 10^9/L	Fall < 30% or nadir < 10 × 10^9/L
Timing of platelet fall	Onset day 5–10 of heparin or < 1 d if patient recently exposed to heparin	Consistent but not clear records or count falls after day 10	Platelets fall < 5 d and no recent (100 d) heparin
Thrombosis	New thrombosis or skin necrosis or systemic reaction with heparin	Progressive or recurrent thrombosis or suspected but not proven thrombosis	None
Other cause for thrombocytopenia	None	Possible	Definite

Notes: Patients with a low probability score are very unlikely to have HIT and can forgo PF4-heparin antibody testing and empiric therapy. Patients with intermediate and high scores should receive empiric therapy until definitive testing can be obtained.
Total score: 6–8, high probability; 4–5, intermediate probability; 0–3, low probability.
Adapted from Lo et al. [25] and Crowther et al. [26].

TABLE 109.6

TREATMENT OF HEPARIN-INDUCED THROMBOCYTOPENIA

Argatroban
Therapy: initial dose of 2 μg/kg/min adjusted to an aPTT of 1.5–3.0 times normal
Reversal: no antidote but $T_{1/2}$ □ 40 min
In severe liver disease (jaundice) dose at 0.5 μg/kg/min adjusted to an aPTT 1.5–3.0 times normal
For patients with multiorgan system failure: 1 μg/kg/min adjusted to aPTT 1.5–3.0 times normal
Post-CABG—0.5–1 μg/kg/min adjusted to aPTT 1.5–3.0 times normal
Indication: prevention and treatment of thrombosis in HIT

Bivalirudin
Bolus: 1 mg/kg
Infusion: 2.5 mg/kg/h for 4 h and then 0.2 mg/kg/h for 14–20 h
Renal adjustment:
For creatinine clearance of 30–59 mL/min, decrease dose by 20%
For creatinine clearance of 10–29 mL/min, decrease dose by 60%
For creatinine clearances less than 10 mg/min, decrease dose by 90%
Note: Antilepirudin antibodies may cross-react with bivalirudin
Indication: Percutaneous coronary intervention, in patients with or without HIT

Lepirudin
Therapy: VERY sensitive to renal function—half-life can go from less than an hour to over 100 h in renal failure. Not recommended in renal insufficiency. May be used in hepatic failure.
- Initial IV bolus 0.4 mg/kg IV push (may be omitted or reduced to 0.2 mg/kg, unless there is life- or limb-threatening thrombosis):
- Continuous infusion: initial rate determined by renal function:
  - GFR > 60 mL/min: 0.10 mg/kg/h
  - GFR 45–60 mL/min: 0.075 mg/kg/h
  - GFR < 45 mL/min: lepirudin not recommended (consider argatroban)
- Perform aPTT at 4-h intervals until steady state within the therapeutic range (1.5–2.0 times patient baseline aPTT) is achieved

Notes: Antilepirudin antibodies form in 60%–80% of patients on lepirudin and can prolong lepirudin effect. Rare patients may have fatal anaphylaxis.
Indication: Prevention and treatment of thrombosis in HIT

Fondaparinux[a]
Therapy: 7.5 mg every 24 h (consider 5.0 mg in patients under 50 kg and 10 mg in patients over 100 kg)
Reversal: protamine ineffective; see Chapter 110: Antithrombotic Therapy.

[a]Fondaparinux is not approved for treatment of HIT. Its use, however, may be considered after initial anticoagulation with a direct thrombin inhibitor has been administered and the platelet count has recovered, while awaiting a therapeutic INR from therapy with warfarin.
Adapted from Laposata et al. [31], Kondo et al. [32], Hyers et al. [212], Hirsh et al. [213], Hirsh et al. [214].

must be used with caution in patients with severe liver disease by using an initial dose of 0.5 μg per kg per minute [32]. Also metabolism appears to be decreased in patients with multiorgan system failure and these patients should receive a dose of 1 μg per kg [34]. Argatroban (like all thrombin inhibitors) prolongs the prothrombin time/INR (PT/INR) making initiation of warfarin therapy difficult. If available, the chromogenic Xa assay can be used to adjust warfarin therapy [35]. Also, if the patient is on a drip of 2 μg per kg per minute or less, one can simply aim for a PT/INR of more than 4.0 as therapeutic. Unfortunately, there is no agent that can reverse argatroban.

Lepirudin, another direct inhibitor of thrombin, is also monitored using the aPTT. The half-life of lepirudin is short, but the drug accumulates in renal insufficiency with the half-life increasing to more than 50 to 100 hours. Recent data indicate that a lower dosing regimen that is recommended on the package insert may result in lower bleeding rates [12]. There is no antidote for lepirudin. Patients with even slight renal insufficiency (creatinine greater than 1.5) must have their lepirudin doses adjusted to avoid overanticoagulation [36]. Up to 80% of patients receiving long-term lepirudin therapy will develop antibodies that reduce the metabolism of hirudin and *increase* the therapeutic effect of lepirudin [37,38]. Patients on long-term (> 6 days) lepirudin therapy should still continue to have monitoring to avoid overanticoagulation.

Bivalirudin is a semisynthetic direct thrombin inhibitor. Its indication involves patients undergoing percutaneous coronary intervention, but other patients may receive it as a treatment for HIT.

The indirect anti-Xa inhibitor fondaparinux does not cross-react with HIT antibodies [12,39], suggesting a potential role in therapy of HIT [40]. However, it has not been studied as extensively in HIT as have the DTIs. Additionally, exposure to fondaparinux has been rarely associated with a syndrome similar to delayed-onset HIT [41]. In the future, newer agents such as dabigatran and rivaroxaban may be suitable for management of patients with HIT.

The issue of platelet transfusion remains controversial [42]. Patients with HIT rarely bleed, which reduces clinical concern over the potential for platelet transfusions, but a prudent

approach would be to reserve transfusion of platelets for the rare patient with severe thrombocytopenia who also has life-threatening bleeding.

As mentioned earlier, initiation of warfarin as the sole antithrombotic agent in the initial treatment of HIT has been associated with limb gangrene. In patients receiving a direct thrombin inhibitor, warfarin can be started in small doses (2 to 5 mg daily) once the platelet count has recovered. These often malnourished patients tend to have a dramatic response to warfarin therapy and excessive anticoagulation can easily occur. One should overlap warfarin and parental therapy by 2 to 3 days as there is evidence that patients may do worse if therapy with a DTI is truncated [32].

Patients with HIT should be carefully screened for any thrombosis, at least by performing lower extremity Doppler ultrasound. If thrombosis is present, at least 3 months of therapeutic anticoagulation are required, whereas HIT without thrombosis usually is treated with 30 days of therapeutic anticoagulation.

Thrombotic Thrombocytopenic Purpura

TTP should be suspected when any patient presents with thrombocytopenia and microangiopathic hemolytic anemia (as evidenced by schistocytes on the blood smear and biochemical evidence of hemolysis); end-organ damage, mostly manifesting as renal insufficiency or neurologic phenomena, and fever also may occur, although the minority of patients with TTP present with all of the aforementioned features [43–45]. Critical care patients with TTP most often present with intractable seizures, strokes, or sequela of renal insufficiency. Postsurgical TTP may occur 1 to 2 weeks after major surgery, and is heralded by decreasing platelet counts and renal insufficiency [46]. Many patients who present to the critical care unit with TTP have been misdiagnosed as having sepsis, "lupus flare," or vasculitis.

Evidence is strong that many patients with the classic form of TTP have an inhibitor against an enzyme that is responsible for cleaving newly synthesized von Willebrand factor (vWF) [45,47,48]. vWF is synthesized as an ultra large multimer that can spontaneously aggregate platelets. The enzyme, ADAMTS13, cleaves vWF into a smaller form that can circulate [48,49]. Presumably when ADAMTS13 is inhibited in TTP, the ultra large multimers can spontaneously aggregate platelets leading to the clinical syndrome of TTP. However, many patients with classic TTP have normal activity of ADAMTS13 and reduced levels are found in other diseases implying other factors are important in pathogenesis of TTP [50–52].

There is currently not a single diagnostic test for TTP but rather the diagnosis is based on the clinical presentation [43,45]. Patients uniformly will have a microangiopathic hemolytic anemia with the presence of schistocytes on the peripheral smear. Renal insufficiency and not frank renal failure is the most common renal manifestation. Thrombocytopenia may range from a mild decrease in platelet number to platelets being undetectable. The findings of thrombocytopenia with a relative normal prothrombin time help eliminate DIC from the differential [53]. The LDH is often extremely elevated and is a prognostic factor in TTP [54]. Finding very low levels of ADAMTS13 due to an inhibitor may also be a negative prognostic factor [55]. However, lack of standardization and slow turnaround time still make this assay difficult to use clinically.

Untreated TTP is rapidly fatal. Mortality in the preplasma exchange era ranged from 95% to 100%. Today plasma exchange therapy is the cornerstone of TTP treatment and has reduced mortality to less than 20% [11,43,56–58].

Glucocorticoid therapy, either 1 to 2 mg per kg of methylprednisolone until remission or 1 g of methylprednisolone initially, may be given to patents presumed to have TTP, although this intervention is not practiced in all centers [45]. The glucocorticoid may be continued until the patient has fully recovered and perhaps longer, given the presumed autoimmune nature of the disease and the high relapse rates. Plasma infusion is beneficial but [47] plasma exchange has been shown to be superior to simple plasma infusion in therapy of TTP [56]. This may be due to the ability of plasma exchange to give very large volumes of fresh frozen plasma and removal of inhibitory antibodies. In patients who cannot be immediately exchanged, plasma infusions should be started at a dose of one unit every 4 hours. Patients with all but the mildest cases of TTP should receive 1 to 1.5 plasma volume exchange each day for at least 5 days [43]. Daily plasma exchange should be continued daily until the LDH has normalized, at which point the frequency of exchange may be taped, starting with every-other-day exchange. If the platelet count falls or LDH level rises, daily exchange should be reinstated [59]. Since the platelet count can be affected by a variety of external influences, the LDH level tends to be the most reliable marker of disease activity [60]. There is increasing evidence that the use of the anti-CD20 therapy may reduce the incidence of relapses and shorten the duration of therapy in refractory disease [48].

Renal insufficiency should be managed in the typical fashion. About 50% of patients require renal replacement therapy.

Hemolytic Uremic Syndrome

Classically, hemolytic uremic syndrome (HUS) comprises the triad of renal failure, microangiopathic anemia, and thrombocytopenia [61,62]. Two major forms are recognized: a "typical" form, which occurs in young children with an antecedent diarrheal illness, and an "atypical" form.

Typical HUS

Typical HUS (also referred to as HUS D+) occurs typically in children under the age of 4, although cases in adolescents and adults may occur. Children often have a prodrome of diarrhea, usually bloody [63,64]. Children come to medical attention due to symptoms of renal failure. In HUS, thrombocytopenia can be mild in the 50,000 per μL range. Extrarenal involvement is common in typical HUS. Neurologic involvement can be seen in 40% of patients with seizure being the predominant feature. Elevated liver function tests are seen in 40% of patients and 10% of patients will have pancreatitis. Patients with classic HUS will respond to conservative therapy and renal replacement therapy, but severe cases or those with prominent extrarenal manifestations may require response to plasma exchange [65]. Unfortunately, although most patients recover some renal function, many patients will have long-term renal damage.

Atypical HUS

Atypical HUS is best described as HUS without preceding *Escherichia coli* infection [66,67]. This description obviously lacks diagnostic precision, but in general, this term has been applied to HUS which has prominent extrarenal symptomatology, and the prognosis is thought to be worse for atypical HUS [65]. HUS in older patients and HUS without preceding diarrhea may also better be described as having atypical HUS. Therapy for atypical HUS is plasma exchange but the effectiveness of this intervention is debatable [68]. Patients with atypical HUS, especially older patients, may require months of plasma exchange several times each week to control the disease. Chronic renal insufficiency or failure often ensues. Some patients are found to have defects in the regulatory proteins of complement such as factor H [69].

Therapy-Related TTP/HUS

TTP/HUS syndromes can complicate a variety of therapies [70,71]. TTP/HUS can be associated with medications such as cyclosporine, tacrolimus, gemcitabine, and clopidogrel. Cyclosporine/tacrolimus-associated TTP/HUS occurs within days after the agent is started manifesting as a falling platelet count, falling hematocrit, and rising serum LDH level [71,72]. Some cases have been fatal but often the TTP/HUS resolves with decreasing the dose of the calcineurin inhibitor or changing to another agent.

In the past TTP/HUS was most commonly seen with the antineoplastic agent mitomycin C, with a frequency of 10% when a dose of more than 60 mg was used [73]. Anecdotal reports indicated that treatment with staphylococcal A columns was useful for this condition [74]. Now, the most common antineoplastic drug causing TTP/HUS is gemcitabine [75–78]. Like with mitomycin, the appearance of the TTP/HUS syndrome associated with gemcitabine can be delayed, and the condition often is fatal. Severe hypertension often precedes the clinical appearance of the TTP/HUS [79]. The use of plasma exchange is controversial [80], since advanced cancer itself can be associated with a TTP-like syndrome that is typically poorly responsive to plasma exchange. The increasing use of vascular endothelial growth factor (VEGF) inhibitors such as bevacizumab and sunitinib has been associated with observation of related TTP/HUS syndromes as well [81–83].

TTP/HUS has been reported with other drugs including the thienopyridines, ticlopidine, and clopidogrel [84]. The frequency of ticlopidine-associated TTP may be as high as 1:1,600, and since this drug was often prescribed for patient with vascular disease, these patients may have been initially misdiagnosed as having recurrent strokes or angina [75,78]. The frequency of TTP using clopidogrel is much less—0.0001%—but since it is widely prescribed, it is the second most common cause of drug-induced TTP [84]. Almost all cases of clopidogrel-induced TTP occur within 2 weeks of starting the drug. All patients with thienopyridine-associated TTP should receive plasma exchange.

TTP/HUS can complicate both autologous and allogeneic hematopoietic stem cell transplants [85–89]. The frequency ranges widely, depending on the criteria used to diagnose TTP/HUS, but it is in the range of 15% for allogeneic and 5% for autologous hematopoietic stem cell transplantation procedures [86,87]. One type, characterized by fulminant multiorgan failure occurs early after transplantation (e.g., within 20 to 60 days), has multiorgan system involvement, is often fatal, and has been associated with severe cytomegalovirus (CMV) infection. Another type of TTP/HUS is similar to cyclosporine/tacrolimus-associated HUS. TTP/HUS that is associated with the conditioning regimen used in the transplantation protocol occurs 6 months or more after total body irradiation, and is associated with primary renal involvement. Finally, patients with systemic CMV infections may present with a TTP/HUS syndrome related to vascular infection with CMV. The etiology of hematopoietic stem cell transplantation-related TTP appears to be different from that of "classic" TTP since alterations of ADAMTS13 have not been found in bone marrow transplant-related TTP implicated in therapy-related vascular damage [90]. The best management of hematopoietic stem cell transplantation-related TTP/HUS is uncertain. Patients should have doses of cyclosporine or tacrolimus decreased, if taking calcineurin inhibitors. Although plasma exchange is often tried, patients with fulminant or conditioning-related TTP/HUS or those with TTP/HUS and concomitant acute graft versus host disease typically do not respond [91–93].

Pregnancy-Related Thrombocytopenic Syndromes

One should consider three syndromes in the critically ill pregnant woman who presents with thrombocytopenia. These are the HELLP syndrome, fatty liver of pregnancy, and TTP (Table 109.7) [94,95].

The acronym HELLP syndrome (**H**emolysis, **E**levated **L**iver tests, **L**ow **P**latelets) describes a variant of pre-eclampsia [96,97]. Classically, HELLP syndrome occurs after 28 weeks of gestation in a patient suffering from pre-eclampsia but can occur as early as 22 weeks in patients with the antiphospholipid antibody syndrome [98]. The pre-eclampsia need not be severe. The first sign of HELLP is a decrease in the platelet count followed by abnormal liver function tests. Signs of hemolysis are present with abundant schistocytes on the smear and a high LDH. HELLP can progress to liver failure and deaths are also reported due to hepatic rupture. Unlike TTP, fetal involvement is present in the HELLP syndrome with fetal thrombocytopenia reported in 30% of cases. In severe cases, elevated D-dimers consistent with DIC are also found. Delivery of the child will most often result in cessation of the HELLP syndrome but refractory cases will require dexamethasone and plasma

TABLE 109.7

PREGNANCY-RELATED DISEASES—TTP/HUS, HELLP SYNDROME, AND ACUTE FATTY LIVER OF PREGNANCY (AFLP)

	HELLP	TTP/HUS	AFLP
Hypertension	Always present	Sometimes present	Sometimes present
Proteinuria	Always present	Sometimes present	Sometimes present
Thrombocytopenia	Always	Always	Always
LDH elevation	Present	Marked	Present
Fibrinogen	Normal to low	Normal	Normal to very low
Schistocytes	Present	Present	Absent
Liver tests	Elevated	Normal	Elevated
Ammonia	Normal	Normal	Elevated
Glucose	Normal	Normal	Low

HELLP, hemolysis, elevated liver tests, and low platelets; TTP/HUS, thrombotic thrombocytopenic purpura/hemolytic uremia syndrome.
Adapted from Sibai [94], Steingrub [95], Egerman and Sibai [104], Esplin and Branch [105].

exchange [99]. About a quarter of women who suffer from HELLP will have a recurrence with a later pregnancy [100].

Fatty liver of pregnancy also occurs late in pregnancy and is only associated with pre-eclampsia in 50% of cases [101–103]. Patients first present with nonspecific symptoms of nausea and vomiting but can progress to fulminant liver failure. Patients develop thrombocytopenia early in the course but in the later stages can develop DIC and very low fibrinogen levels. Mortality rates without therapy can be as high as 90%. Low glucose and high ammonia levels can help distinguish fatty liver from other pregnancy complications [104]. Treatment consists of prompt delivery of the child and aggressive blood product support.

TTP can occur anytime during pregnancy often leading to diagnostic confusion due to the overlap symptoms between TTP and HELLP syndrome [100,104]. There does appear to be a unique presentation of TTP that occurs in the second trimester at 20 to 22 weeks [105]. The fetus is uninvolved with no evidence of infarction or thrombocytopenia if the mother survives. The pregnancy appears to promote the TTP since the TTP will resolve with termination of the pregnancy and can recur with the next pregnancy [106]. Therapy includes terminations of the pregnancy or attempting to support the patient with plasma exchange until delivery. Many patients will have relapses with future pregnancies so this information must be weighed in planning future pregnancies. An unusual complication of pregnancy is a HUS-type syndrome seen up to 28 weeks' postpartum. This form of HUS is severe, and permanent renal failure often results despite aggressive therapy. When evaluated, many of these patients will be found to have defects in regulatory proteins of complement such as factor H deficiency, perhaps explaining the virulence of their renal failure [107].

Disseminated Intravascular Coagulation

At the most basic level, DIC is the clinical manifestation of inappropriate thrombin activation [108–111]. Inappropriate thrombin activation can be due to causes such as sepsis, obstetric disasters, etc. The activation of thrombin leads to (a) conversion of fibrinogen to fibrin, (b) activation of platelets (and their consumption), (c) activation of factors V and VIII, (d) activation of protein C (and degradation of factors Va and VIIIa), (e) activation of endothelial cells, and (f) activation of fibrinolysis.

The clinical manifestations of DIC in a given patient depend on the balance of thrombin activations and secondary fibrinolysis plus the patient's ability to compensate for the DIC. Patients with DIC can present in one of four patterns [108,110]:

1. Asymptomatic. Patients can present with laboratory evidence of DIC but no bleeding or thrombosis. This is often seen in patients with sepsis or cancer. However, with further progression of the underlying disease, these patients can rapidly become symptomatic.
2. Bleeding. The bleeding is due to a combination of factor depletion, platelet dysfunction, thrombocytopenia, and excessive fibrinolysis [108]. These patients may present with diffuse bleeding from multiple sites—IV sites, areas of instrumentation, etc.
3. Thrombosis. Despite the general activation of the coagulation process, thrombosis is unusual in most patients with acute DIC. The exceptions include cancer patients, trauma patients, and certain obstetrical patients. Most often the thrombosis is venous, but arterial thrombosis and nonbacterial thrombotic endocarditis have been reported [112].
4. Purpura fulminans. This severe form of DIC is described in more detail later.

TABLE 109.8

MANAGEMENT OF DISSEMINATED INTRAVASCULAR COAGULATION (DIC): TRANSFUSION

The five basic tests of hemostasis[a]
- Hematocrit
- Platelet count
- Prothrombin time (PT)
- Activated partial thromboplastin time (aPTT)
- Fibrinogen level

Guidelines for transfusion in patients at high risk of bleeding[b]
- A. Platelets < 50,000 per μL: give platelet concentrates or 1 unit of single-donor platelets.
- B. Fibrinogen < 80–100 mg/dL: give 10 units of cryoprecipitate[c]
- C. Hematocrit below 30%: give red cells
- D. Protime > twofold the upper limit of normal *and* aPTT abnormal: give 2–4 units of FFP[d]

[a] These laboratory tests should be repeated after administering blood products serially. A record of the test and the blood products administered should be maintained.
[b] Patients with DIC who are not actively bleeding generally do not require replacement of platelets or coagulation factors, unless an invasive procedure is planned or other circumstances are present; see text.
[c] For a fibrinogen level less then 100 mg/dL, transfusion of 10 units of cryoprecipitate is expected to increase the plasma fibrinogen level by 100 mg/dL.
[d] In patients with DIC and a markedly prolonged PT and aPTT, one can give 2–4 units of fresh frozen plasma (FFP) initially.

The best way to treat DIC is to treat the underlying cause that is driving the thrombin generation [108,109,111, 113,114]. In the past, there was concern about replacement of depleted blood cells and coagulation proteins in DIC due to fears of "feeding the fire." However, such hesitation has not been well validated, and one must provide replacement if depletion occurs and bleeding ensues [115]. Measurement of laboratory tests that will reflect the basic parameters essential for both blood volume and hemostasis may be helpful [18,116]. Replacement therapy is based on the results of these laboratories and the clinical situation of the patient (Table 109.8). Additional discussion regarding transfusion of blood products in critically ill patients is found in Chapter 114. DIC complicating acute promyelocytic leukemia is discussed in detail in Chapter 115.

Heparin therapy is reserved for the patient who has thrombosis as a component of their DIC [109,117,118]. Given the coagulopathy that is often present, one should use specific heparin levels instead of the aPTT to monitor anticoagulation [119,120].

Purpura Fulminans

DIC in association with necrosis of the skin may occur in two situations [121,122]. One, primary purpura fulminans, is most often seen after a viral infection [123]. In these patients, the purpura fulminans starts with a painful red area on an extremity that rapidly progresses to a black ischemic lesion. In many patients, acquired deficiency of protein S is found [121, 124,125].

Secondary purpura fulminans is most often associated with meningococcemia infections, but it can occur in any patient with overwhelming infection [126–128]. Postsplenectomy sepsis syndrome patients and those with functional hyposplenism

due to chronic liver diseases are also at risk [129]. Patients present with signs of sepsis, and the skin lesions often involve the extremities that may lead to amputation. As opposed to primary purpura fulminans, those with secondary purpura fulminans will have symmetrical ischemic at the distal parts of the body (toes and fingers) that ascend as the process progresses. Rarely, adrenal infarction (Waterhouse–Friderichsen syndrome) can occur which leads to severe hypotension [130].

Therapy for purpura fulminans is controversial. Primary purpura fulminans, especially cases with postvaricella autoimmune protein S deficiency, may respond to plasma infusion titrated to keep the protein S level more than 25% [121]. Intravenous immune globulin has also been reported to help decrease the antiprotein S antibodies. Heparin has been reported to control the DIC and extent of necrosis [131]. The starting dose in these patients is 5 to 8 units per kg per hour [109].

Sick patients with secondary purpura fulminans have been treated with plasma drips, plasmapheresis, and continuous plasma ultrafiltration [131–134]. Heparin therapy alone has not been shown to improve survival [135]. Much attention has been given to replacement of natural anticoagulants such as protein C and antithrombin as therapy for purpura fulminans but unfortunately randomized trials using antithrombin have shown mostly negative results [121,125,136–138]. Trials using either zymogen protein C concentrates or rAPC have shown more promise in controlling the coagulopathy of purpura fulminans and improving outcomes in sepsis [132,139–143]. Although bleeding is a concern with use of protein C, most complications occur in patients with platelet counts under 30×10^9/L or in those who have meningitis [144]. If recombinant activated protein C is used, one should also very carefully monitor other parameters of coagulation. Unfortunately, many patients will need debridement and amputation; in one review approximately 66% of patients required amputation [122].

Drug-Induced Hemolytic-DIC Syndromes

A severe variant of the drug-induced immune complex hemolysis associated with DIC has been recognized. Rare patients who receive certain second- and third-generation cephalosporins (especially cefotetan and ceftriaxone) [145] have developed this syndrome [146–151]. The clinical syndrome starts 7 to 10 days after receiving the drug, and often the patient has only received the antibiotic for surgical prophylaxis. Severe Coombs'-positive hemolysis with hypotension and DIC develops. The patients are often believed to have sepsis and often re-exposed to the cephalosporin, resulting in worsening of the clinical status. The outcome is often fatal due to massive hemolysis and thrombosis [148,152–154].

Quinine is associated with a unique syndrome of drug-induced DIC [155–158]. Approximately 24 to 96 hours after quinine exposure, the patient becomes acutely ill with nausea and vomiting. The patient then develops a microangiopathic hemolytic anemia, DIC, and renal failure. Some patients, besides having antiplatelet antibodies, also have antibodies that bind to red cells and neutrophils that may lead to the more severe syndrome. Despite therapy, patients with quinine-induced TTP frequently manifest chronic renal failure.

Treatment of the drug-induced hemolytic-DIC syndrome is based on anecdotal reports. Patients have responded to aggressive therapy including plasma exchange, dialysis, and prednisone. Early recognition of the hemolytic anemia (and the suspicion that it is drug-related) is important for early diagnosis so that the incriminating drug can be discontinued. DIC associated with acute promyelocytic leukemia is discussed in detail in Chapter 115.

Drug-Induced Thrombocytopenia

Patients with drug-induced thrombocytopenia typically present with very low platelet counts 1 to 3 weeks after starting a new medication [159,160]. One of the agents most commonly associated with drug-induced thrombocytopenia in the critical care setting is vancomycin. The thrombocytopenia is acute and severe (below $< 10 \times 10^9$/L), is durably refractory to platelet transfusions, and resolves within days of stopping the drug [161]. In patients with a possible drug-induced thrombocytopenia, the primary therapy is to stop the suspect drug, although patients with severe thrombocytopenia generally should receive platelet transfusions due to the risk of fatal bleeding [159,162]. However, with vancomycin-induced thrombocytopenia, the patient may be refractory to platelet transfusion [161,163]. If there are multiple new medications, the best approach is to stop any drug that is strongly associated with thrombocytopenia [164] (Table 109.9). Immune globulin, corticosteroids, and intravenous anti-D have been suggested as useful in drug-related thrombocytopenia. However, since most of these thrombocytopenic patients recover when the agent is cleared from the body, this therapy is probably not necessary and avoids exposing the patient to additional drug-associated adverse events.

TABLE 109.9

CRITICAL CARE DRUGS COMMONLY IMPLICATED IN THROMBOCYTOPENIA

- Antiarrhythmics
  - Procainamide
  - Quinidine
- Anti-GP IIb/IIIa agents
  - Abciximab
  - Eptifibatide
  - Tirofiban
- Antimicrobial
  - Amphotericin B
  - Fluoroquinolones
  - Rifampin
  - Trimethoprim-sulfamethoxazole
  - Vancomycin
- H_2-blockers
  - Cimetidine
  - Ranitidine
- Acetaminophen
- Bevacizumab
- Carbamazepine
- Danazol
- Efalizumab
- Gold
- Heparin
- Hydrochlorothiazide
- Interferon
- Methyldopa
- Nonsteroidal anti-inflammatory agents
- Trastuzumab
- Quinine

Sepsis

Thrombocytopenia associated with sepsis syndromes classically has been attributed to DIC or destruction by autoimmune mechanisms [165–167]. Increasing evidence, however, points to cytokine-driven hemophagocytosis of platelets [168–171]. Patients with hemophagocytosis appear to have higher rates of multiple organ system failure and higher mortality rates. Inflammatory cytokines, especially monocyte-colony stimulating factor (M-CSF), are thought responsible for inducing the hemophagocytosis [166,172].

Thrombocytopenia may be a diagnostic clue to infection with unusual organisms [173]. Three members of the Ehrlichia family have been reported to cause infections in humans [174,175]. They are transmitted by ticks and the diseases that they produce are similar. Most patients have a febrile illness with high fevers, headaches, and myalgias [174,176]. Patients may have central nervous system signs and marked elevation of the serum levels of liver enzymes. Rarely patients may present with a toxic shock-like syndrome [177]. Although many cases are mild, severe disease is common and the case fatality rate is 2% to 5% [176]. The typical hematologic picture is leukopenia (1.3 to 4 × 10^9 per L) and mild thrombocytopenia (30 to 60 × 10^9 per L). In many patients, the buffy coat reveals the organisms bundled in a 2 to 5 µm morula in the cytoplasm of the granulocytes or monocytes. Consideration of ehrlichiosis is important because highly specific therapy is doxycycline, which is a drug not routinely used for therapy of sepsis syndrome.

The classical hematological presentation of Hantavirus pulmonary syndrome (HPS) can be helpful in the diagnosis of this severe illness. Patients suffer a flu-like prodrome and then rapidly develop a noncardiac pulmonary edema resulting in profound respiratory failure [10,178]. Ventilatory support is required in 75% of cases and the mortality is approximately 50%. A powerful indicator to the presence of Hantavirus is found on the peripheral smear [10,179]. The triad of thrombocytopenia, increased and left-shifted white cell count, and more than 10% circulating immunoblasts can identify all cases of HPS and was seen in only 2.6% non-HPS controls in a recent study [10]. Marked hemoconcentration is also present due to capillary leak syndrome with the hematocrit reaching in some patients as high as 68%.

Viral Hemorrhagic Fevers

Viral hemorrhagic fevers (VHFs) are a diverse group of viral infections that can result in massive bleeding [180–182]. VHFs are an important problem in certain parts of the world but travelers may carry the disease anywhere. In the Southern United States, dengue is becoming an increasing problem and fatal cases of arenavirus have been reported in California [183]. As described in Table 109.10, there are four groups of viruses which can lead to VHFs [184,185].

The typical pattern is a febrile illness that proceeds over a few days to shock and diffuse bleeding with the patient developing signs of thrombocytopenia and in some cases DIC. A key sign is that patients will experience profuse bleeding from the gastrointestinal track and mucosal bleeding often out of proportion to the observed coagulation defects. This finding should serve as a diagnostic clue. Most VHFs are also associated with leukopenia and hemoconcentration. Therapy is aggressive supportive care of the patients and replacement of coagulation factors. As noted in Table 109.10, ribavirin can treat certain VHFs. Given the propensity of many of these infections to spread to healthcare workers, precautions should be taken to prevent nosocomial spread [186].

TABLE 109.10

VIRAL HEMORRHAGIC FEVER-ASSOCIATED THROMBOCYTOPENIA

Arenaviridae
- Diseases: Lassa fever, New World arenaviruses
- Distribution: West Africa (Lassa), South America [rare California] (New World)
- Vector: rodents
- Incubation: 5–16 d
- Therapy: ribavirin
- Unique clinical features: pharyngitis, late deafness (Lassa); neurological involvement–seizures (New World)

Bunyaviridae
- Diseases: Crimean–Congo hemorrhagic virus (CCHF), Rift Valley fever, hemorrhagic fever with renal syndrome (HFRS)
- Distribution: Africa, central Asia, eastern Europe, Middle East (CCHF), Africa, Middle East (Rift), Asia, Balkans, Europe (HFRS)
- Vector: ticks (CCHF), mosquitoes (Rift Valley), rodents (HFRS)
- Incubation: 1–6 d (CHHF), 2 wk to 2 mo (HFRS)
- Therapy: ribavirin
- Unique clinical features: retinitis, hepatitis (Rift Valley), prominent bleeding with DIC, jaundice (CCHF); renal disease (CCHF)

Filoviridae
- Diseases: Ebola, Marburg viruses
- Distribution: Africa
- Vector: ?
- Incubation: 2–21 d
- Unique clinical features: maculopapular rash, high mortality

Flaviviridae
- Diseases: dengue, yellow fever
- Distribution: widespread (dengue), Africa, tropical Americans (yellow)
- Vector: mosquitoes
- Incubation: 3–15 d
- Unique clinical feature: liver involvement (yellow)

Bleeding in the Platelet-Refractory Patient

Bleeding in patients who are refractory to platelet transfusion presents a difficult clinical problem (Table 109.11) [187,188]. If patients are demonstrated to have HLA antibodies, one can transfuse HLA-matched platelets [189]. Unfortunately, matched platelet transfusions do not work in 20% to 70% of these patients. Also, since some loci are difficult to match, effective products may be unavailable. As many as 25% of patients have antiplatelet antibodies in which HLA-matched products will be ineffective. One can perform platelet crossmatching to find compatible units for these patients but this may not always be successful. In the patient who is totally refractory to platelet transfusion, consider drugs as an etiology of antiplatelet antibodies (especially vancomycin) [163]. Use of antifibrinolytic agents such as epsilon aminocaproic acid or tranexamic acid may decrease the incidence of minor bleeding but are ineffective for major bleeding [190]. “Platelet drips” consisting of infusing either a platelet concentrate per hour or one plateletpheresis unit every 6 hours may be given as a continuous infusion [191,192]. For life-threatening bleeding

TABLE 109.11

EVALUATION AND MANAGEMENT OF PLATELET ALLOIMMUNIZATION

1. Check platelet count 15 min after platelet transfusion.
2. If rise in platelet count is less than 5,000 per μL, check for HLA antibodies.
3. Administer HLA-matched platelets and evaluate for response.
4. If three sequential HLA-matched platelet transfusions are ineffective, discontinue HLA-matched platelets.
5. In completely refractory patients:
   A. Evaluate for other causes of thrombocytopenia (HIT, drugs).
   B. Consider institution of antifibrinolytic therapy
1. Epsilon aminocaproic acid 1 g/h IV, or
2. Tranexamic acid 10 mg/kg IV every 8 h
   C. Platelet "drip"—continuous infusion of platelets at the rate of 1 unit over 6 h
   D. Recombinant activated VII for life-threatening bleeding

rVIIa may be of use [193]. For platelet refractory patients with arterial bleeding, the use of angiographic delivery of platelets has been reported to be successful in stopping bleeding [194].

Catastrophic Antiphospholipid Antibody Syndrome

Rarely patients with antiphospholipid antibody syndrome can present with fulminant multiorgan system failure [195–199]. Catastrophic antiphospholipid antibody syndrome is caused by widespread microthrombi in multiple vascular fields. These patients will develop renal failure, encephalopathy, adult respiratory distress syndrome (often with pulmonary hemorrhage), cardiac failure, dramatic livedo reticularis, and worsening thrombocytopenia. Many of these patients have preexisting autoimmune disorders and high titer-anticardiolipin antibodies. It appears that the best therapy for these patients is aggressive immunosuppression, plasmapheresis, and anticoagulation, then (perhaps) IV cyclophosphamide monthly [198]. Early recognition of this syndrome can lead to quick therapy and resolution of the multiorgan system failure.

Posttransfusion Purpura

Patients with this disorder develop severe thrombocytopenia ($< 10 \times 10^9$ per L), and often severe bleeding, 1 to 2 weeks after receiving blood products [200]. Affected patients usually lack the platelet antigen PLA1. For unknown reasons, exposure to the antigens from the transfusion leads to rapid destruction of the patient's own platelets. The diagnostic clue is thrombocytopenia in a patient, typically female, who has received a red cell or platelet blood product in the past 7 to 10 days. Treatment consists of intravenous immunoglobulin [201] and plasmapheresis to remove the offending antibody. If patients with a history of posttransfusion purpura require further transfusions, only PLA1-negative platelets should be given.

Liver Disease

Patients with severe liver disease have multiple hemostatic defects [202–206] (see Chapter 108, Disorders of Hemostasis). Splenomegaly (due to cirrhosis) and infections (e.g., HCV) may be contributory. Additionally, the liver is the source of thrombopoietin and lack of this platelet growth factor may worsen thrombocytopenia [207–209]. Patients may have platelet dysfunction due to the increase in fibrinogen degradation products and circulating plasmin [210]. Platelet transfusion should be given only to patients with platelet counts that are reliably less than 10×10^9 per L who are actively bleeding, or who require a higher platelet count due to an invasive procedure. The thrombopoietin receptor agonist eltrombopag has been used in patients with HCV-associated thrombocytopenia enabling administration of eradication therapy for HCV [211], but the delayed onset of action may make use in the critical care unit, where a need for immediate correction in the platelet count is more likely to be encountered, less feasible.

CHAPTER 110 ■ ANTITHROMBOTIC PHARMACOTHERAPY

CHRISTOPHER D. ADAMS, KEVIN E. ANGER, BONNIE C. GREENWOOD AND JOHN FANIKOS

INTRODUCTION

Thromboembolic disease is commonly encountered among critically ill patients [1]. While these patients are at high risk for developing arterial and venous thrombosis due to underlying comorbidities, central venous catheter placement, and immobility, they are also at high risk for hemorrhagic complications resulting from gastrointestinal stress ulcerations, invasive procedures, liver dysfunction, uremia, or coagulopathy [2]. These divergent features often complicate antithrombotic treatments for prevention or management of thrombosis. Limitations in administration routes, hemodynamic instability, alterations in renal and hepatic function, and drug interactions further complicate the administration of these high-risk medications [3].

This chapter focuses on the mechanism of action, pharmacokinetics, pharmacodynamics, clinical indications, complications of therapy, and reversal options for antithrombotic pharmacotherapy in critically ill patients.

ANTIPLATELET PHARMACOTHERAPY

Overview of Antiplatelet Pharmacotherapy

Antiplatelet agents target mechanisms in platelet activation, adhesion, and aggregation. Pharmacological inhibitors of platelet function fall into four general categories: thromboxane (TXA) inhibitors, antagonists of adenosine diphosphate (ADP)-mediated platelet activation, glycoprotein (GP) IIb/IIIa inhibitors, and phosphodiesterase inhibitors (Fig. 110.1).

Antiplatelet "resistance" and "nonresponse" are terms applied to clinical outcomes characterized by failure to prevent a thrombotic event due to inadequate platelet inhibition [4]. Resistance is conferred by underlying clinical, cellular, and genetic mechanisms. It is best confirmed by platelet function testing [5]. While several methods are available for measuring overall and drug-specific platelet aggregation, standard testing protocols have yet to be established [6].

Aspirin and Aspirin Derivatives

Pharmacology, Pharmacodynamics, and Monitoring

Aspirin, or acetylsalicylic acid, is a prodrug of salicylic acid that blocks platelet activation. Aspirin irreversibly inhibits both cyclooxygenase enzymes (COX-1, COX-2), reducing prostaglandin and TXA byproducts generated from arachidonic acid. Thromboxane A_2 stimulates platelet activation, aggregation, and recruitment. COX-1 enzymes are present in most tissues, but larger amounts are found in the stomach, kidneys, and platelets. The prostaglandin products of COX enzyme activity provide protection from gastrointestinal mucosal injury. COX-2 is found in both nucleated and nonnucleated cells and is responsive to inflammatory stimuli. Inhibition of COX-1 appears to be the primary mechanism by which aspirin inhibits hemostasis. The acetylation of platelet COX-1 enzymes by aspirin causes inhibition of platelet TXA_2 production. The irreversible antiplatelet effect lasts for the life of platelet (7 to 10 days). Saturation of the mechanism occurs at doses as low as 30 mg. Large doses of aspirin (> 3,000 mg daily) are required to inhibit COX-2 and produce systemic anti-inflammatory effects. Consequently, there is a 50- to 100-fold variation between the daily doses required to suppress inflammation and inhibit platelet function [7,8].

Enteric-coated and delayed release formulations have diminished bioavailability, take 3 to 4 hours to reach peak plasma levels, and have delayed onset. Rectally administered aspirin has variable absorption with a bioavailability of 20% to 60% over a 2- to 5-hour retention time [9]. For acute thrombosis, immediate-release aspirin is preferred [10].

The optimal aspirin dose that maximizes efficacy and minimizes toxicity is controversial. Evidence-based recommendations vary from 75 to 325 mg daily. There is currently no data suggesting inferiority of lower (75 to 100 mg) to higher (> 100 mg) maintenance dosing in preventing thromboembolic events [11].

Recurrent vascular thrombotic episodes despite aspirin therapy occur at rates between 2% and 6% of patients per year [4]. Aspirin resistance occurs in 5.5% to 45% of aspirin-treated patients. Possible mechanisms of aspirin resistance

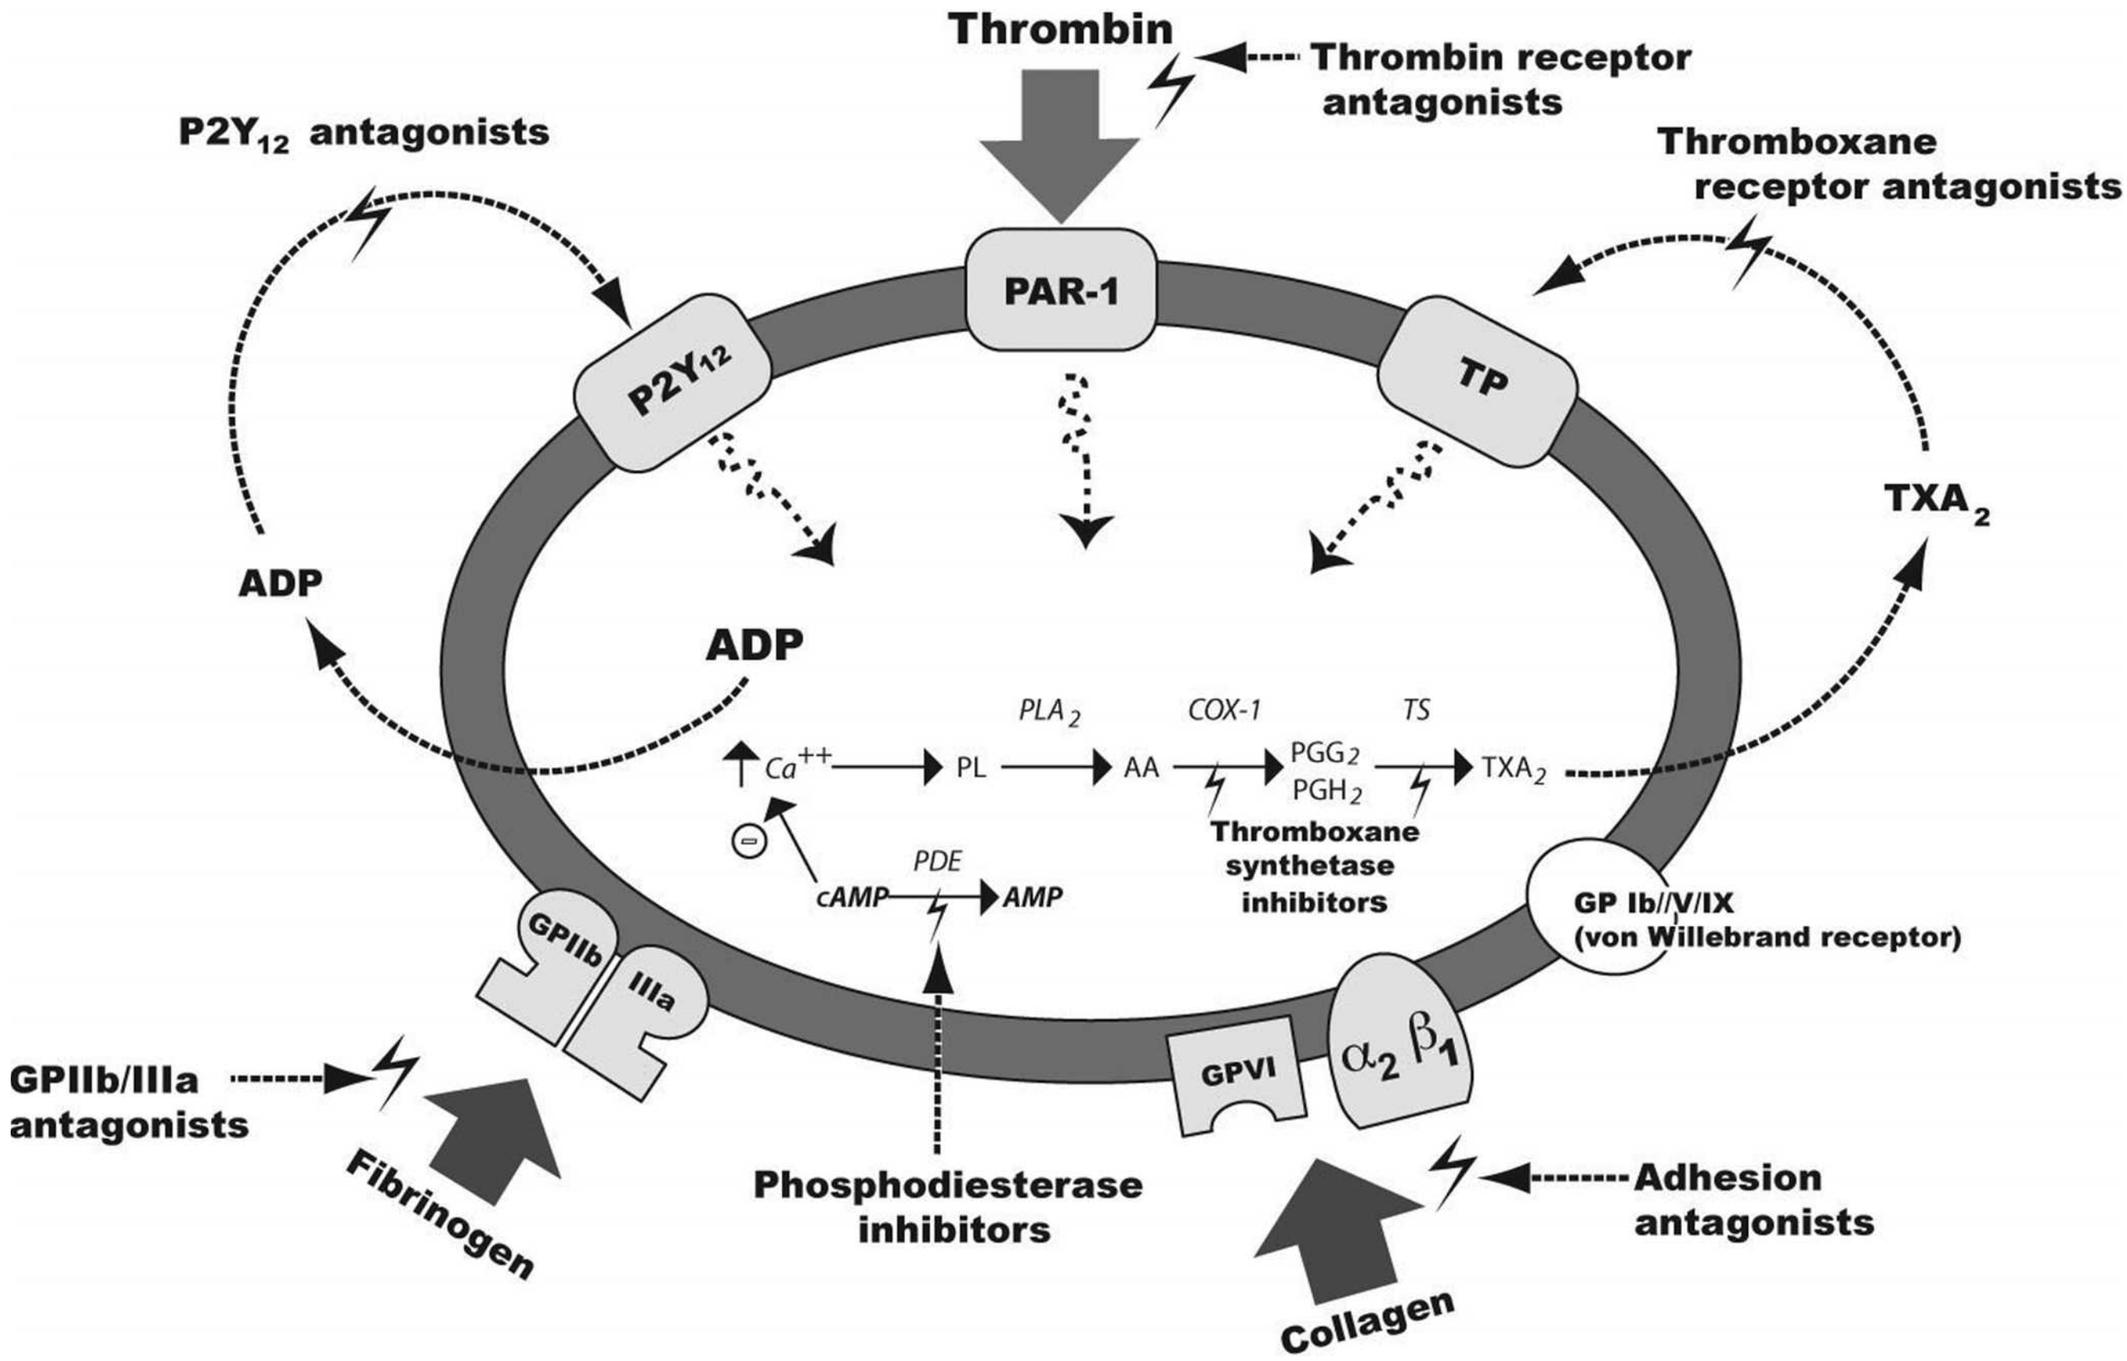

FIGURE 110.1. Platelet activation and pharmacological inhibitors of platelet function. Platelet activation involves four mechanisms: adhesion to sites of vascular injury, release of stimulatory compounds, aggregation, and priming of coagulation. Pharmacological inhibitors of platelet function target adhesion, release, and aggregation mechanisms. Platelet adhesion is a four-step process involving tethering of von Willebrand factor (VWF) to glycoprotein (GP) Ib platelet receptors, a potential target of investigational agents. The rolling phase of adhesion involves interaction between vascular collagen with GP VI and GP Ia/IIa receptors, another potential target of investigational agents. The activation phase of adhesion involves release of thromboxane A_2 (TXA_2) and adenosine diphosphate (ADP) which can be blocked with use of aspirin and $P2Y_{12}$ inhibitors, respectively. The stable adhesion phase involves the interaction of GP IIb/IIIa receptors with fibrinogen and VWF, which can be blocked with the use of GP IIb/IIIa inhibitors.

include extrinsic factors (compliance, absorption, dosage formulation, and smoking) and intrinsic factors (pharmacodynamic alterations, receptor polymorphisms, upregulation of nontargeted platelet activation pathways). In clinical trials, aspirin resistance has been associated with an increased risk of death, acute coronary syndromes (ACS), and stroke [5,12,13].

Clinical Indications

Aspirin is indicated for the primary and secondary prevention of arterial and venous thrombosis (Table 110.1). Aspirin is effective in reducing atherothrombotic disease morbidity and mortality in ACS, stable angina, coronary bypass surgery, peripheral arterial disease (PAD), transient ischemic attack, acute ischemic stroke, and polycythemia vera. A meta-analysis of 145 randomized studies in patients with coronary artery and cerebrovascular disease demonstrated that aspirin 75 to 300 mg per day reduced the risk of nonfatal myocardial infarction (MI) by 35% and the risk of vascular events by 18% [14]. Aspirin provides effective thromboprophylaxis in patients on warfarin with prosthetic heart valves and in patients with nonvalvular atrial fibrillation [15].

Complications and Reversal of Effect

Aspirin increases the incidence of major, gastrointestinal, and intracranial bleeding [15]. The recommended interval for discontinuation of aspirin prior to elective surgery or procedures is 7 to 10 days. Therapy can be resumed approximately 24 hours or the next morning after surgery when there is adequate hemostasis [16]. For patients exhibiting clinically significant bleeding or requiring emergent surgery, platelet transfusion may be warranted. Intravenous desmopressin antagonizes aspirin's effect, suggesting a role in emergent situations as well [17].

Aspirin produces gastrointestinal ulcerations and hemorrhage through direct irritation of the gastric mucosa and via inhibition of prostaglandin synthesis. Aspirin, in recommended doses, increases the risk of gastrointestinal bleeding 1.5- to 3-fold [14,18]. Enteric-coated and buffered aspirin doses $\leq$325 mg do not reduce the incidence of gastrointestinal bleeding [19]. Aspirin-induced gastric toxicity can be prevented with concurrent use of acid-suppressive therapy [20].

Underlying aspirin allergy can exacerbate respiratory tract disease, angioedema, urticaria, or anaphylaxis and is estimated

TABLE 110.1

CLINICAL USES OF ASPIRIN

Drug	Indications	Dosing, timing, duration	Precautions
Acetylsalicylic acid (aspirin)	Treatment of acute coronary syndromes	Load 162–325 mg orally Initial dosing for stents 162–325 mg orally/d: Bare metal 1 mo Sirolimus 3 mo Paclitaxel 6 mo Maintenance: 81–325 mg/d orally	■ Thrombocytopenia ■ Bleeding disorders ■ Pregnancy (third trimester) ■ Gastrointestinal disorders ■ Renal failure ■ Severe hepatic insufficiency ■ Concomitant antithrombotic medication use ■ Alcohol consumption
	Primary and secondary prevention of myocardial infarction in patients with chronic stable angina, previous MI, or unstable angina	81–325 mg/d orally	
	Secondary prevention in stroke and TIA patients	75–325 mg/d orally	
	Acute thrombotic stroke	160–325 mg/d, initiated within 48 h (in patients who are not candidates for fibrinolytics and are not receiving systemic anticoagulation)	
	Secondary prevention in CABG, carotid endarterectomy patients	75–325 mg/d starting 6 h following procedure; if bleeding prevents administration at 6 h after CABG, initiate as soon as possible	

CABG, coronary artery bypass graft; MI, myocardial infarction; TIA, transient ischemic attack.

to occur in 10% of the general population. These patients may be converted to alternative antiplatelet therapies. Leukotriene-modifying agents may reduce aspirin-provoked respiratory reactions but do not eliminate the risk. For patients with a compelling indication for therapy, aspirin desensitization may be considered [21].

$P2Y_{12}$ Inhibitors

Pharmacology, Pharmacodynamics, and Monitoring

$P2Y_{12}$ inhibitors prevent platelet activation by blocking ADP binding to $P2Y_{12}$ receptors. This action prevents activation of the GP IIb/IIIa receptor complex on the platelet surface [10].

Thienopyridine derivatives, clopidogrel, prasugrel, and ticlopidine, are prodrugs requiring hepatic activation via the cytochrome P450 (CYP450) isoenzyme system (Table 110.2). Metabolism by CYP450 plays a key role in the onset of action, potency, and drug interaction profile of these agents [22,23]. A loading dose provides a rapid increase in plasma concentration and a faster onset of action. Both clopidogrel and ticlopidine require a two-step activation process via CYP450. Prasugrel undergoes one-step oxidation by multiple CYP450 isoenzyme pathways which are believed to be responsible for its more predictable action.

While thienopyridine metabolites have a short plasma elimination half-life (1 to 8 hours), their irreversible activity at $P2Y_{12}$ receptors spans the life of the platelet (7 to 10 days). The onset of action, duration of antiplatelet effect, and unpredictable levels of platelet inhibition have led to the development of newer agents [24–26]. Three investigational nonthienopyridine derivatives are currently under investigation for the management of ACS. These agents do not require hepatic activation resulting in immediate, short-acting, dose-dependent inhibition of platelet aggregation [26].

Resistance to clopidogrel occurs in 4% to 34% of patients and depends on the agent, type, and timing of platelet function test, as well as underlying comorbidities such as diabetes and obesity [23]. Possible mechanisms of $P2Y_{12}$ inhibitor resistance include extrinsic factors and intrinsic factors. Recent literature highlighted the importance of genetic and drug-induced alterations of CYP3A4 enzymes, the pathway responsible for thienopyridine activation [27]. Clopidogrel resistance has been associated with an increased risk of death, MI, and stroke. For patients with presumed or confirmed clopidogrel resistance, maintenance dosing up to 150 mg daily or use of more potent agents may be necessary, particularly in patients with in-stent thrombosis [27].

Monitoring the antiplatelet effect of $P2Y_{12}$ inhibitors using platelet function testing is an evolving area of research [27]. The high incidence of varied responses to thienopyridines due to CYP450 polymorphisms and potential drug interactions have suggested a strategy for improving response by using point-of-care platelet function testing.

Clinical Indications

$P2Y_{12}$ inhibitors are indicated for primary and secondary thrombosis prevention in a variety of disease states (Table 110.3). Ticlopidine reduces thrombotic events in patients with stroke, but is associated with neutropenia, thrombocytopenia, and thrombotic thrombocytopenic purpura [28]. Clopidogrel is indicated alone or in combination with aspirin for primary and secondary prevention of ischemic events in ACS, PAD, stroke, and coronary artery disease. Prasugrel is indicated alone or in combination with aspirin for the prevention of thrombotic cardiovascular events, including in-stent

thrombosis, in ACS patients who are managed with percutaneous coronary intervention (PCI) [23].

Complications and Reversal of Effect

The incidence of major bleeding with $P2Y_{12}$ inhibitors varies between agents, dosing, patient populations, and concomitant antithrombotic therapies. Gastrointestinal hemorrhage is a common complication of $P2Y_{12}$ inhibitor therapy [20]. Endoscopic evaluations at 1 week demonstrated less gastrointestinal damage with clopidogrel 75 mg daily than with aspirin 325 mg daily [29]. For patients exhibiting clinically significant bleeding, platelet transfusion may be warranted.

$P2Y_{12}$ inhibitors should be avoided in patients undergoing neuraxial analgesia due to the risk of subdural hematoma [30]. Therapy should be discontinued 7 to 10 days prior to elective surgery or invasive procedure and resumed approximately 24 hours or the next morning after surgery.

TABLE 110.3

CLINICAL USES OF $P2Y_{12}$ INHIBITORS

Drug	Indications	Dosing, timing, duration	Precautions
Clopidogrel (Plavix™)	Treatment of acute coronary syndromes +/− percutaneous intervention	Load 300 mg × 1 PCI load: 300–600 mg × 1 Maintenance 75 mg/d orally Drug-eluting stents: duration of clopidogrel ideally 12 mo following drug-eluting stent	■ Age > 75 y (prasugrel) ■ Interruption of clopidogrel may cause in-stent thrombosis with subsequent fatal and nonfatal myocardial infarction
	Primary and Secondary prevention of myocardial infarction in patients with chronic stable angina, previous MI, or unstable angina Cerebrovascular accident Arteriosclerotic vascular disease Peripheral arterial occlusive disease	75 mg orally once daily	■ Indwelling epidural catheter ■ Combination of aspirin and clopidogrel in patients with recent TIA or stroke ■ Liver disease ■ Thrombotic thrombocytopenic purpura may occur (rare) ■ Recent trauma, surgery/biopsy ■ Hematologic disorders
Ticlopidine (Ticlid™)	Placement of stent in coronary artery Secondary prevention in thromboembolic stroke	250 mg orally twice a day	■ Discontinue if ANC less than 1,200/μL or platelet count less than 80,000/μL (ticlopidine) ■ Elevated triglycerides (ticlopidine)
Prasugrel (Effient™)	Treatment of acute coronary syndromes +/− percutaneous intervention	Load 60 mg × 1 Maintenance: 10 mg/d orally Weight < 60 kg, consider using a lower maintenance dose of 5 mg/d

Glycoprotein IIb/IIIa Inhibitors

Pharmacology, Pharmacodynamics, and Monitoring

GP IIb/IIIa receptors are expressed on the platelet surface, with approximately 50,000 to 80,000 copies per platelet. Blocking GP IIb/IIIa receptors prevents platelet activation, aggregation, and fibrinogen-mediated platelet to platelet bridging.

Intravenous GP IIb/IIIa inhibitors (abciximab, eptifibatide, and tirofiban) vary in their structure and pharmacokinetic properties (Table 110.4) [10,31]. Although the exact threshold required for efficacy with these agents has not been established, > 80% platelet inhibition is thought to be a target associated with adequate antiplatelet activity in patients with ACS and in those undergoing PCI [32].

Abciximab is a human–murine chimeric monoclonal antibody that demonstrates a dose-dependent inhibition of GP IIb/IIIa receptors. After an initial intravenous bolus and infusion, the onset of platelet inhibition is rapid (5 minutes) and 80% to 90% of ADP-induced platelet aggregation is suppressed [31]. Abciximab has a strong affinity for the receptor, resulting in occupancy that persists for weeks. Once discontinued, platelet function recovers gradually, with bleeding time normalizing at 12 hours and ADP-induced aggregation returning at 24 to 48 hours [31,32].

Both eptifibatide, a synthetic peptide, and tirofiban, a synthetic small molecule, demonstrate high selectivity, but reduced affinity for the GP IIb/IIIa receptor when compared to abciximab. Both exhibit platelet inhibition that is linear and dose dependent. An intravenous eptifibatide or tirofiban bolus dose followed by an infusion provides > 80% inhibition of ADP-induced platelet aggregation. For patients undergoing PCI, a second eptifibatide bolus 10 minutes after the initial dose further enhances platelet inhibition at 1 hour. Since both agents dissociate from the GP IIb/IIIa receptor rapidly, normal platelet aggregation is restored within 4 to 8 hours after drug discontinuation [33–35].

Platelet counts should be monitored within the first 24 hours while taking GP IIb/IIIa inhibitors. For abciximab, platelet counts should be evaluated within 2 to 4 hours of initiation due to a higher risk of thrombocytopenia.

Clinical Indication

GP IIb/IIIa inhibitors are included in evidence-based guidelines as adjunctive therapy for patients with ACS and those undergoing PCI (Table 110.5).

Optimal use of GP IIb/IIIa inhibitors involves appropriate patient risk stratification, use with other antithrombotic agents, appropriate dose, and duration of therapy [36].

Complications and Reversal of Effect

The frequency of major bleeding with GP IIb/IIIa therapy ranges from 1% to 14% of patients and depends on the agent, concomitant therapies, and settings of ACS or PCI [32–34]. Failure to adjust dosing in renal dysfunction further increases the risk of bleeding [37]. Factors associated with bleeding risk include age, female gender, body weight, diabetes, congestive heart failure, renal function, concomitant fibrinolytic use, prolonged femoral sheath placement, and heparin dosing [38,39].

The duration of the antiplatelet effect is agent specific and is influenced by platelet binding (abciximab binds to platelets for up to 10 days) and renal function (tirofiban and eptifibatide have half-lives of 1.5 to 3 hours with normal renal function). An intravenous desmopressin dose of 0.3 μg per kg may be beneficial in reducing bleeding time [17].

Nonhemorrhagic side effects of GP IIb/IIIa inhibitors include severe thrombocytopenia. The incidence of thrombocytopenia with eptifibatide and tirofiban is similar to placebo, with rates ranging from 0.2% to 0.3% of treated patients. With abciximab, the incidence is reported as 5%; however, up to 4% of cases can be due to pseudothrombocytopenia as a result of platelet clumping. The onset of thrombocytopenia usually occurs within the first 24 hours of infusion, but delayed onset has been reported [40,41].

Platelet or red blood cell transfusions may be warranted for patients with persistent thrombocytopenia or clinically significant bleeding and must take into account drug concentrations in the plasma or drug bound to platelets [31]. Abciximab has been associated with antibody formation in 6% of patients. The risk of thrombocytopenia and immune-mediated reactions may limit repeat use [8,10,32]. GP IIb/IIIa inhibitor administration should be avoided in patients requiring neuraxial analgesia due to risk of subdural hematoma [30].

Dipyridamole

Pharmacology, Pharmacodynamics, and Monitoring

Dipyridamole inhibits adenosine binding to platelets and endothelial cells. The increase in adenosine leads to a rise in cyclic adenosine monophosphate (cAMP), which in turn decreases platelet responsiveness to various stimuli. Dipyridamole is

TABLE 110.5

CLINICAL USES OF GLYCOPROTEIN IIB/IIIA INHIBITORS

Drug	Indications	Dosing, timing, duration	Precautions
Eptifibatide (Integrilin™)	Treatment of acute coronary syndromes +/− percutaneous coronary intervention	IV bolus 180 µg/kg ABW (maximum 22.6 mg) as soon as possible, followed by 2 µg/kg ABW/min (maximum 15 mg/h) infusion until discharge or CABG surgery, up to 72 h If undergoing PCI, administer a second 180 µg/kg IV bolus 10 min after the first and continue the infusion up to discharge, or for up to 18–24 h after procedure, whichever comes first, allowing for up to 96 h of therapy Renal adjustment CrCl < 50 mL/min, 180 µg/kg actual body weight (maximum 22.6 mg) IV bolus as soon as possible, followed by 1 µg/kg/min (maximum 7.5 mg/h) infusion	■ Concomitant use of fibrinolytics, anticoagulants, antiplatelet agents, and nonsteroidal anti-inflammatory agents ■ Indwelling epidural catheter ■ Do not remove arterial sheath unless aPTT is less than 45 s or ACT less than 150 s and heparin discontinued for 3–4 h ■ Platelet count below 150,000/µL ■ Renal insufficiency (eptifibatide) ■ Severe renal insufficiency, chronic hemodialysis (tirofiban) ■ Readministration of abciximab may result in hypersensitivity, thrombocytopenia, or diminished benefit due to antibody formation ■ Hemorrhagic retinopathy
Abciximab (Reopro™)	Treatment of acute coronary syndromes +/− percutaneous coronary intervention	Initial, 0.25 mg/kg IV bolus (over 5 min), followed by 0.125 µg/kg/min (maximum 10 µg/min) IV infusion for 12 h in combination with fibrinolytic treatment or after PCI, unless complications No adjustment required for renal dysfunction	
Tirofiban (Aggrastat™)	Treatment of acute coronary syndromes	0.4 µg/kg/min IV for 30 min, then 0.1 µg/kg/min for 12–24 h after PCI Severe renal impairment (CrCl less than 30 mL/min): give half the usual dose–0.2 µg/kg/min IV for 30 min, then 0.05 µg/kg/min

metabolized hepatically and has a half-life of approximately 10 hours [10].

Clinical Indications

Dipyridamole is indicated as adjunctive therapy for the prevention of thromboembolism in patients with cardiac valve replacement. Combined with aspirin, dipyridamole is indicated for secondary prevention of cerebrovascular accidents and TIA. The combination of aspirin and extended-release dipyridamole was associated with reductions in major vascular events in patients with stroke or TIA (Table 110.6) [10,42].

Complications and Reversal of Effect

While headache is the most common adverse effect associated with dipyridamole therapy, hemorrhage may also occur. For patients exhibiting clinically significant bleeding, platelet transfusion may be warranted.

Cilostazol

Pharmacology, Pharmacodynamics, and Monitoring

Cilostazol blocks platelet activation via phosphodiesterase 3 (PDE3) inhibition. PDE3 inhibition increases cAMP concentrations resulting in inhibition of platelet aggregation and an increase in vasodilation [43].

Cilostazol is extensively metabolized by CYP 450-3A4 subclass. Avoidance of therapy or reduced dosing may be required for patients taking potent CYP3A4 inhibitors [44].

Clinical Indication

Cilostazol is indicated for treatment of intermittent claudication symptoms and has shown benefit in reducing symptoms and improving walking distance [44].

Complications and Reversal of Effect

Nonhemorrhagic complications of cilostazol therapy include headache, peripheral edema, and tachycardia [44].

Overview of Anticoagulant Pharmacotherapy

Blood coagulation has been summarized previously in Chapter 108. Anticoagulant agents inhibit thrombosis and propagation by inhibiting thrombin directly or indirectly by attenuating thrombin generation (Fig. 110.2). Unfractionated heparin (UFH) and low-molecular-weight heparin (LMWH) are effective in acute thrombosis due to their rapid onset. Since heparins are dependent on the presence of antithrombin (AT) for clotting factor inhibition, they are considered indirect anticoagulants. Heparins contain a pentasaccharide sequence that binds to AT, producing a conformational change that accelerates AT inactivation of coagulation factors XIIa, IXa, XIa, Xa, and IIa (thrombin). Of these, thrombin and Xa play the most critical role in the coagulation cascade. The active pentasaccharide sequence responsible for catalyzing AT is found on one-third and one-fifth of the chains of heparin and LMWH, respectively. Fondaparinux is a synthetic analog of this naturally occurring pentasaccharide [45–47].

TABLE 110.6

CLINICAL USES OF PHOSPHODIESTERASE INHIBITORS

Drug	Indications	Dosing, timing, duration	Precautions
Dipyridamole (Persantine™)	Radionuclide myocardial perfusion study VTE prophylaxis after heart valve replacement	0.142 mg/kg/min IV for 4 min (0.57 mg/kg total) prior to thallium; maximum 60 mg With concomitant warfarin therapy: 75–100 mg orally four times daily	■ Aminophylline injection should be readily available for relieving adverse effects such as chest pain and bronchospasm ■ Hypotension ■ Severe coronary artery disease, abnormal cardiac rhythm ■ Avoid in patients with severe hepatic insufficiency ■ Avoid in patients with severe renal failure (CrCl less than 10 mL/min) ■ Severe coronary artery disease ■ Coagulation abnormalities ■ Severe renal impairment
Dipyridamole extended-release/aspirin (Aggrenox™)	Secondary prevention in stroke and TIA patients	200 mg dipyridamole, 25 mg aspirin (1 capsule) orally twice daily Patients with intolerable headache 200 mg dipyridamole, 25 mg aspirin orally daily at bedtime, with 81 mg of aspirin in the morning Return to usual dose as soon as tolerance to headache develops (usually within a week)	
Cilostazol (Pletal™)	Intermittent claudication	100 mg orally twice a day	

CrCl, creatinine clearance using Cockcroft–Gault equation; IV, intravenous; TIA, transient ischemic attack; VTE, venous thromboembolism.

Unfractionated Heparin

Pharmacology, Pharmacodynamics, and Monitoring

UFH is composed of a heterogeneous mixture of highly sulfated polysaccharide chains that vary in molecular weight, anticoagulant activity, and pharmacokinetic properties. A minimum of 18 saccharide units are required for UFH to form a ternary complex with AT and inhibit thrombin. Once bound to AT molecules, UFH can readily dissociate and bind to other AT molecules. Alternatively, the only requirement for factor Xa inhibition is for the heparin-AT complex to be formed. Heparin has equal inhibitory activity against factor Xa and thrombin, binding in a 1:1 ratio.

Since UFH is poorly absorbed orally, intravenous or subcutaneous injections are the preferred administration routes [47]. When given as subcutaneous injection with therapeutic intent, UFH doses need to be large enough (> 30,000 units per day) to overcome erratic bioavailability. UFH readily binds to plasma proteins after parenteral administration which contributes to variable anticoagulant response. Despite these limitations, intravenous administration rapidly achieves therapeutic plasma concentrations that can be monitored and adjusted based on infusion rates [45].

UFH clearance from systemic circulation is dose related and occurs through two independent mechanisms [46,48]. The initial phase is rapid and saturable binding to endothelial cells, macrophages, and local proteins where UFH is depolymerized. The second phase is a slower, nonsaturable, renal-mediated clearance. At therapeutic doses, UFH is cleared primarily in the initial phase with higher-molecular-weight chains being cleared more rapidly than lower-weight counterparts. As elimination becomes dependent on renal clearance, increased or prolonged UFH dosing provides a disproportionate increase in both the intensity and duration of anticoagulant effect. With therapeutic intravenous doses of heparin, the half-life of UFH is approximately 60 minutes [46,48].

The anticoagulant response to UFH is monitored using activated partial thromboplastin time (aPTT), a measurement sensitive to the inhibitory effects of thrombin. The aPTT should be measured every 6 hours, and doses adjusted accordingly, until the patient sustains therapeutic levels. Once steady state is reached, the frequency of monitoring can be extended.

Weight-based dosing nomograms are recommended for treatment of thromboembolic disease. Such nomograms have been associated with a shorter time to reach a therapeutic level without an increase in bleeding events. Heparin dosing nomograms differ between hospitals due to differences in thromboplastin agents and interlaboratory standards in aPTT measurements [49].

Clinical Indications

Clinical indications for UFH include treatment of ACS, treatment or prevention of venous thromboembolism (VTE), bridge therapy for atrial fibrillation, and cardioversion (Table 110.7) [36,48,50]. Due to UFH's short half-life and reversibility, it remains the best option in patients with bleeding risk or organ dysfunction. Patients with fluctuating renal function or a calculated creatinine clearance less than 30 mL per minute are not candidates for LMWH or fondaparinux due to the risk of accumulation and increased bleeding risk, and should be given UFH [51]. When used for thromboprophylaxis in medical patients, three times daily heparin dosing provides better efficacy in reducing VTE events compared to twice daily dosing, but generates more major, but not minor, bleeding episodes [52].

Complications and Reversal of Effect

The major complications of UFH therapy include bleeding (major bleeding, 0% to 7%; fatal bleeding, 0% to 3%), heparin-induced thrombocytopenia (1% to 5%), and osteoporosis (2% to 3% risk of vertebral fracture with less than 1 month of treatment) [53]. Hemorrhagic episodes are associated with anticoagulation intensity, route of administration (continuous infusions are associated with lower rates), and concomitant use of

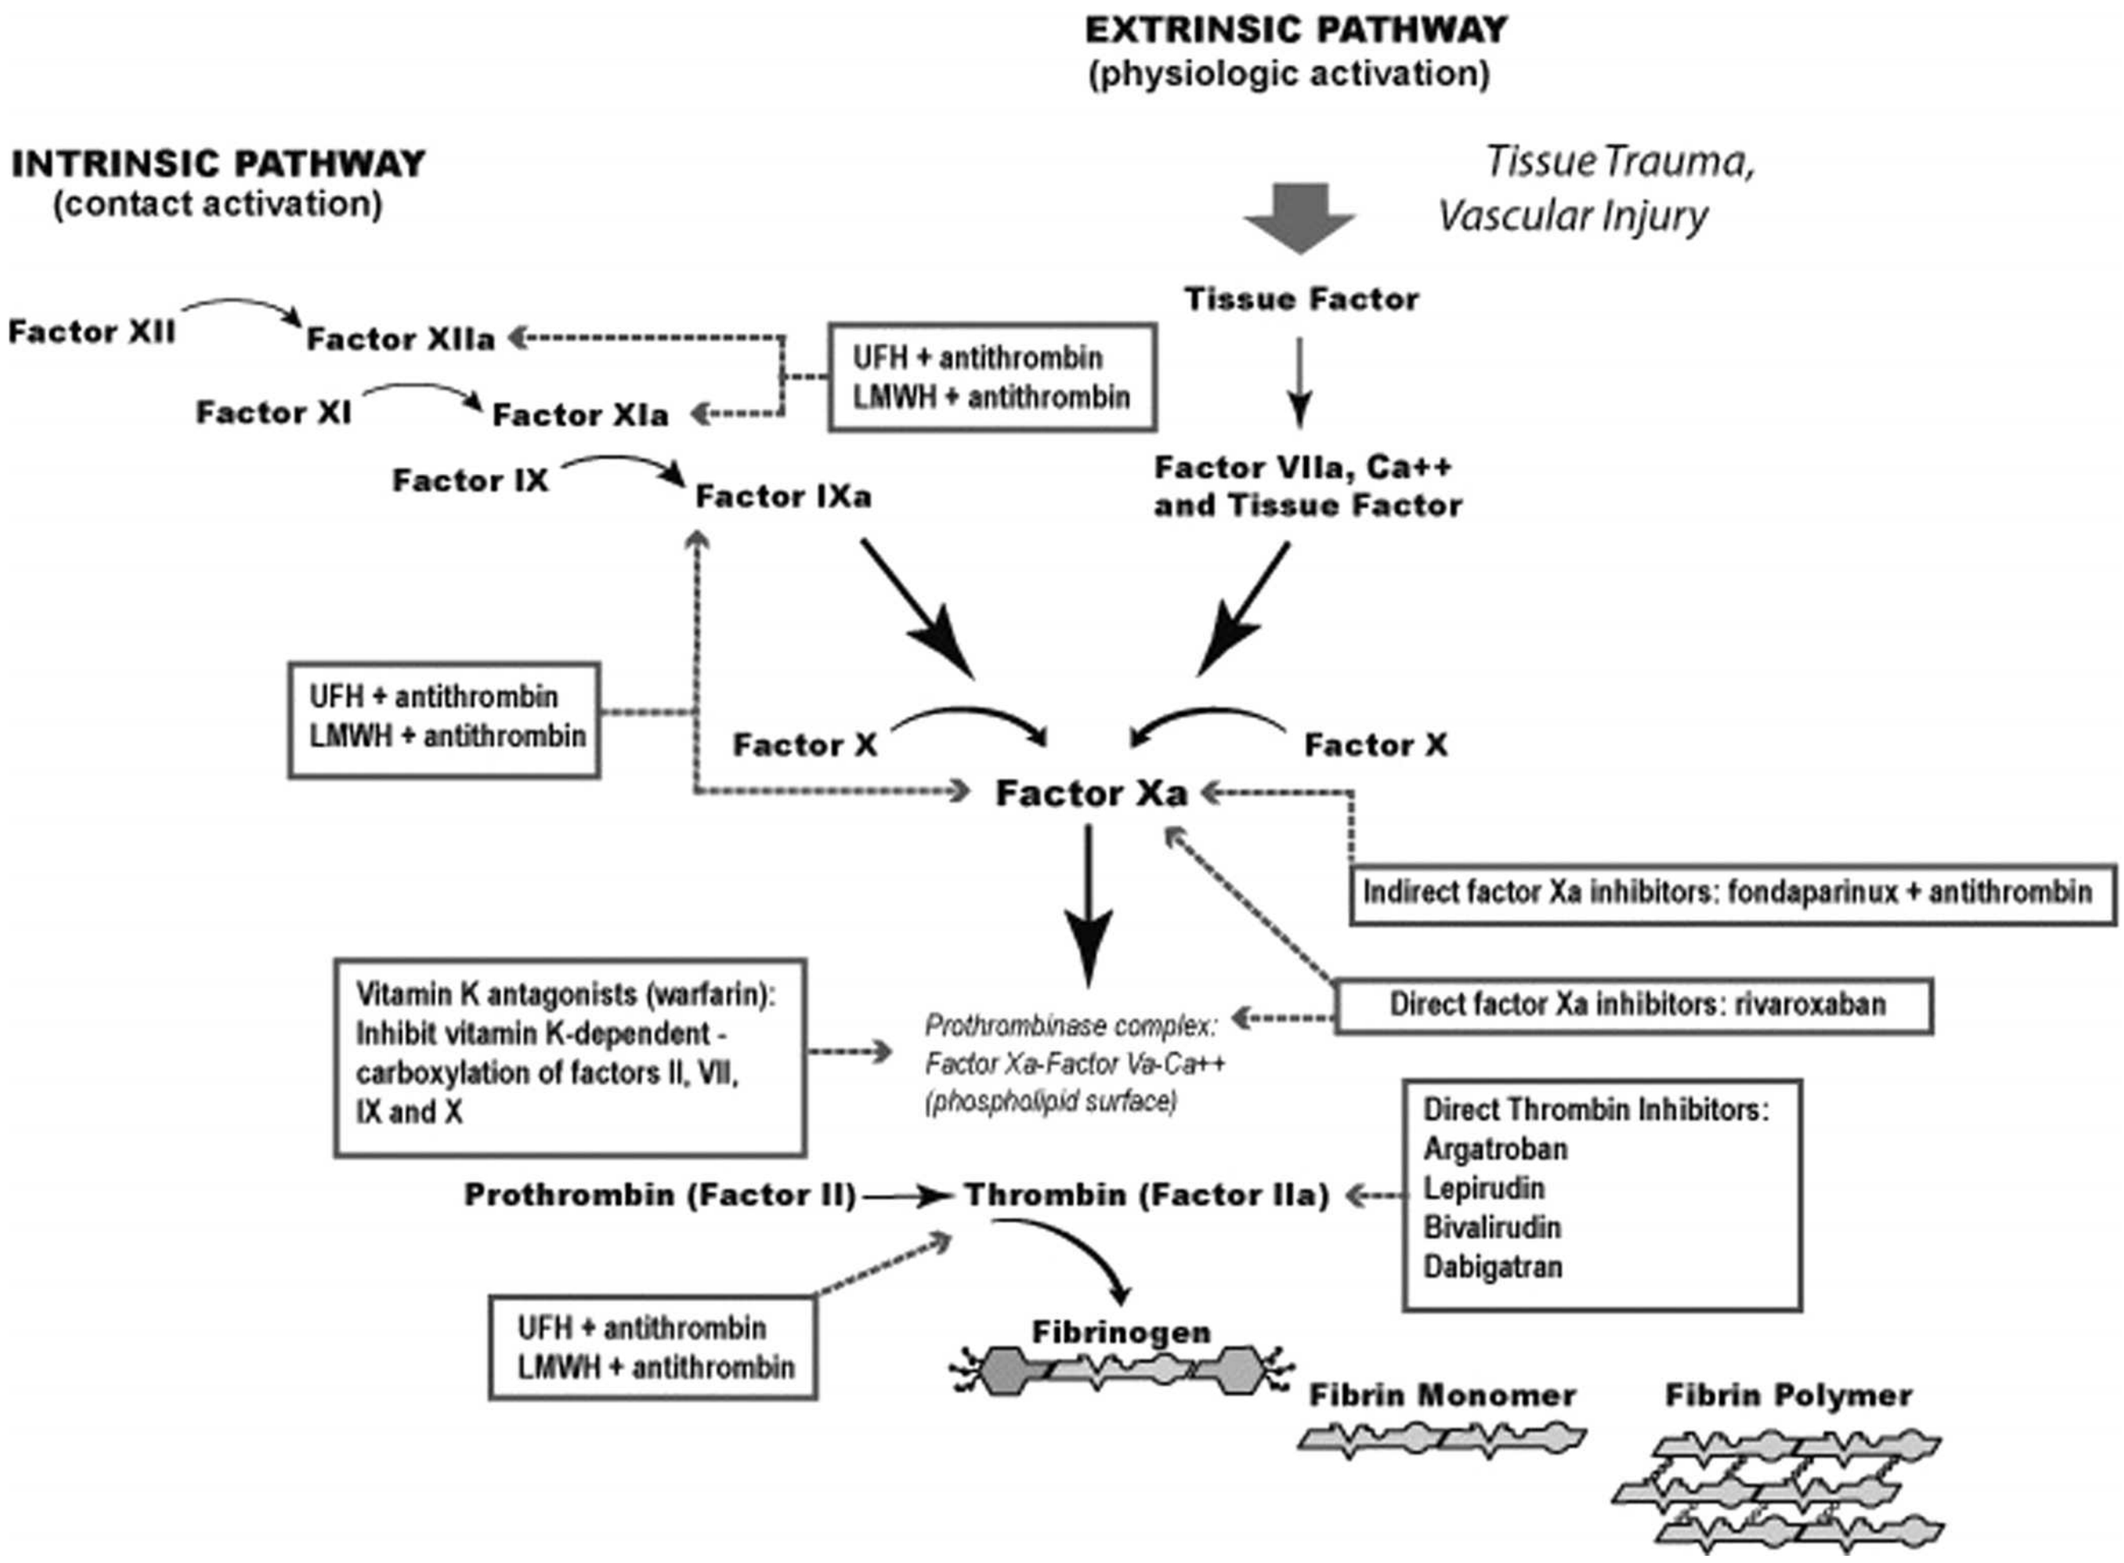

FIGURE 110.2. The coagulation cascade comprises the intrinsic (contact activation) pathway and the extrinsic (tissue factor) pathway. Each pathway generates a series of reactions in which inactive circulating enzymes and their cofactors are activated. These activated factors then catalyze the next reaction in the cascade. Thrombin plays a pivotal role by triggering the conversion of soluble fibrinogen in insoluble fibrin monomers, which serve as the foundation for thrombus formation. Thrombin also activates factors VIII, V, and XIII. Factor XIII generates the covalent bonds that link fibrin strands, ensuring structural integrity. Anticoagulants, either through their interaction with antithrombin, or through a direct inhibition of thrombin, interrupt these enzymatic reactions.

TABLE 110.7

CLINICAL USES OF UNFRACTIONATED HEPARIN

Drug	Indications	Dosing, timing, duration	Precautions
Unfractionated heparin	Treatment of VTE	80 units/kg bolus, then 18 units/kg/h infusion adjusted per local heparin nomogram	■ Allergic or hypersensitivity-type reactions ■ Congenital or acquired bleeding disorders ■ Indwelling epidural catheter ■ Gastrointestinal ulceration and ongoing tube drainage of the small intestine or stomach ■ Hepatic disease with impaired hemostasis ■ Hereditary antithrombin III deficiency and concurrent use of antithrombin ■ Menstruation ■ Neonates and infants weighing < 10 kg ■ Premature infants weighing less than 1 kg
	Treatment of ACS	IV bolus: 60 units/kg (max 4,000 units) 12 units/kg/h (max 1,000 units) +/− fibrinolysis, adjusted to maintain aPTT 1.5–2 times control or per local heparin nomogram	
	Bridge therapy for atrial fibrillation, cardioversion	IV infusion: 60–80 units/kg bolus Target aPTT, 60 s, range, 50–70 s	
	Prophylaxis of VTE in the medically ill or surgical population	5,000 units SC every 8–12 h	
	Prophylaxis of VTE in pregnancy (with prior VTE)	7,500–15,000 units SC every 12 h	

ACS, acute coronary syndrome; aPTT, activated partial thromboplastin time; IV, intravenous; SC, subcutaneous; VTE, venous thromboembolism.

[a]This model assumes a half-life for UFH of 1 h and for LMWH 8 h.
[b]Estimated amounts of UFH remaining at 1 h following initiation of a continuous infusion may be overestimated in this model.
[c]Administer no more than 20 mg of protamine per minute, in divided doses, with no more than 50 mg over any 10-min period.
UFH, unfractionated heparin, LMWH, low-molecular-weight heparin.

GP IIb/IIIa inhibitors, aspirin or fibrinolytic agents [53–55]. Patient-specific risk factors for bleeding include age, gender, renal failure, low body weight, and excessive alcohol consumption [53].

Perioperative anticoagulation must be individualized based on the surgery or procedure and the patient's risks for thrombosis and bleeding. Discontinuing therapeutic doses of heparin 4 hours before surgery and measuring an aPTT is usually sufficient since normal hemostasis is restored in this time frame [16,56,57]. Therapeutic-dose heparin therapy can be restarted 12 hours after major surgery, but should be delayed if evidence of bleeding is present. There is no contraindication to neuraxial techniques in patients receiving twice daily, low-dose UFH subcutaneously, as the risk for developing spinal hematoma appears to be minimal [16,30].

Treatment of UFH-related bleeding includes protamine sulfate, transfusion, and supportive care. Protamine sulfate binds to UFH to form a stable salt, which renders heparin inactive. Protamine dosing is dependent on timing of the last heparin dose. For immediate reversal (< 30 minutes since last heparin dose), 1 mg of protamine is administered for every 100 units of heparin and a followup aPTT can evaluate the reversal response. When UFH is given as a continuous IV infusion, only UFH delivered during the preceding 2 to 2.5 hours should be included in the calculation to determine the protamine dose (Table 110.8) [58]. If the dose of heparin is unknown, the maximal tolerated protamine dose of 50 mg can be slowly administered followed by serial measurements of aPTT. Adverse reactions, such as hypotension and bradycardia, are common. However, reaction severity can be reduced by slowly administering protamine over 1 to 3 minutes. Allergic responses to protamine are more common in patients who have been previously exposed to the drug, but patients can be pretreated with corticosteroids and antihistamines [53,59,60].

Low-Molecular-Weight Heparins

Pharmacology, Pharmacodynamics, and Monitoring

LMWHs are derived from UFH by chemical or enzymatic depolymerization, yielding fragments approximately one-third the molecular weight of UFH. All LMWH molecules contain the active pentasaccharides that catalyze AT inhibition of factor Xa. Because of their smaller size, LMWHs have decreased affinity for plasma proteins and cellular binding sites, resulting in a superior pharmacokinetic profile compared to UFH. LMWHs also have increased bioavailability after subcutaneous injection, renal clearance that is dose-independent, and a longer half-life (17 to 21 hours). LMWHs are administered in fixed doses for thromboprophylaxis or in total body weight-adjusted doses for therapeutic anticoagulation (Table 110.9) [45,61].

With their predictable dose response (peak anti-Xa activity occurs 3 to 5 hours after injection), laboratory monitoring is usually not necessary. Anti-Xa monitoring is optional in high-risk patient populations, specifically renal insufficiency, obesity, and pregnancy. In these cases, anti-Xa plasma levels are drawn 4 hours after administration, and subsequent doses are adjusted to a target range of 0.5 to 1.1 IU per mL [62].

Clinical Indications

LMWHs are suitable replacements for UFH for many indications [63]. LMWHs require fewer injections and produce fewer adverse events. In hospitalized medical patients receiving thromboprophylaxis, LMWH was associated with a lower risk of DVT, fewer injection site hematomas, and no difference in bleeding when compared with UFH [64]. LMWHs have largely replaced intravenous UFH in patients with acute VTE who are able to receive unmonitored anticoagulation in the ambulatory setting. UFH remains the preferred option for ACS patients,

TABLE 110.9

CLINICAL USES OF LOW-MOLECULAR-WEIGHT HEPARINS

Drug	Indications	Dosing, timing, duration	Precautions
Enoxaparin (Lovenox™)	Treatment of VTE	1 mg/kg SC every 12 h OR 1.5 mg/kg SCevery 24 h CrCl < 30 mL/min: 1 mg/kg SC every 24 h	■ Indwelling epidural catheter ■ Recent spinal or ophthalmologic surgery ■ History of recent major bleed (gastrointestinal, intracranial, etc.) ■ Congenital or acquired bleeding disorders ■ History of heparin-induced thrombocytopenia ■ Liver disease ■ Renal impairment (CrCl < 30 mL/min), consider unfractionated heparin ■ Concomitant use of antithrombotic drugs ■ Diabetic retinopathy ■ Uncontrolled hypertension
	Treatment of ACS	30 mg bolus IV followed by 1 mg/kg SC every 12 h WITH tenecteplase CrCl < 30 mL/min: not recommended	
	Prophylaxis/bridge therapy for atrial fibrillation/ cardioversion	1 mg/kg SC every 12 h OR 1.5 mg/kg SC every 24 h CrCl < 30 mL/min: 1 mg/kg SC every 24 h	
	Prophylaxis of VTE in the medically ill or surgical population	40 mg SC every 24 h CrCl < 30 mL/min: 1 mg/kg SC daily	
	Prophylaxis of VTE in the trauma patients	30 mg SC every 12 h OR 40 mg SC every 24 h	
Dalteparin (Fragmin™)	Treatment of VTE	< 56 kg: 10,000 IU daily 57–68 kg: 12,500 IU daily 69–82kg: 15,000 IU daily 83–98 kg: 18,000 IU daily > 99 kg: 18,000 IU daily	
	Treatment of ACS	120 IU/kg SC every 12 h (MAX 10,000 IU/dose)	
	Prophylaxis of VTE after hip or other major surgery (first month)	Initial dose: 2500 IU once Maintenance: 2,500–5,000 IU SC every 24 h	
	Prophylaxis of VTE in the medically ill or surgical population	5,000 IU SC every 24 h	
Tinzaparin (Innohep™)	Treatment of DVT	175 international units anti-Xa/kg SC daily	

ACS, acute coronary syndrome; CrCl, creatinine clearance using Cockcroft–Gault equation; IU, international units; IV, intravenous; SC, subcutaneous; VTE, venous thromboembolism.

those who may require an urgent surgical intervention, those with compromised renal function, or those requiring intensive monitoring for other reasons [48].

Complications and Reversal of Effect

Hemorrhage is the major complication of LMWH therapy, with data suggesting lower rates when compared to UFH. Major bleeding is reported to occur in 0% to 3% of patients [53]. Preprocedural thromboembolic risk assessment, bleeding risk assessment, and physician preference will play a role in determining whether LMWH prophylaxis is continued or withheld in the surgical setting. For patients receiving therapeutic LMWH, therapy should be discontinued 12 to 24 hours prior to the procedure, or earlier in patients with renal dysfunction. Therapeutic doses of LMWH should not be restarted for 24 hours after a major procedure or with neuraxial anesthesia [16,30].

In the setting of overdose or hemorrhage, protamine completely reverses the antithrombin activity of LMWH, but only reverses 60% of the antifactor Xa activity. If immediate reversal is warranted within 8 hours of LMWH administration, a protamine dose of 1 mg neutralizes 100 anti-Xa units or 1 mg of LMWH (Table 110.8). Should bleeding continue, a second dose of 0.5 mg of protamine per 100 anti-Xa units may be administered. Smaller protamine doses are required if the LMWH administration interval is beyond 8 hours [65,66].

Heparin-induced thrombocytopenia (HIT) is an immune-mediated, hypercoagulable disorder that results from antibodies formed against the heparin-platelet factor 4 complex. The incidence in critically ill patients ranges from 1% to 5% and is associated with thrombocytopenia and life-threatening thrombosis in approximately 30% to 50% of antibody-positive patients [67]. HIT typically occurs in patients who have been exposed to UFH or LMWH for 5 to 7 days, or even sooner in patients with prior exposure. A 50% decrease in platelet count occurring 4 to 10 days after the initiation of UFH or LMWH therapy or formation of a new thrombus during therapy may be indicative of HIT. Platelet counts should be measured prior to the initiation of UFH or LMWH and monitored every other day for the first 4 to 10 days of therapy. Since heparin alternatives must be used in patients with HIT, direct thrombin inhibitors are the treatment of choice [68,69].

Patients receiving heparin for a period of greater than 1 month are at risk for developing osteoporosis and vertebral

TABLE 110.10

CLINICAL USES OF FONDAPARINUX

Drug	Indications	Dosing, timing, duration	Precautions
Fondaparinux (Arixtra™)	Treatment of VTE Treatment is for 5–9 d; continue treatment until a therapeutic oral anticoagulant effect is established	< 50 kg: 5.0 mg SC daily 50–100 kg: 7.5 mg SC daily > 100 kg: 10 mg SC daily Renal impairment CrCL 50–80 mL/min—25% reduction in total clearance; consider empiric dosage reduction CrCL 30–50 mL/min—40% reduction in total clearance; consider empiric dosage reduction CrCL less than 30 mL/min—contraindicated	■ Indwelling epidural catheter ■ Recent spinal or ophthalmologic surgery ■ History of recent major bleed (gastrointestinal, intracranial, etc.) ■ Congenital or acquired bleeding disorders
	Treatment of STEMI and NSTEMI[a]	2.5 mg SC daily	
	Prophylaxis of VTE in major surgery and acute medically ill[a]	2.5 mg SC daily	

[a]Indicates off-label use of medication.
CrCl, creatinine clearance using Cockcroft–Gault equation; NSTEMI, non ST-elevation myocardial infarction; SC, subcutaneous; STEMI, ST-elevation myocardial infarction; VTE, venous thromboembolism.

fractures. Osteoporosis reportedly occurs less frequently in patients treated with LMWHs as compared to UFH [48].

Fondaparinux

Fondaparinux is a synthetic analog of the naturally occurring pentasaccharide found in heparins. Fondaparinux selectively and irreversibly binds to AT. This results in neutralization of factor Xa, which ultimately inhibits thrombin formation and thrombus development [48].

Pharmacology, Pharmacodynamics, and Monitoring

After subcutaneous administration, fondaparinux has a half-life of 17 to 21 hours in patients with normal renal function. Fondaparinux is excreted in the urine with clearance reduced in patients with renal impairment. As with LMWHs, monitoring of anti-Xa levels is not required during fondaparinux administration (Table 110.10) [48].

Clinical Indications

Fondaparinux is as safe and effective as the heparins for treatment of deep venous thrombosis (DVT) and pulmonary embolism (PE) and for thromboprophylaxis in surgical and medically ill patients [70–73]. Fondaparinux showed superior efficacy in reducing VTE in patients undergoing knee arthroplasty, hip arthroplasty, and hip fracture surgery [74–76]. In a combined analysis, the overall incidence of major bleeding was statistically higher with fondaparinux (2.7%) compared with LMWH (1.7%) [77]. However, the incidence of clinically relevant bleeding, defined as bleeding leading to death, reoperation, or occurring in a critical organ, did not differ between the agents. Differences in efficacy and safety outcomes could be related to the timing of perioperative drug administration. Fondaparinux given less than 6 hours after surgery has been associated with an increased frequency of major bleeding [77]. Fondaparinux may be an option for thromboprophylaxis in the setting of HIT but conclusive data are not available [78].

Complications and Reversal of Effect

Fondaparinux is contraindicated in patients with severe renal impairment (calculated creatinine clearance < 30 mL per minute) and should not be used for VTE prophylaxis in patients weighing less than 50 kg. No antidote exists for fondaparinux-related hemorrhage and reversal is further complicated by its prolonged half-life [79]. Recombinant factor VIIa (rVIIa) reverses the coagulation defect induced by fondaparinux, but the clinical utility is unknown [80,81]. With a short half-life (2 to 3 hours), rVIIa may require repeat dosing. The use of fondaparinux and neuraxial anesthesia or analgesia should follow the conditions used in clinical trials as closely as possible [30].

Direct Thrombin Inhibitors

The direct thrombin inhibitors (DTIs) are lepirudin, bivalirudin, and argatroban. They exert their antithrombotic effect by binding to the active site of thrombin and inhibiting thrombin-catalyzed reactions. This prevents fibrin formation, activation of coagulant factors V, VIII, XIII, protein C, and platelet aggregation [82].

Pharmacology, Pharmacodynamics, and Monitoring

Lepirudin (*r*-hirudin) is a recombinant derivative of hirudin, produced from leech salivary glands. Bivalirudin is the synthetic analog of r-hirudin. Argatroban, derived from the amino acid arginine, is a small synthetic molecule. The DTIs differ in their pharmacokinetic parameters (Table 110.11) [82]. Lepirudin is eliminated through renal clearance, argatroban by hepatic metabolism, and bivalirudin by proteolytic cleavage in the plasma. Bivalirudin has the shortest half-life, making it a particularly useful agent in the procedural or periprocedural period. DTI selection is predicated on patient-specific characteristics such as hemodynamic stability, hepatic function, and renal function. Critically ill patients typically require lower doses than recommended by the manufacturer [82,83]. DTIs are monitored using aPTT (Table 110.12). The aPTT level should be measured every 6 hours until the patient has sustainable therapeutic levels, then the monitoring frequency can be extended [69].

Clinical Indications

Lepirudin and argatroban significantly reduce the rates of thromboembolic complications in patients with HIT [84,85].

TABLE 110.11

PHARMACOKINETIC AND PHARMACODYNAMIC PROPERTIES OF DIRECT THROMBIN INHIBITORS

Feature	Lepirudin	Argatroban	Bivalirudin
Molecular weight (Da)	6,979	526	2,180
FDA-approved indication	Management of HIT	Management of HIT, or use in patients with HIT who are undergoing PCI	Use in patients with or at risk for HIT or HITTS who are undergoing PCI
Primary elimination route	Renal	Hepatic	Enzymatic
Elimination half-life	1.3 h	39–51 min	10–24 min
Fraction eliminated unchanged by kidney (%)	35	16	20
Laboratory test to monitor	aPTT, ECT	aPTT, ECT	aPTT, ACT, ECT
Target range	aPTT: 1.5–2.5 × control	aPTT: 1.5–3 × control	aPTT: 1.5–2.5 × control
Effects on INR	Minimal	Moderate to clinically significant	Minimal to moderate

ACT, activated clotting time; aPTT, activated partial thromboplastin time; Da, dalton; ECT, ecarin clotting time; FDA, Food and Drug Administration; HIT, heparin-induced thrombocytopenia; HITTS, HIT with thrombosis syndrome; INR, international normalized ratio; PCI, percutaneous coronary intervention.

Bivalirudin has been safely used in critically ill HIT patients [86]. Argatroban and bivalirudin are indicated for prophylaxis of thrombosis in patients with, or at risk for, HIT undergoing PCI. Bivalirudin is also indicated in the treatment of patients undergoing PCI as well as those with unstable angina/non-ST segment elevation myocardial infarction undergoing PCI (see Table 110.12) [87].

Complications and Reversal of Effect

No specific reversal agent is available for DTI-induced hemorrhage.

For lepirudin, hemofiltration may be an alternative in the setting of life-threatening hemorrhage. Anecdotally, rVIIa has been reported to be useful as well [88]. DTIs can produce elevation in the international normalized ratio (INR), an effect that is most pronounced with argatroban, and magnified when coadministered with warfarin. This laboratory interaction has misled clinicians to discontinue argatroban therapy prematurely, predisposing patients to venous limb gangrene [78]. With concurrent administration, the argatroban infusion should be stopped and the INR measured 4 to 6 hours. If the INR is within therapeutic range on warfarin alone, warfarin monotherapy can be continued, otherwise argatroban therapy should be resumed.

Oral Anticoagulants—Vitamin K Antagonists

Warfarin, a vitamin K antagonist (VKA), inhibits the enzyme vitamin K epoxide reductase complex (VKORC), which converts vitamin K to an active form. The absence of vitamin K reduces the hepatic production of functional coagulation factors II (thrombin), VII, IX, and X and the regulatory anticoagulant proteins C, S, and Z. Since thrombin has a longer half-life (60 to 72 hours) compared to the other factors (6 to 24 hours), at least 6 days of warfarin treatment is required for an antithrombotic effect [89].

Warfarin is extensively metabolized by the CYP450 isoenzyme system including CYP2C9, CYP1A1, CYP1A2, and CYP3A4. Several genetic polymorphisms have been identified with CYP2C9 and VKORC that may influence warfarin clearance and dose sensitivity [90,91].

In critically ill patients, alterations in coagulation factors, caused by reduced dietary vitamin K intake, hypoalbuminemia, antibiotic administration, acute hepatic injury, or hypermetabolic states, will impact the effects of warfarin [90,91]. Furthermore, drug interactions alter warfarin absorption, clearance, and plasma protein binding. The interactions could have either synergistic or antagonistic effects [89].

Warfarin's anticoagulant effect is measured using the INR [92]. The INR uses the international sensitivity index of the local thromboplastin reagent to standardize the laboratory result. The INR target range will vary based on indication and the patient's risk for thromboembolic and bleeding complications (see Table 110.13). Nomogram-based warfarin dosing is considered safer and more effective for reaching target INR goals. To prevent excessive anticoagulation, loading doses are avoided and low doses are employed for the elderly [93]. Frequent INR monitoring is necessary during initiation of therapy until steady state is reached.

Clinical Indications

Warfarin is effective for primary and secondary prevention of venous thromboembolism, for prevention of systemic embolism in patients with prosthetic heart valves or atrial fibrillation, and for prevention of stroke, recurrent infarction, or death in patients with acute myocardial infarction [89,94–96].

Complications and Reversal of Effect

Treatment with warfarin increases the risk of major bleeding by 0.3% to 0.5% per year and the risk of intracerebral hemorrhage by approximately 0.2% per year compared to controls [53]. Important risk factors for hemorrhage include anticoagulant intensity, time within therapeutic range, and patient age. Higher goal INR (INR > 3) has been directly associated with increased hemorrhage rates. Elevated INR can be managed by withholding or decreasing warfarin doses. In patients experiencing or at risk of bleeding, vitamin K administration will reverse the anticoagulant effects of warfarin. Vitamin K is given orally or parenterally. Oral vitamin K normalizes supratherapeutic INRs more rapidly than subcutaneous vitamin K [97]. Intravenous vitamin K corrects excessive warfarin anticoagulation quicker and more completely than subcutaneous administration [98].

For patients with an INR > 5.0 but < 9.0 and no significant bleeding, the next two doses of warfarin should be held, and low dose (1 to 2.5 mg) oral vitamin K administered. For patients with an INR > 9.0, the vitamin K dose can be increased to 2.5 to 5 mg [89].

In the setting of serious or life-threatening hemorrhage, warfarin should be held and vitamin K 10 mg administered by slow IV infusion. The supplementation of coagulation factors with

TABLE 110.12

CLINICAL USES OF DIRECT THROMBIN INHIBITORS

Drug	Indications	Dosing, timing, duration	Precautions
Bivalirudin (Angiomax™)	PCI (with glycoprotein IIB/IIIA inhibitor)	0.75 mg/kg IV bolus dose, followed by an infusion of 1.75 mg/kg/h for the duration of the procedure CrCl less than 30 mL/min, a reduction of initial infusion rate to 1 mg/kg/h should be considered; no bolus dose reduction is necessary	■ Indwelling epidural catheter ■ Recent major, spinal or ophthalmologic surgery, or cerebrovascular accident ■ History of recent major bleed (gastrointestinal, intracranial, etc.) ■ Congenital or acquired bleeding disorders ■ Repeat lepirudin courses may require more frequent monitoring due to antibody formation ■ Hepatic impairment (argatroban) ■ Renal dysfunction (bivalirudin and lepirudin)
	Treatment of ACS[a]	Initial IV bolus dose of 0.1 mg/kg, followed by 0.25 mg/kg/h. Titration to aPTT 1.5–2 times control	
	Treatment and prophylaxis of HITT[a]	0.1–0.2 mg/kg/h, titration to aPTT 1.5–2 times control	
Argatroban	Treatment and prophylaxis of HITT	0.5–1.2 µg/kg/min continuous IV infusion to start titration to goal aPTT between 50 and 85 s. Begin VKA therapy, measure INR daily. Stop argatroban when INR > 4. Repeat INR in 4–6 h, if INR is below desired range then resume argatroban infusion	
	Treatment of ACS	Bolus: 100 µg/kg Initial infusion: 1–3 µg/kg/min for 6–72 h; maintain aPTT between 50 and 85 s	
Lepirudin (Refludan™)	Treatment and prophylaxis of HITT ■ aPTT ratio target: between 1.5 and 2.5; begin monitoring aPTT 4 h after initiation of infusion and daily thereafter; recheck aPTT 4 h after any dosage changes ■ aPTT greater than 2.5: discontinue infusion for 2 h, decrease infusion rate by 50% when reinstated ■ aPTT less than 1.5: increase infusion rate in 20% increments until target aPTT is achieved	Bolus: 0.4 mg/kg IV (up to 44 mg) Initial infusion: 0.05–0.15 mg/kg/h (up to 16.5 mg/h) for 2–10 d, adjust infusion rate according to aPTT ratio Renal impairment CrCl < 60 mL/min): Bolus: 0.2 mg/kg IV Initial infusion: 0.001–0.01 mg/kg/h (up to 16.5 mg/h) for 2–10 d, adjust infusion rate according to aPTT ratio	

[a] Indicates off-label use of medication.
ACS, acute coronary syndrome; ACT, activated clotting time; aPTT, activated partial thromboplastin time; CBC, complete blood count; CrCl, creatinine clearance using Cockcroft–Gault equation; HITT, heparin-induced thrombocytopenia and thrombosis; INR, international normalized ratio; IV, intravenous; PCI, percutaneous coronary intervention; PT, prothrombin time; VKA, vitamin K antagonist.

fresh frozen plasma (FFP) or prothrombin complex concentrate may be more effective in cases where immediate reversal of the INR is necessary [98]. Recombinant factor VIIa may be beneficial in patients with refractory bleeding in the setting of elevated INRs, or those requiring an invasive procedure [89,99–101].

Nonhemorrhagic adverse events of warfarin include acute skin necrosis and limb gangrene. These complications are typically observed on the third to eighth day of therapy [89].

In patients scheduled for surgery, warfarin may be continued, interrupted for approximately 5 days, or replaced with short-term parenteral or bridge therapy depending on the patient's risk for venous or arterial thromboembolism. Warfarin is resumed after surgery. Most bridging regimens have been developed from observational studies since there is not a standardized definition of bridging [101,102].

For warfarin-treated patients receiving neuraxial anesthesia with an indwelling catheter, the catheter should be removed when the INR is less than 1.5. Patients with a low risk of bleeding may undergo surgery with an INR of 1.3 to 1.5 [30,101].

TABLE 110.13

CLINICAL USES OF WARFARIN

Drug	Indications	Dosing, timing, duration	Precautions
Warfarin (Coumadin™)	Treatment of VTE	Initial dosing: 2.5–10 mg every 24 h (see precautions) titrated to range INR: 2.0–3.0; target of 2.5	■ Lower initial dosing (< 5 mg may be warranted in patients who are debilitated, or are taking medications known to increase sensitivity to warfarin ■ Cerebrovascular disease ■ Coronary disease ■ CYP2C9 and VKORC1 genetic variation ■ Moderate to severe hypertension ■ Malignancy ■ Renal impairment ■ Recent trauma ■ Malignancy ■ Collagen vascular disease ■ Conditions that increase risk of hemorrhage, necrosis, and/or gangrene, pre-existing ■ Congestive heart failure ■ Excessive dietary vitamin K ■ Vitamin K deficiency ■ Elderly or debilitated patients (lower dosing may be required) ■ Hepatic impairment ■ Hyperthyroidism/hypothyroidism ■ Epidural catheters ■ Infectious diseases or disturbances of intestinal flora, such as sprue or antibiotic therapy ■ Poor nutritional state ■ Protein C deficiency ■ Heparin-induced thrombocytopenia
	Atrial fibrillation	Initial dosing: 2.5–10 mg every 24 h (see precautions) titrated to range INR: 2.0–3.0; target of 2.5	
	Post MI	Initial dosing: 2.5–10 mg every 24 h (see precautions) titrated to range INR 2.0–3.0; target of 2.5	
	Mechanical valve in the atrial position	Initial dosing: 2.5–5 mg every 24 h (see precautions) titrated to range INR 2.0–3.0; target of 2.5	
	Mechanical valve in the mitral position	Initial dosing: 2.5–5 mg every 24 h (see precautions) titrated to range INR 2.5–3.5; target of 3.0	
	Mechanical valve in both the atrial and mitral position	Initial dosing: 2.5–5 mg every 24 h (see precautions) titrated to target INR 2.5–3.5; target of 3.0	
	Bioprosthetic valve in the mitral position	Initial dosing: 2.5–5 mg every 24 h (see precautions) titrated to target INR 2.0–3.0; target of 2.5 for 3 months

FIBRINOLYTIC THERAPY

Overview of Fibrinolytic Pharmacotherapy

Fibrinolytic agents have been used clinically since the 1950s when streptokinase was shown to be effective in dissolving occlusive thrombi.

Pharmacology, Pharmacodynamics, and Monitoring

Fibrinolytic agents promote the conversion of plasminogen to plasmin, which subsequently causes the degradation of fibrin clots [103]. Streptokinase and urokinase are naturally occurring first-generation fibrinolytic agents [104]. Recombinant tissue plasminogen activator (rt-PA) is a second-generation fibrinolytic that causes less overall systemic depletion of fibrinogen

CLINICAL USES OF FIBRINOLYTICS

Drug	Indications	Dosing, timing, duration	Precautions
Alteplase (Activase™ and Cathflo Activase™)	Acute myocardial infarction (accelerated infusion)	>67 kg 15 mg IV bolus, followed by 50 mg infusion over 30 min, then 35 mg infusion over 60 min (total = 100 mg) ≤67 kg 15 mg IV bolus, followed by 0.75 mg/kg infusion over 30 min (max 50 mg), then 0.5 mg/kg over 60 min (max 35 mg)	■ Recent major or minor surgery (within 10 d) ■ Cerebrovascular diseases ■ Recent gastrointestinal or genitourinary bleeding ■ Recent trauma ■ Hypertension: systolic BP greater than or equal to 175–180 mmHg and/or diastolic BP greater than or equal to 110 mmHg ■ Left heart thrombus ■ Acute pericarditis ■ Subacute bacterial endocarditis ■ Hemostatic defects ■ Severe hepatic or renal dysfunction ■ Pregnancy ■ Diabetic hemorrhagic retinopathy or other hemorrhagic ophthalmic conditions ■ Septic thrombophlebitis or occluded arteriovenous cannula at a seriously infected site ■ Advanced age
	Pulmonary embolism	Routine administration for PE (noncardiac arrest): 100 mg IV administered over 120 min During cardiopulmonary resuscitation: 50 mg IV single dose administered over 5 min	
	Acute ischemic stroke (within 3 h of symptom onset)	0.9 mg/kg IV (not to exceed 90 mg total dose) infused over 60 min with 10% of the total dose administered as an initial intravenous bolus over 1 min	
	Arterial thrombosis	Catheter-directed administration: 1.5 mg/h by transcatheter intra-arterial infusion until lysis of thrombus	
	Central venous catheter occlusion	Weight >30 kg 2 mg/2 mL Weight >10 kg but <30 kg 110% of the internal lumen volume, not to exceed 2 mg/2 mL	
Reteplase (Retavase™)	Acute myocardial infarction	10 unit IV bolus, two doses given 30 min apart	■ Patients receiving oral anticoagulants ■ Known or suspected infection in the catheter during use for catheter clearance
	Central venous catheter occlusion[a]	0.4 units/2 mL	
Tenecteplase (TNKase™)	Acute myocardial infarction	<60 kg: 30 mg dose ≥60 to <70 kg: 35 mg ≥70 to <80 kg: 40 mg ≥80 to <90 kg: 45 mg ≥90 kg: 50 mg Single IV bolus over 5 s	■ Severe neurological deficit (NIHSS >22) (ischemic stroke) ■ Patients with major early infarct signs on computerized cranial tomography (ischemic stoke) ■ History of streptococcal infection within 5 d–12 mo (streptokinase)
Streptokinase (Streptase™)	Acute myocardial infarction	1.5 million IU over 60 min	■ Previous streptokinase administration (within 5 d–12 mo)
	Pulmonary embolism	250,000 IU IV over 30 min, then 100,000 IU/h for 24 h	
	Deep venous thrombosis	250,000 IU IV over 30 min, then 100,000 IU/h for 72 h	
	Arterial thrombosis	250,000 IU IV over 30 min, then 100,000 IU/h for 24 h	
Urokinase (Abbokinase™ or Kinlytic™)	Pulmonary embolism	Loading dose: 4,400 IU/kg IV over 10 min, then 4,400 IU/kg/h IV for 12 h	
	Central venous catheter occlusion[a]	5,000 IU, fill volume of catheter for 1–4 h. May repeat with 10,000 IU in catheter if first dose fails.	

[a]Indicates off-label use of medication.
BP, blood pressure; IU, international units; IV, intravenous; MI, myocardial infarction; NIHSS, National Institute of Health Stroke Scale.

and plasminogen compared with streptokinase and urokinase. The half-life of rt-PA is less than 5 minutes when administered as a bolus followed by rapid continuous infusion. Third-generation fibrinolytic agents are synthetic agents with increased fibrin specificity compared to first-generation fibrinolytics and extended half-lives compared to rt-PA [104]. Reteplase is administered in sequential intravenous bolus doses while tenecteplase is administered as a single bolus (Table 110.14). The beneficial properties of the newer agents continue to be evaluated in clinical trials.

Clinical Indications

Fibrinolytic therapy is administered to patients with acute ischemic stroke, venous thromboembolism, acute myocardial

TABLE 110.16

SELECTED EVIDENCE-BASED CLINICAL TRIALS OR META-ANALYSES RELEVANT TO THE CARE OF INTENSIVE CARE UNIT PATIENTS

Indication	Comparison	Result	Reference
Antiplatelet therapies	Meta-analysis of 2,930 patients with cardiovascular disease treated with aspirin regimens ranging from 75 to 325 mg daily Double-blind trial comparing ticagrelor (180-mg loading dose, 90 mg twice daily) versus clopidogrel (300–600-mg loading dose, 75 mg daily thereafter) for the prevention of cardiovascular events in 18,624 patients admitted to the hospital with an acute coronary syndrome.	Overall, 28% of patients were classified as aspirin resistant. A cardiovascular-related event occurred in 41% of patients, an acute coronary syndrome in 40%, and death in 6%. Aspirin-resistant patients are at a greater risk of clinically important cardiovascular morbidity. Over 12 mo the composite of death from vascular causes, myocardial infarction, or stroke occurred in 9.8% ticagrelor patients vs 11.7% of those receiving clopidogrel. There were no significant differences in the rates of major bleeding (11.6% vs 11.2%).	[14] [25]
Antithrombotic therapies Thromboprophylaxis in medically ill patients Treatment of acute pulmonary embolism (MATISSE PE) Reversal of warfarin anticoagulant effect with vitamin K	Meta-analysis comparing the incidence of DVT and PE in hospitalized medically ill patients receiving thromboprophylaxis with UFH twice daily, to UFH tree times daily and to LMWH. Open-label trial comparing fondaparinux to aPTT-monitored intravenous UFH for the initial treatment of hemodynamically stable patients with PE. Open-label trial comparing vitamin K subcutaneous vs intravenous administration in patients with an INR > 6.0 without active bleeding.	UFH dosage of 5,000 units three times daily was more effective in preventing DVT than UFH 5,000 units twice daily. LMWH was associated with a lower risk of DVT and injection site hematoma but no difference was seen in the risk of bleeding or thrombocytopenia. The 3-mo incidence of the composite end point of symptomatic, recurrent PE (nonfatal or fatal) and new or recurrent deep-vein thrombosis was similar in fondaparinux-treated patients (3.8%) and those assigned to UFH (5.0%). Major bleeding occurred in 1.3% of patients treated with fondaparinux and 1.1% of those treated with unfractionated heparin. Intravenous vitamin K corrects excessive warfarin anticoagulation quicker and more completely than subcutaneous administration.	[64] [71] [98]
Thrombolytic therapies Treatment of acute ischemic stroke Treatment of submassive pulmonary embolism Treatment of acute myocardial infarction	Double-blind trial comparing the safety and efficacy of alteplase administered between 3 and 4.5 h after the onset of a stroke. The primary end point was disability. Meta-analysis of randomized trials comparing thrombolytic therapy with UFH in patients with acute pulmonary embolism. Open-label trial comparing the efficacy and safety of tenecteplase plus enoxaparin or abciximab with that of tenecteplase plus weight-adjusted unfractionated heparin in patients with acute MI.	More patients had a favorable outcome at 90 d with alteplase (52%) than with placebo (45%) when measured using the modified Rankin scale. The incidence of intracranial hemorrhage was higher with alteplase than with placebo. Mortality did not differ significantly between the groups. Thrombolytic therapy was associated with a nonsignificant reduction in recurrent pulmonary embolism, death, and a nonsignificant increase in major bleeding when compared to UFH. When thrombolytic therapy was compared with UFH in patients with major (hemodynamically unstable) PE, thrombolysis was associated with a significant reduction in recurrent PE or death. There were significantly fewer efficacy (composites of 30-d mortality, in-hospital reinfarction, or in-hospital refractory ischemia) and efficacy plus safety end points (in-hospital intracranial hemorrhage or in-hospital major bleeding complications) in the enoxaparin and abciximab groups than in the UFH group.	[108] [111] [113]

MATISSE PE, Mondial Assessment of Thromboembolism Treatment Initiated by Synthetic Pentasaccharide with Symptomatic Endpoints—Pulmonary Embolism; UFH, unfractionated heparin; DVT, deep venous thrombosis; LMWH, low-molecular-weight heparin; aPPT, activated partial prothrombin time; MI, myocardial infarction; PE, pulmonary embolism.

infarction, peripheral arterial occlusion, and in those patients requiring venous catheter maintenance (Table 110.15).

The goal of fibrinolytic therapy in acute ischemic stroke is to recanalize vessels and rapidly restore oxygenation to ischemic but salvageable brain tissue. rt-PA has been shown to improve long-term neurological recovery [105,106]. Pooled analysis of six trials comparing rt-PA to placebo showed that treatment benefit increased as time to start of therapy decreased [107]. While recent guidelines recommend intravenous rt-PA treatment within 3 hours of symptom onset, emerging evidence suggests additional benefit without increased bleeding risk in patients treated between 3 and 4.5 hours [108]. The intra-arterial route is recommended for patients with angiographically demonstrated middle cerebral artery occlusion and without major early infarct signs on CT or MRI scan, who can be treated within 6 hours of symptom onset in a center with the appropriate expertise [109]. Streptokinase is not recommended for acute ischemic stroke due to increased mortality and symptomatic intracranial hemorrhage [109]. Anticoagulants and antiplatelet agents should be held for 24 hours, or until coagulation parameters have returned to normal, after treatment with intravenous rt-PA therapy.

Fibrinolytic therapy is indicated for treatment of acute massive PE to accelerate lysis, provide hemodynamic improvement, and reverse cardiogenic shock. Fibrinolytic use is controversial in patients with submassive PE. Treatment is based on risk stratification of PE severity, bleeding risk, and prognosis [110]. A meta-analysis comparing fibrinolytic therapy with heparin alone for initial treatment, however, showed no benefit of fibrinolytic therapy in decreasing recurrent PE or death [111] (Table 110.16).

In centers with expertise, catheter-direct fibrinolytic therapy is a management option for treatment of acute DVT and may reduce long-term complications of postthrombotic syndrome [112].

The goal of therapy for patients presenting with ST-elevation myocardial infarction is rapid reperfusion. For patients presenting to centers without PCI capabilities, or timely transfer to those facilities, fibrinolytic therapy is recommended within 30 minutes of arrival of medical contact or within 30 minutes of hospital arrival if the emergency medical service does not have fibrinolytic capabilities. Fibrinolytic agents have been combined with various anticoagulants and antiplatelet agents to improve outcomes and reduce bleeding [113–115].

A clear role for fibrinolytic therapy, compared with surgical revascularization, for acute limb ischemia has yet to be defined. There is wide variation in fibrinolytic agents employed, doses studied, patient populations, and endpoints of therapy. The greatest benefit has been shown for patients presenting with acute ischemia < 14 days who are at low risk for irreversible ischemia [116].

A common use for fibrinolytic agents is to clear thrombotic occlusions within central venous and dialysis catheters. This therapy is both effective and safe since little to no active drug reaches the systemic circulation [117].

Complications and Reversal of Effect

Because of its derivation from *Streptococcus*, patients may have preformed antibodies to streptokinase from prior streptococcal infections. Adverse drug events include allergic reactions, anaphylaxis, and fever.

Bleeding is the most common and severe complication of fibrinolytic therapy. The most common areas of bleeding are the gastrointestinal and genitourinary tracts as well as sites of interrupted vascular integrity, including catheter access sites, gingiva, and skin [118]. Symptomatic intracerebral hemorrhage rates range between 0.5% and 11% of patients treated with fibrinolytic therapy [119]. A review of six randomized controlled trials of rt-PA for patients with ischemic stroke found an intracerebral hemorrhage rate of 5.9% compared with 1.1% in the placebo groups [107]. Various risk factors for hemorrhage have been identified, but application to clinical practice is limited [120].

Patients receiving fibrinolytic therapy should be closely monitored for intracerebral hemorrhage. Intracerebral hemorrhage should be suspected in patients with sudden focal neurological deterioration (over minutes to hours), decreased level of consciousness, new-onset headache, nausea, vomiting, or acute increases in blood pressure during and within 24 hours of fibrinolytic treatment. Prompt treatment should ensue with replacement of coagulation factors, platelets, FFP, red blood cells, and aminocaproic acid.

CHAPTER 111 ■ DIAGNOSIS AND MANAGEMENT OF PROTHROMBOTIC DISORDERS IN THE INTENSIVE CARE UNIT

ASHKAN EMADI AND MICHAEL B. STREIFF

INTRODUCTION

Arterial and venous thromboembolism are among the most common causes of hospitalization in the United States [1,2]. Given the severity of illness of patients in the intensive care unit (ICU), critical care physicians are likely to manage patients with prothrombotic conditions. In this chapter, we will review the regulation of normal hemostasis (which is required to prevent excessive activity of platelets and/or coagulation factors) and the biology, diagnosis and management of selected prothrombotic disorders in the critical care setting.

Prophylaxis and the general approach to treatment of venous thromboembolism (VTE) are discussed in Chapter 52, "Venous Thromboembolism: Pulmonary Embolism and Deep Venous Thrombosis."

REGULATION OF NORMAL HEMOSTASIS

Hemostasis maintains the integrity of the closed circulatory system after vascular injury. A tenuous balance of prothrombotic (i.e., platelets, coagulation proteins) and endogenous antithrombotic (i.e., antithrombin, nitric oxide) mechanisms ensures hemostasis without pathologic thrombosis. Disruptions of this balance are common in critically ill patients and can lead to clinically significant bleeding or thrombosis. Additional information regarding the normal control of bleeding is present in Chapter 108, "Disorders of Hemostasis in Critically Ill Patients."

The potentially prothrombotic activity of coagulation factors and platelets, however, is opposed by negative regulators of hemostasis. Platelet activation is inhibited by endothelial-derived nitric oxide, prostacyclin, and the ectonucleotidase CD39, which together antagonize platelet activation. The tissue factor pathway is inhibited by tissue factor pathway inhibitor (TFPI). TFPI is synthesized by the endothelium and binds to factor Xa and inhibits its function as well as the activation of factor X by the tissue factor/factor VIIa complex. Since its concentrations increase dramatically with heparin administration, TFPI probably contributes to the antithrombotic efficacy of unfractionated and low-molecular-weight heparin (LMWH) [3,4].

Antithrombin (AT) (formerly antithrombin III) is a liver-derived serine protease inhibitor that inhibits factors XIIa, XIa, IXa, and, in particular, Xa and thrombin by binding to their active sites. Heparin accelerates this reaction to several thousand-fold, thus explaining its potent anticoagulant activity. Protein C (PC) is a liver-derived, vitamin K–dependent protease that is activated on the surface of intact endothelium by thrombin bound to thrombomodulin. This activation event is enhanced by the presence of endothelial PC receptor. Activated protein C (APC) when complexed with its cofactor, protein S (PS), on phospholipid-rich surfaces catalyzes the inactivation of activated forms of factors V and VIII (also known as factor Va and factor VIIIa). PS is a liver-derived, vitamin K–dependent protein that binds to the APC and accelerates its inactivation of factors Va and VIIIa. It exists in the plasma in an active free form that can complex with PC and an inactive form bound to C4b-binding protein [5].

Further regulation of the coagulation cascade is provided by the fibrinolytic system, whose components include plasminogen, tissue plasminogen activator (TPA), plasminogen activator inhibitor I and II, α_2-antiplasmin, and thrombin activatable fibrinolysis inhibitor (TAFI). Plasminogen is a liver-synthesized plasma protein that is converted to plasmin on activation by TPA. Plasmin cleaves fibrin and is principally responsible for clot dissolution and remodeling in the intravascular compartment. Activation of plasminogen is opposed by plasminogen activator inhibitors I and II which inhibit TPA from activating plasminogen. α_2-Antiplasmin is synthesized in the liver and binds to plasmin and prevents it from digesting fibrin clot. TAFI is a carboxypeptidase that is activated by the thrombin–thrombomodulin complex. It removes C-terminal lysine residues from partially digested fibrin clot, thereby downregulating the binding of additional plasminogen to the fibrin clot and thus slowing fibrinolysis [6].

THROMBOPHILIC DISORDERS

Thrombophilic disorders are inherited or acquired conditions that variably increase the risk of venous or arterial thromboembolism depending on the particular alteration and the severity of its impact on the hemostatic mechanism. From a practical diagnostic standpoint, it is most useful to divide these disorders into conditions that are associated with venous or arterial thromboembolism (Table 111.1). A more detailed description of each thrombophilic state follows below along with the appropriate approach to diagnosis.

Factor V Leiden

Factor V Leiden (FVL) is the most common inherited thrombophilic condition affecting approximately 5% of Caucasian European Americans, 2% of Hispanic Americans, 1% of African Americans and Native Americans, and 0.5% of Asian Americans [7]. FVL refers to a single base change (Arg506Gln) in the factor V gene (G1691A) that eliminates the first and most important of three APC cleavage sites. The mutation slows down the inactivation of factor Va by APC leading to more thrombin generation. FVL heterozygosity is associated

TABLE 111.1

INHERITED AND ACQUIRED PROTHROMBOTIC CONDITIONS

Venous thromboembolism	Arterial thromboembolism
Inherited	Inherited
Factor V Leiden	Hyperhomocysteinemia
Prothrombin gene mutation	Dysfibrinogenemia
Antithrombin (III) deficiency	
Protein C deficiency	
Protein S deficiency	
Elevated factor VIII activity	
Elevated factor IX level	
Elevated factor XI level	
Hyperhomocysteinemia	
Dysfibrinogenemia	
Acquired	Acquired
Antiphospholipid syndrome	Antiphospholipid syndrome
Heparin-induced thrombocytopenia	Heparin-induced thrombocytopenia
Cancer	Cancer
Surgery	Surgery
Trauma	Trauma
Pregnancy/postpartum	Inflammation
Central venous catheters	
Vena cava filters	
Immobilization	
Infection/inflammation	
Cardiopulmonary failure	
Exogenous estrogens	

with a 5-fold increased risk of VTE, whereas homozygosity increases this risk by at least 10-fold [8]. FVL does not appear to be associated with an increased risk of arterial thromboembolism [9]. FVL heterozygosity and homozygosity increase the risk of recurrent VTE modestly by 1.56-fold (95% confidence interval [CI], 1.14 to 2.12) and 2.65-fold (95% CI, 1.18 to 5.97), respectively [10]. Diagnosis of FVL relies on a functional screening assay, the APC resistance assay, and confirmatory DNA-based testing.

The Prothrombin G20210A Mutation

The prothrombin gene mutation G20210A (PGM) is present in 1.1% of non-Hispanic Whites and Mexican Americans and in 0.3% of African Americans [11]. It is associated with a 30% increase in prothrombin levels in heterozygotes resulting in a 2.8-fold increased risk of VTE [12]. Homozygosity for the FII mutation is rare, so reliable risk estimates are not available. The PGM does not appear to increase the risk of arterial thromboembolism or recurrent VTE [10,13]. Diagnosis of the PGM is based on DNA testing of peripheral blood.

Compound Heterozygotes for the FVL and FII Mutations

Given the relatively high frequency of FVL and the PGM in the population, double heterozygotes for these mutations are occasionally identified. Compound heterozygosity for both FVL and the PGM is associated with a 20-fold increased risk for first-ever VTE and a 4.8-fold risk for recurrent VTE (95% CI, 0.50 to 46.3) [8,10].

Protein C Deficiency

PC is an important endogenous anticoagulant protein that inactivates factors Va and VIIIa. Heterozygous PC deficiency affects 0.2% of the general population and 3.2% of unselected patients with their first episode of VTE [14]. It is associated with a sevenfold increased risk of VTE [15,16]. Homozygous PC deficiency is a rare thrombophilic syndrome that produces life-threatening thrombotic complications shortly after birth, a condition called *neonatal purpura fulminans*. PC deficiency may result from mutations that produce quantitative (type I deficiency) or qualitative (type II) defects. Therefore, accurate diagnostic testing should include both PC activity and antigen levels. Acquired causes of PC deficiency include disseminated intravascular coagulation/acute thrombosis, vitamin K deficiency, vitamin K antagonist (VKA) therapy (i.e., warfarin), and liver disease. Therefore, diagnostic testing should be performed in the absence of these conditions to ensure that laboratory results are interpretable [17].

Protein S Deficiency

PS is the nonenzymatic cofactor for activated PC. PS circulates in two forms: approximately 60% is bound to C4b binding protein, while the remaining 40% is free. Only free PS has cofactor activity. The incidence of PS deficiency is estimated to be 0.03% to 0.13%. PS deficiency affects 7.3% of unselected patients with venous thrombosis [14,18]. PS deficiency is associated with an eightfold increased risk of VTE [15] and may be a risk factor for arterial thromboembolism [19,20].

Deficiency of PS may by quantitative (type I deficiency) or qualitative (type II). An additional type of deficiency (type III) can be acquired during pregnancy, inflammatory states, and estrogen therapy, which increase C4b binding protein levels leading to reduced free PS. Other acquired causes of PS deficiency include vitamin K deficiency, VKA therapy (i.e., warfarin), acute thrombosis, and liver disease. For accurate diagnosis of PS deficiency, all three tests including PS activity, total PS antigen and free PS antigen should be checked in the absence of conditions associated with acquired PS deficiency [18].

Antithrombin (III) Deficiency

AT inhibits serine protease coagulation factors by binding to the active site of the target protease and forming an inactive complex. Heterozygous type I AT deficiency is rare, affecting 1 in 2,000 in the population. It is associated with an 8- to 10-fold increased risk of thrombosis and is present in 1% to 2% of patients with thrombosis [21]. AT deficiency does not increase the risk of arterial thromboembolism [19,20].

Deficiency of AT may by quantitative (type I deficiency) or qualitative (type II). Complete AT deficiency is incompatible with life. The diagnosis of AT deficiency is made by measuring AT activity and antigen levels. Acquired AT deficiency may occur in acute thrombosis, disseminated intravascular coagulation, and during heparin therapy. Artifactual increases in AT can be seen during therapy with VKAs (e.g., warfarin) [21].

Dysfibrinogenemia

Dysfibrinogenemia is a rare inherited thrombophilic state caused by mutations in the Aα, Bβ, or γ fibrinogen genes and affects fewer than 1% of patients with venous thrombosis. Acquired dysfibrinogenemia is associated with chronic liver disease and cirrhosis as well as liver cancers and renal cell

carcinoma. Approximately one third of cases of dysfibrinogenemia are complicated by thrombosis (venous more commonly than arterial), possibly because of reduced thrombin binding or inhibition of fibrinolysis. Diagnosis of dysfibrinogenemia is made by measuring fibrinogen function (e.g., Clauss fibrinogen assay) as well as fibrinogen antigen. Typically, the fibrinogen activity level is much lower than the fibrinogen antigen level [22,23].

Hyperhomocysteinemia

Homocysteine is a thiol-containing amino acid that is converted to methionine by methionine synthase with vitamin B_{12} and 5-methyltetrahydrofolate as cofactors. Homocysteine is also converted to cysteine by cystathionine β-synthase, which requires pyridoxine (vitamin B_6) as a cofactor. Congenital causes of hyperhomocysteinemia include homocystinuria (deficiency of cystathionine β-synthase) and inheritance of the thermolabile mutation in the methylene tetrahydrofolate reductase (MTHFR) gene. Homocystinuria is associated with markedly increased levels of homocysteine (> 100 μmol per L) and developmental delay, arterial and venous thromboembolism, eye abnormalities, and premature coronary artery disease. Thermolabile mutations in MTHFR produce much more modest elevations in homocysteine (15 to 30 μmol per L) in only a minority of cases, and generally in association with folate deficiency. Acquired causes of hyperhomocysteinemia include deficiency of vitamin B_{12}, folate and pyridoxine, and renal insufficiency [24].

Hyperhomocysteinemia has been associated with a 20% increase in cardiovascular disease for each 5 μmol per L increase in fasting homocysteine levels [25]. Homozygosity for the MTHFR mutation is associated with a 1.16-fold increased risk of coronary artery disease [26]. This risk appeared to be significantly modified by folate status. Hyperhomocysteinemia is also associated with a two- to threefold higher risk of initial and recurrent VTE [27,28]. However, randomized studies of vitamin supplementation in patients with venous and arterial thrombotic disease did not demonstrate improved clinical outcomes [29–31]. Therefore, the utility of homocysteine lowering therapy is in question. The diagnosis of hyperhomocysteinemia is based on demonstrating elevated levels of homocysteine in a fasting blood sample. Methionine loading prior to sampling can increase the sensitivity of testing.

Elevated Coagulation Factor Levels

Elevated factor VIII (> 95 percentile) has been associated with an increased risk of initial and recurrent VTE [32,33]. Elevated factor VIII levels appear to be inherited, but the responsible genetic alterations have yet to be completely characterized. Factor VIII activity levels are the diagnostic test of choice. This test should be done at least 6 months after an episode of VTE and in the absence of inflammation to avoid spurious elevations. Elevated factor IX and XI antigen levels have been associated with a 2.5- and 2.2-fold increased risk of initial VTE, respectively [34,35].

ACQUIRED PROTHROMBOTIC DISORDERS

Although inherited thrombophilic conditions may lead to thrombosis, the attention paid to their potential presence by physicians and patients alike is often disproportionate, because acquired prothrombotic disorders are much more common and, in many cases, more potent causes of thromboembolism. A list of inherited and acquired prothrombotic disorders is displayed in Table 111.1. In this section, we will review several important acquired thrombotic disorders of relevance to the intensive care.

Cancer

Patients with cancer are at four- to sevenfold increased risk of thromboembolism (venous and arterial) compared with patients without cancer [36,37]. The risks of thromboembolism are influenced by the primary site of cancer, its histology, and stage as well as our treatments for cancer including surgery, chemotherapy, and growth factors such as erythropoietic stimulatory agents. High-risk organ sites include pancreas, brain, and stomach, while lung cancer and colon cancer are associated with intermediate risk and breast cancer and prostate cancer are associated with a lower risk. Adenocarcinoma is associated with a higher risk of thromboembolism than squamous cell carcinoma, and metastatic disease is associated with a higher risk than localized disease. Myeloproliferative disorders, in particular polycythemia vera (PV), are associated with an increased risk of thromboembolism that is mediated at least in part by an increased red cell volume. Therefore, it is essential to control erythrocytosis in patients with PV with phlebotomy (see "Hematologic Conditions" section in the chapter and Chapter 113, "Therapeutic Apheresis: Technical Considerations and Indications in Critical Care"). Surgery increases the risk of thromboembolism by 10-fold, whereas chemotherapy further increases the relative risk of thromboembolism by 50% in cancer patients. Erythropoietic stimulatory agents have been noted to be associated with an increased risk of thrombosis when hemoglobin values exceed 12 g per dL [38].

Unlike congenital thrombophilic states, cancer is associated with both arterial and venous thromboembolism. Thromboembolism can be the first clue to the presence of an occult malignancy. Idiopathic events are 4.8-fold more commonly associated with the presence of occult malignancy than triggered episodes of thromboembolism. The risk of occult malignancy in patients with thromboembolism declines to the background rate in the population over 6 months [39]. Although an randomized clinical trial (RCT) was unable to identify a survival benefit with extensive cancer screening in patients with idiopathic VTE [40], we think it is worthwhile to ensure that patients are up-to-date with preventive healthcare cancer screening (colonoscopy, etc.) and consider computed tomographic scanning to identify occult primaries in patients aged 50 or older presenting with idiopathic VTE.

Cancer patients are also two- to threefold more likely to suffer recurrent VTE and bleeding during therapy [41]. LMWH has been shown to reduce the incidence of recurrent VTE by 50% in patients with cancer, and therefore LMWH rather than oral VKAs should be considered the agent of choice for long-term management of VTE in cancer patients [42].

Heparin-Induced Thrombocytopenia

Thrombocytopenia affects 20% of patients in the ICU [43]. While the true prevalence of heparin-induced thrombocytopenia (HIT) in the ICU is debatable [44], accurate diagnosis and treatment are essential due to the potential thrombotic and hemorrhagic risks associated with the condition.

HIT is an immune-mediated, prothrombotic disorder caused by heparin-dependent, platelet-activating IgG antibodies directed against platelet factor 4 (PF4) that trigger activation of platelets, endothelial cells, and monocytes resulting in consumptive thrombocytopenia and, in 50% of untreated cases,

venous and/or arterial thromboses. Digital/extremity gangrene is a classic finding. Less commonly, skin reactions/necrosis at heparin injection sites or acute systemic reactions (fever, hypotension) occur after heparin administration. Surgical patients (particularly, orthopedic and cardiothoracic) are at high risk for HIT, while medical patients are at intermediate risk and obstetric and pediatric patients are at low risk [45,46]. The clinical probability of HIT can be assessed using the "4 T score," a validated, clinical prediction rule (see Chapter 109 for the elements of the 4 T score) [47]. Management of any patient in whom HIT is being seriously considered requires elimination of exposure to all forms of heparin, and prompt initiation of anticoagulation with a direct thrombin inhibitor (see Chapter 109, "Thrombocytopenia and Platelet Dysfunction"). The clinical diagnosis of HIT should be confirmed with objective laboratory testing, such as the widely available enzyme-linked immunosorbent assay (ELISA assay) for heparin-PF4 antibodies. Patients who develop HIT without thrombosis are typically treated with anticoagulation for 1 to 3 months, whereas patients with thrombosis should be at least 3 to 6 months or longer with warfarin as dictated by the thrombotic event. Without treatment, the mortality of HIT is as high as 20% to 25% with a similar percentage of patients surviving with major complications (e.g., stroke or limb loss). Early diagnosis and treatment has improved mortality and morbidity to 5% to 10% [45,46]. Additional information regarding the pathophysiology and management of HIT is discussed in Chapter 109, "Thrombocytopenia and Platelet Dysfunction."

Major Trauma

Major trauma is an important cause of VTE in the ICU. Fifty-eight percent of trauma patients develop venographic VTE in the absence of thromboprophylaxis [48]. Trauma is a potent stimulus for clot formation because it impacts all three elements of Virchow's triad. Patients are immobilized (stasis) and have extensive vascular and tissue injury (vessel wall damage) leading to tissue factor and collage exposure resulting in activated coagulation (hypercoagulability). Risk factors for VTE in the major trauma patient are listed in Table 111.2 [49,50]. Thromboprophylaxis with enoxaparin (30 mg subcutaneously twice daily), which is much more effective than unfractionated heparin (5,000 units twice daily), can reduce the incidence of VTE by 50% [51]. Mechanical prophylaxis with sequential compression devices and/or graduated compression stocking are a useful adjunctive measure if feasible based on the patient's injuries. Given the high incidence of VTE, intensivists should maintain a high index of suspicion and confirm any clinical findings indicative of thrombosis with objective radiologic testing. Although some have advocated routine radiologic surveillance and prophylactic vena cava filter placement as strategies to reduce VTE in trauma patients, the value of these strategies remains unproven [52,53]. Acute VTE should be managed with conventional anticoagulation. If contraindications to anticoagulation exist, an optional vena cava filter can be placed until the patient is safe for anticoagulation. Once anticoagulation is tolerated, the filter can be removed. As with other patients' triggered episodes of VTE, trauma patients should be treated with warfarin for at least 3 to 6 months, as dictated by their thrombotic event. Catheter-directed or systemic thrombolysis should be reserved for patients with life- or limb-threatening thrombotic events. Catheter or surgical embolectomy is also an option for life-threatening thromboembolism.

TABLE 111.2

RISK FACTORS FOR VENOUS THROMBOEMBOLISM IN TRAUMA PATIENTS

Age > 40
Pelvic and or lower extremity fractures with AIS ≥ 3
Head injury with AIS ≥ 3
Mechanical ventilation > 3 d
Major venous injuries
Injuries requiring major surgery
Spinal cord injury
Prolonged immobility
Delayed institution of thromboprophylaxis
Blood transfusions
Femoral venous catheters

AIS, Abbreviated Injury Scale.

Antiphospholipid Antibody Syndrome

The antiphospholipid antibody syndrome (APS) is an acquired, autoimmune hypercoagulable disorder that is associated with venous and/or arterial thromboembolism, recurrent pregnancy losses, thrombocytopenia, renal insufficiency, vasculitis, and cardiac valvular abnormalities. APS may be primary (not due to any immediately apparent underlying disorder) or secondary, most commonly in association with rheumatologic diseases such as systemic lupus erythematosus (SLE). The diagnostic criteria for APS require the occurrence of one or more objectively documented episodes of thromboembolism or recurrent pregnancy losses in association with positive laboratory testing for a lupus anticoagulant or moderate or high-titer IgG or IgM anticardiolipin antibodies or β_2-glycoprotein I antibodies, performed on at least two occasions 12 or more weeks apart, and at least 12 weeks after the thrombotic insult [54].

The prevalence of elevated anticardiolipin antibodies or lupus anticoagulants in the general population varies from 1% to 5%. In patients with SLE, 15% to 30% have an Lupus Anticoagulants (LA) and 20% to 40% have anticardiolipin antibodies. The mean age of onset of symptoms of APS is 31 years and onset after age 50 years is uncommon [54]. In a mixed population of patients with and without SLE, the incidence of thromboembolism was 2.8% per year [55]. In a cohort of lupus patients, 50% of patients suffered a thromboembolic event over 20 years (2.5% per year) [56]. Patients with a positive lupus anticoagulant or β_2-glycoprotein I antibodies appear to be at higher risk for thromboembolism than patients with anticardiolipin antibodies [57]. In addition, IgG β_2-glycoprotein I antibodies appear to confer a greater risk of thrombosis than IgM antibodies [55,58]. Triple positive patients (i.e., patients positive for lupus anticoagulants, β_2-glycoprotein I antibodies and anticardiolipin antibodies) appear to be very high risk for thromboembolism (recurrent thromboembolism 44% over 10 years) [59].

The most common manifestation of APS that would bring patients to the ICU is venous or arterial thromboembolism. A retrospective review of APS patients noted that 59% had VTE, 28% had arterial thromboembolism, and 13% had both venous and arterial thromboembolism [60]. The diagnosis of APS is made by objectively confirming clinical manifestations (thromboembolism, pregnancy morbidity) and documenting laboratory evidence of antiphospholipid antibodies.

Treatment of VTE of patients with APS is similar to patients with other thrombophilic disorders with several important caveats. APS patients who have an LA often have baseline prolongation of their activated thromboplastin time (aPTT). If the standard therapeutic range is used, these patients' unfractionated heparin may be underdosed. Therefore, patients with a prolonged aPTT at baseline should be treated with an LMWH or have their unfractionated heparin therapy monitored with an anti-Xa heparin activity assay. For chronic antithrombotic

therapy of APS, conventional intensity anticoagulation with a VKA targeting an international normalized ratio (INR) of 2 to 3 is appropriate [57,61,62]. Occasional APS patients will suffer recurrent thromboembolic events despite conventional intensity anticoagulation. In these patients, higher INR targets (INR 3 to 4) or use of alternative anticoagulants (e.g., LMWH, fondaparinux) is appropriate. If a VKA is considered for long-term therapy, it is important to confirm that the patient's antiphospholipid antibody does not prolong the baseline prothrombin time. In occasional APS patients, the INR is not an accurate reflection of anticoagulation and specialized tests such as a chromogenic factor X activity assay must be use for VKA management [63]. Since APS patients are at increased risk for recurrent VTE in the absence of anticoagulation, indefinite anticoagulation is appropriate [64].

For patients with APS and arterial thromboembolism, we also prefer anticoagulation rather than aspirin or antiplatelet agents. Although one study suggested that aspirin and warfarin were equally effective for arterial thromboembolism, participants in this study did not fulfill diagnostic criteria for APS; therefore, we prefer conventional intensity anticoagulation (INR 2 to 3) to aspirin [65].

Catastrophic Antiphospholipid Syndrome

A devastating and life-threatening form of APS that occasionally brings a patient to the ICU is the catastrophic antiphospholipid syndrome (CAPS). CAPS is a rare (< 1% of APS patients present with CAPS) life-threatening manifestation of APS characterized by multiorgan (kidneys, brain, skin, liver, etc.) failure resulting from diffuse microvascular thrombosis. CAPS is often triggered by infections, major surgery, discontinuation of immunosuppression, or anticoagulation. Almost all patients with CAPS require ICU level of care. The mortality associated with CAPS approaches 50%. Common manifestations of CAPS-associated organ involvement are displayed in Table 111.3 [66].

CAPS is thought to result from widespread activation of the endothelium, monocytes, and platelets with tissue factor expression and diffuse activation of the coagulation cascade resulting in widespread microvascular thrombosis and tissue infarction. The diagnostic criteria for CAPS are displayed in Table 111.4. *The differential diagnosis* in patients suspected to have CAPS usually includes severe sepsis, thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), disseminated intravascular coagulation (DIC), infectious purpura fulminans, and heparin induced thrombocytopenia thrombosis (HIT/T).

Multimodality therapy is necessary for effective treatment of CAPS. The mainstay of therapy includes anticoagulation (e.g., weight-based unfractionated heparin (UFH) titrated to a therapeutic aPTT) and immunosuppression with corticosteroids (e.g., IV pulse methylprednisolone 1,000 mg per day for 3 to 5 days followed by 1 to 2 mg per kg per day is the most commonly administered dosage). Second-line therapies that are frequently employed in addition to anticoagulation and corticosteroids include intravenous immunoglobulins (IVIG) (total dose of IVIG is 2 g per kg [400 mg per kg for 5 days or 1,000 mg per kg for 2 days]), plasmapheresis, and rituximab (375 mg per m^2 weekly for 4 weeks). Fibrinolytic agents are often used to treat life- or limb-threatening venous or arterial thrombosis. Third-line therapies include cyclophosphamide, prostacyclin (5 ng per kg per minute for 7 days [per case reports]), and defibrotide (100 to 275 mg per kg per day for a minimum of 3 weeks).

TABLE 111.3

CLINICAL MANIFESTATIONS OF CATASTROPHIC ANTIPHOSPHOLIPID SYNDROME

Organ system	Manifestations
Blood	Coombs positive hemolytic anemia, autoimmune thrombocytopenia, disseminated intravascular coagulation, bone marrow infarct
Brain	Infarcts, encephalopathy, seizure, transient ischemic attack
Heart	Valvular lesions (Libman-Sacks endocarditis), myocardial infarction, heart failure
Kidney	A 50% increase in serum creatinine, severe systemic hypertension (> 180/100 mm Hg), and/or proteinuria (> 500 mg/24 h)
Lung	Acute respiratory distress syndrome: most common, pulmonary hypertension with normal cardiac output and pulmonary capillary wedge pressure, pulmonary hemorrhage
Skin	Livedo reticularis, skin ulcers, digital ischemia, purpura, skin necrosis
Vasculature	Venous and/or arterial thromboembolism: most common include deep venous thrombosis, pulmonary embolism, extremity artery thromboembolism, portal vein and inferior vena cava thrombosis, retinal artery, and vein thrombosis

TABLE 111.4

DIAGNOSTIC CRITERIA OF CATASTROPHIC ANTIPHOSPHOLIPID SYNDROME

Diagnostic criteria
1. Evidence of involvement (vascular occlusions) affecting three or more organs, systems, and/or tissues[a]
2. Development of manifestations simultaneously or within 1 week or less
3. Confirmation by histopathology of small vessel occlusion in one organ or tissue[b]
4. Laboratory confirmation of the presence of antiphospholipid antibodies (lupus anticoagulant or anticardiolipin antibodies)[c]
Definite catastrophic antiphospholipid syndrome
All four criteria are met
Probable catastrophic antiphospholipid syndrome
All four criteria are present but only two organs, systems, or tissues are involved
All four criteria are present but confirmation of laboratory tests 6 wk apart not performed
Criteria 1, 2, and 4 are present
Criteria 1, 3, and 4 are present

[a] Objective evidence of vessel occlusions. A 50% rise in serum creatinine, severe systemic hypertension (> 180/100 mm Hg), and/or significant proteinuria (> 500 mg/24 h) are alternative manifestations of renal involvement.
[b] Thrombosis must be present on histopathology. Vasculitis may be present but is not diagnostic in isolation.
[c] If the patient has not had previous laboratory testing for APS, then laboratory confirmation requires that the presence of antiphospholipid antibodies must be detected on two or more occasions at least 12 wk apart (not necessarily at the time of the event).

Treatment of potential precipitating factors is also extremely important. Such measures include broad-spectrum antibiotics for infections, aggressive hemodynamic resuscitation in case of shock, debridement or amputation for necrotic tissues, mechanical ventilation, renal replacement therapy, tight glycemic control, stomach acid suppression, and control of malignant hypertension in case of renal artery/vein thrombosis. Intravascular instrumentation, especially arterial, should be minimized because of the potential for new clot formation [67].

CAPS mortality rate remains as high as 48% despite all therapies. The clinical manifestations related to poor prognosis and mortality include renal involvement, splenic involvement, pulmonary involvement, adrenal involvement, and SLE diagnosis. CAPS recurrence is unusual. Patients usually have a stable course with continued anticoagulation. One fourth of the survivors will develop further APS-related events, but it is rare to develop recurrent CAPS [67].

Drugs

Certain medications have been associated with an increased risk of thrombosis (Table 111.5). Detection of acute thrombosis in a patient receiving one of these medications typically is a sufficient criterion for discontinuation, and use of such agents in patients with a prior history of thromboembolism must be considered very carefully, weighing the potential benefit against the potential for recurrent thrombosis.

TABLE 111.5

MEDICATIONS COMMONLY ASSOCIATED WITH THROMBOEMBOLISM

Medication	Risk of thromboembolism	Risk factors for thromboembolism	Prevention
Chemotherapy	Two- to sixfold increase	Cancer site—(highest risk—pancreatic, gastric; high risk—lymphoma, gynecologic, bladder, testicular)[a] Prechemotherapy platelet count ≥ 350,000/μL[a] Hemoglobin > 10 g/dL or use of ESA[a] Prechemotherapy WBC > 11,000/μL[a] BMI > 35 kg/m^2[a]	LMWH? In high-risk patients
Estrogen receptor modulators (tamoxifen, raloxifene)	Two- to threefold increase (healthy women breast cancer prophylaxis) 1.5–7 fold increase (adjuvant therapy early breast cancer)	Postmenopausal threefold more likely than premenopausal	N/A
Hormone replacement therapy	Two- to threefold increase	Older age, obesity, thrombophilia, oral > transdermal	N/A
Erythropoietin	1.5-fold	Hemoglobin > 12 g/dL	N/A
Thalidomide, lenalidomide	Alone (1%–3%) With high-dose dexamethasone, combination chemotherapy (10%–20%)	Individual VTE risk factors—obesity, previous VTE, cardiac or renal disease, diabetes, infection immobility, surgery, trauma, erythropoietin use, thrombophilia, recent diagnosis, hyperviscosity[b] Treatment risk factors—high-dose dexamethasone, doxorubicin, or combination chemotherapy[b]	Low risk—(0–1 VTE risk factors, no treatment risk factors)—aspirin[b] High risk—2 or more VTE risk factors or a treatment risk factor)—prophylactic dose LMWH or warfarin (INR 2–3)[b]
Hormonal contraceptives	Three- to fourfold increased risk	Age > 35 y, smoking, obesity, thrombophilia, third > second generation, oral > transdermal, progestin mini-pill < estrogens or combined estrogen/progestins	N/A
Antipsychotics	Twofold	Low potency antipsychotics (e.g., chlorpromazine) > high-potency antipsychotics (e.g., haloperidol); initial 3 mo of therapy, two or more antipsychotics, supratherapeutic serum levels	N/A

BMI, body mass index; ESA, erythropoietin stimulating agent; LMWH, low-molecular-weight heparin; INR, international normalized ratio; VIE, venous thromboembolism; WBC, white blood cell.

Hematologic Conditions

Myeloproliferative disorders such as PV and essential thrombocythemia (ET) are associated with an increased risk of thrombotic (arterial and venous) and bleeding complications due to increased blood viscosity associated with erythrocytosis as well as functional abnormalities in leukocytes and platelets and acquired form of von Willebrand disease associated with thrombocytosis. Risk factors for thrombohemorrhagic events include age older than 60 (PV, ET), a previous history of thromboembolism (PV, ET), poorly controlled erythrocytosis (PV), leukocytosis (PV, ET), thrombocytosis (PV, ET), thrombophilia (PV, ET), JAK2 mutation status (PV, ET), and traditional cardiovascular risk factors (hyperlipidemia, smoking, diabetes, and hypertension) (PV, ET). In PV patients, adequate phlebotomy to control erythrocytosis is essential to prevent thrombohemorrhagic complications. Aspirin is useful in PV and ET patients 60 years or older to prevent arterial thromboembolism [68]. In patients who have thrombohemorrhagic events despite these measures, cytoreductive therapy with hydroxyurea, anagrelide, or α-interferon should be prescribed. Anticoagulation is appropriate for patients who suffer VTE [68,69].

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare clonal hematopoietic stem cell disorder that results in the loss of expression of complement regulatory proteins (CD55, CD59) on blood cell membranes. This acquired genetic alteration results in chronic intravascular hemolysis, pancytopenia, and a strong predisposition to venous (more common) and arterial (less common) thrombosis [70,71]. Unusual locations for thrombosis (e.g., hepatic vein thrombosis/Budd–Chiari syndrome, cerebral venous sinus thrombosis, dermal vessel thrombosis) are not uncommon in PNH patients. The diagnosis of PNH can be easily made using flow cytometry to detect the presence/absence of CD55 and CD59 (using antibodies) or glycosylphosphatidylinositol-anchored proteins (GPI-AP) (using fluorescein-labeled aerolysin, a bacterial toxin that binds to all GPI-AP, more sensitive than first technique) on the surface of blood cell membranes. Symptomatic patients with significant hemolysis, fatigue, or end-organ damage or thromboembolism should be treated with eculizumab, a humanized monoclonal antibody against complement protein C5a [71]. For patients with thromboembolism, conventional anticoagulation is appropriate although not always effective in preventing recurrent events. Preliminary data suggest that eculizumab may control the disease process to such an extent that patients with thromboembolism may be able to discontinue anticoagulation [72,73].

DIAGNOSIS APPROACH TO THROMBOPHILIA

Since thrombophilia testing is expensive and has yet to be demonstrated to significantly influence the outcome of patients with thromboembolism [74,75], there should be a strong clinical rationale for considering a thrombophilia evaluation and testing should be focused on patients likely to benefit from the results (Table 111.6). In selected patients, thrombophilia testing may influence the duration of anticoagulation (i.e., in patients with high-risk thrombophilia—AT, PC, or PS deficiency; homozygous FVL; antiphospholipid syndrome; compound heterozygosity for FVL; and the PGM), the management of future pregnancies, provide additional insight into the etiology of a thrombotic event, or improve the adequacy of subsequent VTE prophylaxis efforts during risk periods. These benefits, however, must be weighed against the risks that include increased healthcare insurance costs and unnecessary testing of unaffected family members. Clearly testing should only be performed if it will influence the care of the patient. Therefore, testing should not be performed in patients with idiopathic or recurrent VTE whom you plan to treat indefinitely regardless of the results. Conversely, if the patient has continuing risk factors for bleeding, perhaps the presence of a high-risk thrombophilic state would be sufficient reason to continue anticoagulation despite the presence of these risk factors. In sum, thrombophilia testing should only be done after consideration of its costs and the risks and benefits to the patient [76].

If thrombophilia testing is planned, it should be performed at a time when accurate results can be obtained. Acute thrombosis can result in reductions in AT, PC, and PS activity. Therefore, abnormal results should be interpreted with caution and repeated if possible when the patient is not on anticoagulation. However, if normal results are obtained prior to the initiation of therapy, the patient does not have AT, PC, or PS deficiency. Testing for FVL and PGM may be performed during the acute thrombotic event, as the APC resistance assay and the DNA-based tests are not affected by therapeutic doses of anticoagulation. Fibrinogen assays are generally also insensitive to therapeutic anticoagulation as are antigen assays for factors IX and XI and homocysteine levels. Factor VIII activity should not be measured during an acute episode of thrombosis [76]. Testing for anticardiolipin and β_2-glycoprotein I antibodies can be done during anticoagulation, but lupus anticoagulant testing can be affected by anticoagulation therapy [54]. The timing and recommended tests for prothrombotic conditions are listed in Table 111.7.

It is also important to tailor hypercoagulable testing to the patient's thrombotic process (Table 111.8). FVL and PGM have not been associated with arterial thromboembolism. Therefore, in patients with arterial thrombosis, these tests are not worthwhile ordering, and in patients who are known carriers of FVL or the PGM who suffer an arterial thrombotic event, it is worthwhile looking for another reason for hypercoagulability or for a right-left shunt such as a patent foramen ovale. The link between AT, PC, and, to a somewhat lesser extent, PS and arterial thromboembolism is tenuous and so similar limitations should be considered when testing for these entities. In contrast, cancer, HIT/T, APS, and hyperhomocysteinemia have all been associated with arterial and venous thromboembolism.

TABLE 111.6

CANDIDATE SELECTION FOR LABORATORY TESTING FOR PROTHROMBOTIC CONDITIONS

High yield	Low yield
Young patients (age ≤ 50)	Older patients (age > 50)
Patients with positive family history (first degree relatives)	Patients in situations when artifactual test results may occur (pregnancy, warfarin therapy, etc.)
Patients with idiopathic TE	Patients with cancer
Patients with TE in unusual sites	Patients with strong transient risk factors (major trauma, surgery, etc.)
Patients with recurrent TE	Patients in whom testing will not influence therapy
Patients with warfarin skin necrosis	Patients with arterial TE should not be tested for venous thrombophilic states
Patients planning future pregnancies	

TE, thromboembolism.

TABLE 111.7

LABORATORY TESTING FOR PROTHROMBOTIC CONDITIONS

Condition	Test	Timing	Potential causes of erroneous results
Factor V Leiden	Activated protein C resistance assay	Anytime	Heparin (anti-Xa) level > 1.0 units/mL
	Factor V Leiden DNA-based testing	Anytime	DNA contamination
Prothrombin (factor II) gene mutation	Factor II DNA-based testing	Anytime	DNA contamination
Protein C deficiency	Protein C activity (if abnormal then protein C antigen)	Prior to anticoagulation or after discontinuation	Acute thrombosis, DIC, warfarin, vitamin K deficiency, heparin (anti-Xa) level > 1.0 units/mL, lupus anticoagulant, elevated factor VIII concentrations, liver disease
Protein S deficiency	Protein S activity (if abnormal then total and free protein S antigen)	Prior to anticoagulation or after discontinuation	Acute thrombosis, DIC, warfarin, vitamin K deficiency, estrogen therapy, pregnancy/postpartum, heparin (anti-Xa) level > 1.0 units/mL, lupus anticoagulant, elevated factor VIII concentrations, liver disease
Antithrombin (III) deficiency	Antithrombin activity (if abnormal, antithrombin antigen)	Prior to anticoagulation or after discontinuation	Acute thrombosis, DIC, warfarin, vitamin K deficiency, heparin (anti-Xa) level > 1.0 units/mL, lupus anticoagulant, elevated factor VIII concentrations, liver disease, nephrotic syndrome
Dysfibrinogenemia	Fibrinogen activity (i.e., standard Clauss fibrinogen assay), thrombin time, fibrinogen antigen, reptilase time	Prior to anticoagulation with heparin or direct thrombin inhibitors	Heparin (thrombin time is very sensitive to heparin, fibrinogen less sensitive, reptilase time and fibrinogen antigen insensitive), direct thrombin inhibitors affect thrombin time and fibrinogen activity, myeloma proteins, liver disease
Hyperhomocysteinemia	Homocysteine level	Fasting, with or without methionine loading at anytime	Renal insufficiency, vitamin B_{12} deficiency, folate deficiency
Elevated factor VIII levels	Factor VIII activity	At least 6 mo after thrombotic event in the absence of inflammation	Acute phase response (e.g., infection, inflammation, postsurgery), heparin, direct thrombin inhibitors, DIC
Elevated factor IX levels	Factor IX antigen	At least 6 mo after thrombotic event after discontinuation of warfarin	Acute thrombosis, DIC, warfarin, vitamin K deficiency, liver disease
Elevated factor XI levels	Factor XI antigen	At least 6 mo after thrombotic event	Acute thrombosis, DIC, severe liver disease
Heparin-induced thrombocytopenia	Platelet factor 4 antibody ELISA assay	Anytime	Elevated immune complexes/ immunoglobulin level
	Serotonin release assay	Anytime	
Antiphospholipid syndrome	Activated partial thromboplastin time (low phospholipid reagent) + mixing studies with normal plasma	At diagnosis of thrombotic event and at least 12 wk later	Heparin, direct thrombin inhibitors
	Dilute Russell Viper venom time with confirm procedure	At diagnosis of thrombotic event and at least 12 wk later	Heparin (anti-Xa) level > 1.0 units/mL, direct thrombin inhibitor, fondaparinux, warfarin (?), factor X, V, and II inhibitors
	Platelet neutralization procedure	At diagnosis of thrombotic event and at least 12 wk later	Heparin, factor V deficiency/inhibitors
	Anticardiolipin antibody ELISA	At diagnosis of thrombotic event and at least 12 wk later	Rheumatoid factor, Syphilis and HIV can result in positive test and must be ruled out
	β_2-Glycoprotein I antibody ELISA	At diagnosis of thrombotic event and at least 12 wk later	Rheumatoid factor can produce false-positive results

DIC, disseminated intravascular coagulation; HIV, human immunodeficiency virus; ELISA, enzyme-linked immunosorbent assay.

TABLE 111.8

SELECTED META-ANALYSES AND PROSPECTIVE STUDIES IN THROMBOPHILIC DISORDERS

Thrombophilic disorder	Characteristic	Study methodology	Reference
Factor V Leiden (FVL)	FVL heterozygosity and homozygosity are associated with a 5- and 10-fold increased risk of VTE	Meta-analysis of eight case–control studies including 2,310 cases and 3,204 controls	Emmerich J et al. [8]
	FVL is not a risk factor for myocardial infarction (OR, 1.24 [95% CI, 0.91–1.69] and RR, 0.83 [0.58–1.20]) or stroke (OR, 0.92 [95% CI, 0.56–1.53] and RR, 0.68 (0.45–1.04)	Meta-analysis of three case-control studies and three prospective observational studies	Juul K et al. [9]
	FVL heterozygosity and homozygosity increase the risk of recurrent thrombosis by 1.56-fold (95% CI, 1.14–2.12) and 2.65-fold (95% CI, 1.18–5.97), respectively; FVL is not	Meta-analysis of 46 studies	Segal J et al. [10]
Prothrombin gene mutation	Heterozygous factor II mutation associated with a 3.8-fold increased risk of VTE	Meta-analysis of 8 case–control studies including 2,310 cases and 3,204 controls	Emmerich J et al. [8]
	Prothrombin gene mutation is not associated with myocardial infarction (RR, 0.8 [0.4–1.6]) or stroke (RR, 1.1 [0.5–2.4])	Prospective cohort study of 14,916 U.S. men	Ridker P et al. [13]
	The prothrombin gene mutation is not associated with recurrent VTE (OR, 1.45; 95% CI, 0.96–2.2).	Meta-analysis of 46 studies	Segal J et al. [10]
Compound heterozygotes for FVL and the prothrombin gene mutation	Compound heterozygotes for FVL and the factor II mutation are at 20-fold (95% CI, 11.1–36.1) increased risk for VTE	Meta-analysis of eight case–control studies including 2,310 cases and 3,204 controls	Emmerich J et al. [8]
	The OR for recurrent VTE in compound heterozygotes for FVL and the factor II mutation is 4.81 (95% CI, 0.50–46.3)	Meta-analysis of 46 studies	Segal J et al. [10]
Hyperhomocysteinemia	Homocysteine lowering vitamin supplementation does not reduce the incidence of recurrent VTE	Two prospective, randomized, controlled trials	Ray JG et al. [29] and den Heijer M et al. [30]
	Homocysteine lowering vitamin supplementation does not reduce the incidence of cardiovascular disease in post-MI patients	Prospective, randomized, controlled trial of 5,522 patients	Lonn E et al. [31]
Antiphospholipid syndrome	High intensity vitamin K antagonist therapy (INR, 3–4) is not superior to conventional intensity therapy (INR, 2–3) for treatment of APS patients with previous VTE9	Two prospective, randomized, controlled trials	Crowther M et al. [61] and Finazzi G et al. [62]

CI, confidence interval; INR, international normalized ratio; MI, myocardial infarction; OR, odds ratio; RR, relative risk; VTE, venous thromboembolism.

CHAPTER 112 ■ ANEMIA IN THE CRITICAL CARE SETTING

MARC S. ZUMBERG, MARC J. KAHN AND ALICE D. MA

GENERAL PRINCIPLES

Anemia is common in the critical care setting. Recent studies have shown that 29% to 62% of patients have anemia at the time of admission to critical care units and 20% to 30% have moderate or severe anemia (hemoglobin < 9 g per dL) [1–5]. Anemia will develop in nearly all patients at some point during the course of a prolonged intensive care unit (ICU) stay, and as a result, the majority of patients admitted more than 7 days receive a red blood cell (RBC) transfusion [1–5].

Certain anemias may be encountered more frequently in patients who are admitted to critical care units than in other settings, including anemias arising from iatrogenic sources (e.g., mechanical hemolysis caused by ventricular assist devices or intra-aortic balloon pumps); those producing hemodynamic or systemic compromise that leads to a requirement for critical care (e.g., massive blood loss due to trauma, gastrointestinal lesions, or surgical invasion; thrombotic microangiopathies); and those arising in the context of prolonged critical illness (e.g., anemia of chronic disease/inflammation [ACD]). Losses from an enhanced frequency of phlebotomy for diagnostic testing in the critical care unit may contribute to the development or maintenance of anemia and have been estimated to account for 1 to 2 units lost during a typical hospital stay [5,6].

This chapter provides an overview of the evaluation and laboratory workup of anemia, with a focus on diagnoses that provoke the most clinical concern, are important to recognize quickly, and are the most likely to be encountered in the critical care setting. Accordingly, the hemolytic anemias, including the microangiopathic hemolytic anemias, autoimmune hemolytic anemia (AIHA), and sickle cell syndromes, will be covered in the most detail (Table 112.1). The ACD often develops in patients in the ICU and will also be a focus of this chapter. Anemia due to massive blood loss including trauma and gastrointestinal bleeding is essential to recognize, obtain proper consultation for, and treat appropriately, but the diagnosis is usually self-evident.

Initial Evaluation

The etiologies of anemia in the critical care setting are diverse, but the evaluation of anemia in a critical care patient initially should be approached in a manner similar to the noncritical care setting.

The patient's volume status should be considered first, as an increase in the plasma volume may lead to a decrease in the measured hemoglobin or hematocrit that does not represent a decrease in the red cell mass or oxygen carrying capacity. This situation is known as dilutional or spurious anemia and is particularly common in ICU patients requiring fluid resuscitation [5]. Dilutional anemia does not require treatment.

To better come up with a differential diagnosis of the anemia, it should be determined whether the anemia predated the patient's critical illness, developed in conjunction with the critical illness, or developed during the ICU stay (Table 112.2).

TABLE 112.1

CLASSIFICATION OF THE HEMOLYTIC ANEMIAS: CONGENITAL VERSUS ACQUIRED

Congenital hemolytic anemias
Defects in the erythrocyte membrane
- e.g., hereditary spherocytosis

Deficiencies in erythrocyte metabolic enzymes
- ex. pyruvate kinase deficiency
- ex. glucose-6-phosphate dehydrogenase deficiency

Defects in globin structure and synthesis
- ex. sickle cell disease
- ex. thalassemia

Acquired hemolytic anemias
Autoimmune hemolytic anemias
- ex. warm autoimmune hemolytic anemia
- ex. cold agglutinin disease
- ex. paroxysmal cold hemoglobinuria
- ex. drug-induced hemolytic anemia

Microangiopathic hemolytic anemia
- ex. thrombotic thrombocytopenic purpura
- ex. hemolytic uremic syndrome
- ex. disseminated intravascular coagulation

Hemolytic transfusion reaction
Paroxysmal nocturnal hemoglobinuria
Infectious agents
- ex. malaria

Chemicals, drugs, and physical agents
- ex. arsenic

Advanced liver disease

Laboratory Studies

Anemias can be classified by the size of the RBCs as reflected by the mean corpuscular volume (MCV): microcytic (MCV, < 80 fL), normocytic (80 to 100 fL), and macrocytic (> 100 fL). A finite number of diagnoses constitute each of these categories, allowing the practitioner to narrow the differential diagnosis (Table 112.3). One should take caution to review the MCV prior to the transfusion of RBCs, as donor RBCs may increase or decrease the MCV depending on the pretransfusion value.

TABLE 112.2

SAMPLE DIFFERENTIAL DIAGNOSIS OF ANEMIA BASED ON THE TIME COURSE OF ANEMIA IN RELATION TO THE CRITICAL ILLNESS

Anemia predating the critical illness
- Primary bone marrow disorders
- Vitamin deficiencies
- Hemoglobinopathies
- Congenital anemias

Anemia developing in conjunction with the critical illness
- Anemia of chronic disease/inflammation
- Hemolytic anemias
- Thrombotic thrombocytopenic purpura

Anemia developing during the course of the intensive care unit stay
- Gastrointestinal bleeding
- Frequent phlebotomies
- Drug-induced hemolytic anemia
- Anemia of chronic disease/inflammation

TABLE 112.3

DIFFERENTIAL DIAGNOSIS OF SELECTED ANEMIAS BASED ON RED CELL MEAN CORPUSCULAR VOLUME (MCV)

Microcytic (MCV ≤ 80 fl)
- Fe deficiency
- α-Thalassemia
- β-Thalassemia
- Anemia of chronic disease/inflammation
- Lead poisoning
- Sideroblastic anemia

Normocytic (MCV 80–100 fl)
- Acute blood loss
- Primary bone marrow disorders
- Anemia of chronic disease/inflammation
- Splenomegaly
- Hemolytic anemia with low or normal reticulocyte count
- Endocrine disorders

Macrocytic (MCV > 100 fl)
- Megaloblastic anemia
  - B_{12} deficiency
  - Folic acid deficiency
  - Drug induced
- Hypothyroidism
- Liver disease
- Hemolytic anemia with reticulocytosis
- Myelodysplastic syndrome

Several additional tests may be helpful in the evaluation of anemia. The reticulocyte count, which is a measure of the bone marrow's ability to produce new RBCs, should be the initial test performed. The reticulocyte count is typically elevated in hemolytic anemias, gastrointestinal bleeding, or after supplementation of a missing nutrient such as iron or vitamin B_{12}. The reticulocyte count is typically low in primary bone marrow failure disorders, nutritional deficiencies, the anemia of chronic disease/inflammation, and any condition leading to the underproduction of or resistance to erythropoietin (e.g., renal disease). If a hemolytic anemia is suspected (i.e., due to consistently hemolyzed blood specimens, characteristic findings on physical examination [see later], or refractoriness to erythrocyte transfusion), measurement of total and unfractionated bilirubin (elevated), lactate dehydrogenase (LDH) (elevated), and haptoglobin (decreased) may be useful, although the results are not specific to hemolysis and may be similar in patients with advanced liver disease.

The blood smear itself may help to narrow the diagnosis and quickly identify anemias due to causes that require expeditious, specialized management (e.g., thrombotic microangiopathies). Examples of erythrocyte abnormalities include schistocytes (Fig. 112.1), sickle cells (Fig. 112.2), bite cells (Fig. 112.3), or spherocytes (Fig. 112.4) and identification of these aberrant forms is critical in making the correct diagnosis (Table 112.4).

Further laboratory testing should be guided by the results of the MCV, reticulocyte count, review of the blood smear, and any clinical suspicion of likely diagnoses (Table 112.5).

Therapeutic Red Cell Transfusion

Clinicians caring for patients in critical care settings are often confronted with the decision to transfuse RBCs even before results of laboratory testing or other evaluation has elucidated

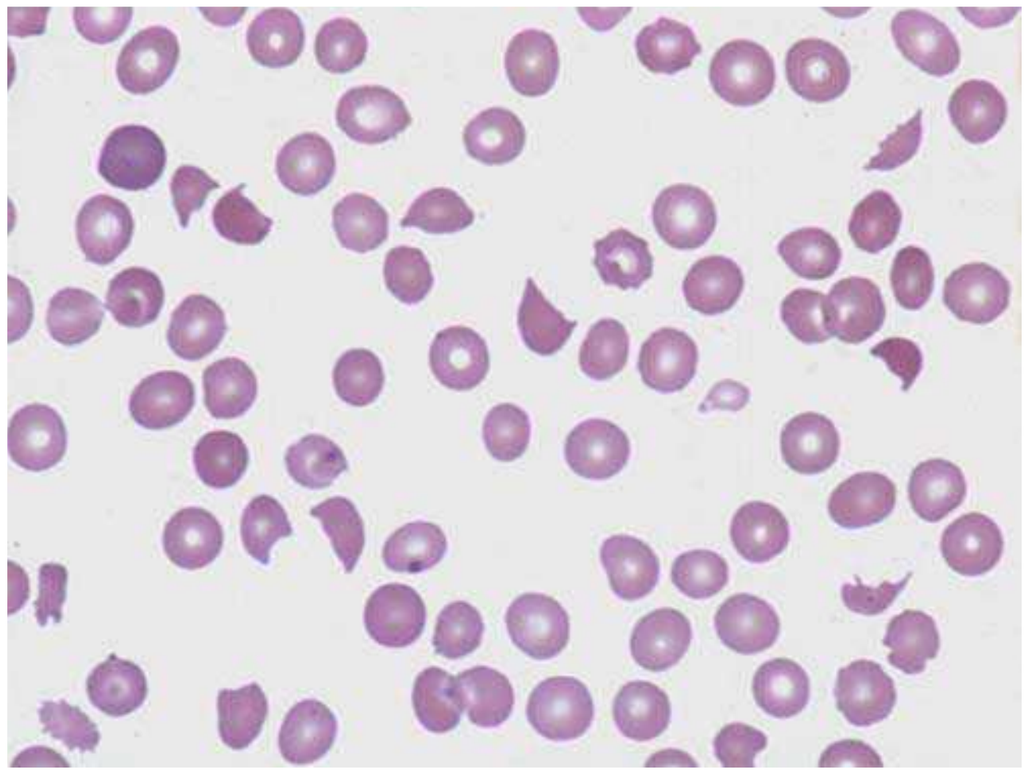

FIGURE 112.1. Peripheral smear from a patient with disseminated intravascular coagulation shows characteristic "helmet: cells. [Reused with permission from Maslak P. ASH Image Bank 2008;2008:8-00102.]

the cause of the anemia. Erythrocyte transfusion in this setting may be guided by hemodynamic considerations, rather than a finite transfusion trigger [7]. Because of the (albeit low) risk of transmission of infectious pathogens and the potential for transfusion reactions and immunomodulation, and in light of increasing evidence from randomized trials that anemia is well tolerated in individuals without cardiopulmonary compromise, more restrictive transfusion policies are becoming more common [8–12]. Principles of transfusion are discussed in greater detail in Chapter 114.

Use of Erythropoiesis-Stimulating Agents

In multiple randomized clinical studies, use of erythropoiesis-stimulating agents (ESAs) in critically ill patients as compared

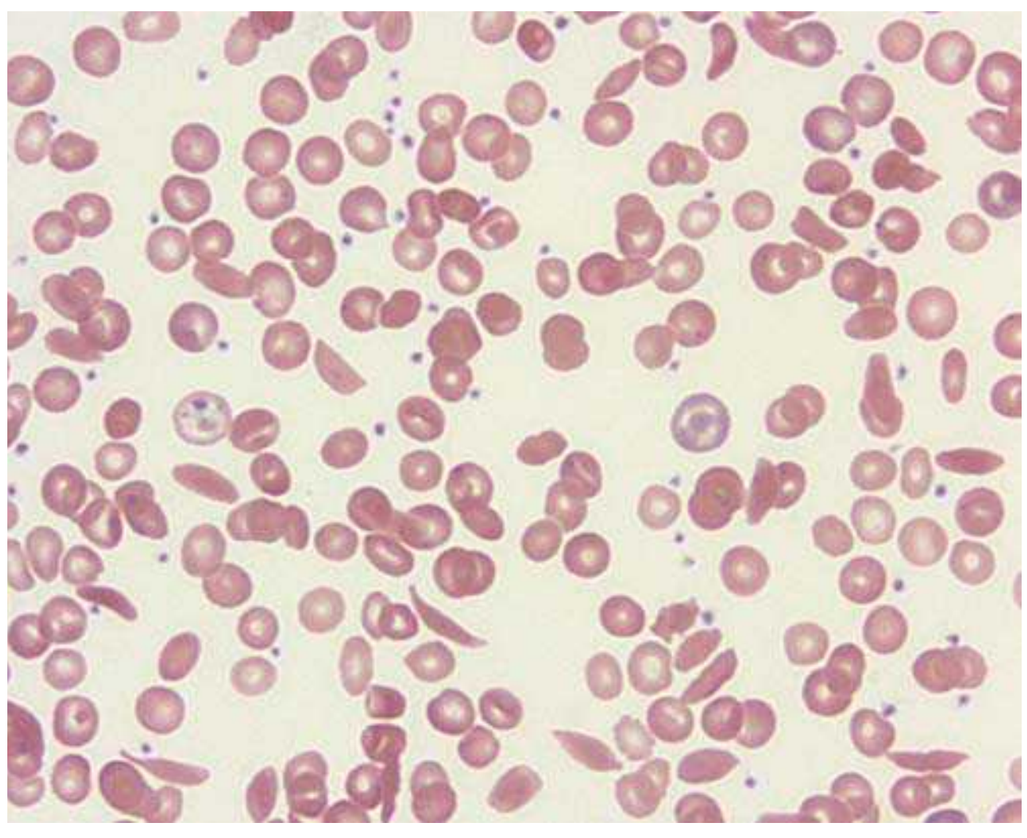

FIGURE 112.2. Peripheral smear from a patient with sickle cell disease illustrates the spectrum of RBC findings in this disorder including sickle cells, polychromatophilic RBCs, target cells, and Howell-Jolly bodies. [Reused with permission from Lazarchick J. ASH Image Bank 2009;2009:9-00044.]

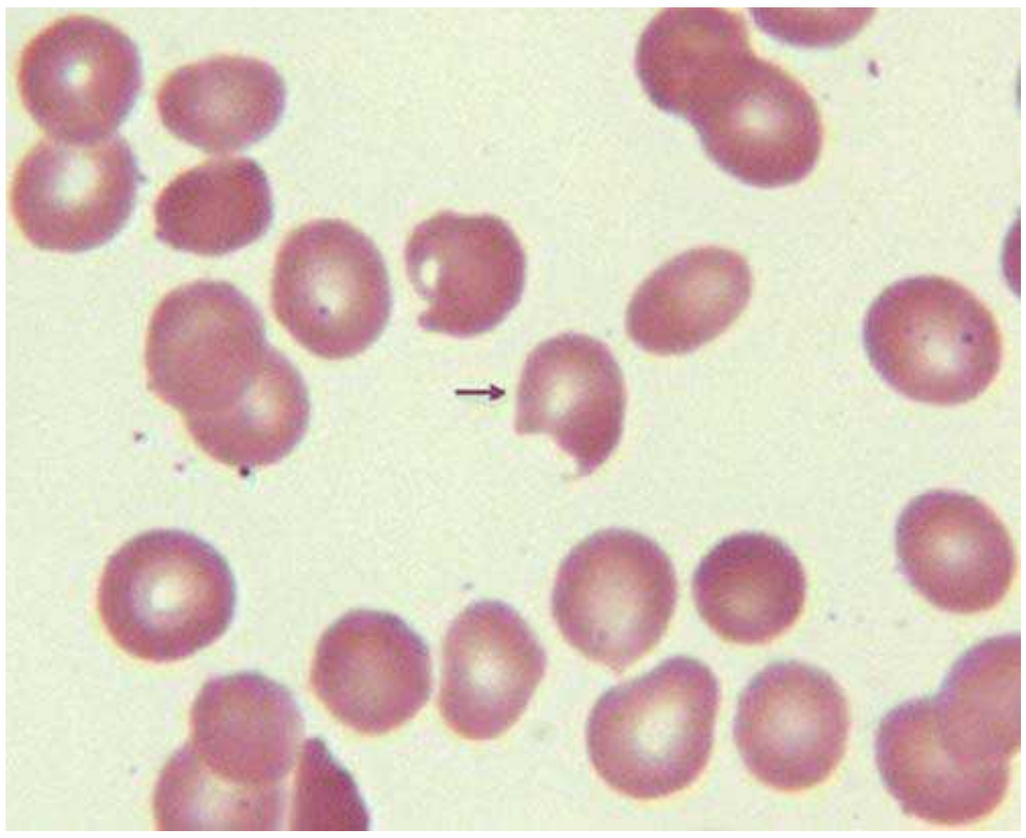

FIGURE 112.3. The RBC deformity (*arrow*) shown in this image is referred to as a "bite" cell. [Reused with permission from Lazarchick J. ASH Image Bank 2008;2008:8-00151.]

with placebo or no intervention had no statistically significant effect on overall mortality, length of hospital stay, ICU stay, or duration of mechanical ventilation [13,14]. A recent meta-analysis, however, has shown that use of ESAs reduced the odds of a patient receiving at least one transfusion and modestly decreased the mean number of units of blood transfused by 0.41 units [13]. The optimal dosing and schedule of erythropoietin remains to be determined [13,15–17], and the need for concomitant supplemental intravenous iron, which may be considered when the serum ferritin drops below 100 to 200 ng per mL or iron saturation drops below 20% [2,15], still is debated. In a recent U.S. multicenter, retrospective, observational study of ESA utilization in anemic critically ill patients admitted to the ICU, practice patterns were highly variable [18]. Thus, at the present time, there remains insufficient evidence to recommend the routine use of ESAs in critically ill anemic patients [13].

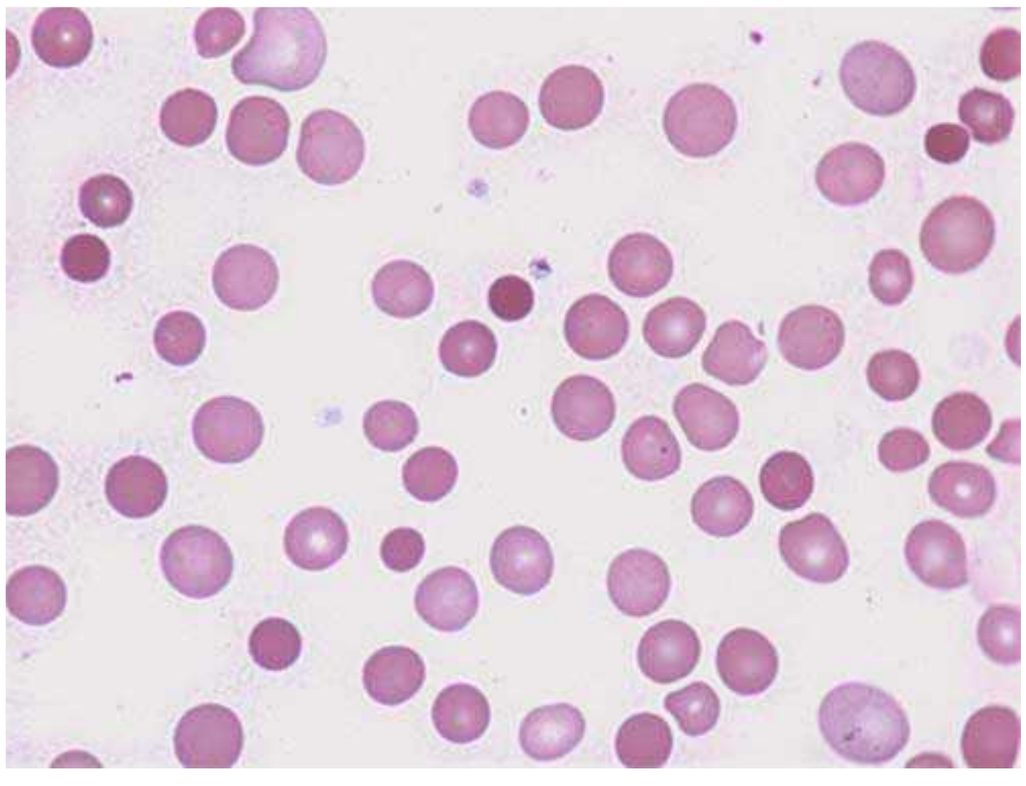

FIGURE 112.4. Spherocytes lack central pallor and may appear smaller than typical red cells. [Reused with permission from Maslak P. ASH Image Bank 2008;2008:8-00103.]

TABLE 112.4

SELECTED BLOOD SMEAR MORPHOLOGIC FINDINGS USEFUL IN THE EVALUATION OF HEMOLYTIC ANEMIA

RBC findings	Associated conditions
Nucleated red blood cells	Hemolytic anemia, postsplenectomy, infiltrative bone marrow process, "revved-up" bone marrow
Schistocytes	Microangiopathic hemolytic anemia including TTP, HUS, HELLP syndrome, DIC, heart valve hemolysis, malignant hypertension
Sickle cells	Sickle cell disease, sickle-thalassemic syndromes
Target cells	Thalassemia, liver disease, hemoglobin C
Spherocytes	Hereditary spherocytosis, warm autoimmune hemolytic anemia
Bite cells	G6PD deficiency
Tear drop cells	Myelofibrosis, infiltrative bone marrow process
RBC agglutination	Cold agglutinin disease
Rouleaux formation	Multiple myeloma, Waldenstrom's macroglobulinemia

DIC, disseminated intravascular coagulation; G6PD, glucose 6 phosphate dehydrogenase; HELLP syndrome, hemolysis, elevated liver enzymes, low platelets; HUS, hemolytic uremic syndrome; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura.

Hematology Consultation

If the etiology of the anemia is not apparent despite the above evaluation or if treatment options remain uncertain, hematology consultation should be initiated. A bone marrow aspirate and biopsy may be useful if the diagnosis remains in question or if a primary bone marrow disorder is suspected due to unexplained abnormalities (morphologic or quantitative) in other blood cell lineages.

HEMOLYTIC ANEMIAS

The hemolytic anemias are characterized by a decreased red cell life span. The physiologic sequelae of these disorders, in addition to the ability of the hemolytic process to cause a decrease in hemoglobin and oxygen carrying capacity in a short period of time, may lead to a requirement for critical care. The patient with hemolysis may be very or only minimally symptomatic, depending on the rate of red cell destruction and the degree of compensation by the bone marrow, which produces young red cells (reticulocytes) in response to the decreased hemoglobin.

Overview of Laboratory Features

Pathologic features of hemolysis differ greatly depending on whether the red cell destruction is primarily intravascular or extravascular. Biochemical evidence for intravascular hemolysis includes elevated levels of LDH and unconjugated bilirubin and decreased levels of haptoglobin, which is cleared from the

TABLE 112.5

SUGGESTED INITIAL SAMPLE LABORATORY EVALUATION BASED ON THE MCV AND RETICULOCYTE COUNT

Laboratory finding	Suspected diagnoses	Diagnostic studies[a]
Decreased MCV/low reticulocyte count	Iron deficiency Thalassemia trait Sideroblastic anemia	Iron studies Hemoglobinopathy evaluation Bone marrow aspirate/biopsy
Decreased MCV/high reticulocyte count	Thalassemia	Hemoglobinopathy evaluation
Normal MCV/low reticulocyte count	Organ dysfunction Anemia of chronic disease Early iron deficiency HIV Multiple myeloma Other bone marrow disorders	Electrolytes, LFTs, TSH, EPO Iron studies, electrolytes, LFTs Iron studies HIV studies Serum protein electrophoresis Bone marrow aspirate/biopsy
Normal MCV/high reticulocyte count	GI bleed Hemolytic anemia	Guaiac stool, endoscopy LDH, bilirubin, haptoglobin, Coombs test
High MCV/low reticulocyte count	Vitamin deficiencies Hypothyroidism Advanced liver disease Bone marrow disorders	Vitamin B_{12}, folic acid TSH LFTs Bone marrow aspirate/biopsy
High MCV/high reticulocyte count	Hemolytic anemia	LDH, bilirubin, haptoglobin, Coombs test

[a]Diagnostic studies may be ordered in succession until diagnostic result is reached.
EPO, erythropoietin; GI, gastrointestinal; HIV, human immunodeficiency virus; LDH, lactate dehydrogenase; LFTs, liver function tests; MCV, mean corpuscular volume; TSH, thyroid stimulating hormone.

circulation after binding free hemoglobin. Hemoglobinuria results when free hemoglobin is filtered through the glomerulus and is released into the urine, imparting a reddish color. Some hemoglobin in the urine is taken up by tubular cells and is converted to hemosiderin. This can be detected by checking for intracellular iron in the urine by staining the urine with Prussian blue stain. Extravascular hemolysis may be evidenced by only a declining hemoglobin level, although cases of brisk destruction of red cells may show elevations in LDH and unconjugated bilirubin.

Increased red cell production is evidenced by an increase in the number of circulating reticulocytes, which are young red cells whose large size typically results in an elevated red cell MCV and red cell distribution width. Circulating nucleated red blood cells (NRBCs) may be seen in cases of brisk hemolysis. Morphologic evidence of red cell destruction may be evident on the blood smear (see following sections and Figs. 112.1 to 112.4).

Immune-Mediated Hemolysis

The pathophysiology of immune-mediated hemolysis involves antibodies binding to red cells, with or without the activation of complement, leading to red cell destruction. If the antibody on the red cell surface is immunoglobulin G (IgG), then red cell destruction is mediated via Fc receptors on macrophages within the reticuloendothelial (RE) system. Complete or partial phagocytosis occurs causing the red cells to take a spherocytic shape as opposed to the normal, more pliable, biconcave disc shape.

Antibodies which lead to hemolysis can be divided into two categories: warm and cold, referring to the temperature at which the antibody optimally reacts with the red cell. Warm antibodies react with red cells best at temperatures 37°C and typically do not agglutinate red cells [19]. Cold antibodies typically react best at temperatures less than 32°C, with maximal reactivity at 4°C and lead to red cell agglutination [20]. The hallmark of AIHA is a positive direct Coombs test, which will detect the presence of either IgG or C3 bound to red cells (Table 112.6).

Warm Autoimmune Hemolytic Anemia

In warm autoimmune hemolytic anemia (WAIHA), IgG antibodies are directed against red cell surface membrane antigens [19]. Most commonly, these antibodies are directed against members of the Rh blood group, but the specificity of the pathogenic IgG antibodies is not always identified. The IgG antibodies coat the red cells and may or may not fix complement (C3). IgG-coated red cell membrane fragments are engulfed by macrophages in the RE system (usually the spleen) [19,21]. As the red cell loses surface area, it loses the ability to retain its biconcave disc shape. Since the shape with the smallest surface area-to-volume ratio is a sphere, the red cell becomes progressively more spherocytic with each pass through the splenic circulation [19].

WAIHA can manifest as a primary disorder, or alternatively, it can be secondary to an underlying disorder, such as collagen vascular disease (e.g., lupus) or a lymphoproliferative disorder (e.g., lymphoma). Approximately 30% of patients with chronic lymphocytic leukemia have a positive Coombs test, although a much lower proportion develops hemolysis [22]. AIHA may be associated with immune thrombocytopenia, a condition called Evans syndrome. AIHA can also be provoked by infection or can be induced by various drugs. Causes of WAIHA are listed in Table 112.7.

TABLE 112.6

INTERPRETATION OF THE COOMBS TEST AND DIFFERENTIAL DIAGNOSIS

	IgG positive	IgG negative
C3 positive	WAIHA Drug-induced hemolysis	Drug-induced hemolysis Cold agglutinin disease PCH
C3 negative	WAIHA	WAIHA (rare)

Notes: In performing this test, red cells from the patient are washed to remove nonspecific proteins and antibodies. Next, antibodies to human IgG, human C3, or both are added to the cells. If the patient's red cells have either IgG or C3 attached to them, the red cells will agglutinate, indicating a positive test. The specificity of the antibody can be tested by testing the patient's serum against panels of red cells that express different subsets of red cell antigens.
IgG, immunoglobulin G; PCH, paroxysmal cold hemoglobinuria; WAIHA, warm autoimmune hemolytic anemia.

TABLE 112.7

CAUSES OF IMMUNE HEMOLYTIC ANEMIAS

- Warm autoimmune hemolytic Anemia
  - Idiopathic
  - Lymphoproliferative disease
  - Autoimmune disease
  - Drugs
  - Infections
  - Solid tumors
- Cold agglutinin disease
  - Idiopathic
  - Lymphoproliferative disease
  - Infections

Clinical Features. Almost all patients present with worsening and often debilitating fatigue. Older patients, and those with rapid hemolysis and ensuing severe anemia, may present with evidence of organ compromise such as dyspnea, angina, or syncope and can suffer myocardial ischemia, hypotension, and/or renal failure. Physical findings can include pallor, jaundice, and splenomegaly. Laboratory findings include an increased reticulocyte count, increased bilirubin (total and indirect), and increased LDH. The direct Coombs test should be positive (Table 112.6), and typically spherocytes, microspherocytes, NRBCs, and/or anisocytosis are seen on the blood smear.

Transfusion in Patients with Warm Autoimmune Hemolytic Anemia. If the patient has heart failure, angina, shock, or evidence of hypoperfusion to vital organs, or if compensatory erythrocytosis is absent or inadequate due to an underlying illness that suppresses the bone marrow, such as leukemia, prior chemotherapy, or renal failure, then red cell transfusion should be performed [19]. The anti-erythrocyte autoantibody itself also occasionally can be directed against red cell precursors in the marrow, leading to an inappropriately low reticulocyte count [19,23]. Any transfusion in patients with WAIHA needs to be coordinated closely with the blood bank or transfusion service. The offending antibody will frequently interfere with performing a crossmatch to identify compatible blood for transfusion. It is critical to obtain a thorough transfusion and pregnancy history to determine the likelihood of an underlying alloantibody which may be masked by the autoantibody; testing a red cell eluate may be helpful in this regard. Crossmatching can be done using low ionic strength solution (LISS) which

will minimize nonspecific interactions, allowing the stronger alloantibody interactions to appear. If time allows, phenotyping can be performed to identify any antigens on the patient's red cells that may be likely to engender an immune reaction when exposed to transfused blood; such a maneuver may help to minimize the risk of a delayed hemolytic transfusion reaction (DHTR). If crossmatched units are not available, phenotypically matched red cells are preferred. If not available, due to time constraints or the patient's condition, then ABO and Rh type-specific, noncrossmatched, or "least incompatible" units should be used. Each unit should be transfused slowly, while the patient's clinical status is closely assessed for evidence of worsening hemolysis. The blood bank may require that samples of the patient's blood be drawn soon after the transfusion begins to record any evidence of hemolysis. This is termed an in vivo crossmatch.

Treatment. After hemostatic instability has been addressed through transfusion of RBCs, the initial treatment of WAIHA consists of immunosuppression which, if successful, may attenuate antibody production and allow the patient's RBCs to survive normally in the circulation. First-line therapy consists of glucocorticosteroids, either intravenously such as methylprednisolone or oral prednisone, typically at 1 to 2 mg per kg daily [19]. Intravenous immunoglobulin (IVIG) has also been used but is less effective than in immune thrombocytopenic purpura (ITP) [19,24]. If steroids are ineffective, or if relapse occurs, then alternative immunosuppression should be considered. Agents which have been reported to be useful in WAIHA include rituximab, cyclophosphamide, mycophenolate mofetil, and azathioprine [19,25–27]. Splenectomy should also be considered as a reasonable second-line treatment option in eligible patients [19]. As with all hemolytic anemias, the administration of folic acid 1 to 5 mg per day, at least as long as hemolysis is ongoing, is recommended. The reticulocyte count and complete blood cell count (CBC) should be followed closely to monitor the effectiveness of therapy. The amount of blood drawn may be minimized by using pediatric tubes or "bullet" tubes, if available.

Cold Agglutinin Disease

In cold agglutinin disease (CAD), immunoglobulin M (IgM) antibodies target red cell surface antigens, typically with specificity to either "I" or "i." These IgM antibodies optimally bind to red cells at "cold" temperatures (typically $< 32^{\circ}C$ and most strongly at $4^{\circ}C$) [20], and, given their ability to bind more than one RBC simultaneously, lead to the agglutination and clumping of RBCs in the distal microvasculature. IgM antierythrocyte antibodies fix complement to the red cell, leading to either intravascular or extravascular hemolysis. CAD may be primary or secondary due to disorders such as lymphoproliferation or infection [28,29].

Clinical Features. In most patients, CAD is a chronic condition characterized by mild to moderate hemolysis and episodic cyanosis and ischemia of the ears, tip of the nose, and digits [29]. When episodic, cold-induced hemolytic episodes occur, intravascular hemolysis may be associated with shock, rigors, back pain, and renal failure.

Laboratory Evaluation. Cold-agglutinin titers can be measured. On Coombs testing, complement (C3) is typically positive while IgG is negative, reflecting the underlying IgM autoantibody which more efficiently fixes complement (Table 112.6). The thermal amplitude of the autoantibody, not the antibody titer, however, best determines the severity of clinical symptoms. If binding occurs only at $4^{\circ}C$ to $30^{\circ}C$, it is less clinically important than if significant binding occurs at temperatures more than $34^{\circ}C$, approximating more physiologic conditions. In fact, many normal individuals will have cold agglutinins detected at $4^{\circ}C$ but have no clinical symptoms.

Treatment. In patients with chronic, mild CAD, the mainstay of treatment is avoidance of cold temperatures. Corticosteroids and splenectomy are typically ineffective in CAD as compared with WAIHA. Other agents, such as chlorambucil, cyclophosphamide, and rituximab, have been used successfully [20,30]. In patients who present with impending or actual end-organ damage such as myocardial ischemia or stroke, plasmapheresis may be effective because IgM remains primarily intravascular and can be efficiently removed. Plasmapheresis may need to be performed preoperatively in surgeries requiring cardiopulmonary bypass or cardioplegia [20,31]. In all patients, care must be taken to keep the extracorporeal tubing warm and to warm intravenous fluids and blood products, or hemolysis may worsen. Folic acid repletion is recommended in all patients.

Paroxysmal Cold Hemoglobinuria

IgG is the pathogenic antibody in this rare condition. Similar to IgM antibodies in CAD, the IgG antibody in paroxysmal cold hemoglobinuria (PCH) binds to red cells only at cold temperatures where it fixes complement. Unlike the antibody in CAD, however, it is activated at warmer temperatures and does not agglutinate red cells. This antibody is called the Donath-Landsteiner antibody and is directed against the "P" red cell antigen [20]. Red cell destruction occurs primarily via activation of the complement cascade and leads to subsequent intravascular hemolysis. In the past, PCH was primarily a disease associated with tertiary syphilis and, therefore, has become much less common in the penicillin era. Currently, PCH is primarily a pediatric disorder (often following a viral infection), only rarely affecting adults. Patients suffer episodic, cold-induced hemolysis. There is no cold-induced digital ischemia.

The diagnosis is made by detection of the Donath-Landsteiner antibody. The Coombs test is typically negative for IgG and positive for C3 (Table 112.6). The blood bank should be alerted to the possibility of this diagnosis, as special considerations are required for detection. Serum is collected from the patient and kept at $37^{\circ}C$. Patient serum and normal red cells are next chilled to $4^{\circ}C$ then warmed to $37^{\circ}C$. The presence of lysis is revealed by detection of free hemoglobin in the sample. Controls must be performed where red cells and serum are incubated at $37^{\circ}C$ and in a separate test tube at $4^{\circ}C$. In both of these scenarios, there should be no lysis detected [32], as a positive test requires the extremes of temperature.

Drug-Induced Hemolytic Anemias

More than 130 drugs have been reported to cause immune-mediated hemolytic anemia [33]. Drugs can induce hemolytic anemia by three general mechanisms: the innocent bystander mechanism, hapten mechanism, and a true autoimmune mechanism [34,35]. These are described in Table 112.8. It should be noted that many drugs may lead to a positive direct Coombs test in the absence of overt hemolysis. Thus, a positive direct Coombs test should not be inferred to represent hemolysis unless there is worsening anemia in conjunction with consistent laboratory evaluation.

Other drugs may cause hemolysis by alternative mechanisms. Oxidant agents such as dapsone and other sulfa drugs may cause hemolysis in a dose-dependent fashion, especially in individuals with glucose 6-phosphate dehydrogenase (G6PD) deficiency who are impaired in their ability to detoxify the oxidant damage to hemoglobin (see "Glucose 6-Phosphate Dehydrogenase Deficiency" section later in the chapter). Ribavirin,

TABLE 112.8

MECHANISMS OF DRUG-INDUCED HEMOLYSIS

Mechanism	Pathophysiology	Examples
Innocent bystander mechanism	Antibodies develop against the drug. The drug and antibody bind together to form immune complexes, which deposit on the surface of the red cell, where they are recognized by the RE system. The drug must be present in order for hemolysis to occur	Quinine Quinidine Isoniazid
Hapten mechanism	Drug binds to the red cell surface, and antibodies form which are directed against the complex of RBC/drug	Penicillins Cephalosporins, especially Cefotetan
True autoimmune mechanism	Certain drugs appear to induce formation of antibodies directed against red cell surface components, independent of any binding to the RBC surface. Once the process has been initiated, antibody production can continue, even in the absence of drug	Alpha methyldopa Levodopa Procainamide Fludarabine

RBC, red blood cell; RE, reticuloendothelial.

used to treat hepatitis C, causes hemolysis in a dose-dependent fashion. Its mechanism of red cell damage is unclear, but it may relate to nucleotide depletion. Other agents such as cyclosporine and tacrolimus may cause a microangiopathic hemolytic anemia due to endothelial damage (see section "Microangiopathic Hemolytic Anemia").

MICROANGIOPATHIC HEMOLYTIC ANEMIA

The microangiopathic hemolytic anemias are defined as disorders in which narrowing or obstruction of small blood vessels results in distortion and fragmentation of erythrocytes leading to hemolysis and subsequent anemia [36]. The hallmark finding on the blood smear is the schistocyte, a fragmented RBC (Fig. 112.1). It is essential that the intensivist recognize the differential diagnosis of microangiopathic hemolytic anemia as many of the diagnoses, some of which may be apparent given the patient's current or recent medical history, require prompt recognition and treatment (Table 112.9) [36,37]. If the underlying etiology of microangiopathic hemolytic anemia is in question, immediate hematology consultation is strongly recommended to evaluate for life threatening diagnosis such as thrombotic TTP.

TTP, once almost uniformly fatal, can now be treated effectively in the majority of patients with prompt recognition and initiation of therapeutic plasma exchange (TPE) [36–38]. The diagnosis should be suspected in any patient who presents with unexplained microangiopathic hemolytic anemia and thrombocytopenia [36–38]. The "classic pentad" of microangiopathic hemolytic anemia, thrombocytopenia, mental status changes, renal failure, and fever is present in fewer than 25% of patients at presentation. Only unexplained microangiopathic hemolytic anemia and thrombocytopenia are required to suspect the diagnosis; the clinical sequela are likely late manifestations of the disease [39].

Moake and others first noted unusually large von Willebrand factor (vWF) multimers in the plasma of affected patients and proposed them to be central in the pathophysiology of the disorder [40]. In the late 1990s, two groups reported that a vWF-cleaving protease (later termed ADAMTS-13, as a member of a disintegrin and metalloproteinase with thrombospondin components family of proteins) was found to be absent in familial TTP and inhibited by an antibody in the majority of cases of acquired TTP [41,42]. The absence of ADAMTS-13 was subsequently shown to prevent the breakdown and lead to the accumulation of ultra large molecular weight vWF multimers [40,43,44]. These ultra large vWF multimers efficiently bind to glycoprotein receptors on platelet surfaces leading to adhesion of platelets to the blood vessel endothelium and subsequently to small vessel occlusion affecting a variety of organs [38,40]. Hemolytic anemia occurs due to the mechanical shearing of RBCs as they transverse the turbulent and occluded microvasculature, thus leading to the classic findings of schistocytes seen on the peripheral blood smear (Fig. 112.1) [36,45].

TABLE 112.9

DIFFERENTIAL DIAGNOSIS OF MICROANGIOPATHIC HEMOLYTIC ANEMIA

- Thrombotic thrombocytopenic purpura

  - Ticlopidine
  - Clopidogrel
  - Chemotherapeutic agents such as mitomycin C and gemcitabine

Clinical Manifestations

As discussed earlier, the clinical manifestations of TTP can be quite varied. Neurologic symptoms may range from subtle confusion to frank seizures or coma. Renal dysfunction may range from mild proteinuria or azotemia to acute renal failure. Occlusion in the blood vessels of the cardiac conduction system may lead to arrhythmias and sudden cardiac death. Pancreatitis has been described and should be considered in patients with abdominal pain. Fever is often noted. Any organ maybe affected leading to a wide range of symptoms.

Laboratory Features

Laboratory evaluation usually reveals a hemolytic anemia with at least (and often more than) 2 schistocytes or greater than 1% of RBCs per 100× field on microscopic exam (Table 112.4 and Fig. 112.1) [37,38]. Coagulation studies such as the activated partial thromboplastin time and the prothrombin time are typically normal, whereas they are usually prolonged in disseminated intravascular coagulation (DIC). The Coombs test is negative. Most cases of classic acquired TTP are associated with a severe deficiency of ADAMTS-13 (< 5%), and an inhibitory antibody can be demonstrated [41–43,45]. ADAMTS-13 results are often not available in real time, are not required to make the diagnosis, and should not routinely be used to make therapeutic decisions regarding the initiation of plasma exchange. ADAMTS-13 levels have prognostic value regarding the risk of relapse but are less useful in determining the likelihood of initial response to plasma exchange. Moderate decreases in ADAMTS-13 are not specific and may be seen in a variety of disorders including sepsis [43].

Schistocytes may be seen in conditions other than TTP (Table 112.9). These conditions usually have in common damage to the blood vessel endothelium, leading to the release of ultra large vWF multimers. The presentation of these syndromes may mimic TTP, although the hemolytic uremic syndrome (HUS) often presents with a primary component of renal failure [36]. Conditions other than TTP are not typically associated with a severe (< 5%) deficiency of ADAMTS-13 and TPE may not be effective, although it is often initiated if HUS is suspected [36,41].

The distinction between TTP and HUS may be difficult to make. Classic childhood HUS is usually preceded by hemorrhagic diarrhea caused by *Escherichia coli* 0157:H7. Atypical HUS as seen in adults may be difficult to differentiate from TTP. Typically, renal failure is more severe and extra renal manifestations are less or absent in HUS [36,38]. Thrombocytopenia and the presence of schistocytes may be more marked. ADAMTS-13 is not usually severely depressed in HUS, suggesting a different pathophysiology between these two related conditions [41]. Atypical HUS has been linked to uncontrolled activation of the complement system due to either congenital or acquired mutations or antibodies against various factors in the complement pathway [46]. As the ability to differentiate between TTP and atypical HUS is often unclear, prompt TPE is often initiated in atypical HUS, even though efficacy may be less as compared to TTP [36,38].

Treatment

TPE with fresh frozen plasma at a 1.0 to 1.5× plasma volume should be initiated as soon as idiopathic TTP is suspected [36,38,44,45]. A dual-lumen, large bore, dialysis-type catheter is often needed for the procedure and should be promptly placed despite the coexisting thrombocytopenia. With prompt TPE, 80% to 90% of patients with classic TTP survive this once uniformly fatal disease [36–38]. The effectiveness of TPE is thought to be due to both the removal of an anti-ADAMTS-13 antibody and the replacement of ADAMTS-13 in donor fresh frozen plasma. If TPE is not readily available, FFP should be infused at a rate of 30 mL per kg per day while arrangements for TPE are made [44]. Randomized trials have supported the efficacy of TPE over simple plasma infusion which could become problematic given the large volume of FFP needed [45,47].

TPE should be continued until the platelet count and LDH have normalized for 2 days [39]. Plasma exchange is often tapered down to every other day upon remission, but this practice has not been critically studied and its efficacy in preventing relapse is uncertain. In refractory or relapsing patients, cryosupernatant plasma, devoid of vWF, should be considered [45,48]. Catheter-related infections should also be investigated and have been documented to lead to relapse. Immunosuppressants such as glucocorticoids and cyclosporine as adjuncts to plasma exchange have been used, but efficacy remains uncertain [36,38]. Aspirin has also been used for its antiplatelet effects but is often avoided until the platelet counts begin to rise [39]. Platelet transfusion is generally avoided, as it was thought to exacerbate the disease although recent data calls this into question [49].

In small case reports and case series, rituximab has been found to be effective in relapsing and refractory cases and should be considered [50,51]. Recombinant ADAMTS-13 is under development and may prove to be effective in the future.

Disseminated Intravascular Coagulation

Although microangiopathic hemolytic anemia may be present in patients with DIC, typically the thrombotic or bleeding manifestations of DIC are more clinically significant. DIC, which is often due to an underlying serious or catastrophic event such as septicemia or an obstetric emergency, will be covered in greater detail in Chapters 108 and 109.

Other Causes of Microangiopathic Hemolytic Anemia

The differential diagnosis of microangiopathic hemolytic anemia includes the other diagnoses listed in Table 112.9. Appropriate consultation and treatment should be pursued dependent on the most likely diagnosis.

HEMOGLOBINOPATHIES

Sickle Cell Anemia

Sickle cell anemia results from the presence of a point mutation leading to an amino acid substitution (valine for glutamic acid) in the sixth position of the beta chain of hemoglobin. An unstable form of hemoglobin (hemoglobin S) is produced which polymerizes in the setting of dehydration or hypoxia, a term referred to as sickling. The sickling of red cells is responsible for a variety of clinical conditions including extremely painful episodes in the back and extremities. Patients may be symptomatic if they are homozygous for hemoglobin S; if they are compound heterozygotes for hemoglobin S, hemoglobin C, hemoglobin D, and hemoglobin E; or if they also have concomitant beta thalassemia. The most common complications of sickling disorders leading to ICU admission are listed in Table 112.10.

Transfusion. Although patients with sickling disorders are nearly always anemic, transfusions are not indicated for hemodynamically stable anemia, routine vasoocclusive crisis, routine

pregnancies, or simple surgical procedures that do not require general anesthesia. In general, hematology consultation is indicated if transfusion is considered, as the need for transfusion usually suggests a more complicated clinical scenario. Transfusion therapy can be simple, chronic, or performed via RBC exchange. Simple transfusion involves infusion of a sufficient volume of red cells to improve tissue oxygenation. Chronic simple transfusions are primarily used to prevent stroke recurrence. RBC exchange, performed (where available) via erythrocytapheresis using a noncollapsible, large bore, dialysis-type catheter, involves the removal of the patient's hemoglobin S red cells, followed by replacement of RBCs from a non–hemoglobin S donor targeting a final hemoglobin no higher than 8 to 10 g per dL with hemoglobin S less than 30%. RBC exchange is often used in the management of acute stroke or severe acute chest syndrome (ACS) as a more rapid and efficient way to remove hemoglobin S and improve oxygen delivery. Alternatively, manual exchange transfusion involves removing 500 cc of blood, followed by infusion of 300 cc normal saline, followed by another 500 cc removal of blood, and subsequent transfusion of 4 to 5 units of packed red cells [52]. Care should be taken to keep the end hemoglobin value no higher than 10 g per dL to minimize the risk for hyperviscosity.

Alloimmunization, typically to the Rh (E, C), Kell (K), Duffy (Fya, Fyb), and Kidd (Jk) antigens, occurs in up to 30% of patients [53]. Alloimmunization can be minimized by transfusing red cells that have been phenotypically matched for these red cell antigens. If phenotypically matched units are not available, crossmatched red cell units that are negative for C, E, and Kell are recommended.

Acute Chest Syndrome

Pulmonary complications frequently cause significant morbidity and mortality in patients with sickling disorders and are a common reason for ICU admission. Among the pulmonary complications, the ACS is among the most frequently observed in the ICU setting.

Clinical Features. ACS can be defined by a constellation of fever, hypoxemia, chest pain, leukocytosis, and new pulmonary infiltrate in a patient with a sickling disorder [54]. Although most common in patients homozygous for hemoglobin S, ACS can also be seen in decreasing frequency in patients with hemoglobin SC disease and S/β+ thalassemia. Importantly, the clinical definition of ACS does not indicate a specific etiology. ACS can be caused by infection, thrombosis, fat embolism, or any combination of these conditions. A large multicenter study showed that a specific cause of ACS could be identified in more than 50% of patients studied [55]. The most common etiologies observed were fat embolism and infection. Specific etiologies of ACS from this study of 671 episodes are listed in Table 112.11.

TABLE 112.11

CAUSES OF THE ACUTE CHEST SYNDROME IN A 30-CENTER STUDY

Cause	Percentage
Fat embolism, with or without infection	8.8
Chlamydia	7.2

Physiologic Markers. Secretory phospholipase A2, a potent inflammatory mediator, has been implicated as a cause of lung damage in patients with ACS [56], and serum levels may be predictive of impending ACS [57]. In addition, circulating activated endothelial progenitor cells have been proposed as a potential etiology of ACS [58].

Treatment. Treatment of ACS depends in part on the clinical presentation. If the sputum Gram stain suggests infection with a particular organism, targeted antibiotic therapy should be initiated without delay. Interestingly, although pneumococcus is a frequent cause of infection in children with ACS, it is much less common in adults, in whom mycoplasma is more frequently implicated [54]. However, when an infectious etiology of ACS is suspected, empiric coverage for pneumococcus remains appropriate. In addition, because of the high mortality associated with ACS, empiric antibiotic coverage for mycoplasma and chlamydia should also be strongly considered. Maintaining hydration and oxygenation during episodes of ACS are imperative to prevent further sickling. However, fluids must be administered carefully to avoid fluid overload. There is no data to support the routine use of anticoagulants in ACS, and in the absence of data, this practice should be avoided.

Patients with ACS and hypoxia ($PO_2 < 75$ mm Hg) should be transfused red cells by either simple or exchange transfusion [59]. One small single-institution study found no difference between the two transfusion modalities [60]. Clinically, decisions between these two strategies are usually based on the degree of hypoxia, the pace of respiratory failure, as well as other comorbidities. Red cell exchange transfusion may be favored in the more severe or rapidly progressive cases and in critically ill patients with hemoglobin SC disease because such patients typically have baseline hemoglobin levels in the 10 to 11 g per dL range. In addition to providing a source of oxygen delivery, exchange transfusion also decreases levels of inflammatory mediators such as soluble vascular cell adhesion molecule-1 [61].

Acute Stroke

Stroke is one of the most morbid complications of sickle cell disease, with a prevalence of more than 20% in some series [62]. In addition to overt stroke, more than 60% of patients with sickle cell disease have evidence of brain damage from occult

infarction that is incidentally found on magnetic resonance imaging [63]. The pathophysiology of stroke in sickle cell patients is complicated. Stroke is related to nitric oxide depletion, hypercoagulability, and abnormalities of the major cerebral arteries. Unfortunately, stroke recurrence is common with more than 50% of cases occurring within 36 months following the initial event [64]. The presence of constricted cerebral arteries with collateralization (moyamoya syndrome) is associated with recurrent stroke and may be alleviated by surgical vascular bypass [65]. Although transcranial Doppler measurement of blood velocity has predictive value for stroke in pediatric patients with sickle cell disease, the measurement of cranial blood flow velocity is less able to stratify the risk of stroke for adults [66].

Treatment. Although there have been no specific trials addressing the issue, antiplatelet agents can be used in the treatment of acute stroke in adults with sickle cell disease, similar to patients without sickle cell disease [67]. Although there are no randomized trials, retrospective studies suggest that the use of red cell exchange transfusion to increase oxygen carrying capacity to the brain in the setting of acute stroke may be of some benefit [59]. For acute stroke in patients with sickle cell disease, emergent red cell exchange transfusion to reduce hemoglobin S to less than 30% has been recommended by some experts [68]. Similarly, consensus opinion suggests that conventional angiography can be used in sickle cell patients suspected of having an aneurysmal subarachnoid hemorrhage [59]. Because of the osmotic dye load which might increase intracerebral sickling, experts also suggest exchange transfusion prior to angiography [59]. Acute retinal artery occlusion can be considered as an ophthalmic stroke. The exact pathophysiology of retinal artery occlusion in sickle cell disease and risk factors for the condition are not known [69]. Similarly, there is scant data on the treatment of retinal artery occlusion in sickle cell anemia. At this time, it is reasonable for sickle cell patients presenting with acute thrombotic stroke or acute retinal artery occlusion to undergo red cell exchange transfusion. In addition, antiplatelet agent administration appears reasonable.

Acute Cholecystitis

Patients with hemolytic disorders, including sickle cell disease, form gallstones composed of the insoluble salt, calcium bilirubinate. For sickle cell patients presenting with acute cholecystitis, laparoscopic cholecystectomy appears safe and effective [70]. A prospective trial supports the idea that most sickle cell patients undergoing cholecystectomy should receive transfusion support [71]. A randomized trial has suggested that simple preoperative transfusion to a hemoglobin level of 10 g per dL is not associated with more complications than preoperative red cell exchange transfusion to a target hemoglobin S less than 30% [72]. In addition, simple transfusion is associated with a lower rate of alloantibody formation, as fewer units of RBCs are transfused. The use of postoperative incentive spirometry is strongly encouraged due to a decreased incidence of ACS [73].

Pulmonary Hypertension

Pulmonary hypertension is a recently recognized cause of morbidity and mortality in sickle cell disease occurring in more than 30% of patients and conferring an increased death rate ratio of 10.1 [74]. Pulmonary hypertension may be secondary to nitric oxide scavenging by free hemoglobin released during hemolysis. Such scavenging can lead to synthesis of vasoconstrictors such as vascular-cell adhesion molecule 1 and E-selectin. Hemolysis also leads to the release of arginase from hemolyzed red cells, reducing nitric oxide synthesis. The formation of reactive oxygen and nitrogen species catalyzed by free hemoglobin may also lead to pulmonary vasoconstriction. Pulmonary hypertension, in conjunction with high cardiac output, is a major cause of congestive heart failure in patients with sickle cell disease.

The management of patients with sickle cell disease and pulmonary hypertension remains controversial. Some authors have noted a decreased incidence of pulmonary hypertension in retrospective studies of patients treated with hydroxyurea [75], but this finding is not universal. A small study found that therapy with sildenafil improved exercise capacity in patients with sickle cell disease and pulmonary hypertension [76]. However, a recent trial using sildenafil in children with sickle cell disease and pulmonary hypertension was prematurely suspended due to an increase incidence of adverse events including painful crisis. Speculation exists that endothelin antagonists, such as bosentan, may also be effective in reducing pulmonary pressures, although prospective trials are lacking. Such is also the case for epoprostenol and oral arginine [77].

Currently, there is insufficient evidence in the medical literature to suggest specific treatment strategies for patients with sickle cell disease and pulmonary hypertension. At a minimum, conservative management including oxygen therapy to treat hypoxia and aggressive treatment of right heart failure are recommended.

Hyperhemolysis

Patients with hyperhemolysis, characterized by a lower posttransfusion hemoglobin compared with the pretransfusion value, present with profound anemia and hemolysis despite red cell transfusion support [78]. The pathophysiology of hyperhemolysis in sickle cell disease remains unclear but may be related to a combination of bystander hemolysis, suppression of erythropoiesis, and destruction of RBCs due to contact lysis via activated macrophages [79]. There are case reports supporting the use of IVIG and corticosteroids in addition to transfusion to maintain enough RBCs to support the circulation [80]. Erythropoietin administration may also be of benefit in cases where the reticulocyte count is inadequate. Although hyperhemolysis can recur, typically it occurs as an isolated event. Prompt recognition is important to avoid life-threatening anemia in the setting of continued erythrocyte transfusion.

Aplastic Crisis

Aplastic crisis in sickle cell disease is usually secondary to either folic acid deficiency or infection with parvovirus B19. Aplasia secondary to folic acid deficiency is more common in late pregnancy when folic acid requirements are increased. Infection with parvovirus can be accompanied by marked marrow necrosis [81]. Treatment of parvovirus infection–induced aplasia in immunocompetent individuals is supportive and resolves upon clearance of the virus.

Sepsis

Because patients with sickling disorders are functionally asplenic, infection remains a common reason for hospitalization. Pneumonia is the most common infection and may be due to pneumococcal species, especially if the patient did not receive appropriate immunizations. Treatment of patient with sickle cell disease and sepsis parallels the treatment of similar patients without a coexistent hemoglobinopathy. Broad-spectrum antibiotics which can later be tailored to the most likely organism should be administered immediately. Adequate hydration must be maintained during an infectious episode to prevent further sickling of erythrocytes. Organisms responsible for sepsis in the sickle cell population can be found in Table 112.12. Consideration of immunization status is important when considering the most likely organism.

Thalassemia

Patients with thalassemia can develop high output heart failure that can lead to ICU admissions. Treatment of heart failure in thalassemic patients is similar to the management of heart failure in other patient populations including the use of diuretics, angiotensin-converting enzyme inhibitors, and beta-blockers. Chelation therapy with deferasirox is recommended in patients with thalassemia major and iron overload especially if iron overload has caused cardiac toxicity. Transfusion support is required in symptomatic anemia. Unless a coexistent hemoglobinopathy is present, stroke, ACS, and other common complications of sickle cell disease are not typically seen.

Hemolytic Transfusion Reactions

Patients may experience hemolytic transfusion reactions that are either immediate (acute) or delayed. Acute hemolytic transfusion reactions (AHTRs) typically manifest with a feeling of impending doom. Subsequently, back pain, hypotension, red urine, and shock develop. Renal failure due to the massive hemoglobin load may occur, and DIC often ensues. Between the years 1990 and 1992, the majority of the 150 preventable transfusion-related fatalities reported to the Food and Drug Administration (FDA) were due to ABO-incompatible RBC transfusions leading to an AHTR [82–84]. Indeed, AHTR is typically the result of human error, in specimen collection, labeling, or transfusion [83]. Errors within the laboratory are much less common. Although this dramatic presentation is classic, it is important to note that a rise in temperature of 1°C above baseline may be the sole initial presentation of a hemolytic transfusion reaction and necessitates the cessation of transfusion of that unit of red cells and initiation of workup for transfusion reaction. In the case of an immediate hemolytic transfusion reaction, hemoglobinuria and hemoglobinemia may be seen, and reaction between the remnant of the transfused unit and the patient's pretransfusion serum can be identified. Treatment consists of stopping the transfusion as soon as the reaction is suspected, hydration, forced diuresis, and maintenance of blood pressure.

Delayed hemolytic transfusion reactions (DHTRs) typically present 1 to 4 weeks after transfusion of a unit of red cells. The patient may present with fatigue, jaundice, pallor, or red- or tea-colored urine. Patients with sickling disorders may come to medical attention due to a new or worsening pain crisis. The hemoglobin will be lower than that seen posttransfusion. The LDH and bilirubin will be increased, the reticulocyte count will likely be elevated, and the antibody screen will be positive, and a new alloantibody often identified. The DHTR is typically due to mismatches of non-ABO red cell antigens. Patients should be issued a card stating the antigen to which they have made a new alloantibody and told to present this card prior to all future transfusions. This is especially important in cases of antibodies to the Kidd antigen, as these alloantibodies are typically transient and may not be detectable on future antibody screens.

Glucose 6-Phosphate Dehydrogenase Deficiency

G6PD deficiency, a sex-linked trait primarily affecting men most commonly of African American or Mediterranean descent, is the most common erythrocyte enzyme defect in the world [85]. G6PD is necessary to maintain glutathione in its reduced state in the erythrocyte. Patients deficient in this enzyme are subject to oxidative hemolysis when exposed to certain drugs and toxins, or during episodes of infection. A sample list of drugs to be avoided in G6PD-deficient patients is provided in Table 112.13. Because acute infection makes oxidative hemolysis more likely, there has been confusion about the safety of certain drugs in G6PD-deficient patients. A list of drugs that can be safely administered to G6PD-deficient patients is shown in Table 112.14. A more exhaustive drug list can be found at many Web sites dedicated to G6PD deficiency (ex. www.g6pd.org). G6PD deficiency is seldom a major issue in critically ill patients because the anemia is typically not severe, and the patients are closely monitored. However, in solid organ transplant recipients who are exposed to oxidant drugs such as trimethoprim–sulfamethoxazole or dapsone, the diagnosis should be strongly considered in the setting of a new hemolytic or unexplained acute anemia [86].

In the more common African American variant of G6PD, enzyme levels are elevated in young reticulocytes, and therefore measurement of this enzyme should not be attempted in the

setting of an acute hemolytic episode, where the majority of circulating red cells are young.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired disease in which an abnormal stem cell clone gives rise to red cells, white cells, and platelets that lack proteins which are normally attached to the cell surface by a glycerophosphatidylinositol (GPI) anchor. Among these proteins are CD55 and CD59, which are responsible for inactivating complement on the surface of red cells. PNH cells are therefore more susceptible to complement-mediated lysis [87]. Patients with PNH may come to the attention of the intensivist with complications such as hemolysis, pancytopenia, arterial, or venous thrombosis (including the Budd–Chiari syndrome/hepatic vein thrombosis). Patients may also develop pancytopenia due to marrow hypoplasia, as there is an association with primary bone marrow disorders such as aplastic anemia, myelodysplastic syndrome (MDS), and acute myelogenous leukemia [88,89].

Flow cytometry showing the absence of GPI-linked surface molecules CD55 and CD59 on erythrocytes and granulocytes has supplanted older testing (such as the Ham's test) for the diagnosis of PNH [88]. Eculizumab has been FDA approved for the treatment of hemolysis due to PNH. Patients treated with eculizumab show markedly lower rates of hemolysis and also thrombosis [90–94] but are at increased risk for infection with meningococcus, requiring immunization prior to use [88].

Hereditary Spherocytosis

Hereditary spherocytosis (HS) is an autosomal dominant disorder, of red cell membrane skeletal proteins leading to a lack of anchoring of the red cell lipid bilayer to its skeletal backbone [95–97], leading to a characteristic spherocytic shape. Patients have lifelong hemolysis which is often well compensated. However, with even mild infections, the hemolysis can accelerate, and the patient can become more anemic. Splenomegaly is present in many patients and splenic rupture may occur after trauma. Patients with HS may present with an aplastic crisis manifested by severe reticulocytopenia and anemia often due to parvovirus B-19 infection which transiently suppresses the bone marrow's ability to produce red cells and compensate for the accelerated hemolysis [97,98]. The Coombs test will be negative and should be used to differentiate HS from warm autoimmune hemolytic anemia, which can present similarly. RBC transfusion may be administered to patients with aplastic crisis.

Hemolysis from Infectious Agents

Certain infectious pathogens cause hemolysis that can be severe or life threatening. Malaria is prototypic; infection with falciparum malaria is known as blackwater fever, due to the massive hemolysis caused by this agent. *Babesia microti* is another intracellular parasite that can lead to hemolysis. It is carried by the same tick as Lyme disease and can look like malarial forms on peripheral smear. *Bartonella bacilliformis*, the agent responsible for Oroya fever, and *Verruca peruvianis*, an extracellular parasite, can lyse red cells leading to dramatic hemolysis. In endemic regions of the world, these organisms are leading causes of hemolysis in critically ill patients. The toxin of *Clostridium welchii*, an agent of gas gangrene, may cause severe hemolysis. The bacterium produces a lysolecithinase, which attacks the red cell membrane bilayer. *Clostridium perfringens*, another agent causing gas gangrene, also leads to hemolysis via the action of phospholipases produced in its exotoxin [99]. In certain cases, the hemolysis can be severe enough to produce a disparity between the hemoglobin and the hematocrit. This infectious complication typically follows bowel or gynecologic surgery.

Hemolysis Associated with Chemical and Physical Agents

Arsenic, especially arsine gas, can lead to hemolysis, as it can elevate levels of copper in the blood. Wilson's disease, which is a disorder of copper metabolism, may present with hemolysis as part of its clinical picture [100]. Some dialysis centers have had difficulty with copper contamination of their water supply, leading to severe hemolysis [101]. Insect and spider bites, especially the bite of the brown recluse spider (*Loxosceles reclusa*), can lead to hemolysis, as can certain snakebites [102]. Severe burns can lead to hemolysis, since the red cell membrane is sensitive to temperatures more than 55°C.

Other Causes of Anemia in the Critical Care Setting

Iron deficiency leads to a hypoproliferative anemia due to the inability to synthesize hemoglobin. Iron deficiency may be caused by chronic blood loss, decreased iron intake (either from dietary reasons or from iron malabsorption as occurs in celiac sprue or following gastrointestinal bypass), or both. In the ICU, red cell transfusion is the most immediate way to correct the anemia, but in patients with a low hemoglobin but no hemodynamic compromise, oral or intravenous iron is preferred. Parenteral iron may be preferred in iron-deficient patients who have undergone gastrointestinal bypass, cancer patients, those who suffer from functional iron deficiency, patients undergoing treatment with erythropoietin, or patients with chronic kidney disease [103–106]. Iron dextran, iron sucrose, iron gluconate, and ferumoxytol are all available for intravenous use. The newer formulations of iron dextran have a lower rate of severe allergic reactions compared with older dextran preparations, but the incidence continues to remain higher than with the newer nondextran iron preparations [107–114].

TABLE 112.15

MECHANISMS OF THE ANEMIA OF CHRONIC DISEASE/CRITICAL ILLNESS

Blood loss
Phlebotomy
Active bleeding
Decreased red cell production
Decreased production of erythropoietin
Blunted response to erythropoietin
Sequestration of iron through up regulation of hepcidin
Renal dysfunction
Increased red cell destruction
Reduced red blood cell deformability

The iron deficit is calculated by the following formula: (desired hemoglobin − actual hemoglobin) × (weight in pounds) + storage iron. Storage iron is estimated at 1,000 g for men and 600 mg for women.

Megaloblastic Anemia

Megaloblastic anemia is a rare cause of anemia in the ICU but should be suspected in the individuals presenting with a macrocytic, hypoproliferative anemia (high MCV, low reticulocyte count) (Table 112.5). Vitamin B_{12} and folic acid levels should be measured, but accuracy may be affected in the acute setting. The measurement of homocysteine and methylmalonic acid (MMA) is a more sensitive way to asses for these nutritional deficiencies but can also be altered in the critically ill patient [115]. Typically, both homocysteine and MMA are elevated in B_{12} deficiency, while homocysteine alone is elevated in folic acid deficiency. Elevation of homocysteine and MMA may be the first laboratory signs of subclinical B_{12} deficiency. The peripheral smear may show oval macrocytes and hypersegmented neutrophils. Other anemias which are hypoproliferative and macrocytic include the MDS, aplastic anemia, the anemia of hypothyroidism, and liver disease (Table 112.5).

Anemia of Chronic Disease (ACD)/Inflammation

The anemia of chronic disease/inflammation is common in the ICU and its etiology is multifactorial (Table 112.15) [1]. Once thought to occur over weeks to months, the ACD has been shown to occur in less than a week and is thus thought to be a major contributor to anemia in critically ill patients [1,116]. Several studies have shown elevated levels of cytokines such as tumor necrosis factor-alpha; interleukin-6; C-reactive protein; and interferons alpha, beta, and gamma in ACD [1,117,118]. This cytokine response has been shown to inhibit erythropoietin production, blunt the erythropoietic response, and play a central role in iron metabolism, leading to the sequestration of iron. Iron metabolism is primarily mediated by the antimicrobial peptide hepcidin, which impairs the ability to export iron from gut epithelial cells and hepatocytes into the bloodstream [119]. Hepcidin is upregulated in the ACD, leading to the sequestration of iron. In the ACD, the serum iron (Fe), total iron-binding capacity (TIBC), and percentage iron saturation (iron/TIBC) are typically low. Ferritin, an acute phase reactant, is often normal or elevated, as opposed to iron deficiency where it is low. Renal failure is common in the ICU and also may contribute to the ACD, especially when progressive [1,120]. Increased red cell destruction has also been noted in the ACD due to decreased RBC deformability [1].

CONCLUSION

As demonstrated in this chapter, anemia is exceedingly common in the critical care setting, but its etiology remains very diverse. A rational approach to the evaluation of anemia includes review of the white blood count, platelet count, MCV, reticulocyte count, peripheral blood smear, and any prior CBCs that may be available. If hemolysis is suspected, LDH, bilirubin, and haptoglobin will provide additional information to support or refute this diagnosis. A Coombs test is often sent if the etiology of hemolysis remains in question. As highlighted in the chapter, certain causes of anemia such as blood loss, microangiopathic hemolytic anemia, complications of sickle cell disease, hemolysis from drugs as well as foreign devices, and ACD are seen with increased frequency in critically ill patients and should be considered in the ICU patient population. Specific treatment recommendations are based on the underlying diagnosis. Minimization of the volume and frequency of blood draws is essential. Conservative transfusion thresholds are increasingly being used in the absence of hemodynamic compromise or acute blood loss. The role of ESAs has been investigated but remains uncertain. If the etiology of the anemia remains obscure, or the management of an underlying diagnosis remains uncertain, hematology consultation is recommended.

CHAPTER 113 ■ THERAPEUTIC APHERESIS: TECHNICAL CONSIDERATIONS AND INDICATIONS IN CRITICAL CARE

THERESA A. NESTER AND MICHAEL LINENBERGER

TECHNICAL RATIONALE AND INSTRUMENTS

Apheresis means *to remove*. Apheresis instruments are designed to separate whole blood into its component parts to selectively remove one component and return the remaining components to the patient. By processing one or more blood volumes, a significant amount of pathologic solutes or cells may be removed while the intravascular compartment remains relatively euvolemic. In an exchange procedure, replacement fluid or blood is given back to the patient to allow plasma or red cells to be removed. With any apheresis procedure, some type of anticoagulant is added to the circuit to ensure that blood flows freely.

Centrifugation apheresis instruments use either a continuous or a discontinuous flow method to deliver blood to the separation device where blood cells and plasma are differentially sedimented according to their specific gravity. Continuous flow methods draw blood into the extracorporeal circuit, separate blood into components in the centrifugation chamber,

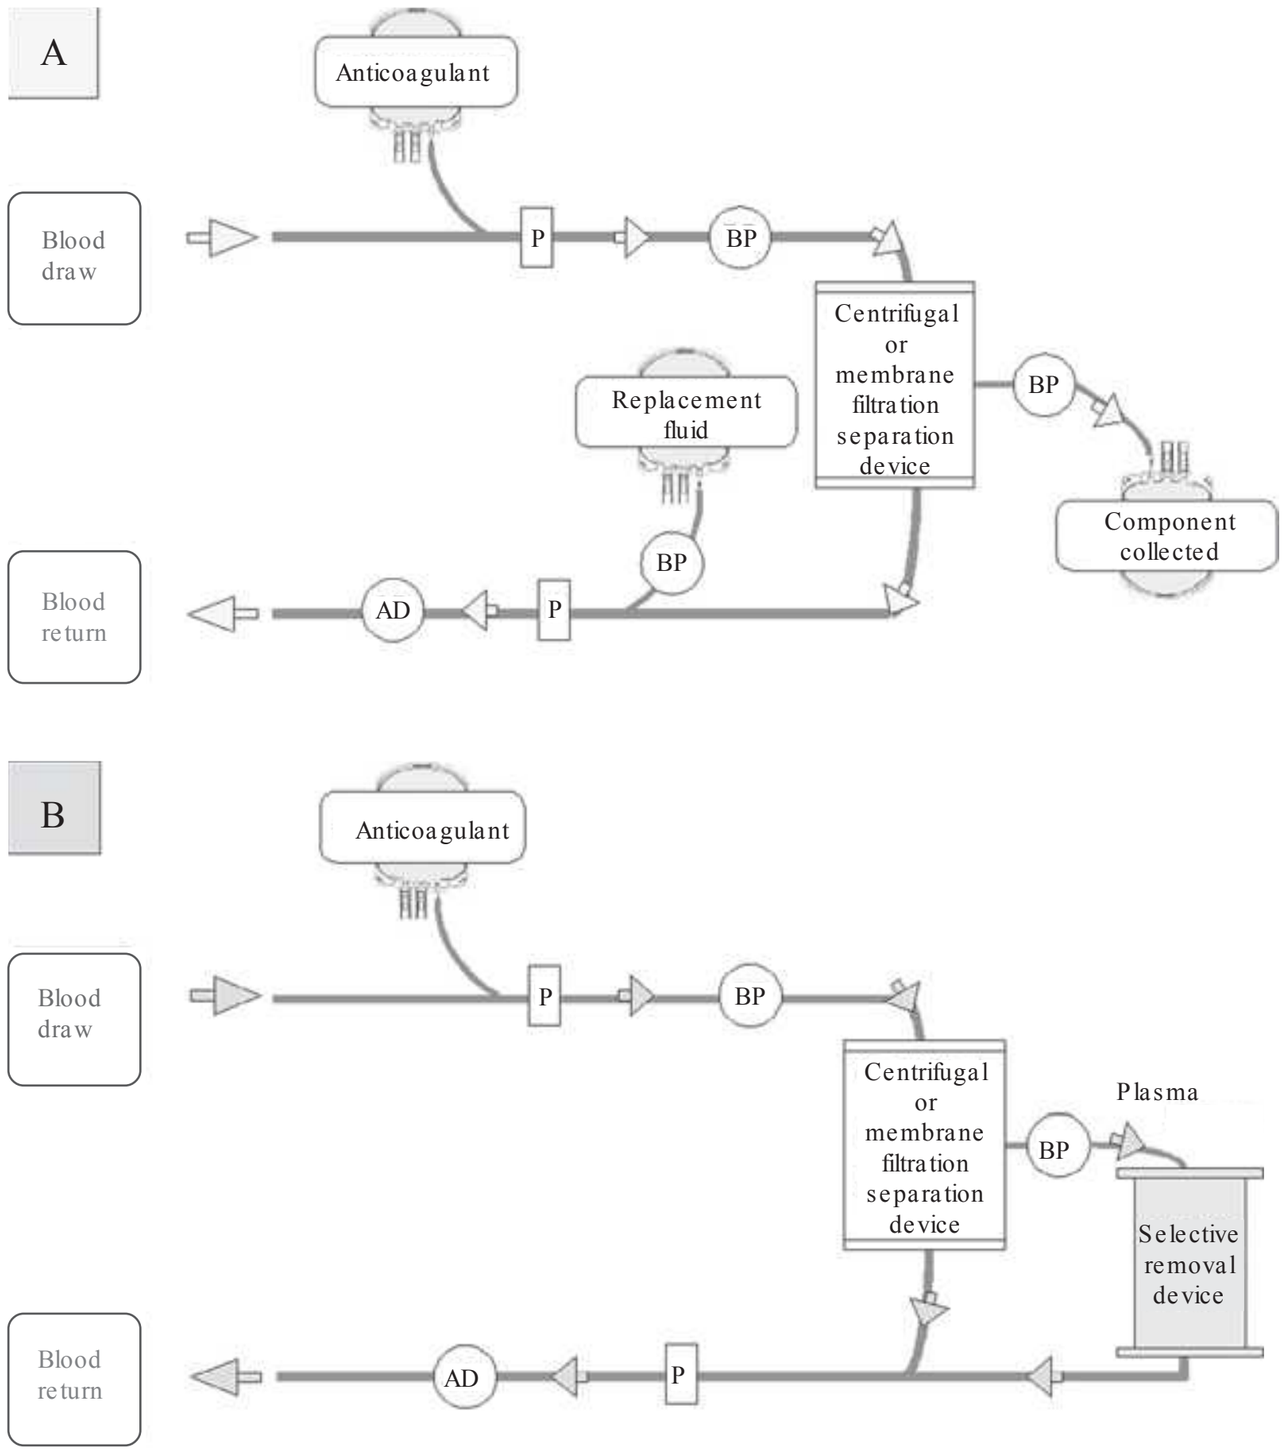

FIGURE 113.1. A: Basic circuitry and instrumentation of component removal in a therapeutic apheresis procedure. Anticoagulant is added to the patient's blood as it is drawn and pumped to the separation device. The component to be collected is pumped from the device to a collection bag, and the remainder of the blood is returned, along with appropriate replacement fluid, to the patient. **B:** Circuitry and instrumentation for selective removal of pathogenic substance from the patient's plasma. The patient's anticoagulated blood is pumped to the separation device, and separated plasma is then delivered to the selective removal device. The purified plasma is then combined with the cellular portion of the patient's blood and returned to the patient. AD, air detector; BP, blood pump; P, pressure monitor. [From Linenberger ML, Price TH: Use of cellular and plasma apheresis in the critically ill patient: part 1: technical and physiological considerations. *J Intensive Care Med* 20:18–27, 2005, with permission.]

divert the unwanted component into a collection bag, and return nonpathologic components to the patient without interruption (Fig. 113.1). Dual venous/catheter access is required for these procedures. Discontinuous, or intermittent, flow methods accomplish the same steps but draw, process, and return a discrete amount of blood extracorporeally before another discrete volume of blood is removed. Discontinuous procedures take a longer time than continuous procedures but require only single vein/catheter access [1].

Some apheresis instruments, predominantly used in Asia and Europe, use a membrane filtration technique to isolate plasma. The extracorporeal membrane consists of either a flat plate or a hollow fiber with a pore size that excludes cellular components from the filtrate. The plasma that is separated in the instrument is diverted for disposal or treatment, while the other blood components are returned to the patient [2].

Specialized columns and instruments have been developed over the years to treat separated plasma, with the goal of selectively removing pathogenic proteins or other solutes [3–8]. One example is hypercholesterolemia therapy. Two different columns are approved for patients with familial hypercholesterolemia who have failed combination drug therapy. The heparin-induced extracorporeal low-density lipoprotein (LDL) precipitation (HELP) system and Liposorber LA-15 system target the removal of LDLs from separated plasma [4]. Additional columns and systems have been tested and used outside the United States [5]. These include a dextran-sulfate column to remove anti-DNA and anticardiolipin antibodies and immobilized polymyxin B or other adsorbers to remove inflammatory cytokines and mediators of sepsis [6–8]. One specialized methodology, called extracorporeal photopheresis (ECP), involves isolating peripheral white blood cells by leukapheresis, treating the cells with a psoralen drug, and exposing them to ultraviolet A light before returning the photoactivated cells to the patient [9]. A dedicated instrument approved by the Food and Drug Administration (FDA) is used to perform ECP, which is beneficial for some patients with cutaneous T cell lymphoma, graft-versus-host disease after hematopoietic stem cell transplantation, systemic sclerosis, and solid organ transplant allorejection. Although ECP is usually an elective procedure, a critically ill patient may undergo treatment as part of a multimodality therapeutic approach.

PHYSIOLOGIC PRINCIPLES

The effectiveness of an apheresis procedure in reducing a plasma molecule or cellular component depends on two factors: (a) the distribution of that component between the intravascular and extravascular space and (b) the rate of regeneration of the component [10]. For solutes that move freely between intravascular and extravascular compartments, complete reequilibration between the compartments occurs at approximately 48 hours after a plasma exchange. Circulating blood cells also traffic between sites of vascular margination and/or splenic sequestration and this, in turn, can affect the efficiency of a therapeutic cytapheresis procedure.

The rate of intravascular regeneration of a pathologic solute or blood cell population after apheresis also depends on the rates of synthesis or production and decay or cell death. Plasma exchange typically removes large molecules at a rate that greatly exceeds their natural synthetic rate; thus, a simple one-compartment mathematical model is used to predict the depletion of soluble plasma substances. Assumptions of

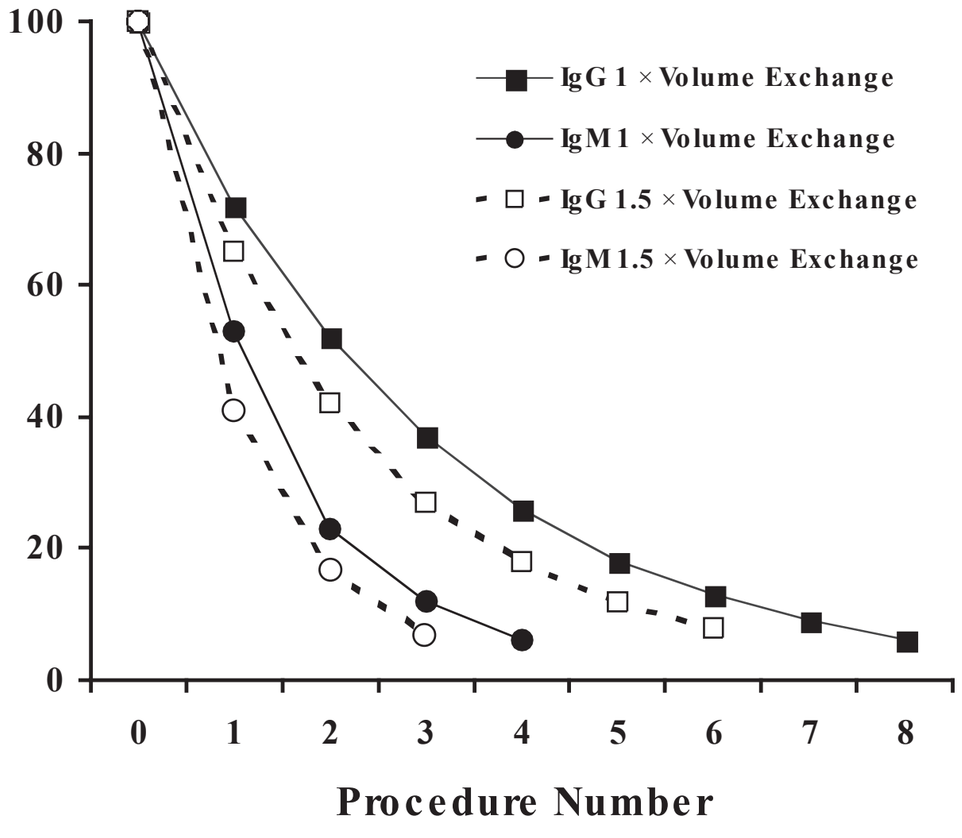

FIGURE 113.2. Hypothetical depletion of whole body immunoglobulin (Ig) levels by therapeutic plasma exchange. The 1-compartment model predicts that approximately 60% of the soluble substance will be removed from the plasma with a 1× plasma volume therapeutic exchange, and approximately 80% will be removed with a 1.5× volume exchange. Because roughly 50% of IgG distributes to the extravascular space, reequilibration between the intravascular and extravascular compartments occurs between sequential procedures, and 6 or 7 1× volume exchanges are needed to deplete whole body IgG to less than 10% of the pretreatment level. By comparison, IgM is predominantly intravascular, and, therefore, only 3 or 4 1× volume exchanges are needed to deplete whole body IgM to less than 10%. By increasing the processing to 1.5× plasma volumes, the same therapeutic goal would require three procedures to deplete IgM and five procedures to deplete IgG. [From Linenberger ML, Price TH: Use of cellular and plasma apheresis in the critically ill patient: part 1: technical and physiological considerations. *J Intensive Care Med* 20:18–27, 2005, with permission.]

the model are that the plasma removed is replaced with a fluid devoid of the target substance, and that complete mixing of the replacement fluid with the remaining intravascular plasma volume occurs [10]. Figure 113.2 depicts the kinetics of removal and regeneration of plasma immunoglobulin G (IgG) and IgM after therapeutic plasma exchange (TPE). The reliability of the one-compartment model to predict removal of soluble substances may be limited by conditions that cause an expanded plasma volume, such as paraproteinemia, molecules with rapid synthetic rates, and situations where rebound IgG production occurs, such as in the setting of humoral solid organ rejection due to a preformed antibody [11].

The efficiency of cell depletion by cytapheresis is less predictable than soluble substance removal by plasma exchange. Factors that may hinder the prediction include a rapid rate of cell production, such as occurs with untreated acute leukemia; the propensity of the spleen to sequester abnormal circulating cells or platelets; and miscalculation of the plasma volume of the patient. In general, a cytapheresis procedure in which 1.5 to 2.0 blood volumes are processed can be expected to remove approximately 35% to 85% of the target cells [12].

ANTICOAGULATION AND FLUID REPLACEMENT

Citrate is the most commonly used anticoagulant for plasma exchange and cytapheresis procedures. Heparin is often used with ECP, specialized column extraction systems, and plasma membrane filtration. Current apheresis instruments limit both the anticoagulant (citrate or heparin) dose and rate of blood return based on the patient's total blood volume. The operator can also adjust the ratio of anticoagulant to whole blood being processed.

The acid-citrate-dextrose (ACD) solution effectively chelates free or ionized plasma calcium, thereby preventing coagulation of blood and plasma in the apheresis circuit. The precise decrease in ionized calcium in vivo during an apheresis procedure is difficult to predict, as this depends on dilution, metabolism, redistribution, and excretion of infused citrate [13]. Fluid replacement with fresh frozen plasma (FFP) or albumin may decrease the ionized calcium further because of citrate in the FFP or calcium binding by albumin. Ionized calcium may typically decrease by 23% to 33%, as measured during donor apheresis procedures [14].

Citrate does not produce an anticoagulant effect in vivo. The half-life in patients with normal renal and hepatic function is approximately 30 minutes. In a patient with severe liver disease, where citrate will not be as quickly metabolized, the operator should reduce the amount and/or rate of ACD used during an exchange. In critically ill patients needing plasma exchange, it is advised that ionized calcium be monitored and intravenous calcium replacement be provided as needed. Some apheresis services use protocols for the infusion of intravenous calcium gluconate or calcium chloride during all TPEs [15].

Continuous reinfusion of extracorporeal heparin during an apheresis procedure will affect the patient's hemostatic parameters. The effect is measurable until the drug is metabolized, usually within 60 to 120 minutes of finishing the procedure. For patients already therapeutically anticoagulated with heparin, the anticoagulation normally used with apheresis may be reduced or eliminated. The primary providers of critically ill patients must communicate with the apheresis team all information regarding systemic anticoagulation, coagulopathy, and contraindications to anticoagulation, especially when heparin is planned for a therapeutic procedure. It is particularly important to document if the patient has known or suspected heparin-induced thrombocytopenia.

Replacement fluid used in plasma exchange may consist of FFP, albumin, or saline. The type of fluid depends on (a) the patient's baseline hemostatic parameters, particularly fibrinogen; (b) the anticipated number and frequency of procedures; and (c) the condition being treated. For a patient with a neurologic illness, such as acute Guillain–Barré syndrome, 1 to 1.5 plasma volume exchanges are typically performed every other day with 5% albumin as replacement fluid. This regimen and schedule allows the fibrinogen level to recover between procedures. Alternatively, if a condition requires that plasma exchange be performed daily, some FFP replacement will likely be needed to maintain the patient's fibrinogen at a hemostatic level. For conditions where a plasma component is felt to be an important part of the therapy, such as with thrombotic thrombocytopenic purpura, FFP should comprise at least half of the replacement fluid [16]. In such cases, fibrinogen and other coagulation factors will not be depleted.

An apheresis instrument that uses a centrifugation technique must deliver a specific volume of packed red cells to the separation chamber to maintain the cell/plasma density gradient necessary for efficient selective extraction. The extracorporeal blood volume (ECV) necessary for this purpose varies according to the specifications of the instrument and disposable tubing kit and the hematocrit of the patient. The AABB (formerly American Association of Blood Banks) recommends that the ECV for a general procedure should not exceed 15% of a patient's total blood volume [17]. The implications for a therapeutic apheresis procedure can be illustrated by the following example. A 60-kg adult with a hematocrit of 40% has a total blood volume of: 60 kg × 70 mL per kg (the standard

conversion factor for an adult male) = 4,200 mL; and a red cell volume of 4,200 mL × 40/100 = 1,680 mL. If the instrument requires 200 mL of extracorporeal red cell volume, then the ECV required to deliver that 200 mL will be 200/1,680 = 0.12, or 12% of the total blood volume. If, however, the same patient has a hematocrit of 20%, the red cell volume will be 4,200 mL × 20/100 = 840 mL; and the required ECV will be 200/840 = 0.24 or 24% of the total blood volume, which exceeds the AABB safety limit. Allogeneic red cells are required when the ECV exceeds 15%. These are either given to the patient as a transfusion prior to the procedure (to increase their pretreatment red cell volume), or used to "prime" the apheresis circuit at the beginning of the procedure (and returned to the patient as part of the return fluid).

VASCULAR ACCESS

The type of vascular access required for therapeutic apheresis depends on the status of the patient's peripheral veins, the condition being treated, and the anticipated treatment schedule. The vein or catheter must be able to withstand negative pressures associated with inlet rates ranging from 30 to 150 mL per minute for the draw line and up to 150 mL per minute for blood being returned to the patient. For a patient needing only one exchange, it may be possible to use antecubital or forearm veins. A 16- to 18-gauge Teflon or silicone-coated steel, back-eye apheresis, or dialysis-type needle is required for the draw line. The patient ideally will be able to help by squeezing a ball during the exchange.

A large bore central venous catheter is often required for critically ill patients, especially those requiring daily procedures [18,19]. Temporary or long-term tunneled catheters for adults weighing more than 40 kg should be at least 10-French size (Table 113.1). Smaller diameter short-term catheters are acceptable for smaller adults and pediatric patients. Plastic central venous catheters such as those used for cardiac pressure monitoring are not adequate for the draw line because they collapse under the negative pressure generated from the high inlet flow rate. These catheters or a peripheral vein may be useful as return access under certain circumstances.

Peripherally inserted central venous catheter (PICC) lines and standard port-a-catheters are also not options for venous access. Subcutaneous ports with a reservoir-type chamber can accommodate flow rates required for some apheresis procedures, typically, chronic red blood cell exchanges rather than plasma exchanges. Recently, the FDA-approved needle used to access these ports was discontinued, and safety concerns related to the use of unapproved needles have been raised [20]. Arteriovenous fistulas created for dialysis access can be used for therapeutic apheresis. The critical care team should consult with the apheresis team prior to placing venous access for the procedure.

LIMITATIONS AND POTENTIAL ADVERSE EVENTS

When considering therapeutic apheresis, two limitations should be remembered. First, apheresis is not the same as dialysis. It is not usually possible to end a procedure with a large net negative fluid balance (i.e., >200 to 400 mL) because the deficit is colloid rather than crystalloid, and hypotension is likely to occur. A safe end fluid balance is plus or minus 10% to 15% of the total blood volume. In addition, it is not recommended that red cells be transfused during the apheresis procedure (other than at the start as a blood "prime") because the cell separation gradient and cell/plasma interface in the separation chamber may be disturbed. The second limitation is that the procedure is almost always an adjunctive, rather than definitive, therapy for the condition being treated. Thus, while apheresis can be performed on very ill patients, one must carefully consider the risks that are associated with hemodynamic instability, hematologic abnormalities, the need for vascular access, and the priorities for more urgent primary treatments.

Possible adverse complications related to therapeutic apheresis are shown in Table 113.2. Central line complications include procedure-related events, infection, and bleeding (Chapter 2). Citrate toxicity occurs in approximately 0.8% to 1.2% of therapeutic procedures [21]. Higher risk is associated with larger process volumes, longer procedure duration, nonphysiological bleeding, severe anemia, unstable vital signs, liver failure, alkalosis due to hyperventilation, and use of replacement fluid consisting of blood components that contain citrate as the anticoagulant [17,22]. Signs and symptoms of hypocalcemia can include a metallic taste in the mouth, muscle

TABLE 113.2

POSSIBLE ADVERSE EFFECTS OF THERAPEUTIC APHERESIS

Central venous catheter-associated complications
Signs and symptoms of hypocalcemia and/or hypomagnesemia
Hypotension related to vasovagal reactions or fluid shifts
Transfusion reactions
Altered hemostatic parameters
Bradykinin reaction in patients on ACE inhibitors undergoing plasma exchange or plasma treatment
Removal of highly protein-bound drugs or immunoglobulins (with frequent plasma exchanges)

ACE, angiotensin-converting enzyme.

or gastrointestinal cramps, perioral numbness, distal paresthesias, and chest tightness. In sedated or unconscious patients, severe citrate toxicity may manifest as tetany, muscle spasm including laryngospasm, a prolonged QTc interval and decreased myocardial contractility [23]. Hypomagnesemia and hypokalemia may also occur, as the kidneys increase cation excretion into the urine to facilitate excretion of the citrate load. Although rare, fatal arrhythmias have occurred during therapeutic apheresis. To avoid these complications, ionized calcium should be monitored and intravenous calcium infused, as indicated, either through the return line or as an additive with the albumin replacement fluid.

Hypotension or vasovagal reactions occur in roughly 0.5% to 2.9% of therapeutic apheresis procedures [23,24]. Patients with preexisting hemodynamic instability or diminished vascular tone, as seen in certain neurologic disorders, may be at particular risk. In such patients, a net negative end fluid balance must be avoided. Transfusion reactions may occur if blood components are part of the replacement fluid. Allergic reactions have also been reported in some patients receiving albumin as the replacement fluid.

Hemostatic alterations and bleeding may occur in severely ill patients with baseline coagulopathy and/or severe thrombocytopenia. A typical 1.3-volume plasma exchange using albumin depletes most coagulation factors to approximately 25% to 45% of their preprocedure values [25]. Repletion time of these coagulation factors depends on their respective rates of synthesis, with most factors returning to baseline values by 24 hours. The exception is fibrinogen, which takes about 3 days to return to baseline values. Because fibrinogen levels are the most severely affected during the course of a series of plasma exchanges, preprocedure fibrinogen levels should be monitored, especially if the replacement fluid does not include at least 50% plasma. Therapeutic leukapheresis removes a portion of circulating platelets, and this decrement could be clinically significant in a patient with preprocedure severe thrombocytopenia. The postprocedure platelet count and coagulation status should be monitored in a critically ill patient, particularly if an invasive procedure is needed shortly after apheresis.

In some patients undergoing plasma exchange with albumin as the replacement fluid, a severe reaction consisting of flushing, hypotension, bradycardia, and dyspnea has been linked to concomitant use of angiotensin-converting enzyme (ACE) inhibitors [26]. This reaction is mediated by bradykinin, which is thought to be generated by prekallikrein-activating factor in the albumin preparation. These reports have led to the recommendation that ACE inhibitors be withheld for 24 to 48 hours (depending on the half-life of the specific drug) before plasma exchange using albumin [26]. If an emergency exchange is required in a patient on an ACE inhibitor, FFP should be used as the replacement fluid to avoid this reaction. Similar reactions involving ACE inhibitors have been seen in patients undergoing plasma treatment with specialized columns; thus, similar precautions must be followed [27].

An additional potential adverse effect of repeated plasma exchange is the removal of highly protein-bound therapeutic drugs and plasma immunoglobulins. The exact effects of exchange on individual drug levels have not been delineated. To avoid this complication, medications should be administered following a plasma exchange procedure whenever possible. Immunoglobulin levels should also be measured periodically in immunosuppressed patients undergoing a series of plasma exchanges, as these proteins will be nonselectively depleted from the circulation, and severe hypogammaglobulinemia could further predispose the patient to infections [28].

INDICATIONS IN CRITICAL CARE

Evidence-based guidelines for clinical applications are published by the American Society for Apheresis (ASFA) every few years [29]. Medical conditions are placed into categories from I to IV, with I indicating that therapeutic apheresis is known to be an effective primary or adjunct therapy based on randomized controlled clinical trials or broad noncontroversial experience, and category IV indicating no demonstrated efficacy, and possibly even a negative impact of therapeutic apheresis for the condition. Examples of evidence-based indications for therapeutic apheresis are shown in Table 113.3.

Therapeutic Plasma Exchange

In the intensive care unit, TPE is likely to be the most frequent apheresis procedure used. Antibody-mediated conditions known to respond to plasma exchange include idiopathic thrombotic thrombocytopenic purpura [16,30,31]; demyelinating diseases including acute inflammatory demyelinating polyneuropathy/Guillain–Barré syndrome [32–34]; severe, acute idiopathic inflammatory demyelinating diseases (Table 113.4); myasthenic crisis [43,44]; demyelinating polyneuropathy with IgG and IgA [45,46]; antiglomerular basement membrane (Goodpasture's) disease; and pulmonary hemorrhage associated with other forms of rapidly progressive glomerulonephritis (RPGN) [47,48]. Among patients with RPGN, the evidence supporting a potential benefit of plasma exchange derives from retrospective and case-control studies among more severely affected patients [49,50], whereas randomized controlled trials have yielded supportive results in some studies [38] but not others [39,40] (see Table 113.4). For patients with renal vasculitis due to causes other than anti-GBM disease, a review of randomized controlled clinical trials demonstrated a significant reduction in end-stage renal disease with use of TPE [41].

With the muscle-specific receptor tyrosine kinase antibody (MuSK-Ab) form of myasthenia gravis, TPE appears to be a more effective therapy than intravenous immunoglobulin (IVIg) infusion [51]. By comparison, with the acetyl cholinesterase receptor (AChR-Ab) form of myasthenia gravis, and with Guillain–Barré syndrome, plasma exchange is effective but not superior to or as tolerable as IVIg infusion [33,34,41] (see Table 113.4). For patients with acute attacks of demyelination, plasma exchange may be useful. Although there is only one randomized controlled trial [37], observations from this study and retrospective data indicate that at least 50% of patients with neuromyelitis optica (NMO), characterized by spinal and visual involvement, achieve increased function with plasma exchange, and that patients with steroid-refractory optic neuritis may also achieve some benefit [52]. A potential

EVIDENCE-BASED INDICATION CATEGORIES FOR THERAPEUTIC APHERESIS FOR DISORDERS POTENTIALLY AFFECTING CRITICALLY ILL PATIENTS

Disease	Apheresis procedure	Indication	Recommendation
		Category	Grade
Renal			
Antiglomerular basement membrane antibody disease	Plasma exchange	I	1A
ANCA-associated rapidly progressive glomerulonephritis (dialysis dependence or diffuse alveolar hemorrhage [DAH])	Plasma exchange	I	1A 1C for DAH
Immune complex rapidly progressive glomerulonephritis	Plasma exchange	III	2B
Myeloma cast nephropathy	Plasma exchange	II	2B
Hemolytic uremic syndrome (typical, diarrhea associated)	Plasma exchange	IV	1C
Allograft rejection (antibody mediated)	Plasma exchange	I	IB
Autoimmune and rheumatologic			
Cryoglobulinemia (severe/symptomatic)	Plasma exchange	I	IB
Idiopathic thrombocytopenic purpura	Plasma exchange	IV	1C
Systemic lupus erythematosus cerebritis or DAH	Plasma exchange	II	2C
Systemic lupus erythematosus nephritis	Plasma exchange	IV	1B
Catastrophic antiphospholipid syndrome	Plasma exchange	II	2C
Hematologic			
Thrombotic thrombocytopenic purpura	Plasma exchange	I	1A
Hyperleukocytosis with leukostasis	Leukapheresis	I	1B
Sickle cell disease with acute stroke	Red cell exchange	I	1C
Sickle cell disease with acute chest syndrome	Red cell exchange	II	1C
Thrombocytosis (symptomatic, myeloproliferative origin)	Plateletpheresis	II	2C
Posttransfusion purpura	Plasma exchange	III	2C
Polycythemia vera or erythrocytosis	Erythrocytapheresis	III	2C
Hyperviscosity (monoclonal IgM, IgA, IgG)	Plasma exchange	I	1B
Coagulation factor inhibitors	Plasma exchange	IV	2C
Babesiosis (severe)	Red cell exchange	I	1B
Malaria (severe)	Red cell exchange	II	2B
Neurologic			
Acute inflammatory demyelinating polyradiculopathy (Guillain–Barré syndrome)	Plasma exchange	I	1A
Acute disseminated encephalomyelitis	Plasma exchange	II	2C
Chronic inflammatory demyelinating polyradiculopathy	Plasma exchange	I	1B
Myasthenia crisis	Plasma exchange	I	1A
Demyelinating polyneuropathy with IgG and IgA	Plasma exchange	I	1B
Demyelinating polyneuropathy with IgM	Plasma exchange	I	1C
Lambert-Eaton myasthenia syndrome	Plasma exchange	II	2C
Multiple sclerosis (acute, fulminant)	Plasma exchange	II	1B
Neuromyelitis optica	Plasma exchange	II	1C
Other disorders			
Drug overdose and poisoning	Plasma exchange	III	2C
Acute hepatic failure	Plasma exchange	III	2B
Toxic epidermal necrolysis	Plasma exchange	N/A	N/A
Severe sepsis and multiple-organ dysfunction syndrome	Plasma exchange	III	2B
Burn shock resuscitation	Plasma exchange	IV	2B

IgA, immunoglobulin A; IgG, immunoglobulin G; IgM, immunoglobulin M.
Category I: Disorders for which apheresis is accepted as first-line therapy, either as a primary standalone treatment or in conjunction with other modes of treatment. *Category II*: Disorders for which apheresis is accepted as second-line therapy, either as a standalone treatment or in conjunction with other modes of treatment. *Category III*: Disorders for which the optimum role of apheresis therapy is not established. Decision making should be individualized. *Category IV*: Disorders in which published evidence demonstrates or suggests apheresis to be ineffective or harmful. IRB approval is desirable if apheresis treatment is undertaken in these circumstances. N/A indicates that the disorder is not ranked by the ASFA criteria.
Note: The Grade system has also been assigned in an effort to parallel an approach more commonly used to evaluate therapeutic recommendations.

TABLE 113.4

RANDOMIZED CONTROLLED TRIALS AND SYSTEMATIC REVIEWS OF RANDOMIZED CONTROLLED TRIALS THAT UTILIZED THERAPEUTIC APHERESIS FOR DISORDERS IN CRITICAL CARE PATIENTS

Disease category [Ref.]	n	Intervention	Outcome
Severe sepsis and septic shock [35]	106	Plasma exchange (PE) vs. standard therapy	**28-d mortality** 18/54 (33%) PE 28/52 (54%) Control ($p = 0.05$)
Sepsis syndrome [36]	30	Plasma filtration (PF) vs. standard therapy	**14-d mortality** 8/14 (57%) PF 8/16 (50%) Control ($p = 0.73$)
Acute inflammatory demyelinating polyradiculopathy/Guillain–Barré syndrome (systematic review of six trials) [33]	649	PE vs. supportive care	**Mechanical ventilation at 4 wk** 85/315 (27%) Control 44/308 (14%) PE (RR 0.53; 95% CI 0.39–0.74, $p = 0.0001$) **Severe sequelae at 1 y** 55/328 (17%) Control 35/321 (11%) PE (RR 0.65; 95% CI 0.44–0.96, $p = 0.03$) **1-y mortality** 18/328 (5.5%) Control 15/321 (4.7%) PE (RR 0.85; 95% CI 0.42–1.45, $p = 0.70$)
Acute inflammatory demyelinating polyradiculopathy/Guillain–Barré syndrome (systematic review of five trials) [34]	582	PE vs. intravenous immunoglobulin (IVIg)	**Median time to discontinuation of mechanical ventilation (two studies)** 34 d ($n = 34$) PE vs. 27 d ($n = 29$) IVIg ($p =$ NS) 29 d ($n = 40$) PE vs. 26 d ($n = 44$) IVIg ($p =$ NS) **Mortality during follow-up** 9/286 (3.1%) PE 7/296 (2.4%) IVIg (RR 0.78; 95% CI 0.31–1.95, $p =$ NS)
Severe, acute idiopathic inflammatory demyelinating diseases of the central nervous system, including multiple sclerosis [37]	22	Active PE vs. sham PE (crossover allowed)	**≥ Moderate acute improvement** 8/19 (42%) Active PE therapy 1/17 (6%) Sham PE therapy
Rapidly progressive glomerulonephritis (RPGN), including antiglomerular basement membrane (anti-GBM) disease and antineutrophil cytoplasmic antibody (ANCA) associated disease [38]	44	PE vs. immunoadsorption (IA)	**6-mo median creatinine clearance** 49 mL/min PE 49 mL/min IA **6-mo mortality** 1/23 (4.3%) PE 2/21 (9.5%) IA ($p =$ NS)
RPGN, including anti-GBM disease and ANCA-associated disease [39]	33	PE vs. standard therapy with immunosuppression	**Dialysis-free survival among patients with type III RPGN** 42% PE ($n = 18$) 49% Control ($n = 15$; $p =$ NS)
RPGN, including anti-GBM disease and ANCA-associated disease [40]	32	PE vs. standard therapy with immunosuppression	**Patients on dialysis at study end** 3/16 (19%) PE 5/16 (31%) Control ($p =$ NS)
Renal vasculitis (adult) other than anti-GBM (systematic review of six trials) [41]		Use of PE	**3-mo response rate** Significant reduction in risk of end-stage renal disease ($p = 0.01$) **12-mo response rate** Significant reduction in risk of end-stage renal disease ($p = 0.002$)
Thrombotic thrombocytopenic purpura [16]	102	PE vs. plasma infusion (PI)	**6-mo response rate** 40/51 (78%) PE 25/51 (49%) PI ($p = 0.002$) **6-mo mortality** 11/51 (22%) PE 19/51 (37%) PI ($p = 0.036$)
Myasthenia gravis [42]	87	PE vs. intravenous immunoglobulin (IVIg)	**Day 15 variation of myasthenic muscular score** +18 PE ($n = 41$) +15.5 IVIg ($n = 46$; $p = 0.65$)

CI, confidence interval; *n*, number; NS, not significant; RR, relative risk; vs., versus.

mechanism of action of TPE with NMO is modulation of the serum autoantibody NMO-IgG, which has been implicated in disease pathophysiology [53].

The optimum role of TPE in the setting of severe sepsis and multiorgan dysfunction is not established. Two randomized controlled trials in adults using either continuous plasma filtration versus supportive care [36] or plasma exchange versus standard care [35] have been published. No differences were observed in the 14-day mortality rates of 14 patients with sepsis syndrome receiving 34 hours of continuous plasma filtration and 16 untreated control patients (57% vs. 50%) [36] (see Table 113.4). By comparison, the 28-day mortality rate was 33.3% among 54 patients with sepsis and septic shock treated with one or two TPE treatments compared with 53.8% among 52 nontreated control patients ($p = 0.05$) [35] (see Table 113.4). When differences between the control and experimental groups were considered using multiple logistic regression, the significance of the treatment variable on mortality was $p = 0.07$.

A nonrandomized observational cohort study evaluated hemodynamic and mortality outcomes in critically ill surgical patients with sepsis treated with TPE and continuous venovenous hemofiltration [54]. No overall difference in mortality was observed between treated patients and an untreated historical control group (42% vs. 46%); however, patients with organ failure limited to one or two systems appeared to benefit, with mortality rates of 10% among 10 treated patients versus 38% among 16 untreated control patients [54]. Although encouraging, these data must be supported by results from additional well-designed randomized controlled trials before plasma exchange can be recommended as a noninvestigational therapy for this indication [55].

Use of red blood cell exchange may be warranted for selected patients with sickle cell disease who are experiencing stroke, acute chest syndrome (ACS), priapism, or multiple organ failure as a complication of their disease [56]. Because automated red cell exchange (also called erythrocytapheresis) can more rapidly reduce the level of hemoglobin S-positive cells (to the goal of < 30%) while maintaining euvolemia and minimizing hyperviscosity complications, this modality has been utilized in preference to simple transfusion by many centers. Although this makes intuitive sense, the data needed to show a clear advantage of automated red cell exchange over simple transfusion are lacking. An observational, retrospective cohort analysis found no differences in postprocedure and total lengths of stay for patients with ACS treated with automated red cell exchange ($n = 20$) compared with those who received simple transfusion support ($n = 20$) [57]. Moreover, the apheresis group required, on average, four times as many units of donor red cells.

Manual exchange transfusion, in which phlebotomized blood is replaced by simple transfusions of allogeneic red cells and FFP, has the added theoretical advantage of reducing the levels of plasma inflammatory mediators, which might augment vaso-occlusive tissue injury in patients with ACS [58]. One nonrandomized trial used a combination of TPE and automated red cell exchange for 7 patients with severe ACS and multiorgan failure, and observed an 86% 1-year survival [59]. Despite these observations, the optimal approach for critically ill patients with ACS and other severe complications remains undefined, in part because crossmatch-compatible blood may be very difficult to locate for heavily transfused sickle cell patients with multiple alloantibodies. Adequately powered randomized clinical trials are sorely needed to clarify the indications for automated or manual red cell exchange versus simple transfusion support and the potential role of TPE.

Red cell exchange may also be useful in patients with severe clinical manifestations of falciparum malaria or babesiosis [60,61]. Although a meta-analysis performed in 2002 showed no survival benefit of red cell exchange compared with antimalarials and aggressive supportive care alone [62], many case reports and series suggest a benefit in clinical status with rapid reduction of hyperparasitemia using adjunctive manual or automated red cell exchange [61,63,64]. The Centers for Disease Control and Prevention (CDC) also recommends consideration of red cell exchange as adjunctive therapy if *Plasmodium falciparum* parasitemia is greater than 10%, or if the patient has severe malaria manifested by nonvolume overload pulmonary edema, renal complications, or cerebral malaria [65]. Quinidine administration should not be delayed and may be given concurrently with the exchange. As in fulminant malaria, several case reports demonstrate that patients with overwhelming parasitemia from Babesia also quickly respond to red cell exchange [61].

Automated red cell exchange may be considered as an alternative to large volume phlebotomy in selected patients with uncontrolled erythrocytosis and polycythemia vera with acute thromboembolism, severe microvascular complications, or bleeding [66]. This method can quickly and more safely normalize the hematocrit in patients who are hemodynamically unstable.

Leukapheresis

Leukapheresis (i.e., selective removal of white blood cells) is commonly used in patients with acute myeloid leukemia (AML) experiencing symptoms of intravascular leukostasis. Signs and symptoms typically manifest as neurologic alterations (confusion, mental status changes, altered level of consciousness) or pulmonary compromise (hypoxemia, diffuse lung infiltrates). Leukapheresis is indicated in patients with AML and a circulating blast count greater than 50,000 per µL who are clearly demonstrating signs of intravascular leukostasis (i.e., symptoms not attributable to infection, bleeding, or metabolic derangements) [67,68]. Leukapheresis may be warranted sooner in monocytic subtypes of AML, as signs of intravascular leukostasis may be seen at blast counts less than 50,000 per µL or after the start of chemotherapy. Prophylactic leukapheresis should be considered in AML patients with circulating blast counts greater than 100,000 per µL, particularly if the count is rapidly rising and definitive therapy with induction chemotherapy is delayed [refer to ASFA Guideline Ref]. In comparison with AML, leukostasis complications are rare in patients with acute lymphoblastic leukemia (ALL) and circulating blast counts less than 400,000 per µL. Studies have shown that prophylactic leukapheresis for asymptomatic patients with ALL and hyperleukocytosis does not offer additional benefit above aggressive supportive care and chemotherapy [69].

Plateletpheresis

Plateletpheresis should be considered as an urgent intervention in patients experiencing thrombosis or hemorrhage in the setting of uncontrolled thrombocytosis associated with a stem cell disorder [70]. Such stem cell disorders include essential thrombocythemia, polycythemia vera, idiopathic myelofibrosis, or unclassified myeloproliferative neoplasm. The goal of the plateletpheresis is to decrease the count below 1 million per µL, with a target closer to 500,000 per µL [70]. Plateletpheresis may also be indicated for the management of perioperative thrombohemorrhagic complications in patients with myeloproliferative neoplasms undergoing splenectomy [71].

For any apheresis procedure, consultation with the apheresis team can be useful in assessing experience and available data

for a given condition. The apheresis physician and team should be viewed as partners in determining the treatment plan. Initial discussion with the apheresis physician will include whether the indication is urgent or routine, the impact of apheresis on other treatment modalities, volume management, fluid replacement, and vascular access. Ongoing discussions should continue through the patient's course so that appropriate adjustments can be made to optimize the therapy.

CHAPTER 114 ■ TRANSFUSION THERAPY: BLOOD COMPONENTS AND TRANSFUSION COMPLICATIONS

TERRY GERNSHEIMER

Transfusion support can be a key element in decreasing morbidity and mortality of the critically ill patient by the support of oxygen delivery and correction of hemostatic abnormalities. An understanding of the benefits, limitations, and risks of blood component therapy is of fundamental importance in the intensive care setting. This chapter will outline blood components available for transfusion, their appropriate dosages, and therapeutic effects. Complications of transfusion therapy, including infectious risks, transfusion reactions, effects of storage, and immunomodulatory effects, as well as methods to minimize these complications, will be discussed.

BLOOD COMPONENT THERAPY

Cellular Blood Components

Red Blood Cells

One unit of "packed" red blood cells (pRBC) is processed by the removal of platelet rich plasma from a donated unit of whole blood and contains approximately 200 mL red blood cells, usually less than 50 mL plasma, and an additive that brings the component to 300 to 350 mL in total volume. Depending upon the additive, the storage life at 4°C will be from 35 to 42 days. Red blood cell storage has multiple theoretic and measurable effects. Any platelets still present in the component are rendered inactive by the cold storage. As red blood cells are stored, intracellular potassium leaks into the plasma space. 2,3-Diphosphoglyceric acid (2,3-DPG) may also be depleted from the red blood cells, which theoretically could cause increased oxygen affinity and decreased release of oxygen at the tissues [1]. This effect reverses after several hours in vivo but may be clinically significant in the patient undergoing massive transfusion. Stored pRBC also have elevated plasma ammonia levels, elevated PCO_2, lowered pH, and increased amounts of microaggregates. These all have theoretic effects on oxygen delivery when given rapidly in large amounts. Massive transfusion can also theoretically result in hypocalcemia and hyperkalemia.

In 1993, Marik and Sibald [2] reported the incidental finding of increased gastric pH in 23 patients with septic shock transfused with 3 units of pRBC, but Walsh failed to find a similar effect in a small randomized control trial in 22 patients with septic shock transfused with pRBC stored for less than 5 or more than 20 days [3]. Hébert found a higher incidence of mortality and life-threatening complications who received blood stored less than 8 days when compared with standard therapy in a randomized study of 66 patients undergoing cardiac surgery [4]. Although van der Watering did find longer ICU stays and decreased survival in a retrospective study of 2,732 patients undergoing coronary artery bypass graft (CABG) who received blood that had undergone a median age of ≥ 18 days or more versus less than 18 days of storage, this difference was not apparent in a multivariate analysis [5]. A retrospective report of a large number of patients (5,902) by Koch et al. [6] showed a significant increase in mortality and complications at 1 year in patients undergoing CABG who received blood > 14 days of age versus < 15 days of age, but differences in characteristics of the two patient groups complicated the analysis. The effect of storage age remains controversial [7] and will require careful

prospective randomized clinical trials in adequate numbers of patients before the true clinical significance of storage age and the nature of the effect becomes clear [8].

Other than factors V and VIII, the activity of most coagulation factors are quite stable during storage, even after 2 weeks, and therefore whole blood (without the plasma removed), when available, may be used in selected patients with coagulopathy and bleeding, and can reduce donor exposure by limiting administration of multiple products (e.g., red cells and plasma) [9]. Factor V levels in stored whole blood are well above 50% and therefore adequate for hemostasis. Factor VIII is produced by endothelial cells as well as by the liver, and levels increase in the setting of inflammation, so a decrease with storage may be less clinically relevant. Whole blood may also be the preferred form of red cell transfusion in patients who require intravascular volume expansion as well as increased oxygen carrying capacity.

The primary function of hemoglobin in RBCs is to transport oxygen efficiently from the lungs to the various tissues of the body. Oxygen transport is a complex process regulated by several different mechanisms of control, involving the heart and vascular system. The most important functional feature of the hemoglobin molecule is its ability to combine loosely and reversibly with oxygen. Decreased hemoglobin oxygen affinity and increased tissue oxygen delivery occur with increased temperature and decreased pH, when there are increased tissue requirements. Oxygen is also less tightly bound with increased 2,3-DPG levels, which increases in the chronically ill patient [10]. In the seriously ill patient with severe acidosis and septic shock, however, 2,3-DPG levels may decrease resulting in decreased tissue oxygen delivery.

In a normovolemic, otherwise healthy individual, the effect of a decreased hematocrit is decreased blood viscosity and a compensatory augmentation of cardiac output and blood flow to most organs [11]. Human and animal studies reveal remarkable tolerance for hematocrit levels as low as 15% [12,13], but an optimum value has not been well defined and is very dependent on the patient's physiologic state. A decrease in the hematocrit also involves a redistribution of blood flow away from the endocardium and may have adverse effects on ischemic cardiac tissue. A retrospective analysis of patients older than 65 years hospitalized with acute myocardial infarction found that in patients with a hematocrit less than 30.0% (and perhaps $<33.0\%$) on admission, transfusion was associated with a lower 30-day mortality rate [14]. However, in patients who had undergone elective CABG, postoperative transfusion for hemoglobin levels greater than 8 did not improve morbidity, mortality, or complication rates [15]. Postoperative patients with known vascular disease and hematocrits less than 28% have been shown to have a significant increase in myocardial ischemia and morbid cardiac events [16], and in one study that retrospectively evaluated patients refusing transfusion on religious grounds, low preoperative hemoglobin was associated with increased morbidity and mortality in patients with cardiovascular disease undergoing surgery [17]. In a large multicenter, randomized trial, there was no difference in adverse outcomes when patients with cardiac disease were transfused at a hemoglobin threshold of 7.0 g versus 10 g [18]. In this study of more than 800 patients, less acutely ill, younger patients (<55 years of age) without cardiac disease who were randomized to the more liberal (higher) transfusion trigger had an overall higher mortality rate. A restrictive RBC transfusion strategy also did not adversely affect outcomes related to mechanical ventilation [19]. In postoperative patients without cardiovascular disease, few data support interference with wound healing or increased anesthesia risk at hemoglobin levels of less than 10 g per dL [20], and hemoglobin values as low as 7 g per dL appear to be safe in otherwise healthy individuals [21].

Advocates of restrictive transfusion strategies point out that transfusing to normal hemoglobin concentrations does not improve organ failure and mortality in the critically ill patient [22] and to data that transfusion may actually be associated with increased infection rates, morbidity and mortality [23]. Proponents of more liberal transfusion strategies point out the possible detrimental effects that may be associated with oxygen debt [24]. A thoughtful transfusion policy is dependent on the time the anemia developed over and can be expected to continue; additional medical problems that may make a patient more susceptible to anemia, such as tissue ischemia and pulmonary disease; and whether there is rapid, ongoing blood loss.

Blunted erythropoietin responses have been noted in critically ill pediatric [25] and adult patients [26]. Long-term intensive care patients may not only fail to increase their erythropoietin level in response to anemia but may have correctable nutritional deficiencies and iron profiles consistent with anemia of chronic disease. Although erythropoietin therapy increases red blood cell production and appears to decrease transfusion needs [27–29], the effect can take weeks and may reduce blood cell transfusion only minimally. It is an expensive alternative to more restrictive transfusion strategies to reduce transfusion exposure in appropriately chosen patients.

Studies in animal models [30] and in humans [31,32] reveal that platelet function and interaction with subendothelium decline at lower hematocrits. In the thrombocytopenic and thrombocytopathic (e.g., uremic) patient, transfusion to higher hematocrit values is appropriate in the patient at risk of bleeding.

Therapeutic Effect. The response to red cell transfusion will depend on intravascular volume, but it can be estimated that one unit of pRBC will increase the hematocrit by approximately 3%. It may take up to 24 hours while intravascular volume equilibrates for full effect. Rapid ongoing red cell destruction or splenic sequestration may also affect the hematocrit increment as well as the red cell survival.

Emergency Blood Usage. Uncrossmatched type O RBCs can be used for a bleeding patient in dire emergency. Type O, Rh-negative RBCs can be transfused to people of any blood type with only a slight risk of hemolysis. This risk increases in patients who have previously been transfused or pregnant and may have formed antibodies [33]. Type O, Rh-positive RBCs are sometimes used for women who are beyond childbearing age and in adult males. When Rh-positive RBCs are used in an Rh-negative patient, there is a chance of a D immunization, and if the patient requires emergency transfusion in the future, they may have preformed antibodies. Anti-D antibodies do not generally cause immediately intravascular hemolysis but rather a slow extravascular hemolysis, so the risk is small overall. Anti–Rh-D (Rhogam®) may be given within 48 hours of giving transfusion of Rh-positive blood to an Rh-negative woman of childbearing age, but the amounts required limit its use in prevention of immunization.

Platelets

Platelets are essential for the initial phase of hemostasis. Following exposure of subendothelial substances, platelets adhere to the subendothelial tissues by von Willebrand factor and other adhesive proteins. This initial adhesion activates platelets, causing release of platelet alpha and dense granules. Some of these granule contents, including factor V, fibrinogen, von Willebrand factor, and calcium, move to the extracellular space via the open canalicular system, increasing their concentrations in the immediate "neighborhood" of the platelet. With platelet activation, anionic phospholipids move to the platelet surface, forming binding sites collectively known as platelet factor 3, upon which coagulation factors can interact with

calcium to form IXa, Xa, and thrombin. Platelet glycoprotein IIb-IIIa is exposed and binds fibrinogen. Thrombin generation causes further platelet activation and converts fibrinogen to fibrin, resulting in a platelet-fibrin mass that can effectively cease bleeding from a break in the endothelium. Fifteen percent of the platelet's protein is actin and myosin, which, upon coupling in the presence of increased concentrations of adenosine diphosphate (ADP) and calcium, leads to cytoskeletal movement and clot retraction.

The threshold of thrombocytopenia at which bleeding may occur will vary depending on the patient's clinical condition. In general, spontaneous bleeding does not occur until the platelet count falls below 5,000 to 10,000/μL [34–37]. The recommended "trigger" for prophylactic platelet transfusions in patients undergoing chemotherapy or hematopoietic stem cell transplantation (HSCT) without bleeding or other comorbid conditions is less than 10,000/μL. For the majority of invasive procedures, a platelet count of 30 to 50,000/μL will be adequate. For high-risk procedures, such as neurologic or ophthalmologic surgeries, a platelet count of 100,000/μL is recommended by the American Society of Anesthesiology [38] and the College of American Pathologists [39]. Technique and experience appear to be as least as important predictors of bleeding following placement of catheters as clotting abnormalities, even in patients with isolated platelet counts less than 20,000/μL [40]. The risk of bleeding with thrombocytopenia increases when complicated by other hemostatic abnormalities.

Platelet counts less than 50,000/μL are associated with increased risk of microvascular bleeding in the massively transfused patient [41]. For this reason, platelet transfusion has been advocated with replacement of every blood volume to avoid the effect of dilutional thrombocytopenia [42]; however, some investigators have found that patients receiving prophylactic platelet transfusion were no less likely to develop microvascular bleeding [43]. In patients with brisk ongoing blood loss, rapid turnaround of platelet counts can direct diagnosis and are important in managing transfusion therapy.

Higher transfusion triggers may be indicated with abnormal platelet function [44]. Platelet function abnormalities may be congenital or acquired. Medications, sepsis, malignancy, tissue trauma, obstetrical complications, and extra corporeal circulation may all adversely affect platelet function. Liver and kidney disease may be associated with severe thrombocytopathy. Hypothermia prolongs bleeding time in trauma patients [45] and arterial hemorrhage in animals [46]. Glycoprotein IIb-IIIa inhibitors may affect platelet number as well as function. If platelet dysfunction is present, the patient with a disrupted vascular system (e.g., trauma or surgery) will require a higher platelet count to achieve hemostasis. Higher counts may be necessary to prevent spontaneous bleeding as well. The transfused platelets may quickly become dysfunctional in the patient, and other therapy may be necessary, such as dialysis and dialysis and desmopressin acetate (DDAVP) for bleeding in renal failure, rewarming of the hypothermic patient, or correction of acidosis.

In several situations, platelet transfusions may not be indicated unless there is significant bleeding. In autoimmune thrombocytopenias (e.g., immune thrombocytopenia (ITP) and posttransfusion purpura), transfusion increments are usually poor and platelet survival is short. Administration of intravenous immune globulin in high doses may improve transfusion response and survival as well as treat the underlying disease [47]. There have been reports of rapid exacerbation of the thrombotic process in the cerebrovascular circulation in patients with thrombotic thrombocytopenic purpura (TTP) following platelet transfusion [48]. These reports are anecdotal and may represent disease progression, but in general, platelet transfusions are felt to be relatively contraindicated in TTP unless there is clinically significant bleeding.

TABLE 114.1

EXPECTED PLATELET INCREMENT WITH TRANSFUSION[a]

	1 unit[b]	4 units	6 units
	0.8×10^{11}	3.2×10^{11}	4.8×10^{11}
50 lb/23 kg	17,600/μL	70,400/μL	105,600/μL
100 lb/45 kg	8,800	35,200	52,800
150 lb/68 kg	5,900	23,500	35,200
200 lb/91 kg	4,400	17,600	26,400

[a] In a patient with a normal sized spleen and without platelet antibodies.
[b] Whole blood platelets. An apheresis platelet component contains the equivalent of 4–8 units of whole blood platelets.

Pooled random donor platelet concentrates are prepared from platelets that have been harvested by centrifuging units of donated whole blood. Up to 8 units of platelets, each from a separate donor, can be pooled into a single bag for transfusion. All units are from the same ABO type. If ABO compatible platelets are unavailable, in most cases, pooled ABO incompatible platelets can be substituted with very little risk. The usual adult dose is 1 unit per 15 kg of body weight. Four to six units of pooled random donor platelets are frequently used in patients receiving prophylactic transfusions; however, a study of more than 1,200 hospitalized patients with thrombocytopenia due to chemotherapy or HSCT for hematologic malignancy showed no difference in bleeding incidence and decreased platelet exposure overall when transfused with low ($1.1 \times 10^{11}/m^2$), medium ($2.2 \times 10^{11}/m^2$), or high ($4.4 \times 10^{11}/m^2$) doses of platelets prophylactically for platelet counts of less than 10,000/μL [49], suggesting that a dose of only 3 or 4 units of pooled random donor platelets is adequate. Patients who received smaller doses did require more frequent transfusions, making this strategy less appropriate for outpatient transfusion.

In a 70-kg patient with a normal sized spleen, each unit is expected to increase the platelet count by approximately 7,000/μL (Table 114.1) when checked 10 minutes to 1 hour after transfusion [50]. The survival of transfused platelets averages 3 to 5 days but will decrease if a consumptive process is present. Platelet concentrates also contain about 60 mL of plasma per unit and small numbers of red blood cells and leukocytes. Platelet units must be maintained at room temperature, as platelets lose shape and release their granular contents when refrigerated. Apheresis platelets, collected from a single donor, are prepared in components equivalent to 4 to 6 pooled units. An apheresis platelet concentrate contains 200 to 400 mL of plasma and, if the plasma is of an incompatible type, may be reduced in volume by centrifugation, although this results in an approximate 10% to 15% loss of platelets and probably some loss of function. Apheresis platelets may be collected for a specific recipient from a family member or other human leukocyte antigen (HLA) compatible donor for patients that have become refractory to random donor platelet transfusions due to alloimmunization. Leukocyte reduction of transfused cellular blood components has been clearly shown to reduce the rate of alloimmunization in patients undergoing chemotherapy for acute myelocytic leukemia [51].

Granulocytes

The degree of granulocytopenia is directly related to the risk of infection [52]. Although antibiotics have improved morbidity and mortality in patients affected by prolonged periods of

neutropenia, most antimicrobials are less effective in the presence of granulocytopenia. Bacterial and, more particularly fungal, infections remain a major cause of death in HSCT patients despite shortening of the period of neutropenia with hematopoietic growth factors [53]. Granulocytes collected by continuous flow centrifugation and filtration leukapheresis function normally in vitro in the quantitative nitroblue tetrazolium, oxygen consumption, and chemotaxis assays [54]. Bacterial killing by filtration leukapheresis granulocytes, which circulate for several hours posttransfusion, is only slightly decreased compared with granulocytes collected by continuous flow centrifugation. Transfused granulocytes rapidly migrate to sites of infection [55].

Early studies showed promise for the use of granulocyte transfusion for treatment of documented infections in neutropenic patients [56–58]; however, their usefulness in the prevention of infection has been more controversial [59], due to limitations in the inability to collect cells in sufficient amounts to provide an effective transfusion dose, poor response to granulocytes in heavily transfused, alloimmunized patients [60], and the early development of alloimmunization in patients transfused with granulocytes [61]. To this end, HLA-compatible donors have been administered corticosteroids prior to granulocyte collection with some limited success.

The administration of granulocyte colony-stimulating factor has been shown to be safe when given to normal donors [62] and has been administered to donors prior to collection to increase collection and posttransfusion increments [63,64]. Whether this will increase the efficacy of granulocyte transfusion in treatment of infection will require further study.

Plasma Components

Fresh Frozen Plasma

One unit of fresh frozen plasma (FFP) is the plasma taken from a unit of whole blood. It is frozen within 8 hours of collection and contains all coagulation factors in normal concentrations. It is free of red blood cells, leukocytes, and platelets. Plasma may also be provided as "frozen plasma" or "thawed plasma." These components are prepared by methods similar to plasma, and their factor concentrations differ only slightly. All will be considered here collectively as "FFP." One unit contains approximately 200 to 250 mL and must be ABO compatible (type AB is the universal donor type). Rh factor need not be considered. Since there are no viable leukocytes, FFP carries minimal risk of cytomegalovirus (CMV) transmission or graft versus host disease (GVHD).

FFP transfusion is indicated in patients with documented coagulation factor deficiencies and active bleeding. FFP should not be used to correct isolated deficiencies in clotting factors when a concentrated replacement source, such as factor VIII or IX, is available, as these concentrates are either recombinant or have undergone processing to inactivate viruses and can correct the deficiency using a much smaller infused volume. Factor deficiencies may be congenital or acquired secondary to liver disease, warfarin anticoagulation, disseminated intravascular coagulation (DIC), or massive replacement with red blood cells and crystalloid/colloid solutions. Usually, there is an increase of at least 1.6 times the normal prothrombin time (PT) or activated partial thromboplastin time (aPTT) before clinically important factor deficiency exists. This corresponds to levels of most factors less than 20% of normal. Above these levels, most routine non–major invasive procedures such as line placement [27], liver biopsy [65], and thoracentesis [66] are not associated with an increased risk of bleeding complications; however, the acceptable upper limits of PT and PTT prior to invasive procedures have not been evaluated in a large prospective randomized study to date [67–69].

TABLE 114.2

FRESH FROZEN PLASMA (FFP)—DOSAGE FOR TRANSFUSION

Volume of 1 unit FFP: 200–250 mL 1 mL plasma contains 1 unit coagulation factors **1 Unit FFP contains 220 units coagulation factors** Factor recovery with transfusion = 40% **1 Unit FFP provides ≈80 units coagulation factors** 70 kg × 0.05 = plasma volume of 35 dL (3.5 L) $\frac{80 \text{ unit}}{35 \text{ dL}}$ = 2.3 unit/dL = 2.3% (of normal 100 unit/dL)
In a 70-kg patient: **1 Unit FFP increases most factors ≈2.5%** **4 Units FFP increase most factors ≈10%**

In the massively transfused patient, consumption and dilution of coagulation factors may cause rapid development of coagulopathy. Patients with a PT or aPTT ratio (reference midrange normal value divided by actual) 1.8 or more had an 80% to 85% chance of exhibiting microvascular bleeding, and either of these tests should be closely monitored during resuscitation of the bleeding patient [33]. FFP transfusion is indicated when the ratio exceeds 1.5 times the midrange normal value in these patients [30]. Usually an increase in factor levels of at least 10% will be needed for any significant change in coagulation status, so the usual dose is 3 to 4 units (approximately 10 to 15 mL per kg), but the amount will vary depending on the patient's size and clotting factor levels (Table 114.2). Reversal of warfarin anticoagulation is indicated only if significant bleeding or risk of bleeding is present. FFP may be used for this purpose, but often, recurrent transfusion is required to maintain normal factor levels.

FFP is indicated in the treatment of TTP, most commonly in conjunction with plasmapheresis. Many other disorders are treated by plasmapheresis, but usually FFP replacement is not used. FFP should *not* be used for volume expansion unless the patient also has a significant coagulopathy and is bleeding.

Cryoprecipitate

Cryoprecipitate is prepared from plasma and contains fibrinogen, von Willebrand factor, factor VIII, factor XIII, and fibronectin. Cryoprecipitate is supplied in bags (each made from one whole blood unit) from multiple donors that have been resuspended in saline or plasma and pooled prior to transfusion. It must be kept at room temperature. The concentration of fibrinogen in cryoprecipitate units is up to 10 times that in FFP and therefore blood levels can be increased rapidly with much smaller volumes.

Fibrinogen levels can drop rapidly in DIC and is usually associated with other coagulation abnormalities that may in combination be treated with FFP. Isolated hypofibrinogenemia is infrequently associated with bleeding in adults, and correction should be reserved for patients with clinical bleeding or patients who are a risk of bleeding due to imminent invasive procedures or trauma [26] with significant hypofibrinogenemia (< 100 mg per dL).

Cryoprecipitate should not be used for patients with von Willebrand disease or hemophilia A (factor VIII deficiency) unless they do not (or are not known to) respond to DDAVP, and recombinant and/or virally inactivated preparations are not available. It is usually given for factor XIII deficiency, when virus-inactivated concentrates of this protein are not available.

Cryoprecipitate is sometimes useful if platelet dysfunction associated with renal failure does not respond to dialysis or DDAVP and in other platelet function defects [70].

The amount of fibrinogen per bag of cryoprecipitate can vary widely between blood centers depending on the donor's fibrinogen concentration. The approximate fibrinogen increment with each bag of cryoprecipitate transfused can be calculated by the formula: 25 mg/plasma volume (in liters). Six bags will increase the fibrinogen level of a 70-kg patient approximately 45 mg per dL. To replace factor VIII or von Willebrand factor when specific factor concentrates are unavailable, the usual dose is 1 bag per 10 kg of body weight. Approximately 150 units of factor VIII and von Willebrand factor are provided per bag. Although single units of cryoprecipitate can be used in the preparation of locally applied fibrin glue for surgery, commercially available, virally inactivated concentrates have a higher fibrinogen concentration and are preferred for this purpose. A patient may donate autologous plasma for processing into cryoprecipitate prior to a planned surgical procedure.

Human fibrinogen concentrate (RiaSTAP®) is a heat-treated, lyophilized fibrinogen (coagulation factor I) powder made from pooled human plasma. It is indicated for bleeding or procedure prophylaxis in patients with congenital hypofibrinogenemia or dysfibrinogenemia.

COMPLICATIONS OF TRANSFUSION

Transfusion-Related Risks

Infectious Complications

Since the recognition that human immunodeficiency virus (HIV) could be transmitted by blood transfusion in the mid-1980s, exclusion of donors with high risk has done more to decrease transfusion transmitted infection than any testing that has been implemented since that time [71]. Enzyme-linked immunosorbent assay (ELISA) testing for anti-HIV antibody was instituted in 1985 dropping the risk of HIV transmitted infection to 1 in 667,000 units [72]. The addition of P24 antigen decreased the window period between infection and detection to approximately 16 days [73].

Blood centers began clinical trials in April 1999 to screen blood with a polymerase chain reaction (PCR) test for hepatitis C virus (HCV) and HIV RNA. Although confirmed data are not available, the current estimated risks/unit are as low as 1:2,000,000 for HIV and HCV [74]. Risks for other viral transmissions are estimated to be 1:500,000–750,000 for hepatitis B and 1:3,000,000 for human T-lymphotropic virus I and II [75,76].

CMV is a DNA virus acquired as a primary infection with body secretions, blood products, or organ allografts. Infection in a normal host usually is asymptomatic but remains latent for life and can cause recurrent infection when it reactivates. CMV infection and seropositivity are extremely common, being 40% in highly industrialized areas, and is close to 100% in warmer climates, densely populated areas, and developing countries [77]. Transfusion-associated CMV infection in the immunocompetent patient with a normal immune system is usually asymptomatic, occurring 4 to 12 weeks after blood component exposure in 0.9% to 17% of patients [78]. In CMV-negative, immunosuppressed neonates and transplant and HIV-positive patients, the risk of CMV infection leading to severe end-organ disease and organ allograft rejection is high [79]. Leukocyte depletion of blood is equivalent to CMV seronegative blood in preventing CMV infection through transfusion [80] but may be more expensive and indicated only if CMV-negative blood is not available or leukocyte-depleted blood components are being provided for another reason. Although CMV seronegative blood is transfused to organ transplant recipients in some centers to prevent infection with secondary strains, the clinical relevance of this practice has not been demonstrated.

Bacterial contamination of red blood cell and platelet units may occur during collection. Red blood cell units may be contaminated with cold-loving organisms such as Yersinia. Platelets are stored at room temperature and multiple organisms can grow in those conditions. Although staphylococcus and streptococcus are most frequently implicated, Gram-negative organisms have also been identified [81]. The incidence of bacterial contamination of platelets has been estimated to be as high as 0.1% [82]. The institution of bacterial testing of platelets in 2004 in the United States is expected to decrease this risk [83]. Symptoms of hypotension, fever, and chills almost always occur within 3 hours of the transfusion and may be complicated by severe shock and DIC [84]. Both the patient and the blood component bag should be cultured if bacterial contamination is suspected.

Other organisms that can be transmitted by blood transfusion include other hepatitis viruses, malaria, and, rarely, syphilis. Trypanosoma cruzi, the parasite responsible for Chagas disease is becoming a commonly transfusion transmitted disease in Central and South America and has been reported in some Southern Border states. Fear of transfusion transmission of new variant Creutzfeldt-Jakob disease has led to stringent criteria on blood donor eligibility and institution of universal leukoreduction in some European countries, but the risk of infection by transfusion is low [85] and testing is not universal.

Transfusion Reactions

A transfusion should be stopped immediately whenever a transfusion reaction is suspected.

An **acute hemolytic transfusion reaction** (AHTR) occurs following transfusion of an incompatible blood component. Most are due to naturally occurring antibodies in the ABO antigen system, but AHTR may occur with incompatibility of Rh, Kell, Kidd, Lewis, and other red blood cell antigen systems. The vast majority of cases are due to failure of appropriate systems to identify the correct transfusion recipient [86]. Signs and symptoms include fever, hypotension, tachycardia, dyspnea, chest or back pain, flushing, and severe anxiety. Release of cytokines, such as tumor necrosis factor, interleukin 8, and monocyte chemoattractant protein-1 [87], is followed by fever, capillary leak, and activation of the hemostatic mechanism. If the reaction is severe, it may go on to cause a consumptive coagulopathy (DIC) and renal failure due to shock and deposition of thrombi in arterioles. Hemoglobinuria may be the first sign of hemolysis in the sedated patient. Centrifuging a tube of blood and examining the plasma for a reddish discoloration can quickly make the diagnosis. Treatment should first of all be immediate discontinuation of the transfusion as soon as AHTR is suspected and maintenance of venous access and fluid resuscitation if necessary. Pressor support may be necessary along with central venous pressure or Swann Ganz monitoring. AHTR is rare, estimated at 1:77,000 units [88].

Delayed hemolytic transfusion reactions (DHTRs) usually occur in patients who have been previously sensitized to an antigen through transfusion or pregnancy. A fall in titer over time may make incompatibility undetectable. A subsequent transfusion causes recall of the antibody followed by a falling hematocrit 5 to 10 days later. The hematocrit will continue to fall until all of the incompatible transfused cells have been destroyed. DHTR can result in symptomatic or asymptomatic hemolysis but has only rarely been reported to cause severe

morbidity or mortality [89]. Once recognized, the patient is usually easily supported by transfusion of compatible red blood cells.

Febrile nonhemolytic transfusion reaction (FNHTR) is a 1°C rise in temperature or greater that cannot be explained by the patient's clinical condition. FNHTR usually occurs within 1 hour of completion of the transfusion. Reactions are more common with platelet transfusions and in patients who have been heavily transfused and can be quite severe. FNHTR is often due to sensitization to antigens on donor leukocytes [90]. Cytokines, released from the white cells during storage of cellular blood components, also appear to play a role [91]. Prestorage leukocyte depletion of red blood cells and platelets by filtration may be helpful in patients for whom this is a problem. Leukocyte-reduced single-donor apheresis platelets are a possible alternative to leukocyte depletion by filtration of pooled random donor platelets. Occasionally, patients with persistent febrile reactions will require removal of most of the plasma (volume reduction) from platelet preparations. FNHTR should be differentiated from bacterial contamination, which is usually associated with higher fevers and other symptoms of sepsis. Antipyretics can be used to prevent or treat FNHTR. Meperidine may be useful in the treatment of rigors.

Transfusion-related acute lung injury (TRALI) can be indistinguishable from adult respiratory distress syndrome [92,93], involving severe bilateral pulmonary edema and hypoxemia. Symptoms of dyspnea, hypotension, and fever typically begin 30 minutes to 6 hours after transfusion and the chest x-ray shows diffuse nonspecific infiltrates. Ventilatory support may be required for several days before resolution but approximately 80% of patients improve within 48 to 96 hours. TRALI occurs when donor plasma contains an antibody, usually against the patient's HLA or leukocyte specific antigens. Lipids generated during prior storage of the transfused product and preexisting lung damage also appear to play parts in the pathogenesis of TRALI. Less often, the patient may have antibodies against donor leukocytes in the component. The blood center should be notified promptly so that components from the donor can be quarantined and the donor tested for antibodies against the patient.

Transfusion-associated cardiovascular overload (TACO) may occur in patients sensitive to increased amounts of intravascular volume with transfusion and may initially present a clinical picture similar to TRALI. Unlike TRALI, diuresis is usually effective in its treatment.

Allergic and anaphylactic reactions are common and are usually due to preformed immunoglobulin E antibodies to specific proteins in the donor's plasma. Mild urticaria complicates up to 3% of plasma infusions [94] and can be avoided with future transfusions by pretreatment with antihistamines, and in severe cases with corticosteroids. Only in cases of severe reactions (anaphylaxis), is washing of RBCs and platelets to remove all plasma indicated. Slowing of the rate of transfusion and centrifugation to remove some of the plasma in a platelet component will sometimes be effective in preventing future reactions in patients for whom this is a recurrent problem.

Transfusion-related graft versus host disease (TRGVHD) is due to infusion of donor lymphocytes that engraft and then proliferate in response to stimulation by foreign (host) antigens. TRGVHD typically begins 2 to 50 days after transfusion with rash, diarrhea, signs of hepatic inflammation, and pancytopenia [95]. TRGVHD occurs in patients with severe defects of cellular immunity, most notably HSCT patients, neonates, and patients with lymphoproliferative disorders. Transfusion from relatives and HLA compatible donors are at risk of causing GVHD. It can be prevented by gamma irradiation of cellular blood components.

Immune Modulation

Transfusions have been known to induce immune tolerance following the observation made more than 20 years ago that multiply transfused kidney transplant recipients had an increased graft survival rate [96]. Transfusion-induced immunosuppression has been implicated in postoperative infection, increased cancer recurrence rates, and development of non-Hodgkin lymphoma [97,98]. There is also evidence from animal studies

TABLE 114.3

RANDOMIZED CLINICAL TRIALS IN TRANSFUSION MEDICINE THAT HAVE RESULTED IN CHANGES IN CLINICAL PRACTICE

Appropriate hemoglobin threshold for RBC transfusion	Hebert et al. [18] Hebert et al. [19] (The TRICC Trial)	A hemoglobin threshold of 7.0 g/dL vs. 9.0 g/dL is not associated with increased morbidity, mortality, or prolonged ventilatory support.
Appropriate platelet count threshold for prophylactic platelet transfusion	Gmur et al. [35] Wandt et al. [36] Rebulla et al. [37]	Platelet transfusion "triggers" of < 10,000/μL are safe for the prevention of bleeding in chemotherapy-induced thrombocytopenia in patients without comorbid conditions.
Prevention of transfusion transmitted CMV infection	Bowden et al. [80]	Leukocyte reduction of cellular blood components is as effective in reducing the risk of CMV transmission as the use of CMV seronegative blood components.
Prevention of platelet alloimmunization	TRAP Study Group [51]	Leukoreduction of cellular blood components prevents HLA alloimmunization in patients with acute leukemia undergoing induction chemotherapy.
Use of leukoreduction to decrease postoperative infection	van de Watering et al. [99]	Leukoreduction of cellular blood components decreases postoperative infection in patients undergoing cardiac surgery.
Appropriate platelet transfusion dose for prophylactic transfusion of thrombocytopenia	Slichter et al. [49]	Low-dose platelet transfusion results in an overall decrease in the number of total platelets transfused and no increase in bleeding. Platelet transfusion frequency is increased.

that transfusion increases the risk of metastatic disease, although data in humans are inconclusive. Removal of donor leukocytes has been shown to decrease the immunomodulatory effects of blood transfusions. The clinical usefulness is clear only in prevention of alloimmunization in patients undergoing chemotherapy for acute myelocytic leukemia [50]. A prospective randomized study in patients undergoing cardiac surgery showed a decrease in infection rates when leukocyte-reduced blood components were used [99]. This has led some centers to adopt policies of universal leukoreduction, but this remains controversial.

Table 114.3 summarizes some of the most important recent advances in transfusion medicine based on randomized, controlled trials or meta-analyses of such trials.

CHAPTER 115 ■ CRITICAL CARE OF PATIENTS WITH HEMATOLOGIC MALIGNANCIES

MATTHEW J. WIEDUWILT AND LLOYD E. DAMON

INTRODUCTION

Although the incidence of aggressive hematologic malignancies like acute myeloid leukemia (AML), acute lymphoblastic leukemia (ALL), and intermediate- and high-grade non-Hodgkin lymphomas is low, these potentially curable diseases frequently require intensive care unit (ICU) management at presentation to prevent early mortality and achieve disease remission. Patients with hematologic malignancies account for approximately 2% of all ICU admissions [1,2]. Approximately 7% of patients with hematologic malignancies admitted to the hospital will become critically ill [3]. The most frequently reported indications for ICU admission in patients with hematologic malignancies are respiratory failure (26% to 91%), severe sepsis (8% to 64%), neurologic impairment (14% to 23%), and acute renal failure (14% to 23%). For all critically ill patients with hematologic malignancies, ICU mortality, in hospital mortality and 6-month mortality rates are 23% to 62%, 54% to 82%, and 66% to 83%, respectively [1–11]. Risk factors for death in the ICU include high disease severity score (APACHE II, SAPS II, SOFA), vasopressor use, leukopenia, increasing number of organ failures, and acute renal failure (see Table 115.1). Notably, mechanical ventilation has not been consistently associated with increased risk of death in this patient population, and some studies suggest improved outcomes with early endotracheal intubation [2,12]. In addition, survival in patients with hematologic malignancies admitted to the ICU after chemotherapy alone versus hematopoietic stem cell transplant (HSCT) are not different, suggesting that critically ill HSCT patients should be treated aggressively on ICU admission [13,14]. In fact, when matched for severity of acute illness upon ICU admission, survival of patients with hematologic malignancies and nononcologic patients appears to be similar [1].

OVERVIEW OF HEMATOLOGIC MALIGNANCIES

Acute Myeloid Leukemia

AML accounts for 22% to 54% of hematologic malignancy admissions to the ICU [1,2,4,6–11]. Patients with AML may require ICU admission for disease- or treatment-related complications including sepsis (frequently complicated by neutropenia), bleeding due to thrombocytopenia and occasionally acute disseminated intravascular coagulation and multiple organ failure.

The incidence of AML in the United States is 3.5 cases per 100,000 persons per year with approximately 12,000 new cases diagnosed annually [15]. More than half of newly diagnosed AML patients are over 65 years of age and a third are older than 75 years. Five-year survival rates are approximately 50% in adults under the age of 45 years but drop to less than 10% in patients over the age of 65 [16]. The risk factors for the development of AML, including genetic and environmental factors, have been well defined [17–27].

AML arises from the acquisition of genetic mutations in myeloid precursors or stem cells leading to various degrees of maturation arrest, unregulated proliferation, and resistance to apoptosis. By the World Health Organization 2008 classification system, the diagnosis of AML requires myeloid blasts to comprise 20% or more of nucleated cells in the peripheral blood or bone marrow except in cases of AML with the recurrent cytogenetic abnormalities t(15;17), t(8;21), inv(16)/t(16;16), myeloid sarcoma (a tumor of myeloblasts), and some cases of erythroleukemia [28]. The recurrent cytogenetic abnormalities t(15;17), t(8;21), inv(16)/t(16;16) and normal cytogenetics accompanied by gene mutations in NPM1 or CEBP-alpha confer a better prognosis in terms of risk of relapse, and the majority of patients obtain durable complete remissions with chemotherapy alone [28,29]. Conversely, patients with poor-risk cytogenetics and those with normal cytogenetics accompanied by mutations in the FLT3 proto-oncogene have a low likelihood of durable remission with chemotherapy alone and typically undergo allogeneic HSCT [29].

Standard induction chemotherapy for AML using 3 days of intravenous (IV) anthracycline (daunorubicin, idarubicin) or anthracenedione (mitoxantrone) and 7 days of cytarabine by continuous IV infusion, ideally initiated within 5 days of diagnosis, leads to complete remission rates of 60% to 80% in young adults under 60 years of age and 50% in patients over 60 years of age. Postremission therapy is tailored to pretreatment risk status, performance status and age and may consist of three to four cycles of high-dose cytarabine, autologous HSCT or, for younger patients at high risk of relapse, allogeneic HSCT [30].

Acute Promyelocytic Leukemia

APL accounts for 5% to 6% of all acute myeloid leukemia with approximately 600 to 800 new diagnoses made each year in the Unites States [31,32]. APL frequently presents with acute disseminated intravascular coagulation (DIC) that can be rapidly fatal due to intracerebral, pulmonary, or gastrointestinal hemorrhage, in all accounting for 50% to 60% of early deaths [33]. Early suspicion and treatment of APL, even prior to definitive genetic diagnosis, is important to reduce the risk of life-threatening hemorrhage [34]. Paradoxically, patients are also at risk for thrombotic events that complicate about 10% to 12% of cases, frequently in those with expression of CD2, CD15, and FLT3-ITD mutation [35,36].

APL occurs due to arrest of myeloid differentiation at the promyelocyte stage leading to accumulation of leukemic promyelocytes in the bone marrow, blood, and tissues. Morphologically, leukemic promyelocytes typically have variable

TABLE 115.1

OUTCOMES OF PATIENTS WITH HEMATOLOGIC MALIGNANCIES ADMITTED TO THE ICU

Number of patients	ICU mortality (%)	In-hospital mortality (%)	Risk factors for death	Reference
7,689	43	59	HSCT, Hodgkin lymphoma, severe sepsis, age, length of hospital stay prior to ICU admission, respiratory failure, neurologic failure, renal failure, anemia	[2]
22	55	82	APACHE II score, number of failing organs, mechanical ventilation	[4]
60	—	78	APACHE II score > 30, number of failing organs, resistant disease, leukopenia	[5]
92	—	77	Progression of underlying malignancy	[6]
78	26	—	Number of failing organs, liver failure	[7]
104	44	—	SAPS II score, mechanical ventilation	[8]
124	42	54	Leukopenia, vasopressors, renal failure	[9]
58	62	—	SAPS II score, SOFA score	[10]
24	—	75	SAPS II score > 66, liver failure, neurologic failure, number of failing organs	[3]
92	50	55	SAPS II, SOFA, ODIN, and LODS scores, allogeneic HSCT, neutropenia, severe sepsis, vasopressor use, invasive mechanical ventilation	[11]
101	23	—	SAPS II score, SOFA score, mechanical ventilation, renal replacement therapy	[1]

HSCT, hematopoietic stem cell transplant; SAPS II, Simplified Acute Physiology Score II; APACHE II, Acute Physiology and Chronic Health Evaluation II; SOFA, Sequential Organ Failure Assessment; ODIN, Organ Dysfunction and/or Infection Score; LODS, Logistic Organ Dysfunction Score.

nuclear morphology with bilobed or reniform nuclei, prominent cytoplasmic granules, and numerous large Auer rods, frequently in bundles [37]. Approximately 5% of APL presents as a microgranular variant characterized by few or absent granules [38]. Patients with this microgranular variant tend to have higher presenting white blood cell counts, placing them at higher risk for complications and relapse. Except in rare instances, APL is characterized by the presence of the recurrent cytogenetic abnormality t(15;17)(q22;q12) leading to a PML-RAR-alpha fusion gene that can be demonstrated by cytogenetic analysis, FISH and quantitative RT-PCR [37]. The chimeric PML-RAR-alpha protein is the target of therapy with all-*trans*-retinoic acid (ATRA) and arsenic trioxide (ATO), agents that cause degradation of the PML-RAR-alpha oncoprotein thereby promoting terminal differentiation of leukemic promyelocytes [39,40].

The diagnosis of APL should be considered in any patient with a new diagnosis of leukemia especially if accompanied by clinical and laboratory evidence of acute DIC. Early institution of treatment with the differentiating agent ATRA is indicated upon suspicion of APL [32,34]. Careful review of the peripheral blood smear from new leukemia patients in consultation with hematologists and hematopathologists should be performed to look for characteristic hypergranular leukemic promyelocytes. Expedited performance of flow cytometry, specifically evaluating for coexpression of CD34, CD15, and CD13 on the surface of leukemic cells can aide in diagnosing the microgranular variant of APL [41].

Greater than 70% of APL patients attain prolonged remissions with current treatment strategies. Induction chemotherapy regimens generally combine ATRA with an anthracycline, typically idarubicin or daunorubicin [32]. ATO is highly active against APL and in combination with ATRA produces CR rates over 90% [42–44]. ATRA or ATO, however, may cause a fatal differentiation syndrome characterized by fever, dyspnea, pulmonary infiltrates, pleuropericardial effusions, weight gain, peripheral edema, renal failure, and hypotension.

Acute Lymphoblastic Leukemia

ALL results from the acquisition of genetic mutations in lymphoid progenitor or stem cells resulting in the arrest of cells at an early stage of differentiation [45]. In 2009, about 5,760 people were diagnosed with ALL in the United States with a median age of 13 years [15]. ALL patients comprise 9% to 27% of ICU admissions for hematologic malignancies [1,2,4,6–11]. The 10-year survival among adults with ALL is less than 30% [45–47]. Favorable disease characteristics in ALL include ages 1 to 15 years, presenting WBC < 50,000 per μL and rapid achievement of complete remission, whereas age > 35 years is unfavorable. Cases with the t(9;22)/BCR-ABL (Philadelphia chromosome, Ph), representing 15% to 20% of adult cases of ALL, and the t(4;11)/MLL-AF4 translocations typically fare poorly, with survival rates of less than 10% with chemotherapy alone and long term survival after allogeneic HSCT ranging 20% to 45% [48–53].

Clinical trial regimens in the last decade have improved complete remission rates to 74% to 93% with 5-year survival rates as high as 48% [54]. Therapy for ALL typically spans 2 to 3 years and includes induction therapy, postremission therapy, central nervous system (CNS) prophylaxis and maintenance chemotherapy in patients who do not undergo HSCT. Induction therapy for ALL typically combines vincristine, an anthracycline (e.g. daunorubicin), and a corticosteroid (prednisone or dexamethasone) with l-asparginase and/or cyclophosphamide. Prophylaxis against CNS relapse includes intrathecal chemotherapy with methotrexate with or without cytarabine and frequently high-dose IV systemic methotrexate. Postremission therapy typically includes the same agents used in induction as well as cytarabine and 6-mercaptopurine. Maintenance therapy consists of oral methotrexate and 6-mercaptopurine often with pulses of vincristine and corticosteroids. Imatinib (Gleevec®) and dasatinib (Sprycel®) inhibit the chimeric BCR-ABL tyrosine kinase produced by the Philadelphia

chromosome and improve complete remission and survival rates in Ph+ ALL [55–63]. Ideally, allogeneic HSCT is performed in patients with poor-risk disease.

Aggressive Non-Hodgkin Lymphomas

Diffuse large B-cell lymphoma (DLBCL) is an aggressive non-Hodgkin lymphoma of intermediate grade that typically presents with rapidly enlarging lymph nodes or extranodal masses frequently with symptoms of organ compromise from lymphomatous involvement of extranodal sites. Diagnosis is typically made by excisional biopsy of a lymph node or mass showing large lymphoid cells that completely efface lymph node architecture. Malignant B-cells express CD19, CD20, and CD22 with variable expression of surface immunoglobulin, CD5 and CD10 [64]. Common genetic abnormalities in DLBCL include constitutive expression of the transcriptional repressor Bcl-6, the antiapoptotic protein Bcl-2, and/or the transcription factor c-myc [65]. The International Prognostic Index for aggressive lymphomas uses five unfavorable variables to establish risk status: age greater than 60 years, poor performance status, advanced stage (Ann Arbor Stage III or IV disease), extranodal involvement at more than one site and elevated serum lactate dehydrogenase [66]. First-line combination chemotherapy with cyclophosphamide, doxorubicin, vincristine, and prednisone (CHOP) in combination with the humanized monoclonal anti-CD20 antibody rituximab results in 2-year overall survival rates of 70% to 90% [65].

Burkitt lymphoma (BL), which has the fastest growth rate of any human malignancy, is an aggressive non-Hodgkin lymphoma with endemic, sporadic, and immunodeficiency-associated clinical variants. BL typically presents with rapidly progressive nodal and extranodal disease, commonly in the abdomen and gastrointestinal tract leading to nausea, vomiting, anorexia, bowel obstruction, and gastrointestinal bleeding. Advanced stage is common at diagnosis with bone marrow involvement in 30% to 38% and CNS involvement in 13 to 17% of adults [67]. Morphologically, lymphoma cells are medium-sized with deeply basophilic cytoplasm containing cytoplasmic lipid vacuoles and a high proliferative index of greater than 90%. A leukemic variant exists and can be distinguished from ALL by surface expression of immunoglobulin, CD20 and CD10, without coexpression of TdT or CD34. BL is genetically characterized by chromosomal translocations that lead to constitutive expression of c-myc, typically t(8;14) and rarely t(2;8) or t(8;22)[68]. High-intensity, brief-duration chemotherapy, typically with cyclophosphamide, doxorubicin, vincristine, and antimetabolite-containing regimens, with intensive CNS prophylaxis, have led to 1-year remission rates as high as 86% [67]. The bulky disease and high cell proliferation rates seen in both DLBCL and Burkitt lymphoma place patients at high risk for tumor lysis syndrome and prophylactic treatment with allopurinol to prevent hyperuricemia is typically given prior to chemotherapy.

Other Malignancies

Other notable hematologic malignancies frequently requiring ICU level care are multiple myeloma, Waldenstrom macroglobulinemia and myeloproliferative neoplasms such as chronic myeloid leukemia, essential thrombocythemia, polycythemia vera, and chronic idiopathic myelofibrosis. In multiple myeloma, spinal cord compression may occur due to encroachment of the spinal canal by epidural plasmacytomas and from pathologic fracture of spinal vertebrae. Emergent imaging of the entire spine with MRI is required for diagnosis (see Chapter 116). In Waldenstrom macroglobulinemia, high concentrations of monoclonal IgM paraprotein in the serum can lead to the hyperviscosity syndrome manifest as mucosal bleeding, confusion, seizures, coma, visual disturbance, and/or headache as well as cryoglobulinemia, cold agglutinin hemolytic anemia, and plasma volume expansion leading to congestive heart failure [69]. Myeloproliferative neoplasms may lead to life-threatening hemorrhage or thrombosis, requiring critical care (see Chapter 111).

DISEASE AND TREATMENT RELATED COMPLICATIONS

Hyperleukocytosis and Leukostasis

In AML, hyperleukocytosis, generally defined as a circulating blast count greater than 50,000 to 100,000 per μL, occurs in 5% to 18% of patients at initial presentation [70,71]. Early mortality during initial treatment of patients with hyperleukocytic AML ranges from 5% to 30% with advanced age, poor performance status, coagulopathy, respiratory compromise, and organ failure associated with early death [70–75]. Hyperleukocytosis in AML is frequently associated with leukostasis manifesting as respiratory failure, visual disturbance, intracranial hemorrhage, and renal failure.

Leukostasis, although typically associated with hyperleukocytosis, can occur at white blood cell counts less than 50,000 per μL (likely due to interpatient variability in leukemia cell biology and individual susceptibility). Myeloid leukemic blasts are less deformable than mature white blood cells possibly predisposing to formation of aggregates of cells in the small blood vessels, tissue ischemia, endothelial damage and tissue infiltration [76–78]. In addition, expression of specific cell surface adhesion molecules on leukemia cells and endothelial cell activation by cytokines secreted by leukemic blasts may play important roles in promoting leukostasis. The expression of CD56/NCAM on the surface of leukemia cells in myelomonocytic AML correlates with the development of leukostasis [79]. In vitro, myeloid blasts promote their own adhesion to the vascular endothelium by upregulating expression of ICAM-1, VCAM-1, and E-selectin on endothelial cells [80]. In ALL, hyperleukocytosis is rarely associated with symptomatic leukostasis except with extreme hyperleukocytosis (WBC > 400,000 per μL) possibly due to the smaller size, easier deformability, and decreased vascular endothelium adherence of lymphoblasts [81]. Notably, lymphoblasts in the rare ALL patients with symptomatic leukostasis are less deformable than lymphoblasts from ALL patients without leukostasis [82]. In AML with hyperleukocytosis, most studies have not shown a demonstrable difference in complete response rates, disease free survival or overall survival after treatment [83]. However, the presence of pulmonary leukostasis, hepatomegaly, hyperbilirubinemia, and hypofibrinogenemia are predictors of poor outcome in patients with hyperleukocytosis [74,75,84].

Hydroxyurea at doses of 20 to 30 mg per kg per day or more can reduce peripheral leukocyte counts, and generally requires 1 to 2 days to take effect. Red blood cell transfusions should be avoided until the leukocyte count is less than 50,000 per μL to avoid ischemic events such as stroke or acute coronary syndrome. Although invasive, leukapheresis is a relatively safe procedure and is frequently used in combination with hydroxyurea to rapidly lower circulating blast counts and theoretically decrease the risk of tumor lysis syndrome and progressive leukostasis. Two blood volumes (140 mL per kg) are processed in the typical leukapheresis procedure. Studies have failed to show a consistent clinical benefit with the use of leukapheresis in hyperleukocytic leukemias [85–88], although some uncontrolled retrospective single institution studies show reduction

of early mortality in patients undergoing leukapheresis without an overall survival benefit [87,88]. Despite the poor prognosis of APL presenting with hyperleukocytosis and organ failure, leukapheresis is contraindicated in this group of patients due to risk of exacerbating acute DIC, initiating vasomotor instability, and increasing induction death [89].

Hyperviscosity Syndrome

The hyperviscosity syndrome occurs in 30% of patients with Waldenstrom macroglobulinemia (also called lymphoplasmacytic lymphoma with IgM monoclonal gammopathy) at presentation and is defined by the presence of increased serum viscosity with neurologic symptoms related to impaired blood flow including headache, vertigo, dizziness, visual impairment, hearing impairment, tinnitus, nystagmus, stupor, stroke, dementia, and coma [90–95]. In addition, mucosal bleeding, including GI hemorrhage, renal failure, and congestive heart failure due to plasma volume expansion and concomitant anemia may occur. Elevated serum IgM, with its large pentameric structure, is most commonly associated with hyperviscosity, although the syndrome has been reported with IgA, IgG, and kappa light chain multiple myeloma [96–101]. Normal serum viscosity measures 1.4 to 1.8 centipoises [102,103] and symptomatic hyperviscosity typically occurs at greater than 4 centipoises [69].

Emergent plasmapheresis is indicated for symptomatic hyperviscosity. One to two plasma volumes are typically exchanged and replaced with 5% albumin in patients with low bleeding risk or fresh frozen plasma (FFP) in patients at high risk for bleeding. Symptoms typically resolve quickly but neurologic deficits can remain. Red blood cell transfusions should be avoided if possible until serum viscosity is lowered. Definitive treatment for the underlying malignancy should be instituted quickly to control paraprotein production. Procedural risks include depletion of clotting factors when 5% albumin is used as the exchange fluid, hypocalcemia from citrate anticoagulant use, dialysis catheter-related infection, pneumothorax or thrombosis, and complications from FFP administration including anaphylaxis, blood-borne infections, and transfusion-related acute lung injury.

Bleeding

Bleeding in hematologic malignancies is a common cause of morbidity and mortality. DIC and thrombocytopenia are common etiologies, but acquired clotting factor deficiencies can also predispose to life-threatening hemorrhage.

Disseminated Intravascular Coagulation

Acute DIC is a common cause of morbidity and mortality during the treatment of many hematologic malignancies and is especially characteristic of acute promyelocytic leukemia and to a lesser degree other forms of acute leukemia. Sepsis, especially gram-negative sepsis occurring in the setting of disease or treatment related neutropenia, is a common cause of DIC as well. Complicating the diagnosis of DIC is the frequent presence of hepatic failure due to malignant infiltration of the liver or treatment-related hepatotoxicity. Clinically, patients are at high risk for death from bleeding and can develop oozing from IV lines and surgical sites, purpura, pulmonary hemorrhage, intracranial hemorrhage, gastrointestinal bleeding, and multiple organ failure.

Acute DIC results from pathologic coagulation within small blood vessels, typically from the release of tissue factor or endotoxin exposure, leading to unmitigated activation of coagulation and consumption of coagulation factors and platelets. Depletion of clotting factors and platelets, activation of plasmin, and the production of anticoagulant fibrin split products can lead to severe bleeding. Laboratory hallmarks of acute DIC include thrombocytopenia, prolongation of clotting times, hypofibrinogenemia, elevated fibrin split products, and sometimes schistocytes on the peripheral blood smear.

The coagulopathy observed in APL resembles acute DIC but with some subtle differences [104]. In APL, leukemic cells produce tissue factor and high levels of a cysteine protease called cancer procoagulant, both of which are downregulated by ATRA treatment in primary and cultured leukemic APL blasts [105–109]. Tissue factor in conjunction with activated Factor VII activates Factor X, whereas cancer procoagulant can directly activate Factor X leading to pathologic coagulation [104,110]. In addition, rapid death of malignant cells leads to increased thrombin generation [111]. Unlike acute DIC, antithrombin and protein C levels are maintained in the coagulopathy of APL [112]. Increased fibrinolysis also complicates APL and can lead to bleeding. APL cells express both cell surface u-PA (urokinase-plasminogen activator) and t-PA (tissue-plasminogen activator). u-PA is transiently upregulated upon differentiation of leukemic cells with ATRA [113,114]. Dexamethasone administered with ATRA suppresses the upregulation of u-PA. Annexin II is highly expressed on leukemic promyelocytes and interacts with plasminogen and t-PA to increase plasmin production [115]. In addition, annexin II is highly expressed on cerebral endothelial cells potentially explaining the high rates of intracerebral hemorrhage in APL [116,117]. Notably, treatment with ATRA downregulates the expression of annexin II on leukemic promyelocytes [115,118].

Reversal of acute DIC requires effective treatment of the underlying cause. Supportive care includes early management of sepsis including the administration of broad-spectrum antibiotic coverage with anti-Pseudomonal activity in neutropenic patients and reversal of organ dysfunction when possible. In the setting of APL, early institution of ATRA combined with cytotoxic chemotherapy in high-risk patients with WBC $> 10{,}000$ per μL is indicated to reduce the burden of leukemic promyelocytes. DIC typically resolves within 48 hours of initiation of ATRA in this setting.

With acute DIC, frequent monitoring of complete blood count, prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen three to four times a day is prudent to monitor the consumptive process and guide replacement of platelets and coagulation factors. In patients with APL-associated DIC who are bleeding or who are at high risk of bleeding, maintenance of platelet count above 30,000 to 50,000 per μL and fibrinogen above 100 to 150 mg per dL with platelet and cryoprecipitate transfusions has been recommended [32]. Fresh frozen plasma also may be given to reduce the prolonged PT and PTT. By inhibiting thrombin and Factor Xa, low-dose heparin (4 to 5 U per kg per hour) could theoretically improve severe bleeding in acute DIC by limiting fibrinogen and platelet consumption, plasminogen activation, and fibrin split product production. Results of clinical studies, however, have been equivocal, and routine use of heparin to prevent or treat acute DIC-related bleeding is not universally standard [104,119–121]. Conversely, thrombosis may occur in acute DIC, and in this setting, the administration of low-dose heparin may beneficial [122,123].

Thrombocytopenia

Thrombocytopenia in patients with hematologic malignancies can be caused by bone marrow infiltration by malignant cells, myelosuppression from chemotherapy and other medications, bacterial sepsis, acute DIC, immune thrombocytopenia and/or hypersplenism from splenomegaly. The risk of major

hemorrhage dramatically increases at platelet counts less than 5,000 per μL and the use of prophylactic platelet transfusions, starting in the 1970s, typically with a transfusion threshold of 20,000 per μL, reduced the frequency of fatal bleeding in this population to less than 1%. However, this strategy led to an increased demand for platelet concentrates [124,125].

The issue of the optimal platelet count to trigger a prophylactic platelet transfusion has been addressed. A 2004 Cochrane Database systematic review included three prospective randomized studies comparing prophylactic platelet transfusions at platelet counts of 10,000 per μL versus 20,000 per μL. None of these studies showed significant differences in severe bleeding events or mortality but the studies were small and possibly underpowered to show noninferiority of the lower transfusion threshold [125]. Current studies suggest that the risk of spontaneous hemorrhage in patients without concomitant coagulopathy or acute DIC, platelet dysfunction, fever, mucositis or uncontrolled hypertension is acceptable until platelets are below 10,000 per μL. Safely minimizing the platelet dose per prophylactic transfusion has recently been studied. A 2010 study randomized 1,272 patients undergoing chemotherapy or HSCT for hematologic and nonhematologic malignancies to receive 1.1×10^{11}, 2.2×10^{11}, or 4.4×10^{11} platelets per square meter of body surface area to be given prophylactically for platelet counts less than 10,000 per μL. The lowest dose group required fewer platelets overall but required more transfusions (five versus three per patient per treatment course). Bleeding rates of all grades were similar between the groups with no deaths from hemorrhage in the low- and medium-dose groups supporting the use of low-dose platelet transfusions [126]. Avoiding drugs that cause platelet dysfunction (especially aspirin, nonsteroidal anti-inflammatory agents [NSAIDs], Cox-2 inhibitors, and clopidogrel), treating underlying coagulopathy and reversing renal dysfunction are important adjuncts to preventing bleeding in thrombocytopenic patients as well.

Acquired von Willebrand Syndrome

The acquired von Willebrand syndrome (aVWS) results from a reduction in the level of von Willebrand factor (VWF) and may rarely occur in monoclonal gammopathy of undetermined significance (MGUS), Waldenstrom macroglobulinemia, multiple myeloma, non-Hodgkin lymphomas, and myeloproliferative neoplasms, especially essential thrombocythemia [127–130]. Treatment of the underlying malignancy to decrease tumor burden or reduce elevated platelet counts is generally effective in resolving acquired von Willebrand disease. Management may include platelet apheresis in the setting of extreme thrombocytosis and active bleeding [131]. High-dose IVIG (dose, 1 g per kg per day for 2 days) may be considered in patients with lymphoid neoplasms who have inhibitory antibodies to VWF [99,100,132,133]. For treatment of acute bleeding, desmopressin (dose, 0.03 μg per kg IV) or purified plasma-derived vWF/FVIII concentrates may be considered [132]. Aspirin and NSAIDs should be avoided until the aVWS has resolved.

Pulmonary Complications

Mechanical ventilation is associated with poor outcomes in patients with hematologic malignancies. Mortality ranges from 39% to 82%, although most studies of respiratory failure in patients with hematologic malignancies are retrospective and have failed to match mechanically ventilated and nonventilated patients for degree of respiratory compromise. Hampshire et al. retrospectively studied 7,689 cases of hematologic malignancies requiring ICU admission in England, Wales, and Northern Ireland. When matched for PaO_2:FiO_2 ratios, mechanically ventilated hematologic malignancy patients had reduced mortality compared with nonventilated hematologic malignancy patients (mortality 67% vs. 85% for PaO_2:FiO_2 < 100 mm Hg, 50% vs. 69% for PaO_2:FiO_2 100 to 199 mm Hg)[2]. In a smaller study, invasive mechanical ventilation within 24 hours after ICU admission was associated with lower mortality rates compared with patients receiving noninvasive positive pressure ventilation [12]. After HSCT, however, patients who require mechanical ventilation appear to fare less well. Short-term mortality is 82% to 96% and worsens to 98% to 100% in the setting of combined renal and hepatic failure [101]. Only 9% to 14% of mechanically ventilated HSCT patients are alive 6 months after ICU admission [93,101].

Diagnostic approaches to identify the etiology of respiratory failure include blood cultures, blood and urine infectious serologies, diagnostic imaging, bronchoscopy, and surgical lung biopsy. Flexible bronchoscopy with bronchoalveolar lavage (BAL) detects pulmonary infections in approximately 50% of patients with hematologic malignancies presenting with respiratory deterioration leading to a change in antimicrobial therapy in 38% of patients [94,95]. In one study there was no survival advantage to BAL and respiratory deterioration requiring mechanical ventilation occurred in 36% of patients as a short-term consequence of BAL highlighting the need for careful patient selection and the broad use of noninvasive diagnostic tests prior to pursuing BAL [95]. In two retrospective studies of surgical lung biopsy among hematologic malignancy patients with unexplained pulmonary infiltrates, a specific diagnosis was made in 62% to 67% of patients and led to change in therapy 40% to 57% of the time. A specific diagnosis was significantly associated with decreased mortality in both studies (absolute reduction in mortality, 29% to 33%) [103,134].

Infection is the most common identifiable cause of respiratory distress in hematologic malignancies. Pulmonary hemorrhage, diffuse alveolar damage, pulmonary embolism, and congestive heart failure are the most common identifiable noninfectious causes. Pulmonary infections are typically due to *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and streptococcal species with *Legionella pneumophila* and mycobacterial infections being less common pathogens. Prolonged neutropenia from underlying disease or myelotoxic chemotherapy places patients at risk for mycelial fungal pneumonia with *Aspergillus* spp being the most common offenders. Patients with lymphoid malignancies and those treated with allogeneic HSCT are also at risk for *Pneumocystis jiroveci* pneumonia and viral pneumonias including cytomegalovirus infection. Effective antimicrobial treatment can be difficult in this group of patients as mixed infections and antimicrobial resistance are common [135,136]. Ganciclovir and related antiviral agents in combination with IV immunoglobulin have reduced the mortality of CMV pneumonia in HSCT patients [137].

Noninfectious etiologies of respiratory failure in patients with hematologic malignancies, including those undergoing HSCT, include cardiogenic pulmonary edema, diffuse alveolar hemorrhage, engraftment syndrome, idiopathic pneumonia syndrome, bronchiolitis obliterans syndrome (BOS), cryptogenic organizing pneumonia, granulomatous inflammation and malignant infiltration of the lungs. Chemotherapeutic agents such as carmustine (BCNU), busulfan, and bleomycin are known to cause lung injury. ICU patients with hematologic malignancies are also at high risk for pulmonary embolism given immobility, active malignancy, and frequently DIC.

Diffuse alveolar hemorrhage (DAH) accounts for 20% to 30% of pulmonary complications after allogeneic HSCT [138] and is a cause of early death in 1.5% of patients with APL [33]. DAH occurs with hematopoietic engraftment in allogeneic HSCT patients and presents with cough, hemoptysis, declining hemoglobin, and hypoxemia with diffuse alveolar filling on lung imaging. Serial lavage during BAL shows increasingly bloody fluid return. Treatment for DAH includes

replacement of platelets and coagulation factors to maintain hemostasis, supportive mechanical ventilation as needed, and corticosteroids. Small retrospective studies support the use of high-dose corticosteroids (methylprednisolone 30 to 1,500 mg per day) for treatment of DAH after allogeneic HSCT [139–141]. Administration of parenteral recombinant activated factor VII has been associated with resolution of DAH occurring after HSCT in several case reports [142–147].

In addition to DAH, early onset noninfectious pulmonary complications after allogeneic HSCT include pulmonary engraftment syndrome and idiopathic pneumonia syndrome. Pulmonary engraftment syndrome mimics DAH and is characterized by fever, pulmonary infiltrates, hypoxia, and a skin rash developing early after HSCT, coinciding with recovery of circulating neutrophils (ANC > 500 per μL). It is typically a self-limited process lasting 1 to 2 weeks that is treated with supportive care and a short course of standard-dose corticosteroids [118]. Idiopathic pneumonia syndrome (IPS), which occurs in about 10% of HSCT patients, presents with fever, cough, shortness of breath, hypoxemia, and diffuse bilateral pulmonary infiltrates without an identifiable infection by BAL. IPS occurs after hematopoietic engraftment with a median onset of 21 to 52 days after HSCT and carries a 60% to 90% mortality [117,148,149]. Pathologically the syndrome is characterized by an interstitial infiltrate comprised primarily of lymphocytes. In a study of 15 patients with IPS, the combination of etanercept, a tissue necrosis factor-alpha (TNF-alpha) antagonist, and corticosteroids given at 2 mg per kg daily (methylprednisolone equivalent) resulted in 10 complete responses and a 28-day survival of 73% [150].

Late-onset noninfectious pulmonary complications after HSCT typically occur more than 3 months after stem cell infusion and include BOS and cryptogenic-organizing pneumonia (COP, formerly referred to as bronchiolitis obliterans with organizing pneumonia). BOS occurs in 14% of allogeneic HSCT patients with chronic graft-versus-host disease (cGVHD). BOS is a manifestation of cGVHD whereby alloreactive donor T-cells generate fibromuscular proliferation of the walls of small airways. This produces an obstructive physiology with air trapping and occasionally the need for supplemental oxygen. There is no standard treatment for BOS beyond immunosuppression for cGVHD, although investigations are ongoing combining aerosolized corticosteroids with azithromycin and montelukast (a leukotriene receptor antagonist). COP tends to occur late after allogeneic HSCT and demonstrates restrictive pulmonary physiology. COP is associated with GVHD and may be a manifestation of the disease itself. Some insult triggers inflammation of the small airways causing a proliferative bronchiolitis and deposition of cellular matrix materials into alveoli leading to hypoxemia. Unlike BOS, COP is reversible and corticosteroid responsive [151].

Common pulmonary processes complicating hematologic malignancies are summarized in Table 115.2.

Infection

Chemotherapy for high-grade hematologic malignancies commonly causes neutropenia (phagocytic immunocompromise) and cellular and/or humoral immunosuppression. For uncertain reasons, AML patients retain adequate cellular and humoral immunity even during periods of severe bone marrow suppression. Neutropenic patients are susceptible to infections by endogenous skin, genitourinary and gastrointestinal tract flora as well as hospital-acquired infections including nosocomial and ventilator-associated pneumonias, central venous line infections, *Clostridium difficile* colitis, and infections with *Pseudomonas* spp, *Stenotrophomonas* spp, *Burkholderia* spp, vancomycin-resistant enterococcus, methicillin-resistant *S. aureus*, and extended spectrum beta-lactamase-producing Gram-negative organisms. Prolonged neutropenia, especially with concomitant corticosteroid administration or diabetes mellitus, places patients at risk for invasive fungal infections, especially *Aspergillus* spp. Immunosuppressed patients, particularly those with lymphoid malignancies and those undergoing allogeneic HSCT, are at additional risk for opportunistic infections such as *P. jiroveci*, herpes simplex virus, varicella zoster virus, and cytomegalovirus. Treatment of febrile patients with neutropenia or immunosuppression involves rapid evaluation for infectious causes and initiation of empiric broad-spectrum antibiotic therapy with adequate coverage of *Pseudomonas aeruginosa* and methicillin-resistant *S. aureus*. For patients with persistent fever and prolonged neutropenia (>7 days), the addition of antifungal therapy targeting *Aspergillus* spp is indicated. Afebrile neutropenic patients with an absolute neutrophil count less than 500 per μL should receive daily prophylactic treatment with a fluoroquinolone antibiotic. A meta-analysis of 95 trials including 52 trials using fluoroquinolone prophylaxis showed that neutropenic patients receiving fluoroquinolone prophylaxis had significant decreases in all cause mortality, infection-related mortality, fever and documented infection with a nonsignificant trend toward increasing antimicrobial resistance [152]. The use of granulocyte stimulating growth factors (e.g., G-CSF) in patients receiving myelotoxic chemotherapy reduces total days of neutropenia and hospital length of stay without promoting tumor cell growth or affecting overall survival [153].

Differentiation Syndrome

Differentiation syndrome (DS), formerly referred to as retinoic acid syndrome, is a potentially fatal process of unclear mechanism (likely, detrimental cytokine storm) that occurs in 2% to 27% of APL patients treated with ATRA or arsenic trioxide [154]. Symptoms include fever, peripheral edema, weight gain more than 5 kg, pleuropericardial effusions, shortness of breath, interstitial pulmonary infiltrates, acute renal failure and hypotension after initiating APL treatment with the differentiating agents ATRA or arsenic trioxide. The diagnosis requires at least two of the above findings. Moderate DS is defined as having two to three of the above findings whereas severe DS has four or more findings [155]. Elevation of liver transaminases may also occur. Symptoms can develop at any time within the first 4 weeks of treatment with highest incidences in the first and third weeks of treatment. Risk factors for the development of severe DS include WBC > 5,000 per μL and elevated serum creatinine [154].

The diagnosis of DS is difficult at times as frequent complications of APL and its treatment, such as pneumonia, pulmonary hemorrhage, heart failure, acute renal failure, and sepsis, can mimic the syndrome. Early consideration of DS is important, however, so that prompt treatment with dexamethasone can be initiated. In both moderate and severe cases, dexamethasone is given at 10 mg PO or IV twice a day. Although no controlled studies of dexamethasone treatment have been published, since the inception of this practice the mortality rate from differentiation syndrome has dropped to less than 1% in recent studies. In moderate cases, ATRA and/or arsenic trioxide can be continued safely with close monitoring for worsening symptoms. In severe cases, ATRA and/or arsenic trioxide are held until symptoms resolve at which point it is generally safe to resume treatment. Administration of chemotherapy early in ATRA treatment has been shown to reduce the incidence if differentiation syndrome [156]. Patients with high suspicion of APL and a WBC > 10,000 per μL should be treated immediately with cytotoxic chemotherapy in addition to ATRA prior

TABLE 115.2

FREQUENTLY ENCOUNTERED PULMONARY COMPLICATIONS IN HEMATOLOGIC MALIGNANCIES

Complication	Context	Timing	Diagnosis	Management
Infection	Neutropenia	Variable: ≤7 days of neutropenia: bacterial, *Candida* spp >7 days of neutropenia: bacterial, fungal including *Aspergillus* spp	Blood cultures, fungal serologies, BAL, lung biopsy (transbronchial, VATS, open) CXR/CT/HRCT	Empiric antimicrobials may include coverage of MRSA, GNRs, *Pseudomonas* spp, typical and atypical bacterial pathogens, *Candida* spp, *Aspergillus* spp
	HSCT	After engraftment: viral including CMV, RSV, Herpesviridae, fungal, bacterial, mycobacterial, *Pneumocystis jiroveci*	Blood cultures, fungal serologies, respiratory virus DFA and PCR, CMV PCR (blood), BAL, lung biopsy (transbronchial, VATS, open) CMV shell culture, viral PCR, fungal, bacterial and mycobacterial cultures with BAL and lung biopsy CXR/CT/HRCT	Prophylaxis: Herpesviridae: Acyclovir/valacyclovir. PCP: TMP/SMX, dapsone, atovaquone or inhaled pentamidine Treatment: Empiric coverage of MRSA, GNRs, *Pseudomonas* spp, typical and atypical bacterial pathogens, *Candida* spp, *Aspergillus* spp pending diagnosis Targeted therapy for diagnosed infection
Diffuse alveolar hemorrhage	DIC, APL	Anytime until DIC resolves	Cough, hemoptysis, hemoglobin drop CXR/CT/HRCT: Diffuse ground glass opacities, consolidations BAL: Increasingly bloody return on serial lavage	DIC: Treat underlying cause Platelet goal >50,000/μL Fibrinogen goal >100–150 mg/dL HSCT: High-dose corticosteroids, platelet goal >50,000/μL, correct coagulopathy, consider recombinant activated factor VII
	HSCT	First 3–4 wk after transplant, around engraftment		
Drug toxicity	HSCT (Carmustine, Busulfan) Busulfan	3 mo–2 y after exposure	CXR/CT/HRCT: Ground glass opacities, interstitial pneumonitis PFTs: Decreased DLCO	Corticosteroids, supportive care
Pulmonary engraftment syndrome	HSCT	At count recovery (ANC >500/μL)	Associated findings: fever, rash	Self-limited lasting 1–2 wk Corticosteroids
Idiopathic pneumonia syndrome	HSCT	3 wk–4 mo after HSCT	CXR/CT/HRCT: Interstitial pulmonary infiltrate	Corticosteroids Consider etanercept
Cryptogenic organizing pneumonia	HSCT	Late (>100 d after HSCT)	CXR/CT/HRCT: Bilateral patchy alveolar filling, areas of ground glass opacities and consolidation PFTSs: Restrictive physiology	Corticosteroid responsive Reversible
Bronchiolitis obliterans syndrome	HSCT, chronic GVHD	Late (>100 d after HSCT)	CT/HRCT: Air trapping, bronchiolitis PFTs: Obstructive physiology	Treat underlying GVHD Irreversible, corticosteroids may slow progression

BAL, bronchoalveolar lavage; VATS, video-assisted thoracoscopic surgery, CXR, chest X-ray; CT, computed tomography; HRCT, high-resolution computed tomography; MRSA, methicillin-resistant *Staphylococcus aureus*; GNR, Gram-negative rod; HSCT, hematopoietic stem cell transplant; CMV, cytomegalovirus; RSV, respiratory syncytial virus; DFA, direct fluorescence assay; PCR, polymerase chain reaction; PCP, *Pneumocystis jiroveci pneumonia*; TMP/SMX, trimethoprim/sulfamethoxazole; DIC, disseminated intravascular coagulation; APL, acute promyelocytic leukemia; PFTs, pulmonary function tests; DLCO, diffusing capacity; ANC, absolute neutrophil count; GVHD, graft-versus-host disease.

to molecular diagnosis as these patients are at especially high risk for severe differentiation syndrome and death during induction therapy [157]. Even with improved recognition and treatment, 26% of patients in the LPA96 and LPA99 trials developing severe DS died during induction therapy, 11% from DS alone [154].

Therapeutic Agents

Treatment of aggressive hematologic malignancies typically requires toxic, myelosuppressive chemotherapy regimens. Patients are prone to life-threatening bacterial and

TABLE 115.4

SELECTED EVIDENCE-BASED APPROACHES FOR HEMATOLOGIC MALIGNANCIES

Clinical relevance	Comparison	Results	Reference
ICU outcomes			
Patients with hematologic malignancies have similar mortality to nononcologic patients when matched for disease severity.	Retrospective study of 101 consecutive ICU admissions of patients with hematologic malignancies vs. 3,808 nononcologic admissions.	Mortality of hematologic malignancy and nononcologic patients similar when matched for SAPS II score (OR = 0.59, 95% CI = 0.32–1.08, $p = 0.09$).	[1]
Hyperleukocytosis			
Improved short-term but not long-term survival with leukapheresis in hyperleukocytic AML.	Retrospective analysis of leukapheresis in 53 vs. no leukapheresis in 28 AML patients with hyperleukocytosis (WBC > 100,000/μL).	Reduced 21-day mortality in leukapheresis group vs. no leukapheresis (16% vs. 32%, $p = 0.015$). No difference in overall survival (median 6.5 vs. 7.5 months).	[88]
Prophylactic platelet transfusion			
Equivalent bleeding rates with platelet transfusion threshold 10,000/μL vs. 20,000/μL.	Meta-analysis of three prospective randomized trials.	No difference in mortality, remission rates, severe bleeding events or RBC transfusion requirements between two threshold levels. Studies potentially underpowered.	[125]
Noninvasive positive pressure ventilation			
Improved survival with addition of noninvasive positive pressure ventilation to standard care alone in patients with early hypoxemia.	Prospective, randomized trial of 52 immunosuppressed patients with fever, pulmonary infiltrates, and early hypoxemic respiratory failure treated with NIPPV vs. supplemental oxygen-based therapy alone.	NIPPV superior to supplemental oxygen based therapy alone for incidence of endotracheal intubation (2 vs. 20 patients, $p = 0.03$), serious complications (13 vs. 21, $p = 0.02$), death in the ICU (10 vs. 18, $p = 0.03$) and death in the hospital (13 vs. 21, $p = 0.02$).	[185]
Invasive ventilation			
Improved survival with early intubation of hypoxemic patients.	Retrospective analysis of 166 consecutive admits requiring mechanical ventilation with NIPPV vs. IMV.	Intubation within 24 hours of ICU admission associated with improved survival (OR = 0.29, 95% CI = 0.11–0.78). Survival equivalent between NIPPV and IMV when matched for SAPS II score.	[12]
Prophylactic antibiotics during neutropenia			
Use of prophylactic antibiotics in afebrile neutropenic patients improves survival and supports use of fluoroquinolone prophylaxis.	Meta-analysis of 100 trials (10,275 patients).	Compared to placebo, antibiotic prophylaxis associated with reduced risk of death (RR = 0.66, 95% CI = 0.54–0.81), infection related death (RR = 0.58, 95% CI = 0.45–0.74) and fever (RR = 0.52, 95% CI = 0.37–0.84). Fluoroquinolone prophylaxis with reduced all-cause mortality (RR = 0.52, 95% CI = 0.37–0.84).	[152]
Growth factors for neutropenia			
G-CSF shortens duration of neutropenia without improving overall survival.	Prospective, randomized trial of G-CSF vs. placebo following AML induction chemotherapy.	Neutrophil recovery 15% earlier in G-CSF treated patients ($p = 0.014$). No difference in complete remission rates or 6-mo survival.	[186]
Differentiation syndrome			
Early institution of chemotherapy after starting ATRA for APL reduces the incidence of differentiation syndrome.	Randomized, prospective analysis of rates of differentiation syndrome in APL patients with WBC < 5,000/μL treated with ATRA until complete remission followed by chemotherapy vs. ATRA with chemotherapy starting day 3.	Incidence of differentiation syndrome 18% in ATRA with delayed chemotherapy vs. 9.2% in ATRA with early chemotherapy ($p = 0.035$).	[156]

SAPS II, simplified acute physiology score II; AUC, area under the curve; CI, confidence interval; NIPPV, noninvasive positive pressure ventilation; IMV, invasive mechanical ventilation; OR, odds ratio; RR, relative risk; G-CSF, granulocyte colony-stimulating factor; ATRA, all-trans-retinoic acid; APL, acute promyelocytic leukemia.

fungal infections as a result of prolonged neutropenia, bleeding from thrombocytopenia, and organ failure from the toxic effects of chemotherapy. Selected toxicities of agents commonly used in the treatment of hematologic malignancies and their management are supplied in Table 115.3.

Additional complications of malignant hematologic diseases or their treatment, including tumor lysis syndrome and malignant epidural cord compression, are discussed in detail in Chapter 116.

Selected evidenced-based approaches for managing patients with hematologic malignancies are presented in Table 115.4.

CHAPTER 116 ■ ONCOLOGIC EMERGENCIES

DAMIAN J. GREEN, JOHN A. THOMPSON AND BRUCE MONTGOMERY

The clinical presentation of oncologic emergencies has not changed dramatically over the past 50 years; however, the efficacy and variety of therapeutic interventions have improved considerably. Because a patient's prognosis has a significant impact on the choice of treatments, it is of paramount importance for the intensivist and the care team to determine the following: (a) Is the clinical scenario truly emergent? (b) Is the syndrome related to malignancy, a side effect of treatment, or a benign process? (c) What is the specific tumor type that is responsible for the syndrome? (d) What is the stage of disease? (e) What studies are necessary to establish the diagnosis? (f) What are the wishes of the patient and family? The prognostic implications and the expected impact of treatment can then be weighed and appropriate therapy instituted or modified.

SUPERIOR VENA CAVA SYNDROME

Physiology

The superior vena cava (SVC) syndrome develops as a result of impaired blood return through the SVC to the right atrium. Obstruction results in venous hypertension, with the severity of ensuing signs and symptoms dependent on the site of obstruction and the rapidity with which the block occurs. The SVC is formed by the union of the left and right brachiocephalic veins in the middle third of the mediastinum and extends inferiorly

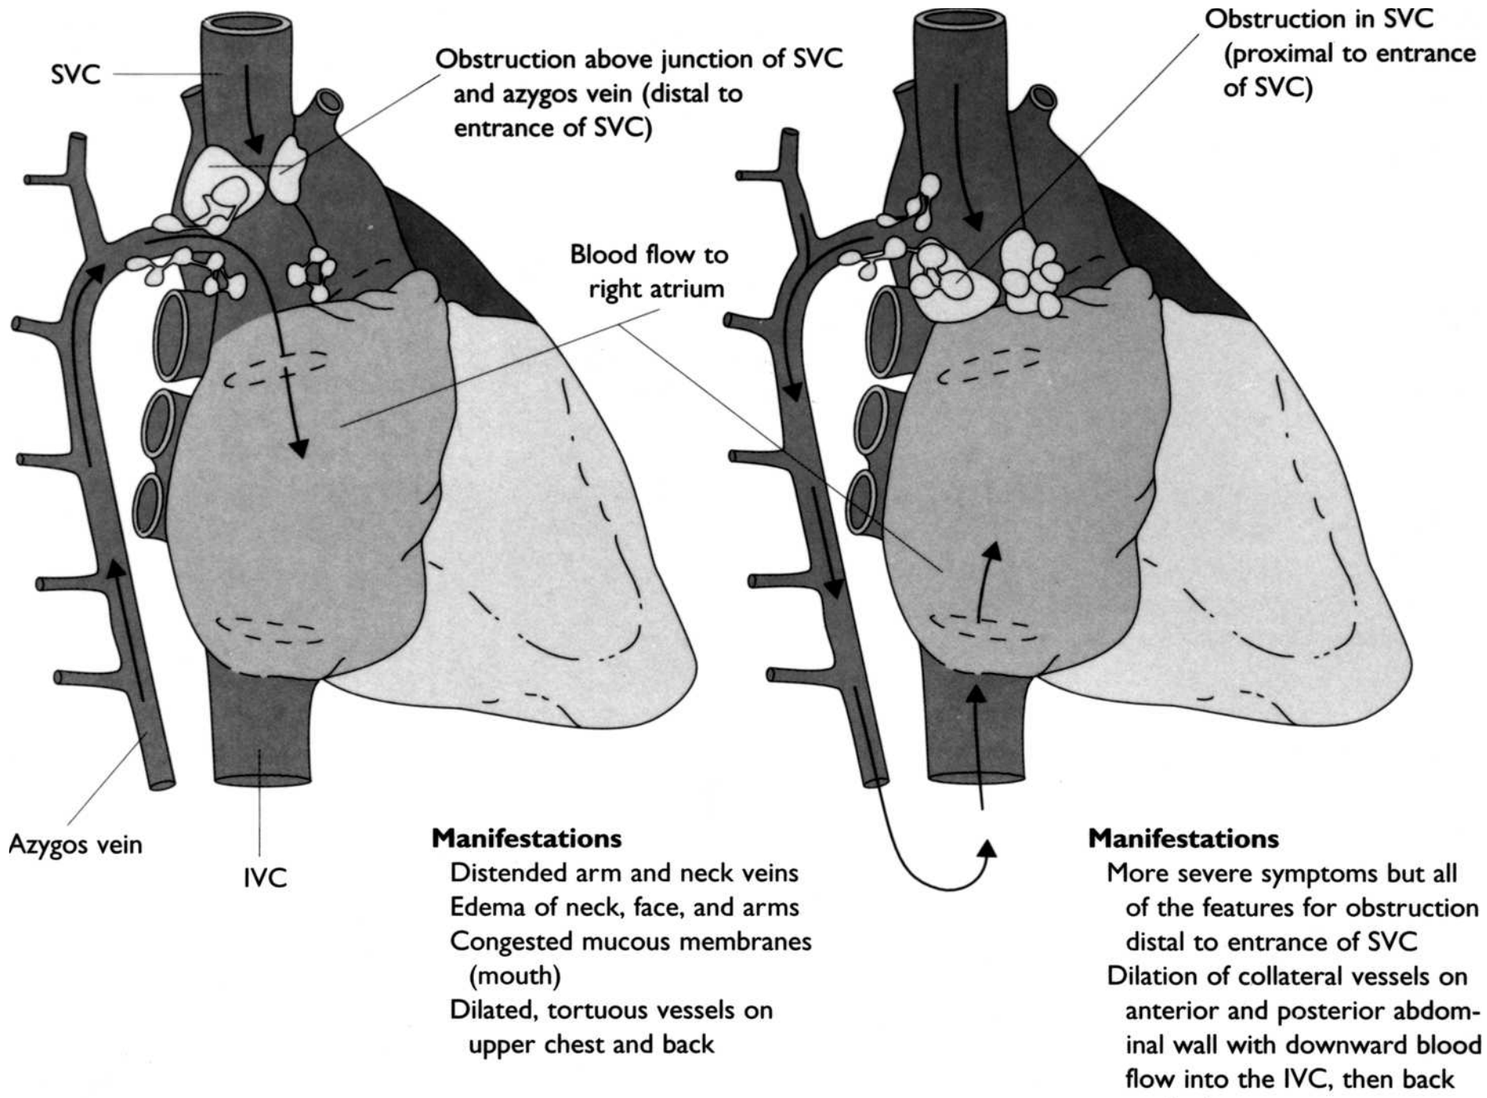

FIGURE 116.1. Anatomic locations of superior vena cava (SVC) obstruction leading to the SVC syndrome. IVC, inferior vena cava. [Reprinted from Skarin AT (ed): *Atlas of Diagnostic Oncology*. 2nd ed. St. Louis, Mosby, 1996, with permission.]

for 5 to 8 cm, terminating in the right atrium (Fig. 116.1). The SVC serves as the principal venous drainage for the head, neck, and upper extremities. The major collateral, the azygous vein, joins posteriorly just over the right mainstem bronchus and drains the posterior thorax. The SVC is thin walled and is bounded by the mediastinal parietal pleura and the right paratracheal, azygous, hilar, and subcarinal lymph nodes. As a result, it is extremely susceptible to extrinsic compression by adjacent lymph nodes or the aorta, with subsequent stasis, occlusion, or thrombosis. If obstruction occurs distal to the azygous vein, collateral flow through the azygous can adequately compensate for diminished return. However, if the obstruction is proximal to the azygous, flow must completely bypass the SVC and return via internal mammary, superficial thoracoabdominal, and vertebral venous systems to the inferior vena cava. This more circuitous route results in significantly higher venous pressures. The trachea and bronchi of children are smaller and significantly more susceptible to extrinsic compression, increasing the risk of fatal complications.

Etiology

The vast majority of patients with SVC syndrome have bronchogenic carcinoma, most commonly of the small cell histology (Table 116.1). Non-Hodgkin lymphoma, breast cancer, and other neoplasms make up the remainder of the malignant causes. Despite a high frequency of mediastinal involvement, Hodgkin lymphoma patients rarely present with SVC compression. Benign causes of SVC syndrome make up 6% to 20% of all cases and include thrombosis due to indwelling intravenous catheters or pacemakers and granulomatous disease [1,2]. Infectious causes of the SVC syndrome decreased substantially with the advent of antibiotics but must be considered in the differential diagnosis for patients from endemic areas or with potential human immunodeficiency virus infection. Blastomycosis, actinomycosis, histoplasmosis, tuberculosis, nocardia, and syphilis occasionally cause fibrosing mediastinitis and aortitis leading to SVC syndrome. An extensive list of rare causes may include idiopathic mediastinal fibrosis, goiter, thymoma, Behçet's syndrome, sarcoidosis, prior radiation with local vascular fibrosis, and unusual metastases of common malignancies.

Clinical Manifestations

The presentation of SVC syndrome depends largely on the acuity of the obstruction to flow. In patients with benign causes, extensive collateral flow often develops that minimizes symptoms

TABLE 116.1

PRIMARY DIAGNOSIS IN 125 CASES OF SVC SYNDROME

Histology	% of Cases	Total (%)
Lung carcinoma		79
Small cell	34	
Squamous cell	21	
Adenocarcinoma	14	
Large cell/other	11	
Lymphoma		14
Non-Hodgkin's lymphoma	13	
Hodgkin's lymphoma	0.8	
Other malignancy		6
Adenocarcinoma	3	
Kaposi's sarcoma	0.8	
Seminoma	0.8	
Acute myelomonocytic leukemia	0.8	
Leiomyosarcoma	0.8

for months to years. Acute compression by tumor or thrombosis does not allow time for collateralization, and venous hypertension inevitably induces symptoms. Symptoms include dyspnea, edema of the face, neck, upper torso, and extremities; and cough. In rare instances, patients complain of hoarseness, syncope, headaches, chest pain, or dysphagia due to esophageal compression. Physical signs include jugular venous distention, edema of the face or upper extremities, dilated venous collaterals, plethora, and tachypnea and, in rare instances, papilledema or stridor.

Diagnosis

Initial evaluation should include a chest radiograph and contrast enhanced computed tomography (CT) to confirm the clinical diagnosis, identify a potential etiology, and localize the obstruction. Venography or magnetic resonance imaging (MRI) may be appropriate in subsequent evaluation to better define the extent of obstruction, particularly if stenting of the obstruction is considered (Fig. 116.2). Of note, focal hepatic contrast enhancement on CT has been noted in patients with SVC syndrome due to collateralization through patent remnants of the umbilical vein or of the musculophrenic venous system [3]. These abnormalities could be mistaken for metastatic disease and should be further evaluated in patients in whom therapy would be changed in the presence of isolated metastases. If a malignant cause of SVC obstruction is considered, all reasonable efforts should be made to obtain diagnostic material, as treatment depends on the underlying histology. The approach may include sputum cytology, bronchoscopy, transthoracic needle aspiration, biopsy of palpable lymph nodes, mediastinoscopy, thoracotomy, or video-assisted thoracoscopy. Despite concerns regarding surgical complications, morbidity associated with surgical procedures necessary to procure a diagnosis is not substantially different from that in patients without SVC syndrome [1,4]. The rapidity of the diagnostic workup depends on the likelihood of morbid complications at the time of presentation. Most series suggest that patients with malignant SVC syndrome have had symptoms an average of 45 days before presentation, and the vast majority of patients with malignancy do not die of SVC syndrome but of other complications of their disease [1]. The significant complications of SVC syndrome are tracheal obstruction and cerebral edema, and fatalities from cerebral edema are extremely rare. Therefore, the truly emergent situation in adults is a patient who presents with stridor or other evidence of significant airway compromise or the rare patient with cerebral edema. In essentially all other settings, treatment should be instituted only after the malignant or benign cause of the syndrome has been established because outcome is not compromised by delay for appropriate evaluation.

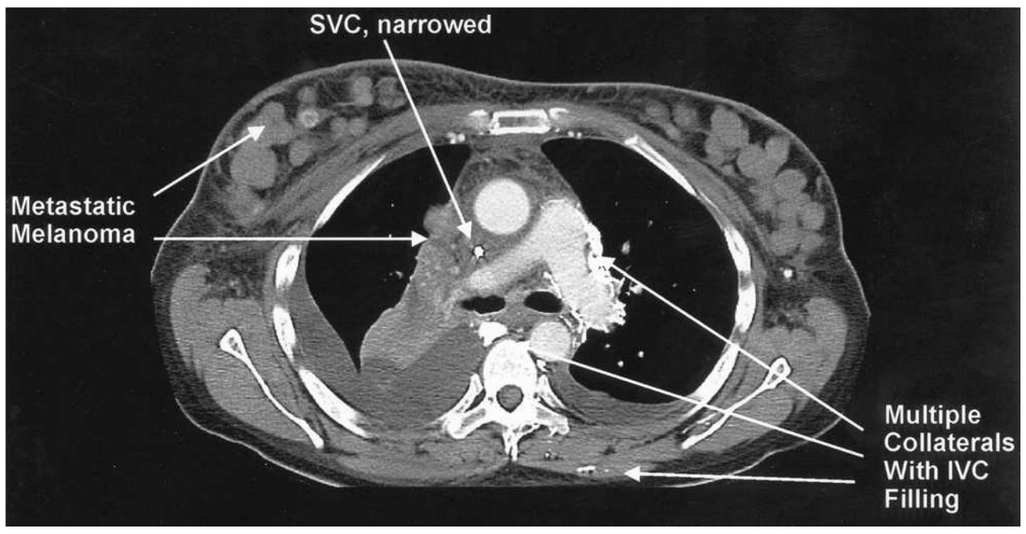

FIGURE 116.2. Upper extremity contrast injection demonstrating severe narrowing of the superior vena cava (SVC) with the development of multiple collaterals and inferior vena cava (IVC) filling.

Treatment

Once the diagnosis is established, initiation of therapy depends on the etiology, the severity of symptoms, the acuity of presentation, and the goals of treatment. If patients are minimally symptomatic, the azygous is patent, and treatment is focused on palliation, observation is a reasonable option. Chemotherapy is the treatment of choice for SVC syndrome due to small cell lung carcinoma, non-Hodgkin lymphoma, and germ cell tumors. Although radiation is often considered in addition to chemotherapy even in the palliative setting, 80% of these patients have a complete or partial response of their symptoms to chemotherapy alone [5]. Other histologies should be treated with endovascular stent placement, radiation therapy, or both. Radiation therapy prior to biopsy has been associated with a significant reduction in rates of histologic diagnosis and should be avoided [6]. Although external beam radiation effectively palliates symptoms in more than 70% of patients within 2 weeks [7], relapse after radiotherapy occurs in 15% to 30% of cases.

Endovascular stent placement, as a primary intervention, is a particularly attractive option for patients who lack a tissue diagnosis and whose symptoms on presentation require a rapid palliative intervention; including all patients, regardless of histology, who present with airway compromise or cerebral edema. In these patients, SVC stent placement provides rapid relief of symptoms (less than 48 hours) while awaiting response to systemic chemotherapy or radiation treatment. Responses to endovascular stent placement are durable (90% symptom free at time of death, versus 12% with palliative radiation) and the primary patency rates for malignant SVC syndrome are 50% to 100% [8]. Some authors have suggested a role for stent placement in first-line management of all SVC syndrome patients; however, no randomized controlled trials have been published [8].

Anticoagulation after stent placement is controversial, with some studies suggesting a high rate of thrombosis unless patients are anticoagulated, whereas other series, using no anticoagulation, report efficacy and thrombotic risk equivalent to those who use anticoagulation [9,10].

In patients with an established diagnosis, radiation therapy remains an appropriate intervention. Many fractionation protocols have been used, with the majority of patients receiving 30 Gy in 10 fractions, whereas patients treated with curative intent often receive 50 Gy in 25 fractions. Although high doses of radiation have often been given early in the treatment course to achieve rapid tumor response, there is little evidence to suggest that this is necessary [11]. In cases of SVC thrombosis with an indwelling catheter or pacemaker, thrombolytic agents may be useful as primary therapy or as an adjunct to stent placement [12]. The additional benefit of thrombolytics or anticoagulation in patients treated for malignant SVC syndrome is not well established.

Surgical resection and reconstruction of the SVC is reserved for patients with benign disease or the rare patient with tracheal obstruction in the setting of chemotherapy or radiotherapy-resistant disease.

SVC syndrome has been thought to predict for poor outcome. However, the presence of SVC syndrome is not a negative prognostic factor in small cell carcinoma and lymphoma independent of the stage and bulk of disease, and patients should be treated with curative intent if otherwise appropriate [13].

CARDIAC TAMPONADE

Physiology

Cardiac tamponade results from accumulation of fluid within the pericardium that impairs left ventricular expansion and diastolic filling. As stroke volume drops, compensatory tachycardia occurs to offset progressive hypotension. Ultimately, pressures equalize in the left atrium, pulmonary vasculature, right atrium, and SVC, and circulatory collapse ensues. As with SVC syndrome, the severity of symptoms is dependent on the speed of progression. Tamponade occurs when the pericardium cannot expand because fluid accumulation is too rapid or because the pericardium is thickened or fibrotic.

Etiology

Pericardial or cardiac involvement with malignancy occurs in 1% to 20% of patients with cancer and is often not diagnosed antemortem [14,15]. In up to 40% of unselected patients presenting with tamponade, malignancy is identified as the cause; the frequency with which tamponade develops as the initial manifestation of a patient's disease has led to standard cytologic examination of all significant effusions [16]. Tumors may involve the pericardium by direct extension from intrathoracic organs or hematogenous spread. Malignancies most often associated with pericardial effusions are lung, breast, lymphoma, and leukemia. Pericardial effusions in patients with cancer are due to pericardial or cardiac involvement in 60% of cases, with idiopathic pericarditis and radiation-induced pericarditis causing 32% and 10% of cases, respectively [17]. Other potential causes include infection, Dressler's syndrome, rheumatic disease, and hypothyroidism.

Clinical Manifestations

The common symptoms of pericardial effusion include dyspnea (85%), cough (30%), orthopnea (25%), and chest pain (20%). The common signs of pericardial effusion are jugular venous distention (100%), tachycardia (100%), pulsus paradoxus (89%), systolic blood pressure of less than 90 (52%), and pericardial rub (22%) [16]. Other signs of right- and left-sided heart failure may include hepatosplenomegaly, rales, peripheral edema, and ascites. Plain films demonstrate cardiac enlargement in at least half of all cases, and electrocardiography may reveal abnormalities suggestive of pericarditis (low-voltage, ST-segment elevation) or electrical alternans.

Diagnosis

Echocardiography is the most useful means of rapidly detecting hemodynamically significant effusions. Early signs include right atrial collapse and mitral regurgitation with later detection of left atrial or right ventricular collapse. Echocardiography also allows estimation of the volume, fluidity, and contents of the effusion, although it is difficult to distinguish tumor, thrombus, or fibrinous material from one another. The specificity of echocardiography for hemodynamic compromise has been called into question, and in many centers right heart catheterization with demonstration of equalization of pressures is required to diagnose tamponade physiology definitively. Emergent treatment of tamponade invariably involves drainage of the effusion, and cytologic evaluation of the fluid provides a very specific means of establishing a malignant etiology. The detection rate of pericardial fluid cytology ranges from 50% to 100%, and certain histologies, such as lymphoma and mesothelioma, are more difficult to demonstrate in pericardial fluid [14,18,19]. Pericardial biopsy is occasionally required to establish a diagnosis in difficult cases and can be performed under local anesthesia using a subxiphoid approach. The presence of a pericardial effusion correlates with a shortened survival among patients with cancer (median survival 15.1 weeks) and the definitive identification of neoplastic cells in the pericardial fluid by cytology portends an even worse prognosis (median survival 7.3 weeks) [20].

Treatment

Cardiac tamponade requires immediate treatment to relieve the increased end-diastolic pressure and inadequate ventricular filling. Oxygen, pressor agents, and intravenous fluids to improve cardiac output should be provided as appropriate. Inotropic agents are frequently ineffective however, because a state of intense adrenergic stimulation is already present [21]. When airway management is required, significant caution should be used because the positive intrathoracic pressure that results from initiation of mechanical ventilation places tamponade patients at particularly high risk for profound postintubation hypotension [21]. Emergent pericardiocentesis is indicated for significant hypotension, and it has been suggested that a pulse pressure of less than 20 mm Hg, a paradoxic pulse greater than 50% of the pulse pressure, or a peripheral venous pressure above 13 mm are other absolute indications for emergent intervention [22]. Fluid should be evaluated with cell counts, cultures, and cytology as noted earlier. Patients who present with malignant tamponade have recurrence after simple pericardiocentesis in 58% to 83% of cases [16,23]. Pericardial effusions without clinical tamponade may be observed if patients are asymptomatic or have minimal effusion (less than 1 cm), as progression to tamponade requiring pericardiocentesis in a single study was 20% for all patients, and progression of effusions of less than 1 cm in size to greater than 1 cm was only 4% [23]. Because of the high recurrence rate after pericardiocentesis in patients with tamponade, additional therapy is generally indicated if the patient's survival or quality of life would be otherwise compromised. Symptomatic relief with pericardiocentesis alone is 90% to 100%, with a complication rate of 3% [24]. Radiation therapy is noninvasive and allows treatment of the majority of the pericardium but carries a theoretical risk of radiation-induced pericarditis. As a single modality, radiation controls pericardial effusion in 67% of cases, with a particularly high success in hematopoietic tumors (93%). Systemic therapy is generally used only for diseases that are considered to be chemosensitive, such as breast cancer or lymphoma; in these individuals, it prevents recurrence in 73% of treated patients.

Instillation of sclerosing agents, radionuclides, and chemotherapy through indwelling catheters have been widely used with the intent to induce nonspecific inflammation with obliteration of the pericardial space or to achieve specific antineoplastic effects. Typically, a catheter is placed into the pericardial sac and drainage continued until output is less than 100 mL per day. Sclerosing agent or chemotherapy is injected into the catheter every 24 to 48 hours until fluid output is less than 25 to 50 mL per day, and the catheter is removed. A review of 20 different studies reported an overall control rate of 82% with common toxicities, including fever, pain, arrhythmias, and occasional cytopenias [24]. Tetracycline, which is no longer available, has the most extensive track record; however, doxycycline and minocycline have shown similar efficacy in malignant pericardial and pleural effusions. Chemotherapeutic agents that demonstrate response rates greater than 50%

include bleomycin, cisplatin, carboplatin, mitoxantrone, fluorouracil, and thiotepa [24–29]. In a randomized trial of 80 patients comparing intrapericardial bleomycin with observation alone following drainage, the 2-month failure free survival was 46% versus 29%; and median survival was 119 days versus 79 days for the groups, respectively. Because of the small size of this trial, these differences did not achieve statistical significance [30].

One small prospective trial ($n = 21$) comparing bleomycin with doxycycline showed bleomycin to be better tolerated, with less retrosternal pain and shorter periods of catheter drainage [28]. The use of sclerosing agents in the treatment of recurrent malignant pericardial effusions may result in an increased risk of both subsequent constrictive pericarditis and tamponade, leading some groups to favor the instillation of nonsclerosing chemotherapeutic agents [31]. In the absence of randomized studies, no single agent is accepted as the gold standard for intervention.

A surgical procedure or balloon catheter can be used to create a pericardial window to drain the fluid. This can be done by performing a subxiphoid pericardiotomy, thoracotomy or thoracoscopy with window, pleuroperitoneal window, or subcutaneous balloon pericardiotomy. These procedures control the effusion in 85% to 95% of patients [24,32–34]. An advantage of subxiphoid or balloon pericardiotomy is that both can be performed without general anesthesia, reducing operative morbidity.

Prognosis

The development of malignant pericardial effusion and tamponade usually reflects uncontrolled metastatic disease and portends a dire prognosis. Median survivals for patients treated for tamponade range from 3.3 to 4.5 months. Nonrandomized studies suggest that patients with lung and breast cancer have substantially better survival rates if systemic therapy can be instituted [35,36]. The decision to intervene in a patient with malignant cardiac tamponade depends on the patient's histology and sensitivity to treatment as well as the patient's condition. Patients for whom treatment of tamponade provides meaningful palliative benefit should be considered for the treatment that is likely to provide durable relief of symptoms with the minimum of morbidity and requirement for hospitalization.

MALIGNANT EPIDURAL CORD COMPRESSION

Few complications of malignancy are more dreaded than epidural cord compression. The associated pain, neurologic deficits, and dramatically impaired quality of life are serious problems for the patients who develop this condition and by extension for their families. Early recognition of the signs and symptoms of cord compression may prevent serious compromise in survival and functional capacity. *Epidural cord compression* is defined by compression of the dural sac and its contents by an extradural tumor mass. Minimum radiologic evidence for compression is indentation of the theca at the level of clinical features, which include pain, weakness, sensory disturbance, or evidence of sphincter dysfunction [37].

Physiology

Epidural cord compression by malignancy occurs as a result of metastasis or primary tumor involvement of the vertebral column, paravertebral space, or epidural space. Damage to the cord occurs when the tumor compromises the vertebral venous plexus or compresses neural tissue directly or when compromised bone impinges on the cord. The resulting vasogenic edema and hemorrhage induce further ischemic damage. The vertebral body is the most common source of compressive lesions, predominantly in the thoracic (70%), followed by the lumbar (20%) and cervical (10%) regions [38]. Tumor invasion through the intervertebral foramen and cord compression without bone involvement is most often seen with lymphoma, leading to normal plain films and radionuclide scans despite clinical compression. Multiple noncontiguous levels are involved in 10% to 40% of cases [39,40].

Data from Weissman DE, Gilbert M, Wang H, et al: The use of computed tomography of the spine to identify patients at high risk for epidural metastases. *J Clin Oncol* 3:1541–1544, 1985; Ruff RL, Lanska DJ: Epidural metastases in prospectively evaluated veterans with cancer and back pain. *Cancer* 63:2234–2241, 1989.

Etiology

The most common causes of malignant cord compression are tumors with a propensity for bony metastases, including breast and lung, followed by hematopoietic malignancy and gastrointestinal and genitourinary primaries [41,42] (Table 116.2). Cord compression afflicts 5% of patients during their course and is found in up to 10% of patients at autopsy. Benign causes of cord compression include stenosis, epidural abscess, or hematoma.

Clinical Manifestations

The cardinal sign of malignant cord compression is pain, present in 95% of patients at diagnosis. Weakness, autonomic dysfunction, and sensory changes are present in more than 50% of cases [43]. The pain is typically worse with recumbency, coughing, straining, or exercise. Radicular pain develops later and is an important localizing sign. Weakness, sensory loss, and incontinence are also late findings. Urinary retention alone is very rarely a presentation of cord compression. Duration of symptoms before severe cord compression and paralysis is remarkably variable, ranging from years to 24 to 48 hours.

Diagnosis

The diagnosis of cord compression relies primarily on MRI, given its sensitivity, speed, and the ability to detect compression at multiple levels. The utility of radionuclide studies and radiographs for predicting cord compression is dependent entirely

on the patient's disease status (known vs. initial diagnosis of malignancy), symptoms, and neurologic examination [44]. In fact, at least 20% of patients with malignancy, back pain, and cord compression have neither localizing neurologic signs nor abnormal radiographs and would be misdiagnosed without further imaging studies [44]. MRI allows evaluation of the entire neuraxis, is more sensitive for detection of paraspinal disease, and may demonstrate leptomeningeal and intramedullary disease. Because the risk of malignant cord compression at the site of plain film abnormalities in a symptomatic patient with malignancy is so high, it has been proposed to bypass MRI and to radiate the cord two segments above and below the defined lesion [41]. However, a prospective study analyzed the expected outcome with that approach compared with treatment planning on the basis of MRI and found that MRI changed the radiotherapy plan in 53% of patients [45]. These changes included 21% of patients in whom all paraspinal disease would not have been treated and 5% of those in whom additional levels of true cord compression would not have been treated. In 30% of patients, the demonstrated level of compression on MRI was more than two vertebral levels away from the level indicated by neurologic examination. If patients are unable to undergo MRI because of claustrophobia, the presence of metal implants, or access, myelography can be performed instead. CT scanning is superior to MRI for definition of vertebral body anatomy and may be useful before consideration of surgical intervention.

Treatment

Therapeutic options include corticosteroids, surgery, and radiation. In emergent situations, corticosteroids are generally given while awaiting MRI to decrease peritumoral edema and to prevent edema formation during radiation. On the basis of laboratory studies and a single randomized controlled trial that compared high-dose dexamethasone with radiation to radiation alone [46], some authors support the use of high-dose dexamethasone, defined as a 100-mg intravenous bolus followed by 96 mg per day tapered over a 2-week period. This approach is efficacious, but adverse side effects are reported in up to 30% of patients [47]. Alternatively, a more standard approach is 10 mg intravenously followed by 4 mg every 6 hours tapered over 2 weeks, especially in patients who are clinically stable. Ambulatory patients without progressive deficit may forgo steroids altogether during radiotherapy without undue risk [48]. Historically, radiation therapy and direct decompressive surgery were felt to be equally effective as initial interventions in patients with metastatic spinal cord compression. A recent randomized trial comparing direct decompressive surgery plus postoperative radiotherapy to radiotherapy alone revealed a statistically significant outcome benefit to the combined approach under certain conditions. Compared with patients who received radiotherapy alone, more patients who underwent surgery were able to walk after treatment (84% vs. 57%) and were ambulatory for a significantly longer duration (median: 122 days, versus 13 days) [49]. A secondary data analysis from this randomized trial revealed no benefit from surgical intervention for patients greater than 65 years of age [50]. First-line radiation therapy remains an important option for patients who are known to have highly radiosensitive tumors; nonsurgical candidates; patients with multiple areas of spinal cord compression; and those who experienced symptoms of total paraplegia for longer than 48 hours at presentation. Because surgical complication rates approach 20% [51], radiation therapy should generally be used as the first-line intervention in patients over age 65. Specific radiation treatment plans for cord compression vary between centers. The most common course is 30 Gy in 10 fractions over 2 weeks.

TABLE 116.3

INCIDENCE OF HYPERCALCEMIA IN ADVANCED MALIGNANCY

Histology	% Who develop hypercalcemia
Breast	19–30
Lung	10–35
Multiple myeloma	20–30
Head and neck	5–24
Renal	17

Prognosis

Early intervention is vital to preserving function. For patients who are ambulatory at the time of treatment, at least 80% remain ambulatory. The development of paraparesis decreases the ambulation rate to 50%, and patients who are paraplegic at the time of therapy recover ambulation only 10% to 19% of the time after radiation therapy alone [37,43,49,52–55]. In paraplegic patients, outcomes appeared to be better for individuals who were candidates for upfront surgical decompression (62% of patients randomized to combined surgery plus radiation regained the ability to walk compared with 19% of those who received radiation alone), the difference was statistically significant, but the sample size was small ($n = 32$) [49].

HYPERCALCEMIA

Hypercalcemia of malignancy (HCM) is the most common emergent metabolic disorder associated with cancer, affecting 10% to 20% of patients with malignancy at some time during their clinical course (Table 116.3). Diagnosis and timely interventions are life saving in the short term but also enhance patients' compliance with primary and supportive treatments and may improve quality of life.

Physiology

In healthy persons, vitamin D and parathyroid hormone (PTH) control absorption and mobilization of calcium. Calcitriol, the active form of vitamin D, enhances gastrointestinal absorption and mobilizes calcium from bone. PTH increases renal calcium resorption in the distal tubule and also mobilizes calcium from bone. In patients with HCM, increased calcium mobilization combines with renal insufficiency to cause symptomatic hypercalcemia. At least two mechanisms are proposed: direct osteolysis by tumor or increased osteoclastic resorption as a result of humoral mediators. Both mechanisms may be active in many patients. The parathyroid hormone-related protein (PTHrP) is postulated to play a role in the majority of patients with HCM, as levels are elevated in at least 80% of cases [56]. PTHrP is a 139 amino acid protein that may give rise to several peptides with differing biologic activities [57,58]. PTHrP appears to have important roles in calcium transport and developmental biology, and the N-terminal 13 amino acids share amino acid sequence and homology with intact PTH. PTHrP stimulates osteoblasts to produce receptor activator of nuclear factor-κB ligand (RANKL) which in turn activates osteoclast precursors and leads to both osteolysis and the release of bone-derived growth factors. These growth factors, including transforming growth factor-β and insulin like growth factor-1, are known to both promote tumor cell proliferation and further increase production of PTHrP, which then continues to drive renal

calcium reabsorption [59]. Circulating vitamin D metabolites may be increased in some lymphomas, enhancing intestinal calcium absorption and causing or exacerbating hypercalcemia [60].

Normal kidneys are capable of filtering and excreting four to five times the normal calcium concentration in the serum to maintain serum calcium homeostasis. PTHrP increases renal tubular resorption and osteolytic calcium release, causing rapid and persistent elevation of extracellular calcium. The subsequent calciuria and osmotic diuresis result in volume depletion. Decreased glomerular filtration limits the kidney's ability to filter and excrete calcium, and proximal tubular calcium and sodium reabsorption increase, leading to further increases in serum calcium concentrations.

Symptoms of nausea and vomiting worsen the dehydration. If the concentration of calcium in the glomerular filtrate exceeds its solubility, calcium may precipitate in the renal tubules, further compromising renal function.

Etiology

HCM occurs most frequently in patients with breast cancer, multiple myeloma, and squamous cell malignancies of the lung, head and neck, and esophagus (Table 116.3). For instance, the incidence of hypercalcemia in patients with metastatic breast carcinoma is 20% to 30% [61,62]. A tumor "flare" can develop in patients with breast cancer after initiation of hormonal therapy, with associated pain and hypercalcemia, and this response may predict for better response to treatment [63]. Hypercalcemia develops in patients with metastatic lung carcinoma in 10% to 35% of cases but, almost invariably in non–small cell rather than small cell histology [64,65]. The development of hypercalcemia in patients with lung carcinoma in several series suggested that disease was unresectable and prognosis uniformly poor [66]. Some malignancies are rarely associated with hypercalcemia despite a propensity for widespread metastases, including prostate cancer and small cell lung cancer. Multiple myeloma commonly causes hypercalcemia, and up to 20% of myeloma patients may present with this complication. It represents advanced disease and, although associated with a worse prognosis, survival is substantially better than for patients with hypercalcemia resulting from solid tumors [67].

Clinical Manifestations

As with other oncologic emergencies, the rapidity with which hypercalcemia develops often determines the severity of symptoms. Patients may have significant symptoms with minimally elevated calcium and require therapy, whereas other patients are minimally symptomatic despite long-standing hypercalcemia. Many of the symptoms of hypercalcemia are relatively nonspecific, and the possibility of hypercalcemia must be kept in mind when considering patients with nausea, fatigue, lethargy, and mental status changes. Decreased intravascular volume and hypercalcemia cause malaise, fatigue, anorexia, and polyuria. Hypercalcemia decreases neuromuscular excitability and decreased muscle tone. Neuromuscular symptoms include weakness and diminished deep tendon reflexes. Neuropsychiatric manifestations may include confusion, lethargy, psychosis, or even coma. Hypercalcemia heightens cardiac contractility and irritability, and this is reflected by electrocardiographic changes, such as prolonged PR interval, widened QRS complex, and a shortened QT. With progressive hypercalcemia, bradyarrhythmias and bundle-branch block may develop, which can evolve to complete heart block and asystole.

Diagnosis

The diagnosis of hypercalcemia is documented by the presence of elevated corrected serum calcium, defined by the following formula: [4.0 − patient (Alb)] × 0.8 + [Ca], where Alb signifies albumin. Alternatively, an elevation of serum ionized calcium documents hypercalcemia and does not require the concomitant measurement of serum albumin. Other laboratory studies that should be considered include PTH, PTHrP, blood urea nitrogen and creatinine, phosphate, and magnesium. The assessment of a patient presenting with hypercalcemia should include several important aspects of disease history. Although hypercalcemia is a common complication of malignancy, other nonmalignant causes (including hyperparathyroidism, intravenous fluids, total parenteral nutrition, milk-alkali syndrome, thiazide diuretics, vitamins A and D, and lithium) are present in 10% to 15% of cancer patients who present with hypercalcemia and should be considered in the differential diagnosis.

Treatment

The decision to treat hypercalcemia should be dictated by the patient's history, current disease status, quality of life, and the wishes of the patient and family. The prognosis for most patients with HCM is poor. Severe pain, obstruction, or irreversible structural symptoms may be an indication not to pursue therapy. However, relief of the symptoms of hypercalcemia may improve quality of life and functional status for many patients during the remainder of their lifetimes. Patients who are symptomatic and who have no other potential etiology of hypercalcemia should be treated. If calcium is elevated but the patient is asymptomatic, specific hypocalcemic therapy can be held, with close observation, particularly if effective systemic therapy is to be initiated. Because most symptoms and the underlying physiology of hypercalcemia are due in part to volume depletion, intravenous hydration is the initial therapy of choice (Table 116.4). Although no randomized controlled clinical trials have been conducted to inform the approach to hydration, in general patients require repletion with 3 to 7 L intravenous saline over 24 to 36 hours to achieve euvolemia. If congestive heart failure is a concern or if the patient has severe hypercalcemia, loop diuretics can be used, but only after it is clear that adequate volume expansion has been achieved. If diuretics are used before the glomerular filtration rate has been restored, renal clearance of calcium is impaired further, and hypercalcemia may worsen despite the best intentions. Loop diuretics suppress

TABLE 116.4

ALGORITHM FOR CLINICAL MANAGEMENT OF HYPERCALCEMIA OF MALIGNANCY

Calcium Level	Symptoms	Therapy
< 12 mg/dL	None	Observation, or hydration followed by observation
< 12 mg/dL	Present	Hydration, bisphosphonate
12–14 mg/dL	Present	Hydration, bisphosphonate
> 14	Present	Hydration, bisphosphonate
> 14	Severe	Hydration, loop diuretics, calcitonin, bisphosphonate Alternatives: plicamycin, gallium nitrate, prednisone phosphate, dialysis

proximal absorption of sodium and calcium, augmenting calciuresis.

Bisphosphonates are the most useful hypocalcemic agents available for controlling HCM. They inhibit prenylation of small guanosine triphosphatases, which are necessary for osteoclast function and are cytotoxic to osteoclasts through a number of different mechanisms [68]. Zoledronic acid and pamidronate are the bisphosphonates currently in clinical use. Two randomized trials comparing pamidronate and zoledronic acid demonstrated improved response rates for zoledronic acid, 4- and 8-mg infusions; complete response rates by day 10 were 88.4%, 86.7%, and 69.7% for zoledronic acid, 4 mg and 8 mg, and pamidronate, 90 mg, respectively. Normalization of calcium occurred by day 4 in 50% of patients treated with zoledronic acid and 33% of those given pamidronate. Median duration of complete response favored zoledronic acid, 4 and 8 mg, over pamidronate, with response durations of 32, 43, and 18 days, respectively. Zoledronic acid is administered intravenously over 5 minutes. Optimal zoledronic acid dosage and administration schedules have not been established; the standard dose is 4 mg, with 8 mg reserved for patients with recurrent or refractory hypercalcemia. The onset of zoledronic acid's effect is apparent within 3 to 4 days, with maximal effect within 7 to 10 days, and lasts for 14 days to 2 months. Adverse effects include transient low-grade temperature elevations that typically occur within 24 to 36 hours after administration and persist for up to 2 days (≤20% of patients). Other bisphosphonates (except clodronate) may also produce transient fever, and the incidence of temperature elevation, nausea, anorexia, dyspepsia, and vomiting may be increased by rapid administration. New-onset hypophosphatemia and hypomagnesemia may occur; preexisting abnormalities in the same electrolytes may be exacerbated by treatment. Serum calcium may fall below the normal range, although symptoms are rare. Renal insufficiency has occurred in ongoing clinical trials at the 8-mg dose level and must be considered in patients with existing renal insufficiency [69]. No dose reduction is recommended for patients receiving the 4-mg dose of zoledronic acid when the measured serum creatinine is less than 3.0 mg per dL [70]. Another bisphosphonate, ibandronate, has demonstrated comparable activity and a longer duration of efficacy when compared to pamidronate in a randomized study of patients with hypercalcemia. Ibandronate appears to be the least nephrotoxic bisphosphonate agent, leading some authors to advocate its use in patients with renal impairment; however ibandronate is not currently approved for the management of hypercalcemia of malignancy by the Food and Drug Administration (FDA) in the United States [71]. An association has been reported between bisphosphonate therapy and subsequent development of osteonecrosis of the jaw.

The incidence is higher with zoledronic acid than with pamidronate (10% vs. 4%) and the risk is significantly increased in individuals with underlying dental conditions or those undergoing dental procedures during treatment. Patients on chronic therapy appear to be at greatest risk [72].

Other treatments for HCM include corticosteroids, calcitonin, plicamycin, and gallium nitrate. Calcitonin rapidly inhibits bone resorption and decreases renal calcium reabsorption. Salmon calcitonin is administered at 4 IU per kg subcutaneously or intramuscularly every 12 hours, and tachyphylaxis occurs rapidly, necessitating dosing increases to 8 IU every 6 to 12 hours. Efficacy is limited to the first 24 to 48 hours after initiation of therapy, and additional treatment with bisphosphonate should be considered concurrent with calcitonin. Corticosteroids are effective in lymphoma and multiple myeloma, tumors in which steroids are often cytotoxic. The onset of action is slow, over several weeks, and the mechanism of effect is through treatment of the underlying malignancy and suppression of gastrointestinal calcium absorption. Therapies designed to interfere with RANKL binding, including the monoclonal antibody denosumab and a decoy RANLK receptor, osteoprotegerin, appear to decrease serum calcium levels in preclinical and clinical settings, however no randomized clinical trials have been performed to evaluate these agents in patients with hypercalcemia [59,73–75]. Dialysis should be considered for patients with severe renal insufficiency and associated electrolyte abnormalities, particularly in patients for whom effective therapy is available.

Hypercalcemia reflects biologically aggressive, advanced disease. For patients with solid tumors, particularly those with chemotherapy-resistant disease, the prognosis is extremely grim, with median survivals of 30 to 60 days in most studies [76]. By contrast, hypercalcemia in patients with multiple myeloma and breast cancer is associated with relatively longer survival. The argument has been made that treatment of HCM prolongs survival in patients in whom other morbid complications of their disease will develop. In fact, it is clear that hypocalcemic agents do not prolong survival but can have impressive palliative benefit in relieving symptoms from hypercalcemia, such as nausea, emesis, and constipation, and improving pain control for some patients who achieve normocalcemia [76].

LEUKOSTASIS

Physiology

Leukostasis is a potentially devastating complication of leukemia in patients who present with hyperleukocytosis, defined as a leukocyte count greater than 100,000 per μL. The syndrome of leukostasis is related to obstruction of flow in capillary beds of the central nervous system, lungs, and heart by immature, rigid blasts. Although viscosity might be expected to play a role, it is rarely elevated because the principal determinant of viscosity, red blood cells, is often low due to marrow replacement by leukemic blasts. The obstruction of capillary beds by blasts and restricted flow results in tissue hypoxia, cytokine release, and coagulation. Tissue invasion also occurs and is not affected by leukapheresis. The risk of leukostasis was evaluated by Lichtman and Rowe [77], who demonstrated that the leukocrit, which is proportional to the number and volume of circulating leukocytes and blasts, was the parameter most closely associated with the development of leukostasis. Although integrins are postulated to play a role in the syndrome, analysis of vascular endothelium in patients with leukostasis compared with controls showed no significant differences in expression of vascular cellular adhesion molecule-1, endothelial–leukocyte adhesion molecule-1, or intercellular adhesion molecule-1 [78]. In vitro studies suggest that in the presence of inflammatory cytokines, leukemic blasts can adhere to vascular endothelium and that these blasts are capable of secreting multiple mediators of endothelial damage [79]. Until clinical correlations between cytokine excretion, integrin expression, and the development of leukostasis are available, the role of integrins in development of the syndrome will remain speculative.

Etiology

Hyperleukocytosis occurs in 10% to 20% of patients with acute myelogenous leukemia (AML) at presentation and is much less common in patients with chronic myelogenous leukemia, acute lymphoblastic leukemia, or chronic lymphocytic leukemia. For equivalent degrees of leukocytosis, the risk of leukostasis is much higher with AML than with other diagnoses because of the larger size and adhesion characteristics of

TABLE 116.5

ALGORITHM FOR TREATMENT OF SYMPTOMATIC HYPONATREMIA

Acute	Mildly symptomatic	Na < 125 mg/dL	Free water restriction 500–1,000 mL/d Demeclocycline Avoid in renal/hepatic dysfunction
Acute	Severe symptoms	Na < 115 mg/dL	3% saline Furosemide diuresis

AML blasts. The risk of developing leukostasis depends on total white blood cell count (WBC), the percentage of blasts, and the rate at which counts are rising. The clinical presentation, diagnosis, and management of hyperleukocytosis are discussed in further detail in Chapter 115.

HYPONATREMIA

Physiology

Clinically symptomatic hyponatremia is a relatively rare complication of malignancy affecting only 1% to 2% of cancer patients. In the majority of these individuals, the syndrome of inappropriate antidiuretic hormone (SIADH) develops. Secretion of ectopic ADH occurs almost solely in patients with small cell bronchogenic carcinoma, and the majority of other patients have coincident central nervous system or pulmonary disease. As a result of excess ADH, excessive water resorption occurs in the collecting ducts, and extracellular fluid osmolality decreases inappropriately. Water is able to move freely, and the decrease in extracellular osmolality results in a shift to the intracellular compartment with associated cellular edema. When hyponatremia occurs acutely, this edema causes dramatic neuronal edema and subsequent neurologic symptoms. Plasma volume expands, and urinary sodium excretion parallels the rate of oral sodium intake. Typically, the patient with SIADH is euvolemic to slightly hypervolemic, urine sodium is greater than 20 mEq per L, and plasma urea, uric acid, creatinine, and rennin activity are normal or low.

Etiology

At presentation, hyponatremia develops in more than 50% of patients with small cell carcinoma after free water loading, but symptoms develop in fewer than 10% of patients. SIADH has also been reported in a broad variety of other malignancies but is most commonly found in the setting of central nervous system or pulmonary metastases. SIADH may also develop in patients with malignancy due to other conditions, including the use of opiates, vinca alkaloids, β agonists, chlorpropamide, and cyclophosphamide. Hypoadrenalism due to rapid tapering of therapeutic corticosteroids is also a common etiology for mild hyponatremia. Other etiologies include volume contraction due to emesis or diarrhea, renal wasting due to diuretics or intrinsic renal disease, and pseudohyponatremia from excess serum lipids or paraproteins. Hypothyroidism and pulmonary or central nervous system disease are also potential causes of SIADH.

Diagnosis

Hyponatremia is often manifested as fatigue, nausea, myalgia, headaches, and subtle neurologic symptoms. Rapid drops in serum sodium or levels less than 115 mg per dL cause altered mental status, seizures, coma, pathologic reflexes, and papilledema. The diagnostic evaluation includes a review of medications and assessment of volume status as well as serum and urine electrolytes, osmolality, and creatinine. Patients with SIADH have inappropriately elevated urine sodium, and urine osmolality is greater than plasma osmolality but never reaches maximal dilution (less than 100 μOsm). Thyroid and adrenal dysfunction cause similar electrolyte imbalances and must be ruled out if laboratory studies suggest SIADH. CT or radiographs of the chest and brain may be necessary to eliminate pulmonary or central nervous system disease as causes of excessive ADH secretion.

Treatment

Treatment of the hyponatremia is tailored to the acuity with which it developed and the extent of symptoms that the patient is experiencing. Chronic severe hyponatremia should be treated with fluid restriction alone. Treatment of the underlying malignancy may alleviate SIADH due to small cell carcinoma. Local therapy to brain or pulmonary metastases may improve serum sodium, and discontinuing offending medications should be effective. Acute symptomatic hyponatremia can be treated as indicated in Table 116.5.

Free water restriction is expected to improve hyponatremia within 7 to 10 days. Demeclocycline induces a dose-dependent, reversible nephrogenic diabetes insipidus and is expected to correct sodium within 3 to 4 days. The primary side effect of demeclocycline is renal toxicity, and the risk of toxicity is increased by renal or hepatic dysfunction. The initial dose of demeclocycline is 600 mg daily to a maximum of 1,200 mg per day in two- to three-times-a-day dosing.

Patients who are seizing, comatose, or rapidly decompensating should be treated with hypertonic saline and furosemide to induce an isotonic diuresis as originally proposed by Gross et al. [80] and Hantman et al. [81]. Once the sodium level is above 120 mg per dL, more conservative measures are appropriate. The primary risk of rapid correction of hyponatremia is central pontine myelinolysis, which typically occurs 3 to 5 days after repletion with corticobulbar spinal dysfunction, dysphasia, quadriparesis, and delirium. Although controversial, most data support the idea that the risk of pontine myelinolysis is greatest for patients with chronic, severe hyponatremia who are treated too rapidly. Generally, the sodium level should not be corrected at a rate faster than 0.5 mM per L per hour even in acute circumstances [82].

TUMOR LYSIS SYNDROME

Physiology

Tumor lysis syndrome (TLS) is a metabolic emergency that remains a significant risk for patients with hematopoietic

malignancy and is being recognized with greater frequency in patients with solid tumors. TLS results from the release of intracellular purines, phosphate, and potassium from rapidly proliferating tumor cells, which may occur spontaneously or with the initiation of therapy. The massive tumor necrosis that initiates the syndrome may occur as a result of tumor hypoxia or with the use of chemotherapy, radiation, or embolization of tumor. Tumor lysis is followed by hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia, and renal insufficiency. The hyperuricemia, combined with metabolic acidosis, results in crystallization of uric acid in the collecting ducts of the kidneys and ureters, leading to obstructive uropathy. Hyperphosphatemia may also cause metastatic calcification in the renal tubules. The resultant renal insufficiency worsens hyperkalemia and hypocalcemia.

Etiology

Patients at highest risk include those with lymphoma, particularly high-grade Burkitt's or non-Burkitt's non-Hodgkin's lymphoma and acute leukemia. The frequency of TLS depends on the criteria used, which are not well established or accepted. In Burkitt's lymphoma the incidence may be as high as 30%, and in patients with acute leukemia with hyperleukocytosis, electrolyte disturbances develop consistent with TLS in 50% of cases [83,84]. A variety of solid tumors have been reported to cause the syndrome, but the most common appear to be small cell lung carcinoma, breast carcinoma, and neuroblastoma. Others include ovarian and vulvar carcinoma, medulloblastoma, sarcomas, seminoma, and melanoma [85,86]. The pretreatment variables that predict the occurrence of the syndrome are azotemia and elevated lactic dehydrogenase and hyperuricemia, evidence of a rapidly proliferating tumor undergoing spontaneous necrosis. Generally, these malignancies are clinically aggressive and sensitive to chemotherapy or radiation.

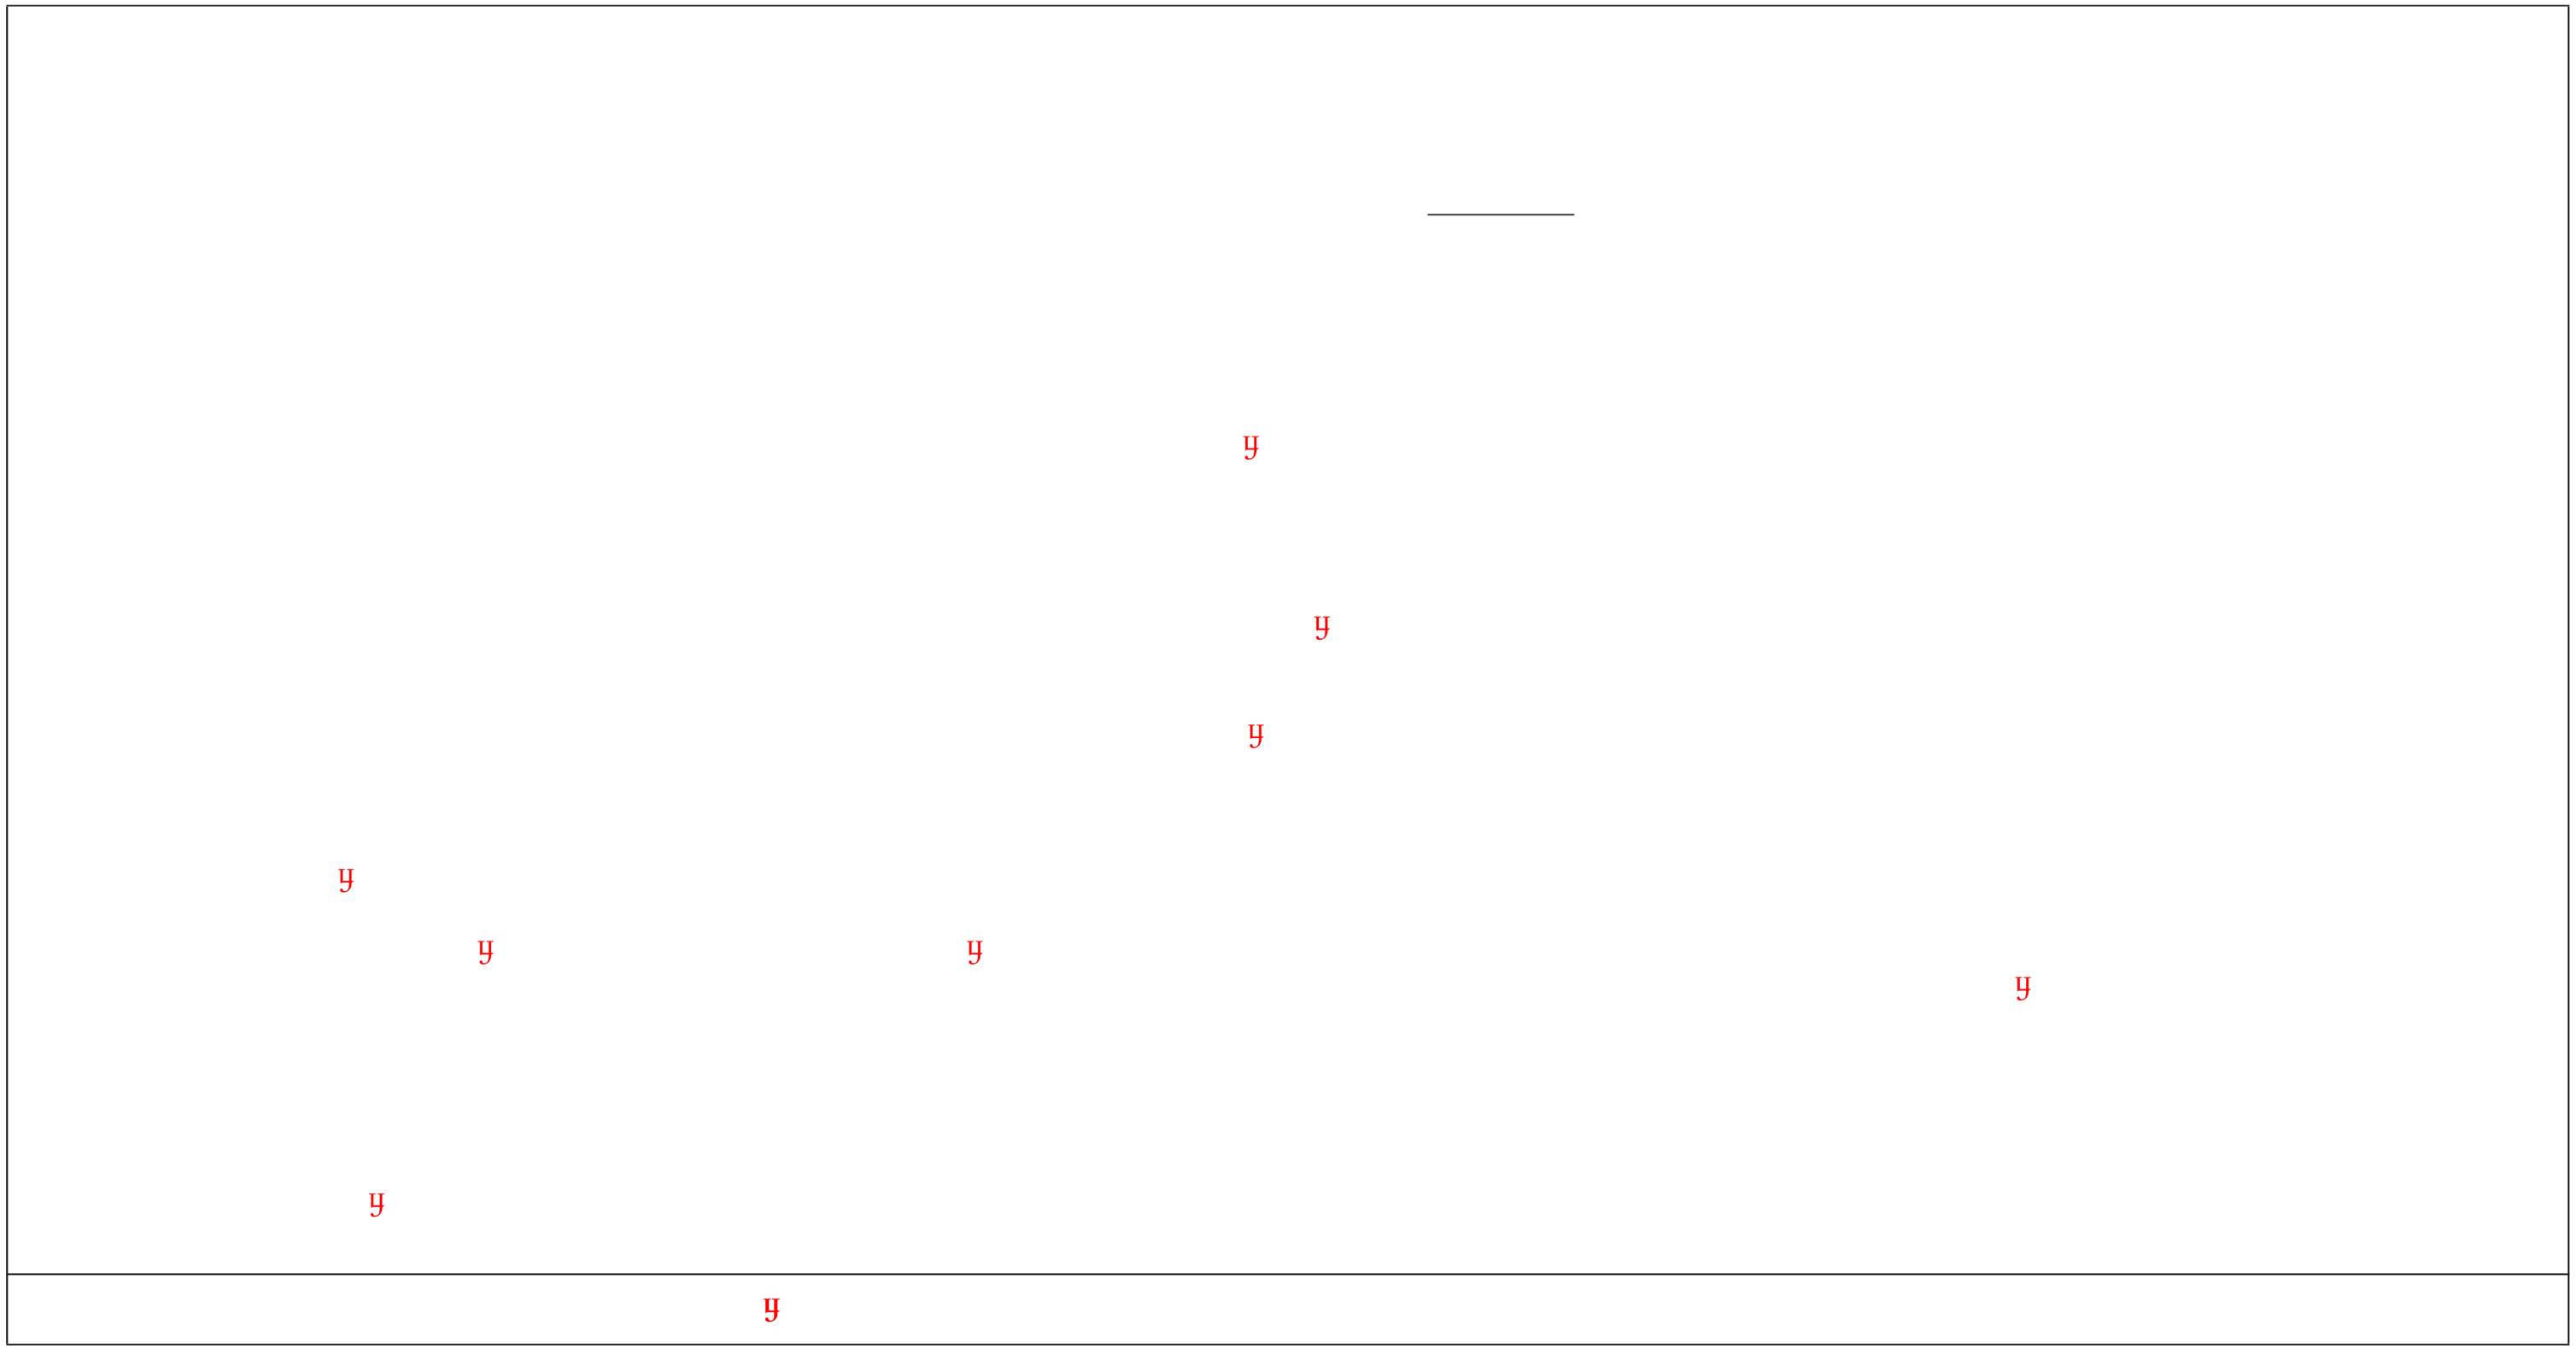
Diagnosis

The diagnosis of TLS is a clinical one, as there is no specific pathognomonic finding or laboratory value that is specific to the syndrome. The diagnosis of TLS is made on the basis of the presence of azotemia, hyperuricemia, hyperphosphatemia, and hypocalcemia in a patient with extensive, rapidly proliferating tumor. The incidence of hyperkalemia is somewhat more variable. Profound metabolic acidosis out of proportion to the degree of renal insufficiency is common. Many of the metabolic abnormalities of TLS may occur as a result of acute renal failure alone, and a urinary uric acid to creatinine ratio greater than 1 helps to distinguish acute uric acid nephropathy from other catabolic forms of acute renal failure in which serum urate is elevated.

Treatment

Management can be grouped into prevention/conservative therapy and hemodialysis. Allopurinol in doses of 200 to 600 mg per m^2 per day should be initiated before therapy to decrease uric acid production [87]. Intravenous allopurinol is safe and effective and is indicated for patients who are unable to take oral allopurinol because of being non per os (NPO) for surgery or having respiratory distress/intubation or abnormal gastrointestinal motility/absorption [88]. Intravenous hydration at 200 to 300 mL per hour containing 25 to 50 mEq per L $NaHCO_3$ should be given to expand volume, alkalinize the urine, and wash out the renal medulla. It is preferable to decrease urine osmolality to isotonic and to increase urinary pH to greater than 7.0. In practice this is sometimes difficult, and in our experience isotonic $NaHCO_3$ (1.4%) more effectively achieves alkaline urine, although the risk of fluid overload is somewhat greater. Increasing metastatic calcification with the development of alkalemia is also a risk; however, the incidence of this complication is far less than that of renal insufficiency related to deposition of insoluble uric acid. Hyperkalemia should be aggressively managed with potassium restriction and sodium polystyrene sulfonate as appropriate. Hemodialysis is often necessary and is indicated to control volume, reduce phosphorus and uric acid levels, and manage uremia. Some proposed criteria for initiation of hemodialysis are persistent hyperkalemia despite conventional treatment, rapidly rising phosphate, symptomatic hypocalcemia, fluid overload, severe metabolic acidosis, and hyperuricemia. Typically, daily dialysis is necessary because the catabolic rate is sharply increased in patients with TLS. Daily weights, close monitoring of fluid intake and output, and serum electrolytes, including potassium, calcium, phosphorus, and uric acid, should be performed at least twice a day in a patient at high risk and more frequently if dialysis is instituted. Allopurinol is associated with a significant number of side effects and should be discontinued within 3 days of completion of treatment if there is no evidence of tumor lysis. Rasburicase is a recombinant urate oxidase that converts uric acid to more soluble allantoin. A randomized study of rasburicase and allopurinol in pediatric patients at high risk of tumor lysis demonstrated that uric acid levels were substantially lower in patients receiving prophylactic rasburicase. The size of the trial was too small to demonstrate a significant difference in renal failure, and the incidence of tumor lysis was not reported [89]. Two compassionate-use rasburicase trials involving pediatric and adult cancer patients have documented impressive efficacy in both the prevention and treatment of hyperuricemia [90,91]. Rasburicase was approved by the U.S. FDA for the initial management of elevated plasma uric acid levels in 2009. Approval was based on findings from a postmarketing surveillance randomized multicenter trial (EFC 4978) which demonstrated a statistically significant difference in response rate (fraction of patients with a plasma uric acid levels <7.5 mg per dL) among rasburicase-treated leukemia, lymphoma, and solid tumor patients (87% response) when compared with patients treated with allopurinol (66%). Interestingly, although the serum uric acid was significantly lower in the rasburicase-treated group, there was no difference between the arms in incidence of TLS. Rasburicase was administered at a dose of 0.2 mg per kg per day for 5 days. The most common rasburicase-associated toxicities included edema (50%), vomiting (38%), hyperbilirubinemia (16%), and sepsis (12%) [92]. A subsequent randomized trial of 64 patients comparing rasburicase administered daily (0.15 mg per kg per day) for 5 days versus a single dose followed by "as needed" dosing in adult patients with hematologic malignancies at risk for developing tumor lysis syndrome. The single-dose group demonstrated a sustained response in 87% of patients demonstrating that it is reasonable to decrease the duration of administration and follow uric acid levels in selected patients [93]. When rasburicase is used, it is important to recognize that the enzyme can continue to degrade uric acid in blood samples at room temperature. Samples must be collected in prechilled heparinized tubes, transported on ice, and analyzed within 4 hours of collection. Rasburicase is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency.

Outcome with development of full-blown tumor lysis syndrome is variable. In the reported cases of solid tumor TLS, the fatality rate was very high (36%) [85]. Institution of prophylaxis in patients identified as high risk (even those with solid tumors), which includes both rasburicase and consideration



for early use of hemodialysis, are highly recommended. Some institutions initiate induction therapy with vincristine, oral cyclophosphamide, and corticosteroids for patients with high-grade lymphoma in an attempt to decrease tumor burden more slowly and avoid the metabolic effect of sudden lysis [94]. No reports to date quantify the effect of this intervention on the incidence of TLS.

Advances in oncologic emergencies, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 116.6.

CHAPTER 117 ■ GENERAL CONSIDERATIONS IN THE EVALUATION AND TREATMENT OF POISONING

IAN M. BALL AND CHRISTOPHER H. LINDEN

The objective of this chapter is to provide the general intensivist with both an overview and an approach to the management of the critically ill poisoned patient. General concepts germane to the intensive care unit (ICU) will be introduced and explored. Every attempt has been made to be as evidence based as possible, within the intrinsic limitations of the medical toxicology literature.

Because overdose studies cannot ethically be performed in humans and animal data may not be available or applicable to humans, predicting the severity of poisoning must be based on toxicodynamic data from previously published reports of human poisonings. However, such data are often incomplete or altogether unavailable and are always limited by the accuracy of the overdose history.

Poisoning or *intoxication* is defined as the occurrence of harmful effects resulting from exposure to a foreign chemical or xenobiotic. Such effects may be local (i.e., limited to exposed body surfaces), subjective (i.e., symptoms only) or systemic and objective (e.g., behavioral, biochemical, cognitive, or physiologic). In the absence of signs or symptoms, external or internal body contact with a potentially harmful amount of a chemical is merely an exposure. An *overdose* is an excessive exposure to a chemical that in specified (e.g., therapeutic) amounts is normally intended for human use. Whether an exposure or overdose results in poisoning depends more on the conditions of exposure (primarily the dose) than the identity of the agent involved. Ordinarily safe chemicals, even those essential for life such as oxygen and water, in excessive amounts or by an inappropriate route can result in harmful effects. Conversely, by limiting the dose, chemicals usually thought of as poisons can be rendered harmless. Poisoning is distinguished from adverse allergic, intolerance, and idiosyncratic pharmacogenetic reactions in that effects are concentration or dose related and, hence, predictable. As such, it includes adverse drug reactions due to unwanted secondary effects and pharmacokinetic and pharmacodynamic interactions.

Poisonings, exposures, and overdoses may be characterized by the route, duration, and intent of exposure. Ingestion, dermal or ophthalmic contact, inhalation, and parenteral injection (including bites and stings) are the most common routes, but rectal, urethral, vaginal, bladder, peritoneal, intraocular, and intrathecal exposures can also occur. Events that occur once or during a short period of time are considered acute, whereas those that occur repeatedly or over a prolonged time interval are said to be chronic

EPIDEMIOLOGY

Although comprehensive data regarding the true incidence of poisoning are not available [1], it is clearly a significant medical problem. Just under two and a half million human exposures were reported to the National Poison Data System in 2007 [2]. Of these, 20% to 25% are treated at a health care facility, and approximately 6% are admitted to a hospital. Half of those admitted are treated in an ICU. In other countries, the ICU admission rate for those evaluated at a health care facility varies from 5% to 22% [3–5].

Exposures and poisonings are responsible for 1% to 5% of emergency department visits, 5% to 10% of all ambulance transports, 5% to 14% of adult ICU admissions, and 2% to 5% of pediatric hospital admissions [3–9]. In addition, 25% of routine medical admissions involve some form of drug-related adverse patient event (an adverse drug reaction or noncompliance), and up to 30% of acute psychiatric admissions are prompted by attempted self-harm via chemical exposure. Although the incidence of poisoning in children has decreased since the introduction of the Poison Prevention Packaging Act in 1970 [10], the overall incidence of poisoning is increasing, particularly that due to suicide attempts in teens, middle-aged adults, and the elderly. The volume of calls handled by United States Poison Centers increased by 7.6% in 2007 [2]. Poisoning is second only to firearms as the leading cause of suicide [5]. Poisoning is the second leading cause of injury death [2]. The yearly medical cost for the treatment of poisoning in the United States is estimated to be $26 billion [11]. Poisoning accounts for 6% of the economic costs of all injuries in the United States [11].

Most exposures reported to US poison centers are acute (90.9%), unintentional (83.2%), occur at home (92.9%), cause minor or no harmful effects (95%), result from ingestion (78.4%), and involve children 6 years of age or younger (51.2%) [2].

Poisoning accounts for 2% to 14% of all ICU admissions, with an average length of stay of about 3 days [3,5,7–9]. The mortality rate for such patients varies from 0.6% to 6.1% [3,4,6–9]. Although only 1,239 poisoning fatalities were reported by US poison centers in 2007 [2], death certificate data indicate that the true number of poisoning deaths is 20 to 50 times higher [12]. Poison center statistics vastly underestimate mortality from poisoning because they rarely capture cases in which the victim is found dead and goes directly to the medical examiner.

PHARMACOLOGIC CONCEPTS

Toxic exposures all undergo the same pharmacologic steps, as outlined in Table 117.1. Clinician familiarity with toxicokinetics is essential for predicting the effect of a particular exposure and guiding appropriate treatment and disposition. Only a

TABLE 117.1

TOXICOKINETIC STAGES

1. Absorption
2. Distribution
3. Metabolism
4. Excretion

brief overview of these concepts is presented here. The reader is referred to other sources for additional information [13–17]. Details regarding the disposition and toxic effects of specific agents can be found in subsequent chapters and other references [14–27].

Mechanism of Action

Most chemicals are absorbed and cause systemic poisoning by selectively binding to and disrupting the function of specific targets (e.g., enzymes, proteins, membrane lipids, or neurohumoral receptors). Effects may be systemic or limited to a specific organ or tissue, depending on the distribution and location of target site.

Poisoning is usually functional and reversible. Hence, if end organ function can be supported, complete patient recovery is possible upon toxin elimination. However, if normal activity of the target site is essential for cell viability, a toxic exposure may result in necrosis. Agents that can cause fatal cellular damage include acetaminophen, carbon monoxide, corrosives, toxic alcohols, heavy metals, and neurotoxic hydrocarbons.

Absorption

Absorption involves the translocation of chemicals across the membranes of cells that make up mucosal surfaces, pulmonary epithelium, and skin, all of which function as biologic barriers. Translocation occurs by filtration or passive diffusion through gaps or membrane pores by dissolving in and diffusing through the membrane itself (e.g., lipid-soluble chemicals), or by attaching to carrier molecules in the membrane, which actively or passively facilitate diffusion (e.g., water-soluble chemicals). The rate and extent of absorption depend on physical properties of the chemical and the route of exposure. In general, only chemicals that are small (i.e., <4 nm in diameter), have low molecular weight (i.e., <50 Da), and are soluble in both water and lipids at the pH of body fluids can readily cross membranes.

Absorption after intravenous injection is complete and almost instantaneous. Peak arterial and venous blood concentrations occur within 30 to 90 seconds. Most toxins cross biologic membranes by simple passive diffusion. The rate at which this occurs is governed by Fick's law of diffusion.

$$\text{Rate of Diffusion} = dQ/dt = [DAK(C1 - C2)]/d$$

where D is the diffusion constant (constant for each toxin), A is the membrane surface area, K is the partition coefficient (represents the lipid: water partitioning of the toxin), d is the membrane thickness, and C is the toxin concentration.

Pulmonary absorption is rapid but incomplete. Blood concentrations peak within seconds to minutes. The absorption of chemicals after intramuscular or subcutaneous injection is slower but relatively complete. Peak blood levels generally occur within an hour of administration. Poor water solubility (low K) is responsible for the slow absorption and long duration of action of intramuscular depot formulations (e.g., neuroleptics).

The rate and extent of absorption after ingestion are variable. Peak blood levels are typically noted within 0.5 to 2.0 hours of a therapeutic dose. The absorbed dose is proportional to, but not necessarily equal to, the administered dose. The rate and extent of absorption after contact with other mucosal surfaces (e.g., oral, nasal, ophthalmic, rectal) is similar to ingestion. Skin absorption, if it occurs at all, is usually considerably slower. Regardless of route, absorption tends to follow first-order kinetics (i.e., the amount of chemical absorbed per unit of time is directly proportional to its concentration). *Hence, threshold tissue concentrations are usually reached more quickly and effects begin sooner after an overdose than after a therapeutic dose.*

Zero-Order Kinetics: rate of reaction is not proportional to toxin concentration

First-Order Kinetics: rate of reaction is proportional to toxin concentration

The dissolution and solvation of particulate material is often a rate-limiting step in gastrointestinal (GI) drug absorption. Hence, pill, solid, and suppository formulations tend to be absorbed more slowly than liquids, powders, or suspensions. Slow dissolution and solvation also account for the delayed and prolonged absorption of enteric-coated tablets (e.g., aspirin, potassium), sustained-release preparations (e.g., cardiovascular drugs, lithium, phenytoin, theophylline), drugs that tend to form concretions (e.g., ethchlorvynol, glutethimide, heavy metals, iron, lithium, and meprobamate), and those with poor water solubility (e.g., carbamazepine and digoxin). The rate of dissolution is also inversely related to the tablet concentration. *Hence, absorption generally takes longer and peak effects occur later after an overdose than after a therapeutic one.*

Ingested chemicals are predominantly absorbed from the small intestine rather than the stomach because the small intestine has a larger surface area. Hence, decreased gastric emptying or bowel activity caused by the presence of food, disease, or the effects of ingested agents (e.g., anticholinergics, opioids, sedative–hypnotics, salicylates) can also delay or prolong absorption. Food and coingestants may decrease absorption by binding to the chemical within the gut lumen or by competitively inhibiting its dissolution and translocation. Absorption may also be decreased if intestinal motility is excessive.

Distribution

During distribution, chemicals may become bound to and inactivated by endogenous nontarget molecules such as serum proteins. The final distribution of chemical is uneven and reflects its affinity for active and inactive binding sites and the locations of such sites. It is also influenced by biologic variables such as age, sex, weight, and disease states as they relate to body composition (e.g., water, fat, muscle content) and serum protein concentrations. The extent of distribution of a chemical is reflected by its apparent volume of distribution, measured in liters per kilogram of body weight, and calculated most simply by dividing the amount of chemical in the body (i.e., the absorbed or bioavailable dose) by its plasma concentration.

$$\text{Volume of Distribution} = \text{Bioavailable Dose}/\text{Plasma Concentration}$$

Because distribution is also a translocation process, it is influenced by the same chemical characteristics as absorption and follows first-order kinetics. Distribution generally occurs much faster than absorption, as evidenced by the occurrence of peak effects within minutes of an IV drug injection. Slow distribution is partly responsible for the delayed onset of action of some agents (e.g., digitalis, heavy metals, lithium, and salicylates).

Tissue Concentration

The severity of poisoning reflects the concentration of a chemical at its site(s) of action and is proportional to the dose. Because the blood concentration of a chemical is also proportional to the dose, blood levels are sometimes used as a surrogate to assess the severity of poisoning. However, blood and target site concentrations are not always in steady-state equilibrium. When distribution occurs more slowly than absorption (e.g., after IV administration, inhalational exposure, and the ingestion of agents with inherently slow distribution), blood levels may be higher than those in tissue. Conversely, when redistribution of a chemical from tissue to blood occurs more slowly than elimination (e.g., after extracorporeal removal), blood levels may be lower than those in tissue. In both instances, blood levels do not accurately reflect those in tissue and do not correlate with the severity of poisoning.

Age, genetic influences, tolerance, underlying disease, and the presence or absence of other chemicals may have synergistic or antagonistic effects and may also influence the response to a given level of toxin exposure. The effect of metabolites must also be considered. Many chemicals have metabolites that remain pharmacologically active. Some (e.g., acetaminophen, toxic alcohols, chlorinated hydrocarbons, meperidine, paraquat, and certain organophosphate insecticides) undergo metabolic activation, resulting in the production of compounds that are more toxic than the parent one.

Metabolism/Elimination

Elimination of chemicals from the body (detoxification) is accomplished by urinary, pulmonary, GI, and glandular (e.g., bile, milk, tears, saliva, sweat) excretion or metabolic inactivation. Hepatic metabolism and renal excretion are the major routes of elimination for most agents. Pulmonary excretion also plays a major role in the elimination of gases and volatile chemicals. Elimination generally follows first-order kinetics. For some toxins, hepatic metabolism has a finite capacity (i.e., becomes "saturated") and proceeds at a constant rate (zero-order kinetics). When the primary route of elimination is a zero-order metabolism, a small increase in dose can result in a large increase in blood and tissue concentrations and potential poisoning. Chemicals exhibiting such metabolism include alcohols, phenytoin, salicylate, and theophylline.

Renal excretion is accomplished by translocation processes (e.g., glomerular filtration, tubular secretion, and reabsorption) and is therefore influenced by the same factors as absorption and distribution. Any condition that impairs hepatic or renal blood flow or function can decrease toxin elimination. Metabolic enzymes are also subject to genetic influences and to induction or inhibition resulting from past or current chemical exposures. Regardless of the kinetics and route of elimination, the time required for elimination increases as the tissue concentration of chemical increases. *Hence, the duration of the effect tends to be longer after an overdose than after a therapeutic dose.*

CLINICAL CONSIDERATIONS

The principal objectives in the diagnosis and evaluation of the poisoning are recognition of an exposure or poisoning, identification of the offending agent(s), prediction of potential toxicity, and assessment of the severity of clinical effects. Treatment objectives include resuscitation, prevention of further absorption, enhancement of elimination, and the administration of antidotal therapy (Table 117.2).

TABLE 117.2

TREATMENT OBJECTIVES—GENERAL PRINCIPLES

1. Resuscitation
2. Prevention of further exposure
3. Enhanced elimination
4. Novel/antidotal therapy

Early accurate diagnosis is a prerequisite for optimal management.

The priority of assessment and treatment objectives depends on the phase of poisoning [28]. During the preclinical phase (i.e., the time between exposure and the onset of clinical or laboratory evidence of toxicity), management priorities include chemical identification, prediction of toxicity, and prevention of absorption (i.e., decontamination). The sooner decontamination is accomplished, the greater its efficacy. Hence, the physical examination and gathering of ancillary data should initially be brief. Assessment should focus on the exposure history, whether or not poisoning is likely to ensue, and whether or not decontamination is indicated.

During the toxic phase (i.e., the time between the onset of toxicity and its peak), assessment of the severity of poisoning, resuscitation, prevention of further absorption, enhancement of elimination, and antidotal therapy are the primary objectives. If the patient is critically ill, the history, physical examination, and diagnostic testing must be conducted concurrently with resuscitation.

During the resolution phase (i.e., the time between peak toxicity and full recovery), continued supportive care, enhancement of elimination, antidotal therapy, and reassessment of severity (i.e., evaluation of the response to treatment) are the most important management considerations. Measures to prevent subsequent reexposure should also be initiated before discharge.

Recognition of Poisoning

Although poisoning can cause a wide variety of nonspecific signs and symptoms, the diagnosis can usually be established by the history, physical examination, routine and toxicologic laboratory evaluation, and the clinical course. Ideally, criteria similar to Koch's postulates for infectious disease should be met: A chemical is identified in or on the body in an amount known to cause the observed signs and symptoms within the reported time frame. In reality, the diagnosis is often made on the basis of a history of exposure, a clinical course consistent with poisoning, and exclusion of other etiologies.

Making the diagnosis is easy when an accurate history of exposure is available. However, patients may be unaware of an exposure, unwilling to admit to one, or unable to give a history at all. Patients may give a history that is vague, confusing, or intentionally disguised.

Circumstances that should arouse suspicion of occult poisoning include sudden or unexplained illness in a previously healthy individual; similar unexplained symptoms in a group of individuals; a psychiatric history, alcoholism, or drug abuse; a recent change in health, economic status, or social relationships; and the onset of illness shortly after ingesting food, drink, or medication. Poisoning should always be considered in patients with metabolic abnormalities (especially acid–base disturbances), gastroenteritis, or changes in behavior or mental status of unclear etiology. Leakage of illicit drug packets that have been ingested or concealed in body cavities should be suspected in patients with altered mental status or unusual

behavior who have just arrived from abroad (especially Asia and South America) or who have recently been arrested or incarcerated for criminal activity [29,30]. Drug intoxication is a risk factor for trauma and suicide and should also be considered in all injured patients [31].

To avoid missing the diagnosis of poisoning, the physician must specifically inquire about toxin exposure. In suspicious cases, the physician should assume the role of detective to elicit historical support for the diagnosis [32]. Paramedics, police, and family, friends, employer, pharmacist, or personal physician can be questioned regarding the circumstances and events surrounding the illness, particularly the availability of chemicals and the likelihood of exposure. The patient's clothes and place of discovery should be searched for a suicide note, xenobiotics, and open or empty medication containers. Third parties should be instructed to search the house for such evidence and to bring it in for inspection.

In the absence of a history of exposure, the characteristic clinical course of poisoning may also suggest the diagnosis. Signs and symptoms of poisoning typically develop within minutes to an hour of an acute exposure, progress to a maximum within several hours, and gradually resolve over a period of hours to a few days. In such situations, toxicology screening (see later) may allow for a positive diagnosis if signs and symptoms are consistent with the known toxicity of the toxin(s) detected and other etiologies have been excluded.

Identification of the Offending Agent

History

The etiology of poisoning may or may not be disclosed by the patient history. Even when a history is available, its accuracy and reliability must be assessed. The identity of the toxin involved is incorrectly reported by up to 50% of patients with intentional ingestions [33]. The amount reportedly taken is also unreliable. Hence, in such patients, the history should be approached with caution. Layperson misidentification of acetaminophen as aspirin and vice versa is also relatively common. To avoid missing the correct diagnosis, the presence or absence of both drugs should be confirmed by laboratory analysis when an overdose of any kind is suspected.

Pill, Product, Plant, and Animal Identification

Drugs in pill form can often be identified by the imprint code, the alphabetical and numeric markings on tablets and capsules. A listing of imprint codes with the corresponding trade name and ingredient(s) can be found in the Identidex portion of *Poisindex* [27], which is available at virtually all poison centers in the United States. It also provides the identities of street drugs based on their slang names. Prescription drugs may be identified by contacting the dispensing pharmacy. Drug samples can sometimes be identified by direct chemical analysis (Toxicology Screening section). Police and government toxicology laboratories may be of assistance when illicit drug use is involved.

By US law [34], the ingredients of potentially hazardous commercial products used in and around the home must be stated on their label. This information, however, is not necessarily present or accurate, and labels may be missing or unreadable. In such cases, the ingredients may be identified by consulting *Poisindex* [27] or a regional poison center. Alternatively, the manufacturer or distributor can be called to obtain information on drugs or products that they produce or distribute. This action may be particularly helpful if the product is an outdated formulation or a recently reformulated or released one. Most large companies maintain 24-hour emergency telephone numbers for such purposes, and many employ medical consultants who can also provide management advice. Although industrial products do not have the same labeling requirements as household ones, right-to-know legislation requires that companies make information regarding the ingredients and potential toxicity of products they make, distribute, or use available to workers and health care providers [35]. Such information can be obtained by requesting a Material Data Safety Sheet (MSDS).

Information on drugs and chemical products manufactured or obtained outside the United States can be found in *Poisindex* [27] and *Martindale: The Complete Drug Reference* [21], or obtained from a domestic or foreign poison center. Information on drugs undergoing clinical trials in the United States may also be found in *Martindale*, since such drugs are often already available in other countries. Most foreign poison centers have English-speaking staff or translators available.

Plants (including fungi or mushrooms), along with their active parts and chemical constituents, can be identified by consulting *Poisindex* [27] if either their common or botanical name is known. If the name is not known but a sample is available, a representative from a local nursery, horticultural or mycologic society, or university botany department may be of assistance in identifying it. Similarly, pet stores, zoos, veterinarians, amateur or academic entomologists, herpetologists, zoologists, and field guides can be helpful in identifying potentially venomous insects, reptiles, snakes, and other animals. Poison centers usually maintain lists of local experts who are willing to help with such identifications.

Toxidromes

A toxidrome is a clinical syndrome that involves multiple physiologic systems and facilitates bedside identification of the culprit toxin [36]. The physiologic state of the patient can usually be characterized as excited (i.e., central nervous system [CNS] excitation with increased blood pressure, pulse, respirations, and temperature), depressed (i.e., decreased level of consciousness and decreased vital signs), discordant (i.e., inconsistent, mixed, or opposing CNS and vital sign abnormalities), or normal. The differential diagnosis can then be narrowed to the common or characteristic causes of these physiologic states (Table 117.3).

The *excited state* is primarily caused by sympathomimetics (agents that directly or indirectly stimulate α- and β-adrenergic receptors), anticholinergics (agents that block parasympathetic muscarinic receptors), hallucinogens, and withdrawal syndromes. The *depressed state* is primarily caused by sympatholytics (agents that block adrenergic receptors or depress cardiovascular activity), cholinergics (agents that directly or indirectly stimulate muscarinic receptors), opioids, or sedative hypnotics (which enhance the effect of the inhibitory CNS neurotransmitter gamma-aminobutyric acid [GABA] or depress neuronal membrane excitability). The *discordant state* is primarily due to asphyxiants (agents that decrease the availability, absorption, transport, or use of oxygen), membrane active agents (those that block sodium channels or otherwise alter the activity of excitable cell membranes), and agents that cause a variety of CNS syndromes due to interference with dopamine, GABA, glycine, or the synthesis, metabolism, or function of serotonin. A *normal physiologic state* may be due to a nontoxic exposure (Table 117.4), psychogenic illness, or presentation during the preclinical phase of poisoning. Agents that have a long preclinical phase (i.e., delayed onset of toxicity) are known as toxic "time bombs." Delayed onset of toxicity may result from slow absorption or distribution, metabolic activation, or a mechanism of action

TABLE 117.3

DIFFERENTIAL DIAGNOSIS OF POISONING BASED ON PHYSIOLOGIC ASSESSMENT AND UNDERLYING MECHANISMS

TABLE 117.4

CRITERIA FOR A NONTOXIC EXPOSURE

Patient is asymptomatic by both history and physical examination
Amount and identity of all chemicals and time of exposure are known with high degree of certainty
Exposure dose is less than the smallest dose known or predicted to cause toxicity

that involves the disruption of metabolic or synthetic pathways. Psychogenic illness should be considered when symptoms are inconsistent with the reported exposure and cannot be substantiated by objective physical findings, laboratory abnormalities, and toxicologic testing and other etiologies have been excluded [37].

An excited or depressed state may be mischaracterized as a discordant one when the activity of a stimulant or depressant is selective for a receptor subtype or results in a compensatory or opposing autonomic response. For example, hypotension caused by an alpha-blocker, β_2-agonist, or vasodilator may be

TABLE 117.5

PHYSIOLOGIC GRADING OF THE SEVERITY OF POISONING

	Signs and symptoms	
Severity	**Stimulant poisoning**	**Depressant poisoning**
Grade 1	Agitation, anxiety, diaphoresis, hyperreflexia, mydriasis, tremors	Ataxia, confusion, lethargy, weakness, verbal, able to follow commands
Grade 2	Confusion, fever, hyperactivity, hypertension, tachycardia, tachypnea	Mild coma (nonverbal but responsive to pain); brainstem and deep tendon reflexes intact
Grade 3	Delirium, hallucinations, hyperpyrexia, tachyarrhythmias	Moderate coma (respiratory depression, unresponsive to pain); some but not all reflexes absent
Grade 4	Coma, cardiovascular collapse, seizures	Deep coma (apnea, cardiovascular depression); all reflexes absent

accompanied by tachycardia, and hypertension due to a selective α-agonist (e.g., phenylpropanolamine) may be accompanied by bradycardia. Severe stimulant or depressant poisoning can also cause what appears to be a discordant state (Table 117.5). For example, prolonged seizures and extreme hyperthermia caused by sympathomimetics can culminate in cardiovascular collapse as a consequence of anaerobic metabolism, acidosis, or depletion of neurotransmitters. Similarly, marked hypotension and hypoventilation caused by physiologic depressants can precipitate seizures and tachyarrhythmias as a result of ischemia, anoxia, and acidosis. In addition, paradoxic excitation can result from the preferential inhibition of cortical function that normally controls social activity by low doses of CNS depressants, most notably alcohol and other sedative hypnotics. In such cases, the physiologic state and its cause can often be correctly identified by the overall clinical picture and course of events.

The severity of mental status changes and the nature of associated autonomic findings can be used to narrow the differential diagnosis of physiological stimulation and depression to one of four subcategories (see Table 117.3). In the excited patient, marked vital sign abnormalities (e.g., severe hypertension with end-organ ischemia, tachyarrhythmias, hyperthermia, cardiovascular collapse) with minor mental status changes suggest an agent with peripheral sympathomimetic activity as the cause. Conversely, marked mental status abnormalities with nearly normal vital signs suggest a centrally acting hallucinogen. Anticholinergic poisoning (Table 117.6) can be differentiated from sympathomimetic (Table 117.7), hallucinogen, and withdrawal syndromes by the presence of dry, flushed, and hot skin; decreased or absent bowel sounds; and urinary retention. Other causes of excitation are usually accompanied by pallor, diaphoresis, and increased bowel or bladder activity.

In the patient with physiological depression, marked cardiovascular abnormalities (e.g., hypotension and bradycardia) with relatively clear sensorium suggest a peripherally acting sympatholytic, whereas marked CNS and respiratory depression with minimal pulse and blood pressure abnormalities suggest a centrally acting agent (opioid or sedative hypnotic). Cholinergic poisoning (Table 117.8) can be distinguished from other causes of physiologic depression by the presence of characteristic autonomic findings: *S*alivation, *l*acrimation, *u*rination, *d*efecation, *G*I cramps, and *e*mesis (SLUDGE syndrome). In addition, cholinergic poisoning causes pallor and diaphoresis, whereas the skin is usually warm and dry with opioid and sedative–hypnotic poisoning.

Other findings can sometimes help narrow the differential diagnosis further. Only the most common and diagnostically useful ones are noted here. Because of limited specificity and sensitivity, the presence or absence of a particular sign or symptom cannot be used to confirm or exclude a given etiology.

Ocular findings can sometimes help narrow the diagnostic possibilities. Although mydriasis can be caused by any agent or condition that results in physiologic excitation (see Table 117.3), it is most pronounced in anticholinergic poisoning, in which it is associated with minimal pupil response to light and accommodation. Similarly, although miosis is a nonspecific manifestation of physiologic depression, it is usually most pronounced in opioid poisoning. Notable miosis can, however, also be caused by cholinergic agents and sympatholytics with alpha-blocking effects (e.g., phenothiazines). Visual disturbances suggest anticholinergic, cholinergic, digitalis, hallucinogen, methanol, and quinine poisoning. Horizontal nystagmus and disconjugate gaze are nonspecific manifestations

of sedative–hypnotic poisoning. Although vertical and rotary nystagmus can be seen in patients with lithium and phenytoin poisoning, they are most suggestive of phencyclidine intoxication. These etiologies should be readily distinguishable by assessing the physiologic state. Rapidly alternating lateral "ping-pong" gaze has been described in monoamine oxidase inhibitor poisoning. Except for abnormalities due to topical chemical exposure, both eyes are equally affected. Although failure to respond to topical miotics has been said to be diagnostic of drug-induced pupillary dilatation, this is only true for topical exposures. Hence, unilateral pupillary abnormalities should generally prompt evaluation for a central, structural lesion.

Dermatologic abnormalities may also be helpful. Flushed skin can be caused by anticholinergics, boric acid, a disulfiram-ethanol reaction, monosodium glutamate, niacin, scombroid (fish poisoning), and rapid infusion of vancomycin (red man syndrome). The skin is hot and dry in anticholinergic poisoning but normal or moist with other etiologies. Flushing should not be confused with the orange skin discoloration caused by rifampin. Pallor and diaphoresis may be due to cholinergics, hallucinogens, hypoglycemics, sympathomimetics, and drug withdrawal (see Table 117.3). As noted previously, manifestations of the SLUDGE syndrome distinguish cholinergic poisoning from other etiologies. Cyanosis may be due to agents that cause cardiovascular or respiratory depression, methemoglobinemia, pneumonitis, or simple asphyxia. In methemoglobinemia, it may have a chocolate-brown or slate-gray hue and is unaffected by oxygen administration. Cyanosis should not be confused with the blue discoloration of the skin caused by amiodarone or by topical exposure to blue dyes. The latter condition can be diagnosed by wiping the skin with acetone or alcohol. Hair loss, mucosal pigmentation, and nail abnormalities are suggestive of heavy metal poisoning (e.g., arsenic, lead, mercury, thallium).

Finally, the presence of neuromuscular abnormalities may suggest certain etiologies. Seizures and tremors can be caused by cholinergics, hypoglycemic agents, lithium, membrane-active agents, some narcotics (e.g., meperidine, propoxyphene), and most physiologic stimulants [38] (see Table 117.3). They can also occur in patients poisoned by agents that cause asphyxia, low lactate increased AGMA (see later), and cerebral hypoperfusion or hypoventilation (e.g., physiologic depressants; see Table 117.3). The most common causes of seizures due to poisoning are tricyclic antidepressants, sympathomimetics, antihistamines (primarily diphenhydramine), theophylline, and isoniazid. Although carbon monoxide, hypoglycemics, lithium, and theophylline can cause focal seizures, seizures due to poisoning are usually generalized. Because hypertensive and traumatic CNS hemorrhages are known complications of poisoning, the possibility of a structural lesion should be considered if focal signs and symptoms are present. Myoclonus suggests anticholinergic or sympathomimetic poisoning. Fasciculations are typical of cholinergic insecticide poisoning but can also be caused by sympathomimetics. Rigidity may be seen in phencyclidine and sympathomimetic poisoning and in those with CNS syndromes (see Table 117.3). Dystonic posturing is most often caused by antipsychotic agents. It is also a characteristic feature of strychnine poisoning.

Laboratory Findings

Acid–base status, anion gap, serum osmolality, ketone, electrolyte, glucose, and organ function abnormalities identified by routine laboratory tests can be extremely helpful in the differential diagnosis of poisoning. As with clinical manifestations, the diagnostic sensitivity and specificity of a single finding is not sufficiently high for its presence or absence to confirm or exclude a specific etiology. The use of anion and osmolar gaps and serum ketone and lactate levels in the diagnosis of poisoning of unknown etiology is summarized in Figure 117.1.

Assessing acid–base status and calculating the anion gap is particularly important because an increased AGMA may be due to advanced ethylene glycol, methanol, and salicylate poisoning. In such cases, prompt initiation of specific therapies is essential to prevent progressive, irreversible, or fatal poisoning [39,40]. The normal anion gap is 13 ± 4 mEq per L in unselected acutely hospitalized patients. In ethylene glycol and methanol poisoning, AGMA is primarily due to the accumulation of acid metabolites. In salicylate poisoning, it is caused by the accumulation of a variety of endogenous organic acids resulting from salicylate's interference with intermediary metabolism. Agents that cause hypoxemia, cellular asphyxia, seizures, shock, or extensive tissue necrosis can also cause an AGMA, but in these instances, the accumulation of lactic acid generated by anaerobic metabolism is responsible for the AGMA. When the underlying cause is unclear, measuring the serum lactate level may be helpful. The lactate concentration is usually low (< 5 mEq per L) or significantly less than the anion gap in ethylene glycol, methanol, and salicylate poisoning, but high (> 5 mEq per L) or nearly equal to the anion gap in conditions associated with anaerobic metabolism.

Other common toxicologic causes of a low-lactate AGMA include ethanol, which can cause ketoacidosis by disrupting intermediary metabolism in susceptible alcoholics, and toluene, which can cause renal tubular acidosis with bicarbonate wasting. Rarely, this metabolic picture occurs in poisoning by formaldehyde (which is metabolized to formic acid), paraldehyde (presumably as a result of its metabolism to acetic acid), phosphate [41], and sulfur (and possibly sulfates) [42]. It can also be seen with large overdoses of ibuprofen (and probably all nonsteroidal anti-inflammatory agents) and valproic acid (due to high levels of these acidic drugs and their metabolites) [43,44]. Metformin and nucleoside reverse transcriptase inhibitor antiretroviral agents (e.g., zidovudine or azidothymidine) can interfere with normal-lactate metabolism and cause a high-lactate AGMA at therapeutic as well as excessive doses [45,46]. A high-lactate AGMA can rarely occur soon after massive acetaminophen ingestion [47].

An abnormally low anion gap may be seen in severe bromide, calcium, iodine, lithium, magnesium, and nitrate intoxication [39,48,49]. In bromide, iodine, and lithium intoxication, the low anion gap results from spuriously elevated chloride levels, and with nitrate poisoning, it is due to falsely elevated bicarbonate levels.

Serum osmolality can help differentiate the toxic causes of a low-lactate AGMA. An increased osmole gap may be seen early in the course of ethylene glycol and methanol (when high serum levels of the parent compounds are present) but not salicylate poisoning. Although not strictly accurate from a physical chemistry perspective [50], the osmole gap is typically defined

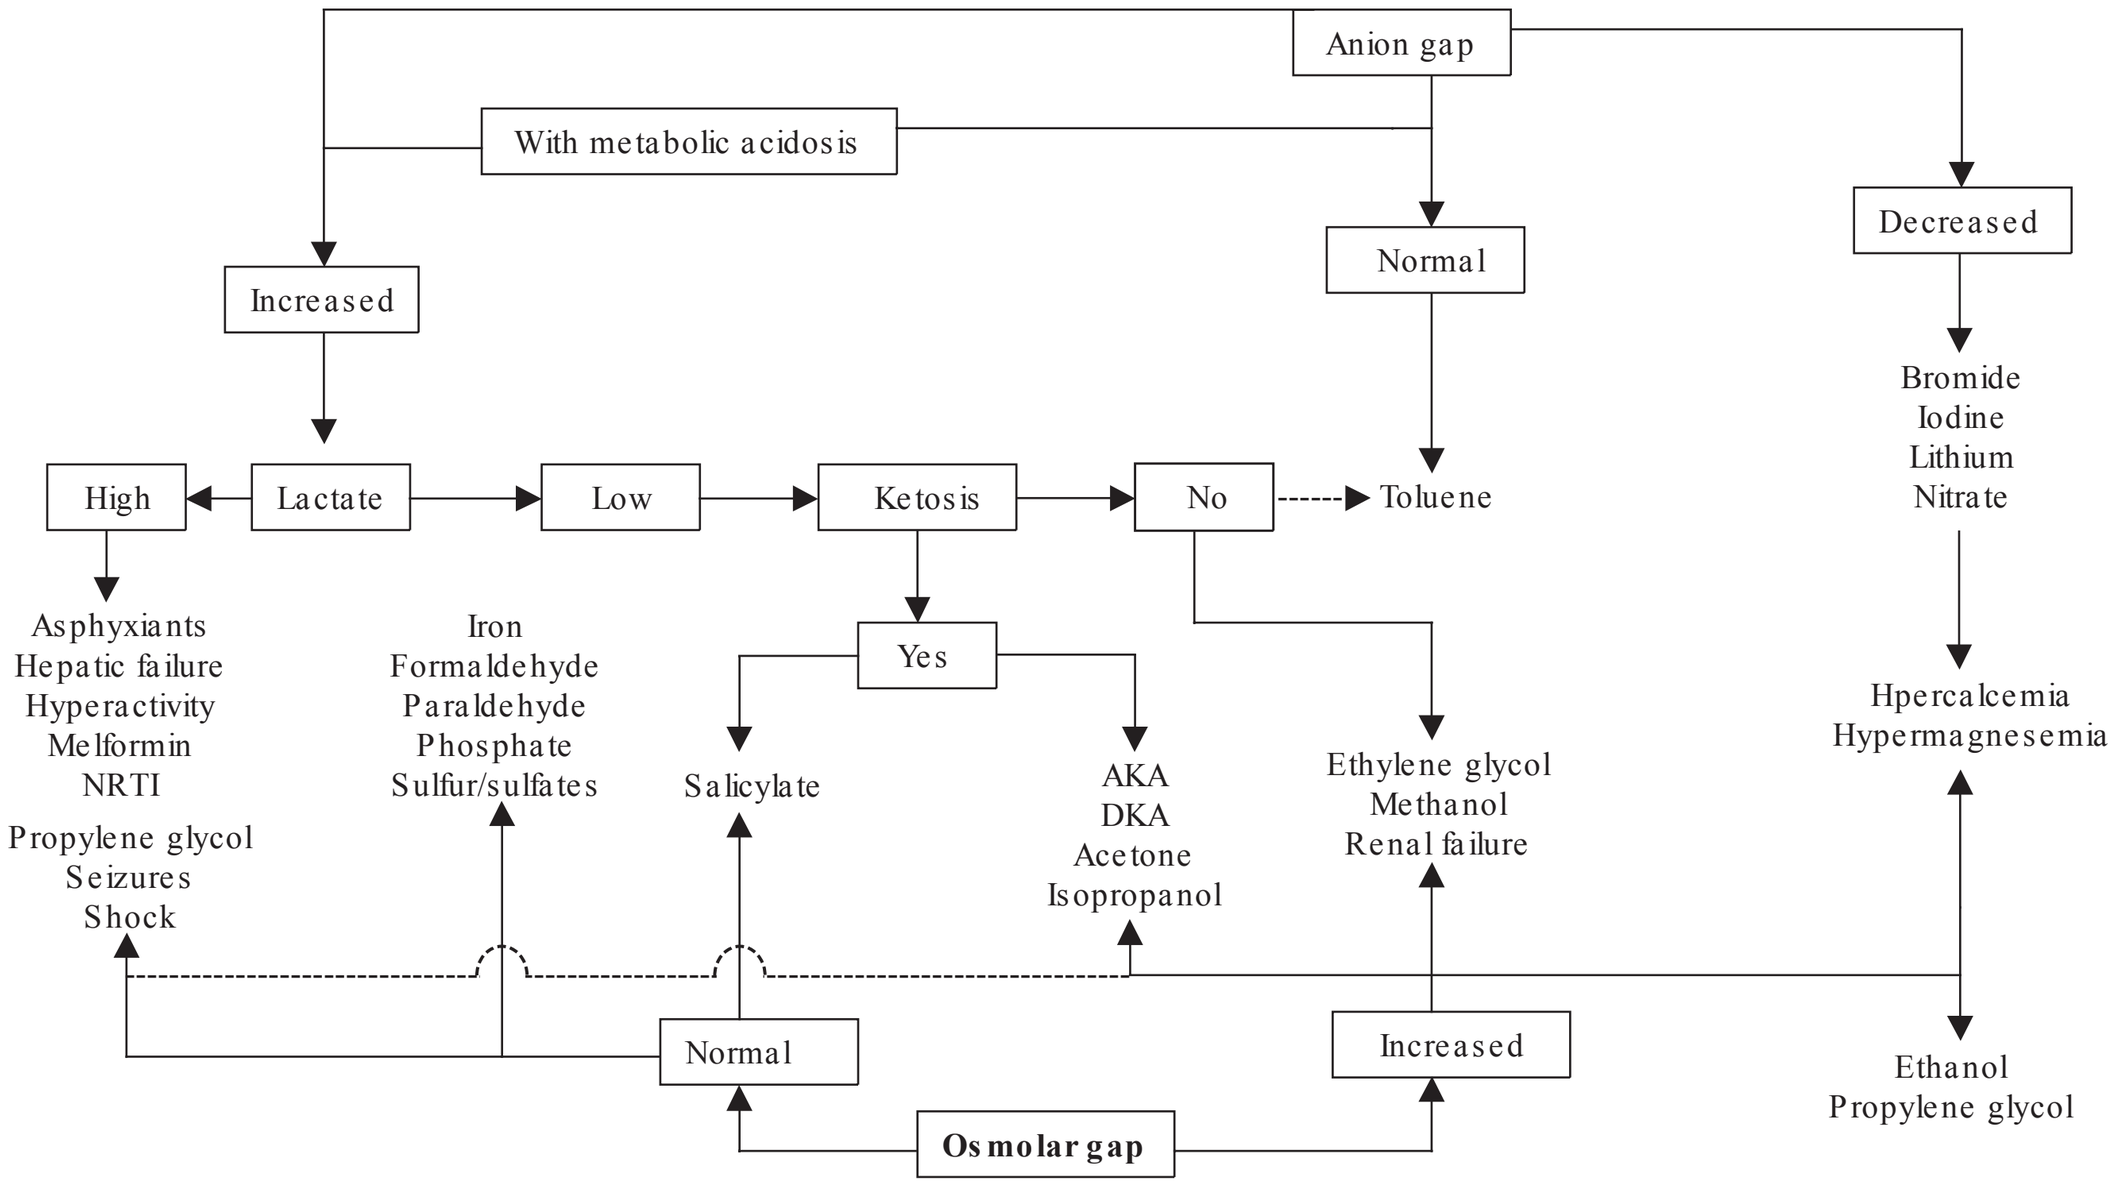

FIGURE 117.1. Use of routine laboratory findings and calculated gaps in the differential diagnosis of poisonings. AKA, alcoholic ketoacidosis; DKA, diabetic ketoacidosis; NRTI, nucleoside/nucleotide reverse transcriptase inhibitors.

as the difference between the measured serum osmolality and the calculated serum osmolality.

$$\text{Serum Osmolality } (\mu\text{mol/L}) = 2\,(\text{serum Na}) + \text{serum glucose} + \text{serum BUN}$$

where normal serum osmolality is 290 ± 10 mOsm per kg of H_2O normal osmole gap is 5 ± 7 mOsm per kg (in unselected acutely hospitalized patients [40]).

$$\text{Osmole gap} = [\text{calculated serum osmolality} - \text{measured serum osmolality}]$$

Normal osmole gap is 5 ± 7 mOsm per kg (in unselected hospitalized patients [40])

This formula assumes that all concentrations are measured in millimoles per liter. If the glucose and BUN concentrations are measured in milligrams per deciliter, dividing them by 18 and 3, respectively, gives their approximate concentrations in millimoles.

Additional causes of an increased osmolar gap include other low-molecular-weight solutes, such as acetone, ethanol, isopropyl alcohol, magnesium, mannitol, and propylene glycol [51]. The approximate concentration of these substances that will increase the serum osmolality by 1 mOsm per kg of H_2O, calculated on the basis of their molecular weights, is shown in Table 117.9. When direct measurements are not readily available, the serum concentration of these agents can be estimated by multiplying this amount by the osmolar gap. Serum osmolality must be measured by freezing point depression rather than the headspace or vapor pressure method to detect the presence of volatile agents such as acetone and toxic alcohols. An increased osmolar gap has also been reported in alcoholic ketoacidosis and conditions causing lactic acidosis [52].

Serum ketones can also help to differentiate the toxic causes of a low-lactate AGMA. Ketosis, as defined by a positive nitroprusside reaction, is relatively common in salicylate poisoning but unusual in ethylene glycol and methanol poisoning. Ketosis is also seen in alcoholic ketoacidosis and in acetone and isopropyl alcohol poisoning.

The urinalysis, serum calcium concentration, and the overall clinical picture can also be helpful in differentiating the toxic causes of a low-lactate AGMA. Crystalluria, hypocalcemia, and back pain or flank tenderness suggest ethylene glycol; visual symptoms implicate methanol; and tinnitus or impaired

TABLE 117.9

EFFECTS OF SOME SOLUTES ON SERUM OSMOLALITY

Solute	Approximate concentration required to increase serum osmolality by 1 mOsm/kg
Alcohols, glycols, and ketones	
Acetone	5.8 mg/dL
Ethanol	4.6 mg/dL
Ethylene glycol	5.2 mg/dL
Isopropanol	6.0 mg/dL
Methanol	2.6 mg/dL
Propylene glycol	7.6 mg/dL
Electrolytes	
Calcium	4.0 mg/dL (1 mEq/L)
Magnesium	2.4 mg/dL (1 mEq/L)
Sugars	
Mannitol	18 mg/dL
Sorbitol	18 mg/dL

hearing point to salicylates. Crystalluria can also be caused by acyclovir [53], felbamate [54], indinavir [55], oxalate [56], primidone [57], and sulfa drugs [58]. Hypocalcemia is also seen in fluoride and oxalate [56] intoxication.

Serum potassium and glucose abnormalities may also provide clues to the etiology of poisoning [18,59,60]. Toxicologic causes of hypokalemia include barium, β_2-adrenergic agonists, calcium channel blockers, chloroquine, diuretics, insulin, licorice, methylxanthines, and toluene. Hyperkalemia can be caused by α-adrenergic agonists, angiotensin-converting enzyme inhibitors, beta-blockers, digitalis, fluoride, potassium-sparing diuretics, and trimethoprim. Common toxicologic causes of hypoglycemia are ethanol, beta-blockers, hypoglycemics, quinine, and salicylate. Common causes of hyperglycemia include acetone, β-agonists, calcium channel blockers, iron, and methylxanthines.

Common toxicologic causes of acute liver dysfunction are acetaminophen, ethanol, halogenated hydrocarbons (e.g., carbon tetrachloride), heavy metals, and mushrooms (e.g., *Amanita phalloides* and related species) [61]. Acute renal toxicity is most often due to ethylene glycol, halogenated hydrocarbons, heavy metals, nonsteroidal anti-inflammatory drugs, toluene, envenomations, and agents that cause hemolysis or rhabdomyolysis [62]. An elevated creatinine with a normal BUN can be seen in acetone and isopropyl alcohol poisoning because acetone interferes with colorimetric assays for creatinine, resulting in falsely high results. Acute hemolysis (in the absence of glucose-6-phosphate dehydrogenase deficiency) can result from poisoning by arsine gas, naphthalene, and inducers of methemoglobinemia. Rhabdomyolysis is associated with toluene abuse, CNS syndromes (see Table 117.3), and severe physiologic dysfunction (e.g., extreme agitation, deep or prolonged coma, hyperthermia, seizures) of any etiology [63]. The most common agents involved are sympathomimetics, ethanol, heroin, and phencyclidine.

Electrocardiographic Findings

The ECG may provide clues to the cause of poisoning [18]. Ventricular tachyarrhythmias that occur in patients with normal QRS and QT intervals suggest myocardial irritation (i.e., increased automaticity) as the underlying mechanism. Sympathomimetics, digitalis, and cardiac-sensitizing agents such as chloral hydrate and aliphatic or halogenated hydrocarbons, which potentiate the action of endogenous catecholamines, are common causes [64]. In contrast, ventricular tachyarrhythmias that occur in the setting of depolarization and repolarization abnormalities, reflected by QRS and QT interval prolongation, respectively, suggest a reentrant mechanism. Causes include electrolyte abnormalities, organophosphate insecticides, and other membrane active agents (see Table 117.1) [65,66]. Torsades de pointes (polymorphous) ventricular tachycardia strongly implicates an agent that prolongs the QT interval.

Atrioventricular conduction abnormalities (atrioventricular block) and bradyarrhythmias can be caused by beta-blockers, calcium channel blockers, digitalis, membrane-active psychotherapeutic agents, organophosphate insecticides, and α-agonists such as phenylpropanolamine. With α-agonists, they are a reflex (i.e., homeostatic) response to hypertension, but with other causes, they are associated with generalized cardiovascular depression and hypotension.

Radiologic Findings

Ingested chemicals can sometimes be visualized within the GI tract by abdominal radiographic imaging, and such imaging can occasionally be helpful in suggesting the etiology or amount of an unknown ingestion. Although a large variety of chemicals can be detected by routine radiography in vitro, relatively few are visible in vivo [67]. Agents most likely to be visible on plain films are indicated by the mnemonic CHIPES (Table 117.10) [18].

TABLE 117.10

XENOBIOTICS VISIBLE ON PLAIN STOMACH RADIOGRAPHS

Chlorinated hydrocarbons
Heavy metals
Iodinated compounds
Packets of drugs
Enteric-coated drugs
Salicylates

Ingested drug packets may appear as uniform, ovoid or round, marble-sized densities scattered along the GI tract [29,30]. Ingested hydrocarbons may sometimes appear as a double gastric fluid level or "double bubble" because of the air–fluid and fluid–fluid interface lines created when less dense hydrocarbons layer on top of gastric fluids. Computed tomography may be superior to plain films in detecting ingested drug packets but the optimal test in this setting remains unclear [68,69]. Whether contrast should be used or not remains controversial. Abdominal ultrasound can detect ingested pills, particularly enteric-coated and sustained-released formulations [70]. Such imaging may be useful in confirming or refuting some recent specific (CHIPES) ingestions. Because the volume of pills can be determined, plain radiography may be used to guide GI decontamination.

Abnormal findings on chest radiography can be caused by a wide variety of chemicals [18,71]. Diffuse or patchy infiltrates (i.e., pneumonitis or acute lung injury) can be due to the inhalation of irritant gases (e.g., ammonia, chlorine, hydrogen sulfide, nitrogen oxides, phosgene, smoke, sulfur dioxide), fumes (e.g., beryllium, metal oxides, polymers), and vapors (e.g., acids, aldehydes, hydrocarbons, isocyanates, mercury). They can also be seen in patients who have ingested or injected cholinergic agents (e.g., carbamate and organophosphate insecticides), metabolic poisons (e.g., cyanide, carbon monoxide, heavy metals, hydrogen sulfide), paraquat, phencyclidine, salicylates, thiazide diuretics, and tocolytics and in patients with envenomations. Aspiration pneumonitis is quite common and can occur in patients with coma or seizures of any etiology [72]. Acute lung injury can also develop in any patient with prolonged or pronounced anoxia, hyperthermia, or hypotension (e.g., those with severe opioids or sedative–hypnotic or sympathomimetic poisoning). Chronic chemical exposure can cause pulmonary fibrosis, granulomas, or pleural plaques.

Response to Antidotes

The use of antidotes for diagnostic purposes has largely fallen from favor. The availability of point of care blood glucose measurement negates the need for empiric intravenous dextrose in altered patients. Many antidotes may be harmful if used inappropriately, including flumazenil physostigmine, glucagon, nitrites, and chelators. Naloxone remains a reasonably safe therapy in a patient with clinical signs of opiate intoxication. Clinicians should be prepared to manage acute withdrawal and its sequelae.

Toxicology Screening

Analysis of a sample of the toxin itself, or patient urine, blood, gastric contents, or hair [71,73] can sometimes be helpful in identifying the cause of poisoning. Urine is generally the best specimen to analyze because large quantities can be obtained

for extraction procedures and many chemicals are normally concentrated in urine. However, toxicology testing can detect only a small fraction of all chemicals (primarily drugs) and is not always reliable [74]. Immunoassay screens are inexpensive and provide results within minutes, but they are only capable of detecting a few agents. They suffer from many false positives and false negatives. Patients may be misdiagnosed and potentially harmed by clinicians acting solely on the results of immunoassay screens [75]. Comprehensive screens are expensive and require 2 to 6 hours for completion (excluding transportation times). Although results may increase diagnostic certainty or specificity, they rarely change disposition or treatment in patients who are asymptomatic or who have signs and symptoms consistent with the reported exposure [75–80]. Noteworthy exceptions are acetaminophen and salicylate, which are widely available, commonly ingested, sometimes misidentified, require specific treatment, and cause few or nonspecific early signs and symptoms. Hence, in most overdose patients, quantitative acetaminophen and salicylate levels are the only toxicology tests likely to be clinically useful.

Critically ill poisoned patients suffering seizures, cardiovascular instability, acid–base abnormalities, multiple organ dysfunction, nonsinus cardiac rhythms, or cardiac conduction disturbance without a toxicologic diagnosis should generally have comprehensive toxicology screening.

Knowledge of the methods used for chemical detection (e.g., colorimetric spot tests; thin-layer paper or plate chromatography; gas- or high-pressure liquid chromatography; absorbance, atomic absorption, flame ionization, or fluorometric assays; enzyme-multiplied and radionuclide immunoassays; gas chromatography with mass spectrometry) is required for accurate interpretation of the results of screening tests [75,81–83]. A positive result on one assay should always be confirmed by repeat analysis using a different technique. The physician should speak directly with the laboratory technician to determine which chemicals can be detected by the screening methods used and the sensitivity and specificity of each assay. In addition, directed analysis (e.g., coma, hallucinogen, or stimulant screen), with more rapidly available results, can be performed if the technician and clinician communicate.

A negative result from a screen should never be used to exclude the diagnosis of poisoning when clinical findings suggest otherwise. It may simply mean a chemical is not detectable by the assay(s) used, its concentration is below the limit of detection of the assay(s), or its concentration is too low to be confirmed. It may also mean the time of sampling or the specimen submitted is inappropriate for testing (e.g., the chemical may be undergoing absorption and is not yet present in urine or it may already have been metabolized or eliminated). In such cases, repeating the test on a sample obtained at an earlier or later time may be revealing.

Prediction of Potential Toxicity

The prediction of toxicity requires knowledge of the dose, time, and identity of an exposure and is necessary for determining the appropriate treatment. For commercial products, the amount and concentration of every ingredient should be identified. Household products deemed hazardous by the US Consumer Product Safety Committee are required by law to bear a label describing the nature of their toxicity and first aid measures as well as a "keep out of reach of children" warning and a signal word that indicates the degree or severity of potential toxicity [34]. The signal words "caution," "warning," and "danger" identify a product or its constituent(s) as a weak irritant (i.e., may damage mucosal surfaces), strong irritant (i.e., can damage skin and mucosa), or corrosive (i.e., can cause permanent tissue damage or death) after topical exposure or moderately toxic, highly toxic, or extremely toxic (oral median lethal dose: 50 to 500 mg per kg, 1 to 50 mg per kg, or < 1 mg per kg, respectively) after ingestion. Label information is frequently inaccurate or incomplete [34,84] and should generally be confirmed by consulting an independent information source.

The dose of drug in a pill or tablet can be determined using the resources cited in "Identification of the Offending Agent" section of this chapter. For liquids and powders, the dose can be estimated or measured using the container or the weights and volumes listed on the label. An exposure may also be reported in tablespoons or swallows. Standard flatware volumes can vary from 3 to 7 mL for a teaspoon and from 7 to 14 mL for a tablespoon. The volume of a swallow varies with age, height, weight, sex, the orifice size of the container, and the viscosity of the ingested liquid and ranges from 1 to 5 mL in infants to 4 to 40 mL in adults [85].

The accuracy and reliability of the history must be evaluated when assessing potential toxicity. The amount and time of ingestion are frequently erroneous when reported by patients with intentional self-poisoning. It is best always to assume a worst-case scenario: that the maximum possible dose (i.e., the entire amount available or not clearly accounted for) was ingested. The potential toxicity can then be estimated from previously reported toxicodynamic data. For drugs with CNS and cardiovascular activity, the ingestion of 5 to 10 therapeutic doses by an adult and one adult dose by a young child can result in significant toxicity. Beta-blockers, calcium channel blockers, and oral hypoglycemics can cause toxicity after only one or two therapeutic doses, particularly in those physiologically naïve to their effects. The ingestion of only one to two tablets, capsules, or teaspoonfuls of an antimalarial (e.g., chloroquine, hydroxychloroquine), antipsychotic (e.g., chlorpromazine, thioridazine), camphor, calcium channel blocker, methyl salicylate, opioid, oral hypoglycemic, theophylline, or tricyclic antidepressant (e.g., imipramine, desipramine) can be fatal to a toddler [86].

The time of exposure is important because it allows for prediction of the time of onset of toxicity and the time of peak toxicity. Only when the time elapsed since exposure clearly exceeds the longest reported or predicted interval between exposure and peak toxicity should the possibility of subsequent poisoning be excluded (see Table 117.5). Peak toxicity usually occurs within 4 to 6 hours of an oral overdose. Important exceptions to this generalization are the toxic time bombs described earlier. For some of these agents (e.g., acetaminophen, ethylene glycol, methanol, paraquat), the serum concentration measured during the preclinical phase can be used to predict subsequent toxicity. Peak toxicity may also be delayed (up to 12 to 24 hours) after exposure to irritants and corrosives. The possibility of pregnancy and potential toxicity to the fetus should also be considered.

Assessment of Severity

The severity of poisoning is primarily determined by findings on physical examination. Because poisoning is far more dynamic than most diseases and illnesses, frequent reevaluations are required. Poisoned patients can rapidly deteriorate, with few or no warning signs.

A complete physical examination should ultimately be performed in all patients. The examination should initially be directed toward assessment of cardiovascular stability, respiratory function, and neurologic status. Accurate and timely measurement of all vital signs is essential. The respiratory rate should be measured for a full minute. A core or rectal temperature should be obtained to detect severe or occult abnormalities. The sickest patients are the ones most likely to have significant temperature abnormalities. They are also the ones in

whom preoccupation with cardiovascular and respiratory therapy can lead to delayed temperature measurement. In contrast, an abbreviated mental status examination is usually sufficient. The degree of physiologic dysfunction should be objectively described.

The number and type of ancillary tests required to assess metabolic or organ function is determined primarily by clinical severity and secondarily by the history. Asymptomatic but potentially poisoned patients with reliable histories and unintentional exposures should have blood and urine samples obtained on presentation. Samples can be saved and subsequently sent for (baseline) analysis in the event of deterioration. Pregnancy testing, however, is recommended in all susceptible women of childbearing age. Patients who are symptomatic or suicidal should have serum electrolytes, BUN, creatinine, and glucose measurements; urinalysis; and 12-lead ECG. Arterial blood gas, serum osmolality, and ketone and methemoglobin analyses may also be indicated. Anion, osmolal, and oxygen saturation gaps should be calculated whenever their determinants are measured. Assessment of patients with respiratory complaints or grade 2 or greater stimulant or depressant poisoning (see Table 117.5) should include a chest radiograph. A complete blood cell count, coagulation studies, serum amylase, calcium, magnesium, creatine phosphokinase, and hepatic enzyme levels should also be determined in any patient with grade 2 or greater physiologic dysfunction. Additional testing (e.g., biopsies, invasive monitoring, neurodiagnostic studies, radiologic examinations) should be individualized and based on the findings of physical examination, the history, and the results of routine ancillary studies.

The measurement of chemical concentrations in serum, whole blood, or urine can sometimes help in assessing the severity of poisoning. Agents for which quantitative measurements are necessary or desirable for optimal patient management include acetaminophen, acetone, alcohols, antiarrhythmics, antiepileptics, barbiturates, carbon monoxide, digoxin, electrolytes (including calcium and magnesium), ethylene glycol, heavy metals, lithium, salicylate, and theophylline [75,81]. Quantitative or qualitative assays for other toxins are not generally helpful because they serve only to confirm the clinical impression and do not affect treatment (which is either supportive or must be initiated long before laboratory results are available in order to be effective).

Provision of Supportive Care

Meticulous supportive care is necessary to maintain physiologic and biochemical homeostasis and to prevent secondary complications (e.g., anoxia, aspiration, bedsores, shock-induced organ injury, sepsis) until detoxification can be accomplished by normal mechanisms or therapeutic interventions. Despite advances in preventing absorption, enhancing elimination, and antidotal treatment, supportive care remains the most effective therapy for most poisoned patients. Details of supportive therapy (e.g., treatment of vital sign abnormalities and organ dysfunction) can be found in other chapters. Only considerations of special relevance to the poisoned patient are discussed here.

Monitoring

Unless toxicity is minimal and predicted with a high degree of certainty to remain so, venous access should be established and continuous cardiac monitoring initiated. Because fluid resuscitation may become necessary, normal saline is the preferred IV solution. Pulse oximetry should be performed on presentation and monitored frequently if abnormal or significant (grade 2 or greater) physiologic dysfunction (see Table 117.5) is present. Until the ultimate severity of poisoning is known, frequent or continuous visual observation is also necessary. Patients with intentional self-poisoning also need close behavioral observation until the possibility of a repeat suicide attempt has been evaluated in detail and assessed to be unlikely.

Respiratory Care

Pulmonary aspiration of gastric contents is a relatively common complication of poisoning and its treatment (e.g., GI decontamination procedures) [87,88]. Patients with CNS depression or seizures are at risk for aspiration and airway obstruction. Although spontaneously breathing patients who respond to painful stimulation can sometimes be successfully managed by aspiration-preventative positioning (e.g., left lateral decubitus and Trendelenburg position) and close observation, definitive airway management is recommended for those who cannot respond by voice. Using the gag reflex to assess the need for intubation should be abandoned [87]. Many normal individuals have an absent gag reflex, and many comatose patients will gag if sufficiently stimulated and yet be unable to protect their airway. In addition, attempting to elicit a gag reflex may itself induce vomiting and cause aspiration in a patient with an altered mental state. Prophylactic or therapeutic intubation may also be required for patients with extreme behavioral or physiologic stimulation who require aggressive pharmacologic therapy with sedative, antipsychotic, anticonvulsant, or paralyzing agents. Even in comatose patients, pretreatment with a sedative and neuromuscular blocking agent can facilitate intubation [88]. An endotracheal tube with a low-pressure high-volume cuff is recommended to reduce aspiration, but it is by no means completely effective [89]. In intubated patients who can tolerate it, elevating the head of the bed may decrease the incidence of aspiration [90]. Extracorporeal membrane oxygenation, cardiopulmonary bypass, nitric oxide, prone positioning, and oscillation should be considered in patients with reversible poisoning who cannot otherwise be adequately oxygenated or ventilated.

Cardiovascular Therapy

Because of adverse drug interactions, therapy intended to maintain or restore normal blood pressure, pulse, and sinus rhythm may worsen, rather than alleviate, cardiovascular toxicity. Hence, the severity and trend of cardiovascular abnormalities and the potential complications of treatment should be considered before instituting pharmacologic therapy. In addition, because the causes of cardiovascular toxicity are varied and multiple mechanisms may be concurrently operative, invasive hemodynamic monitoring may be necessary for accurate diagnosis and optimal treatment. Aggressive supportive measures, such as transvenous cardiac pacing and intra-aortic balloon pump or cardiopulmonary bypass should be considered in patients with reversible poisoning who are unresponsive to routine therapeutic measures [91].

In the absence of extremes of heart rate, hypotension due to poisoning is most often caused by loss of peripheral vascular tone rather than pump failure. Bedside echocardiography can also be useful to assess cardiac output. Norepinephrine is generally considered the first line vasopressor in patients who do not respond to fluid administration.

When hypertension causes end organ dysfunction, therapy is indicated. In patients with sympathomimetic poisoning, beta-blockade may result in unopposed α receptor stimulation. This leads to increased peripheral vascular resistance, increasing the demand on a beta blocked heart. Hence, treatment with a non-selective sympatholytic or with an arteriodilator followed by a beta blocker is preferred.

Sinus tachycardia can usually be managed with sympatholytics. In patients with sympathomimetic poisoning and

signs or symptoms of myocardial ischemia, a beta-blocker (with or without an arteriodilator, depending on the presence or absence of coexisting hypertension) or a calcium channel blocker can be used.

Lidocaine is generally first line therapy for ventricular tachyarrhythmias. Underlying electrolyte and metabolic abnormalities should be corrected. Sodium bicarbonate or hypertonic saline may be effective in treating wide-complex tachycardias due to toxins with sodium channel blocking properties.

Normalizing electrolytes and continuous electrocardiographic monitoring is the mainstay of treatment for toxins that prolong the QT interval. The clinician must be prepared to manage Torsades des Pointes. Antibodies are available to treat serious dysrhythmias caused by cardiac glycosides. Magnesium may also be effective in digitalis poisoning. Procainamide, other class 1 A agents, beta-blockers, and physostigmine should not be used for arrhythmias caused by membrane-active agents or those associated with prolonged QRS or QT intervals because of the potential for worsening rhythm disturbances and conduction abnormalities.

Bradycardia requires treatment only if it is associated with hemodynamic instability. In most cases, atropine, dopamine, and epinephrine are the agents of choice. Calcium, glucagon, and high dose insulin can be effective in calcium channel blocker and beta-blocker poisoning.

Treatment of Neuromuscular Hyperactivity

Profound metabolic acidosis and sudden cardiac arrest can occur in patients with severe agitation who continue to struggle while being physically restrained. Prompt pharmacologic treatment of behavioral and muscular hyperactivity in such patients is critical. In general, benzodiazepines are preferred to antipsychotic agents because the latter lower the seizure threshold and prolong QTc. In phencyclidine poisoning, however, haloperidol, a central dopaminergic antagonist, may be more effective than benzodiazepines because phencyclidine has central dopaminergic activity. Similarly, chlorpromazine may be more effective than benzodiazepines in hallucinogen poisoning. The combined use of benzodiazepines and neuroleptics can be more effective than either alone; doses and side effects can often be minimized using this approach. For agitation and hallucinations due to anticholinergic poisoning, physostigmine may be considered.

Seizures can usually be effectively treated with GABA agonists such as benzodiazepines and barbiturates. Pyridoxine is usually necessary in isoniazid poisoning. Phenytoin, a Vaughn–Williams class 2 anticonvulsant, should be avoided in all cases where a toxin with sodium channel blocking properties may have been ingested. Seizures due to cyanide, hydrogen sulfide, and organophosphate insecticides usually require specific antidotes.

Severe agitation or prolonged convulsions can also cause rhabdomyolysis and hyperthermia. Because these complications can result in additional organ dysfunction, neuromuscular blocking agents should be given to patients who do not respond to sedatives and anticonvulsants. During such therapy, seizures should continue to be monitored (by electroencephalography) and treated to prevent permanent neurologic damage. Nondepolarizing agents are preferable to succinylcholine for inducing paralysis, because the latter agent may be hazardous in patients with rhabdomyolysis [23].

Prevention of Absorption

Early and effective decontamination can limit the surface exposure and systemic absorption of chemicals and reduce toxicity. Decontamination should be considered in all patients unless the exposure is clearly nontoxic (see Table 117.4), the time of predicted peak toxicity has passed, or the benefit of decontamination is minimal.

Body Cavity Exposure

The removal of chemicals from body cavities (e.g., bladder, external auditory canal, nose, rectum, vagina) can be accomplished by aspiration and irrigation using normal saline. Particulate matter (e.g., pills, suppositories, drug packages) should be manually removed, preferably under direct visualization. The removal of ingested drug packages from the GI tract is discussed in "Ingestion" section of this chapter.

Eye and Skin Exposure

Decontamination after topical exposure includes manual removal of particulate material, irrigation of exposed surfaces, and a scrub for skin exposure to noncorrosive chemicals. Because "time is damage," particularly with corrosives, tap water or any other readily available liquid that is clear and drinkable can be used in the prehospital setting. If exposure involves an unknown chemical, its pH should be measured. Searching for pH paper (e.g., pHydrion), usually available in the emergency department or the labor and delivery area, should not delay treatment. Irrigation should initially be performed for about 20 minutes. Prolonged irrigation (up to 24 hours) may be beneficial for corrosive exposures, especially those involving strong alkali.

With ocular exposures, blepharospasm secondary to pain can prevent effective irrigation unless treatment is preceded by the instillation of a topical anesthetic. Particulate material should be removed with a moist cotton-tipped swab or eye spud. Normal saline and lactated Ringer's solution are traditionally used irrigation fluids. It is unclear whether commercially available pH-balanced saline solutions and normal saline adjusted to a pH of 7.4 with sodium bicarbonate are less irritating than normal saline or lactated Ringer's solution [92,93]. Warming the solution may decrease discomfort [94], but this is not necessary if an anesthetic is used. Irrigating solutions can be administered via an IV infusion setup, directly through the tubing, or via an irrigating (Morgan) lens attachment. A low-pressure squeeze bottle also may be used. One or two liters is usually sufficient. For acid or alkali exposures, the tear pH (normally 7.3 to 7.7) should be determined after and before irrigation. Irrigation should continue until the pH is between 5 and 8.

For skin exposures, treatment should begin with the removal of contaminated clothing. Gloves should be worn to prevent contamination of caretakers. Particulate matter should be removed from the skin using a soft brush, forceps, or handheld vacuum cleaner before irrigation. Washing the skin with soap and water or isopropyl alcohol more effectively prevents pesticide absorption than simply rinsing with water [95]. For some toxins, a triple wash (irrigation and washing with soap before and after an alcohol scrub) may provide better decontamination than irrigation alone. Because it contains 30% alcohol, tincture of green soap has been recommended as a skin detergent [27].

Inhalational Exposure

The patient should be removed from the contaminated atmosphere and supplemental oxygen administered. Under no circumstances should a rescuer enter a hazardous dust, fume, gas, or vapor environment without adequate eye, skin, and respiratory protection.

Ingestion

GI decontamination can be accomplished with activated charcoal, gastric lavage, whole-bowel irrigation, and endoscopic or surgical removal of the ingested chemical. There is little to no role for Ipecac. Cathartics, although often used in conjunction with other treatments, are not an effective method of decontamination [96,97]. Except in cases of corrosive ingestion, the same is true for diluents.

Despite extensive experimental data documenting the efficacy of GI decontamination measures in preventing chemical absorption in animals and in human volunteers, there is no conclusive evidence that these interventions improve the outcome in actual overdose patients [98–103]. Clinical efficacy is difficult to prove because the overdose history is frequently unreliable, and most overdoses do not cause severe or life-threatening toxicity. In addition, the efficacy of GI decontamination decreases as the time between ingestion and treatment increases. Experimental data showing that GI decontamination is effective in preventing chemical absorption when initiated more than 1 hour after ingestion is limited. Since the mean time between ingestion and arrival at a hospital is more than 1 hour in children and more than 3 hours in adults [104–110], most patients present for treatment at a time when the efficacy of GI decontamination remains unknown.

With the sophisticated monitoring and supportive techniques available today, it is likely that most poisoned patients will recover fully without any decontamination therapy [105,109]. However, since experimental studies show that decontamination can limit toxin absorption and shorten the duration of toxicity, and since absorption is prolonged after overdose, decontamination may be effective longer after ingestion than experimentally proven. It is therefore recommended that it be performed unless the exposure is nontoxic (see Table 117.4), or the risk of decontamination outweighs the potential benefit.

The choice of decontamination method should be based on the relative efficacy, and contraindications of the available options. Activated charcoal has equal or greater efficacy, fewer contraindications, less frequent and less serious complications than other methods of decontamination, and is the preferred treatment for most overdoses [103–114]. Emptying the stomach via lavage is rarely indicated. Overdose patients treated with gastric lavage or syrup of ipecac in the emergency department have longer emergency department stays and have a higher incidence of pulmonary aspiration (which sometimes necessitates admission of a patient who would otherwise be discharged) than those treated with activated charcoal [104,106,107].

Gastric lavage is indicated in a recent life-threatening ingestion, when the toxin is small in size or easily dissolved in the stomach, not well adsorbed by activated charcoal and not responsive to other therapies. Syrup of ipecac is virtually never the best method of GI decontamination and is no longer routinely recommended, even for the home management of ingested poisons [115]. Whole-bowel irrigation should be considered in patients who have ingested toxic amounts of agents that are slowly absorbed or not amenable to decontamination by other techniques. Endoscopy and surgery should be reserved for patients with potentially severe poisoning in whom alternative methods of decontamination are unsuccessful or contraindicated.

Activated Charcoal. Activated charcoal can prevent absorption of ingested chemicals by binding them within the gut lumen. Its clinical efficacy remains controversial [103] because it is neither absorbed nor metabolized, the toxin bound to it is normally eliminated with stool [102,105,116,117]. Activated charcoal is a fine black powder produced by the activation (i.e., pyrolysis, oxidation, and purification) of carbon-containing materials such as bone, coal, peat, petroleum, and wood. It is odorless, tasteless, and insoluble in liquids. The activation process yields particles that have an extensive internal network of minute, branching, irregular, interconnecting channels (i.e., pores) that range in size from approximately 10 to 100 nm in diameter and account for the extremely large surface area of activated charcoal. The surface area of activated charcoal in clinical use ranges from 600 to 2,000 m^2 per g.

The absorption or adherence of chemical molecules to the external and internal surfaces of activated charcoal is rapid (within minutes of contact). It is due to relatively weak van der Waals forces and can be described by the following reversible equilibrium: activated charcoal + toxin ↔ activated charcoal – toxin complex. Hence, as the amount of activated charcoal is increased, the fraction of unbound or free chemical decreases (i.e., the equilibrium shifts to the right according to the law of mass action). At an activated charcoal to chemical ratio of 10 to 1 or greater, 90% or more of most chemicals is adsorbed into charcoal in vitro. The absorptive capacity (i.e., the amount of chemical that can be absorbed by 1 g of charcoal in vitro) ranges from a few milligrams to more than 1 g depending on the molecular size, structure, and solubility of the chemical, the pore size and surface area of activated charcoal, the negative logarithm of acid ionization constant of the chemical and the pH of the solution, and the presence or absence of competing solutes. Small, highly ionized molecules of inorganic compounds, such as acids, alkali, electrolytes (e.g., potassium), and the readily dissociable salts of arsenic, bromide, cyanide, fluoride, iron, and lithium, are not well adsorbed by activated charcoal [116,117].

In animal studies and in simulated overdoses using therapeutic or slightly greater doses in human volunteers, activated charcoal prevents the GI absorption of nearly all chemicals [116]. In agreement with in vitro studies, as the ratio of activated charcoal to chemical increases, its efficacy increases; with simultaneous dosing of activated charcoal and chemical at a ratio of 10 to 1 or greater, charcoal prevents the absorption of most chemicals by more than 90%. At a constant charcoal to chemical ratio, the efficacy of activated charcoal in preventing chemical absorption increases as the amount and concentration of either agent increases [116,117], suggesting that the efficacy of activated charcoal may be relatively greater after actual overdose than it is after a simulated one. Diluting a dose of activated charcoal and administering it in aliquots by gastric lavage is less effective than administering the same dose as a single concentrated bolus [117]. Administering a dose before and after gastric lavage is more effective than giving one only after lavage.

The interval between administration of toxin and activated charcoal also has a significant effect on the in vivo efficacy of charcoal. As this interval (i.e., the time for uninhibited absorption) increases, the ability of activated charcoal to prevent chemical absorption decreases. In controlled studies using doses of activated charcoal many times greater than those of toxin, charcoal decreased chemical absorption an average of 71% (range, 10% to 100%) when it was given within 5 minutes, 52% (range, 17% to 75%) when given at 30 minutes, and 38%, 34%, 21%, 29%, and 14% when given at 1, 2, 3, 4, and 6 hours, respectively [102,105].

The ability of activated charcoal to prevent the absorption of a toxin in vivo generally correlates with its ability to adsorb that chemical in vitro [116]. However, the absorption of some toxins that are poorly adsorbed by activated charcoal (e.g., cyanide, malathion, tolbutamide) is significantly reduced. Conversely, the absorption of some toxins that are relatively well adsorbed by activated charcoal in vitro (e.g., ethanol, ipecac, *N*-acetylcysteine) is not significantly inhibited in vivo.

The presence of food in the stomach appears to enhance the efficacy of activated charcoal in preventing the absorption of ingested agents, possibly by slowing gastric emptying. Coingested antacids, cathartics, chocolate, ethanol, and excipients have variable but relatively minor or no effect on its efficacy.

Activated charcoal is administered as an aqueous suspension; a minimum of 8 mL of water should be added to each gram of powdered charcoal if a premixed formulation is not available. Premixed product containers should be thoroughly agitated to resuspend sedimented charcoal before use.

Activated charcoal can be given orally to awake patients or by gastric tube to comatose or uncooperative patients. A nipple bottle can be used for infants. Putting the suspension in an opaque container and having the patient sip it through a straw may enhance its acceptability in adults. The recommended dose is at least 10 times the weight of the ingested toxin. Because of volume constraints, the maximum single dose is generally limited to 1 to 2 g per kg of body weight.

Compared with other methods of GI decontamination, the advantages of activated charcoal are ease of administration, rapidity of action, extensively documented safety and efficacy, lack of absolute contraindications, and its ability to enhance toxin elimination (see "Multiple-Dose Activated Charcoal" section of this chapter). The main disadvantages are its color (black), gritty taste, ability to stain clothing (which can limit its acceptance by staff and patients), and low or reversible binding of some chemicals. It can also prevent the enteral absorption and enhance elimination of drugs administered for therapeutic purposes.

In controlled studies in human volunteers, activated charcoal is equal or superior to gastric lavage and emesis in preventing drug absorption [118,119]. Activated charcoal was more effective than gastric lavage and emesis in preventing the absorption of drugs from sustained-release preparations 1 hour after drug ingestion [119] but less effective than whole-bowel irrigation at 4 hours after ingestion [120]. In awake overdose patients, activated charcoal alone caused fewer adverse effects and was equal or superior to syrup of ipecac followed by charcoal in terms of clinical outcome [107–110]. It was equally or more effective than gastric lavage followed by charcoal in obtunded patients [107,108], particularly those who presented more than 1 hour after overdose [108], although this was not observed in patients treated earlier [107]. In asymptomatic overdose patients, there was no difference in clinical outcome between those who were treated with activated charcoal and those who received no decontamination [109].

Activated charcoal is nonreactive and nonabsorbable and has little or no intrinsic toxicity. Adverse effects associated with activated charcoal therapy include nausea, vomiting, abdominal cramps, diarrhea, and constipation. These effects may be related to excessive volumes or rapid administration, concomitant cathartic therapy, prior treatment with syrup of ipecac, or the ingested toxin because they are rarely observed in volunteers given activated charcoal. Aspiration of activated charcoal along with gastric contents can result in large and small airway obstruction, pneumonitis, and death [121–124]. Aspiration of an aqueous suspension of activated charcoal can also increase airway resistance, pulmonary microvascular permeability, and shunt fraction, and decrease vital capacity [125]. If activated charcoal gets into the eyes, it can cause corneal abrasions [124].

Although there are no absolute contraindications, activated charcoal is not recommended for ingestions of acids, alkali, and hydrocarbons that are poorly absorbed and have low systemic toxicity (i.e., low-viscosity petroleum distillates and turpentine) [102,103,105,112,117]. It does not adsorb these corrosives and obscures endoscopic assessment of the extent of injury. With hydrocarbons, it may promote vomiting and increase the risk of pulmonary aspiration.

Gastric Lavage. Gastric lavage can directly remove ingested chemicals from the stomach and thereby prevent their absorption [100]. As with activated charcoal, the efficacy of gastric lavage decreases as time between ingestion and treatment increases. In animal studies and in simulated overdoses using therapeutic or slightly greater doses in human volunteers, gastric lavage decreased chemical absorption an average of 42% (range, 29% to 90%) when performed within 20 minutes of chemical administration, 26% (range, 13% to 38%) when performed at 30 minutes, and 17% (range, 8% to 32%) when performed at 60 minutes [100]. Efficacy is enhanced if activated charcoal is given before and after lavage [115], but not if it is only given afterward [118].

Gastric lavage is performed by first aspirating stomach contents and then repetitively instilling and withdrawing fluid through a nasogastric or orogastric tube [125]. It appears to be most effective if the patient is placed in a left lateral decubitus Trendelenburg position. The left lateral decubitus position has also been shown to delay spontaneous drug absorption [126]. An unknown fraction of gastric contents may enter the duodenum during gastric lavage [127]. Although theoretically reasonable and commonly stated as fact, there is no direct evidence that a large-bore tube (i.e., 28 to 40 Fr) is more effective than a small-bore (i.e., 16 to 18 Fr) tube. On the contrary, no difference in the recovery of either solid (i.e., pill) or liquid formulations with respect to tube size has been found in experimental or clinical [128] studies. Most intact pills do not fit through the lumen of even the largest tube [129]. They are, however, designed to disintegrate rapidly [127]. Hence, unless lavage is accomplished very soon after ingestion, the size of the tube is probably irrelevant.

The simplest, quickest, and least expensive method to use is a funnel connected to the lavage tube, raising it 2 to 3 feet above the level of the stomach when administering fluid and lowering it 2 to 3 feet below the stomach to allow drainage [130].

Tap water is the lavage fluid of choice for patients older than 2 years. Because of the potential for inducing fluid and electrolyte disturbances, normal saline is recommended for younger patients [131]. Using warm fluids may increase pill dissolution and inhibit gastric emptying, and massaging the epigastrium may promote the mixing and suspension of gastric contents and enhance the efficacy of gastric lavage. The optimal volume of fluid for each lavage cycle is unclear. Recommended amounts range from 60 to 800 mL for adults and up to 10 mL per kg of body weight for children [100,125,127]. Larger aliquots (5 to 10 mL per kg body weight) are superior to smaller ones. The majority of chemical recovery occurs with the initial aspiration and first few lavage cycles, but estimation of recovery on the basis of visible pill fragments in the lavage effluent is unreliable [128], probably because most of what is seen consists of insoluble excipients and bears little relation to the amount of drug present. Nevertheless, it is recommended that lavage be continued until the return is relatively clear. It is rarely necessary to use more than 5 L of fluid. Injection of air into the stomach may prevent or alleviate obstructed drainage due to mucosal collapse around lavage tube orifices. When performed successfully, the amount of fluid recovered should be 90% or more of that instilled.

Endotracheal intubation is neither necessary nor sufficient to prevent aspiration during gastric lavage. On the contrary, gastric lavage can safely be performed on awake patients without endotracheal intubation [100,131,132], and the presence of an endotracheal tube does not preclude aspiration [89,100]. In both situations, however, proper positioning is essential. In awake but uncooperative patients, it is intuitively safer to use a small-bore tube rather than a large one. The practice of physically restraining a combative patient and forcibly inserting a large-bore tube invites a mechanical complication (see later)

and should be abandoned. If a large-bore tube is deemed necessary (e.g., a witnessed ingestion of a highly lethal quantity of chemical), therapeutic sedation with or without paralysis, along with endotracheal intubation, is recommended. Short-acting agents should be used.

In experimental animal and human studies, gastric lavage is not as effective as activated charcoal [120]. In adult overdose patients, gastric lavage followed by activated charcoal was no more effective in preventing clinical deterioration than charcoal alone [104,108,110], except in comatose patients who presented within 1 hour of ingestion.

Gastric lavage can sometimes recover large amounts of chemicals. However, significant quantities of drugs are recovered in only a small fraction of patients. In acutely inebriated patients, gastric aspiration removed the equivalent of more than 40 mg per dL of ethanol in only 18% [133]. Gastric endoscopy after gastric lavage revealed residual solid in the stomach of 88% of overdose patients [134].

As in experimental studies, the clinical efficacy of gastric lavage decreases as the time between overdose and initiation of treatment increases. The efficacy of gastric lavage increases in cases of toxin induced gastroparesis or decreased intestinal motility.

Gastric lavage can result in significant morbidity and mortality. It is associated with an increased incidence of aspiration and ICU admission [104] and was thought to have contributed to death in 8 of 22 (36%) patients who died after this procedure [135]. Misplacement of the lavage tube in the trachea can result in pneumothorax, pneumonia, and death [136–138]. Malpositioning of the tube, primarily in the esophagus, has been reported in 50% of pediatric patients undergoing gastric lavage [139]. Basing tube insertion length on the child's height or length and radiographic imaging have been suggested as ways to improve and document tube placement. The lavage tube can also become kinked and impacted in the esophagus [140,141]. Because forceful removal can lead to esophageal perforation [141], inserting a flexible pediatric esophagoscope into the lumen of the tube under fluoroscopy and advancing the kinked area into the stomach where the tube can be straightened has been recommended as treatment for this complication. Esophageal spasm can prevent tube removal, a problem that can be reversed by administering glucagon [142]. Esophageal perforation can occur during tube insertion [143]. Laryngospasm [144], hypoxia, ECG changes and dysrhythmias [145], and cardiac arrest [128] have also been reported. Other complications include hematemesis, gastric rupture, charcoal empyema, and pneumoperitoneum [126,140,146,147]. On endoscopy, esophageal and gastric erosions are noted in almost all patients treated by gastric lavage using a large-bore tube [148].

Although there are no absolute contraindications to gastric lavage, its use in corrosive and hydrocarbon ingestions is rarely advisable [100,123,124,147–150]. With corrosives, insertion of a tube may increase the risk of esophageal perforation. Hence, it should be reserved for large ingestions of liquid acid or alkali and for agents that can cause systemic toxicity (e.g., heavy metals, hydrazine), and only done if it can be performed within 1 to 2 hours of exposure. Because lavage may increase the risk of pulmonary aspiration after hydrocarbon ingestion [150], it should be reserved for large ingestions of agents that have systemic toxicity (i.e., camphor, halogenated and aromatic derivatives, and those that contain heavy metals or pesticides).

Syrup of Ipecac. Although syrup of ipecac is simple to use, and was once widely available for home administration, it is less effective than activated charcoal in preventing chemical absorption in experimental studies and has more contraindications [99]. Vomiting exposes patients to aspiration risks and may preclude the administration of activated charcoal or other oral antidotes (e.g., *N*-acetylcysteine). There is virtually no role for Ipecac in the critically ill poisoned patient.

Whole-Bowel Irrigation. *Whole-bowel irrigation* refers to the enteral administration of large volumes of an electrolyte solution. It is commonly used to cleanse the GI tract before colonoscopy, barium enema radiography, and bowel surgery and can prevent the absorption of ingested chemicals by promoting enhancing gut motility [98,101,151–154].

In experimental studies, whole-bowel irrigation decreased chemical absorption by about 70% (range, 67% to 73%) when initiated 1 hour after simulated overdose of ampicillin, paraquat, and sustained-release formulations of aspirin and lithium and 4 hours after a supratherapeutic dose of enteric-coated aspirin [120,154–157]. Whole-bowel irrigation is also a form of dialysis. It has been used in the treatment of uremia [158] and can enhance elimination of previously absorbed chemicals [159]. Whole-bowel irrigation solutions have been found both to enhance [160,161] and to interfere [152–154,157] with the in vitro adsorptive capacity of activated charcoal.

Whole-bowel irrigation is performed by orally administering a solution of electrolytes and polyethylene glycol (e.g., CoLyte, GoLYTELY) at a rate of 0.5 L per hour in children 9 months to 6 years of age, 1 L per hour for 6- to 12-year-olds, and 2 L per hour for those older than 12 years, until the rectal effluent is clear, which typically takes 2 to 4 hours. In the ICU setting, the solution should be administered by nasogastric tube. The head of the bed should remain elevated during treatment.

In human volunteer studies, whole-bowel irrigation was more effective than gastric lavage and more or less effective than activated charcoal in preventing drug absorption [120,154,162]. The combination of charcoal followed by whole-bowel irrigation was more effective than whole-bowel irrigation alone but equally or less effective than charcoal alone [155–157]. Although no controlled studies addressing efficacy in overdose patients have been performed, it may be useful for ingestions of enteric-coated or sustained-release pharmaceuticals, foreign bodies (e.g., bezoars, button batteries, drug packets, lead paint chips), and agents that are poorly adsorbed by activated charcoal (e.g., iron and other metals), and in patients with extremely large ingestions or delayed presentation [102,151–174]. Potential complications of whole-bowel irrigation include regurgitation and aspiration of gastric contents and abdominal distension with cramping [102,151,156,175]. Fluid and electrolyte abnormalities have not been noted. Disadvantages of whole-bowel irrigation are that it is unpleasant, labor intensive, and time-consuming. Contraindications include bowel obstruction, perforation or ileus, and hemodynamic instability. It can be safely performed in intubated obtunded patients.

Endoscopy and Surgery. Gastric endoscopy, using baskets or snares to grasp or break up particulate chemicals, can be used to remove foreign bodies (e.g., button batteries that break apart or fail to pass beyond the pylorus) and gastric pill bezoars or concretions (see Absorption section) [176–178]. It should be reserved for patients with severe or potentially lethal poisoning, such as those with large amounts of heavy metal visible in the stomach on radiograph and those who continue to deteriorate and have rising drug levels despite attempts at GI decontamination by other methods. Endoscopy should never be used for the removal of drug packets, because it may cause rupture and lethal toxicity [179].

Immediate retrieval by laparotomy is indicated for patients who develop toxicity after the ingestion of packets containing cocaine [179]. Surgery should also be considered when

TABLE 117.11

CHEMICALS AND TOXIC SYNDROMES WITH SPECIFIC ANTIDOTES

Agent/condition	Antidotes
Acetaminophen	*N*-acetylcysteine
Anticholinergic poisoning	Physostigmine
Anticoagulants	Phytonadione (vitamin K), protamine
Benzodiazepines	Flumazenil
β-adrenergic antagonists	Glucagon, calcium salts
Calcium channel blockers	Calcium salts, glucagons
Carbon monoxide	Oxygen, hyperbaric oxygen
Cholinergic syndrome	Atropine, pralidoxime
Cyanide	Nitrites, thiosulfate, hydroxycobal
Digoxin (digitalis)	Fab antibody fragments, magnesium
Dystonic reactions	Benztropine, diphenhydramine
Ethylene glycol	Ethanol, 4-methylpyrazole, pyridoxine, thiamine
Envenomations (arthropod, snake)	Antivenins
Fluoride	Calcium and magnesium salts
Heavy metals (arsenic, mercury, lead)	British antilewisite (dimercaprol), dimercaptosuccinic acid, d-penicillamine, calcium disodium, ethylenediaminetetraacetic acid
Hydrogen sulfide	Oxygen, nitrites
Iron	Deferoxamine
Isoniazid (hydrazines)	Gamma-aminobutyric acid agonists, pyridoxine
Methanol	Ethanol, 4-methylpyrazole, folate
Methemoglobinemia	Methylene blue
Opioids	Naloxone, nalmefene, naltrexone
Sympathomimetics	Adrenergic blockers
Vacor (*N*-3-pyridylmethyl-*N′*-*p*-nitrophenylurea)	Nicotinamide (niacinamide)

endoscopic removal is unsuccessful or impossible because of the location of the toxin or foreign body [180,181].

Cathartics. Cathartics are osmotically active saccharides (e.g., mannitol, sorbitol) or salts (e.g., magnesium citrate, magnesium sulfate, disodium phosphate) that cause retention of fluids within the gut, thereby stimulating GI motility and the evacuation of intestinal contents [96,97,124,149,182–184]. In animal and human volunteer studies, cathartics have variable but clinically insignificant effects on chemical absorption [96,97]. Their effect on the efficacy of activated charcoal is also minimal and clinically insignificant [185–189]. There is currently no role for cathartics in the critically ill poisoned patient.

Dilution. The administration of water, milk, or other drinkable liquids is now recommended as a primary treatment only for corrosive ingestions [190]. In this setting, dilution may lower the concentration of chemical and limit its toxicity. To be effective, dilution should be accomplished as soon as possible. The volume of fluid should not exceed 5 mL per kg, because larger amounts may induce vomiting and cause further esophageal exposure. Dilution is no longer recommended to prevent toxin absorption. It may facilitate the dissolution of solid chemicals, increase the amount of chemical in solution, and stimulate gastric emptying, thereby enhancing chemical absorption.

Antidotal Therapy

Antidotes directly or indirectly counteract the effects of toxins [15,18,191–195]. They can be classified as *selective* or *nonselective*. Selective antidotes act by competing with chemicals for target sites or metabolic pathways, by binding and neutralizing them (e.g., antibodies and chelators), by promoting their metabolic detoxification, and by antagonizing their autonomic effects via activation or inhibition of opposing neuronal pathways (see Table 117.11). Nonselective antidotes act by correcting metabolic derangements or enhancing nonmetabolic toxin elimination.

Although antidotes can reduce morbidity and mortality, few are available and most are potentially harmful, and reasonable diagnostic certainty is necessary for their safe and effective use. Specific indications, contraindications, dosing, and potential complications are discussed in the chapters that deal with specific poisonings. A summary Table of antidotes can be found in the Appendix.

Enhancement of Elimination

The nonmetabolic elimination of most toxins can be accelerated by therapeutic interventions such as diuresis, urine alkalization, GI dialysis (i.e., multiple-dose activated charcoal or whole-bowel irrigation), and extracorporeal techniques. To be of potential clinical importance, a significant fraction (i.e., 25%) of the dose must be removed, or the rate of elimination, as assessed by clearance or half-life, must be significantly greater (i.e., 25%) than that accomplished by intrinsic mechanisms.

All enhanced elimination procedures are associated with potential complications, and some require specialized equipment and expertise. Reasonable diagnostic certainty is generally a prerequisite to their use. In general, invasive elimination procedures should be reserved for patients with severe poisoning

who deteriorate or fail to improve despite aggressive supportive care, antidotal therapy, and noninvasive methods of toxin removal [196–199].

Diuresis and Manipulation of Urinary pH

Maintenance of a dilute urine flow enhances toxin excretion by decreasing the passive distal tubular reabsorption of toxins that have undergone glomerular filtration and proximal tubular secretion [14–18,196–200]. Increasing urinary pH (considered neutral at a pH of 6) can enhance the renal excretion of acidic toxins by the mechanism known as ion trapping. Like all membranes, those of the nephron, particularly the distal tubule, are generally more permeable to nonionized and nonpolar molecules than to ionized and polar ones. After filtration and secretion, nonionized forms of weak acids or become ionized and trapped in an alkaline urine. Diuresis and urinary alkalinization act synergistically [201].

Diuresis alone can enhance the renal excretion of alcohols, bromide, calcium, fluoride, lithium, meprobamate, potassium, and isoniazid. Except for calcium and potassium, however, clinical efficacy remains unproven.

Alkalinization of the urine can enhance the excretion of the chlorophenoxy acetic acid herbicide 2,4-D (and probably 2,4,5-T), chlorpropamide, diflunisal, fluoride, methotrexate, phenobarbital (and probably other long-acting barbiturates), sulfonamides, and salicylates. Only for phenobarbital and salicylate poisoning is urinary alkalization accepted as clinically effective [202].

The goal of diuresis is a urine flow of 3 to 8 mL per kg per hour and that of alkalinization is a urine pH of 7.5 or greater. IV administration of 0.9% saline (sodium chloride) is used for inducing diuresis. An alkaline diuresis solution can be prepared by adding three ampules (132 mEq) of sodium bicarbonate to dextrose 5% in water such that the final solution is nearly isotonic. Fluids are administered roughly at the same rate as the desired urine output. Acetazolamide should not be used to produce an alkaline urine, because it may worsen toxicity by causing a concomitant systemic acidosis, resulting in an increase in the amount of unionized drug in the blood and enhanced tissue distribution [203]. It may also compete with acidic drugs for tubular secretion and thereby inhibit their elimination.

Acid–base status, fluid balance, electrolyte parameters, and clinical response must be carefully monitored during therapy. Urine pH should be measured hourly.

Multiple-Dose Activated Charcoal

Repetitive activated charcoal administration can enhance the elimination of previously absorbed chemicals by binding them within the GI tract as they are excreted in the bile, secreted by cells of the stomach or intestine, or passively diffuse into the lumen of the gut [116,204–206]. The charcoal–chemical complex is then excreted with stool. In most cases, reverse absorption (enterocapillary exsorption) is the mechanism, with the entire surface of the gut acting as a dialysis membrane. Activated charcoal keeps the concentration of free toxin in gut fluids near zero, and chemicals merely diffuse from blood perfusing the gut into luminal fluids as a result of concentration gradients. Interruption of enterohepatic or enteroenteric recirculation appears to be the underlying mechanism of action for a minority of toxins. Theoretically, multiple-dose charcoal can enhance the elimination of any chemical whose absorption is decreased by a single dose. Efficacy is predicted to be greatest for chemicals with a high charcoal binding capacity, physical and pharmacokinetic characteristics that make them amenable to removal by extracorporeal methods (see later), and a long intrinsic elimination half-life (e.g., amiodarone, isotretinoin, organochlorine pesticides, organometallic compounds) [207].

Multiple-dose activated charcoal enhances the elimination of most chemicals regardless of whether the chemical is administered orally or parenterally [206]. As with most forms of decontamination, the clinical efficacy of this therapy remains unproven [208]. Although clinically significant reductions in half-life have been noted in patients with carbamazepine, dapsone, phenobarbital, quinine, and theophylline overdose, there are no prospective studies showing that this therapy reduces morbidity or mortality [206].

The efficacy of multiple-dose activated charcoal increases as the cumulative amount of charcoal administered increases, either by increasing the amount or frequency of charcoal dosing [209]. When the cumulative amount of charcoal remains constant, there is no difference in the efficacy of different dosing regimens (e.g., 25 g every 2 hours vs. 50 g every 4 hours) [210]. With normal bowel activity, doses of activated charcoal of 0.5 to 1.0 g per kg every 4 hours are generally well tolerated. In those with decreased GI motility, smaller doses or less frequent intervals should be used. Alternatively, charcoal can be given by a slow, continuous nasogastric infusion. This method of administration may also be better for patients who cannot retain charcoal because of vomiting. Metoclopramide and odansetron (or other serotonergic antiemetics) can also be given to control or prevent vomiting. Gastric aspiration should be performed before repeating the dose of charcoal. In the event of gastrostaxis, regurgitation, or abdominal distension, treatment should be withheld.

Complications of multiple-dose activated charcoal are similar to those for charcoal used for GI decontamination. In addition, intestinal obstruction, pseudo-obstruction, and nonocclusive intestinal infarction have been reported in patients with decreased bowel motility treated with multiple doses of activated charcoal [211–215].

Extracorporeal Methods

Peritoneal dialysis, hemodialysis, hemoperfusion, hemofiltration, plasmapheresis, and exchange transfusion are theoretically capable of removing any chemical from the blood [210,216–222]. There remains very little evidence regarding the efficacy of continuous renal replacement therapy in the management of human poisonings. Most toxins undergo significant tissue distribution, and few remain in the blood in amounts high enough to warrant extracorporeal removal. Hemodialysis is therefore most effective for toxins with volumes of distribution less than 1 L per kg. In addition, with dialysis techniques, only toxins that are small (i.e., molecular weight less than 500 to 1,500 Da), water soluble, uncharged, and not highly bound to serum proteins (90% to 95% or less) readily diffuse across dialysis membranes. (Table 117.12)

The clearance of a toxin by extracorporeal removal must be significantly greater than its intrinsic total body clearance (i.e., the sum of metabolic, renal, and other routes of clearance) to be considered effective from a pharmacokinetic perspective. As with other treatments, their clinical efficacy (i.e., ability to decrease morbidity and mortality) is based on observation, experience, and retrospective comparisons rather than on controlled prospective studies.

Hemodialysis is considered effective for the treatment of barbiturate, bromide, chloral hydrate, ethanol, ethylene glycol, isopropyl alcohol, lithium, methanol, procainamide, acetaminophen, theophylline, salicylate, and possibly heavy metal poisoning [196–198]. Because hemodialysis can remove toxins from the blood faster than they can redistribute from tissue to blood, a rebound increase in blood concentration and clinical relapse may occur within 1 or 2 hours of treatment.

Other techniques are less effective than hemodialysis. Peritoneal dialysis may be useful when these methods are not

TABLE 117.12

PROPERTIES OF A DIALYZABLE TOXIN

5. Low protein binding

available or technically difficult (e.g., in neonates) or when anticoagulation may be hazardous [197,198]. Complications include infection, injury to intra-abdominal organs, and hypothermia. Plasma exchange may also be a useful alternative in neonates. It is effective for treating hemolysis (e.g., arsine poisoning) and methemoglobinemia. Two blood-volume exchanges are usually performed using central or peripheral arteriovenous or venovenous access. Complications include transfusion reactions and hypothermia. The roles of hemofiltration and plasmapheresis in the treatment of poisoning remain to be defined [219–222].

Safe Disposition

ICU admission is recommended for patients with coma, refractory hemodynamic instability, respiratory depression, seizures, and/or dysrhythmias [223,224]. Patients with extremes of temperature, severe agitation, or life-threatening metabolic abnormalities also benefit from intensive care. CNS depression may be the best predictor of serious complications [7]. Patients who are less ill, stable, or even asymptomatic are frequently unnecessarily admitted to the ICU because of physician uncertainty, fear of late deterioration and potential litigation, and lack of an alternative monitored setting. Some patients may require close observation and cardiac monitoring; but unless active interventions are likely to be necessary, admission to an intermediate care unit, telemetry unit, or emergency department observation unit is adequate. Length of hospital stay in patients with self-poisoning can be reduced by use of a multidisciplinary team that involves a toxicologist and psychiatrist as well as medical personnel [225].

Prevention of Recurrence

Suicidal patients require psychiatric assessment. If they are given prescriptions, the amount of drug (e.g., a 1- to 2-week supply) and number of refills should be limited. Substance abusers should be counseled regarding attendant medical risks and given the opportunity for rehabilitation through referral for behavior modification, supervised withdrawal, and abstinence or maintenance therapy.

Adults with accidental poisoning should be educated regarding the safe use of drugs and other chemicals. Assistance with the administration of medications may be required for visually impaired, elderly, developmentally delayed, or confused patients. Preventive education may be indicated for health care providers who have committed dosing errors or who are unaware of adverse drug interactions. When poisoning results from environmental or workplace exposure, the appropriate governmental agency (e.g., Environmental Protection Agency; Occupational Safety and Health Administration; National Institute of Occupational Safety and Health; or local, state, or federal health departments) should be notified. Unsafe working conditions should be brought to the attention of employers. Industrial hygiene and occupational health services should be offered if available. Finally, physicians have a duty to warn the general public (e.g., via press releases) of acute environmental hazard.

CHAPTER 118 ■ ACETAMINOPHEN POISONING

STEVEN B. BIRD

PHARMACOLOGY

Acetaminophen (*N*-acetyl-para-aminophenol [APAP]) is a nonnarcotic analgesic with excellent antipyretic activity but almost no anti-inflammatory effects. It belongs to the same drug family as phenacetin and acetanilid, the coal tar or aminobenzene analgesics [1,2]. Although APAP is the active metabolite of phenacetin, unlike phenacetin it rarely, if ever, causes nephrotoxicity and does not cause methemoglobinemia and hemolytic anemia. Unlike aspirin, APAP has no barrier-breaker effect on the gastrointestinal tract and no effect on platelet function, has a high therapeutic index, and has not been implicated as a factor in Reye's syndrome. As a result, APAP is the preferred agent

for the treatment of fever and mild to moderate pain when anti-inflammatory and antiplatelet action is not important.

Acetaminophen is an active ingredient in several hundred products, including pure APAP formulations, combinations with opioid analgesics, and numerous combination cough and cold preparations. It is also available in an extended-release (ER) formulation (which contains 325 mg of immediate-release and 325 mg of delayed-release acetaminophen per tablet) and as a suppository, but there is no commercial intravenous formulation.

Acetaminophen has a pK_a of 9.5 and is quickly and almost completely absorbed after ingestion of therapeutic doses of immediate-release formulations (10 to 15 mg per kg every 4 hours), yielding peak plasma concentrations between 5 and 20 µg per mL within 30 to 120 minutes. Clinical effects are noted within 30 minutes. Liquid preparations are absorbed slightly faster than solid formulations. Rectal absorption is similar to that of oral ingestion. The volume of distribution of APAP is 0.9 to 1.0 L per kg, and protein binding is negligible. Therapeutic plasma concentrations range from 10 to 20 µg per L, and elimination after therapeutic dosing follows first-order kinetics, with an average half-life of 2 to 4 hours [1]. Elimination is slower in neonates and young infants [3], the elderly [2], and in patients with hepatic dysfunction [4]. Clinical effects persist for 3 to 4 hours after therapeutic doses.

After overdose, peak acetaminophen levels are usually noted within 4 hours. The ingestion of very large doses and the concomitant ingestion of agents that delay gastric emptying (e.g., anticholinergics and opioids) may result in peak levels occurring later. Prolonged absorption with a late rise in the acetaminophen level has also been reported after an ER overdose [5].

TOXICOLOGY

The short- or long-term therapeutic use of APAP is rarely associated with adverse effects. Hypersensitivity reactions, such as urticaria, fixed drug eruption, angioedema, laryngeal edema, and anaphylaxis, are extremely rare [6]. Although high-dose APAP has been associated with chronic renal impairment [7], a cause-effect relationship has not been established.

Despite remarkable safety in appropriate doses, APAP can cause fatal hepatic necrosis after overdosage. This was first recognized in Europe more than 40 years ago and the first cases of hepatotoxicity in the United States were reported in 1975. Since that time, the incidence of APAP poisoning has increased dramatically in parallel with its increased availability and use; APAP is now the most common drug involved in exposures reported to US poison control centers, accounting for more than 140,000 calls in 2007 [8]. The incidence of occult poisoning is unknown, but based on retrospective data approximately 1 of every 70 overdose patients have a detectable acetaminophen concentration and 1 in 500 a potentially toxic APAP ingestion [9].

The metabolism of APAP explains its toxicity and the rationale for the current treatment of overdose (Fig. 118.1) (Table 118.1) [2]. After therapeutic doses, approximately 90% of APAP metabolism occurs by hepatic conjugation with sulfate or glucuronide to form inactive, nontoxic, renally eliminated metabolites. In adults, glucuronidation is the predominant route; in infants and young children, sulfation is the major pathway. Less than 5% of APAP is eliminated unchanged in the urine. The small remaining fraction (approximately 5%) undergoes oxidation by the P450 mixed-function oxidase enzyme system (CYP2E1) to yield the highly reactive, potentially toxic, electrophilic intermediate *N*-acetyl-para-benzoquinoneimine (NAPQI) [10]. NAPQI is quickly detoxified by reduced glutathione (GSH) to form nontoxic cysteine and mercapturic acid conjugates that are excreted in the urine.

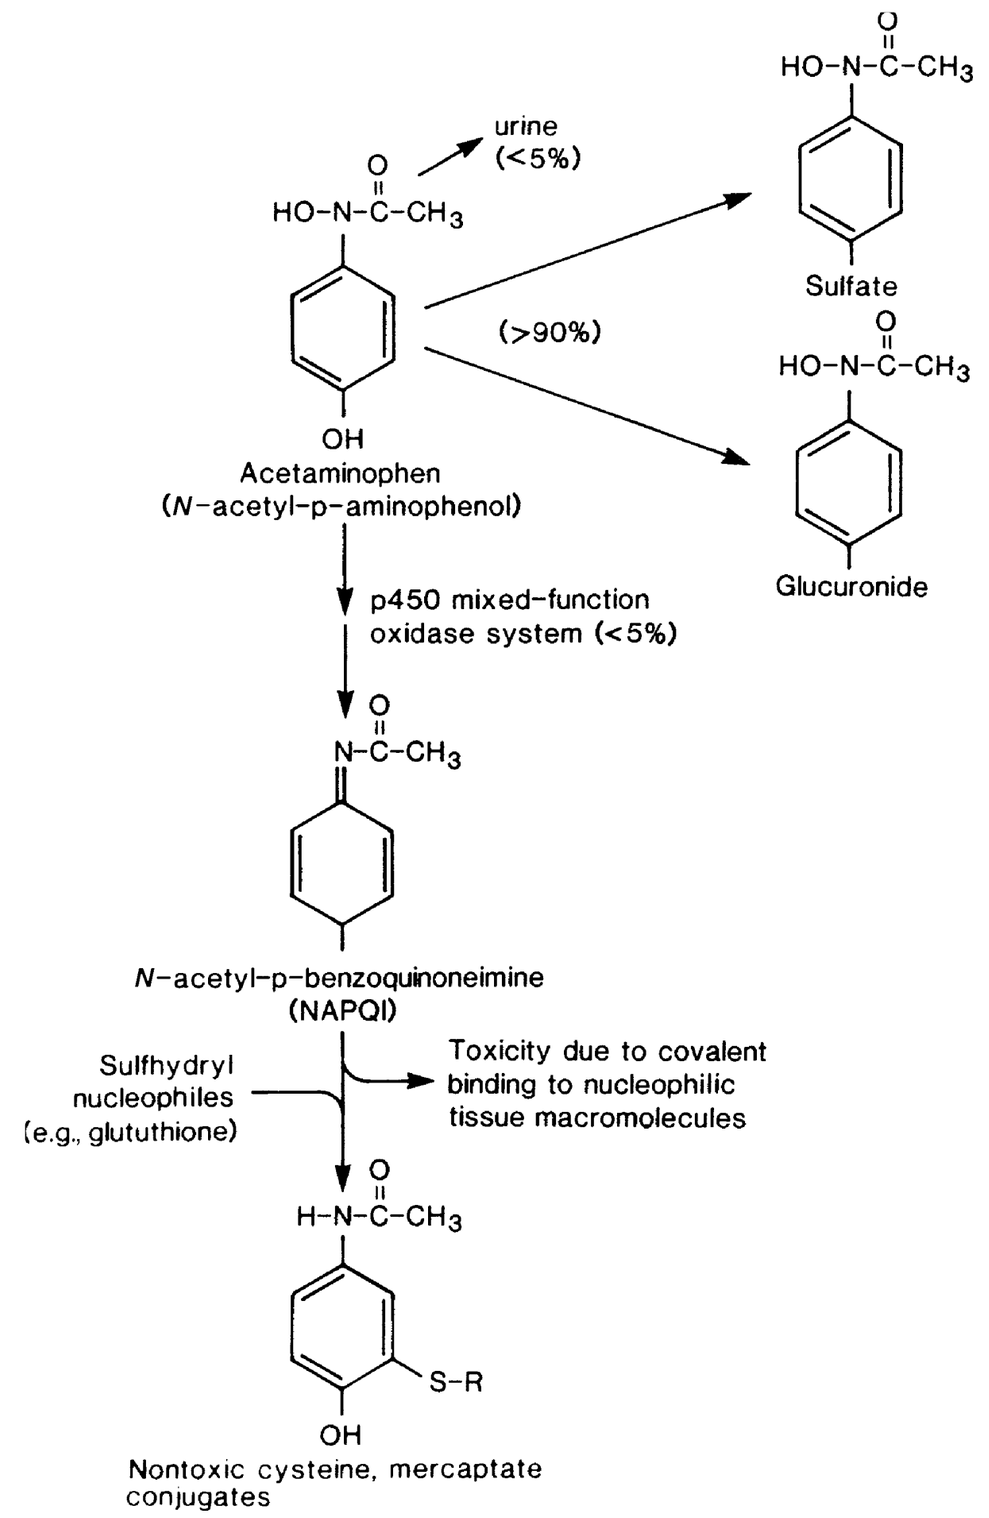

FIGURE 118.1. Postulated metabolism of acetaminophen. Toxicity occurs when the supply of sulfhydryl nucleophiles (e.g., glutathione) is inadequate to prevent the persistence of *N*-acetyl-para-benzoquinoneimine (NAPQI) and subsequent binding to hepatocyte macromolecules.

After overdose, the amount of drug metabolized by the P450 route increases, because of a greater total drug burden and saturation of alternative enzymatic pathways [11]. As a result, GSH utilization increases. If GSH regeneration is inadequate to meet demand and becomes significantly depleted, NAPQI can persist and react with hepatocyte macromolecules, resulting in the death of hepatocytes. In animal studies, such injury occurs when GSH stores reach less than 30% of normal [12]. Hepatocyte necrosis is most pronounced in areas of highest CYP2E1 activity: the centrilobular (central venule) zones of the liver. The degree of injury can range from asymptomatic

TABLE 118.1

TREATMENT OF ACETAMINOPHEN POISONING OR ASSOCIATED HEPATOTOXICITY

1. Administer activated charcoal if ingestion within 1–2 hours
2. Administer NAC either IV (preferred) or orally
3. Early consultation with hepatology and or transplant services for critically ill patients
4. Psychiatric evaluation for all intentional overdoses

elevations in aminotransferase levels to fulminant liver failure. Although far less common, the same process can occur in the kidney [13]. Very rarely, renal toxicity can occur in the absence of serious hepatotoxicity [14].

Pancreatitis, in some cases fulminant, can occur, and diffuse myocardial necrosis has been noted in fatal cases. Very rarely, with massive ingestions, early coma and metabolic acidosis may be seen [15]. Although uncommon, thrombocytopenia after acute overdose has also been described [16]. The mechanisms causing these atypical toxicities are unknown, and it is unclear to what extent these effects are directly due to APAP.

The precise dosage required to produce hepatotoxicity is unknown and almost certainly varies to some degree with individual differences in CYP2E1 activity, GSH stores, and capacity for GSH regeneration. Retrospective data suggest that significant toxicity is likely only after acute overdoses of greater than 250 mg per kg in adults [13], and prospective studies have suggested that toxicity is unlikely in unintentional pediatric ingestions of up to 200 mg per kg [17]. The possibility of toxicity at lower doses and skepticism regarding the accuracy of overdose histories have led to acceptance of a more conservative definition of risk, particularly in the United States. On the basis of APAP's volume of distribution and the well-established accuracy of APAP blood levels in predicting toxicity (see later), it is currently recommended that single ingestions of greater than 140 to 150 mg per kg be considered potentially toxic.

Elevated aminotransferase concentrations have also been reported after repeated ingestions of therapeutic or slightly greater doses of APAP [18]. Individuals who have conditions associated with increased CYP2E1 activity (e.g., chronic alcoholics) or glutathione depletion such as children younger than 10 years of age [19], those with chronic malnutrition, recent fasting (due to intercurrent illness), or recent ethanol use [20] may be at increased risk for such toxicity, but the accuracy of these reports has been challenged, and their therapeutic implications remain controversial. Such individuals are likely to have low hepatic carbohydrate and sulfate stores and, hence, decreased capacity for APAP metabolism via the glucuronidation and sulfation. There is currently no valid estimation of the amount, frequency, or duration of the dosing that defines risk. It appears that after repeated doses, accumulation of APAP to concentrations associated with toxicity after acute overdose is not required and that sustained moderate elevations are sufficient to cause GSH depletion and toxicity [21]. Such observations suggest that the APAP level at which NAPQI production exceeds GSH regeneration is near, or possibly within, the therapeutic range and that GSH stores and the capacity for its regeneration are the most important factors in the development of hepatotoxicity. They also support the concept that hepatotoxicity is more dependent on the area under the curve (time vs. concentration) of APAP than the peak drug level.

Intentional acute overdose is the most common cause of toxicity and fatalities, but accidental therapeutic overdosing and the abuse of opioids with unintentional coingestion of APAP (e.g., with codeine or propoxyphene) have also been reported. Therapeutic overdoses may result from dosing calculation errors, excessive self-treatment, the use of adult formulations or extra-strength formulations when lower dosage formulations were intended, and errors involving substitution of higher-dose rectal suppositories for similar-appearing lower dosage forms.

The importance of accurately diagnosing APAP toxicity soon after overdose extends beyond the high frequency with which it is encountered and its potential for causing morbidity and mortality. Acetaminophen is unique among common toxic exposures because effective treatment requires recognition of potential poisoning and initiation of therapy when no reliable clinical signs of overdose are present. Physicians must therefore consider occult APAP ingestion and liberally obtain APAP levels on all overdose patients to avoid missing the diagnosis.

CLINICAL MANIFESTATIONS

Acetaminophen hepatotoxicity can be divided into four clinical stages based on the time interval after ingestion: stage I (0 to 24 hours), the latent period; stage II (24 to 48 hours), the onset of hepatotoxicity; stage III (72 to 96 hours), maximal hepatic injury; and stage IV (4 days to 2 weeks), recovery [2,13].

During stage I, patients may be completely asymptomatic but often experience nausea, vomiting, and malaise, which may be accompanied by pallor and mild diaphoresis. There is no known correlation between presence or absence of early symptoms and the risk of hepatotoxicity. Although late in stage I very sensitive indicators of hepatic injury, such as γ -glutamyltransferase level, may be elevated, more widely used laboratory studies (e.g., aspartate aminotransferase [AST], alanine aminotransferase, prothrombin time, bilirubin) are completely normal. Early coma and metabolic acidosis have been reported in patients with massive ingestions [15], but these findings are so atypical that other causes should be suspected. They should be attributed to APAP only if the APAP concentration is extremely high and other etiologies have been excluded.

Symptoms during stage II are typical of hepatitis and include right upper-quadrant abdominal pain, nausea, fatigue, and malaise. Physical examination often reveals right upper-quadrant tenderness and hepatomegaly. The first elevation of aminotransferase levels usually occurs between 24 and 36 hours after APAP ingestion, but in the most severe cases, it can occur by 16 hours or earlier. Early in stage II, tests reflecting liver function, such as bilirubin and prothrombin time, are most often normal or only slightly elevated. Marked elevations of aminotransferase levels (greater than 1,000 IU per L) within 24 hours or bilirubin and prothrombin time within 36 hours should suggest that the time of ingestion was earlier than reported. Although unusual, in severe cases, marked liver function abnormalities may be evident by 36 to 48 hours. Complications during stage II are directly related to the degree of liver injury and may include coagulopathy, encephalopathy, acidosis, and hypoglycemia. With few exceptions, life-threatening problems are not seen earlier than 48 hours, and death in this period is distinctly rare. Renal dysfunction, manifested by rising creatinine and an active urinary sediment, may become evident during this stage but usually lags somewhat behind the hepatic injury. The blood urea nitrogen may also be elevated, but it can be normal in the presence of hepatic failure and resultant decreased urea formation.

Biochemical evidence of liver injury becomes most pronounced during stage III. With successful treatment, however, peak aminotransferase levels may sometimes occur earlier (Fig. 118.2). Most patients, even those with markedly elevated aminotransferase levels, go on to recover fully. Most deaths occur 3 to 7 days after ingestion and result from intractable metabolic disturbances, secondary complications such as cerebral edema or dysrhythmias, or exsanguination due to coagulopathy. Oliguric or anuric renal failure may result from acute tubular necrosis and is sometimes accompanied by flank pain. Some degree of renal dysfunction occurs in approximately 25% of patients with significant hepatotoxicity [15]. Even when severe, renal failure is almost always reversible.

During stage IV, if sufficient hepatocytes remain viable and the patient survives, the liver regenerates. Recovery is often complete by day 5 or 6 in patients with minimal toxicity, but those with more serious poisoning may not be clinically normal for 2 weeks or more. It is interesting that even patients with severe toxicity who survive regain normal liver function. There are no known cases of chronic or persistent liver abnormalities from APAP poisoning. In those who ultimately die, a slow decline in aminotransferase levels without clinical improvement may be seen. Declining enzyme levels merely

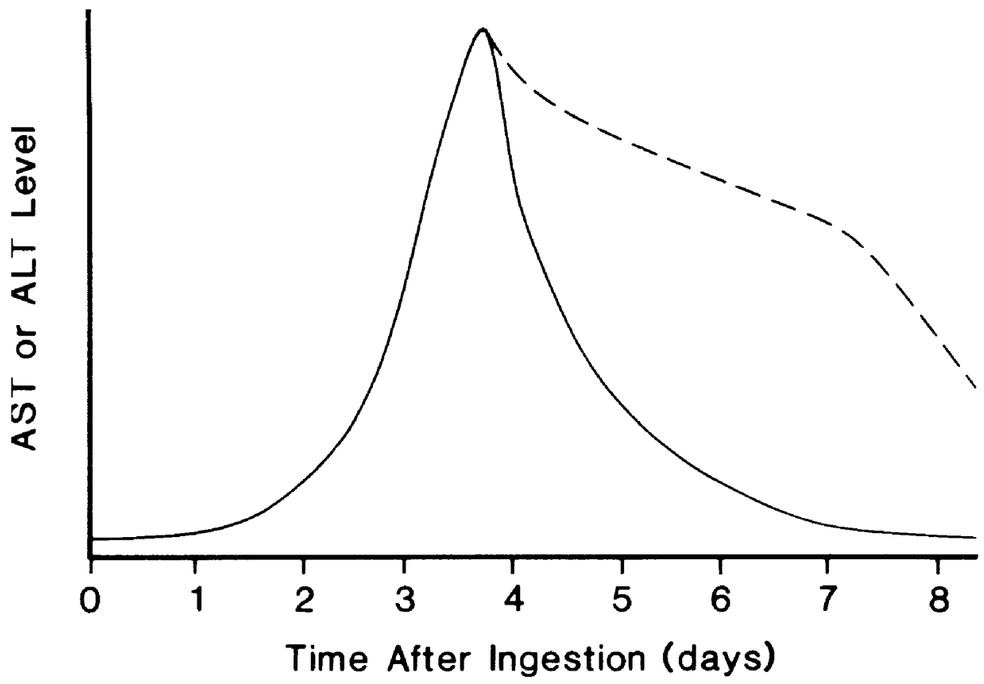

FIGURE 118.2. Expected time course of aminotransferase elevation due to acetaminophen-induced hepatotoxicity. The solid line represents typical course; the dashed line represents course of severe toxicity. ALT, alanine aminotransferase; AST, aspartate aminotransferase [Adapted from Jaeschke H, Mitchell JR: Neutrophil accumulation exacerbates acetaminophen-induced liver injury (abstract). *FASEB J* 3:A920, 1989, with permission.]

represent a washout of those released at the time of the initial insult, not a recovery of normal liver function. These patients can be identified by persistent or increasing marked elevations of bilirubin and prothrombin time. Although this pattern is occasionally seen in patients who recover, most survivors do not have significant or persistent bilirubin or prothrombin time elevation after aminotransferase levels fall.

Because of variations in dosing patterns and patient characteristics, the time course of toxicity in patients with repeated ingestions is not well defined. With chronic toxicity, dose–response patterns differ from those of acute overdose, but the clinical manifestations are the same.

DIAGNOSTIC EVALUATION

The diagnostic evaluation consists of determining the risk of toxicity and assessing for it. The serum APAP concentration is used to predict toxicity after acute overdose. If the APAP concentration between 4 and 24 hours after ingestion falls on or above the acetaminophen treatment nomogram line (Fig. 118.3), the patient should be considered at risk for hepatotoxicity, and hence, in need of antidotal therapy (see later). Conversely, if the APAP concentration is even slightly below the nomogram line, the risk of hepatotoxicity is negligible and antidotal therapy is not necessary. The original Rumack–Matthew nomogram line, which defined the risk of toxicity based on the natural course of untreated patients [22], was actually 25% higher than the line now used in the United States. Hence, the nomogram has a 25% safety margin that allows one to be fairly rigid when using the nomogram to make treatment decisions.

There are, however, some important caveats regarding use of the nomogram. First and foremost, it applies only to single acute ingestions. Second, when there is uncertainty about the exact time of ingestion, the worst-case scenario should be assumed. For example, if the ingestion was between 4 and 6 hours earlier, the 6-hour value on the nomogram should be used. And finally, when levels are obtained 20 to 24 hours after overdose, the limit of detection of the APAP assay must also be considered. Because most hospitals use immunoassays with a detection limit of 10 µg per mL, potentially toxic APAP levels during this period will be below this limit and reported as nondetectable, which does not necessarily mean nontoxic. Again,

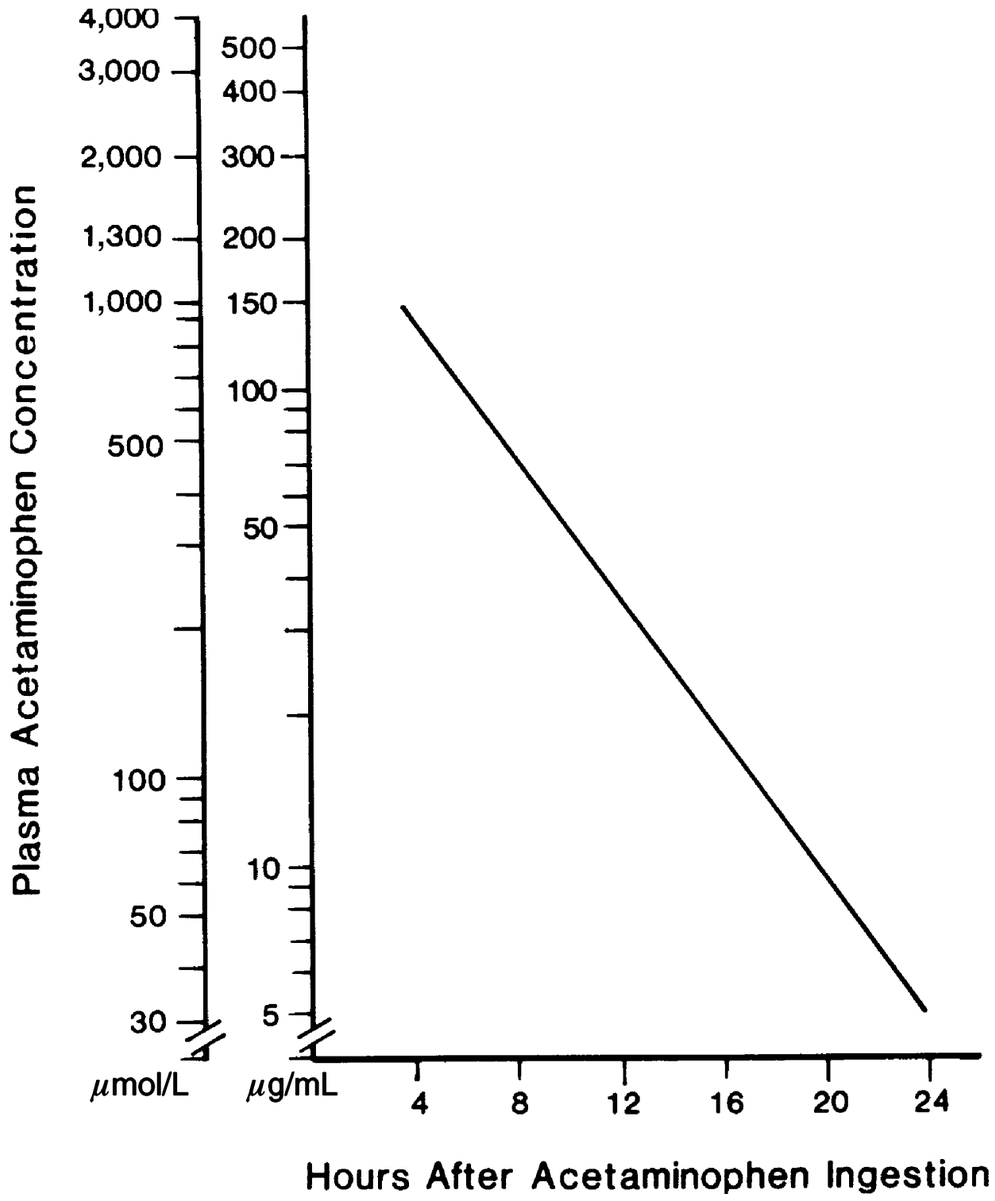

FIGURE 118.3. Acetaminophen treatment nomogram. Patients with acetaminophen concentrations on or above the line require treatment with *N*-acetylcysteine. [Adapted from Jaeschke H, Mitchell JR: Neutrophil accumulation exacerbates acetaminophen-induced liver injury (abstract). *FASEB J* 3:A920, 1989, with permission.]

a worst-case scenario should be assumed, and antidotal treatment should be given until the level is confirmed to be nontoxic by a more sensitive assay, or until it has been determined that the patient is asymptomatic and has no laboratory evidence of hepatotoxicity.

With rare exceptions (see later), a single APAP concentration within the time period specified by the nomogram is sufficient to plan appropriate therapy. Although it is true that the elimination half-life of APAP is related to the likelihood of toxicity, half-lives should not be relied on in making therapeutic decisions. The observations that half-lives greater than 4 hours were associated with toxicity and that toxicity was negligible if APAP half-life was less than 4 hours [23] were based on multiple APAP determinations in untreated patients over a 36-hour period. Because treatment must be started as early as possible [24] and treatment may alter APAP elimination [11], half-life determinations are not relevant to current standards of care.

There are three situations in which repeat measurements may be of value. The first is in the patient with a time of ingestion that is unknown but that was within 4 hours. In this situation, an increasing APAP level indicates ongoing absorption from a recent ingestion. To detect a rising level and define the peak value, repeat determinations must be frequent (every hour) until the level declines. This prevents underestimation of the peak value due to incomplete absorption at the time of the first level. It also may rule out toxicity by detecting a peak value less than 150 µg per mL.

The second situation in which repeating the APAP may be useful is after an overdose of an ER formula. Because of prolonged absorption, patients with nontoxic APAP levels soon after ingestion may have subsequent levels that are toxic by the nomogram [25]. The optimal time to repeat drug levels to detect such nomogram line-crossers is unknown. In one patient, a

potentially toxic APAP level did not occur until 14 hours after ingestion [5]. The manufacturer recommends obtaining a second APAP level 4 to 6 hours after the initial one [26]. Others have recommended that to avoid missing a potentially toxic level, drug levels should be measured every 2 hours from 4 to 16 hours after overdose [27].

Finally, repeat APAP levels may be of value in the patient with very high levels and slow elimination in whom it is possible that APAP may still be present at the completion of therapy. Antidotal treatment should not be discontinued while APAP is still present. This is particularly relevant as shorter courses of antidotal therapy have become the routine.

In assessing the patient who is found to be at risk for toxicity and hence requires hospitalization and antidotal treatment, a complete blood count, electrolytes, blood urea nitrogen, creatinine, glucose, prothrombin time, aminotransferase levels, and bilirubin should be obtained at admission and repeated every 24 hours until resolution of toxicity is noted. If liver failure develops, laboratory values, particularly prothrombin time and glucose, must be obtained more frequently. Renal function, acid–base status, amylase, and electrocardiogram may also need to be evaluated or repeated. Assessment of renal, pancreatic, and myocardial toxicity should follow the same guidelines as those for other etiologies.

MANAGEMENT

Treatment includes gastrointestinal decontamination, antidotal treatment (if indicated), and support of organ function. Unless clinically significant hepatic or renal failure develops, management consists only of antidote administration and monitoring of signs, symptoms, and laboratory parameters. Although this can be accomplished outside the intensive care unit, patients often require monitoring or treatment for toxicity due to coingestions or constant observation because of suicide risk. If significant hepatic failure ensues, intensive care unit admission is required for close monitoring and treatment of complications. Invasive monitoring is infrequently required, but may be useful if multisystem failure occurs.

Gastrointestinal Decontamination

Gastrointestinal decontamination is recommended for patients who can be treated within 1–2 hours of APAP overdose. Although once considered controversial and even contraindicated, activated charcoal is now considered the method of choice. As routine treatment of APAP poisoning has moved from oral *N*-acetylcysteine (NAC) to intravenous administration, this formerly contentious point has been rendered moot.

Antidotal Treatment

The observation that hepatotoxicity occurs only when GSH is depleted led to a search for agents that might increase available sulfhydryl groups either by increasing GSH or by providing alternative sulfhydryl sources. Exogenous GSH does not readily enter cells, so various precursors and substitutes, including cysteamine, methionine, and NAC [24,28], have been tried. Although all regimens are effective when started within 8 to 10 hours of ingestion, cysteamine was abandoned because of its toxicity, and methionine has been replaced by NAC, which is more effective and probably carries less risk of worsening hepatic encephalopathy when liver failure is present.

There are several suggested mechanisms of action of NAC. In cells, NAC is converted to cysteine, a GSH precursor, and thus increases GSH stores. Second, NAC or cysteine can substitute directly for GSH because it has available sulfhydryl groups. Third, NAC augments the sulfation of APAP to nontoxic metabolite by providing sulfur substrate [11]. Fourth, NAC may promote the back conversion of NAPQI to its precursors, although this has not been demonstrated in humans. Finally, there is accumulating evidence that NAC may be beneficial, even after liver injury has occurred, through mechanisms other than its effects on APAP metabolism [29]. Suggested mechanisms for these late effects of NAC include direct antioxidant action to modify postinflammatory radical-mediated destruction, restoration of enzyme function in injured tissue, and correction of microvascular function by restoring endothelial-derived relaxing factor [29]. It is likely that the relative importance of each of the previously described effects of NAC in any given patient varies with the severity of the overdose and the delay to NAC initiation. These variations may explain apparent differences in efficacy between different NAC protocols.

Two treatment regimens are currently approved for use in the United States. The first consists of a 72-hour course of oral NAC given as a 140 mg per kg loading dose, followed by 17 doses of 70 mg per kg every 4 hours beginning 4 hours after the loading dose, for a total NAC dose of 1,330 mg per kg [30]. The second regimen, approved by the FDA in 2004, consists of an intravenous loading dose of acetylcysteine of 150 mg per kg in 200 mL dextrose 5% in water (D_5W) over 15 minutes, followed by 50 mg per kg in 500 mL D_5W over 4 hours, then 100 mg per kg in 1 L D_5W over the next 16 hours [31]. This is identical to the standard treatment regimens in Europe and Canada [28]. Because the FDA-approved dosing requires three separate intravenous formulations, some Poison Control Centers, hospitals, and medical toxicologists have simplified NAC protocols that differ from the FDA-approved dosing [32].

For oral therapy, NAC is usually supplied as a 20% solution (20 g per 100 mL), which should be diluted 3 to 1 to yield a 5% mixture with juice or a soft drink to increase its palatability and decrease gastrointestinal side effects. Antiemetics (e.g., metoclopramide, 0.1 to 1.0 mg per kg intravenous (IV), initial adult dose 10 mg; droperidol, 20 to 150 µg per kg IV, initial adult dose 1.25 mg) may be required to treat antecedent vomiting or vomiting due to NAC. Ondansetron (50 to 150 µg per kg IV, initial adult dose 4 mg) may be effective when traditional antiemetics are not. If antiemetics fail, NAC can be given by gastric or duodenal tube. Various other methods may prove helpful in decreasing emesis after dosing: chilling the solution with ice chips, using a straw and covering the container, diluting to a 10% solution, or administering the solution over 15 to 60 minutes instead of as a bolus. If vomiting occurs within 1 hour of any dose, that dose should be repeated.

The use of oral or IV NAC is dependent on the experience of the clinician, the local hospital formulary, severity of the patient, and physician preference. Most patients can be adequately treated with oral NAC if it is begun within 8 to 10 hours of ingestion. Other patients, particularly those who present after 8 to 10 hours or those with encephalopathy, should receive IV NAC therapy.

There are no well-documented serious side effects of oral NAC, although nausea and vomiting are extremely common [33]. Side effects from intravenous NAC are far less common but potentially more serious. There are several reports of serious or fatal anaphylactoid reactions (e.g., hypotension, bronchospasm, rash, death) to intravenous NAC during the 20-hour protocol, and minor dermatologic reactions are common [34,35]. It is important to recognize that adverse effects to intravenous NAC are not truly anaphylactic; they are dose and concentration dependent [34]. As a result, more dilute and slowly administered doses are better tolerated [36]. Except for an anaphylactoid reaction in one patient after an NAC overdose, there were no serious adverse reactions reported during

the 48-hour intravenous protocol [36]. Transient skin rash occurred in approximately 15% of patients during the loading dose but did not necessitate discontinuing treatment. Even with more serious reactions, NAC therapy can often be continued or resumed after treatment with diphenhydramine [35].

All dosing protocols appear to be equivalent when NAC is started within 8 hours of ingestion. Efficacy decreases with longer delays in therapy, with apparent differences between the dosing regimens when NAC is started after 16 hours. With late treatment, 82% of high-risk patients treated with the 20-hour regimen developed aminotransferase values above 1,000 IU per L, an incidence not significantly different from the 89% incidence reported in untreated historical control subjects [28]. After treatment with 48 hours of intravenous NAC, only 58% of late-treated patients developed hepatotoxicity, a result that was significantly better than that with the 20-hour course or no treatment [36]. After 72 hours of oral NAC, only 41% of late-treated patients developed hepatotoxicity [24], although this was not statistically different from the 48-hour protocol [36]. These studies included only patients receiving NAC within 24 hours of ingestion.

In the first controlled study of NAC started more than 24 hours after overdose, intravenous NAC started after onset of liver failure (median 53 hours after APAP) reduced cerebral edema, need for pressors, and mortality [37]. It is interesting that this study used the same NAC dosing that had earlier been found ineffective more than 15 hours after overdose [28], but instead of discontinuing NAC after 20 hours, therapy was continued until either recovery or death occurred.

The numerous actions of NAC may explain why various NAC protocols are equivalent when started early but not when started late. When started within 8 hours of overdose, NAC probably exclusively affects APAP metabolism and GSH turnover, and its role is preventative before GSH depletion and NAPQI covalent binding. In this setting, NAC may be needed only until APAP metabolism is complete; thus, shorter courses of NAC are effective. With further treatment delay, the role of NAC may increasingly be to ameliorate the effects of NAPQI covalent binding, and by 16 hours after ingestion, this may be its sole action and would explain why longer courses of NAC, continued during the period of maximal liver injury, appear to be superior. These considerations have led to selective management, such as short-course NAC for those treated early who do not develop aminotransferase elevations or late treatment with NAC for any patient who develops liver injury (see later).

Cimetidine has been suggested as a possible antidote for APAP because of its inhibitory effect on P450 activity. Animal studies showed efficacy of high-dose cimetidine given before or soon after APAP, but there is no evidence of efficacy in humans [38]. Even if the massive dose suggested by animal studies proved to be safe and effective in humans, its theoretic effect would require early administration. In problematic cases, such as late presentation, there is no theoretic or experimental support for cimetidine use. Hence, although cimetidine is not contraindicated, it has no proven role and should never be considered an alternative to NAC.

Supportive Care

The management of hepatic failure, renal failure, or other end-organ manifestations of APAP toxicity should be treated according to usual guidelines. In view of the increased availability and success of liver transplantation, the most severely ill patients deserve this consideration. Several successful transplants have been done after APAP overdose. The greatest challenge is early identification of patients destined for irreversible hepatic failure (see "Prognosis and Outcome" section of this chapter).

SPECIAL CONSIDERATIONS

Acute Overdose in Alcoholics and Other High-Risk Patients

Certain subgroups of patients appear to be at greater or lesser risk for APAP toxicity, but this fact is of more theoretic than practical value in the management of acute overdose. Higher risk is expected in patients with increased CYP2E1 enzyme activity from chronic use of agents that induce this enzyme (e.g., ethanol, barbiturates, phenytoin, sedative–hypnotics, griseofulvin, haloperidol, tolbutamide) [39] or decreased GSH stores or low GSH turnover rates (e.g., malnourished patients or those with liver disease). Lower toxicity might be expected when CYP2E1 activity is inhibited by chronic use of agents such as cimetidine or when a patient has coingested an agent that is metabolized by this enzyme, thus competing with APAP and decreasing NAPQI formation [2].

Acute overdose studies in animals demonstrated increased toxicity after chronic ethanol use and decreased toxicity when ethanol and APAP were coingested [40]. The protective effect of ethanol coingestion appears to be due to competitive inhibition of NAPQI formation by P450 ethanol metabolism. Chronic ethanol use, particularly in an alcoholic that is currently abstinent [41] could worsen toxicity by causing P450 induction, GSH depletion, or some other unknown mechanism. For example, an alcoholic might be protected by the acute coingestion of ethanol or be nutritionally deprived and have lower P450 activity.

Despite suggestions that some of these factors may be important [42], the amount of chronic ethanol or drug use that is clinically significant is unknown and certain to be variable.

Because the treatment nomogram line is conservative, treatment decisions after acute overdose should be made in the same manner as described previously, regardless of chronic coingestants.

Acute Overdose in Pediatric Patients

Of 417 children with acute APAP overdose, 49 of whom had plasma APAP levels over the nomogram line, indicating potential toxicity, only three (6.1%) developed an AST or ALT greater than 1,000 IU per L [43]. This incidence is less than that reported in adults, leading to speculation that children are relatively protected from APAP toxicity.

Several pharmacokinetic differences between children and adults have been noted. The most consistent finding is that the ratio of APAP-sulfate to APAP-glucuronide is higher in children than in adults [44], but this difference in nontoxic routes of metabolism has not been shown to be associated with a decrease in production of NAPQI. Thus, increased sulfation has not been proven favorably to alter NAPQI formation. Decreased P450 activity, and thus decreased NAPQI formation, has also been postulated in children, but decreased P450 activity is noted only in fetal and neonatal subjects [45]. Most APAP poisonings occur outside the newborn period, when P450 activity may be even greater than in adults. Hence, this theory cannot explain a hepatoprotective effect in older children. If children are actually less susceptible to APAP toxicity, it may be because of an increased ability to regenerate GSH, but this, too, is unproven.

Perhaps the most likely explanation is that pediatric overdoses are quantitatively less severe. In adults, particularly those treated late, the outcome is worse in patients with very high APAP levels [24]. Substantial toxicity has also developed in children with very high levels, but there are too few cases to

allow for any conclusions. Until larger numbers of children with very high APAP levels are studied, patients of all ages with a significant overdose must still be considered at substantial risk and managed accordingly. As with adults, the longer the time between ingestion and presentation or treatment in children with potentially toxic drug levels, the greater the incidence of hepatotoxicity and the worse the prognosis [21].

Acute Overdose in Pregnancy

Although experience with overdose in pregnancy is limited [46], certain conclusions seem valid. First, there is clear evidence that APAP overdose can result in morbidity and mortality to woman and fetus at all stages of pregnancy. Second, there currently is no evidence that NAC is harmful to a pregnant woman or her fetus. Third, NAC is hepatoprotective to the woman. Fourth, NAC crosses the human placenta [47], and this is likely to be beneficial to the fetus. On the basis of these observations, it is recommended that pregnant women be treated according to standard guidelines regardless of gestational age of the fetus and that newborns delivered during a course of maternal NAC treatment should also complete a course of NAC after delivery.

Acute Overdose of Extended-Release Acetaminophen

Because experience with ER APAP overdose is limited, the applicability of the nomogram, which was derived from clinical outcome data in patients with immediate-release APAP overdose, to those with ER APAP overdose remains to be determined [25–27]. Although it is agreed that patients who have a potentially toxic APAP level after acute acetaminophen ER overdose require NAC, the management of those with levels that are elevated but nontoxic is controversial. Some have suggested that such patients do not require NAC [48]. Given that peak drug levels after supratherapeutic but nontoxic doses of ER acetaminophen are only two-thirds of those seen after equivalent doses of an immediate-release formulation, despite nearly identical areas under the curve [49], others recommend treatment if any APAP level is two-thirds or more of the one that is indicated toxic by the nomogram [27].

Chronic Overdose

There are occasional reports of serious toxicity from chronic overdose in infants with acute febrile illness [19,21]. Chronic toxicity has also been reported after doses only slightly higher than recommended and even with therapeutic ones in adults with fasting and alcohol use [50]. Although alcoholics do appear to be at greater risk for toxicity from therapeutic doses, the validity of data on fasting has been questioned [51]. There is no evidence that this occurs in otherwise healthy individuals. Similarly, in the absence of continued ethanol abuse, there is no evidence that therapeutic dosing carries an increased risk in patients with cirrhosis or other forms of chronic liver disease [52]. On the basis of current knowledge, there is no reason to avoid APAP in any of these groups, although patients must be clearly instructed to avoid overdosing.

Evaluation of patients with chronic overdose should include a detailed history of the timing of doses, particularly the last dose; the amount ingested at each dose; possible increased risk factors (e.g., chronic alcoholism, use of other P450 inducers); symptomatology; an APAP level at least 4 hours after the last dose; and aminotransferase levels. In such cases, the nomogram has never been studied and has little or no validity. Because there are currently no reliable guidelines to assess risk, it is best then to consult with a toxicologist or regional poison center to determine the best course of action. One approach is to treat according to the guidelines discussed the next section.

Late Treatment

Treatment decisions in patients who present more than 24 hours after an overdose are problematic. Initial studies of the 20-hour intravenous NAC protocol suggested that NAC was of no value if started more than 12 to 15 hours after ingestion [28], and initial results of the 72-hour oral protocol indicated that treatment more than 16 hours after ingestion was ineffective [30]. As a result, studies of treatment initiated after 24 hours were not performed initially. More extensive data and analysis of patients treated with 72 hours of oral NAC revealed that patients first treated between 16 and 24 hours after overdose experienced less hepatotoxicity than untreated historical control subjects or historical control subjects treated late with a 20-hour course of intravenous NAC [24].

Subsequently, a series of studies showed theoretic and clinical benefit to late NAC administration [29,53,54]. In the most remarkable of these, NAC started a median of 53 hours after ingestion and after evidence of severe liver injury reduced morbidity and mortality [29]. Although the issue of which cases warrant late treatment is not well defined, the following approach to the treatment of patients who present late is offered: If the APAP level is undetectable and aminotransferase levels are normal, NAC is not indicated, because the possibility of hepatotoxicity is extremely low. If hepatotoxicity is evident, a full course of NAC is indicated. For patients who have detectable APAP levels and no hepatotoxicity, NAC therapy should be started. It can be discontinued before completing a full course of therapy when the APAP concentration falls to zero, as long as aminotransferase levels remain normal.

Short-Course ORAL Treatment

Treatment of acute APAP overdose with an abbreviated course of oral NAC is based on the observation that treatment for 20 hours with intravenous NAC [28] and for 48 hours with oral NAC [36] is just as effective as treatment with oral NAC for 72 hours [24] when treatment is started within 8 to 16 hours of ingestion (see previous section), and that patients who develop hepatotoxicity exhibit laboratory evidence of such toxicity within 24 to 36 hours of ingestion [9,55]. In short-course protocols, oral NAC is initiated in patients with toxic or potentially toxic APAP levels (by the nomogram) in the same dose as used in the standard 72-hour regimen, and APAP levels and aminotransferases are obtained at 24 and 36 hours postingestion. As with late treatment, if the APAP level becomes undetectable and aminotransferase levels are normal at either point in time, NAC is stopped, whereas if hepatotoxicity becomes evident, a full course of NAC is indicated. For patients who have detectable APAP levels and no hepatotoxicity, NAC therapy should be continued. It can be discontinued before completing a full course of therapy if the APAP concentration subsequently becomes undetectable and if aminotransferase levels remain normal. Although toxicologists have been successfully using short-course NAC therapy for years, published data are limited [56], and poison centers have been slow to adopt this approach. Hence, consultation with a toxicologist is advised when contemplating such treatment.

PROGNOSIS AND OUTCOME

Severe hepatotoxicity after APAP overdose has traditionally been defined by an ALT or AST greater than 1,000 IU per L, although most patients with such elevations have no significant short- or long-term sequelae. By using this definition, the risk of hepatotoxicity can be estimated based on the initial APAP concentration. Without NAC therapy, hepatotoxicity develops in less than 8% of all overdose patients, in 60% of probable risk cases (APAP concentration above a nomogram line intersecting 200 µg per mL at 4 hours and 50 µg per mL at 12 hours), and in 89% of high-risk cases (APAP concentration above a nomogram line intersecting 300 µg per mL at 4 hours and 75 µg per mL at 12 hours) [13].

Far less toxicity occurs in patients treated with NAC, although outcome depends on APAP concentration and the time NAC was started. Even in high-risk late-treated cases, only 41% of patients treated with oral NAC for 72 hours developed toxicity. Most important is that regardless of APAP level, NAC is extremely effective when started within 8 hours [24]. Hepatotoxicity occurred in less than 5% of patients in this subset.

Death is unusual after APAP overdose. When patients at probable risk for hepatotoxicity are considered, the reported mortality rate in untreated cases varies from 5.3% [28] to 24% [57]. A mortality rate of 1.1% has been noted in similar patients treated with the 20-hour intravenous NAC protocol [29], and it was found to be 0.68% in patients treated with the 72-hour oral NAC protocol [24]. In fact, even among high-risk cases first treated between 16 and 24 hours after overdose, the mortality rate was only 3.1% after oral NAC therapy [24].

It is not uncommon to see aminotransferase elevations greater than 10,000 IU per L during stage III, with eventual complete recovery [2]. As a result, aminotransferase levels alone are inadequate to judge prognosis. Evidence of hepatic dysfunction, such as marked elevations in prothrombin time and bilirubin, or evidence of persistent hypoglycemia, lactic acidosis, or hepatic encephalopathy, indicates true hepatic failure and a poor prognosis. Previous reports suggested that a bilirubin greater than 4 mg per dL or a prothrombin time greater than twice control indicates a poor prognosis [58]. More recently, a pH less than 7.30, prothrombin time greater than 100 seconds, serum creatinine greater than 3.4 mg per dL, and grade III or higher encephalopathy have been used to define poor prognosis [59], as has the single criterion of an increasing prothrombin time on day 4 after overdose [60] or a lactate of greater than 3.5 mmol per L shorter after admission [61]. Most recently, Schmidt and Dalhoff [62] demonstrated that an increasing alpha-fetoprotein serum concentration (particularly a concentration of more than 3.9 µg per L on the day after peak ALT) is associated with survival. As noted previously, patients meeting these criteria may benefit from NAC treatment [29,53]. Standard measures for the treatment of liver failure, including arrangements for possible liver transplantation, should also be provided.

The presence or absence of aminotransferase elevation at the time of treatment initiation appears to be the most sensitive early prognostic indicator. To date, all reported patients who died from APAP toxicity already had some degree of AST or ALT elevation at the time a 72-hour course of oral NAC was started [24]. Hence, all patients with liver enzyme values that are normal when oral NAC is started would be expected to survive.

ACKNOWLEDGMENT

CHAPTER 119 ■ ALCOHOLS AND GLYCOL POISONING

JENNIFER L. ENGLUND, MARCO L.A. SIVILOTTI AND MARSHA D. FORD

The accidental or deliberate consumption of alcohols and glycols is a major cause of health problems [1,2]. Although light consumption of ethanol may be associated with health benefits in some populations [3–5], heavy consumption increases overall mortality, especially mortality due to trauma, suicide, cirrhosis, and malignancies [6]. Ethanol is estimated to contribute to 100,000 deaths annually in the United States; with economic costs in excess of $200 billion [7,8]. Ethanol is involved in at least 10% of fatalities reported to US poison centers, and other alcohols and glycols, especially methanol and ethylene glycol, are responsible for another 3% of all fatalities [9]. These so-called toxic alcohols, namely methanol and ethylene glycol, are usually involved in sporadic poisonings, often involving the accidental exposure of a young child to automotive or household products or the intentional suicidal ingestion in adults. Furthermore, multiple-victim poisonings can occur after recreational substitution for ethanol, during illicit manufacture of ethanol, or after the addition of other glycol products [10–12].

ETHANOL

Ethanol is consumed by most adults and is the most serious drug of abuse in Western society. Approximately one-third of the US population can be categorized as moderate-to-heavy drinkers, consuming four or more alcoholic drinks per week and of these, about one in five can be considered problem drinkers or alcoholics [13]. Ethanol use is a factor in about 8% of emergency department visits [14], 10% to 50% of hospital admissions [15], and its projected economic costs due to job absenteeism and poor job performance are staggering [8,13]. Chronic ethanol consumption can cause multiorgan system

TABLE 119.1

COMPARATIVE DATA ON THE TOXIC ALCOHOLS AND GLYCOLS

Substance	Formula	Molecular weight	Specific gravity	V_d (L/kg)	Elimination half-life ($t^{1}/_{2}$)	Boiling point (°C)	Onset of toxicity	Important metabolites
Ethanol	$CH_3\,CH_2OH$	46	0.79	0.6	Zero order at 15–30 mg/dL/h	78.5	30–60 min	Acetaldehyde Acetic acid
Methanol	CH_3OH	32	0.79	0.7	Zero order at 8.5 mg/dL/h without ethanol; first order: $t^{1}/_{2}$ = 46.5 h with ethanol or fomepizole and 2.5 h with hemodialysis	64.7	12–24 h[a]	Formaldehyde Formic acid
Ethylene glycol	$CH_2(OH)–CH_2(OH)$	62	1.11	0.68	First order: $t^{1}/_{2}$ = 2.5–4.5 h without ethanol and with normal kidneys, 17 h with ethanol or fomepizole and < 3 h with hemodialysis	197.6	4–12 h[a]	Glycoaldehyde Glyoxylic acid Glycolic acid Oxalic acid
Isopropanol	$CH_3\,CH(OH)CH_3$	60	0.79	0.6–0.7	First order: $t^{1}/_{2}$ = 2.5–3.5 h	82.5	30–60 min	Acetone
Propylene glycol	$CH_2(OH)\,CH(OH)CH_3$	76	1.04	0.55	First order: $t^{1}/_{2}$ = 2–5 h in adults, 19.3 h in infants	188.2	Seconds with intravenous, ? with dermal	Pyruvate Lactate Acetate
Benzyl alcohol	$C_6H_5–CH_2OH$	108	1.04	?	?	204.7	?	Benzoic acid Hippuric acid
Diethylene glycol	$CH_2(OH)\,CH_2\,O\,CH_2\,CH_2(OH)$	106	1.12	?	?	245	?	2-Hydroxyethoxyacetic acid

[a]For metabolite effects; may be longer if ethanol coingested.

disease, nutritional disorders, and teratogenic effects. In addition to beverages (typically 4% to 50% ethanol by volume), ethanol can be found in a myriad of colognes, perfumes, mouthwashes, aftershaves, and over-the-counter medicinals. Many of these products contain 50% to 99% ethanol and can be sources for intoxication, especially for children [16].

The chemical properties and kinetics of ethanol are summarized in Table 119.1. Ethanol is a small, slightly polar aliphatic alcohol with a weak electric charge, miscible in water and lipids. It diffuses easily into all body tissues. It is postulated that ethanol influences multiple ion channels, possibly by causing subtle alterations in their tertiary structure or their dynamic interaction with cell membranes. The behavioral effects of ethanol may result from its ability to antagonize the excitatory *N*-methyl-d-aspartate–glutamate receptor and to potentiate the inhibitory γ-aminobutyric acid A receptor [17–20]. Ethanol is also known to interact with glycine, nicotinic acetylcholine, 5-HT_3, and P_{2X} purinergic receptors, as well as the L-type calcium- and potassium-channel proteins [21,22]. The major metabolite, acetate, has been shown to mimic adenosine's effects via the P_1 receptor [23]. The precise role of these and other effects in producing intoxication, dependence, and withdrawal (see Chapter 145) is uncertain.

Ethanol is readily absorbed from the gastrointestinal tract, with 57% of the absorption occurring in the small intestine. Peak ethanol levels typically occur 30 to 60 minutes after ingestion if the stomach is empty [16]. Women have higher peak ethanol concentrations after a given dose because of smaller body mass and smaller relative body water, rather than gender differences in gastric mucosal alcohol dehydrogenase (ADH) activity [24–27].

Metabolism of ethanol occurs predominantly in the liver by three enzymatic systems: the cytosolic ADH enzyme family (especially class I), the cytochrome P450 enzymes (microsomal ethanol oxidizing system, largely CYP2E1 but also 3A4 and 1A2), and peroxisomal catalase [28]. Metabolism is Michaelis–Menten with zero-order kinetics prevailing at levels over 100 mg per dL [29]. Only a small fraction of ethanol is exhaled or secreted in urine and sweat [13,30].

ADH is responsible for greater than 57% of ethanol metabolism at low doses. In the ADH metabolic pathway (Fig. 119.1), ethanol is oxidized to acetaldehyde and then to acetate in a process that reduces oxidized nicotinamide adenine dinucleotide (NAD^+) to nicotinamide adenine dinucleotide (NADH). The increased ratio of NADH to NAD^+ can inhibit NAD^+-dependent reactions, such as gluconeogenesis,

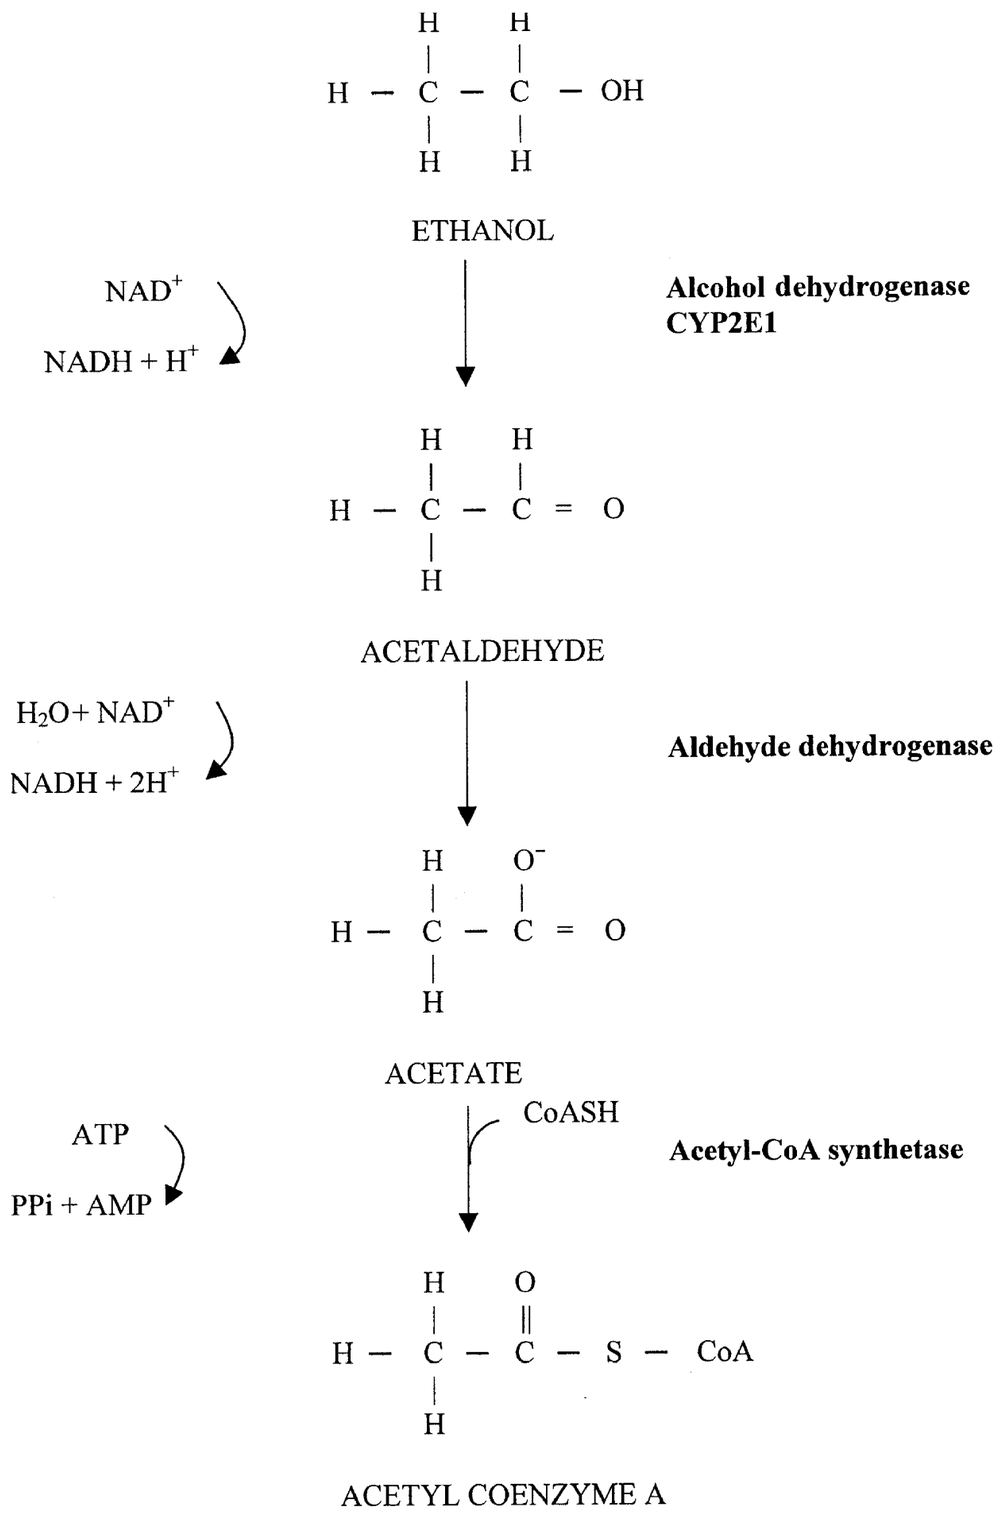

FIGURE 119.1. Ethanol metabolism. AMP, adenosine monophosphate; ATP, adenosine triphosphate; Co, coenzyme; NAD^+, oxidized form of nicotinamide adenine dinucleotide; NADH, nicotinamide adenine dinucleotide; PPi, inorganic pyrophosphate.

as well as slowing subsequent ethanol oxidation and clearance [31]. Acetate is linked to coenzyme A (acetyl-CoA), which can then participate in the citric acid cycle, fatty acid synthesis, or ketone formation [30]. Genetic variations in ADH and aldehyde dehydrogenase have been extensively characterized and may play a role in determining susceptibility to alcoholism [32–35]. Normally, the cytochrome P450 and catalase systems play minor roles in ethanol metabolism [36,37]. Chronic ethanol use can induce CYP2E1 activity 4- to 10-fold, allowing habitual users to metabolize ethanol twice as quickly as occasional drinkers [38].

Ethanol is a central nervous system (CNS) depressant. After acute ingestion, there is often an initial stage of paradoxical excitation due to release of learned social inhibitions. For nontolerant individuals, a blood ethanol concentration as low as 20 mg per dL impairs driving-related skills involving perception and attention [39]. At concentrations of 50 mg per dL, gross motor control and orientation may be affected, and intoxication may become apparent [40]. Lethargy, ataxia, and muscular incoordination may be seen at serum levels of 150 mg per dL or greater, coma at approximately 250 mg per dL, and death with levels greater than 450 mg per dL [16,41]. Tolerant drinkers can achieve higher levels before developing similar symptoms, and survival has been reported despite a serum level of 1,500 mg per dL [42]. At high doses, ethanol functions as an anesthetic, causing CNS depression, autonomic dysfunction (e.g., hypotension, hypothermia), coma, and death from respiratory depression and cardiovascular collapse. The estimated LD_{50} in adults is 5 to 8 g per kg and 3 g per kg for children [16].

Tolerance to ethanol's effects develops both acutely and after chronic consumption. With acute consumption, the physiologic effects at a given serum level of ethanol have been noted to be less when ethanol concentrations are declining rather than when levels are rising (Mellanby effect) [43]. Compared with inexperienced drinkers, chronic drinkers experience diminished effects to a given amount of ethanol. Tolerance is accompanied by changes in membrane-associated receptors [21,22].

Clinical Manifestations

Patients may present with varying degrees of altered consciousness, including agitation, stupor, and coma. The odor of ethanol or its congeners on their breath is usually present. Slurred speech, ataxia, and nystagmus are noted in patients with mild to moderate intoxication. Disconjugate gaze is frequently seen in comatose patients. Acute intoxication may be accompanied by vomiting, particularly in novice drinkers. Children younger than 10 years of age are most susceptible to alcohol-induced hypoglycemia, which can occur at relatively low serum ethanol levels (discussed later).

Diagnostic Evaluation

The physical examination should be directed toward evaluation of the airway and a search for complicating or contributing factors such as trauma, infection, and hemorrhage. In patients with moderate-to-severe poisoning, laboratory studies including complete blood cell count, serum electrolytes, blood urea nitrogen, creatinine, glucose, ethanol, magnesium, calcium, and phosphorus level, liver function tests, prothrombin time, electrocardiogram, chest radiograph, arterial or venous blood gas, and urinalysis should be obtained as clinically indicated. If the level of consciousness is inconsistent with the serum ethanol level or does not improve over a few hours, the physician should reconsider the diagnosis of ethanol intoxication (Table 119.2).

Management

Patients with stupor or coma who cannot be aroused to a verbal (but not necessarily coherent) state or who have a poor respiratory effort should be intubated to ensure airway patency and to protect against pulmonary aspiration. Intravenous (IV) naloxone (0.1 to 2 mg), dextrose (25 to 50 g) and thiamine hydrochloride (100 mg) should be administered when opioid toxicity, hypoglycemia, or Wernicke's encephalopathy are considerations.

Activated charcoal should be withheld unless potentially toxic coingestants are suspected. Hypothermia, if present, is usually mild in the absence of environmental exposure, and can be managed with warm blankets. Nutritional, electrolyte, and fluid deficiencies should be corrected. A variety of interventions trying to increase ethanol clearance or decrease its effects, including supplemental IV fluids, dextrose, and fructose, are neither clinically useful nor recommended [44,45].

ALCOHOLIC KETOACIDOSIS

Alcoholic ketoacidosis (AKA) develops as a result of hormonal, nutritional, and metabolic changes caused by ethanol (Fig. 119.2). Because ethanol retards ketogenesis, AKA usually occurs when ethanol levels are low to absent [30]. Ethanol

metabolism indirectly impairs gluconeogenesis and increases fatty acid and ketone formation. Inadequate nutritional intake in alcoholics depletes glycogen, minerals, and vitamin stores. Vomiting results in decreased intravascular volume and increased catecholamine levels that blunt insulin release [46] activate lipase, and accelerate free fatty acid oxidation. Glucagon activates the carnitine acyltransferase system producing excess acetyl-CoA.

Acetyl-CoA cannot be used by mammals to form pyruvate or higher carbohydrates. Instead, it can undergo only three metabolic fates: fatty acid synthesis, oxidation to CO_2 in the citric acid cycle, and cholesterol or ketone body formation via 3-hydroxy-3-methylglutaryl-CoA. The ketogenic pathway has the largest capacity and requires the least adenosine triphosphate for handling acetyl-CoA overload [46]. Nutritional deficiencies impair acetyl-CoA conversion to triglycerides and its entrance into the citric acid cycle [30]. Finally, the increased NADH to NAD^+ redox ratio caused by ethanol oxidation favors the conversion of acetoacetate to β-hydroxybutyrate, which is largely responsible for the ketoacidosis.

Other acid–base abnormalities may occur in alcoholics. Respiratory acidosis may be caused by hypoglycemia or ethanol-induced respiratory depression. Lactic acidosis can occur secondary to seizure activity, an increase in the NADH to NAD^+ ratio that favors lactate formation from pyruvate, decreased gluconeogenesis, thiamine deficiency impairing pyruvate's entry into the citric acid cycle, and liver dysfunction [47]. Vomiting may cause volume contraction, hypokalemia, and metabolic alkalosis [46]. A mild acetic acidosis may be seen when peripheral tissues incompletely oxidize acetate. An unexplained hyperchloremic metabolic acidosis has been observed in acutely intoxicated patients [47].

Clinical Manifestations

Patients with AKA usually present with a recent history of binge alcohol drinking and poor nutritional intake followed by vomiting. The fruity odor of ketones may be detected along with Kussmaul's breathing, dry mucous membranes, tachycardia, orthostatic hypotension, and poor skin turgor [30].

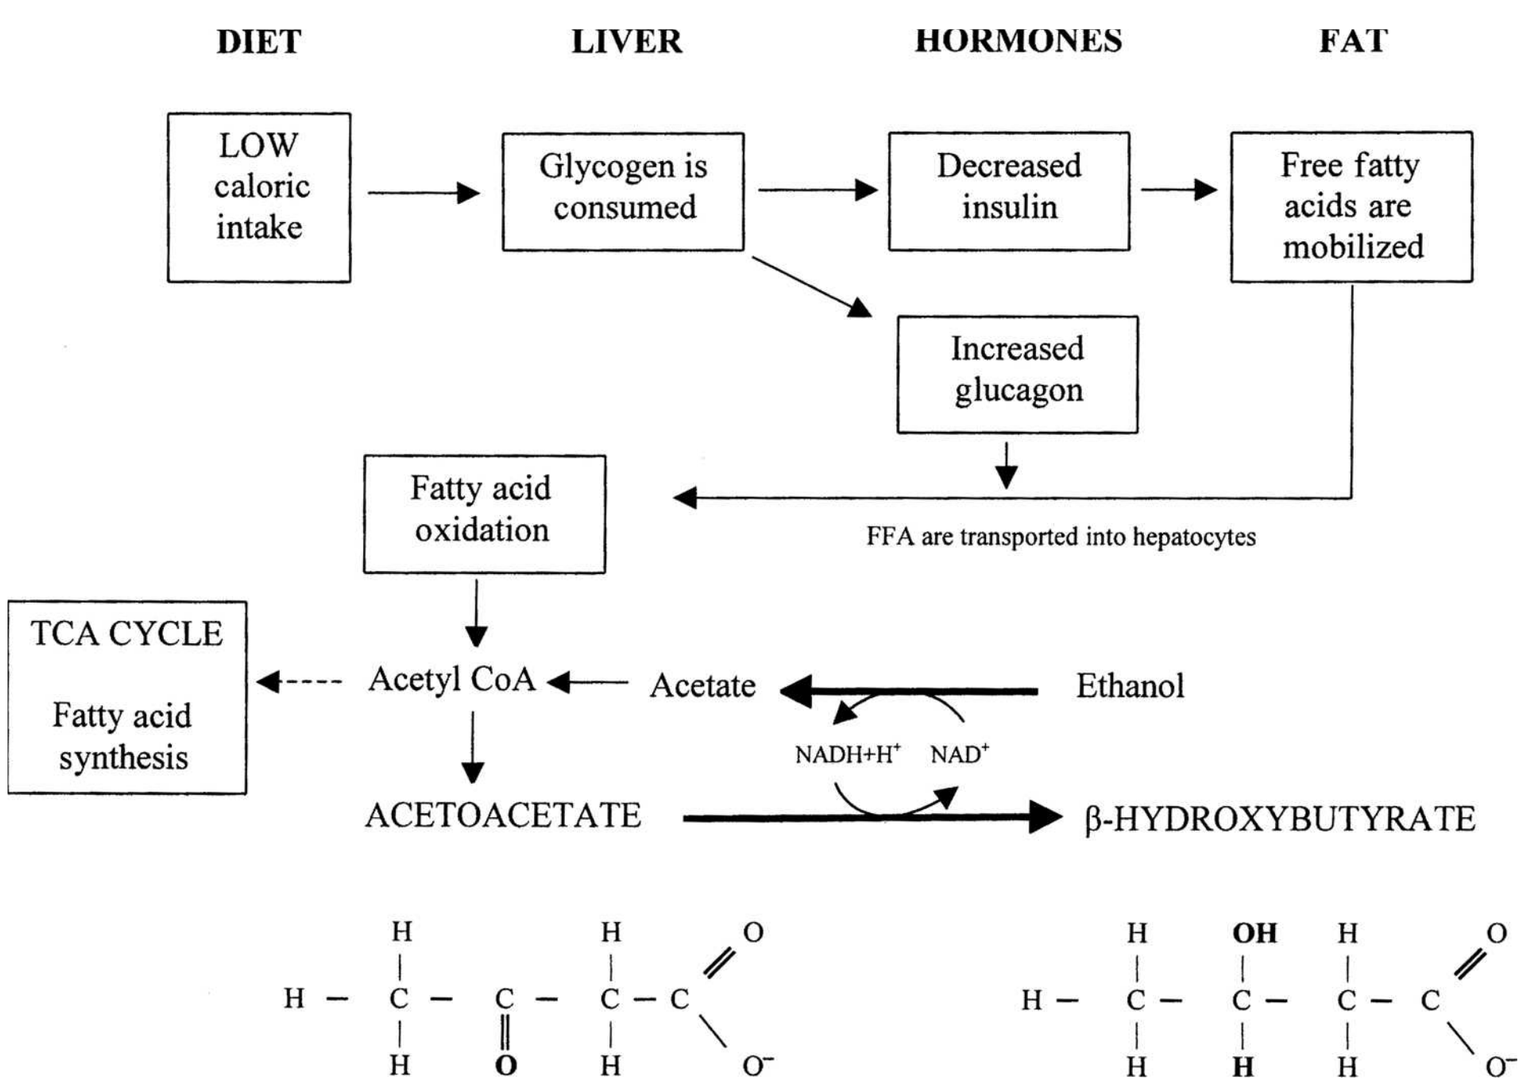

FIGURE 119.2. Mechanism of alcoholic ketoacidosis. [Adapted from Eckardt MJ, Harford TC, Kaelber CT, et al: Health hazards associated with alcohol consumption. *JAMA* 246:648, 1981, with permission.]

Abdominal pain is typical, with nonspecific tenderness on examination [48].

Diagnostic Evaluation

The diagnosis of AKA is a diagnosis of exclusion. Signs and symptoms of concomitant gastritis, pancreatitis, hepatitis, gastrointestinal hemorrhage, and vitamin and mineral deficiencies are often present. Laboratory studies should include those listed for acute ethanol intoxication plus serum ketones, lactate, and osmolality. Ethanol levels are often low to undetectable, and hypoglycemia may be present [49,50]. A respiratory or metabolic alkalosis may be present in addition to the anion gap metabolic acidosis. At presentation, the predominant serum ketone is usually β-hydroxybutyrate due to the altered redox state, which results in falsely low serum ketones by the semi-quantitative nitroprusside test for acetoacetate [30]. Many laboratories now measure β-hydroxybutyrate directly to mitigate this concern. Hypokalemia is uncommon, in part because acidosis shifts potassium out of the cell. The osmol gap may be elevated from glycerol, acetone, and its metabolites [51], even after correcting for the serum ethanol concentration [52].

The differential diagnosis of an anion gap metabolic acidosis includes lactic acidosis; salicylate poisoning; uremia; diabetic ketoacidosis; and intoxication from iron, ibuprofen, toluene, methanol, ethylene glycol, and diethylene glycol. Hypoxia and hypotension are the most common causes of lactic acidosis, but malignancies, leukemia, and toxicity due to cyanide, metformin, and carbon monoxide should also be considered [53]. AKA can usually be differentiated from diabetic ketoacidosis by the lack of significant hyperglycemia, minimal alteration of consciousness, a relatively mild acidosis, and rapid improvement with supportive therapy [54]. The presence of more than mild tenderness on abdominal examination should prompt investigation for other pathology such as pancreatitis, hepatitis, sepsis, or pneumonia [48].

Management

Supportive therapy is the same as that noted for acute intoxication. IV fluid resuscitation, glucose (25 to 50 g), and thiamine (100 mg) reverse the ketogenic process and are the mainstays of therapy. Maintenance fluids should consist of dextrose (5%) in normal saline [30]. Thiamine facilitates the entry of pyruvate into the citric acid cycle and protects against Wernicke's encephalopathy [55]. Once urine output is established, supplemental potassium and magnesium should be administered. Hypophosphatemia may develop with increased glycolysis and carbohydrate refeeding and should be corrected with potassium phosphate [49,54]. Hospitalization and refeeding of malnourished patients may be required.

ETHANOL-RELATED HYPOGLYCEMIA

Four types of hypoglycemia associated with or induced by ethanol have been delineated: alcohol-induced fasting hypoglycemia, reactive hypoglycemia of chronic alcoholism, alcohol potentiation of drug- or exercise-induced hypoglycemia, and alcohol-promoted reactive hypoglycemia [56]. Alcohol-induced fasting hypoglycemia is the best understood. Marginal nutritional status is the only requirement for its development, and it can occur in poorly nourished alcoholics and in young children, fasted normal subjects, patients on low-carbohydrate diets, and those with thyrotoxicosis and adrenocortical deficiency [49,56,57]. When these patients consume ethanol rather than food, their marginal glycogen stores are readily depleted by glycogenolysis and the body's metabolic needs become dependent on gluconeogenesis. Ethanol inhibits this reaction [57], however, probably by the increasing NADH to NAD^+ ratio. This effect preferentially shunts pyruvate to lactate and thus blocks pyruvate from participating in gluconeogenesis or other reactions in which it is the key intermediate (Fig. 119.3) [30].

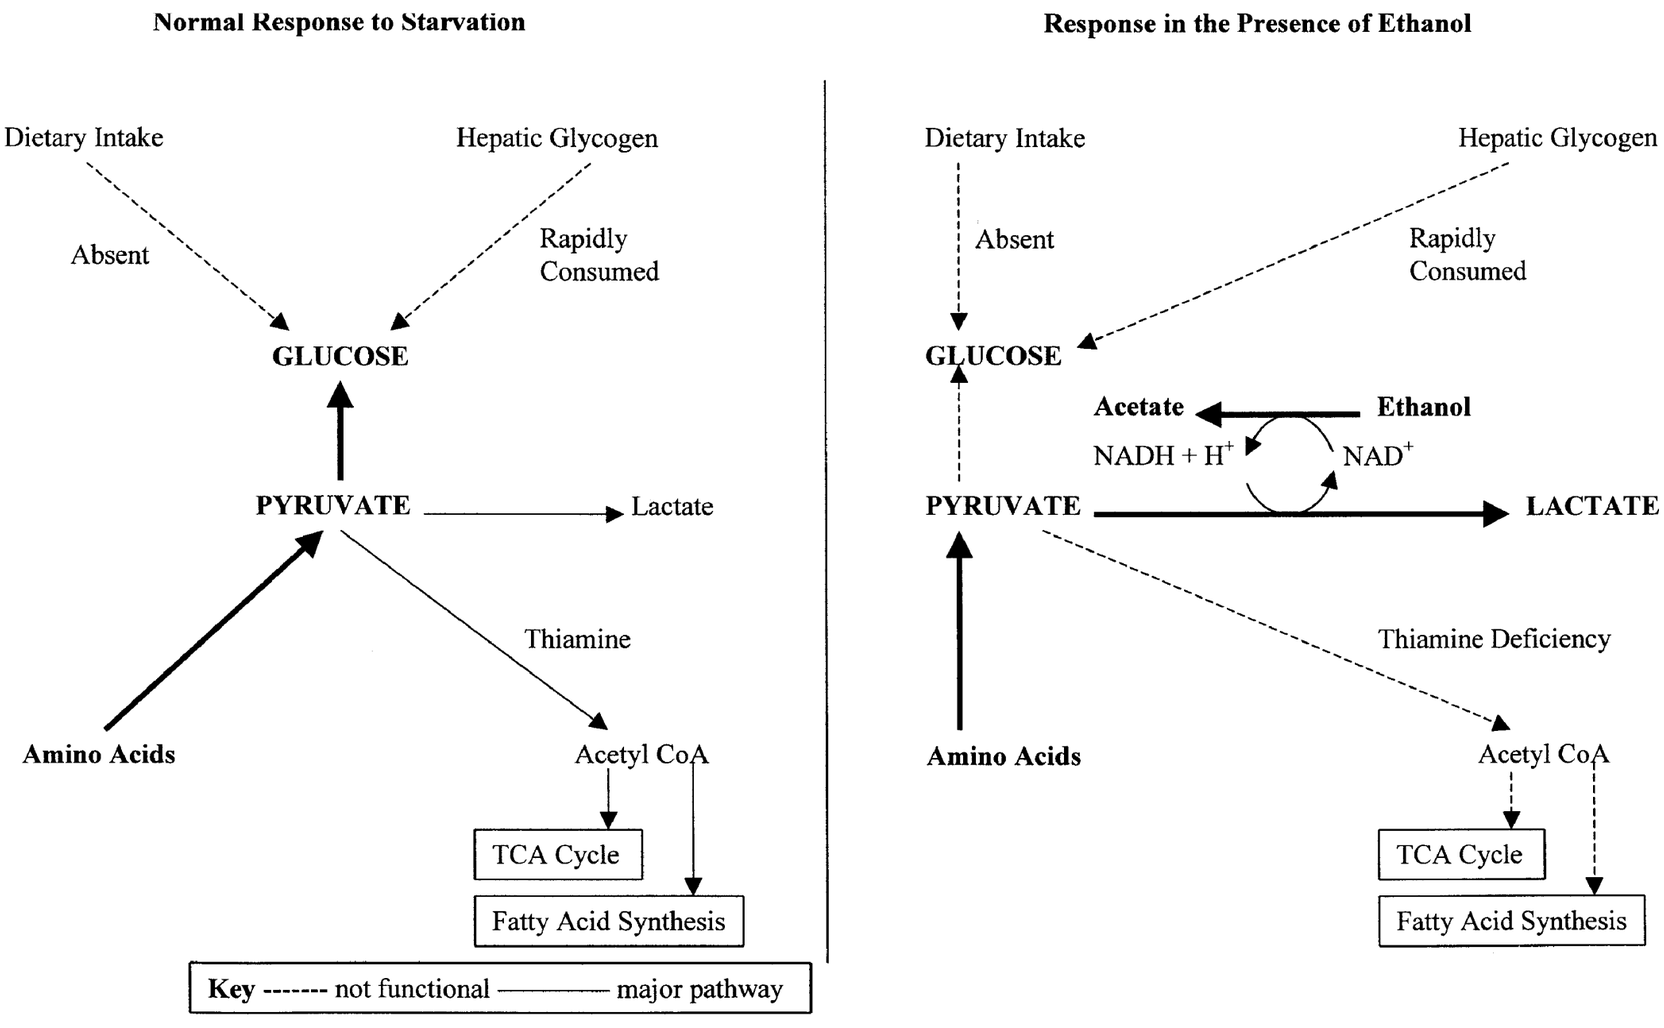

FIGURE 119.3. Ethanol-induced hypoglycemia. Co, coenzyme; NAD^+, oxidized form of nicotinamide adenine dinucleotide; NADH, nicotinamide adenine dinucleotide; TCA, tricarboxylic acid cycle (also known as *citric acid cycle*). [Adapted from Hoffman RS, Goldfrank LR: Ethanol-associated metabolic disorders. *Emerg Med Clin North Am* 7:943, 1989, with permission.]

Contributory endocrinologic abnormalities may include impaired cortisol release and decreased growth hormone secretion due to hypothalamic–pituitary dysfunction [56,57]. Lactic acidosis may result from excessive lactate production [57].

The biochemical mechanisms underlying the other types of hypoglycemia are poorly understood [56,58], but alcohol-promoted reactive hypoglycemia may be due to potentiation of insulin secretion by ethanol [56]. Liver disease is not necessary for the development of hypoglycemia [59].

Clinical Manifestations

CNS depression ranging from confusion to coma, seizures, and symptoms of increased sympathetic activity such as diaphoresis, anxiety, tremulousness, palpitations, and weakness are the hallmarks of hypoglycemia. Hypothermia occurs frequently [56].

The CNS effects of hypoglycemia and ethanol intoxication can mimic one another, whereas hypoglycemia-induced adrenergic signs and symptoms can be mistaken for ethanol withdrawal. The differential diagnoses are similar to those for acute ethanol intoxication (Table 119.2).

Diagnostic Evaluation

Laboratory evaluation is the same as for a patient with acute intoxication. If metabolic acidosis is present, the studies recommended for AKA are also indicated. Serum glucose concentrations are usually less than 40 mg per dL, ethanol levels are often low [56], and lactate levels may be elevated [57].

Caution is advised when assessing capillary blood glucose levels with point-of-care testing. Errors can be introduced by the age of the strips, and by the accuracy of machines used to read them especially outside the calibration range. The effect of varying ethanol levels on the accuracy of these strips has not been adequately studied. Given the morbidity and mortality of severe hypoglycemia, the potential errors in testing, and the benign nature of IV glucose, all symptomatic patients with an equivocal glucose reading should be treated with glucose, especially if diabetic or alcohol impaired [30].

Management

Therapy for ethanol-induced hypoglycemia parallels that for acute ethanol intoxication. An IV dextrose bolus of 25 to 50 g should be followed by a 10% dextrose infusion. In young children, 25% dextrose should be given in a bolus of 0.25 to 1 g per kg, followed by a maintenance infusion. Blood glucose levels should be frequently monitored and repeat dextrose boluses may be necessary.

Most patients immediately respond to therapy and return to normal levels of consciousness without major morbidity, but persistent encephalopathy and death have been reported [30].

ETHYLENE GLYCOL AND METHANOL

Ethylene Glycol

Ethylene glycol (1,2-ethanediol) is a colorless, sweet liquid [60,61] that imparts a warm sensation to the tongue and esophagus when swallowed. It is found primarily in automotive antifreeze solutions. Ingestions usually result from suicide attempts, intentional substitution of ethylene glycol for ethanol,

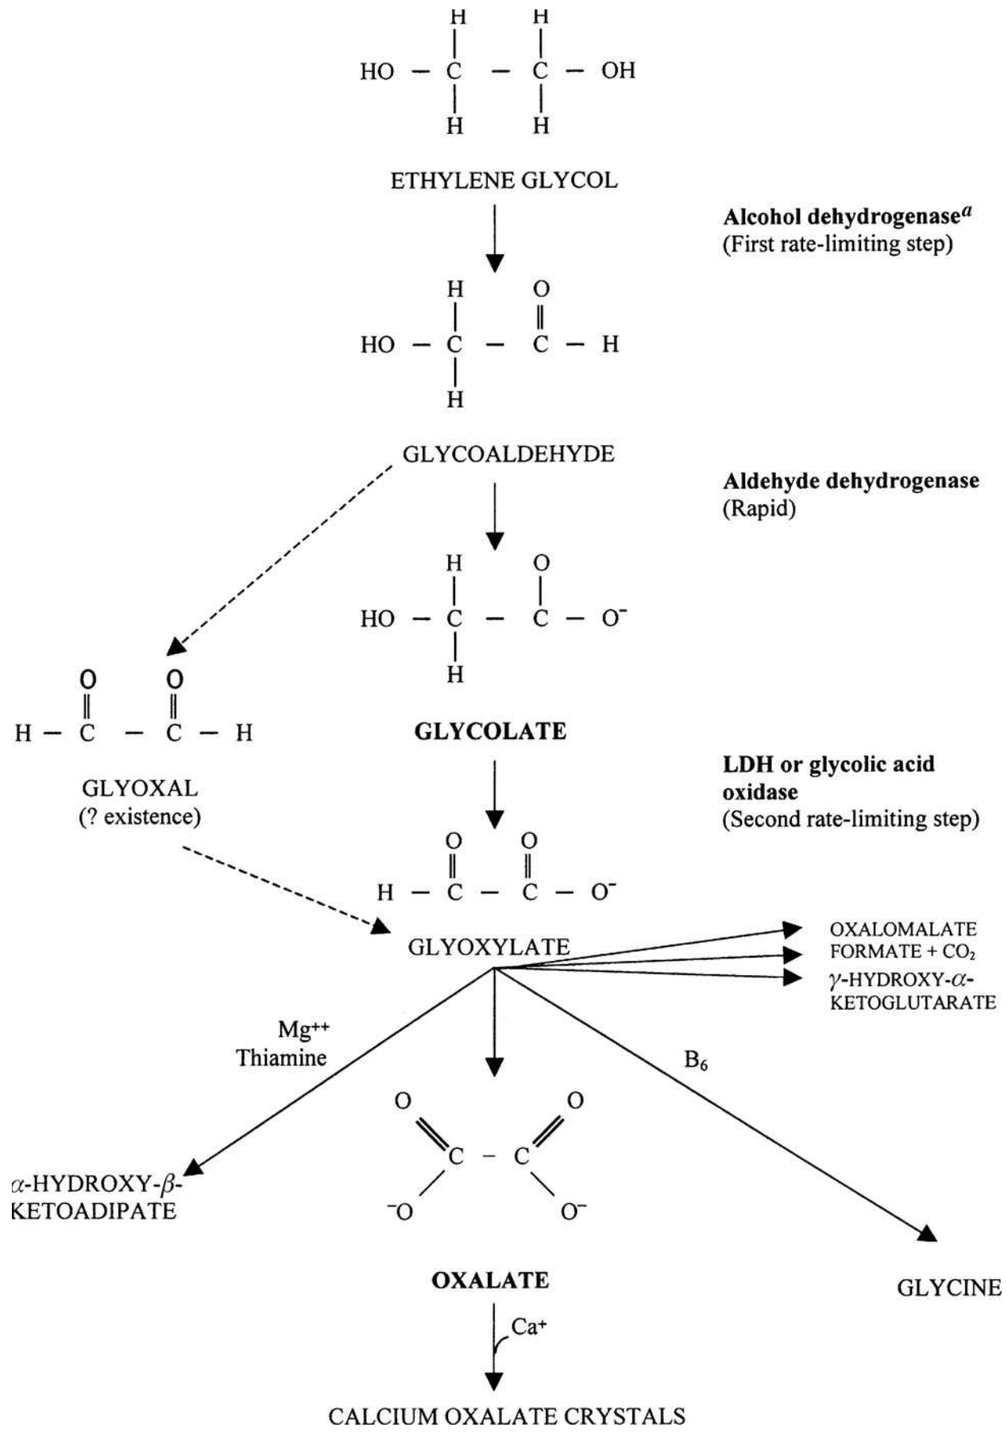

FIGURE 119.4. Ethylene glycol metabolism. [a]Blocked by ethanol and fomepizole. LDH, lactate dehydrogenase.

or accidental exposure. Ethylene glycol itself causes little toxicity other than ethanol-like inebriation until it is metabolized in the liver into its toxic acid metabolites (Fig. 119.4). Ethylene glycol is first metabolized in the liver by ADH to glycoaldehyde, which is rapidly transformed via aldehyde dehydrogenase to glycolic acid. Glycolic acid is slowly converted to glyoxylic acid, which in turn is converted to multiple metabolites, including oxalic acid [61,62]. It is uncertain which of these metabolites is most directly responsible for renal tubular toxicity [63–65].

The anion gap metabolic acidosis seen in ethylene glycol poisoning is due predominantly to elevated glycolic acid levels, [62,66–68] although oxalic acid, glyoxylic acid and glycoaldehyde may be more toxic [61,62]. Elevated lactic acid levels contribute to the acidosis [62,67–72], and have been attributed to the increased NADH to NAD^+ ratio caused by metabolism of ethylene glycol [64,73], and to the toxicity of glyoxylic acid on mitochondrial respiration [61,62,74]. Some lactate assays may misinterpret glycolate as lactate and report falsely elevated lactate levels [75–77].

Pathologic changes are noted in the CNS, kidneys, lungs, heart, liver, muscles, and retina [16,78]. Renal findings include dilation of the proximal tubules with swelling and vacuolization of the epithelial cells, distal tubular dilation, intratubular deposition of calcium oxalate crystals, and interstitial edema [73]. Pulmonary edema, interstitial pneumonitis, and hemorrhagic bronchopneumonia may occur. In some cases, interstitial myocarditis, skeletal muscle inflammation, and centrilobular hepatic fatty infiltration may develop. CNS findings include cerebral edema, meningoencephalitis, and cerebellar changes, including focal loss of Purkinje cells [78].

The chemical properties and kinetics of ethylene glycol are summarized in Table 119.1. Oral absorption of ethylene glycol occurs rapidly. Percutaneous absorption through intact skin is negligible. Ethylene glycol has a high boiling point and toxicity from vapor inhalation does not occur. Hepatic metabolism predominates yet renal elimination of the parent compound is initially substantial. The ensuing renal failure markedly prolongs the elimination of ethylene glycol and its metabolites [67,73,79,80].

The reported minimum lethal dose is 1.6 g per kg in humans. Hence, the estimated fatal dose widely quoted for a 70-kg person is 100 mL of 100% ethylene glycol, but this value is based on limited data [81] and assumes no treatment. With early and intensive treatment, survival has been reported in patients with serum ethylene glycol concentrations as high as 1,889 mg per dL [70,82,83].

Methanol

Methanol is a colorless liquid and has an odor distinct from that of ethanol [84,85]. Dietary sources and endogenous metabolism can produce serum methanol levels of 0.15 mg per dL [86]. Exogenous sources of methanol include windshield washing fluid, de-icing fluids, carburetor cleaners, paint removers, and paint thinners.

Methanol is oxidized in the liver by ADH to formaldehyde, which is quickly converted to formic acid (formate) by hepatic aldehyde dehydrogenase (Fig. 119.5). In primates, formate accumulates due to saturation of one-carbon metabolism. High levels of formate, an inhibitor of mitochondrial cytochrome oxidase, cause histotoxic hypoxia and are responsible for the characteristic metabolic acidosis and ocular toxicity seen with methanol toxicity [73]. Formaldehyde is also very toxic, but it has a very short half-life.

Formate plays a pivotal role in methanol toxicity. Blood formate concentrations account for nearly the entire observed anion gap and base deficit [87–89]. Symptoms and prognosis also correlate better with formate than with methanol levels [90,91]. Primates infused with formic acid develop ocular toxicity, even when the acidosis is controlled with sodium bicarbonate [92]. Ocular toxicity results from the inhibition of cytochrome oxidase by formic acid in the optic nerve, leading to disruption of mitochondrial electron transport and decreased axoplasmic flow and electrical conduction [93]. Although this produces changes in the optic nerve head, direct retinal toxicity can also occur [94].

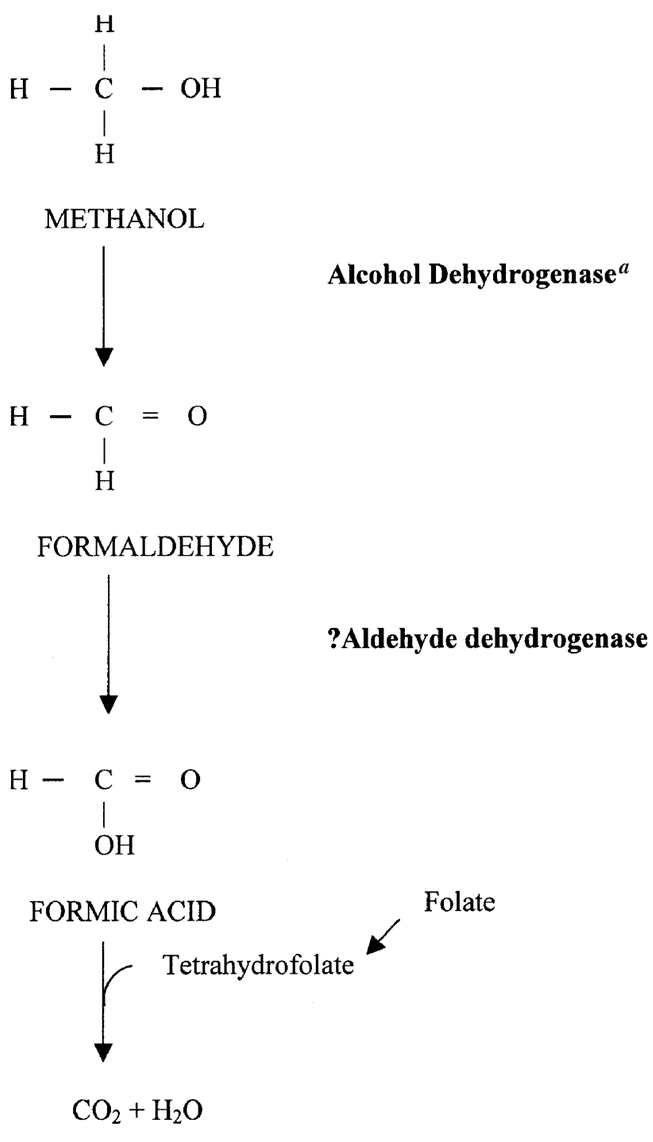

FIGURE 119.5. Methanol metabolism. [a]Blocked by ethanol and fomepizole.

The chemical properties and kinetics of methanol are summarized in Table 119.1. Methanol is absorbed orally, dermally, and via inhalation [84,95]. Exposure can occur intentionally or accidentally, as occurred in Estonia in 2001 when 68 patients died after consuming illegal spirits contaminated with methanol [96]. A retrospective hospital record review of 16 individuals who inhaled carburetor cleaning fluid fumes identified 48 hospital presentations with serum methanol levels greater than 20 mg per dL and 19 greater than 50 mg per dL [74]. Methanol's metabolism is slower than that of ethylene glycol or ethanol [73], which may explain why methanol toxicity develops more slowly. Hepatic oxidation predominates, with only trivial amounts eliminated via the lungs and kidneys [84]. Elimination follows first-order kinetics at low doses and during hemodialysis [97–99]. At higher doses, zero-order (Michaelis–Menten) kinetics may prevail. In one untreated patient, methanol elimination occurred at a rate of 8.5 mg per dL per hour [100]. The elimination half-life of formate in one untreated patient was 3.7 hours [90], and averaged 3.4 ± 1.5 hours in eight patients treated with fomepizole (4-methylpyrazole) and leucovorin [89]. With hemodialysis, the formate elimination half-life was estimated to be between 1.1 and 2.8 hours [87,89,90].

Reported lethal doses in patients with inadequate, delayed, or no therapy vary considerably and are not well established. In one epidemic, the minimal lethal dose was 15 mL of a 40%-by-weight methanol solution. In another outbreak, one patient survived a 600-mL ingestion of pure methanol but had permanent sequelae, whereas another reportedly imbibed 500 mL without complications [10].

Clinical Manifestations

Ethylene Glycol

Ethanol-like intoxication usually begins within an hour of ingestion. Symptoms due to toxic metabolites usually occur 4 to 12 hours after ingestion, but are delayed further if ethanol was coingested by delaying the metabolism of ethylene glycol. Patients may present alert, intoxicated, or in a coma, depending on the time since ingestion, the dose of ethylene glycol, coingestion of ethanol, and cross-tolerance [61,62,73,78,101,102]. Vital signs can be normal. Ocular exposure can produce a chemical conjunctivitis and chemosis [78], but systemic toxicity does not occur.

The classic division of ethylene glycol poisoning into three stages is primarily of historical interest. In reality, patients rarely exhibit sequential toxicity that can be readily divided into distinct stages. Shortly after ingestion and before significant metabolism of ethylene glycol has occurred, CNS effects such as ethanol-like intoxication, stupor, nausea, and vomiting predominate. As toxic metabolites begin to accumulate, a metabolic acidosis ensues with associated cardiovascular and pulmonary signs, including Kussmaul's respirations, tachycardia, cyanosis, and cardiogenic or noncardiogenic pulmonary edema [101]. As renal injury progresses, flank pain and tenderness, proteinuria, and anuria may occur. Acute renal failure occurs in nearly all untreated patients who manifest

metabolic acidosis (serum bicarbonate less than 10 mmol per L). Renal dysfunction can develop within 9 hours of ingestion [103]. Patients may also develop myositis with muscle tenderness and elevated creatine kinase [61,73]. Death may result from severe metabolic derangements, cardiovascular or respiratory failure, or progressive CNS depression. Prolonged seizures, coma, and a cerebral herniation syndrome have also been reported [104]. Preterminal dysrhythmias and hypotension are rare [70]. The presence of hyperkalemia, severe acidemia, seizures, and coma at presentation demonstrate severe toxicity.

Seizures are usually generalized but do not occur in all cases. Jacksonian seizures have been reported, as have myoclonic jerks and tetanic contractions due to hypocalcemia [70,78]. Progressive CNS depression and prolonged seizures usually result from cerebral edema [73]. Transient nystagmus and cranial nerve (II, V, VI, VII, VIII, IX, and X) palsies have been reported to occur 4 to 18 days postingestion [82,104–107].

Methanol

Onset of toxicity usually occurs within 30 hours of methanol ingestion [108]. In one epidemic, a range of 40 minutes to 72 hours was reported. Factors influencing time to symptoms include the dose, ethanol coingestion, and folate stores [85,108].

Neurologic, ophthalmologic, and gastrointestinal symptoms predominate [20,21,97,98,109,110]. Methanol is a less potent CNS depressant than ethanol. Patients may be alert on admission and complain only of headache and dizziness. Amnesia, restlessness, acute mania, lethargy, confusion, coma, and convulsions may follow. Cases mimicking subarachnoid hemorrhage with severe headache, vomiting, hypertension, and bradycardia followed by loss of consciousness have been described. Dyspnea is reported by only 8% to 25% of patients [96].

Early on, many patients offer no visual complaints. Visual symptoms accompany the metabolic acidosis and usually develop when the blood pH falls below 7.2. Blurred vision, photophobia, scotomata, eye pain, partial or complete loss of vision, and visual hallucinations (e.g., bright lights, "skin over eyes," "snowstorm," dancing spots, flashes) have been reported. These disturbances can persist after formate has been completely eliminated and the acidosis has resolved.

Methanol can produce severe hemorrhagic gastritis and pancreatitis, causing upper abdominal pain, nausea, vomiting, and diarrhea. Liver function abnormalities have been documented in moderately to severely ill patients.

Vital signs may reveal tachycardia and Kussmaul's respirations, but the blood pressure is usually maintained. Untreated, patients can die from sudden respiratory arrest [84]. The skin may be cool and diaphoretic, and abdominal muscles rigid without rebound tenderness.

The most notable physical findings are those discovered on ophthalmologic examination, but these are late findings. Pupils may react sluggishly or may be fixed and dilated [10]. Funduscopic examination may show hyperemia of the optic discs followed by retinal edema, which develops initially along the retinal vessels and then spreads to the central areas of the fundus. Retinal vessel engorgement accompanies the retinal edema [110]. Papilledema may develop [20]. Ophthalmologic findings do not necessarily correlate with visual complaints.

Diagnostic Evaluation

Poisoning by ethylene glycol and methanol should be suspected in all patients with a history of ingesting ethanol substitutes or who have an unexplained anion gap metabolic acidosis.

Ethylene Glycol

Laboratory studies should include complete blood cell count; serum electrolytes; glucose; blood urea nitrogen; creatinine; arterial or venous blood gas; calcium; serum osmolality; ethanol, methanol, and ethylene glycol levels; and urinalysis. Additional laboratory studies may include electrocardiogram, chest radiograph, and head computed tomography as clinically indicated. Early after ingestion, before significant metabolism of ethylene glycol, an osmol gap may be present [111] with neither metabolic acidosis nor an anion gap (see later discussion on osmol gap). As ethylene glycol is metabolized, the osmol gap decreases and an anion gap metabolic acidosis develops. Patients who present very late may have renal failure with normal osmol and anion gaps, normal pH, and unmeasurable ethylene glycol levels.

Perhaps the greatest diagnostic challenge in managing a patient suspected to have ingested a toxic alcohol or glycol is the limited availability of methanol and ethylene glycol testing. Gas chromatography can reliably quantify the presence of ethylene glycol or methanol, but most hospitals are unable to obtain these tests in a timely fashion [112]. Moreover, some hospitals offer a "toxic alcohol screen" that detects methanol, ethanol, and isopropanol but not ethylene glycol, which is a diol. This nomenclature can mislead a clinician into interpreting a negative "toxic alcohol screen" as excluding the presence of ethylene glycol. Interference due to propionic acid, propylene glycol, glycerol, 2,3-butanediol, and β-hydroxybutyrate has been described [113–116]. Testing for glycolic acid or formic acid is even less available [76,117,118]. A rapid bedside qualitative test for ethylene glycol is available but not approved for diagnostic use in humans [119]. Breath alcohol analysis can mistake methanol for ethanol, providing indirect evidence of exposure. Therefore, diagnostic and therapeutic decisions are often based on circumstantial evidence derived from the history and available laboratory testing, pending confirmatory testing. It is essential for the physician to understand the strengths and the limitations of these indirect markers of toxicity.

Arterial pH measurements in ethylene glycol exposed patients can range from 6.7 to 7.5 [62,103]. Ethylene glycol poisoning often results in higher anion gaps than other causes of this abnormality [64]. A gap of 58 has been reported [70]. The differential diagnosis of an increased anion gap metabolic acidosis is discussed above (see Alcoholic Ketoacidosis section). In young children, child abuse and inborn errors of organic acid metabolism should be considered in the differential diagnosis [116,120]. Hyperkalemia may be seen in association with acidosis and with renal failure [61,78,101]. The creatinine and blood urea nitrogen are normal unless renal failure has supervened. Calcium levels are initially normal but may drop significantly as calcium complexes with oxalic acid to form calcium oxalate. The electrocardiogram may show ST-T wave and QTc changes consistent with hypocalcemia, hyperkalemia, or both.

The osmol gap (refer to Chapters 71, 101, and 117) is frequently used as a diagnostic test in the evaluation of these patients. Extreme caution must be used when interpreting the osmol gap, however. First, the serum osmolality should be measured by the freezing point depression, as vapor pressure osmometry will not detect methanol, ethanol, and isopropanol [121].

Although an osmol gap greater than 10 mOsm is often sought as indirect evidence of the presence of an exogenous alcohol or glycol, *failure to find an elevated osmol gap does not rule out significant alcohol or glycol ingestion* [122]. Cumulative measurement error in the formula parameters, variations in the formula itself, and the natural variability in the osmol gap at baseline contribute to imprecision in the calculated osmol gap [52,123,124]. This variability can hide a significant amount of an alcohol or glycol. Furthermore, as the parent

alcohol or glycol is oxidized to the toxic charged metabolite, the osmol gap disappears. Conversely, an elevated osmol gap is not specific for alcohols or glycols, as lactic acidosis, ketoacidosis, and sepsis can also increase the osmol gap [122].

In studies of various control populations not exposed to methanol, isopropanol, or ethylene glycol, osmol gaps averaged approximately −1 to −2 mOsm per kg [125–127]. The variability was substantial, however, with standard deviations of between 5 and 8 mOsm per kg. Thus, although an arbitrary upper limit of 10 mOsm per kg has historically been used for the normal osmol gap [128], an osmol gap of 10 mOsm per kg in a patient whose usual baseline gap is 0 could represent substantial serum concentrations of ethylene glycol (62 mg per dL) or methanol (32 mg per dL) [129]. One patient with an osmol gap of only 11 mOsm per kg had an ethylene glycol level of 38 mg per dL and subsequently developed renal failure [64], whereas another patient with an osmol gap of 7.2 mOsm per kg required hemodialysis for ethylene glycol toxicity [130]. Thus, an elevated osmol gap may suggest the presence of an alcohol or glycol, but a normal gap does not rule out a small ingestion or a late presentation [122,126,131,132].

Microscopic examination of the urine for crystals is another indirect diagnostic test frequently recommended. Less than 50% of patients have crystalluria at presentation, however. Sequential urinalysis may improve sensitivity in detecting crystalluria [60,67,133]. Calcium oxalate monohydrate (needle shaped) and calcium oxalate dihydrate (envelope shaped) crystals can be seen. The monohydrate crystals are the predominant form at all concentrations and are more specific for ethylene glycol toxicity, but may be confused with uric or hippuric acid crystals [64,67]. The dihydrate crystals tend to occur at higher concentrations and convert to the monohydrate form within 24 hours [134]. They are less specific and can also be found in the urine after ingestion of oxalate-containing foods such as rhubarb. Other nonspecific urinary findings can include low specific gravity, proteinuria, hematuria, and pyuria. Some antifreeze manufacturers add fluorescein to their products to facilitate the detection of radiator leaks. Wood's lamp examination of the urine or gastric aspirate to detect fluorescence is unreliable and should not be used to make or exclude the diagnosis [135,136]. Other drugs, food products, toxins, and even endogenous compounds cause urine to fluoresce, as do many urine collection containers themselves [137,138].

Methanol

The laboratory studies listed for ethylene glycol evaluation should be obtained. Methanol can also cause an anion gap metabolic acidosis and an osmol gap [109]. The caveats noted under ethylene glycol for the evaluation and interpretation of these parameters apply equally to methanol. Elevated lactate levels, mild hypokalemia, and leukocytosis may occur. Lactic acidosis may be seen late in the course of methanol poisoning and may result from inhibition of the mitochondrial electron transport system or from poor tissue perfusion [73]. Serum lactate concentrations of 11.5 and 23 mmol per L have been reported 24 hours or more after ingestion. Amylase elevations and pancreatitis can occur in up to one half of severely poisoned patients [10,100]. Computed tomography scanning can demonstrate cerebral edema, as well as frontal lobe and basal ganglia hemorrhages and infarcts associated with poor clinical outcomes.

Management

The focus of treatment for ethylene glycol and methanol poisoning is to prevent the formation of toxic metabolites by inhibiting liver ADH and enhancing the removal of the parent compound and metabolites. Antidotal therapy, cofactor therapy, and hemodialysis may be necessary in addition to supportive care to achieve these goals.

Initial treatment includes airway management in the comatose patient, IV fluids, cardiac monitoring, and appropriate laboratory studies. Gastric aspiration via a nasogastric tube may be beneficial when performed within an hour of an intentional ingestion [83]. Oral activated charcoal is ineffective but may be considered when coingestants are suspected [81,139].

IV sodium bicarbonate should be administered to correct serum pH to at least 7.3 [100,139]. Large doses of sodium bicarbonate may be required. Sodium bicarbonate is useful in ethylene glycol and methanol poisonings for three reasons. First, unlike the metabolites in lactic acidosis and ketoacidosis, the metabolites of ethylene glycol and methanol cannot be transformed to regenerate bicarbonate [64], and the acidosis must be corrected with exogenous alkali. Second, increasing the serum pH enhances the ionization of acid metabolites, making them less diffusible, trapping them in the blood and extracellular fluid, and limiting their tissue penetration [73]. Third, urinary alkalinization may increase excretion of acid metabolites through ion trapping, provided renal function remains normal [67]. In ethylene glycol poisoning, however, the hypocalcemia that occurs as calcium complexes with oxalate may be worsened by alkali administration. Calcium chloride/gluconate should be administered to correct symptomatic hypocalcemia including seizures, but the indiscriminate use of calcium salts to correct a laboratory value should be avoided, because it may increase the precipitation of calcium oxalate crystals [140]. In methanol poisoning, increasing the serum pH may increase the concentration of ionized formate, thus diminishing formic acid access to the CNS and possibly ameliorating retinal toxicity [73].

Seizures should initially be treated with standard anticonvulsants, such as benzodiazepines and barbiturates. Hypocalcemia and hypoglycemia should be excluded. Recurrent or persistent coma or seizures should prompt evaluation for underlying cerebral edema. Cerebral edema should be managed acutely with hyperventilation, mannitol (provided renal function is intact), and potentially intracranial pressure monitoring and decompression. Cardiopulmonary complications may require inotropes and vasopressors.

Ethanol and fomepizole are antidotes for ethylene glycol and methanol poisoning. These agents inhibit liver ADH, and block the initial oxidation of ethylene glycol and methanol to their more toxic metabolites. After ADH is inhibited, ethylene glycol and methanol can be eliminated via endogenous or extracorporeal routes [85,141]. Antidotal therapy has no effect on the elimination of the acid metabolites. Indications for antidotal therapy in cases of known or possible methanol or ethylene glycol intoxication are outlined in Table 119.3 [101,103,139,142].

Recognition that ethanol is the preferred substrate for ADH [143] suggested its clinical use as a competitive inhibitor of this enzyme [144]. While most sources recommend administering sufficient ethanol to maintain serum ethanol concentrations between 100 and 150 mg per dL [97], limited data support this target concentration. Because ethanol is a competitive inhibitor of ADH, extremely high levels of ethylene glycol or methanol must by necessity be met with higher doses of ethanol. Targeting a 1:4 molar ratio [73,143] a serum ethanol concentration of 100 mg per dL should suffice for methanol concentrations as high as 257 mg per dL or ethylene glycol as high as 540 mg per dL. Dosage guidelines to achieve an ethanol concentration of 100 mg per dL are outlined in Table 119.4 [84,145].

There are disadvantages to using ethanol therapeutically [81,146,147]. Perhaps the most important limitation is the toxicity of ethanol itself, including coma, airway compromise, respiratory depression, and agitation [30,148,149]. At

TABLE 119.3

INDICATIONS FOR ALCOHOL DEHYDROGENASE INHIBITOR THERAPY

A serum methanol or ethylene glycol concentration > 20 mg/dL[a]

When serum methanol or ethylene glycol levels are not readily available:
- Documented ingestion of a consequential amount of methanol or ethylene glycol, especially when it is associated with a falling serum bicarbonate level or serum osmol gap > 10 mOsm/kg by freezing point depression
- History or strong clinical suspicion of methanol or ethylene glycol ingestion and one of the following:
  - A falling serum bicarbonate level or a serum bicarbonate < 20 mmol
  - Arterial pH < 7.3
  - Renal dysfunction or ocular toxicity

[a] Attempts should be made to obtain confirmatory methanol or ethylene glycol concentrations as soon as possible when contemplating alcohol dehydrogenase inhibitor therapy. In all cases, consultation with a medical toxicologist is strongly recommended.

recommended doses, ethanol induces inebriation in the nontolerant individual. Subsequent behavioral effects and severe mental status depression may require interventions, such as sedation and endotracheal intubation shortly after initiation of therapy. The need for these interventions as well as the continuous infusion of ethanol itself can complicate and delay interfacility transfer. Although IV ethanol administration is generally preferred over oral ethanol, this requires extemporaneous compounding from dehydrated ethanol and an infusion of a hypertonic solution (10% ethanol by volume is 1,700 mOsm per kg), usually via a central venous catheter. Maintaining an adequate ethanol level can be difficult and interindividual variation in metabolism and removal during hemodialysis necessitate frequent monitoring of serum concentrations and dosage adjustments [148]. Finally, ethanol therapy is relatively contraindicated in patients on disulfiram or similar medications, patients with hepatic disease, and patients with alcohol addiction [81]. Admission to an intensive care setting is considered mandatory for an individual receiving ethanol therapy.

Given these limitations to ethanol therapy, fomepizole has emerged as the preferred antidote. A more potent competitive inhibitor of ADH [67,140,150–154], parenteral fomepizole is approved by the U.S. Food and Drug Administration for therapy of methanol and ethylene glycol poisoning in adults [130,142,155,156]. Fomepizole has many advantages over ethanol: wide therapeutic margin, ease of administration, fixed dosing schedule, lack of CNS or behavioral toxicity, lack of metabolic or fluid balance effects, patient and provider safety, and no need for drug concentration monitoring [81,146,147,149,154]. Currently, fomepizole is only available in a parenteral formulation, though oral administration of this same formulation has similar pharmacokinetics and efficacy [157]. Highly selected patients treated with fomepizole may also avoid hemodialysis (discussed later), intensive care unit admission, or even interfacility transfer [67,79,81,146,151,156–160]. These advantages are even more important in the setting of mass epidemics [95].

A minimum serum fomepizole concentration of 10 μM (0.8 mg per dL) [161] effectively halts ethylene glycol and methanol oxidation [79,103,142,153,162] and is much higher than the in vitro K_i of fomepizole for human ADH of 1 μM [163]. Recommended dosing (Table 119.5) achieves and maintains serum fomepizole concentrations greater than 100 μM, eliminating the need for drug concentration monitoring [164]. Adverse drug events associated with fomepizole therapy are infrequent, but include rash, eosinophilia, minimal hepatic transaminase elevations, nausea, vomiting, and abdominal pain [148,165]. Hypersensitivity to pyrazoles, such as celecoxib and zaleplon, is the only contraindication to its use. Fomepizole does not appear to affect retinol dehydrogenases

TABLE 119.4

ETHANOL DOSING FOR ETHYLENE GLYCOL OR METHANOL POISONING

Loading dose of ethanol:
- 0.8 g/kg (1 mL/kg) of 100% ethanol
- Oral or via nasogastric tube: Use 20%–30% concentration (e.g., 5 mL/kg of 20% ethanol; recall "80 proof" = 40% by volume)
- Intravenous: use 5%–10% concentration, load over 1 h (e.g., 10 mL/kg of 10% ethanol in D_5 W over 1 h)

If ethanol is already present, the amount of ethanol required to achieve a serum ethanol level of 100–150 mg/dL may be calculated as follows:
- Amount ethanol (mg) = [desired concentration (mg/dL)—known concentration (mg/dL)] × V_d of ethanol (0.6 L/kg) × body weight (kg) × 10 dL/L

Maintenance doses of ethanol:
- Begin during administration of the loading dose.
- Give 80 mg/kg/h of ethanol orally or intravenously (as above). For a patient on hemodialysis, the maintenance dose should be higher: 250–350 mg/kg/h. Chronic alcoholics also require higher doses (average 150 mg/kg/h). Because of potential hypoglycemia, glucose should be given along with ethanol. Serum ethanol and glucose levels must be monitored frequently.

D_5 W, dextrose 5% in water; V_d, volume of distribution

TABLE 119.5

FOMEPIZOLE INTRAVENOUS DOSING PROTOCOL

Loading dose: 15 mg/kg

Maintenance dose (beginning 12 h after loading dose):
- 10 mg/kg every 12 h; increase dose to 15 mg/kg every 12 h if more than 48 h after loading dose

Dosing during hemodialysis:
- At initiation of dialysis:
  - If < 6 h since last dose, no additional dose
  - If > 6 h since last dose, next scheduled dose
- During hemodialysis: next scheduled dose every 4 h
- At completion of hemodialysis:
  - If < 1 h since last dose, no additional dose
  - If 1–3 h since last dose, half of next scheduled dose
  - If > 3 h since last dose, next scheduled dose

Each dose diluted in 100 mL normal saline and infused over 30 min

involved in vision [166,167]. Its dosing protocol is based on zero-order elimination kinetics, increased clearance during hemodialysis, and potential auto-induction of metabolism via cytochrome P450–2E1 [130,154,155,168,169] (Table 119.5).

The main disadvantage to fomepizole therapy is the higher acquisition cost of the drug compared to ethanol [170,171], although this acquisition cost must be balanced against improved patient safety and reduced intensity of monitoring and therapy [146,159,172]. Although there are no prospective clinical studies directly comparing the safety of ethanol with fomepizole, a recent hospital record review reported far fewer adverse drug events with fomepizole [184]. In this study, the *number needed to harm* with ethanol was only two, and only seven when restricted to severe harm (mostly coma, violent agitation, and hemodynamic instability) [149]. Fomepizole is the antidote of choice, when available [171], especially for a patient who has coingested other CNS depressants, for the critically ill patient with a profound anion gap metabolic acidosis of uncertain etiology, for the patient in whom hemodialysis may be technically challenging (e.g., infants), and during times of limited resources as may occur during mass poisonings [81,147,173].

Fomepizole has also been successfully used to treat combined methanol/isopropanol [174] and diethylene glycol/triethylene glycol [158] overdose in humans. Treatment with fomepizole or ethanol should be continued until the metabolic acidosis has resolved and serum methanol or ethylene glycol levels fall below 20 mg per dL.

Cofactor therapy in patients poisoned by ethylene glycol includes IV pyridoxine (100 mg) and thiamine (100 mg) once a day until ethylene glycol levels are unmeasurable and acidemia has cleared. Pyridoxine is required for the conversion of glyoxylic acid to glycine, whereas thiamine and magnesium are required for the conversion of glycolic acid to γ-hydroxy-α-ketoadipate. Administering these cofactors may shunt metabolism away from the formation of oxalic acid [60,61], although benefit has not been documented in human poisonings. Magnesium should be administered to patients with hypomagnesemia.

Patients poisoned with methanol should receive IV folinic acid (leucovorin), 1 to 2 mg per kg every 4 to 6 hours until methanol and metabolic acidosis have been cleared [90,140]. Folic acid (folate) can be substituted if leucovorin is unavailable. Hepatic formate metabolism occurs through a folate-dependent mechanism (see Fig. 119.5). The susceptibility of primates to methanol toxicity correlates with reduced hepatic 5,6,7,8-tetrahydrofolate (THF, or reduced folate) stores compared with lower mammals [140], and exogenous folinic acid (5-formyl-THF) or folate may increase their capacity to remove formate. Although human data are limited, monkeys pretreated with folic or folinic acid resulted in marked attenuation of serum formate levels and metabolic acidosis after methanol administration [175]. Folinic acid given after the onset of methanol toxicity was also beneficial.

Hemodialysis effectively removes ethylene glycol, methanol, glycolic acid, formic acid, and probably the other toxic metabolites, and should be used in nearly all cases with acidosis or end-organ toxicity [66,79,89,97]. Early hemodialysis can prevent subsequent toxicity [21,134]. Addition of extra sodium bicarbonate to the dialysate can assist in correcting acidosis, and hemodialysis may assist in controlling volume status. The frequency of fomepizole dosing must be increased during hemodialysis to compensate for its removal. When using ethanol, its infusion rate should be empirically doubled at the start of hemodialysis, and serum ethanol levels should be monitored hourly.

Recommendations for hemodialysis are outlined in Table 119.6 [79,82,85,140,146,147]. Traditional criteria for hemodialysis have included a serum ethylene glycol or methanol concentration greater than 50 mg per dL, independent of symptoms, acid–base status, or other markers of end-organ toxicity [140]. Selected patients have been successfully managed with fomepizole, cofactors, and IV fluid hydration alone despite serum ethylene glycol concentrations >400 mg per dL, though consultation with a toxicologist is strongly recommended [153,159,176,177]. Such patients must be hemodynamically stabile, and have near normal acid–base status and renal function. If minimal ethylene glycol metabolism has occurred before initiation of fomepizole therapy, the endogenous ethylene glycol elimination half-life is expected to be less than 18 hours [79]. Thus, patients with a normal serum creatinine and arterial pH at the start of fomepizole therapy may forgo hemodialysis despite high serum ethylene glycol concentrations [79,81,160]. Although a similar strategy has been reported in a patient with combined methanol/isopropanol ingestion [174], the prolonged methanol elimination half-life (approximately 50 hours) after ADH inhibition [178] would favor hemodialysis when readily available and technically feasible. Acid–base status, renal function, and serum ethylene glycol or methanol levels must be closely monitored in patients in whom hemodialysis is withheld [146].

Ethylene glycol clearance rates of 156 to 226 mL per minute (fractional excretion 43% to 92%; half-life 2.3 to 3.5 hours) can be expected during hemodialysis, as compared with renal clearance rates of 27.5 ± 4.1 mL per minute (fractional excretion 26% ± 9%) in patients with normal renal function, and clearance rates of 1 to 6 mL per minute in patients with renal dysfunction [79,80]. Glycolic acid is removed by hemodialysis, with a clearance of 105 to 170 mL per minute (half-life 2.5 hours) [62,64,68]. The hemodialysis elimination rate for methanol is 142 to 286 mL per minute; for formate, it is 148 to 203 mL per minute [20,89,97,101,145].

Hemodialysis should be continued until serum ethylene glycol or methanol levels are below 20 mg per dL and acid–base derangement has been corrected [73,81]. The required duration of hemodialysis in hours can be estimated using the formula $[-V \ln (20/A)/0.06\,k]$, where V is total body water in liters, A is the initial alcohol concentration in mg per dL, and k is 57% of the dialyzer urea clearance in milliliters per minute at the observed blood flow rate [179–181]. More than one round of hemodialysis may be necessary in massive overdoses and for ethylene glycol poisoned patients with renal failure.

TABLE 119.6

INDICATIONS FOR HEMODIALYSIS IN METHANOL OR ETHYLENE GLYCOL POISONING

Renal dysfunction as evidenced by increased serum creatinine concentration[a]
Severe metabolic acidosis (pH < 7.25) with evidence of end-organ toxicity (abnormal renal function for ethylene glycol, visual toxicity for methanol) independent of parent compound concentration
Serum methanol or ethylene glycol concentration > 50 mg/dL

[a] Selected patients with ethylene glycol concentrations above 50 mg/dL *and* normal creatinine and arterial pH at initiation of fomepizole treatment may be eligible for conservative treatment without hemodialysis. In all cases, consultation with a medical toxicologist is strongly recommended.

Adapted from Barceloux DG, Krenzelok EP, Olson K, et al: American Academy of Clinical Toxicology practice guidelines on the treatment of ethylene glycol poisoning. *J Toxicol Clin Toxicol* 37:537, 1999.

Peritoneal dialysis is markedly inferior to hemodialysis. Continuous arteriovenous hemofiltration with dialysis has been used in a hemodynamically unstable patient, but is less efficient at toxin removal [182]. Sorbent-based hemodialysis systems were inadvertently shown to be ineffective for methanol removal due to rapid saturation of the sorbent cartridge [183] and charcoal cartridges saturate within a few hours [175].

Patients with ethylene glycol poisoning who have acute renal failure may require hemodialysis for several months. Recovery of renal function is the expected course, although renal dysfunction may be permanent [61,62,67,73,83,184]. Full neurologic recovery is possible even after prolonged coma and seizures. Transient cranial nerve palsies developing 4 to 18 days after ingestion have been reported in under- or untreated patients [80,105–107]. Bilateral basal ganglia and brainstem infarction can occur in severely ethylene glycol poisoned patients [185].

Seizures, coma, and severe acidosis in patients with methanol poisoning portend a poor prognosis [109]. Cerebral edema is a common postmortem methanol toxicity finding [160]. The development of dilated, unresponsive pupils may indicate either severe optic nerve damage or cerebral edema [110]. Other neurologic sequelae include a parkinsonian-like syndrome, spasticity, transient resting tremor, cognitive defects, and paraplegia. Computed tomography, magnetic resonance, and autopsy studies have documented frontal lobe and basal ganglia hemorrhages and infarcts, especially in the putamen [186–191]. Bilateral putaminal hemorrhage and/or insular subcortex white matter necrosis correlate with a poor clinical outcome following methanol toxicity. The etiology of these lesions remains uncertain, but they are likely due to the direct toxicity of methanol and/or its metabolites. These abnormalities usually occur in severely acidemic patients with delayed presentation or diagnosis.

Harvesting of organs for transplant is not precluded in patients who die from ethylene glycol or methanol poisoning. Several centers have reported successful experience with kidney, heart, lung, pancreatic beta cell, and liver procurement from methanol-poisoned patients [172,192–196].

ISOPROPANOL

Isopropanol (isopropyl alcohol) is a clear, colorless, volatile liquid with a disagreeable taste and characteristic odor [197]. It is commonly available over the counter in 70% solutions of "rubbing alcohol." Because of its ready availability at an inexpensive price, abusers of alcohol often ingest isopropanol as an ethanol substitute. Cases of toxicity have been reported in children who were sponge bathed with the compound [198,199].

Isopropanol produces CNS depression, coma, and death from respiratory depression. In this respect, it has twice the potency of ethanol [200,201], a phenomenon attributed to its higher molecular weight [197] and possibly the CNS depressant effects of its metabolite, acetone. Depending on individual tolerance, serum concentrations of 150 mg per dL or greater may induce coma, and levels of 200 mg per dL or greater can be fatal in untreated patients, although lower concentrations may produce severe adverse effects [202].

The chemical properties and kinetics of isopropanol are summarized in Table 119.1. Oral absorption usually occurs within 30 minutes. Eighty percent of an absorbed dose is oxidized to acetone via ADH (Fig. 119.6) [197,201]. Acetone cannot undergo further oxidation to a carboxylic acid, however. Therefore, metabolic acidosis is not a feature of isopropanol toxicity unless respiratory depression with hypoxia or

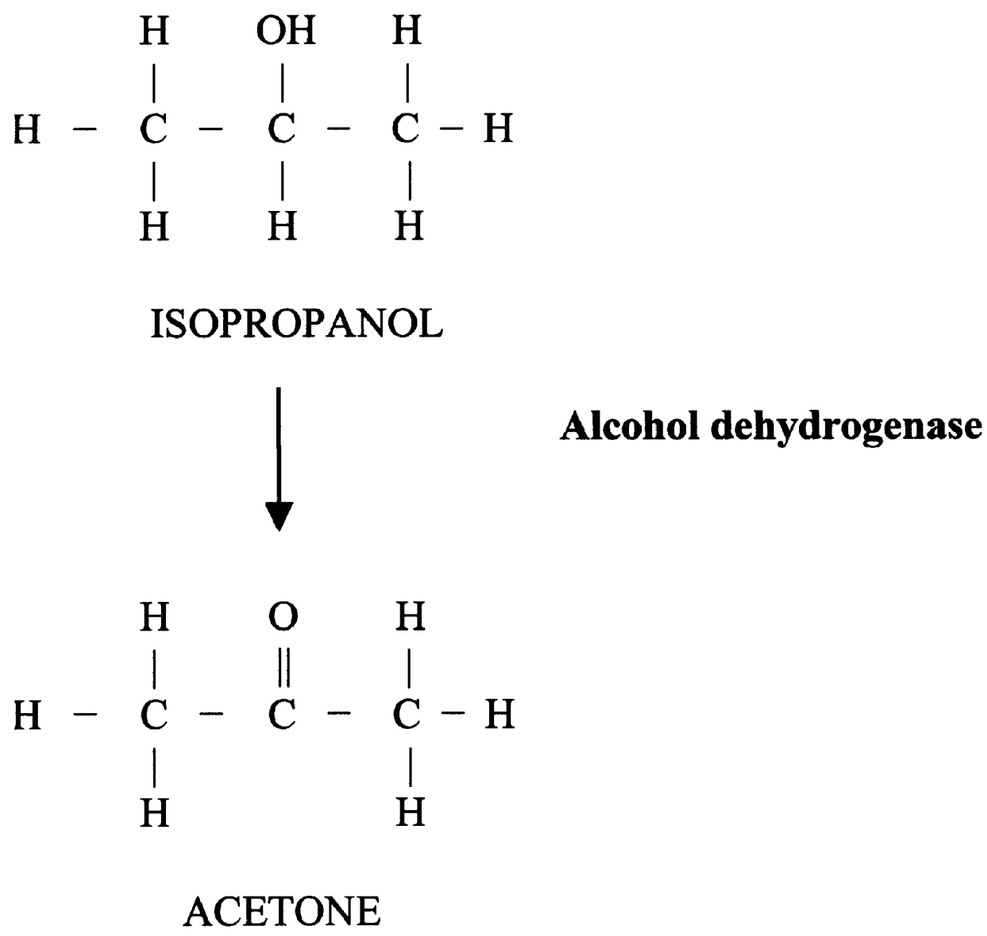

FIGURE 119.6. Isopropanol metabolism.

hypotension results in lactate production. Excretion of acetone and unchanged isopropanol (20% of an absorbed dose) is predominantly renal, with some excretion by respiratory, gastric, and salivary routes [201]. Acetone can be detected in the urine within 3 hours of ingestion [203]. The elimination half-life of isopropanol can be as long as 5.8 hours in infants [204]. Serum acetone levels frequently remain elevated after isopropanol levels are undetectable because acetone is eliminated slowly, with a half-life of 10.8 to 31.0 hours. The contribution of acetone to the prolonged duration of CNS depression remains speculative [197].

Clinical Presentation

An "intoxicated" patient without acidemia, yet with positive serum or urinary ketones and a fruity breath odor, should be suspected of isopropanol intoxication. Initial signs and symptoms usually consist of mild intoxication followed by gastritis, abdominal pain, nausea, vomiting, and possibly hematemesis [197]. Hemorrhagic tracheobronchitis may occur. As CNS depression progresses, patients become ataxic, dysarthric, confused, stuporous, and comatose. Pupils are typically miotic, but mydriasis has been reported [197,198,205,206]. Respiratory depression and hypotension may occur in severe intoxication [207]. Because of the profound and prolonged cerebral depressive effects of isopropanol, comatose patients may develop compartment syndromes and rhabdomyolysis with myoglobinuria. Delayed hypoglycemia may occur via the mechanism described for ethanol [197,198,202].

Many patients who ingest isopropanol are ethanol abusers who have a multitude of associated diseases, including chronic liver disease, pancreatitis, traumatic injuries, and chronic obstructive pulmonary disease, which may complicate the clinical picture.

Diagnostic Evaluation

Patients with known or suspected isopropanol poisoning should have quantitative isopropanol and acetone serum levels

along with the laboratory studies noted for acute ethanol intoxication. The presence of high levels of acetone can interfere with older creatinine assays based on a colorimetric method, producing a falsely high creatinine value in the presence of a normal BUN [208,209]. In patients who may have also ingested other toxic alcohols, serum osmolality, ethanol, ethylene glycol, and methanol levels should also be obtained.

The differential diagnosis of isopropanol poisoning includes toxic and metabolic states in which ketonemia may develop, such as alcoholic, diabetic, and starvation ketoacidosis. Patients with these conditions have elevated acetoacetate, β-hydroxybutyrate, and acetone levels compared with the isolated acetonemia seen with isopropanol intoxication. Traces of isopropanol may be detected in patients with diabetic or AKA due to the back reduction of acetone to isopropanol [210,211]. Poisoning by salicylate, cyanide, and acetone itself (which is found in nail polish and super glue remover) and inborn errors of metabolism should also be considered in the differential diagnosis of unexplained ketosis. Some degree of metabolic acidosis is expected in most of these conditions, whereas it is absent in uncomplicated isopropanol or acetone poisoning cases.

Management

Treatment is similar to that described for acute ethanol intoxication. Airway management and evaluation for hemorrhagic gastritis are particularly important. IV fluids should contain glucose, and serum glucose levels should be periodically checked. Isopropanol and acetone are removed by hemodialysis, but such therapy is rarely indicated [205]. Occasionally, patients with serum isopropanol concentration greater than 400 mg per dL accompanied by hemodynamic instability despite IV fluids may benefit from hemodialysis [197]. Since acetone is less toxic than isopropanol, there is no indication for either fomepizole or ethanol therapy [174,212].

Most patients recover with appropriate airway management and treatment of complicating factors. CNS depression and volume depletion secondary to vomiting can cause hypotension [197]. Pulmonary edema and hemorrhage are common findings on autopsy [202] and should be anticipated in severely ill patients.

PROPYLENE GLYCOL

Propylene glycol (1,2-propanediol) is commonly used as a solvent (e.g., in laundry stain removers), as an antifreeze, and as a diluent for a number of pharmaceuticals, including IV formulations of chlordiazepoxide, lorazepam, diazepam, etomidate, phenobarbital, pentobarbital, phenytoin, procainamide, nitroglycerin, and theophylline and topical silver sulfadiazine cream. Oral and dermal absorption is usually poor, but toxic amounts may be absorbed through abraded or burned skin [213]. Approximately one-half of a dose undergoes hepatic oxidation via ADH to lactate, and then to pyruvate and acetate. The rest is excreted unchanged in the urine [214].

Although oral doses of as much as 1 g per kg are essentially nontoxic, toxicity can occur following rapid or prolonged infusion of higher doses. Rapid IV infusion, as might occur during phenytoin loading, can cause prolonged PR and QRS duration, idioventricular rhythms, and cardiorespiratory depression and arrest [215]. Infusion of smaller doses has also precipitated cardiac standstill [216]. Propylene glycol, rather than phenytoin, is responsible for such toxicity [215]. Elderly patients, especially those with severe underlying cardiac disease, are at increased risk and should be infused with medications containing propylene glycol at rates slower than those usually recommended.

Alternatively, frequent repeat IV dosing of medications using propylene glycol as a diluent, as might occur with extremely high doses of diazepam for ethanol withdrawal, massive ingestion of products containing propylene glycol, or the chronic dermal absorption of silver sulfadiazine through damaged skin, can lead to accumulation of propylene glycol and its metabolites, resulting in seizures, and decreased level of consciousness [217–219]. On laboratory testing, an osmolar gap and high serum lactate concentrations are expected. Propylene glycol can be mistaken for ethylene glycol on gas chromatography [220].

Management consists of immediately stopping IV infusion or dermal application and supportive therapy. Fomepizole has been used to block the metabolism of propylene glycol, but this therapy cannot be recommended in the absence of information on the relative toxicity of the parent compound to its metabolites [221]. Hemodialysis and continuous venovenous hemofiltration have reportedly been used to treat patients with propylene glycol toxicity [222,223].

DIETHYLENE GLYCOL

Diethylene glycol (2,2′-dihydroxydiethyl ether, ethylene diglycol, 2,2′-oxydiethanol, 3-oxapentane-1,5-diol; DEG) is a viscous and sweet tasting liquid found in resins, antifreeze, brake fluids, cosmetics, wallpaper strippers, inks, lubricants, liquid heating/cooking fuels, plasticizers, adhesives, paper, and packaging materials [12,224]. Over the years, diethylene glycol has resulted in tragic outbreaks of renal failure and death following its substitution for propylene glycol in medications [225,226]. Unlike propylene glycol, diethylene glycol can cause acute renal failure, elevated liver enzymes, encephalopathy, and delayed neurologic toxicity. Since the first reported outbreak that occurred in the United States in 1937, there have been other outbreaks worldwide, including South Africa (1969), Spain (1985), India (1986 and 1998), Nigeria (1990 and 2008), Bangladesh (1990 to 1992), Argentina (1992), Haiti (1996), Panama (2006), and China (2006). These outbreaks often involved medications, such as acetaminophen, cough syrup, or teething syrup, ingested by children. The number of identified deaths during each outbreak ranged from 5 to 236. The median toxic dose is estimated to be approximately 1 g per kg [227].

Following diethylene glycol ingestion, patients may present with gastrointestinal symptoms, inebriation, CNS depression, acidosis, and renal failure. Interestingly, additional neurologic symptoms may develop up to several weeks after the ingestion and include cranial nerve palsy, peripheral neuropathy, dysphonia, lethargy, mental status changes, quadriparesis, and seizures [225,228]. Metabolism of diethylene glycol via hepatic ADH leads to 2-hydroxyethoxyacetic acid (2-HEAA) [224]. Although 2-HEAA is believed to be the primary toxic metabolite, the parent glycol itself may also be directly toxic. Although the name suggests the potential to be metabolized to two ethylene glycol molecules, this does not occur in vivo [224]. Survivors with renal failure tend to remain dialysis dependent and the degree of renal injury may be a predictor of delayed neurologic sequelae. Treatment is similar to ethylene glycol, including ADH inhibition, extracorporeal elimination, and supportive care. Fomepizole without hemodialysis, however, is not recommended given the uncertain toxicity of the diethylene glycol itself [159,224,225].

CHAPTER 120 ■ ANTIARRHYTHMIC AGENTS

MICHAEL GANETSKY

The therapeutic use, misuse, and intentional overdose of antiarrhythmic drugs are associated with severe morbidity and mortality [1]. The recognition, management, and prevention of antiarrhythmic toxicity require an understanding of the pharmacology of these drugs as they are related to cardiac electrophysiology. A general review of the mechanisms involved as well as the principles of management of poisoning is followed by a discussion of individual agents.

PHARMACOLOGY

Antiarrhythmic drugs are most commonly classified on the basis of their predominant physiologic effect and mechanism of action as originally proposed by Vaughan Williams [2] and Campbell [3] (Tables 120.1 and 120.2; Fig. 120.1).

The major effect of class I agents is blockade of the fast inward sodium current responsible for the rapid upstroke and conduction of the action potential [4] (see Fig. 120.1). This effect is also known as *local anesthetic* or *membrane stabilizing action*. Class I drugs depress automaticity, particularly in Purkinje fibers. Class I drugs comprise a large group of antiarrhythmic agents, many of which have diverse electrophysiologic properties; consequently, this class has been subdivided into classes IA, IB, and IC (see Table 120.2) [3].

The class II antiarrhythmic drugs are β-adrenergic antagonists; they inhibit the proarrhythmic effects of catecholamines, which shorten refractory periods and facilitate reentrant circuits. The slowly conducting, calcium-channel–dependent action potentials of the normal sinoatrial (SA) and atrioventricular (AV) nodes (see Fig. 120.1) rely partially on sympathetic tone. Class II drugs depress conduction and automaticity through these specialized tissues, leading to bradycardia and AV block. Toxicity due to beta-blockers is covered further in Chapter 125.

Class III agents prolong the refractory period by increasing the cardiac action potential duration (APD), especially in phases 2 and 3 (see Fig. 120.1). This effect is produced by blockade of the major outward potassium-rectifying (repolarizing) current. Amiodarone is the prototypic class III agent, whereas ibutilide and dofetilide are newer class III agents.

Class IV drugs (calcium antagonists or calcium channel blockers) antagonize the slow inward calcium current responsible for the slow upstroke and conduction of the action potentials of SA and AV nodal cells [4] (see Fig. 120.1). Verapamil, diltiazem, and nifedipine represent the three subclasses of calcium channel antagonists. Both verapamil and diltiazem have negative inotropic and chronotropic properties and are useful for slowing the ventricular response rate in patients with atrial

TABLE 120.1

VAUGHAN WILLIAMS CLASSIFICATION OF ANTIARRHYTHMIC ACTIONS

Class	Drugs	Actions
I	Quinidine Procainamide Disopyramide Moricizine Lidocaine Tocainide Mexiletine Flecainide Propafenone	Block fast sodium current (hence slow conduction)
II	Beta-blockers	Block effects of catecholamines
III	Amiodarone Sotalol Ibutilide Bretylium	Prolong action potential and, hence, refractoriness by blocking K^+ current
IV	Verapamil Diltiazem	Block cardiac calcium channel

TABLE 120.2

SUBGROUPS OF CLASS I DRUGS

Class	Drugs	Effects on action potential	Summary of clinical effects
IA	Quinidine Procainamide Disopyramide Moricizine	Reduce rate of depolarization; prolong duration of action potential	Moderate slowing of cardiac conduction; prolongation of refractory periods
IB	Lidocaine Mexiletine Tocainide	Reduce rate of depolarization selectively in ischemic cells; shorten action potential duration	Selective depression of ischemic tissue; may shorten refractory periods
IC	Flecainide Propafenone	Marked depression of depolarization rate	Marked slowing of cardiac conduction; small increase in refractory periods

fibrillation. In therapeutic dosing, calcium channel antagonists such as nifedipine have little effect on cardiac conduction or inotropic state and are, therefore, not used for their antiarrhythmic properties. Calcium channel blocker toxicity is discussed in Chapter 126.

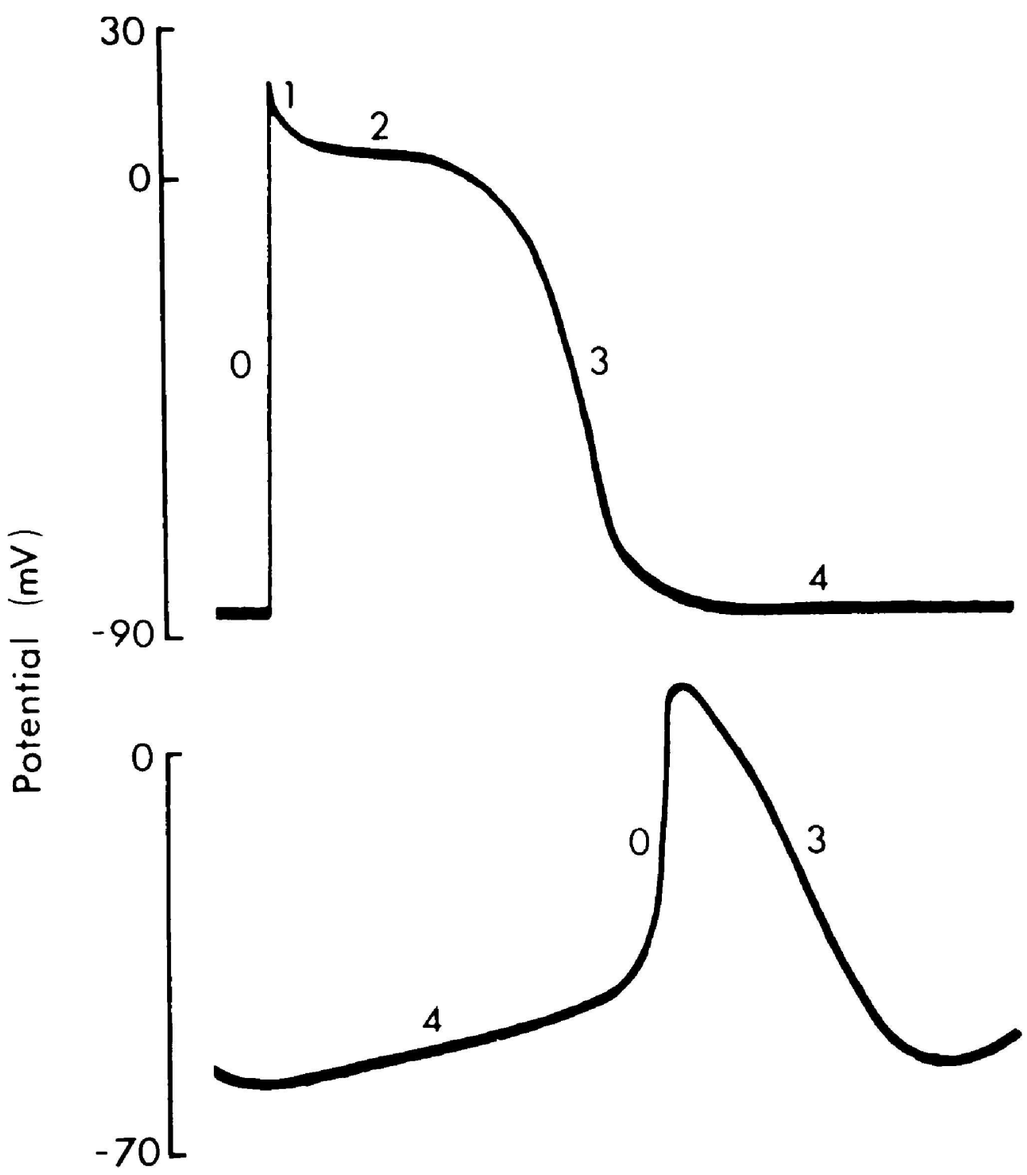

FIGURE 120.1. Typical cellular action potentials recorded from working myocardium (*upper trace*) and the atrioventricular node (*lower trace*). The nodal cell has an action potential of smaller amplitude, with a much slower rate of depolarization in phase 0. The nodal cell exhibits spontaneous diastolic (phase 4) depolarization ("pacemaker" activity). Rapid depolarization in phase 0 (atrial and ventricular cells and Purkinje fibers) is produced by a fast inward sodium current (depressed by class I drugs). A slower inward calcium current is also present but is the only inward current found in sinoatrial and atrioventricular nodal cells. This explains their slower rate of depolarization in phase 0 and their sensitivity to calcium-channel blockers. Repolarization (phase 3) is produced by a number of outward potassium currents; the rapid component of the delayed rectifier potassium current is the most important. Blockade of this current by antiarrhythmic or other drugs prolongs repolarization and action potential duration (class III action).

Adenosine and digoxin are two drugs with antiarrhythmic effects that do not fall within the Vaughan Williams classification. Adenosine is an endogenous nucleoside that produces AV nodal conduction block and vasodilation via specific adenosine-sensitive receptors. The antiarrhythmic properties and toxicity of digoxin are discussed in Chapter 127.

The cellular electropharmacology of antiarrhythmic agents involves suppression of automaticity, decreased cardiac conduction, and refractory period prolongation. Automaticity, the spontaneous depolarization of pacemaker myocytes, occurs in SA and AV nodes as well as in Purkinje fibers. In SA and AV nodal cells, the rate of firing depends on several different inward and outward currents; the combination of currents renders these cells relatively insensitive to depression by antiarrhythmic drugs [1,4,5]. In Purkinje fibers, however, automaticity occurs as an escape phenomenon that arises in the presence of AV block. Escape beats probably result from the action of a single inward sodium channel (the "pacemaker current") and are suppressed by therapeutic concentrations of most class I antiarrhythmic agents. Therefore, Purkinje fiber automaticity is more susceptible to depression by antiarrhythmic agents than is sinus node automaticity. Nonetheless, clinical suppression of the sinus node leading to asystole, particularly in the presence of the high vagal tone commonly seen in the early phases of acute myocardial infarction, is an uncommon but well-recognized complication of therapy with antiarrhythmic agents such as lidocaine.

Reentrant circuit arrhythmias depend on conduction rates around the circuit and the refractory periods of pathway components. If the conduction time falls below the refractory period of part of the circuit, the "excitable gap" disappears, the advancing wavefront meets only refractory tissue, and the arrhythmia terminates. An ideal antiarrhythmic agent would, therefore, accelerate conduction and prolong refractoriness within the substrate for reentry. Many antiarrhythmic agents prolong refractory periods in myocardium, but none accelerates conduction in therapeutic use. Almost invariably, conduction tends to slow. This combination of decreasing conduction and refractory period prolongation can be either proarrhythmic or antiarrhythmic [5]. However, clinicians cannot predict which outcome is likely for a given drug in a given patient. Some antiarrhythmic agents (in particular, class IB drugs and amiodarone [3]) show selectivity for depressing conduction in ischemic or otherwise abnormal myocardium by binding preferentially to the inactivated state of the sodium channel. A complete conduction block through an ischemic segment of a reentrant circuit may be the mechanism of arrhythmia termination; this could occur without slowing conduction in healthy myocardium. Other drugs tend to show less selectivity and depress conduction in normal myocardium at therapeutic

concentrations, probably explaining the greater propensity of class IC drugs to be proarrhythmic both in therapeutic use and in overdose [3].

Although most antiarrhythmic agents prolong refractoriness, lidocaine, mexiletine, and tocainide tend to shorten it, particularly in low concentrations; this may explain some cases of drug-associated arrhythmogenesis in patients with reentrant tachycardias. Lengthening of refractoriness should be proarrhythmic, but if conduction is slowed simultaneously, the net effect on the reentrant circuit determines the outcome.

Antiarrhythmic drugs suppress most forms of automaticity known to cause tachyarrhythmias. The major exception to this rule is the form of triggered automaticity due to *early after-depolarizations* (EADs). EADs can be defined as a marked slowing of repolarization, visible on the action-potential recording and due to reduction of the normal repolarizing outward potassium current. If voltage conditions are appropriate, prolonged depolarization may trigger a series of automatic action potentials. The upstrokes of these action potentials are due to inward current flow through the normal calcium channels that had been inactivated, had recovered from inactivation, and had found the membrane potential still within their activation range. The channels then reactivate and produce a secondary upstroke. Increased intracellular calcium concentrations activate calcium-sensitive potassium channels and accelerate repolarization. This process can occur as a single event or as an oscillatory series of action potentials, depending on the prevailing conditions of voltage and calcium levels [6–8].

The induction of EADs may be the basis of arrhythmias, including torsade de pointes associated with long QT syndromes [5,6,9]. According to this theory, the slowing of repolarization leads directly to the QT wave prolongation, often with associated prominent, bizarre TU waves. Any triggered activity, should it occur, results in ventricular tachyarrhythmias.

The class IA antiarrhythmic agents quinidine, disopyramide, and procainamide are all capable of producing EADs and torsade de pointes [6]. This is also true of the class III drugs, such as amiodarone, sotalol, ibutilide, and dofetilide. The class IB agents, lidocaine, mexiletine, and tocainide, do not produce EADs and do not cause torsade de pointes. Class IC compounds infrequently cause significant slowing of repolarization and have not been shown to cause torsade de pointes. Of the class IV agents, only mibefradil has an effect on repolarization, which usually manifests as TU-wave changes. Experimental models suggest that this effect is not proarrhythmic; however, there has been a report of torsade due to QT prolongation from therapeutic dosing of mibefradil [10,11].

CLINICAL PRESENTATION

Toxicity common to therapeutic doses and overdoses of antiarrhythmic agents include depression of automaticity and cardiac conduction, which may be caused by a combination of direct electrophysiologic and secondary metabolic effects. Symptoms following acute overdose usually begin within 4 hours and can occur at any time during chronic therapy. Drug absorption may continue for many hours following the ingestion of large doses, sustained-release preparations, or agents with anticholinergic effects, resulting in delayed or progressive toxicity. Respiratory depression and hypotension produce acidosis and myocardial ischemia that further aggravate depressed conduction. Cardiac manifestations include QRS prolongation, QTc prolongation, sinus node dysfunction, bradycardia, AV block, ventricular arrhythmias, and poor ventricular function. These derangements can culminate in intractable arrhythmias, cardiogenic shock, or death. Manifestations of acute toxicity may also include dizziness, visual disturbances, psychosis, anticholinergic symptoms, hypoglycemia, hyperglycemia, and hypokalemia. Seizures may result from class I (particularly IB) toxicity. Procainamide and quinidine can cause hypotension if infused too rapidly.

Warning signs that indicate an increased risk of torsade include a QTc interval greater than 560 milliseconds, previous history of torsade, bradycardia, increased frequency and complexity of ventricular premature beats, or a ventricular premature beat falling on the T wave [12].

The electrocardiogram (ECG) may provide a clue to the agent or class involved in cases where the drug ingested is not known. Class IB drugs usually have no effect on the QT interval; whereas class IA, IC, and III agents prolong it. With class IA agents, QT prolongation is due to slowing of both depolarization and repolarization. Hence, both the QRS duration and JT interval are increased. In contrast, QT prolongation primarily results from slowed depolarization with class IC agents, resulting in an increased QRS (but not JT) duration and from prolonged repolarization with class III agents, resulting in an increased JT (but not QRS) interval.

The differential diagnosis of bradyarrhythmias includes beta-blocker, calcium channel blocker, cholinergic agent (carbamate and organophosphate insecticides), clonidine, cyclic antidepressant, and digitalis poisoning. Other agents that cause QRS and QT interval prolongation include antihistamines, antipsychotic agents, cyclic antidepressants, magnesium, and potassium. Ventricular tachyarrhythmias may occur in poisoning with sympathomimetics (see Chapter 144). Hypoglycemia, hypoxia, and metabolic disturbances should be considered in the differential diagnosis of patients with neurologic symptoms.

DIAGNOSTIC EVALUATION

Physical examination should focus on vital signs and respiratory, cardiovascular, and central nervous system (CNS) function. Frequent vital signs and continuous cardiac monitoring should be performed. Essential tests include an ECG and serum electrolytes, blood urea nitrogen, creatinine, and magnesium measurement; liver function tests and serum drug levels, if available, may also be helpful. A chest radiograph should be obtained as clinically indicated. Patients with hypotension and hypoxemia should have arterial blood gas and serum lactate measurements.

MANAGEMENT

The general features of antiarrhythmic drug overdose and their management are discussed below (Table 120.3). Care of the antiarrhythmic poisoned patient centers on general supportive and critical care principles. Unique aspects pertinent to individual drugs are discussed in later sections. All patients suspected of ingesting an overdose of antiarrhythmic agents should receive oral activated charcoal. Patients with complications of therapeutic dosing may also benefit from oral activated charcoal to reduce absorption of a recently administered drug dose. The greatest amount of absorption to charcoal will occur if given within 1 to 2 hours of ingestions. CNS and respiratory depression commonly require airway support by endotracheal intubation. Seizures are managed by benzodiazepine therapy. Phenytoin should never be used to treat seizures secondary to drug toxicity because of the risk of increased mortality.

Initial therapy for hypotension involves administration of intravenous fluids. Because poisoned patients are infrequently hypovolemic, fluid administration should be monitored closely. In general, if a response in blood pressure is not seen with 2 L of intravenous fluids, pressors such as norepinephrine should be administered. Early consideration should be given to

TABLE 120.3

MANAGEMENT OF LIFE-THREATENING ANTIARRHYTHMIC DRUG OVERDOSE

Supportive care
Activated charcoal for acute (< 1 h) oral ingestions
Correct acidosis, hypoxia
Benzodiazepines for seizure control
Enhance drug elimination
Activated charcoal
Consider extracorporeal elimination if appropriate
Hypotension
Fluid administration
Alkalinization (hypertonic $NaHCO_3$) for class I drugs
Inotropes, vasopressors
Consider pulmonary artery catheter for monitoring
Circulatory assist devices
Impaired conduction
Temporary pacing for atrioventricular block or bradycardia
Alkalinization (hypertonic $NaHCO_3$) for class I drugs
Ventricular arrhythmias
Torsade de pointes
Temporary pacing
$MgSO_4$
Isoproterenol
Monomorphic ventricular tachycardia
Cardioversion, if causing hypotension
Hypertonic $NaHCO_3$ for class I drugs
Lidocaine, except for class IB drugs
Overdrive pacing
PEA cardiac arrest
Intravenous lipid emulsion for bupivacaine (may consider for other lipophilic agents or in refractory cases). Loading dose of 1.5 mL/kg administered over 1 min, repeated one to two times every 3–5 min as needed. If hemodynamic improvement is noted, the loading dose should be followed by a continuous infusion at a rate of 0.25–0.5 mL/kg/min

circulatory assist devices for patients with cardiogenic shock. Intra-aortic balloon pump counterpulsation has been used successfully to treat patients with severe quinidine or disopyramide toxicity [13,14], and partial cardiac bypass has been used to maintain circulation during massive lidocaine or flecainide toxicity [15–17].

Decreased ventricular conduction, as measured by QRS prolongation in quinidine, procainamide, flecainide, and encainide toxicity, are often treated with sodium bicarbonate infusion [18–22]. In animals, hypertonic sodium bicarbonate reverses ventricular arrhythmias caused by flecainide toxicity [23] and reverses hypotension due to tricyclic antidepressants with class IA antiarrhythmic effects [20]. Hypertonic sodium bicarbonate should be considered for the treatment of QRS widening greater than 100 milliseconds or ventricular tachyarrhythmias in the setting of class IA or IC drug toxicity. Common practice is to administer intravenous boluses of sodium bicarbonate (50 mEq of 1 mEq per mL solution) as needed to increase and maintain blood pH between 7.45 and 7.55. As an alternative, a continuous infusion of 1,000 mL of 5% dextrose in water containing 2 to 3 amps of sodium bicarbonate and potassium chloride is an option. Bicarbonate should be administered for 12 to 24 hours and then gradually withdrawn while watching for QRS lengthening to recur. At present, there is no evidence that prophylactic alkalinization before QRS widening changes outcome. In the most severely poisoned patients, however, alkalinization may be ineffective, especially if there is persistent metabolic acidosis. In a series of patients with class I antiarrhythmic drug overdose requiring cardiopulmonary resuscitation, only 2 of 29 survived despite the use of hypertonic sodium bicarbonate [24].

Sodium bicarbonate appears to act by increasing the extracellular sodium concentration and reducing the drug-induced sodium channel blockade [25]. Hypertonic sodium chloride has proven effective in animals and, anecdotally, in humans, but sodium bicarbonate is generally preferable because increasing pH is equally or more important in some models [20,25–27] (see Chapter 123 for more detail).

The treatment of recalcitrant ventricular tachycardia typically consists of repeated cardioversions, cardiopulmonary resuscitation, vasopressor support, and mechanical ventilation. Treatment with other class IA and IC antiarrhythmic drugs is contraindicated, given the potential for further arrhythmia aggravation [28]. Lidocaine may be considered because it does not depress conduction, but it is often ineffective. Suppression of ventricular tachycardia and hemodynamic improvement has been anecdotally described with sodium bicarbonate [21,22]. Overdrive pacing may also be effective.

The treatment of torsade de pointes should include 1 to 2 g of a 25% solution of intravenous magnesium sulfate. Direct-current cardioversion is often effective in terminating torsade de pointes, but it frequently recurs. Increasing the ventricular rate to greater than 90 to 110 beats per minute by an infusion of isoproterenol or ventricular pacing may also be effective [29,30]. In one study, infusion of potassium chloride at 0.5 mEq per kg for 60 to 90 minutes normalized excessive quinidine-induced QT prolongation, but simply correcting hypokalemia did not suppress torsade de pointes [31]. Lidocaine is inconsistently effective [32,33]. Treatment with class IA or III antiarrhythmic drugs is contraindicated because further prolongation of repolarization and the QT interval may exacerbate torsade de pointes. Magnesium therapy should also be considered in patients at increased risk for this arrhythmia (see earlier); it has been found to prevent occurrence of torsade in a dog model (dose of 30 to 60 mg per kg) [34].

Although most antiarrhythmic drugs are weak bases, urine acidification is contraindicated because systemic acidosis may aggravate cardiotoxicity [20]; treatment with hypertonic alkaline solution to reduce cardiotoxicity is likely to be of greater benefit. Hemodialysis is of limited benefit for antiarrhythmic toxicity because drug clearance is limited by protein binding and high lipid solubility [26,35,36]. Hemoperfusion using charcoal resin is more effective in removing drugs with high protein binding and high lipid solubility; however, this modality is rarely available. Hemoperfusion is of greatest value for disopyramide [37] or *N*-acetylprocainamide (NAPA) toxicity [38].

INDIVIDUAL AGENTS

Class IA Agents

Quinidine

Quinidine is administered orally as sulfate or gluconate. The usual dose of immediate-release quinidine sulfate is 200 to 400 mg, four times per day, with gluconate doses being approximately 30% higher. Bioavailability is approximately 70% for both forms; peak plasma levels are reached earlier for the sulfate (60 to 90 minutes) than for the gluconate. Quinidine is metabolized by CYP3A4 to 3-OH quinidine and

TABLE 120.4

DOSE AND PHARMACOKINETICS OF CLASS I AND II ANTIARRHYTHMIC AGENTS

Drug	Usual daily dose	Therapeutic or usual plasma concentration (μg/mL)	Volume of distribution (L/kg)	Elimination half-life	% Excreted unchanged in Urine	% Bound in plasma	Active metabolites	Methods of enhancing elimination
Class IA								
Quinidine	Depends on formulation (see text)	2–7	2.0–3.5	7 h	17–50[a]	80–90	3–OH quinidine	—
Procainamide	3–6 g	4–8 (NAPA, 7–15)	2 (NAPA, 1.4)	2.5–4.5 h (NAPA, 5–9 h)	40–60 (NAPA, 80)	10–20 (NAPA, 10)	NAPA	HD, HP
Disopyramide	300–600 mg	2–6	1.0–1.5	4–10 h	40–60	50–65	—	HD, HP
Moricizine	600–900 mg	0.1–3.0[b]	8–11	1.5–13.0 h	1	95	—	—
Class IB								
Lidocaine	1–3 μg/min	1.5–6.0	1.0–1.7	1.5–2.5 h[c]	< 10	60–80	Monoethylglycinexylidide, glycine xylidide	?HP
Tocainide	1.2–2.4 g	3–10	1.5–3.2	11–20 h	40	10	—	HD, HP
Mexiletine	600–1,200 mg	0.5–2.0	5–7	6–17 h	8–15	50–70	—	—
Class IC								
Flecainide	100–300 mg	0.07–0.50	9	12–18 h[a,d]	70	50	—	—
Propafenone	400–800 mg	0.2–1.8	1.9–3.0	3.6 h (17 h)[e]	—	—	5–hydroxypropafenone	—
Class III								
Amiodarone	100–400 mg	1.0–2.5[b]	70	40–49 d	< 1	99	Desethylamiodarone	—
Sotalol	160–320 mg	0.6–3.2	2	12–15 h	> 75	0	—	HD, HP
Bretylium	See text	?	7	4–10 h	95	1–6	—	—

[a] Shorter with lower urine pH.
[b] Correlates poorly with therapeutic effect.
[c] Longer in patients with congestive heart failure.
[d] Dose dependent.
[e] Slow metabolizers at CYP2D6 locus.
HD, hemodialysis; HP, hemoperfusion; NAPA, *N*-acetylprocainamide.

quinidine-*N*-oxide; these metabolites have less electrophysiologic activity than quinidine [39,40]. Details of pharmacokinetics are listed in Table 120.4.

Torsade de pointes is an adverse effect of therapeutic doses of quinidine (also known as *quinidine syncope*). Risk factors for this arrhythmia are recent initiation of quinidine therapy, concurrent digoxin therapy, female gender, structural heart disease, hypokalemia, and hypomagnesemia. Possible mechanisms include prolongation of the QTc interval and potentiation of EADs [40].

In therapeutic doses, sustained-release quinidine formulations produce therapeutic plasma concentrations for up to 8 hours in most patients. In overdose, however, saturation of enzymes that metabolize the drug may dramatically prolong serum concentrations. Consequently, serial serum drug monitoring is warranted (see Table 120.4), especially when potentially interactive agents, are coadministered. Agents that are CYP3A4 inhibitors, such as cimetidine, can increase quinidine serum concentration. Mild quinidine overdose presents as cinchonism (headache, tinnitus, deafness, diplopia, confusion), vertigo, visual disturbances (blurred vision, photophobia, scotomata, contracted visual fields, yellow vision), or delirium. Severe toxicity is characterized by CNS toxicity (lethargy, coma, respiratory depression, seizures), gastrointestinal tract toxicity (nausea, vomiting, diarrhea), and cardiovascular collapse [41]. Noncardiac side effects include nausea, cinchonism, thrombocytopenia, and drug-induced fever.

Initial therapy for acute quinidine overdose should include gastric decontamination with activated charcoal. Treatment of CNS toxicity is supportive, with intubation and ventilation for CNS depression and benzodiazepines for seizures. Deaths from quinidine overdose are usually secondary to arrhythmias or hypotension. When pacing is indicated for bradycardia, failure to capture is common in the face of drug-induced myocardial depression. QRS prolongation should be treated with bicarbonate infusion. Hypotension may result from vasodilation from β-adrenergic blockade, impaired contractility from sodium channel blockade, or arrhythmias. Vasodilation may be treated with fluid administration and alpha-acting vasopressors such as norepinephrine; large doses may be required.

Refractory hypotension has been successfully treated with an intra-aortic balloon pump [13] and partial circulatory bypass.

Procainamide

Procainamide is eliminated by hepatic metabolism and renal excretion [42,43]. The major metabolite is NAPA, which has potent class III and some class I antiarrhythmic activity [44]. In fast acetylators or in renal failure, as much as 40% of a dose of procainamide may be excreted as NAPA. Because the prevalence of the fast and slow acetylator phenotypes varies between ethnic groups, widely variable procainamide and NAPA concentrations may occur in specific populations [45]. Blood concentrations of NAPA may exceed those of the parent drug, given its dependence on renal elimination.

The cardiovascular side effects of procainamide are very similar to those of quinidine except that the drug has no β-adrenergic antagonist activity. Acute procainamide toxicity is manifested primarily by hypotension, but QRS widening and ventricular arrhythmias may also occur [46]. Inappropriate drug dosing in renal insufficiency or before achieving steady-state concentrations is the most common cause of procainamide toxicity. Toxic levels of NAPA (> 25 µg per mL) may begin to accumulate as a result of acute or chronic renal insufficiency, potentially leading to torsade. Approximately 40% of patients receiving long-term oral therapy with procainamide develop a syndrome resembling systemic lupus erythematosus that usually resolves after drug withdrawal [47].

Signs and symptoms of acute procainamide overdose are similar to those of quinidine overdose. Patients with non–life-threatening procainamide toxicity (e.g., hypotension) and adequate renal function can be managed with supportive care. Seizure has been reported in a pediatric ingestion [48]. Hypertonic sodium bicarbonate may be useful for QRS prolongation, monomorphic ventricular tachycardia, or hypotension [18]. This therapy has minimal benefit in NAPA toxicity because this metabolite has primarily class III effects. Torsade de pointes should be treated as already discussed. Anecdotal reports have showed increased procainamide and NAPA clearance with hemodialysis or hemoperfusion; however, clinical significance is unclear [38,46].

Disopyramide

Disopyramide, unlike most other antiarrhythmic drugs, has protein binding that shows nonlinear, saturable characteristics [49,50]. This is clinically important because small increases in total plasma level within the therapeutic range (see Table 120.3) may mask larger rises in free (active) drug concentration. When administered intravenously, disopyramide produces hypotension less frequently than do quinidine or procainamide. Widening of the QRS complex, prolongation of the QT interval, and drug-induced ventricular tachyarrhythmias have all been reported as side effects [51]. There are numerous reports of QTc prolongation, torsade, or monomorphic ventricular tachycardia from the interaction of disopyramide and macrolide antibiotics. Erythromycin, clarithromycin, and azithromycin have all been implicated; a possible mechanism is inhibition of hepatic CYP3A4 [52].

Acute disopyramide overdose is similar to that of quinidine or procainamide, with QRS prolongation, severe refractory hypotension, and arrhythmias [14,53–55]. Hypoglycemia is a recognized adverse effect [55]. Data regarding management are limited, but an approach similar to that for quinidine toxicity is appropriate. Hypotension refractory to intravenous fluids and vasopressors has been treated with an intra-aortic balloon pump [14]. Because of its relatively small volume of distribution, disopyramide clearance is substantially increased by hemoperfusion [14,37,56].

Class IB Agents

Lidocaine (and Other Local Anesthetics)

Amide-type local anesthetics (e.g., articaine, bupivacaine, etidocaine, lidocaine, mepivacaine, prilocaine, and ropivacaine) are extensively metabolized by hepatic dealkylation, hydrolysis, ring hydroxylation, and conjugation. Ester-type agents are metabolized by hepatic and plasma esterases. Derivatives of para-aminobenzoic acid (e.g., benzocaine, procaine, tetracaine) are predominantly hydrolyzed by plasma pseudocholinesterase, whereas other esters (e.g., cocaine, dyclonine, proparacaine) are predominantly metabolized in the liver [57]. Allergic cross-reactivity occurs within the amide and ester groups but not between them.

Extensive first-pass metabolism prevents effective oral therapy with lidocaine and local anesthetics, but toxicity can occur after ingestion [57]. The maintenance infusion rate of lidocaine must be reduced in patients with cardiac failure or hepatic dysfunction and in the elderly [58]. Plasma concentrations should be monitored for infusions lasting longer than 24 hours. Lidocaine has two active metabolites, monoethylglycinexylidide (MEGX) and glycine xylidide (GX). Although these metabolites have short elimination half-lives of 2 hours and 1 hour, respectively, they may contribute significantly to toxicity, which can occur several hours after an infusion is started [57,58]. Most lidocaine toxicity is caused by errors in dosing and administration [59]. Life-threatening toxicity and death have occurred after inadvertent overdose, surgical procedures such as liposuction, and parenteral, mucosal, and topical anesthesia [60–62]. The safety of tumescent liposuction, in which large volumes of lidocaine solutions are infused subcutaneously, has been called into question following several reported deaths [63].

All local anesthetics have toxicity similar to lidocaine, with neurologic signs and symptoms usually preceding cardiac manifestations, except in massive acute overdose [64,65]. Neurologic symptoms, the most significant of which is seizures, include auditory disturbances, visual disturbances, paresthesias, and ataxia. Lidocaine has a bimodal concentration-dependent effect on seizures; lidocaine suppresses seizures at concentrations between 0.5 and 5 µg per mL but increases the risk at levels above 8 to 9 µg per mL. The relative contribution to epileptogenicity of the parent compound compared with the metabolites MEGX and GX is still unclear [66]. Adverse cardiac effects from lidocaine administration are unusual in the absence of severe underlying conduction-system disease, acute myocardial ischemia, or massive overdose. Persons with third-degree heart block requiring ventricular arrhythmia suppression should have a prophylactic pacemaker inserted before lidocaine administration [67]. However, lidocaine administration in asymptomatic patients with bundle-branch block or intraventricular conduction disease carries a low risk [68].

Acute massive overdose of lidocaine is characterized by seizures, coma, respiratory arrest, and cardiovascular collapse [61,64,69–71]. Hypotension is due to myocardial depression [72]. Lidocaine has little or no effect on the QT interval; however, QRS prolongation, AV block, and depressed automaticity with bradycardia or asystole can occur. Data regarding management are anecdotal. Seizures should be managed using intravenous diazepam; phenytoin should be avoided. Bradyarrhythmias may respond to isoproterenol infusion or cardiac pacing. Hypotension and shock respond to fluid administration and vasopressors such as dopamine. If QRS prolongation is present, hypertonic sodium bicarbonate may be useful. Intra-aortic balloon pump and cardiopulmonary bypass have been used successfully in patients with circulatory collapse [15,16].

Amide-type local anesthetics can also induce methemoglobinemia [57,70,73]. This effect has been described after

percutaneous absorption of benzocaine-containing formulations, during use of prilocaine as an epidural anesthetic agent, and due to prilocaine found in eutectic mixture of local anesthetics (EMLA) cream. Amide agents are hydrolyzed to an amino group that exerts an oxidizing stress in susceptible individuals—such as those with G-6-PD deficiency—to produce methemoglobinemia. In some cases, patients may also exhibit red blood cell hemolysis. Methemog-lobinemia is treated with methylene blue (see Chapter 147).

Bupivacaine intoxication can lead to PEA cardiac arrest that is not responsive to standard ACLS protocols. This is a dreaded complication of regional anesthesia after inadvertent intravenous injection of bupivacaine. Intravenous lipid emulsion (Intralipid) is rapidly becoming accepted as standard treatment for bupivacaine-induced cardiac arrest. Even though no human trials exist, there is excellent animal evidence and several human case reports [74]. The mechanism is still unclear, but effects are likely from partitioning of bupivacaine away from cardiac receptors and into an intravenous lipid phase. Therefore, intralipid may be an effective therapy for other lipophilic anesthetic agents. The initial loading dose is 1.5 mL per kg (typically 100 mL in an average adult) administered over 1 minute, which can be repeated one to two times every 3 to 5 minutes. If hemodynamic improvement is noted, the loading dose should be followed by a continuous infusion at a rate of 0.25 to 0.5 mL per kg per minute [75].

Tocainide

Adverse effects are common during tocainide therapy, with up to 50% of patients requiring dosage adjustments or discontinuation [76]. The most common side effects are nausea, vomiting, and anorexia, and neurologic effects such as dizziness, paresthesias, tremor, ataxia, and confusion. Tremor suggests that the maximum tolerable dose of tocainide has been reached. Serious toxicity resulting from pulmonary fibrosis in up to 0.1% and agranulocytosis and leukopenia in 0.2% of patients has been reported [77]. Monitoring for clinical or laboratory signs of agranulocytosis has been recommended, particularly during the first 12 weeks of therapy.

Massive tocainide overdose causes effects similar to those of lidocaine overdose: loss of consciousness, seizures, high-degree AV block, asystole, and ventricular fibrillation [76,78–80]. Treatment considerations are also similar. Because 40% of tocainide elimination is renal, urine acidification theoretically increases tocainide excretion but is not recommended because of enhanced systemic toxicity.

Mexiletine

Mexiletine is structurally similar to lidocaine and undergoes extensive metabolism in the liver to largely inactive compounds [81,82]. Hepatic impairment can significantly prolong the elimination half-life to 25 hours or longer. Patients with chronic liver disease, such as hepatic cirrhosis, undergo a marked reduction in the hepatic metabolism of mexiletine [83,84]. Smoking enhances mexiletine elimination, reducing the half-life by 35% compared with nonsmokers [85]. Phenytoin, rifampin, and phenobarbital induce hepatic enzymes and lower mexiletine plasma concentrations. Antacid therapy, cimetidine, and narcotic analgesics can slow the absorption of mexiletine [86].

Mexiletine is generally well tolerated, with little effect on hemodynamics, even in patients with congestive heart failure [87]. Mexiletine shares much of the side effect profile of lidocaine, including cross-reactivity in allergic individuals. Dizziness, ataxia, and tremor are relatively common. Overdose effects resemble those of lidocaine. Heart block or asystole accompanied by hypotension occur with massive overdose [88,89]. Status epilepticus requiring diazepam and phenobarbital has been described [90]. The prolonged duration of seizures compared with lidocaine overdose may be due to mexiletine's longer elimination half-life of 5.5 to 12 hours. A urine drug immunoassay was reported as positive for amphetamines in the setting of a mexiletine overdose, likely from cross-reactivity due to structural similarity of these compounds [91].

Class IC Agents

Flecainide

Flecainide is very well absorbed orally, with negligible hepatic first-pass effect. Flecainide displays polymorphic drug metabolism because it is metabolized via CYP2D6 to active metabolites. This phenomenon effectively results in two distinct populations of patients having very different clearance rates. The average half-life is between 8 and 10 hours, with substantial individual variability. Inhibitors of the CYP2D6 pathway, such as INH, quinidine, selective serotonin-uptake inhibitors, and other agents metabolized by this pathway, may decrease or increase the clearance of flecainide when added to or deleted from therapy. Amiodarone can double the serum concentration of flecainide when the two drugs are concomitantly administered; the flecainide dose should be reduced by 50% when these drugs are coadministered. Serum concentrations can be followed but are rarely used. The proposed therapeutic range is 200 to 1,000 ng per mL.

Flecainide is approved for the management of paroxysmal atrial fibrillation or flutter associated with disabling symptoms, but there are many restrictions due to its adverse effects. Flecainide has a very narrow therapeutic index and can be toxic even at therapeutic concentrations [92]. In the Cardiac Arrhythmia Suppression Trial (CAST) [93], postinfarction patients being treated for ventricular arrhythmias demonstrated an increased mortality relative to patients treated with placebo. Furthermore, flecainide possesses considerable negative inotropic effects that limit its usefulness in the setting of congestive heart failure. Other dose-related side effects occur, including CNS toxicity such as blurred vision, dizziness, headache, nausea, and paresthesias. Flecainide also increases the ventricular pacing threshold.

Flecainide is highly toxic in overdose; in one series, the mortality rate was 10% [24]. Overdose is characterized by QRS prolongation with a normal JT interval, hypotension, coma, or seizures [24,94]. Serious cardiac effects that can occur include severe bradycardia, high-grade conduction blocks, and ventricular dysrhythmias. Cardiac arrest is not uncommon after overdose; survival after full arrest is rare [92]. Data regarding management are mostly anecdotal. In rats, hypertonic sodium bicarbonate, 3 to 6 mEq per kg, reduced flecainide-induced QRS prolongation [95], and in dogs, this treatment largely abolished ventricular tachycardia [23]. In overdose patients, both hypertonic sodium bicarbonate and sodium lactate have been reported to be effective [96,97]. Hypertonic sodium bicarbonate or sodium lactate should be considered in patients with evidence of disturbed ventricular conduction. Cardiopulmonary bypass and extracorporeal membrane oxygenation (ECMO) have been used to support perfusion until spontaneous perfusion returned [17,98]. In one report, a patient who developed refractory ventricular fibrillation due to a flecainide overdose was successfully resuscitated after a 300-mg amiodarone bolus was given [92].

Propafenone

Propafenone is used for select patients with atrial fibrillation and for refractory ventricular tachycardia and fibrillation. Like flecainide, propafenone undergoes significant first-pass hepatic metabolism via the CYP2D6 isoenzyme pathway.

Bioavailability ranges from 5% to 50%, depending on the patient's phenotype; agents that inhibit CYP2D6 lower the clearance rate. Administering propafenone with food may significantly increase bioavailability in extensive metabolizers by diminishing first-pass drug extraction [99,100].

Propafenone has other drug interactions as well. Propafenone administration may increase digoxin concentrations between 35% and 85% due to impairment of nonrenal digoxin clearance. Quinidine is a specific and potent inhibitor of CYP2D6 and can significantly increase propafenone concentration [101]. Coadministration of propafenone with warfarin may result in a 25% increase in prothrombin time from unknown mechanisms. Similar to flecainide, propafenone has a narrow therapeutic index.

Propafenone overdose is similar to that of flecainide; toxicity includes QRS prolongation, hypotension, bradycardia, coma, and seizures [24,102,103]. Seizures appear to be more common in propafenone overdose than in flecainide overdose. PR interval prolongation is a characteristic finding in propafenone toxicity [104,105]. Hypertonic sodium bicarbonate has been beneficial for QRS prolongations and aberrant ventricular conduction [106,107]. Benzodiazepines should be used for seizures; phenytoin should be avoided [108]. Management of cardiovascular toxicity is similar to that of flecainide overdose. Transvenous cardiac pacing was successful in a case with severe bradycardia due to a high-grade conduction block [104].

Class III Agents

Amiodarone

Amiodarone was first used as a vascular smooth-muscle relaxant. In addition to its class III activity (prolonging the cardiac APD), amiodarone possesses properties common to all Vaughan Williams classifications. These include calcium channel–smooth-muscle relaxant (class IV), noncompetitive antiadrenergic (class II), and some sodium-channel–blocking (class I) activity.

Amiodarone is generally considered the most effective antiarrhythmic agent for treatment and prophylaxis of most types of arrhythmia [109]. Its clinical use, however, is complicated by unusual pharmacokinetics (see Table 120.4) and prevalent side effects [110,111]. After oral administration, amiodarone widely distributes into body tissues where drug concentration generally exceeds that of the plasma. It is highly lipophilic, highly bound to plasma proteins, and has an extremely long (average, 53 days) elimination half-life [112]. Metabolism occurs in the liver and possibly in the gastrointestinal tract. The major metabolite, desethylamiodarone, accumulates in plasma and tissues and has electrophysiologic properties that are similar to the parent compound [113,114].

Many side effects are dose dependent, but therapeutic drug monitoring is of little benefit, except to determine compliance. Evidence suggests a limited correlation between drug level and antiarrhythmic effect [115] and serious noncardiac toxicity seems to be more likely at levels above 2.5 µg per mL [116,117].

Pulmonary fibrosis is an important and potentially life-threatening side effect of long-term therapy [118]. Pulmonary toxicity is somewhat dose dependant; its prevalence ranges from 5% to 15% in patients who take at least 500 mg per day, but is 0.1% to 0.5% when the dose is less than 200 mg per day [119]. Common presenting features include dyspnea, nonproductive cough, fever, and general malaise. A diffuse interstitial pattern on the chest film, similar to congestive heart failure, is the most typical radiographic finding. Symptoms usually resolve with withdrawal of amiodarone therapy. Corticosteroids may improve prognosis and prevent relapse [119].

Amiodarone generally does not produce congestive heart failure, even in patients with poor ventricular function, because its vasodilator properties may offset negative inotropic effects. Sinus bradycardia is common during therapy, and symptomatic sinus pauses or sinus arrest can occur in 2% to 4% of patients. AV block may occur in patients with underlying conduction-system disease. Torsade de pointes has been reported, but is much less likely than with other class III agents.

Amiodarone is iodinated and interferes with conversion of thyroxine to triiodothyronine, causing significant elevations of thyroxine and slight reductions in triiodothyronine concentrations [120]. Most patients are typically euthyroid, with normal thyroid stimulating hormone levels. Peripheral neuropathy, tremor, and nervousness develop initially in up to 30% of patients, but these symptoms often improve over time. Asymptomatic corneal microdeposits are present in almost all patients on long-term therapy. Dermatologic effects include increased photosensitivity and blue-gray skin discoloration.

Asymptomatic elevation of hepatic transaminase is relatively common with long-term amiodarone therapy; the reported incidence is 24% to 26%. Transaminase can reach up to 3 times normal and resolve with or without discontinuation of therapy [121]. Acute hepatitis following intravenous loading of amiodarone is much less common but not infrequently described in the literature [121,122]. Transaminitis can be severe and rarely lead to fatality. Postulated mechanisms include a polysorbate 80 additive used in the intravenous preparation, immunologic-mediated injury, or a direct hepatotoxic effect [123].

Acute amiodarone overdoses generally tend to follow a benign course. There are several reports of ingestions developing self-limited episodes of ventricular tachycardia, QT prolongation, or mild bradycardia [124,125]. No CNS depression or seizures have been reported. Cholestyramine modestly reduces the elimination half-life of amiodarone from 44 to 28 days, perhaps by interrupting enterohepatic recirculation [126]. There is likely a role for multidose activated charcoal, even up to 12 hours after the ingestion, since amiodarone has delayed an erratic enteral absorption [127].

Sotalol

Sotalol is a β-adrenergic antagonist with class III activity. It is used for the prophylaxis and treatment of AV reentrant and ventricular tachycardias. It has excellent oral bioavailability and is mostly renally excreted unchanged. Overdoses manifest both pharmacologic properties of sotalol; β-adrenergic antagonism causes bradycardia, hypotension, low cardiac output, and CNS depression, while the class III activity causes QT prolongation, ventricular ectopy, and dysrhythmias, especially torsade de pointes. Reported cases of ventricular arrhythmias due to sotalol overdose are typically associated with bradycardia [127]. Management should include treatment of the beta-blocker toxicity (see Chapter 127 for discussion) and control of QT prolongation and torsade de pointes with agents such as magnesium or isoproterenol (see earlier for further discussion). There are reports of lidocaine suppressing torsade from sotalol overdose [127,128].

Bretylium

Bretylium tosylate is the prototypic adrenergic neuron-blocking drug with antiarrhythmic activity. It was first used for the treatment of hypertension and subsequently as a prophylactic antiarrhythmic agent and for the treatment of ventricular fibrillation [129,130].

Bretylium administration produces an initial sympathomimetic effect caused by norepinephrine release from adrenergic neurons followed by adrenergic blockade. Elimination is significantly reduced in renal failure [131]. Rapid

administration produces a biphasic hemodynamic response, with an initial increase followed by a subsequent decrease (within 15 to 30 minutes) in heart rate and blood pressure [132]. Patients with a fixed cardiac output from severe pump failure or aortic stenosis may be unable to compensate for the peripheral vasodilation caused by bretylium. Hypotension is postural and may be treated by placing the patient supine or in Trendelenburg's position. If this is insufficient, volume expansion or infusion of vasopressors such as dopamine or norepinephrine may be required. Patients receiving long-term bretylium infusions often demonstrate exaggerated catecholamine responsiveness [132]. After overdose, hemodynamic effects may persist for longer than 3 days.

Ibutilide and Dofetilide

Ibutilide and dofetilide, the newest class III, and first "pure" action potential–prolonging agents, are approved for termination of atrial fibrillation and flutter [133–135]. Both drugs are structurally similar to sotalol but have no beta-blockade effect. They prolong APD by a dual mode of action, initially blocking the rapid component of the delayed rectifier potassium current and enhancing the noninactivating component of the inward sodium current that flows during the plateau (phase 2) of the action potential. The net effect is to increase atrial and ventricular refractory period APD. Although very little information is available about overdose toxicity, development of torsade de pointes is the major concern. With therapeutic doses, the incidence of this arrhythmia ranged from 3.6% to 12.5% in clinical trials. Most episodes were self-limited, but some were sustained and required cardioversion. Nonsustained monomorphic ventricular tachycardia may also be provoked by ibutilide [136].

Adenosine

Adenosine is an endogenous purine nucleoside normally present in all cells in the human body. Intravenous adenosine, administered as a rapid infusion, is used for termination of supraventricular arrhythmias. An increased heart rate as compensation for peripheral vasodilation has been reported in patients with atrial fibrillation and flutter or if an atrial impulse is conducted via an accessory pathway [137–139]. Adenosine may also induce atrial fibrillation as a result of the decrease in atrial APD. It should be used with caution in patients with asthma because it can provoke bronchospasm. Short periods (longer than 6 seconds) of asystole are commonly seen after termination of supraventricular arrhythmias.

Therapeutic and toxic doses of adenosine induce intense vasodilation, flushing, and a feeling of pressure or pain in the chest that patients often describe as extremely unpleasant. The duration of these effects is extremely short (measured in seconds) with bolus therapy but can be prolonged in patients receiving continuous infusions during radionuclide studies or those patients taking dipyridamole [140].

CHAPTER 121 ■ ANTICHOLINERGIC POISONING†

KEITH K. BURKHART

The classic anticholinergic syndrome manifests an easily recognizable toxidrome, but patients may present with some but not all of the classic symptoms. Decreased secretions, tachycardia, mydriasis, and delirium are those most commonly seen [1]. The presence of coingestants and the multiple pharmacologic actions of many anticholinergic drugs may mask anticholinergic manifestations, although anticholinergic effects often persist longer than other pharmacologic actions [2]. The anticholinergic syndrome is more accurately an antimuscarinic syndrome. However, it is conventionally called anticholinergic and is referred to as such herein.

Anticholinergic poisoning may result in seizures, delirium, and coma, along with their associated complications. Anticholinergic-induced coma and respiratory failure may require mechanical ventilation. As with any toxicologic emergency, supportive care is of paramount importance. Physostigmine is an effective antidote with proven benefits, but also has a risk for serious adverse events.

†*The views expressed in this chapter do not necessarily represent the views of the Food and Drug Administration of the United States.*

EPIDEMIOLOGY AND SOURCES

A variety of pharmaceuticals and naturally occurring products can produce an anticholinergic syndrome (Table 121.1). Many drugs with anticholinergic effects may be classified in a manner that does not identify this activity (e.g., histamine-1 [H_1]–blockers, gastrointestinal and genitourinary tract antispasmodics, cough and cold preparations, over-the-counter sleep aids, and anticholinergic plants). For some, anticholinergic effects are desirable (e.g., atropine to treat bradycardia induces mydriasis and inhibits secretions). For others, the anticholinergic effects are an undesirable side effect (e.g., antihistamines, antipsychotics, and tricyclic antidepressants).

Pharmaceuticals and plants with anticholinergic action may be intentionally abused for mind-altering effects; especially common is the use of *Datura stramonium* (jimsonweed) [3]. Anticholinergic toxicity has occurred by a number of routes other than ingestion, including inhalation of nebulized medication [4], inhalation of pyrolysis products (e.g., the smoking of plant parts) [3], transdermal use, and ocular instillation.

PHARMACOLOGY

Anticholinergic agents antagonize the effects of the endogenous neurotransmitter acetylcholine (ACh). Receptors for ACh are widely distributed in the body, including the central nervous system and the sympathetic and parasympathetic ganglia, postganglionic parasympathetic terminals, and motor end plates of the peripheral nervous system.

ACh receptors are divided into two types, muscarinic and nicotinic, based on their ability to bind muscarine or nicotine. This division has a functional significance as well, best described in the peripheral nervous system, where muscarinic receptors predominate in the parasympathetic terminals and nicotinic receptors in autonomic ganglia and motor end plates. Most drugs have predominant effects on one of the two main ACh receptors, but at high doses, there may be some crossover effect. For example, nicotine primarily stimulates nicotinic receptors. Stimulation produces tachycardia, hypertension, muscle fasciculations, and receptor fatigue, with consequent paralysis at high doses. Nicotinic antagonists, such as the nondepolarizing muscle relaxants (e.g., pancuronium), block the action of ACh at the motor end plate and produce skeletal muscle paralysis. Excessive muscarinic receptor stimulation (e.g., organophosphate poisoning) leads to the cholinergic toxidrome (see Chapters 128 and 141). Agents that block muscarinic receptors may cause anticholinergic toxicity, the focus of this chapter.

Many drugs with anticholinergic properties undergo extensive hepatic metabolism into active and inactive metabolites. A number of these drugs may have half-lives greater than 12 to 24 hours (e.g., tricyclic antidepressants). More important may be the persistence of muscarinic receptor binding. In the intensive care unit (ICU), many patients emerge from coma into a delirious state. Reversal by physostigmine suggests persistence anticholinergic delirium rather than ICU psychosis [2].

CLINICAL PRESENTATION

Anticholinergic effects have been classically described by the mnemonic "Blind as a bat, Hot as Hades, Dry as a bone, Red as a beet, and Mad as a hatter" in reference to the consequences of ciliary muscle paralysis, hyperthermia, anhydrosis, vasodilation, and delirium, respectively. The toxidrome has been subdivided into the peripheral anticholinergic syndrome and the central anticholinergic syndrome (Table 121.2). The former

TABLE 121.1

SOME AGENTS THAT CAUSE ANTICHOLINERGIC SYNDROME[a]

Pharmaceuticals	Plants
Antihistamines (H1-blockers)	*Atropa belladonna* (deadly nightshade)
Brompheniramine	*Brugmansia arborea* (angel's trumpet)
Chlorpheniramine	*Brugmansia suaveolens* (angel's trumpet)
Clemastine	*Cestrum diurnum* (day-blooming jessamine)
Cyclizine	*Cestrum nocturnum* (night-blooming jessamine)
Cyproheptadine	*Cestrum parqui* (willow-leaved jessamine)
Dimenhydrinate	*Datura metel* (downy thorn apple)
Diphenhydramine	*Datura stramonium* (jimson weed)
Hydroxyzine	*Hyoscyamus niger* (black henbane)
Meclizine	*Lycium halimifolium* (matrimony vine)
Promethazine	Mushrooms
Pyrilamine	Myristicaceae
Tripelennamine	*Myristica fragrans* (nutmeg)
Antiparkinsonian drugs	*Amanita muscaria* (fly agaric)
Benztropine	*Amanita pantherina* (panther mushroom)
Biperiden	Physalis heterophylla (ground cherry)
Ethopropazine	Solanaceae
Procyclidine	*Solanum carolinense* (wild tomato)
Trihexyphenidyl	*Solanum dulcamara* (bittersweet)
Antipsychotics[b]	*Solanum nigrum* (black nightshade)
Acetophenazine	*Solanum pseudocapsicum* (Jerusalem cherry)
Chlorpromazine	*Solanum tuberosum* (potato)
Clozapine	Verbenaceae
Fluphenazine	*Lantana camara* (wild sage)
Haloperidol	
Iloperidone	
Loxapine	
Molindone	
Olanzapine	
Paliperidone	
Perphenazine	
Prochlorperazine	
Quetiapine	
Risperidone	
Thioridazine	
Thiothixene	
Trifluoperazine	
Ziprasidone	
Antispasmodics	
Anisotropine	
Clidinium	
Dicyclomine	
Isometheptene	
Methantheline	
Propantheline	
Stramonium	
Tridihexethyl	
Belladonna alkaloids and related synthetic congeners	
Atropine (racemic hyoscyamine)	
Glycopyrrolate	
Hyoscine	
Ipratropium

[a] Many of these agents have other significant toxic manifestations in addition to their anticholinergic effects.
[b] Some of the antipsychotics have minimal muscarinic binding.

TABLE 121.2

MANIFESTATIONS OF THE ANTICHOLINERGIC SYNDROME

Peripheral anticholinergic signs and symptoms
Cardiovascular: hypertension and tachycardia
Skin: dry and flushed with dry mucous membranes
Eyes: mydriasis (variable)
Genitourinary: urinary retention and decreased bowel sounds (ileus)
Central anticholinergic signs and symptoms
Loss of short-term memory and confusion, disorientation, psychomotor agitation
Visual/auditory hallucinations or frank psychosis
Incoordination and ataxia
Picking or grasping movements and extrapyramidal reactions
Seizures
Coma with respiratory failure

is due to quaternary amines (e.g., glycopyrrolate), which are charged molecules that poorly penetrate the blood–brain barrier, whereas the latter is due to tertiary amines (e.g., atropine), which are uncharged and reach the central nervous system. The most serious anticholinergic manifestations include agitated delirium, hyperthermia, and seizures. Patients may present with primarily peripheral signs and symptoms, primarily central ones, or both. In addition, central symptoms may persist longer than the peripheral manifestations.

The clinical presentation may be complicated by other pharmacologic actions of the intoxicant (e.g., tricyclic antidepressants) or the actions of other potentially toxic substances (e.g., salicylates, sympathomimetics).

MANAGEMENT

Traditionally, anticholinergic-poisoned patients have been managed with conservative supportive care. Obtaining and assessing historical and physical data confirms or provides the diagnoses that guide management decisions. Historical data may be simple in terms of a single agent, such as jimsonweed, or complex, as in a polydrug overdose. An analysis of the pharmacologic properties of the known intoxicants guides management decisions.

Delirium and coma are typically the most serious anticholinergic consequences that would require ICU admission. Shortly after exposure, most patients demonstrate sinus tachycardia and hypertension. These abnormalities are usually mild, but occasionally require medical intervention. Patients' respiratory status should be continuously monitored because of potential for respiratory failure. Hyperthermia, although not often present, is occasionally severe and may require rapid cooling measures. Foley catheter insertion may be needed for urinary retention.

Laboratory studies that should be considered in patients with moderate to severe anticholinergic toxicity include serum electrolytes; blood urea nitrogen; creatinine; and creatine phosphokinase, urinalysis, and electrocardiogram. Rhabdomyolysis and dehydration may be evident. A urine toxicology screen does not detect most anticholinergic agents and typically contributes little to the diagnostic workup or patient management. Many anticholinergic agents are not detected even on comprehensive toxicology screens that take hours to return [5]. Resolution of mental status changes after physostigmine administration may be the most rapid and cost-effective way to arrive at the diagnosis and simultaneously treating the poisoning.

Gastrointestinal decontamination (see Chapter 117) should be considered, especially for plant ingestions where symptoms often persist for days. Administration of activated charcoal is recommended. Its administration, however, may be problematic for the agitated or delirious patient. Physostigmine administration has also been recommended to facilitate activated charcoal administration [6].

Hallucinations, agitation, and delirium have been traditionally treated with benzodiazepines (e.g., diazepam, lorazepam) and butyrophenones (e.g., haloperidol). Heavily sedating doses may often be required such that endotracheal intubation becomes necessary, however [2]. Furthermore, haloperidol use often worsens the anticholinergic delirium, and should not be used. Physostigmine, as an antidote, reversibly binds to acetylcholinesterase and prevents this enzyme from degrading ACh, thereby allowing the neurotransmitter to persist, accumulate, and competitively reverse muscarinic receptor inhibition at its postsynaptic sites of action. Physostigmine, as opposed to similar drugs such as neostigmine and pyridostigmine, is a tertiary rather than a quaternary amine and effectively crosses the blood–brain barrier. As a result, it is effective in reversing central as well as peripheral anticholinergic effects. A more liberal use of physostigmine has the potential to help many patients and save resources. Use as a diagnostic tool may avoid an expensive workup. It may also avoid alternative treatment with other drugs and the costs of potentially having to intubate the heavily sedated patient [7,8].

Physostigmine administration allegedly has contributed to poor outcomes, especially after cyclic antidepressant poisoning [7–9]. When administered in excessive amounts or to a patient not in an anticholinergic state, signs and symptoms of cholinergic excess may appear. Several case reports [9,10] and an animal study [11] describe asystole, seizures, and death when physostigmine was used to treat tricyclic antidepressant poisoning. A recent review of reports and studies questions the justification for an absolute contraindication to physostigmine's use in all cyclic antidepressant cases [12]. A retrospective series of 39 patients treated with physostigmine included cyclic antidepressant poisoned patients [13]. None of these patients developed dysrhythmias or needed atropine, while one patient had a self-limited seizure. Reports have also described the benefits following olanzapine poisoning [7,8]. Close observation is mandatory following reversal of anticholinergic-induced respiratory or CNS depression, especially early in the course of intoxication. The awakening and cholinergic effects theoretically could enhance gut activity and further absorption of ingested drugs such that when physostigmine is cleared the patient might have greater toxicity than at the time of first administration.

Physostigmine can be both diagnostic [13] and therapeutic (Table 121.3). Administration to the confused, febrile patient may return mental status to normal and reduce fever. A head computerized axial tomogram and lumbar puncture may be avoided if the patient awakens and provides a history that is consistent with the anticholinergic toxicity. On theoretic grounds, it has been suggested that physostigmine may be useful for seizures unresponsive to conventional treatment; severe hypertension resulting in acute symptoms or end-organ dysfunction; and supraventricular tachycardias resulting in hemodynamic instability, cardiac ischemia, or other organ dysfunction. In clinical practice, these indications rarely arise and physostigmine is almost exclusively used as a diagnostic aid and for the treatment of central nervous system excitation (psychomotor agitation) and coma.

Contraindications to the use of physostigmine include bronchospasm and mechanical obstruction of the intestine

TABLE 121.3

SUMMARY TREATMENT RECOMMENDATIONS FOR ANTICHOLINERGIC TOXICITY AND USE OF PHYSOSTIGMINE

Place patient on cardiac and pulmonary monitor
Obtain electrocardiogram—If QRS prolonged more than 100–110 msec, physostigmine should not be used
Consider a urinary catheter
Consider pretreatment with 1 mg lorazepam IV
If no QRS prolongation, administer 2 mg physostigmine IV over 4 minutes
If no resolution of delirium and no bradycardia or seizures, consider repeat dosing of 1–2 mg physostigmine IV
If appropriate response, repeat 1–2 mg physostigmine as necessary

or urogenital tract. It should be used with caution in patients with asthma, gangrene, diabetes, cardiovascular disease, or any vagotonic state, and with choline esters or depolarizing neuromuscular-blocking agents (e.g., succinylcholine). Physostigmine should also be used cautiously after cyclic antidepressant overdose and is contraindicated in patients with evidence of cardiac conduction delay (e.g., atrioventricular block and prolonged QRS interval) on electrocardiogram.

Patients receiving physostigmine should be placed on continuous cardiac monitoring and be under continuous careful observation. Recommendations for the safe use of physostigmine center on its slow intravenous infusion at a rate not to exceed 0.5 mg per minute to avoid adverse drug events such as bradydysrhythmia and seizures. Slower rates of administration can be used and simply delay the onset. The average does needed for adults is approximately 2 mg [2]. Mental status improvement is usually seen within 5 to 20 minutes of administration. If no reversal of anticholinergic effect has occurred after 10 to 20 minutes, an additional 1 to 2 mg may be administered. Administration by continuous infusion has been used following the ingestion of an anticholinergic plant, *Atropa belladonna* [14]. The recommended dose in pediatric patients is 0.02 mg per kg at 0.5 mg per minute. The half-life of physostigmine is short and its duration of action after the 2-mg dose typically is only 1 to 6 hours [15]. The action of many anticholinergic agents persists longer and, therefore, additional doses may be needed [15]. In one case series of physostigmine use for anticholinergic toxicity, two-thirds of patients required just one dose of physostigmine, and no patient required another dose more than 6.5 hours after the first dose [15]. If cholinergic toxicity emerges, atropine is not needed unless severe toxicity develops. Seizures are rare and usually self-limited; diazepam is recommended as needed. Anecdotally, some physicians have administered lorazepam, 1 mg, before the physostigmine as an additional safety measure.

CHAPTER 122 ■ ANTICONVULSANT POISONING

STEVEN B. BIRD

Anticonvulsants can be divided into four groups based on their primary mechanism of action: those that primarily act on neuronal membranes (membrane-active agents), those that act on neurotransmitters or their receptor sites (synaptic agents), those with multiple sites of action, and those that are not yet understood. Membrane-active agents alter ion fluxes and include carbamazepine (CBZ), oxcarbazepine, ethosuximide, zonisamide, phenytoin, and lamotrigine (LTG). Synaptic agents primarily affect the activity of gamma-aminobutyric acid (GABA) and include barbiturates, benzodiazepines, gabapentin (GBP), tiagabine, and vigabatrin. Agents that have multiple sites of action include valproate, GBP, felbamate, and topiramate, and those for which mechanisms of action still are not understood are levetiracetam, stiripentol, and remacemide [1–3].

(Barbiturates and benzodiazepines are discussed in Chapter 143.) The precise action mechanisms of many of the newer anticonvulsants also remain unknown. Even within groups, the site or mechanism of action may differ. Pharmacologic differences are important from a therapeutic standpoint. In the treatment of seizures, combining agents from different groups may be effective whenever a single agent is ineffective or requires a toxic dose for efficacy. Therapeutic synergism may also occur when different agents of the same group are combined (e.g., benzodiazepines and barbiturates).

PHENYTOIN

Phenytoin (diphenylhydantoin) is the most commonly used anticonvulsant medication [4]. It is also used in the treatment of trigeminal neuralgia. Phenytoin was the antidysrhythmic of choice for digitalis toxicity before the advent of digitalis Fab fragments [5]. Iatrogenic intoxications can occur with drug interactions because distribution, protein binding, and clearance of phenytoin are affected by other medications and disease states. Toxicity may occur when the daily-administered dose exceeds endogenous metabolism and elimination [6–8]. Toxicity may also result when switching dosage forms or between generic and proprietary forms of the drug because of different release and absorption characteristics. There are idiosyncratic and hypersensitivity reactions associated with therapeutic use that are unrelated to dose, most commonly seen in patients with underlying neurologic disorders [9].

Pharmacology

Phenytoin is the prototypic membrane-active anticonvulsant. It acts on sodium pumps and channels in excitable cell membranes and is classified as a type 1B antidysrhythmic agent. By blocking the accumulation of intracellular sodium during tetanic stimulation, it limits the posttetanic potentiation of synaptic transmission and prevents seizure foci from detonating adjacent areas.

Phenytoin is a weak acid, with a pK_a of 8.5. The intravenous (IV) form has a pH of 10 to 12, contains 50 mg per mL, and is dissolved in a 40% propylene glycol and 10% ethanol vehicle. The phenytoin prodrug fosphenytoin (Cerebyx) has a pH between 8.6 and 9.0 and greater solubility. It is compatible with common IV preparations, lacks the cardiotoxic diluent propylene glycol, and may be administered intramuscularly as well as intravenously. It has a conversion half-life of 8.4 to 32.7 minutes to active phenytoin and is dosed in phenytoin equivalent (PE) units (75 mg per mL of fosphenytoin equals 50 mg per mL of phenytoin) [10]. In many institutions, fosphenytoin has replaced phenytoin.

Absorption occurs in the duodenum but depends on dosage form, gastric emptying, and bowel motility. Peak levels occur between 2.6 and 8.9 hours after oral dosing of an extended-release capsule. In overdosage, absorption may continue for up to 7 days, possibly due to decreased gastric motility and pharmacobezoar formation. The volume of distribution (V_d) of phenytoin is 0.6 L per kg, and it distributes preferentially into the brainstem and cerebellum [11]. Phenytoin is highly protein bound; decreased protein binding increases the free, pharmacologically active form of the drug and the V_d. Because usually only total phenytoin levels are measured, toxicity from increased free phenytoin may occur at lower total phenytoin levels [8].

Hepatic metabolism of phenytoin follows first-order elimination kinetics, with an average half-life of 22 hours (range: 7 to 55 hours). When plasma levels exceed 10 µg per mL, metabolism follows zero-order elimination kinetics, yielding a much longer half-life. The enzyme system may be induced or inhibited by other drugs, inherited genetic disturbances, or liver disease [12,13].

The anticonvulsant effects of phenytoin occur with plasma levels between 10 and 20 µg per mL. This can be achieved within 45 to 60 minutes by an IV-loading dose of 15 to 20 mg per kg of phenytoin or PE units of fosphenytoin. The rate of IV phenytoin administration should not exceed 50 mg per minute because of propylene glycol toxicity [14]. To avoid hypotension, fosphenytoin administration should not exceed 150 PE units per minute. Phenytoin has been successfully administered by the interosseous route in children with poor venous access. Maintenance dosing is usually 4 to 6 mg per kg per day in single or divided doses, although neonates may require higher doses (5 to 8 mg per kg per day) [15]. Death from isolated phenytoin ingestions is unusual but has been reported in young children with ingestions of 100 to 220 mg per kg [16,17]. Death results from central nervous system (CNS) depression with respiratory insufficiency and hypoxia-related complications.

Clinical Manifestations

Toxicity resulting from acute and chronic intoxication has a similar presentation. Patients with serum phenytoin concentrations between 20 and 40 µg per mL typically have nausea, vomiting, normal to dilated pupils, nystagmus in all directions, blurred vision, diplopia, slurred speech, dizziness, ataxia, tremor, and lethargy [18]. They may also be excited and agitated. As phenytoin serum concentration increases, confusion, hallucinations, and apparent psychosis may develop. Progressive CNS depression occurs, and nystagmus may improve. Pupillary response becomes sluggish, and deep tendon reflexes diminish [7]. Severe toxicity with coma and respiratory depression occurs with serum concentration exceeding 90 µg per mL [19]. Slowing of alpha wave activity is seen on electroencephalograms. As toxicity increases, brainstem evoked potentials are suppressed and may be absent. Paradoxical hyperactivity has been reported in patients with underlying neurologic deficits, with findings of dystonia, dyskinesia, choreoathetoid movements, decerebrate rigidity, and increased seizure activity [7,20]. Patients with baseline focal neurologic deficits may show contralateral abnormalities, including hemianopia, hemianesthesia, and hemiparesis. Patients recover completely if no anoxic or hypoxic complications develop during acute toxicity. Cerebellar atrophy after acute intoxication with phenytoin that was not known to be attributed to hypoxia has been reported, however [21]. Recovery may take 1 week or longer.

In rare instances, chronic toxicity has been associated with a syndrome of inappropriate antidiuretic hormone [22], encephalopathy, and cerebellar degeneration [11]. Chronic use of phenytoin causes hyperglycemia, vitamin D deficiency and osteomalacia, folate depletion, megaloblastic anemia, and peripheral neuropathy. Other adverse drug events include altered collagen metabolism that causes hirsutism, gingival hyperplasia, keratoconus, and hypertrichosis [23].

Non–dose-dependent phenytoin adverse drug events include hypersensitivity reactions such as fever, rash eosinophilia, hepatitis, lymphadenopathy, myositis, a lupuslike syndrome, rhabdomyolysis, nephritis, vasculitis, and hemolytic anemia [9]. Phenytoin administration during pregnancy has resulted in fetal hydantoin syndrome [24].

Phenytoin-induced dysrhythmias, hypotension, congestive failure, respiratory arrest, and asystole result predominately from propylene glycol toxicity during rapid IV phenytoin administration (e.g., > 50 mg per minute). If the rate of infusion is slowed or temporarily halted, these effects usually resolve spontaneously but may persist for 1 to 2 hours [17,25]. Cardiovascular toxicity from phenytoin intoxication itself is rare,

represents significant toxicity, and primarily occurs in patients with underlying cardiac disorders [26,27].

Diagnostic Evaluation

Essential laboratory studies should include sequential serum phenytoin levels (free and total, if available) and levels of other anticonvulsant medications, particularly when enteric-coated dosage form is involved. The interval between drug levels should be based on factors such as severity of intoxication, rate of rise of levels, and time since exposure. Intervals should be more frequent during the initial evaluation phase, while absorption is still occurring, than later, during the postabsorptive phase. In stable patients whose drug levels have peaked or started to decline, it may be appropriate to obtain levels every 12 to 24 hours until they return to the therapeutic range. Recommended laboratory studies include serum complete blood cell count, electrolytes, blood urea nitrogen, creatinine, glucose, albumin, and liver function tests. In hypoalbuminemic patients, the corrected phenytoin concentration is equal to the measured phenytoin concentration multiplied by 4.4 and divided by the serum albumin level. In all deliberate overdoses, an electrocardiogram (ECG) and acetaminophen and salicylate levels should be obtained. Arterial blood gas, chest radiograph, head computed tomography, and lumbar puncture should be obtained as clinically indicated.

The differential diagnosis of phenytoin intoxication includes sedative–hypnotic agents, other anticonvulsants, phencyclidine, neuroleptic agents, and other CNS depressant drugs. Other conditions such as diabetic ketoacidosis; hyperosmolar nonketotic coma; sepsis; CNS infection, tumor, and trauma; seizure disorders; extrapyramidal syndromes; postictal states; and cerebellar abnormalities may also mimic phenytoin intoxication.

Management

Patients should have a rapid evaluation of respiratory status followed by intubation if hypoxia or risk of aspiration is present. Vascular access should be established and the patient placed on continuous cardiac monitoring. If the mental status is abnormal, a fingerstick blood sugar should be obtained. Patients who are hyperglycemic from phenytoin intoxication can be treated with discontinuation of the drug; insulin therapy is rarely required. Flumazenil, the benzodiazepine antagonist, has no role in managing phenytoin intoxication, even if benzodiazepines are part of the polypharmacy overdose, as its use may increase the risk of status epilepticus, particularly in patients with a preexisting seizure disorder.

Hypotension occurring during phenytoin infusion is treated with discontinuation of the infusion and administration of crystalloids. Pressors are rarely necessary. Treatment of cardiac dysrhythmias is supportive, with use of the appropriate antidysrhythmics when indicated. Type IB antidysrhythmic agents should be avoided [28].

Patients with a seizure disorder should be placed on seizure precautions due to the possibility of paradoxical seizures during the acute intoxication phase or breakthrough seizures during the recovery phase when phenytoin levels may be in the subtherapeutic range. Seizures should be treated with benzodiazepines or a different anticonvulsant.

Because phenytoin has a long elimination half-life, measures to increase the rate of elimination should be considered. Gastrointestinal (GI) tract decontamination uses oral-activated charcoal administration. Phenytoin undergoes enterohepatic recirculation with active gut secretion; multiple-dose oral activated charcoal (MDAC) can increase the rate of elimination and may decrease hospital stay [29,30] (see Chapter 117). MDAC is indicated in patients with a phenytoin concentration greater than 40 μg per mL, moderate neurologic toxicity, or rising levels after GI tract decontamination. As drug levels may continue to decline for many hours after stopping MDAC, such therapy should be discontinued before drug levels reach the therapeutic range in patients who require phenytoin for therapeutic purposes. Serum levels of concurrent anticonvulsant medications may also decline when MDAC is administered, increasing the risk of breakthrough seizures. An observation period is necessary to ensure establishment of a therapeutic anticonvulsant regimen and documentation of stable therapeutic serum levels even after passage of charcoal stools. Because phenytoin has a high degree of protein binding and hepatic elimination, forced diuresis, hemodialysis, and hemoperfusion are not useful [31]. It is anticipated that hemofiltration would not be useful for similar reasons.

Disposition

Because the majority of patients with phenytoin poisoning do well with supportive therapy alone, determining the degree of toxicity is important. After adequate GI decontamination, the patient should be assessed for progression of toxicity. Patients who are not suicidal or ataxic, have no underlying cardiac dysrhythmia, can feed themselves, and are not at risk of hurting themselves can be discharged, providing serum phenytoin levels are not rising and a reliable caretaker is available. Patients who do not meet these criteria should be admitted. Severely toxic patients, those with underlying cardiac or CNS disorder, intubated patients, or patients with rapidly progressive signs of toxicity require intensive care monitoring.

VALPROIC ACID

Valproic acid (VA) 2-propylpentanoic or 2-propyl valeric acid is structurally unique among the anticonvulsants. VA is a branched-chain carboxylic acid with a pK_a of 4.8. In addition to being an anticonvulsant medication, VA is commonly used for the treatment of acute manic episodes, mood stabilization, and prophylaxis of migraine and affective disorders.

VA is marketed as a sodium salt (Depakene); in a syrup solution; in a prodrug form, divalproex sodium (Depakote); and as a sustained-release form of divalproex sodium (Depakote ER). The latter is a molecular complex that dissociates in the GI tract into two molecules of VA. There is also a parenteral form for VA.

Pharmacology

VA is thought to mediate its anticonvulsant effect by increasing cerebral and cerebellar levels of GABA [32] by blocking its metabolism through inhibition of GABA transferase and succinic aldehyde dehydrogenase. It may also prolong the recovery of inactivated sodium channels and have effects on potassium channels in neuronal cell membranes.

VA's pharmacokinetic profile is significantly altered in an overdose setting. Within its therapeutic range (50 to 100 mg per mL), VA is 80% to 95% serum protein bound [33,34]. The degree of protein binding decreases and the V_d (0.13 to 0.22 L per kg) increases as VA levels exceed 90 μg per mL [33,34]. The resultant increase in free VA levels is evident by enhanced distribution into target organ systems and better than predicted extracorporeal drug removal. This has been demonstrated by

a higher cerebrospinal fluid-to-serum level and hemodialysis extraction ratio in the VA-poisoned patient [35,36]. Protein binding of VA may also be decreased in uremic patients or in the presence of other highly protein-bound agents (e.g., acetylsalicylic acid), which displace VA from its binding sites [37].

VA is highly bioavailable, with the time to peak serum levels after ingestion dependent on the dosage form and VA species. In capsule form, VA itself achieves peak serum levels after 1 to 4 hours in therapeutic dosing, whereas peak serum levels may be delayed 4 to 5 hours after ingestion of the enteric-coated divalproex sodium tablets. Peak serum levels may be delayed out to 17 hours in overdose [38]. This may be explained by the enteric-coating dissolution time and the sequential process of intestinal conversion of divalproex to the sodium salt. This is followed by the final conversion to the free acid, the only form absorbed from the GI tract. There is no evidence suggesting formation of pharmacobezoars from large numbers of VA tablets.

VA is metabolized predominantly by the liver, with 1% to 4% excreted unchanged in the urine [33]. It undergoes beta and omega oxidation to several metabolites: hydroxyvalproate, 2-propylglutarate, 2-propylpent-4-enoate, 5-hydroxyvalproate, and 4-hydroxyvalproate. At high doses of VA, the omega oxidation pathway may become saturated, leading to a decrease in total VA body clearance [35]. The metabolites undergo glucuronidation and biliary excretion, with a possible enterohepatic recirculation [35,39]. At therapeutic levels, VA elimination half-life averages 10.6 hours (range: 5 to 20 hours), but in an overdose it may extend to 30 hours.

VA disrupts amino acid and fatty acid metabolism, sequesters acetyl coenzyme A by forming valproyl coenzyme A, and interrupts the ornithine–citrulline shuttle and carnitine transport [40–42]. This may result in encephalopathy associated with hyperammonemia at therapeutic levels of VA [43,44], acutely contribute indirectly to the CNS-depressant effects, and chronically contribute to other target organ toxicity. VA metabolites have been implicated in the metabolic perturbations associated with VA poisoning [44,45], interfere with urine ketone determinations, and may be the hepatotoxic mediators of VA. There may be a link between VA- and opiate-induced CNS toxicity because of their similar influence on the GABAnergic systems [19,46]. Because VA and its metabolites are low molecular weight, branched chain carboxylic acids, they may be used as substrates for several enzymatic processes. This leads to inhibition of critical biochemical pathways, such as the urea cycle, and subsequent fatalities in some sensitive patient populations. Death has occurred after therapeutic doses of VA in patients with a congenital deficiency of ornithine carbamoyltransferase [47]. In addition, a frequently fatal Reye-like hepatitis has been observed in patients receiving therapeutic doses. Those at greatest risk appear to be very young patients (younger than 2 years of age), those being treated with multiple anticonvulsants, and those with other long-term neurologic complications. The fatality rate is 1 per 500 in this patient population [48]. This hepatotoxic reaction occurs in chronic exposure and may be mediated by metabolites formed via the cytochrome P450 pathway. These metabolites in turn depress fatty acid oxidation in the hepatocyte mitochondria [49]. This effect may parallel that seen after ingestion of ackee fruit containing hypoglycin, causing Jamaican vomiting sickness [49]. VA can produce a hyperammonemia and encephalopathy exclusive of the hepatotoxic reaction [39]. This may be associated with VA-induced carnitine deficiency [44].

Valproate as the sodium salt provides a significant sodium load (13.8 mg sodium per 100 mg VA) in overdose. VA and its metabolites are low-molecular-weight, osmotically active, free-acid, or anionic species. They may produce a slightly elevated osmolar gap and an elevated anion gap metabolic acidosis with a reduction in circulating endogenous cations, particularly calcium [35,40,49–53]. Valproate may have a dose-related toxic effect on bone marrow and platelet function, with resultant hematologic consequences such as thrombocytopenia, anemia, and leukopenia [54–56].

The morbidity and mortality from dose-related acute or acute-on-chronic VA poisoning appear to be related to hypoxic sequelae from respiratory failure, aspiration, or terminal cardiorespiratory arrest [35,50–52,57]. Although it has been speculated that VA has a direct, irreversible, neurotoxic effect, this has not been substantiated and it is indistinguishable from hypoxic injury [52].

Patients ingesting greater than 200 mg per kg are at high risk for significant CNS depression, but poor correlation exists between peak serum level and dose of VA ingested [57]. Patients who die from acute VA poisoning have had peak serum VA levels ranging from 106 to 2,728 µg per mL, whereas survival has been reported in a patient with a peak serum level of 2,120 µg per mL [40,49,56]. Although serum VA levels may not correlate with clinical effect, in general, serum levels of 180 µg per mL are usually associated with serious CNS toxicity (e.g., coma and apnea) and significant metabolic derangement (e.g., acidosis and hypocalcemia) [40,49,56,58,59]. The duration of toxicity is proportional to the peak serum VA level.

On the basis of endogenous VA clearance, it will take 3 days for the serum level to drop within the therapeutic range in a patient with a serum level greater than 1,000 µg per mL.

Clinical Manifestations

In acute intoxication, hypotension, mild tachycardia, decreased respiratory rate, and elevated or depressed temperature may be seen. Miosis may be present. The hallmarks of VA toxicity are global CNS-related depression in conjunction with unique metabolic changes. The mental status varies on a continuum from confusion and disorientation to obtundation and deep coma with respiratory failure. Tremor, hallucinations, and hyperactivity have been reported, but there is a notable lack of cerebellar–vestibular effects. Patients with an underlying seizure disorder may have breakthrough seizures. Most patients with serious acute VA poisoning manifest CNS toxicity for at least 24 hours and this may extend to several days. Laboratory abnormalities observed in patients with high serum VA levels include an anion gap metabolic acidosis, hypocalcemia, hyperosmolality, and hypernatremia. Transient rises in serum transaminase levels have been observed without evidence of functional liver toxicity. Hyperammonemia associated with vomiting, lethargy, and encephalopathy may occur at therapeutic serum levels. Although rare, complications or delayed sequelae associated with severe VA intoxication include optic nerve atrophy, cerebral edema, acute respiratory distress syndrome, and hemorrhagic pancreatitis.

Non–dose-related toxicity (e.g., hepatic failure, pancreatitis, red blood cell aplasia, neutropenia, and alopecia) has not been reported in acute overdoses with high serum levels of VA. Pancreatitis is usually considered a non–dose-related effect but has been observed [55]. Alopecia, thrombocytopenia, leukopenia, and anemia have been associated with acute and chronic VA intoxication.

The differential diagnosis should include opioid toxicity and a list of substances causing an increased anion gap metabolic acidosis. VA intoxication can be indistinguishable from opioid poisoning by signs and symptoms, and VA-poisoned patients may occasionally respond to naloxone. VA may cause a false-positive urine ketone determination, thereby misdirecting the clinician to causes of ketosis [40].

Diagnostic Evaluation

Essential laboratory studies should include sequential serum VA levels and levels of other anticonvulsant medications, particularly when the enteric-coated dosage form is involved. It should be recognized that VA metabolites are highly cross-reactive on enzyme-multiplied immunoassay technique assay for VA [35], and there may be an overestimation of serum VA levels as high as 50%. Recommended laboratory studies include complete blood cell count, reticulocyte count, serum electrolytes, blood urea nitrogen, creatinine, glucose, calcium, ammonia, and liver function tests. In addition, serum amylase and lipase levels should be obtained to rule out pancreatitis.

In all deliberate overdoses, an ECG and acetaminophen and salicylate levels should be obtained. Arterial blood gas, chest radiograph, head computed tomography, and lumbar puncture should be obtained as clinically indicated.

Management

As with any consequential CNS depressant ingestion, the patient's airway and respiratory status should be frequently assessed; early intubation and ventilation help prevent hypoxic sequelae. Vascular access and continuous cardiac monitoring should be established. Patients with altered mental status should have a fingerstick blood sugar determination or receive IV dextrose, followed by naloxone and thiamine as clinically indicated.

Naloxone (0.8 to 2.0 mg) has been reported to be effective in increasing the level of consciousness of patients with signs and symptoms of opioid toxicity and serum VA levels between 185 and 190 µg per mL [58,59]. Patients with higher VA serum levels have not responded to larger doses of naloxone [56,60]. Naloxone has been shown experimentally to antagonize GABA, the inhibitory neurotransmitter increased by VA [19,46]. It is therefore worth trying naloxone (up to 10 mg) all comatose patients with suspected VA poisoning. Flumazenil, the benzodiazepine antagonist, should be avoided in patients with a preexisting seizure disorder.

Carnitine has been used for the treatment of hyperammonemia because VA interferes with the citrulline–ornithine cycle and carnitine's availability to shuttle fatty acids across the mitochondrial membrane. There are some pediatric data suggesting that carnitine improves mental status [42,43,61–63]. The oral and parenteral carnitine doses range from 1.5 to 2.0 g, divided into 3 to 4 doses per day.

GI decontamination should be performed in patients with suspected VA, even if several hours have elapsed since ingestion [64]. Activated charcoal is preferred; gastric lavage and whole-bowel irrigation for enteric-coated preparations are additional options. Methods to enhance elimination may be effective since an increase in the free serum drug fraction, decreased protein binding, and marked prolongation in elimination half-life occur after overdose. MDAC may enhance the clearance and reduce the VA half-life by interrupting enterohepatic recirculation and GI tract dialysis [65]. Extracorporeal removal by hemodialysis or hemoperfusion is also effective. Indications for extracorporeal removal are not clearly defined, requiring a risk-benefit analysis on a case-by-case basis. It should be considered when the VA level exceeds 1,000 µg per mL and is recommended for patients with levels exceeding 2,000 µg per mL. In a patient with a level exceeding 2,000 µg per mL, prompt institution of hemodialysis led to complete resolution of toxicity within 3 days, whereas a similar patient managed with only supportive care died [40,56]. Patients not responding to conventional therapy or who have severe acid–base derangement may also benefit from hemodialysis. VA clearance during hemodialysis has been as high as 270 mL per minute, with a four- to fivefold decrease in elimination half-life [36]. Hemodialysis has the added benefit of correcting acid-base derangements secondary to VA and removal of its metabolites. Because of VA's extensive protein binding and predominate hepatic elimination, it is anticipated that forced diuresis, manipulation of urine pH, and hemofiltration would not be useful in the management of VA intoxication. Charcoal hemoperfusion used for VA intoxication has demonstrated clearance similar to that of hemodialysis [48,66]. Use of hemodialysis and hemoperfusion in series may be more advantageous due to a more consistent extraction of VA as its degree of protein binding increases coincident with declining levels and desaturation of binding sites [67].

Disposition

The disposition of the VA-poisoned patient is based on the severity of CNS toxicity, quantitative serum levels, evidence of hypoxic insult, risk of secondary complications, and the amount of VA ingested. Patients with serum VA levels exceeding 150 µg per mL are at risk for CNS and respiratory depression and should be observed until levels return to the therapeutic range. Patients with VA serum levels exceeding 1,000 µg per mL are at high risk for serious prolonged toxicity and should be admitted to an intensive care unit.

CARBAMAZEPINE

CBZ is an iminostilbene compound with a chemical structural backbone resembling that of the tricyclic antidepressants. It is stereochemically similar to phenytoin. CBZ has long been recognized as a well-tolerated and effective agent for the management of various types of seizure disorders. It is also used for the treatment of trigeminal and glossopharyngeal neuralgias, tabetic pain, and affective disorders [68]. A sustained-release formulation is available.

Pharmacology

Because CBZ is unionized and highly lipophilic, there is no parenteral dosage form, and the rate-limiting step for systemic absorption is tablet dissolution time [69]. Consequently, the pharmacokinetics and toxicokinetics of CBZ are not well defined and are subject to significant inter- and intrapatient variability. CBZ is 80% protein bound and may have twice the V_d of other anticonvulsants, such as phenytoin and phenobarbital.

In overdose, systemic absorption of CBZ may be inconsistent over time. This leads to intermittent surges of drug released into the circulation and may cause unexpected clinical deterioration of patients. This may explain the "cyclic coma" associated with CBZ poisoning [70–72]. Patients have been reported to relapse into deep coma as late as 2 days after admission to the hospital coincident with a marked increase in plasma levels of CBZ, even after the patient's condition has appeared to stabilize or improve clinically. CBZ's V_d ranges from 1.4 to 3.0 L per kg at toxic levels [4,73].

CBZ is predominantly metabolized in the liver, with 1% to 3% excreted unchanged in the urine. Endogenous clearance is 0.6 to 1.3 mL per minute per kg [4,68]. The variability in clearance may be attributed to alteration in the metabolic capabilities of hepatic enzymes, particularly the cytochrome P450 system [68]. This system is sensitive to autoinduction during chronic administration or, conversely, inhibition with concurrent administration of enzyme inhibitors such as erythromycin [74]. The elimination half-life of CBZ in naive users may

exceed 24 hours, whereas in chronic users it may be less than 15 hours [4,68,69,75]. Half-life determinations of CBZ, especially in overdose, often are misleading due to erratic absorption and inability to determine the contribution of sustained absorption from the GI tract [75]. Most evidence suggests that CBZ undergoes first-order kinetics, although it is postulated that some of its metabolic pathways, such as epoxidation, may follow Michaelis–Menton kinetics and saturate at high levels [75].

Forty percent of CBZ is converted to the active metabolite CBZ-10,11-epoxide (CBZ-epoxide), further complicating the kinetic and toxicity profile of CBZ [68,72]. An inactive metabolite is also formed. CBZ-epoxide elimination half-life is 5.0 to 9.8 hours and is in turn converted to the 10,11-dihydroxide [73,75]. CBZ-epoxide is much less protein bound than CBZ (50% vs. 80%) [68]. The therapeutic CBZ concentration is 3 to 14 µg per mL. Within this range, adverse drug events including nystagmus, ataxia, dizziness, and anorexia have been noted [4,76].

CBZ may be best described as a CNS depressant with mild anticholinergic activity and a proclivity for alteration of the cerebellar–vestibular brainstem function. CBZ mediates its pharmacologic effects by mechanisms that include stabilizing the inactive sodium channel, alteration of neurotransmitter activity (norepinephrine, acetylcholine), enhancement of adenosine, stimulation of benzodiazepine receptors, and depression of evoked repetitive firings in neurons and the brainstem reticular formation [68].

CBZ has been described as similar to tricyclic antidepressants in its toxicity profile [71,77–80]. Although these agents share sedative, anticholinergic, and sodium channel blocking activity, CBZ has a higher therapeutic index, and malignant cardiac dysrhythmias and seizures do not usually occur in patients with a normal cardiac and neurologic function [81]. In overdose with extremely high CBZ levels, however, fatal dysrhythmias may develop [76,82,83].

CBZ toxicity can be defined as dose dependent or non–dose dependent. Non–dose-dependent toxicity includes idiosyncratic and immunologic-mediated reactions such as bone marrow suppression, hepatitis, tubulointerstitial renal disease, cardiomyopathy, hyponatremia, and exfoliative dermatitis. It is responsible for the majority of CBZ-related fatalities [4,80,84] and is recognized in the course of chronic therapeutic dosing. Dose-related effects in sensitive populations include those with existing neurologic deficits and myocardial disease. Dose-related toxicity has been reported in acute overdoses, with survival in adults after 80-g ingestions. Death has been reported after acute ingestion of 60 g and after a 6-g ingestion in a patient receiving long-term maintenance therapy [78,85,86].

Respiratory depression and significant neurologic toxicity and death have been reported, with peak serum CBZ levels ranging from 20 to 65 µg per mL [70,72,73,76,78,79,86–92]. Patients with serum levels in the range of 10 to 20 µg per mL usually respond to verbal stimuli unless other coexisting medical complications or additional sedative–hypnotic substances are present [76].

There is poor correlation between serum CBZ levels and clinical outcome. Prognosis appears to depend on occurrence of respiratory depression and aspiration of gastric contents [71,72,76,78,79,86–89,91,93]. All reported deaths occurred in patients with a history of seizure disorders. Surviving patients may have a protracted course (days to weeks) because of secondary complications arising from hypoxic-related sequelae from respiratory and CNS depression, prolonged GI tract absorption, and a prolonged elimination half-life.

The kinetics of CBZ toxicity are affected by the active metabolite CBZ-epoxide, which may partially account for the lack of correlation between peak CBZ levels and the severity of symptoms. The concentration of CBZ-epoxide is only 40% that of CBZ. CBZ-epoxide concentration in the free, unbound form may be equal to or greater than that of CBZ, however [94,95].

Toxicity may occur by gradual accumulation of CBZ in patients receiving therapeutic dosing because of improper dosing protocols or as a result of a drug interaction with enzyme inhibitors such as erythromycin or verapamil [74] and from generic substitution [96].

Clinical Manifestations

Patients with acute and chronic exposures have similar findings. Key findings suggestive of CBZ poisoning include the triad of coma, anticholinergic syndrome, and adventitious movements [79]. Physical findings include CNS depression with pronounced effects on the cerebellar–vestibular system (e.g., nystagmus, ataxia, ophthalmoplegia, diplopia, absent doll's eye reflex, and absent caloric reflexes), central and peripheral anticholinergic toxicity (e.g., hyperthermia, sinus tachycardia, hypertension, urinary retention, mydriasis, and ileus), and neuroleptic-type movement disorders (e.g., oculogyric crisis, dystonia, opisthotonus, choreoathetosis, and ballismus), which can occur in patients without preexisting neurologic disorders.

Other effects, which are not clearly reproducible and may be indirectly related to hypoxia or occur in patients with preexisting disease, include cardiac conduction disturbances, hypotension, hypothermia, respiratory depression, deep coma, diminished or exaggerated deep tendon reflexes, and dysarthria. Some patients may be agitated and restless, combative, or irritable, experience hallucinations, or have seizures. Because CBZ has prolonged absorption from the GI tract and prolonged elimination half-life, the clinical course may be extremely protracted and deceptive, and sudden deterioration may occur days after admission [70,72].

Seizures associated with high levels of CBZ appear to occur predominantly in patients with preexisting neurologic disorders. In many reports, it is unclear whether witnessed motor activity was a true seizure or another movement disorder and whether the seizure occurred primarily or was secondary to hypoxic insult [70,71,76,77,79,88,94].

Cardiac conduction disturbances such as prolongation of the PR, QRS, and QTC intervals and complete heart block have been reported [71,88,90,97]. Patients with an underlying abnormal cardiac conduction system may be at particular risk for the development of complete heart block [98]. In most patients, conduction defects are not seen or there is marginal prolongation of intervals without progression to malignant dysrhythmia despite extremely high CBZ levels [77–79,81,90,99].

Diagnostic Evaluation

Essential laboratory studies should include sequential serum CBZ levels and levels of other anticonvulsant medications, serum electrolytes, blood urea nitrogen, creatinine, and ECG. Recommended laboratory studies include complete blood cell count and liver function tests. In all deliberate overdoses, acetaminophen and salicylate levels should be obtained. Arterial blood gas, chest radiograph, head computed tomography, and lumbar puncture should be obtained as clinically indicated.

CBZ and CBZ-epoxide are highly cross-reactive on enzyme-multiplied immunoassay technique assays for CBZ and can result in a falsely elevated CBZ level. The clinical consequence of this is debatable, however. High-pressure liquid chromatography assay has the ability to distinguish between CBZ and CBZ-epoxide. Using the ratio of CBZ to CBZ-epoxide, an index can be generated that may reflect the rapidity of absorption of CBZ from the GI tract. A ratio greater than 2.5 is evidence of

rapid or continued CBZ absorption from the GI tract. Cases in which patients appear to relapse or deteriorate may be due to an abrupt increase in absorption occurring as late as 48 hours after the initial ingestion [72,78,90,92]. In cases in which serial CBZ and CBZ-epoxide levels were monitored, the ratio greatly increased just before and coincident with the clinical deterioration [70,72,90].

Patients whose serum CBZ level continues to significantly rise, manifesting delayed symptoms, or who appear to relapse or deteriorate after appropriate GI decontamination should be suspect for harboring pharmacobezoars in their GI tract. Radiographic contrast study should be considered to confirm this diagnosis; CBZ is not radiopaque [85,99]. The differential diagnosis of CBZ toxicity includes tricyclic antidepressants, neuroleptics, sedative–hypnotics, anticholinergic agents, and other anticonvulsant poisonings.

Management

Management begins with treatment of respiratory, neurologic, and cardiovascular derangements. Early intubation and ventilation should be considered, as poor outcomes with CBZ-poisoned patients are primarily associated with pulmonary complications. Vascular access and continuous cardiac monitoring [68,70,76] should be established. Hypotension should be initially managed with crystalloid fluid challenges followed by pressor agents (e.g., dopamine) [70,78]. There is no specific antidysrhythmic regimen for CBZ-induced cardiac toxicity. IV sodium bicarbonate therapy should be considered in patients whose QRS is greater than 100 milliseconds. Patients with altered mental status should have a fingerstick blood sugar determination or receive IV dextrose, followed by naloxone and thiamine as clinically indicated. Seizures are usually self-limited but respond to IV diazepam or phenytoin [73].

GI decontamination should be initiated as soon as possible with activated charcoal. MDAC may double the elimination of systematically absorbed CBZ [100] (see Chapter 119) and should also be considered in patients with serum CBZ concentration greater than 20 µg per mL. MDAC should be discontinued before CBZ levels decline to the therapeutic range in those with an underlying seizure disorder [101]. Although MDAC therapy significantly reduces serum CBZ levels, it has not been shown to improve patient outcome [102]. In patients with rising drug levels despite initial GI tract decontamination, whole-bowel irrigation may also be useful (see Chapter 119).

Hemoperfusion has been used to enhance CBZ clearance in overdose cases but with modest results, usually no more than the increase achieved by MDAC, which is less invasive [78,87–88]. In one case, it was equivalent to an increase in CBZ excretion of 200 mg per hour [78]. If used at all, extracorporeal removal should be reserved for those with greatly elevated serum levels and concomitant deep coma. Neither urinary manipulation nor hemodialysis is useful.

Although there is one case report of a CBZ-poisoned patient (serum level: 27.8 µg per mL) who responded to a dose of flumazenil [91], this agent may precipitate seizures and is contraindicated in CBZ overdose. Physostigmine has been reported to be effective in the treatment of dystonia associated with CBZ poisoning [77]. Given that CBZ-associated dystonias are self-limited, the risks of physostigmine therapy likely outweigh its potential benefits.

Disposition

Because CBZ displays erratic absorption, the decision should be in favor of admission and a prolonged observation period in an intensive care setting for patients with a history suggestive of a large ingestion despite initial clinical presentation and CBZ serum level. CBZ-poisoned patients at greatest risk for significant sequelae should also be admitted to the intensive care unit. This would include patients whose CBZ levels exceed 20 µg per mL or are readily rising, who are obtunded or comatose, those with cardiovascular symptoms, whose ECG shows a QRS greater than 100 milliseconds, and those with seizures. The majority of patients at risk for significant sequelae require observation for a minimum of 48 hours.

NEWER ANTICONVULSANTS

Felbamate (Felbatol)

Felbamate is a phenyl dicarbamate with a structure similar to that of the sedative-hypnotic agent meprobamate. Its mechanism of action is believed to have some indirect effect on the $GABA_A$-receptor supramolecular complex [103,104], block repetitive neuronal firing, and affect the sodium channel on the neuronal membrane. Felbamate is rapidly absorbed, with a bioavailability of 90% and peak plasma concentrations occurring 1 to 4 hours after oral dosing. Its V_d is 0.75 L per kg. The drug circulates as the free drug and is only 20% to 30% protein bound. Absorption and elimination are linear and plateau at high levels. The drug undergoes partial hepatic metabolism with an inactive metabolite and renal excretion. Approximately 40% of a dose is eliminated unchanged in the urine. The elimination half-life is 20 to 23 hours. Felbamate does not induce its own metabolism [105].

Felbamate has significant drug interactions. It can inhibit and induce the P450 cytochrome system. This affects the metabolism of coadministered medications. Felbamate induces the metabolism of CBZ and inhibits the metabolism of phenytoin and VA. The effect of felbamate on metabolism takes 2 to 3 weeks to clear after discontinuation of the drug [105,106].

Although uncommon, serious adverse drug events include aplastic anemia and hepatic failure, which is associated with a 20% mortality rate. Other adverse drug events include nausea, vomiting, abdominal pains, headache, insomnia, palpitations, tachycardia, blurred vision, diplopia, tremors, and ataxia. Children are likely to demonstrate anorexia and somnolence [105].

There is limited information regarding deliberate felbamate overdose [107,108]. A 20-year-old woman developed altered mental status, massive crystalluria, and acute renal failure after an overdose of felbamate and VA. Macroscopic urinary crystals were identified by gas chromatography as containing felbamate. Crystalluria and acute renal failure resolved with hydration. A 44-year-old man who ingested an unknown amount of felbamate, haloperidol, and benztropine recovered with supportive care. Symptoms were predominately neurologic, with ataxia, nystagmus, weakness, abnormal movements, and agitation [109]. The management of felbamate overdose is supportive care. Gut decontamination with activated charcoal would appear to be reasonable. There are no data on hemodialysis, hemoperfusion, or urinary manipulation [109].

Lamotrigine (Lamictal)

LTG, or 3–5-diamino-6 (2,3-dichlorophenyl)-1,2,4-triazine, is not structurally related to other anticonvulsants. The mechanism of action of LTG is believed to involve voltage-sensitive sodium channels and stabilizes neuronal membranes. Lamotrigine has no effect on the release of GABA, acetylcholine,

norepinephrine, or dopamine. In oral dosing, LTG is rapidly absorbed, with a bioavailability of 98%. Peak plasma levels are reached 1 to 4 hours after dosing. Protein binding is 55%, and the V_d ranges from 0.9 to 1.4 L per kg. LTG is metabolized in the liver and excreted as the glucuronide metabolite. LTG does not induce its own metabolism. The elimination half-life of the parent compound is 12 to 50 hours (mean: 30 hours) [103,105].

Adverse drug events include Stevens–Johnson syndrome, toxic epidermal necrolysis, drowsiness, dizziness, headache, unsteady gait, tremor, ataxia, somnolence, diplopia, blurred vision, and nausea [105].

There is limited information regarding deliberate LTG overdose [108,110–112]. One patient presented with nystagmus and ataxia 1 hour after ingestion. The initial ECG showed a normal sinus rhythm with a QRS of 112 milliseconds, which gradually resolved over 48 hours. In another case, ataxia, rotary nystagmus, and a normal ECG were noted. A 2-year-old boy developed tremor, muscle weakness, ataxia, hypertonia, and generalized tonic–clonic seizure after ingesting 800 mg of LTG.

The management of acute LTG overdose should include GI decontamination, continuous cardiac monitoring, and supportive care. It would be prudent to closely monitor a patient with serial ECGs for 24 to 48 hours if the initial ECG shows a prolonged QRS duration (greater than 100 milliseconds). IV sodium bicarbonate therapy has not been studied but should be considered. Benzodiazepines are appropriate for the treatment of seizures. There are no data on hemodialysis or hemoperfusion.

Gabapentin (Neurontin)

GBP is an engineered molecule based on GABA and altered to increase membrane permeability and entrance through the blood–brain barrier. Chemically, GBP is GABA with a cyclohexane ring (1-[aminomethyl]-cyclohexane) [105].

Gabapentin appears to bind to a specific site in the CNS but does not affect ligand binding to $GABA_A$, $GABA_B$, benzodiazepine, glutamate, glycine, and *N*-methyl-d-aspartate sites on the neuronal membrane [103,105].

GBP is 50% to 60% absorbed from the GI tract, with peak serum levels occurring 1 to 3 hours after oral administration. Its V_d is 0.8 to 1.0 L per kg. GBP is not protein bound and does not appear to be metabolized; all of a dose is excreted unchanged in the urine. The terminal elimination half-life is 5 to 7 hours. Renal elimination and half-life are proportional to renal function. The elimination rate can neither be induced, nor can the elimination half-life be altered with repetitive dosing [105,113].

Adverse drug events include CNS depression, nystagmus, blurred vision, diplopia, mood changes, headache, weight gain, seizures, fatigue, nausea, dizziness, slurred speech, and unsteady gait [106]. Lethargy, somnolence, dizziness, drowsiness, dysarthria, diplopia, sedation, ataxia, slurred speech, and GI distress have been observed after overdose [114,115]. Signs and symptoms resolved within 48 hours without specific therapy. Treatment is supportive. There are no data on binding to activated charcoal, urinary manipulation, hemodialysis, or hemoperfusion.

Oxcarbazepine (Trileptal)

Oxcarbazepine is the dihydro derivative of CBZ and can be thought of as being a prodrug, which is almost 100% biotransformed during hepatic first-pass metabolism to the active metabolite 10,11-dihydro-10-hydroxycarbamazepine. It has the same anticonvulsant effect as CBZ. The parent and the metabolite are lipophilic and pass into the CNS. Its advantages are that it has better tolerability and does not form the CBZ-epoxide. Peak serum drug levels occur 4.5 hours after an oral dose. The V_d is 49 L per kg. The elimination half-lives of oxcarbazepine and its metabolite are 1.0 to 2.5 hours and 8 to 11 hours, respectively. Adverse drug events include hyponatremia (in up to 30% of patients) headache, ataxia, dizziness, nausea, memory impairment, concentration difficulties, anorexia, and weight gain [113,116]. Evaluation and treatment considerations are the same as for CBZ. CBZ assays cannot be used to measure oxcarbazepine levels. Oxcarbazepine concentrations are not routinely available and are generally not useful in patient management [117].

Tiagabine (Gabitril)

Tiagabine is a GABA reuptake inhibitor derived from nipecotic acid to which a lipophilic moiety has been added to improve passage into the CNS. By selectively inhibiting neuronal GABA reuptake, it prolongs the action of GABA in the synapse. It is rapidly absorbed orally, with a peak level by 0.5 to 1.0 hours after ingestion. The drug is 96% protein bound and is metabolized in the liver. There is some degree of enterohepatic circulation. The elimination half-life ranges from 4 to 7 hours in patients receiving enzyme-inducing drugs [113]. Adverse drug events include CNS depression, seizures, nausea, hypertension, tachycardia, asthenia, sedation, dizziness, mild memory impairment, abdominal pain, and nausea. Treatment is supportive.

Topiramate (Topamax)

Topiramate is a sulfamate-substituted monosaccharide compound different from other anticonvulsants. Its mechanism of action may be in part due to sodium-channel blockade, enhancing the action of GABA, and diminishing kainate-induced excitatory receptor stimulation. Oral absorption is rapid, with a peak serum level at 1.8 to 4.3 hours. The plasma protein binding of topiramate is 9% to 17%, and its V_d is 0.7 L per kg. It is 70% to 97% eliminated unchanged in the urine. The elimination half-life is 18 to 24 hours.

Development of a nonanion-gap metabolic acidosis is a relative common occurrence with topiramate use, both in therapeutic dosing as well as overdose [118]. This occurs by impairing both the normal reabsorption of filtered bicarbonate by the proximal renal tubule and the excretion of hydrogen ions by the distal renal tubule. This combination of defects is termed mixed renal tubular acidosis (RTA) [119]. Treatment of the metabolic acidosis includes cessation of the topiramate and fluid resuscitation as needed. The use of parenteral sodium bicarbonate is rarely needed. Other adverse drug events include sedation, cognitive dysfunction, paresthesias, dizziness, fatigue, weight loss, diarrhea, and urolithiasis. Treatment is supportive [113].

Levetiracetam (Keppra)

Levetiracetam (Keppra) is a new anticonvulsant used to treat partial complex seizures that is also being investigated for its mood-stabilizing properties. Although its precise mechanism of action is unknown, levetiracetam does not appear to directly interact with the GABA system. There are few case reports of overdose with levetiracetam. It appears the most common adverse effects in overdose are sedation and respiratory

depression [120,121]. There are no data regarding specific antidotal therapy for levetiracetam overdose. Treatment is supportive care.

Vigabatrin (Sabril)

Vigabatrin is an engineered GABA-related anticonvulsant with limited availability in the United States. Chemically, it is gamma-vinyl-GABA. It is a stereospecific GABA transaminase inhibitor, the S(+) enantiomer being biologically active. Its peak serum level occurs 0.5 to 3.0 hours after ingestion, and its V_d is 0.8 L per kg. There is virtually no plasma protein binding of the drug, and more than 80% of the drug is eliminated unchanged. The plasma half-life ranges from 4 to 8 hours. The cerebrospinal fluid level is 0% to 15% of the serum level [114]. Adverse drug events include visual field defects [122], diplopia, drowsiness, irritability, agitation, anxiety, psychomotor effects, depression, sedation, confusion, and ataxia [113]. A patient who ingested 8 to 12 g in an overdose developed a psychotic episode lasting 36 hours [123]. Supportive care is the mainstay of management.

CHAPTER 123 ■ ANTIDEPRESSANT POISONING

CYNTHIA K. AARON AND ABHISHEK KATIYAR

Cyclic antidepressants constitute a major component of reported drug overdoses requiring treatment in an intensive care setting [1]. These medications are freely available to patients who are at high risk for suicide or overdose. The consequences of overdose are severe and predominantly affect the central nervous system (CNS) and cardiovascular system. Treatment of overdose is directed toward limiting drug absorption and managing complications of toxicity; there is no antidote for cyclic antidepressant toxicity.

Although iminodibenzyl was synthesized in the late nineteenth century, the pharmacology of cyclic antidepressants was not detailed until the 1940s. These compounds were designed to have antihistaminic, sedative, analgesic, and antiparkinsonian properties. Imipramine, the first of the dibenzazepines, was synthesized as a phenothiazine derivative but was found to be ineffective as a neuroleptic agent. In the late 1950s, patients taking imipramine reported that the drug had mood-elevating effects. Imipramine and later congeners have since been used in the treatment of endogenous depression. Other indications for cyclic antidepressants include therapy of enuresis in children, treatment for migraine headaches, chronic pain control, smoking cessation, panic disorders, premenstrual dysphoric syndrome, and cocaine detoxification [2,3].

Classic tricyclic antidepressants have a seven-membered central ring with a terminal nitrogen containing either three constituents (tertiary amines) or two constituents (secondary amines). Tertiary amines include amitriptyline, imipramine, doxepin, trimipramine, and chlorimipramine (clomipramine). Secondary amines include desipramine, protriptyline, and nortriptyline. Included with cyclic antidepressants are two dibenzoxazepine compounds that contain the central seven-membered ring with a heterocyclic constituent: loxapine and its demethylated metabolite amoxapine.

Maprotiline, a dibenzobicyclooctadiene, mianserin, and mirtazapine (Remeron®) are tetracyclic antidepressants [4]. Mirtazapine, a derivative of mianserin, has additional α_2-antagonist activity. Bicyclic compounds include viloxazine, venlafaxine, and zimeldine.

Trazodone and nefazodone are triazolopyridine derivatives that are structurally and pharmacologically different from the other cyclic antidepressants. Atypical antidepressants include bupropion, a unicyclic phenylaminoketone [5–10], and a large group of antidepressants called *selective serotonergic reuptake inhibitors* (SSRIs). Currently available SSRIs include fluoxetine, a straight-chain phenylpropylamine; paroxetine, a phenylpiperidine derivative; sertraline; fluvoxamine; citalopram, and escitalopram.

Venlafaxine and duloxetine are considered SSNRIs, since they have norepinephrine-reuptake inhibition effects. Although not classically considered SSRI, some antidepressant agents having serotonergic activity include mirtazapine, trazodone, nefazodone, and clomipramine. Cyclic antidepressants that are not available in the United States because of side effects include mianserin (agranulocytosis), nomifensine (hepatotoxicity and hemolytic anemia), lofepramine (hepatotoxicity and hyponatremia), and zimeldine (Guillain–Barré syndrome) [11–14].

A third class of antidepressants is the monoamine oxidase inhibitors (MAOIs; e.g., moclobemide, pargyline, phenelzine, tranylcypromine, selegiline, and isocarboxazid). They are used to treat depression, panic disorders, phobias, and obsessive-compulsive behavior. A group of MAOIs that selectively inhibit the monoamine oxidase (MAO) isoenzyme type B (MAO-B) are being used as agents to treat Parkinson's disease [15].

PHARMACOLOGY

The therapeutic effects of cyclic antidepressants are relatively similar, but their pharmacology differs considerably. The cyclic antidepressants act as neurotransmitter postsynaptic receptor blockers for histamine, dopamine, acetylcholine, serotonin, and norepinephrine (NE). They inhibit the reuptake of neurotransmitter biogenic amines and have quinidine-like membrane-stabilizing effects [3,4,11,13,14,16–19] (Tables 123.1 through 123.3). These agents may induce atrioventricular blocks [20–23] and have a direct negative cardiac inotropic effect, demonstrated by a decrease in the rate of change in left ventricular pressure and an increase in left ventricular end-diastolic pressure [17,24,25]. CNS effects may be

TABLE 123.1

CYCLIC ANTIDEPRESSANT EFFECTS ON NEUROTRANSMITTERS

Antidepressant	Effect
Receptor blockade	
Acetylcholine (antimuscarinic)	Sinus tachycardia, gastrointestinal hypomotility, warm dry skin, urinary retention, mydriasis, lethargy, hallucinations, seizures, coma
Norepinephrine	Hypotension, reflex tachycardia, orthostasis, ? seizures
Histamine	Antihistamine effects, sedation, hypotension
Serotonin	Hypotension, ejaculation disturbances
Dopamine	Endocrine disturbances (galactorrhea, impotence), dystonias
Biogenic amine reuptake blockade	
Dopamine	Hypotension, psychomotor retardation, antiparkinsonian effects
Norepinephrine	Transient hyperadrenergic state (tremor, tachycardia), adrenergic depletion (hypotension, antidepressant effects), ejaculation disturbances
Serotonin	Seizures, ejaculation disturbances, antidepressant effects

related to neurotransmitter and to direct membrane effects [24,26,27]. All tricyclic antidepressants increase the density of β-adrenoreceptors.

SSRIs and SSNRIs alter serotonergic neurotransmission. The International Union of Pharmacological Societies Commission on Serotonin Nomenclature has classified at least twelve 5-hydroxytryptamine (5-HT) receptors based on operational criteria (Table 123.4). SSRIs block some serotonin receptors and inhibit the reuptake of serotonin at other receptor subtypes. Buspirone, a nonbenzodiazepine sedative-hypnotic, is a 5-HT_{1A} partial agonist and is inhibitory on serotonin neuronal firing. It has anxiolytic and antidepressant activity. Excessive stimulation can lead to hypotension. Antagonists at 5-HT_{1C}, such as ritanserin, may be anxiolytic. 5-HT_{1D} receptor subtype stimulation leads to inhibition of neurotransmitter release, and its agonist is sumatriptan, an antimigraine medication. 5-HT_2 stimulation can cause vasoconstriction. 5-HT_3 antagonists have antiemetic and antipsychotic activity (ondansetron) [28]. Classic tricyclic antidepressants affect serotonin neurotransmission by enhancing the sensitivity of postsynaptic 5-HT_{1A} postsynaptic receptors. The SSRIs alter the release of serotonin presynaptically, leading to an increase in the amount of serotonin that is available for neurotransmission without changing the sensitivity of the 5-HT_{1A} postsynaptic receptors [29]. In general, the SSRIs normalize the number and function of 5-HT_{1A} and 5-HT_2 receptors [28]. As a group, the predominant difference between SSRIs is in their effect on the hepatic cytochrome P450 system and drug–drug interactions.

Venlafaxine and duloxetine are considered selective serotonergic and NE reuptake inhibitors. Blockade of NE-α_2 receptors leads to decrease in 5-HT release. Selective serotonergic and NE reuptake inhibitors induce desensitization and downregulation of 5-HT and NE receptors, leading to disinhibition of serotonergic neurons, interruption of feedback inhibition, and increased release of synaptic 5-HT.

MAOIs inhibit the activity of MAO, a flavin-containing enzyme located in the mitochondrial membranes of most tissues [30]. MAO enzymes are divided into two families: MAO-A, which uses 5-HT as its predominant substrate, and MAO-B, whose primary substrates are 2-phenylethylamine, benzylamine, phenylethanolamine, and *O*-tyramine. Monoaminergic neurons contain predominantly MAO-A; serotonergic neurons have both. MAO-A metabolizes epinephrine, NE, metanephrine, and 5-HT. Both MAO-A and MAO-B metabolize tyramine, octopamine, and tryptamine [31]. MAO regulates intraneuronal catecholamine metabolism and mediates the oxidative deamination of epinephrine, NE, dopamine, and 5-HT. MAO also regulates ingested monoamine (tyramine, ethanolamine) in the gut that would normally be absorbed into the portal circulation [20,21]. The effect of MAOs is to increase the catecholamine storage pool by preventing intraneuronal degradation of catecholamines and 5-HT. These catecholamines can be released by indirectly acting sympathomimetic agents (e.g., amphetamine, tyramine, and dopamine). MAO-A is predominantly found in the intestinal mucosa, placenta, biogenic nerve terminals, liver, and brain, whereas MAO-B is found in the brain, platelets, and liver [22]. Exogenously administered catecholamines are metabolized through catechol-*O*-methyl transferase (COMT).

MAOIs can be divided into reversible agents (moclobemide) or irreversible (selegiline, phenylzine, isocarboxazid, and tranylcypromine). They may also be selective to MAO-A (moclobemide) or MAO-B (pargyline, selegiline). The original MAOIs (e.g., phenelzine, isocarboxazid, and tranylcypromine) are nonselective irreversible MAO-A and MAO-B inhibitors., selegiline [23]. Selegiline and tranylcypromine are metabolized to desmethylselegiline, levoamphetamine, and levomethamphetamine and will give a positive amphetamine on drugs of abuse urine screening [32].

TABLE 123.4

INTERNATIONAL UNION OF PHARMACOLOGICAL SOCIETIES COMMISSION ON SEROTONIN NOMENCLATURE[a]

Receptor	Second messenger	Location	Agonist	Effect	Antagonist	Effect
5-HT_{1A}	cAMP	CNS	Buspirone	Anxiolytic	—	—
5-HT_{1B} (rodent only)	cAMP	CNS, PNS	mCPP	—	—	—
5-HT_{1C}	cAMP	CNS	—	—	Ritanserin	Anxiolytic
5-HT_{1D}	cAMP	CNS and extracerebral vascular smooth muscle	Sumatriptan, methylsergide	Antimigraine	—	—
5-HT_{1E}	cAMP	CNS	Ergotamine	—	Methylsergide	—
5-HT_{1F}	cAMP	CNS	Ergotamine	—	Methylsergide, yohimbine	—
5-HT_{2A}	IP_3DG	Vascular smooth muscle	—	Hypertension	Ketanserin, ritanserin	Hypotension
5-HT_{2B}	IP_3DG	Stomach	Tryptamine	—	—	—
5-HT_{2C}	IP_3DG	CNS, choroid plexus	mCPP (trazodone metabolite)	—	—	—
5-HT_3	Ionic channel	CNS, PNS	—	—	Ondansetron, granisetron	Antiemetic
5-HT_4	cAMP	Cardiac (nonventricular), gastrointestinal tract, bladder	Renzapride, cisapride	Gastric motility	—	—
5-HT_5–5-HT_7	cAMP	—	—	—	—	—

[a]All 5-HT receptors are G-proteins except for 5-HT_3 receptors, which are ionic channel receptors. 5-HT_1 are negatively coupled to adenylyl cyclase; 5-HT_2 are coupled to protein kinase C via phosphoinositide breakdown; 5-HT_3 are ionic channels; 5-HT_4, 5-HT_6, and 5-HT_7 are positively coupled to adenylyl cyclase.

cAMP, 3′,5′-cyclic adenosine monophosphate; CNS, central nervous system; 5-HT, serotonin; IP_3DG, inositol triphosphodiglyceride; mCPP, *m*-chlorophenyl piperazine; PNS, peripheral nervous system.

Cyclic antidepressants are well absorbed orally in therapeutic dosing; peak serum levels occur 2 to 6 hours after ingestion [33]. In overdose [33,34], gastrointestinal (GI) absorption may be delayed secondary to anticholinergic and antihistaminic properties of these drugs. Metabolism is predominately hepatic, with a small enterohepatic circulation [35,36]. Some cyclic antidepressants have active metabolites. The volume of distribution is large, with distribution occurring within the first several hours after ingestion [36]. Elimination half-life averages 8 to 30 hours but may be prolonged in overdose [37]. Elimination is hepatic, with minimal renal involvement. Fluoxetine has an active metabolite with an elimination half-life that extends into weeks. Cyclic antidepressants are extensively bound to serum proteins, particularly α_1-acid glycoprotein (AAG), and binding appears to be pH dependent [38]. MAO inhibitors are well absorbed orally with relatively short elimination half-lives [32]. Since the irreversible agents permanently inhibit the activity of MAO, their effects can last 4 to 6 weeks.

Toxicity from cyclic antidepressants results in CNS depression, seizures, hypotension, dysrhythmias, and cardiac conduction abnormalities [38]. Hyperthermia may occur as a result of increased muscle activity, seizures, and autonomic dysfunction [39]. These toxic effects are believed to have multiple etiologies, none of which has been fully elucidated.

Patients who ingest large amounts of cyclic antidepressants frequently present with hypotension. Several mechanisms have been suggested, including direct negative inotropic effects [17,25] and dysrhythmias, with subsequent decreases in filling time and cardiac output [39–41]. Receptor blockade produces vasodilation and autonomic dysfunction. In addition, blockade of the biogenic amine pump prevents adequate uptake and release of these neurotransmitters as active substances, thereby contributing to hypotension [11,16,40].

The CNS effects in cyclic antidepressant overdose can be quite profound. Although some of the newer cyclic antidepressants are less toxic in overdose, they can cause seizures and alteration in mental status [8,42,43]. The etiology of coma, seizures, and myoclonus is multifactorial and involves receptor blockade and direct membrane effects which all contribute to CNS derangements [42–45]. Cyclic antidepressants interact with both the $GABA_A$ and $GABA_B$-chloride ion channel in the CNS and may alter chloride flow across the receptor [46–48].

Dysrhythmias and conduction abnormalities often provide a clue to the recognition of cyclic antidepressant overdose. Action potential propagation, particularly in ventricular myocardial cells and the conduction system, is significantly affected by these drugs [49]. Cyclic antidepressants blunt phase 0 of the action potential depolarization by blocking the fast inward flux of sodium through the sodium channel [50]. This, in turn, slows the rate of rise of phase 0 (V_{max}) and slows overall action potential depolarization. As ventricular conduction slows, the QRS complex widens [50–52]. This also contributes to unidirectional blocks and reentrant dysrhythmias [52]. Because inward sodium flux is coupled to the calcium excitation in myocardial cells, the myocardial cells are unable to contract fully and become less efficient. A less toxic effect is seen on phase 4 of the action potential (spontaneous diastolic depolarization), leading to decreased automaticity [49]. Delayed repolarization occurs and may contribute to QTc interval prolongation,

which has been associated with torsades de pointes [53–56]. Because cyclic antidepressants have their tightest myocardial binding during diastole, toxicity appears to be directly related to heart rate; in amitriptyline-poisoned dogs, increasing heart rate caused a decrease in V_{max} and widened the QRS complex [50–52,57,58]. Interventions that slowed the heart rate, such as beta-blockers, improved conduction but led to irreversible hypotension [53,57].

The decrease in V_{max} during phase 0 appears to be pH sensitive [51,53,58]. Alkalinization with molar sodium lactate, sodium bicarbonate, or hyperventilation, or increasing extracellular sodium concentration, produces an increase in the rate of rise of the action potential (V_{max}), narrows the QRS complex, decreases the incidence of ventricular tachycardia, and improves blood pressure [53,58–65]. These studies also show that decreasing pH worsens conduction abnormalities, produces hypotension, and increases the incidence of dysrhythmias. A combination of increased extracellular sodium and alkalosis (or hyperventilation plus sodium bicarbonate) in vitro has been shown to be equally and possibly more effective than either alone [52,58]. The use of lidocaine in animal studies decreased automaticity and ectopy and improved conduction. However, it did not have the same salutary effect on the blood pressure as alkalinization and may have worsened inotropy [58]. Although binding of cyclic antidepressants to AAG is increased at an alkalotic pH, infusion of AAG in animals to increase serum protein binding has not been shown to be beneficial [38].

SSRI toxicity results from exaggeration of its pharmacologic activity and is manifest as the serotonin syndrome. The pathophysiology is not fully understood but is believed to result from excessive 5-HT_{1A} stimulation, although dopamine and other neurotransmitters may be involved. The serotonin syndrome is associated with SSRI use alone, change in dose, overdose, or in combination with other agents [e.g., serotonin precursor or agonists, lithium, tricyclic antidepressants, 5-HT analogs, other SSRIs, meperidine, pentazocine, tramadol, cocaine, 3,4-methylenedioxy-*N*-methylamphetamine (Ecstasy), MAOIs, and herbal remedies such as St. John's Wart].

Two forms of toxicity are caused by MAOI: acute overdose and drug and food interactions. Toxicity from acute MAOI overdose results from the exaggerated pharmacologic effects of MAOI and may be associated with secondary complications [66]. The primary drug-drug interaction occurs when MAOI is taken with an indirectly acting sympathomimetic agent (e.g., ephedrine, phenylephrine, phenylpropanolamine, and amphetamine), which causes an NE surge in the peripheral sympathetic nerve terminals. MAOI and food interaction primarily involve the small amounts of tyramine or tryptophan that are normally present in certain foods (e.g., aged cheeses, smoked or pickled meats, yeast and meat extracts, red wines, Italian broad beans, pasteurized light and pale beers, and ripe avocados) and are often termed the *cheese reaction*. These indirectly acting agents are usually metabolized by MAO-A in the gut. When MAO-A is inhibited, tyramine absorption is unregulated, enters into the portal circulation, and causes release of stored catecholamines with resultant hypertensive response [67,68].

CLINICAL TOXICITY

The onset of symptoms from cyclic antidepressant overdose is rapid. Most patients who die from overdose do so before arriving at the hospital and after having ingested large (> 1 g) amounts of drug [66]. Signs and symptoms usually occur within the first 6 hours after ingestion. Patients who survive the first 24 hours without hypoxic insult generally do well [66]. The progression of toxicity is rapid and unpredictable, with patients capable of deteriorating from an awake, alert state to seizures, hypotension, and dysrhythmias within 30 to 60 minutes and with minimal warning signs [6,69–75]. Cardiac arrest due to cyclic antidepressant poisoning may sometimes respond to prolonged resuscitative efforts. One case reports a patient who survived after a resuscitation of approximately 70 minutes [76].

Vital signs on presentation usually include tachycardia, although patients taking beta-blockers or those with underlying conduction blocks, or those in a premorbid state may present with bradycardia. Cyclic antidepressants without major antimuscarinic effects, such as trazodone, nefazodone, and the SSRIs, may not cause significant tachycardia. Bupropion-toxic patients almost always have vital signs reflecting a hyperadrenergic state [77–79]. Initial blood pressure may be elevated but can rapidly change to hypotension. The respiratory rate and body temperature may be elevated. If marked myoclonus or seizures develop, severe hyperthermia may result [39,43,71]. Cyclic antidepressants with prominent antimuscarinic effects may cause mydriasis, urinary retention, ileus, and cutaneous vasodilation (Table 123.2). Absence of these signs does not rule out cyclic antidepressant ingestion.

Dependent on the ingested agent, progression of toxicity may be precipitous and lead to coma, hypotension, seizures, dysrhythmia, and death. The newer agents (e.g., nefazodone, trazodone, the SSRIs) are more likely to be sedating and less likely to exhibit cardiovascular toxicity [69,70,73–75]. Maprotiline, venlafaxine, amoxapine, and loxapine tend to cause CNS toxicity before cardiovascular toxicity [71,80–92]. Bupropion may cause seizures in therapeutic dosing and exhibits a dose-dependent increase in toxicity (greater than 450 mg) [77,93,94]. With the cyclic antidepressants, it is unusual for patients to have significant cardiovascular disturbances without an altered mental status [10].

Cyclic antidepressant-induced seizures are generally single or brief flurries of motor activity. However, status epilepticus may occur without any prodrome, and this is especially true with amoxapine, loxapine, or bupropion. Status epilepticus may be difficult to treat; if prolonged, it leads to overall deterioration in the patient's condition, particularly with cyclic agents [25,77,93–102].

Signs of cardiovascular toxicity may exist even with therapeutic dosing of classic cyclic antidepressants. A prolonged QTc interval and sinus tachycardia may be observed on the electrocardiogram (ECG) in non-overdose states [103]. Sinus tachycardia is frequently the presenting dysrhythmia; aberrancy and ventricular tachycardia develop with increasing toxicity. As cardiovascular toxicity progresses, the frontal plane axis shifts rightward. This is gradually followed by repolarization abnormalities, intraventricular conduction delays, ventricular dysrhythmia, high-grade atrioventricular blocks, profound bradycardias, and asystole [40,104–108]. Trazodone, citalopram, and escitalopram may cause marked QTc interval prolongation and torsades de pointes (polymorphous) ventricular tachycardia in the absence of other ECG abnormalities [109].

Many of the cyclic antidepressants show early changes to the ECG axis. The terminal 40 milliseconds of the frontal plane QRS complex shifts to a rightward vector of 130 to 270 degrees. If computerized vector analysis is not available, a widened slurred S wave in leads I and aVL and an R wave in aVR represent this vector. Looking for these changes in overdosed or comatose patients may help in establishing a diagnosis. However, a small portion of the population normally has this unusual vector. Patients with extreme leftward axis deviation as a baseline may not show the rightward change with cyclic antidepressant toxicity [70,74,99,110–113]. The absence of this finding does not rule out a classic cyclic antidepressant poisoning; its presence with coma, seizures,

dysrhythmias, or hypotension is very suggestive of cyclic antidepressant toxicity [69].

The serotonin syndrome varies from mild to life threatening. Classic manifestations are altered mental status, autonomic dysfunction, and neuromuscular irritability. Signs and symptoms include tachycardia, unstable blood pressure, hyperthermia, mydriasis, diaphoresis, blurred vision, nausea, vomiting, diarrhea, shivering, tremor, incoordination, hyperreflexia, myoclonus, rigidity, agitation, confusion, delirium, seizure, and coma. Lactic acidosis, rhabdomyolysis, myoglobinuria, and multiorgan failure may develop in severe cases [101,114,115].

SSRIs, except for venlafaxine, citalopram, and escitalopram [101,109], are expected to have minimal cardiac effects. Citalopram, escitalopram, and ritanserin may significantly affect the QTc with at least one case of arrhythmia reported from citalopram [109]. Overdoses with extremely large amounts of fluoxetine and citalopram have caused atrial fibrillation and bradycardias. Evidence of Na^+ and Ca^{2+} channel blockade has been shown at extremely high serum levels [89]. Animal experiments with paroxetine required much larger doses, compared to amitriptyline, to induce dysrhythmias [6,7,82–89,91].

The onset of MAOI and food or drug interaction usually occurs within 30 to 60 minutes of ingesting the offending substance. Signs and symptoms of this type of reaction include hypertension, tachycardia or reflex bradycardia, severe (occipital) headache, nausea and vomiting, hyperthermia, altered mental status, seizures, intracranial hemorrhage, and death.

Patients with acute MAOI overdoses may be asymptomatic on presentation. Signs and symptoms typically develop within 6 to 12 hours of ingestion if the person is on the medication chronically but may be delayed for 24 hours if this is a new medication for the patient. An initial stage of neuromuscular excitation such as agitation, tremors, myoclonus, and hyperreflexia with hypertension usually occurs. The face may be flushed. As toxicity progresses, the mental status deteriorates, and there is a general elevation of all vital signs. Seizures may develop. As monoamine neurotransmitters become depleted, hypotension and cardiovascular collapse may ensue. Respiratory depression may occur and the mental status will deteriorate. If the patient survives this progression, there may be secondary complications from rhabdomyolysis, electrolyte abnormalities, lactic acidosis, and multiple organ system failure. Toxicity may last for up to 72 hours [66]. MAOI ingestions can be very challenging to manage as the patient can variably show either a hyperadrenergic state or a catecholamine depleted state. The swings in the vital signs can be rapid, unexpected, and uncontrolled [116–118].

Secondary complications, such as noncardiogenic pulmonary edema, aspiration pneumonia, and rhabdomyolysis, frequently develop in patients with antidepressant overdoses. Overdoses with agents that have prominent antimuscarinic properties (e.g., amitriptyline) may cause urinary retention, ileus, and abdominal distention. Although rare, tardive dyskinesia, neuroleptic malignant syndrome, and the syndrome of inappropriate antidiuretic hormone secretion all have been reported in association with cyclic antidepressant overdose [39,119–122]. In addition to causing seizures and cardiovascular toxicity, venlafaxine may cause direct muscle toxicity leading to severe rhabdomyolysis [123].

In therapeutic doses, cyclic antidepressant agents and SSRIs may interact with other medications, increasing the effect of one or both agents. This effect may be magnified after an overdose. Drug interactions may alter metabolism, elimination, or the free fraction of the drug. Most antidepressants are metabolized through the CYP 2D6 microsomal agents and as such, are subject to induction and interference. Agents that stimulate the hepatic P450 microsomal system (phenobarbital, carbamazepine, phenytoin, and rifampin, and cigarette smoking) increase the clearance of cyclic antidepressants. Cimetidine, as a competitor for the hepatic microsomal enzymes, leads to an increase in cyclic antidepressant levels. The coadministration of cyclic antidepressants and antipsychotic agents may lead to competitive inhibition of the metabolism of both drugs. Other medications that increase the steady-state levels of cyclic antidepressants include chloramphenicol and disulfiram, whereas erythromycin decreases the level. Acute ethanol intoxication may decrease cyclic antidepressant metabolism, resulting in markedly prolonged serum drug half-life [106].

Patients taking MAOIs should avoid any agents that have serotonergic effects or act as indirect sympathomimetics (e.g., amphetamine, ephedrine, dopamine, phenylpropanolamine, meperidine, tramadol, dextromethorphan, and St. John's wort) [124–126]. Similar effects have been reported with paroxetine with the use of phenobarbital, cimetidine, and phenytoin. The potential exists for the potentiation of warfarin effect when they are administered in conjunction with paroxetine. The interaction of fluoxetine and cyclic antidepressants causes an increase in serum levels of the cyclic antidepressant and can lead to cyclic antidepressant toxicity. Therapeutic administration of an SSRI and a cyclic antidepressant with strong serotonergic effects (e.g., clomipramine) or two SSRIs may induce the serotonergic syndrome. The interaction of MAOIs and cyclic antidepressants may lead to significant and life-threatening toxicity, particularly with those antidepressants that have predominantly serotonergic effect (trazodone, clomipramine, and the SSRIs) [29]. The administration of the selective MAO-B inhibitor selegiline with an SSRI or a cyclic antidepressants does not appear to have as strong a serotonergic effect but still may cause drug interactions [127].

Although the differential diagnosis includes many substances that share some of the effects of cyclic antidepressants, duplicating the entire constellation of signs and symptoms is relatively unusual. Like cyclic antidepressants, anticholinergic and antihistaminic medications can cause dilated pupils, GI hypomotility, confusion, and seizures. Phenothiazines also cause these effects and may increase the QTc. Thioridazine and mesoridazine, two phenothiazines, prolong the QRS and QTc. The atypical neuroleptics (risperidone and olanzapine) have similar sedative, cardiac, and movement effects. Other drugs that affect QRS width include type IA antiarrhythmics (quinidine, procainamide, and disopyramide) and type IC antiarrhythmics (flecainide, encainide, and propafenone). Hyperkalemia and hypocalcemia also widen the QRS complex, and the latter can cause muscle twitching and myoclonus. Beta-blockers, particularly propranolol, cause seizures and conduction abnormalities in overdose. Tramadol, an opiate analgesic that also causes biogenic amine reuptake inhibition, may cause opioid and serotonergic toxicity, especially when given in conjunction with an SSRI or MAOI. Cyclobenzaprine, a muscle relaxant, and carbamazepine share the cyclic antidepressant structure and can cause a similar picture with sedation, hypotension, and prolonged QTc interval.

DIAGNOSTIC EVALUATION

Patients with suspected cyclic antidepressant overdose should have routine blood analyses. Stress leukocytosis may occur with any antidepressant overdoses, especially if seizures have occurred. Electrolyte, blood urea nitrogen, creatinine, and glucose levels should be determined, with special attention to the anion gap. Because rhabdomyolysis may occur, most frequently with seizures, creatinine kinase should be followed [39,119]. Urinalysis is also useful in the diagnosis of rhabdomyolysis and possible myoglobinuric renal failure. Frequent ECGs are a necessity and should be done any time that the patient has a change in status. Arterial blood gas and chest radiograph should be obtained as clinically indicated. Since repetitive arterial sampling may be extremely painful and is sometimes

TABLE 123.5

DRUGS THAT MAY INTERFERE WITH THE TRICYCLIC ANTIDEPRESSANT QUALITATIVE DRUG SCREEN

Drugs	Minimal serum concentration level
Carbamazepine	Therapeutic range
Chlorpromazine	Therapeutic range
Cyclobenzaprine	10 to 20 µg/L
Cyproheptadine	390 to 400 µg/L
Diphenhydramine	>120 µg/L
Quetiapine	Therapeutic range
Thioridazine	Therapeutic range

associated to complications such as infection, injury, and thrombosis [128], and since venous pH has shown to strongly correlate that of an arterial sample in cyclic antidepressant overdose [128], using venous blood for the serial measurement of serum pH is recommended.

Quantitative tricyclic antidepressant levels rarely if ever contribute to the clinical patient management. Although total tricyclic levels of more than 1,000 ng per mL have been associated with significant toxicity [33,36,69,105,108], there is poor correlation between toxicity and serum level. Repeated levels during resolution of toxicity may be misleading; physical signs of toxicity abate before a significant drop in serum levels because of the prolonged elimination half-life and extensive protein binding [36]. A qualitative screen using a tricyclic antidepressant immunoassay is usually sufficient. However, other drugs that have structural similarity can produce a false-positive result (Table 123.5) [129–135] and if clinical findings are inconsistent with immunoassay results, it may be necessary to perform a more specific test such as gas chromatography with mass spectrometry. Although a toxicology testing is discretionary, acetaminophen and salicylate levels and a pregnancy test in a woman of childbearing age should always be checked.

MANAGEMENT

Patients who have ingested cyclic antidepressants require immediate evaluation and stabilization. Those who are awake and alert should receive an oral dose of activated charcoal. Patients who have ingested a classic agent (amitriptyline, nortriptyline, imipramine, desipramine, clomipramine, doxepin, dothiepin, protriptyline, and maprotiline) can be safely observed in the emergency department if they are asymptomatic. An asymptomatic patient implies one with a normal ECG throughout the observation period, a mild sinus tachycardia that resolves within the first 1 to 2 hours, clear mental status, and a nontoxic acetaminophen level. This observation period is defined as a 6-hour interval during which the patient is on continuous ECG monitoring and has intravenous access in place [49,105,119,120,136,137,139,141]. In addition, these patients must have had adequate GI decontamination and, preferably, have passed a charcoal stool. Patients should always be referred for psychiatric evaluation and pregnant women should be directed to prenatal counseling.

No consensus has been reached on emergency department observation for patients with ingestions of bupropion, trazodone, nefazodone, venlafaxine, and the SSRIs because of the paucity of overdose data for these medications [80,82,141,142]. Observation of asymptomatic patients for 6 to 8 hours or until the ECG returns to normal or baseline is reasonable. Any patient with signs or symptoms of toxicity should be admitted to the intensive care unit. Admission (or prolonged observation) is also prudent for patients with sustained-release bupropion overdose, as seizures have been reported as far as 12 to 16 hours after ingestion [141].

Symptomatic patients should have a rapid evaluation of the airway and, if obtunded or hypoventilating, be immediately intubated. Because cyclic antidepressant toxicity increases with acidemia, an ABG demonstrating a pH <7.4 or hypercarbia should prompt intubation and hyperventilation even in the patient who is able to protect his or her airway. Once an airway is established, the patient should be appropriately ventilated to prevent respiratory acidosis and subsequent deterioration of his or her condition. If the patient has an altered mental status, a rapid bedside determination of serum glucose or administration of 25 to 50 g dextrose (0.5 to 1.0 g per kg), 2 mg naloxone, and 100 mg thiamine should be given intravenously [34].

GI decontamination for severely ill patients should consist of activated charcoal with or without gastric lavage. Because some cyclic antidepressants have a small enterohepatic circulation, an additional one to two doses of aqueous charcoal (25 g) may be considered [36,138–140]. This dose should not be administered in the presence of an ileus or gastric distention. Because the majority of these agents are extensively protein bound, hemodialysis and hemoperfusion are not effective in reducing the toxic effects of cyclic antidepressants [143–146].

Single or brief flurries of seizures should be treated with a benzodiazepine [26,45,143]. Seizures are frequently isolated, and the additional use of an anticonvulsant is not indicated in this situation. Status epilepticus should be aggressively managed to prevent the development of acidosis, hyperthermia, and rhabdomyolysis [26]. As cardiotoxicity worsens dramatically in the presence of acidemia, rapid control of seizures is mandatory. Status epilepticus should be managed with large doses of benzodiazepines [143]. Failing this, management becomes controversial. Administering a nondepolarizing short-acting neuromuscular blocking agent such as vecuronium along with a barbiturate anticonvulsant (e.g., phenobarbital, 15 to 20 mg per kg, or thiopental, 3 to 5 mg per kg) is one option [146,148]. Chemical paralysis helps treat or prevent hyperthermia, rhabdomyolysis, acidosis, and further deterioration. If available, continuous electroencephalographic monitoring should be used. If the patient continues to have seizure activity once the paralytic has worn off, an additional dose of vecuronium should be given and an alternative anticonvulsant or general anesthesia should be administered [26,81,146–149]. Propofol may be useful since it has both GABA and NMDA activity but there are no data on its use in this setting. Serum alkalinization does not affect seizure activity [146].

Hypotension often responds to fluid resuscitation. Because concomitant acidosis or abnormal cardiac conduction is often present, a sodium bicarbonate solution can be used for both fluid resuscitation and serum alkalinization. A solution of 1,000 mL dextrose 5% in water with 150 mEq $NaHCO_3$ (roughly equivalent to 0.9% NaCl) is suggested. The rate of fluid administration should be adjusted to maintain a serum pH of 7.45 to 7.55 without causing hypernatremia. In an adult, an initial rate of approximately 200 to 300 mL per hour (1.5 to 2.0 times maintenance fluids) is usually adequate. Many clinicians give boluses of sodium bicarbonate (44 to 50 mEq per bolus) to achieve the same effect.

In the event of refractory hypotension, invasive monitoring (arterial line, central venous pressure, or Swan–Ganz catheterization) may be necessary. Pressor therapy with direct-acting sympathomimetics, such as NE (Levophed™), phenylephrine (Neo-Synephrine™), or epinephrine, has been shown to be more effective than indirect-acting agents, such as dopamine [26,142,150,151]. In experimental rat models, the combination of epinephrine and sodium bicarbonate increased survival and decreased the frequency of arrhythmias [142]. Moreover, this duo drug regimen was found to be more efficacious than the

combination of sodium bicarbonate and norepinephrine [152]. If hypotension remains refractory, an inotropic agent such as dobutamine may be required [142,150,151]. If the patient still persists with severe hypotension, then the use of vasopressin in addition to the use of fluids, bicarbonate, and vasopressors may be warranted. Vasopressin has been shown to sustain blood pressure and improve organ perfusion in several critical care settings, including once case study that showed immediate success in a patient who overdosed on amitriptyline [152,153]. Unlike other conventional treatments that are dependent on the catecholamine receptors, vasopressin works directly on the smooth muscle causing an influx of calcium into the cell, resulting in vasoconstriction [154]. This mechanism is mediated via the G-receptor protein, called V1. The dose required to see significant improvement is still unclear, but most authors suggest dose < 0.4 U per minute to minimize the possible adverse effects such as end organ vasoconstriction and platelet aggregation [155].

Abnormal conduction (QRS complex > 100 milliseconds in the limb leads) and ventricular dysrhythmias are treated with alkalinization. A combination of sodium bicarbonate infusion and hyperventilation may be more useful than either alone, although hyperventilation is effective if the patient cannot tolerate the sodium load [51,58,60,62,150]. By combining the two modalities, the arterial partial pressure of carbon dioxide can be maintained at approximately 30 to 35 mm Hg, which prevents cerebral vasoconstriction, while serum sodium is kept within reasonable limits. Optimal arterial pH is between 7.45 and 7.55. Ventricular dysrhythmias that are not responsive to alkalinization may respond to lidocaine or hypertonic saline. Other than β-adrenergic blockers, no antidysrhythmics have been studied; although phenytoin has been used anecdotally (see the Controversies section). In animal studies, propranolol was effective in improving conduction but led to intractable hypotension [51,58,59]. Other type IA and IC antidysrhythmics are contraindicated because they worsen cardiotoxicity. Amiodarone, a class III antidysrhythmic, was found to be of no benefit in TCA-poisoned animal models. In addition, it was felt that the use of amiodarone may have been detrimental because it can further prolong the QTc interval and cause negative inotropy [156]. The successful use of magnesium sulfate was reported in a 23-month-old child who presented with ventricular tachycardia after ingesting unknown amounts of amitriptyline. The child had received normal saline, lidocaine, bicarbonate infusion, and cardioversion without effect. Subsequent magnesium sulfate resulted in normalization of the cardiac rhythm and clinical improvement [76]. Overdrive pacing is another option, but controlled studies are lacking [54].

More recently, the use of intralipids in the clinical scenario of lipid-soluble drug toxicity such as local anesthetics and calcium channel blockers, have been gaining wide acceptance in the practice of critical care and emergency medicine [144,157–160]). Numerous studies have demonstrated significant cardiovascular improvement with severe lipid-soluble drug toxicity when infused with lipid emulsions. Most cyclic antidepressants are lipid soluble and produce significant cardiovascular instability and collapse that may be refractory to standard measures and sodium bicarbonate therapy. In animal models, infusion with intralipids proved to be more potent in reversing cardiac arrest and hypotension and also preventing further cardiovascular collapse [144,157]. Currently, there are two theories that explain why lipid emulsions may be effective. The first theory is based on the fact that the intralipids create a lipid basin that sequesters lipid-soluble drugs away from their site of action. The second theory is that lipid emulsions provide relief to a stressed myocardium by providing high energy to the heart [157,158]. This concept is similar to the use of high-dose insulin regimen for calcium channel blockers toxicity. In conclusion, intralipid infusion should be strongly considered when conventional treatments such as oxygen therapy, fluids, vasopressors, and sodium bicarbonate have failed to provide significant results.

Treatment of the serotonin syndrome is primarily supportive. Sedation, paralysis, intubation and ventilation, anticonvulsants, antihypertensives, and aggressive rapid cooling may all be necessary. Some success has been achieved with the nonspecific serotonin antagonist cyproheptadine (4 to 12 mg every 8 hours orally or 4 mg per hour) [114,115]. Dopamine-2-receptor antagonists, such as haloperidol, have occasionally been effective, but safety and efficacy data are lacking. Bromocriptine increases brain serotonin levels and is contraindicated, and dantrolene may enhance brain 5-HT metabolism and should not be used.

Any patient with an acute MAOI overdose or persistent signs and symptoms from food or drug interactions should be admitted to an intensive care setting for at least 24 hours. Therapy for food or drug interactions is aimed at lowering the blood pressure. A rapidly direct-acting agent that is easy to titrate is recommended (e.g., nitroprusside or nitroglycerine).

Treatment of MAOI overdose is entirely supportive. Muscular hyperactivity and seizures are treated with high-dose benzodiazepines. Hyperthermia that does not respond to benzodiazepine therapy and cooling requires rapid-sequence intubation and paralysis with a nondepolarizing agent to completely shut down muscle activity. Bromocriptine should not be used, as it has drug interactions and is an uncontrolled D_2 agonist and stimulant. Dantrolene is ineffective as it works peripherally and does not affect the central causes of hyperthermia [66,161–163]. Symptomatic or severe cardiovascular (sympathetic) hyperactivity should be treated with agents that have readily reversible effects and can be titrated to response. Agents such as nitroprusside, nitroglycerine, and esmolol are recommended. Nicardipine can also be used. For cardiovascular depression, direct-acting agents, such as epinephrine, norepinephrine, and isoproterenol, are preferred. Although MAO inhibition may prolong their effects, these agents are also metabolized by catechol-*O*-methyltransferase.

With the exception of MAOI overdosed patients, those who survive the first 24 hours without major complications (hypoxia, prolonged seizures, profound acidosis, and hyperthermia) generally do well. Most patients show some improvement within 24 hours. Once cardiac conduction improves (narrowing of QRS complex to 100 milliseconds), alkalinization can be discontinued (usually within 12 hours) and the pH allowed to normalize. If the QRS complex again widens, alkalinization should be resumed and the weaning process repeated. Once the ECG has normalized without alkalinization, the patient should be monitored for an additional 12 to 24 hours in the intensive care unit. The patient should be awake and alert and have passed a charcoal stool before transfer out of the unit. All overdose patients should be referred for psychiatric evaluation before discharge [6,104–106].

OTHER MANAGEMENT CONSIDERATIONS

Controversial or investigational therapies for cyclic antidepressant poisoning include phenytoin, physostigmine, prophylactic alkalinization, mechanical cardiovascular support, antibody therapy, and adenosine antagonists. Although phenytoin binds to voltage-dependent Na^+ channels and prevents propagation of seizures, it has no GABA effect and does not prevent toxic seizures. Some animal studies suggested that phenytoin was effective but others did not [151,164]. Studies using phenytoin to improve cardiac conduction were poorly controlled and not reproducible [105,147,164–166]. Canine data showed that

phenytoin transiently facilitates conduction but then increases the incidence and duration of ventricular tachycardia and does not improve survival, suggesting that phenytoin is potentially detrimental [164].

Physostigmine (see Chapter 121) has been used to antagonize the antimuscarinic effects of cyclic antidepressants such as agitated delirium [147,167–169]. However, bradycardia and asystole have been reported with physostigmine in the presence of aberrant conduction, and as a carbamate, it may precipitate seizures [65]. Thus, physostigmine is not advocated to treat acute cyclic antidepressant overdose [169] and is contraindicated in those with cardiac conduction disturbances.

No studies have been done regarding prophylactic alkalinization in patients with normal cardiac condition. Because altering the pH alters the reliability of the QRS width as a predictor of cardiotoxicity, such therapy is not recommended. Alkalinization is also not without risks, including hyperosmolality, cerebral vasoconstriction, and alterations in ionized calcium concentrations. There is no evidence that it affects the seizure threshold.

In moribund patients in whom conventional therapy has failed, the use of mechanical circulatory support, such as intraaortic balloon pump assist or partial cardiac bypass, may be life-saving. In this situation, the use of extracorporeal measures supports myocardial, hepatic, and cerebral perfusion while allowing the liver endogenously to detoxify the cyclic antidepressant [170].

Adenosine receptors may be involved in cyclic antidepressant-induced cardiovascular toxicity. Adenosine receptor activation has been shown to cause peripheral vasodilation, decrease in cardiac output, and degranulation of mast cells [171]. In animals with cyclic antidepressant poisoning, adenosine receptor antagonists have reversed hypotension and QRS prolongation [171].

CHAPTER 124 ■ ANTIPSYCHOTIC POISONING

MICHAEL J. BURNS AND CHRISTOPHER H. LINDEN

Antipsychotic agents, sometimes termed *neuroleptics* and *major tranquilizers*, are primarily used to treat schizophrenia, the manic phase of bipolar disorder, and agitated behavior. They are also used as preanesthetics and to treat drug-associated delirium and hallucinations, nausea, vomiting, headaches, hiccups, pruritus, Tourette's syndrome, and a variety of extrapyramidal movement disorders (e.g., chorea, dystonias, hemiballismus, spasms, tics, torticollis). Antipsychotics are a structurally diverse group of heterocyclic compounds; more than 50 different drugs are available for clinical use worldwide with numerous others in various stages of development. Classes include benzamide, benzepine, butyrophenone (phenylbutylpiperidine), dibenzo-oxepino pyrrole, diphenylbutylpiperidine, indole, phenothiazine, quinolinone, rauwolfia alkaloid, and thioxanthene derivatives (Table 124.1). The phenothiazine and thioxanthene classes are further subdivided into three groups (aliphatic, piperazine, and piperidine) based on central ring side-chain substitution.

Although traditionally classified by structure, antipsychotics are more ideally classified by pharmacologic profile. Each agent has a unique receptor-binding profile (Table 124.2), and this profile can be used to predict adverse effects in both therapeutic and overdose situations [1–3]. Clinical toxicity is the result of exaggerated pharmacologic activity. Antipsychotics are also classified as *typical* or *atypical* (Tables 124.1 and 124.2). Traditional or conventional antipsychotics, which readily produce extrapyramidal signs and symptoms (EPS) at antipsychotic doses, are considered typical. Newer agents that have minimal extrapyramidal side effects at clinically effective antipsychotic doses are effective for treating the negative symptoms (e.g., alogia, avolition, social withdrawal, flattened affect) of schizophrenia and have a low propensity to cause tardive dyskinesia with long-term treatment are considered atypical [1–4]. The characterization of antipsychotics as typical or atypical is ultimately determined by receptor binding. One or more of several different receptor-binding characteristics are associated with drug atypia, and each agent is atypical for different reasons [4,5]. Understanding how specific receptor-binding characteristics produce clinical effects has facilitated the development of antipsychotics that separate antipsychotic activity from other activity, thus minimizing adverse effects and maximizing patient compliance.

Antipsychotic toxicity may occur as an idiosyncratic reaction during therapeutic use or following accidental or intentional overdose. Central nervous system (CNS) and cardiovascular disturbances are the most common dose-related toxic manifestations, but other effects include the anticholinergic syndrome (see Chapter 121) and various extrapyramidal syndromes. Therapeutic use has been associated with agranulocytosis, aplastic anemia, diabetes mellitus, hepatotoxicity, hypertriglyceridemia, fatal myocardial infarction, myocarditis, neuroleptic malignant syndrome (see Chapter 66), pancreatitis, seizures, sleep apnea, sudden infant death syndrome, sudden adult death, venous thromboembolism, and vasculitis [21–29]. Most deaths are the consequence of suicidal overdose by psychotic or depressed adults and frequently involve mixed ingestions or ingestion of the agents chlorpromazine, loxapine, mesoridazine, quetiapine, or thioridazine [30,31]. Because of a large toxic to therapeutic ratio for most antipsychotics, fatalities rarely occur. In 2007, there were 46,239 antipsychotic exposures reported to United States poison centers, of which 41,607 (90%) were due to atypical agents and 4,632 (10%) were due to phenothiazines [32]. Major toxicity and death occurred in 1.1% and 0.02% of atypical agent exposures, and in 0.8% and 0.04% of phenothiazine exposures. From this data, death occurred in less than four patients for every 1,000 antipsychotic agent toxic exposures. Quetiapine was most commonly associated with fatality in both mixed and single substance ingestions but this may reflect usage pattern and not individual agent toxicity [32]. From another study, the most toxic antipsychotics result in death from poisoning for every 100 patient-years of use [30]. Dose-related effects are most pronounced in nonhabituated patients at the extremes of age.

Recent data has demonstrated that users of antipsychotic drugs have higher rates of sudden cardiac than do nonusers and former users of antipsychotic drugs [6]. The increased risk of sudden cardiac death is similar in magnitude for both typical and atypical agents, with adjusted incidence-rate ratios of 1.99 and 2.26, respectively, when compared with nonusers. For both classes of drugs, the risk of sudden cardiac death increases significantly with an increasing dose. Users of clozapine and thioridazine had the greatest increased of sudden cardiac death, with an adjusted incidence rate that was more than three times that for nonusers.

PHARMACOLOGY

Antipsychotics bind to and antagonize presynaptic (autoreceptors) and postsynaptic type 2 dopamine (D_2) receptors in the CNS and peripheral nervous system [7]. Initially, dopamine neurons increase the synthesis and release of dopamine in response to autoreceptor antagonism. With repeated dosing, however, depolarization inactivation of the neuron occurs, and decreased synthesis and release of dopamine occur despite ongoing postsynaptic receptor blockade [7,8].

All antipsychotics produce their therapeutic antipsychotic effect from mesolimbic D_2-receptor antagonism. D_2-receptor affinity (potency) in this region strongly correlates with the daily therapeutic dose (see Table 124.1) [1,4,9]. Simultaneous antagonism of other D_2 receptors produces additional clinical effects, the majority of which are undesirable. Mesocortical receptor blockade appears to create cognitive impairment and further worsens the negative symptoms of schizophrenia [10]. Excessive D_2-receptor blockade in mesocortical and mesolimbic areas, as occurs after neuroleptic overdose, may partly mediate CNS depression from these agents. Antagonism of nigrostriatal D_2-receptors produces EPS (e.g., acute dystonia, akathisia, parkinsonism). D_2-receptor potency in nigrostriatal relative to mesolimbic areas correlates with the likelihood of developing EPS [1,2,4,11,12]. Typical antipsychotics antagonize basal ganglia D_2 receptors in the same dose range necessary for limbic D_2-receptor blockade, thus creating high EPS liability [11,12]. The high-potency or typical agents (i.e., fluphenazine,

TABLE 124.1

CLASSIFICATION AND DOSING OF NEUROLEPTIC AGENTS

Structural class	Generic name (trade name)	Affinity of neuroleptic agent for dopamine (D_2) receptor (potency)[a]	Daily dose range (mg)
Typical agents			
Butyrophenone (phenyl-butylpiperidine)	Droperidol (Inapsine)	3+	1.25–30
	Haloperidol (Haldol)	2+	1–30
	Other: benperidol, bromperidol, melperone, pipamperone, trifluperidol[c]		
Diphenylbutylpiperidine	Pimozide (Orap)	2+	1–20
	Other: fluspirilene, penfluridol[c]		
Indole	Molindone (Moban)	1+	15–225
	Other: oxypertine[c]		
Phenothiazine			
Aliphatic	Chlorpromazine (Thorazine)	2+	25–2,000
	Promazine (Sparine)[b]	—	50–1,000
	Promethazine (Phenergan)	2+	25–150
	Triflupromazine (Vesprin)	—	5–90
Piperazine	Acetophenazine (Tindal)	—	40–400
	Fluphenazine (Prolixin)	3+	0.5–30
	Perphenazine (Trilafon)	3+	4–64
	Prochlorperazine (Compazine)	2+	10–150
	Trifluoperazine (Stelazine)	3+	2–40
	Thiethylperazine (Torecan)	—	10–30
Piperidine	Mesoridazine (Serentil)	2+	30–400
	Thioridazine (Mellaril, Millazine)	2+	20–800
	Other: diethazine, ethopropazine, levomepromazine, perazine, pipotiazine thiopropazate, thioproperazine, pericyazine[c]		
Thioxanthene	Chlorprothixene (Taractan)	2+	30–600
	Clopenthixol[c]	—	—
	Flupenthixol[c]	3+	4
	Thiothixene (Navane)	3+	6–60
	Zuclopenthixol (Cisordinol, Clopixol)[c]	3+	10–50
Atypical agents			
Benzamides	Amisulpride[c]	2+	100–1,200
	Raclopride[c]	3+	5–8
	Remoxipride[c]	1+	150–600
	Sulpiride[c]	2+	100–1,600
	Sultopride[c]	2+	100–1,200
	Trimethobenzamide (Tigan)[b]	—	100–600
	Other: epidepride, eticlopride levosulpiride, nemonapride, tiapride[c]		
Benzepine			
Dibenzodiazepine	Clozapine (Clozaril, Leponex)	1+	150–900
Dibenzo-oxazepine	Loxapine (Loxitane)	1+	20–250
Thienobenzodiazepine	Olanzapine (Zyprexa)	2+	5–20
Dibenzothiazepine	Quetiapine (Seroquel)	1+	300–600
Dibenzothiazepine	Zotepine[c]	2+	100–300
	Other: butaclamol, fluperlapine, clothiapine, metiapine, savoxepine[c]		
Indole			
Benzisoxazole	Risperidone (Risperdal)	3+	2–16
	Paliperidone (Invega)	3+	3–12
Imidazolidinone	Sertindole (Serlect)[c]	3+	12–24
Benzisothiazole	Ziprasidone (Zeldox)	3+	40–160
	Other: iloperidone[c]		
Pyrrole	Asenapine (Saphris)	3+	10–20
Quinolinone	Aripiprazole (Abilify, Abitat)	3+	10–30
	Bifeprunox[c]		

[a] A higher numerical value indicates greater binding affinity (greater antagonism) at D_2 receptor. Binding affinity (potency) at D_2 receptor correlates with daily dose range.
[b] Antiemetic only.
[c] Not available for clinical use in the United States.
0, minimal to none; 1+, low; 2+, moderate; 3+, high to very high.

TABLE 124.2

RELATIVE NEURORECEPTOR AFFINITIES FOR NEUROLEPTICS[a]

Neuroleptic agent	Receptor					
	H_1 Histaminergic	α_1-Adrenergic	α_2-Adrenergic	M_1 muscarinic	5-HT_{2A} serotonergic	EPS risk[b]

[a]Relative neuroreceptor affinity [neuroreceptor affinity at receptor X/dopamine (D_2)-receptor affinity] indicates relative receptor antagonism at therapeutic (D_2-blocking) antipsychotic doses.
[b]A higher M_1 and 5-HT_2 relative neuroreceptor affinity confers a lower EPS risk.
[c]Dose-dependent incidence of extra EPS.
Adapted from references [1–20].
0, minimal to none; 1+, low; 2+, moderate; 3+, high; 4+, very high; EPS, extrapyramidal side effects.

haloperidol, perphenazine, thiothixene, and trifluoperazine) are most commonly associated with EPS [1]. Atypical agents have low D_2-receptor potency and occupancy (i.e., clozapine, olanzapine, quetiapine) at therapeutic doses, are partial D_2-receptor agonists (e.g., aripiprazole), or are more site selective (i.e., sulpiride, raclopride) and preferentially antagonize limbic D_2 receptors [2–4,8,13]. Thus, they are less likely to cause EPS or worsen negative symptoms of schizophrenia at therapeutic doses.

D_2-receptor blockade in the anterior hypothalamus (preoptic area) may alter core temperature set point and block thermosensitive neuronal inputs and thermoregulatory responses [7]. Hypothermia or hyperthermia may result. D_2-receptor blockade in the pituitary (tuberoinfundibular pathway) results in sustained elevated prolactin secretion, which may cause galactorrhea, gynecomastia, menstrual changes, and sexual dysfunction (impotence in men) [1,11]. The antiemetic activity of antipsychotics results from similar inhibition of dopaminergic receptors in the chemoreceptor trigger zone (area postrema) of the medulla oblongata [7]. Antagonism of dopamine receptors present on peripheral sympathetic nerve terminals and vascular smooth muscle cells may produce autonomic dysfunction (i.e., tachycardia, hypertension, diaphoresis, pallor) [7,33–35]. Simultaneous blockade of D_2 receptors in the hypothalamus, striatum, mesocortical and mesolimbic areas, peripheral sympathetic nerve terminals, and vasculature mediate the neuroleptic malignant syndrome in susceptible individuals (see Chapter 66).

In addition to D_2 receptors, antipsychotics are competitive antagonists at a wide range of neuroreceptors; varied binding affinities exist at α-adrenergic ($\alpha_{1,2}$), dopaminergic (D_{1-5}), histaminergic (H_{1-3}), muscarinic (M_{1-5}), and serotonergic (5-HT_{1-7}) receptors (see Table 124.2) [1,4,12]. The neuroreceptor-binding profile for each agent predicts clinical effects. The ratio of other neuroreceptor-binding affinities to D_2-receptor–binding affinity (relative binding affinity) predicts the likelihood of producing those receptor-mediated effects at clinically effective antipsychotic (D_2-blocking) doses and in overdose [1,12]. A ratio similar to or greater than 1 makes other receptor-mediated effects likely. High relative α_1-adrenergic antagonism (i.e., aliphatic and piperidine phenothiazines, asenapine, clozapine, olanzapine, risperidone, ziprasidone) correlates with the incidence and severity of orthostatic hypotension, reflex tachycardia, nasal congestion, and miosis [11]. Significant relative α_2-adrenergic blockade, as occurs with asenapine, clozapine, paliperidone, and risperidone, may result in sympathomimetic effects (e.g., tachycardia). High relative H_1-receptor blockade (e.g., aliphatic and piperidine phenothiazines, asenapine, clozapine, olanzapine, quetiapine) produces sedation, appetite stimulation, and hypotension [1,11]. Relative potency at M_1 receptors correlates directly with anticholinergic effects (i.e., tachycardia, hypertension, mydriasis, blurred vision, ileus, urinary retention, dry skin and mucous membranes, cutaneous flushing, sedation, memory dysfunction, hallucinations, agitation, delirium, and hyperthermia) and inversely with the incidence of extrapyramidal

reactions [1]. Olanzapine, clozapine, and aliphatic and piperidine phenothiazines are associated with clinically significant anticholinergic effects. The ability of clozapine to produce sialorrhea is likely mediated by its partial agonism at M_1 and M_4 receptors [1]. High relative antagonism at 5-HT_{1A} and 5-HT_{2A} receptors appears to predict a low EPS risk [1,7,36,37]. The clinical effects that occur with other neuroreceptor subtype binding are not well understood.

The advent of atypical agents, which provide an improved motor side effect profile, marks significant progress in neuroleptic development. Atypical agents may be subdivided into four functional groups: (a) the D_2-, D_3-receptor antagonists (i.e., amisulpride, raclopride, remoxipride, and sulpiride); (b) the D_2-, $5HT_{2A}$-, and α_1-receptor antagonists (i.e., paliperidone, risperidone and ziprasidone); (c) the broad-spectrum, multireceptor antagonists (i.e., asenapine, clozapine, olanzapine, quetiapine); and (d) the D_2-, 5-HT_{1A}-receptor partial agonists (i.e., aripiprazole, bifeprunox), also known as dopamine and serotonin system stabilizers [3] (see Table 124.2). One or more of several different pharmacologic mechanisms define drug atypia. Low D_2-receptor potency (high-milligram dosing), low (less than 70%) D_2-receptor occupancy in mesolimbic and nigrostriatal areas at therapeutic drug doses, partial agonist activity at D_2 receptors, selective mesolimbic D_2-receptor antagonism, and high D_1-, D_4-, M_1-, $5HT_{1A}$-, $5HT_{2A}$-receptor potencies relative to D_2-receptor–binding are pharmacologic characteristics that alone or in combination may be responsible for the atypical nature of these agents [1–3,7,13,36,37]. Conversely, typical antipsychotics are characterized by high D_2-receptor potency (low-milligram dosing) and a narrow receptor profile in the brain [1]. Unlike typical agents, atypical agents also appear to have a minimal propensity to elevate serum prolactin concentrations.

Serotonin antagonism enhances antipsychotic efficacy and reduces the incidence of EPS [36,37]. $5HT_{2A}$-receptor antagonism in the striatum and prefrontal cortex offsets neuroleptic-induced D_2-receptor blockade and reduces EPS and negative symptoms of schizophrenia, respectively [7,10,36–38]. $5HT_{2A}$-receptor antagonism also increases serotonin levels in the limbic system, which may have a direct antipsychotic effect [7,10]. Drugs with high relative $5HT_{2A}$-receptor antagonism as compared to D_2-receptor antagonism (i.e., amperozide, asenapine, clozapine, olanzapine, paliperidone, risperidone, ziprasidone) can be given in smaller clinically effective antipsychotic doses and thus have a smaller risk of inducing EPS [1,11,38,39]. In addition, antipsychotics that stimulate $5HT_{1A}$ autoreceptors in the striatum (i.e., aripiprazole, clozapine, ziprasidone) reduce striatal D_2-receptor blockade, thereby decreasing the likelihood of EPS [8,36,37].

Aliphatic and piperidine phenothiazines (e.g., chlorpromazine, thioridazine, mesoridazine) have local anesthetic, quinidine-like (type Ia) antiarrhythmic, and myocardial depressant effects [7]. These agents block both fast-sodium channels responsible for myocardial membrane depolarization [40]. Sodium channel blockade is voltage and frequency dependent; blockade is augmented at less negative membrane potentials and faster heart rates [40]. Thus, the anticholinergic properties (e.g., tachycardia) and tissue acidemia-producing effects (e.g., seizures, hypotension) of these drugs potentiate their sodium channel blocking effects. Although specifically demonstrated for sertindole and thioridazine only, all neuroleptics appear to variably antagonize delayed-rectifier, voltage-gated, potassium channels responsible for myocardial membrane repolarization; antagonism occurs specifically at the potassium channel encoded by the human ether-a-go-go (*hERG*) gene [41,42]. Potassium-channel blockade is concentration-, voltage-, and reverse-frequency dependent; blockade is increased at higher tissue concentrations, less negative membrane potentials, and slower heart rates [41,42]. Potassium channel blockade may result in early after depolarizations and subsequent torsade de pointes (TdP)–type ventricular tachycardia. Haloperidol, mesoridazine, thioridazine, and pimozide share an added property of calcium channel blockade [43,44].

Electrophysiologic effects variably include a depressed rate of phase 0 depolarization, depressed amplitude and duration of phase 2, and prolongation of phase 3 repolarization. Ventricular repolarization abnormalities, such as T-wave changes (blunting, notching, inversion), increased U-wave amplitude, and prolongation of the QT interval, are the earliest and most consistent electrocardiographic changes produced by neuroleptics [45–48]. Dose-related prolongation of the QT interval has been described with droperidol, haloperidol, loxapine, phenothiazines, pimozide, quetiapine, risperidone, sertindole, and ziprasidone [31,41,42,45–57]. Conduction disturbances (i.e., bundle-branch, fascicular, intraventricular, and atrioventricular [AV] blocks) and supraventricular and ventricular tachyarrhythmias (i.e., monomorphic and polymorphic TdP ventricular tachycardia, ventricular fibrillation) have been reported [31,49,57–61]. Cardiac effects are dose and concentration dependent but can occur with therapeutic as well as toxic doses. Ventricular tachyarrhythmias and asphyxia (due to seizures, aspiration, or respiratory depression) have been postulated as etiologies of sudden death for patients taking therapeutic doses of antipsychotics, particularly phenothiazines [29,62].

Antipsychotics produce dose-related electroencephalographic changes, and some agents have been shown to lower the seizure threshold [26,27,63–66]. The risk of seizures is dose related, and thus, greatest after overdose [27,65,66]. Chlorpromazine, clozapine, and loxapine are the most likely agents to produce seizures [26,27,54,63–66]. Most other agents, however, are uncommonly associated with seizures, even after overdose. The mechanism by which antipsychotics produce seizures is not well understood but likely involves dose-related blockade of norepinephrine reuptake, antagonism of gamma-aminobutyric acid type A receptors, and altered neuronal transmembrane ionic currents.

Antipsychotics have a relatively flat dose-response curve. Effective therapeutic doses vary over a wide range (see Table 124.1). The optimal dose is determined by the clinical response, not by serum drug levels. Pharmacologic effects generally last 24 hours or more, allowing for once-daily dosing. Tablet, capsule, and liquid oral preparations, suppository, and injectable immediate-release and sustained-release (depot) solutions are available [7]. Oral preparations include both rapidly disintegrating (sublingual absorption) and sustained-release formulations. Paliperidone, the active metabolite of risperidone, is commercially available in an extended-release oral preparation (Invega®). Following a single dose, plasma concentrations gradually rise and do not peak until approximately 24 hours after dosing [67]. Slow-release, highly lipophilic depot formulations (i.e., fluphenazine enanthate and decanoate, haloperidol decanoate, paliperidone palmitate) for intramuscular injection are created by esterifying the hydroxyl group of an antipsychotic with a long-chain fatty acid and dissolving it in a sesame oil vehicle. A long-acting formulation of risperidone (Risperdal Consta®) is available that contains an aqueous suspension of risperidone mixed with a biodegradable carbohydrate copolymer.

Antipsychotic pharmacokinetics are complex and incompletely understood [7]. When administered orally, they are well absorbed, but bioavailability is unpredictable (range: 10% to 70%) due to large interindividual variability and presystemic (hepatic and intestinal) metabolism [7,68,69]. After parenteral administration, drug bioavailability is 4 to 10 times greater than with oral dosing because of the absence of first-pass metabolism [7,68,69]. Hence, therapeutic intravenous (IV) or intramuscular (IM) doses are substantially less than oral ones. Plasma concentrations peak 1 to 6 hours after therapeutic oral and sublingual dosing, 30 minutes to 1 hour after immediate-release IM injection, and within 24 hours after oral

dosing of extended-release preparations. After a single intramuscular dose of a depot preparation, plasma concentrations peak variably from a few days to over 2 weeks after initial injection. [67–69]. After oral overdose, absorption should occur more rapidly (first-order kinetics), but peak plasma concentrations are delayed, as more time is required for complete absorption. As a result, clinical effects are expected to occur sooner and last longer. Erratic absorption may occur after ingestion of agents with significant anticholinergic effects.

After absorption, antipsychotics are highly bound to plasma proteins (75% to 99%) [7,68,69]. However, because they are also highly lipophilic, volumes of distribution are large (10 to 40 L per kg) and serum drug levels after therapeutic doses are quite low (one to several hundred ng per mL). These pharmacokinetic characteristics make extracorporeal removal by hemodialysis or hemoperfusion impractical. Antipsychotics tend to accumulate in the brain, easily cross the placenta, and are found in breast milk [7]. Elimination occurs slowly and extensively by hepatic metabolism, with serum concentration half-lives averaging 20 to 40 hours. Depot antipsychotics have an apparent elimination half-life of 1 to 3 weeks due to slow tissue absorption [68]. Small amounts (1% to 3%) are excreted unchanged by the kidney. As a rule, hepatic metabolism yields multiple metabolites, some of which are pharmacologically active and likely to extend parent drug effects after therapeutic or toxic dosing [70,71]. Metabolites are eliminated by urinary and biliary excretion and can be detected in the urine for several days after a single ingestion and for a month or more after cessation of long-term therapy [7,69]. Large interindividual variations in the metabolism of neuroleptics result in significant differences in steady-state plasma concentrations with fixed, therapeutic dosing [7,68,69,72]. There is often little correlation between neuroleptic dose, serum concentrations, and clinical effects.

Renal insufficiency may rarely result in drug accumulation and toxicity [73]. Renal excretion accounts for a significant proportion of total drug elimination for the benzamide (e.g., remoxipride, sulpiride) and benzisoxazole derivatives (e.g., paliperidone, risperidone) [67–69]. Thus, dose alteration is recommended for patients with renal insufficiency who regularly take these agents. Other neuroleptics, however, do not routinely require dose alteration for patients with renal impairment. Dose adjustment is also recommended for those patients who have a diminished ability to clear neuroleptics, such as the elderly and those with significant hepatic disease or specific cytochrome P450 enzyme deficiencies (i.e., CYP2D6, CYP1A2) [7,69]. Most antipsychotics are pregnancy category C and should be used in pregnancy only if the potential benefit justifies the potential risk to the fetus. Breast feeding is not recommended for women taking neuroleptics because most neuroleptics are secreted into breast milk, and their safety in infants is not established.

The majority of patients who take an accidental or intentional overdose of an antipsychotic agent remain asymptomatic or develop only mild toxicity [5,32]. Toxic effects result from exaggerated pharmacologic activity and include CNS and consequent respiratory depression, miosis or mydriasis, cardiovascular abnormalities, agitation, confusion, delirium, anticholinergic stigmata, seizures, EPS, and myoclonic jerking. Hypothermia and, less commonly, hyperthermia have occurred. Hypothermia may result from α_1-adrenergic–mediated peripheral vasodilation at low ambient temperature, hypotension, coma, loss of shivering capabilities, and disrupted hypothalamic thermoregulation. Peripheral vasodilation at high ambient temperature, seizures, neuromuscular agitation, loss of sweating capabilities, and hypothalamic dysfunction may contribute to hyperthermia. Seizures are uncommon and occur mainly in patients with underlying epilepsy and those with clozapine and loxapine overdoses. In one study of 299 patients with neuroleptic overdose, the incidence of seizure was only 1% [31]. Rhabdomyolysis, myoglobinuria, and acute renal failure may occur after prolonged convulsions [65,74]. CNS depression is the most frequent clinical finding after neuroleptic overdose [31,75–79]. Sinus tachycardia and orthostatic hypotension are the most frequent cardiovascular findings [31,75–79]. Other cardiovascular effects include hypertension, cardiac conduction disturbances, tachyarrhythmias, bradyarrhythmias, and, rarely, pulmonary edema [80,81]. Anticholinergic stigmata (see Chapter 121) may occur after overdose with aliphatic and piperidine phenothiazines, clozapine, and olanzapine [5,76,79,82–86].

Of the thousands of antipsychotic overdoses reported each year, less than 1% result in fatal toxicity [30,32]. Fatality is most often due to respiratory arrest before medical intervention, arrhythmias, or aspiration-induced respiratory failure [5,7,29,32]. Toxic and lethal doses are highly variable and are influenced by the agent ingested, the presence of coingestants and comorbid illness, the age and habituation of the patient, and the time to treatment. Nonhabituated patients at the extremes of age are more sensitive to the toxic effects of these drugs than those who have taken this drug chronically before an acute overdose. The ingestion of a single tablet of chlorpromazine, clozapine, loxapine, mesoridazine, olanzapine, quetiapine, or thioridazine may cause CNS and respiratory depression in young children [5,73,74,84]. Death of an infant was reported after the ingestion of only 350 mg of chlorpromazine. Adult fatalities have been reported after ingestions of 2.0 g of clozapine and chlorpromazine, 2.5 g of loxapine and mesoridazine, 1.5 g of thioridazine, and 600 mg of olanzapine [87,88]. Many patients, however, have survived much higher ingestions. In general, acute ingestion of greater than twice a maximal therapeutic dose is potentially serious.

Unintended adverse effects that occur during therapeutic use may be idiosyncratic or dose related, occur early or late during the course of therapy, or result from interactions with other drugs, and are often due to receptor antagonism. The major adverse side effect, both in terms of prevalence and in terms of the distress that it causes, is the tendency to induce extrapyramidal dysfunction.

Extrapyramidal syndromes are a group of movement disorders that result from the interference with neurotransmitter (primarily D_2-receptor blockade) function in the basal ganglia. EPS occur in up to 75% of patients treated with low-milligram, high-potency traditional agents (e.g., fluphenazine, haloperidol, thiothixene), but an incidence not significantly different from placebo (< 5%) has been described with newer atypical agents (e.g., aripiprazole, clozapine, olanzapine, quetiapine) [89–91]. EPS may occur early (i.e., within a few hours to days), at an intermediate stage (i.e., a few days to months) or late (i.e., after > 3 months) in the course of therapy. Early EPS include acute dyskinesia (acute dystonic reactions), intermediate syndromes include akathisia and parkinsonism, and late disorders include tardive dyskinesia, tardive dystonia, and focal perioral tremor (rabbit syndrome). EPS are more commonly associated with therapeutic doses of neuroleptics but may follow acute overdose (e.g., acute dystonic reactions [ADRs]), particularly in children [5,75,92]. Only ADRs, the acute syndrome most likely to develop in the intensive care unit, are discussed.

ADRs are reversible motor disturbances consisting of sustained, uncoordinated, and involuntary spasmodic movements of various muscle groups. Although ADRs most often occur after administration of therapeutic doses of antipsychotics [93], they have also been described after administration of antihistamines (both H_1- and H_2-blockers), anticholinergics (e.g., benztropine, diphenhydramine), anticonvulsants (e.g., carbamazepine, phenytoin), calcium channel blockers (e.g., nifedipine, verapamil), metoclopramide, cyclic antidepressants (e.g., amitriptyline, amoxapine, doxepin, imipramine),

selective serotonin reuptake inhibitors (e.g., fluoxetine, sertraline), monoamine oxidase inhibitors (e.g., phenelzine, tranylcypromine), anesthetic induction agents (e.g., ketamine, etomidate, thiopental), cholinergics (e.g., bethanechol, insecticides), and cocaine. ADRs can also occur as a primary (non–drug-related) disorder [94].

The pathophysiology of ADRs is not fully elucidated but involves a disruption of cholinergic (interstriatal) and dopaminergic (nigrostriatal) pathways in the basal ganglia. Normally, dopamine is an excitatory neurotransmitter and acetylcholine is an inhibitory neurotransmitter [95]. Normal balance between these closely linked pathways is necessary for coordinated muscular activity. Dopaminergic D_1-, gamma-aminobutyric acid- (striatonigral), glutaminergic- (corticostriatal), noradrenergic-, $5HT_{1A}$- and $5HT_{2A}$- (raphe-striatal and raphe-nigral), and sigma (σ)- (red nucleus, substantia nigra, and cranial nerve motor nuclei) receptor inputs modulate this balance [7,8,36,37,96,97]. Blockade of striatal D_2 receptors by high-potency neuroleptics disrupts the dopaminergic–cholinergic balance in favor of cholinergic excess, and dystonia results [98,99]. Agents that balance D_2-receptor antagonism with D_1-, M_1-, or $5HT_{2A}$-receptor antagonism or $5HT_{1A}$-receptor agonism prevent striatal cholinergic excess and are less likely to precipitate acute dystonia [1,14,36,37,100]. Gamma-aminobutyric acid–receptor affinity correlates inversely, whereas σ- and *N*-methyl-d-aspartate-glutamate receptor–binding affinities correlate directly with the clinical incidence of acute dystonia [8,96,97].

Paradoxically, ADRs may also result from hyperdopaminergic function induced by D_2-receptor blockade in the basal ganglia [101,102]. Acute D_2-receptor blockade may stimulate increased dopamine synthesis and release from nigrostriatal neurons and postsynaptic receptor upregulation (supersensitivity). As brain concentration of drug declines hours to days after a dose, a state of dopamine excess develops, and dystonia results [101,102].

ADRs usually occur soon after initiation of therapy or after an increase in dose. Fifty percent of ADRs occur within 48 hours of initiating therapy, and 90% within 5 days [103–105]. Peak incidence occurs when drug levels are declining in the serum. Although the absolute incidence of ADRs is unknown, they are estimated to occur in 25% of patients treated with IM depot preparations, 16% of patients who have been given haloperidol, 8% of patients treated with thiothixene, 2% to 12% of all patients who take phenothiazines, 3.5% of patients treated with chlorpromazine, and 1% or less in patients taking atypical agents [11,88,98,103,104]. Phenothiazines that contain a piperazine side chain (i.e., prochlorperazine, trifluoperazine, perphenazine, fluphenazine, and acetophenazine) are associated with a higher incidence of dystonic reactions than are other phenothiazines [103]. Atypical agents (particularly clozapine) are unequivocally associated with a reduced incidence of ADRs [11]. The likelihood of an ADR is more dependent on individual susceptibility than on neuroleptic structure, potency, dose, and duration of therapy [106]. ADRs most commonly occur in men, patients 5 to 45 years of age (particularly those younger than 15 years old), and those with a personal or family history of dystonia or a recent history of drug (i.e., cocaine) or alcohol abuse [103–105,107].

Seizures are an uncommon side effect of certain antipsychotics (e.g., clozapine, chlorpromazine, loxapine). They typically occur at higher therapeutic doses and after overdose in susceptible patients. Seizures are usually generalized and of the major motor type. Clozapine, the most epileptogenic agent at therapeutic dosing, is associated with a seizure rate of approximately 1% at doses lower than 300 mg per day, a rate of 2.7% at doses between 300 and 600 mg per day, and a rate of 4.4% with doses larger than 600 mg per day [64,65]. A cumulative seizure risk of 10% after 3.8 years of treatment has been demonstrated with clozapine [79,80]. Newer, atypical agents show no increase in seizure risk when compared with haloperidol or placebo [26]. Other risk factors for seizures include a history of organic brain disease, epilepsy, electroconvulsive therapy, abnormal baseline electroencephalogram, polypharmacy, and initiation and rapid dose titration of neuroleptics [26,66]. After overdose, the incidence of seizures is as high as 60% and 10% for loxapine and clozapine, respectively, whereas the incidence for most other neuroleptics is approximately 1% [5,31,54,76].

Agranulocytosis (absolute neutrophil count < 500 cells per mm^3) is a serious idiosyncratic side effect of clozapine and phenothiazine therapy. It is rare (0.1 to 1.0 per 1,000 persons) with phenothiazines and usually occurs in the first 12 weeks of therapy [108,109]. A cumulative risk of 0.91% (9 per 1,000 persons) at 18 months is reported with clozapine; more than 80% of cases occur in the first 3 months [21,110]. Initial mortality rates associated with agranulocytosis ranged from 30% to 85%, but with regular white blood cell count monitoring and treatment with granulocyte colony stimulating factor (G-CSF), mortality rates have dropped to 3% to 4% [21,110,111]. The mechanism underlying clozapine-induced agranulocytosis may be both immune-mediated and the result of direct myelotoxicity from the drug [112]. Granulocyte colony-stimulating factor has been useful in treatment, halving recovery time from 16 to 8 days [113,114]. Agranulocytosis has not been reported after acute overdose. Neutropenia has also been associated with the therapeutic use of olanzapine, quetiapine, and risperidone [115–117].

Hepatic transaminitis is an adverse side effect of most antipsychotics [11,23]. Hepatotoxicity is idiosyncratic, often occurs within the first 3 months of treatment, and is usually mild and self-limiting (most patients remain asymptomatic). The patterns of hepatoxicity are both hepatitic (including nonalcoholic steatohepatitis) and cholestatic [118,119].

Most atypical neuroleptics result in an increased appetite and weight gain. More importantly, and perhaps causally related, the therapeutic use of atypical agents has been associated with an increased risk of developing type II diabetes mellitus [107–124]. Several cases of fatal diabetic ketoacidosis and hyperglycemia hyperosmolar nonketotic coma have been reported in patients taking clozapine and olanzapine [124–126]. Pancreatitis has been associated with the use of clozapine, and hypertriglyceridemia has been reported in patients treated with clozapine, olanzapine, and quetiapine [106,127–130].

Allergic dermatitis, cholestatic jaundice, irreversible pigmentary retinopathy, photosensitivity reactions, and priapism are uncommon idiosyncratic reactions associated with phenothiazine therapy [11,23,131–134]. Myocarditis and cardiomyopathy have been rarely associated with the use of clozapine; these conditions are idiosyncratic, frequently fatal, often occur within the first 2 weeks of treatment, and are likely the result of acute hypersensitivity [25,135,136].

Drug interactions and adverse effects may be pharmacodynamic (i.e., receptor or channel mediated) or pharmacokinetic (i.e., altered absorption, metabolism, or protein binding) [137,138]. Combining antipsychotics with other CNS depressants (i.e., antihistamines, cyclic antidepressants, ethanol, opiates, sedative–hypnotics) may produce enhanced CNS and respiratory depression. Respiratory depression and arrest has been reported with the coadministration of clozapine and lorazepam or diazepam [139–142]. Exaggerated anticholinergic effects may occur with concurrent use of tricyclic antidepressants, certain skeletal muscle relaxants, antihistamines, and antiparkinson agents. The combination of antipsychotics with significant α_1-adrenergic blockade and certain antihypertensive agents (e.g., hydralazine, prazosin) may precipitate hypotension. Enhanced cardiotoxicity may occur when mesoridazine or thioridazine is combined with type IA

antiarrhythmic agents or tricyclic antidepressants. High-dose droperidol, haloperidol, sertindole, thioridazine, and ziprasidone may potentiate QT prolongation produced by other cardioactive agents.

Most antipsychotic agents are extensively metabolized by the hepatic cytochrome P450 (CYP) enzyme system, particularly the CYP2D6 and CYP1A2 isoenzymes. Other drugs that are substrates (i.e., cyclic antidepressants), inhibitors (i.e., cimetidine, erythromycin, selective serotonin reuptake inhibitors), or inducers (i.e., anticonvulsants) of similar CYP isoenzymes may alter antipsychotic metabolism and precipitate adverse effects. These interactions often go unnoticed, but they may be clinically significant. Cimetidine, erythromycin, and fluvoxamine have precipitated clinical clozapine toxicity from hepatic CYP1A2 isoenzyme inhibition [143–146]. Paroxetine may precipitate risperidone toxicity from CYP2D6 isoenzyme inhibition. Knowledge of antipsychotic-associated drug interactions facilitates recognition and treatment of these increasingly common iatrogenic events.

CLINICAL TOXICITY

Acute overdose may result in nausea and vomiting soon after ingestion. CNS and cardiovascular effects, however, usually dominate the clinical picture [5,31,55–58,61,75–79]. In mild intoxication, findings include ataxia, confusion, lethargy, slurred speech, tachycardia, and hypertension or orthostatic hypotension. Anticholinergic signs (e.g., dry skin and mucosa, decreased bowel sounds, urinary retention) and hyperreflexia may also be present. Although usually considered an idiosyncratic reaction, EPS (e.g., ADRs) have been described after acute neuroleptic overdose, particularly in children [5,75,92]. Electrocardiographic changes such as prolonged PR and QT intervals, ST-segment depression, T-wave abnormalities (biphasic, blunting, inversion, notching, widening), and increased U waves may be seen [31,45–48]. Other than sinus tachycardia, repolarization abnormalities are the earliest and most common electrocardiographic findings associated with neuroleptic poisoning [31,45–48,52,147].

Signs and symptoms of moderate poisoning include low-grade coma (see Chapter 117), respiratory depression, and hypotension. Miosis or mydriasis may occur. Miosis is more likely to occur following overdose of both atypical and typical agents; it has been described in 75% of adults and 72% of children after phenothiazine overdose [5,77,79,84,148]. Internuclear ophthalmoplegia has been reported [149]. Paradoxical agitation, delirium, hallucinations, psychosis, myoclonic jerking, and tachypnea may occur [5,76,79,82–86,150]. Central and peripheral anticholinergic stigmata frequently occur after overdose with chlorpromazine, clozapine, mesoridazine, olanzapine, and thioridazine [5,76,79,82–86].

In severe poisoning, high-grade coma with loss of most or all reflexes, apnea, hypotension, seizures, and a variety of cardiac conduction disturbances and arrhythmias may develop. Conduction disturbances include all degrees of AV block, bundle-branch and fascicular block, and nonspecific intraventricular conduction delay [31,46,48,49,54,58–61,147]. Bradyarrhythmias occur uncommonly and, when present, may signify impending respiratory arrest. Tachyarrhythmias include sinus and supraventricular tachycardias, supraventricular and ventricular premature beats, ventricular tachycardia and fibrillation, and TdP [5,31,45–49,57–61,151]. The latter arrhythmia typically occurs in the setting of QT-interval prolongation and has been described with amisulpride, droperidol, haloperidol, mesoridazine, pimozide, and thioridazine [152]. TdP has also been described when critically ill patients are given haloperidol for sedation. In one study, TdP occurred in 3.6% of such patients; the incidence was 64% in those given greater than 35 mg of haloperidol in less than 6 hours and 84% when given to those with a corrected QT (QTc) interval greater than 500 milliseconds [153]. TdP has been rarely associated with therapeutic (usually large) doses of droperidol [49,50,154]. Discovery of this association prompted the Federal Drug Administration to issue a "black box" warning to U.S. health care personnel for droperidol in 2001 [155]. Serious cardiovascular toxicity occurs more commonly when piperidine phenothiazines have been ingested [31]. In one study of 299 patients with neuroleptic overdose, thioridazine was associated with a significantly greater incidence of prolonged QRS, prolonged QTc, and arrhythmia as compared to other neuroleptics [31]. Electrocardiographic abnormalities or obvious cardiotoxicity should be evident within several hours of overdose. Newer agents alter cardiac conduction less frequently but are not entirely void of cardiotoxicity. Prolonged QRS and QT intervals and hypotension have been described after risperidone overdose, and ventricular tachycardia has occurred after remoxipride overdose [61]. The new drug approval application for sertindole was withdrawn in the United States due to dose-related prolongation of the QT interval that occurred during premarketing trials with the drug [53].

Although the overall seizure incidence is about 1% for patients that overdose on neuroleptics, the incidence is much greater following ingestion of chlorpromazine, clozapine, loxapine, mesoridazine, and thioridazine [5,30,31,54,76]. Occasionally, hypothermia or hyperthermia may be seen [156]. Pulmonary edema has been reported rarely as a complication of overdose with chlorpromazine, clozapine, haloperidol, and perphenazine [5,80,81]. Neuroleptic malignant syndrome (NMS) is an idiosyncratic reaction that rarely occurs after acute overdose. Acute overdose, however, may infrequently produce a clinical picture (i.e., the presence of hyperthermia, autonomic instability, neuromuscular hyperreactivity, and hypertonia) that could be misinterpreted as NMS [15]. Agents that produce anticholinergic effects (e.g., clozapine, mesoridazine, olanzapine, thioridazine) would be more likely to do this.

Loxapine poisoning results in an atypical clinical picture. Cardiovascular effects are mild or absent, but convulsions are common and often lead to rhabdomyolysis and subsequent renal failure [54,157].

Following overdose, toxic effects (e.g., CNS depression) begin within 1 to 2 hours, maximal severity is usually evident by 2 to 6 hours, and resolution usually occurs by 24 to 48 hours after ingestion. The presentation is the same regardless of age and whether the overdose is acute or chronic. Early deaths are due to respiratory arrest, arrhythmias, shock, or aspiration-associated respiratory failure. Later complications include cerebral and pulmonary edema, disseminated intravascular coagulation, rhabdomyolysis, myoglobinuric renal failure, and infection.

ADRs are characterized by abrupt onset, intermittent and repetitive nature, normal physical examination except for muscular findings, a history of recent neuroleptic use, and rapid response to anticholinergic drug therapy [98,103–105]. Muscle contractions may sometimes be sustained but usually last from seconds to minutes. They may be focal at the onset and then spread to contiguous muscles; occasionally, they are generalized [158]. Patients remain alert and oriented during these reactions.

Although dystonia may occur in any striated muscle, one of five areas is typically affected [98,103–105,159–161]. ADRs involving the muscles of the eye (oculogyric crisis) cause upward gazing, rotation of the eyes, and spasm of the lids. Those involving muscles of the tongue and jaw (buccolingual crisis) produce trismus, protrusion of the tongue, dysphagia, dysarthria, and facial grimacing. Contractions of muscles of the neck or back result in abnormal head positioning (torticollic reactions) or arching and twisting of the torso (opisthotonic posturing), respectively. When muscles of the abdominal wall are involved, patients present with abdominal wall pain and

spasm, bizarre gait patterns, kyphosis, and lordosis (tortipelvic and gait crises). Buccolingual and torticollic ADRs are the most common [103–105].

Although ADRs are rarely life threatening, those involving the tongue, jaw, neck, and chest can result in upper airway compromise and impaired respiratory mechanics [162,163]. Stridor can occur in those with buccolingual and torticollic reactions. Death from respiratory failure has been reported [162,164].

DIAGNOSTIC EVALUATION

The diagnosis of antipsychotic poisoning is made from a history of exposure, physical findings, and supporting evidence from electrocardiographic, laboratory, and other ancillary studies. A complete history should be obtained from the patient as well as the person(s) who found or brought the patient (to corroborate the patient's history). As with all drug ingestions, the name, quantity, and time of ingestion of the drug(s) should be determined. For patients who become toxic during chronic therapy, a recent medication or dose change or an illness may be responsible. Patients and family members should be specifically questioned about the possibility of antipsychotic exposure when signs of an EPS are present.

Physical examination should focus on the vital signs, respiratory function, and neurologic status. Physical findings that suggest neuroleptic poisoning include CNS and respiratory depression, sinus tachycardia, miosis, anticholinergic stigmata, orthostatic hypotension, and the presence of EPS. The patient should be examined for evidence of coexisting trauma. An initial rhythm strip and subsequent 12-lead electrocardiogram (ECG) should be evaluated. Arterial blood gas determinations and a chest radiograph should be ordered in patients with significant CNS depression. An abdominal radiograph showing radiopaque densities in the gastrointestinal (GI) tract may suggest butyrophenone or phenothiazine poisoning if the etiology of symptoms is unknown. The absence of this finding, however, does not rule out poisoning by these agents. Routine laboratory evaluation should include a complete blood cell count and electrolyte count and blood urea nitrogen, creatinine, and glucose tests. Measurements of serum acetaminophen and salicylate should be performed on all patients with intentional overdose. In patients with seizures, hyperthermia, and severe poisoning, laboratory evaluation should include urinalysis (routine and for myoglobin); creatinine phosphokinase, calcium, magnesium, and phosphate tests; and a coagulation profile. Women of childbearing age should have a pregnancy test performed.

Toxicologic analysis of the urine and serum by immunoassay and chromatography–mass spectrometry may be performed to confirm the identity of the offending agent and to rule out other ingestants [165]. Quantitative drug levels are not helpful in predicting clinical toxicity or guiding treatment [7,68,69,72]. Although neither sensitive nor specific, or readily available, the Forrest, Mason, and Phenistix (Ames Company, Inc., Elkhart, IN) colorimetric tests are rapid urine screens that may be positive with phenothiazine ingestions [166]. These tests, however, do not detect nonphenothiazine neuroleptic agents. Certain neuroleptics (e.g., chlorpromazine, mesoridazine, quetiapine, and thioridazine) will commonly produce false positive results for tricyclic antidepressants on most commercially available immunoassay screens used by hospitals to test for drugs of abuse [167].

Patients with ADRs should be questioned regarding current medications, previous ADRs, recreational drug use, and change in the dose of a neuroleptic or other medication associated with this syndrome. The diagnosis is made on the basis of history of drug exposure and the physical examination.

A complete blood cell count should be performed on patients who develop a fever or infection while taking clozapine or phenothiazines.

Agents that cause CNS and cardiovascular effects similar to those resulting from antipsychotic poisoning include antiarrhythmic, anticholinergic, anticonvulsant, antidepressant, antihistamine, opioid, other psychotropic agents (e.g., lithium, bupropion) and sedative–hypnotics, and skeletal muscle relaxants. It may be impossible to distinguish cyclic antidepressant or type IA antiarrhythmic agent poisoning from poisoning due to chlorpromazine, thioridazine, or mesoridazine without toxicologic analysis. CNS infection, cerebrovascular accident, occult head trauma, and metabolic abnormalities should also be considered in the differential diagnosis.

The differential diagnosis of an ADR includes primary dystonias, seizures, cerebrovascular accident, encephalitis, tetanus, hypocalcemia, drug intoxication (especially anticholinergic, anticonvulsant, and strychnine), hysterical conversion reactions, joint dislocations, meningitis, hypomagnesemia, torticollis, and alkalosis.

MANAGEMENT

All patients who are symptomatic after acute overdose should be observed until they are alert. Those with mild toxicity can often be managed in the emergency department or a similarly equipped observation unit. Those with protracted hypotension, significant CNS depression or agitation, seizures, acid-base disturbances, nonsinus arrhythmias, and cardiac conduction disturbances should be admitted to an intensive care unit. Patients with ECG abnormalities (e.g., prolonged QRS or QTc intervals) who are otherwise asymptomatic should be admitted to a cardiac monitored bed; such findings have been implicated in sudden death.

Treatment is primarily supportive. The tempo and sequence of interventions depend on the clinical severity. Advanced life support measures should be instituted as necessary, and underlying metabolic abnormalities corrected. All patients require cardiac and respiratory monitoring. Vital signs should be obtained frequently. Endotracheal intubation for airway protection or ventilatory support may be required. Patients with seizures or hyperthermia should have continuous (rectal probe) temperature monitoring. Those with altered mental status should receive supplemental oxygen and be given a diagnostic trial of naloxone (2 mg IV), dextrose (25 g IV), and thiamine (100 mg IV). Although reversal of CNS depression after naloxone administration has been reported [168], such a response is inconsistent with the pharmacology of neuroleptics and should not be expected.

Hypotension should be initially treated with Trendelenburg's position and several liters (10 to 40 mL per kg IV) of normal saline. α_1-adrenergic agonists (i.e., norepinephrine, phenylephrine) are first-line agents for treating refractory hypotension, particularly in patients who have been poisoned by antipsychotics with significant α_1-adrenergic blockade. Central venous, intra-arterial, and pulmonary artery pressure monitoring may be necessary for optimal management of patients who are hemodynamically unstable.

Sinus and supraventricular tachycardias rarely require specific treatment. If they are associated with hypotension, correction of this abnormality is often all that is necessary. Sodium bicarbonate (1 to 2 mEq per kg IV) may be effective and is strongly recommended for patients who have wide QRS complexes or ventricular tachyarrhythmias. Lidocaine (1 to 1.5 mg per kg IV) and electrical cardioversion are alternative treatments for patients with ventricular tachyarrhythmias, depending on hemodynamic stability. Type IA (i.e., disopyramide, quinidine, procainamide), type IC (i.e., propafenone), and type III (i.e., amiodarone) antiarrhythmic drugs are not recommended and are potentially dangerous; they may worsen cardiac conduction abnormalities [169]. TdP ventricular tachycardia should be treated with magnesium (50 to 100 mg per kg

IV over 1 hour); or an increase in heart rate (overdrive pacing) should be treated using isoproterenol or electricity [170–172]. Increasing the heart rate may shorten a prolonged QT interval and thus facilitate conversion of this arrhythmia. The blood pressure should be carefully monitored during isoproterenol administration, as it may cause or worsen hypotension. A search for and correction of hypokalemia, hypomagnesemia, and other electrolyte disturbances is requisite to the management of TdP. Bradyarrhythmias associated with hemodynamic compromise should be treated with atropine, epinephrine, dopamine, and isoproterenol according to current advanced cardiac life support protocols. Complete heart block may require temporary cardiac pacing.

Recent literature supports the antidotal use of intravenous fat emulsions (IFE) for severe central nervous system or cardiovascular toxicity from highly lipophilic drugs [173]. IFE infusions may create a "lipid sink" whereby lipophilic drugs are sequestered in a newly created intravascular lipid compartment, thereby reducing tissue binding. Alternatively, IFE infusions may restore myocardial function by providing exogenous fatty acid substrate or by increasing intracellular calcium for myocyte function [173]. In a rabbit model of chlorpromazine toxicity, IFE treatment decreased free drug available for tissue toxicity and increased survival in poisoned animals [174]. In human case reports, IFE administration has been temporally associated with attenuation of QTc prolongation and CNS depression from quetiapine overdose [175,176]. The overwhelming majority of antipsychotic-overdose patients do well with good supportive care and would not necessitate IFE infusion therapy. ILE treatment, however, should be strongly considered and is recommended for patients with severe and refractory cardiovascular or CNS toxicity from antipsychotic drugs. IFE is commonly administered an IV bolus followed by a 3 to 24 hour continuous infusion. A reasonable dosing algorithm for both adults and children is a 1 to 2 mL per kg IV bolus of 20% IFE over 1 minute followed by 0.25 to 0.5 mL per kg per minute continuous IV infusion (total dose 2 g per kg per day IFE) [173].

Seizures are often self-limited and may not require specific treatment. If prolonged or recurrent, seizures should be treated with incremental doses of diazepam or lorazepam (initial dose, 0.05 to 0.10 mg per kg IV). A short-acting barbiturate (e.g., amobarbital, 10 to 15 mg per kg IV at a maximal rate of 100 mg per minute) or a long-acting one (e.g., phenobarbital, 20 mg per kg IV at a maximal rate of 30 mg per minute) may sometimes be necessary. The effectiveness of phenytoin is not established for neuroleptic-associated seizures. Refractory convulsions, as seen in loxapine poisoning [54,157], may require the use of a paralyzing agent to prevent complications such as hyperthermia and rhabdomyolysis. A nondepolarizing neuromuscular blocker, such as pancuronium (0.06 to 0.10 mg per kg IV) or vecuronium (0.08 to 0.10 mg per kg IV) is recommended over succinylcholine. Continued treatment of seizures, as indicated by electroencephalogram monitoring, is necessary during therapeutic paralysis. Diuresis and alkalinization of urine may be useful in preventing myoglobinuric renal failure for patients with rhabdomyolysis (see Chapter 73).

Physostigmine may be used safely and effectively in poisoned patients who have significant peripheral or central anticholinergic stigmata (i.e., agitated delirium) and normal PR and QRS intervals on ECG (see Chapter 121) [99]. Its use has been described with chlorpromazine, clozapine, olanzapine, and thioridazine poisoning [83,85,86]. Physostigmine should be given slowly intravenously (0.02 mg per kg in children or 2 mg in adults) over 3 minutes. Alternatively, agitated delirium from the anticholinergic syndrome may be treated with benzodiazepines.

After stabilization, GI decontamination should be performed for patients with acute ingestions. Oral activated charcoal (1 g per kg) with or without a cathartic is the preferred method for the majority of patients. Although gastric lavage may benefit comatose patients who present within 1 hour of drug ingestion, it is not routinely recommended for neuroleptic overdose for which the mortality rate is very low [177]. If performed, gastric lavage should always be followed with activated charcoal administration. Because of decreased GI tract motility resulting from poisoning, decontamination (activated charcoal administration) may be of benefit many hours after overdose.

Although clinical improvement was reported during combined hemodialysis and charcoal hemoperfusion [178], the effect was transient, and measures to enhance the elimination of neuroleptic agents, such as diuresis, dialysis, and hemoperfusion, have not been shown to be pharmacokinetically effective [179,180]. Repeated oral doses of activated charcoal are of potential but unproved benefit. Use of multidose charcoal is not recommended and potentially harmful for patients who have developed an ileus.

The vast majority of patients with neuroleptic poisoning recover completely within several hours to several days, depending on severity. Patients with intentional overdosage require psychiatric evaluation before discharge.

Patients with respiratory distress secondary to ADRs should be given supplemental oxygen. Those with buccolingual and torticollic crises should be given nothing by mouth, because doing so could precipitate choking. Because ADRs rarely result from an overdose, GI tract decontamination is usually not indicated and may, in fact, be hazardous because of the potential for airway complications.

Administration of an anticholinergic agent readily reverses ADRs, presumably by restoring the balance between cholinergic and dopaminergic pathways in the basal ganglia [98]. Benztropine mesylate, 1 to 2 mg, or diphenhydramine, 50 to 100 mg, given intravenously over 1 to 2 minutes, can be used. Reversal of signs and symptoms usually occurs within a few minutes. In some cases, a second dose is needed for complete resolution. Benztropine appears to be more effective and is less likely to cause sedation and hypotension than diphenhydramine and is the preferred agent in adults [105,181]. Although benztropine is contraindicated in children younger than 3 years of age because of its anticholinergic effects [182], this is precisely the desired effect, and its administration in small doses (e.g., 0.25 to 0.50 mg) is appropriate in this situation. As an alternative, diphenhydramine (1 mg per kg IV) can be used. Benztropine and diphenhydramine can also be given intramuscularly, but it may take 30 to 90 minutes for the ADR to resolve when this route is used. Cases resistant to anticholinergic agents may respond to diazepam (0.1 mg per kg IV) or lorazepam (0.05 to 0.10 mg per kg IV).

Subsequent therapy with an oral anticholinergic agent should be continued for 48 to 72 hours. Without such therapy, the ADR may recur because it may take several days to eliminate completely the agent that caused it and the duration of action of drugs used to treat it is much shorter. In addition to benztropine and diphenhydramine, biperiden (2 mg 1 to 3 times a day), trihexyphenidyl (2 mg twice per day), or amantadine (100 to 200 mg twice per day) can be used for oral therapy. For reasons already noted, benztropine (1 to 2 mg twice per day) is the preferred agent for adults. Children younger than 3 years can be given diphenhydramine (1 mg per kg orally three or four times per day). Although patients who have had an ADR are at increased risk for future ADRs, those requiring continued antipsychotic therapy can usually continue or resume taking the offending agent provided they are also maintained on anticholinergic therapy. As an alternative, they can be switched to atypical antipsychotic with less dopaminergic-blocking activity.

CHAPTER 125 ■ BETA-BLOCKER POISONING

SHAN YIN AND JAVIER C. WAKSMAN

Since 1958, when dichloroisoprenaline, the first β-adrenergic blocker, was synthesized, more than a dozen beta-blockers have been introduced into the international pharmaceutical market. Originally developed for the treatment of angina pectoris and dysrhythmias, beta-blockers are now used in a wide variety of disorders. Intoxication may result from oral, parenteral, and even ophthalmic use [1].

PHARMACOLOGY

Beta-blockers act by competitively inhibiting the binding of epinephrine and norepinephrine to β-adrenergic neuroreceptors in the heart (β_1), blood vessels, bronchioles (β_2), and other organs (Table 125.1). Binding to the β receptor (G-protein–coupled receptor) activates phosphodiesterase and increases cytoplasmic cyclic adenosine monophosphate (cAMP). This in turn leads to modification of cellular processes and changes in ionic channel conductance. By reducing the activity of β receptors, the production of cAMP is decreased and β effect is diminished [2].

Beta-blockers are usually rapidly absorbed after oral administration. The beta-blocker dose required to produce a toxic effect is variable, depending on the sympathetic tone and metabolic capacity of the person and the pharmacologic properties of the particular beta-blocker [2]. The first signs of toxicity may appear 20 minutes after ingestion, with peak effects typically occurring 1 to 2 hours after an immediate-release preparation overdose. Absorption of modified-release formulations may be erratic after an overdose, however, and clinical

TABLE 125.1

DISTRIBUTION AND FUNCTION OF β-RECEPTORS

Receptor subtype	Location	Response to stimulation
β_1	Eye	Aqueous humor production
	Heart	Increased automaticity, conduction velocity, contractility, and refractory period
β_2	Kidney	Renin production
	Blood vessels	Smooth muscle contraction
	Bronchioles	Smooth muscle contraction
	Fat	Lipolysis
	Liver	Gluconeogenesis, glycogenolysis
	Pancreas	Insulin release
	Skeletal muscle	Increased tone, potassium uptake
	Uterus	Smooth muscle relaxation

toxicity may be significantly delayed. The duration of toxicity may be several days [2].

The pharmacologic and pharmacokinetic properties of beta-blockers are variable (Table 125.2). Cardioselectivity tends to be lost at high doses, and membrane-stabilizing effects, which are minimal at therapeutic doses, assume a more important role [2]. Membrane dysfunction may account for many of the central nervous system (CNS) and myocardial depressant effects in patients poisoned by membrane-active drugs such as propranolol. The half-life may be significantly prolonged in patients with decreased hepatic and renal perfusion [2]. Intrinsic heart, kidney, and liver disease as well as the concomitant use of drugs with similar activity increase the risk of toxicity.

CLINICAL TOXICITY

The major manifestations relate to the cardiovascular system and CNS. Respiratory, peripheral vascular, and metabolic (hypoglycemic and hyperkalemic) effects have been infrequently reported [2,3].

Patients with severe poisoning frequently present with hypotension and bradycardia. Tachycardia and hypertension have been reported with agents possessing intrinsic sympathomimetic activity, however, particularly pindolol [2]. Congestive heart failure and pulmonary edema have infrequently been reported and mainly occur in patients with underlying heart disease [4]. Electrocardiographic manifestations may include prolonged PR interval, intraventricular conduction delay, progressive atrioventricular heart block, nonspecific ST-segment and T-wave changes, early repolarization, prolonged corrected QT (QTc) interval, and asystole [5–7]. Sotalol poisoning may result in ventricular tachycardia, torsade de pointes, ventricular fibrillation, and multifocal ventricular extrasystoles [8,9]. Labetalol, which also has mild β-receptor–blocking properties, may cause profound hypotension, possibly from decreased peripheral resistance.

Depression in the level of consciousness, ranging from drowsiness to coma with seizures, is another common feature of beta-blocker poisoning. Significant CNS depression has been reported in the absence of cardiovascular compromise [2] or hypoglycemia and may be due to direct membrane effects [10]. Cerebral hypoperfusion, hypoxia, and metabolic or respiratory acidosis frequently contribute to CNS toxicity. Beta-blockers with high lipid solubility (e.g., propranolol, penbutolol, metoprolol) appear more likely to cause CNS effects than those with low lipid solubility (e.g., atenolol) [11,12].

Bronchospasm is a relatively rare consequence of beta-blocker poisoning and usually occurs more frequently in patients with preexisting reactive airway disease. In most instances, respiratory depression appears to be secondary to a CNS effect [13–16].

Although it does occur, hypoglycemia is not a common complication of beta-blocker poisoning [17]. It appears to be more common in diabetics, children, and uremic patients and it is the consequence of impaired glycogenolysis and hepatic gluconeogenesis [18]. A blunted tachycardic response to hypoglycemia may occur in patients with beta-blocker toxicity, although other symptoms of hypoglycemia appear unaffected.

Oliguric renal failure has been reported as a complication of labetalol poisoning [19]. Mesenteric ischemia and subsequent cardiovascular collapse have occurred after propranolol overdose [20].

Sudden discontinuation of long-term beta-blocker therapy may precipitate angina pectoris and myocardial infarction. This is the result of the "beta-blocker withdrawal phenomenon," explained by the theory that long-term beta-blocker therapy not only diminishes receptor occupancy by catecholamines but also increases the number of receptors sensitive to adrenergic stimulation. When beta-blockers are suddenly withdrawn, the increased pool of sensitive receptors responds more readily to the stimulation of circulating catecholamines [17].

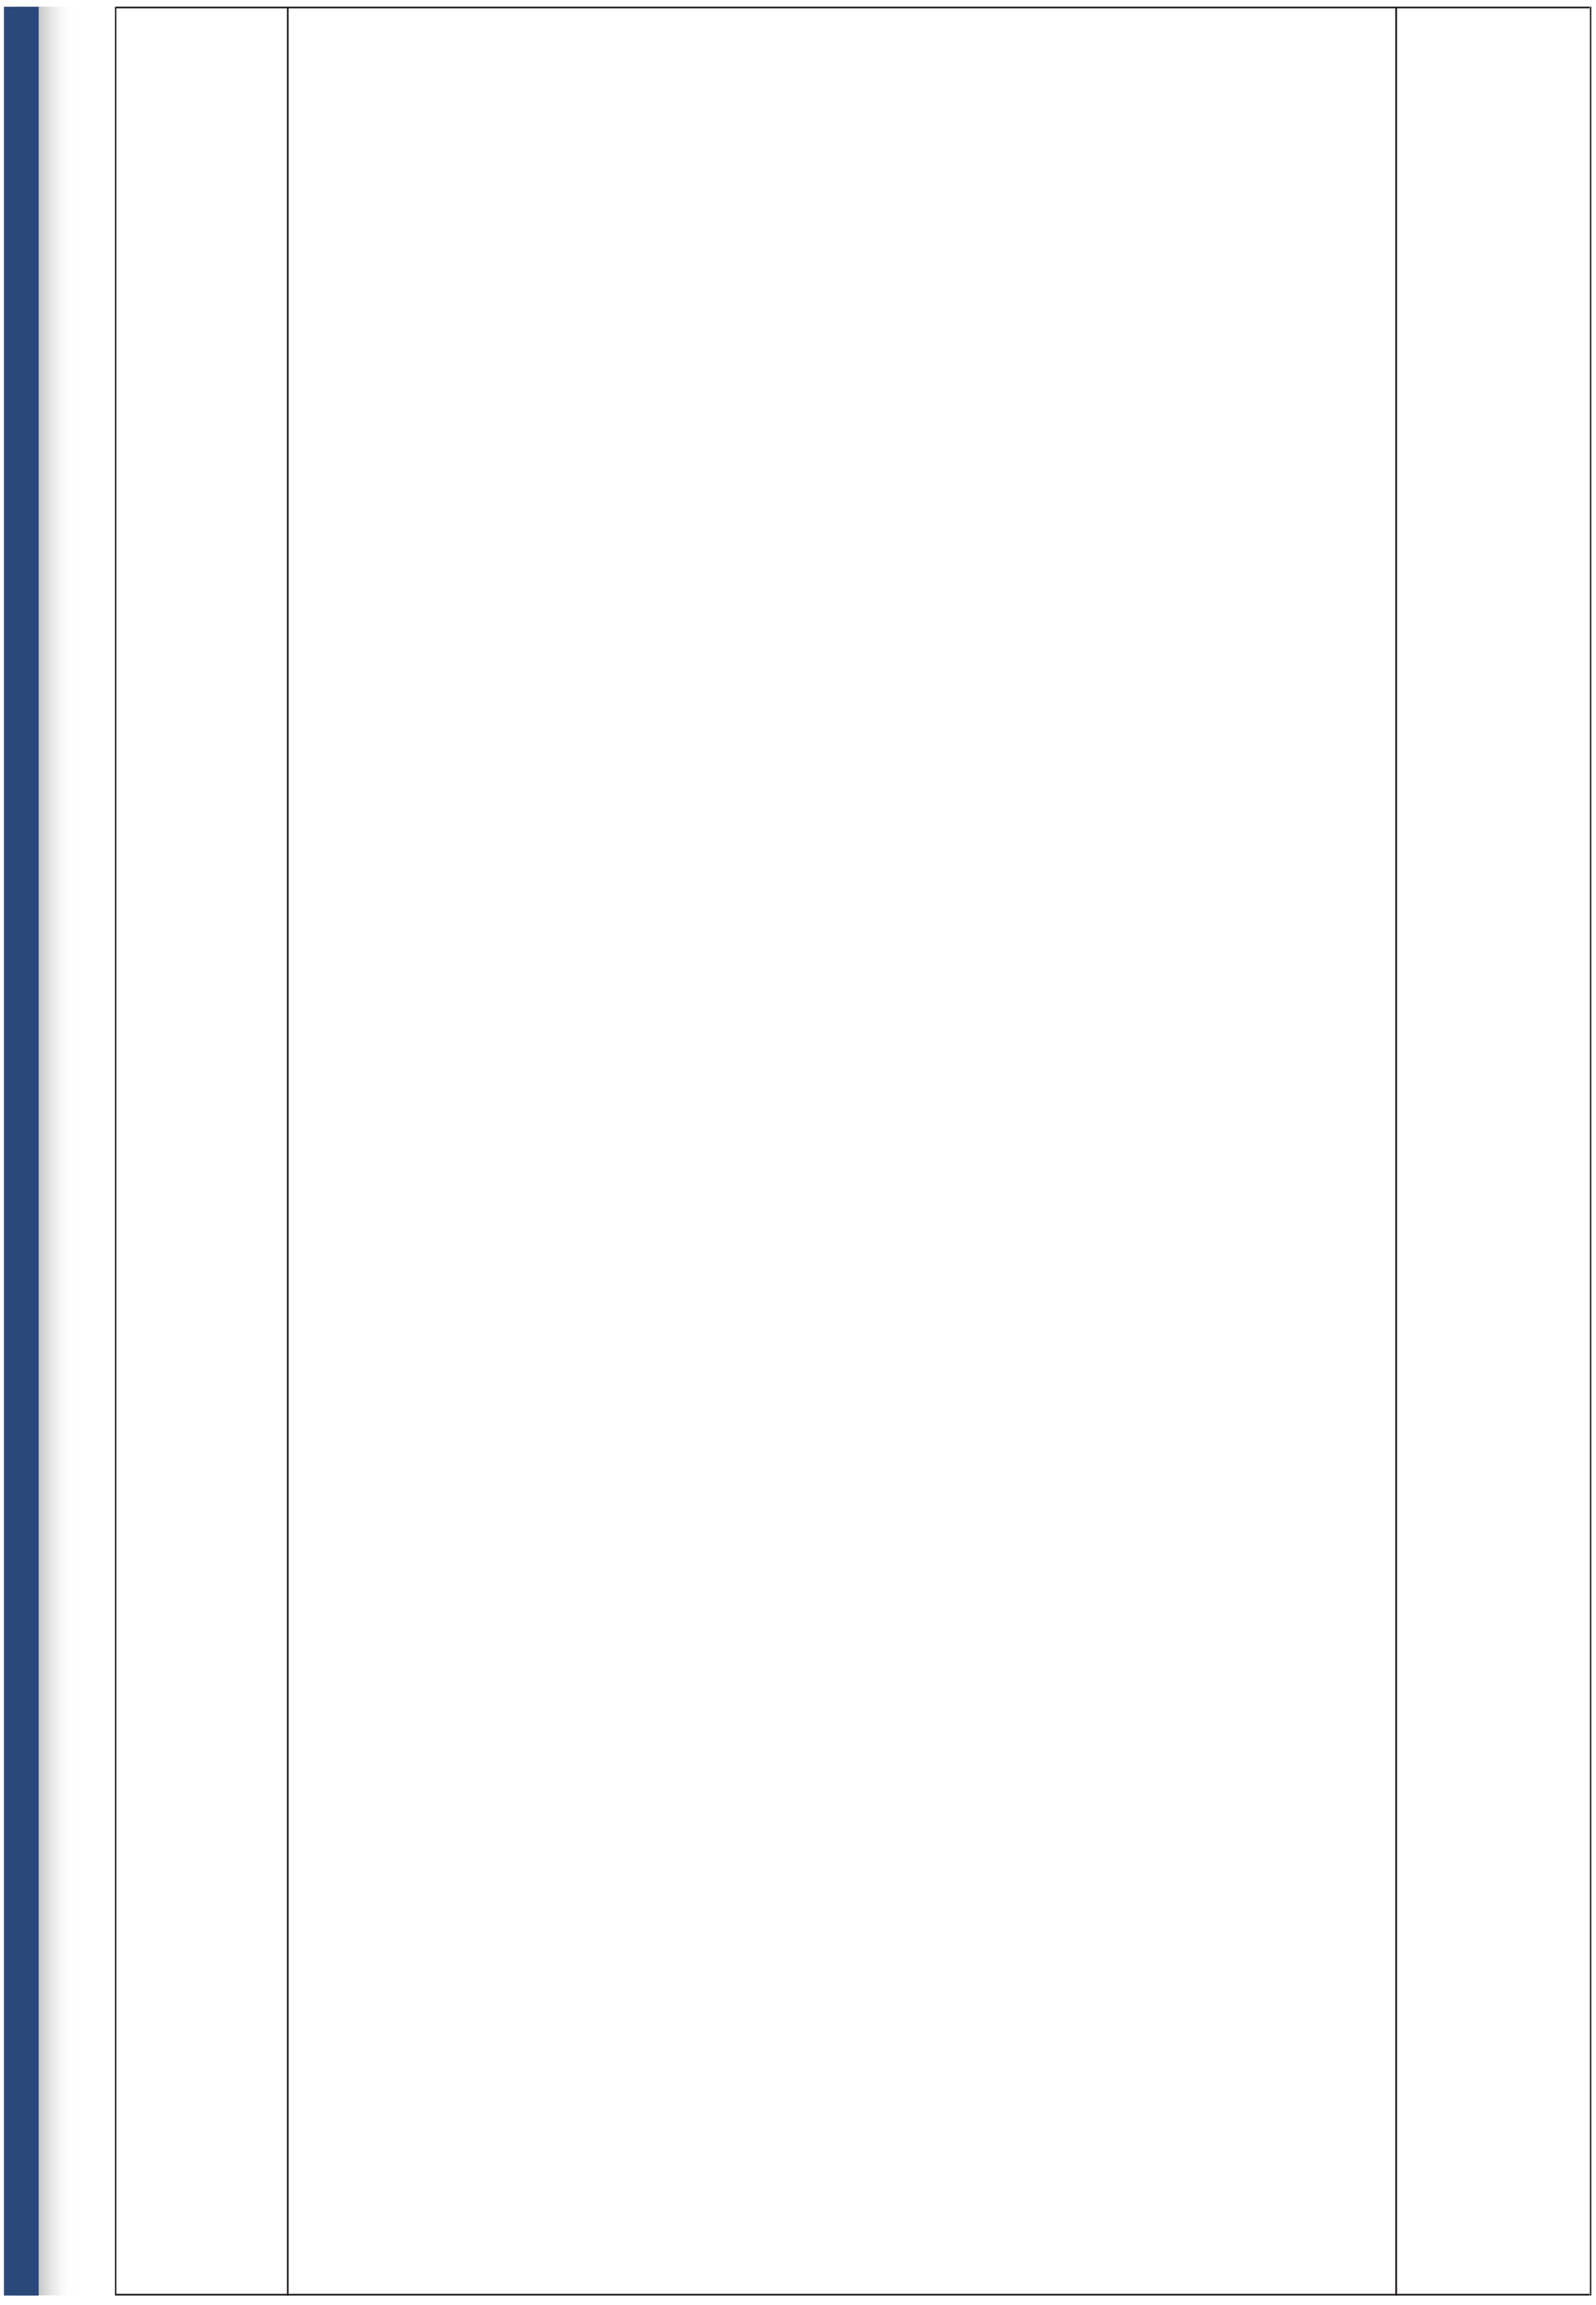
DIAGNOSTIC EVALUATION

The history should include the time, amount, and formulation of drugs ingested; the circumstances involved; time of onset and nature of any symptoms; and treatments rendered before arrival, as well as underlying health problems. Beta-blocker poisoning may be difficult to recognize, especially when multiple drugs have been ingested [2]. Beta-blocker poisoning should be suspected in a patient in whom hypotension or seizures suddenly develop or who has bradycardia resistant to the usual doses of chronotropic drugs [21]. Evaluation of patients with suspected beta-blocker poisoning should begin with a complete set of vital signs, continuous cardiac rhythm monitoring, and a 12-lead electrocardiogram. Physical examination should focus on the cardiovascular, pulmonary, and neurologic systems. Vital signs and physical examination should be frequently repeated.

Serum drug levels may help confirm the diagnosis but are rarely available quickly enough to be clinically useful. In addition, differences in individual patient metabolism and sympathetic tone may make interpretation of blood levels difficult [2,3]. A serum and urine specimen can be saved for later analysis in forensic cases. Continuous cardiac rhythm monitoring, interpretation of 12-lead electrocardiograms, and measurement of oxygen saturation should be routine. Laboratory evaluation of symptomatic patients should include electrolytes, blood urea nitrogen, creatinine, bicarbonate, and glucose. Arterial blood gas and a chest film should be obtained as clinically indicated. Serum acetaminophen and aspirin levels should be obtained in patients with suicidal ideation.

The differential diagnosis of beta-blocker toxicity includes antidysrhythmic drugs, calcium channel blockers, cholinergic agents, clonidine, digitalis, narcotics, sedative hypnotics, and tricyclic antidepressants. Anaphylactic, cardiogenic, hypovolemic, and septic shock should also be considered.

The prognosis associated with beta-blocker intoxication is generally positive. A review of two regional poison control centers [22] found that 15% of patients developed cardiac toxicity, and only 1.4% died. The only factor associated with increased



morbidity was coingestion of cardioactive drugs such as calcium channel blockers, cyclic antidepressants, and neuroleptics [22].

MANAGEMENT

Treatment is primarily supportive. This may include prompt endotracheal intubation and mechanical ventilation and management of life-threatening bradydysrhythmias, hypotension, bronchospasm, and seizures. These attempts should precede any measures (as described later) used to prevent or reduce drug absorption. A bedside glucose measure or, alternatively, an intravenous bolus of glucose (50 mL of $D_{50}W$ in adults; 4 mL per kg of $D_{25}W$ in children) as well as naloxone (2 mg in adults and children) should be given to patients with altered mental status (Fig. 125.1).

Activated charcoal is the preferred methods for gastrointestinal decontamination [14]. Gastric lavage has not been shown to improve outcome after poisoning and should not be used routinely, but considered for recent life-threatening ingestions in patients who have not already vomited [23]. Lavage may cause bradycardia from vagal effects. Thus, atropine should be given prior to initiation, and lavage should be withheld in patients with existing bradycardia and conduction abnormalities. Whole-bowel irrigation with polyethylene glycol (Golytely^{TM}) at a rate of 2 L per hour until the rectal effluent is clear may be considered for gastrointestinal decontamination in modified-release preparation overdoses.

Hypotension should be first treated with judicious intravenous crystalloid fluids. Because hypotension seldom responds solely to this treatment and because administration of high volumes (greater than 2 L) of intravenous fluids may pose a risk to develop pulmonary edema, the prompt use of inotropic drugs such as dopamine, dobutamine, epinephrine, norepinephrine, and phenylephrine is usually required [24]. Bradycardia from β-adrenergic antagonist poisoning seldom responds to atropine.

Calcium

The goal of calcium therapy is to increase extracellular calcium concentrations thus increasing calcium influx through any unblocked calcium channels. Calcium has demonstrated effectiveness in animal models [25] and improvement reported in human cases [26]. However, responses are variable and often short-lived, and patients with significant toxicity usually fail to improve with calcium alone. Conduction disturbances, contractility, and blood pressure, may be improved, but generally there is no increase in heart rate. Optimum dosing has yet to be established.

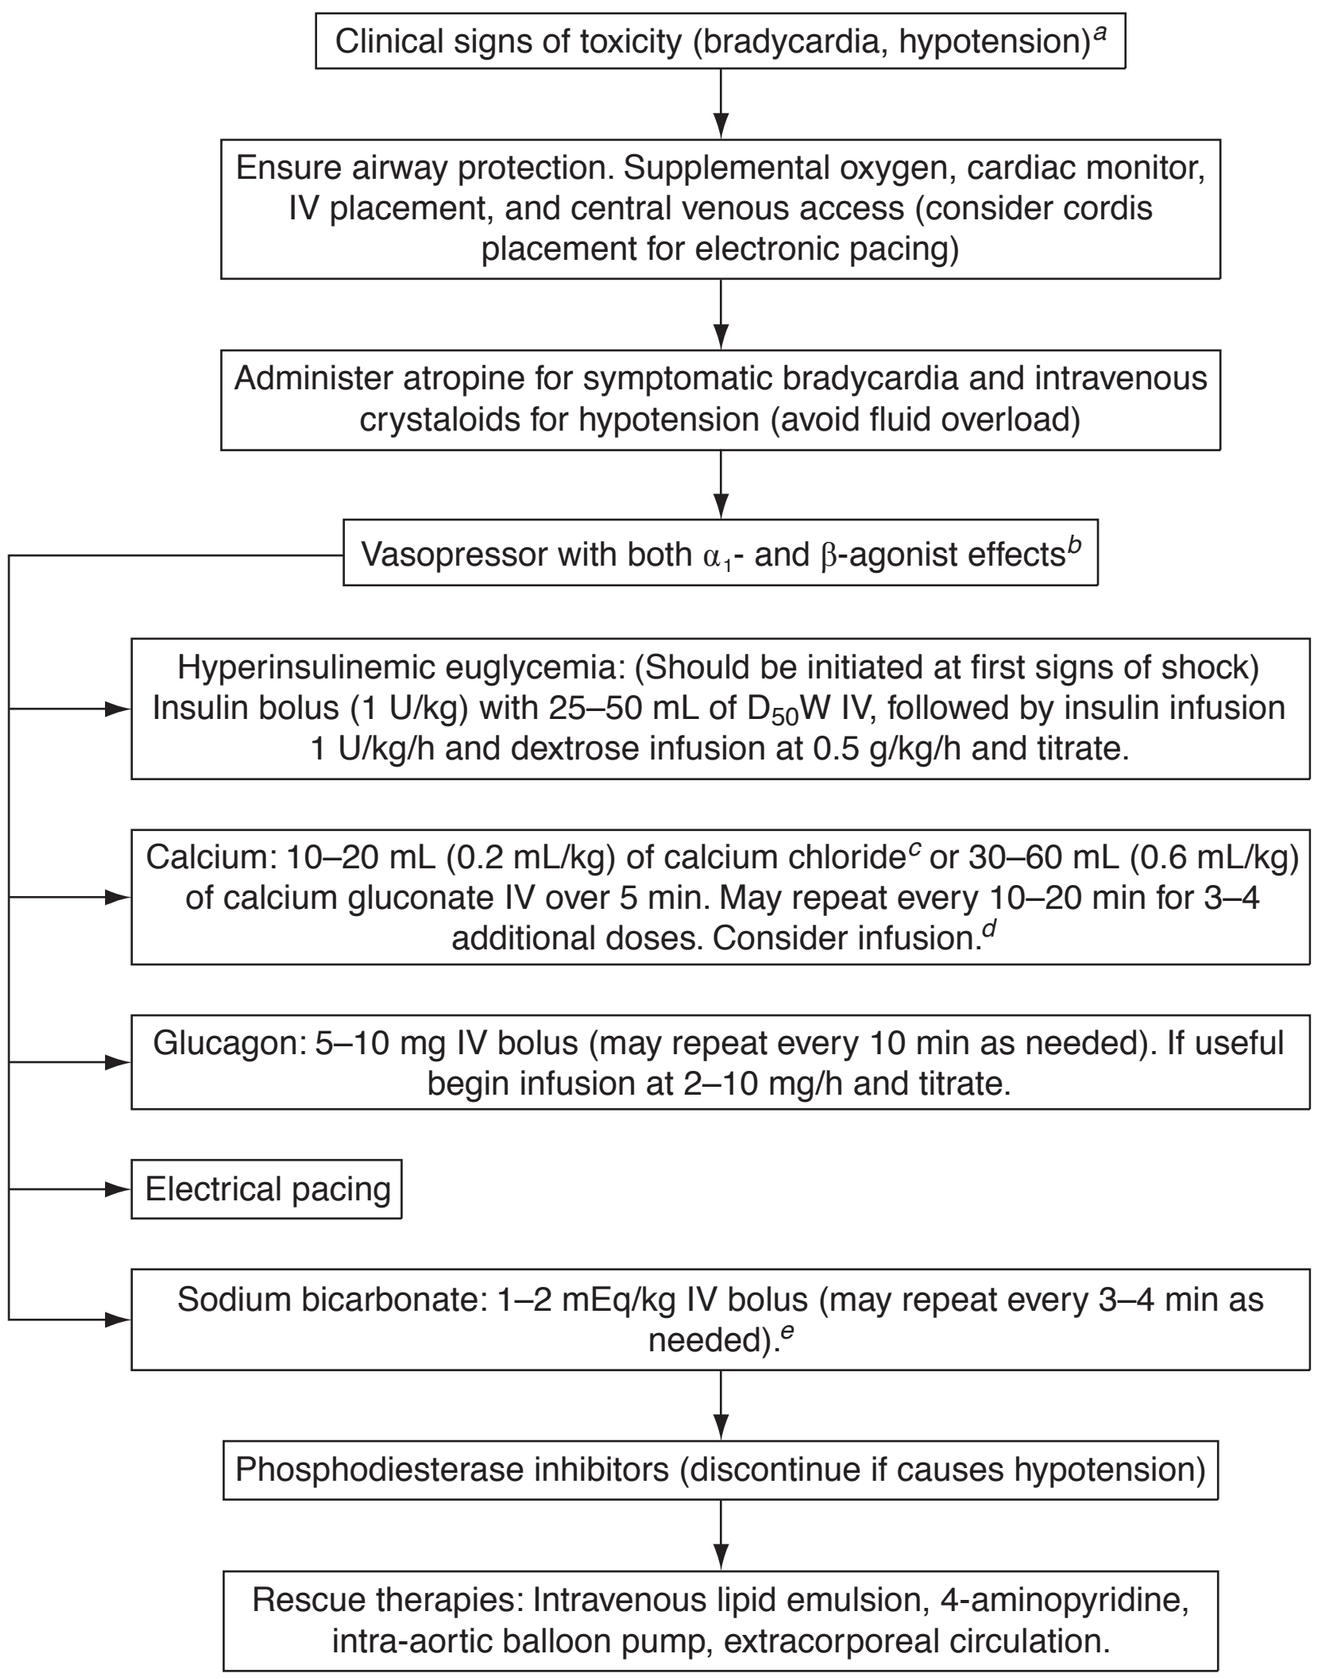


FIGURE 125.1. Suggested algorithm for treatment of beta-blocker poisoning. [a]Patients with significant toxicity will often require multiple therapies and the initiation of these simultaneously. In less severely poisoned patients, therapies can be added sequentially depending on clinical response. Decontaminate on a case-by-case basis, but preservation of vital signs takes precedence over decontamination. [b]May need multiple pressors at very high doses. [c]Administer calcium chloride via a central venous catheter. [d]Calcium infusion: 0.4 mL/kg/h of calcium chloride or 1.2 mL/kg/h of calcium gluconate. May allow higher doses and permissive hypercalcemia depending on response. [e]Administer sodium bicarbonate for wide complex conduction defects caused by beta-blocking agents with membrane stabilizing activity.

Calcium chloride compared to calcium gluconate contains three times the amount of elemental calcium on a milliequivalent basis (10% calcium chloride: 272 mg elemental calcium or 13.6 mEq per 1 g ampule; 10% calcium gluconate: 90 mg elemental calcium or 4.5 mEq per 1 g ampule). However, it is recommended to only give calcium chloride via a central venous catheter. Calcium gluconate can be given via a peripheral line.

Optimum calcium dosing is not well established. Initial doses are generally given as boluses (10 to 20 mL of 10% calcium chloride or 30 to 60 mL of 10% calcium gluconate). Additional boluses may be given every 10 to 20 minutes. Boluses should be given over a 5-minute period in conjunction with cardiac monitoring as rapid infusions have resulted in hypotension, atrioventricular dissociation, and ventricular fibrillation. The effects of boluses may be transient, and a constant infusion required. Infusions can be started at 0.4 mL per kg per hour for calcium chloride and 1.2 mL per kg per hour for calcium gluconate and titrated to effect. Additional boluses can be given as needed. Calcium levels should be monitored. Raising serum ionized calcium to 2 to 3 mEq per L improves canine cardiac performance in verapamil poisoning, and is a reasonable goal to attain. It may be necessary to continue therapy despite high serum calcium levels if the patient is only responding to calcium administration. Hypercalcemia can lead to renal failure and limb or mesenteric ischemia. It is recommended to stop calcium infusions if no beneficial effect is observed.

Glucagon

Although there are no controlled trials of glucagon for beta-blocker overdose in humans, glucagon has served as an effective agent for reversing hypotension and bradycardia in multiple case reports [14,27–29]. Glucagon has a half-life of 20 minutes, so a continuous intravenous infusion of 1 to 10 mg per hour is recommended after an initial bolus of 3 to 10 mg for adults. In children, an initial intravenous dose of 0.05 mg per kg should be followed by a continuous infusion of 0.07 mg per kg per hour [2,3,27]. This dose is titrated to patient response, and large total doses may be required. The dose should be tapered once the patient's clinical condition improves. The mechanism by which glucagon produces a positive inotropic and chronotropic effect on the heart is believed to be activation of the adenyl cyclase pathway, which converts adenosine triphosphate to cAMP through an independent receptor, changing membrane ion conductivity, altering calcium influx, and augmenting contractility even in the presence of complete β-adrenergic blockade [28]. It is recommended that glucagon be reconstituted in a solution of 5% dextrose in water or in preservative-free saline, rather than the diluent provided by the manufacturer, as the latter contains phenol that might be toxic in the large doses often needed to treat beta-blocker toxicity [27,30]. Severe phenol toxicity is usually manifested as chemical burns, lethargy, coma, cardiac dysrhythmias, and death [31]. Non–phenol-containing, high-dose glucagon preparations are now available [32].

Phosphodiesterase Inhibitors

The simultaneous use of multiple agents may be effective when a single agent fails. Although theoretically promising, phosphodiesterase inhibitors such as amrinone and milrinone, which inhibit the breakdown of cAMP to AMP, have not proven to be superior to glucagon in reversing the hemodynamic effects of beta-blocker overdose in a canine model [33,34]. Other studies using dogs have shown no additional benefit of combining a phosphodiesterase inhibitor with glucagon [35,36]. It has been suggested that phosphodiesterase inhibitors might be used in cases of beta-blocker poisoning when adequate doses of glucagon are not available [33]. The phosphodiesterase inhibitor enoximone has been successfully used in cases of beta-blocker overdoses [37].

Sodium Bicarbonate

A number of beta-blockers (propranolol, carvedilol, pindolol, and acebutolol) also affect cardiac sodium channels producing membrane stabilizing effects which may result in quinidine-like dysrhythmias (e.g., wide QRS complexes). This effect may respond to intravenous boluses of sodium bicarbonate albeit in a canine model; sodium bicarbonate was ineffective in treating propranolol toxicity that resulted in bradycardia, hypotension, and wide QRS intervals [38]. In a case report, sodium bicarbonate appeared to reverse QRS widening following an acebutolol overdose [39]. The recommended dose is 1 to 2 mEq per kg given as a rapid infusion over several minutes.

Hyperinsulin–Euglycemia Treatment

High-dose insulin while maintaining euglycemia has been proposed as an antidote for beta-blocker poisoning [40]. Insulin is an inotropic agent which may enhance response to catecholamines and reverse metabolic acidosis. Although results in animals remain encouraging [41–43], further studies are needed in humans. Several case reports described successful insulin–euglycemia therapy for calcium channel blocker toxicity [44] (one patient also ingested a beta-blocker). Therefore, this treatment should be considered an option in patients with refractory beta-blocker toxicity as both classes bear similarities in the clinical manifestation and mechanism of toxicity [45]. The recommended doses are 0.5 to 1.0 IU per kg per hour [40]. A second intravenous infusion of $D_{10}W$ or $D_{25}W$ containing potassium chloride should be simultaneously administered to the insulin infusion at a rate sufficient to maintain the serum glucose and potassium concentrations in the normal range.

Vasopressin

The use of vasopressin in beta-blocker toxicity has been suggested. In one animal trial which compared vasopressin with glucagon in the treatment of beta-blocker toxicity, vasopressin was neither found to increase survival nor had a significant effect on any of the cardiac parameters tested relative to glucagon [46]. High-dose insulin treatment also improved survival when compared to vasopressin with epinephrine in a swine model [43].

Lipid Emulsion

The use of lipid emulsion has been suggested in the treatment of the cardiotoxic effects of local anesthetics. Various animal models of bupivacaine toxicity have demonstrated faster return of spontaneous circulation following treatment with lipid emulsion therapy [47,48] as well as improved cardiodynamic parameters when compared with epinephrine [49]. However, a pig model did not show any improvement in survival when compared to saline controls [50]. Positive outcomes with the use of lipid emulsion were described in human case reports of bupivacaine [51–53], bupropion and lamotrigine [54], and quetiapine and sertraline overdoses [55]. Lipid emulsion was also investigated for the treatment of beta-blockers toxicity; however, there is currently no experience in humans. In a rabbit model, lipid emulsion successfully improved hypotension

induced by propranolol when compared with placebo [56]. In a separate study on rats, pretreatment with lipid emulsion resulted in a significant reduction in QRS duration and a non-significant improvement in bradycardia induced by propranolol when compared to placebo [57]. The mechanism of how lipid emulsion may be beneficial is not completely understood. The possible explanations include the creation of lipid sink for fat-soluble drugs, augmentation of cardiac energy substrates, or the improvement of myocardial function by increasing intracellular calcium [58]. No standard dosing regimen exists. However, a loading dose of 1.5 mL per kg administered over 1 minute, repeated one or two times every 3 to 5 minutes as needed is often used. If hemodynamic improvement is noted, the loading dose should be followed by a continuous infusion at a rate of 0.25 to 0.5 mL per kg per minute. Further information can be found at www.lipidrescue.org.

Extracorporeal Removal

Although the efficacy of hemodialysis in acute beta-blocker poisoning has not been studied in controlled clinical trials, it is theoretically useful in removing beta-blockers that have a low volume of distribution, are not significantly protein bound, and are hydrophilic. This would include acebutolol, atenolol, nadolol, sotalol, and timolol. Hemodialysis appeared to be clinically useful in a number of case reports involving atenolol, acebutolol, sotalol, and nadolol poisoning [59,60] and in cases of refractory torsade de pointes due to sotalol [61,62]. Charcoal hemoperfusion has also been suggested as an adjunctive therapy in patients severely poisoned with beta-blockers, although experience is limited [63]. Continuous venovenous hemodiafiltration was also successfully used in the treatment of a combined atenolol/nifedipine overdose [64]. The molecular adsorbent recirculating system (MARS) is a blood purification system that may be effective in removing protein bound toxins. There are case reports describing its successful use in theophylline [65] and phenytoin [66] MARS may theoretically be helpful in removing highly protein bound beta-blockers such as propranolol and carvedilol.

Other Interventions

Transient blood pressure elevations caused by pindolol usually require no specific treatment. Short-acting agents such as nitroprusside should be used if marked blood pressure elevation occurs, especially if it is accompanied by organ ischemia. Ventricular dysrhythmias induced by sotalol have been treated with lidocaine, isoproterenol, magnesium, and cardioversion defibrillation [6]. Electrical cardiac pacing may be needed if bradycardia, hypotension, and heart block fail to respond to pharmacologic therapy [2], or if ventricular tachydysrhythmias associated with a prolonged QTc interval are difficult to control [6]. In severe overdoses, a pacemaker may not capture. If capture occurs, the increased heart rate may not increase blood pressure. Heart rates greater than 90 to 100 beats per minute significantly decrease diastolic filling time and may adversely affect inotropy. Intra-aortic balloon pump counterpulsation [32] and extracorporeal circulation [67,68] have been successfully used for cardiovascular support.

Patients with beta-blocker overdose who have abnormal vital signs, altered mental status, or dysrhythmias on presentation should be admitted to an intensive care unit. If vital signs can be supported, complete recovery should be expected within 24 to 48 hours. Patients may be discharged after at least 6 hours of emergency department observation if they have ingested an immediate-release product, present with mild to absent toxicity and remain or become asymptomatic, have normal vital signs on discharge, and have received activated charcoal. These patients should be referred for psychiatric evaluation in the event of an intentional overdose or discharged in the care of a reliable observer after an accidental overdose. Any other symptoms mandate longer observation or admission. Because of the potential for delayed toxicity, prolonged observation is recommended after modified-release preparation overdose.

CHAPTER 126 ■ CALCIUM CHANNEL ANTAGONIST POISONING

CHRISTOPHER R. DEWITT

INTRODUCTION

Calcium channel antagonists (CCA) effectively treat a variety of medical conditions. Yet, accidental and intentional overdoses of theses agents can be life threatening. CCAs consistently top the list of cardiovascular medications with the greatest proportion of deaths per exposure [1–3]. Severely poisoned patients demonstrate cardiovascular collapse as well as metabolic derangements similar to diabetic acidosis. Cardiovascular instability is often refractory to typical cardiotonic therapies and medication doses. There is no antidote for CCAs, and no controlled clinical studies to guide therapy. Treatment recommendations are therefore based on case series, case reports, animal

studies, and extrapolation. Simultaneous use of multiple therapies is often required and should be tailored to the patient's cardiovascular and metabolic responses. Overall goals of treatment are to provide supportive care, optimize cardiovascular and metabolic function, and decrease drug absorption. If vital signs can be supported until the drug is metabolized or eliminated, most patients will survive without sequelae.

PHYSIOLOGY AND PATHOPHYSIOLOGY

Available CCAs antagonize calcium influx through L-type voltage sensitive channels [4], a specific type of calcium channel found in the heart, vascular smooth muscle, and pancreatic β-islet cells. Multiple physiologic functions are dependent on this calcium influx.

In the cardiovascular system, calcium influx through L-type channels is responsible for the spontaneous pacemaker activity of the sinoatrial (SA) node and depolarization of the atrioventricular (AV) node [4,5]. Other myocardial cells rely on sodium influx for initial depolarization [5,6], but calcium entry via L-type channels contributes to the plateau phase of their action potential [5,7]. Calcium entering during the plateau phase signals the release of additional calcium from the sarcoplasmic reticulum into the cytosol, allowing contraction to occur [5,8,9]. The magnitude and duration of sarcoplasmic calcium release and myocardial contraction is proportional to the magnitude and duration of calcium entry via L-type channels [8]. Vascular smooth muscle tone is also maintained by a similar mechanism [8]. Thus, therapeutic clinical effects of CCAs arise from blockade of L-type channels resulting in decreased cytosolic calcium levels. Depending on the class of CCA administered (see Pharmacology section), the clinical result is depression of SA node automaticity, AV node conduction, myocardial contractility, and vasodilation. The pathophysiologic effects of CCA overdose are essentially an exaggeration of pharmacologic effects that lead to cardiovascular shock. In canines, shock ensues despite a 14-fold or greater increase in endogenous catecholamine concentrations [10–12].

In addition to cardiovascular effects, CCA poisoning also produces a diabetogenic effect of hyperglycemia and acidosis. Insulin secretion is dependent on calcium influx into pancreatic β-islet cells. Although generally not a concern at therapeutic doses, CCBs decrease insulin secretion [13–16]. In canine models of verapamil-induced shock, systemic insulin levels fail to increase in response to an intact glucogenic response and hyperglycemia [10,12,17]. Experimentally, verapamil toxicity also produces systemic [12,18] and myocardial [10] resistance to insulin-mediated carbohydrate uptake. The cause of this resistance may be multifactorial involving decreased substrate delivery from poor perfusion, interference with calcium-dependent cellular insulin responsiveness and glucose uptake, and inhibition of calcium-stimulated mitochondrial dehydrogenases (i.e., pyruvate dehydrogenase) and glucose catabolism [12]. More recent evidence suggests CCAs interfere with cellular signaling, specifically recruitment of glucose transporter proteins (GLUTs) from the intracellular space to cell membranes [19]. These GLUTs are responsible for normal cellular uptake of glucose.

Verapamil toxicity also produces a state of hyperlacticacidemia due to a combination of tissue hypoperfusion and probably a defect in carbohydrate metabolism [12]. In stressed states such as CCA toxicity, the heart switches from preferentially using free fatty acids to carbohydrates (glucose and lactate) for energy production [10,11,17]. Although there is an abundance of circulating carbohydrates (e.g., glucose and lactate), they are essentially unavailable for use because of insulin resistance and decreased insulin availability.

In essence, CCAs decrease cytosolic calcium levels resulting in desirable cardiovascular effects at therapeutic doses, and at toxic doses an exaggeration of those effects. Additionally, toxicity produces a vicious cycle where the myocardium is preferentially metabolizing carbohydrates yet carbohydrate utilization is hindered by impaired insulin release and insulin resistance.

PHARMACOLOGY

In the United States, available CCAs fall into one of three classes: phenylalkylamine (verapamil), benzothiazepine (diltiazem), and dihydropyridines (nifedipine and all other agents). At therapeutic doses, each class has differing affinities for myocardial tissues and vascular smooth muscle. Verapamil and diltiazem are potent inhibitors SA node automaticity, AV node conduction, myocardial contractility, and cause modest vasodilation [20,21]. Verapamil affects the SA node, contractility, and vasodilation more than diltiazem [20,21]. This is probably why verapamil generally causes more deaths than other CCAs [1–3]. Dihydropyridines are far more selective for vascular smooth muscle, and at therapeutic doses have very little effect on cardiac pacemaker cells or contractility [9,20,21]. In significant poisoning this selectivity is lost however.

Pharmacologic properties of CCAs make extracorporeal removal of limited or no value as demonstrated in several cases [22–24], although plasmapheresis was believed to be beneficial in several cases [25–27]. Therapeutic half-lives of CCBs are variable, but in overdose can be prolonged [22,28–31]. The duration of toxicity in most cases is less than 24 hours, but has been reported to last 48 hours with sustained release (SR) verapamil [32] and for more than 5 days with amlodipine [33].

Verapamil, diltiazem, nifedipine, and several of the newer dihydropyridines are available in both immediate release (IR) and SR formulations. This information becomes important when considering how long to observe asymptomatic patients after an overdose. Immediate-release preparations produce signs or symptoms of toxicity within 6 hours of ingestion [34] whereas toxicity with SR products may be delayed 6 to 12 hours [34–37] or rarely longer [38]. Amlodipine, a dihydropyridine, has unique pharmacokinetics however. It is not a sustained release product, but has a late onset of peak effect and long half-life allowing for delayed and prolonged toxicity.

There is no accurate definition of a toxic dose, and patients have demonstrated significantly different effects at similar doses. Unintentional overdoses are common, but uncommonly result in significant effect. However, several adult patients have developed toxicity and death at doses less than maximum recommended daily doses [39]. Factors that could have contributed to this are advanced age, underlying medical conditions, additional medications, and chewing and swallowing SR preparations—essentially changing the pharmacokinetics into an IR formulation [39]. In general, the most significant poisonings are large intentional ingestions, but patients with significant underlying medical diseases, or advanced age can have significant effects at lower doses.

CLINICAL MANIFESTATIONS

Cardiovascular effects are the primary manifestation of CCA poisoning. Alterations in mental status without significant hypotension should not be attributed to CCA ingestion. Minimally intoxicated patients, or those who present soon after ingestion, may demonstrate no signs of toxicity. All CCAs can cause hypotension in overdose. However, the cause of the hypotension is typically an extension of the drugs' therapeutic effects. (i.e., dihydropyridines causing significant vasodilation with reflex tachycardia where verapamil and diltiazem slow

SA and AV node conduction, decrease contractility, and cause vasodilation) Thus, in overdose normal sinus rhythm or reflex tachycardia is commonly seen with nifedipine [34,37,40], where sinus bradycardia, AV nodal blocks, and junctional rhythm are common with verapamil and diltiazem [34,37,41]. This selectivity may be lost in large overdoses so that dihydropyridine poisoning results in bradycardia and/or impaired cardiac conduction [33,34,37,42–47]. Although overdose experience with dihydropyridines other than nifedipine is limited [33,45–48], they would be expected to have effects similar to nifedipine. The exception may be amlodipine where toxic effects may be delayed [46].

Severe poisoning is characterized by hypotension and bradycardia [34,37,40,49,50], hyperglycemia [37,38,40,42,45–47, 49–59] and metabolic acidosis [17,33,42,46,47,49,52,53,56, 59]. Hyperglycemia is due to aforementioned alterations in insulin and carbohydrate homeostasis (see Physiology and Pathophysiology section). In fact, in a recent review of 40 CCA overdoses the degree of hyperglycemia was the best predictor of the composite end points of death, pacemaker requirement, or vasopressor requirement [60]. Dysfunctional carbohydrate metabolism and tissue hypoperfusion result in hyperlacticacidemia. In addition, tissue hypoperfusion can result in cerebrovascular accidents, seizures, renal failure, myocardial infarction, and noncardiogenic pulmonary edema [61].

DIFFERENTIAL DIAGNOSIS

CCA poisoning should be considered in any patient presenting with hypotension and bradycardia. Suspicions that the patient is poisoned with a CCA should be raised even further if there is associated hyperglycemia and acidosis. However, the differential diagnosis of a patient with hypotension and bradycardia includes other toxicologic causes such as beta-blockers, digoxin and other cardiac glycosides, antidysrhythmics, and clonidine. However, nontoxicologic causes such as myocardial disease, hyperkalemia, sepsis, and hypothyroidism should also be considered.

MANAGEMENT

General

Management of a patient with CCA poisoning begins with airway management and maintenance of vital signs. Vascular access should be obtained and continuous blood pressure and cardiac monitoring initiated. Preemptive intubation should strongly be considered in patients with significant ingestions or signs of toxicity due to the potential for rapid deterioration. In bradycardic patients, administration of atropine before intubation may prevent vagal responses from laryngoscopy. An electrocardiogram (ECG) should be obtained. The presence of dysrhythmias or conduction disturbances, which may be as subtle as PR prolongation in some patients, should be noted. Measurements of renal function, electrolytes, complete blood counts, liver function tests, arterial blood gases, and acetaminophen, salicylate, and digoxin levels should be guided by the clinical picture and medical history.

Serum CCA levels are not routinely available and do not help with patient management, but may be necessary for confirmation of the diagnosis. In patients with severe or refractory hypotension, urinary catheterization and central venous catheterization are recommended to guide fluid and vasopressor therapy. Finally, early consultation with a medical toxicologist, regarding medical therapy, and a cardiologist, regarding pacemaker or intra-aortic balloon pump placement, is recommended.

Gastrointestinal Decontamination

Definitive data regarding the utility of gastrointestinal decontamination in overdoses are lacking, and all forms of decontamination carry potential risks. However, CCA overdoses can result in serious morbidity and mortality, so that potential benefits of decontamination may outweigh risks in significant ingestions. Risks and benefits should be considered on a case-by-case basis, and interventions necessary to maintain vital signs take precedence over decontamination. Aspiration is one of the main risks associated with decontamination. Thus, assurance of airway control prior to decontamination is necessary.

Activated charcoal should be administered to all significant ingestions. The greatest benefit of charcoal administration occurs within the first 2 hours after ingestion [62]. However, it may hold benefit, especially for SR preparations, up to 4 hours after ingestion [63]. Gastric lavage should not be used routinely, but considered for recent life-threatening ingestions in patients who have not already vomited [64]. Like laryngoscopy, lavage may theoretically cause bradycardia from vagal effects. Thus, atropine should be given prior to initiation, and lavage should be withheld in patients with existing bradycardia and conduction abnormalities [20].

Large ingestions of SR preparations may provide a gastrointestinal depot of drug causing recurrent cardiovascular compromise, or rise in serum drug levels up to 18 hours after initial decontamination [35,38,49,53,58,65,66]. A rise in serum amlodipine levels has been demonstrated 24.5 hours after ingestion—approximately 22 hours after decontamination [47]. Therefore repeat charcoal doses or whole bowel irrigation (WBI) with polyethylene glycol should be considered for large ingestions of SR products in patients with functioning gastrointestinal tracts [61]. Repeat charcoal dosing has also been recommended in large overdoses of IR products [29]. One or two additional doses of activated charcoal (0.5 g per kg without cathartic) separated by 2 to 4 hours may be sufficient. Because of the large volumes necessary, polyethylene glycol WBI should be administered via nasogastric tube (0.5 L per hour for small children and 1 to 2 L per hour for adults). However, it may be prudent to withhold WBI in patients with hemodynamic compromise [67].

Cardiovascular Support

Hypotension can initially be treated with intravenous crystalloids with close monitoring for fluid overload. Although usually ineffective in severe poisoning [34,38,40,41,58], atropine should be given for symptomatic bradycardia. Treatment beyond general supportive care, intravenous fluids, and atropine will depend on the clinical situation. Seriously poisoned patients may require rapid simultaneous administration of multiple therapies. Transvenous pacing may be attempted, but in significant poisoning there may be failure to capture, and blood pressure may not improve despite an increase in heart rate [34,38].

Vasopressors

The exact sequence of pharmacologic therapies has not been studied. However, healthcare providers generally have the greatest familiarity with dosing and administration of vasopressor agents. Thus, these agents can often be initiated rapidly and may improve cardiovascular instability. Ideally and agent with both α_1- and β-agonist effects should be instituted. Improvements have been noted with dopamine, dobutamine, norepinephrine, isoproterenol, and epinephrine [34,37,49,50, 52,68]. However, no specific agent has demonstrated superiority so it is reasonable for clinicians to start with the agent they

are most familiar with. There is scant information regarding vasopressin utility in CCA poisoning, but based on available data it should not be used as monotherapy in CCA poisoning. Animal models have demonstrated either no improvement in mean arterial pressure [69] or decreased survival [70] with vasopressin compared to saline controls. However, there was improvement in systemic vascular resistance and blood pressure after vasopressin was administered to two patients unresponsive to multiple other therapies [71].

Multiple simultaneous vasoactive agents may be required depending on the hemodynamic response, and require doses much higher than ACLS-based doses [72]. Because vasopressors can result in tachydysrhythmias, increased myocardial oxygen consumption and vasospastic events, these agents should be the first to be weaned from a patient who has stabilized.

Hyperinsulinemic Euglycemia

Hyperinsulinemic euglycemia (HIE) refers to the administration of high-dose regular insulin while maintaining normal serum glucose levels. HIE is thought to overcome the CCA-induced compromise of cardiovascular carbohydrate uptake thus improving hemodynamic embarrassment. The exact mechanisms underlying these actions still remain controversial [73], but may be best described in the following animal studies.

Four animal studies (mongrel dogs) of HIE in verapamil poisoning [10,11,17,74] have been rated as very good to excellent quality by an expert panel [72]. Where survival from poisoning was measured, 100% of animals treated with insulin survived [74]. However, survival with epinephrine [17,74], glucagon [17,74], and calcium [17] was 33%, 0%, and 17%, respectively. Insulin also increased the mean lethal dose of verapamil and time to death compared to epinephrine and glucagon [11]. In these studies HIE improved and sustained cardiac contractility, systolic and diastolic function, and systemic and cardiac blood flow compared to calcium, glucagon, and epinephrine [10,11,17,74]. Insulin improved myocardial metabolism and function without increasing myocardial oxygen consumption [10,11]. Epinephrine, glucagon, and calcium however contribute to oxygen wasting [17].

The first report of HIE therapy, published in 1999, included five CCA-poisoned patients who failed to respond to other therapies [48]. The benefit of HIE was striking. Insulin dosing included a 10 to 20 IU bolus with a 25-g bolus of glucose followed by an infusion of 0.1 to 1.0 IU per kg per hour (mean 0.5 IU per kg per hour) and dextrose 10 to 75 g per hour (mean 28.4 g per hour). One patient failed to improve with respiratory support, crystalloids, atropine, calcium, and glucagon. After initiation of HIE blood pressure improved, complete heart block resolved, and echocardiographically measured ejection fraction increased from 10% to 30%. Many other cases have been published and the clinical data supporting HIE have recently been reviewed [73,75]. The data provides multiple examples of CCA-poisoned patients improving with HIE therapy after failing treatments such as atropine, pacing, vasopressors, calcium, glucagon, and phosphodiesterase inhibitors.

Clinical improvement is gradual and may take 30 minutes or more. However, one patient who failed to respond to dopamine, norepinephrine, calcium, and glucagon showed a dramatic response within 15 minutes of receiving a 10-fold dosing error of insulin (1,000 IU) [76]. Patients responding to insulin therapy demonstrate improved blood pressure, myocardial contractility, and metabolic acidosis, whereas effects on bradycardia and cardiac conduction are variable [73].

Failures of HIE therapy have also been reported [77]. Our lack of knowledge regarding optimum dosing of insulin has been suggested as a reason for failures with HIE [78]. Canine studies of verapamil toxicity employed insulin doses of up to 16 IU per kg per hour, but a dose–response relationship for insulin has not been determined [78]. The timing of HIE administration may also be a consideration. In several failures HIE was initiated multiple hours after ingestion when significant hemodynamic compromise was already present. This suggests a threshold point in CCA poisoning where there may be no beneficial intervention once that threshold is crossed. Therefore, HIE should be instituted well before profound shock supervenes. Although an optimal dosing scheme has yet to be established, a rational starting point is an initial insulin bolus of 1 IU per kg with 25 g of dextrose, followed by an infusion at 1 U per kg per hour and 0.5 g per kg per hour of dextrose [61,73]. It is believed supraphysiologic insulin doses are required to overcome CCA inhibition of insulin responsive GLUTs (see Physiology and Pathophysiology section) [19]. Increasing the insulin dose may be of benefit if response is insufficient. Serum glucose should be monitored closely and dextrose infusions adjusted to maintain normal ranges.

Hypoglycemia and hypokalemia, expected adverse effects of HIE, can be easily detected and treated. The safety of HIE therapy was recently demonstrated in a prospective observational study [79]. Serum glucose and potassium were monitored every 30 minutes until stable and then 1 to 2 hourly thereafter. Out of seven patients only one episode of hypoglycemia (43.5 mg per dL) occurred (occurring 33.5 hours after ingestion when the maximal effects of CCA-induced insulin resistance would be waning). Hypokalemia (2.5 to 3.5 mmol per L) occurred in two patients without any clinical significance. However, it has been suggested that mild hypokalemia may provide a beneficial effect in CCA poisoning [48,59].

Hypoglycemic effects of insulin last for hours after infusions are discontinued which requires continued monitoring of blood glucose during this period. Aggressive correction of insulin-induced hypokalemia is unnecessary unless the patient is symptomatic, or potassium level falls below an arbitrarily suggested level of 2.5 mEq per L [48].

Calcium

The goal of calcium therapy is to increase extracellular calcium concentrations thus increasing calcium influx through any unblocked calcium channels. Calcium has demonstrated effectiveness in animal models [80–83], and improvement reported in human cases [37,38,41,44,56,84,85]. However, responses are variable and often short-lived, and patients with significant toxicity often fail to improve with calcium alone [28,34,40,43,49]. Conduction disturbances, contractility, and blood pressure, may be improved, but generally, there is no increase in heart rate [34,40,49,58]. Optimum dosing has yet to be established, and 4.5 to 95.3 mEq were used in one case series without an identifiable dose–response [34].

Calcium chloride compared to calcium gluconate contains three times the amount of elemental calcium on a milliequivalent basis (10% calcium chloride: 272 mg elemental calcium or 13.6 mEq per 1 g ampule; 10% calcium gluconate: 90 mg elemental calcium or 4.5 mEq per 1 g ampule). However, it is recommended to only give calcium chloride via a central venous catheter [84]. Calcium gluconate can be given via a peripheral line.

Optimum calcium dosing is not well established. Initial doses are generally given as boluses (10 to 20 mL of 10% calcium chloride, or 30 to 60 mL of 10% calcium gluconate) [46,86–88]. Additional boluses may be given every 10 to 20 minutes. Some authors suggest more aggressive dosing of 1 g every 2 to 3 minutes until clinical response is seen [37]. Boluses should be given over a 5-minute period in conjunction with cardiac monitoring as rapid infusions have resulted in hypotension, atrioventricular dissociation, and ventricular fibrillation [89,90]. The effects of boluses may be transient, and

a constant infusion required [37,46,86,87]. Infusions can be started at 0.4 mL per kg per hour for calcium chloride and 1.2 mL per kg per hour for calcium gluconate and titrated to effect. Additional boluses can be given as needed. Calcium levels should be monitored. One author recommends maintaining serum ionized calcium levels approximately twice normal [91]. Raising serum ionized calcium to 2 to 3 mEq per L improves canine cardiac performance in verapamil poisoning [17,80] and is a reasonable goal to attain. It may be necessary to continue therapy despite high serum calcium levels if the patient is only responding to calcium administration. Significantly poisoned patients have tolerated high serum calcium levels without untoward effect [35,37,44,66], including one patient who obtained a peak serum calcium level of 23.8 mg per dL [38]. However, a patient in another report achieved a peak calcium level of 32.3 mg per dL and developed anuric renal failure and eventually died [92]. It has been recommended to stop calcium infusions if no beneficial effect is observed [93]. In addition, calcium should not be administered to a patient with proven or potential digoxin toxicity.

Glucagon

Glucagon possesses both inotropic and chronotropic effects [94], and experimentally increases heart rate, cardiac output, and reverses AV nodal blocks in CCA poisoning [95]. Several case reports noted improvement with glucagon therapy [50,51,65,96], but failures are also reported [52,58,59,97]. Five to ten milligrams (150 µg per kg) given intravenously over 1 to 2 minutes is a typical starting dose [95]. Cardiovascular effects of glucagon last only 10 to 15 minutes [98,99], so repeat boluses may be required every 5 to 10 minutes followed by a continuous infusion of 2 to 10 mg per hour (50–100 µg per kg per hour) [20,95]. Glucagon is a potent emetic [98], so airway control should be ensured before administration. Hyperglycemia and hypokalemia may also be observed with glucagon administration [98].

Phosphodiesterase Inhibitors

Phosphodiesterase inhibitors (PDI) such as inamrinone (amrinone) and milrinone increase cytosolic calcium and improve inotropy. Phosphodiesterase inhibitors have been used in combination with other therapies to treat CCA-poisoned patients [54,55], and appear to be effective in animal models [100,101]. However, they can be difficult to titrate and cause vasodilation and hypotension.

RESCUE AND EXPERIMENTAL THERAPIES

Nonpharmacologic Therapies

If available, intra-aortic balloon counterpulsation [57], or cardiopulmonary bypass [58,102] may provide a bridge to survival in patients unresponsive to other therapies.

Pharmacologic Therapies

4-Aminopyridine

4-Aminopyridine is an orphan drug used to treat spinal cord injury and multiple sclerosis. It improves contractility by indirectly increasing intracellular calcium levels and has shown benefit in animal studies of verapamil toxicity [103,104] and in one human case report [24]. Unfortunately, it causes seizures and has a narrow therapeutic index. It may be considered if all other treatments are failing.

Intravenous Lipid Emulsion

Perhaps, the most promising new therapy for CCA poisoning is intravenous lipid emulsion (ILE). Intravenous lipids have traditionally been used as a source of free fatty acids in parenteral nutrition. A chance observation led to the finding that ILE is beneficial in the treatment of local anesthetic-induced cardiac arrest [105]. Multiple animal studies followed demonstrating dramatic results with ILE for local anesthetic toxicity. This led to the incorporation of ILE into anesthesiology guidelines for the treatment of local anesthetic cardiotoxicity [106].

Intravenous lipids have recently been investigated in verapamil toxicity. In a rat model, ILE significantly prolonged survival and doubled the median lethal dose of verapamil [107]. Intravenous lipid emulsion dramatically improved blood pressure and survival rate compared with saline in dogs pretreated with atropine and calcium chloride [108]. The two case reports of ILE for CCA poisoning have suggested a benefit [109,110].

Proposed mechanisms of ILE therapy include creation of a "lipid sink" where lipid soluble toxins are sequestered, augmenting cardiac energy supplies, and increasing intracellular calcium in cardiac myocytes [111]. In addition, ILE is inexpensive and readily available. The main safety concern regarding ILE therapy is pulmonary fat emboli. The one study to specifically examine this failed to demonstrate signs of fat emboli with ILE therapy [112].

Although experimental evidence for ILE for CCA poisoning is currently limited, it should be considered for patients who are failing other more traditional therapies. Dosing recommendations can be found at www.lipidrescue.org.

DISPOSITION

Patients with signs or symptoms of toxicity require ICU admission. Disposition of symptomatic patients depends on the formulation ingested. Patients with large or intentional ingestions of SR products or amlodipine should undergo appropriate decontamination and 24 hours of observation in a closely monitored setting. Patients with small unintentional ingestions of SR products may be medically cleared after appropriate decontamination if they remain asymptomatic with normal vital signs and ECGs for 8 to 12 hours. Close attention should be paid to subtle ECG signs of toxicity such as PR prolongation. Patients ingesting non-SR products may be cleared after 6 to 8 hours of observation if normal vital signs and ECGs are maintained.

CHAPTER 127 ■ CARDIAC GLYCOSIDE POISONING

MARK A. KIRK AND BRYAN S. JUDGE

Cardiac glycosides (CGs) are naturally occurring substances whose medicinal benefits have been recognized for centuries [1]. Digoxin is the major CG used for medicinal purposes today. It is most widely used in the treatment of congestive heart failure and acute atrial fibrillation associated with a rapid ventricular response rate [2]. Although digoxin is responsible for most cases of CG poisoning, exposure to plant (i.e., dogbane, foxglove, lily of the valley, oleander, red squill, and Siberian ginseng) and animal (i.e., *Bufo* toad species) sources and topical aphrodisiacs can also result in serious toxicity [3–5].

PHARMACOLOGY

Digoxin exerts a positive inotropic effect, thereby enhancing the force of myocardial contraction. Direct effects of digoxin

include prolongation of the effective refractory period in the atria and the atrioventricular (AV) node, which diminishes the conduction velocity through those regions. CGs are readily absorbed through the gastrointestinal tract; digoxin has up to 80% bioavailability [6]. Digoxin has a volume of distribution (V_d) of 5.1 to 7.4 L per kg [7] and a half-life of 36 to 48 hours [2]. The generally accepted therapeutic serum concentration range for digoxin is 0.8 to 2.0 ng per mL for inotropic support in patients with left ventricular dysfunction. Higher concentrations (1.5 to 2.0 ng per mL) may be needed for ventricular rate control in patients with atrial dysrhythmias. Digoxin is primarily eliminated by the kidneys. In patients with renal dysfunction, digoxin clearance is reduced. Serum digoxin concentrations can be altered by numerous drug interactions [8–10].

Toxicity results from an exaggeration of therapeutic effects [6]. Cardiac glycosides bind to and inactivate the sodium–potassium adenosine triphosphatase pump (Na^+–K^+-ATPase) on cardiac cell membranes. This pump maintains the electrochemical membrane potential, vital to conduction tissues, by concentrating Na^+ extracellularly and K^+ intracellularly. When Na^+–K^+-ATPase is inhibited, the Na^+–calcium exchanger removes accumulated intracellular sodium in exchange for calcium. This exchange increases sarcoplasmic calcium and is the mechanism responsible for the positive inotropic effect of digitalis. Intracellular calcium overload causes delayed after depolarizations and gives rise to triggered dysrhythmias. Increased vagal tone and direct AV depression may produce conduction disturbances. The decreased refractory period of the myocardium increases automaticity.

CLINICAL PRESENTATION

Differences between the presentations of patients with CG poisoning due to a single acute ingestion and those with chronic toxicity resulting from excessive therapeutic doses are illustrated in Table 127.1. Diagnosing chronic CG toxicity is more difficult because the presentation may mimic more common illnesses, such as influenza or gastroenteritis. Patients with chronic CG toxicity may present with constitutional, gastrointestinal, psychiatric, or visual complaints that may not be recognized as signs of digitalis toxicity. Symptoms most commonly reported include fatigue, weakness, nausea, anorexia, and dizziness [11]. Neuropsychiatric signs and symptoms include headache, weakness, vertigo, syncope, seizures, memory loss, confusion, disorientation, delirium, depression, and hallucinations [12]. The most frequently reported visual disturbances are cloudy or blurred vision, loss of vision, and yellow-green halos or everything appearing "washed in yellow" (xanthopsia) [13].

Cardiac manifestations of CG toxicity are common and potentially life threatening. An extremely wide variety of dysrhythmias has been reported [14,15]. Dysrhythmias frequently associated with CG toxicity include premature ventricular contractions, paroxysmal atrial tachycardia or atrial fibrillation with a conduction block, junctional tachycardia, sinus bradycardia, AV nodal blocks, ventricular tachycardia, and ventricular fibrillation. Atrial tachycardia (enhanced automaticity) with variable AV block (impaired conduction), atrial fibrillation with an accelerated or slow junctional rhythm (regularization of atrial fibrillation), and fascicular tachycardia are highly suggestive of CG toxicity [16,17]. Bidirectional ventricular tachycardia, a narrow-complex tachycardia with right bundle-branch morphology, is highly specific, but not pathognomonic for digitalis toxicity [14].

True end-organ digoxin sensitivity is seen with myocardial disease, myocardial ischemia, and metabolic or electrolyte disturbances [18]. Hypokalemia, hypomagnesemia, and hypercalcemia predispose to toxicity [2]. The elderly are at increased risk, whereas renal impairment, hepatic disease, hypothyroidism, chronic obstructive pulmonary disease, and drug interactions alter sensitivity to CGs [1].

DIAGNOSTIC EVALUATION

Essential laboratory tests include serum digoxin concentrations, electrolytes, blood urea nitrogen, creatinine, calcium, magnesium, and electrocardiogram. Additional laboratory tests should be obtained as clinically indicated. Serum digoxin concentrations can assist in the diagnosis of CG poisoning but often are unreliable indicators of toxicity [17]. A therapeutic concentration does not exclude poisoning, as predisposing factors can cause an individual to become poisoned despite a concentration within the therapeutic range. Conversely, high serum

TABLE 127.1

CHARACTERISTICS OF ACUTE AND CHRONIC CARDIAC GLYCOSIDE TOXICITY

Clinical finding	Acute toxicity	Chronic toxicity
Gastrointestinal toxicity	Nausea, vomiting	Nausea, vomiting
Central nervous system toxicity	Headache, weakness, dizziness, confusion, and coma	Confusion, coma
Cardiac toxicity	Bradydysrhythmias, supraventricular dysrhythmias with AV block; ventricular dysrhythmias are uncommon	Virtually any dysrhythmia (ventricular or supraventricular dysrhythmias with or without AV block); ventricular dysrhythmias are common
Serum potassium	Elevated but may be normal (high concentrations correlated with toxicity)	Low or normal (hypokalemia secondary to concomitant diuretic use)
Serum digoxin concentration	Markedly elevated	May be within "therapeutic" range or minimally elevated

AV, atrioventricular.
Adapted and combined from references [1,11,12,14,32].

digoxin concentrations after an acute ingestion are not always indicative of toxicity [19]. Digoxin follows a two-compartment model of distribution, with relatively rapid absorption into the plasma compartment and then slow redistribution into the tissue compartment [2]. Serum digoxin concentrations most reliably correlate with toxicity when obtained after distribution is complete, which occurs 6 hours or more after oral or intravenous digoxin administration.

Naturally occurring digitalis glycosides from plants and animals can cross-react with the digoxin assay. The degree of cross-reactivity is unknown, and no good correlation has been established between serum concentrations of these glycosides and toxicity [5]. A false-positive digoxin assay (usually less than 3 ng per mL), may occur in neonates and patients with renal insufficiency, liver disease, and pregnancy [20–22] because of endogenous digoxin-like immunoreactive factors.

Hyperkalemia may be a better indicator of end-organ toxicity than the serum digoxin concentration in the acutely poisoned patient [23]. In contrast, hypokalemia and hypomagnesemia are commonly seen in the chronically intoxicated patient, presumably as a result of concomitant diuretic use.

MANAGEMENT

The management of CG poisoning includes supportive care, prevention of further drug absorption, antidotal therapy, and safe disposition. Meticulous attention to supportive care and a search for easily correctable conditions, such as hypoxia, hypoventilation, hypovolemia, hypoglycemia, and electrolyte disturbances, are top priorities. All patients should have vascular access established and continuous cardiac monitoring. Patients with clinical toxicity or elevated serum digoxin concentrations should be admitted to the intensive care unit.

Prevention of further drug absorption should be addressed after life support measures have been initiated. Gastric lavage has little if any benefit in the management of digoxin toxicity. Activated charcoal effectively binds cardiac glycosides, and multiple doses of activated charcoal enhance intestinal digoxin elimination after oral and intravenous digoxin administration [24,25]. A recent study demonstrated that activated charcoal favorably impacts the pharmacokinetic profile of CGs in patients self-poisoned with seeds from the yellow oleander tree [26]. However, further research is necessary to clarify whether patients poisoned with yellow oleander will benefit from activated charcoal since clinical outcomes reported in previous studies have been conflicting [27,28].

Conventional treatment of bradydysrhythmia includes the use of atropine, isoproterenol, and cardiac pacing. However, atropine sulfate has been used with variable success in patients with digitalis toxicity exhibiting AV block [29], isoproterenol may increase ventricular ectopy and cardiac tissue may be unresponsive to electrical pacing, the fibrillation threshold may be lowered, and the pacing wire itself may induce ventricular fibrillation [30]. Digoxin-specific antibody fragments (Fab) are now considered first-line therapy in patients with symptomatic bradycardia [31].

Digoxin-specific antibody Fab is also the treatment of choice for life-threatening ventricular dysrhythmias. If this therapy is not immediately available, phenytoin and lidocaine, which depress increased ventricular automaticity without slowing AV nodal conduction, should be the initial therapy [17,32]. Amiodarone was successful in two cases refractory to other antidysrhythmics [33,34]. Intravenous magnesium, 2 to 4 g (10 to 20 mL of a 20% solution) over 1 minute, may also be useful [35]. Quinidine and procainamide are contraindicated in digitalis toxicity because they depress AV nodal conduction and may worsen cardiac toxicity [1]. Electrical cardioversion of the digitalis-toxic patient should be performed with extreme caution and considered a last resort. A low-energy setting (e.g., 10 to 25 W per second) should be used and preparations made to treat potential ventricular fibrillation [32].

Hyperkalemia is common in patients with acute digoxin poisoning, and empiric administration of supplemental potassium should be avoided [36]. This increase in serum potassium concentration reflects a change in potassium distribution and not an increase in total body potassium stores. Significant hyperkalemia due to acute overdose is another indication for digoxin-specific antibody Fab. If digoxin-specific antibody Fab are not immediately available and the patient has hyperkalemia with associated electrocardiogram changes, intravenous glucose and insulin, sodium bicarbonate, continuous inhaled β agonists such as albuterol (if there is no tachydysrhythmia or ectopy), and sodium polystyrene sulfonate should be administered. The use of intravenous calcium to treat hyperkalemia in CG toxic patients remains controversial and has been previously avoided by many clinicians because additional calcium has been reported to enhance cardiac toxicity [18]. However, some authors have questioned this dogma—citing animal studies and human case reports that document no untoward effects when calcium is administered in the setting of CG toxicity—and recommend the use of intravenous calcium in those patients with CG toxicity who have life-threatening hyperkalemia with significant changes on the electrocardiogram such as loss of P waves or widening of the QRS [37]. Hemodialysis may be of benefit in a CG-poisoned patient with renal failure and hyperkalemia.

Supplemental potassium may be beneficial in chronic digitalis toxicity when diuretic-induced hypokalemia is a factor. Potassium should be administered cautiously, as renal dysfunction may be the cause of digitalis toxicity. Hypomagnesemia is common in patients with chronic CG toxicity, and supplemental magnesium is recommended for such patients [38].

Digoxin-specific antibody Fab therapy is indicated for patients with dysrhythmias that threaten or result in hemodynamic compromise and patients with serum potassium greater than 5.0 to 5.5 mEq per L after acute CG overdose [39,40]. Chronically poisoned patients who are asymptomatic can often be managed with discontinuation of digoxin and close observation. The threshold for treatment with digoxin-specific antibody Fab should be lower in those patients with signs of cardiac toxicity or who have predisposing conditions such as chronic pulmonary disease, hypokalemia, hypothyroidism, renal dysfunction, or underlying cardiac disease [11]. Animal studies and case reports suggest digoxin-specific antibody Fab may be an effective treatment for patients poisoned by plant or animal sources of CG [3,5].

Digoxin-specific antibody Fab can reverse digitalis-induced dysrhythmias, conduction disturbances, myocardial depression, and hyperkalemia. In a multicenter study, 90% of patients with digoxin or digitoxin toxicity had a complete or partial response to digoxin-specific antibody Fab therapy [39]. Complete resolution of toxicity occurred in 80% of the patients, and partial response occurred in 10%. The time to initial response from end of digoxin-specific antibody Fab infusion was within 1 hour (mean 19 minutes), and the time to complete response was 0.5 to 6.0 hours (mean: 1.5 hours). Treatment failures have been attributed to inadequate or delayed dosing, moribund clinical state before digoxin-specific antibody Fab therapy, pacemaker-induced dysrhythmias, and incorrect diagnosis of digitalis toxicity [39,41].

Digoxin-specific antibody Fab dosage (number of vials) calculations are based on the serum digoxin concentration or

estimated body load of digoxin. It is assumed that equimolar doses of antibody fragments are required to achieve neutralization [42]. A 40-mg dose of digoxin-specific antibody Fab (one vial) binds 0.6 mg of digoxin. The number of vials required can be calculated by dividing the total body burden by 0.6. The body burden can be estimated from the milligram amount of an acute ingestion or by multiplying the serum digoxin concentration (ng per mL) by the volume of distribution of digoxin (= 5.6 L per kg times the body weight in kg) and dividing by 1,000.

In the largest study of Fab for digoxin poisoning (n = 150, mean serum concentration of 8 ng per mL), the dose of Fab required to reverse digoxin toxicity was five vials with a range from 3 to 20 vials [39]. A severely toxic patient in whom the quantity ingested acutely is unknown should be given 5 to 10 vials at a time and the clinical response observed. If cardiac arrest is imminent or has occurred, the dose can be given as a bolus. Otherwise, it should be infused over 30 minutes. In contrast, patients with chronic therapeutic overdose often have only mildly elevated digoxin concentrations and respond to one to two vials of digoxin-specific antibody Fab. The recommended dose for a given patient can be determined using the tables in the package insert or by contacting a regional poison center or toxicology consultant.

The dose of digoxin-specific antibody Fab needed to treat nondigoxin CG poisoning is unknown but likely to be greater than that necessary for digoxin poisoning. Starting with 5 to 10 vials and repeating this dose as necessary is a reasonable approach.

Free digoxin concentrations are decreased to zero within 1 minute of digoxin-specific antibody Fab therapy, but total serum digoxin concentrations are markedly increased [39,43]. Because most assay methods measure total (bound and free) digoxin, very high digoxin concentrations are seen after digoxin-specific antibody Fab treatment, but they have no correlation with toxicity [43]. Serum concentrations may be unreliable for several days after digoxin-specific antibody Fab therapy [44].

The digoxin–Fab complex is excreted in the urine and has a half-life of 16 to 20 hours [45]. In patients with renal failure, elimination of the digoxin–Fab complex is prolonged and free digoxin concentrations gradually increase over 2 to 4 days after digoxin-specific antibody Fab administration [46]. In one report of 28 patients with renal impairment given digoxin-specific antibody Fab, only one patient had recurrent toxicity, which occurred 10 days after digoxin-specific antibody Fab treatment and persisted for 10 days [47]. Monitoring of free digoxin concentrations may be beneficial for titrating effect in those patients reliant on the inotropic action of digoxin, detecting rebound toxicity in patients with renal impairment, assessing the need for further treatment with digoxin-specific antibody Fab, or in guiding the reinstitution of digoxin therapy [48]. Hemodialysis has not been reported to enhance digoxin–Fab complex elimination.

Digoxin-specific antibody Fab therapy has been associated with mild adverse drug events such as rash, flushing, and facial swelling [39,41]. However, neither acute anaphylaxis nor serum sickness has been described [41]. Before digoxin-specific antibody Fab administration, an asthma and allergy history should be obtained. Intradermal skin testing should be considered in high-risk patients. If a patient with a positive skin test is dying, however, the risk–benefit ratio obviously favors treatment [41]. A precipitous drop in the serum potassium, recurrence of supraventricular tachydysrhythmias previously controlled by digoxin, and development of cardiogenic shock in a patient dependent on digoxin for inotropic support have all been associated with digoxin-specific antibody Fab therapy [39]. Recurrent toxicity has been observed in 3% of patients [41]. In most, it was attributed to inadequate initial dose of digoxin-specific antibody Fab dosing and reversed with a repeat dose.

Patients who receive digoxin-specific antibody Fab require continued monitoring in an intensive care unit for at least 24 hours. Those with elevated drug concentrations resulting from chronic therapy who are hemodynamically stable can be observed on a telemetry unit. Discontinuing the use of digoxin or decreasing the dose, modifying predisposing factors, and closely monitoring subsequent therapy are necessary to avert further toxic episodes. Patients with suicidal ingestions should have a psychiatric evaluation before discharge.

CHAPTER 128 ■ CHOLINERGIC POISONING

CYNTHIA K. AARON

Cholinergic (acetylcholinesterase inhibitor) agents are used in medicine, as insecticides, and as "nerve agent" chemical weapons. Most poisonings are accidental dermal contamination during agricultural use of pesticides [1]. The majority of suicide attempts are ingestions [2]. Food-borne exposures have produced epidemics such as "Ginger Jake paralysis" (delayed neuropathy) due to contamination of an alcoholic drink with triorthocresyl phosphate [3] and a large epidemic of mild-to-moderate symptoms related to use of the insecticide aldicarb on watermelons [4].

PHARMACOLOGY

Cholinesterase inhibitors act by blocking the active site of acetylcholinesterase (AChE). Organophosphates form a covalent phosphate linkage at the enzyme active site. Enzyme regeneration occurs by either de novo synthesis, hydrolysis of the serine–organophosphorus bond, or oxime regeneration. However, over 24 to 48 hours, most phosphorylated molecules *age* or become resistant to reactivation by oxime therapy. Carbamates are reversible inhibitors of AChE, occupying (but not modifying) the catalytic region of the enzyme. AChE activity is restored when the carbamate spontaneously leaves the enzyme's active site [5]. AChE inhibitors such as tacrine, rivastigmine, donepezil, and galantamine have been used for treatment of Alzheimer's dementia. The characteristics and treatment of exposure to these products is covered at the end of this chapter.

Inhibition of AChE allows the neurotransmitter acetylcholine to accumulate and remain active in the synapse, resulting in sustained depolarization of the postsynaptic neuron or effector organ. This effect occurs in the central nervous system (CNS) as well as at muscarinic sites in the peripheral nervous system, nicotinic sites in the sympathetic and parasympathetic ganglia, and nicotinic sites at the neuromuscular junction. In general, effects at muscarinic sites are sustained, whereas nicotinic sites are stimulated and then depressed (hyperpolarization block). Signs and symptoms of cholinergic toxicity typically appear when 60% to 80% of cholinesterase activity has been inhibited [6]. The pharmacologic and toxicologic effects of acetylcholinesterase inhibitor are an extension of their mechanism of action (Table 128.1).

In addition to acute cholinergic effects, organophosphates cause two other toxic effects. Intermediate syndrome (IMS) is a recurrence of weakness that occurs hours to days after a serious organophosphate exposure [7]. Some authors have suggested that IMS is caused by inadequate oxime therapy when serum organophosphate concentrations remain elevated due to redistribution, altered metabolism, or decreased clearance [8]. It is also possible that IMS is due to desensitization block with downregulation and eventual decrease in the nicotinic receptor activity. Since the nicotinic receptor has five subunits, there is probably significant polymorphism at this receptor affecting clinical response [9].

TABLE 128.1

PHARMACOLOGIC EFFECTS OF CHOLINESTERASE INHIBITION RECEPTOR TYPE

Location	Effects
Muscarinic (increased stimulation)	
Pupils	Miosis (constriction)
Ciliary body	Blurred vision
Exocrine glands	Increased secretions
Lacrimal	Tearing
Salivary	Salivation
Respiratory	Bronchorrhea, rhinorrhea
Heart	Bradycardia
Smooth muscle	Contraction
Bronchial	Bronchoconstriction
Gastrointestinal	Nausea, vomiting, abdominal cramps, diarrhea
Bladder	Incontinence, frequency
Sphincter of Oddi	Pancreatitis
Central nervous system	Variable[a]
Nicotinic (stimulation; then depression)	
Skeletal muscle	Weakness, cramps, fasciculation, paralysis
Sympathetic ganglia	Tachycardia, hypertension; then hypotension
Central nervous system	Variable symptoms from anxiety and restlessness to confusion, obtundation, coma, and seizures[a]

[a]Relative contributions of nicotinic and muscarinic receptors to central nervous system effects are unclear.

The second noncholinergic effect is organophosphorus-induced delayed peripheral neuropathy (OPIDN). This is a delayed peripheral neuropathy, which appears to be mediated by a membrane-bound specific "neuropathy target esterase." Organophosphates that have been associated with OPIDN are aryl organophosphorus esters that contain either a pentavalent phosphorus atom (type I, including derivatives of phosphoric, phosphonic, and phosphoramidic acids, or phosphorofluoridates) or a trivalent phosphorus atom (type II or phosphorus acid derivatives). This neuropathy primarily involves motor fibers. Histologic analysis shows progressive neuronal degeneration, beginning with axonal swelling followed by demyelination, axonal degeneration, and neuronal cell body death and Wallerian degeneration or "dying back" phenomenon [10].

CLINICAL MANIFESTATIONS

Excessive acetylcholine produces symptoms of muscarinic and nicotinic excess. These clinical effects are outlined in Table 128.2. One mnemonic used to describe the muscarinic toxidrome is DUMBELS (*d*iarrhea, *u*rination, *m*iosis, *b*ronchospasm, *e*mesis, *l*acrimation, *s*alivation). Miosis may be the most sensitive marker for moderate or severe exposure to a acetylcholinesterase inhibitor [11]. Lacrimation, rhinorrhea, salivation, and profuse sweating are common in moderate to severe poisoning. Abdominal cramping, diarrhea, and vomiting are very common with severe poisoning. Fasciculations are typically observed in severe overdoses.

Respiratory failure is a common cause of death from acetylcholinesterase inhibitor poisoning [2]. Cholinergic excess has direct deleterious effects on the respiratory center; causes bronchial muscle spasm and noncardiogenic pulmonary edema with exuberant mucus production; and severe respiratory muscle impairment. Respiratory failure may be further complicated by aspiration.

Cardiac toxicity has been increasingly described as a complication of organophosphate poisoning. There are three phases of reported toxicity including a brief period of intense sympathomimetic tone, a period of enhanced parasympathetic activity, and corrected QT (QTc) interval prolongation with potential for torsade de pointes. Prolongation of the QTc is a marker of severity and patients with a QTc greater than 440 milliseconds require higher doses of atropine and have a higher mortality than those a QTc less than 440 milliseconds [12]. Electrocardiographic abnormalities including nonspecific ST-T changes, tachydysrhythmias, bradydysrhythmias, and polymorphic (torsade de pointes) ventricular tachycardia have been reported [13]. The effect on blood pressure is variable. Patients poisoned with dimethoate have an initial benign course but develop refractory hypotension and cardiogenic shock within 36 to 48 hours [2].

The CNS effects of cholinergic poisoning include altered mental status seizures and coma [2]. Dystonias and choreoathetoid movements have also been observed [14]. Less severe

TABLE 128.2

SYMPTOMS OF CHOLINERGIC POISONING

Exposure only	Mild poisoning	Moderate poisoning	Severe poisoning
No symptoms	Can walk Fatigue Headache Dizzy Nausea Vomiting Numbness Sweating Salivation Chest tightness Abdominal cramps Diarrhea ChE 20%–50% of normal	Cannot walk Weakness Difficulty speaking Fasciculations Miosis ChE 10%–20% of normal	Unconscious Unreactive pupils Fasciculations Flaccid paralysis Secretions mouth/nose Moist rales Respiratory distress Seizures ChE < 10% of normal

ChE, RBC cholinesterase.

acute manifestations include anxiety, agitation, emotional lability, headaches, insomnia, tremor, difficulty in concentrating, slurred speech, ataxia, and hyperreflexia or hyporeflexia. In some cases, acute organophosphate poisoning may produce longer-lasting neuropsychiatric sequelae [15]. This has been labeled the chronic organophosphorus-induced neuropsychiatric disorder (COPIND). These problems seem most severe after serious acute intoxications and usually resolve within 1 year [15].

Cholinergic signs and symptoms typically begin minutes to hours after exposure [2]. Symptom onset is rarely more than 12 hours after exposure. Onset may be delayed for lipophilic compounds (e.g., fenthion, dichlofenthion, leptophos) [2] or compounds that require hepatic metabolism to a more toxic intermediate (e.g., parathion is metabolized to paraoxon) [16]. Progressive or prolonged symptoms raise the suspicion of continued absorption of the poison.

Life-threatening cholinergic symptoms from organophosphate toxicity generally abate within 1 to 3 days, although many cases requiring weeks of intensive care are reported [17]. Symptoms usually resolve within 12 to 48 hours after exposure to carbamates and other reversible cholinesterase inhibitors [18].

The intermediate syndrome, characterized by weakness of neck muscles, motor cranial nerves, proximal limb muscles, and respiratory muscles, but without prominent muscarinic findings beginning 24 to 96 hours after the onset of poisoning and lasting 4 to 18 days has been described [8]. An early clinical indication of this syndrome is that affected patients are unable to lift their heads up from their beds [17].

Delayed neuropathy occurs 1 to 3 weeks after the acute cholinergic crises. Patients may initially recover then show progressive signs and symptoms of OPIDN. Since this is a dying back axonopathy that usually spares the neuronal cell body, the peripheral neuropathy is characterized by both paresthesias and motor dysfunction occurring first in the longest skeletal nerves with development of foot drop and a high-stepping gait. Symptoms develop slowly and can be divided into three phases: progressive, stationary, and improvement. During the progressive phase, patients have a peripheral sensory neuropathy with complaints of burning, tightness, or pain in the legs and feet. This is followed by numbness and tingling. Subsequently, motor weakness develops, with weakness and atrophy of the peroneal muscles causing a foot drop. After approximately 1 week, the paresis may ascend symmetrically into the upper extremities. The sensory loss may occur in a stocking–glove distribution, and the patient loses proprioception. With time, a positive Romberg's sign and loss of lower-extremity deep tendon reflexes may develop. Flaccid paralysis may occur in severe cases. During the stationary phase, paresis may persist or resolve within 2 to 9 weeks, and motor findings may cease to progress. This may occur over 3 to 12 months. The improvement phase may begin 6 to 18 months after exposure. Partial or complete motor function returns in reverse order of loss. During this phase, central cord or brain lesions may be unmasked and spasticity may develop [19].

DIAGNOSTIC EVALUATION

The diagnosis of the cholinergic poisoning is based on a history of exposure, clinical findings (toxidrome), and improvement after appropriate antidotal therapy. The primary laboratory studies for evaluating anticholinesterase poisoning are plasma cholinesterase (also known as butyrylcholinesterase or pseudocholinesterase) and red blood cell (RBC) acetylcholinesterase. These tests are not rapidly available in most clinical settings. Both may be used to confirm the clinical diagnosis. RBC acetylcholinesterase has a similar structure to synaptic acetylcholinesterase and it has been validated as a surrogate for synaptic acetylcholinesterase [20].

Plasma cholinesterase is synthesized in the liver. It falls and recovers more rapidly than RBC cholinesterase. Only transient decreases of RBC and plasma cholinesterase occur with carbamate poisoning, because inactivated AChE spontaneously reactivates with plasma elimination half-lives of 1 to 2 hours [21].

In suspected cholinesterase inhibitor poisoning, plasma and RBC acetylcholinesterase levels should be sent for laboratory determination initially and repeated if the clinical course is atypical [22]. Blood for cholinesterase determination should be drawn into a fluoride free tube as fluoride inactivates enzyme systems. Samples should be spun down and frozen for storage. The assaying laboratory should be contacted to obtain specific drawing and storing instructions.

Acute exposures are usually classified based on the degree of depression of RBC cholinesterase: mild (20% to 50% of baseline), moderate (10% to 20% of baseline), and severe (less than 10% of baseline) (see Table 128.2). An EMG using repetitive tetanic nerve stimulation can be done to characterize the block and to estimate the amount of enzyme inhibition [23]. Since there is a wide range for normal RBC cholinesterase level (substantial interindividual variation), a person's baseline needs to be established if return to working with pesticides is a consideration. [24] Workers should be removed from exposure until RBC cholinesterase is at least 75% of their baseline values [25]. Workers who do not have an established RBC cholinesterase baseline should not return to work until their RBC cholinesterase levels have reached a plateau.

Several organophosphates are metabolized to *p*-nitrophenol that can be easily detected in the urine soon after poisoning [26]. Organophosphate concentrations can be measured in serum [27], but contribute little to patient management. These measurements can be useful in determining residual organophosphate residue in a patient with prolonged signs of toxicity and perhaps whether oxime therapy needs to be continued, particularly when combined with the ability to reactivate the AChE [23]. Supplemental studies include serum electrolytes, blood urea nitrogen, creatinine, glucose, calcium, magnesium, lipase, arterial blood gases, electrocardiography, and chest radiography.

The intermediate syndrome is diagnosed by clinical findings associated with a reproducible EMG-nerve conduction study using repeated submaximal tetanic nerve stimulation and measuring compound muscle action potentials [28]. No specific laboratory studies are available for evaluating OPIDN. Electromyography (EMG) may help to determine the extent of the peripheral neuropathy, and there are specific EMG findings associated with OPIDN [29].

Toxicologic differential diagnosis for cholinergic toxicity includes nicotine, carbachol, methacholine, arecoline, bethanechol, pilocarpine, and Inocybe or Clitocybe mushrooms. Nontoxicologic diagnoses that may be mistaken for cholinergic toxicity include myasthenia gravis and Eaton–Lambert syndrome.

MANAGEMENT

Patients with all but the mildest symptoms should be admitted to an intensive care unit for careful observation and antidotal therapy as clinically indicated. The initial priorities are managing the patient's airway, breathing, and circulation. All personnel who are involved in the resuscitation and decontamination process should wear masks or respirators, aprons, and nitrile or butyl rubber gloves to avoid secondary contamination.

Most patients with severe cholinergic poisoning will require airway management and ventilatory assistance for respiratory

failure. Succinylcholine should be used with caution to aid intubation because prolonged (hours to days) paralysis may result [30]. A reasonable alternative is to use a double-dose of a nondepolarizing neuromuscular blocker (such as vecuronium) Airway and bronchial secretions are treated with atropine. The initial adult dose is 1 to 2 mg parenterally, which is doubled every 5 minutes (pediatric dose, 0.05 mg per kg) as needed until pulmonary secretions are controlled [31].

Initial resuscitation with IV fluids is needed because of significant gastrointestinal (GI) fluid losses Blood pressure support may require direct-acting pressors such as norepinephrine, phenylephrine, epinephrine and cardiac depression may require the use of dobutamine [2]. Patients should be treated with atropine (using the dosing scheme describe in the previous paragraph) until the systolic blood pressure is greater than 80 mm Hg and urine output exceeds 0.5 mL per kg per hour [31]. Electrical pacing is rarely needed to treat ventricular dysrhythmias. Potassium and magnesium should be normalized to minimize QTc prolongation.

Seizures should be treated with IV atropine and a benzodiazepine (diazepam, 0.2 to 0.4 mg per kg or an equivalent). Animal studies suggest that both atropine and benzodiazepine are efficacious [32]. Given the potential benefits of benzodiazepines in severe organophosphate poisonings to mitigate neuropsychiatric sequelae, it is reasonable to administer a benzodiazepine even if seizures are not apparent.

Decontamination can limit absorption and prevent reexposure. All of the patient's clothing should be removed and discarded, and the body should be thoroughly washed with mild soap and water. If the ingestion is recent, nasogastric suction can used to attempt to aspirate any product remaining in the stomach [33]. Although single and multidose charcoal did not change outcome in one trial [34], many of the subjects in this trial had long delays before treatment and it is possible that early treatment may limit toxicity. Dilute hypochlorite solution (household bleach) inactivates the organophosphorus ester and can be used to decontaminate equipment but should not be used on skin [35].

Antidotal therapy is comprised of two complementary agents, atropine and an oxime such as pralidoxime (North America, India, and Asia) or obidoxime (Europe and Middle East). Atropine is a competitive antagonist of acetylcholine at the muscarinic receptors but has no effect on muscle weakness or paralysis and does not affect the AChE regeneration rate. As noted above, atropine is primarily indicated for control of pulmonary secretions and bronchospasm. It has a secondary role in helping to control seizures and CNS manifestations of poisoning [36]. Careful titration of atropine to the individual patient is required, with frequent clinical reevaluation to prevent atropine toxicity [33]. Atropine therapy should be restarted at the first signs of cholinergic excess. A continuous atropine infusion may be necessary to stabilize the patient, after which the infusion can be titrated back while close observation is maintained. Most patients will respond to 3 to 5 mg per hour [33]. In general, higher doses of atropine are required during the first 24 hours with organophosphate pesticides than with nerve agents. Tachycardia is not a contraindication to atropine therapy; it may reflect hypoxia or sympathetic stimulation. Mydriasis may be an early response but is a poor marker for adequate atropinization. A common pitfall is inadequate atropine dosing during serious cholinergic agent overdoses. High doses of atropine are commonly needed for control of secretions. Daily doses in excess of 100 mg are occasionally required for several days [37]. Glycopyrrolate is an antimuscarinic agent that does not penetrate the CNS. It can be substituted for atropine when isolated peripheral cholinergic toxicity is present. The recommended dose is 0.05 mg per kg. One study suggested that a combination of atropine and glycopyrrolate may improve outcomes [38].

Pralidoxime (2-PAM) and obidoxime are nucleophilic oximes that regenerate AChE at muscarinic and nicotinic synapses by reversing the AChE active site phosphorylation. Although pralidoxime does not enter the CNS well, rapid improvement in coma or termination of seizures has been observed after pralidoxime administration [39]. The antidotal effect of atropine and oximes is synergistic.

Although oximes remain a standard therapy for organophosphate poisoning, recent studies have highlighted our limited understanding of their role. Although one recent randomized controlled trial showed a dramatic treatment effect with pralidoxime [40], a second trial found no benefit and a trend toward worse outcomes [41]. There are several possible explanations for these discrepant results, including differences in the lipophilicity, side chains (O′-dimethyl vs. O′-diethyl organophosphates), rate of aging, and interaction between inhibition/re-inhibition and spontaneous reactivation of the parent and oxime-bound compounds. Future studies will have to address these differences.

Although the optimal treatment protocol for pralidoxime is not known, there is consensus that many older protocols used insufficient doses [42]. Animal studies suggested that a serum concentration of 4 mg per mL were effective [43], and earlier pharmacokinetic studies suggested the use of 1 to 2 g IV pralidoxime followed by 1 g every 6 to 12 hours would produce a serum level of 4 mg per mL [44,45]. Subsequent studies in poisoned patients have shown that the amount of circulating inhibitor (parent or metabolite of the original organophosphate) determines the need for oxime [46]. Patients who have ingested massive amounts of an organophosphate may have prolonged high levels of circulating inhibitor for days after ingestion and the pralidoxime blood level of 4 mg per mL is too low to allow for continued reactivation of the acetylcholinesterase. Ideally, poisoned patients should be followed by serial evaluation of the ability to reactivate their cholinesterase in vitro [6]. Since this is not feasible for most patients, the following suggestions can be made. The World Health Organization recommends an initial pralidoxime dose of 30 mg per kg IV followed by 8 mg per kg per hour or alternatively, 30 mg per kg every 4 hours if a continuous infusion is not possible [42]. The appropriate dose of obidoxime 250 mg initially followed by 750 mg over 24 hours [47]. Muscle fasciculation and weakness should show a response within 60 minutes after dosing and the dose titrated upwards if the patient has breakthrough signs and symptoms. In mass casualty situations, the intramuscular route of administration may be more practical. The duration of therapy is based on clinical response and is usually 24 to 48 hours. Under ideal conditions, serum samples can be assayed for acetylcholinesterase reactability and this can be used to guide oxime therapy [48]. Some patients may require continuous treatment for greater than 1 week, depending on the body burden of organophosphate and reinhibition of reactivated acetylcholinesterase.

Although hemoperfusion can enhance the elimination of anticholinesterase agents [49], the availability of specific antidotes for organophosphates and the relatively short course of carbamate intoxications make this procedure unnecessary.

Carbamate poisonings are expected to have a good prognosis because the duration of serious signs and symptoms is limited. Severe organophosphate poisonings may require prolonged respiratory support, with its attendant complications. Death from acute organophosphate poisonings usually occurs within 24 hours in untreated cases, although exposures to fenthion and dimethoate may lead to death within 72 hours even if treated [2]. Aggressive respiratory management, timely antidotal therapy, and intensive supportive care are expected to improve morbidity and mortality. Recovery from OPIDN may be gradual or not at all. CNS anoxic sequelae have the worse prognosis and are not specific to

cholinesterase inhibitors but rather a consequence of prolonged hypoxia.

Toxicity of AChE Inhibitors Used to Treat Alzheimer's Disease

With the increasing use of AChE inhibitors to treat dementia, there has been an increasing number of exposures to these medications. Symptoms can range from general weakness [50] to salivation and GI effects [51] but are generally milder than pesticides. However, one case of deliberate ingestion of 288 mg of rivastigmine results in seizures, respiratory muscle weakness and bronchial secretions [52]. Muscarinic effects should be treated with atropine and one report has suggested that isolated CNS effects without peripheral muscarinic symptoms can be treated with pralidoxime alone [53].

NERVE AGENTS USED IN WARFARE

Since the Persian Gulf War and in the aftermath of the terrorist attacks of September 11, 2001, there has been increasing concern about the potential use of nerve agents such as GA (Tabun), GB (Sarin), GD (Soman), and VX. These chemicals are similar in structure and function to the organophosphate insecticides but have a much greater potency. Please see Chapter 214 for a complete discussion of this topic.

CHAPTER 129 ■ COCAINE POISONING

RICHARD D. SHIH AND JUDD E. HOLLANDER

Cocaine (benzoylmethylecgonine) is an alkaloid compound derived from the South American plant *Erythroxylon coca*. Its use as an illicit drug of abuse has reached epidemic proportions. Thirty-four million US citizens have used cocaine at least once; 5.9 million have used cocaine in the past year; and 2.1 million have used cocaine in the past month [1]. Among drug-related emergency department visits, cocaine is the most commonly used illicit substance seen [2]. Of all drug-related emergency department visits in the United States, cocaine is involved in approximately 20% [2].

PHARMACOLOGY

The pharmacologic effects of cocaine are complex, and they include direct blockade of the fast sodium channels, increase in norepinephrine release for the adrenergic nerve terminals, interference with neuronal catecholamine reuptake, and increase in excitatory amino acid concentration in the central nervous system (CNS). Blockade of the fast sodium channels stabilizes axonal membranes, producing a local anesthetic-like effect and a type I antidysrhythmic effect on the myocardium. The increase in catecholamine levels produces a sympathomimetic effect. The result of increased excitatory amino acid concentration in the CNS is increased extracellular dopamine concentration.

Cocaine is well absorbed through the mucosa of the respiratory, gastrointestinal, and genitourinary tract, including less common routes of absorption such as the urethra, bladder, and vagina. The cocaine hydrochloride salt is the form most often abused nasally or parenterally. Crack cocaine and cocaine freebase are alkaloid forms of cocaine that are produced by an extraction process. These forms are heat stable, can be smoked, and are absorbed through the pulmonary system. When intravenously administered or inhaled, cocaine is rapidly distributed throughout the body and CNS, with peak effects in 3 to 5 minutes. With nasal insufflation, absorption peaks in 20 minutes.

Cocaine has a half-life of 0.5 to 1.5 hours. It is rapidly hydrolyzed to the inactive metabolites ecgonine methyl ester and benzoylecgonine, which account for 80% of cocaine metabolism. These compounds have half-lives of 4 to 8 hours, with effects similar to those of cocaine. Minor cocaine metabolites include ecgonine and norcocaine. Urinary toxicology screens for recreational drugs typically assess for the presence of benzoylecgonine, which is usually present for 48 to 72 hours after cocaine use [3].

Cocaine is frequently abused in combination with other drugs. In particular, ethanol is a frequent coingestant [2]. This may be a popular combination because ethanol antagonizes cocaine's stimulatory effects. The metabolism of cocaine in the presence of ethanol produces cocaethylene, which has additional cardiovascular and behavioral effects [4]. Cocaethylene and cocaine are similar with regard to behavioral effects. However, cocaethylene has been more likely to result in death in animal studies. Human studies demonstrate that cocaethylene produces milder subjective effects and similar hemodynamic effects when compared with cocaine. Cocaethylene also has a direct myocardial depressant effect [4].

Cocaine toxicity is due to an exaggeration of its pharmacologic effects, resulting in myriad consequences that have an impact on every organ system. The widespread effects of cocaine are related to its ability to stimulate the peripheral and central sympathetic nervous systems, in addition to local anesthetic-like effects. Cocaine-induced seizures are most likely due to excess catecholamine stimulation.

Cocaine causes vascular effects through multiple pathophysiologic mechanisms that have been best described in the heart [5–7]. These include arterial vasoconstriction, in situ thrombus formation, platelet activation, and inhibition of endogenous fibrinolysis. In addition, myocardial oxygen demand is increased by cocaine-induced tachycardia and hypertension [5–8]. The direct local anesthetic-like effect of cocaine or secondary cocaine-induced myocardial ischemia [5,9] may be responsible for cardiac conduction disturbances [9] and dysrhythmias.

CLINICAL PRESENTATION

Clinical manifestations of acute cocaine toxicity may occur in a number of different organ systems. Most severe cocaine-related toxicity and cocaine-related deaths are manifested by signs of sympathomimetic overdrive (e.g., tachycardia, hypertension, dilated pupils, and increased psychomotor activity). This increased psychomotor activity causes increased heat production and can lead to severe hyperthermia and rhabdomyolysis [10].

Cocaine-induced cardiovascular effects are common. Of cocaine-related emergency department visits, chest pain is the most common complaint. Although most of these patients do

not have serious underlying etiology, myocardial infarction due to cocaine is a well-established entity and needs to be excluded [11,12]. It occurs in 6% of patients presenting with cocaine-associated chest pain [13]. The risk of myocardial infarction is increased 24-fold in the hour after cocaine use. In patients aged 18 to 45 years, 25% of myocardial infarctions are attributed to cocaine use [14]. Cocaine-associated myocardial infarction typically occurs in patients aged 18 to 60 years without apparent massive cocaine exposure or without evidence of cocaine toxicity. Patients with cocaine-associated myocardial infarctions frequently have atypical chest pain or chest pain that is delayed hours to days after their most recent cocaine use [5,11].

Cardiac conduction disturbances (e.g., prolonged QRS and QTc) and cardiac dysrhythmias (e.g., sinus tachycardia, atrial fibrillation/flutter, supraventricular tachycardias, idioventricular rhythms, ventricular tachycardia, torsade de pointes, and ventricular fibrillation) may occur after cocaine use [15–17]. Aortic dissection and endocarditis associated with cocaine abuse are uncommon [18].

The neurologic effects of cocaine may be manifested in a number of ways. Altered mental status and euphoria are typically short lived and without serious sequelae. The stimulatory effects of cocaine can lead to seizures, cerebral infarction, intracerebral bleeding, subarachnoid hemorrhage, transient ischemic attacks, migraine-type headache syndromes, cerebral vasculitis, anterior spinal artery syndrome, and psychiatric manifestations [19–21]. Cocaine is associated with a sevenfold increased risk of stroke in women [22].

Cocaine-induced seizures are typically single, brief, generalized, self-limited, and not associated with permanent neurologic deficit. These seizures may occur in the presence or absence of concurrent structural disease, such as infarction or hemorrhage. Multiple or focal seizures are usually associated with concomitant drug use or an underlying seizure disorder [19].

Cocaine has a number of direct and indirect effects on the lungs, and they are associated with how the drug is used [23]. These effects include asthma exacerbations, pneumothorax, pneumomediastinum, noncardiogenic pulmonary edema, alveolar hemorrhage, pulmonary infarction, pulmonary artery hypertrophy, and acute respiratory failure [24,25]. Asthma exacerbations are more common with crack cocaine usage, most likely due to particulate by-products of combustion [26]. Inhalation of cocaine is typically associated with deep Valsalva maneuvers to maximize drug delivery and can cause pneumothorax, pneumomediastinum, and noncardiogenic pulmonary edema.

The intestinal vascular system is particularly sensitive to cocaine effects because the intestinal walls have a wide distribution of α-adrenergic receptors. Acute intestinal infarction has been associated with all routes of cocaine administration [27].

The most deadly gastrointestinal manifestation of cocaine usage is seen in the patient who presents after ingesting packets filled with cocaine. These patients have been termed *body packers* or *body stuffers*. Body packers are patients who swallow carefully prepared condom or latex packets filled with large quantities of highly purified cocaine for the purposes of smuggling this drug into the country. In contrast, body stuffers are typically "street" drug dealers who swallow packets of cocaine while fleeing the police. These packets were generally prepared for distribution to individual customers and not to protect the body stuffer from absorbing cocaine. It was previously thought that cocaine ingested orally was metabolized in the gastrointestinal track and did not lead to systemic toxicity. This is clearly not the case and toxicity can develop in body stuffers and packers from cocaine leaking out of the swallowed packets. The dosage of cocaine exposure in body stuffers is generally substantially less than that of a body packer. However, toxicity is more likely to occur in the setting of body stuffers. Although massive exposure to leakage from a condom or latex-filled packet of a body packer can occur, most body packers identified by airport immigration officers, do not develop clinical toxicity. However, any patient identified as a body packer who has developed any signs of systemic cocaine toxicity (tachycardia, hypertension, diaphoresis, etc.) can rapidly develop worsening symptoms including life-threatening ones. These patients, when identified, have a high potential for progressively worsening toxicity and mortality [28].

Premature atherosclerosis can develop in chronic cocaine users. Further, cocaine-induced left ventricular hypertrophy can lead to hypertrophic and eventually a dilated cardiomyopathy and congestive heart failure [5]. Cocaine-associated dilated cardiomyopathy appears to have a reversible component, and some patients have demonstrated improvement after cessation of cocaine use [5].

Chronic severe cocaine users can present with lethargy and a depressed mental status that is not attributable to any other etiology (diagnosis of exclusion), the "cocaine washout syndrome." This self-limited syndrome usually abates within 24 hours but can last for several days and is thought to result from excessive cocaine usage that depletes essential neurotransmitters [29].

Chronic inhalational use of cocaine does not appear to lead to long-term pulmonary effects. Spirometry and lung mechanics are typically normal even in heavy chronic users [30].

Chronic cocaine usage during pregnancy increases the chance for premature delivery and abruptio placentae [31]. Maternal cocaine usage is associated with low birth weight, small head circumference, developmental problems, and birth defects in the neonate [32–34]. Neonates exposed to cocaine in utero may develop cocaine withdrawal syndrome, which typically begins 24 to 48 hours after birth and is characterized by irritability, jitteriness, and poor eye contact.

DIAGNOSTIC EVALUATION

Patients manifesting cocaine toxicity should have a complete evaluation focusing on the history of cocaine use, signs and symptoms of sympathetic nervous system excess, and evaluation of specific organ system complaints. It is of paramount importance to determine whether signs and symptoms are due to cocaine itself, underlying structural abnormalities, or cocaine-induced structural abnormalities.

Friends or family of patients with altered mental status should be questioned about a history of cocaine usage and the events before presentation. Many patients deny cocaine use. Urine drug testing may be helpful in establishing recent cocaine use [35,36].

When the history is clear and symptoms are mild, laboratory evaluation is usually unnecessary. In contrast, if the patient manifests moderate or severe toxicity, routine laboratory evaluation should include a complete blood cell count, serum electrolytes, glucose, blood urea nitrogen, creatinine, creatine kinase (CK), cardiac marker determinations, arterial blood gas analysis, and urinalysis. Sympathetic excess may result in hyperglycemia and hypokalemia. Elevated CK is associated with rhabdomyolysis. Cardiac markers are elevated in myocardial infarction. However, false elevations of CK–MB fraction are common [12]. In the setting of an elevated absolute CK–MB, caution should be placed on the use of the CK–MB relative index, because it may be falsely low when there is concurrent myocardial infarction and rhabdomyolysis. Cardiac troponin I is the preferred method to distinguish true- from false-positive CK–MB determinations [12].

Chest radiography and electrocardiography (ECG) should be obtained in patients with chest pain or cardiovascular

complaints. The initial ECG is a less useful diagnostic tool than for patients with chest pain that is unrelated to cocaine. Many young cocaine-using patients have ST-segment elevation in the absence of acute myocardial infarction. This is due to early repolarization changes [15,16].

Observation for a 9- to 12-hour period is also a useful tool for the evaluation of patients presenting with cocaine-associated chest pain. Patients without new ischemic changes on ECG, a normal troponin test, and no cardiovascular complications during this observation (dysrhythmias, acute myocardial infarction or recurrent symptoms) can safely be sent home with follow up and planned outpatient workup [17,37]. Recent data also suggests that a strategy using coronary computerized angiographic tomography might identify patients safe for discharge in a slightly more rapid time frame [38].

A brief seizure temporally related to cocaine use in an otherwise healthy person should be evaluated with a head computed tomography (CT). Further workup in an otherwise asymptomatic patient may not be necessary [19]. Patients with concurrent headache, suspected subarachnoid hemorrhage, or other neurologic manifestations may necessitate lumbar puncture after head CT to rule out serious pathology. Patients who are suspected of body stuffing should be evaluated by abdominal radiographs and cavity searches (digital or visual examination of the rectum or vagina).

MANAGEMENT

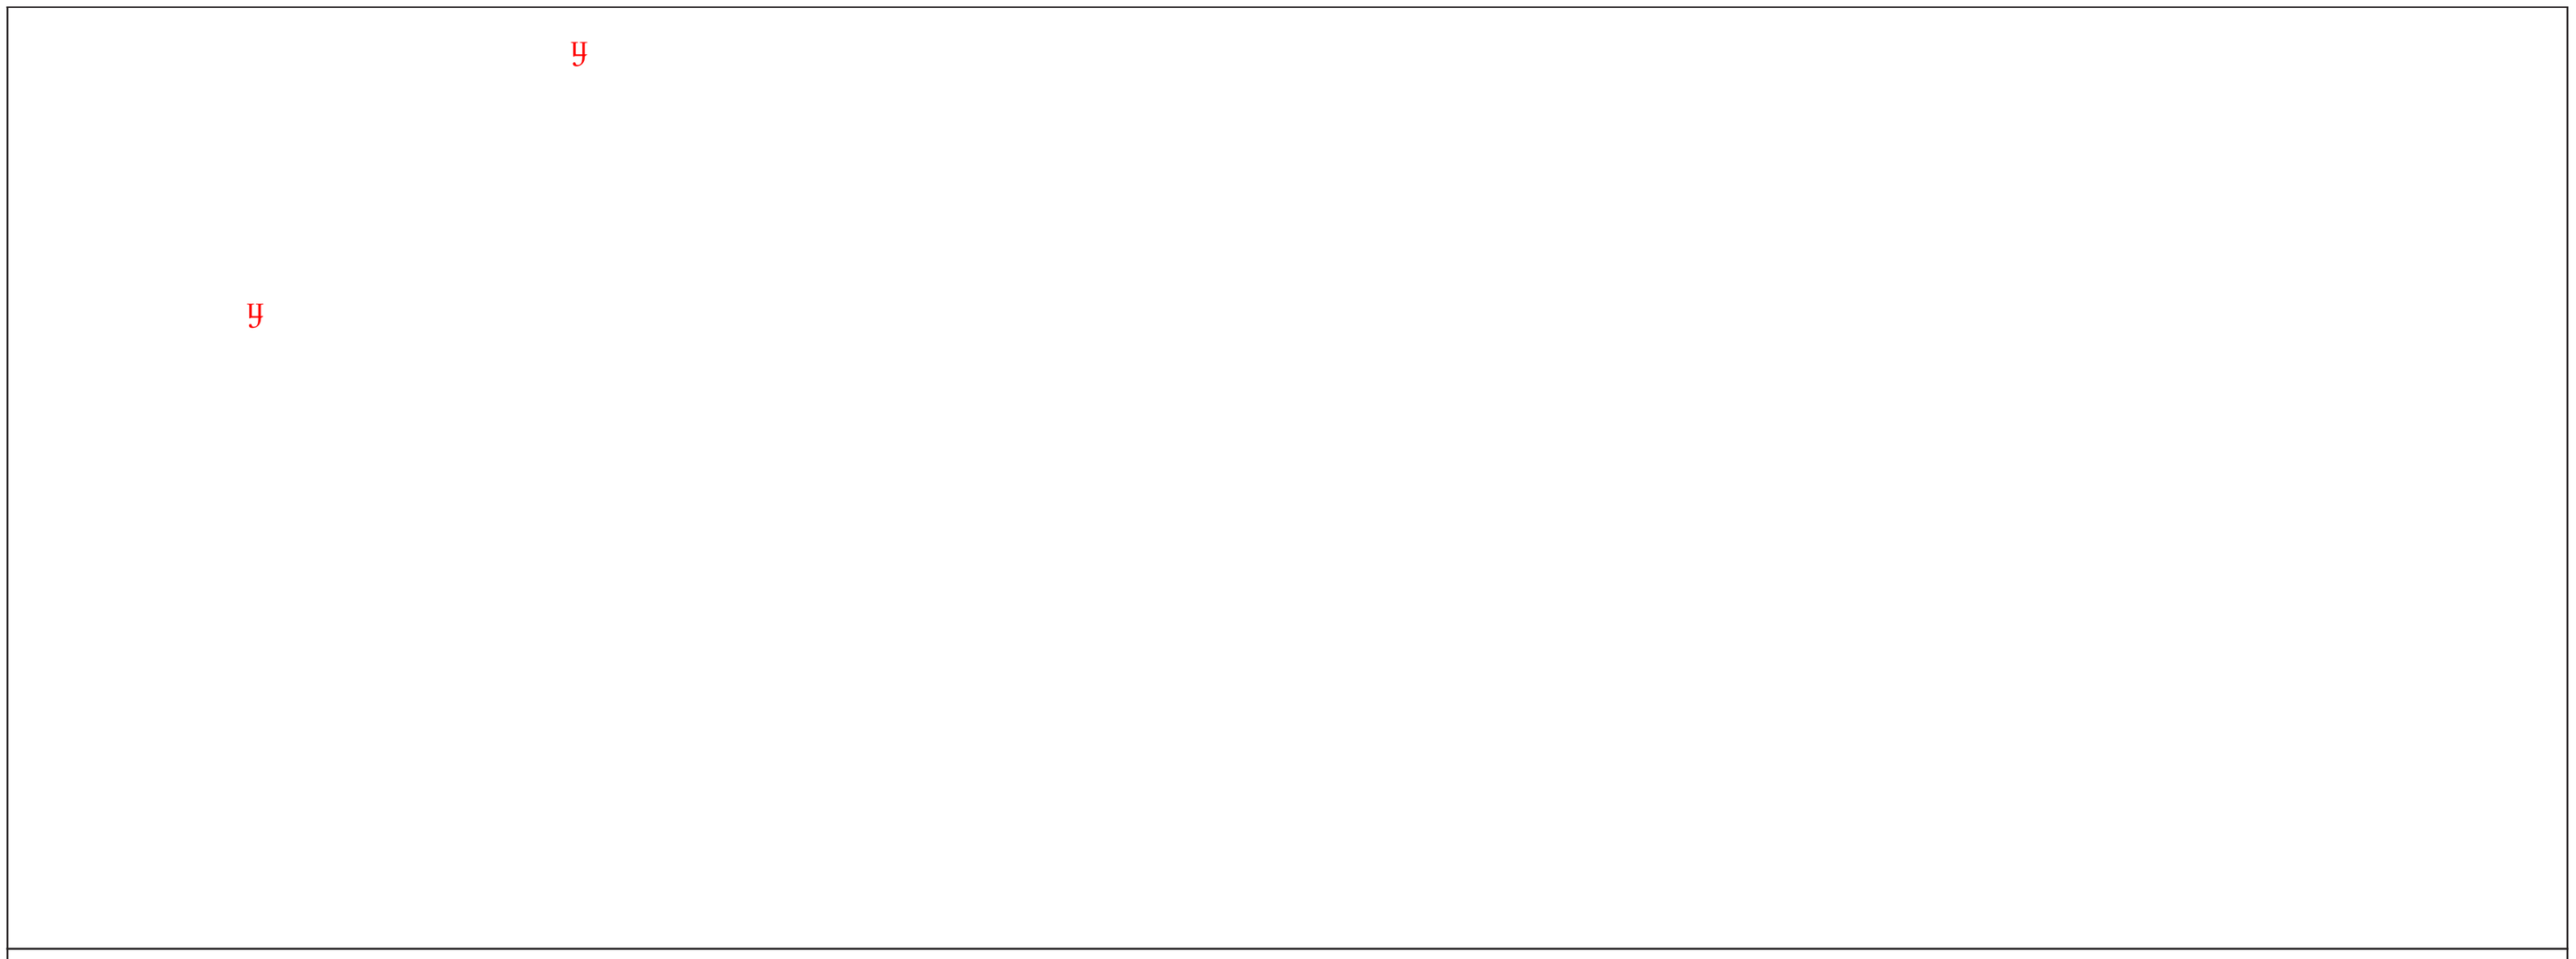
The initial management of cocaine-toxic patients should focus on airway, breathing, and circulation. Treatments are directed at a specific sign, symptom, or organ system affected and are summarized in Table 129.1.

Patients who present with sympathetic excess and psychomotor agitation are at risk for hyperthermia and rhabdomyolysis. Management should focus on lowering core body

TABLE 129.1

TREATMENT SUMMARY FOR COCAINE-RELATED MEDICAL CONDITIONS

Medical condition	Treatments
Cardiovascular	
Dysrhythmias	
Sinus tachycardia	Observation Oxygen Diazepam or lorazepam
Supraventricular tachycardia	Oxygen Diazepam or lorazepam Consider diltiazem, verapamil or adenosine If hemodynamically unstable: cardioversion
Ventricular dysrhythmias	Oxygen Diazepam or lorazepam Consider Sodium bicarbonate and/or lidocaine If hemodynamically unstable: defibrillation
Acute coronary syndrome	Oxygen Aspirin Diazepam or lorazepam Nitroglycerin Heparin For ST segment elevation (STEMI): Percutaneous intervention (angioplasty and stent placement) preferred. Consider fibrinolytic therapy. Consider morphine sulfate, phentolamine, verapamil or glycoprotein IIb/IIIa inhibitors
Hypertension	Observation Diazepam or lorazepam Consider nitroglycerin, phentolamine and nitroprusside
Pulmonary edema	Furosemide Nitroglycerin Consider morphine sulfate or phentolamine
Hyperthermia	Diazepam or lorazepam Cooling methods If agitated, consider paralysis and intubation
Neuropsychiatric	
Anxiety and agitation	Diazepam or lorazepam
Seizures	Diazepam or lorazepam Consider phenobarbital
Intracranial hemorrhage	Surgical consultation
Rhabdomyolysis	IV hydration Consider sodium bicarbonate or mannitol If in acute renal failure: hemodialysis
Cocaine washout syndrome	Supportive care
Body packers	Activated charcoal Whole-bowel irrigation Laparotomy or endoscopic retrieval



temperature, halting further muscle damage and heat production, and ensuring good urinary output. The primary agents used for muscle relaxation are benzodiazepines [11].

The use of antipsychotic agents for cocaine-induced neurobehavioral agitation is controversial [39]. In mild cases, antipsychotics may be useful. In cases of severe cocaine-induced agitation, few data exist on antipsychotics' safety and efficacy. In these cases, benzodiazepines are preferred and supranormal cumulative doses may be necessary. Core body temperatures may be highly elevated. This should be treated aggressively with iced water baths or cool water mist with fans. Some cases of severe muscle overactivity may require general anesthesia with nondepolarizing neuromuscular blockade. Succinylcholine, a depolarizing neuromuscular-blocking agent, may increase the risk of hyperkalemia in the setting of severe cocaine-induced rhabdomyolysis. In addition, plasma cholinesterase is responsible for the metabolism of both succinylcholine and cocaine. When these two agents are used simultaneously, prolonged clinical effects of either or both agents might result. Therefore, nondepolarizing agents are preferred.

Patients with severe hypertension can usually be safely treated with benzodiazepines. When benzodiazepines are not effective, nitroglycerin, nitroprusside, or phentolamine can be used. Beta-blockers are contraindicated. Their use in this setting can lead to unopposed alpha stimulation with paradoxic exacerbation of hypertension and worsening coronary vasoconstriction [40,41].

Patients with chest pain and suspected cocaine-induced ischemia or myocardial infarction should be treated with aspirin, benzodiazepines, and nitroglycerin as first-line agents. Benzodiazepines decrease the central stimulatory effects of cocaine, thereby indirectly reducing its cardiovascular toxicity [11]. Benzodiazepines have been shown to have a comparable and possibly an additive effect to nitroglycerin with respect to chest pain resolution and hemodynamic and cardiac functional parameters (cardiac output) for patients with cocaine-associated chest pain [42,43] (Table 129.2). Weight-adjusted unfractionated heparin or enoxaparin would be reasonable to use in patients with documented ischemia. Patients who do not respond to these initial therapies can be treated with phentolamine or calcium channel blocking agents [44,45]. The International Guidelines for Emergency Cardiovascular Care recommend α-adrenergic antagonists (phentolamine) for the treatment of cocaine-associated acute coronary syndrome [46]. Beta-blockers are contraindicated, as they can exacerbate cocaine-induced coronary artery vasoconstriction [40].

Primary reperfusion therapy is best done with percutaneous interventions, when available [47]. Fibrinolytic therapy in this setting is somewhat controversial. The mortality from cocaine-associated myocardial infarction is low. Patients with cocaine-associated chest pain have a high prevalence of "false-positive ST-segment elevations," up to 43% in one study [48]. Therefore, treatment of all patients with cocaine-associated chest pain who meet standard ECG thrombolysis in myocardial infarction criteria would result in fibrinolytic administration to more patients without acute myocardial infarction than with acute myocardial infarction.

Supraventricular dysrhythmias may be difficult to treat. Initially, benzodiazepines should be administered. Adenosine can be given, but its effects may be temporary. Use of calcium channel blockers in association with benzodiazepines appears to be most beneficial. Beta-blockers should be avoided [46].

Ventricular dysrhythmias should be managed with benzodiazepines, lidocaine, or sodium bicarbonate [46]. Bicarbonate is preferred in patients with QRS widening and ventricular dysrhythmias that occur soon after cocaine use. In this setting, the dysrhythmias are presumably related to sodium channel blocking effects of cocaine. Lidocaine can be used when dysrhythmias appear to be related to cocaine-induced ischemia [9,46].

Seizures should be treated with benzodiazepines and phenobarbital. Phenytoin is not recommended in cases associated with cocaine. Although no studies have compared barbiturates to phenytoin for control of cocaine-induced seizures, barbiturates are theoretically preferable because they also produce CNS sedation and are generally more effective for toxin-induced convulsions. If these agents are not rapidly effective, nondepolarizing neuromuscular blockade and general anesthesia are indicated.

Patients with cerebrovascular complications or focal neurologic findings should be managed as usual. However, the utility of fibrinolytic agents in cocaine-associated cerebrovascular infarction is unknown.

Cocaine body stuffers who are asymptomatic should be given activated charcoal [49]. Whole-bowel irrigation with subsequent radiologic verification of passage of all drug-filled containers should be considered [28]. Body stuffers who manifest clinical signs of toxicity should be treated similarly to other cocaine-intoxicated patients. Body packers who develop any signs of cocaine toxicity, need to be identified as quickly as possible and treated very aggressively. These individuals have a high likelihood of developing worsening toxicity and life-threatening symptomatology. Initial use of activated charcoal and surgical removal of ruptured cocaine packets is warranted in almost all cases and can be life saving [29].

CHAPTER 130 ■ CORROSIVE POISONING

ROBERT P. DOWSETT AND CHRISTOPHER H. LINDEN

Initially referring to acids, the term *corrosives* is now used synonymously with *caustics*, a term originally applied to alkalis. In solution, acids and bases donate or accept a proton altering the hydrogen ion concentration. This is measured as pH, the negative logarithm of the H^+ ion concentration (M/L) Water, at 25°C, has a pH of 7 and is considered neutral. Solutions with a pH of less than 2 or greater than 12 are considered strongly acidic or basic. The pH levels of some common solutions are listed in Table 130.1.

Corrosives cause injury by reacting with organic molecules and disrupting cell membranes. They also cause thermal burns if heat is generated by dissolution and neutralization reactions. Reactions between strong acids and strong bases are usually highly exothermic. Metallic lithium, sodium, potassium, some aluminum and lithium salts, and titanium tetrachloride react violently when placed in water, producing large amounts of heat. Chlorine reacts with water in an exothermic reaction to form hydrochloric and hypochlorous acids, elemental chlorine, and free oxygen radicals. Similar reactions occur with bromine. Ammonia combines with water to form ammonium hydroxide in a reaction that liberates heat; the hydroxide formed is then responsible for corrosive effects. Nitrogen dioxide reacts with water to release heat and produce nitric and nitrous acid. Hydrogen peroxide liberates oxygen on contact with water.

The mixing of chemicals can result in reactions that liberate caustic gases. Mixing ammonia with hypochlorite (household bleach) generates chloramine gases (NH_2Cl and $NHCl_2$), which are highly irritating to mucosal epithelia. Combining bleach with acid (acid toilet bowl or drain cleaners) produces chlorine gas. A number of metallic compounds react with acids, resulting in the liberation of potentially explosive hydrogen gas. Hydrogen sulfide and sulfur oxide gas result from the action of acids on sulfur-containing compounds such as orthopedic plaster casting material in sink drains [1]. Zinc hydroxide, present in soldering flux, is corrosive in an acidic environment such as the stomach [2].

TABLE 130.1

APPROXIMATE pH OF COMMON SOLUTIONS

Solution	pH
1.0 M hydrochloric acid	0
1 M hydrochloric acid solution	0
1 M nitric acid solution	0
0.1 M sulfuric acid	0.96
Battery acid (1% solution)	1.4
Gastric juice	1.2–3.0
Lemon juice	2
Domestic toilet cleaner (1%)	2.0
1 M acetic acid solution	2.37
1 M carbonic acid	5.7
Rain water	6.5
Water (pure, at 25°C)	7.0
Bleach (1% solution)	9.5–10.2
Automatic dishwasher detergents	10.4–13.0
Laundry detergents	11.6–12.6
Domestic ammonium cleaners	11.9–12.4
Ammonia 10%	12.5
Oven cleaner	13
Drain cleaner	13.3–14.0
1.0 M potassium hydroxide	14
1.0 M NaOH	14
Saturated ammonia solution	15

During 2007, 147,703 exposures to corrosive chemicals were reported by U.S. poison centers; actual exposures are estimated to be several times greater [3]. Lethal exposures constituted 1.9% of all reported deaths due to poisoning [3]. Exposures to chemicals accounted for 7.6% of poisonings in children younger than 6 years of age. Only a few of these cases resulted in serious injury, with only three deaths. Adults, usually by deliberate intent, ingest a larger amount of corrosive [4]. Deaths most commonly result from intentional exposure to drain cleaners and acidic cleaners [3].

Concentrated lye (sodium or potassium hydroxide) solutions used for laundering and plumbing purposes caused most of the serious injuries due to corrosive ingestions before 1970 [5]. Currently available liquid lye drain cleaners are less concentrated (less than 10%) but are still responsible for the largest number of severe gastrointestinal injuries; however, acid bowl cleaners now account for almost as many deaths [3]. Severe alkali injuries can result from the ingestion of powdered automatic dishwasher detergents and oven cleaners [6,7]. Household ammonia and bleaches, and hydrogen peroxide solutions are in general much less potent than industrial ones but can cause significant injury if ingested in large amounts [4,6].

PATHOPHYSIOLOGY

Alkalis cause liquefaction necrosis, a process resulting from the saponification of fats, dissolution of proteins, and emulsification of lipid membranes. The resultant tissue softening and sloughing may allow the alkali to penetrate to deeper levels. Tissue injury progresses rapidly over the first few minutes but can continue for several hours [8]. Over the ensuing 4 days, bacterial infection and inflammation cause additional injury. Granulation tissue then develops, but collagen deposition may not begin until the second week. The tensile strength of healing tissue is lowest during the first 2 weeks. Epithelial repair may take weeks to months. Scar retraction begins in the third week and continues for months.

Acid burns are characterized by coagulation necrosis. Protein is denatured, resulting in the formation of a firm eschar [9]. The release of heat is typically higher than for alkali reactions [10]. Subsequent responses are similar to those seen with alkalis.

Hydrocarbons can produce injury by dissolving lipids in cell membranes and coagulating proteins. Significant damage may occur with ingestion or after prolonged dermal contact [11]. Ingestion of a toluene containing glue can cause caused corrosive esophagitis [12]

Alkaline solutions with a pH of greater than 12.5 are likely to cause mucosal ulceration, with deeper tissue necrosis resulting if the pH approaches 14 [13]. However, solutions with a pH of less than 12.5 can still cause significant injury, and solutions of different chemicals but the same pH produce different degrees of tissue damage [13].

The physical state of a chemical also influences its toxicity. Corrosives that are gases at room temperature primarily affect the skin, eyes, and airways. Saturated acid solutions may liberate significant amounts of acid fumes, particularly if heated. Solid compounds tend to produce highly concentrated solutions on contact with body fluids and cause more severe injuries [14]. Solutions with a high viscosity tend to cause deeper burns [13].

Most systemic effects that occur after exposure to corrosives are secondary to inflammation, acidosis, infection, and necrosis [15]. Fluid and electrolyte shifts occur, resulting in hypovolemia, acidosis, and organ failure. Some chemicals, such as phenol, hydrazine, and chromic acid, can be absorbed after dermal exposure or ingestion and cause systemic toxicity [16,17].

CLINICAL MANIFESTATIONS

Chemical burns to the eye range from irritation to severe and permanent damage [18]. Eye pain, blepharospasm, conjunctival hemorrhages, and chemosis are seen in all grades of injury. Decreased visual acuity may result from excessive tearing, corneal edema and ulceration, anterior chamber clouding, or lens opacities. Roper-Hall's classification of injury predicts severity of subsequent vision loss [19] (Table 130.2).

TABLE 130.2

GRADING OF SEVERITY OF OCULAR CHEMICAL BURNS

Grade	Cornea	Limbal ischemia	Prognosis
I	Epithelial loss	None	Good
II	Stromal haze, iris details visible	$< 1/3$ of vessels affected	Good
III	Total epithelial loss, iris details obscured	$1/3$–$1/2$ of vessels affected	Doubtful, vision reduced
IV	Opaque, no view of iris or pupil	$> 1/2$ of vessels affected	Poor

Severe burns can result in increased intraocular pressure, anterior chamber clouding, lens opacities, and perforation of the globe [18]. Severity can be assessed by the extent of ischemia of conjunctival vessels at the limbus of the eye. If more than half of these vessels are obliterated, the prognosis is poor [19].

Significant differences exist between thermal and chemical burns of the skin. Although pain usually occurs immediately, it may be delayed several hours after corrosive exposure [20]. Assessing the depth of dermal injury can be difficult. Chemical burns rarely blister, and the affected skin is usually dark, insensate, and firmly attached regardless of the burn depth [21]. Healing usually takes longer than for thermal burns.

Some chemical warfare agents cause severe dermal injury. Sulfur mustard, the most common antipersonnel agent used, and lewisite (chlorovinylarsine dichloride) are potent alkylating agents, resulting in severe vesiculation of the skin 4 to 12 hours after exposure. Phosgene oxide has a similar action, but its effects are almost immediate. Respiratory burns are nearly always associated with sulfur mustard exposure [22]. White phosphorus is used in incendiary devices and in the manufacture of fertilizers and insecticides. It ignites spontaneously when exposed to air.

Ingested corrosives typically injure the oropharynx, esophagus, and stomach but may cause damage as distal as the proximal jejunum [23,24]. Areas most commonly affected are those of anatomic narrowing: the cricopharyngeal area, diaphragmatic esophagus, and antrum and pylorus of the stomach [23]. Multiple sites are affected in up to 80% of patients [24]. Esophageal lesions are seen predominantly in the lower half, and gastric burns are usually most severe in the antrum [24]. In the presence of food, gastric injuries tend to be less severe and involve the lesser curve and pylorus [10]. Vomiting is associated with a higher incidence of severe esophageal injuries [25].

Ingestion of alkali is associated with a higher incidence and severity of esophageal lesions than ingestion of acid, which typically causes stomach injury although this is not a consistent finding [4,25]. Alkaline agents have little taste, but acids are extremely bitter and more likely to be expelled if accidentally ingested.

Alkaline solids may adhere to mucosa of the oropharynx and cause oral pain that limits the quantity swallowed, thus sparing the esophagus [26]. If alkaline solids are swallowed, severe upper esophageal burns are seen [27]. Shallow ulcers may result when tablets become lodged in the esophagus (pill esophagitis). Hemorrhage and stricture formation may occur after esophageal impaction of potassium chloride, iron, quinidine, etidronate, antibiotics, and anti-inflammatory agents [28].

Common symptoms from corrosive ingestion are oropharyngeal pain, dysphagia, abdominal pain, vomiting, and drooling [29]. Less commonly, stridor, hoarseness, hematemesis, and melena are seen. Patients who are asymptomatic are unlikely to have significant injuries, although this may be difficult to assess in children who may appear to have no or minimal symptoms [29]. Vomiting, drooling, and stridor appear to be predictive of more severe injuries [29].

The absence of burns in the oropharynx does not exclude burns further along the gastrointestinal tract, and it is not predictive of less severe distal injuries [29]. Patients with laryngeal burns have a greater incidence and severity of esophageal lesions [25].

Hemorrhage, perforation, and fistula formation may occur in patients with full-thickness esophageal necrosis [24]. Untreated, perforations rapidly progress to septic shock, organ failure, and death. Some gastric perforations may become walled to form an abscess around the liver or in the lesser sac.

Severe gastric burns may extend to adjacent organs [30]. Perforation of the anterior esophageal wall may lead to formation of a tracheoesophageal fistula and tracheobronchial necrosis [31,32]. Tracheoesophageal–aortic and aortoesophageal fistulas, rare and uniformly fatal complications, are suggested by hemoptysis or hematemesis, which develops into torrential bleeding [33,34].

Burns to the larynx occur in up to 50% of patients and are the most common cause of respiratory distress [25]. Typically, the epiglottis and aryepiglottic folds are edematous, ulcerated, or necrotic. The absence of respiratory symptoms on presentation does not exclude the presence of laryngeal burns that may eventually require intubation [25]. Respiratory distress may also be due to the aspiration of corrosives [35].

Esophageal strictures develop in up to 70% of burns that result in deep ulceration, whether discrete or circumferential, and nearly all burns resulting in deep necrosis [24]. Strictures do not develop after superficial mucosal ulceration [35]. Strictures may become symptomatic as early as the end of the second week; half develop during initial hospitalization, and 80% are evident within 2 months [36]. Those that develop early often progress rapidly and require urgent intervention. Gastric outlet strictures may also occur, but only 40% become symptomatic [24]. Strictures can develop in the mouth and pharynx [25].

Esophageal pseudodiverticulum may occur in patients with esophageal stricture as early as 1 week after corrosive ingestions. It appears to result from incomplete destruction of the esophageal wall and usually resolves with dilation of associated strictures [37].

Deaths that occur are in patients who have extensive necrosis in the upper gastrointestinal tract. Sepsis secondary to perforation is the most common cause of death; severe hemorrhage or aspiration may also contribute [24].

Esophageal carcinoma, usually squamous cell, is a well-documented complication of alkali burns [38]. It occurs most commonly at the level of the tracheal bifurcation and is estimated to occur 1,000 times more frequently in patients who have had corrosive injuries than in the general population. Symptoms can develop 22 to 81 years after the initial insult.

Systemic toxicity has occurred with burns caused by arsenic and other heavy metals, cyanide, acetic acid, formic acid, fluoride, hydrazine, hydrochloric acid, nitrates, sulfuric acid, and phosphoric acid [39–43]. Severe acid burns may be accompanied by a metabolic acidosis and hypotension. The anion gap is usually elevated, although a hyperchloremic acidosis may be seen in hydrochloric acid and ammonium chloride ingestion. After hydrochloric acid ingestion, cardiovascular collapse is the most common cause of early death; myocardial infarction has occurred after large ingestions. Other findings associated with severe acid injuries include hemolysis, hemoglobinuria, nephrotoxicity, and pulmonary edema [40,41,43].

Acute hemolysis, hyperkalemia, hypoxia, and cardiorespiratory arrest have occurred after the use of dialysis equipment and syringes sterilized with bleach [44]. Vascular oxygen embolization can occur after the ingestion of concentrated hydrogen peroxide [45]

DIAGNOSTIC EVALUATION

Resuscitation and decontamination should take priority over completing a detailed history and physical examination. Medical staff should wear protective clothing to avoid becoming secondary casualties. The duration of exposure, symptoms, and details of prehospital treatment should be noted. Identification of the compounds involved and any measures required for their safe handling can be established by a number of means: Container labeling, material safety data sheets and safety officers in cases of workplace exposure, fire department hazardous materials units, and regional poison information centers. Measuring the pH of a product may be helpful.

If the exposure is the result of an industrial or transportation accident, the patient should be evaluated for traumatic injuries. Suicidal patients should be evaluated for other possible toxic exposures (e.g., ingestion of alcohol or medications). Pulmonary exposures should be evaluated as outlined in Chapter 64.

After decontamination, assessment of eye exposures should include measurement of visual acuity and conjunctival pH and a slit-lamp examination. Chemosis, conjunctival hemorrhages, corneal epithelial defects, stromal opacification, and loss of limbic vessels should be noted. If injury to the anterior chamber is suspected, intraocular pressure should be measured.

Assessment of dermal injury is similar to that for thermal burns. Location, size, color, texture, and neurovascular status should be noted. If the affected area is greater than 15% of total body surface area or if systemic toxicity is possible, a complete physical examination with appropriate monitoring and laboratory testing should be performed.

With ingestions, the ability to swallow secretions and findings on examination of the oropharynx, neck, chest, and abdomen should be noted. Particular attention should be given to assessing the patency of the airway. Patients with signs and symptoms suggestive of significant injuries should have an electrocardiogram, arterial blood gas analysis, complete blood cell count, type and cross-match, coagulation profile, and biochemistry testing, including electrolytes, glucose, and liver and renal function. Radiologic studies should include a chest radiograph and an upright abdominal film. Upper gastrointestinal endoscopy should be performed in symptomatic patients or those with visible burns in the mouth or throat. Although the absence of symptoms or signs does not preclude the presence of gastrointestinal burns, in patients with accidental ingestions, such injuries are always of a minor nature and endoscopy is not necessary [23]. Minor symptoms or grade I visible burns following the accidental ingestion of substances shown to have low toxicity, such as sodium hypochlorite household bleach (less than 10% solution) and hair relaxer gel, do not necessarily require endoscopy, as significant injuries are rare in this setting [46–48]. However, endoscopy is still recommended if excessive drooling or dysphagia or significant mucosal burns occur after ingestion of these products or if there is doubt about the exact composition of the ingested substance [46,47]. In contrast, in those with ingestions of strong acids or bases, significant injuries may be present in the absence of clinical findings, and endoscopy is indicated. The optimal timing of endoscopy appears to be 6 to 24 hours after exposure. Because injuries may progress over several hours, endoscopy performed earlier may not detect the full extent of injury and therefore may need to be repeated [2]. If performed later, the risk of perforation is increased [24].

In the past, it was recommended that the endoscope not be passed beyond the first circumferential or full-thickness lesion because of the risk of iatrogenic perforation [48]. This complication was a significant problem in the days when rigid endoscopes were used. It is extremely rare with flexible endoscopy. Not examining beyond the first significant lesion results in failure to detect more distal lesions of the stomach or duodenum [49]. Flexible endoscopy, preferably using a small-diameter (e.g., pediatric) endoscope, of the entire upper gastrointestinal tract is safe and usually well tolerated [24]. The endoscope should be advanced across the cricopharynx under direct vision to assess for the presence of laryngeal burns [24]. If laryngeal edema or ulceration is noted, the airway should be intubated before endoscopy is continued. Examination should be done gently with minimal air insufflation, avoiding retroversion or retroflexion, and the procedure terminated if the endoscope cannot be easily passed through a narrowed area. Therapeutic dilation of the esophagus on initial endoscopy carries a high risk of perforation and should be avoided [23]. It should also be avoided during the subacute phase (5 to 15 days after ingestion), when the tensile strength of tissues is lowest [24].

TABLE 130.3

EXAMPLES OF CLASSIFICATIONS FOR GRADING SEVERITY OF GASTROINTESTINAL CORROSIVE INJURY

Grade I	Mucosal inflammation
Grade II	A. Hemorrhages, erosions, and superficial ulceration
	B. Deep discrete or circumferential ulceration
Grade III	A. Small, scattered areas of necrosis
	B. Extensive necrosis involving the whole esophagus
First degree	Mucosal inflammation, edema, or superficial sloughing
Second degree	Damage extends to all layers of, but not through, the esophagus
Third degree	Ulceration through to periesophageal tissues

A number of different systems for grading gastrointestinal burns have been proposed [23,24]. Some parallel grading systems used for thermal skin burns; others differentiate several levels of ulceration and necrosis (Table 130.3). The important findings are depth of ulceration and presence of necrosis. Injuries that consist only of mucosal inflammation or superficial ulceration and do not involve the muscularis are not at risk for stricture formation [24]. Patients with full-thickness circumferential burns and extensive necrosis are at high risk for perforation and stricture formation. Deep ulceration, whether transmural or not, and discrete areas of necrosis can sometimes lead to stricture formation.

Contrast esophagography is less sensitive than endoscopy in visualizing ulceration but has a role in the detection of suspected perforation [50]. A water-soluble contrast agent should be used. Cineesophagography can detect esophageal motility disorders, the pattern of which may predict the likelihood of stricture formation. Strictures can be expected to develop in all patients with an atonic dilated or rigid esophagus and in some individuals with abnormal, uncoordinated contractions [51]. Endoscopic ultrasonography can accurately grade corrosive injuries and predict complications [52]. Esophageal motility studies may predict the risk of stricture formation in those patients with no peristaltic response; these motility abnormalities persist for at least 3 months [53].

Evaluation of patients with symptoms and signs of systemic toxicity should include routine monitoring and ancillary testing. The extent and type of testing depend on the nature and severity of clinical abnormalities and the chemical involved. Patients with significant exposure to some phenols (e.g., nitrophenol and pentachlorophenol) and to hydrazine should have methemoglobin level determination.

MANAGEMENT

Advanced life support measures should be instituted as appropriate. Decontamination is the next priority; procedures are specific to the route of exposure. Treatment of systemic poisoning is primarily supportive; in some cases, antidotal therapy may also be necessary.

Irrigation should be performed immediately for eye exposures. The procedure is described in Chapter 117. The persistence of eye pain despite irrigation for at least 15 minutes indicates significant injury or incomplete decontamination. Failure

to irrigate the eye adequately or remove particles after chemical exposure is associated with chronic complications [54]. Up to one third of patients with lime burns still have particles present in the eye on presentation [54]. All cases in which injury is detected or symptoms persist require ophthalmologic evaluation. Management may consist of topical antibiotics, mydriatics, steroids, and eye patching. The role of neutralization of chemical burns is currently under investigation. Ascorbic acid had been used to treat alkali burns, but its effectiveness has not been well studied, and it cannot be recommended [18].

The initial treatment of dermal exposure is prompt irrigation with copious amounts of water for at least 15 minutes for acid exposures and 30 minutes for alkali exposures (see Chapter 119). Longer irrigation is recommended for alkalis because they have detergent properties [20]. Although tissue neutralization occurs within 10 minutes with acids and 1 hour with alkalis in experimental studies, delayed irrigation may be beneficial [55]. Clothes act as a reservoir, and failure to remove them may result in full-thickness burns developing from even mildly corrosive chemicals [20]. Neutralization has been used [56], but because data on its efficacy are lacking, such therapy cannot be recommended.

Water irrigation may sometimes be dangerous or ineffective. Metallic lithium, sodium, potassium and cesium, titanium tetrachloride, and organic salts of lithium and aluminum react violently with water; burns caused by these agents should be inspected closely and any particles removed and placed in an anhydrous solution (oil) before the area is irrigated. Alternatively, the area can be wiped with a dry cloth to remove particles and the skin then deluged with water to dissipate any heat. Phenol is not water soluble, and dilution with water may aid its penetration into tissues, increasing systemic absorption [16]. Soaking experimental phenol burns with isopropyl alcohol or polyethylene glycol in mineral oil is superior to rinsing with water [57]. Isopropyl alcohol and polyethylene glycol may be absorbed by burns, and their use should be followed by liberal washing with water. Ready-mixed concrete can be easily removed from skin by soaking or irrigating with 50% dextrose in water [58].

Application of a copper sulfate solution has been suggested to assist in identification and neutralization of white phosphorus particles on the skin, but systemic absorption of copper sulfate can result in massive hemolysis with acute renal failure and death [59]. The use of a Wood's lamp to detect fluorescent phosphorus particles is safer [16]. Such burns should be kept wet because phosphorus ignites in dry air. Because sulfur mustard is poorly water soluble, a mild detergent should be used for its removal. Military decontamination kits contain chloramine wipes, which inactivates sulfur mustard [60]. British antilewisite, or dimercaprol, is an effective chelator of lewisite and can be applied topically to the skin or eye [22].

Patients with second- or third-degree skin burns should be referred to a surgeon. Definitive management is the same as for thermal burns, although more aggressive use of early débridement and grafting has been suggested [21].

Despite the rapidity of tissue injury following ingestion, decontamination should be considered. Rinsing with water or saline is recommended for mouth exposures. Dilution by drinking up to 250 mL (120 mL for a child) water or milk is recommended for particulate ingestion, because the corrosive may adhere to the esophageal wall. Although this procedure exposes the stomach to the corrosive agent, it further dilutes the substance. As the efficacy of dilution is greatest if performed within 5 minutes of exposure and declines rapidly thereafter, it is reasonable to use any drinkable beverage, except carbonated ones, if water or milk is not immediately available. The role of dilution for liquid ingestion is less clear, but it is usually recommended. It may, however, promote emesis and may not be effective in limiting tissue damage unless undertaken within minutes of injury. Emesis is contraindicated because of the risk of aspiration and its association with an increased severity of esophageal and laryngeal burns [25].

The administration of weak acids or bases can neutralize, as well as dilute, ingested corrosives [61]. Although weak acids are more effective than milk or water in neutralizing the pH, neutralization, which is accompanied by the production of heat, could lead to thermal injury in addition to corrosive effects. The heat generated by in vitro neutralization is small (less than 3°C) for liquid alkali but may be greater for solid forms [61]. The benefit of such therapy is unknown and not recommended [62].

Using a nasogastric tube for gastric aspiration, dilution, or lavage is another subject of debate [9]. Esophageal perforation is a potential complication, but no cases of nasogastric tube perforation have been reported. Placement of a gastric tube with fluoroscopic or endoscopic guidance has been suggested, but the blind, gentle introduction of a small-bore tube in a cooperative patient, particularly for an ingested acid, also appears to be safe [23]. If inserted, the tube should be firmly taped in place to avoid motion. Gastric contents should be aspirated. Dilution or lavage with small aliquots (120 to 250 mL) of water can then be performed.

Activated charcoal does not adsorb inorganic acids or alkali. In addition, because it interferes with endoscopic evaluation, unless a corrosive that has significant systemic toxicity and is known to be bound by activated charcoal has been ingested, this agent should be avoided. Symptomatic patients should otherwise be given nothing by mouth before endoscopy.

Corticosteroids have been used to reduce the incidence and severity of esophageal strictures after alkali burns. Such therapy is based on studies showing a decrease stricture formation in animals pretreated with steroids [63]. Because strictures do not develop in patients with first-degree esophageal burns, steroids are not indicated in those with such findings [64]. Similarly, steroids do not appear to influence the development of esophageal strictures after extensive deep ulceration or necrosis [64], and hence they are not recommended in patients with these injuries. Studies on the efficacy of steroids in patients with injuries of moderate severity have yielded conflicting results (Table 130.4). Most have been retrospective and poorly controlled [65–67]. Three analyses of pooled data from retrospective and prospective studies concluded a lower incidence of stricture formation with steroids in one study, but no difference in the other two [68–70]. There have been three prospective controlled studies of steroid use [71–73]. Two studies came to different conclusions; one showing a benefit with steroids, the other not [71,72] A criticism of the negative study was the delay to commencing steroids [74]. In an unpublished prospective randomized controlled trial of 362 patients, steroids did not show a benefit (73).

If steroids are administered, the recommended dose is 1 to 2 mg per kg per day prednisolone or methylprednisolone for 3 weeks followed by gradual tapering [74]. One comparative study suggested improved burn healing and reduced the need for dilatations with dexamethasone (1 mg per kg per day) compared with prednisolone (2 mg per kg per day) [75]. To approximate experimental conditions showing a beneficial effect, the initial dose of steroids should be given on presentation. Active bleeding and perforation are contraindications to steroid use.

Prophylactic antibiotics have also been advocated for patients with significant gastrointestinal injuries. Their benefits have not been studied in humans, and opinions differ as to their value. Controlled animal experiments have shown a combination of steroids and antibiotics to give the best outcome with respect to stricture formation and mortality [76] and suggest that a broad-spectrum antibiotic (e.g., a second-generation

TABLE 130.4

RESULTS OF CONTROLLED TRIALS OF STEROIDS FOR ESOPHAGEAL STRICTURES FOLLOWING CORROSIVE ESOPHAGEAL BURNS

Intervention	Year	Study	No. of patients	Findings	Reference
Prednisolone 25 mg 6 hourly (children 1.5 mg/kg/d for 2 weeks then tapered	1970	Retrospective controlled trial	21	Esophageal stricture rate: 27% in study group; 0% in controls	[64]
Methylprednisolone 125 mg IM, two doses 6 hours apart, then 40 mg 6 hourly for 5 days followed by reducing Depo-Medrol until healed	1980	Prospective randomized controlled trial	20	Esophageal stricture rate: 22% in study group; 36% in controls	[72]
Prednisolone 2 mg/kg/d IV until oral intake: 2.5 mg/kg/d for 21 days	1990	Prospective randomized controlled trial	25	Esophageal stricture rate: 7% in study group; 0% in controls	[71]
Steroid (not specified) 2 mg/kg/d (max. 30 mg/d) for 3 weeks	2005	Prospective randomized controlled trial	223	Esophageal stricture rate: 12% in study group; 19% in controls (NS)	[73]

cephalosporin) should be administered, particularly in those treated with steroids.

If initiated, the decision to continue or cease steroid and antibiotic therapy should be based on endoscopic findings. Patients with no injury or mucosal inflammation or small areas of superficial ulceration are not at risk for strictures or perforation and require supportive therapy only. Symptomatic relief can be provided with antacids, sucralfate, histamine-2–blockers (H_2-blockers), or analgesics. Patients with persistent symptoms or inconclusive findings on endoscopy should be admitted for observation. If symptoms persist, endoscopy should be repeated. Patients can commence oral fluids when they are able to swallow their own secretions. They can be discharged when tolerating oral fluids.

Patients with deep discrete ulcerations, circumferential or extensive superficial ulcerations, or small isolated areas of necrosis are at risk for stricture formation and should be given nothing by mouth. Fluids, analgesics, and H_2-blockers should be administered parenterally. Intravenous steroids and antibiotics should also be considered in those with alkali burns. Patients with deep transmural ulceration or necrosis are at risk for perforation as well as stricture formation. Although the use of steroids in this group is potentially hazardous and not recommended, antibiotics should be given along with other supportive measures. Hyperalimentation, either parenteral or by jejunostomy feeding tube, may be required.

Surgical exploration is indicated if perforation or penetration into surrounding tissues is suspected by findings such as fever, progressive abdominal or chest pain, hypotension, or signs of peritonitis or proved by endoscopic or radiographic findings. Tracheoesophageal fistulas are usually fatal unless recognized early and repaired, although one case reported successful conservative treatment [32]. Laparotomy and early excision have been suggested for patients with extensive full-thickness necrosis, but an advantage of this approach over more conservative treatment is not clear [77]. The mortality for patients who have major emergency surgery is 9% to 66% [77,78].

Stricture formation is usually treated with endoscopic dilatation beginning 3 to 4 weeks after ingestion. An average of eight sessions is required, but recurrence is common in the first 12 months [79]. In a group of 195 patients with corrosive-induced esophageal strictures, the risk of perforation for each dilatation session was 1.3%, but, because of the requirement for multiple dilations, the risk per patient was 17% [79]. Perforations were most likely to occur during the first three dilations. Features of perforation include dyspnea, malaise, tachycardia, fever, and subcutaneous crepitations. The majority are detected during the procedure or by the presence of pneumomediastinum, or pneumothorax or hydrothorax on chest radiograph, but occasionally contrast esophagography or esophagoscopy is required for confirmation. The death rate from perforation is 16% to 23% [79]. Early or prophylactic bougienage is of unclear benefit and has been associated with an increased risk of perforation. One study has shown a decrease in the number of dilatations required following interlesional steroid injection [80].

Placement of specialized nasogastric tubes or stents has lowered the rate of stricture formation in uncontrolled clinical trials and is superior to steroids in animal experiments [81]. An additional benefit of combining the use of a stent with systemic steroids has been suggested [81]. Oral sucralfate and H_2-blockers have no proven benefit in increasing tissue healing or reducing complications [82].

Surgery may ultimately be required if there is complete or near-complete obliteration of the esophageal lumen for more than 3 cm, if dysphagia recurs within a few weeks after successful dilation, or if perforation occurs during dilation [74]. Occasionally, resection and end-to-end anastomosis are possible, but usually extensive reconstruction, with colonic interposition, is necessary. The overall mortality from colonic replacement surgery is 2.0% to 3.6% and commonly results from sepsis secondary to anastomosis leakage or colonic graft necrosis [83]. Gastrectomy or gastrojejunostomy may also be required if gastric outlet obstruction develops [84]. Early definitive surgery for gastric outlet obstruction appears to be more advantageous than staged surgery [85]. Endoscopic balloon dilation may be an acceptable alternative procedure [86]. Diode laser-assisted radial lysis using a rigid endoscope has also been used to treat strictures successfully [87].

Supportive management is the mainstay of treatment for systemic toxicity. Heavy metal, cyanide, and hydrogen sulfide poisoning may require antidotal therapy (see Chapter 133). Neurologic toxicity due to hydrazine may respond to intravenous pyridoxine, administered at an initial dose of 25 mg per kg repeated in several hours, if necessary [42] (see Chapter 137). Methemoglobinemia may require treatment with methylene blue (see Chapter 117). Hemodialysis may enhance the elimination of heavy metals and dichromate, particularly if renal failure develops [88].

CHAPTER 131 ■ SALICYLATE AND OTHER NONSTEROIDAL ANTI-INFLAMMATORY DRUG POISONING

MARCO L.A. SIVILOTTI AND CHRISTOPHER H. LINDEN

Nonsteroidal anti-inflammatory drugs (NSAIDs) include aspirin, related salicylates (Table 131.1), and a variety of other drugs (e.g., ibuprofen, indomethacin, phenylbutazone, and ketorolac), which modulate inflammation by inhibiting cyclooxygenase (COX). In clinical use for 100 years, aspirin still enjoys widespread popularity in the adult population, both by self-medication and by physician-recommended usage.

While the institution of child-resistant packaging and concerns about Reye's syndrome resulted in a dramatic decline in pediatric overdose, aspirin remains a leading cause of death due to pharmaceutical overdose [1–3]. Reducing the amount of aspirin available over the counter was associated with a fewer overdose deaths in the United Kingdom [4]. Nevertheless, vigilance remains necessary because chronic salicylate intoxication, particularly in the elderly, is commonly unrecognized or mistaken for other conditions, such as dehydration, dementia, sepsis, and multiorgan failure. In contrast, most other NSAIDs have a substantially greater safety margin than aspirin in overdose. Although availability without prescription has resulted in increased use and frequency of overdose, significant acute toxicity is uncommon [1,5,6].

PHARMACOLOGY

All NSAIDs have analgesic and antipyretic as well as anti-inflammatory activity. These effects are due to inhibition of COX, also known as *prostaglandin G/H synthase*, the enzyme responsible for the conversion of arachidonic acid to prostaglandins and thromboxanes [7,8]. The analgesic dose of most NSAIDs is approximately one-half the anti-inflammatory dose. For some NSAIDs, such as aspirin, ibuprofen, and fenoprofen, this gap is larger, whereas the converse is true for sulindac and piroxicam [9]. Antipyretic effects appear to be due to decreased pyrogen production peripherally as well as to a central hypothalamic effect. The existence of central nervous system (CNS) sites of action mediating analgesic activity has been postulated [10].

Two isoforms of COX have been characterized: COX-1, constitutionally present in platelets, endothelium, gastric mucosa, and the kidneys; and COX-2, induced by a variety of inflammatory mediators (e.g., cytokines, endotoxin, growth factors, hormones, and tumor promoters) but suppressed by glucocorticoids [8,11]. The anti-inflammatory and analgesic properties of NSAIDs appear to be primarily due to the inhibition of COX-2. Their adverse effects on gastric mucosa (e.g., hemorrhage, ulceration, and perforation) and kidney function (e.g., decreased renal blood flow and glomerular filtration rate), and their effects on platelet function appear to be mediated primarily by COX-1, but COX-2 inhibition may also be involved [8,12,13].

NSAIDs can be classified on the basis of their selectivity for COX-2. In particular, the coxibs rofecoxib, valdecoxib, and celecoxib were developed specifically for their COX-2 selectivity and the promise of improved safety. However, an increased risk of thrombotic events, primarily myocardial infarction and stroke, was identified in clinical trials and led to regulatory restrictions on the selective COX-2 inhibitors [14,15]. These adverse cardiovascular effects appear to be due to a relative excess of COX-1–generated thromboxane A2, which is vasoconstrictive and platelet-activating (i.e., prothrombic), and a relative lack of COX-2–generated prostaglandin I_2 (prostacyclin), which is vasodilatory and platelet inhibitory (i.e., antithrombotic) [8,14]. It is important to note that traditional NSAIDS diclofenac, meloxicam, and nabumetone exhibit partial COX-2 selectivity, and that other traditional, nonselective NSAIDs may also contribute to adverse cardiovascular events. Thus, selectivity is relative, and all NSAIDs inhibit both COX isoforms in a dose-dependent manner.

Inhibition of COX-1 may result in increased lipoxygenation of arachidonic acid to leukotrienes. This alternate metabolic pathway seems to be responsible for the sometimes fatal allergic reactions to NSAIDs especially prevalent in adults with asthma

TABLE 131.1

SALICYLATE PREPARATIONS

Compound	Common/trade names	Percentage salicylate
Acetylsalicylic acid	Aspirin	75
Bismuth subsalicylate	In Pepto-Bismol	37
Choline salicylate	Arthropan	56
Choline and magnesium salicylate	Trilisate	76
Difluorophenyl salicylic acid	—	—
Diflunisal	Dolobid	—[a]
Homomenthyl salicylate	In sunscreens	51
Magnesium salicylate	Doan's Caplets, Magan	90
Methyl salicylate	Oil of wintergreen	89
Salicylic acid	In topical keratolytics	100
Salicylsalicylic acid	Salsalate, Disalcid	96
Sodium salicylate	Pabalate	84
Trolamine salicylate	Aspercreme	48

[a]Not hydrolyzed to salicylic acid but may cause screening tests for salicylate to be falsely positive.

and nasal polyps [16,17]. The expression or upregulation of COX-2 may be involved in the pathogenesis of Alzheimer's disease and some cancers (e.g., colon).

Aspirin (acetylsalicylic acid) is unique in that it acetylates a serine residue near the active site of COX, thereby irreversibly inhibiting its catalytic function. In contrast, the inhibition of COX by other NSAIDs is reversible and transient. This difference in activity is most notable in platelets, in which thromboxane A_2 is essential for normal function [18]. Even in low doses (80 mg), aspirin inhibits platelet aggregation and prolongs the bleeding time for up to 1 week (pending the production of new platelets), whereas other NSAIDs do not have clinically significant platelet effects [19].

In high doses, aspirin and other salicylates also inhibit the hepatic synthesis of clotting factor VII and, to some degree, factors IX and X, thereby prolonging the prothrombin time. This effect appears to be due to interference with the activity of vitamin K and can be reversed by administration of phytonadione (vitamin K_1). In contrast, other NSAIDs have insignificant effects on clotting-factor synthesis [19].

Salicylates

Salicylates are available in oral, rectal, and topical formulations. Enteric-coated and sustained-release aspirin tablets are also marketed. Aspirin preparations frequently contain other drugs such as anticholinergics, antihistamines, barbiturates, caffeine, decongestants, muscle relaxants, and opioids. The recommended pediatric dose of aspirin is 10 to 20 mg per kg of body weight every 6 hours, up to 60 mg per kg per day; for adults, the recommended dose is 1,000 mg initially, followed by 650 mg every 4 hours for anti-inflammatory effect. Therapeutic doses of other salicylate salts are similar but depend on their salicylate content (see Table 131.1) and formulation. After a single oral dose of aspirin, therapeutic effects begin within 30 minutes, peak in 1 to 2 hours, and last approximately 4 hours.

Being a weak acid (pK_a, 3.5), aspirin is predominantly nonionized at gastric pH and, therefore, theoretically well absorbed in the stomach. However, gastric acidity reduces the solubility of aspirin, thereby slowing the dissolution of tablets. Hence, despite its higher pH, most absorption actually occurs in the small intestine, probably because of its much larger surface area. Peak serum salicylate levels of 10 to 20 mg per dL (0.7 to 1.4 mmol per L) occur 1 to 2 hours after ingestion of a single therapeutic dose. Levels up to 30 mg per dL can occur with long-term therapy and may be necessary for maximal anti-inflammatory effects in some patients. Absorption is delayed or prolonged after ingestion of enteric-coated or sustained-release preparations and suppository use [20]. With overdose, slow pill dissolution, and delayed gastric emptying due to aspirin-induced pylorospasm may lead to absorption continuing for 24 hours or longer after ingestion [21].

During absorption, aspirin is rapidly hydrolyzed by plasma esterases to its active metabolite, salicylic acid. At physiologic pH, salicylic acid (pK_a: 3.0) is more than 99.9% ionized to salicylate, which, in contrast to nonionized salicylic acid, diffuses poorly across cell membranes. The drug may become sequestered preferentially in inflamed tissue due to this pH-dependent ionization.

The apparent volume of distribution of salicylate at pH 7.4 is only 0.15 L per kg, in part due to its extensive protein binding. Only free (i.e., unbound) salicylate is pharmacologically active. However, salicylate is unique in that its apparent volume of distribution is not constant. High drug levels (e.g., as a result of chronic therapeutic dosing or acute overdose), low albumin levels, and the presence of other drugs that bind to albumin increase the amount and fraction of free drug [22]. When this occurs, the apparent volume of distribution may increase to 0.60 L per kg [23]. Acidemia, as a consequence of either concomitant illness or severe poisoning, may additionally increase the fraction of nonionized, diffusible drug, promote its tissue penetration, and increase the apparent volume of distribution even more.

After single therapeutic doses, salicylate is metabolized in the liver to the inactive metabolites salicyluric acid (the glycine conjugate; 75% of the dose), salicyl phenolic glucuronide (10%), salicyl acyl glucuronide (5%), and gentisic acid (less than 1%). The remaining 10% of the dose is excreted unchanged in the urine. When serum concentrations exceed 20 mg per dL, the two main pathways of metabolism become saturated, and elimination changes from first order (i.e., proportional to the serum level) to zero order (constant), as described by Michaelis–Menton kinetics. Hence, the apparent half-life of salicylate is 2 to 3 hours after a single therapeutic dose, 6 to 12 hours with chronic therapeutic dosing (i.e., serum levels of 20 to 30 mg per dL), and 20 to 40 hours with overdose (i.e., when levels exceed 30 mg per dL) [24]. Because of saturable metabolism, a small increase in the daily dose can lead to a large increase in serum drug levels, with the potential

for unintentional poisoning [25]. Depletion of glycine stores may reduce the capacity of the salicyluric acid pathway and further slow elimination in overdose [26].

Renal excretion of salicylate becomes the most important route of elimination when hepatic transformation becomes saturated. The rate of excretion is determined by the glomerular filtration, active proximal tubular secretion of salicylate, and passive distal tubular reabsorption of salicylic acid. Alkalinization of the urine decreases the passive reabsorption of salicylic acid by converting it to ionized, nondiffusible salicylate and thereby increases drug excretion. Similarly, increasing the rate of urine flow increases drug clearance by increasing the glomerular filtration and decreasing the distal tubular reabsorption of salicylic acid (by diluting its concentration in the tubular lumen). Combined alkalinization and diuresis can augment the renal elimination of salicylate by 20-fold or more [27,28]. Conversely, dehydration and aciduria perhaps due to preexisting illness or to salicylate poisoning itself decrease salicylate excretion, and increase the duration of toxicity once it develops.

Salicylates readily cross the placenta and enter breast milk. Salicylate elimination in the fetus or infant may be prolonged because of immature metabolic pathways and renal function [29]. It may also be prolonged in patients with liver or renal disease.

The pathophysiology of salicylate poisoning is multifactorial [30–35]. Initially and in mild poisoning, direct stimulation of the respiratory center in the medulla by toxic salicylate concentrations results in a respiratory alkalosis, unless blunted by concomitant ingestion of CNS depressants [31]. Direct stimulation of the medullary chemoreceptor zone and irritant effects on the gastrointestinal tract are responsible for nausea and vomiting. Exaggerated antipyretic effects involving the hypothalamus may cause vasodilation and sweating [36]. Dehydration results from gastrointestinal, skin, and insensible fluid losses. The osmotic diuresis that occurs as bicarbonate is excreted in response to alkalemia also contributes to dehydration. Sodium and potassium depletion result from excretion of these electrolytes along with bicarbonate (in exchange for hydrogen ion reabsorption). A functional hypocalcemia (decreased ionized calcium) may accompany alkalemia and cause or contribute to cardiac arrhythmias, tetany, and seizures.

Subsequently, in moderate poisoning, the accumulation of salicylate in cells causes uncoupling of mitochondrial oxidative phosphorylation, inhibition of the Krebs cycle, inhibition of amino acid metabolism, and stimulation of gluconeogenesis, glycolysis, and lipid metabolism [37,38]. These derangements result in increased but ineffective metabolism, with increased glucose, lipid, and oxygen consumption and increased amino acid, carbon dioxide, glucose, ketoacid, lactic acid, and pyruvic acid production. High serum levels of organic acids contribute to an increased anion-gap metabolic acidosis, and the renal excretion of these acids results in aciduria. However, increased carbon dioxide production further stimulates the respiratory center, and the respiratory alkalosis persists, resulting in alkalemia with paradoxical aciduria. An osmotic diuresis further accentuates fluid and electrolyte losses.

In severe poisoning, progressive dehydration and impaired cellular metabolism cause multisystem organ dysfunction. Metabolic acidosis with acidemia becomes the dominant acid–base disturbance. Respiratory acidosis, lactic acidosis, and impaired renal excretion of organic acids due to dehydration and acute tubular necrosis contribute to the acidemia. Acidemia increases the fraction of nonionized salicylate in serum, thereby promoting its tissue penetration and toxicity, and rapid clinical deterioration may ensue with increasing brain salicylate levels. Impaired cellular metabolism can cause increased capillary permeability [39] leading to cerebral edema and noncardiogenic pulmonary edema or acute respiratory distress syndrome. Coma and seizures may result from impaired cellular metabolism, cardiovascular depression, cerebral edema, acidemia, hypoglycemia, and acute white matter damage due to myelin disintegration and activation of glial caspase-3 [41,42]. Respiratory alkalosis may be replaced by respiratory acidosis if coma or seizures cause respiratory depression. Tissue hypoxia resulting from pulmonary edema, impaired perfusion, or seizures may lead to anaerobic metabolism and concomitant lactic acidosis.

Hemorrhagic diathesis may result from increased capillary fragility, decreased platelet adhesiveness, thrombocytopenia, and coagulopathy secondary to liver dysfunction. It occurs primarily in patients with chronic poisoning.

Other Nonsteroidal Anti-inflammatory Drugs

Despite their structural diversity, the pharmacokinetics of traditional NSAIDs are quite similar. Like aspirin, they are weak acids, with pK_a ranging from 3.5 to 5.6 and pH-dependent ionization being the major determinant of tissue distribution and sequestration. They are rapidly absorbed after ingestion, have small volumes of distribution (0.08 to 0.20 L per kg), and are 90% to 99% protein bound (principally to albumin). Most have half-lives of less than 8 hours, with low non–flow-dependent hepatic clearance, primarily by the CYP2C subfamily of cytochrome P450 enzymes, to inactive metabolites that are then conjugated, mostly with glucuronic acid, and excreted in the urine. Sulindac is one exception in that its sulfide metabolite is the active form of the drug and has a half-life of 16 hours [42]. Nabumetone is also a prodrug, and its active metabolite, 6-methoxy-2-naphthylacetic acid, has a half-life of more than 20 hours (and even longer in the elderly) [43]. Phenylbutazone, oxyphenbutazone, and piroxicam are notable for half-lives of longer than 30 hours. Diflunisal, like aspirin, has a dose-dependent half-life of 5 to 20 hours. Indomethacin, sulindac, etodolac, piroxicam, carprofen, and meloxicam undergo enterohepatic recirculation [42,44,45]. Small amounts (less than 10%) of nonsalicylate NSAIDs are excreted unchanged in the urine, limiting the effect of urine pH on clearance. The coxibs are nonacidic drugs [13], highly protein bound and primarily metabolized in the liver.

In contrast to salicylates, the metabolism of most nonsalicylate NSAIDs is not saturable or prolonged in overdose, and elimination follows first-order kinetics. An exception is phenylbutazone, whose elimination may follow Michaelis–Menton kinetics.

Toxic effects of NSAIDs appear to be primarily due to exaggerated pharmacologic effects, with gastric irritation and renal dysfunction resulting from the inhibition of prostaglandin synthesis [46]. In contrast to salicylate poisoning, the acidosis that sometimes occurs with large overdoses of these agents appears to be due to high levels of parent drug and metabolites rather than to disruption of metabolism [47]. Mechanisms responsible for their CNS toxicity remain to be defined.

CLINICAL TOXICITY

Salicylates

Salicylate poisoning may occur with acute as well as chronic overdose [30–35,48–55]. It most commonly results from ingestion, but poisoning due to topical use [56] and rectal self-administration [57] has been reported. The ingestion of topical preparations of methyl salicylate (oil of wintergreen, also present in Chinese propriety medicines) can result in

TABLE 131.2

SEVERITY OF SALICYLATE POISONING

Severity grade	Serum pH	Underlying acid–base abnormality
Mild	> 7.45	Respiratory alkalosis
Moderate	7.35–7.45	Combined respiratory alkalosis and metabolic acidosis
Severe	< 7.35	Metabolic acidosis with or without respiratory acidosis

rapid-onset poisoning, due to its concentration, rapid absorption kinetics, and higher lipid solubility [58]. Infants may become poisoned by ingesting the breast milk of women chronically taking therapeutic doses of salicylate [59]. Intrauterine fetal demise resulting from poisoning during pregnancy [60] and neonatal poisoning resulting from the transplacental diffusion of therapeutic doses of salicylate taken before delivery [61] have also been described. Delays to presentation, diagnosis, and chronicity each increase the severity and mortality [50,62,63] and with severe poisoning, the fatality rate may be as high as 50% [51,55].

Regardless of whether poisoning is acute or chronic, it can be characterized as mild, moderate, or severe on the basis of the serum pH and underlying acid–base disturbance (Table 131.2). This approach was first described in the classic papers by Done [48,64], who also developed a nomogram that attempted to correlate the severity of poisoning with a timed salicylate level after acute ingestion. Although Done's nomogram has subsequently been shown to have poor predictive value in acute poisoning [49] and is not applicable to chronic poisoning, to acute poisoning by enteric-coated aspirin and nonaspirin salicylates, or to patients with acidemia [62] his observation that the clinical severity of poisoning correlates with acid–base status remains undisputed.

Mild poisoning is characterized by alkalemia (serum pH greater than 7.45) and a pure respiratory alkalosis. It may develop 2 to 8 hours after acute ingestion of 150 to 300 mg per kg of aspirin [48,64] or any time during chronic therapy. Associated signs and symptoms include nausea, vomiting, abdominal pain, headache, tinnitus, tachypnea (or subtle hyperpnea), ataxia, dizziness, agitation, and lethargy. The anion gap (see Chapter 71) is normal until late in this stage, when compensatory renal bicarbonate excretion eventually lowers the serum bicarbonate level. Serum glucose, potassium, and sodium values may be high, low, or normal. Despite total body fluid and electrolyte depletion and clinical dehydration, laboratory evidence of dehydration (e.g., hemoconcentration, increased serum blood urea nitrogen [BUN] and creatinine, increased urine specific gravity) may be absent.

Moderate poisoning is characterized by a near normal serum pH (7.35 to 7.45) with an underlying metabolic acidosis as well as respiratory alkalosis. It can occur 4 to 12 hours after an acute overdose of 300 to 500 mg per kg of aspirin [48,64]. It may also occur in patients with chronic ingestion who delay seeking medical care for symptoms of mild poisoning and continue to take salicylate. Electrolyte analysis demonstrates a low serum bicarbonate value with an increased anion gap. Gastrointestinal and neurologic symptoms are more pronounced. There may be agitation, fever, asterixis, diaphoresis, deafness, pallor, confusion, slurred speech, disorientation, hallucinations, tachycardia, tachypnea, and orthostatic hypotension. Coma and seizures can also occur. Leukocytosis, thrombocytopenia, increased or decreased serum glucose and sodium values, hypokalemia, and increased serum BUN, creatinine, and ketones may be present.

Severe poisoning is defined by the presence of acidemia (serum pH less than 7.35) with underlying metabolic acidosis and respiratory alkalosis or acidosis and a high anion gap. It can occur 6 to 24 hours or more after the acute ingestion of more than 500 mg per kg of aspirin [48,64] or in unrecognized or untreated chronic poisoning. Severe dehydration and marked sinus tachycardia are often present. Other findings may include coma, seizures, papilledema, hypotension, dysrhythmias, congestive heart failure, oliguria, hypothermia or hyperthermia, rhabdomyolysis and multiple organ failure [55,63,65,66]. Laboratory abnormalities are similar to those seen in moderate poisoning but are more pronounced. Hypoglycemia, pulmonary edema and cerebral edema or hemorrhage may be present [54,67]. Asystole is the most common terminal dysrhythmia, but ventricular tachycardia and ventricular fibrillation can also occur [54,55,68,69]. When cardiac arrest occurs, death appears to be inevitable. Successful resuscitation in this situation has yet to be reported [69].

Although an increased anion-gap metabolic acidosis is often said to be a hallmark of salicylate poisoning, in reality a variety of acid-base disturbances may be seen depending on the delay to presentation and severity of poisoning. As noted earlier, the anion gap may be normal and acidosis absent in early or mild intoxication. In addition, the anion gap is rarely above 20 mEq per L, even in advanced poisoning [31]. It is, therefore, more appropriate to say that an abnormal acid–base status is the hallmark of salicylate poisoning. In adults, combined respiratory alkalosis and metabolic acidosis is the most common finding (50% to 61%), followed by pure respiratory alkalosis (20% to 25%), pure metabolic acidosis (15% to 20%), and a combined respiratory and metabolic acidosis (5%) [31,55]. Metabolic acidosis is more common and respiratory alkalosis less common (and often absent) in children than in adults [50,55] suggesting that children progress more rapidly from mild-to-moderate to severe poisoning, perhaps because of more rapid and extensive tissue distribution of drug [70]. Metabolic acidosis is also more common in patients with large acute ingestions, chronic intoxication, and delayed presentation or treatment [31,50,51,55,71]. The onset and progression of toxicity may be delayed after overdose with enteric-coated or sustained-release formulations [20].

Potential complications of both therapeutic and toxic doses of salicylate include gastrointestinal tract bleeding, increased prothrombin time, hepatic toxicity, pancreatitis, proteinuria, and abnormal urinary sediment. Significant bleeding, gastrointestinal tract perforation, blindness, and inappropriate secretion of antidiuretic hormone are rare complications of acute poisoning.

Other Nonsteroidal Anti-inflammatory Drugs

With the exception of mefenamic acid and phenylbutazone, significant toxicity from acute overdose is unusual. Manifestations typically include nausea, vomiting, abdominal pain, headache, confusion, tinnitus, drowsiness, and hyperventilation [5,72,73]. Glycosuria, hematuria, and proteinuria are also common. Occasionally, acute renal failure (acute tubular necrosis or interstitial nephritis) can develop. Symptoms rarely last more than several hours, and acute renal toxicity is almost always reversible over a period of a few days to a few weeks. Experience with selective COX-2 inhibitor overdose is limited, but acute toxicity appears to be similar [74].

Muscle twitching and grand mal seizures have been reported in 30% of mefenamic acid overdoses [75]. Apnea, coma, and cardiac arrest can also occur [75]. Metabolic acidosis, coma, seizures, hepatic dysfunction, hypotension, and cardiovascular

collapse are relatively frequent after phenylbutazone overdose [72,73,76–78]. Uncommonly, coma, hyperactivity, hypothermia, seizures, metabolic acidosis, acute renal insufficiency, thrombocytopenia, acute respiratory distress syndrome, upper gastrointestinal tract bleeding, and respiratory depression are seen in ibuprofen poisoning [47,78–87]. Death can result from ibuprofen alone or combined with other drugs [1,88–90], but despite the frequency of overdose, it is extremely rare [1,5,6]. Seizures and metabolic acidosis have also been reported in ketoprofen and naproxen poisoning [91,92].

Minimum toxic and lethal doses are not well defined. Little correlation was found between the amount of ibuprofen reportedly ingested and symptoms in adults [77]. In the pediatric population, however, the mean amount ingested was much greater in symptomatic patients (440 mg per kg) than asymptomatic ones (114 mg per kg) [79]. The spectrum of toxicity appears to be the same in children and adults [90]. Elderly patients are at increased risk of developing toxicity with both therapeutic doses and overdoses [93]. Even with severe poisoning, complete recovery usually occurs within 24 to 48 hours.

DIAGNOSTIC EVALUATION

The history should include the time or times of ingestion, the specific product and formulation, the amount ingested, and any concomitant ingestion or medication use. Physical examination should focus on vital signs, neurologic and cardiopulmonary function, and assessment of the state of hydration. Vital signs should include an accurate temperature and respiratory rate and, if possible, orthostatic measurements of pulse and blood pressure. The fundi should be examined for papilledema. Stool and urine should be tested for occult blood. Peritoneal signs should be sought on abdominal examination.

Salicylates

Laboratory evaluation of patients with salicylate poisoning should include arterial or venous blood gases, complete blood cell count, serum electrolyte, glucose, BUN, creatinine, and salicylate levels, and urinalysis. Patients with moderate-to-severe salicylate poisoning should also have serum calcium, magnesium, and ketones, liver function tests, coagulation profile, electrocardiogram; and chest radiograph. Because patients often confuse aspirin and acetaminophen, testing should be performed for both.

The ferric chloride spot test can be used to rapidly detect the presence of salicylate in urine or commercial products [94]. Several drops of 10% ferric chloride added to urine turn purple if salicylate is present. A positive urine test indicates exposure but not overdose because positive results are seen with therapeutic dosing. False-positive reactions may be caused by acetoacetic acid, phenylpyruvic acid, phenothiazines, and phenylbutazone. A quantitative serum salicylate level is necessary to confirm the diagnosis of poisoning. Diflunisal may result in falsely elevated salicylate levels when measured by fluorescence polarization immunoassay or the Trinder colorimetric assay [95].

Salicylate levels must be interpreted with respect to the duration (i.e., acute vs. chronic overdose) and time of ingestion. At similar salicylate levels, patients with chronic poisoning tend to be more ill than those with acute poisoning [32,54,55]. Soon after an acute overdose, levels can be quite high (e.g., greater than 60 mg per dL) in the absence of significant toxicity. Conversely, with chronic overdosage and late in the course of an acute overdose, moderate or severe toxicity may be present despite serum salicylate concentrations in the high therapeutic range. At similar salicylate levels, children, the elderly, and those with underlying disease tend to be more ill than otherwise healthy adults [32,52,70,96]. Poisoning in such patients, particularly if chronic, can occasionally be seen with therapeutic salicylate levels. Hence, as noted previously, the severity of poisoning is ultimately determined by acid–base status and clinical findings.

Serial salicylate levels are necessary for confirming the efficacy of gastrointestinal tract decontamination and enhanced elimination procedures but do not obviate the need for continued clinical and metabolic monitoring. Depending on the severity and course of poisoning, drug levels and other laboratory tests should be repeated at 2- to 6-hour intervals. Monitoring of drug levels for at least 12 hours is necessary to exclude significant ongoing absorption after overdose.

Historically, at least 25% of patients with chronic salicylate poisoning are initially undiagnosed [31,51,71]. These patients are typically elderly, have a variety of presenting complaints and underlying illnesses, and have been medicating themselves with aspirin. To avoid missing the diagnosis, all patients should be asked specifically about the use of nonprescription drugs. Asking about tinnitus or hearing distortion, which occurs with salicylate levels in the high end of the therapeutic range (i.e., 20 to 30 mg per dL), may also suggest the diagnosis in patients with unknown ingestions or unexplained complaints. Occult salicylate poisoning should be considered in any patient with an unexplained acid–base disturbance, altered mental status, fever, diaphoresis, dyspnea, vomiting, and pulmonary edema [31,71].

The differential diagnosis of salicylate poisoning includes infection (particularly meningitis); CNS trauma and tumors; congestive heart failure; chronic obstructive pulmonary disease; carbon monoxide, isoniazid, lithium, and valproate intoxication; toxic gas inhalation; and other toxic causes of an elevated anion-gap acidosis, particularly methanol and ethylene glycol (see Chapters 71 and 119). Hemodynamic, autonomic, and laboratory manifestations of severe poisoning resemble the systemic inflammatory response syndrome and may be mistaken for sepsis [61,65,66,97]. Salicylate poisoning has also been misdiagnosed as alcohol intoxication, alcohol withdrawal, dementia, diabetic ketoacidosis, impending myocardial infarction, nonspecific asterixis and encephalopathy, and viral encephalitis.

In infants and children, salicylate poisoning may be confused with inborn errors of metabolism. It may be particularly difficult to distinguish from Reye's syndrome, because they are not only similar in presentation but appear to be interrelated [98,99]. Fatty infiltration of the liver on pathologic examination of a biopsy specimen, low (i.e., subtherapeutic) cerebrospinal fluid salicylate levels, and high alanine, glutamine, and lysine levels indicate Reye's syndrome rather than salicylate poisoning. Radiopaque densities in the stomach on abdominal radiograph suggest the possibility of an enteric-coated or sustained-release formulation or a magnesium or bismuth salt of salicylate [100].

Other Nonsteroidal Anti-inflammatory Drugs

The initial evaluation of patients with nonsalicylate-NSAID overdose is similar to that for salicylates. Evaluation of acid–base, electrolyte, and renal parameters is particularly important. Additional ancillary testing is dictated by clinical severity. Quantitative serum levels of nonsalicylate NSAIDs are neither routinely available nor necessary for treatment.

Many medical conditions and other intoxications cause signs and symptoms similar to those seen in nonsalicylate NSAID poisoning. In the absence of a history of ingestion, the diagnosis is made by exclusion of other etiologies.

MANAGEMENT

Salicylates

Supportive care, limiting drug absorption, and enhancing drug elimination are the goals of therapy. Resuscitative measures should be instituted as necessary. It is critically important to remember that, should endotracheal intubation be necessary, hyperventilation must be accomplished before, during, and after this procedure to prevent worsening acidemia, which increases the fraction of nonionized salicylic acid available for tissue distribution, thereby enhancing toxicity. The administration of respiratory depressants or failure to adequately hyperventilate unconscious or paralyzed patients can result in rapid deterioration and death of severely poisoned patients [62,68,101]. Because an increase in the partial pressure of carbon dioxide (PCO_2) is almost inevitable following intubation and mechanical ventilation, it is recommended that patients with arterial PCO_2 values below 20 mm Hg be given an intravenous bolus of 1 to 2 mEq per kg sodium bicarbonate at the time of intubation. Arterial blood gases should always be checked after intubation and after bicarbonate therapy.

Because CNS hypoglycemia may occur despite a normal serum glucose value [101], 50 mL of 50% dextrose in water should be given intravenously to any patient with an altered mental status whose capillary glucose concentration is not already elevated [49]. Anticonvulsants (e.g., benzodiazepines, propofol, and barbiturates) as well as supplemental glucose should be given to patients with seizures. It is also prudent to treat seizures with $NaHCO_3$, as acidemia is likely to worsen. Hyperthermia should be treated with cooling blankets, ice packs, and evaporative methods (see Chapter 66).

Central venous pressure monitoring may be necessary for optimal treatment of hypotension, especially if there is evidence of heart failure or pulmonary edema. Patients with noncardiac pulmonary edema should be treated with positive pressure ventilation rather than diuretics. Again, maintaining hyperventilation and reducing acidemia are critical in patients with compromised pulmonary function.

Additional supportive measures are directed at correction of dehydration and metabolic derangements. The degree of dehydration parallels the severity of poisoning [64], but it is often unappreciated, underestimated, or undertreated. Patients with mild, moderate, or severe poisoning typically have volume deficits of 1 to 2, 3 to 4, or 5 to 6 L (20, 40, and 60 mL per kg in children), respectively. In the presence of acidemia, hypokalemia is more severe than indicated by the serum potassium level (by approximately 0.6 mEq per L for each 0.1 unit of decrease in pH) and should be treated aggressively.

Acidemia should also be treated aggressively with intravenous $NaHCO_3$. Since the respiratory alkalosis is a concomitant primary acid–base disturbance and not just a compensatory response, the administration of bicarbonate is unlikely to blunt the respiratory drive and increase the PCO_2, which might otherwise limit the change in serum pH. In addition, the goal of therapy is to limit the tissue distribution of salicylates by increasing the serum pH. The dose of bicarbonate needed may be substantial, and is typically 4 to 5 ampules or 200 to 300 mEq in an adult with severe poisoning.

As with repleting volume, at least half of the $NaHCO_3$ deficit should be given during the first hour either by continuous infusion or by 0.5 to 1.0 mEq per kg boluses every 10 minutes. Arterial blood gases should be reevaluated during after such therapy. Potential complications of $NaHCO_3$ administration include excessive alkalemia, hypokalemia, hypocalcemia, hypernatremia, and fluid overload. Relative contraindications to hypertonic $NaHCO_3$ include oliguric renal failure, congestive heart failure, and cerebral or pulmonary edema.

Tetany should be treated with intravenous calcium chloride or calcium gluconate (10 mL of a 10% solution over 5 to 10 minutes). Fresh-frozen plasma, red blood cell, and platelet transfusions may be required for patients with active bleeding or significant blood loss. Asymptomatic increases in international normalized ratio can be treated with subcutaneous vitamin K.

Gastrointestinal decontamination should be performed in all patients with intentional overdoses and those with accidental ingestions of greater than 150 mg per kg. Because of delayed absorption, decontamination may be effective for as long as 24 hours after overdose, even in patients with spontaneous vomiting [21]. Considerable diversity in opinion exists, however, regarding the optimal method of decontamination [103].

Activated charcoal is effective in preventing salicylate absorption in simulated overdose [104] and, therefore, it is recommended for all significant ingestions, regardless of delay in presentation. Multiple oral doses of charcoal [105] or gastric lavage preceded and followed by another dose of activated charcoal may be the more effective for preventing the absorption of large overdoses [106]. Many grams of aspirin have been recovered by lavage up 24 hours after ingestion [21]. Repeated doses of activated charcoal or whole-bowel irrigation may be effective for patients who have ingested enteric-coated or sustained-release formulations and those with serum drug levels that continue to rise despite other decontamination measures [107].

The efficacy of multiple-dose charcoal therapy in enhancing salicylate elimination may depend on the formulation. Increases in serum salicylate elimination reported using an effervescent preparation containing bicarbonate [108] could not be replicated with multiple doses of noneffervescent charcoal in simulated overdose (i.e., less than 3 g) in humans [109–112]. Oral charcoal does not substantially accelerate the elimination of intravenously administered salicylic acid in pigs, discounting the role of gut dialysis or enterohepatic circulation [113]. If multiple-dose charcoal is used, sorbitol should not be included with the subsequent doses [114,115].

Salicylate elimination can be enhanced by urine alkalinization and diuresis [27,28,32–34,116], extracorporeal removal [117], and perhaps by glycine administration [52]. It should be emphasized that serum and urine alkalinization and establishing a urine output of 1 to 2 mL per kg per hour are equally important goals in the management of patients with salicylate toxicity [35,118,119]. Moreover, alkalinization of the urine is difficult to achieve in patients with acidemia and aciduria (i.e., severe clinical toxicity) [64]. Theoretical concerns regarding pulmonary or cerebral edema should not preclude aggressive fluid therapy, as administering only maintenance fluids intravenously is insufficient treatment for a patient with salicylate poisoning.

Indications for urine alkalinization and alkaline diuresis include acid-base abnormalities and systemic symptoms with a salicylate level that is greater than 30 mg per dL after an acute overdose. Patients with chronic overdoses may be symptomatic and require treatment, despite lower salicylate levels. The goal is to achieve a urine pH of 7.5 or greater. All patients treated with alkaline diuresis need close monitoring in an intensive care unit or similar setting. Bladder catheterization is essential in those with moderate or severe poisoning, in whom hourly monitoring of urine output and pH is required. Arterial or venous blood gases, electrolytes, BUN, creatinine, glucose, and salicylate concentrations should initially be rechecked at 2- to 4-hour intervals, depending on the severity of poisoning, the results of previous testing, and the response to therapy. Cardiac monitoring and frequent reevaluations of vital signs, mental status, and pulmonary function are also necessary during alkaline diuresis.

Alkalinization of the urine may be impossible to achieve in the presence of dehydration and hypokalemia because hydrogen ions are excreted in exchange for reabsorbed sodium and potassium, respectively [62,120]. Therefore, correction of fluid and potassium deficits is critical.

The amount of bicarbonate and supplementary potassium necessary to achieve and maintain an alkaline urine depends on the severity of poisoning (Table 131.2). For example, the initial intravenous fluids for a moderately poisoned patient could be 1 L of 5% dextrose in one-half normal saline to which 75 mEq of sodium bicarbonate (i.e., 1.5 ampules of 8.4% sodium bicarbonate) and 40 mEq of potassium chloride have been added. In severe poisoning, however, 150 mEq of sodium bicarbonate (i.e., 3 ampules of 8.4% sodium bicarbonate) and 60 mEq of potassium chloride should be added to each liter of 5% dextrose in water initially, and adjusted as necessary. In patients with hypernatremia, a more hypotonic solution should be used. Again, the use of a dextrose-containing solution is important because of the potential for occult CNS hypoglycemia. Although forced diuresis (e.g., 500 mL per hour urine output in adults) is no longer recommended [121], a moderate rate of fluid administration (3 to 4 mL per kg per hour) is recommended. Although counterintuitive, even patients with mild poisoning (i.e., alkalemia) should be given bicarbonate (and fluids); this is necessary to replace ongoing renal losses and prevent deterioration. The onset of diuresis may be delayed an hour or two after the institution of therapy.

Carbonic anhydrase inhibitors (e.g., acetazolamide) should never be used to alkalinize the urine (especially without concomitant bicarbonate therapy) because the resultant systemic acidosis may promote tissue distribution of salicylate and result in clinical deterioration [122,123]. Similarly, the use of tris-hydroxymethyl aminomethane, an organic H^+ buffer that increases serum and urine pH, is not recommended. Although tris-hydroxymethyl aminomethane has been suggested for the treatment of acidemia and aciduria refractory to bicarbonate administration, it has not been studied in human salicylate poisoning and has a number of potential adverse effects (e.g., hypoglycemia, extravasation necrosis, phlebitis, respiratory depression, and increased intracellular pH leading to decreased pH gradients with increased tissue distribution and intracellular trapping of salicylate) [124].

As with $NaHCO_3$ therapy for acidemia, complications of alkaline diuresis include excessive alkalemia, hypokalemia, hypocalcemia, hypernatremia, and fluid overload [52,119,121]. Young children, the elderly, and those with severe poisoning are most susceptible to such complications. Alkaline diuresis is contraindicated in patients with oliguric renal failure, congestive heart failure, and cerebral or pulmonary edema. Such therapy should be withheld or discontinued if the serum pH exceeds 7.55.

Hemodialysis is indicated in patients with severe poisoning and those with moderate poisoning who fail to improve with alkaline diuresis [34–36,51,52,62]. Hemodialysis is essential for successful outcome in patients with coma, seizures, cerebral or pulmonary edema, and renal failure [36,55]. Whether the term *coma*, as used here, should include altered mental status (e.g., confusion and disorientation) and any impairment in the level of consciousness as well as unresponsiveness is controversial. Erring on the side of treatment is recommended. Acidemia and temperature greater than 38°C are associated with high mortality [55] and should also be considered potential indications for hemodialysis, particularly if the patient is resistant to bicarbonate and fluid therapy. Similarly, patients with moderate poisoning who have liver dysfunction and, hence, impaired ability to eliminate salicylate may also benefit from hemodialysis.

A high salicylate level is often cited as an indication for hemodialysis but recommendations vary widely with cutoffs ranging from 40 to 200 mg per dL (100 mg per dL being the most common) for acute ingestions and 60 to 80 mg per dL for chronic exposures [124]. In one study [51], salicylate levels in fatal cases ranged from 34 to 193 mg per dL and in another [54], some patients died with drug levels in the therapeutic range. Moreover, drug levels do not discriminate patients who die from survivors [54,55]. Clearly, the salicylate level should not be used as the sole indication for hemodialysis. Instead, the severity of poisoning is determined by clinical findings, which reflect tissue drug concentration and effect, depend on factors that influence tissue distribution, and do not necessarily correlate with blood levels, particularly when acidemia is present [122]. Moreover, a serum salicylate concentration should be interpreted in the context of a simultaneous measurement of serum pH. Hence, hemodialysis is appropriate for patients with high drug levels who have severe clinical toxicity (particularly acidemia), but it may not be necessary in those without such manifestations [55]. Conversely, patients with low salicylate levels, particularly those with significant underlying cardiorespiratory disease, should be treated with hemodialysis if they exhibit clinical or laboratory manifestations of severe toxicity. Because of delays inherent in the turnaround time for salicylate determinations and in preparing for hemodialysis, the projected clinical course should also be considered. Waiting for the salicylate level to reach some predetermined level before initiating hemodialysis in patients who are severely poisoned or deteriorating despite other treatments is ill-advised.

Hemodialysis is preferred over continuous renal replacement therapy or hemoperfusion due to the rapid clearances and correction of fluid, electrolyte and acid–base abnormalities achieved [117,126,127]. A high-bicarbonate (e.g., up to 40 mEq per L) dialysate solution (bath) should be used, and potassium should usually be added to the dialysate solution. Peritoneal dialysis and exchange transfusion are also less effective [128].

Failure to adequately correct fluid deficits prior to initiating hemodialysis can result in disastrous consequences. In contrast to the typical dialysis (i.e., renal failure) patient who is fluid overloaded, those with salicylate poisoning are typically hypovolemic. Uncorrected or occult hypovolemia can result in cardiovascular decompensation with hemodynamic instability and even cardiac arrest when dialysis is started because of the acute decrease in intravascular volume that occurs when blood is removed and used to prime the dialysis tubing and pump at the beginning of dialysis. This complication can be prevented or minimized by ensuring adequate volume resuscitation, giving a bolus of saline, and priming the tubing and pump with saline (rather than blood) prior to initiating dialysis.

Oral administration of glycine or *N*-glycylglycine has been used in overdose patients to promote drug clearance [26,129]. Because the conjugation of salicylic acid with glycine to form salicyluric acid becomes saturated and glycine levels decrease in overdose patients, supplemental glycine can enhance the formation and excretion of this metabolite. To date, clinical experience with this therapy is limited, its comparative efficacy is unknown, and the side effects of nausea and vomiting with glycine have been problematic. Doses used ranged from 8 g dissolved in water initially, followed by 4 g every 4 hours for 16 hours, to 20 g followed by 10 g every 2 hours for 10 hours for glycine. The dose for *N*-glycylglycine was 8 g dissolved in water followed by 2 to 4 g every 2 hours for 16 hours.

Other Nonsteroidal Anti-inflammatory Drugs

The treatment of nonsalicylate NSAID poisoning is supportive and symptomatic. Although most patients require only observation, airway protection, mechanical ventilation, and fluid resuscitation, use of anticonvulsants for seizures, bicarbonate

for acidosis, vitamin K or fresh-frozen plasma for coagulopathy, antacids and histamine$_2$–receptor antagonists for gastritis, and blood products for gastrointestinal tract bleeding may occasionally be required. Naloxone has been reported to reverse CNS depression in a toddler with ibuprofen toxicity [81]. Renal function should be monitored carefully in patients with abnormal urinalysis, underlying renal disease, or advanced age. Liver function tests should be followed in patients with severe phenylbutazone and piroxicam poisoning [78].

Gastrointestinal decontamination with activated charcoal should be considered for patients who present soon after a significant ingestion, defined as greater than ten therapeutic doses in adults and more than five adult doses in children [72,73]. Although charcoal hemoperfusion has been used to treat a patient with severe phenylbutazone poisoning who had impaired renal and hepatic function [76], extracorporeal elimination measures are unlikely to be effective because of the high-protein binding and rapid intrinsic elimination of these agents. Multiple-dose charcoal therapy enhances the elimination of therapeutic doses of phenylbutazone by 30% [130] and may be similarly effective for other agents, but the clinical benefit of such therapy after overdose is likely to be limited.

CHAPTER 132 ■ ENVENOMATIONS

ROBERT L. NORRIS

"Their supreme arrogance, developed over millions of years as masters of their environment, commands respect out of all proportions to their size" [1].

Although made in reference to snakes, this statement could easily apply to any of the vast numbers of venomous creatures on the planet. Few areas of medicine are immersed in such controversy and misperception as the management of envenomations. This chapter provides guidance for the evaluation and management of bites and stings of venomous snakes, spiders, and scorpions indigenous to North America. While the general principles of management of envenomations outlined here may be applicable to other regions of the world, specific approaches, such as indications for and types and doses of antivenoms, vary by region, and local experts should be consulted for advice.

SNAKE ENVENOMATION

All of the terrestrial American venomous snakes belong to one of two families: Viperidae (subfamily Crotalinae, or pit vipers) and Elapidae (or coral snakes). Venomous snakes are native to every state of the United States except Alaska, Hawaii, and Maine.

Pit Viper Envenomation

At least 99% of venomous snakebites in the United States are inflicted by pit vipers [2]. The pit vipers of North America include the rattlesnakes (genera *Crotalus* and *Sistrurus*), and the cottonmouth water moccasins, copperheads, and cantils (*Agkistrodon* spp). These snakes are characterized by paired, pitlike heat receptors (foveal organs) located on the anterolateral aspects of the head. These receptors aid the snake in aiming its strike and likely function in determining the quantity of venom to be injected [3,4].

Pit viper venoms contain numerous enzymatic components and a number of nonenzymatic, low-molecular-weight polypeptides [3–5]. Venom compositions vary not only from species to species, but from snake to snake within a species, and even in an individual snake depending on its age, size, health, and other factors [3,4]. In general, the most serious envenomations in North America are caused by the rattlesnakes (particularly *Crotalus* spp), with cottonmouth water moccasin (*Agkistrodon piscivorus* ssp) bites being less severe and copperhead (*A. contortrix* ssp) bites causing predominantly local findings with little serious systemic toxicity.

The major enzymes in pit viper venoms include hyaluronidase (spreading factor), phospholipase A (responsible for cell membrane disruption), and various proteases (causing local tissue destruction) [4,5]. Venom metalloproteinases, termed *disintegrins*, result in disruption of vascular integrity [6]. Despite the impressive toxicity of such enzymes, the nonenzymatic, low-molecular-weight polypeptide fractions appear to be up to 20 times more lethal, on a weight-for-weight basis, than crude venom [7]. The toxicity of pit viper venom is enhanced by release of various autopharmacologic compounds from damaged tissue (e.g., histamine, bradykinin, and serotonin) [4].

Clinical Manifestations

Envenomated patients typically experience moderate-to-severe pain at the bite site within 5 to 10 minutes. The pain is often described as burning and may radiate along the bitten extremity. Swelling at the bite site soon follows and may progress along the entire extremity within hours. There is often local ecchymosis because of disruption of blood vessels. A persistent bloody effluent from the wound suggests the presence of snake venom anticoagulants. Rapid lymphatic absorption of venom may lead to impressive, early lymphangitis and regional adenopathy [3].

Within the first 24 to 36 hours, hemorrhagic bullae or serum-filled vesicles may develop at the bite site and along the bitten extremity. These are less common in bites treated early with adequate amounts of antivenom [4,7]. Petechiae or purpura may also be present.

Systemic manifestations of pit viper envenomation can involve virtually any organ system. Nausea and vomiting are common and may appear early with severe bites [7]. Weakness, diaphoresis, fever and chills, dizziness, and syncope may also occur [3,4]. Some patients experience a minty, rubbery, or metallic taste in their mouth and hypersalivation [4,7]. Muscle fasciculations or paresthesias of the scalp, face, tongue, or digits indicate a moderate-to-severe envenomation. Systemic coagulopathy can lead to bleeding at any anatomic site, including the gastrointestinal, respiratory, genitourinary, and central nervous systems, although clinically significant bleeding is uncommon following bites in North America [3,7].

Alterations in heart rate and blood pressure may occur. Early hypotension is usually due to pooling of blood in the pulmonary and splanchnic vascular beds, whereas delayed shock is due to blood loss, third spacing of intravascular volume, and hemolysis [3,4,8]. Pulmonary edema can occur in severe envenomations, and is secondary to disruption of pulmonary vasculature intimal linings and pooling of pulmonary blood [3,5].

Multifactorial renal failure may occur, but is uncommon. Contributing factors include hypotension; hemoglobin, myoglobin, and fibrin deposition in renal tubules; and direct venom nephrotoxicity [3,7].

Muscle weakness may be seen after bites by some rattlesnakes that possess phospholipase A_2 neurotoxins in their venoms, such as the eastern diamondback rattlesnake (*Crotalus adamanteus*) [9] or some specimens of the Mohave rattlesnake (*Crotalus scutulatus*) [10]. Neuromuscular respiratory failure is rare, but can occur in severe bites by the Mohave rattlesnake in certain geographic locations [7].

Snake venoms do not appear to cross the blood–brain barrier to any significant extent, and rare findings such as seizures and coma are secondary to hypotension, hypoxia, or intracranial bleeding [2].

Diagnostic Evaluation

Important aspects of the history include details of the incident (such as type and size of snake if known, time and number of bites, and methods of first aid applied) and the patient's medical

TABLE 132.1

CLINICAL GRADING SCALE AND RECOMMENDED CROFAB® DOSAGES FOR NORTH AMERICAN PIT VIPER ENVENOMATION[a]

Severity grade	Nonenvenomation	Mild	Moderate	Severe
Fang marks	±	+	+	+
Pain	None	Mild to moderate	Severe	Severe
Edema (proximal extent)	None	Minimal (0–15 cm)	Moderate (15–30 cm)	Severe (> 30 cm)
Erythema	None	+	+	+
Ecchymosis	None	±	+	+
Systemic signs or symptoms	None	None	Mild	Moderate to severe
Laboratory values	Normal	Normal	Mildly abnormal	Very abnormal
Initial CroFab dose (number of vials)[b]	0	0 (if no progression) 4–6 (if progressing)	4–6	6[c]

[a]Not applicable to coral snake envenomations or envenomation by snakes outside of North America.
[b]CroFab® (BTG International Inc., West Conshohocken, PA)—If findings of envenomation progress during the first hour following the initial dose, the dose should be repeated. Once stabilization occurs, two vials are given every 6 hours for three additional doses (see text).
[c]Larger doses may be required in some cases with acute, life-threatening envenomation.

history (including any prior snakebites, medications, allergies, and tetanus immunization status).

Pit viper envenomation is a true emergency with potential for multisystem involvement. The severity of the bite must be assessed, and the clinical severity grading scale in Table 132.1 may be useful in evaluating most pit viper bites [4]. Approximately 20% of bites by U.S. pit vipers result in no envenomation ("dry bites") [4,7,11]. It must be understood, however, that severity can progress rapidly, and the patient must be frequently reevaluated for a worsening clinical condition. Good clinical judgment is more important than overreliance on grading scales. Consultation with an authority in the area of toxinology is prudent.

Puncture-wound patterns can be misleading in the diagnosis of snakebite. Occasionally, there is only a single puncture wound or many tiny punctures [12]. A dry bite may or may not have fang puncture marks, but there is no more pain than would be expected from simple puncture wounds. Envenomation is confirmed by the presence of local tissue effects (particularly progressive swelling), systemic effects, and/or laboratory abnormalities.

Essential laboratory studies include a complete blood cell count, serum electrolytes, blood urea nitrogen, creatinine, prothrombin time or international normalized ratio, fibrinogen, fibrin degradation products, and urine analysis. Blood for type and screening should also be sent for evaluation as soon as possible as direct venom effects and antivenom effects may interfere with this process later [13]. Also helpful are creatine phosphokinase as a measure of muscle damage and intracompartmental pressure measurements in patients with suspected compartment syndrome. Obtain a chest radiograph, arterial blood gases, and an electrocardiogram as clinically indicated.

Occasionally, the history and diagnosis may be unclear, especially in children [14]. When patients present without having seen a snake and have no findings other than puncture wounds and mild pain, the differential diagnosis includes a dry bite, bite by other animal or arthropod (e.g., nonvenomous snake, centipede, or spider), and puncture wounds from inanimate objects (e.g., thorns).

Management

First-aid efforts are best limited to reassuring the victim, immobilizing and splinting the extremity at heart level, and transporting the victim as quickly as possible to a hospital.

Previously recommended first-aid measures including incision, suction, constriction bands pressure immobilization, tourniquets, packing of the extremity in ice, or application of electric shocks should be avoided as they are ineffective and may result in further complications [15–17].

Two large-bore intravenous (IV) lines infusing normal saline should be established, preferably in sites other than the bitten extremity, and blood work sent to the laboratory. Continuous cardiac and pulse oximetry monitoring are indicated, and oxygen is administered if hemoglobin saturation is low or if the patient is experiencing any respiratory distress. Any devices applied in the field in an attempt to limit venom spread should be left in place until an IV line is established.

Management of significant pit viper envenomation centers on the judicious use of an appropriate antivenom. In North America, antivenom therapy is indicated for victims with progressive local tissue findings or systemic abnormalities (significant systemic symptoms or signs, or laboratory abnormalities [e.g., paresthesias, hypotension, prolongation of prothrombin time or international normalized ratio, hypofibrinogenemia, or thrombocytopenia]) (see Fig. 132.1). Controversy exists, however, on the use of antivenom for copperhead (*A. contortrix*) bites presenting with progressive soft-tissue swelling in the absence of systemic abnormalities. Given that most such bites do well with conservative therapy alone [7], the cost–benefit ratio of giving antivenom in these cases is currently unclear and requires further research [18,19].

Antivenom Administration

If possible, informed consent should be obtained before antivenom administration. Antivenom should be administered in a closely monitored setting. Epinephrine and endotracheal intubation equipment should be immediately available at the bedside during antivenom administration, and a physician should be in attendance to observe and manage any acute adverse drug effects that may develop.

In the United States there is currently a single commercially available antivenom for pit viper bites—CroFab® Crotalidae Polyvalent Immune Fab, Ovine (BTG International Inc., West Conshohocken, PA). This antiserum contains purified Fab immunoglobulin fragments from sheep immunized with one of four different pit viper venoms. It comes in a lyophilized state and is effective against all North American pit vipers.

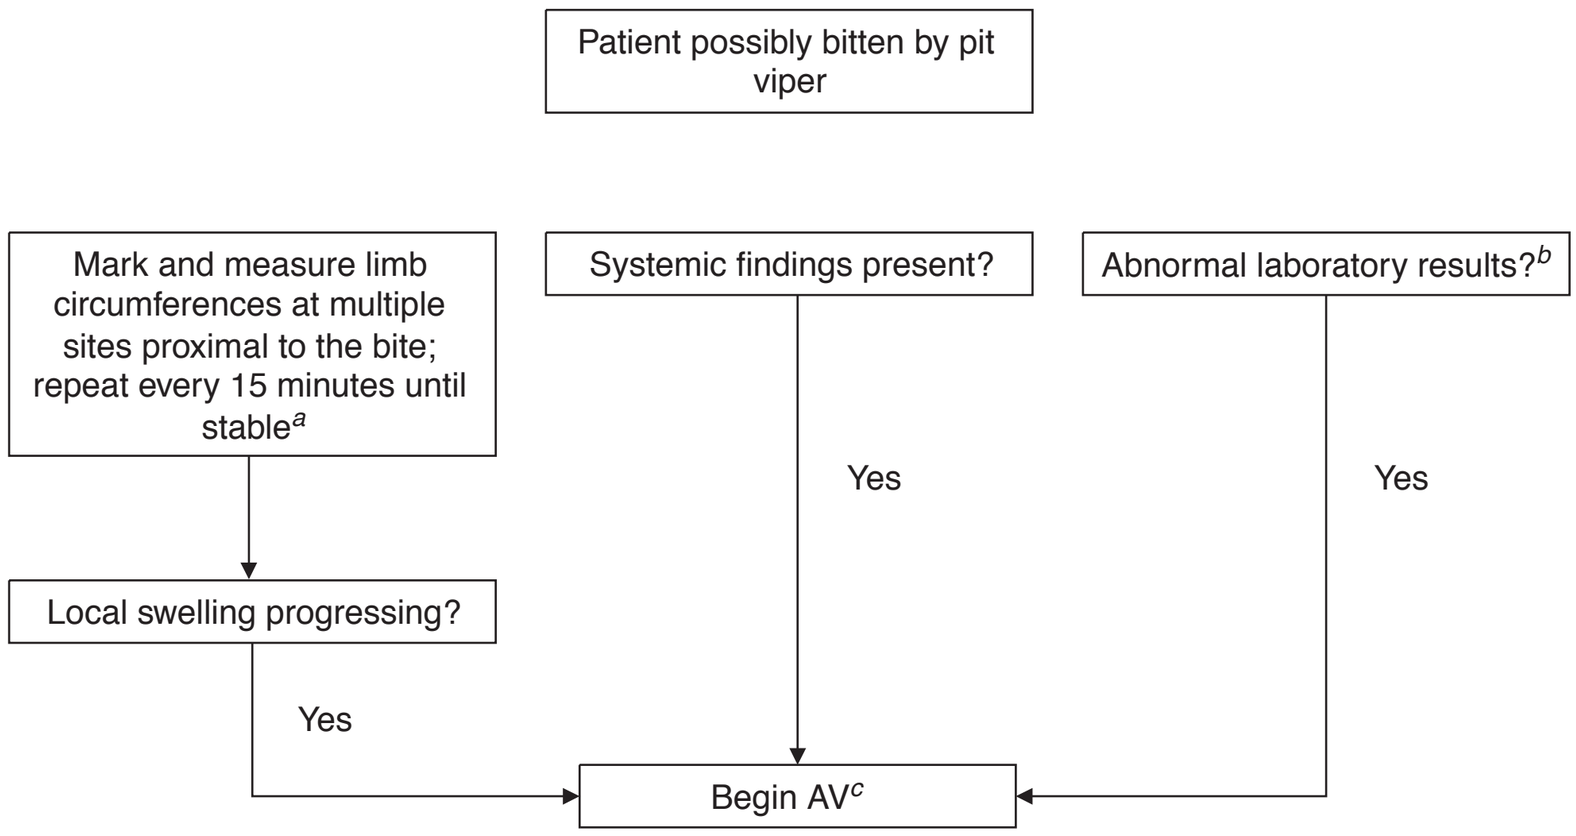

FIGURE 132.1. Guidelines for beginning antivenom therapy for victims of pit viper bite in the United States (see text for details). [a]Keep extremity at heart level, being careful to differentiate redistribution of edema (with changing limb position) from progression of severity of swelling. [b]Repeat normal lab work every hour for 4–6 hours until AV is started or the decision is made that AV is not necessary (i.e., the bite resulted in no envenomation or a mild, nonprogressive envenomation). [c]Abnormal coagulation studies may not return to normal for 4–6 hours after antivenom administration—time necessary for the body to replete coagulation factors after neutralization of venom. AV, antivenom.

Antivenom should be started as soon as possible after indications for administration are met. Although there are no defined end points in terms of time or dosage for when to withhold antivenom, antivenom is beneficial for treating only findings directly related to continued presence of unbound venom in the circulation (e.g., ongoing coagulopathy). It is ineffective in reversing end-organ damage that has resulted from prior venom effects (e.g., renal failure). The efficacy of antivenom in preventing local wound necrosis is limited, as it cannot reverse local cellular damage once it has been initiated by rapidly acting venom enzymes and nonenzymatic polypeptides [14,20,21]. Any ability to reduce necrosis depends on early administration.

Dosing of CroFab® is based on severity of the bite (see Table 132.1), not on age or size of the patient. The initial dose is four to six vials for patients with signs or symptoms of systemic toxicity or evidence of progressive local venom effects. Each CroFab® vial should be reconstituted with 10 mL of warm sterile water or saline. The total dose to be administered is diluted in 250 mL of crystalloid and infused over 1 hour (starting slowly at the onset of infusion and gradually increasing the rate). During the hour after the initial dose is completed, the patient is monitored for further progression of local effects and systemic symptoms, and laboratory studies are repeated [13]. The starting dose of CroFab® is repeated if venom effects continue to progress. This pattern is continued until the patient stabilizes. Coagulation studies may not normalize after the initial dose, as time is required for repletion of coagulation factors after venom neutralization, but they should show evidence of improvement [22,23]. After stabilization, two vials of CroFab® are administered every 6 hours for three additional doses. Further doses may be needed at the physician's discretion.

Adverse effects of antivenoms, as heterologous serum products, are divided into three major groups: acute allergic and nonallergic anaphylaxis, and delayed serum sickness. Acute reactions most commonly manifest with hives and/or bronchospasm [24], though hypotension and angioedema can also occur. Serum sickness is characterized by pruritus, fever, arthralgias, lymphadenopathy, and malaise, which can occur 1 to 2 weeks after antivenom therapy [3]. The incidence of acute reactions to CroFab® is approximately 15% and serum sickness occurs in approximately 3% of patients [25]. Management of acute reactions centers on rapid diagnosis, temporarily halting the infusion and treating with epinephrine, antihistamines, and steroids (see Chapter 194). Generally, once the reaction is controlled, the antivenom infusion can be restarted, possibly in a more dilute state and at a slower rate. Serum sickness is relatively benign and easily treated with steroids, antihistamines, and nonsteroidal anti-inflammatory drugs until symptoms resolve [26]. Most cases do well with oral prednisone (1 to 2 mg per kg per day) until symptoms resolve, followed by a taper over another week.

Supportive Measures

Venom-induced hypotension should be treated with antivenom and volume expansion. If organ perfusion fails to respond promptly with crystalloid infusion (1 to 2 L in an adult and 20 to 40 mL per kg in a child), administration of albumin is advisable as this agent is likely to stay in the leaky vascular system for longer periods of time [4,8]. Pressors should be used as a last resort [4].

Although pit viper envenomation can result in significant coagulopathies, the incidence of clinically significant bleeding in the United States is low [13,27]. Management of coagulopathy in patients with evidence of clinically significant bleeding, other than microscopic hematuria or minor gingival bleeding, may require administration of packed red blood cells, platelets, fresh-frozen plasma, and/or cryoprecipitate [4,28]. There is limited experience using recombinant factor VIIa for severe coagulopathy following rattlesnake bite [29]. It is important to begin antivenom therapy before the infusion of such products to avoid adding fuel to an unabated consumptive coagulopathy.

Therapy to prevent acute renal failure includes ensuring adequate hydration and monitoring urinary output. Hemoglobinuria and myoglobinuria are treated in standard fashion. If renal failure occurs, dialysis may be required, although it does not remove circulating venom components [4,7].

Although steroids are useful in the management of adverse reactions to antivenom (see previous discussion), there is no role for them in the primary management of snake envenomation.

Wound Care and Surgery

Wound care begins with cleaning the bite site with a suitable germicidal solution and covering it with a dry, sterile dressing. As soon as antivenom has been started, if indicated, the extremity should be elevated in a well-padded splint in a position of function with cotton between the digits [3,4]. Antibiotics are unnecessary unless field management involved incisions into the bite site [30] or the wound becomes clinically infected. Tetanus immunization status should be updated as necessary.

Intact hemorrhagic blebs and bullae should be protected. If ruptured, they should be unroofed after any attendant coagulopathy has been reversed [7,31]. Further debridement may be necessary if there is significant tissue necrosis. The use of hyperbaric oxygen therapy to treat these wounds has yet to be fully studied [4,32]. Physical therapy is important in returning the extremity to functional capacity.

The role of surgery in the primary management of pit viper envenomation is very limited. The speed with which snake venom is absorbed makes routine excision of the bite site fruitless [33], and routine exploration of the site does nothing to mitigate systemic effects of venom, may worsen the overall outcome by adding surgical trauma, and prolongs hospitalization [4].

The incidence of compartment syndrome after snake envenomation appears low despite the frequently impressive local findings of bitten extremities [34,35]. Myonecrosis that occurs is usually due to direct venom effects and rarely vascular compromise from elevated intracompartmental pressures [21,34,35]. In combined series of nearly 2,000 victims of pit viper envenomation, only 4 patients required fasciotomy; each of these patients received inappropriate ice treatment or inadequate antivenom [34,35]. If there is concern about an impending compartment syndrome, intracompartmental pressures should be checked using any standard technique. If pressures exceed 30 to 40 mm Hg and remain elevated for more than 1 hour despite appropriate antivenom administration, limb elevation and possibly mannitol infusion (1 to 2 g per kg in a normotensive patient), fasciotomy may be required [35,36]. While some evidence suggests that fasciotomy may actually worsen local myonecrosis [37], unabated elevation of intracompartmental pressures can have disastrous effects, such as debilitating neuropathy [38], and fasciotomy may still be required. Whenever possible, informed consent should be obtained prior to proceeding with fasciotomy.

Disposition and Outcome

Patients with apparent dry bites can be discharged from the emergency department if they remain asymptomatic with normal laboratory values (repeated prior to discharge) after 8 hours of observation [39]. The envenomated patient can be discharged from the hospital when all venom effects have begun to resolve and when antivenom therapy is complete, which is usually within 48 hours after admission. At the time of discharge, every patient should have appropriate follow-up arranged for continued wound care and physical therapy, and should be warned about the symptoms of serum sickness. If such symptoms occur, the patient should seek medical care promptly.

Venom-induced coagulopathy and thrombocytopenia may recur anytime up to 14 days after the last dose of antivenom [40]. Therefore, patients should be followed closely for this phenomenon after discharge from the hospital. If there is evidence of clinically significant bleeding on follow-up or if the laboratory coagulopathy is severe, additional antivenom can be considered, although its efficacy at reversing delayed recurrence of coagulopathy appears to be reduced and the need to treat asymptomatic coagulopathy during recovery is controversial [22,23,40]. Nevertheless, patients who developed coagulopathy during the acute phase of envenomation should be warned to avoid elective procedures and risky activities (such as contact sports) for at least 2 weeks.

The historical mortality rate for patients treated with antivenom in the United States was 0.28%, compared to 2.61% for patients not receiving antivenom [41]. The impact of CroFab® on mortality rates remains to be determined. Death after pit viper poisoning is most likely to occur 6 to 48 hours after envenomation [41,42]. Fewer than 17% of deaths occur within 6 hours and fewer than 4% within 1 hour [41,42]. The major reasons for poor outcome in pit viper envenomation are delay in presentation, inadequate fluid resuscitation, inappropriate use of vasopressors, and delay in administration or inadequate dosing of antivenom [2,43]. The incidence of upper-extremity functional disability after pit viper envenomation is at least 32% [44], and may be higher when careful, objective functional measurements are obtained [45].

Coral Snake Envenomation

There are fewer than 100 coral snake bites reported in the United States each year [46]. The U.S. coral snakes include the eastern coral snake (*Micrurus fulvius*), the Texas coral snake (*Micrurus tener*), and the Sonoran coral snake (*Micruroides euryxanthus*). Mexico boasts 15 *Micrurus* species as well as the Sonoran coral snake [47]. Native U.S. coral snakes can be identified by a characteristic red, yellow, and black banding pattern, with the red and yellow bands contiguous and the bands completely encircling the body. This color pattern does not, however, reliably identify coral snakes south of Mexico City [48]. Coral snakes lack the pitlike heat-receptor organs of pit vipers. While only 40% of coral snake bites result in envenomation because of their much less effective venom-delivery mechanism (small fangs fixed in an upright position on the anterior maxillae) [4,49], it has been estimated that one large coral snake is capable of delivering enough venom to kill four to five humans [50,51]. In the United States, it appears that the severity of envenomation tends to be greatest with the eastern coral snake (*M. fulvius*), less with the Texas coral snake (*M. tener*) and least with the Sonoran coral snake (*Micrur. euryxanthus*) [4,52].

Clinical Manifestations

Coral snake venoms are primarily neurotoxic; low-molecular-weight polypeptides in the venom are capable of inducing nondepolarizing, postsynaptic blockade at neuromuscular junctions [3,53]. There are few local findings at the bite site, and the onset of systemic symptoms may be delayed for many hours [3,49,54]. Fang marks may be small and difficult to detect [55], with variable pain and little swelling at the site [54]. The patient may experience local paresthesias that may radiate proximally and be associated with muscle fasciculations [54,56]. The earliest systemic findings may include alteration of mental status [3,57]. Nausea and vomiting may occur, along with increased salivation [3,49]. Bulbar-type paralysis can occur as early as 90 minutes after the bite and progress to peripheral paralysis [4]. Findings may include extraocular muscle paresis, ptosis, pinpoint pupils, dysphagia, dysphonia, slurred speech, and laryngeal spasm [49,54,56]. Death from coral snake envenomation has been reported because of respiratory failure or cardiovascular collapse [4].

Diagnostic Evaluation

The important history is similar to that obtained in victims of pit viper bites. In areas where coral snakes coexist with harmless coral snake mimics, it is helpful if the color pattern of the offending snake can be recalled.

The clinical grading scale outlined for pit viper envenomation does not apply to coral snake bites because of the paucity of local findings and the potential delay in the onset of systemic symptoms [4]. There are no characteristic changes in routine laboratory tests in coral snake envenomation [2].

The differential diagnosis of coral snake envenomation is usually limited to bites by other brightly colored snakes, such as milk snakes (*Lampropeltis* sp). With these harmless coral snake mimics, the red and yellow bands are separated by black bands, and the bands do not completely encircle the body. The simple rhyme "red on yellow, kill a fellow; red on black, venom lack" is applicable only to snakes found north of Mexico City [48]. The remainder of the differential diagnosis is the same as for pit vipers.

Management

Rapid transportation to a hospital is of utmost priority following coral snake bites [2]. In Australia, where all native venomous snakes are elapid relatives of the coral snake, a potentially beneficial first-aid intervention is use of a pressure-immobilization wrap. In this technique, the entire bitten extremity is firmly wrapped with an elastic or crepe bandage and splinted [58]. The wrap is applied snuggly—as tightly as for a sprained ankle [58]—and it is important that the extremity be kept as immobile as possible and the patient carried to medical care [59]. One small animal study has demonstrated apparent benefit of the technique in prolonging survival following coral snake venom injection [60].

As with pit viper bites, attention is initially directed to the patient's airway, breathing, and circulatory status. Supplemental oxygen should be administered, cardiac and pulse oximetry monitoring established, and at least one IV line should be started. Impending respiratory failure is suggested by cyanosis, trismus, laryngeal or pharyngeal spasm, increased salivation, or any sign of cranial nerve paralysis [54]. If any of these findings is present, prophylactic intubation is indicated to prevent aspiration. Once the airway and respiratory status are addressed, a more complete physical examination is performed. Any swelling should be documented and observed for progression.

Antivenom Therapy

As with most venomous snakebites, definitive management of significant *Micrurus* bites should center on the use of appropriate antivenom. However, the only approved antivenom for coral snake bites in the U.S., Antivenin (*Micrurus fulvius*) (Wyeth Laboratories Inc., Marietta, PA) has been discontinued with remaining stocks due to expire in October 2011. It is possible that another pharmaceutical company may resume coral snake antivenom production for the U.S. Research into the use of an alternative foreign-produced antivenom for U.S. coral snake bites is also under way. (Updates on this topic can be obtained by contacting regional poison control centers.) If an effective coral snake antivenom is available, it should be administered in a monitored setting (with epinephrine available), in consultation with an expert in snake venom poisoning, and with informed consent if possible. Antivenom administration to any patient clearly bitten by a positively identified *Micrurus* specimen, even in the absence of signs or symptoms, has been recommended given that once signs or symptoms begin to appear, it may be difficult to reverse or halt their progression [49,54]. This is likely unnecessary, however, if the offending snake was a Texas coral snake (*M. tener*) [52].

There is no antivenom for the Sonoran coral snake (*Micruroides. euryxanthus*), but the venom of this snake is much less toxic, and there have been no reported deaths after its bite [4,57]. Management of any coral snake bite, in the absence of available antivenom, is entirely supportive. Airway protection and ventilatory support may be required for days following *Micrurus* bites [54], but with modern intensive care, the prognosis should be good nonetheless.

Wound Care

The wounds from a coral snake bite should be washed with a germicidal solution and tetanus prophylaxis updated as necessary. Prophylactic antibiotics are not indicated.

Disposition and Outcome

All patients with potential coral snake bites should be admitted to an intensive care unit for at least 24 hours for close monitoring regardless of symptoms or antivenom requirement [61]. The projected case-fatality rate in untreated cases is up to 10% [49]. Total resolution of all signs or symptoms (e.g., weakness) may take several weeks [54,56].

Exotic (Imported) Snake Envenomation

Exotic venomous snakes are commonly kept in zoos, museums, and sometimes by private individuals in "underground zoos." Occasionally, they may be inadvertently found in imported goods and produce. If the setting of a victim of exotic venomous snakebite, every effort should be made to correctly identify the snake. This can be done by contacting available zoo personnel or biologists. The treating physician should then call a regional poison control center for assistance (1-800-222-1222). These centers have access to a national listing of available sources of exotic antivenoms in stock in the United States. Antivenoms tend to be quite specific for the species against which they protect, and should be used only if there is clear evidence of their efficacy against the offending species. Sound supportive care, combined with an appropriate antivenom when available, should offer the best chances of an optimal outcome.

SPIDER ENVENOMATION

While many spiders are capable of biting humans, only two types are medically significant in North America: the widow spiders (*Latrodectus* sp) and the recluse spiders (*Loxosceles* sp).

Widow Spider Envenomation

Of five known species of widow spider in the United States, the black widows (*Latrodectus mactans*, *Latrodectus hesperus*, and *Latrodectus variolus*) are the best known [62]. The female black widow is dark black and oval shaped, with a characteristic ventral red, orange, or yellow (hourglass-shaped) marking on the abdomen. The body is approximately 1.5 cm long and the leg span up to 4 cm. The other two species in the United States are the red-legged widow or red widow (*Latrodectus bishopi*) and the brown widow (*Latrodectus geometricus*) [62]. Widow spiders are found in all of the 48 contiguous states and Hawaii [63], and are responsible for most of the very rare spider-related deaths in North America. Only the female is dangerous to humans; the male, a nondescript and much smaller brown spider, is incapable of delivering a bite through human skin [64].

The venom of all species of widow spiders is similar in composition and toxic effects [65]. The most deleterious venom component is alpha-latrotoxin, a potent neurotoxin that acts primarily at the neuromuscular junction [64]. The venom initially stimulates the release of neurotransmitters (acetylcholine, epinephrine, and norepinephrine) and then blocks

neurotransmission by depleting synaptic vesicles [64–66]. It does not cause dermonecrosis or hemolysis [67].

Clinical Manifestations

The widow spider bite may be unnoticed by the patient or may be felt as a pinprick [65]. The bite site may be visible, with tiny fang marks approximately 1 mm apart, and the area may be slightly warm and blanched with a surrounding erythematous, indurated zone [68]. Swelling is minimal [69].

Significant symptoms usually appear 10 minutes to 2 hours after envenomation [42,68]. The most prominent symptom is pain. It begins at the bite site as a dull ache and spreads first to local muscle groups and then to larger regional muscle groups of the abdomen, back, chest, pelvis, and lower extremities. Muscle spasms and rigidity are classically present [68,70,71]. Spasms of abdominal musculature can mimic an acute abdomen, though rebound tenderness is absent. Chest muscle rigidity may produce respiratory distress [70,71]. The respiratory rate increases, and there may be associated tachycardia and hypertension. Pain severity typically peaks after several hours [72]. In patients at risk, the hypertension can lead to cerebrovascular accidents, exacerbation of congestive heart failure, and myocardial ischemia [64,65,73]. Cardiac dysrhythmias and priapism have been reported [68,74].

Associated signs or symptoms include diaphoresis, fever, headache, nausea and vomiting, restlessness and anxiety, periorbital edema, and skin rash [68,70]. Deep tendon reflexes may be increased [71].

Diagnostic Evaluation

The history surrounding a widow spider bite is confusing if a spider was not seen. A high index of suspicion should be maintained in patients presenting with compatible complaints. It is important to obtain a medical history, such as hypertension, pregnancy status, allergies, and tetanus immunization status. The physical examination entails a general screening with particular attention to the vital signs, which should be checked at frequent intervals. Close examination for a bite site may be productive.

There are no diagnostic changes in routine laboratory tests in widow spider envenomation. An elevation in white blood cell count and serum creatine phosphokinase values may be seen [75], and proteinuria has been reported [76]. An electrocardiogram and chest radiograph should be obtained as clinically indicated. A pregnancy test should be obtained in women of childbearing age as widow spider venom is a potent abortifacient.

The differential diagnosis includes envenomations by other arthropods, such as neurotoxic scorpions (see the section "Scorpion Envenomation"), and systemic disorders, such as acute rhabdomyolysis, heat cramps, heat stroke, neuroleptic malignant syndrome, tetanus, and strychnine poisoning. Various causes of abdominal pain and rigidity should be considered.

Management

Although there are no specific first-aid measures effective in widow spider bites, temporary application of ice to the bite site may reduce pain [64]. Adequate airway, respiration, and circulatory status should be ensured. After providing oxygen, cardiac and pulse oximetry monitoring, and starting an IV line, attention should be directed to alleviating painful muscle spasms. Although there are anecdotal reports of successful treatment of painful muscle spasms with IV calcium gluconate [69,70], larger case series have found it completely ineffective [62]. Similarly, methocarbamol has met with only limited anecdotal success [69]. Benzodiazepines and opioids can be administered in usual doses and are often most effective when administered in combination [62].

Hypertension usually responds to bed rest, muscle relaxants, analgesics, and sedation [64]. Specific antihypertensive agents can be used if necessary [64].

Antivenom

A specific, equine, whole-immunoglobulin widow spider antivenom, Antivenin (*L. mactans*) (manufactured by Merck & Co., Inc., West Point, PA) is effective regardless of which *Latrodectus* species is involved [77]. Indications for antivenom use remain controversial [78], but are generally accepted to include a patient who is severely envenomated, is pregnant or in labor, or has a history of cardiovascular disease or other major medical problems and evidence of significant envenomation despite benzodiazepine and opioid therapy [68,71,72]. Antivenom is very effective in relieving pain, but its use solely for this purpose is controversial [69,79]. *Latrodectus* antivenoms manufactured by other countries appear to be effective in managing bites by widow spiders native to the United States [80,81].

As with snake antivenom administration, informed consent should be obtained and antivenom administered in a monitored setting with epinephrine available at the bedside. Prior to antivenom administration, the patient can be premedicated with IV antihistamines (H_1 and H_2 blockers), though the benefit of such an approach is unproven. The antivenom can be given intravenously (one reconstituted vial further diluted in 50 to 100 mL of normal saline, administered over 30 minutes) or intramuscularly (one reconstituted vial in the anterolateral thigh) [82], with the physician in immediate attendance to observe for any sign of adverse drug events. The IV route is preferred if the patient is in shock or younger than 12 years [82]. The dosage is the same for children [64,70]. One vial is generally adequate, but a second vial can be administered if necessary [70,72]. Signs or symptoms should completely resolve within a few hours of antivenom administration [70,72].

The types of adverse drug events seen with widow spider antivenom are the same as for snake antivenoms, but the risk of serum sickness may be less because of the smaller total amount of foreign protein infused [72].

The clinical course of most patients with widow spider envenomation is benign [68], but significant pain and spasms can persist for 2 to 3 days [72,79]. Most healthy adults do well with supportive measures and adequate administration of parenteral benzodiazepines and opioids [68].

Disposition and Outcome

Patients can be discharged from the hospital when signs or symptoms of envenomation have been significantly controlled, though it may be best to admit and observe younger children. Patients should be given analgesics and muscle relaxants, prescribed bed rest, and instructed to return if they worsen. The mortality rate from widow spider envenomation in the United States is less than 1% [65,68]. Recovery from widow spider envenomation may sometimes be slow, with weakness, fatigue, paresthesias, headache, and insomnia persisting for several months [64].

Recluse Spider Envenomation

Of the 13 species of recluse spider (*Loxosceles* spp) found in the United States [83], the brown recluse (*Loxosceles reclusa*) is best known [84]. It is characterized by a violin-shaped marking on the dorsal aspect of the cephalothorax and three pairs of

eyes, in contrast to the four pairs found in most spiders. The adult body is 10 to 15 mm long and the legs span 2 to 3 cm. Both the male and female spiders are dangerous [72].

The brown recluse is found throughout the southern, south-central, and midwestern United States; other species are found in the western part of the country [62]. While recluse spiders may cause severe dermonecrosis (necrotic arachnidism), the majority of bites actually result in insignificant lesions [85].

The venoms of the different species of recluse spider have similar toxic effects [86]. They contain a number of different proteins, most of which demonstrate enzymatic activity [87]. Sphingomyelinase D is likely responsible for the venom's cytotoxic and hemolytic effects [88–90]. Venom activation of the complement cascade induces a series of autopharmacologic changes that amplify toxicity to a variable degree in victims [91].

The cutaneous changes seen after a recluse spider bite are initiated by venom-induced endothelial damage in small dermal vessels that become occluded with microthrombi, producing vascular stasis and infarction [92]. Polymorphonuclear leukocytes are attracted to the site via a chemotactic response and propagate the inflammatory, necrotic reaction [92,93]. Accumulation of polymorphonuclear leukocytes at the site appears to be a vital component of the dermonecrotic response and is related to complement activation [93].

Clinical Manifestations

The clinical course of recluse spider envenomation varies from a mild temporary irritation at the bite site to a rare, severe, potentially fatal outcome [84]. The bite is occasionally felt as a mild stinging sensation, although it may go completely unnoticed [94]. During the next several hours, there may be pruritus, tingling, mild swelling, and redness or blanching at the bite site [95]. Variable degrees of local pain and tenderness due to local vasospasm and ischemia occur within 2 to 8 hours [95,96]. At 12 to 18 hours, a small central vesicle (clear or hemorrhagic) often develops at the site and is surrounded by an irregular zone of erythema or ecchymosis and edema, which may have a distinct gravitational distribution around the central lesion [97]. The vesicle ruptures, and the erythema gives way to violaceous discoloration [96]. In 5 to 7 days, the bite site undergoes aseptic necrosis (i.e., dry, gangrenous slough), with the center becoming depressed below the normal level of the skin, and a black eschar forms. The eschar later sloughs, leaving an open ulcer that heals in weeks to months [96]. Bites to fatty regions of the body tend to be more severe, with undermining of the skin and more extensive scarring [96]. Necrosis rarely involves deeper structures such as nerves, muscles, tendons, or ligaments [98]. Lesions destined to develop significant necrosis usually demonstrate early evidence of local ischemia [95].

Systemic (viscerocutaneous) loxoscelism is rare, but can be rapidly progressive and severe, particularly in children [72]. Systemic symptoms generally start 24 to 72 hours after the bite and occasionally occur before cutaneous findings become impressive [99]. Symptoms are often flulike, with fever, chills, headache, malaise, weakness, nausea and vomiting, myalgias, and arthralgias [96]. Hemolytic anemia with hemoglobinemia, hemoglobinuria, jaundice, thrombocytopenia, disseminated intravascular coagulation, acute renal failure, seizures, and coma have been reported [72]. The severity of systemic symptoms is directly related to the quantity of venom deposited, but does not necessarily correlate with the severity of cutaneous changes [97].

Diagnostic Evaluation

It is rare for a victim of a *Loxosceles* bite to see the offending spider because the bite is relatively painless and a large percentage of bites occur while the victim is asleep [85]. Because the spider is rarely available for identification, determining the cause of early lesions is difficult [97], and the diagnosis of spider bite is usually presumptive. The working diagnosis should be cutaneous necrosis if the precise cause is unknown and necrotic arachnidism if a biting spider was seen but not identified.

An examination for evidence of systemic loxoscelism should be performed. The severity of any lesion present should be assessed and any evidence of secondary infection noted. There are no characteristic changes in routine laboratory tests in recluse spider envenomation. In patients with severe envenomation, laboratory studies should include a complete blood cell count and urinalysis [96]. If there is any evidence of consumptive coagulopathy, hemolysis, or hemoglobinuria, further studies should include prothrombin time and partial thromboplastin time, electrolytes, blood urea nitrogen, and creatinine, and a specimen should be sent for blood typing and screening. The white blood cell count may be as high as 20,000 to 30,000 per mm^3, and the hemoglobin may fall to as low as 4 g per dL [67,72,96]. Serial complete blood cell counts and urinalyses should be obtained in patients with significant lesions or systemic loxoscelism [96].

There is no commercially available test to definitively diagnose recluse spider envenomation. The differential diagnosis for *Loxosceles* envenomation includes bites or stings by other arthropods (e.g., other spiders, ticks, scorpions, ants, fleas, kissing bugs, and biting flies), superficial skin infections (especially methicillin-resistant *Staphylococcus aureus*), cutaneous anthrax, diabetic ulcers, plant puncture wounds, sporotrichosis, toxic epidermal necrolysis, pyoderma gangrenosum, erythema nodosum, erythema migrans, herpes zoster, herpes simplex, erythema multiforme, purpura fulminans, and contact dermatitis.

Management

No commercial antivenoms exist for *Loxosceles* bites in the United States. The majority of cases require only local wound care, including cleansing of the bite site, application of a sterile dressing, immobilization with a well-padded splint, and tetanus prophylaxis as necessary [67]. Frequent local application of ice or cold packs during the first 72 hours to reduce sphingomyelinase D activity is probably beneficial [84]. If an ulcer develops, it should be cleaned several times each day with hydrogen peroxide or povidone–iodine solution [96]. Pruritus can be treated with antihistamines. Antibiotics to prevent secondary cellulitis may be beneficial [84] and should include coverage for methicillin-resistant *S. aureus* [100].

It is important to emphasize to patients that nothing has been proven to decrease the extent of dermonecrosis after these bites and that most lesions heal quite satisfactorily with conservative management alone [67,96,101]. Controversial modalities for managing the wound include the use of steroids, dapsone, colchicine, surgery, hyperbaric oxygen therapy, and topical nitroglycerine application [78,87,102–105]. Routine use of these agents should be avoided until prospective controlled studies prove that benefits outweigh risks.

Early excision of the wound site is contraindicated because it is impossible to predict the ultimate extent and severity of the lesion [87]. Severe-appearing lesions commonly involute and regress spontaneously to leave minimal defects [106]. Surgical procedures that might be required, such as skin grafting, should be postponed at least 6 to 8 weeks to ensure that the necrotic process has been completed and to improve chances of healing [87]. Hyperbaric oxygen therapy may be useful in particularly severe wounds, but this remains unproven [87,107].

Initial management of systemic loxoscelism includes adequate hydration, maintaining electrolyte balance, and

administering nonsalicylate antipyretics and analgesics [67,96]. Although the use of systemic corticosteroids to stabilize red blood cell membranes has yet to be studied in a controlled fashion, an early, short course of therapy may be beneficial in patients with hemolysis. The recommended dose is 1 mg per kg per day of prednisone orally for 2 to 4 days [67]. Blood products are used as indicated to treat anemia or thrombocytopenia [67]. If hemoglobinuria occurs, hydration becomes critically important, and urine output should be maintained at 2 to 3 mL per kg per hour [96]. If renal failure develops, dialysis may be indicated [67,96]. Dialysis does not remove venom or hemoglobin from the circulation, however [96].

Disposition and Outcome

Patients may be discharged from the hospital when systemic effects have resolved. Close follow-up (daily wound checks) should be provided to patients with cutaneous lesions. Although there have been no reports of deaths in patients bitten by positively identified recluse spiders in the United States [72,96], there is risk of death from systemic loxoscelism, especially in children.

SCORPION ENVENOMATION

The only scorpion species of major medical importance that is native to the United States is the bark scorpion (*Centruroides sculpturatus* [formerly *C. exilicauda*]) [108]. This species is found throughout Arizona and immediately surrounding regions of neighboring states [109]. Other closely related *Centruroides* scorpions of medical importance are found in Mexico. The bark scorpion is 13 to 75 mm long and yellow brown in color, with variable striping on the dorsum [109–111], and has a small subaculear tubercle at the base of the stinger [112].

The venom of *C. sculpturatus* is complex. It contains at least five distinct neurotoxins that cause release of neurotransmitters from the autonomic nervous system and adrenal medulla and stimulate depolarization of neuromuscular junctions [113,114]. Its venom contains no major enzymatic components [115].

Clinical Manifestations

Most *C. sculpturatus* stings are minor, with the most serious envenomations occurring in children [116]. The sting usually produces intense pain at the site, although local pain may be absent in children younger than 10 years [110]. Pain or numbness may radiate up the extremity [110]. Soft-tissue swelling and ecchymosis are notably absent [115].

Systemic symptoms may include restlessness or anxiety, uncoordinated neuromotor hyperactivity, oculomotor dysfunction, and respiratory distress related to excess secretions, airway obstruction, and in some cases, noncardiogenic pulmonary edema [116,117]. Hyperactivity may be mistaken for seizures [118]. Supraventricular tachycardia and hypertension have been reported [113], and severe hyperthermia may occur [111]. The duration of symptoms appears to be inversely proportional to age and may persist for up to 30 hours [110].

Local consequences after envenomation by other scorpions in the United States consist of immediate, brief, intense pain; mild soft-tissue swelling; and mild ecchymosis [119]. Systemic manifestations are uncommon, and allergic reactions are rare [77].

Diagnostic Evaluation

Patients stung by scorpions frequently see the offending organism. A general medical history should be obtained, symptoms assessed, and prehospital treatments noted. Vital signs should be frequently monitored. The sting site should be inspected and the patient examined for signs of systemic toxicity.

There are currently no commercial laboratory tests of diagnostic benefit in patients suspected of *C. sculpturatus* envenomation. The white blood cell count and serum glucose may be elevated [113]. Increases in serum amylase, creatine phosphokinase, and renal function studies, mild abnormalities in coagulation parameters, and cerebral spinal fluid pleocytosis have been reported [117].

The diagnosis is usually not difficult because adults often relate the history of a scorpion sting; in children, the clinical picture after a *C. sculpturatus* sting is rarely confused with other diagnoses [110]. The differential diagnosis includes central nervous system infection, widow spider envenomation, tetanus, dystonic drug reaction, intoxication (e.g., pesticides, anticholinergics, sympathomimetics, xanthines, propoxyphene, and strychnine), drug withdrawal, anaphylaxis, and seizure disorder.

Management

The majority of *C. sculpturatus* stings can be treated with cold compresses and analgesics [113]. Patients with more severe envenomations should receive oxygen and have an IV line established, along with continuous cardiac and pulse oximetry monitoring. The airway should be secured if there are signs of respiratory failure or inability to handle secretions [117]. Anxiety, restlessness, muscular hyperactivity, and moderate hypertension can initially be treated with parenteral benzodiazepines and bed rest [109]. β-Adrenergic–blocking agents have been recommended for hemodynamically significant supraventricular tachycardia [113,114], though caution must be used to ensure that hypertension is not exacerbated because of unopposed α-adrenergic effects. A combined beta-/alpha-blocking agent has theoretical advantages in such scenarios. Antihypertensive agents can be used for severe blood pressure elevation. Narcotics should be avoided because they appear to have a synergistic neurotoxic effect with the venom [120].

At the time of this writing, there were no commercially available antivenoms for scorpion stings in the United States. Recent work, however, demonstrates significant efficacy in the use of scorpion-specific $F(ab')_2$ antivenom (Anascorp, *Centruroides* [scorpion] immune $F(ab')_2$ intravenous [equine], Instituto Bioclon, Mexico) in rapidly reversing the neurotoxic effects, benzodiazepine requirements, and serum venom levels in children stung by bark scorpions in Arizona [116]. The University of Arizona Poison and Drug Information Center should be contacted for updates and availability of this product (phone: 1–800-222–1222). In the absence of available antivenom, the treating physician faced with a severely envenomated victim must rely on sound supportive care in an intensive care setting. Such care may be required for several days [116].

Deaths after a *C. sculpturatus* sting are exceptionally rare [109,113], but the potential for a fatal outcome should not be underestimated, especially in small children and the infirm.

SUMMARY (Table 132.2)

TABLE 132.2

SUMMARY OF HOSPITAL MANAGEMENT RECOMMENDATIONS FOR ENVENOMATIONS IN NORTH AMERICA

Syndrome	Management
Pit viper	
Rattlesnake (*Crotalus* or *Sistrurus* spp), cottonmouth water moccasin, or copperhead (*Agkistrodon* spp)	■ ABCs, O_2, cardiac/pulse oximetry monitoring, two large-bore IV lines, physiologic saline infusion ■ Measure extremity circumferences every 15 minutes during acute phase ■ Laboratory assessment (see text) ■ Update tetanus immunization status as needed ■ No evidence of envenomation—monitor for a minimum of 8 hours [39] ■ Mild envenomation without evidence of progression—no antivenom, admit for monitoring [24] ■ Mild envenomation with progression or moderate-to-severe envenomation (evidence of systemic toxicity [systemic signs or symptoms, or laboratory abnormalities])—administer antivenom (see text) [24] ■ Shock management includes IV physiologic saline boluses (10–20 mL/kg) and antivenom; if refractory, consider albumin [8] and, as last resort, vasopressors [4] ■ Blood products uncommonly required after administration of adequate antivenom [28] ■ If concerned re: compartment syndrome, measure intracompartmental pressures (see text); fasciotomy only for documented increase in pressures unresponsive to elevation of the extremity and antivenom [36] ■ Antibiotics only for evidence of secondary infection (uncommon) [30]
Coral snake	
Texas or Eastern coral snake (*Micrurus* spp)	■ ABCs, O_2, cardiac/pulse oximetry monitoring, at least one large-bore IV line, physiologic saline infusion ■ Early intubation and respiratory support if any evidence of difficulty with breathing or handling secretions [54] ■ Update tetanus immunization status as needed ■ No evidence of envenomation—admit for monitoring (minimum of 24 hours) [61] ■ Evidence of neurotoxicity—administer antivenom if available (see text); if no antivenom available, supportive care only; admit for monitoring until recovered
Sonoran coral snake (*Micruroides euryxanthus*)	■ ABCs, O_2, cardiac/pulse oximetry monitoring, at least one large-bore IV line, physiologic saline infusion ■ Update tetanus immunization status as needed ■ No evidence of envenomation—admit for monitoring (minimum of 24 hours) ■ Evidence of neurotoxicity—admit for monitoring until recovered, supportive care only
Widow spider (*Latrodectus* spp)	■ ABCs, O_2, cardiac/pulse oximetry monitoring, at least one large-bore IV line, physiologic saline infusion ■ Update tetanus immunization status as needed ■ No evidence of envenomation—monitor for 6–8 hours) ■ Evidence of envenomation Mild: analgesics and muscle relaxants (narcotics and benzodiazepines) [62] More severe or high-risk patient (see text): consider antivenom administration with informed consent (see text) [68]
Recluse spider (*Loxosceles* spp)	■ Laboratory assessment (see text) ■ Conservative wound care (cleansing, splinting, debride only clearly necrotic tissue) ■ Update tetanus immunization status as needed ■ Any evidence of infection: broad-spectrum antibiotics (include MRSA coverage) [84,100] ■ Daily wound checks until progressive healing ■ Delay any required skin grafts for 6–8 weeks (see text) [87] ■ If evidence of systemic toxicity: admit, IV fluids, steroids (see text); blood product transfusion and dialysis for renal failure as needed [67,96]
Scorpion	
Neurotoxic scorpion (e.g., *Centruroides sculpturatus*)	■ ABCs, O_2, cardiac/pulse oximetry monitoring, at least one large-bore IV line, physiologic saline infusion ■ Analgesics (nonnarcotic), benzodiazepines [109,120] ■ Update tetanus immunization status as needed ■ If severe: consider antivenom if available, otherwise conservative care [116]
Nonneurotoxic scorpion	■ Analgesics as needed ■ Update tetanus immunization status as needed

ABCs, airway, breathing, circulation assessment and management as needed; O_2, oxygen; IV, intravenous; MRSA, methicillin-resistant *Staphylococcus aureus*.

CHAPTER 133 ■ HEAVY METAL POISONING

LUKE YIP[□]

This chapter focuses on the aspects of acute poisoning by arsenic, lead, and mercury that are potentially life threatening or may lead to permanent organ damage and hence require immediate, usually intensive, medical care. Reviews of the evaluation and management of asymptomatic exposures and nonacute poisoning can be found elsewhere [1,2].

[□]The views expressed do not necessarily represent those of the agency or the United States.

ARSENIC

Exposure to arsenic may come from natural sources, industrial processes, commercial products, food, or intentionally

administered sources either with a benevolent (acute promyelocytic leukemia [APL] treatment, folk and naturopathic remedies) [3,4] or malevolent intent. Today, acute arsenic poisoning is most commonly the result of an accidental ingestion or the result of a suicidal or homicidal intent.

Pharmacology

Arsenic compounds can be classified into three major groups: inorganic, organic, and arsine gas (AsH_3). The latter is discussed separately. Arsenic compounds can also be classified by their valence state. The three most common valence states are the metalloid (elemental [0] oxidation state), arsenite (trivalent [+3] state), and arsenate (pentavalent [+5] state). In general, the arsenic compounds can be arranged in their order of decreasing toxicity: inorganic trivalent compounds, organic trivalent compounds, inorganic pentavalent compounds, organic pentavalent compounds, and elemental arsenic. Trivalent arsenic is generally two- to tenfold more toxic than pentavalent arsenic. The minimum oral lethal human dose of arsenic trioxide (trivalent) is probably between 10 and 300 mg. Some marine organisms and algae contain large amounts of organic arsenic in the form of arsenobetaine—a trimethylated arsenic compound—and arsenocholine. Arsenobetaine and arsenocholine are excreted unchanged in the urine, with total clearance in about 2 days, and exert no known toxic effects in humans.

The major routes of entry into the human body are ingestion and inhalation. Soluble forms of ingested arsenic are 60% to 90% absorbed from the gastrointestinal (GI) tract. The amount of arsenic absorbed by inhalation is also thought to be in this range. Toxic systemic effects have been reported from rare occupational accidents in which arsenic trichloride or arsenic acid was splashed on worker's skin.

After absorption, arsenic is bound to proteins in the blood and redistributed to the liver, spleen, kidneys, lungs, and GI tract within 24 hours. Clearance from these tissues is dose dependent. Two to four weeks after exposure ceases, most of the arsenic remaining in the body is found in keratin-rich tissues (e.g., skin, hair, and nails).

Both forms of arsenic, arsenite and arsenate, undergo biomethylation in the liver to monomethylarsonic acid (MMA) and dimethylarsinic acid (DMA). The methylation process may represent detoxification because the metabolites exert less acute toxicity in experimental lethality studies. The liver's efficiency in methylation decreases with increasing arsenic dose. When the methylating capacity of the liver is exceeded, exposure to excess concentrations of inorganic arsenic results in increased retention of arsenic in soft tissues.

Arsenic is eliminated from the body primarily by renal excretion. Urinary arsenic excretion begins promptly after absorption, and depending on the amount of arsenic ingested, urinary arsenic excretion may remain elevated for 1 to 2 months. After acute intoxication by inorganic arsenic, arsenic is excreted in the urine as inorganic arsenic, MMA and DMA, but their proportion varies with time [5]. During the first 2 to 4 days after the intoxication, arsenic is excreted mainly in the inorganic form. This is followed by a progressive increase of the proportion excreted as MMA and DMA. The time at which arsenic is primarily excreted as its methylated metabolites depends on the severity and duration of the intoxication. Pentavalent arsenic is cleared more rapidly than trivalent arsenic. Because arsenic is quickly cleared from the blood, blood concentrations may be normal, while urine concentrations remain markedly elevated. Renal dysfunction may be a major impediment to normal elimination of arsenic compounds.

Inorganic arsenic can cross the human placenta. This was evident by the high arsenic concentrations found in a neonate following acute maternal arsenic intoxication [6].

There are two major mechanisms by which arsenic compounds appear to produce injury involving multiorgan systems. It is believed that arsenic's overt toxicity is related to its reversible binding with sulfhydryl enzymes, leading to the inhibition of critical sulfhydryl-containing enzyme systems. Trivalent arsenite is particularly potent in this regard. The pyruvate and succinate oxidation pathways are particularly sensitive to arsenic inhibition. Dihydrolipoate, a sulfhydryl cofactor, appears to be a principal target. Normally, dihydrolipoate is oxidized to lipoate via a converting enzyme, dihydrolipoate dehydrogenase. Arsenic reacts with both dihydrolipoate and dihydrolipoate dehydrogenase, preventing the formation of lipoate. Lipoate is involved in the formation of key intermediates in the Krebs cycle. As a result of lipoate depletion, the Krebs cycle and oxidative phosphorylation are inhibited. Without oxidative phosphorylation, cellular energy stores (adenosine triphosphate [ATP]) are depleted, resulting in metabolic failure and cell death.

The other major mechanism by which arsenic is believed to produce cellular injury is termed *arsenolysis*. Pentavalent arsenate can competitively substitute for phosphate in biochemical reactions. During oxidative phosphorylation, energy is produced and stored in the form of ATP. The stable phosphate ester bond in ATP can be replaced by an arsenate ester bond. However, the high energy stored in the arsenate ester bond is wasted because it is unstable and rapidly hydrolyzed. Cellular respiration is stimulated in a futile attempt to restore this wasted energy. In effect, trivalent arsenic compounds inhibit critical enzymes in the Krebs cycle, leading to inhibition of oxidative phosphorylation, and pentavalent arsenic compounds uncouple oxidative phosphorylation by arsenolysis. This results in the disruption of cellular oxidative processes, leading to endothelial cellular damage. The fundamental lesion seen clinically is loss of capillary integrity, resulting in increased permeability of blood vessels and tissue hypoxia, leading to generalized vasodilation, transudation of plasma, hypovolemia, and shock.

In vitro, the effects of arsenic trioxide on repolarizing cardiac ion currents appear to be one of antagonism on both I_{Kr} and I_{Ks} as well as activation of I_{K-ATP}, which maintains normal repolarization [3]. In addition, arsenic trioxide increases cardiac calcium currents and reduces surface expression of the cardiac potassium channel human ether-a-go-go-related gene. The variability in QTc interval prolongation and the onset of ventricular dysrhythmias during arsenic therapy may represent these competing effects.

Clinical Toxicity

The most prominent clinical findings associated with acute arsenic poisoning are related to the GI tract. Some arsenic is corrosive. Acute ingestion may lead to oral irritation and a burning sensation in the mouth and throat. A metallic taste and/or a garlicky odor to the breath have been described, but often are not present. Nausea, vomiting, and abdominal pain are common. The toxic effects of arsenic on the GI tract are manifested as increased peristalsis and profuse watery stools and bleeding. In serious cases, hemorrhagic gastroenteritis may ensue within minutes to hours after acute ingestion. Nausea, vomiting, and severe hemorrhagic gastroenteritis can all lead to profound intravascular volume loss resulting in hypovolemia shock, which is the major cause of mortality and morbidity.

Noncardiogenic pulmonary edema may occur from increased capillary permeability, and cardiogenic pulmonary edema may occur from myocardial depression. Electrocardiogram (ECG) changes associated with arsenic poisoning consist of nonspecific ST- and T-wave changes, sometimes mimicking ischemia or hyperkalemia and QTc prolongation [7–9]. These

TABLE 133.1

ADVERSE DRUG EVENTS ASSOCIATED WITH ARSENIC TRIOXIDE INDUCTION THERAPY

Cardiovascular	QTc prolongation (≥500 msec), torsades de pointes, sudden death, tachycardia
Hematologic	Hyperleukocytosis (10,000–170,000 cells/μL)
Nervous system	Peripheral neuropathy, headache
Metabolic	Hypokalemia, hypomagnesemia, hyperglycemia
APLDS	Fever, pleural or pericardial effusion, pleural infiltrates, respiratory distress, weight gain, musculoskeletal pain
GI	Nausea, vomiting, diarrhea
Dermatologic	Skin rash

APLDS, acute promyelocytic leukemia differentiation syndrome; GI, gastrointestinal.

ECG abnormalities are reported to occur in half the patients with arsenic poisoning, and these ECG changes may be evident from 4 to 30 hours postingestion, persisting for up to 8 weeks.

At least five cases of arsenic-induced polymorphic ventricular tachycardias consistent with torsades de pointes have been reported [8,9]. In all these cases, QTc prolongation was evident on the admission ECG. Except in the case of the patient who presented with cyanosis and cardiorespiratory arrest, peripheral neuropathy was a prominent finding on physical examination at the time of hospital admission, and the polymorphic ventricular tachydysrhythmias were ultimately self-limited. Although these cases were able to document as to when during the hospital course torsades de pointes were observed, the time between arsenic exposure and the onset of cardiac dysrhythmias can only be speculated.

Arsenic was abandoned 30 years ago as an anticancer medicinal, but has attracted renewed attention as a treatment for APL on the basis of impressive results from clinical studies in China and the United States [3]. Arsenic trioxide is licensed for use in patients with relapsed or refractory APL. Induction therapy in APL patients receiving daily median arsenic trioxide infusions of 0.15 mg per kg (range, 0.06 to 0.2 mg per kg) during 1 to 2 hours until bone marrow remission or for a maximum of 60 days has been associated with adverse drug events (Table 133.1) [3]. In patients receiving multiple courses of arsenic trioxide therapy, their QTc intervals returned to pretreatment values before their second course, signifying that arsenic trioxide may not permanently prolong the QTc interval.

Both acute and chronic arsenic poisoning may affect the hematopoietic system. A reversible bone marrow depression with pancytopenia, particularly leukopenia, may occur. However, it is the chronic form that is usually associated with severe hematopoietic derangements. A wide variety of hematologic abnormalities have been described with arsenic poisoning, including anemia, absolute neutropenia, thrombocytopenia, eosinophilia, and basophilic stippling [10]. Anemia is, in part, due to an increase in hemolysis and disturbed erythropoiesis/myelopoiesis with reticulocytosis and predominant normoblastic erythropoiesis. Accelerated pyknosis of the normoblast nucleus, karyorrhexis, is characteristic of arsenic poisoning, and the typical "cloverleaf" nuclei may be evident [11]. Hematologic findings may appear within 4 days after acute arsenic ingestion, and in the absence of any specific therapy, erythrocytes, leukocytes, and thrombocytes were reported to return to normal values within 2 to 3 weeks after discontinuing arsenic exposure.

Neurologic manifestations of arsenic poisoning have included confusion, delirium, convulsions, encephalopathy, and coma [12]. Neuropathy is usually not the initial complaint associated with acute arsenic poisoning. Arsenic-induced polyneuropathy has traditionally been described as an axonal-loss sensorimotor polyneuropathy (low-amplitude/unelicitable sensory and motor conduction responses, often with preserved motor conduction velocities). The first symptoms of neuropathy have been reported to appear 1 to 3 weeks after the presumptive arsenic exposure [12,13]. Clinical involvement spans the spectrum from mild paresthesia with preserved ambulation to distal weakness, quadriplegia, and respiratory muscle insufficiency. Arsenic neuropathy is a symmetrical sensorimotor neuropathy, with the sensory component being more prominent in a "stocking-and-glove" distribution [13,14]. This polyneuropathy may progress in an ascending fashion to involve proximal arms and legs. Dysesthesias begin in the lower extremities, with severe painful burning sensation occurring in the soles of the feet. There is loss of vibration and positional sense, followed by the loss of pinprick, light touch, and temperature sensation. Motor dysfunction is characterized by the loss of deep tendon reflexes and muscle weakness. In severe poisoning, ascending weakness and paralysis may occur and involve the respiratory muscles, resulting in neuromuscular respiratory failure [15,16]. It has been reported that many of the patients with arsenic neuropathy were initially thought to have Landry–Guillain–Barré disease [12,16].

Because the fundamental lesion in arsenic toxicity is the loss of capillary integrity, increased glomerular capillary permeability may result in proteinuria. However, the kidneys are relatively spared from the direct toxic effects of arsenic. Hypovolemic shock associated with the prominent GI symptoms may lead to hypoperfusion of the kidneys, resulting in oliguria, acute tubular necrosis, and renal insufficiency or failure. The kidneys are the main route of excretion for arsenic compounds. Normal-functioning kidneys can excrete more than 100 mg of arsenic in the first 24 hours [17]. Because of shock and decreased glomerular filtration rate and depending on the dose of arsenic ingested, peak urinary arsenic excretion may often be delayed by 2 to 3 days. Hemodialysis contributes minimally to arsenic clearance compared with the normal-functioning kidneys [18].

Dermal changes occurring most frequently in arsenic-exposed humans are hyperpigmentation, hyperkeratosis, and skin cancer [19]. The lesions usually appear 1 to 6 weeks after the onset of the illness. In most cases, a diffuse, branny desquamation develops over the trunk and extremities; it is dry, scaling, and nonpruritic. Patchy hyperpigmentation—dark-brown patches with scattered pale spots, sometimes described as "raindrops on a dusty road"—occurs particularly on the eyelids, temples, axillae, neck, nipples, and groin. Arsenic hyperkeratosis usually appears as cornlike elevations, less than 1 cm in diameter, occurring most frequently on the palms of the hands and on the soles of the feet. Most cases of arsenic keratoses remain morphologically benign for decades, and in other cases, marked atypia (precancerous) develops and appears indistinguishable from Bowen's disease—an in situ squamous cell carcinoma. Skin lesions take several years to manifest the characteristic pigmented changes and hyperkeratoses, whereas it takes up to 40 years before skin cancer becomes evident. Brittle nails with transverse white bands (leukonychia striata arsenicalis transversus) appearing on the nails have been associated with arsenic poisoning and are known as Reynolds–Aldrich–Mees lines [20–22]. It reflects transient disruption of nail plate growth during acute poisoning. Leukonychia striata arsenicalis transversus takes about 5 to 6 weeks to appear over the lunulae after an acute poisoning. Thinning of the hair and patchy or diffuse alopecia are also associated with arsenic poisoning [12,23].

Diagnostic Evaluation

The temporal sequence of organ system injury may suggest acute arsenic intoxication. After a delay of minutes to hours, severe hemorrhagic gastroenteritis becomes evident, which may be accompanied by cardiovascular collapse or death. Bone marrow depression with leukopenia may appear within 4 days of arsenic ingestion and usually reaches a nadir at 1 to 2 weeks. Encephalopathy, congestive cardiomyopathy, noncardiogenic pulmonary edema, and cardiac conduction abnormalities may occur several days after improvement from the initial GI manifestation. Sensorimotor peripheral neuropathy may become apparent several weeks after resolution of the initial signs (gastroenteritis or shock) of intoxication resulting from ingestion.

The differentiation between arsenic neuropathy and Landry–Guillain–Barré disease is based on clinical and laboratory findings in that arsenic neuropathy rarely involves the cranial nerves, sensory manifestations are more prominent, weakness in the distal portions of the extremities is more severe, and the cerebrospinal fluid protein concentrations are usually less than 100 mg per dL [12,13].

Laboratory investigation should include complete blood count with peripheral smear, electrolytes, liver enzymes, creatine phosphokinase, arterial blood gas, renal profile with urine analysis, ECG, chest radiograph, and blood and urine arsenic concentrations. Nerve conduction velocity studies may be indicated if peripheral neurologic symptoms are present. Some arsenic compounds, particularly those of low solubility, are radiopaque, and if ingested, they may be visible on an abdominal radiograph.

The most important diagnostic test is urinary arsenic measurement. Urine arsenic concentrations may be measured as "spot," that is, the concentration in a single-voided urine specimen, reported in µg per L. Urine arsenic concentrations may also be measured as a timed urine collection, or the concentration in urine collected during a 12- to 24-hour period, reported in micrograms per 12 or 24 hours. The quantitative 24-hour urine collection is considered the most reliable. In an emergency situation, the spot urine sample may be of value. Normal total urinary arsenic values are less than 50 µg per L or less than 25 µg per 24 hours. In the first 2 to 3 days following acute symptomatic intoxications, total 24-hour urinary arsenic excretion is typically in excess of several thousand micrograms, with spot urine concentration greater than 1,000 µg per L, and depending on the severity, it may not return to background for weeks. Recent ingestion of seafood may markedly elevate urinary arsenic values for the next 2 days. Therefore, it is important to take a careful dietary history of the past 48 hours when only total urinary arsenic is measured. Speciation of the urinary arsenic can be performed in some laboratories. Otherwise, the urinary arsenic test should be repeated in 2 to 3 days. Whole blood arsenic, normally less than 1 µg per dL, may be elevated early on in acute intoxication. However, blood concentrations decline rapidly to normal values despite elevated urinary arsenic excretion and continuing symptoms. Elevated arsenic content in hair and nail segments, normally less than 1 part per million, may persist for months after urinary arsenic values have returned to background. However, caution should be exercised when interpreting the arsenic content obtained from hair and nails because the arsenic content of these specimens may be increased by external exposure.

Management

The management of acute arsenic poisoning relies on supportive care and chelation therapy. Treatment begins with eliminating further exposure to the toxin and providing basic and advanced life support. Anyone with arsenic intoxication necessitating hospitalization should initially be admitted to an intensive care unit (ICU).

Gastric lavage should be performed following an acute ingestion and should be considered if the ingestion has been within the past 24 hours, as some arsenic compounds of low solubility may be retained in the stomach for a prolonged period of time. Frequently, seriously poisoned patients will have already vomited, evacuating some of their stomach contents. Activated charcoal and cathartics may be used, but their efficacy is unclear [24]. When there is evidence of a heavy metal burden on an abdominal radiograph, whole-bowel irrigation (WBI) with a polyethylene glycol electrolyte solution may rapidly help clear the GI tract of the metallic load. However, the absence of radiopacities on the abdominal radiograph is nondiagnostic and WBI should still be considered when there is a definite history that a poorly soluble arsenic compound has been ingested.

Intravascular volume depletion may require aggressive replacement with crystalloids, colloids, and blood products. Vasopressors are recommended for refractory hypotension. Invasive monitoring of the patient's hemodynamic status may be necessary.

In acute arsenic poisoning, extended cardiac monitoring for ventricular dysrhythmias is indicated for all patients who have prolonged QTc on their ECG. Electrolyte abnormalities—in particular, hypokalemia and hypomagnesemia—should be aggressively corrected, and concomitant QTc interval–prolonging drugs should be avoided. Serum potassium concentrations should be maintained at more than 4.0 mmol per L and magnesium concentrations at more than 1.8 mg per dL (0.74 mmol per L). There are no good data to indicate that suppression of ventricular dysrhythmias decreases mortality rates. If dysrhythmias occur, they should be treated according to current advanced cardiac life support guidelines. Type IA antidysrhythmic cardiac medications should be avoided because these drugs may themselves cause further QTc prolongation and worsen the polymorphic ventricular tachycardia. Lidocaine, magnesium, and isoproterenol have been used with limited success in the management of arsenic-induced torsades de pointes. A transvenous pacemaker for overdrive pacing may be necessary. Noncardiogenic and cardiogenic pulmonary edema should be managed according to current guidelines. In patients receiving arsenic trioxide induction therapy who develop prolonged QTc of more than 500 milliseconds on ECG, the risk/benefits of continuing therapy should be considered.

Hematologic effects of arsenic poisoning should be managed symptomatically with blood product transfusions and antibiotics as necessary for severe anemia, bleeding, or infections.

Patients with arsenic polyneuropathy should be given analgesics for pain and physical therapy for rehabilitation. Patients with polyneuropathy associated with severe arsenic poisoning should be observed closely for respiratory dysfunction. Neuromuscular respiratory failure may be delayed 1 to 2 months after the initial presentation. In cases in which there is progressive sensorimotor dysfunction, particularly ascending weakness, respiratory muscle function should be monitored carefully. When there is evidence of impending neuromuscular respiratory failure, aggressive supportive measures should be initiated in a timely fashion.

Patients with renal failure may benefit from hemodialysis. However, hemodialysis has limited use when normal renal function is present. Hemodialysis (initiated 24 to 96 hours postingestion) has been reported to remove about 4 mg of arsenic during a 4-hour period in patients with established renal failure [18]. It should not be surprising that only small amounts of arsenic are removed by dialysis as minimal amounts of arsenic are left in the central compartment once tissue distribution and equilibration is complete.

The principle behind chelation therapy is to increase excretion of the metal and decrease the target organ's metal burden. A chelator is an organic compound that has a selective affinity for heavy metals. It competes with tissues and other compounds containing thiol groups for metal ions, removes metal ions that previously have been bound, and binds with the metal ion to form a stable complex (chelate), rendering the metal less reactive and less toxic. The metal–chelator complex is water soluble and can be excreted in the urine, bile, or both, and to some extent, it can be removed by hemodialysis.

Dimercaprol (2,3-dimercapto-1-propanol [British anti-Lewisite, BAL]) is the traditional chelating agent that has been used clinically in arsenic poisoning. In humans and animal models, the antidotal efficacy of BAL has been shown to be most effective when it was promptly administered (i.e., minutes to hours) after acute arsenic exposure [25]. In cases of suspected acute symptomatic intoxication, treatment should not be delayed while waiting for specific laboratory confirmation. BAL is administered parenterally as a deep intramuscular (IM) injection. The initial dose is 3 to 5 mg per kg every 4 hours, gradually tapering to every 12 hours during the next several days. As the patient improves, this may be switched to 2,3-dimercaptosuccinic acid (DMSA; succimer) (see section "Lead" of this chapter). In the United States, DMSA is available only in an oral formulation. This precludes its use in acute severe arsenic intoxication when shock, vomiting, gastroenteritis, and splanchnic edema limit GI absorption. For patients with stable GI and cardiovascular status, a dose regimen of 10 mg per kg every 8 hours for 5 days, reduced to every 12 hours for another 2 weeks, may be employed. d-Penicillamine has also been reported to be successful adjunct treatment in cases of acute pediatric arsenic toxicity [26]. Oral d-penicillamine, 25 mg per kg every 6 hours (maximum of 1 g per day), should be used if BAL or DMSA is unavailable or if the patient is unable to tolerate these medications. Disadvantages in using d-penicillamine include that it is administered only by the oral route, it is usually not well tolerated, it should be used with caution in patients who are allergic to penicillin, and it entails potential enhanced absorption of arsenic–chelate complex. Adverse drug events associated with long-term d-penicillamine treatment include fever, pruritus, leukopenia, thrombocytopenia, eosinophilia, and renal toxicity. A complete blood count and renal function tests should be monitored weekly during d-penicillamine therapy.

BAL and its metal chelate dissociate in an acid medium and maintenance of an alkaline urine may protect the kidneys during chelation therapy [27]. BAL should be administered with caution in patients with glucose-6-phosphate dehydrogenase deficiency because it may cause hemolysis. The adverse drug events of BAL appear to be dose dependent, with an incidence of greater than 50% at a dose of 5 mg per kg [28]. The reported adverse drug events include pain at the injection site; systolic and diastolic hypertension with tachycardia; nausea; vomiting; headache; burning or constricting sensation in the mouth, throat, and eyes; lacrimation; salivation; rhinorrhea; muscle aches; tingling of the extremities; pain in the teeth; sense of constriction in the chest; abdominal pain; sterile or pyogenic abscesses at the site of injection; and a feeling of anxiety or unrest. In addition to these adverse drug events, a febrile reaction may occur in children. These signs and symptoms are most severe within 30 minutes after administration of BAL and usually dissipate within 1 to 1.5 hours. The adverse drug events may be lessened by the use of epinephrine or by pretreatment with antihistamine or ephedrine [28].

The therapeutic end points of chelation are poorly defined. Usually 24-hour urinary arsenic excretion is followed before, during, and after chelation with continued chelation therapy until the urinary arsenic excretion is less than 25 µg per 24 hours. Alternatively, when it can be demonstrated that more than 90% of the total arsenic excreted in the urine is in the form of MMA and DMA, endogenous biomethylation and detoxification may obviate the need for continued chelation [5]. This is likely to occur during the recovery period when urinary inorganic arsenic concentration has declined to less than 100 µg per 24 hours or total blood arsenic concentration is less than 200 µg per L [5].

Chelation therapy may not reverse neuropathy [12–14,29]. Early treatment may prevent incipient peripheral neuropathy in some, but not all, patients. However, the value of chelation in the treatment of an established arsenic neuropathy has not been demonstrated. In cases of chronic symptomatic arsenic intoxication with high urinary arsenic excretion, an empiric course of chelation may be warranted.

ARSINE GAS

Arsine (AsH_3) is a colorless, nonirritating, inflammable gas with a garlicky odor. It is considered to be the most toxic of the arsenic compounds. The garlic-like odor is not a reliable indicator of exposure as hazardous effects may occur below the odor threshold [30]. Exposure usually occurs in industrial/occupational settings, such as smelting and refining of metals and ores, galvanizing, soldering, etching, lead plating, metallurgy, burning fossil fuels, and the microelectronic/semiconductor industry [31]. (Computer chips made of gallium arsenide are etched with strong acids.)

Pharmacology

Arsine binds to red blood cells (RBCs) causing a rapid and severe Coombs' negative hemolytic anemia. The exact mechanism by which arsine is lytic to the RBC has not been definitively elucidated [31,32]. In vitro and animal studies indicate that hemolysis requires the presence of oxygen, there is a reduction in the RBCs' glutathione concentration, which is time- and concentration dependent on arsine gas exposure, and there is an inverse correlation between the reduced glutathione concentration and the extent of hemolysis. These findings are consistent with a mechanism of oxidative stress-induced damages to the RBCs, resulting in hemolysis.

Toxic concentrations of arsine appear to have deleterious effect on the kidneys. Acute renal failure was often a common cause of death prior to advent of hemodialysis [31,33,34]. Postulated mechanisms of arsine-induced renal failure include direct toxic effects of arsine on renal tubular cell respiration, hypoxia due to the hemolytic anemia, and the massive release of the "arsenic–hemoglobin–haptoglobin complex" precipitating in the tubular lumen, resulting in a toxic effect on the nephron [35]. Depending on the severity, renal failure may be evident by 72 hours from the time of exposure [31].

Clinical Toxicity

The severity and time to manifestation of arsine poisoning depend on the concentration and duration of the exposure. After an acute massive exposure, death may occur without the classic signs and symptoms of arsine poisoning. It is believed that after low-concentration exposures, arsine is rapidly and efficiently cleared from plasma into the RBCs. However, high concentrations of arsine may exceed the binding capacity of the erythrocytes, and the gas may directly damage vital organs. In cases in which signs and symptoms of arsine poisoning develop over time, the associated morbidity and mortality is partly related to the consequences of its hematologic and renal effects. In general, after a significant exposure to arsine, there is usually

a delay of 2 to 24 hours before symptoms of arsine poisoning become apparent [31].

Initial complaints include dizziness, malaise, weakness, dyspnea, nausea, vomiting, diarrhea, headache, and abdominal pain [31,36]. Dark-red discoloration of the urine, hemoglobinuria, and/or hematuria frequently appear 4 to 12 hours after inhalation of arsine. Depending on the severity of the exposure, reddish staining of the conjunctiva and duskily bronzed skin may become apparent within 12 to 48 hours [36]. However, the sensitivity of this sign is unclear. The conjunctival and skin discoloration is due to the presence of hemoglobin. This should be distinguished from true jaundice due to the presence of bilirubin. The triad of abdominal pain, hematuria, and bronze-tinted skin is recognized as a characteristic clinical feature of arsine poisoning [31].

In one study, ECG changes associated with arsine poisoning included peaked T waves, particularly in the precordial leads [30]. The most pronounced T-wave changes occurred between the second and the twelfth day after exposure. The severity of illness did not correlate with the height of the T wave. There was no delay in atrioventricular or intraventricular conduction times. There was progressive normalization of the T-wave amplitude evident on the weekly follow-up ECG. The exact cause of the ECG change remains speculative.

Management

All patients hospitalized for arsine poisoning should be admitted in the ICU. The management of arsine poisoning should be directed at preventing further exposure to the gas, restoring the intravascular RBC concentration, monitoring the serum potassium, preventing further renal insult, and providing aggressive supportive care. In cases of acute and severe arsine poisoning, exchange transfusion or plasma exchange may be an efficient and effective means of management [31,34,37]. It is important to maintain good urine output (2 to 3 mL per kg per hour) at all times. Alkalinization of the urine has been recommended to prevent deposition of RBC breakdown products in the kidneys. In situations in which there is evidence of renal insufficiency or failure, both exchange transfusion and hemodialysis may be required. There are practical and theoretic considerations for using exchange transfusion. It restores the intravascular RBC concentration and removes erythrocyte debris and arsenic–hemoglobin complexes [34]. Hemolysis due to arsine poisoning can be a dynamic process; there is one report of ongoing hemolysis for at least 4 days in patients not selected for exchange transfusion [38]. Theoretic support for the use of exchange transfusion came from animal studies where a large proportion of the fixed arsenic in the blood of animals poisoned with arsine was in a nondialyzable form, and adequate removal of arsine and its associated toxic complexes would be a problem with hemodialysis alone. It has been suggested that with early diagnosis of arsine poisoning and prompt institution of exchange transfusion, the incidence of renal damage and long-term renal insufficiency may be reduced [33,38].

The results of using BAL in the treatment of acute arsine poisoning have been disappointing [36,39]. BAL does not appear to afford protection against arsine-induced hemolysis. It remains speculative whether BAL would be of benefit in subacute or chronic arsine poisoning [31].

LEAD

The use of lead and its environmental contamination has increased dramatically since the beginning of the Industrial Revolution. However, for the past 20 years, environmental and occupational exposure to lead as well as the severity of lead poisoning have decreased because of government regulations and increased public health awareness of the problems associated with lead, especially at low-concentration exposures.

The major environmental sources of lead include vehicle exhaust, paint, food, and water. Combustion of leaded gasoline by motor vehicles produced lead in automobile emissions, which is the main source of airborne lead. Airborne lead can be inhaled directly or deposited in the environment (soil, water, and crops). The content of lead in residential paint was not regulated until 1977. More than half of the older residential and commercial structures built prior to 1960 have been painted with lead-based paints. With time, flaking, chipping, peeling, and chalking of the paint occurs—a potential source of lead exposure. Industrial use of corrosion-resistant lead paint continues. High-concentration exposure may result from renovation, sandblasting, torching, or demolition of older applications. Food may contain lead that has been deposited in the soil or water. Food may be contaminated with lead when it is harvested, transported, processed, packaged, and prepared. Lead exposure may occur from use of lead-glazed pottery or ceramic ware for cooking and eating as well as from the consumption of food from lead-soldered cans. Water from leaded pipes, soldered plumbing, and water coolers is also a potential source of lead exposure. Some traditional Hispanic, Asian, and Middle Eastern folk medicine has been shown to contain significant amounts of lead. Mexican folk remedies, "azarcon" and "greta," are prescribed by the local folk healers (curanderos) to treat nonspecific GI symptoms collectively known as "empacho." Azarcon is a bright-orange powder and greta is a fine yellowish powder. Other names such as alarcon, coral, liga, Maria Luisa, and rueda have been given to these lead-containing folk remedies. In Asian communities, lead-containing folk remedies include bali goli, chuifong tokuwan, ghasard, knadu, payloo-ah, and Po Ying Tan. Middle Eastern lead-containing folk medicines include alkohl, cebagin, kohl, saoott, and surma.

The most significant way in which children are exposed to lead is through inhalation and ingestion. Children can ingest chips from lead-painted surfaces, or by mouthing items contaminated with lead from dust, soil, or paint. Some children are given folk remedies containing large quantities of lead. Another potential source of lead exposure in children is the preparation of infant formulas in vessels with lead solder.

Aside from the environmental sources, lead exposure in adults primarily comes from the occupational setting, particularly for electricians; cable splicers; plumbers; lead, copper, zinc, and silver miners; printers; lead smelters and refiners; steel welders and cutters; painters; auto repairers (radiator repair mechanics); sandblasting, demolition, and construction workers; battery manufacturers; solderers; bricklayers; silversmiths; glass manufacturers; and ship builders. One source of lead exposure that is not often considered is retained lead bullets, especially those that are near synovial surfaces.

Hobbies and related activities such as home remodeling, target shooting at indoor firing ranges, stained glass making, glazed pottery making, lead soldering, and making illicitly distilled whiskey ("moonshine") can potentially subject adults and their families to high concentrations of lead.

Pharmacology

In adults, about 10% of an ingested dose is absorbed, whereas in children, up to 50% may be absorbed. GI absorption may be increased by iron or calcium deficiency and varies directly with the solubility of the lead compound ingested and inversely with particle size. The oral dose associated with the lowest observable effect level in humans is uncertain. Acute human ingestion of 15 g of lead oxide has resulted in fatality.

Inhalation of lead is a significant route of exposure as lead particles (e.g., dust) and fumes can potentially reach the alveoli, where absorption from the lower respiratory tract is nearly complete. Airborne lead particles are usually too large to enter the alveoli of small children. These particles (when inhaled) are returned to the posterior pharynx through ciliary action and swallowed. Dermal absorption of lead is rapid and extensive for alkyl lead compounds, but minimal for inorganic lead.

After absorption, almost all lead in the blood is located within the RBCs [40]. RBC lead has a half-life of 30 to 40 days and is circulated and distributed into soft tissues and bones. The half-life of lead in the soft tissues is about 40 days, whereas the half-life in bones is 20 to 30 years. Hence, blood lead concentration may be declining as the soft tissue and bone burdens are rising. Equilibration between bone and blood lead does occur. The major depot for lead in the body is the skeletal system, which contains more than 90% in adults and more than 70% in children, in terms of the total body lead burden [41]. The primary sources of lead that cause clinical and subclinical symptoms are the blood and soft tissues. Lead that is deposited and incorporated into the matrix of bone can be mobilized during pregnancy, lactation, osteoporosis, and prolonged immobilization [42]. In addition, lead that is deposited in bone may have some toxic effects on bone growth and function.

The kidneys filter lead unchanged (with some active tubular transport at high concentrations), and the excretion rate depends on the glomerular filtration rate and renal blood flow. The kidneys account for about 75% of daily lead loss [40]. However, elimination of lead from the body is influenced by the relative concentration of lead in the various body compartments.

Common forms of inorganic lead are generally devoid of significant irritant or corrosive effects. However, alkyl lead compounds may be moderately irritating. The multisystemic toxicity of lead is mediated by at least two primary mechanisms: the inhibition of enzymatic processes, sometimes as a result of sulfhydryl group binding, and interaction with essential cations, in particular calcium, zinc, and ferrous iron. Pathologic alterations in cellular and mitochondrial membranes, neurotransmitter biosynthesis and function, heme biosynthesis, and nucleotide metabolism may also occur.

One of the principal toxic effects of lead is inhibition of enzymes along the heme biosynthesis pathway. Specifically, lead inhibits the enzymes δ-aminolevulinic acid (ALA) dehydrase and ferrochelatase. As a result, δ-ALA cannot be converted to porphobilinogen and iron cannot be incorporated into protoporphyrin IX. This is reflected by a measurable increase in serum ALA and protoporphyrin concentrations. The increase in protoporphyrin forms the basis of the erythrocyte protoporphyrin (EP) test, which has been used to screen for chronic lead exposure. Lead also inhibits the nonenzymatic mobilization of iron stores, which further contributes to the effect of anemia. Impaired heme biosynthesis may have widespread effects because of its impact on the cytochrome systems. In addition, lead appears to shorten erythrocyte survival time by interfering with the sodium-potassium–adenosine triphosphatase pump mechanism and by attaching to RBC membranes, causing increased mechanical fragility and cell lysis. Decreased heme synthesis and increased RBC destruction results in reticulocytosis. Inhibition of pyrimidine-5′-nucleotidase by lead results in accumulation of ribonucleic acid degradation products and aggregation of ribosomes in RBCs, which produce punctate basophilic stippling. However, neither anemia nor basophilic stippling is a sensitive or specific indicator of lead intoxication. Lead-induced anemia results from either a prolonged exposure or a concentrated short-term exposure with a latent period of several weeks.

Lead toxicity produces anatomic lesions in the proximal tubule and loops of Henle, which is characterized by round acidophilic intranuclear inclusion bodies. Most often, lead-induced renal injury is associated with prolonged exposure to large amounts of lead, resulting in progressive renal insufficiency.

The toxic effects of lead involve both the peripheral nervous system and the central nervous system (CNS). Peripheral nervous system toxicity is known as lead palsy and is due to the degenerative changes in the motoneurons and their axons, with secondary effects involving the myelin sheaths [43]. Lead palsy is usually a pure motor neuropathy and is the result of advanced chronic lead poisoning. Both adults and children can present with CNS dysfunction; however, children are the ones who present with encephalopathy [44,45]. Although lead encephalopathy is rare today, it is the most serious consequence of lead poisoning and is probably due to inhibition of the intracellular enzyme systems within the CNS.

Clinical Toxicity

Poisoning is usually the result of continued exposure to small amounts of lead rather than a single acute event. However, acute ingestion can produce lead toxicity [44, 46]. Usually the clinical presentation of acute lead toxicity appears to be associated with a sharp incremental rise in the concentration of lead in various soft tissues, and this often occurs against the background of chronic lead poisoning.

The multisystemic toxicity of lead presents a spectrum of clinical findings ranging from overt, life-threatening intoxication to subtle, subclinical deficits. Acute ingestion of very large quantities of lead (gram quantities) may cause abdominal pain, toxic hepatitis, and anemia (usually hemolytic).

Subacute or chronic exposure causes nonspecific constitutional symptoms such as fatigue, arthralgias, decreased libido, irritability, impotence, depression, anorexia, malaise, myalgias, weight loss, and insomnia [47]. GI symptoms include nausea, constipation or diarrhea, and intestinal spasm. The intestinal spasm, "lead colic," can cause severe, excruciating, paroxysmal, abdominal pain. CNS findings range from impaired concentration, visual–motor coordination, and headache, to severe, life-threatening encephalopathy characterized by vomiting, tremors, hyperirritability, ataxia, confusion, delirium, lethargy, obtundation, convulsions, coma, and death. A peripheral motor neuropathy, predominantly affecting the upper extremities, may result in extensor weakness. In rare instances, severe cases may produce frank "wrist drop." Decreased intelligence, impaired neurobehavioral development, decreased stature or growth, and diminished auditory acuity may occur. Hematologic manifestations include normochromic or microcytic anemia. This may be accompanied by basophilic stippling of the erythrocytes. Nephrotoxic effects include overt reversible acute tubular dysfunction, in particular, Fanconi-like aminoaciduria in children, and chronic progressive renal interstitial fibrosis following heavy long-term exposure in lead workers. Sometimes hyperuricemia, with or without evidence of gout, may be associated with the renal insufficiency [48]. An association between lead exposure and hypertension may exist in susceptible populations.

Repeated, intentional inhalation of leaded gasoline may result in ataxia, myoclonic jerking, hyperreflexia, delirium, and seizures.

Diagnostic Evaluation

Although encephalopathy and abdominal colic following a suspect activity may readily suggest the diagnosis of severe lead intoxication, the nonspecific nature of mild-to-moderate intoxication frequently presents a diagnostic challenge.

Exposure is often not suspected, and symptoms are commonly attributed to a "nonspecific viral illness." Lead intoxication should be considered in patients presenting with multisystem findings including headache, abdominal pain, and anemia, and less commonly, motor neuropathy, gout, and renal insufficiency. Lead encephalopathy should be considered in any child with delirium or seizures, and milder degrees of intoxication should be considered in children with neurobehavioral deficits or developmental delays. Lead encephalopathy has usually been associated with blood lead concentrations of 100 µg per dL or more [49]. Blood lead concentrations greater than 80 µg per dL are occasionally associated with acute severe illness.

Whole blood lead concentration and EP are the two methods most commonly used in testing for lead intoxication. Whole blood lead concentration is the most useful screening and diagnostic test for acute or recent lead exposure. This test does not measure total body lead burden, but it does reflect abrupt changes in lead exposure. Elevation in EP (> 35 µg per dL) reflects lead-induced inhibition of heme biosynthesis. Because only actively forming erythrocytes are affected, elevations in EP will typically lag behind lead exposure by 2 to 6 weeks. EP value may help distinguish between recent and remote lead exposure. An extremely high whole blood lead concentration in the presence of a normal EP concentration would suggest a recent lead exposure. An elevated EP concentration is not specific for lead exposure, and may also occur with iron deficiency. EP is not a sensitive screening tool for low-concentration (< 30 µg per dL) lead poisoning. EP and blood lead concentrations should be used as complementary methods of testing for lead intoxication.

EP, free EP, and zinc EP measure the same basic process and have very similar interpretations, but are not identical. EP is the most precise terminology. Because lead blocks (ferrochelatase) the final step in heme biosynthesis, it was originally thought that "free" EP was formed. However, it was subsequently shown that other porphyrins were measured in minute amounts, and most protoporphyrin had nonenzymatically bound zinc and was therefore not "free" [50].

Relationships between blood lead concentrations and clinical findings have generally been based on subacute and chronic exposure, and not on transiently high values that may result immediately following exposure prior to tissue equilibration (Table 133.2). Interindividual variability in response is extensive.

Measurement of urinary lead excretion is not very useful in the diagnosis of lead exposure. Urinary lead excretion reflects the plasma lead concentration, which increases and decreases more rapidly than blood lead concentration.

Nonspecific laboratory criteria consistent with lead toxicity include normochromic or microcytic anemia, basophilic stippling of RBC on peripheral smear, increased urinary ALA, and coproporphyrin. Liver transaminases may be elevated in acute intoxication. Low-molecular-weight proteinuria and enzymuria may precede elevations in serum creatinine. Radiopacities on abdominal radiograph may be evidence of lead in the GI tract following recent ingestion. This is especially true for lead-based ceramic glazes [46].

Management

Acute lead encephalopathy is a medical emergency that requires intensive care and monitoring of the patient. Prompt consultation with a toxicologist should be obtained to assist in the management. Because up to 25% of the children who survive an acute episode of encephalopathy sustain permanent CNS damage [49], medical treatment should be instituted before its onset. It has long been recommended that any child who is symptomatic from lead poisoning or has a whole blood lead concentration greater than 80 µg per dL should be hospitalized immediately and treated as a medical emergency [49]. More recently, the Centers for Disease Control has issued a statement that children with blood lead concentrations of 70 µg per dL or greater require immediate chelation therapy [51].

Although present-day recommendations for the treatment of lead encephalopathy were derived from experiences in managing children [49,52–54], they have been extrapolated to adults. The basic treatment plan consists of supportive measures and the use of chelating agents. As with any potential life-threatening emergency, assessment and aggressive management of the airway, breathing, and circulation should be paramount.

GI decontamination, beginning with gastric lavage, is indicated following acute ingestion of virtually any lead-containing substances because even small quantities of paint chip or a sip of lead-containing glaze may contain several hundred milligrams of lead. The use of activated charcoal has been suggested; however, its efficacy is unknown. Abdominal radiograph may reveal radiopaque foreign bodies in the GI tract following recent ingestion of lead-containing substances such as paint chips, lead weights, and lead-based ceramic glazes [46]. WBI with polyethylene glycol solution has been suggested as a means of decontaminating the GI tract when the presence of lead is evident on radiographic examination of the abdomen [46]. The effectiveness of WBI can be followed by serial abdominal radiographs. Although it is important to eliminate the source of continued lead absorption, therapy should not be delayed by attempts at GI decontamination, especially in cases

TABLE 133.2

WHOLE BLOOD LEAD CONCENTRATION AND ASSOCIATED CLINICAL FINDINGS

Whole blood lead concentration (µg/dL)	Associated clinical findings
< 25	Decreased intelligence and impaired neurobehavioral development among children with in utero or early childhood exposure; generally without demonstrable toxic effects in adults
20–60	Mild overt effects such as headache, irritability, difficulty concentrating, slowed reaction time, and impaired visual–motor coordination, and insomnia may emerge
	Anemia may begin to appear
	Reversible, subclinical slowing of motor nerve conduction velocity may be detected
60–80	Subclinical effects on renal function
	GI symptoms (e.g., anorexia, constipation, and/or diarrhea, and abdominal colic) may emerge
> 80	Serious overt intoxication, including abdominal pain (colic), and nephropathy
> 100	Encephalopathy and overt neuropathy

of encephalopathy. Ultimately, the chief priority is to identify and eradicate the source of lead exposure and institute control measures to prevent repeated intoxication. In addition, other possibly exposed persons should be promptly evaluated.

Lead-containing buckshot, shrapnel, or bullets in or adjacent to synovial spaces should be surgically removed if possible, especially if associated with evidence of systemic lead absorption.

In a child presenting with encephalopathy, immediate treatment should begin with establishing an adequate urine output [49]. This can be accomplished by intravenous (IV) infusion (10 to 20 mL per kg) of 10% dextrose in water during 1 to 2 hours. If this fails to produce a urine output, infusion of a 20% mannitol solution (1 to 2 g per kg) is recommended at 1 mL per minute. Once urine output has been established, IV fluids should be restricted to the calculated basal water and electrolyte requirements plus a careful assessment of continuing losses. An indwelling Foley catheter should be used to monitor the rate of urine formation. IV fluids should be adjusted hourly in order to maintain urine flow that is within the basal metabolic limits, which is 0.35 to 0.50 mL of urine secreted per calorie metabolized per 24 hours or 350 to 500 mL per m^2 per 24 hours. Such management is designed to avoid excessive fluid administration and prevent further development of cerebral edema. Severe lead encephalopathy can occur without cerebral edema [52]. However, when cerebral edema occurs in the presence of encephalopathy, there is further insult to the brain, and it may be the immediate cause of death. Children with encephalopathy may exhibit syndrome of inappropriate antidiuretic hormone [54].

Benzodiazepines should be used for immediate control of seizures. If paralysis with sedation or general anesthesia is required for controlling seizure activities, a bedside electroencephalogram should be obtained to rule out electrical status. Because high doses of phenytoin and phenobarbital were required to control the initial seizures in lead encephalopathy, paraldehyde was formerly used [54]. However, barbiturates were recommended in the prevention of seizures during the early convalescent phase of lead encephalopathy [49]. Repeated seizures and hypoxia can exacerbate cerebral edema [49,54], so it was suggested that anticonvulsants be administered when there is evidence of increased muscle tone or muscle twitching; one should not wait for obvious seizure activity [49].

Computed tomography scan of the head should be performed in patients presenting with encephalopathy to rule out cerebral edema. If there is evidence of cerebral edema, intracranial pressure (ICP) monitoring should be performed (with neurosurgical consultation) to assist with the management of the patient. Avoid performing a lumbar puncture when there is increased ICP associated with cerebral edema. Measures advocated to control cerebral edema and increased ICP include careful sedation and neuromuscular paralysis, elevation of the head of the bed, hyperventilation, restriction of fluid therapy, ventricular drainage, diuretics (e.g., mannitol or furosemide), and steroids. These measures are "borrowed" from the neurosurgical experience in managing increased ICP. Restriction of fluids and the use of mannitol have been discussed previously. Maintaining the arterial partial pressure of carbon dioxide between 25 and 30 mm Hg by controlled hyperventilation has been shown to result in cerebral vasoconstriction and reduced ICP. The benefit of glucocorticoids in treating perifocal vasogenic edema due to an intrinsic intracranial mass lesion is well established. However, glucocorticoids have not been proved beneficial in models of intracellular cytotoxic edema, and neurologic outcome studies do not support the routine use of glucocorticoids following head injury, global brain ischemia, and cerebral vascular accidents [55]. If the cerebral edema associated with lead encephalopathy is believed to be vasogenic in origin, the empiric use of dexamethasone should be considered. Surgical attempts to relieve ICP by flap craniotomy have not been shown to be beneficial [56]. However, ventricular drainage (via the intracranial bolt placed for ICP monitoring) may effectively reduce a rising ICP.

Chelating agents have been shown to decrease blood lead concentrations and increase urinary lead excretion. Chelation has also been associated with improvement in symptoms and decreased mortality. However, controlled clinical trials demonstrating therapeutic efficacy is lacking, and treatment recommendations have been largely empiric. Although there appears to have been a sharp reduction in pediatric mortality due to acute lead encephalopathy with the advent of chelation treatment, there were concomitant advances in the management of elevated ICP, and the decline in mortality cannot necessarily be attributed to the use of chelation alone. BAL and calcium disodium edetate (CaEDTA) are the two chelators used in the treatment of lead encephalopathy. DMSA is used for less severe poisoning.

BAL increases both fecal and urinary excretion of lead. It is distributed widely throughout all body tissues, including the brain and RBCs. Because BAL is excreted in the urine and to some extent in the bile, patients with renal failure are not precluded from the use of BAL, whereas patients with hepatic insufficiency may have a lower tolerance to BAL [57]. Details regarding the use of this agent are discussed in section "Arsenic" of this chapter. BAL and medicinal iron can form a toxic complex that is a potent emetic, but the treatment of anemia with iron should be delayed until BAL therapy has been completed. If severe anemia requires prompt intervention during chelation therapy, transfusion would be preferable.

CaEDTA enhances the elimination of lead and, to a lesser extent, the elimination of endogenous metals (e.g., zinc, manganese, iron, and copper). Increased urinary lead excretion begins within 1 hour and is followed by a decrease in whole blood lead concentration over the course of treatment. CaEDTA diffuses rapidly and uniformly throughout the body, but it does not appear to enter RBCs and very slowly diffuses across the blood–brain barrier [58]. CaEDTA mobilizes lead (primarily) from soft tissues and from a fraction of the larger lead stores present in bone. CaEDTA is not metabolized; rather, it is cleared from the body by urinary excretion. It can be administered IV or IM, with the former being the preferred and most effective route. Oral administration of CaEDTA has been known to increase absorption of lead from the GI tract; therefore, it should not be given by this route. The principal toxic effect of CaEDTA is on the kidneys, which can result in renal tubular necrosis [59]. The renal toxicity is dose related and reversible. Because CaEDTA increases renal excretion of lead and its accumulation increases the risk of nephrotoxicity, anuria would be a contraindication in its use. An adequate urine flow should be established before initiating CaEDTA therapy.

In the management of patients with lead encephalopathy, some clinicians would advocate the use of BAL and CaEDTA beginning with a priming dose of BAL at the same time that an adequate urine output is being established. The priming dose of BAL is 75 mg per m^2 (3 to 5 mg per kg) IM and is administered every 4 hours. After 4 hours have elapsed since the priming dose of BAL, a continuous slow IV infusion of CaEDTA 1,500 mg per m^2 per day (30 mg per kg per day) is started. In cases where there is evidence of cerebral edema and/or increased ICP associated with encephalopathy, CaEDTA (same dosage) should be given by deep IM injection in two to three divided doses every 8 to 12 hours. When the IM route is preferred, procaine (0.5%) should be given along with CaEDTA because IM administration of CaEDTA is extremely painful. BAL and CaEDTA are usually continued for 5 days. In patients with high body lead burdens, cessation of chelation is often followed by a rebound in blood lead concentration as bone stores equilibrate with lower soft-tissue concentrations.

A second course of chelation may be considered on the basis of whole blood lead concentration after 2 days of interruption of BAL and CaEDTA treatment, and the persistence or recurrence of symptoms. A third course may be required if the whole blood concentration rebounds to 50 µg per dL or greater within 48 hours after the second chelation treatment. If chelation is required for the third time, it should begin a week after the last dose of BAL and CaEDTA.

In the management of symptomatic patients with lead poisoning who are not overtly encephalopathic, most clinicians would advocate the same course of treatment as for those with encephalopathy, but with lower doses of BAL and CaEDTA. The priming dose of BAL is 50 mg per m^2 (2 to 3 mg per kg) IM and is administered every 4 hours. After 4 hours have elapsed since the priming dose of BAL, a continuous slow IV infusion of CaEDTA 1,000 mg per m^2 per day (20 to 30 mg per kg per day) is started. Alternatively, CaEDTA may be given in two to three divided doses every 8 to 12 hours by continuous infusion or deep IM injection. BAL and CaEDTA should be continued for 5 days with daily monitoring of whole blood lead concentrations. BAL may be discontinued any time during these 5 days if the whole blood lead concentration decreases to less than 50 µg per dL, but CaEDTA treatment should continue for 5 days. A second or third course of chelation may be considered on the basis of the same guidelines as discussed in the previous paragraph.

In the management of asymptomatic patients with whole blood lead concentrations 70 g per dL or greater, some clinicians would advocate the use of BAL and CaEDTA in the same doses and with the same guidelines as for treatment of symptomatic lead poisoning without encephalopathy. A second course of chelation with CaEDTA alone may be necessary if the whole blood lead concentration rebounds to 50 µg per dL or more within 5 to 7 days after chelation has ceased. Some clinicians prefer DMSA.

A water-soluble analogue of BAL, DMSA enhances the urinary excretion of lead, mercury, and arsenic. It has an insignificant effect on elimination of the endogenous minerals calcium, iron, and magnesium. Minor increases in zinc and copper excretion may occur. Oral DMSA is rapidly but variably absorbed, with peak blood concentrations occurring between 1 and 2 hours. The drug is predominantly cleared by the kidneys, with peak urinary elimination of the parent drug and its metabolites occurring between 2 and 4 hours. DMSA is approved for use in lead and mercury intoxications, in which it is associated with increased urinary excretion of the metals, and concurrent reversal of metal-induced enzyme inhibition. Oral DMSA is comparable to parenteral CaEDTA in decreasing whole blood lead concentration during treatment. Although treatment with DMSA has been associated with subjective clinical improvement, controlled clinical trials demonstrating therapeutic efficacy have not been reported. Reported adverse drug events of DMSA include GI disturbances (anorexia, nausea, vomiting, and diarrhea), mercaptan-like (sulfur) odor to the urine, rashes, mild-to-moderate neutropenia, and mild, reversible increases in hepatic transaminases.

Although DMSA is officially approved for use only in children with whole blood concentration in excess of 45 µg per dL, it has similar ability to lower whole blood lead concentration in adults. Treatment is initiated at an oral dose of 10 mg per kg (350 mg per m^2) every 8 hours for 5 days. Treatment is then continued at the same dose every 12 hours for an additional 2 weeks. An additional course of treatment may be considered on the basis of posttreatment whole blood lead concentrations and the persistence or recurrence of symptoms. Whole blood lead concentration may decline by more than 50% during treatment, but patients with large body burdens may experience rebound to within 20% of pretreatment concentrations as bone body stores reequilibrate with tissue concentrations. An interval of 2 or more weeks may be indicated to assess the extent of posttreatment rebound in whole blood lead concentration. Experience with oral DMSA in severe lead intoxication (e.g., lead encephalopathy or lead colic) is very limited, and consideration should be given to parenteral chelation therapy in such cases.

MERCURY

Mercury (Hg) is a naturally occurring metal that is mined chiefly as mercuric sulfate (HgS) in cinnabar ore. It is converted into three primary forms, each with a distinct toxicology: elemental (Hg^0) mercury, inorganic (mercurous [Hg^{+1}] and mercuric [Hg^{2+}]) mercury salts, and organic (alkyl and phenyl) mercury. The pattern and severity of toxicity are highly dependent on the form of mercury and route of exposure, mostly because of different pharmacokinetic profiles.

Elemental Mercury

Elemental mercury is the only metal that exists in liquid form at standard temperature and pressure. As such, metallic mercury can evaporate slowly at room temperature or rapidly when heated, and can contribute to the partial pressure of the ambient air that is breathed. A small spill in an enclosed space (e.g., a bedroom) can also produce high concentrations of mercury in the air because of its high vapor pressure. Various instruments contain elemental mercury including thermometers, manometers, barometers, switches, pumps, and special surgical tubes (such as Miller-Abbott, Canter, and Kaslow). Dental amalgam is prepared with elemental mercury and contains approximately 50% elemental mercury by weight.

Personnel in occupational settings who are potentially exposed include chlor-alkali mercury cell operation workers, electroplaters, explosives manufacturers, laboratory personnel, pesticide/fungicide production and application workers, manufacturers of batteries or mercury vapor lamps, metallurgists, and miners and processors of cinnabar, gold, silver, copper, and zinc. Exposure to mercury vapor from elemental mercury spill, work hazard, home gold ore purification, accidental heating of metallic mercury, and vacuum cleanup of a mercury spill have also been reported [60].

Pharmacology

When ingested, elemental mercury is poorly absorbed (< 0.01%) from the healthy, intact, and normal-functioning GI tract. In contrast, inhaled mercury vapor is believed to cross the alveolar membranes rapidly because of its high diffusibility and high lipid solubility. About 75% of the inhaled dose is retained [61]. The absorbed elemental mercury vapor rapidly diffuses into the RBCs, where it undergoes oxidation to the mercuric ion and binds to ligands in the RBC. However, a certain amount of the dissolved vapor persists in the plasma to reach the blood–brain barrier, which it crosses readily [62]. Once in the brain tissue, the dissolved mercury vapor is oxidized to mercuric ion, trapping it within the CNS, where it is available for binding tissue ligands. Elemental mercury vapor is also easily transported across the placenta [63].

Elemental mercury vapor is eliminated from the body mainly as mercuric ion by urinary and fecal routes. Exhalation of mercury vapor and secretion of mercuric ions in saliva and sweat do occur and contribute to the elimination process. The rate of excretion is dose dependent. Elemental mercury follows a biphasic elimination rate, initially rapid and then slow, with a biologic half-life in humans of about 60 days.

Mercuric ion has an affinity to bind and react with sulfhydryl moieties of proteins, leading to nonspecific inhibition of enzyme systems and pathologic alteration of cellular membranes.

The pulmonary and central nervous systems bear the brunt of the insult in elemental mercury vapor poisoning. Damage to the respiratory system results from acute inhalation exposure to high concentrations of elemental mercury vapor, which acts as a direct airway irritant and a cellular poison [60,64]. Pulmonary toxicity is characterized by exudative alveolar and interstitial edema, erosive bronchitis and bronchiolitis with interstitial pneumonitis, and desquamation of the bronchial epithelium. The ensuing obstruction results in alveolar dilatation, interstitial emphysema, pneumatocele formation, pneumothorax, and mediastinal emphysema.

In the CNS, a cumulative toxic effect occurs as the inhaled elemental mercury vapor is oxidized to mercuric ion, leading to progressive CNS dysfunction. As would be expected, CNS toxicity is typically the result of chronic elemental mercury vapor exposure.

Clinical Toxicity

The ingestion of elemental mercury usually causes no adverse effects [65]. However, systemic absorption of mercury is possible in the presence of any bowel abnormality affecting mucosal integrity or impeding normal motility and transit. In addition, inflammatory bowel disease or enteric fistula allowing for prolonged elemental mercury exposure and the conversion of metallic mercury to an inorganic absorbable ion has been reported [66]. Elemental mercury that is retained in the appendix can result in local inflammation, perforation, and the consequent possibility of systemic mercury intoxication. Signs of appendiceal inflammation or systemic mercury absorption and toxicity should be appropriately monitored and treated. Prophylactic appendectomy in the absence of signs and symptoms of appendicitis should be avoided because of the risk of mercury extravasation through the surgical anastomosis and intra-abdominal suppurative complications [67].

Subcutaneous injection of elemental mercury may cause a local fibrous reaction, local abscess, granuloma formation, and systemic embolization, and systemic absorption with toxic manifestations has been reported [68,69].

IV injected elemental mercury has been reported to cause pulmonary and systemic mercury embolization, associated with an elevated blood mercury concentration, and sequelae may include tremor, lower extremity weakness, and reduced carbon monoxide diffusing capacity [68,70,71]. Mercury extravasation at the injection site can produce a severe local inflammatory reaction. Granuloma formation with fibrosis and inflammation with systemic mercury absorption has also been reported.

Acute intense inhalation of mercury vapor in a confined or poorly ventilated space may result in death. Initial symptoms usually occur within several hours following exposure and include fever, chills, headache, dyspnea, gingivostomatitis, nausea, vomiting, metallic taste in the mouth, paroxysmal cough, tachypnea, chest tightness, diarrhea, and abdominal cramps [64]. These symptoms may subside or, in severe cases, may progress to interstitial pneumonitis, bilateral infiltrates, atelectasis, noncardiogenic pulmonary edema, interstitial pulmonary fibrosis, and death [64]. In addition, complications such as subcutaneous emphysema, pneumomediastinum, and pneumothorax may occur. Children younger than 30 months seem to be particularly susceptible to such exposures [72].

Aspiration of elemental mercury may cause no acute respiratory symptoms, cough and mild dyspnea, acute pneumonitis, or progressive cough with copious amounts of frankly bloody sputum production, leading to respiratory compromise and death [73]. Most patients remain asymptomatic or recover without any significant sequelae. In two cases, systemic absorption of the aspirated elemental mercury was suggested by elevations in the 24-hour urinary mercury concentrations, but neither patient became symptomatic. Elemental mercury was consistently evident on chest radiographs obtained on follow-up examination, which varied from 1 month to 20 years. One case with postmortem findings from the lungs 22 years later included globules of elemental mercury surrounded by extensive fibrosis and granuloma formation. Subclinical changes in peripheral nerve function and renal function have been reported, but symptomatic neuropathy and nephropathy are rare.

Diagnostic Evaluation

Diagnosis depends on integration of characteristic findings with a history of known or potential exposure, and the presence of elevated whole blood mercury concentration and urinary mercury excretion. Abdominal radiographs may be used to document the extent of the GI contamination following elemental mercury ingestion. Radiographs of the injection site may help to define the extent of the infiltrated mercury. Chest radiograph and computed axial tomography scan may be useful in determining the location of systemic embolization.

Whole blood and urinary mercury concentrations are useful in confirming exposure. In most people without occupational exposure, whole blood mercury concentration is less than 2 µg per dL and "spot" or single-voided urine mercury concentration is less than 10 µg per L. A quantitative 24-hour urinary mercury excretion, usually less than 50 µg per 24 hours, is probably the most useful tool in diagnosing acute exposure (Table 133.3).

Management

Any patient requiring hospitalization because of acute elemental mercury inhalation or aspiration should be admitted to the ICU. As with any potential life-threatening emergency, assessment and aggressive management of the airway, breathing, and circulation should be paramount. Treatment is primarily supportive. Another priority is to identify and eradicate the source of elemental mercury exposure and to identify and evaluate other possibly exposed persons.

In cases in which elemental mercury ingestion has been documented, WBI with polyethylene glycol electrolyte solution or surgical removal may be necessary, depending on radiographic evidence of mercury retention, elevated blood urine mercury concentrations, and the patient's clinical status. Repeat abdominal radiographs may be used to document the effectiveness of WBI or to follow the progress of the ingested metallic mercury.

Aggressive local wound management of the injection site(s) should include prompt excision of all readily accessible

TABLE 133.3

ELEMENTAL MERCURY VAPOR EXPOSURE

Urine mercury concentration (µg/L)	Associated clinical findings
30–50	Subclinical neuropsychiatric effects
50–100	Early subclinical tremor
> 100	Overt neuropsychiatric disturbances
> 200	True tremors

subcutaneous areas in which metallic mercury is demonstrated, copious saline irrigation to remove metallic mercury droplets, and suction removal of the mercury [74]. Surgical excision of mercury granulomas has also been recommended [68]. Injection of dimercaprol BAL into the wound is not recommended as it may delay wound healing [75].

Patients acutely exposed to elemental mercury vapor should be monitored closely for respiratory symptoms. Chest radiographs, arterial blood gases, and pulmonary function should be followed in symptomatic patients. Oxygen and bronchodilators should be administered as needed. Progressive deterioration of respiratory function may require aggressive airway management with tracheal intubation, mechanical ventilation, and positive end-expiratory pressure. Early treatment with corticosteroids has been used in an attempt to reduce the complication of pulmonary fibrosis. However, neither corticosteroids nor prophylactic antibiotics have proved to be beneficial in the management of elemental mercury vapor-induced pulmonary complications.

Patients who have aspirated elemental mercury should be managed in a similar fashion. Vigorous suctioning, postural drainage, and good pulmonary toilet may assist the patient in expectorating some of the aspirated mercury. In addition, bronchoscopy may be indicated.

Chelating agents that are commercially available in the United States for use in the treatment of mercury poisoning include BAL, DMSA, and d-penicillamine (see sections "Arsenic" and "Lead" of this chapter). The choice of chelator depends on the form of mercury involved and the presenting signs and symptoms of the patient. DMSA and d-penicillamine may facilitate the absorption of mercury from the GI tract and should not be given when there is still evidence of mercury present in the gut. Because animal studies show that BAL may redistribute mercury to the brain from other tissue sites [76–78] and the brain is a target organ in elemental mercury poisoning, it would seem prudent not to use BAL for the treatment of inhalational exposures. DMSA appears to be associated with fever adverse events and more efficient mercury excretion when compared with d-penicillamine and is preferred for mercury vapor poisoning. DMSA may enhance urinary mercury excretion and reduce nephrotoxicity after GI absorption of elemental mercury [79]. The initial recommended dose of DMSA is 10 mg per kg every 8 hours, tapering to every 12 hours during the next several days. DMSA can be administered via nasogastric tube in severe poisoning cases in which endotracheal intubation is required.

The therapeutic end points of chelation are poorly defined. Probably the only objective measurable effectiveness of chelation therapy is enhanced urinary excretion of mercury. A potential end point for chelation may be when the patient's urinary mercury concentration approaches normal. Although the use of chelators is recommended to increase excretion and relieve target organs of metal burden, the use of BAL has not been proved to affect the course of elemental mercury-induced respiratory failure, and the effect of DMSA on clinical outcome has not yet been fully studied.

There is no role for multiple-dose activated charcoal, hemoperfusion, or hemodialysis in removing elemental mercury.

Inorganic Mercury

Acute inorganic mercury poisoning is usually the result of intentional or accidental ingestion. Most of the literature on inorganic mercury poisoning deals with mercuric chloride (mercuric bichloride [$HgCl_2$]), with the lethal adult dose estimated to be between 1 and 4 g.

Mercurials are available in medications (antiparasitic, antihelminthic, vermifuge, antiseptic, antipruritic, and disinfectant), paints, stool fixatives, permanent-wave solutions, teething powder, button batteries, fungicides/biocides, folk remedies (Mexican-American treatments for "empacho," a chronic stomach ailment; Asian, particularly Chinese, herbal or patent medications), and occult practices (Latin American and Caribbean natives). Although mercurial medications have largely been replaced by less toxic drugs, topical antiseptics containing mercury are still being used.

Pharmacology

Absorption of inorganic mercury salt from the GI tract is probably dose dependent. After absorption, the salt dissociates into the ionic form and is initially distributed between RBCs and plasma. Distribution of mercury within the body and within the organs varies widely. It has been demonstrated by animal autoradiographic study that mercuric ion is accumulated predominantly in the renal cortex [80]. Mercury ions do not appear to significantly cross the blood–brain barrier or the placental barrier. However, on the basis of the autoradiographic study, the brain does take up mercury slowly and retains it for a relatively longer period of time [80]. Mercury ions are eliminated from the body mainly by the urinary and fecal routes. The rate of excretion is dose dependent. Inorganic mercury follows a biphasic elimination rate, initially rapid and then slow, with a biologic half-life of about 60 days in humans.

Mercury ions have an affinity to bind and react with sulfhydryl moieties of proteins, leading to nonspecific inhibition of enzyme systems and pathologic alteration of cellular membranes. In addition, inorganic mercurials are highly corrosive substances.

The target organs of inorganic mercury poisoning are the GI tract and kidneys. The caustic property of the inorganic mercurials could potentially cause damage throughout GI tract, including corrosive stomatitis, necrotizing esophagitis, gastritis, and ulcerative colitis. A report of postmortem examination of patients who died within 48 hours postingestion showed severe hemorrhagic necrosis of the upper GI wall [81]. Nephrotoxicity following inorganic mercury poisoning from acute tubular necrosis of the distal portions of the proximal convoluted tubules resulted in acute oliguric renal failure and uremia [81,82]. The CNS is usually spared because only small amounts of mercuric ion can cross the blood–brain barrier. However, cases of CNS toxicity have been described with chronic mercury ingestion.

Clinical Toxicity

The clinical effects of acute inorganic mercury poisoning can be divided into the initial local corrosive effect on the GI tract followed by the injury that occurs at the site of excretion, which is the kidneys.

Inorganic mercury is a highly caustic substance. Depending on the amount ingested, the GI symptoms that follow may vary from mild gastritis to severe necrotizing ulceration of the intestinal mucosa, which can be fatal within a few hours [83]. Ingestion of 100 mg of inorganic mercury has been reported to be associated with a bitter metallic taste in the mouth, a sense of constriction about the throat, substernal burning, gastritis, abdominal pains, nausea, and vomiting [82]. A serious acute inorganic mercury ingestion may cause the abrupt onset of hematemesis, hemorrhagic gastroenteritis, and abdominal pain. Intestinal necrosis may ensue. In addition, massive bleeding from the colon has been reported to occur as late as 8 to 9 days postingestion [81]. Most of the bleeding came from the

rectum, which was the most severely involved section of the colon. Such injuries to the GI tract can lead to massive fluid, electrolyte, and blood loss, resulting in shock and death.

Acute inorganic mercury ingestion may lead to acute oliguric renal failure because of acute tubular necrosis. Invariably, those patients who develop renal involvement initially have severe GI symptoms [83]. Typically, oliguric renal failure occurs within 72 hours postingestion, and as such, the initial GI symptoms may be resolving while renal toxicity may not yet be [81,83]. Spontaneous resolution of acute toxic anuria with renal tubular regeneration may be expected to occur between 8 to 12 days [84], with clinical recovery (if it occurs) between 9 and 14 days [81,83]. Chronic exposure may result in CNS toxicity.

Diagnostic Evaluation

Diagnosis depends on integration of characteristic findings with a history of known or potential exposure and presence of elevated whole blood mercury concentration and urinary mercury excretion. Inorganic mercury may be visualized on an abdominal radiograph as radiopaque foreign bodies in the GI tract. A positive radiograph would support the diagnosis, but a negative one would not exclude it.

Whole blood and urinary mercury concentrations (see section "Elemental Mercury" of this chapter) are useful in confirming exposure. Whole blood mercury concentration greater than 50 µg per dL in acute inorganic mercury poisoning is often associated with gastroenteritis and acute renal tubular necrosis.

Management

General management considerations are the same as for elemental mercury poisoning. In patients with acute ingestion, GI decontamination should be performed as soon as possible to minimize absorption and decrease the corrosive effect of the ingested inorganic salt. As with the ingestion of any corrosive substance, inducing emesis is to be discouraged. Elective tracheal intubation may be prudent prior to attempting GI decontamination. Gastric lavage should be performed with caution as the GI tract may have already been severely damaged. Endoscopy is recommended if corrosive injury (drooling, dysphagia, and abdominal pain) is suspected. Although theoretically reasonable but not rigorously studied, the use of a protein gastric lavage solution (1 pint of skim milk with 50 g of glucose, 20 g of sodium bicarbonate, and three eggs beaten into a mixture) to bind the mercury has been suggested, along with rinsing the stomach with egg white or concentrated human albumin after the lavage [82]. Activated charcoal may be considered as 1 g of charcoal is capable of binding 850 mg of mercuric chloride [82].

In cases in which there is radiographic evidence of radiopaque foreign bodies in the GI tract and if there is no evidence of gastroenteritis, WBI with polyethylene glycol electrolyte solution should be considered. Repeat abdominal radiographs may be used to document the effectiveness of WBI.

GI injury may result in severe fluid, electrolyte, and blood loss, and attention should be given to monitoring the patient's volume status. Replace intravascular and GI losses by the appropriate administration of crystalloid, colloid, and blood product. An indwelling Foley catheter should be placed to carefully monitor the urine output, which should be maintained at 2 to 3 mL per kg per hour. It is important to distinguish between oliguria due to inadequate volume resuscitation and oliguria due to toxic nephropathy resulting in renal failure. Invasive hemodynamic monitoring may be necessary.

It should be remembered that inorganic mercury is a highly corrosive substance. Aggressive surgical intervention may be required in cases in which there is severe gastric necrosis or when hemorrhagic ulcerative colitis becomes life threatening [81,85]. It has been suggested that the rectum should be resected at the time of colectomy when it is indicated for controlling hemorrhage from the colon [81].

BAL and DMSA (see sections "Arsenic" and "Lead" of this chapter) are the chelating agents of choice. The effectiveness of BAL depends on the promptness of its administration and the administration of an adequate dose. BAL is most effective if given within 4 hours of ingestion [86]. Prompt intervention is paramount in reducing renal injury, so expedient chelation therapy would be prudent in suspected cases of acute inorganic mercury poisoning. Chelation should not be withheld while waiting for laboratory confirmation of mercury poisoning. DMSA is also effective, but the capacity of the GI tract to absorb orally administered DMSA may be very much impaired in cases of severe inorganic mercury poisoning when hemorrhagic gastroenteritis, hemodynamic instability, and splanchnic edema are present. Once the GI and cardiovascular status has been stabilized, chelation with DMSA may be substituted for BAL.

Once renal damaged has occurred from inorganic mercury poisoning, therapy should be directed at the acute renal failure that may ensue. Hemodialysis should be used to support the patient through the oliguric or anuric renal failure period. A potential problem arises with continued BAL therapy in patients who develop renal insufficiency because the kidneys are one of the main routes by which BAL-Hg is eliminated. In such circumstances, BAL therapy may be judiciously continued as there is some evidence from animal studies that a significant fraction of BAL-Hg is also excreted in the bile. Some studies indicate that hemodialysis may contribute to the elimination of BAL-Hg in patients with renal failure [87–89]. In a patient who has renal failure but is otherwise stable and has a functional GI tract, DMSA may be an alternative to BAL.

Organic Mercury

The organomercurials are compounds in which the mercury atom is joined to a carbon atom via a covalent bond. It is the relative stability of this covalent bond that determines the toxicology of the organic mercury compounds. The organomercurials can be classified as short-chain alkyl (methyl-, ethyl-, and propylmercury), long-chain alkyl, and aryl (phenyl) mercury compounds. In general, the short-chain alkyl group, particularly methylmercury, is considered the most toxic. Acute ingestion of 10 to 60 mg per kg of methylmercury may be lethal, and chronic daily ingestion of 10 µg per kg may be associated with adverse neurologic and reproductive effects.

Potential sources of exposure to organic mercury include herbicide, fungicide, germicide, and timber preservative. In the general population, the major source of exposure to methylmercury is through the consumption of predacious fish (e.g., pike, tuna, and swordfish). Major incidents of human poisoning with methylmercury have occurred (Minamata and Iraq epidemics) with devastating outcomes.

Pharmacology

Organic mercury antiseptics undergo limited skin penetration; however, in rare cases, such as topical application to an infected omphalocele, dermal absorption can occur.

Methylmercury is well absorbed after inhalation, ingestion, and probably dermal exposure. It is widely distributed throughout the body [90]. In the blood, more than 90% is found in the

RBCs, with whole blood-to-plasma ratios of 200:1 to 300:1 [91]. Methylmercury is present in the body as water-soluble complexes mainly attached to thiol ligands and is highly mobile. It enters the endothelial cells of the blood–brain barrier as a specific complex with l-cysteine. This l-complex is structurally similar to the large neutral amino acid l-methionine and carried across the cell membrane on the large neutral amino acid carrier [92]. Methylmercury is transported out of mammalian cells as a complex with reduced glutathione and is secreted into bile as a glutathione complex. The glutathione moiety is degraded in the bile duct and gallbladder and finally to the l-cysteine complex. It is reabsorbed and returned to the liver, thereby completing the enterohepatic cycle [93–95]. In humans, about 10% of the body's methylmercury burden is in the CNS and the biologic half-life of methylmercury is 45 to 70 days [96]. Methylmercury readily passes the blood–brain barrier as well as the placenta barrier [97]. In animal studies, the dissociation between the carbon and mercury bond of methylmercury is very slow [91], and phenylmercury undergoes rapid breakdown to inorganic mercury within 24 hours [90,98]. In humans, the major route of excretion of methylmercury is in the feces, with less than 10% appearing in the urine [99]. Extensive enterohepatic recirculation in the GI tract has been demonstrated to occur with methylmercury [100].

Mercury has an affinity to bind and react with sulfhydryl moieties of proteins, leading to nonspecific inhibition of enzyme systems and pathologic alteration of cellular membranes. The CNS is particularly vulnerable to the toxic effects of methylmercury and is a potent teratogen and reproductive toxin. Methylmercury has been shown to alter brain ornithine decarboxylase, an enzyme associated with cellular maturity, and neurotransmitter uptake at the pre- and postsynaptic adrenergic receptor sites [101].

Clinical Toxicity

Most of the detailed information regarding toxicity has been derived from methylmercury poisoning cases. Methylmercury is a cumulative poison, primarily affecting the CNS. There does not appear to be a distinct difference between acute and chronic methylmercury poisoning. Following acute methylmercury intoxication, symptoms are usually delayed for several weeks or months. The classic triad of methylmercury poisoning is dysarthria, ataxia, and constricted visual fields [102]. Other signs and symptoms include paresthesias, hearing impairment, progressive incoordination, loss of voluntary movement, and mental retardation. Perinatal exposure to methylmercury has caused mental retardation and a cerebral palsy type of syndrome in offspring. Ethylmercury compounds may also cause gastroenteritis. Phenylmercury compounds produce a pattern of toxicity intermediate between alkyl and inorganic mercury.

Diagnostic Evaluation

Diagnosis depends on integration of characteristic findings with a history of known or potential exposure, and presence of elevated whole blood mercury concentration, which may reflect recent exposure. Whole blood mercury concentrations greater than 20 µg per dL have been associated with symptoms. Hair concentrations have been used to document remote exposure. Urinary mercury concentrations are not useful.

Management

General management considerations are the same as for elemental mercury poisoning. Following acute ingestion of organic mercurials, gastric lavage should be performed. Administration of activated charcoal may be of benefit. A successful way to increase the rate of methylmercury excretion is to introduce a nonabsorbable mercury-binding substance (polythiol resin) into the GI tract so as to interrupt the enterohepatic recirculation of methylmercury [103,104]. Repeated oral administration of a polythiol resin in methylmercury intoxication may be beneficial.

Limited data suggest that oral neostigmine may improve motor strength in patients with moderate-to-severe chronic methylmercury intoxication [104]. DMSA is the preferred chelating agent. BAL has been ineffective in treating neurologic symptoms because of methylmercury poisoning [105]. In addition, animal studies show that BAL may redistribute mercury to the brain from other tissue sites [76–78]. In contrast, DMSA was effective in reducing the brain concentration of methylmercury [106], and DMSA prevented the development of cerebellar damage in methylmercury-poisoned animals [107]. However, in humans, the effect of DMSA on clinical outcome has not yet been fully studied.

Hemodialysis is of little value because methylmercury has a large volume of distribution, and a considerable amount of methylmercury resides within the RBCs.

CHAPTER 134 ■ HYDROCARBON POISONING

WILLIAM J. LEWANDER AND ALFRED ALEGUAS JR

Hydrocarbons are a group of organic compounds composed primarily of hydrogen and carbon. Although often mixtures, hydrocarbons may be divided into four basic types: aliphatic, halogenated, aromatic, and terpene.

Hydrocarbon exposures are frequent and account for an inordinate number of health care visits and hospital admissions. The American Association of Poison Control Centers reported 54,766 hydrocarbon exposures in 2007 [1,2]. Twenty-two percent were seen in a health care facility, and there were seven deaths. Nearly 32% of total exposures occurred in children younger than 6 years of age and involved ingestions, and most of these were accidental.

Storage in unmarked, readily accessible containers and an attractive color or aroma account for the high percentage of exposures in young children. In adolescents and adults, poisoning generally results from inhalational abuse, occupational exposure, intentional ingestion, or accidental aspiration during the siphoning of fuels. Cutaneous and even intravenous exposures have also been described. Ingestions in adults usually involve larger volumes, and there is a much greater likelihood of other coingested drugs or toxins. The majority of deaths are due to intentional inhalation abuse.

ALIPHATIC HYDROCARBONS

Aliphatic hydrocarbons, known as petroleum distillates, are straight-chain compounds produced from the fractional distillation of natural petroleum (Table 134.1). They are the most common cause of hydrocarbon poisoning.

After ingestion, the major toxicity of petroleum distillates is their potential to cause a fulminant, and sometimes fatal, chemical pneumonitis. Aspiration of even small amounts may produce severe pulmonary toxicity. Although vomiting often precedes and precipitates aspiration, lack of vomiting does not preclude the possibility that aspiration has occurred. Little or no systemic toxicity occurs even with intragastric administration of large doses (12 to 18 mL per kg) [3,4].

The risk of aspiration increases with low viscosity, low surface tension, and high volatility. Viscosity, the tendency to resist flow, is the most important property determining aspiration potential [5]. Substances with low viscosity (e.g., gasoline, mineral seal oil, and kerosene) have a high aspiration potential, whereas those with high viscosity (e.g., mineral oil and fuel oil) have a low potential for aspiration. Reduced surface tension may also allow a substance to spread rapidly from the upper gastrointestinal (GI) tract to the trachea. High volatility (tendency of a liquid to become a gas) increases the likelihood of pulmonary absorption.

Aspirated petroleum distillates inhibit surfactant, resulting in alveolar collapse, ventilation–perfusion mismatch, and subsequent hypoxemia. In addition, bronchospasm and direct capillary damage lead to a chemical pneumonitis and hemorrhagic bronchitis–alveolitis [2,5,6]. In animals exposed to kerosene, acute alveolitis peaked at 3 days and resolved by 10 days [7]. Histologically, a chronic proliferative process occurred, peaking at 10 days and resolving over several weeks. When highly viscous petroleum distillates are aspirated, a less inflammatory but more localized and indolent lipoid pneumonia may occur [8].

TABLE 134.1

COMMON PETROLEUM DISTILLATES

Product	Synonym	Main use
Gasoline	Petroleum spirits	Fuel
Petroleum naphtha fluid	Ligroin	Cigarette lighter
VM and P naphtha thinner	Varnish naphtha	Paint or varnish
Mineral spirits	Painter's naphtha	Dry cleaner
	Stoddard solvent	Solvent
	White spirits	Paint thinner
	Varsol	
	Mineral turpentine	
	Petroleum spirits	
Kerosene fluid	Coal oil	Charcoal lighter
		Solvent
		Fuel for stoves, lamps
Fuel oil	Home heating oil	Fuel
Diesel oil	Gas oil	Furniture polish

Central nervous system (CNS) manifestations result principally from hypoxia and acidosis caused by pulmonary toxicity [9]. Although systemic toxicity is uncommon, it may be seen if the petroleum distillate is a vehicle for more toxic substances (e.g., heavy metal and pesticide), if it contains additives, or if a concomitant or massive ingestion has occurred [10]. Cardiovascular, hepatic, renal, and hematologic toxicities depend on the specific toxic substance involved.

Use of aliphatic hydrocarbons as volatile substances of abuse (VSA) is a serious and growing problem. It is most often seen in adolescents who use VSA as an easily available, legal, and affordable substitute for other intoxicants [11,12]. The most common aliphatic VSA are *n*-hexane, *n*-butane, isobutane, and propane—seen in adhesives, aerosols, liquefied petroleum gas (i.e., cigarette lighter refills and camp stoves), and gasoline. Inhalation may involve sniffing, "huffing" (spraying the solvent onto a cloth held to the mouth and nose), "bagging" (spraying the solvent into a paper or plastic bag and repeatedly inhaling the vapors), or a variant of these techniques [11]. These highly lipid-soluble substances are rapidly absorbed through the lungs and distributed to the CNS and fatty tissues [13]. The onset of symptoms occurs in seconds to minutes, with peak effects occurring somewhat later due to slower diffusion into tissues. Elimination of aliphatic hydrocarbon VSA is primarily by pulmonary excretion, and successive oxidation and metabolism by hepatic cytochrome P450 mixed-function oxidases [13].

Aliphatic VSA toxicity includes acute and chronic neurologic dysfunction; asphyxia; cardiovascular abnormalities; and pulmonary, GI, and cutaneous irritation. CNS toxicity ranges from stimulation at initial or low doses to a depressant effect, with general inhibition of cortical function at high doses [14]. Peripheral neuropathy and irreversible CNS damage have been reported [15–18]. Inhaled aliphatic hydrocarbons are asphyxiants (as well as pulmonary irritants) and may cause hypoxemia by decreasing the concentration of oxygen in inspired air. Their arrhythmogenic effects are thought to be due to their potentiation of endogenous catecholamines ("cardiac sensitization"), which may promote dysrhythmias (e.g., ventricular tachycardia or fibrillation) [19]. Additional factors such as hypoxia, acidosis, electrolyte abnormalities, and underlying cardiac conditions may contribute to arrhythmias. Dermal and mucosal irritation is due to their ability to dissolve lipids after prolonged or high-dose exposure [20]. Deaths associated with inhalational abuse may result from coma with respiratory depression, aspiration, or injuries incurred while intoxicated as well as from cardiac arrhythmias [21].

Clinical Manifestations

The clinical course after the ingestion of petroleum distillates primarily depends on the presence or absence of concomitant aspiration and its severity. Patients who aspirate generally demonstrate symptoms within 30 minutes; those who do not have symptoms within 6 hours of exposure remain asymptomatic [22]. Presenting signs and symptoms usually involve three main organ systems: pulmonary, CNS, and GI. Cardiovascular, renal, hematologic, and cutaneous toxicity have also been reported [23,24]. In most cases, symptoms resolve during the next 2 to 5 days with supportive care [22,25].

Initial coughing, gasping, and choking may progress and peak during the first 24 to 48 hours to tachypnea with grunting respirations, nasal flaring, retractions, and cyanosis [10,22]. The odor of petroleum distillates may be apparent on the breath. Wheezing, rhonchi, and rales may be heard on auscultation. In severe cases, pulmonary edema and hemoptysis occur. Arterial blood gases may demonstrate hypoxemia from ventilation–perfusion mismatch and early hypocarbia, which progresses to hypercarbia and acidosis. Abnormalities on chest radiographs occur in up to 75% of hospitalized patients, appearing within 2 hours in 88% of patients and by 12 hours in 98% [10,26], but may be delayed up to 72 hours. Early radiographic abnormalities include unilateral, but more commonly bilateral, basilar infiltrates and fine punctate perihilar densities. Localized areas of atelectasis are often present, whereas pleural effusions, pneumatoceles, and pneumothoraces occur infrequently [25,26]. Pneumatoceles generally occur 3 to 15 days after ingestion and resolve during 15 days to 21 months [2,27]. Radiographic findings correlate poorly with clinical symptoms and may persist for several days to weeks after symptoms have resolved [25–27]. Asymptomatic patients may have abnormal chest radiographs, whereas symptomatic patients may have minimal or no radiographic abnormalities early in the course [10].

Within the first 24 to 48 hours, fever (38°C to 39°C) and leukocytosis are common [22]. The persistence of fever beyond 48 hours suggests bacterial superinfection.

CNS involvement may occur in those with aspiration-induced hypoxemia, large intentional ingestions, or ingestions of mixtures that contain other toxic agents (e.g., aromatic hydrocarbons). Symptoms range from dizziness and lethargy (91%) to somnolence (5%) and, rarely, coma (3%) and convulsions (1%) [10,28]. The severity of CNS dysfunction often correlates with the severity of aspiration.

GI symptoms, such as local irritation of the oropharynx (e.g., burning), nausea, vomiting, and abdominal pain, are commonly reported. Hematemesis and melena occur rarely [10]. Vomiting appears to increase the likelihood of aspiration [25,29]. Cardiovascular toxicity is uncommon, but dysrhythmias and sudden death after gasoline siphoning have been reported [30].

Inhalation abuse may result in a range of acute CNS manifestations, including dizziness, incoordination, restlessness, excitement, euphoria, confusion, hallucinations, slurred speech, and coma with respiratory depression [31]. Peripheral neuropathy has been reported after chronic exposure [15,16]. Pulmonary toxicity may present as respiratory distress with cyanosis, or syncope with tachycardia or bradycardia. GI irritation may cause nausea, vomiting, and abdominal pain. Dermatologic manifestations range from perioral frost or pigmentation (after direct inhalation from a container) to local skin irritation [10].

Cases of acute renal tubular necrosis [32,33], hemoglobinuria secondary to intravascular hemolysis [34,35], severe burns after prolonged immersion in gasoline [36], and supraglottitis [37] have been reported. Aliphatic hydrocarbons are highly flammable, especially gasoline, and accidental thermal burns may occur during recreational use [38]. Therefore, patients with unexplained burns should be questioned regarding possible inhalation abuse. Chronic gasoline inhalation may also be accompanied by organo-lead poisoning [20,21,39]. Parenteral administration of petroleum distillates has caused local cellulitis, thrombophlebitis, and necrotizing myositis, with resultant compartment syndromes. Associated systemic effects include febrile reactions, hemorrhagic pneumonitis, pulmonary edema, seizures, and CNS depression [23,40,41].

Diagnostic Evaluation

After ingestion, diagnostic evaluation includes a thorough history (e.g., identity, amount, and concentration of toxin; time of ingestion; and symptoms before presentation at health care facility) and a physical examination (focusing on vital signs and the respiratory, CNS, and GI systems). Pulse oximetry should be monitored and a chest radiograph obtained in all symptomatic patients and in cases in which aspiration is suspected.

In symptomatic patients or those who have ingested concomitant toxins or toxic additives, laboratory evaluation should include an arterial blood gas determination; complete blood cell count; electrolyte, blood urea nitrogen, creatinine, and glucose measurements; liver function tests; and urinalysis.

Management

Patients with ingestions who remain or become asymptomatic with a normal chest radiograph (obtained 2 hours or more after exposure) may be discharged after 6 hours of observation. All symptomatic patients, those with abnormal chest radiographs, arterial blood gases, or pulse oximetry, and patients with suicidal intent should be hospitalized. Gastric decontamination is not recommended in petroleum distillate ingestion because absorption and systemic toxicity are minimal, and spontaneous or induced vomiting increases the risk of aspiration and pneumonitis [28,42]. Gastric decontamination is recommended only if potentially toxic amounts of aromatic or halogenated hydrocarbons, pesticides, heavy metals, or other substances have been ingested. Ipecac syrup is not recommended for GI decontamination. Patients who are unconscious, unable to protect the airway (e.g., poor or absent gag reflex), or deteriorating should be intubated with a cuffed endotracheal tube (in patients older than 6 years of age) and then have gastric aspiration or lavage performed. Activated charcoal and cathartic are indicated only if a toxic additive is present or concomitant ingestion has occurred. If cutaneous exposure has occurred, contaminated clothing should be removed and the skin thoroughly washed with soap and water [10].

All patients with respiratory symptoms should be given oxygen, placed on a cardiac monitor, and have intravenous access established. An arterial blood gas determination and chest radiograph should be obtained. The need for intubation should be based on clinical assessment of respiratory distress and objective data from arterial blood gases or pulse oximetry. Chest radiographs do not always correlate with clinical status and should not be used as the sole determinant for respiratory interventions. Continuous positive airway pressure may be necessary to maintain oxygenation, but the patient should be carefully monitored for the development of a pneumothorax. Bronchospasm should be treated with β_2-agonist bronchodilators because of potential myocardial sensitization to catecholamines [43].

Supportive care of pneumonitis includes careful monitoring of acid–base, fluid, and electrolyte balance (e.g., cautious hydration to avoid pulmonary edema), serial arterial blood gases or pulse oximetry, and chest radiograph evaluation. Complete blood cell counts with differential, serial sputum, or tracheal aspirate Grams stains and cultures assist in determining if bacterial superinfection has occurred. Baseline renal and liver function studies and a toxic screen should be obtained if toxic additives or concomitant ingestion is suspected. Animal and clinical investigations have failed to demonstrate any beneficial effect of steroid treatment [44,45]. Two animal studies indicate that they may be harmful [46–48]. In addition, prophylactic antibiotics have not been shown to be helpful [42,45,46]. Fever and leukocytosis secondary to chemical pneumonitis are common during the first 24 to 48 hours in the absence of superimposed bacterial pneumonia [10]. Antibiotics (e.g., penicillin or clindamycin) should be given only to patients with documented bacterial pneumonias (e.g., Grams stain or culture of sputum or tracheal aspirate) or worsening chest radiograph, leukocytosis, and fever after the first 40 hours [10]. Successful use of high-frequency jet ventilation and extracorporeal membrane oxygenation for the treatment of respiratory failure has been reported [49–51]. Other measures such as cardiopulmonary bypass, partial liquid fluorocarbon ventilation, and exogenous surfactant have been suggested for refractory cases, but the data to support their use are limited. [52,53].

Most patients with petroleum distillate poisoning recover fully with supportive care. Because minor pulmonary function abnormalities have been detected in as many as 82% of patients with aspiration pneumonitis who subsequently become asymptomatic [54], follow-up care with pulmonary function testing should be considered. When appropriate, the patient should receive psychiatric evaluation and poison-prevention education before final disposition.

HALOGENATED HYDROCARBONS

Halogenated hydrocarbons are aliphatic and aromatic derivatives that contain one or more atoms of chlorine, bromine, fluorine, or iodine. Although dozens of halogenated hydrocarbons are currently recognized, relatively few account for the majority of the toxic exposures. Like the aliphatic agents, halogenated hydrocarbons pose an aspiration risk. However, they are more readily absorbed from the GI tract and can cause systemic toxicity, most notably of the CNS, cardiovascular system, and hepatic and renal systems.

Halogenated hydrocarbons are used in the household and industry. They are frequently used as solvents, degreasers, dry-cleaning agents, refrigerants, aerosol propellants, and fumigants. Toxic exposures occur most commonly through inhalation, and several halogenated hydrocarbons (e.g., trichloroethylene, methylene chloride, and fluorocarbons) are intentionally inhaled for recreational purposes [55]. Bagging and huffing have been associated with a number of solvent-abuse deaths.

After absorption from the GI tract and occasionally through the skin, halogenated hydrocarbons are concentrated in adipose tissue, liver, and kidney. Metabolism and elimination vary according to the individual substance, with most undergoing at least some excretion through the lungs as unchanged parent compound and nearly all undergoing some degree of metabolism in the liver, with subsequent excretion of metabolites by the lungs and/or kidneys. Carbon tetrachloride (CCl_4), methylene chloride, and trichloroethane are prototypes of this class.

Carbon Tetrachloride

Previously used as a dry-cleaning agent and antihelminthic, CCl_4 is now restricted to industrial use, primarily in the production of refrigerants, aerosol propellants, and solvents. It is well absorbed through the skin [56], lungs, and GI tract, and it is concentrated in adipose tissue [57]. Approximately 50% of an absorbed dose is excreted unchanged by the lungs. Most of the remainder is metabolized by the liver to reactive intermediates or free radicals, or both, which covalently bind to proteins and induce lipid peroxidation, resulting in hepatocellular damage [58]. Ethanol, methanol, and isopropyl alcohol all increase CCl_4 hepatotoxicity, presumably through enzyme induction [59]. At lower doses, fatty degeneration of the liver occurs; at higher concentrations, centrilobular necrosis results [60]. In addition to hepatic damage, CCl_4 produces acute tubular necrosis of the kidney, affecting the proximal tubules and Henle's loop [61]. Although a direct nephrotoxic effect is likely [62], volume contraction may contribute to renal failure in some patients [63].

Inhalation exposure to CCl_4 may produce symptoms ranging from mild CNS depression to coma and death [64]. Although the estimated lethal dose of orally ingested CCl_4 is 90 to 100 mL, deaths have occasionally been reported after much smaller doses.

Nausea, vomiting, abdominal pain, diarrhea, drowsiness, and light-headedness usually occur within a few hours of exposure, regardless of route of exposure. Although liver enzymes may start to rise on the first day after exposure, clinical hepatotoxicity generally occurs on days 2 to 4, with fever, liver tenderness and enlargement, and jaundice [64]. Decline in renal function may occur concomitantly with hepatic dysfunction, although renal failure occasionally appears in the absence of hepatic failure [65]. Rarely, CCl_4 toxicity is accompanied by coma, convulsions, or myocarditis.

Early fatalities are the result of respiratory depression or cardiac dysrhythmias caused by cardiac sensitization to circulating catecholamines. Later deaths occur as the result of hepatic or renal failure, generally within the first week. In nonfatal cases, liver function tests generally return to normal within 2 weeks; recovery is usually complete.

Treatment initially involves stabilization and monitoring for respiratory depression and cardiac dysrhythmias. Exposure should be interrupted by removing victims of inhalation from the exposure site; in dermal exposures, contaminated clothing should be removed and the skin washed thoroughly. Patients who ingest more than 0.3 mL per kg should undergo gastric aspiration or lavage, preferably within 3 to 4 hours of ingestion [66]. Abdominal radiographs may be helpful in confirming suspected ingestions because CCl_4 is radiopaque [67]. There is no evidence regarding the use of activated charcoal in adsorbing CCl_4. Laboratory evaluation should include a complete blood cell count, routine serum chemistries, liver function tests, and urinalysis. Patients with respiratory symptoms or altered mental status should also be evaluated for possible aspiration pneumonitis, as described for aliphatic hydrocarbon exposures. Although CCl_4 appears not to be well removed by hemodialysis, dialysis may be required in cases of renal failure [68].

Animal studies suggest that hyperbaric oxygen may increase survival after intragastric administration of CCl_4 [69], although little human data exist on this topic [70,71]. Additional experimental work is being conducted to examine the utility of *N*-acetylcysteine in the reduction of CCl_4-induced hepatotoxicity. Because toxic intermediates of hepatic P450 are thought to be responsible for CCl_4 toxicity, it is thought that *N*-acetylcysteine may help prevent the development of liver failure [72,73]. Although human experience with this therapy is extremely limited in this setting and still considered experimental, a dosage schedule identical to that for acetaminophen is generally used.

Methylene Chloride

Methylene chloride is a colorless, volatile liquid commonly used as a solvent in aerosol products and as a degreaser and paint remover. It is well absorbed through the lungs and GI tract, but absorption through intact skin appears to be minimal. The majority of a dose is metabolized by the liver to carbon dioxide and carbon monoxide with small amounts exhaled unchanged [74].

The main toxicity of methylene chloride is CNS depression, which results from direct effects and from cellular asphyxia due to elevated levels of carboxyhemoglobin [75,76]. An 8-hour exposure to 250 ppm of methylene chloride resulted in carboxyhemoglobin fractions greater than 8% [77], and with large exposures, carboxyhemoglobin fractions up to 50% have been reported. In the few cases of methylene chloride ingestion that have been reported, CNS depression, tachypnea, and corrosive injury to the GI tract were the most common findings [78]. When the carboxyhemoglobin fraction is elevated, signs and symptoms of carbon monoxide poisoning may also be evident [79,80]. Nephrotoxicity and hepatotoxicity have also been reported [81,82].

Treatment involves stabilization, evaluation, and monitoring for aspiration, CNS and cardiovascular depression, dysrhythmias, corrosive injury, carbon monoxide poisoning, and hepatic and renal dysfunction. The patient should be removed from the source of inhalation exposure, and contaminated clothing should be removed. Exposed skin should be washed with soap and water. In cases of ingestion, gastric aspiration or lavage should be considered. The role of activated charcoal in methylene chloride ingestions is unclear [83]. In all cases, the carboxyhemoglobin fraction as well as complete blood cell count, routine serum chemistries, liver function tests, and urinalysis should be determined and supplemental oxygen provided.

Although hyperbaric oxygen is commonly used in cases of severe carbon monoxide poisoning, its role in methylene chloride toxicity is still being delineated [84,85]. It would appear reasonable to institute hyperbaric therapy when elevated carboxyhemoglobin levels are documented. Management is otherwise supportive.

Trichloroethane

1,1,1-Trichloroethane has been widely marketed as a safer alternative to CCl_4 for use as a cleaning agent and degreaser. It is also present in typewriter correction fluid and aerosol hairsprays, water repellents, and furniture polishes. In spite of its relative safety, death can occur, usually as a result of occupational or recreational inhalation exposure [86,87].

Trichloroethane is rapidly absorbed through the lungs and GI tract. Under most circumstances, significant cutaneous absorption is unlikely. Distribution is greatest to tissues with a high concentration of lipid, including the CNS. Most of an absorbed dose is excreted unchanged through the lungs, with smaller quantities metabolized in the liver and excreted by the kidneys [10].

Toxicity primarily involves the CNS, with signs and symptoms ranging from dizziness, headache, fatigue, and ataxia with mild-to-moderate exposures to seizures, coma, apnea, and death at higher vapor concentrations [88].

As with the aliphatic hydrocarbons, trichloroethane-induced cardiac sensitization to the effects of circulating catecholamines is thought to be responsible for sudden death associated with inhalational exposure [89,90]. Premature ventricular contractions and ST depression have been observed after acute inhalation [91], and myocarditis has been reported after chronic inhalation abuse [92]. Hepatic and renal toxicities are rare.

Management involves evaluation and treatment for aspiration, CNS and cardiovascular depression, and dysrhythmias. Decontamination measures may also be appropriate. In the absence of sudden death, recovery is generally rapid and complete.

AROMATIC HYDROCARBONS

Aromatic hydrocarbons contain one or more benzene rings. They include benzene, toluene, xylene, diphenyl, phenol, and styrene. Aromatic hydrocarbons are common constituents of glues, paints, paint removers, lacquers, degreasers, and adhesives. Although the aromatic hydrocarbons have aspiration risks similar to those of the other hydrocarbons, they also exhibit potentially severe systemic toxicity. Exposure is primarily through inhalation (occupational or abuse) or from ingestion. Benzene, toluene, and xylene are the three most commonly encountered agents.

Benzene

Benzene is a colorless liquid used widely in the chemical industry and less commonly as a solvent. It is well absorbed through the lungs and GI tract, but absorption through the skin is limited [93]. The lungs excrete up to 50% of an absorbed dose unchanged, whereas most of the remaining amount is metabolized by hepatic P450 enzymes to potentially cytotoxic metabolites [61,94]. Elimination of the parent compound and its metabolites generally occurs within 48 hours.

Benzene has acute and chronic toxicity [95]. Acute exposure primarily causes CNS depression [10]. Initial euphoria is rapidly followed by nausea, dizziness, and headache; subsequent progression to ataxia, seizures, and coma may occur. Persistent symptoms may include insomnia, anorexia, and headache.

Inhalation of high concentrations may lead to development of pulmonary edema; as with other hydrocarbons, aspiration and cardiac dysrhythmias may develop. Long-term exposure to benzene may result in a depression of bone marrow elements, which may progress to aplastic anemia [64,96]. Epidemiologic studies also suggest an increased risk of acute myelocytic and monocytic leukemia in workers with prolonged exposure to benzene [97,98].

Management should focus on stabilizing the patient and evaluation and monitoring for aspiration, CNS and cardiovascular depression, and dysrhythmias. It is generally agreed that amounts in excess of 1 to 2 mL per kg should be removed from the GI tract (via gastric aspiration or lavage), although some sources recommend removal of virtually any amount. The role of activated charcoal in this setting is unproved [10,99]. Subsequent therapy is supportive.

Toluene

Toluene is a colorless, volatile, sweet-smelling liquid that is a common ingredient in paints, paint thinners, lacquers, and glues (e.g., airplane model glue). Although toxicity may occur accidentally in industry or in the household, toluene is one of the most commonly abused solvents [100,101]. It is highly lipid soluble, and peak blood concentrations occur within 15 to 30 minutes with inhalation [64]. Animal studies suggest that ingested toluene is well absorbed from the GI tract, with 1 to 2 hours after exposure. Absorption through intact skin is slow.

Approximately 20% of an absorbed dose is exhaled unchanged. Most of the remainder is metabolized by the liver's cytochrome P450 system. Elimination is biphasic, with an initial alpha-phase having a half-life of 4 to 5 hours [102] and representing exhalation combined with distribution to fatty tissues [13]. The beta-phase has an apparent half-life of 15 to 20 hours and represents hepatic metabolism.

Toxic effects involve the CNS and peripheral nervous system as well as the kidney and heart [103]. Electrolyte and metabolic disturbances may also result. Acute exposure to toluene has variable effects on the CNS, depending on the concentration and duration of exposure [101,104,105]. Initially, toluene causes intoxication, which can progress to coma with prolonged exposure to high concentrations. Chronic abuse may also lead to persistent signs and symptoms of acute toxicity, including neuropsychiatric symptoms, weakness, nausea, vomiting, peripheral neuropathy, rhabdomyolysis [101], and abdominal pain [11]. Toluene toxicity is associated with a high incidence of renal dysfunction, particularly renal tubular acidosis (i.e., bicarbonate wasting) [101,106,107]. Laboratory findings include metabolic acidosis (with or without an increased anion gap), electrolyte disturbances (e.g., hypokalemia, hypocalcemia, hypophosphatemia, and hyperchloremia), and hematuria, proteinuria, and pyuria [106]. These abnormalities are the result of tubulointerstitial damage and are generally reversible on cessation of exposure. As with other hydrocarbons, acute toluene inhalation has also been associated with sudden cardiorespiratory arrest [108,109].

The diagnosis of toluene poisoning is generally made on the basis of the history, with known exposure or solvent abuse the prominent features. Toluene toxicity should also be considered in any individual with altered mental status and metabolic acidosis of unclear cause [110]. Management includes evaluation and treatment for aspiration; CNS and cardiovascular depression; dysrhythmias; renal dysfunction; fluid, electrolyte, and acid–base disturbances; and rhabdomyolysis. Laboratory testing should include calcium and phosphate levels. Gastric aspiration or lavage may be appropriate in cases of ingestion (with recognition of the aspiration risk).

Xylene

Xylene is a clear liquid that is widely used as a solvent in paints and lacquers, degreasers, adhesives, cleaning agents, and aviation fuel. It is rapidly absorbed by the pulmonary and GI systems and, to some extent, through the skin. The highest concentrations are found in the adrenal gland, bone marrow, spleen, brain, and blood [64]. Small amounts are excreted unchanged through the lungs; most of the remainder is metabolized in the liver and metabolites excreted in the urine. Ethanol consumption causes delays to metabolic clearance of xylene.

Xylene primarily affects the CNS [111]. As with other hydrocarbons, inhalation has been associated with sudden death, presumably secondary to cardiac dysrhythmia [112]. At low doses, headache, nausea, light-headedness, and ataxia may develop; at higher doses, confusion, coma, and respiratory depression may develop. Hepatic damage, Fanconi's syndrome, and pulmonary edema have also been described [112–114]. The evaluation and treatment of xylene exposure is similar to that described for other aromatic hydrocarbons.

TERPENES

Terpenes are aliphatic cyclic hydrocarbons. They include turpentine, pine oil, and camphor. Camphor is discussed elsewhere [10,115]. As its name suggests, pine oil is the product of pine trees and composed primarily of terpene alcohols. It is a component in household cleaners (e.g., Pine-Sol, Clorox Company, Oakland, CA), normally present in concentrations of 20% to 35%, but occasionally in concentrations exceeding 60%. Turpentine is a pine tree distillate commonly used as a solvent for paint and varnish.

Toxicity almost always results from ingestion. The aspiration risk appears to be somewhat less than that of other aliphatic hydrocarbons, presumably because of the lower volatility of terpenes; CNS and GI effects are more pronounced, however. Ingestions of more than 2 mL per kg of turpentine are considered potentially toxic [116]. Although 60 to 120 g of pine oil is commonly cited as the lethal dose in adults, survival has been reported after ingestion of 400 to 500 g [117]. The minimal lethal dose of pine oil reported in children is 14 g [118].

Turpentine is well absorbed through the lungs and GI tract [116] and distributed throughout the body, with highest concentrations in the liver, spleen, brain, and kidney [116]. Although the specifics of its metabolism are unclear, turpentine or its metabolites are largely excreted through the kidney. Pine oil is also well absorbed from the GI tract, and after absorption,

it is metabolized by the epoxide pathway and excreted in the urine [117]. Although the volume of distribution is unknown, it is thought to be quite large, with high concentrations in the brain, kidney, and lung.

Manifestations of toxicity include nausea, vomiting, diarrhea, weakness, somnolence, or agitation. In severe cases, stupor or coma may result, although seizures appear to be uncommon [119]. Systemic toxicity, when it occurs, usually develops within 2 to 3 hours of ingestion. In mild and moderate cases, GI and CNS symptoms generally resolve within 12 hours. Turpentine ingestion has been associated with hemorrhagic cystitis, with dysuria and hematuria occurring 12 hours to 3 days after exposure [120].

Management includes evaluation and treatment for aspiration, gastroenteritis, and CNS depression. The distinctive odors of turpentine and pine oil may provide a clue to diagnosis. Gastric aspiration or lavage is recommended for patients who present within 2 hours of ingesting greater than 2 mL per kg of turpentine or 5 mL of pure pine oil [121]. Because of the risk of aspiration, airway protection should be considered in all but the most alert patients.

Patients who remain asymptomatic or have only mild GI or CNS symptoms 6 hours after ingestion are unlikely to develop serious complications. Patients with pulmonary complications or severe CNS depression require intensive care unit admission and often require ventilatory support.

CHAPTER 135 ■ HYDROFLUORIC ACID POISONING

KENNON HEARD

INTRODUCTION

Hydrofluoric acid (HF) is a commonly encountered industrial reagent that is available in concentrations from 6% to 90%. It is used for the production of fluorocarbons, etching glass, and silicone, and as a household rust-removal agent. Sodium fluoride is used as a rodenticide and also as a preservative in blood collection tubes. A related compound, ammonium bifluoride is used in rust removers, commonly found in commercial car washes.

MECHANISM OF ACTION

HF (pK_a = 3.8) is a weak acid. Hence, compared with other acids, it is relatively less ionized at any given pH. This allows HF to penetrate more deeply into tissue and to be more readily absorbed into the systemic circulation than other acids. Once absorbed, it disassociates and the fluoride anion binds to divalent cations, forming insoluble salts (primarily calcium fluoride, fluorapatite, and magnesium fluoride). This results in tissue and systemic hypocalcemia and hypomagnesemia. Fluoride also directly poisons several enzymes and cellular transport proteins. High-concentration HF exposures result in rapid onset of local pain and tissue injury with or without systemic toxicity, whereas low-concentration exposures can result in life-threatening hypocalcemia and hypomagnesemia, with minimal or absent local corrosive effect.

DERMAL EXPOSURE

Clinical Manifestations

While most dermal exposures will result in minor symptoms or superficial chemical burns, systemic toxicity may occur following dermal exposure. Symptoms may be delayed for 24 hours or more following low-concentration (< 20% HF) exposure, and there is often severe pain with minimal skin abnormalities. Symptoms can develop within several hours of exposure to medium concentrations (20% to 50% HF). While the initial injury is not always visible, patients exposed to medium-concentration products often go on to have erythema, blanching, or necrosis of the involved area. High-concentration (> 50% HF) exposures result in the immediate injury expected after exposure to concentrated acids. Patients may develop full- or partial-thickness injury that includes tissue necrosis and eschar formation [1].

Evaluation and Treatment

Laboratory studies are not indicated for small, low-concentration dermal exposures. However, exposure to products containing more than 50% HF that involve more than 1% of the skin or exposure to any HF product that affects more than 5% of the skin can cause hypocalcemia, so patients with these burns should have serum calcium levels monitored, as described in the systemic toxicity section below [2].

The most important step in treatment is decontamination by irrigating the affected area for at least 15 minutes as quickly as possible. In one large case series of exposures, many of which involved concentrations of greater than 40% HF, immediate irrigation produced excellent outcome in the majority of patients [3]. Hexafluoride, an irrigating solution developed to bind fluoride, does not appear to offer any improvement over water irrigation [4].

After irrigation, apply a 2.3% to 2.5% calcium gluconate preparation in a water-soluble gel to the exposed areas for at least 30 minutes or until symptoms resolve [5]. This treatment often remains effective if it is delayed several hours after symptoms develop [6]. The role of topical therapy following high-concentration exposures is less well defined, but it is recommended [7].

If pain is not relieved by topical therapy, regional intra-arterial or intravenous calcium perfusion should be initiated. The major drawback of intra-arterial perfusion is the requirement for arterial catheterization. Brachial, radial, and femoral catheterization have all been described. Following cannulation, monitor arterial waveform to assure that the catheter remains patent and properly placed within the artery. If there is any question as to adequate placement, perform arteriography prior to infusing calcium. Flushing the catheter with heparin may help keep the catheter patent [2]. The largest case series reported infusion of 50 mL of 2.5% calcium gluconate in saline over 4 hours [2]. It is not uncommon to have to repeat the dose several times over a 12- to 24-hour period.

Regional perfusion using a Bier block may allow treatment without arterial cannulization. Some clinicians advocate this technique before proceeding to intra-arterial administration. This technique requires venous cannulation in the affected extremity. The extremity is exsanguinated by elevation and compression with an Esmarch bandage. The blood pressure cuff should be inflated to a pressure 100 mm Hg above systolic pressure and remain up for 15 to 20 minutes following calcium administration. The usual dose is 40 mL of a 2.5% calcium gluconate solution [8]. The cuff is then gradually deflated over 5 minutes. Pain is usually relieved within minutes of the calcium administration.

If the affected area is not an extremity, calcium can be directly injected into the burn. The most common method is injection of 0.3 to 0.5 mL per cm^2 of 2.5% calcium gluconate. Calcium chloride should not be used as it can cause tissue injury. Excision of exposed tissue is not recommended.

OCULAR EXPOSURE

Clinical Manifestations

While most human reports describe good outcomes following ocular HF exposure, animal studies have demonstrated that

severe injury is possible. Although most patients have rapid onset of pain, HF can penetrate the eye and cause severe and delayed injury.

Evaluation and Treatment

Immediate irrigation is the most important treatment. Irrigation with calcium salts appears to offer no benefit over saline in animal models, and may increase the incidence of ulceration [9]. Following irrigation, the pH should be measured and a fluorescein examination should be performed. All patients with persistent symptoms or obvious corneal damage should have immediate evaluation by an ophthalmologist. Some will require admission for continuous irrigation. Patients who are asymptomatic after irrigation should have next-day follow-up with an ophthalmologist. Routine therapy for corneal burns from HF has included mydriatics, topical antibiotics, and steroids [10–12]. Treatment of these burns with calcium gluconate eyedrops has been suggested, but no systematic human studies have been reported [12].

INHALATION

Clinical Manifestations

Inhalation of HF may result in severe airway injury, pulmonary injury, and systemic fluoride poisoning. Patients may present with severe or minimal symptoms and go on to develop complications over time [13]. While systemic fluoride poisoning may occur [14], the major mechanism of pulmonary injury is acute lung injury.

Evaluation and Treatment

Following inhalation of HF, patients should have chest radiographs, evaluation of oxygenation, and monitoring for hypocalcemia. Treatment is supportive, and early airway intervention may be required for patients with symptoms of upper airway obstruction. There are several uncontrolled reports of good outcomes following treatment with nebulized calcium gluconate solution (2.5% to 5.0%) [15,16].

INGESTION

Clinical Manifestations

Oropharyngeal burns are rarely noted, even in fatal poisonings [17]. While gastrointestinal symptoms such as nausea, vomiting, and gastritis may occur, the primary manifestation of oral HF exposures is systemic fluoride toxicity (see below). Following accidental sip ingestions, patients who are able to swallow should be given 30 to 60 mL of water to drink to dilute any HF still in contact with the esophageal mucosa. While it is commonly recommended to administer calcium or magnesium antacids, animals studies have found that very high doses are required to affect mortality [18,19]. Patients with accidental ingestion of products containing more than 7% HF or deliberate ingestion of any HF or ammonium fluoride product are at risk for systemic poisoning and require continuous cardiac monitoring, reliable vascular access, and close monitoring of serum calcium levels, as described in the next section.

Systemic Toxicity

Systemic fluoride toxicity may occur following inhalation and dermal or oral exposure to HF-containing products. While the exact mechanism of fluoride toxicity requires continued research [20], human cases of fatal HF toxicity consistently demonstrate profound hypocalcemia) [21]. Other manifestations include hypomagnesemia, acidosis, and hyperkalemia. Minimally symptomatic patients may progress rapidly to cardiovascular collapse [22].

Because successful resuscitation from cardiac arrest following systemic fluoride poisoning is rare, treatment should be started early to prevent cardiac dysrhythmias and arrest. Patients should have continuous cardiac monitoring, reliable vascular access, and frequent measurement of serum calcium and magnesium. If the history suggests that there has been a significant exposure, prophylactic calcium should be initiated at a rate of 1 g over 30 minutes [20]. Patients who have normal vital signs and remain stable should have serum calcium levels monitored every 30 minutes for the first 2 to 3 hours. Calcium chloride 1-g boluses should be repeated as needed to maintain the serum calcium in the high normal range. Patients with hypocalcemia, dysrhythmias, or hypotension should receive 2 to 3 g of calcium every 15 minutes, and central venous access should be obtained. Successful treatment of cardiac arrest has generally been associated with administration of large doses (> 10 g) of calcium. Intravenous magnesium sulfate 2 to 6 g over 30 minutes followed by a continuous 1- to 4-g infusion has also been suggested.

Beyond calcium and magnesium administration, fluoride-poisoned patients require excellent supportive care. Patients with symptoms of airway involvement should be intubated. Similarly, ventilation and oxygenation problems are rare but should be treated aggressively if present. Successful electrical cardioversion for dysrhythmias following calcium and magnesium therapy has been reported [23].

A therapy that is unproven but has theoretical benefit is serum and urine alkalinization. One animal study showed that systemic alkalosis increased the fatal fluoride dose in rats [24]. While this study has obvious limitations, serum alkalinization should be considered in critically ill patients. However, overalkalinization may worsen hypocalcemia; therefore, serum pH should be maintained between 7.4 and 7.5. While fluoride is cleared by hemodialysis, patients with severe poisoning will be too unstable to be dialyzed.

CHAPTER 136 ■ IRON POISONING

MILTON TENENBEIN

Historically, iron poisoning is the most common cause of poisoning death in children younger than 6 years [1]; however, morbidity and mortality have decreased secondary to unit-dose packaging of iron supplements [2]. Notably, a clinically important proportion of iron overdoses is purposeful, involves adolescents and adults, and results in significant morbidity and mortality [3].

Iron occurs naturally in the body. It is highly reactive, and there are complex mechanisms for its absorption, transport, and storage. The capacity of these systems to cope with an acute overdose is unknown; it likely varies from individual to individual and with the state of iron stores. Incomplete understanding of iron toxicokinetics is primarily responsible for controversies regarding (a) the toxic dose; (b) the optimal method of gastrointestinal decontamination; (c) the efficacy of intragastric complexation therapies; and (d) the indications, dose, duration, and efficacy of deferoxamine therapy.

PHARMACOLOGY

Iron is readily available as ferrous salts, either alone or in combination with other minerals and vitamins. Its common salts are ferrous gluconate, sulfate, fumarate, and succinate, which are 12%, 20%, 33%, and 35% elemental iron, respectively. These fractions are important because toxicity is related to the amount of elemental iron ingested. Iron is marketed in both conventional and delayed-release formulations. Product labels may not specify the tablet formulation, an important determinant of the onset and duration of toxicity. Carbonyl iron is a highly purified form of metallic iron. It is uncharged and not a salt [4].

Iron absorption, transport, and storage are well reviewed elsewhere [5]. Because there is no endogenous mechanism for iron excretion, total body iron is a function of the absorptive process. Absorption occurs in the proximal small bowel, with approximately 10% of the ingested dose absorbed, but with tenfold variations depending on iron stores and the amount ingested. The actual mechanism of iron absorption is not well understood, but it is believed to be an active process. Iron can also be passively absorbed once the active process is saturated, such as after a massive overdose [6]. Even in such a situation, a relatively small amount (15%) is actually absorbed [6].

Peak serum iron concentrations occur within 4 to 6 hours after an overdose of conventional tablets. The time to peak serum concentration is not known for delayed-release products. The half-life after therapeutic dosing is approximately 6 hours [5], with rapid decline because of tissue distribution. In plasma, iron is bound to transferrin, a specific β_1-globulin responsible for iron transport throughout the body. In iron overdose, transferrin-binding capacity is exceeded, but free plasma iron does not truly exist. Iron complexes with other plasma proteins and organic ligands and is referred to as *nontransferrin-bound plasma iron* [7]. However, it is only loosely bound and is quite available to produce tissue damage and organ dysfunction.

There are two typical overdose scenarios: innocent overdose by young children and purposeful overdose by adolescents and adults. Serious iron overdose in young children frequently involves the ingestion of a product intended for adults, typically a prenatal iron supplement. Ingestion of pediatric preparations, such as multivitamin plus iron tablets, is more common [8]; such preparations are unlikely to result in significant toxicity because of their low elemental iron content (as little as 4 mg per tablet). Although liquid iron preparations are often found in homes with infants and toddlers, there are no published cases of clinically important iron poisoning because of these products. Iron overdose is less common among teenagers and adults, but when it occurs, it is typically more severe. Of particular note is the high incidence of deliberate iron overdose in pregnant women [9].

Iron exerts both local and systemic effects. The local irritant effect on the gastrointestinal tract results in nausea, vomiting,

abdominal cramps, and diarrhea. These symptoms are produced by relatively small doses (20 mg per kg of elemental iron). The degree of systemic toxicity is, however, dose related. Because most published data are anecdotal, specific values have not been established. In the pediatric literature, more than 60 mg per kg of elemental iron produces significant systemic toxicity [10], with a lethal dose being 200 to 250 mg per kg [10]. Both the figures are likely overestimates; more realistic figures are probably half as much. The lowest reported lethal dose for a toddler is approximately 75 mg per kg of elemental iron [11]. The author's own experience and that of others [12] suggests that the range of toxicity in adults is similar to that in children. An ingestion of 1.5 g of elemental iron by an adult should be cause for concern. Adults have died after ingestion of as little as 2 [13] and 5 g [12] of elemental iron; the former patient had significant hepatic disease and the latter ingested 70 mg per kg. There have been no published reports of serious or fatal poisoning from the ingestion of carbonyl iron products [4]. Although its bioavailability after therapeutic dosing is similar to ferrous salts, its absorption is limited after an overdose. Single doses of 10 g (140 mg per kg) have been tolerated in humans.

Poor, unpredictable absorption of iron and its unknown capacity for binding by ferritin and as hemosiderin contribute to uncertainty regarding the toxic dose. As reflected by serum iron concentrations, which are measured in micrograms per deciliter, the size of the potentially toxic iron pool is likely to be small—on the order of milligrams—even after gram quantities of iron have been ingested. That the body burden of iron is relatively small after an overdose is not well appreciated, but it has important implications for the dose and duration of deferoxamine therapy.

Iron itself is neither caustic nor corrosive. It is a potent catalyst of free radical formation, which results in highly reactive species that attack many intracellular molecules [14]. Iron-generated free radical formation is thought to contribute to acute iron toxicity [15] and to be responsible for much of the damage and dysfunction of chronic iron overload [7].

Free radicals produce damage at their site of origin. Because of local protective mechanisms, a significant concentration of free radicals is required to cause damage. Sites exposed to high iron concentrations are most susceptible to injury. One such area is the gastrointestinal tract. Gastrointestinal mucosal necrosis and bleeding [16] may occur without systemic toxicity. Notably, gut toxicity can occur distally with proximal sparing [16] and may be absent in the face of fatal systemic poisoning [6].

Systemic toxicity results when the absorbed iron is transported to target organs, such as the liver and heart. Nontransferrin-bound iron is rapidly cleared by the liver [17], putting this organ at risk for toxicity [18].

CLINICAL TOXICITY

Traditionally, acute iron intoxication is divided into five clinical stages [19]: gastrointestinal toxicity, relative stability, circulatory shock, hepatic necrosis, and gastrointestinal scarring. An orderly progression through all these stages may not occur. Fatalities are possible without significant gastrointestinal involvement [6], and hepatotoxicity may be absent in otherwise severe poisoning. Presenting signs and symptoms depend on the time since ingestion.

The most common time of presentation is during the first stage (gastrointestinal toxicity), when abdominal pain, vomiting, diarrhea, hematemesis, and hematochezia are seen. Gastrointestinal toxicity usually occurs within the first few hours of overdose. If enteric-coated tablets have been ingested, gastrointestinal toxicity can be delayed as long as 12 hours. The severity of this stage is variable. Life-threatening hypovolemic shock may occur, especially if initial symptoms were severe or ignored. Occasionally, segmental intestinal infarction may occur, necessitating bowel resection [16]. Isolated hepatotoxicity or gastrointestinal obstruction would be an unlikely presentation of iron poisoning.

The second stage, a period of relative stability, follows initial gastrointestinal symptoms. Apparent improvement in the patient's clinical status should not lead to complacency. Patients are not completely asymptomatic; careful assessment and repeated monitoring should document some degree of hypovolemia, circulatory shock, and acidosis.

The third stage, circulatory shock, can occur within several hours of iron overdose and may persist up to 48 to 72 hours. Its pathogenesis is complex and poorly understood and is based on the results of limited experimental animal data [20–23]. Circulatory shock may be hypovolemic, distributive, or cardiogenic. The time of onset can be somewhat helpful in elucidating its cause, but there is considerable overlap. Shock occurring within a few hours of the overdose suggests hypovolemia secondary to fluid and, rarely, blood loss from the gastrointestinal tract. Hyperferremia-associated coagulopathy may contribute to bleeding [24]. Distributive shock depends on iron absorption and begins within the first 24 hours. Suggested mechanisms include direct effects of iron or ferritin or an effect mediated by release of vasoactive substances, resulting in decreased vascular tone or increased vascular permeability [22]. Cardiogenic shock usually occurs 1 to 3 days after overdose [25].

The occurrence of metabolic acidosis in iron poisoning usually precedes circulatory shock. Acidosis is a direct toxic effect of iron that occurs after the plasma's capacity to bind the absorbed ferric ion has been exceeded. When this occurs, the ferric ion becomes hydrated and protons are released [$Fe^{3+} + 3H_2O \rightarrow Fe(OH)_3 + 3H^+$]. Thus, each unbound ferric ion generates three protons. The acidosis can be quite profound, requiring large amounts of bicarbonate for treatment [23]. Other factors contributing to acidosis include the generation of organic acids resulting from iron's interference with intracellular oxidative metabolism and lactate production secondary to shock.

The fourth stage, hepatotoxicity, is second only to shock as a cause of death [18]. It may occur any time during the first 48 hours after overdose. The pathogenesis of hepatic necrosis is believed to be iron-catalyzed free radical production and subsequent lipid peroxidation of hepatic mitochondrial membranes [15].

The fifth stage, gastrointestinal scarring, is the consequence of iron's local action on the gut and usually occurs 2 to 4 weeks after overdose. Ongoing and protracted abdominal pain during the first week is associated with the later development of this complication [16]. Most cases involve the gastric outlet, but isolated strictures of distal intestine have been reported [16].

The consequences of iron poisoning in pregnant women are no different from those in other patients, but because transplacental iron passage is an energy-requiring saturable process, the fetus is relatively protected [26]. Although deferoxamine in animals is associated with potential harm to the fetus, its risk in humans is overemphasized [26]. The health of the fetus depends on its mother, and treatment should be no different from that given to a nonpregnant woman.

DIAGNOSTIC EVALUATION

Essential laboratory tests include abdominal radiographs, serum iron and bicarbonate concentrations, and blood gas determinations. Because iron tablets are radiopaque, an abdominal radiograph can be used to verify an overdose and quantify

the amount ingested [27–29]. However, iron tablets may not be visible if they have dissolved or been chewed, a liquid preparation has been ingested, or there is only a small amount of iron in each tablet (e.g., pediatric iron-containing multivitamins) [30]. If tablets are visible, serial abdominal radiographs may be used to judge the effectiveness of gastrointestinal decontamination.

Serum iron concentration is the single most important test. It verifies the ingestion, guides management, and provides prognostic information. A peak serum concentration of less than 500 µg per dL (90 µmol per L) is usually associated with negligible-to-mild systemic toxicity; however, there may be significant gastrointestinal symptoms. Moderate systemic toxicity is expected with a peak concentration of 500 to 1,000 µg per dL (90 to 180 µmol per L). A peak serum concentration greater than 1,000 µg per dL (180 µmol per L) is associated with severe toxicity, such as profound acidosis, shock, hepatotoxicity, coma, and death. Mortality approaches 100% when serum concentration is greater than 10,000 µg per dL (1,800 µmol per L). The time of blood sampling to estimate peak serum iron concentration should be 4 to 6 hours after an overdose of conventional tablets and several hours later for an overdose of delayed-release formulations. However, the type of preparation ingested is usually unknown at the time a patient seeks treatment and is difficult to establish even after the fact [31]. Serial serum iron concentration determinations are recommended during the early hours after overdose, especially when the first value is 300 to 500 µg per dL (55 to 90 µmol per L). Determinations should be obtained every 2 hours until a definite downward trend is established. A concurrent abdominal radiograph may be helpful. If many tablets are visible, the subsequent serum iron level will likely be higher. However, a negative radiograph does not guarantee that peak serum iron level has occurred. It is desirable to obtain blood specimens before initiating deferoxamine therapy because it can confound the laboratory determination of serum iron concentration, resulting in falsely lower levels [32]. When clinically indicated, deferoxamine therapy should not be delayed because of blood sampling issues.

Blood gas or serum bicarbonate determinations should be done early because acidosis is the first objective indicator of systemic toxicity. Frequency of blood gas determinations is guided by previous values, the need for bicarbonate therapy, and clinical course. A pH of less than 7.30 is indicative of significant toxicity.

Recommended laboratory tests include blood coagulation panels and hepatic and renal function tests. Blood coagulation panels should be done early and repeated throughout the first few days in patients with significant toxicity because a biphasic coagulopathy may develop [24]. Blood should be typed and cross-matched as clinically indicated. Hepatic function should be monitored daily during the first 72 hours and longer if values remain significantly abnormal. Renal function tests should be obtained regularly, especially during deferoxamine therapy, because of the risk for acute renal failure [33].

The total iron-binding capacity (TIBC) is not recommended in the assessment or management of patients with iron overdose [34]. Routine methods for TIBC determination are unreliable during hyperferremic states and are time consuming [34]. The TIBC becomes falsely elevated in the presence of high serum iron concentrations, and it has yet to be demonstrated that iron toxicity occurs only when the serum iron concentration exceeds the TIBC [34]. A serum iron concentration that is less than the TIBC does not rule out acute iron poisoning.

One retrospective study of acute iron overdose showed that vomiting was a highly sensitive predictor of a serum iron concentration greater than 300 µg per dL (54 µmol per L). In addition, a white blood cell count greater than 15,000 per µL or a serum glucose concentration greater than 150 mg per dL (8.3 mmol per L) has a positive predictive value of 100% for a serum iron level greater than 300 µg per dL (54 µmol per L) [35]. However, these tests have unacceptably low sensitivity and negative predictive value. Although such surrogate markers may be helpful when serum iron concentrations are not readily available, these associations have not been confirmed in subsequent studies [36,37]. The absence of vomiting, a white blood cell count less than 15,000 per µL, or a serum glucose concentration of less than 150 mg per dL (8.3 mmol per L) should not be relied on as a surrogate marker for a serum iron level of less than 300 µg per dL (54 µmol per L).

It is difficult to accurately predict outcomes because the published literature chiefly consists of anecdotal reports. Survival is expected with peak serum iron concentrations of less than 1,000 µg per dL (180 µmol per L) and appropriate supportive care. The chief causes of death are shock and hepatic failure. Acute renal failure may result from shock or deferoxamine therapy without adequate volume replacement [33]. *Yersinia septicemia* has been reported in patients treated with deferoxamine [27,38].

Differential diagnosis becomes an issue only when the history of iron overdose is unknown. In such situations, diagnosis can be quite problematic because of the multiple and varied clinical features at presentation (e.g., abdominal pain, gastrointestinal hemorrhage, shock, and coma). From the poisoning perspective, corrosive ingestion and acute heavy metal poisoning are the main considerations.

MANAGEMENT

The initial management of a patient with an iron overdose presents a challenge because the patient often presents before the peak of clinical toxicity. Many patients, especially young children, may be asymptomatic or only mildly ill. The challenge lies in identifying those who are at risk for significant toxicity in order to place them in an appropriate setting for the required level of care. The decision for the iron-overdosed critically ill patient is straightforward. Table 136.1 provides guidelines for intensive care unit admission for those patients who are not critically ill.

TABLE 136.1

SUGGESTED CRITERIA FOR ADMISSION OF THE NONCRITICALLY ILL IRON-OVERDOSED PATIENT TO AN INTENSIVE CARE UNIT

	Admit to ICU	Strongly consider admission to ICU
Amount of elemental iron ingested		
Child (< 6 y)	> 60 mg/kg	45–60 mg/kg
Adult (all others)	> 3.0 g	2.0–3.0 g
Tablets seen in radiograph[a]		
Child (< 6 y)	1/kg	0.75–1.00/kg
Adult (all others)	> 50	33–50
Peak serum iron concentrations	> 1,000 µg/dL (> 180 µmol/L)	750–1,000 µg/dL (135–180 µmol/L)
Arterial pH	< 7.30	7.30–7.35

[a] Assuming 60-mg elemental iron/tablet.
Note: Not all criteria need to be present.

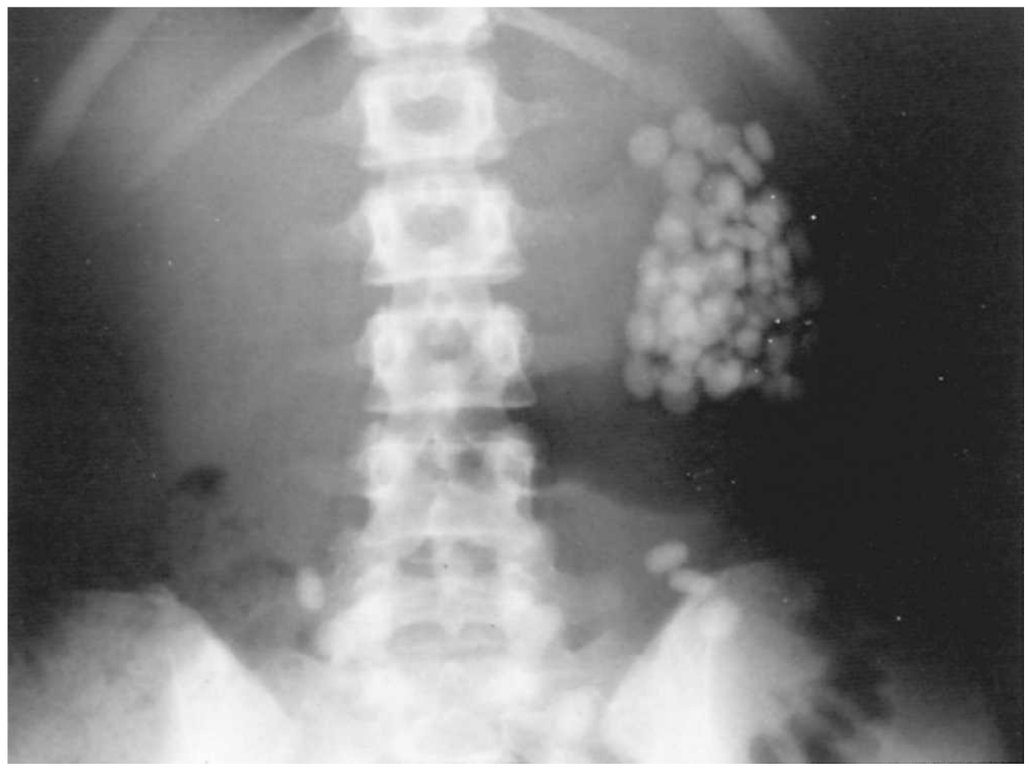

FIGURE 136.1. Abdominal radiograph of a 16-year-old girl with a potentially lethal iron overdose after syrup of ipecac-induced emesis and gastric lavage. Gastroscopy ruled out adherence of iron to the stomach wall and medication concretion. She subsequently underwent whole-bowel irrigation. Her peak serum iron concentration was 253 µg per dL (46 µmol per L), and she was not treated with deferoxamine.

Because activated charcoal does not adsorb iron [28], whole-bowel irrigation (WBI; Fig. 136.1) is recommended as the decontamination procedure of choice for the iron-overdosed patient [29]. WBI should be initiated when there is radiographic documentation of iron ingestion and considered when there is a history of elemental iron ingestion greater than 60 mg per kg in children and 1.5 g per kg in adults. If emesis hampers effective WBI, consider metoclopramide (1 mg per kg intravenously in adults and 0.1 mg per kg in children) or ondansetron (8 mg per kg intravenously in adults or 0.1 to 0.2 mg per kg in children).

Iron can become adherent to the gastrointestinal mucosa or may form tablet bezoars [39]. The latter is primarily a problem with conventional iron tablets and not with the enteric-coated varieties. Radiographs in three planes (flat, upright, and decubitus) should identify these two situations. A computed tomographic (CT) scan is another consideration. Barium studies are unlikely to be helpful because of the anticipated lack of contrast between barium and iron. If WBI is ineffective, removal of iron via gastrotomy should be considered [39,40]. For surgical intervention to be effective, it should be done before the iron is absorbed and most tablets must be in a localized area rather than scattered throughout the gastrointestinal tract. A combined approach of gastrotomy for tablet retrieval followed by WBI after surgery has been described [40]. The former removed the iron from the stomach and the latter removed it from the intestinal tract. Endoscopic removal of an iron bezoar from the stomach has been reported [41].

The oral administration of bicarbonate, phosphate, or deferoxamine is not recommended. These agents have been advocated as a way to decrease iron absorption by precipitating it as an insoluble salt or by chelating it. In vitro [42] and animal [43] studies do not support bicarbonate or phosphate administration, and the latter therapy has resulted in hypocalcemia and hypovolemia in iron-overdosed patients [44]. Oral deferoxamine is not recommended. It is neither appreciably toxic nor absorbed from the gastrointestinal tract, but the same is not true of its chelate, ferrioxamine [19,21,45]. The latter has been shown to be lethal in animals [21,46].

Supportive care should be provided concurrently with gastrointestinal decontamination. In patients with severe poisoning, two intravenous (IV) lines are required: one for fluid resuscitation and bicarbonate administration and the other for deferoxamine therapy. Very large amounts of crystalloid and bicarbonate may be required [23], and occasionally, colloid or blood may be necessary. Because of the complex nature of shock in iron poisoning, early placement of a Swan-Ganz catheter may be needed to assist in diagnosis and monitor the effectiveness of therapy. Early shock should respond to vigorous volume resuscitation; occasionally, pressor therapy may be needed. Late shock usually requires inotropic support. Failure of inotropic support suggests the need for afterload reduction [25]; once a patient has reached this point, the prognosis is grave. An arterial catheter for frequent blood gas determinations and a Foley catheter for monitoring urine output are essential in all critically ill patients.

Parameters requiring serial monitoring include arterial blood gas, hematocrit, serum electrolytes, renal and hepatic function, and blood coagulation. The frequency of these determinations depends on previous results and the patient's clinical condition and response to the therapy.

Acute hepatic failure is managed by standard protocols. Acute renal failure may be a consequence of shock or deferoxamine therapy in the setting of hypovolemia [33]. Hemodialysis may be required in such situations, especially if deferoxamine therapy is continued, to remove the toxic chelate, ferrioxamine. Coagulopathy during the first few hours after overdose is related to serum iron concentration and is transient. Specific therapy is unnecessary. Deferoxamine lowers the serum iron concentration and may hasten its resolution [24]. Coagulopathy occurring many hours to a few days after overdose is a manifestation of hepatic failure. Administration of fresh-frozen plasma is recommended, as vitamin K_1 is unlikely to be helpful.

Hemodialysis or hemoperfusion is not recommended for iron removal because of the rapid extravascular distribution of the iron and its binding to plasma proteins as nontransferrin-bound iron [7]. However, hemodialysis is indicated for patients with renal failure.

Deferoxamine, the specific treatment of choice for acute iron poisoning [15,19], is a naturally occurring siderophore isolated from *Streptomyces pilosus*. Its pharmacology was described in the early 1960s [47,48]. Its binding constant for ferric iron is 10^{31}, which compares with 10^{27} to 10^{29} for transferrin. It is capable of removing iron from ferritin and hemosiderin and, to a very minor degree, from transferrin, but not at all from cytochromes, hemoglobin, or myoglobin.

Although deferoxamine is regarded as the treatment of choice, its effectiveness has been questioned because it has limited chelating capacity and only small amounts of iron are recovered in the urine after its administration to iron-poisoned patients [49]. The manufacturer's recommended daily deferoxamine dosage of 6 g is capable of chelating 510 mg of iron or 8.5 ferrous sulfate tablets. Although this would seem to be insignificant in the patient who has ingested 50 tablets, the poor absorption of iron and the body's large storage capacity for it result in only a relatively small amount being responsible for toxicity. Therefore, the chelation of small amounts of iron may be quite beneficial. Alternatively, 510 mg of iron is approximately 10% of the total amount of iron and approximately 35% of the nonheme iron in a 70-kg man [50].

Historically, therapy was based on the deferoxamine chelation challenge test and relied on visual detection of a change in urine color to rusty orange (vin rosé) caused by the presence of ferrioxamine after intramuscular administration of deferoxamine. This test has never been validated and is not recommended.

Traditional indications for deferoxamine therapy have been based on the peak serum iron concentration, the serum iron concentration relative to the TIBC, the results of a chelation challenge test, and the patient's clinical condition. The therapy has been recommended for those with peak serum iron

concentrations ranging from 300 to 500 µg per dL (55 to 90 µmol per L) [51]. Significant morbidity is unlikely with peak concentrations of less than 500 µg per dL (90 µmol per L). Values at the lower end of the above range are based on the upper limit of normal for TIBC, which, as discussed earlier, is invalid. Hence, a serum iron concentration of 500 µg per dL (90 µmol per L) or greater is recommended as an indication for deferoxamine therapy in an otherwise asymptomatic patient. Deferoxamine therapy is indicated when toxic signs and symptoms are present, regardless of the serum iron concentration. Such symptoms include acidosis, shock, and decreased level of consciousness or coma. Although some toxicologists also advocate deferoxamine therapy for those with recurrent vomiting or diarrhea, these symptoms can be seen in patients who do not develop systemic toxicity.

Deferoxamine can be given intravenously or intramuscularly. The manufacturer recommends intramuscular therapy unless the patient is in shock, presumably because of concern for hypotension, which is associated with rapid IV administration. The patient should be fluid resuscitated, and IV deferoxamine therapy should be initiated slowly and gradually increased to 15 mg per kg per hour during 20 to 30 minutes. Continuous IV infusion is the recommended method for administering deferoxamine. This is based on studies in patients with transfusion-induced iron overload, demonstrating that IV deferoxamine results in greater urinary iron elimination, higher peak deferoxamine serum concentrations, and more stable serum deferoxamine levels [52].

The optimal dose of deferoxamine is uncertain. The manufacturer recommends a daily maximum dose of 6 g given in divided doses. A continuous infusion protocol of 15 mg per kg per hour until 24 hours after the urine returns to its normal color has also been recommended [15]. The latter protocol exceeds the manufacturer's guidelines for patients heavier than 17 kg. Neither recommendation is evidence based. Only two patients treated with 15 mg per kg per hour over a prolonged course have been well described in the literature [53,54]. Furthermore, continuous IV deferoxamine therapy in patients with acute iron poisoning for longer than 24 to 48 hours has been associated with the development of adult respiratory distress syndrome [55]. Four patients with mild-to-moderate iron poisoning without evidence of shock, acidosis, or sepsis who received 15 mg per kg per hour of deferoxamine intravenously for 2 to 3 days died of noncardiogenic pulmonary edema [55]. Continuous IV deferoxamine therapy should not routinely exceed the first 24 hours. If prolonged chelation therapy is deemed necessary, interrupting therapy for 12 of every 24 hours to allow excretion of ferrioxamine can be considered. Careful monitoring of pulmonary status is required during prolonged therapy.

Indications for discontinuing deferoxamine therapy include resolution of the signs and symptoms of systemic iron toxicity and correction of acidosis. Deferoxamine therapy is rarely needed beyond 24 hours and should be used with caution for periods longer than this.

Adverse drug events from short-term deferoxamine therapy are few, but significant. Rapid IV administration is associated with tachycardia, hypotension, shock, a generalized beet-red flushing of the skin, blotchy erythema, and urticaria. Acute renal failure can result when deferoxamine is administered to patients with hypovolemia [33]. Pulmonary toxicity and acute respiratory distress syndrome are associated with continuous IV therapy over several days [55]. Patients receiving deferoxamine may be at increased risk for *Yersinia* infections [27,38].

Before discharge, a psychiatric assessment is indicated for all patients with purposeful ingestions. Those who have required deferoxamine therapy should have a follow-up visit approximately 1 month after discharge. At this time, the patient's iron status and gastrointestinal tract should be assessed. He or she should also be advised of the symptoms of gastrointestinal obstruction and to return immediately if they occur. Chronic hepatic or cardiac dysfunction has not been reported after acute iron overdose.

CHAPTER 137 ■ ISONIAZID POISONING

JAMES B. MOWRY AND R. BRENT FURBEE

Isoniazid (isonicotinic acid hydrazide [INH]) is the cornerstone of treatment and prevention of tuberculosis. It is available under a variety of brand names in 50-, 100-, and 300-mg tablets; as an oral syrup (50 mg per 5 mL); as an injectable solution (100 mg per mL); and in powder form. It is also available in combination with rifampin, pyridoxine, and other antitubercular drugs.

In 2007, the American Association of Poison Control Centers reported 330 cases with exposure to INH, including 228 single exposures [1]; 33% of the cases involved adults, with 34% being intentional. No deaths were reported, but 33% of the cases exhibited moderate-to-severe toxicity.

PHARMACOLOGY

As a bactericidal agent, INH interferes with lipid and nucleic acid biosynthesis in the growing *Mycobacterium* organism. It is rapidly and nearly completely absorbed after oral administration, with peak plasma concentrations occurring within 1 to 2 hours [2]. The rate and extent of absorption are decreased by food. The volume of distribution of INH approximates total body water (0.67 ± 0.15 L per kg), with cerebrospinal fluid concentrations 90% of those of serum [3]. INH passes into breast milk and through the placental barrier. There is little protein binding.

Between 75% and 95% of an INH dose is metabolized in the liver within 24 hours by acetylation to acetylisoniazid and hydrolysis to isonicotinic acid and hydrazine [2]. Genetic variation in its metabolism significantly alters plasma concentration, elimination half-life, and toxicity [4]. The elimination half-life in rapid acetylators (e.g., Asians, Eskimos, and American Indians) is 0.5 to 1.5 hours, whereas it is 2 to 4 hours in slow acetylators (e.g., people of African descent and Caucasians) [5]. The elimination half-life can be prolonged in people with liver disease. Rapid acetylators excrete 2.5% of INH as unchanged drug, compared with 10% in slow acetylators [2]. In addition, slow acetylators may have a higher percentage of the dose metabolized to hydrazine, a potential hepatotoxin [6]. INH exhibits dose-dependent inhibition of the mixed-function oxidases CYP2C19 and CYP3A, increasing the risk of adverse drug reactions in slow acetylators during the coadministration of drugs metabolized by these enzymes (e.g., phenytoin, carbamazepine, and diazepam) [7].

The usual adult INH dose is 5 mg per kg per day (maximum, 300 mg). The dose is increased to 15 mg per kg (maximum, 900 mg) when INH is used in combination with other antitubercular drugs and administered twice weekly. Acute ingestion of 1.5 to 3.0 g in adults may be toxic, with 6 to 10 g uniformly associated with severe toxicity and significant mortality [8]. The pediatric INH dose is 10 to 15 mg per kg per day (maximum, 300 mg) and is increased to 20 to 30 mg per kg (maximum, 900 mg) when concurrent INH and other antitubercular drugs are administered twice weekly. When INH is used in combination with rifampin, limiting the INH dose to 10 mg per kg per day and the rifampin dose to 15 mg per kg per day may minimize hepatotoxicity in children [9]. In patients with preexisting seizure disorders, convulsions have occurred with doses as low as 14 mg per kg per day; 19 mg per kg per day resulted in seizures in a 7-year-old child [8].

Daily therapeutic INH doses produce peak serum concentrations between 1 and 7 µg per mL. Intermittent INH therapy may produce concentrations between 16 and 32 µg per mL. Serum INH concentrations in acute ingestions have ranged from 20 µg per mL to more than 710 µg per mL, with little correlation to severity of intoxication [10–13].

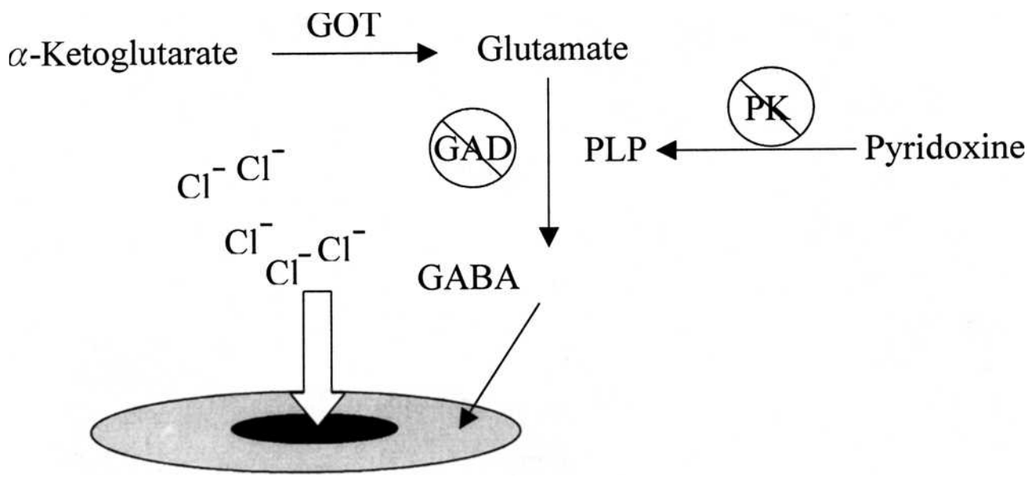

FIGURE 137.1. Role of isoniazid in the reduction of γ -aminobutyric acid (GABA) concentration. Cl^-, chloride ions; GAD, glutamic acid decarboxylase; GOT, glutamic oxaloacetic transaminase; PK, pyridoxine kinase; PLP, pyridoxal 5′-phosphate; ⊘, inhibited by isoniazid.

The central nervous system toxicity of INH and its metabolites is believed to be due to a decrease in the concentration of γ -aminobutyric acid, an inhibitory neurotransmitter that suppresses neuronal depolarization by opening chloride ionophores (Fig. 137.1). INH combines with pyridoxine (vitamin B_6) and is excreted in the urine as pyridoxal isonicotinylhydrazine [14]. It also competes with pyridoxine for pyridoxine kinase, the enzyme that converts pyridoxine to pyridoxal 5′-phosphate, the cofactor for glutamic acid decarboxylase–mediated conversion of glutamate to γ -aminobutyric acid [15]. In addition, INH inhibits glutamic acid decarboxylase activity. Its metabolism results in metabolites such as hydrazides and hydrazones, which inhibit pyridoxal 5′-phosphate and pyridoxine kinase, respectively [16].

INH causes a peripheral neuropathy that may be responsive to pyridoxine supplementation [17]. Wallerian degeneration of the myelin sheath and axon with blockade of fast axoplasmic transport is noted, with sensory nerves affected more than motor nerves [18–22]. Peripheral neuropathy is most commonly associated with chronic INH use in slow acetylators but may occur after acute massive overdose [23,24].

The mechanism of INH-induced hepatic injury is not understood. Hepatitis occurs in 0.1% to 1.1% of patients receiving INH, especially those with advanced age and alcohol consumption [25–28]. Concurrent rifampin therapy increases the incidence of hepatitis to 2.7% in adults and 6.9% in children [9,25–28]. It is unclear whether this effect is due to an influence of rifampin on INH metabolism or to the additive effect of two hepatotoxic drugs [28]. The histopathologic pattern of hepatic injury closely resembles viral hepatitis. Hypersensitivity seems unlikely, as rechallenge often fails to produce recurrence. Hepatic damage may be due to hydrazine metabolites of INH, covalently binding to liver macromolecules and producing necrosis [29]. Both rapid and slow acetylators have been described as having a greater risk for hepatotoxicity, although other researchers failed to find an association with acetylator status [26,30]. More recent work suggests that slow acetylators may be more susceptible to antitubercular drug–induced hepatitis and may develop more severe hepatotoxicity than do rapid acetylators [31].

The severe metabolic acidosis seen in acute INH intoxication is almost entirely due to seizure activity [32]. Although INH may interfere with nicotinamide adenine dinucleotide–mediated conversion of lactate to pyruvate, acidosis was not observed in animal studies until seizures occurred and lactic acidosis resolved within 2 hours after seizures ceased [32]. β-Hydroxybutyric acid production has also been reported after INH overdose, but does not appear responsible for INH-induced acidosis [33].

Hyperglycemia may result from disruptions of the Krebs cycle that require nicotinamide adenine dinucleotide and from stimulation of glucagon secretion [12].

CLINICAL PRESENTATION

Signs and symptoms usually appear within 30 minutes to 2 hours after acute INH overdose. Nausea, vomiting, dizziness, slurred speech, blurred vision, and visual hallucinations (e.g., bright colors, spots, and strange designs) are among the first manifestations [8,10]. Stupor and coma can develop rapidly, followed by intractable tonic–clonic generalized or localized seizures, hyperreflexia or areflexia, and cyanosis [8,10]. In severe cases, cardiovascular and respiratory collapse results in death. Oliguria progressing to anuria has been reported [8]. The metabolic alterations are striking and include severe metabolic acidosis, hyperglycemia, glycosuria, ketonuria, and hyperkalemia [8,10,12]. The triad of metabolic acidosis refractory to sodium bicarbonate therapy, seizures refractory to anticonvulsants, and coma suggests INH toxicity.

Hepatotoxicity usually presents as elevated serum aspartate aminotransferase values within the first few months of therapy. Fatalities from INH-induced hepatitis during chemoprophylaxis are between 4.2 and 7.0 per 100,000 persons [34]. When peripheral neuropathy occurs, it is within 3 to 35 weeks of initiating the therapy [22]. Other chronic effects include dysarthria, irritability, seizures, dysphoria, and inability to concentrate [25]. Optic neuritis and optic atrophy have also been reported, but their occurrence is often associated with the administration of ethambutol as well [35,36].

DIAGNOSTIC EVALUATION

Initial laboratory evaluation should include serum electrolytes, blood urea nitrogen, creatinine, glucose, calcium, and magnesium levels. Laboratory workup for anion-gap metabolic acidosis (e.g., serum methanol, ethylene glycol, salicylate, and acetaminophen levels) should also be considered. Arterial blood gases, electrocardiogram, chest radiograph, head computed tomography, and lumbar puncture should be obtained as clinically indicated.

Qualitative INH identification in urine using reagent-impregnated paper strips or a point-of-care testing device sensitive to INH metabolites [37,38] and quantitative serum INH identification are not widely enough available to be clinically useful to confirm diagnosis.

Acute INH intoxication should be considered in the differential diagnosis of any patient presenting with unexplained neurologic symptoms, particularly intractable seizure activity [8,13]. Conditions that may resemble INH toxicity include (a) central nervous system tumors and infections; (b) electrolyte abnormalities; (c) thyroid dysfunction; (d) hypoglycemia; (e) poisoning by anticholinergic, cholinergic, and sympathomimetic agents, or by tricyclic antidepressants (e.g., amoxapine), theophylline, organophosphates, meperidine (normeperidine), propoxyphene (norpropoxyphene), carbon monoxide, or cyanide; and (f) withdrawal syndromes [39]. Other causes of an anion-gap metabolic acidosis such as diabetic ketoacidosis, uremia, ethylene glycol, methanol, and salicylates should also be considered.

Ingestion of rifampin–INH combination products may produce, in addition to the symptoms of INH poisoning, (a) a striking red-orange discoloration of the skin, urine, sclera, and mucus membranes; (b) periorbital or facial edema; (c) pruritus; and (d) nausea, vomiting, or diffuse abdominal tenderness [40]. Transient elevations in total bilirubin and alkaline phosphatase, indicating cholestasis, may also be noted.

MANAGEMENT

The initial management of a patient with acute INH overdose focuses on protection of airway, support of respiration, treatment of seizures, correction of metabolic acidosis, minimization of drug absorption, and in selected cases, enhancement of INH elimination.

Gastrointestinal decontamination, if performed, should consist of the administration of activated charcoal. In severely ill patients, gastric lavage should be considered. Emesis is contraindicated because of the potential for rapid and unpredictable onset of seizures and coma.

Patients who have ingested a potentially toxic INH dose should be observed for at least 6 hours [8]; those who remain asymptomatic after gastrointestinal decontamination may be referred for psychiatric evaluation. All symptomatic patients should be admitted to an intensive care setting.
