Hypoglycemic Encephalopathy

Hypoglycemia can occur as an isolated problem or as a complication of liver failure, of tumors producing insulin-like substances, or of urea cycle defects. The most common case is that of a diabetic with an accidental or deliberate overdose of insulin or oral hypoglycemic agents. An initial insulin reaction occurs when the serum glucose drops below approximately 40 mg per dL, producing flushing, sweating, faintness, palpitations, nausea, and anxiety. This persists for several minutes before the patient becomes confused and either agitated or drowsy [26]. Focal neurologic signs such as hemiparesis, cortical blindness, or dysphasia may appear at this point, mimicking an acute stroke [27]. If the serum glucose drops precipitously below 30 mg per dL, generalized convulsions may occur in flurries followed by a postictal coma. Prompt correction of the hypoglycemia at this point leads to reversal of the neurologic deficits, but repeated episodes can result in a subtle dementia evolving over many years [28].

When severe hypoglycemia is sustained for more than 10 minutes, stepwise progression of neurologic signs occurs. The first step is motor restlessness with frontal release signs such as sucking, grasping, and a tonic jaw jerk. Next, diffuse muscle spasms appear and sometimes myoclonic jerks. Finally, decerebrate rigidity is seen before the so-called medullary phase of hypoglycemia. The *medullary phase* describes a state of deep coma with dilated pupils, bradycardia, hypoventilation, and generalized flaccidity, much like hypoxic–ischemic coma. The pathologic changes associated with bouts of hypoglycemic encephalopathy are also similar to hypoxic–ischemic insults, although the cerebellum is relatively spared [29].

Differentiating hypoglycemic coma from a seizure disorder, a cerebrovascular accident, or a drug overdose is not possible at the outset unless stat serum glucose is obtained before IV fluids are administered. One should not delay treatment with a bolus of 50 mL 50% glucose (1 ampoule) if there is doubt about the cause of a rapidly evolving coma, because hypoglycemic

encephalopathy can result in permanent neurologic deficits if not reversed in 20 minutes or less. The first bolus of glucose must be followed by close monitoring of blood glucose levels, because most agents that lead to symptomatic hypoglycemia are long acting [30].

Hyperglycemic Encephalopathy

Hyperglycemia that is severe enough to produce mental status changes rarely occurs in isolation from other metabolic disturbances. Hypokalemia and hypophosphatemia, hyperosmolality and ketoacidosis, or lactic acidosis often accompany serum glucose levels more than 300 mg per dL. In contrast, acidosis may be absent in nonketotic hyperglycemic hyperosmolar states, whereas the serum osmolality is often more than 350 mOsm per kg and serum glucose more than 800 mg per dL. The neurologic changes in any case appear to correlate best with abnormalities of serum osmolality and the rate at which it is corrected [31]. In juvenile or "brittle" diabetics, ketoacidosis develops after a dose of insulin is missed or an occult infection occurs. The first changes are mild confusion, lethargy, and deep regular inspirations (Kussmaul's breathing) in addition to signs of dehydration. Elderly patients are more prone to nonketotic hyperglycemia, especially when they have an inadequate diet, take medications that interfere with insulin metabolism [e.g., phenytoin (Dilantin), steroids], or take oral hypoglycemic agents [32]. Lactic acidosis may be present, in particular, with phenformin. These patients also tend to have focal or generalized seizures and transient or shifting hemiplegia as the level of coma deepens. The preservation of pupillary and oculocephalic responses helps to identify the clinical picture in such cases as being metabolic rather than structural.

The hyperosmolality occurring with hyperglycemia of any type causes a shift of water from the intracerebral to intravascular space with resulting brain shrinkage [33]. How this produces the neurologic changes observed is not known. More importantly, rapid correction of hyperosmolality by IV hydration and insulin results in cerebral water intoxication and signs of increased intracranial pressure. This is exemplified by the patient who begins to awaken from a hyperglycemic coma during IV therapy but later develops a headache and recurrent lethargy and seems to drift back into the previous state. Significant morbidity and mortality follow if these fluctuations are not observed and the IV treatment is modified appropriately [34]. Other details of the management of diabetic coma are addressed in Chapter 101.

Other Electrolyte Disturbances

Hyponatremia and *hypernatremia* cause fluid shifts and critical changes in serum osmolality, with the same effects on cerebral dysfunction as those described above. Mild to moderate *hyponatremia* (120 to 130 mEq per L) is evidenced by confusion or delirium with asterixis and multifocal myoclonus. If the serum sodium goes below 110 mEq per L, or drops at a rate more than 5 mEq per L per hour to 120 mEq per L and below, seizures and coma are likely to follow. This course of events portends permanent neurologic damage even after careful therapy [35]. Common causes of hyponatremia are (a) the syndrome of inappropriate antidiuretic hormone secretion (SIADH), with myriad etiologies; (b) excess volume expansion with hypotonic IV solutions; and (c) renal failure with a decreased glomerular filtration rate [36]. Other less common causes include psychogenic polydipsia, severe congestive heart failure, and Addison's disease.

The neurologic signs of hyponatremia are nonspecific, and the general approach to evaluation of an encephalopathy often identifies the problem. Treatment is directed toward the underlying cause with fluid restriction in mild cases, unless total body sodium is depleted. In moderate cases (i.e., a serum sodium of 105 to 115 mEq per L), PO sodium supplementation may be needed as well. A serum sodium below 100 mEq per L is life threatening. This requires judicious treatment with IV hypertonic saline at a rate calculated to replace about half of the total sodium deficit in 3 to 6 hours (averaging less than or equal to 0.5 mg Na^+ per hour). The remainder of the deficit should be administered in the next 24 to 48 hours [37]. Excessively rapid correction of severe hyponatremia, especially in alcoholic or malnourished individuals, can be associated with another serious neurologic complication known as *central pontine myelinolysis* [38]. Central pontine myelinolysis starts with a flaccid quadriparesis and inability to chew, swallow, or talk, or "locked-in syndrome" developing over a period of days. Patients who recover from the underlying systemic disorder are left with a spastic paraparesis and pseudobulbar speech; some may improve over several months.

Hypernatremia is not seen very often outside the hospital setting except in children with severe diarrhea and inadequate PO fluid intake. Excess diuretic therapy, hyperosmolar tube feedings, and restricted access to PO fluids are reflected in a serum sodium of more than 155 mEq per L in institutionalized patients. Clinically, one sees progressive confusion and obtundation in subacute cases. With levels of sodium more than 170 mEq per L developing acutely, the brain may shrink, and subdural hematomas can occur as a result of stretching of the dural vessels. These patients may complain of headache, develop seizures, or simply drift into a stupor. Catastrophic complications such as venous sinus thrombosis and irreversible coma are seen with a serum sodium level of more than 180 mEq per L due to the marked hyperosmolality that accompanies it.

The cause of profound hypernatremia is often diabetes insipidus, which may be secondary to head trauma. Impaired thirst mechanisms or depressed consciousness interfere with the polydipsia that is pathognomonic of diabetes insipidus [39]. The treatment of symptomatic hypernatremia depends on its cause: dehydration alone or complicated by additional sodium depletion due to hyperosmolar diuresis or excessive sweating. Fluid replacement is accomplished with 5% dextrose and water at a rate dependent on the total body water deficit—half of the water needed being administered IV in the first 12 to 24 hours and no faster. Saline solutions of half normal strength (0.45%) are used in most other cases. The exception is hyperosmolar diabetic coma, in which insulin and normal saline are both necessary to correct the severe serum hypertonicity.

Metabolic acidosis by itself produces only mild delirium or confusion [40] but may be accompanied by organ failure, direct CNS toxicity from drug metabolites, or volume depletion. The first sign of an encephalopathy caused by metabolic acidosis is hyperpnea followed by mental status changes and mild muscular rigidity. Ingestion of toxic doses of poisons such as methanol, ethylene glycol, and salicylates result in encephalopathy along with low serum bicarbonate levels (less than 15 mEq per L) [41]. Therapy must be directed toward vigorous correction of the metabolic acidosis while the specific cause is being elucidated.

Pancreatic Failure

Acute pancreatitis rarely leads to mental status changes during the initial bout. When recurrent or chronic, symptoms of encephalopathy may prominently wax and wane [42]. The clinical presentation is abdominal pain followed over 2 to 5 days by hallucinosis, delirium, focal or generalized seizures, and bilateral extensor Babinski responses. As the serum amylase continues to rise, the patient may lapse into a coma as

a result of secondary hyperglycemia, hypocalcemia, and hypotension. The exact cause of the encephalopathy is unknown; the prognosis and treatment depend on the underlying cause and severity of the pancreatitis [43].

Endocrine Disorders

Adrenal disorders are an important consideration in acute encephalopathy, because hypo- and hyperadrenalism produce alterations in CNS function.

Addison's disease or *secondary adrenocortical deficiency* occurs acutely in the setting of septicemia, surgery, and, most frequently, sudden withdrawal of chronically administered steroids. In the latter, one does not see the stigmata of chronic adrenocorticotropic hormone deficiency but rather hypotension, a mild hyponatremia, hypoglycemia, and hyperkalemia, together with a delirium or stupor that fluctuates erratically [44]. The electrolyte disturbances in most cases are not severe enough to explain the encephalopathy; other pathologic mechanisms such as cerebral hypoperfusion or water intoxication have been suggested. Unlike many metabolic encephalopathies, adrenocortical insufficiency is associated with *decreased* muscle tone and deep tendon reflexes. Seizures and papilledema may appear when the patient has a profound adrenocorticotropic hormone deficiency and coma. The neurologic picture does not clear until cortisone replacement is given along with treatment of the electrolyte imbalances. These patients are also particularly sensitive to sedative medications and may lapse into coma with small doses of narcotics or barbiturates [45].

Excess steroids produce different forms of encephalopathy depending on whether the source is endogenous or exogenous. In Cushing's disease, psychomotor depression and lethargy are the norm, whereas high doses of prednisone usually cause elation, delirium, or frank psychosis [46]. The latter is not uncommon in the ICU setting due to the administration of stress levels of steroids and multiple other CNS toxins. The behavioral changes are key to recognizing this problem because there are no specific metabolic markers [47]. Treatment consists of withdrawal of the steroids and sometimes temporary use of tranquilizers or lithium for the psychiatric features as well. Full neurologic recovery may lag behind the treatment by several days to weeks.

Hypothyroidism is now a rare cause of encephalopathy and coma. It may be confused initially with other causes of hypotension, hypoventilation, and hyponatremia, such as septic shock, brainstem infarcts, or an overdose of sedatives. The diagnosis should be considered in any patient with hypothermia, pretibial edema, pseudomyotonic stretch reflexes (e.g., delayed relaxation of the knee jerk), and coarse hair or facies. Muscle enzymes, serum cholesterol, and lipids may be elevated along with the thyroid-stimulating hormone level [48]. Diagnostic confirmation is often delayed pending results of thyroid function tests, but replacement therapy should be initiated early with IV triiodothyronine or thyroxine. The constitutional symptoms may take several weeks to respond, but the neurologic picture clears promptly with proper treatment. Another form of hypothyroid associated encephalopathy is seen in Hashimoto's thyroiditis with a subacute subtle change in personality, memory deficits, and cerebellar ataxia accompanied by cerebellar atrophy on imaging studies. Confirmation of the diagnosis requires specific tests for antithyroglobulin and antithyroperoxidase antibodies along with an elevated TSH. Treatment with thyroid replacement therapy often results in recovery over a few months.

Thyrotoxicosis is more difficult to recognize because it can present in an apathetic form, as a thyroid storm, or in a subacute form. Elderly patients are more likely to appear depressed or stuporous and without evidence of hypermetabolism [49]. The key to the diagnosis in such cases is evidence of recent weight loss and atrial fibrillation, often with congestive heart failure and a proximal myopathy. In a thyroid storm, the patient with indolent hyperthyroidism may be stressed by an infection or surgery and responds with marked signs of hypermetabolism: tachycardia, fever, profuse sweating, and pulmonary or congestive heart failure. Neurologically, the individual becomes acutely agitated and delirious and then progresses into a stupor [50]. The subacute picture that precedes this is one of mild irritability, nervousness, tremors, and hyperactivity and is often misconstrued as an affective disorder rather than endocrine in origin. Ophthalmologic signs such as proptosis, chemosis, and periorbital edema are useful in identifying this form of thyrotoxicosis.

Therapy for thyrotoxic encephalopathy is aimed at ablation of the gland, but supportive care may require beta-blockers, digoxin, diuretics, and sometimes dexamethasone and sedatives for the associated hypermetabolic state. Encephalopathy is also seen in disorders of the pituitary gland and parathyroid gland, although rarely as a primary process. *Hypopituitarism* may result from radiation or surgery to the area of the sella and can present as a chronic encephalopathy with features of thyroid or adrenal insufficiency, or both. An acute coma due to infarction or hemorrhage of the pituitary gland, known as *pituitary apoplexy*, can be seen in acromegalics with large adenomas or in patients with postpartum hemorrhage and hypotension (Sheehan's syndrome) [51]. Subarachnoid blood and ocular abnormalities plus signs of increased intracranial pressure help to identify the lesion in such cases. Encephalopathy from *hyperpituitarism* reflects the specific neurohumoral substance that is being released in excess and does not represent a unique syndrome.

Hyperparathyroidism may be manifest neurologically with asthenia or a vague change in personality. The patient is mildly depressed, lacks energy, and fatigues easily. A serum calcium more than 12 mg per dL and elevated parathormone levels are important diagnostic findings. Occasionally, psychiatric symptoms predominate, starting with delirium and psychosis, or obtundation and coma when the serum calcium exceeds 15 mg per dL. Hypercalcemia caused by metastatic bone lesions, paraneoplastic parathormone-like substances, sarcoidosis, primary bone diseases, and renal failure are associated with a subacute or chronic encephalopathy similar to hyperparathyroidism. Treatment in these cases must be directed toward the underlying disease rather than addressing the hypercalcemia alone. Primary hyperparathyroidism is effectively managed by ablation of the overactive gland. This is not always possible, because the glands often are ectopic and may escape discovery on selective angiography or exploratory surgery.

Hypocalcemia due to *hypoparathyroidism* produces an encephalopathy that parallels the depression of serum calcium levels. At less than 4.0 mEq per L calcium, a blunted effect and seizures are common and may be confused with a dementing process or epilepsy. The motor signs of hypocalcemia, that is, tetany or neuromuscular irritability, should make one suspicious of a metabolic disturbance [39]. Another diagnostic dilemma is the occasional presentation of hypocalcemia with papilledema and headache. The opening pressure on lumbar puncture is elevated to the same degree as in pseudotumor cerebri, but a head CT is likely to show basal ganglia calcifications [48]. Furthermore, the presence of cataracts and mental dullness in a previously normal individual should lead one to check the serum calcium and parathormone levels.

The mechanism by which hypocalcemia and hypoparathyroidism produce these varied neurologic symptoms is not known. Replacement of serum calcium by dietary means is usually inadequate to correct the CNS disorder. Supplementation with vitamin D and calcitriol enhances the absorption and utilization of oral calcium.

Other Causes of Encephalopathy

The list of causes of diffuse or metabolic encephalopathies is so lengthy that the problem of diagnosis must be resolved by a process of elimination. Drugs and toxins lead all other possible causes, with a frequency of approximately 50% (see Chapters 117 through 145). Hepatic, renal, or pulmonary failure is causative in another 12% and endocrine or electrolyte disturbances in approximately 8%. Other less common etiologies include thiamine deficiency (Wernicke's encephalopathy), cardiac bypass surgery, subacute bacterial endocarditis, and hyperthermia. All of these disorders produce microembolic or microhemorrhagic/petechial lesions in specific areas of the brain.

Wernicke's encephalopathy develops acutely in the clinical setting of an alcoholic or a malnourished individual, especially when IV glucose solutions without vitamin supplementation are given. Because thiamine is a cofactor in the utilization of cerebral glucose, it is depleted by the IV infusion [52]; confusion, obtundation, and loss of short-term memory rapidly ensue. The hallmark of this entity is a striking impairment of ocular movements, causing an external ophthalmoplegia, nystagmus, and diminished oculocephalic responses. Prompt IV and PO administration of 100 mg thiamine restores ocular function completely. The cerebral symptoms resolve slowly with the addition of 100 mg PO thiamine daily for 3 days or more. If untreated, the patient may lapse into a coma due to autonomic failure with accompanying shock and hypothermia and often dies. Repeated or untreated episodes of Wernicke's disease may result in a chronic Korsakoff's psychosis with profound memory impairment [49].

More recently, recognition of autoantibodies to potassium channels (VGKC-Ab) and NMDA receptors presenting with a subacute limbic-type encephalopathy has led to exciting research into the role of channel blockade in reversible mental status changes. In many cases, there is no evidence of an occult cancer (e.g., testicular or ovarian in young people) and the prognosis with immunoglobulin or steroid therapy is good [50].

Hyperthermia due to heat stroke also has a characteristic clinical setting—young individuals experiencing excessive sweating caused by overactivity and elderly people receiving anticholinergics who are exposed to a hot environment [51]. In both cases, neurologic changes occur when the core body temperature reaches 42°C (107.6°F). The patient may become agitated and confused with intermittent generalized seizures or may immediately lapse into a coma as if due to a stroke. The presence of tachycardia, hot and dry skin, and diffuse hypertonus occurring in the appropriate circumstances identifies the likely etiology. Normal pupillary size and reflexes (except with anticholinergics) and oculocephalic responses, and the absence of focal motor signs also point to a nonstructural lesion. However, if the core body temperature is not lowered early in the course, the patient may be left with sequelae similar to those seen in hypoxic–ischemic encephalopathy. Other causes of temperature more than 42°C are rare and are not discussed here [53].

Up to 20% of patients with *bacterial or marantic endocarditis* can present with a subacute encephalopathy manifested by confusion and hyperpnea with or without fever [54]. It should be suspected in any patient with Gram-negative sepsis [37]; ovarian cancer; malignant melanoma; adenocarcinoma of the lung, breast, prostate, or pancreas; and an immunocompromised state. Definitive diagnosis rests on the blood culture results and an echocardiogram showing vegetations. Treatment is directed toward reducing or removing the cardiac source.

CONCLUSIONS

Metabolic encephalopathy is one of the most frequently seen neurologic disorders in the ICU arena. It is also one of the most diverse in its clinical presentations and requires a systematic approach to define the etiology and to institute effective treatment. The features that distinguish most metabolic encephalopathies from structural lesions are (a) a nonfocal neurologic examination, (b) increased motor activity, (c) intact ocular and pupillary reflexes, and (d) laboratory abnormalities that support the clinical picture. Additional tests such as an EEG, head CT, or toxicology screen are useful in ruling out other possible causes.

One should keep in mind that many patients in the ICU have an underlying chronic encephalopathy due to long-standing illness [56]. Therefore, they are more susceptible to minor metabolic perturbations induced by small doses of drugs, slight shifts of fluid balance, or worsening organ failure. Early recognition and correction of such factors improve the patient's prognosis for a full neurologic recovery. Toward this end, it is prudent to consult the neurologist before the complications of multiple treatments and further changes confound the clinical course.

CHAPTER 171 ■ GENERALIZED ANOXIA/ ISCHEMIA OF THE NERVOUS SYSTEM

CAROL F. LIPPA AND MAJAZ MOONIS

Anoxic brain injury results from inadequate oxygen supply to the brain. The clinical picture ranges from mild confusion to deep coma with loss of brainstem responses. Anoxic damage can be caused by circulatory collapse, respiratory failure, or inadequate hemoglobin binding to oxygen. Prognosis and management of the anoxic patient depend in part on which of these mechanisms has caused the injury.

PATHOGENESIS

The brain is unique in that it uses almost exclusively aerobic metabolism of glucose. The continuous availability of oxygen is secured by the cerebral vasculature's autoregulatory mechanism [1], which controls the rate of blood flow over a wide range of blood pressures. If blood pressure drops too low for autoregulatory mechanisms to operate, oxygen extraction from the blood increases. Failure of this compensatory mechanism results in a changeover from aerobic to anaerobic metabolism.

In cardiac arrest, depletion of brain oxygen reserves occurs within 10 seconds, thereby eliminating the major source of neuronal energy from ATP (adenosine triphosphate) and phosphokinase. Excessive glutamate release and reduced reuptake lead to activation of the NMDA (*N*-methyl-d-aspartate) receptors and consequent ischemic cascade. The resulting intracellular (cytotoxic) edema leads to increased intracranial pressure.

The changeover to anaerobic metabolism results in neuronal catabolism. In cardiovascular collapse, loss of venous outflow leads to the accumulation of lactic acid and pyruvate, the end products of anaerobic metabolism. Buildup of these catabolites potentiates the cellular damage.

DIAGNOSIS

The first question to address when evaluating a comatose or obtunded patient with a possible hypoxic insult is whether the impaired consciousness is the result of a metabolic insult or a structural brain lesion. Coma caused by a mass lesion is usually associated with focal neurologic signs. Computed axial tomography (CT) or magnetic resonance imaging (MRI) scans usually reveal focal lesions in this setting. Metabolic causes, including anoxic encephalopathy, should be suspected when patients with impaired consciousness present with a non-focal examination.

The diagnosis is often suggested by the clinical setting (e.g., cardiac arrest in patients with arrhythmias or myocardial infarctions, or severe episodes of intraoperative hypotension). Arterial blood gas determination, if obtained during the causal event, can confirm the diagnosis. A partial pressure of oxygen of less than 40 mm Hg causes confusion and less than 30 mm Hg results in coma [2]. Associated abnormalities that potentiate anoxic damage include anemia, acidosis, hypercapnia, hyperthermia, and hypotension.

The internist or neurologist is often consulted to evaluate the patient who has impaired consciousness after well-documented cerebral hypoperfusion that has occurred during surgical operations requiring the use of extracorporeal circulation. The neurological examination is nonfocal. Because surgical patients with such a history often have preexisting illnesses (vascular disease, borderline renal function, hepatic impairment, diabetes), it is the obligation of the intensive care physician to determine new deficits due to anoxic encephalopathy, or other treatable conditions secondary to metabolic, infectious, and iatrogenic factors such as sedating medications. Intracerebral hemorrhage and subdural hematomas should also be sought, because they can occur spontaneously in the perioperative period, especially in anticoagulated patients.

CLINICAL COURSE AND PROGNOSIS

The clinical outcome of patients with anoxic injuries depends on the degree and duration of oxygen deprivation to the brain as well as the maintenance of blood flow. With complete cessation of blood flow to the brain, consciousness is lost after several seconds. If anoxia is moderately prolonged, the patient awakens but may have residual deficits, such as cognitive impairment, or later sequelae, including extrapyramidal movement disorders or seizures, which may not develop for days to weeks.

A delayed postanoxic syndrome may occur rarely in patients with anoxic insults after the initial coma. Three to 30 days following the initial anoxic insult, after the patient has regained consciousness and cognitive function, there is a secondary decline characterized by irritability, confusion, lethargy, clumsiness, and increased muscle tone; patients may become comatose again and die. This uncommon condition occurs most often in cases of carbon monoxide poisoning. Pathologically, widespread demyelination is seen without gray matter changes. The cause is unknown, but it may be due to alteration of enzymatic processes, edema, or damage to small blood vessels [2,3].

The overall prognosis for a meaningful recovery in patients with nontraumatic coma is guarded; the longer patients are in coma, the worse the outcome [4–6]. Most improvement occurs within the first 30 days. Non-anoxic metabolic coma carries the best prognosis, while anoxic coma has a better prognosis than coma resulting from structural lesions. A good outcome is seen in 50% of patients who awaken within 24 hours. Although infrequent seizures or myoclonus do not affect prognosis, myoclonic or nonconvulsive status epilepticus is a grave prognostic sign and is associated with poor recovery [4,7].

If consciousness is maintained during a hypoxic event, there is rarely permanent brain damage. Irreversible damage is rarely seen in healthy individuals if the duration of anoxia is less than 4 minutes, although it may be incurred in individuals with preexisting cerebrovascular disease in shorter periods.

In cases of nontraumatic coma, the most valuable prognostic information is obtained from the physical examination. Favorable prognostic indicators include

1. Recovery of multiple brainstem responses within 48 hours (pupillary, oculocephalic, and corneal) [4];
2. Return of purposeful responses to painful stimuli by 24 hours;
3. Primary pulmonary event leading to coma;
4. Hypothermia at the time of the anoxic event may be protective; patients who have experienced near-drowning, submerged in cold water up to 40 minutes may return to normal neurologic function [8];
5. Younger age (children and young adults) [9,10].

Poor prognostic indicators in persistent coma include

1. Absence of pupillary or corneal responses, and absent motor response to pain by the third day [11];
2. The loss of vestibulo-ocular responses at 12 hours and the presence of decerebrate or decorticate posturing at 24 hours [5,8];
3. Electroencephalogram (EEG) patterns: nonreactive EEG; burst suppression; alpha coma. Serial EEGs documenting improvement are associated with a better prognosis [12,13];
4. Short-latency somatosensory evoked potential tests are noninvasive tests of the sensory system that are absent in brain death but preserved in severe reversible comas, such as barbiturate coma that can mirror brain death [14,15]. Absent cortical N20 on somatosensory evoked response at 72 hours is associated with irreversible coma. N20 present at 8 hours has a 25% chance of recovery [15,16];
5. The presence of either diffuse edema or watershed infarctions on CT scans;
6. Loss of gray white matter distinction on CT scan and severe abnormalities on diffusion-weighted imaging [17,18];
7. Myoclonus or status epilepticus the first day.

A recent Academy of Neurology Practice Parameter by Wijdicks et al. [19] is an evidence-based review for predicting the outcome in survivors of cardiopulmonary resuscitation. The authors conclude that "Pupillary light response, corneal reflexes, motor response to pain, myoclonus status epilepticus, serum neuron-specific enolase and somatosensory evoked potential studies can reliably assist in accurately predicting poor outcome in comatose patients after cardiopulmonary resuscitation for cardiac arrest."

When prognosticating by the clinical criteria alone, one must be careful that no sedative, anesthetic, or anticonvulsant (Dilantin, phenobarbital) is being used, because these agents can suppress brainstem reflexes.

Respiratory insufficiency with maintained circulation carries a better prognosis. A low partial pressure of oxygen does not necessarily convey a bad prognosis in cases of isolated hypoxia [20] if circulation is carefully maintained [21].

Conversely, the presence of metabolic abnormalities, such as lactic acidosis, worsens prognosis.

In cases of out-of-hospital cardiac arrest, survival depends on the total time required to establish effective cerebral blood flow. The arrest time (AT) and the cardiopulmonary resuscitation (CPR) time to effective cardiac function represent a continuum from absence of cerebral blood flow to effective circulation, and together represent the total duration of ineffective cerebral blood flow. Short AT is compatible with good outcomes even after longer periods of CPR, whereas increasing lengths of AT reduce the time window for successful CPR. If AT is less than 6 minutes, prognosis for recovery is related to CPR time; over half of patients on whom CPR is successful within 30 minutes make a good neurologic recovery. When CPR time is longer, prognosis for neurologic recovery drops significantly. If AT exceeds 6 minutes, the chances of good neurologic outcome decrease [22]. Unsuccessful CPR before arrival at the emergency room predicts a poor prognosis [23]. Emergency crew–witnessed arrests, consciousness level on admission, and requirement for ventilation are independently useful to predict in-hospital outcome and mortality [24].

Magnetic resonance spectroscopy demonstrating elevated lactate and reduced *N*-acetyl acetate peaks is associated with a poor prognosis [25,26].

Cerebrospinal fluid (CSF) lactate levels [27], neuron-specific enolase, and brain-type creatine kinase isoenzyme levels may have predictive value 24 hours after cardiac arrest. Patients with either CSF neuron-specific enolase more than 33 µg per L at 24 hours or cerebrospinal fluid brain-type creatine kinase isoenzyme more than 50 U per L at 48 to 72 hours usually die. Creatine phosphokinase levels above 205 U per L are uniformly associated with a fatal outcome. A potentially useful laboratory screening test when lumbar puncture is not feasible is the serum neuron-specific enolase level, which has a fair correlation with outcome [28–30]. Similarly, S-100 protein, an astroglial marker, is elevated in anoxic arrest. Values of more than 0.2 mmol per L on day 2 are associated with 100% mortality, whereas values below this are associated with an 89% survival [31].

After out-of-hospital cardiac arrest, the overall probability of awakening is roughly 50% [32,33]. Much of this depends on the duration of coma. In cases of cardiac arrest, complete recovery occurs in 80% of patients in whom the coma resolves within 24 hours [32,33]. Others have shown that 72 hours is the upper limit for recovery of brain function sufficient to permit some degree of speech [34].

TREATMENT

Treatment approaches for cardiac arrest and perioperative hypoxic encephalopathy are similar. Optimal therapy is directed at preventing the recurrence of hypoxia. To ensure that the oxygen-carrying capacity of the blood is restored, excess oxygen administration is suggested for several hours after anoxic events. There is strong evidence that mild or moderate hypothermia may improve outcome after cardiac arrest [35,36]. Blood pressure is maintained at normotensive or mildly elevated levels. Mean arterial pressure should be 90 to 110 mm Hg in patients who are usually normotensive. The partial pressure of oxygen should be more than 100 mm Hg. The partial pressure of carbon dioxide is kept at the patient's baseline (usually 40 mm Hg), unless there are active signs of cerebral herniation; if herniation is suspected, the patient should be hyperventilated. Mild hypovolemia and elevation of the head of the bed to 30 degrees reduce intracranial pressure. Vital signs, hematocrit, electrolytes, blood sugar, and serum osmolality should be maintained in the normal range [12]. In all cases, a head CT or MRI scan and complete metabolic studies should be obtained to exclude structural and other functional causes. When any uncertainties exist, a neurologist should be consulted.

Seizures occur in 25% of patients in anoxic coma [4]. They are treated with loading and then maintenance doses of fosphenytoin (Cerebyx) (loading dose, 15 to 20 mg phenytoin equivalents per kg, rate not to exceed 100 mg phenytoin equivalents per minute; maintenance dose, 5 mg phenytoin equivalents per kg per day). Alternatively, intravenous phenytoin can be used (loading dose, 18 to 20 mg per kg; rate, 50 mg per minute; maintenance dose, 5 mg per kg). Patients with cardiac conduction abnormalities need to be carefully monitored while being loaded with fosphenytoin or phenytoin. Phenobarbital is usually avoided because of its sedative effects. If necessary, loading doses in adults are up to 500 mg intravenously, and maintenance doses are 2 to 4 mg per kg per day [37]. Because status epilepticus or frequent untreated seizures can further damage the brain, an EEG should be obtained if there is any question of subclinical epileptiform activity [10]. Some postanoxic patients develop delayed intention myoclonus. This can be distinguished from seizure activity because the latter is accompanied by an epileptiform discharge on the EEG, whereas myoclonus is not. Intention myoclonus can be treated with valproic acid.

Steroids, mannitol, and glycerol are ineffective and result in elevated serum blood glucose, which increase production of lactic acid, possibly potentiating preexisting damage. High dose barbiturates or calcium channel blockers have not demonstrated any improvement in outcome [38,39].

If the patient awakens, mobilization is initiated early to minimize the risk of bedsores and deep venous thrombosis. An empiric 7 to 10 days of bed rest may minimize the chance of developing postanoxic encephalopathy in cases of carbon monoxide poisoning [2,3].

Induced hypothermia may be protective. A randomized, controlled trial assessed the effects of moderate hypothermia and normothermia in patients who remained unconscious after resuscitation from out-of-hospital cardiac arrest. Of the 77 patients who were randomly assigned to treatment with hypothermia (core body temperature 33°C within 2 hours after the return of spontaneous circulation and maintained at that temperature for 12 hours) or normothermia, 21 of the 43 patients treated with hypothermia (49%) survived and had a good outcome, discharged home or to rehabilitation as compared with 9 of the 34 treated with normothermia (26%; $p = 0.046$). The odds ratio for a good outcome with hypothermia as compared with normothermia was 5.25 (95% confidence interval, 1.47 to 18.76; $p = 0.011$). Hypothermia was associated with a nonsignificant lower cardiac index, higher systemic vascular resistance, and hyperglycemia. The narrow inclusion criteria resulted in an international recommendation to cool only a restricted group of primary cardiac arrest survivors. In a broader retrospective study the efficacy and safety of endovascular cooling in unselected survivors of cardiac arrest was assessed. Consecutive comatose cardiac arrest survivors were either cooled to 33°C with endovascular cooling for 24 hours or treated with standard post-resuscitation therapy. Patients in the endovascular cooling group had twofold increased odds of survival (67/97 patients versus 466/941 patients; odds ratio 2.28, 95% CI, 1.45 to 3.57; $p < 0.001$). After adjustment for baseline imbalances, the odds ratio was 1.96 (95% CI, 1.19 to 3.23; $p = 0.008$). Bayesian analysis revealed odds ratios of 1.61 (95% credible interval, 1.06 to 2.44). In the endovascular cooling group, 51/97 patients (53%) survived with good outcome as compared with 320/941 (34%) in the control group (odds ratio 2.15, 95% CI, 1.38 to 3.35; $p = 0.0003$; adjusted odds ratio 2.56, 1.57 to 4.17). There was no difference in the rate of complications except for bradycardia. The investigators concluded that endovascular cooling improved survival when compared with standard treatment in comatose adult survivors of cardiac arrest [40].

CONCLUSION

The effects of oxygen deprivation depend on many factors; the degree and duration of hypoxia are the most important. In cases of cardiac arrest, brain damage is proportional to the amount of time without perfusion. The patient's age, underlying medical conditions, infection, and other metabolic imbalances also play a role in the body's ability to withstand oxygen deprivation.

Treatment strategies for the acute phase focus on supportive care. Elevation of the head of the bed, maintaining a relatively hypovolemic state, and avoidance of hypotension may be of benefit. A vigorous search should be made for concurrent metabolic abnormalities. Induced hypothermia improves outcome; administration of steroids, osmotic agents, neuroprotective agents, and prophylactic anticonvulsants are ineffective measures and may worsen the prognosis.

Prognosis is best determined by the early return of brainstem and cranial nerve function. Absence of brainstem functions 72 hours after the event is associated with irreversible coma [11]. Other poor prognostic signs include a brainstem auditory evoked response showing no cortical waves 8 hours after the arrest and a CT scan demonstrating diffuse edema, loss of gray–white matter distinction, or watershed infarcts. The overall functional recovery rate is approximately 13%. If a patient has not regained consciousness by 6 hours after the onset of coma, the chance of survival for 1 year is 10%, and many of these survivors remain in a vegetative state.

Data from recent studies of out-of-hospital cardiac arrest patients treated by induced hypothermia to 32°C suggest a better prognosis (survival increased threefold and neurological recovery almost 4.5 fold compared to patients who did not undergo hypothermia.) This better outcome was limited to patients with a primary cardiac arrest who had initiation of successful CPR within 15 minutes and had a stable circulation within 60 minutes. Patients with significant pretreatment hypothermia, bleeding disorders, terminal or other serious comorbid conditions and unstable circulation after CPR were excluded. If one takes into account the retrospective nature of this study, the results are at best limited to the above population and can be considered hypothesis-generating data for future trials.

CHAPTER 172 ■ STATUS EPILEPTICUS

JAISHREE NARAYANAN AND CATHERINE A. PHILLIPS

DEFINITION AND CLASSIFICATION

Status epilepticus (SE) was originally defined as seizures lasting longer than 30 minutes, or 30 minutes of recurrent seizures without return to baseline neurologic status between events [1]. This has been largely replaced by an operational definition of SE, which is a 5-minute duration of continued seizure activity, or two or more seizures between which there is incomplete recovery. SE is considered to be a condition in which there is "a failure of the 'normal' factors that serve to terminate a typical generalized tonic-clonic seizure" [2,3]. This approach is more clinically appropriate and promotes early treatment with antiepileptic medication. SE is usually divided into: (a) convulsive SE, in which the patient does not regain consciousness between repeated generalized tonic-clonic attacks; (b) simple partial SE, characterized by continuous or repetitive focal seizures without loss of consciousness [4]; and (c) nonconvulsive SE (NCSE), such as absence or complex partial SE, characterized by a prolonged confusional state of 30 minutes or longer. NCSE is also used to describe continued seizure activity in patients who have few or no clinical signs other than coma.

Convulsive Status Epilepticus

Most generalized tonic-clonic SE consists of partial seizures that have secondarily generalized; primary generalized SE is less common [5]. Most patients do not convulse continuously. Instead, seizures of a few minutes' duration may be followed by a prolonged period of unconsciousness that leads to the next seizure. During convulsive SE, massive autonomic discharge occurs with tachycardia and hypertension. Corneal and pupillary reflexes are lost and plantar reflexes may be extensor. As SE continues, the motor manifestations may evolve into more subtle activity such as low-amplitude focal twitching, nystagmus, eye deviation, or recurrent pupillary hippus. This is sometimes called *subtle generalized SE* [4]. SE may also present in this more subtle form, without initial convulsive activity, in patients who are very encephalopathic; electroencephalography (EEG) is required to confirm the diagnosis. Myoclonic SE is often classified as a form of convulsive SE; it can occur in children with chronic epilepsy and mental retardation. It is characterized by repetitive, asynchronous myoclonus with variable clouding of consciousness and may evolve into generalized tonic-clonic SE. In adults, the myoclonic syndromes that occur are usually secondary to toxic or metabolic encephalopathies, most commonly severe cerebral anoxia [6]. The patients are usually comatose, and the prognosis is poor. In both forms of myoclonic SE, the EEG shows repetitive generalized epileptiform discharges.

Simple Partial Status Epilepticus

Simple partial status epilepticus is the second most common form of SE, after generalized tonic-clonic SE [4]. In partial motor SE, focal clonic or tonic-clonic activity is localized to the face or an extremity. This activity may spread, corresponding to the somatotopic organization of the motor cortex, known as a Jacksonian march. Alternatively, the partial motor seizures may be multifocal, in this case often precipitated by metabolic disorders, such as hyperglycemia with a hyperosmolar nonketotic state [7]. *Epilepsia partialis continua* refers to a form of partial motor SE characterized by continuous, highly localized seizures that do not secondarily generalize and in which consciousness is maintained.

Nonconvulsive Status Epilepticus

NCSE is an under-recognized cause of coma. In a recent study, NCSE was documented in 8% of all comatose patients, without signs of seizure activity [8]. In additional studies, 31% to 37% of patients with unexplained altered mental status in intensive care units were in NCSE. NCSE is more likely to occur in the setting of acute medical problems, both systemic and neurologic [8–10].

Nonconvulsive SE includes absence and complex partial SE [4]. Clinically, both absence and complex partial SE present with a prolonged period of altered behavior and can masquerade as a psychiatric fugue state. Absence SE involves a variable level of altered consciousness, which may be accompanied by subtle myoclonic movements of the face, eye blinking, and occasional automatisms of the face and hands. The EEG is diagnostic, revealing continuous or discontinuous generalized spike and slow-wave activity. Complex partial SE involves either a series of complex partial seizures with staring, unresponsiveness, and motor automatisms, separated by a confusional state, or a more prolonged state of partial responsiveness and semipurposeful automatisms. In both of these forms of SE, the patient is partially or totally amnestic for the episode.

ETIOLOGY

Some of the major underlying etiologies and precipitants of SE are shown in Table 172.1. Precipitants are factors that provoke SE where it otherwise would not have occurred, but they are not the underlying cause of the seizure disorder. Symptomatic SE, defined as SE resulting from an acute or chronic neurologic or metabolic insult, is typically more common than idiopathic SE (presumed genetic etiology for the seizures in an otherwise neurologically normal person) [5]. In most series, at least two-thirds of cases of SE are symptomatic. In adults, a major cause of SE is stroke, comprising more than 25% of the cases in one series [5]. Decreasing antiepileptic drugs was also a significant cause of SE in this same series, occurring in approximately 20% of the cases. Other major causes include alcohol withdrawal, anoxia, metabolic disease, viral encephalitis including Epstein–Barr virus or herpes simplex virus, HIV infection, and drug abuse [11,12]. The acute insults can cause SE in patients with or without epilepsy. Children younger than 1 year and adults older than 60 years represent the populations most at risk for developing SE [5].

TABLE 172.1

ETIOLOGIES AND PRECIPITANTS OF STATUS EPILEPTICUS

- Etiologies
  - Structural brain lesion
    - Brain trauma
    - Brain tumors
    - Strokes
    - Hemorrhage
  - Central nervous system infections
    - Encephalitis
    - Meningitis
  - Toxic
    - Drugs (e.g., theophylline, lidocaine, penicillin)
    - Withdrawal states (e.g., alcohol, barbiturate)
  - Metabolic
    - Hypocalcemia
    - Hypomagnesemia
    - Hypoglycemia, hyperglycemia
    - Hyponatremia
    - Hyperosmolar state
    - Anoxia
    - Uremia
- Precipitants
  - Changes in anticonvulsant blood levels
    - Errors in medication
    - Change in drug regimens
    - Altered drug absorption
    - Noncompliance
  - Intercurrent infection
    - Fever (e.g., upper respiratory or gastrointestinal infections)
  - Alcohol withdrawal

PROGNOSIS AND SEQUELAE OF STATUS EPILEPTICUS

Mortality in SE depends on the specific etiology, duration of the episode, and the age of the patient [13]. The acute insult triggering SE is one of the most important factors influencing mortality. Among the etiologic groups, anoxia has been associated with the highest mortality rate, followed by hemorrhage, tumor, metabolic disorders, and systemic infection. Alcohol withdrawal and antiepileptic drug discontinuation have been associated with a low mortality rate. Patients with idiopathic SE have a low mortality rate. The duration of SE strongly affects the ultimate prognosis. In one study, patients with seizure duration of longer than 60 minutes had a mortality of 32.0%, whereas patients with seizure duration of shorter than 60 minutes had a mortality of 2.7% [13]. Age is significantly associated with mortality, with patients above the age of 70 having a dramatically greater mortality [5,13,14]. Despite improved medical care, convulsive SE still has an overall mortality rate in the range of 7% to 25% [5,13–15]. The mortality of complex partial SE was 18% in one study [16]. Other adverse outcomes include intellectual deterioration, permanent neurologic deficits, and chronic epilepsy.

SE itself can produce profound neuronal damage. Neuropathologic studies of the brains of children and adults who died shortly after SE reveal ischemic neuronal changes in the hippocampus, middle layers of the cerebral cortex, cerebellum (Purkinje cells), basal ganglia, thalamus, and hypothalamus [17]. These changes mimic those of severe hypoxia or hypoglycemia. The degree of hyperthermia during an episode of SE has also been shown to correlate closely with the degree of central nervous system (CNS) damage [18].

The perpetuation of SE is most likely caused by an imbalance between excitotoxic (primarily mediated by glutamate) and inhibitory (primarily mediated by γ-aminobutyric acid [GABA]) mechanisms [15,16]. This can be related to downregulation in GABA receptors or excitotoxic mechanisms involving glutamate receptors—both NMDA(*N*-methyl-d-aspartate) and non-NMDA receptors [3,15,19]. Calcium influx during excitation appears to be a critical component of neuronal injury and cell death, with activation of proteases and lipases leading to degradation of intracellular elements [19].

Abnormal neuronal activity alone can cause permanent neurologic injury. This is supported by the observation that patients with complex partial or partial motor SE who do not have concomitant hypotension, hypoxia, or hyperpyrexia can still have subsequent neurologic injury in the region of the brain associated with the seizure. Chronic memory impairment may follow complex partial SE [20], and focal neuronal necrosis (and edema) in the region of the brain involved with seizure activity has been found after partial motor status [21,22]. Focal magnetic resonance imaging (MRI) changes can be seen after prolonged epileptic activity, particularly on diffusion-weighted and perfusion MRI [23].

The natural history of NCSE is not well defined, especially mortality and morbidity. This is partly due to methodological issues, such as the lack of a uniform accurate definition of NCSE, and not assigning appropriate significance to the underlying etiology, mental status changes, and associated complications [24–26]. Kaplan [27,28] reviewed the prognosis of NCSE and suggested that prognosis depends not only on detailed assessment of NCSE type, but also on level of consciousness. In another study designed specifically to determine the rate of morbidity and mortality, mortality was associated with an acute medical cause as the underlying etiology, severe mental status impairment, and development of acute complications, but not the type of EEG changes [10].

SYSTEMIC COMPLICATIONS

If convulsive SE is not terminated promptly, secondary metabolic and medical complications occur (Table 172.2). Cardiac arrhythmias occur due to autonomic overactivity, acidosis, and hyperkalemia. This can be further complicated by shock due to lactic acidosis or by pharmacologic intervention for the status itself. Respiratory dysfunction may be caused by mechanical impairment from tonic muscle contraction, disturbed respiratory center function, massive autonomic discharge producing increased bronchial constriction and secretions, aspiration pneumonia, and neurogenic pulmonary edema. Neurogenic pulmonary edema results from ictal increases in pulmonary circulation with transcapillary fluid flux [17]. Renal impairment may occur from a combination of rhabdomyolysis with myoglobinuria and hypotension with poor renal perfusion. Hyperthermia can result from excessive muscle activity and hypothalamic dysfunction; alternatively, it may be due to an underlying infection that is responsible for the initiation of SE. The distinction of hyperthermia from an infection or from SE itself can be complicated by the peripheral leukocytosis [17] that occurs with status epilepticus due to demargination. This can result in a white blood cell count in the range of 12,700 to 28,000 cells per mm^3. The differential may be normal or may show lymphocytic or polymorphonuclear predominance, but band forms are rarely present. In addition, a mild cerebrospinal fluid (CSF) pleocytosis can occur with SE [17]. The maximum cell count is usually less than 80 cells per mm^3, with an initial polymorphonuclear predominance that reverts to a lymphocytic predominance as the pleocytosis resolves over a

TABLE 172.2

MEDICAL COMPLICATIONS OF STATUS EPILEPTICUS

	Early	Late (after 30 min)
Cardiovascular system	Tachycardia Hypertension	Bradycardia Hypotension Cardiac arrest Shock
Respiratory system	Tachypnea Apnea with carbon dioxide retention	Apnea Cheyne–Stokes Aspiration pneumonia Neurogenic pulmonary edema
Renal system	—	Uremia Acute tubular necrosis Myoglobinuria
Autonomic nervous system	Mydriasis Salivary and tracheobronchial hypersecretion Excessive sweating Bronchial constriction	Hyperpyrexia
Metabolic	Lactic acidosis Hyperglycemia Hyperkalemia	Lactic acidosis Hypoglycemia Liver failure Elevated prolactin

few days. Mild transient elevations in CSF protein may also occur. However, lowering of the CSF glucose level does not occur, and reduced CSF glucose immediately suggests an underlying bacterial or fungal infection.

Increased lactate production from maximally exercised muscles results in metabolic acidosis within minutes after the start of SE. There is a variable respiratory contribution to the acidosis from carbon dioxide retention. The degree of acidosis does not correlate with the extent of neuropathologic damage [17]. After cessation of the seizure, lactate is rapidly metabolized, resulting in spontaneous resolution of the acidosis. Initially, hyperglycemia develops due to catecholamine and glucagon release; later, hypoglycemia occurs due to increased plasma insulin, increased cerebral glucose consumption, and excessive muscle activity.

INITIAL ASSESSMENT AND MEDICAL MANAGEMENT

SE is a medical emergency and must be treated immediately in a critical care setting. Pharmacologic intervention is more effective at an early stage of SE than after a delay [3,14,15,19,29,30]. Treatment must be fourfold: termination of seizures, prevention of recurrent seizures, identification of etiology, and treatment of complications. This discussion concentrates on generalized tonic-clonic SE, which is the most common form of status in adults and has the most harmful neurologic sequelae.

The initial step is to confirm the diagnosis. The patient must be carefully observed to be sure that generalized seizures are recurring without recovery of consciousness. A flurry of seizures separated by a normal level of consciousness does not constitute SE (although urgent treatment may still be required). In the intensive care unit, NCSE may present clinically with a change in mental status only. As mentioned earlier, in this setting NCSE appears to be greatly underdiagnosed. For diagnosis of NCSE, certain well-defined EEG criteria need to be met, including repetitive epileptiform activity at more than 3 per second, or repetitive epileptiform activity at less than 3 per second but with incrementing or decrementing onset for 10 seconds or more and/or clinical improvement after antiepileptic drug (AED) use. The EEG ictal episodes should be continuous or recurrent for more than 30 minutes without improvement in clinical state, or return to preictal EEG between seizures [27,28].

Once a diagnosis of SE is made, treatment must proceed rapidly but deliberately. For generalized SE, the initial assessment and treatment should begin within 5 to 10 minutes of the onset of seizure activity. Table 172.3 outlines a management protocol.

It is important to obtain as much history as possible within the first few minutes of assessment, including any history of a preexisting chronic seizure disorder and antiepileptic drug use, alcohol or drug abuse, or any recent neurologic insult. The examination should focus on signs of systemic illness (e.g., uremia, hepatic disease, and infection), illicit drug use, evidence of trauma, or focal neurologic abnormalities. After appropriate blood samples have been obtained, glucose administration is recommended. Hypoglycemia is a rare but easily reversible cause of SE and may result in irreversible CNS damage if left untreated. Because glucose administration may precipitate Wernicke–Korsakoff syndrome in some individuals with marginal nutrition, thiamine should also be given. Subsequent intravenous (IV) infusions should consist of saline solution, as some AEDs precipitate in glucose solutions. The patient must be assessed for other metabolic consequences of status. Hyperthermia should be treated and oxygenation must be maintained. The metabolic acidosis that occurs does not adversely affect neurologic outcome and does not need treatment with bicarbonate [14,31]. Blood pressure must be carefully monitored; the systemic hypertension and decreased cerebrovascular resistance of early SE provide adequate blood flow for the increased metabolic demand in the brain, but eventually hypotension may occur, making the brain vulnerable to inadequate perfusion. Pharmacologic intervention for the seizures can exacerbate any hypotension.

TABLE 172.3

MANAGEMENT GUIDELINES FOR GENERALIZED STATUS EPILEPTICUS IN ADULTS

0–9 min:
If diagnosis is uncertain, observe for: recurrence of generalized seizures without intervening recovery of consciousness; continuous seizure activity > 5 min.

ABCs
Establish airway; pulse ox; administer 02; cardiac monitor.
Establish IV access (NS or saline lock), bedside rapid glucose determination.
Labs: CBC/diff, electrolytes, BUN/Cr/Glu, anticonvulsant drug levels, tox screen, other labs as indicated by history/examination.
If hypoglycemic give glucose (D50) 50–100 mL and thiamine 100 mg IV.

5–30 min:
Lorazepam 0.1 mg/kg IV (< 2 mg/min), given 2 mg at a time (or diazepam 0.1–0.2 mg/kg, < 2 mg/min).
Phenytoin 20 mg/kg IV at ≤ 50 mg/min (fosphenytoin 150 mg PE[a]/min), slower rate in elderly or if hypotension or bradycardia develop. Draw blood for level 10 min after infusion complete.
Cardiac monitoring, frequent BPs, careful observation of respiratory status, oximetry.
EEG monitoring, if possible.
Consider additional 5 mg/kg boluses of phenytoin to a maximum dose 30 mg/kg if seizures persist.
Lorazepam as needed for seizure during phenytoin load.

31–60 min:
If seizures persist: phenobarbital 20 mg/kg IV load, ≤ 100 mg/min. Or: induce coma, as below.
Anticipate respiratory depression and need for intubation.
If neuromuscular blockade required for intubation: EEG monitoring indicated.

> 1 h:
For persistent status: induce coma. Intubate if not previously done.
Continuous EEG to monitor for seizures and level of anesthesia.
Pentobarbital 5 mg/kg IV load (give over 20 min); repeat as needed to produce burst-suppression pattern. EEG may need to be completely suppressed if seizure activity persists during the bursts. Maintenance infusion 0.5–10 mg/kg/h.

OR
Midazolam 0.2 mg/kg IV bolus, infusion 0.1–2.0 mg/kg/h (tolerance after 72 h);

OR
Propofol 3–5 mg/kg IV bolus, 1–15 mg/kg/h infusion
Monitor for hypotension, ileus. Continue maintenance doses of phenytoin and phenobarbital; maintain therapeutic levels.
Once burst-suppression pattern established, monitor EEG every 1–2 h. Review at least 5 min of EEG every hour. Adjust medication dose as needed.
Taper medication at 12 h. If seizures recur, resume infusion for 24 h, then taper again. Continue this process as necessary.

[a]Fosphenytoin dosing in "phenytoin equivalents" (PE).
BP, blood pressure; BUN, blood urea nitrogen; CBC, complete blood cell; Cr, creatine; EEG, electroencephalogram; Glu, glucose; IV, intravenous; NS, normal saline.

It is essential to determine whether a metabolic disorder is causing the SE; if this is the case, pharmacologic intervention for SE alone is not effective. Systemic and CNS infections must be excluded, and lumbar puncture is often necessary. A contrast-enhanced head CT scan can be useful after the patient has been medically stabilized and the SE has terminated. MRI is preferred for suspected small or subtle lesions but is often not practical in the emergent setting.

PHARMACOLOGIC MANAGEMENT

A variety of drugs are available to treat SE. It is important to understand the pharmacokinetics of these drugs to ensure effective use. Table 172.4 outlines some of these properties.

IV benzodiazepines are an appropriate initial treatment. The Veterans Affairs Status Epilepticus Cooperative Study Group trial suggested that phenobarbital is also effective as initial therapy, but phenytoin alone without a benzodiazepine may be less effective [29,32]. Diazepam and lorazepam are both effective in treating generalized SE [33], but lorazepam has a longer duration of action (2 to 24 hours), compared to diazepam (10 to 25 minutes) [34], and does not have extensive peripheral tissue uptake, unlike diazepam. Although lorazepam has slower CNS penetration than diazepam, the onset of action of less than 3 minutes is acceptable. For these reasons, lorazepam is the recommended first-line agent in status epilepticus. Both these drugs have significant and essentially the same cardiac, respiratory, and CNS depressant side effects [30]. Respiratory depression and apnea, which are potentiated by age and previous administration of sedative drugs, may occur abruptly with doses as small as 1 mg. Hypotension, which occasionally occurs, may be partially due to the propylene glycol solvent contained in the IV forms of diazepam and lorazepam.

If IV access is not available, rectal diazepam has been successful in achieving rapid therapeutic levels and effectively terminating prolonged generalized seizures. A commercially prepared diazepam rectal gel is available for this purpose [35]. Significant respiratory depression from rectal diazepam has not been reported [36]. Intramuscular (IM) administration is unsuitable for the treatment of status due to delayed peak levels [37]. Furthermore, the peak concentration after IM injection is much less than that after IV injection for both agents.

Phenytoin is usually given with benzodiazepines to control the SE and prevent recurrent seizures. A 20 mg per kg load is recommended, given at 50 mg per minute. If seizures continue,

TABLE 172.4

PROPERTIES OF DRUGS USED TO TREAT STATUS EPILEPTICUS

Drug	Route	Loading dose	Rate of administration	Time to enter brain	Time to peak brain concentration (min)	Minimum effective plasma concentration (μg/mL)	Side effects
Diazepam	IV, rectal	0.1–0.2 mg/kg, up to 20 mg	2 mg/min IV	< 10 s	8	0.2–0.8	Respiratory depression/apnea (may be abrupt); hypotension; sedation, especially in combination with barbiturates
Lorazepam	IV	0.1 mg/kg	2 mg/min	< 2–3 min	23	0.03–0.10	Same as diazepam; amnesia
Phenytoin	IV	20 mg/kg	50 mg/min	1–3 min	3–6	15–30	Hypotension and electrocardiogram changes during acute administration; sedation at high doses
Phenobarbital	IV	20 mg/kg	100 mg/min	3 min	5–15	10–40	Respiratory depression and sedation common with increasing doses, especially when benzodiazepines used; hypotension

IV, intravenous.

additional doses of up to another 10 mg per kg can be given. The serum level of phenytoin should be 15 to 30 μg per mL. IM administration should not be used because it results in precipitation at the injection site and has slow, erratic absorption. Hypotension, electrocardiogram changes, and respiratory depression can occur and may be due partly to the propylene glycol diluent [3]. Simultaneous cardiac monitoring should be performed, and slower infusion rates (25 mg per minute) should be considered in patients who are elderly or have a history of cardiac arrhythmias, compromised pulmonary function, or hypotension [38]. The most common adverse effect is hypotension, which is age related and much less common in patients younger than 40 years. Intravenous infusion of phenytoin carries a risk of medication extravasation into adjacent tissue. Tissue necrosis can rarely occur [39].

Fosphenytoin, a water-soluble prodrug of phenytoin, is rapidly converted enzymatically to phenytoin. Rapid and complete absorption occurs after IM administration [40,41]. Therapeutic phenytoin concentrations are attained in most patients within 10 minutes of rapid IV infusion (150 mg per minute) and within 30 minutes of slower IV infusion or IM injection [40,41]. Dosing for fosphenytoin is the same as for phenytoin, but needs to be given in "phenytoin equivalents." Cardiac monitoring is required during IV infusions of fosphenytoin. Maintenance doses of phenytoin or fosphenytoin should be started within 24 hours of the loading dose, with levels maintained in the high therapeutic range (15 to 25 μg per mL).

The antiepileptic effect of phenytoin or fosphenytoin is maximal within 10 minutes after the infusion is completed. SE persisting after this time is considered refractory SE (RSE). Treatment from this point on may vary. A loading dose of phenobarbital may be given, 10 mg per kg at a rate of 100 mg per minute, repeated as needed up to a total dose of 20 mg per kg. Target blood levels are 30 to 40 μg per mL. Respiratory depression is a major side effect, especially if benzodiazepines have been used. The response rate to a third-line agent such as phenobarbital may be very low [3], and because of this, some centers proceed at this point to a drug-induced coma rather than administering phenobarbital. For drug-induced coma, all patients must be intubated, as anesthetic doses of medication are required. Agents commonly used for RSE include pentobarbital, midazolam, and propofol [38]. All are extremely effective at suppressing clinical and electrographic seizures. Simultaneous EEG monitoring is mandatory during induction of coma. Phenobarbital is not used for this purpose, because it results in very prolonged coma. Pentobarbital is administered as a loading dose of 5 mg per kg, given slowly, and repeated as necessary with additional 5 mg per kg loads to stop electrographic seizure activity. The maintenance dose is 0.5 to 10 mg per kg per hour [3,30,38]. Cardiac depression is often produced, and careful hemodynamic monitoring is required. Vasopressors are frequently needed, and ileus is also common.

Treatment with midazolam is initiated with a 0.2 mg per kg IV bolus followed by an infusion of 0.1 to 2.0 mg per kg per hour [42,43]. Patients regain consciousness more rapidly after discontinuation of midazolam than with pentobarbital. The short elimination half-life of midazolam may be significantly prolonged in critically ill patients and can lead to accumulation of the drug [44]. Tolerance to the effects of midazolam also can develop after 36 to 48 hours, which can lead to escalating dose requirements. Because of this, if status is not terminated within 72 hours of midazolam treatment, changing to a pentobarbital infusion is recommended.

Propofol, a GABA agonist, has also been used as a potent antiepileptic agent. The loading dose is 3 to 5 mg per kg, with an infusion rate of 1 to 15 mg per kg per hour [30,45,46]. One significant disadvantage of this drug is the propofol infusion syndrome. This consists of profound hypotension, rhabdomyolysis, hyperlipidemia, cardiac arrhythmias, and metabolic acidosis. It has been described primarily in pediatric patients, and propofol is therefore not recommended for pediatric SE. Propofol has the advantage of rapid induction and elimination, but slow downward titration is important to avoid recurrent seizures [47].

There is relatively little prospective data to suggest that propofol, pentobarbital, or midazolam are dramatically different in efficacy for SE. Several studies seem to indicate that patients treated with pentobarbital have fewer treatment

failures and breakthrough seizures, but more frequent episodes of hypotension. There is no clear difference in mortality among the three agents [48].

The dose of pentobarbital, midazolam, or propofol must be sufficient to terminate any seizure activity seen on the EEG. In many cases, the goal is to produce a burst-suppression EEG pattern, characterized by a flat background punctuated by bursts of mixed-frequency activity. If the bursts contain electrographic seizure activity, the coma should be deepened, at times to virtual electrocerebral silence. It is unclear if the coma needs to be deepened if only periodic sharp activity is seen on EEG. Further studies are needed to clarify fully what the appropriate EEG endpoint should be. During this time of drug-induced coma, maintenance doses of phenytoin and phenobarbital need to be continued and the serum levels kept in therapeutic range. Recently, propylene glycol toxicity has been reported in patients treated with barbiturate coma for refractory status epilepticus. These patients can develop hypotension and hepatic and renal failure. Hemodialysis is an option in these cases [49].

There is some evidence to suggest that intravenous valproate could be an appropriate second-line therapy. Intravenous valproate is well tolerated, with few adverse effects [50,51]. A loading dose of 25 mg per kg and an infusion rate of 3 to 6 mg per kg per minute have been used [52]. Studies have shown that it can be effective [53,54]. Although these early data appear promising, the overall role of IV valproate in the treatment of SE remains to be defined.

NCSE must be treated quickly, although the urgency is not as great as for convulsive SE. Diazepam and lorazepam are both effective in treating complex partial, partial motor, and absence SE. The response to benzodiazepines may be helpful in confirming the diagnosis if it is in question. The patient should also be started on antiepileptic medication appropriate for long-term management, given as a loading dose if appropriate. Valproic acid is an ideal drug for absence SE and can be given intravenously. The recommended starting dose is 15 mg per kg per day. Complex partial and partial motor SE both respond to phenytoin and phenobarbital, although epilepsia partialis continua can be notoriously resistant to treatment. Newer antiepileptic medications such as topiramate may also be effective, but need to be given orally [55]. The drug of choice for myoclonic status is valproate, but phenytoin and phenobarbital are also effective.

CONCLUSION

Status epilepticus is a true medical emergency and needs to be treated promptly and definitively. In convulsive SE, lorazepam is the drug of choice for immediate, short-term termination of ongoing seizure activity. A phenytoin loading dose should be administered simultaneously with the lorazepam. Phenytoin is safe and effective, has a rapid onset of seizure control, and may be used for maintenance therapy. If these drugs are ineffective, phenobarbital may be added, and if status still persists, a drug-induced coma should be induced. Physicians should be familiar with a treatment protocol, as appropriate therapy greatly reduces morbidity and mortality.

CHAPTER 173 ■ CEREBROVASCULAR DISEASE

MAJAZ MOONIS, JOHN P. WEAVER AND MARC FISHER

Cerebrovascular disease encompasses ischemic stroke from thrombosis or embolism, and hemorrhagic stroke including intracerebral hemorrhage (ICH) and subarachnoid hemorrhage. Many patients require management in the intensive care unit (ICU) due to the severity of disease or for monitoring after acute thrombolytic therapy. This chapter reviews the basic concepts of pathogenesis, diagnosis, evaluation, and management for patients with ischemic cerebrovascular disease (ICVD) and ICH. Subarachnoid hemorrhage is discussed in Chapter 78.

ISCHEMIC CEREBROVASCULAR DISEASE

ICVD comprises 85% of all strokes and is the most common neurologic problem that leads to acute hospitalization. Admission to the ICU is indicated in patients with (a) impaired consciousness; (b) associated comorbid conditions, particularly myocardial infarction; (c) stroke after coronary artery bypass grafting; (d) symptomatic secondary hemorrhagic conversion with neurologic deterioration; (e) for the initial 24 hours after administration of intravenous (IV) recombinant tissue plasminogen activator (rt-PA); and (f) after intra-arterial thrombolysis, angioplasty, stenting, or thrombectomy.

Pathophysiology

To ensure accurate diagnosis and appropriate therapy, ICVD is categorized along three axes: degree of completeness, anatomic territory, and underlying mechanism.

Degree of Completeness

Three degrees of completeness can be recognized: transient ischemic attack (TIA), stroke-in-evolution, and completed stroke. A TIA is an episode of temporary focal cerebral dysfunction occurring on a vascular basis. It typically resolves within minutes but may last up to 24 hours. A new definition was proposed and accepted when it was recognized that a significant percentage of patients whose deficits last up to 24 hours have minor stroke, not TIA. The new definition states TIA to be an acute vascular neurological deficit that is reversible within 60 minutes with no evidence of infarction on CT or MRI. A stroke-in-evolution is a neurovascular event that worsens over several hours to several days. In a completed stroke, the deficit remains fixed for at least 24 hours in the carotid system and for up to 72 hours in the vertebral-basilar system.

Anatomic Territory

Two broad clinical anatomic categories of ICVD syndromes are recognized, based on division of the cerebrovascular supply into those areas supplied by the carotid system (anterior circulation) and those supplied by the vertebral-basilar system (posterior circulation).

Symptoms commonly encountered in carotid system disease include aphasia, monoparesis or hemiparesis, monoparesthesias or hemiparesthesias, binocular visual field disturbance (hemianopia), or monocular visual loss. Symptoms that may be seen in vertebral-basilar system disease include hemianopia, cortical blindness, diplopia, vertigo, dysarthria, ataxia, and limb paresis or paresthesias, frequently with ipsilateral involvement of cranial nerve functions, and contralateral body involvement. Loss of consciousness or isolated vertigo rarely occurs without other vertebral-basilar symptoms. Other isolated symptoms, such as diplopia, amnesia, dysarthria, and light-headedness, usually do not serve as a basis for the diagnosis of vertebral-basilar disease; however, association with other brainstem symptoms may support this diagnosis [1].

Underlying Mechanism

Acute ICVD can be categorized as *large vessel thrombosis*, *small vessel thrombosis*, *cardioembolism*, or *stroke of*

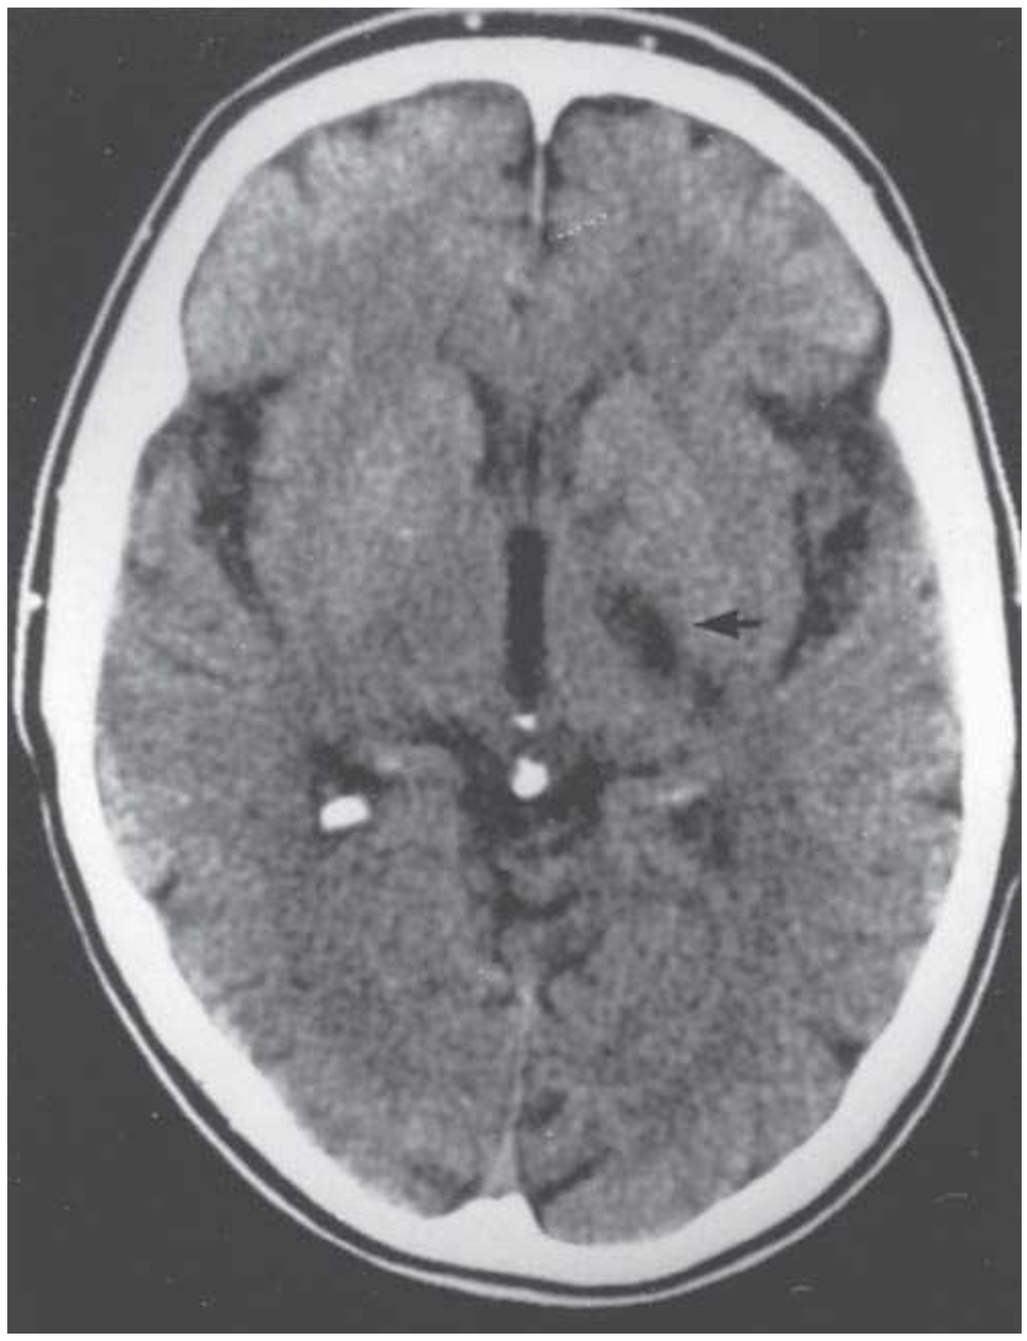

FIGURE 173.1. Lacunar infarct involving the left internal capsule seen on a computed tomography scan.

undetermined etiology. Large vessel atherothrombotic occlusion is due to atherosclerosis in the carotid or vertebral-basilar arteries and is a common cause of acute ICVD. The pattern and severity of the neurologic deficit depend on the arterial territory, completeness of occlusion, and collateral flow [1]. Small vessel occlusion occurs due to lipohyalinosis of the lenticulostriate arteries or basilar penetrators, and results in a small area of cerebral infarction called a *lacune* (Fig. 173.1). If a lacune is strategically placed in the internal capsule, thalamus, or basis pontis, substantial neurologic deficits occur. The most common lacunar syndromes are pure motor hemiparesis, pure sensory loss, ataxic hemiparesis, and dysarthria-clumsy hand syndrome [2].

The typical presentation of a cardioembolic stroke is with maximal deficit at onset, although a small minority may have a stuttering clinical course. Diagnosis may be difficult if the patient has coexistent large arterial lesions; as many as one third of patients with a cardiac embolic source have another potential explanation for their strokes [3]. The most common cardiac sources associated with cerebral embolic events are outlined in Table 173.1. Nonvalvular embolic source with atrial fibrillation is associated with a stroke risk of 4% to 5% per year, increasing with advancing age, the presence of paroxysmal/chronic atrial fibrillation, and an enlarged left atrium [4]. Transmyocardial infarction, atrial fibrillation, and mechanical valves are associated with a high risk, while the risk is lower in patients with bioprosthetic valves. Patent right-to-left cardiac shunts have been recognized by contrast echocardiography with increasing frequency in younger stroke patients. In the absence of a hypercoagulable state or atrial septal aneurysm, a patent foramen ovale (PFO) is not a significant risk factor for cardioembolic stroke, as up to 5% of the healthy population have a small PFO [5].

TABLE 173.1

CARDIAC SOURCES FOR CEREBRAL EMBOLI

Common
Nonvalvular atrial fibrillation
Acute anterior wall myocardial infarction
Ventricular aneurysms and dyskinetic segments
Rheumatic valvular disease
Prosthetic cardiac valves
Right-to-left shunts
Bacterial endocarditis
Less common
Mitral valve prolapse
Cardiomyopathy
Bicuspid aortic valve
Atrial myxoma
Nonbacterial endocarditis
Mitral annulus calcification
Idiopathic hypertrophic subaortic stenosis
Atrial septal aneurysm

Watershed infarction is due to globally diminished cerebral blood flow resulting from cardiac arrest or systemic hypotension, with focal infarction and deficits occurring in well-described patterns in the endarterial distribution between major vessels [6] (Fig. 173.2). In the carotid circulation, watershed infarcts occur between the distribution of the middle cerebral artery and either the anterior or posterior cerebral arteries. The usual anterior infarction causes contralateral weakness and sensory loss sparing the face; in posterior watershed infarcts, homonymous hemianopia with little or no weakness is most common. Quadriparesis, cortical blindness, or bilateral arm weakness (the "man-in-the-barrel" syndrome) may also be seen.

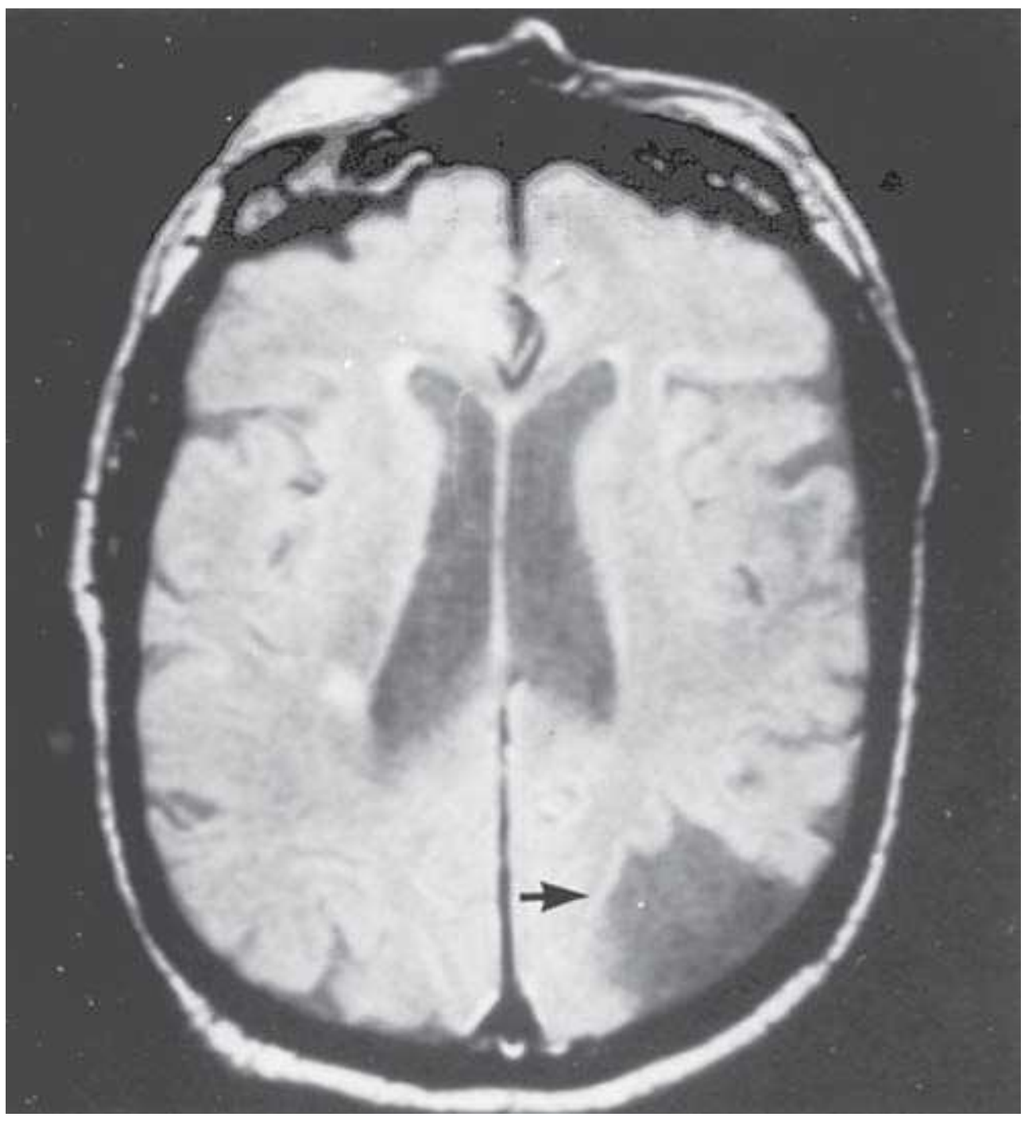

FIGURE 173.2. T1-weighted magnetic resonance imaging scan demonstrating a watershed infarction (*arrow*) in the border zone between the middle and posterior cerebral arteries.

Prognosis

The eventual prognosis of a completed stroke in either the carotid or vertebral-basilar distribution cannot be predicted with certainty during the initial phase of the ictus. The overall mortality varies from 3% to 20% in both vascular distributions [7]. Patients presenting with an altered level of consciousness, conjugate gaze paresis associated with contralateral dense hemiplegia, or decerebrate posturing have a poorer prognosis. However, functional outcome varies widely, with a favorable outcome observed in 20% to 70% of cases [8]. Lacunar syndromes are associated with very low 1-month mortality (approximately 1%) and good functional recovery in 75% to 80% of patients 1 to 3 months after stroke. The clinical course varies: One third of patients with large-artery atherothrombotic strokes have a progressive or fluctuating course, whereas less than one fifth of patients with cardioembolic disease follow a similar pattern [9]. More than 40% of patients with vertebral-basilar symptoms attributable to large-artery thrombosis have a progressive course.

Differential Diagnosis

The history and neurologic examination along with brain imaging enable the physician to differentiate among the major subtypes of ICVD: degree of completeness, territory involved, and ischemic mechanism. It is especially important to differentiate ICVD patients from those with primary ICH. Patients with cerebral hemorrhage typically have a progressive course, with evolution of symptoms over hours [10]. With recent improvement in imaging techniques (spiral computed tomography [CT], magnetic resonance imaging [MRI]), symptoms considered classic for ICH such as early obtundation, coma, seizures, headache, and vomiting are now known to be less reliable in making that diagnosis, since a similar presentation can be seen with ischemic stroke. Urgent imaging should remain the goal in all stroke patients presenting early within the first 3 hours of stroke onset, or those demonstrating worsening neurologic status. Conditions other than cerebrovascular events can occasionally cause acute focal neurologic deficits and must be considered. Primary or metastatic brain tumors with hemorrhage into the tumor may resemble a stroke (Fig. 173.3). Subdural hematomas may rarely present with acute focal neurologic deficits and must be considered in elderly patients, even without a history of head trauma. Patients with migraine headaches sometimes develop focal neurologic symptoms either before or during the early phase of the headache. Rarely, these deficits may occur in the absence of a headache (acephalgic migraine) or may persist (migrainous infarction). Patients with focal seizures may develop sensory, motor, and aphasic symptoms that can mimic ICVD, although they are usually stereotyped and transient. Occasionally, focal neurologic deficits may follow seizures and persist for 24 hours or longer (Todd's paralysis). In these cases, MR angiogram (MRA) or CT angiogram (CTA) can demonstrate arterial occlusion, making it more likely to be a stroke than Todd's paralysis. An important, uncommon, and reversible cause of acute neurological deficits is hypoglycemia, which should always be looked for before any aggressive treatment is initiated for a presumed ischemic stroke. Similarly in young patients or patients with a psychiatric history, objective neurological signs or corroborative radiological evidence must be established to avoid treating a functional paralysis with relatively aggressive therapy. Finally, worsening of an old deficit should prompt a metabolic/infectious evaluation, because the damaged cortex may act as a *locus minoris resistentiae*, with focal clinical worsening of a chronic deficit.

FIGURE 173.3. Malignant glioma with associated edema on a computed tomography scan in a patient who abruptly developed a pure motor deficit. The arrow points to the lacunar infarct.

Laboratory and Radiologic Evaluation

A comprehensive workup to determine stroke subtype, severity, and identification of possible multiple risk factors is important to determine effective treatment options. Early imaging in most ICVD patients helps in the differential diagnosis and is key in protocols for therapeutic intervention with rt-PA. Both CT and MRI scans are reliable and sensitive means of differentiating between ICVD, hemorrhage, and other mass lesions. MRI scans are more sensitive than CT scans for the identification of brain tumors, subarachnoid hemorrhage, and subdural hematomas, and MRI can identify ischemic infarction at an earlier stage (within 4 to 24 hours). MRI is probably more sensitive than CT in detecting intracerebral hemorrhage [11]. Newer MRI techniques, such as diffusion-weighted imaging (DWI) and perfusion imaging (PI), have important bearings on acute stroke diagnosis and treatment [12]. With DWI, ischemic lesions can be seen within minutes of onset. PI identifies areas of reduced blood flow, whereas in most cases, DWI hyperintensity indicates an area of irreversible ischemic injury. If the PI deficit is greater than the DWI area (DWI–PI mismatch), it demonstrates an ischemic tissue that is potentially reversible (ischemic penumbra). Magnetic resonance angiography (MRA), especially contrast-enhanced MRA (CEMRA), approaches the sensitivity of a four-vessel conventional angiogram. CEMRA has the added advantage of visualization of the vertebrobasilar system and the intracranial circulation with minimal increase in scan acquisition time. Early restoration of blood flow may result in normalization of this region, a reduced volume of infarction, and better stroke outcome. This is the basis of

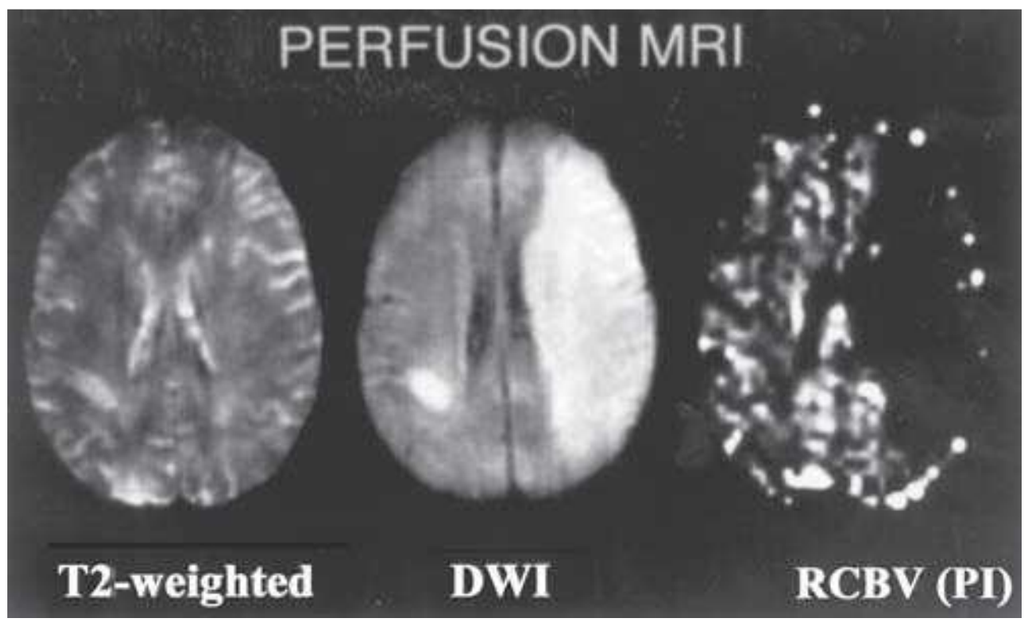

FIGURE 173.4. Magnetic resonance image of the brain with T2-weighted imaging, diffusion-weighted imaging (DWI), and perfusion imaging (PI) in a patient with acute ischemic stroke. Although T2 reveals very little change, there is a large DWI hyperintensity corresponding to a PI deficit (DWI-PI mismatch), demonstrating a completed infarct and a situation in which recombinant tissue plasminogen activator is not indicated. RCBV, regional cerebral blood volume.

thrombolytic therapy, and a persistent ischemic penumbra beyond 4.5 hours may be a reason to consider intra-arterial interventions [13,14] (Fig. 173.4).

An electrocardiogram should be obtained to assess possible underlying or concurrent cardiac rhythm or ischemic changes. Confusion may arise because T-wave, ST-segment, QRS complex changes, and rhythm disturbances may occur secondary to the cerebral ischemic event. Two-dimensional transthoracic, or transesophageal echocardiography, and telemetry/Holter monitoring should be done routinely because patients often have more than one potential underlying pathophysiology, and a cardiac structural or rhythm abnormality may change the treatment approach (Fig. 173.5). A transesophageal echocardiogram should especially be considered in younger patients, patients with an enlarged left atrium, and in cryptogenic stroke at all ages [14,15] (Fig. 173.6).

If an MRA has not been obtained to image the craniocervical vasculature, carotid artery ultrasound—a fast, reliable, and noninvasive technique—should be employed in suspected ischemic stroke of the carotid system as well as small vessel stroke, because of a high incidence of coexisting large vessel atherosclerotic stenosis. Transcranial Doppler ultrasound (TCD) can also provide information about the status of the

FIGURE 173.5. Echocardiogram in a patient with cardioembolic stroke, demonstrating a large thrombus (*arrow*) attached to the left mitral valve.

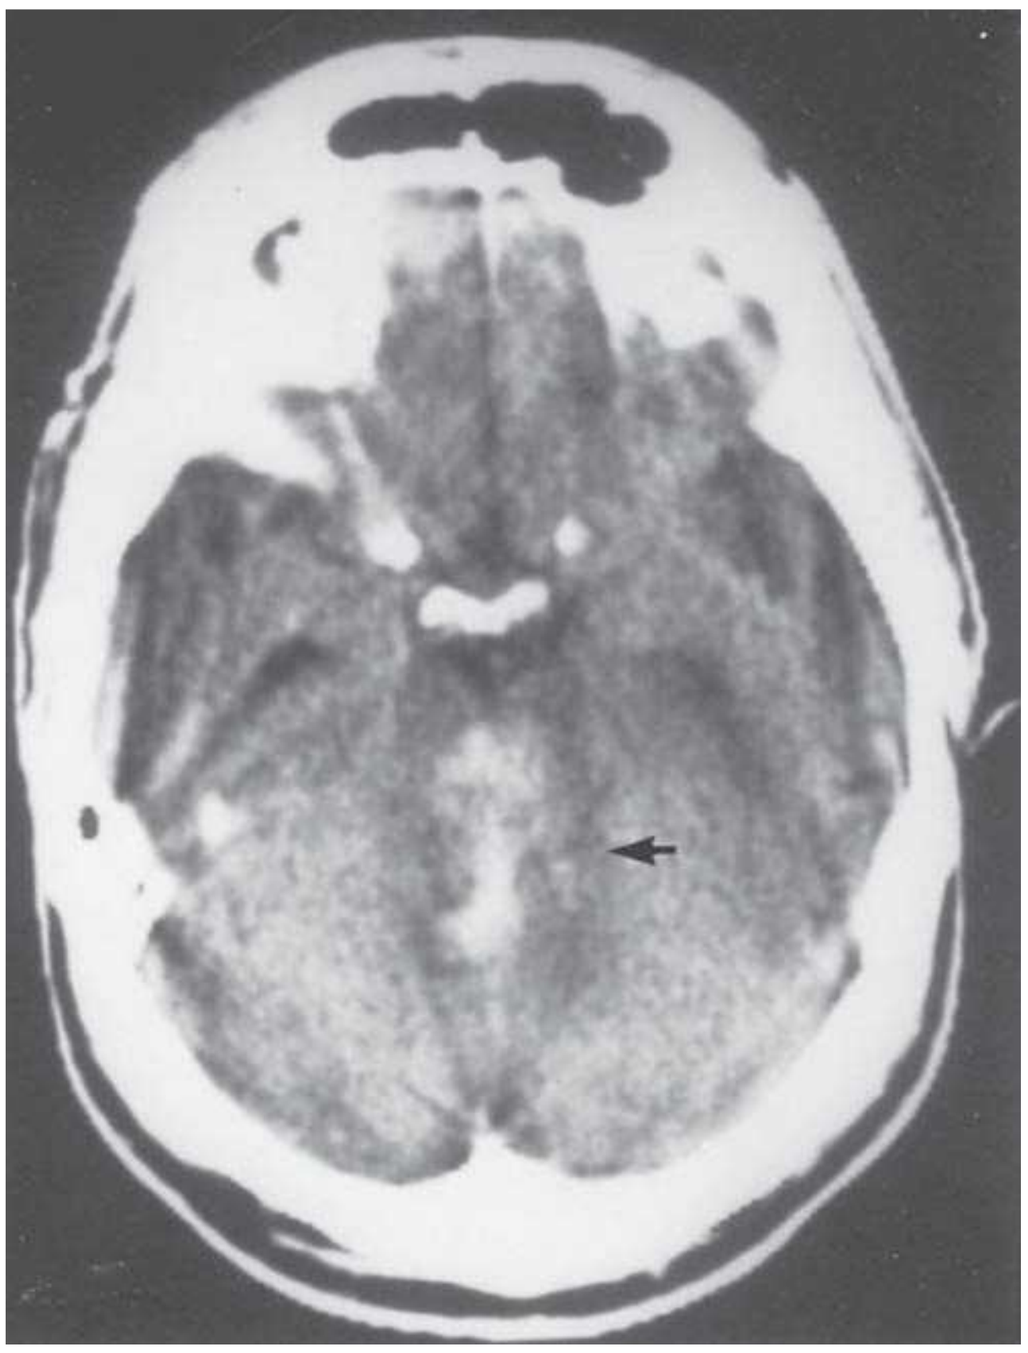

FIGURE 173.6. Midline cerebellar hemorrhage (*arrow*) seen on a computed tomography scan.

intracranial vessels, both in the carotid and vertebral-basilar arterial territories [16,17]. Advances in CT angiography (CTA) provide high-resolution vascular imaging as well as the ischemic penumbra with perfusion CT (CTP) studies. With a combination of noncontrast CT (NCCT), CTA, and CTP, it is possible to rule out hemorrhage, assess the extent of early signs of infarction, and determine the site of arterial occlusion and ischemic penumbra. The latter two studies are important in making decisions in acute stroke management (i.e., to proceed with intravenous or intra-arterial interventions). This CT based combination allows a more rapid triage compared to MRI, since every minute wasted before thrombolysis is initiated results in a progressive reduction of salvageable tissue.

Complete blood count, partial thromboplastin time (PTT), prothrombin time (PT), comprehensive blood chemistry, chest radiograph, erythrocyte sedimentation rate, syphilis serology, and urinalysis should be obtained on day 1. Of these, if thrombolytic therapy is being contemplated, the blood glucose, PTT, PT, and platelet count should be obtained immediately. Fasting lipid profile, homocysteine, and C-reactive protein should be obtained by day 2 in all cases. Other blood studies, including anticardiolipin antibodies, hypercoagulable workup (protein S, protein C, antithrombin 3, factor V Leiden, prothrombin-2 gene mutation), serum viscosity, serum protein electrophoresis, and fibrinogen, should be completed in younger patients and in patients with a history of cancer, recurrent deep vein thrombosis, or a family history suggestive of an autosomal-dominant pattern of stroke. A lumbar puncture should be performed only if meningitis is suspected, in suspected vasculitis of the nervous system, or when aneurysm rupture is a consideration, despite a negative result in a brain imaging study (NCCT or MRI). Electroencephalography may be helpful when associated seizure activity is suspected.

Treatment

The treatment of ICVD can be divided into four major categories: prevention, acute interventions, supportive therapy, and newer approaches.

Stroke Prevention

Stroke prevention has improved as risk factors have been identified and treatments developed [18]. The treatment of hypertension and smoking cessation are helpful in the prevention of stroke. Systolic blood pressure reduction by 5 to 10 mm Hg may reduce relative risk of ischemic stroke by 20% to 25%. Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers may offer additional protection against first or recurrent ischemic stroke. Patients with hyperglycemia should be aggressively treated to maintain euglycemic control (fasting blood glucose of less than 100 mg per dL). Use of HMG CoA reductase inhibitors (statins) reduces the risk of ischemic stroke by 25% to 30% in patients with underlying ischemic heart disease and possibly improves the outcome after AIS. The American College of Chest Physicians and American Stroke Association guidelines recommend starting all in-patients with hyperlipidemia (low-density lipoprotein [LDL] greater than 100 mg per dL) on statins. More recent trials of statins suggest that reducing LDL cholesterol to 70 mg per dL is safe and may have a plaque stabilization effect [19]. Patients with TIA have a substantial risk of stroke and should be completely investigated before discharge from the hospital. This is especially true for patients older than 60 years, those presenting with aphasia, motor deficits, or with associated diabetes. Patients with *symptomatic* carotid artery stenosis of greater than 70% benefit from carotid endarterectomy, provided the combined mortality and morbidity of the surgical procedure in the treating institution is less than 5.65% [20]. In nonsurgical TIA patients, antiplatelet therapy with aspirin, aspirin and extended-release dipyridamole (25/200 mg) twice daily, clopidogrel 75 mg once daily, or ticlopidine 250 mg twice daily is beneficial [21,22]. Indirect comparison of newer antiplatelet agents as compared to aspirin suggests that aspirin/extended-release dipyridamole (25/200 mg) (ERDP/ASA) twice daily is 23% more effective than aspirin alone, while clopidogrel offers no advantage over aspirin. However, the recently completed head-to-head comparative trial of clopidogrel vs ERDP/ASA failed to demonstrate a significant difference between the two medications. The combination of ERDP/ASA was associated with nonsignificantly fewer ischemic events, but with a greater number of intra- and extracerebral hemorrhages. On the other hand, there was a nonsignificant trend toward less congestive heart failure with this combination [23]. Atrial fibrillation with or without valvular heart disease is associated with a high stroke risk. Anticoagulation using warfarin reduces the absolute recurrent stroke relative risk by 8% in patients with nonvalvular atrial fibrillation. The annual risk of symptomatic hemorrhage is 1%, which can be minimized by keeping the international normalized ratio (INR) between 2 and 3 [15]. Ximelagatran, a thrombin inhibitor, in a head-to-head study with warfarin, failed to show noninferiority in reducing ischemic recurrent events and did not require INR monitoring, but the drug was not approved by the U.S. Food and Drug Administration (FDA) because of concerns of significant hepatic toxicity [24].

Supportive Therapy

Supportive therapy for ICVD patients should begin upon hospitalization. Elevated blood pressure should not be treated in the first 24 hours of an ischemic stroke unless malignant hypertension (> 220 over 120 mm Hg) is present or other end-organ failure becomes evident (e.g., congestive heart failure, renal failure). The blood pressure typically returns to baseline with bed rest; if it remains substantially elevated, it should be carefully lowered by no more than 20% of the mean arterial pressure. Subcutaneous heparin therapy should be considered for immobilized ICVD patients to reduce the risk of pulmonary emboli. Indwelling urinary catheters and excessive IV lines should be avoided, as they can promote infection. Elevated temperature should be lowered, as hyperthermia is clearly deleterious. Aspiration pneumonia can be avoided by delaying oral feedings until swallowing is well performed. Early mobilization and rehabilitation should be attempted.

Acute Treatment

Standard therapies in ICVD patients are directed at reversing the neurologic deficit and preventing progression. The National Institute of Neurological Disorders and Stroke (NINDS) trial demonstrated that patients treated with rt-PA within 3 hours of stroke onset had a 10% to 12% absolute greater chance of being free of disability or being left with minor disability at 3 months. The benefit was greatest for those treated within the first 90 minutes of stroke onset compared to those treated between 90 and 180 minutes. There was a tenfold greater incidence of ICH in treated patients as compared to placebo (6.4% vs. 0.6%). However, overall mortality at 3 months was comparable in the rt-PA and placebo groups. Predictors of ICH include large hemispheric infarcts, National Institutes of Health Stroke Scale (NIHSS) score greater than 23, and the presence of associated severe hypertension [25]. More recently, based on prospective trial (ECASS III) results it may be possible to extend the time window of intravenous rt-PA up to 4.5 hours. The absolute benefits, as expected, were less in this extended time window (ARR of 7%) and the results apply to mild and moderate stroke patients based on the NIHSS (median 8). While the study excluded older patients, those on anticoagulation (irrespective of the INR or PTT), and those with diabetes mellitus and stroke, the validity of these exclusions has not been substantiated and individual management should be decided for individuals based on the physician's judgment [26]. The total dose of 0.9 mg per kg is given as a 60-minute IV infusion, with 10% of the total dose given as an initial bolus. After rt-PA infusion, patients need to be admitted to the ICU. Blood pressure and neurologic status need to be carefully assessed at specified time periods. Systolic blood pressure above 185 mm or mean blood pressure over 130 mm are treated with intravenous labetalol/nicardipine or dose-titrated intravenous sodium nitroprusside. Neurologic worsening should prompt an urgent CT scan to look for possible hemorrhagic conversion of the infarct. Anticoagulants and antiplatelet agents are avoided in the first 24 hours. IV access and invasive procedures should be kept to a minimum in the first 24 hours after rt-PA administration. A recent trial of intra-arterial prourokinase, given within 6 hours of stroke onset, demonstrated improved stroke outcome in middle cerebral artery embolic infarctions [27].

Patients presenting beyond 4.5 hours who are not candidates for intravenous thrombolytic therapy may benefit from intra-arterial thrombolysis or mechanical embolectomy. The results of the Multi Mechanical Embolus Removal in Cerebral Ischemia (Multi MERCI) trial have limited application in the general stroke population because special equipment and trained interventionists are required for such interventions, and the outcomes in the extended time window of up to 8 hours did not demonstrate a result superior to intravenous rt-PA as in the NINDS trial. However, it did demonstrate that results comparable to the rt-PA outcomes were possible with delayed reperfusion [28]. This benefit still remains to be confirmed with the ongoing prospective, randomized trials (IMS 111) and MR and recanalization of stroke clots using embolectomy (MR RESCUE) where IV thrombolysis is followed by intra-arterial

interventions if no clinical improvement is demonstrated with the intravenous therapy. The results of a large retrospective analysis of intra-arterial interventions suggested that there was a significant 67% chance of achieving improved outcome (modified Rankin scale [MRS] ≤ 3) in the absence of a combination of older age, blood glucose > 150 mg per dL, and NIHSS > 18 [29].

Anticoagulation with heparin or low-molecular-weight heparin has been used traditionally without any proof of efficacy. However, heparin has been routinely considered in patients with a clear embolic source, with stroke-in-evolution to prevent progression, and with multiple TIAs to prevent stroke development. However, there is no evidence that supports the use of IV heparin anticoagulation to improve stroke outcome in progressive stroke. Furthermore, the risk of recurrent stroke is low (2% to 3%) in the first few weeks after an acute ischemic stroke (AIS) [30,31]. Cardioembolic stroke patients have a higher risk of recurrence (4.5% to 8.0%) within 2 weeks of the initial event, especially with associated intracardiac thrombi. Heparin therapy may reduce this risk and may be considered within 24 to 48 hours of the initial stroke [30]. Patients with large infarcts should not receive heparin, because they have a higher risk of bleeding into the area of infarction [19,30]. An alternative and safer approach is to begin warfarin as soon as the patient can safely swallow, leading to adequate anticoagulation within 5 to 7 days of stroke onset. The use of heparin therapy in stroke-in-evolution and in multiple TIAs is still under debate. If used, heparin should be initiated as a constant infusion without a bolus (although some stroke neurologists give a small initial bolus of 3,000 to 5,000 U), maintaining the PTT at 1.5 to 2.0 times control. Frequent PTT checks at 6-hour intervals and dose adjustment may reduce the frequency of serious intracranial and systemic hemorrhage [32].

Aspirin may reduce the risk of stroke recurrence after TIA or established stroke and is widely used for this indication [20]. Combined aspirin and extended-release dipyridamole therapy is twice as effective as aspirin alone in reducing stroke recurrence [21]. In aspirin-allergic patients, clopidogrel or ticlopidine can be used. The incidence of serious side effects is greater with ticlopidine, which may cause neutropenia and thrombotic thrombocytopenic purpura. Because thrombotic thrombocytopenic purpura has been reported with both drugs, weekly complete blood count and liver function tests should be done in the first 4 to 6 weeks of initiating therapy [33].

Cerebral edema in ICVD patients is maximal between 48 and 72 hours after onset, and corticosteroids are not effective in ICVD [34]. Osmotic diuretics, such as mannitol, are of uncertain value for cerebral edema associated with ICVD, but we consider using pulse doses (1.00 g per kg, then 0.25 g per kg every 6 hours) if massive edema begins to develop. Intracranial pressure (ICP) monitoring to guide therapy should also be considered. Controlled hyperventilation is perhaps the fastest and most effective temporizing measure to reduce cerebral edema, but its effects are transient and regional cerebral ischemia may worsen due to vasoconstriction. Timely decompressive hemicraniectomy reduces the risk of death by 50% (1 in 2 patients) and improves the outcome by 25% (1 in 4 patients). This has been validated in patients younger than 50 years, although there is no reason not to apply the procedure in older patients. Interestingly enough, the outcomes of this trial were independent of the side of infarction or the presence or absence of aphasia [34].

Recent Advances

Cerebral ischemic insult results in activation of the ischemic cascade. Under these circumstances, reduced reuptake and increased release of glutamate leads to activation of the *N*-methyl-D-aspartate receptors; reduced inhibition of γ-aminobutyric acid and glycine; and increased intracellular calcium influx, lipid peroxidation, and release of free radicals that hasten the process of cell death. Several neuroprotective agents blocking steps of the ischemic cascade have undergone animal studies and human trials. Although almost all reduce the infarct size in animal models of ischemic stroke, so far none have demonstrated any clinical efficacy [35–42]. There were several reasons why neuroprotective therapies have not proven effective in clinical trials. Serious side effects limited the effective doses of medications, the inclusion time to treatment may have been too long, and reperfusion was not established. To overcome these limitations, recent studies have begun to use combination therapies, combining rt-PA with neuroprotective drugs as well as combinations of two neuroprotective drugs with different sites of action [43]. Recently NXY-059, a free radical trapping agent, was reported to improve outcome of AIS, although the phase 3 trial results of the Stroke Acute Ischemic NXY-059 (SAINT) 11 trial conducted in the United States failed to confirm these findings [44]. Induced hypothermia may be useful in limiting damage from large hemispheric infarcts but at present remains an experimental procedure for ischemic stroke. Major problems limiting its use are the lack of availability of appropriate cooling devices, difficulty in obtaining rapid temperature reduction to target values, and complications during subsequent rewarming. Bihemispheric laser therapy of the brain showed promise as a method of improving outcome after ischemic stroke in phase 2 trials but failed to demonstrate efficacy in a subsequent phase 3 randomized trial [45].

Summary

Advances are being made in the treatment of ICVD. It is clear that successful therapy requires early intervention and close assessment for favorable responses and side effects, likely requiring an ICU setting initially. It is recognized that IV thrombolysis may not be effective in large vessel occlusions such as the internal carotid, proximal middle cerebral, and basilar arteries; however, randomized trials are underway to assess this. The current practice of giving full-dose IV rt-PA followed by intervention is widely practiced, but this is neither an FDA-approved therapy nor has it been shown to be beneficial in any case series. Perhaps ECASS 111 and MR RESCUE will provide the answers. Treatment of TIA has undergone a dramatic change since we recognized that the risk of a full-blown ischemic stroke is 10.5% after a cursory ER visit, and the risk can be reduced by 80% with acute in-patient management for 1 to 2 days, as demonstrated by the Oxfordshire study and the 2009 guidelines on management of TIA [46]. The recognition that acute high-dose statins reduce the risk of stroke and improve outcome irrespective of the low-density lipoprotein (LDL) levels is an important addendum to our management strategy within the acute period after an ischemic stroke. In the future, it is probable that a combination of treatments directed at the multiple metabolic and perfusion abnormalities associated with ICVD will be required [47]. Finally, stroke prevention is the most effective means of reducing the first or recurrent stroke. Aggressive use of statins in patients with either hyperlipidemia or elevated C-reactive proteins reduces the risk of progression of atherosclerotic small and large vessel disease and has a cardioprotective role.

INTRACEREBRAL HEMORRHAGE

Nontraumatic ICH occurs less frequently than ICVD but often requires management in the ICU. The majority of cases are due to spontaneous (primary) ICH or rupture of saccular

aneurysms and arteriovenous malformations. As the approach to these entities and their management differ considerably, they are discussed separately.

Primary ICH is defined as bleeding within the brain parenchyma without an underlying cause, such as neoplasm, vasculitis, bleeding disorder, prior embolic infarction, aneurysm, vascular malformation, or trauma. One-half of primary ICH cases result from longstanding hypertension. Due to the aggressive control of hypertension, the incidence of ICH has decreased since the mid-1960s. Nonetheless, ICH accounts for 4% to 11% of all stroke cases in the United States and 16% to 26% of all stroke-related deaths [47].

Pathophysiology

ICH is believed to be due to extravasation of arterial blood from ruptured microaneurysms along the walls of small intracerebral arterioles. Microaneurysms known as *Charcot–Bouchard or miliary aneurysms* tend to form on vessels at the usual sites of ICH and develop at sites of vascular branching where mechanical stress is maximal. The aneurysm wall lacks normal vascular histology and is composed mainly of connective tissue layers, which represent a weak point in the arterial system. The formation of these aneurysms is favored by the processes of lipohyalinosis and fibrinoid necrosis, which weaken the walls of arterioles, and are accelerated by chronic hypertension. Although Charcot–Bouchard aneurysms also appear in the normotensive aging brain, their frequency is notably increased in hypertensive patients. They are commonly observed along the lenticulostriate arteries, thalamoperforate arteries, and paramedian branches of the basilar artery. Although this distribution corresponds to the common sites of ICH, it is impossible to prove that these aneurysms are always the cause of bleeding, and the concept of arteriolar microdissection has been raised as an alternative explanation [48].

Continued extravasations of blood result in the formation of a hematoma with secondary accumulation of cerebral edema. The lesion may become massive enough to cause midline shift of cerebral structures followed by transtentorial herniation, which leads to secondary brainstem hemorrhages known as *Duret hemorrhages*. These linear lesions in the midbrain and upper pons are generally multiple and bilateral. Progression of this process results in brainstem dysfunction and death. Depending on the size and location of the ICH, intraventricular extension can occur and lead to the development of acute obstructive hydrocephalus or the later development of a chronic communicating hydrocephalus from impaired cerebrospinal fluid resorption. Some cases of thromboembolic stroke may be misclassified as ICH, because blood may extravasate and accumulate into large hematomas in areas of infarction. This secondary hemorrhage may be mislabeled if an early imaging study is not performed.

Clinical Manifestations

The clinical presentation of ICH is distinctive. In most cases, the onset is during the waking state when the patient is active; it is unusual for ICH to occur during sleep. The onset is abrupt, and the development of neurological deficits occurs progressively over minutes to hours. This contrasts with the fluctuating or stepwise progression of deficits commonly seen in atherothrombotic infarcts, and with the appearance of maximal deficits at onset in cardioembolic strokes. In addition, prior TIA is rare with ICH and relatively common with ischemic stroke. The average age of onset of ICH, 50 to 70 years, is younger than that of other types of stroke. Patients may report lateralized headache; vomiting is common and nuchal rigidity may be present. Seizures are seen more frequently at the onset of ICH (17%) than in ICVD and are more likely to occur if the bleeding involves the cerebral cortex [49]. When first seen by a physician, 44% to 72% of patients are comatose.

The clinical presentation of ICH is monophasic, with active bleeding usually lasting no longer than 2 hours. However, secondary bleeding and subsequent deterioration may occur. Subsequent clinical deterioration is due to the effects of cerebral edema [50]. It was recently suggested that thalamic hemorrhages may bleed further in patients whose hypertension is not adequately controlled [51].

Diagnosis

The diagnosis of ICH can be made by CT scan, which provides accurate information about the size and site of the hematoma as well as the midline shift, and development of cerebral edema. Typically, the hemorrhage is hyperdense on CT scan during the acute phase, although severe anemia or ongoing hemorrhage may make the appearance more iso- or hypodense. The appearance of blood on the MRI scan varies because signal intensity is related to the state of degradation of the hemoglobin. This state changes with time; therefore, MRI is not the study of choice for initial imaging of ICH. In summary, deoxyhemoglobin is found in the first 3 days after ICH and is not well visualized on T1-weighted images but appears as an area of reduced signal intensity on T2-weighted images. Days 3 to 10 after ICH, methemoglobin appears as increased signal intensity of T1-weighted images, but the intracellular portion has reduced signal intensity on T2-weighted images. In the chronic state, the ICH has broken down to hemosiderin, which is poorly visualized on T1-weighted images but appears as reduced signal intensity on T2-weighted images. Magnetic resonance or conventional angiography should be considered in selected cases if an underlying aneurysm or arteriovenous malformation is suspected.

Lumbar puncture is contraindicated in ICH because of the risk of herniation from mass effect. Testing on admission for ICH should include coagulation profile and platelet counts in all patients, as well as bleeding time, if the patient is on aspirin.

Differential Diagnosis

Although the majority of ICH is hypertensive in origin, other etiologies should always be considered. Secondary cerebral hemorrhage may occur after embolic infarction as the lodged embolus fragments and ischemic distal vessels may rupture on reperfusion. This is more common in patients with large embolic infarcts, in patients who are anticoagulated, and in patients with poorly controlled hypertension. ICH secondary to reperfusion may also occur after carotid endarterectomy.

ICH accounts for 0.5% to 1.5% of all bleeding events related to the use of oral anticoagulants. Oral anticoagulation increases the risk of ICH 8- to 11-fold, compared to unanticoagulated patients. Compared with patients with spontaneous ICH, there is a trend toward larger hematomas and a higher mortality rate in patients on anticoagulants [52]. Cerebellar hemorrhage is relatively common in anticoagulated patients, and mortality in these cases may be as high as 65%. Therefore, in anticoagulated patients the onset of focal neurological signs, even if slowly progressive, necessitates CT scan to rule out ICH [53].

The use of fibrinolytic therapy, such as rt-PA, for coronary artery occlusion has also been associated with ICH, especially when concomitant heparin therapy is used. These cases have shown a predilection for the subcortical white matter and lobar areas, generally having a poor prognosis [54]. Surprisingly, the

risk for ICH is slightly higher with rt-PA than with streptokinase [55].

ICH associated with the presence of primary or secondary brain tumors is infrequent, accounting for only 2% of all cases of ICH. Higher-grade malignancies, such as glioblastoma multiforme, are more likely to bleed. The presence of thin-walled vessels in areas of neovascularization is thought to be the underlying reason for these hemorrhages. Metastatic lesions with the tendency to bleed include bronchogenic carcinoma, melanoma, renal cell carcinoma, and choriocarcinoma. ICH is frequent in hematologic disorders such as leukemia and reflects both the underlying thrombocytopenia and disseminated intravascular coagulopathy. When disseminated intravascular coagulopathy is due to other organ failures, it can also lead to ICH.

Sympathomimetic drugs, such as methamphetamine, pseudoephedrine, and phenylpropanolamine, have caused ICH in the subcortical white matter. These agents are suspected of inducing a vasculitis. Cocaine, which blocks dopamine and norepinephrine reuptake, has been associated with ICH. Cocaine, especially crack cocaine, appears to incite cerebral vasospasm rather than a vasculitis. The secondary hypertension related to sympathetic stimulation may also cause ICH from any of these agents. This may explain the lack of abnormal angiographic findings in some of these cases [56,57], although recently cerebral vasospasm was demonstrated with magnetic resonance angiography after acute cocaine administration [58]. Acute elevation of blood pressure in otherwise normotensive people, such as that which may follow migraine, is postulated to result at times in ICH.

Specific Syndromes of Intracerebral Hemorrhage

ICH tends to occur in stereotyped locations. In order of descending frequency, these locations are the putamen (30% to 50%), subcortical white matter (15%), thalamus (10%), pons (10%), and cerebellum (10%) [59].

ICH in the putamen is caused by bleeding from a lenticulostriate vessel. Clinically it is manifested by development of flaccid hemiplegia, hemisensory disturbances of all primary modalities, homonymous hemianopia, paralysis of conjugate gaze to the side opposite the lesion, and early alteration in level of consciousness. Subcortical aphasia may occur when a putamen hemorrhage involves the dominant hemisphere, and a hemineglect syndrome when it is on the nondominant side.

Hemorrhages in the subcortical white matter (lobar hemorrhages) are being observed with increasing frequency, particularly in the elderly, and are less commonly related to hypertension than is ICH in other locations. The signs and symptoms depend on the location. Lobar ICH occurs at the gray-white junction and is, therefore, associated with a higher incidence of seizures and headache at onset; it most commonly occurs in the parietal and occipital lobes. Of all ICH locations, lobar hemorrhages have the lowest mortality (approximately 15%) and carry the best prognosis for a good functional recovery. Lobar ICH is frequently caused by cerebral amyloid angiopathy due to the deposition of amyloid in the walls of the small vessels of the cortex and leptomeninges, typically in the frontal and occipital lobes. The process generally spares vessels of the basal ganglia, deep white matter, brainstem, and cerebellum. The abnormal vessel walls take up Congo red stain, thus the alternative term *congophilic angiopathy*. Amyloid angiopathy weakens the walls of many arteries and may be associated with recurrent lobar ICH. Five to ten percent of cases of spontaneous ICH result from amyloid angiopathy, making it second to hypertension as an etiology for ICH [60].

Thalamic ICH is characterized by a unilateral sensorimotor deficit in which sensory findings predominate. A variety of eye signs occur: Parinaud's syndrome, forced disconjugate downgaze deviation medially on the side opposite the lesion, pseudoabducens paresis, up-gaze paralysis, and so forth. The most specific localizing sign is inferomedial disconjugate gaze paresis contralateral to the side of the lesion. A permanent skew deviation, with vertical separation of images, may leave the patient with persistent diplopia. Due to the location, thalamic ICH may rupture into the ventricular system.

Pontine ICH has the highest mortality. Quadriplegia, brainstem dysfunction, and small, unreactive pupils are seen at presentation and many patients rapidly develop coma. Bleeding typically arises from a paramedian branch of the basilar artery and almost always extends into the fourth ventricle. Cases of unilateral pontine ICH have a better outcome [61].

Cerebellar ICH most commonly involves the dentate nucleus (see Fig. 173.5). Alteration of consciousness is unusual at onset, but progressive deterioration with drowsiness typically occurs. The majority of patients initially manifest two of the following: (a) gait, truncal, or limb ataxia; (b) lower motor neuron facial paresis; and (c) an ipsilateral gaze palsy. Other common presenting signs and symptoms are headache, nausea, vomiting, vertigo, nystagmus, and limb ataxia [62]. Early surgical intervention is indicated for lesions larger than 3 cm or in smaller lesions with clinical progression, because cerebellar hemorrhage causes death in up to 60% of cases. Neurologic deterioration due to hemorrhage, causing obstructive hydrocephalus at the level of the fourth ventricle, is not uncommon. Surgical mortality is greatly reduced if the patient is still awake before operation; therefore, early intervention is indicated [62].

Approximately 3% of cases of ICH are primarily intraventricular in location. These events have minimal focal signs, but generally, there is loss of consciousness at onset. Hydrocephalus is a major complication [63].

Treatment

The acute medical management of ICH is aimed at correction of any predisposing systemic factors to prevent further clinical deterioration. Following ICH, there is a hematoma growth of 22% within the first 24 hours and hypertension is a major management problem in these cases. In response to the acute elevation of ICP caused by the hematoma, systemic blood pressure rises to maintain adequate cerebral perfusion pressure. This response, known as *Cushing's reflex*, serves to protect the brain against ischemia, but autoregulation of cerebral blood flow can be impaired after ICH or infarction. In patients with underlying chronic hypertension, the result may be excessively high blood pressure. The best management of this dilemma remains controversial. In chronic hypertension, the lower limit of cerebral autoregulation is shifted toward higher blood pressure; and acute lowering of systolic blood pressure is known to result in unfavorable decreases in cerebral perfusion pressure. Sustained hypertension in the acute phase of ICH, however, can lead to further bleeding or rapid accumulation of cerebral edema [59]. The recommended goal of systolic blood pressure in the acute phase of ICH is between 110 and 160 mm Hg [64]. Blood pressure should be lowered gently, and beta-blockers are the agents of choice. Alternatively, a calcium channel blocker such as intravenous nicardipine may be useful because it does not elevate ICP like other vasodilators [59].

If the hematoma and associated cerebral edema raise ICP, clinical deterioration typically occurs. Acutely, hyperventilation effectively lowers ICP, but only for a matter of hours. Hyperosmolar agents, such as mannitol, sorbitol, and glycerol, provide more sustained reductions in ICP. These drugs reduce the fluid content of the intact brain so that the cranial

cavity can accommodate cerebral edema. The osmotic diuresis induced by these agents can lead to dehydration, electrolyte imbalances, and pulmonary edema if the patient is not closely monitored. Treatment of ICH with steroids can be detrimental to overall outcome, so they are not routinely administered [65]. The value of ICP monitoring in these situations remains controversial [65]. Elevation of ICP due to hydrocephalus is treated with ventricular cerebrospinal fluid diversion.

Anticonvulsants are not routinely used in ICH. If seizures are not present at onset, patients are generally at low risk for developing seizures, but hemorrhage into the cortex, regardless of site of origin, predisposes to seizures. Subarachnoid or intraventricular extension of bleeding does not increase the risk of seizures. Seizures have been noted with hemorrhages in the caudate but not with putaminal or thalamic events. Although the incidence of chronic epilepsy from ICH is low (6.5% to 13.0%), any seizures usually begin within the first 2 years after the event [66]. Prophylaxis against peripheral venous thrombosis should be accomplished with pneumatic boots.

After the patient is acutely stabilized, angiography may be performed if there is no history of hypertension or the bleeding is in an atypical location. This is particularly important or pertinent for younger patients, in whom a larger percentage of cases of ICH are due to underlying vascular lesions, such as arteriovenous malformation or aneurysm. At present, surgery may be indicated for lobar ICH in which the patient continues to deteriorate, and for most cerebellar ICH. Emergency ventriculostomy to relieve hydrocephalus should be considered if this condition develops acutely. Surgical intervention for putaminal ICH remains controversial; it is inappropriate for thalamic and pontine hemorrhages.

The prognosis for ICH is worse for larger lesions. By location, pontine ICH has the highest mortality, followed by cerebellar and then basal ganglia lesions. Lobar ICH carries the most favorable outlook for survival and functional recovery [52]. Three factors that have accurately predicted 30-day survival in 92% of ICH patients reviewed are hemorrhage size, Glasgow Coma Scale score, and pulse pressure [46].

Summary and Advances

ICH can be neurologically devastating. Patients with ICH often require an ICU setting because of the severity of disease, particularly when it is complicated by markedly increased ICP. Evacuation of the hematoma was not found to be helpful in randomized trials [67]. However, subgroup analysis suggested a possible role of surgical evacuation in hematoma that are superficial and less than 1 cm from the cortex. A subsequent trial, STICH 2, is underway to address this issue. Recombinant factor VII showed promise in phase 2 trials in reducing hematoma growth and improving outcome but a randomized phase 3 trial did not show any significant improvement in outcome after intracerebral hemorrhage, even though the hematoma growth was reduced [68,69]. Off-label use in reversal of anticoagulation-based ICH is sometimes practiced but with uncertain outcomes.

CHAPTER 174 ■ NEURO-ONCOLOGICAL PROBLEMS IN THE INTENSIVE CARE UNIT

N. SCOTT LITOFSKY AND MICHAEL C. MUZINICH

INTRODUCTION

Neuro-oncology encompasses the care of patients with neoplasms affecting the brain, spinal cord, and peripheral nervous system. These tumors may arise either within the nervous system itself or spread from systemic malignancies. Neuro-oncology patients may require care in an intensive care unit (ICU) at a number of different phases of their illnesses. Usually, postoperative patients with brain tumors are admitted to the ICU. Neuro-oncology patients are also admitted to the ICU if they suffer catastrophic or near catastrophic neurologic decline or if they are at high risk to suffer such a change. Lastly, neuro-oncology patients may also suffer from medical processes that require intensive care.

This chapter discusses the intensive care issues that may be encountered in neuro-oncology patients, either following their surgery or as complications of their diseases. These issues include elevated intracranial pressure (ICP), hydrocephalus, seizures, postoperative complications, spinal neoplastic disease, and medical systemic complications.

ELEVATED INTRACRANIAL PRESSURE

Elevated ICP frequently complicates the course of patients with cerebral neoplasms. Both primary and metastatic tumors in the brain can cause elevated ICP. Patients with aggressive brain

tumors often succumb as a consequence of uncontrollable elevations in ICP.

Pathophysiology

Normal intracranial pressure ranges between 5 and 15 cm H_2O. This pressure is generated by the volumes of the various components contained in the "closed box" of the skull. These components include brain parenchyma, cerebrospinal fluid (CSF), extracellular water, and blood in vascular spaces. A perturbation of any of these components can increase ICP. Any additional tissue not normally present in the brain, such as a primary or metastatic tumor, or a hemorrhage associated with a tumor, can also increase ICP. While the numerical value of the ICP cannot be ascertained by neurodiagnostic images, some of the perturbations are evident on either computed tomography (CT) scan or magnetic resonance imaging (MRI).

Brain tumors can affect each intracranial component. In addition to the volume of the neoplasm itself, cerebral neoplasms can produce vasogenic edema [1], secondary to increased permeability of blood vessels within or adjacent to the tumor, thereby increasing extracellular water [2,3]. Radiographically, this edema corresponds to hypodensity on CT or hyperintensity on T2-weighted MRI around the enhancing bulk of tumor. Tumor mass, or brain parenchyma displaced by tumor, may obstruct CSF pathways, causing hydrocephalus. Hydrocephalus will be discussed in further detail in the section "Hydrocephalus." Intravascular blood volume also can increase in patients with tumors as a result of hypoventilation. Hypoventilation occurs either related to seizure activity or ICP elevation, both of which can reduce respiratory drive. Hypoventilation increases PCO_2, which causes arterial vasodilation, thereby increasing intravascular volume and ICP. This increase can cause a vicious positive feedback loop by further reducing ventilatory drive.

Signs and Symptoms

Patients can experience a variety of symptoms and signs caused by elevated ICP. These findings do not necessarily correlate with the degree of elevated pressure, though generally the higher the ICP, the more significant the neurologic findings.

As ICP increases, compression of the reticular activating system depresses the patient's level of consciousness. These findings tend to occur sequentially, with the patient progressing from an awake and alert status to progressively more lethargic states and may eventually lead to coma.

Patients may develop a variety of cognitive changes resulting from elevated ICP. Disorientation, short-term memory loss, decreased fund of knowledge, and loss of insight and judgment can occur to varying degrees.

As increasing ICP approaches pressure of the central retinal vein, the patient will usually lose the spontaneous venous pulsations that are seen on routine funduscopic examination. Further elevation of ICP exceeding the central retinal vein pressure causes swelling of the optic disks (papilledema). Papilledema does not usually occur rapidly in the setting of elevated ICP. Usually several days of elevated ICP must ensue before papilledema is evident. A patient with long-standing papilledema may have constriction of his/her visual fields and/or decreased visual acuity.

Brain masses causing elevated ICP can cause brain shifts from one intracranial compartment to another. Usually a brain shift, also known as a "herniation," is away from the mass causing the elevated ICP. Supratentorial masses may cause the brain to herniate inferiorly through the tentorial incisura. With a resulting central diencephalic herniation syndrome, the patient experiences simultaneous bilateral pupillary dilation from compression of the tectum, containing the Edinger–Westphal nucleus of the oculomotor nerve (CN III). A lateral cerebral mass, particularly if in the temporal lobe, forces the uncus of the temporal lobe to herniate through the incisura. This uncal herniation causes compression of CN III between the posterior cerebral artery and the superior cerebellar artery, resulting in unilateral pupillary dilation. In both herniation syndromes, the constrictive phase of the light reflex can also cease to function (unreactive pupils). Usually, though not always, decrease in the patient's level of consciousness precedes pupillary dysfunction.

Patients can also have light-near dissociation. Pressure on the tectum can compress the retinotectal fibers that are part of the afferent limb of the pupillary light reflex; the pupil does not constrict to light appropriately. However, those fibers involved in the afferent limb of pupillary accommodation to near vision, which travel to the tectum through other pathways, are not affected. Patients, therefore, can have pupils that constrict to accommodation but not to light. This is often a very subtle sign of elevated ICP.

Double vision may also be present. The abducens nerve (CN VI), which controls abduction of the eye, has the longest intracranial course of the cranial nerves and is at highest risk of dysfunction when ICP is elevated. Diplopia is usually more pronounced with increasing lateral gaze, either unilaterally or bilaterally.

As the dura and blood vessels are stretched by elevated ICP, the patient may experience headache. Headache is frequently described as "band like" or "pressure like." It tends to occur more commonly in the early morning and may wake the patient from sleep. While the patient is sleeping, the recumbent position decreases venous return to the heart, elevating ICP. In addition, hypoventilation that occurs during sleep will also elevate ICP, increasing the headache.

Not uncommonly, headache is associated with projectile vomiting. Vomiting occurs because of increased pressure on the area postrema.

In addition to the symptoms and signs described earlier, patients with elevated ICP often experience neurologic deficits from the compressive effects of the mass of the tumor on adjacent neural structures. These deficits can include the following: hemiparesis, aphasia, visual field deficits, hearing loss, ataxia (truncal or appendicular), and sensory loss. The presence of these findings is based on the size, location, and rapidity of growth of the mass. Slower growing tumors allow the brain to compensate; focal findings may not be evident until late in the patient's course.

Management

Mechanical and pharmacologic therapies are available to treat elevated ICP, with expectant reduction or elimination of its signs and symptoms. Some require very minimal intervention, while others are much more intensive or invasive.

Head elevation of 30 to 45 degrees is perhaps the easiest treatment available. It increases venous drainage from the brain, thereby reducing blood volume within its intravascular compartment. Head elevation poses minimal risk to the patient. Theoretically, cerebral perfusion could be diminished, but such a reduction is negligible in a patient with normal blood pressure.

Mannitol, an osmotic diuretic, draws fluid out of the brain and into the vascular system by increasing serum osmolarity. From the vascular spaces, the fluid follows the mannitol as the kidney excretes it. Therefore, mannitol reduces intracellular and extracellular water in the brain. Furthermore, mannitol improves blood rheology; ischemic areas of brain adjacent to the tumor mass are better perfused [4]. Mannitol is

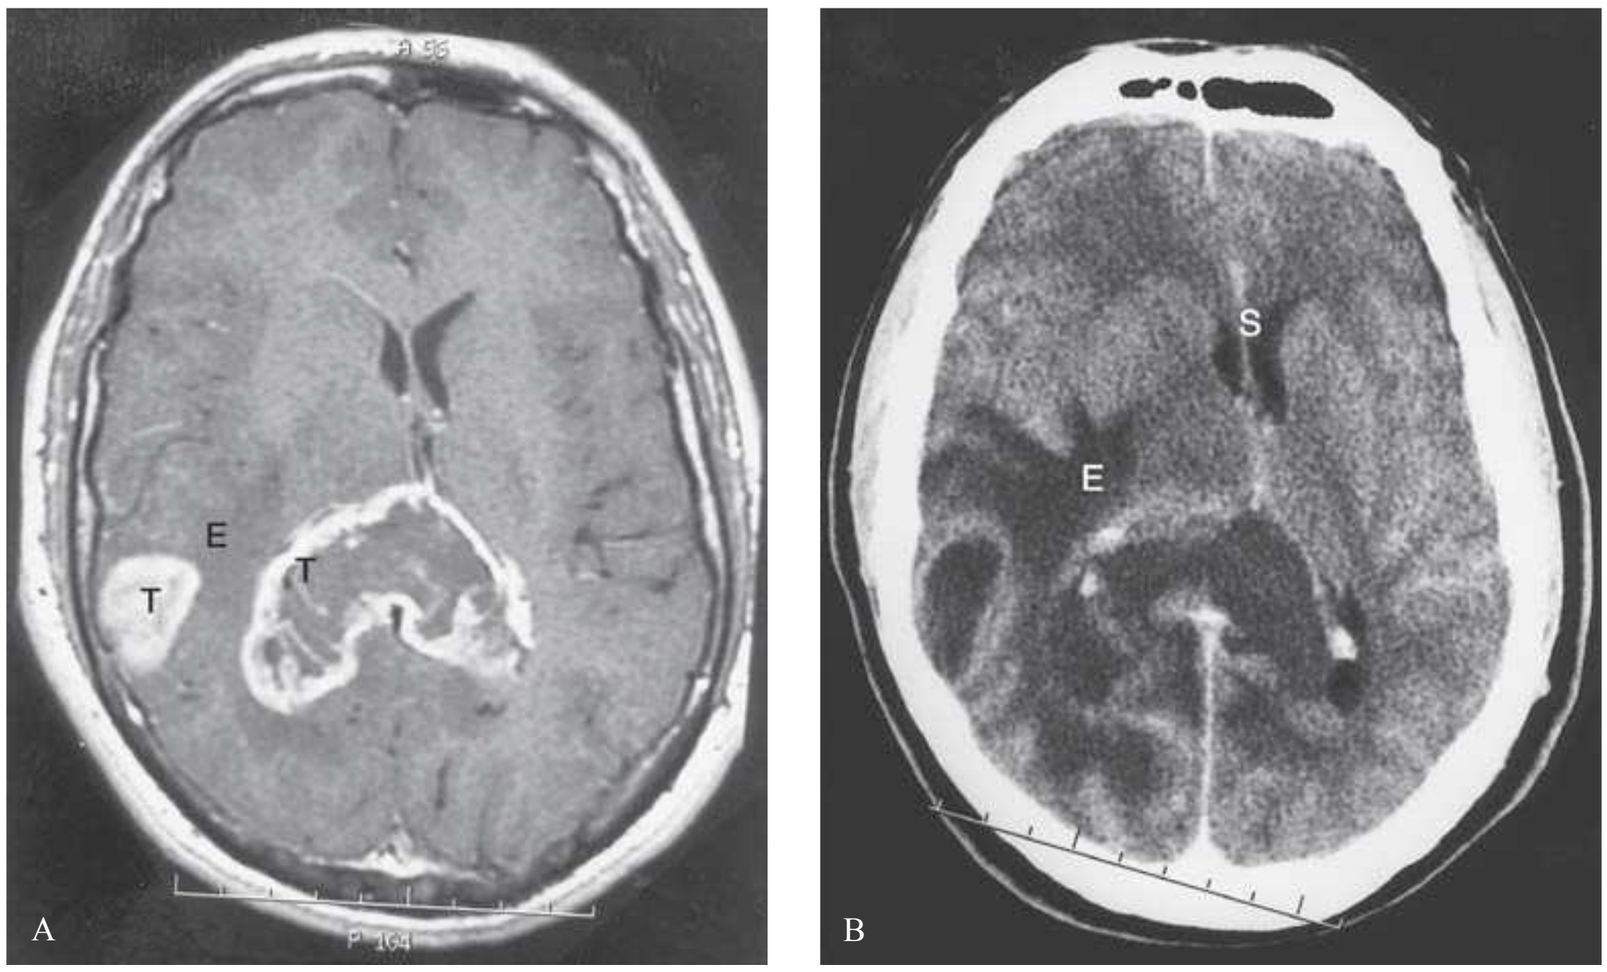

FIGURE 174.1. A: This magnetic resonance imaging, performed on a patient presenting with headache and memory lapses, shows an enhancing mass (T) involving the corpus callosum and right parietal area, with surrounding edema (E). Stereotactic biopsy revealed glioblastoma multiforme. **B:** One week following biopsy, the patient was admitted to the intensive care unit with obtundation and left hemiparesis. His computed tomography shows increased edema (E) and right-to-left midline shift (S)—parafalcine herniation. He required mannitol, increased Decadron, and surgical decompression to improve.

frequently given as an initial resuscitative dose of 1 gm per kg, followed by 0.25 gm per kg every 4 to 6 hours to maintain the diuresis and control ICP. Mannitol is quite effective in lowering ICP and/or reversing early cerebral herniation. It may also be used if patients have significant mass effect identified on neuroimaging studies to stabilize and improve their condition (Fig. 174.1). A number of potential risks are present with long-term mannitol use. Hypotension can occur in already hypovolemic patients. Patients can also become hyperosmolar and hypernatremic. Therefore, mannitol is usually withheld from the patient if serum osmolarity exceeds 320 mOsm per L. Lastly, there is some concern that mannitol may lose effectiveness if used continuously for more than 72 hours.

Furosemide (Lasix), a loop diuretic, rapidly reduces systemic circulating volume. Extracellular and intracellular water in the brain are drawn into the vascular system and are redistributed. Lasix also promotes venous pooling, leading to similar redistribution of fluids. While mannitol is generally used as the first-line agent, Lasix may be used at an initial resuscitative dose of 1 mg per kg in patients with cerebral herniation. Risks are minimal in this setting, as electrolyte abnormalities are unlikely to occur with only a single dose. In a patient who has had frequent vomiting and is already dehydrated, Lasix can cause hypotension from the additional hypovolemia.

Hypertonic saline enhances cerebral blood flow by increasing intravascular osmolarity that creates a gradient to move free water from the interstitial and intracellular compartments to the intravascular space. This is associated with an acute plasma expansion with hemodilution, increase in arterial blood pressure, and reduced vascular resistance [5]. Hypertonic saline has also been found to have some inotropic effects that appear to be derived from improvement in cardiac microcirculation and contractility [6]. However, significant polyuria has been observed in the acute setting which may lead to excessive diuresis and subsequent dehydration. Patients on hypertonic therapy should also have frequent blood draws every 6 hours to monitor serum osmolality and serum sodium. It is generally recommended to have a target serum sodium from 145 to 155 mmol per L and serum osmolality of less than 320 mOsm per L. Serum sodium should not increase more than 15 mmol per L daily and should not be allowed to drop more than 10 mmol per L daily to decrease the risk of central pontine myelinolysis [7].

Glucocorticosteroids can markedly improve symptoms of elevated ICP and/or mass effect in patients with cerebral neoplasms. They work by stabilizing cell membranes and reducing vasogenic edema [8,9]. Dexamethasone (Decadron) is the most commonly used glucocorticosteroid. An initial dose of 10 to 20 mg is followed by 4 to 6 mg every 4 to 6 hours, depending on the severity of the patient's clinical condition. Solu-Medrol (100 mg initially, and then 20 to 40 mg every 4 to 6 hours) is another option. Glucocorticosteroids are the medical mainstay of brain tumor care because their effects are sustained over time. A patient with vasogenic edema from tumor may require steroids for a significant period of time. In the short term, steroids can cause hyperglycemia and exacerbate diabetes mellitus, changing the patient's insulin requirements. Gastrointestinal hemorrhage or ulceration can occur; H_2 blockers, such as Pepcid, Nexium, or Zantac, are frequently given prophylactically. The stimulatory effect of steroids frequently disrupts sleep. Long-term use of steroids may be associated with proximal muscle weakness, avascular necrosis of the femoral head, easy bruising, and other findings of Cushing's syndrome.

In contrast to cerebral vasodilation caused by hypoventilation, hypocarbia from hyperventilation causes cerebral vasoconstriction, which reduces the arterial intravascular blood volume within the brain. Hyperventilation can therefore rapidly reduce ICP and reverse a cerebral herniation syndrome. Although initial hyperventilation can be performed with an AMBU bag valve mask, sustained hyperventilation requires endotracheal intubation and mechanical ventilation of the patient. Moderation of hyperventilation is necessary because at PCO_2 less than 25 mm Hg, cerebral ischemia may result from profound vasoconstriction. A vasodilatory rebound from hyperventilation occurs after approximately 24 hours, thereby negating its positive effects if hyperventilation is used chronically [10].

One of the most effective means of rapidly reducing ICP is to drain CSF. Such a maneuver is effective whether or not the patient has hydrocephalus. In a patient with a brain tumor, the safest method of draining CSF is to place a ventriculostomy, a catheter usually passed into the frontal horn of the lateral ventricle via a small hole drilled through the skull. The procedure can be performed by a neurosurgeon at the bedside. After placement of a ventriculostomy, drainage of CSF into a bag at bedside can reduce ICP. The catheter can also be coupled to a pressure transducer so that ICP can be measured. Usually, CSF is drained if ICP exceeds 15 to 20 mm Hg. The risks of the procedure include hemorrhage and infection. Therefore, coagulation studies are appropriate before the procedure is done, especially in patients who have received recent chemotherapy. The risk of infection increases the longer the catheter remains in place. Sometimes, prophylactic antibiotics are used.

Regardless of what means are necessary to stabilize and/or resuscitate the patient, the best means of controlling ICP in long term is to remove the tumor if possible. Unfortunately, some tumors are unresectable. Gliomas or metastases involving the thalamus or basal ganglia are generally not resected, except in unusual circumstances. In these instances, medical management is necessary to control ICP until adjuvant therapy, such as radiation therapy, can shrink the tumor and reduce its edema-producing capabilities. The same rationale applies to patients with multifocal cerebral masses; patients with more than one metastasis do not usually have multiple operations to resect each tumor, especially if symptoms are controllable with steroids. On the other hand, if the tumor is resectable, its removal can relieve the brain of the extra mass, relieve obstruction to the flow of CSF, and reduce vasogenic edema. In addition to relieving the signs and symptoms of elevated ICP, tumor resection can also relieve the effects of compression on the surrounding brain, improving lateralizing findings. Some tumors can be removed completely. These include meningiomas, vestibular schwannomas, craniopharyngiomas, pituitary adenomas, and metastatic tumors. Microscopic disease may still be present in the tumor bed, particularly in the case of metastases or craniopharyngioma, which may require adjuvant therapy, but ICP can be well controlled. Primary glial neoplasms, however, cannot be completely removed in most cases. The bulk of tumor can be resected, and postoperative neurodiagnostic images may show no residual tumor, but most of these tumors have infiltrating fingers of tumor still present. Even so, removing tumor bulk can alleviate elevated ICP; edema can sometimes be exacerbated with only partial resection, so caution is required.

HYDROCEPHALUS

Brain tumors often can cause hydrocephalus, a situation in which the patient has an increased volume of CSF under increased pressure. Hydrocephalus is typically associated with enlargement of the ventricular system (or a portion thereof) and compression of the normal brain parenchyma. A patient with hydrocephalus may require urgent or emergent intensive care monitoring and treatment. Hydrocephalus is a special case of elevated ICP and warrants separate discussion.

Etiology

Hydrocephalus can occur from a variety of mechanisms in patients with brain tumors. It is as important to identify the etiology of the hydrocephalus as its presence because the definitive treatment of hydrocephalus will be based on its mechanism of formation. Some tumors, as discussed later, are more likely to be associated with certain mechanisms of hydrocephalus than others.

Leptomeningeal infiltration by tumor cells in the subarachnoid space can prevent the absorption of CSF by the arachnoid granulations, either by occluding the granulations or preventing the flow of CSF from the outlet foramen of the fourth ventricle around the dorsolateral convexities to the granulations. Metastatic tumors from the lung, breast, lymphoma, and leukemia are the most frequently involved systemic tumors; primary tumors behaving in this fashion include primitive neuroectodermal tumors (i.e., medulloblastoma), ependymoblastoma, and glioblastoma multiforme. A patient with carcinomatous meningitis will frequently have a stiff neck or cranial neuropathy in addition to symptoms and signs of elevated ICP.

Large extra-axial "benign" tumors, usually in the posterior fossa, can cause hydrocephalus (Fig. 174.2). These tumors include those in the cerebellopontine angle, such as meningioma or vestibular schwannoma. These tumors displace the cerebellar hemisphere and obstruct the fourth ventricle to prevent adequate circulation of CSF. Rarely a choroid plexus papilloma can emerge from the foramen of Luschka and similarly compress the cerebellar hemisphere. Meningiomas of the clivus or tentorium can also displace CSF pathways with resulting hydrocephalus.

Some tumors may originate in a ventricle or protrude into a ventricle and occlude CSF pathways, thus producing hydrocephalus. These tumors include medulloblastoma, ependymoma, choroid plexus papilloma, intraventricular meningioma, colloid cyst, giant cell astrocytoma of tuberous sclerosis, and pineal region tumors.

Parenchymal tumors often can occlude CSF pathways. Primary or metastatic tumors in the thalamus or basal ganglia can displace brain parenchyma and occlude the foramen of Monro or the third ventricle [11]. Tumors in the pineal region may occlude the posterior third ventricle or cerebral aqueduct (Fig. 174.3). Brain stem gliomas or tumors in the cerebellar hemispheres can compress the fourth ventricle [12].

Symptoms and Signs

The clinical picture of a patient with hydrocephalus is frequently the same as that of a patient with elevated ICP. In fact, hydrocephalus must be considered in the differential diagnosis for causes of elevated ICP. Patients with midline masses or carcinomatous meningitis usually do not have lateralizing neurologic deficits such as hemiparesis. Those patients with unilateral brain masses may have lateralizing deficits from compression of the previously normally, but marginally, functioning brain by the progressive hydrocephalus.

Evaluation

If hydrocephalus is suspected, evaluation should proceed promptly. Two questions must be answered—"Does the patient have hydrocephalus?" and "What is the cause of the hydrocephalus?" Either MRI or CT can answer these questions. Because MRI delineates better anatomic definition of the brain, more readily illustrates the relationship of the lesion to CSF pathways, and shows these features in multiple planes, MRI with gadolinium is the preferred study. Sometimes, however, the patient is too ill to obtain an MRI easily, or MRI is not readily available. In these circumstances, a CT scan with IV contrast is sufficient. The purpose of the contrast agent with either study is to characterize the location of the lesion and its relationship to CSF pathways better. The addition of proton magnetic resonance spectroscopy to standard anatomic MRI

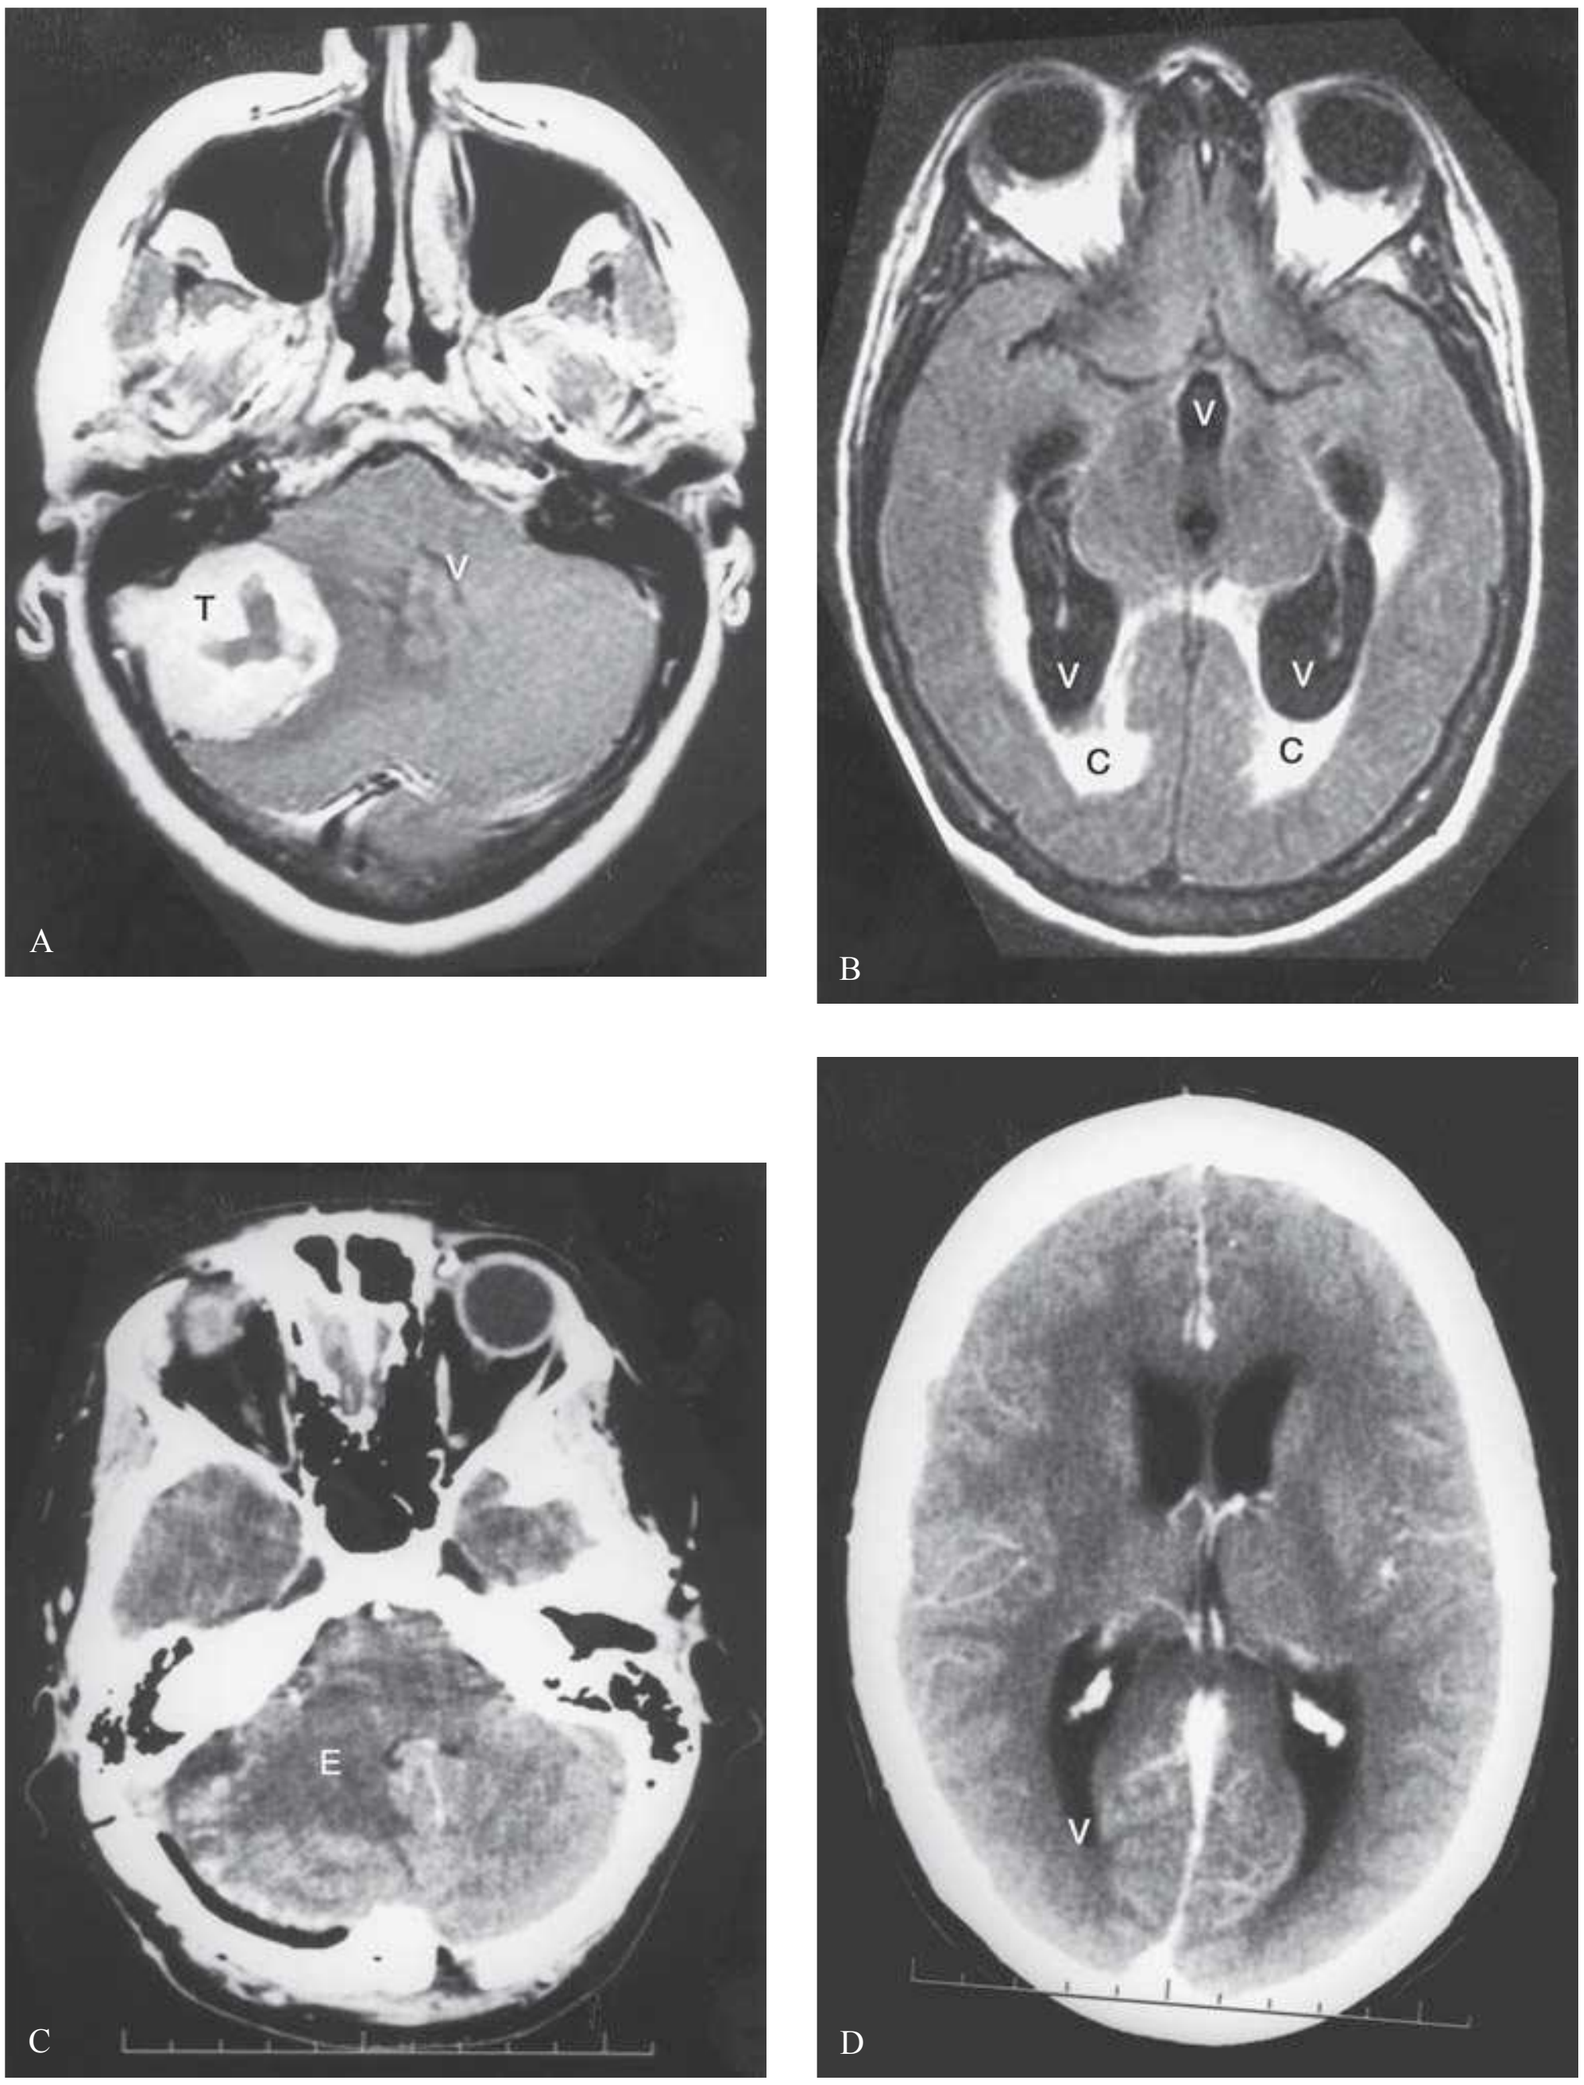

FIGURE 174.2. A: This magnetic resonance imaging (MRI), performed on a patient presenting with headache and obtundation, shows an enhancing mass in the right cerebellopontine angle (T) with displacement of the fourth ventricle (V) to the left. **B:** Additional views of the MRI show hydrocephalus, with enlarged, rounded ventricles (V) and transependymal spread of cerebrospinal fluid (CSF) (C). A ventriculostomy to drain CSF was placed to temporize the patient prior to surgery. **C:** After resection of the tumor, a meningioma, the fourth ventricle, returns toward its normal position. Edema (E) in the cerebellar hemisphere is still present. **D:** Hydrocephalus has resolved, with the ventricle (V) returning to normal size and shape.

may improve the diagnostic accuracy in assessing intracranial mass lesions.

Management

The appropriate intervention for a patient with hydrocephalus depends on several factors. These include the cause of the hydrocephalus, the anatomic location of the obstruction to CSF flow, and the patient's clinical condition.

In patients experiencing rapidly progressive deterioration, such as cerebral herniation, emergent management with a ventriculostomy, as described previously, to divert CSF temporarily can improve the patient's clinical picture. Usually, the drainage chamber is set so that the system can be opened intermittently to drain CSF for ICP greater than 20 mm Hg. Some patients, however, require a lower ICP to achieve neurologic improvement, so the system can be opened for lower pressures. An alternative method of draining CSF in patients with hydrocephalus is to set the system to drain CSF continuously at a particular

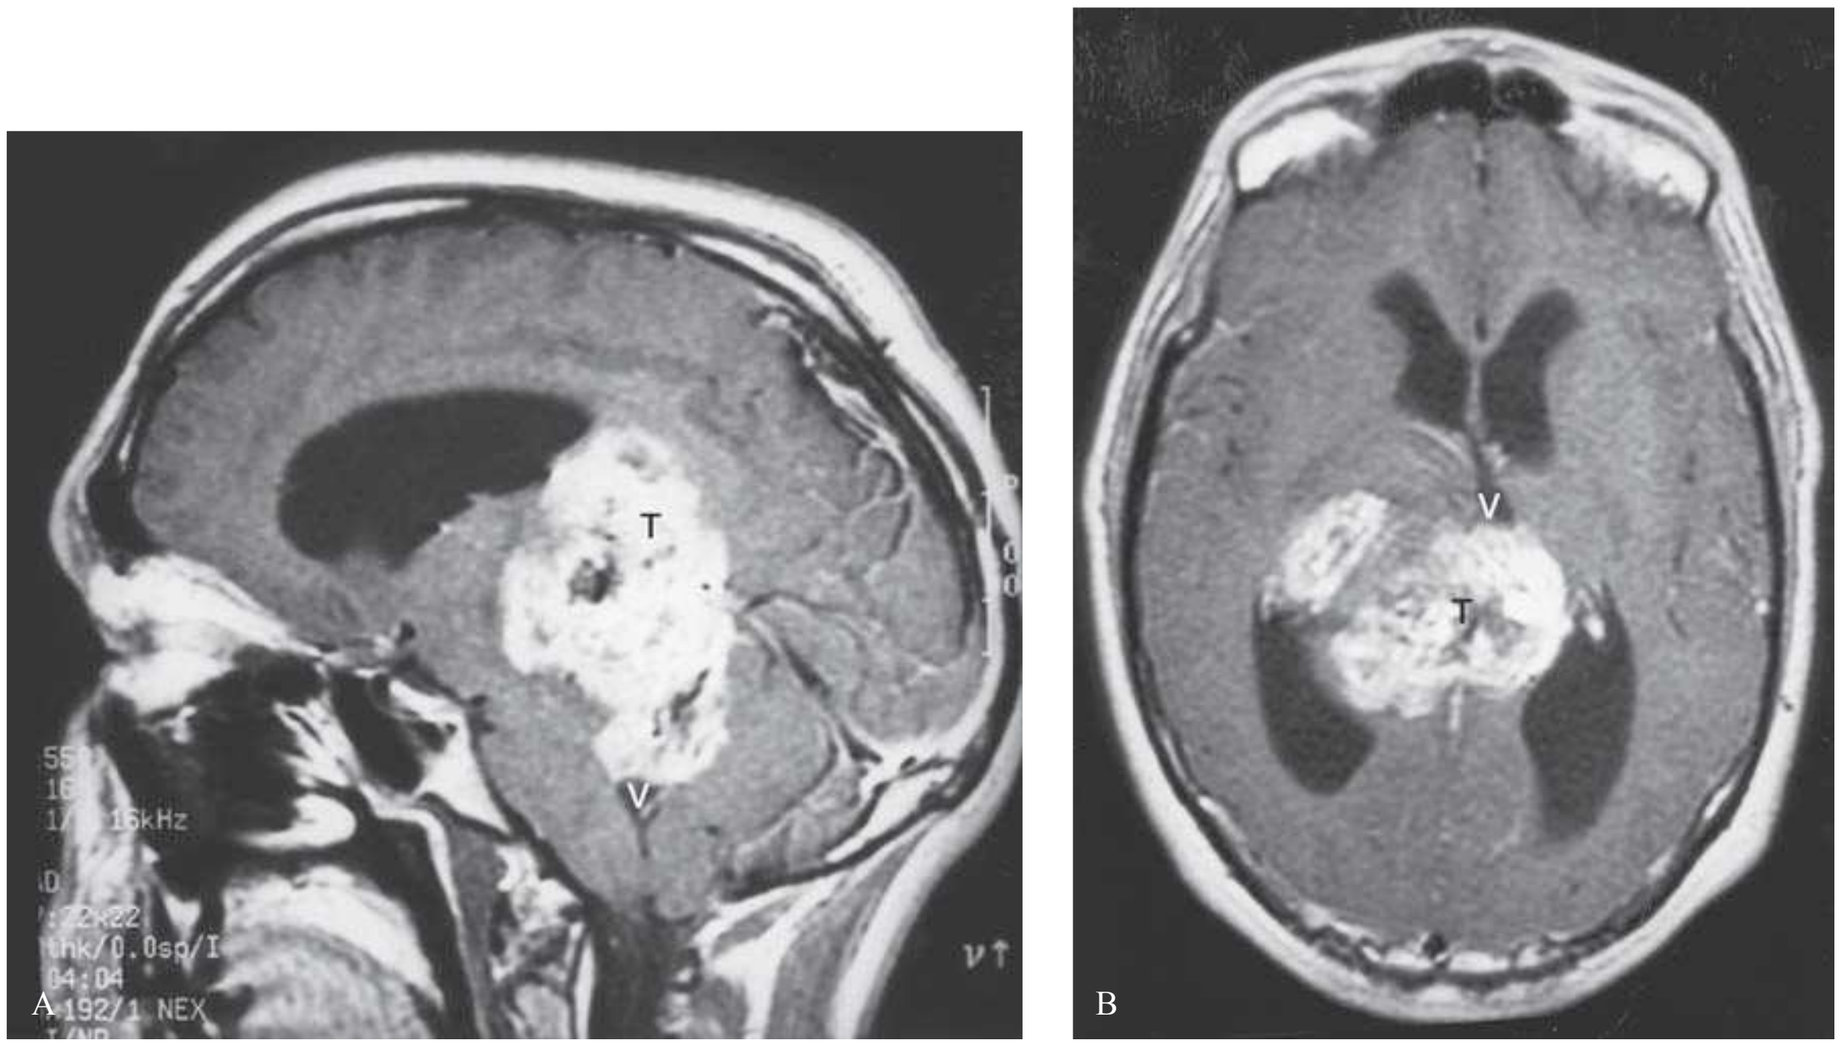

FIGURE 174.3. A: This sagittal magnetic resonance imaging on a patient with headache, lethargy, and diffuse weakness shows an enhancing mass (T) extending from the pineal region to the fourth ventricle (V). **B:** Axial views show the tumor (T) compressing the third ventricle (V) with hydrocephalus. Despite an aggressive surgical resection of this glioblastoma multiforme, the patient subsequently developed recurrent hydrocephalus and required a ventriculoperitoneal shunt.

pressure, for instance, at 15 mm Hg. ICP is then recorded on an hourly basis. This technique of CSF drainage should be approached with some caution as large volumes of CSF may drain if the patient strains or coughs, increasing intrathoracic pressure and therefore ICP temporarily. If too much CSF drains, patients may develop subdural or intraparenchymal hemorrhages.

A patient may have only mild hydrocephalus and not be significantly impaired clinically. Emergent intervention may not be necessary, and the patient can be stabilized with Decadron with or without mannitol or other hyperosmolar agent. In this situation, resection of the tumor can provide long-term treatment of hydrocephalus by decompressing the CSF pathways, particularly with posterior fossa or pineal region tumors. The patient may not require CSF diversion at all. Surgery should proceed in a timely fashion, though.

Occasionally, hydrocephalus does not respond to surgical decompression alone. Anatomic considerations are frequently responsible. It may not be possible to resect enough tumor to decompress the CSF pathways. Alternatively, absorptive capabilities may be compromised by inflammatory process from blood or tumor products. In these cases, a permanent shunt, usually from a lateral ventricle to the peritoneum (ventriculoperitoneal), is necessary to treat the hydrocephalus. This procedure is performed in the operating room. Shunts are usually well tolerated and very effective. One concern in a patient with a tumor in which malignant cells are present in the CSF is that the patient will have intraperitoneal spread of tumor via the shunt. This complication occurs uncommonly, though. Persistent symptomatic hydrocephalus dictates that the shunt be placed regardless of this concern.

A more commonly occurring concern in a patient with hydrocephalus who has been shunted is shunt malfunction [13]. Cellular debris, proteinaceous material, or normal choroid plexus can occasionally occlude a shunt. This occurrence is manifested by symptoms and signs of hydrocephalus and elevated ICP. Treatment requires operative revision of the occluded portion of the shunt, usually with replacement of the ventricular catheter or the valve.

Hydrocephalus can be somewhat problematic to treat in a patient with a tumor adjacent to the third ventricle. In this uncommon situation, the lateral ventricles may not communicate with each other through the third ventricle. In the most extreme case, the frontal horns of the lateral ventricles do not communicate with the occipital and temporal horns. Therefore, a single shunt will be ineffective in relieving the CSF obstruction. A ventriculogram, in which intrathecal contrast is placed into the lateral ventricle via a ventricular catheter (either a ventriculostomy or the ventricular portion of a shunt), can define the nature of the obstruction. The patient may require two, three, or even four ventricular catheters to drain CSF adequately. Tumors where this problem should be of concern include craniopharyngioma, central neurocytoma, pilocytic astrocytoma of the hypothalamus, and glioblastoma, among other tumors involving the medial septal structures of the brain.

SEIZURE

Seizures are a common occurrence in patients with brain tumors. About 40% of patients with gliomas initially present to medical attention with seizure; about 55% of glioma patients have a seizure at some point in the course of their disease. Some low-grade gliomas, such as oligodendroglioma, have a very high likelihood of seizure. Approximately 20% of patients with metastatic tumors have a seizure at some time [14,15].

Seizures may be focal or generalized. A patient remains conscious during a focal seizure. The seizure may be a motor seizure in which the patient's mouth twitches or an extremity moves uncontrollably for a period of time. With a dominant hemisphere lesion, aphasia may also occur. During a generalized seizure, the patient loses consciousness. Tonic–clonic movements may occur, and the patient may lose bladder control or bite their tongue. A patient can also experience status

epilepticus, a series of seizures occurring in rapid succession with the patient not regaining consciousness between seizures. Status epilepticus is a medical emergency that is addressed in Chapter 172. Occasionally, a patient can have a seizure that is not witnessed or is subclinical in activity. The patient experiences a neurologic deficit, which subsequently improves, leaving healthcare providers puzzled as to the etiology of the transient deficit.

Further evaluation of the known brain tumor patient with seizure is necessary. A seizure can occur in a patient with a known brain tumor for a number of reasons. The most common reason is that the patient's anticonvulsant medication level(s) is (are) subtherapeutic. Drug requirements may change as steroid requirements change; Decadron may interact with Dilantin to lower serum levels [16,17]. Serum drug levels are therefore essential. Other reasons for seizure include a change in the character of the tumor. The tumor may have grown in size [18] or a hemorrhage within the tumor may have occurred. A CT scan of the head without contrast helps to differentiate among these possibilities.

Treatment

While a single generalized seizure usually does not have long-term consequences, such an event may precipitate rapid deterioration in a patient with elevated ICP. The associated hypercarbia from hypoventilation can increase ICP substantially; a stable patient can rapidly deteriorate even to the point of developing a herniation syndrome. Hypoxia can further compromise brain function by causing damage similar to cerebral ischemia, especially in the area already affected by the tumor. Prompt intervention is therefore necessary.

Maintenance of an adequate airway and reestablishment of adequate ventilation is essential. Oxygen should be provided to the patient. Intubation and mechanical ventilation may be required if the patient experiences hypoventilation.

The best medication to stop seizure activity in patients with status epilepticus is Ativan. The initial dose is 2 mg IV, and the dose is repeated acutely every 5 minutes as needed, up to a total of 8 mg until the seizure activity stops. Should 8 mg be required, mechanical ventilation will likely be required. Dilantin (15 mg per kg IV) or phenobarbital (15 mg per kg IV) must be used acutely in conjunction with Ativan, as the Ativan is only for short-term seizure control.

Prophylactic anticonvulsants administered without a seizure having occurred are rarely indicated unless the patient is going to surgery [19]. Following a seizure, the patient should be started on an anticonvulsant, such as Dilantin. The initial loading dose is 15 mg per kg intravenously, with oral or intravenous maintenance dosing of 100 mg three times daily or 200 mg twice a day. Phenobarbital, although more sedating than Dilantin, can also be used. Both Dilantin (or fosphenytoin) and phenobarbital are available in intravenous forms and may be used if the patient is unable to take oral or enteral medications. Tegretol, on the other hand, is only available in an oral form, so it cannot be used in status epilepticus or in patients who cannot tolerate enteral intake. Keppra is available in both oral and intravenous formulas, has fewer interactions with other medications, and tends to have less sedating side effects.

POSTOPERATIVE COMPLICATIONS

One of the most common reasons for a patient with a neuro-oncological illness to be admitted to an ICU is for observation following a neurosurgical procedure. This period of observation may just be overnight or it may be longer, being dictated by the patient's neurologic and/or medical condition. Although perioperative mortality is less than 2%, medical or neurologic complications may occur in up to 30% of cases; older patients and those with increased neurologic deficits are more likely to suffer these morbidities [20]. Therefore, a variety of intraoperative and postoperative complications must be recognized before the patient's neurologic or medical status is irreversibly compromised. Intervention can then proceed promptly.

To anticipate potential complications, vital signs and neuro-checks are taken hourly by nurses in the ICU. One of the most important components of the neuro-checks is the patient's level of consciousness, usually denoted by the Glasgow Coma Scale (GCS) score [21,22]. This three-part score consists of patient responses in eye opening, motor, and verbal spheres. Originally developed to document the level of consciousness in patients with head trauma, use of the GCS can readily, reliably, and reproducibly identify changes in the patient's level of consciousness—either deterioration or improvement. Furthermore, its use can help evaluate the effectiveness of interventions by the reported trends. Other components of neuro-checks include pupillary light responses, orientation, and motor function. Any decrement in function warrants prompt evaluation. Such an evaluation should include a CT or MRI scan of the head, serum electrolytes, blood gases, and anticonvulsant level(s). Other tests may be required based on the patient's condition. Recent technological advancements have allowed for production of mobile CT scanners for use in the ICU. While the resolution is significantly less than traditional CT scanning, the mobile CT scanner can be utilized to ascertain gross intracranial pathology in patients who may otherwise be too unstable for transport. Evaluation of the ICU patient for intracerebral hemorrhage or increased ventricular size can be performed at the patient's bedside and allow for rapid diagnosis in patients with acute changes in mental status. Mobile CT scanning has also been utilized intraoperatively during resection of glial tumors, which may allow for more complete resection of intracranial pathology [23].

Intracranial Hemorrhage

One of the most dramatic complications that can occur in the postoperative period is intracranial hemorrhage. Significant hemorrhage usually becomes evident within 6 to 12 hours after the completion of surgery. A patient can bleed into the tumor bed (Fig. 174.4), or into the subdural or epidural spaces. Although steps are taken at surgery to prevent such complications, oozing from small vessels in the tumor bed can occur. Traction by the brain, slackened by tumor removal, mannitol, Lasix, hypertonic saline, hyperventilation, and CSF drainage, can tear or stretch draining veins, leading to blood accumulation in the subdural space. Because the dura is separated from the bone to perform the craniotomy, the epidural space is no longer just a potential space; rather, it is a real space into which blood can ooze from underneath the bone edges and accumulate. Patients who experience significant hypertension or persistent coughing and "bucking" as they emerge from anesthesia are at greater risk for developing postoperative hemorrhage. Hypertension can cause bleeding from arterial-side vessels. The increase in intrathoracic pressure that occurs with coughing or bucking against the endotracheal tube can precipitate venous-side bleeding, as can thrombosis in a draining vein from manipulation.

Postoperative hemorrhage should be suspected in a patient who fails to emerge adequately from anesthesia. Intracranial hemorrhage should also be a concern if the patient deteriorates following emergence from anesthesia and develops progressive decline in level of consciousness, pupillary abnormalities, or

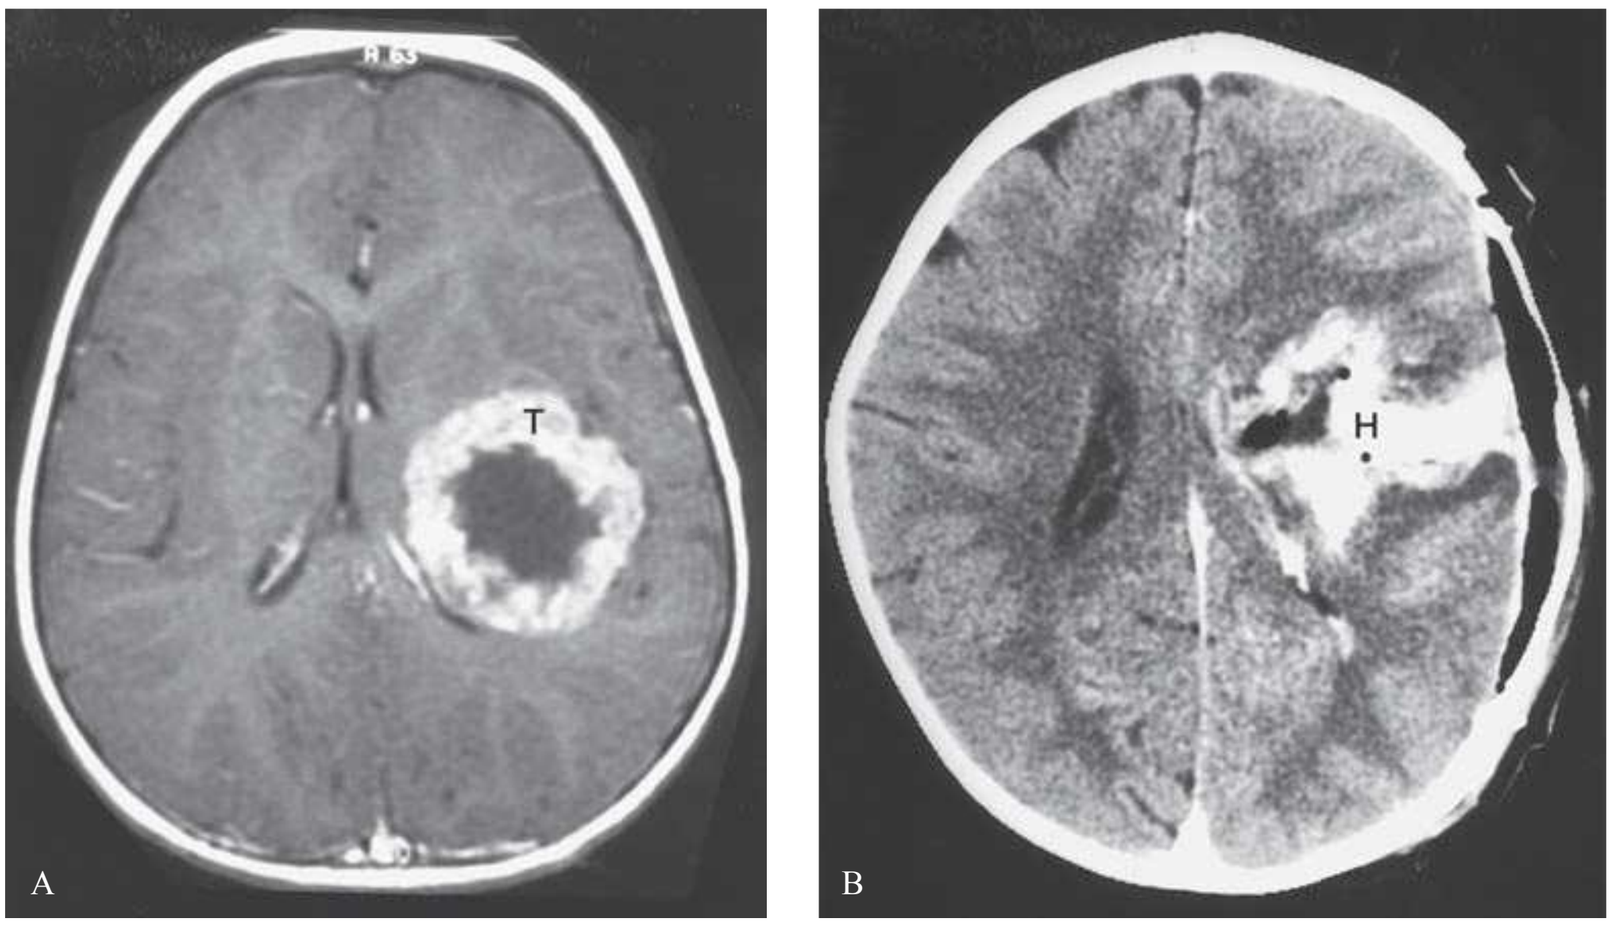

FIGURE 174.4. A: This magnetic resonance imaging on a 2-year-old boy shows a large enhancing mass (T) in the left temporoparietal area. **B:** Immediately following surgery to remove the rhabdoid neuroepithelial tumor, the patient had sustained hypertension and awakened slowly from her anesthesia with a mild right hemiparesis. This computed tomography scan shows hemorrhage (H) in the tumor bed. With blood pressure control and observation, the patient recovered to a normal level of consciousness with resolution of her hemiparesis over several days.

new motor deficits. Emergent evaluation with a CT scan is indicated. Coagulation deficits, particularly in patients who have had chemotherapy recently or who have liver disease, should be ruled out with laboratory testing for prothrombin time, partial thromboplastin time, and platelet count.

Should a significant intracranial hemorrhage be identified, the patient may need to return to the operating room to evacuate the hemorrhage. Mannitol and reintubation may be required to stabilize the patient's condition. Occasionally, if the neurologic deterioration is mild, observation or mannitol by itself may be sufficient intervention. As the blood degrades over time and edema subsides, the patient should improve clinically. Frequent follow-up CT scanning is necessary in nonoperative management to evaluate the status of the hemorrhage and surrounding brain.

Cerebral Edema

Manipulation of the tumor and adjacent brain can lead to cerebral edema. Clinical signs can appear quite similar to postoperative hemorrhage, although deficits from edema tend to occur in a more delayed fashion. Prompt treatment with mannitol and Decadron is indicated following a CT scan to confirm the etiology of the patient's neurologic change.

Endocrinopathy

Pituitary tumors may be associated with hypersecretory or hyposecretory states. Other tumors in the sella and parasellar areas may also be associated with endocrinopathy, usually hypopituitarism. Surgery for tumors in these locations can cause endocrine deficits too. Most endocrinopathies encountered in the ICU are related to pituitary hypofunction.

The major neurologically related endocrinopathy evident in the ICU setting is diabetes insipidus, most commonly after craniopharyngioma or pituitary tumor resection. It usually occurs between 18 and 36 hours following surgery. Signs of diabetes insipidus include an increase in urine output greater than 200 mL per hour for 2 consecutive hours, a corresponding drop in urine specific gravity to less than 1.005, and an increase in serum sodium to greater than 147 mEq per L. A patient who is conscious usually experiences increased thirst. Hypotension can occur if the complication is not recognized early. Treatment with DDAVP 0.25 mL (1 mg) subcutaneously or intravenously is indicated when diabetes insipidus is recognized. DDAVP is usually given twice a day. One must be cautious that the patient is actually experiencing diabetes insipidus and is not just mobilizing surgical fluids. In a patient who has had a transsphenoidal resection of a pituitary tumor, increased thirst may be present only because the patient's nasal packs force him/her to mouth-breathe. Diabetes insipidus is usually transient, resolving by about 72 hours postoperatively, so the patient should be permitted to drink freely. For this reason, over the first several days, it is probably better to give the DDAVP only when the patient's findings indicate treatment is appropriate. Occasionally, diabetes insipidus may be permanent. Intranasal DDAVP 0.2 mL at night is an effective dosing regime for these patients in the subacute to chronic phases of diabetes insipidus.

Low serum cortisol is frequently not observed acutely in the ICU as patients are usually on glucocorticosteroids. However, after abrupt cessation of steroid treatment, a patient may experience an Addisonian crisis. Hypotension, weakness, and fatigue are the major findings. Because the steroid depletion is acute, hyponatremia, hyperkalemia, and hyperpigmentation generally are not observed. Treatment should be instituted promptly with hydrocortisone 100 mg IV every 6 hours.

Hypothyroidism usually does not become evident for at least a week following surgical injury to the pituitary gland or hypothalamus. Fatigue, lethargy, and hyporeflexia may be present. Laboratory testing shows low T4 and free thyroxine uptake, as well as low thyroid-stimulating hormone. For a patient with a sellar or parasellar tumor, preoperative recognition and treatment of hypothyroidism help prevent this endocrinopathy from becoming evident postoperatively.

Postoperative Central Nervous System Infections

Infections of the central nervous system are uncommon in neuro-oncology patients. Perioperative antibiotics, such as cefazolin 1 gm IV just prior to the skin incision and then for several doses following surgery, reduce the infection rate [24,25]. The likelihood of a postoperative infection in the absence of CSF leak in a clean operative field (one which does not involve the paranasal or mastoid sinuses) is about 0.8% [26]. Should CSF leak occur or if operative time is extended, the risk of infection increases. Infection can occur in any of the operative spaces.

A patient may develop wound cellulitis. This superficial infection is associated with erythema, induration, and sometimes wound drainage or breakdown. The patient may have a fever and/or elevated white blood cell count. This complication usually occurs within the first week after surgery. It will usually respond to antistaphylococcal antibiotics within several days. A 10-day course of antibiotics is usually sufficient. If drainage from the wound is present, then it should be cultured to tailor antibiotics appropriately.

Bone flap infections are more involved than simple postoperative cellulitis. They tend to occur in a delayed fashion. Drainage from a breakdown in the suture line or from the scalp near the bone flap will usually be present and should be cultured. White blood cell count and erythrocyte sedimentation rate are usually elevated. A CT scan of the head may show an epidural purulent collection or a moth-eaten appearance of the bone. Parenteral antibiotics for several weeks are necessary, though usually insufficient by themselves. Unfortunately, because the bone flap is devascularized, removal of the infected bone flap is usually necessary to eradicate the infection. A cranioplasty can be performed 6 months after the infection has resolved to reconstitute the integrity of the skull.

Postoperative meningitis occurs infrequently, usually in the first week after surgery. Fever without another focus of infection, or "stiff neck" are usually present. Lumbar puncture is essential to rule out meningitis. Usually a CT scan is performed first to rule out a structural cause of the change in level of consciousness that frequently accompanies the infection. The occurrence of meningitis often necessitates the return of the patient from the floor to the ICU. If meningitis is suspected, parenteral antibiotics should be instituted immediately after lumbar puncture. If cultures are positive, or the glucose is low in the presence of a neutrophil pleocytosis in the CSF, then a 14-day course of broad-spectrum antibiotics is appropriate [27]. If the cultures are negative, the antibiotics can be stopped.

A patient with cerebral empyema or abscess after surgery for a brain tumor typically experiences headache and other symptoms and signs of elevated ICP. Lateralizing neurologic deficits are often present. A CT or MRI scan with IV contrast is essential. In subdural or epidural empyema, the dura or arachnoid usually densely enhances with an adjacent low-density fluid collection. An abscess will show ring enhancement at the surgical site, which can look very similar to the original tumor in some cases. Suspicion of empyema or abscess necessitates an urgent return to the operating room to drain the collection of pus and obtain cultures. Six weeks of parenteral antibiotics are then necessary.

Radiation-Related Complications

Most patients with high-grade primary brain tumors or metastatic tumors will receive external beam radiation as an adjuvant therapy to control tumor growth for as long as possible. Although such treatment is usually tolerated without difficulty, a patient may have worsening of his/her neurologic condition during treatment. This "early effect" worsening is usually related to cerebral edema. CT scan and MRI show an increase in low density/intensity signal around the tumor volume. The edema tends to be responsive to high-dose glucocorticosteroids. Once the patient improves, steroids can be slowly tapered to usual maintenance doses.

Much more rarely, a patient may deteriorate in a delayed fashion. "Late effects" occur about 6 to 24 months after completing radiation therapy [28]. Imaging studies show intense enhancement in the area treated. It is often difficult to differentiate radiation necrosis from tumor recurrence solely on the basis of a contrast CT or gadolinium MRI as the two entities, particularly in the case of primary glioma, look similar. Single positron emitting CT, MR spectroscopy, or MR arterial spin labeling studies can often be helpful in establishing the diagnosis; tumor tends to have high metabolic activity and blood flow, while radiation necrosis is metabolically hypoactive. Sometimes, a stereotactic brain biopsy may be required to make a definitive diagnosis. High glucocorticosteroid doses are necessary to treat radiation necrosis. Mannitol may initially be required if the patient has significantly deteriorated in order to stabilize the patient and allow steroids the time to work. Occasionally, a craniotomy to remove the necrotic tissue is required as well.

Single-fraction stereotactic radiosurgery is more likely to be associated with the development of symptomatic radiation necrosis than conventional external beam radiation. In radiosurgery, the patient receives a high dose of radiation to the tumor volume, sparing the surrounding normal brain. Even so, the radiation that the surrounding brain receives may exceed its tolerance if previous radiation therapy was also used. Treatment is as described earlier. Approximately 13% to 50% of gliomas and 10% of metastatic tumors treated with radiosurgery may require subsequent surgical decompression [29,30].

SPINAL TUMORS

Spinal tumors are much less common than intracranial tumors. Most patients with spine tumors do not require ICU treatment. Exceptions include patients with spinal tumors involving the cervical spine or those who have had transthoracic approaches to thoracic spinal neoplasms. These patients will frequently have ICU treatment requirements.

A patient with a cervical spinal cord tumor may have compromise of intracostal musculature or decreased diaphragmatic function with resultant inability to maintain adequate ventilation, depending on the level of the tumor. Vital capacity should be assessed every 6 hours, as its decrement will usually be noted before respiratory insufficiency occurs. A decrease below 10 to 12 cc per kg usually requires semiurgent intubation and mechanical ventilation. Once oxygen desaturation is noted, the patient decompensates rapidly, and emergency resuscitative efforts may be required.

After spinal cord surgery, a patient may experience a temporary ileus. Bowel sounds may stop and the abdomen may become distended. Frequently the patient will need a nasogastric tube. No oral or enteral intake is appropriate until the ileus subsides. Medications will need to be given parenterally.

A spinal cord tumor is not infrequently associated with development of a neurogenic bladder. The patient often requires a Foley catheter to decompress the bladder; although such intervention is necessary, it can mask the findings. Attention to urinary retention following removal of the Foley is in order. Urinary tract infections are also not uncommon, either related to long-term Foley placement or suboptimal bladder emptying.

A long-term intermittent catheterization program to maintain bladder volumes less than 500 cc is necessary if urinary retention persists.

SYSTEMIC COMPLICATIONS

Not infrequently, patients with neuro-oncological primary problems will experience systemic complications necessitating evaluation and treatment in the ICU.

Deep Venous Thrombosis and Pulmonary Embolism

Patients with brain and spinal cord tumors are at risk for development of deep venous thrombosis (DVT) and subsequent pulmonary embolism (PE). Decreased movement of an extremity from a motor deficit predisposes the patient to develop a DVT. Additionally, tumors may be associated with a hypercoagulable state, which can also lead to the development of DVT. Precautions, including TED stockings or sequential leg compression boots, should be taken to prevent DVT from developing. Subcutaneous heparin (5,000 units twice a day) or prophylactic enoxaparin is also an option. Venous duplex scanning can recognize DVT before it becomes symptomatic.

DVT should be suspected if the patient complains of leg pain or has a fever or elevated white count without a clear explanation. PE usually presents with shortness of breath and chest pain. Blood gases show hypocarbia with mild to moderate hypoxia. Administration of oxygen is necessary and prompt evaluation with chest x-ray, V/Q scan, and/or spiral CT of the chest is in order.

Once identified, treatment with anticoagulation may be problematic, especially in the immediate postoperative period [31,32]. In a patient at high risk for PE, some advocate anticoagulation beginning 3 to 5 days after surgery [33], though this time frame is not accepted by all. Most often the patient will have placement of an inferior vena cava (Greenfield) filter to prevent PE until 2 weeks have transpired from surgery. After that time, the use of anticoagulation is much less risky and is the preferred treatment.

Cerebral Infarction

Approximately 15% of cancer patients have significant cerebrovascular pathology noted at autopsy [34]. Patients with primary brain neoplasms are also at risk for cerebral infarction. This complication may be related to the hypercoagulable state present in patients with malignancies. Alternatively, because these patients may be older with premorbid atherosclerosis, they may suffer cerebral infarction. This event should be differentiated from hemorrhage into a tumor or progressive tumor enlargement. CT scan or MRI scanning is essential. The issues regarding anticoagulation must be addressed as with DVT or PE. Daily aspirin is generally safe. Coumadin, if indicated, should be reserved for patients who have not had hemorrhage into the tumor and who are at least 2 weeks postoperative.

Systemic Infections

Systemic infections are not uncommon, and most often include pneumonia, urinary tract infections, or sepsis secondary to line placement. Their management does not differ in the neuro-oncology patient from any other patient in the ICU.

END OF LIFE IN THE ICU

Unfortunately, despite the variety of available therapies, almost all primary high-grade gliomas will progress, and the patient harboring the tumor will succumb to the disease. A patient with metastatic brain disease may fail tumor treatments as well. Ideally, the patient's physicians will have discussed these possibilities as the patient begins to show signs of decline. The patient and family may decide to limit the intensity of care, and treatment in the ICU is not an issue. However, a patient may deteriorate quickly from the illness and elevated ICP before limits on treatment can be discussed and defined. When these circumstances occur, the physicians in the ICU may need to discuss limiting care with the patient and family. The most intensive interventions—surgery, ventriculostomy, and intubation for hyperventilation—may be most readily decided against. Other interventions, such as mannitol, may be withheld. Sometimes, a decision is made to stop all treatment. Abrupt cessation of Decadron generally leads to a rapid demise of the patient.

On occasion, an aggressively treated patient will continue to deteriorate. Elevated ICP can cause cardiac arrhythmias in the end stage. Prior to the onset of such cardiac difficulties, however, the patient may progress to the point of "brain death." In the United States, the definition of brain death requires that the patient is not hypotensive, hypothermic, or on paralytic or sedative medications. The etiology of the patient's condition should be known. The clinical examination shows the patient to be comatose, without any brainstem reflexes, motor responses, or spontaneous respirations, and on no sedative medications. An apnea test is also necessary. In this test, the patient is provided flow-by oxygen at 100% to maintain adequate oxygenation. The patient is disconnected from the ventilator and observed for the absence of respirations for 10 minutes (until a PCO_2 of 60 mm Hg is reached). Confirmatory tests, such as electrocerebral silence on an electroencephalogram or absence of brain blood flow on a radionucleotide cerebral flow study, can also be helpful [35]. If these criteria are present, the patient should be declared brain dead and removed from life support. Organ donation can be considered and discussed with the family, although systemic malignancy, infection, or specific organ failure would be contraindications to donation.

CHAPTER 175 ■ GUILLAIN–BARRÉ SYNDROME

ISABELITA R. BELLA AND DAVID A. CHAD

Guillain–Barré syndrome (GBS) was described by Guillain, Barré, and Strohl in 1916 as an acute flaccid paralysis with areflexia and elevated spinal fluid protein without pleocytosis [1]. It is the most common cause of rapidly progressive weakness due to peripheral nerve involvement, with an annual incidence of 0.6 to 2.0 cases per 100,000 population [2]. For decades, GBS has been viewed as an acute inflammatory *demyelinating* polyradiculoneuropathy (AIDP) affecting nerve roots and cranial and peripheral nerves of unknown cause that occurs at all ages. In the past 20 years, the recognition of primary *axonal* forms of GBS has broadened the spectrum of GBS to include both the demyelinating form (AIDP) and axonal forms—acute motor axonal neuropathy (AMAN) and acute motor sensory axonal neuropathy (AMSAN), as well as the Miller–Fisher syndrome. AIDP is the most common subtype in developed countries, while axonal forms are more common in northern China.

Over the years, it has become clear that the condition may be fatal because of respiratory failure and autonomic nervous system abnormalities [3]. It is, therefore, recognized as a potential medical and neurologic emergency that may require the use of intensive care units (ICUs) experienced in handling the complications of the illness [4].

DIAGNOSIS

Clinical Features in Acute Inflammatory Demyelinating Polyradiculoneuropathy

GBS often occurs 2 to 4 weeks after a flulike or diarrheal illness caused by a variety of infectious agents [3], including cytomegalovirus, Epstein–Barr and herpes simplex viruses, mycoplasma, chlamydia, and *Campylobacter jejuni* [5]. It can also be an early manifestation of human immunodeficiency virus (HIV) infection before the development of an immunosuppressed state [6]. Lyme disease may rarely produce a syndrome of polyradiculopathy reminiscent of GBS [7]. Other antecedent events include immunization, general surgery and renal transplantation, Hodgkin's disease, and systemic lupus erythematosus [2,3].

The illness is heralded by the presence of dysesthesias of the feet or hands, or both. The major feature is weakness that evolves rapidly (usually over days) and classically has been described as ascending from legs to arms and, in severe cases, to respiratory and bulbar muscles. Weakness may, however, start

in the cranial nerves or arms and descend to the legs or start simultaneously in the arms and legs [2]. Approximately 50% of patients reach the nadir of their clinical course by 2 weeks into the illness, 80% by 3 weeks, and 90% by 1 month [8]. Progression of symptoms beyond 4 weeks but arresting within 8 weeks has been termed *subacute inflammatory demyelinating polyneuropathy* (SIDP) [9], while progression beyond 2 months is designated *chronic inflammatory demyelinating polyradiculoneuropathy* (CIDP), a disorder with a natural history different from GBS [10]. A small percentage of patients (2% to 5%) have recurrent GBS [11].

The extent and distribution of weakness in GBS are variable. Within a few days, a patient may become quadriparetic and respirator dependent, or the illness may take a benign course and after progression for 3 weeks produce only mild weakness of the face and limbs.

Physical Findings

In a typical case of moderate severity, the physical examination discloses symmetric weakness in proximal and distal muscle groups associated with attenuation or loss of deep tendon reflexes (Table 175.1). In the early stage of illness, there is no muscle wasting or fasciculation. If the attack is particularly severe and axons are interrupted, then after a number of months, muscles undergo atrophy and scattered fasciculations may be seen (see later). Sensory loss is usually mild, although a variant of GBS is described in which sensory loss (involving large fiber modalities) is widespread, symmetric, and profound [8]. Respiratory muscles are often involved; between 10% and 25% of patients require ventilator assistance [12] initiated within 18 days (mean of 10 days) after onset [13].

There is often mild to moderate bilateral facial weakness. Mild weakness of tongue muscles and the muscles of deglutition may also develop. Ophthalmoparesis from extraocular motor nerve involvement is unusual in the typical patient with GBS. In the Miller–Fisher variant [14], however, there is ophthalmoplegia in combination with ataxia and areflexia, with little limb weakness per se. Pupillary abnormalities have been noted in GBS [15] and in the Miller–Fisher variant [16]. Papilledema is exceedingly rare [17].

Disturbances of the autonomic nervous system are found in 50% of patients and are potentially lethal [3,4]. Autonomic dysfunction takes the form of excessive or inadequate activity of the sympathetic nervous system or the parasympathetic nervous system, or both [18]. Common findings include cardiac arrhythmias (e.g., persistent sinus tachycardia, bradycardia, ventricular tachycardia, atrial flutter, atrial fibrillation, and asystole), orthostatic hypotension, and transient and persistent hypertension. Other changes include transient bladder paralysis, increased or decreased sweating, and paralytic ileus. These changes are not completely understood but may be due to inflammation of the thinly myelinated and unmyelinated axons of the peripheral autonomic nervous system. A neuropathy predominantly affecting the peripheral autonomic nervous system has been described that may have a pathogenesis similar to that of GBS [19].

TABLE 175.1

FEATURES OF GUILLAIN–BARRÉ SYNDROME

Clinical features	Laboratory features
Rapidly progressive weakness Loss of reflexes Mild dysesthesias (in AIDP) Autonomic dysfunction Respiratory compromise	Elevated cerebrospinal fluid protein Acellular cerebrospinal fluid Electromyogram: In AIDP: slow nerve conduction velocities, conduction block, dispersed responses In axonal GBS: low motor amplitudes, normal conduction velocities, and normal sensory responses in AMAN

AIDP, acute inflammatory demyelinating polyradiculoneuropathy; AMAN, acute motor axonal neuropathy; GBS, Guillain–Barré syndrome.

Clinical Features in Axonal Forms

Axonal forms, like AIDP, present with rapidly progressive weakness, areflexia, and albuminocytological dissociation but differ in the following ways. AMAN patients lack sensory abnormalities and are more commonly found in northern China during summer months among children and young adults. Patients with AMAN also appear to have a more rapid progression to nadir, but recovery times are quicker [20] or similar [21] to AIDP in some patients, while others have a more prolonged course [20].

AMSAN is generally associated with a more severe course and longer time to recovery. In the series by Feasby et al. [22], these patients had a much shorter time to peak severity (1 week), more severe symptoms with more than half requiring mechanical ventilation, inexcitable motor nerves, and most had a poor recovery.

Laboratory Features

The most characteristic laboratory features of GBS are an abnormal cerebrospinal fluid (CSF) profile showing albuminocytologic dissociation (elevated protein without pleocytosis) and abnormal nerve conduction studies.

CSF examination is most helpful in reaching the diagnosis of GBS. Although the CSF profile is usually normal during the first 48 hours after onset [8], by 1 week into the illness, the CSF protein is elevated in most patients, sometimes to levels as high as 1 g per dL. Rarely, even several weeks after onset of GBS, the CSF protein remains normal and the diagnosis must rest on the presence of otherwise typical clinical features [8]. The cell count may be slightly increased but rarely exceeds 10 cells per μL; the cells are mononuclear in nature. When GBS occurs as a manifestation of HIV infection or Lyme disease, the CSF white cell count is generally increased (25 to 50 cells per μL. The CSF glucose is expected to be normal.

Electrodiagnostic studies in AIDP typically disclose slowing (less than 80% of normal) of nerve conduction velocity, most often along proximal nerve segments, with increases in distal motor and sensory latencies [8,23]. The amplitude of the evoked motor responses may be reduced because of axon loss or distal nerve conduction block, and the responses are frequently dispersed because of differential slowing along still-conducting axons [8,23]. Because the pathologic process may be restricted to spinal nerve roots and proximal nerve segments, routine nerve conduction studies may be normal on initial testing. In such cases, however, H-reflexes may be absent and F-responses may be abnormal because of involvement of the most proximal segments of the motor fibers. This, together with a normal sural nerve and abnormal upper extremity sensory action potential, is characteristic of early GBS [24].

Also early in the course of GBS, needle electrode examination electromyography may demonstrate only decreased numbers of motor unit potentials firing on voluntary effort because of nerve conduction block. Several weeks later, active denervation changes, such as fibrillation potentials and positive sharp waves, may be seen if axon loss has occurred.

In patients with the severe axonal form of GBS, AMSAN, motor and sensory nerves may be electrically inexcitable [22]. In AMAN, motor responses are low or absent while conduction velocities and sensory responses are normal [25].

Except for a mild increase in the erythrocyte sedimentation rate, hematologic studies are normal. Serum electrolytes may disclose hyponatremia [3], sometimes to a marked degree, because of inappropriate secretion of antidiuretic hormone caused by a disturbance of peripheral volume receptors. There may be evidence of previous viral or *mycoplasma* infection, such as lymphopenia or atypical lymphocytes. In some cases, evidence of recent viral infection may be sought by measuring antibody (immunoglobulin [Ig] M) titers against specific infectious agents, especially cytomegalovirus, Epstein–Barr virus, and *C. jejuni*. In selected cases, screening for HIV infection should be undertaken.

DIFFERENTIAL DIAGNOSIS

A number of well-defined conditions cause an acute or subacute onset of generalized weakness and must be differentiated from GBS (Table 175.2). These are disorders of the motor unit affecting the neuromuscular junction (e.g., myasthenia gravis and botulism), peripheral nerve (e.g., tick paralysis, shellfish poisoning, toxic neuropathy, acute intermittent porphyria, and diphtheritic neuropathy), motor neuron (e.g., amyotrophic lateral sclerosis, poliomyelitis, and West Nile virus [WNV] neuroinvasive disease), and muscle (e.g., periodic paralysis, metabolic myopathies, and inflammatory myopathies). Other conditions characterized by severe generalized weakness are defined by the setting in which they are encountered—the ICU—and are designated *critical illness polyneuropathy* and the *myopathy of intensive care*.

Intensive Care Unit–Related Weakness

Unlike neuromuscular emergencies such as GBS, myasthenia gravis, or porphyria, in which rapidly progressive weakness develops before admission to the ICU, a number of conditions (polyneuropathy, myopathy, and neuromuscular junction disease) affect patients already in the ICU because of severe systemic illnesses. These conditions are discussed in more detail in Chapter 180. Critical illness polyneuropathy is an axonal sensory-motor polyneuropathy characterized by difficulty weaning from the ventilator, distal greater than proximal muscle weakness, and reduced or absent reflexes that develop in patients with sepsis and multiorgan failure [26]. The development of weakness in the midst of critical illness, as seen in critical illness polyneuropathy, helps differentiate this disorder from axonal GBS, in which weakness develops days to weeks after an infection [27]. A severe necrotizing myopathy can also be seen in critically ill patients [28]. An acute myopathy of intensive care initially described in patients treated with a combination of high-dose corticosteroids (equal to or greater than 1,000 mg methylprednisolone) and neuromuscular blocking agents (NMBAs) for status asthmaticus [29] may also be encountered in the setting of trauma, organ transplantation, burns, and critical illness. Patients have variable degrees of generalized weakness, including respiratory muscles, and this is often recognized when a patient has difficulty weaning from the ventilator. Prolonged neuromuscular blockade after use of the nondepolarizing NMBAs can be seen especially in patients with coexistent renal failure and metabolic acidosis. Presumably, the presence of an active metabolite accounts for the prolonged weakness [30].

TABLE 175.2

CONDITIONS THAT MAY MIMIC GUILLAIN–BARRÉ SYNDROME

Disorder	Major distinguishing features
Myasthenia gravis	Reflexes are spared Ocular weakness predominates Positive response to edrophonium EMG: decremental motor response
Botulism	Predominant bulbar involvement Autonomic abnormalities (pupils) EMG: normal velocities, low amplitudes, incremental response (with high-frequency repetitive nerve stimulation)
Tick paralysis	Rapid progression (1–2 d) Tick present
Shellfish poisoning	Rapid onset (face, finger, toe numbness) Follows consumption of mussels/clams
Toxic neuropathies	EMG: usually axon loss
Organophosphorus	Acute cholinergic reaction toxicity
Porphyric neuropathy	Mental disturbance Abdominal pain
Diphtheritic neuropathy	Prior pharyngitis Slower evolution Palatal/accommodation paralysis Myocarditis
Poliomyelitis	Weakness, pain, and tenderness Preserved sensation Cerebrospinal fluid: protein and cell count elevated
West Nile virus neuroinvasive disease	Associated fever, meningitis, or encephalitis Asymmetric weakness Cerebrospinal fluid: protein and cell count elevated
Periodic paralysis	Reflexes normal Cranial nerves and respiration spared Abnormal serum potassium concentration
Critical illness neuropathy	Sepsis and multiorgan failure > 2 wk EMG: axon loss
Acute myopathy of intensive care	Tetraparesis and areflexia Follows prolonged treatment with neuromuscular-blocking agent and corticosteroids Trauma, status asthmaticus, and organ transplantation associated Clinical and EMG features of myopathy

EMG, electromyogram.

Disorders of the Neuromuscular Junction

In patients with myasthenia gravis, limb weakness is predominant proximally and almost always associated with ocular and sometimes pharyngeal muscle weakness (see Table 175.2; see Chapter 176). Muscular fatigability is a hallmark of the disease. Botulism may also cause acute weakness 6 to 36 hours after ingestion of the toxin formed by *Clostridium botulinum*. The condition is characterized by weakness of cranial nerve–innervated muscles, autonomic abnormalities (unreactive pupils and ileus), and occasional respiratory muscle weakness necessitating ventilator assistance.

Disorders of Peripheral Nerve

Tick paralysis is produced by a toxin contained in the head of the tick *Dermacentor andersoni* or *vanabilis* that blocks nerve conduction in the fine terminal portions of motor and sensory nerves. Weakness associated with sensory impairment develops rapidly after the tick has embedded itself into the victim, usually over 1 to 2 days. Shellfish poisoning gives rise to symptoms immediately after contaminated mussels or clams are eaten. Patients complain of face, finger, and toe numbness and then note the development of rapidly progressive descending paralysis, which may involve respiratory muscles.

Toxic neuropathies may be caused by a number of heavy metals, including arsenic, thallium, and lead. These and other potential neurotoxins (e.g., nitrofurantoin) and industrial agents (e.g., the hexacarbons) may produce a rapidly evolving peripheral neuropathy. Most acute toxic neuropathies are axon-loss in character, but in the case of arsenic poisoning, electrodiagnostic features may simulate a demyelinating process identical to some forms of GBS [31]. Organophosphorus insecticide toxicity causes a short-lived acute cholinergic phase marked by miosis, salivation, sweating, and fasciculation followed in 2 to 3 weeks by an acute axon-loss polyneuropathy [32]. An intermediate syndrome occurring 24 to 96 hours after the cholinergic phase and characterized by multiple cranial nerve palsies and respiratory failure has also been described [33]. The latter probably results from a defect at the neuromuscular junction.

Acute intermittent porphyria causes an acute polyneuropathy clinically similar to GBS but differing by its association with mental disturbance and abdominal pain. Attacks of paralysis are precipitated by ingestion of a variety of drugs, including alcohol, barbiturates, estrogens, phenytoin, and sulfonamides. The diagnosis may be established by demonstrating increased levels of porphobilinogen and δ-aminolevulinic acid in the urine.

Diphtheritic neuropathy occurs 2 to 8 weeks after a throat infection. During the height of the infection, there is numbness of the lips and paralysis of pharyngeal and laryngeal muscles. At the time of the neuropathy, diphtheria organisms may be cultured from the throat. Other clues to the diagnosis are clinical and electrocardiographic features of myocarditis.

Disorders of Motor Neurons

Amyotrophic lateral sclerosis is a chronic disorder of the motor system that generally evolves over several years to produce a state of severe generalized muscle weakness, atrophy, and fasciculations. In most instances, respiratory muscle weakness occurs in the latter stages of the illness after the diagnosis has been established. Rarely, however, patients present with acute to subacute respiratory muscle weakness (ventilatory failure) as the first clinical manifestation of this disease. The examination of such patients often discloses some features of lower motor neuron loss (muscle atrophy and fasciculations) in limb and bulbar muscles. The presence of brisk deep tendon reflexes and preserved sensation helps to distinguish this disorder from the neuropathies that might cause acute ventilatory failure. Unlike the situation in GBS where a picture of albuminocytologic dissociation is found, the CSF findings in amyotrophic lateral sclerosis are normal.

Poliomyelitis is rarely seen today, but it has developed in close contacts of newborns immunized with the live attenuated oral vaccine, and individuals whose own immunity to the virus has become inadequate. The disease is characterized by weakness of rapid onset along with severe muscle pain and tenderness. Respiratory muscles are often involved. Deep tendon reflexes are depressed. The illness is distinguished from GBS clinically by the preservation of sensation and the CSF findings. Serum antibody studies may help identify the illness.

A poliomyelitis-like syndrome may also be seen with WNV neuroinvasive disease. Infection of the anterior horn cells by the WNV produces an acute flaccid paralysis, with asymmetric weakness of one or more limbs, particularly the legs, along with hyporeflexia or areflexia. Overt sensory loss is typically absent while loss of bowel and bladder function may occur. Unlike GBS, there may be an associated meningitis, encephalitis, or fever in addition to CSF pleocytosis and elevated CSF protein. Diagnosis depends on detection of WNV-specific antibodies in serum or CSF [34].

Disorders of Muscles

Periodic paralysis (hyperkalemic or hypokalemic) is a disorder of muscle usually inherited in an autosomal-dominant fashion. Patients develop generalized weakness over a period of hours (see Table 175.2). Cranial nerve–supplied muscles are spared, there is generally no respiratory muscle involvement, reflexes are normal, and there is no sensory involvement. Serum potassium measurements aid in the diagnosis.

Rarely, metabolic myopathies may present with the sudden onset of muscle weakness. Patients with abnormalities of glycogen metabolism (e.g., phosphorylase deficiency) or lipid metabolism (e.g., carnitine palmityl transferase deficiency) may develop weakness associated with severe cramps and muscle fiber necrosis; the latter may result in creatine kinase elevations and myoglobinuria.

Dermatomyositis, an inflammatory myopathy, may present with the acute onset of proximal muscle (and, rarely, respiratory muscle) weakness. In contrast to the acute polyneuropathies, deep tendon reflexes are spared, cranial nerves are rarely involved, and serum creatine kinase is elevated.

PATHOGENESIS

AIDP is caused by immunologically mediated demyelination of the peripheral nervous system [3]. It is likely that humoral and cellular components of the immune system participate in macrophage-induced peripheral nerve demyelination [2,35]. Although the histological appearance of AIDP resembles experimental autoimmune neuritis, in which a predominantly T-cell–mediated immune response is directed against peripheral nerve myelin proteins, the role of T-cell–mediated immunity in AIDP remains unclear [35]. The finding of complement activation markers along the outer surface of the Schwann cell [36] have led to the speculation that complement-fixing antibodies directed toward as yet unidentified epitopes on the outer surface of the Schwann cell play a role in AIDP. Axonal degeneration may occur, especially in severe cases, as a "bystander" when there is intense inflammation [37,38].

In axonal subtypes, the immune response is targeted to a different portion of the peripheral nerve, the axon [39]. There is strong evidence that antibodies directed against ganglioside antigens on the axolemma target macrophages to invade the axon at the node of Ranvier [35]. The rapid decline and subsequent quick recovery in many AMAN patients suggests that severe axonal degeneration of the nerve roots is unlikely to be the pathological basis for this disorder; proposed mechanisms include physiological block of conduction or very distal degeneration and subsequent regeneration of the intramuscular motor nerve terminals [21].

The presence of antiganglioside antibodies (GM1 antibodies in both demyelinating and axonal GBS, and GD1 a, GM1b, and GalNAcGD1 a antibodies in axonal GBS) and the finding of ganglioside-like epitopes on some strains of *C. jejuni* have led to the concept of molecular mimicry [40], in which an immune attack occurs on the epitope shared by the nerve fiber and infectious organism [41], as a possible mechanism for GBS, especially *C. jejuni*–associated GBS. There is increasing evidence that anti-GM1 antibodies block sodium ion channels at the nodes of Ranvier, transiently producing conduction failure [42]. In addition, Koga et al. [43] found evidence that the genetic polymorphism of *C. jejuni* determines the production of specific autoantibodies and correlates with the clinical presentation of GBS, possibly through modification of the host-mimicking molecule.

PATHOLOGY

Pathologic studies of nerves in those patients dying with GBS have usually shown infiltration of the endoneurium by mononuclear cells, with a predilection for a perivenular distribution [37]. The inflammatory process occurs throughout the length of the nerve, from its origin at a root level to the distal ramifications of nerve twigs in the substance of muscle fibers. The brunt of the inflammatory process, however, occurs at more proximal levels (e.g., roots, spinal nerves, and major plexuses) and takes the form of discrete foci of inflammation. Macrophages invade intact myelin sheaths and denude the axons [35]. Patients with prominent axon loss are least likely to recover fully and may be left with functionally significant residual motor weakness.

In AMAN and AMSAN, there is evidence of Wallerian-like degeneration of nerve fibers, but only minimal inflammation or demyelination [25]. Macrophages are seen within the periaxonal space especially at the nodes of Ranvier, displacing or surrounding the axon, and leaving the myelin sheath intact [25]. Abnormalities are seen in nerve roots and peripheral nerves; in those with AMSAN, motor and sensory fibers are affected, while only motor fibers are affected in AMAN, with sparing of sensory fibers.

NATURAL HISTORY

The natural history of GBS in the moderately to severely affected patient (i.e., a patient who is unable to walk or who has severe respiratory muscle weakness requiring a ventilator) is usually one of gradual improvement. The ability to walk unassisted returns, on average, in approximately 3 months; in the subset of respirator-dependent patients, the average time to recovery is 6 months [44].

MANAGEMENT

The three major treatment issues in GBS are controlling respiration and deciding when to intubate the patient, recognizing and managing autonomic dysfunction, and determining which patients are candidates for plasmapheresis or intravenous immunoglobulin (IVIG) (Table 175.3).

TABLE 175.3

MANAGEMENT OF GUILLAIN–BARRÉ SYNDROME

General	Monitor respiratory parameters: VC, arterial blood gas Intubate if: VC < 12–15 mL/kg Oropharyngeal paresis with aspiration Falling vital capacity over 4–6 h Respiratory fatigue with VC 15 mL/kg Use short-acting medications to control autonomic dysfunction Nursing care: frequent turns to avoid pressure sores Place pads at elbows and fibular head to avoid compression neuropathies Physical therapy Subcutaneous heparin
Treatment:	
Plasmapheresis	Exchange a total of 200 mL plasma/kg body weight over 7–14 d (40–50 mL/kg for 3–5 sessions)[a] Albumin is used as replacement solution, not fresh-frozen plasma During plasmapheresis, monitor blood pressure and pulse every 30 min Obtain complete blood cell count (baseline and before each exchange to calculate plasma volume) Obtain immunoglobulin levels before first exchange and after last exchange; if immunoglobulin G < 200 mg/dL after last plasma exchange, infuse 400 mg/kg IVIG
IVIG	2 g/kg divided over 5 consecutive d[b] (0.4 g/kg/d for 5 d)

[a]This is the authors' approach, following the Guillain–Barré Syndrome Study Group guidelines [44]. Other published guidelines recommend two sessions (exchanging 40 mL/kg per session) for ambulatory patients and four sessions (exchanging 40 mL/kg per session) for nonambulatory patients [53].
[b]The authors adhere to the protocol published by the Dutch Guillain–Barré Study Group [54].
IVIG, intravenous immunoglobulin; VC, vital capacity.

Patients with GBS require excellent nursing care, medical management, and emotional support. Respiratory failure is one of the most serious complications of GBS. Need for a ventilator cannot be reliably predicted on the basis of extent of weakness; however, patients who are highly likely to require mechanical ventilation are those with rapid disease progression, bulbar weakness, autonomic dysfunction, and bilateral facial weakness [45]. Patients must be followed carefully with measurements of maximum inspiratory pressure and forced vital capacity (FVC) (Fig. 175.1) until weakness has stopped progressing so the respiratory insufficiency can be anticipated and managed appropriately. A normal FVC is 65 mL per kg; a level of 30 mL per kg is generally associated with a poor forced cough and requires careful observation and management with supplemental oxygen and chest physical therapy. At 25 mL per kg, the sigh mechanism is compromised and atelectasis occurs, leading to hypoxemia. Ropper and Kehne [46] suggest intubation

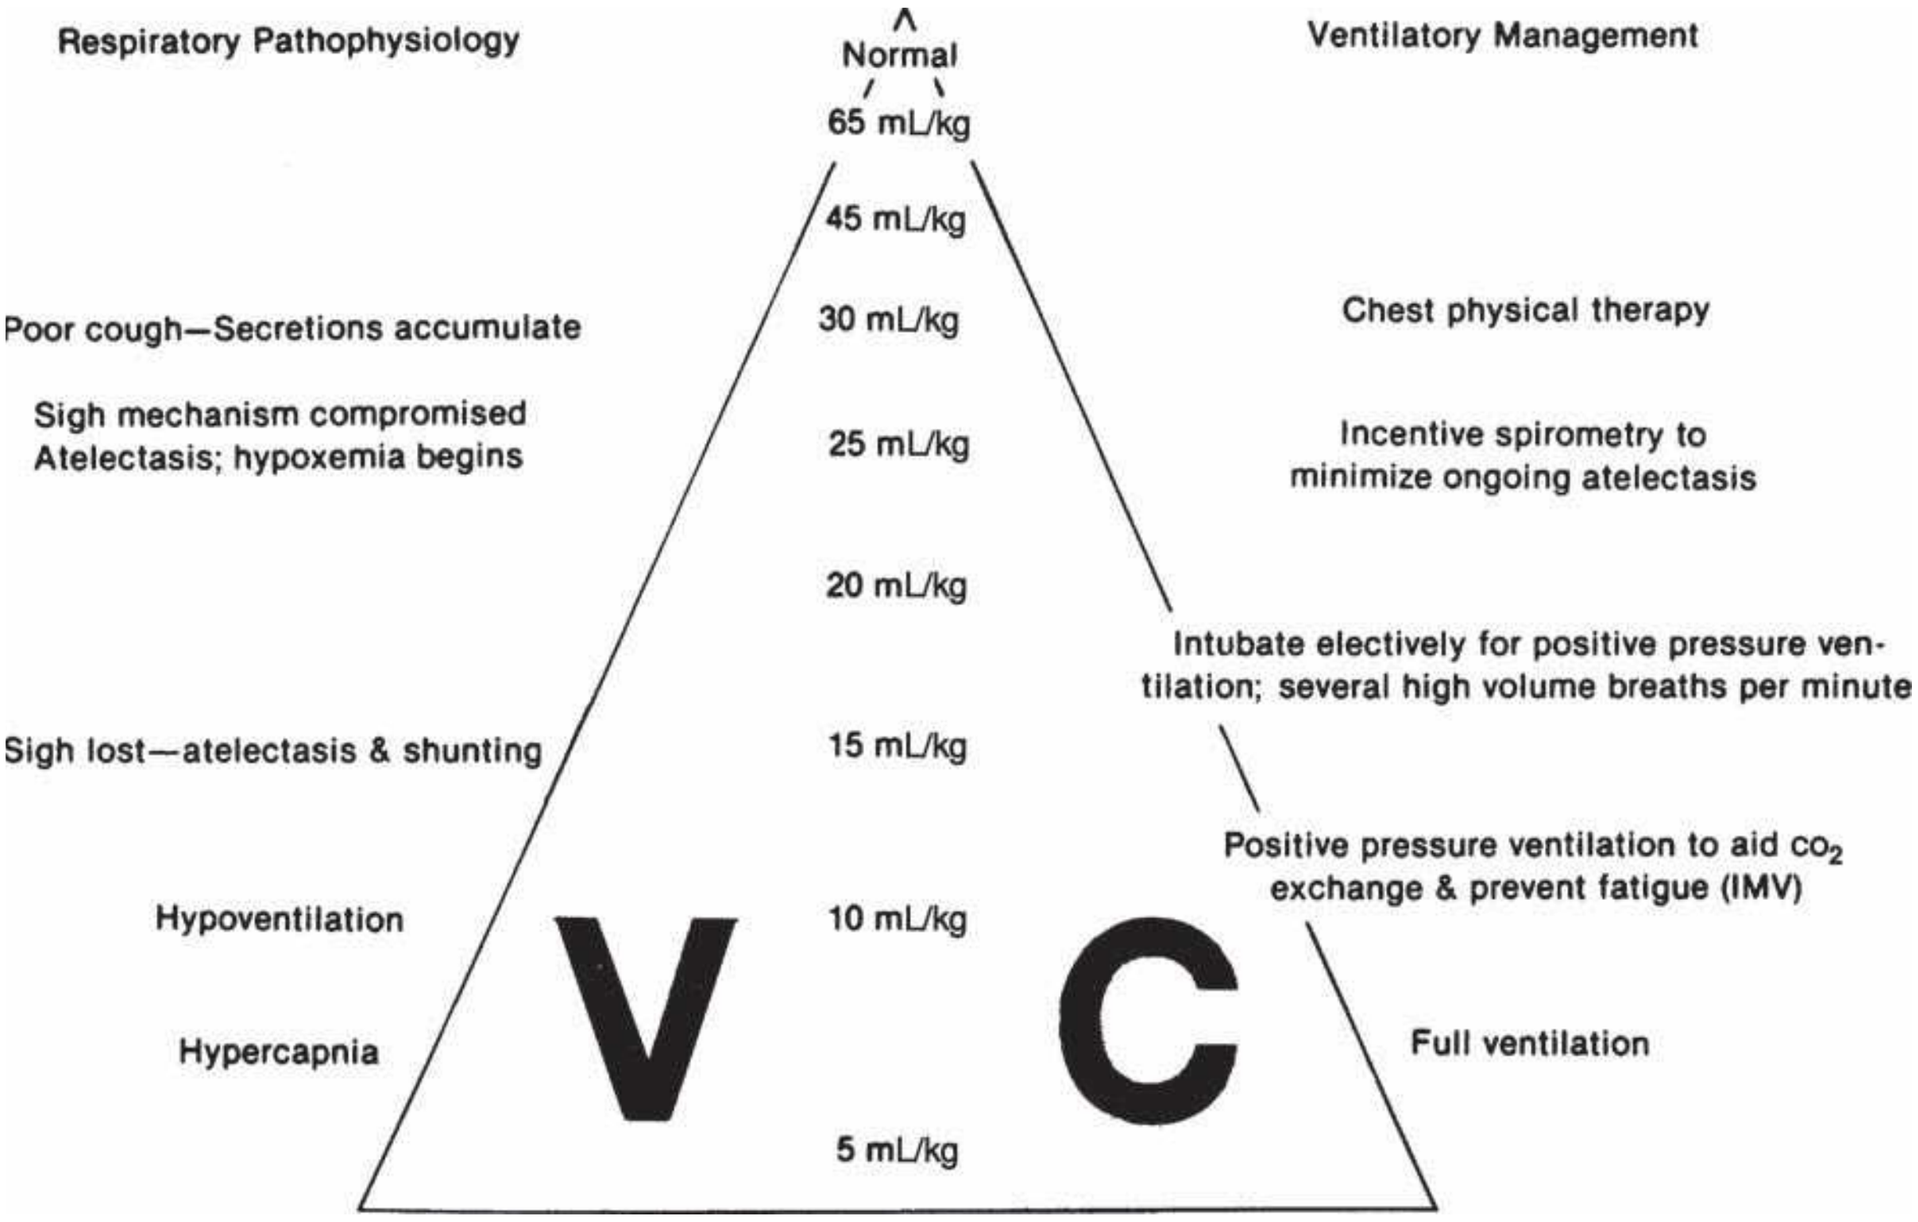

FIGURE 175.1. Relations between vital capacity (VC), pathophysiology of lung function, and suggested therapy in mechanical ventilatory failure. IMV, intermittent mandatory ventilation. [From Ropper AH: Guillain-Barré syndrome, in Ropper AH, Kennedy SK, Zervas NT (eds): *Neurological and Neurosurgical Intensive Care*. Baltimore, University Park Press, 1983, with permission.]

if any one of the following criteria is met: mechanical ventilatory failure with reduced expiratory vital capacity (VC) of 12 to 15 mL per kg, oropharyngeal paresis with aspiration, falling VC over 4 to 6 hours, or clinical signs of respiratory fatigue at a VC of 15 mL per kg. Lawn et al. [45] found the following respiratory factors to be highly associated with progression to respiratory failure: VC less than 20 mL per kg, maximal inspiratory pressure (MIP) less than 30 cm H_2O, maximal expiratory pressure (MEP) less than 40 cm H_2O, or a reduction of more than 30% of VC, MIP, or MEP in 24 hours. Elective intubation may be considered in these patients at particularly high risk for progression to respiratory failure. Intubation should be accomplished with a soft-cuff low-pressure endotracheal tube. A decision to delay tracheostomy for 7 to 10 days is likely to avoid the operation in as many as one-third of patients who improve rapidly and can be extubated after the first few days [46]. Complications of intubation and ventilator assistance are described in Chapters 1 and 58.

The nursing and medical team must also be aware of the many autonomic nervous system disturbances that can occur [18]. Fluctuating blood pressure with transient hypertensive episodes, sometimes associated with extreme degrees of agitation, may be present. Other manifestations of sympathetic nervous system overactivity include sudden diaphoresis, general vasoconstriction, and sinus tachycardia. Evidence of underactivity of the sympathetic nervous system includes presence of marked postural hypotension and heightened sensitivity to dehydration and sedative-hypnotic agents. Excessive parasympathetic nervous system activity is reflected in facial flushing associated with a feeling of generalized warmth and bradycardia. Electrocardiographic changes, consisting of ST- and T-wave changes, also occur. Therefore, careful monitoring of blood pressure, fluid status, and cardiac rhythm is absolutely essential to manage the GBS patient. Hypertension may be managed with short-acting α-adrenergic blocking agents, hypotension with fluids, and bradyarrhythmias with atropine [18]. As noted earlier, hyponatremia may occur and is probably best managed by fluid restriction.

The bedridden patient needs to be turned frequently to avoid the development of pressure sores. Paralyzed limbs require the attention of the physiotherapist so that passive limb movements can be carried out and contractures prevented. The treatment team needs to be aware of the potential for development of compression neuropathies (most commonly of the ulnar and peroneal nerves), and insulating pads should be placed over the usual susceptible sites (the elbow and the head of the fibula). Pain may be treated with standard doses of analgesic agents, but they do not often provide adequate relief. Gabapentin or carbamazepine is particularly helpful in treating the pain in the acute phase [47] and, when disabling, epidural morphine may be necessary [48]. Deep venous thrombosis and pulmonary embolism are ever-present dangers in the bedridden patient with immobilized limbs; for these patients, in addition to physical therapy, subcutaneous heparin (5,000 U twice per day) and support stockings are recommended [47].

A number of multicenter studies [44,49,50] showed that plasmapheresis has a beneficial effect on the course of the illness, even in those patients with several poor prognostic signs [51]. Patients treated with plasmapheresis are able to walk, on average, 1 month earlier than untreated patients; respirator-dependent patients so treated walk 3 months sooner than those who do not receive plasma exchange [44]. The GBS study group guidelines recommend exchanging 200 to 250 mL plasma per kg body weight over 7 to 14 days in three to five treatments [44]. Five percent salt-poor albumin is used as replacement fluid (fresh-frozen plasma should be avoided because of risks

of hepatitis, HIV, and occasionally pulmonary edema). It is important to keep in mind, however, that there are also possible risks with albumin, including bleeding, thrombosis, and infection (due to loss of coagulating factors and γ-globulins during plasma exchange, which are not present in the albumin replacement fluid). After each exchange, γ-globulin can be infused to prevent infection.

Plasmapheresis, in general, is recommended for patients who have reached or are approaching the inability to walk unaided, who require intubation or demonstrate a falling VC, and who have weakness of the bulbar musculature leading to dysphagia and aspiration [52]. The French Cooperative Group on Plasma Exchange in Guillain–Barré Syndrome [53] also showed that treatment of patients with mild GBS (i.e., those who are still ambulatory) is beneficial; two plasma exchanges were more beneficial than none in time to onset of motor recovery in patients with mild GBS. Patients with moderate (not ambulatory) or severe (mechanically ventilated) GBS benefited from four exchanges; those with severe GBS did not benefit any further with the addition of two more exchanges. Because of its potential for inducing hypotension, patients who have compromise of their cardiovascular system or autonomic dysfunction may not tolerate this procedure. Plasmapheresis is safe in pregnant women and children [4]. Plasmapheresis is generally not used in patients who are no longer progressing 21 days or more after the onset of GBS.

For many years, plasmapheresis was the gold standard in the treatment of GBS. In 1992, a large randomized trial performed by Dutch investigators demonstrated that treatment with IVIG was at least as effective as plasmapheresis and might be superior [54]. A subsequent large randomized controlled trial (the Plasma Exchange/Sandoglobulin Guillain–Barré Syndrome Trial Group) confirmed the equivalence of IVIG and plasma exchange; in addition, there was no substantial benefit in using a combination of plasma exchange followed by IVIG [55]. In light of these studies, plasma exchange or IVIG may be used to treat GBS. Although both treatments are equally efficacious, IVIG has become the preferred treatment because of its relative ease of administration (plasmapheresis is not available in all centers, and it requires good venous access and a stable cardiovascular system). In 3% to 12% of patients given IVIG, side effects may occur that range from minor reactions such as flulike symptoms, headache, nausea, and malaise to more severe side effects, including anaphylactic reactions in IgA-deficient persons, transmission of hepatitis C, aseptic meningitis, and acute renal failure in those with renal insufficiency. Absolute contraindications to IVIG are unusual, however. For example, patients with IgA deficiency may be given an IgA-poor preparation with precautions (can be pretreated with Benadryl or Tylenol), whereas those with renal insufficiency may be given an IVIG sucrose-poor preparation with close monitoring of their renal status.

A recent American Academy of Neurology practice parameter recommends treatment of GBS patients who are unable to walk with either plasmapheresis or IVIG; treatment is beneficial if given within 4 weeks of onset of neuropathic symptoms for plasmapheresis and within 2 weeks (and possibly 4 weeks) of onset for IVIG [56]. For those patients who are still ambulatory, plasmapheresis may also be considered if given within 2 weeks of onset. Treatment with plasmapheresis followed by IVIG is not recommended.

In a small number of patients (5%), spontaneous relapse occurs within days to weeks after treatment with IVIG or plasmapheresis, oftentimes in those treated early in their illness. Relapse rates are similar in frequency between IVIG and plasmapheresis [57]. Although retreatment with the same therapy is commonly practiced [58], generally with half the initial dose used [59], evidence-based literature is lacking regarding the efficacy of repeat treatment [57].

Although it seems intuitively obvious that treatment of GBS with corticosteroids should be beneficial, corticosteroids are generally ineffective. Hughes and colleagues [60] reviewed six randomized trials of corticosteroid use for GBS; they found no significant difference in disability-related outcome between corticosteroid and placebo groups. Oral corticosteroids delayed recovery while IV methylprednisolone alone was not beneficial or harmful [60]. Although the combination of IVIG and IV methylprednisolone (500 mg per day for 5 days) showed no significant difference over IVIG alone unless adjusted for various factors, there is a trend toward shortened time to independent ambulation with combination treatment [58,61]. Corticosteroids are not recommended in the treatment of GBS.

Finally, it is most important to address the emotional needs of the patient with GBS, who will almost certainly be anxious, fearful, and depressed. The strong likelihood of a good outcome, even in ventilated patients, is noted later in this chapter. Sometimes it is helpful for the patient to speak with a person who has recovered from GBS.

OUTCOME AND PROGNOSTIC FACTORS

In most patients recovery occurs over weeks or months, but in some patients, muscle strength may take 1.5 to 2.0 years to reach its best state with an intensive rehabilitation program [2]. Recovery is not always complete, with only approximately 15% of patients resolving with no residual deficits [4]. Another 50% to 65% of patients are restored to nearly normal function and can resume their work and leisure activities, although some degree of ankle dorsiflexor weakness or numbness of the feet is commonly encountered. Many patients never regain normal stretch reflexes. Severe residual motor weakness or major proprioceptive loss that seriously impairs walking occurs in approximately 10% of patients. Despite close monitoring in the ICU, deaths from GBS do occur, with mortality in the range of 3% to 8% [4]. Causes of fatal outcomes include dysautonomia, sepsis, acute respiratory distress syndrome, and pulmonary emboli [4].

Poor prognostic factors include older age (≥ 50 years), severe disease at nadir (bedbound or requiring mechanical ventilation), rapid onset of disease, and evidence of axonal loss (reflected on electrodiagnostic studies) [35,42,62]. More recently, elevated CSF neurofilament levels predicted poor outcome, presumably reflecting axonal damage of the proximal motor nerve root [63].

SUMMARY

Careful attention to the patient's history and thorough examination usually point to the diagnosis of GBS, which may be corroborated by the CSF findings (i.e., albuminocytologic dissociation) and results of electrophysiologic testing (i.e., acquired demyelinating or axon-loss polyneuropathy). The mainstay of treatment is excellent nursing and medical care, with close attention to respiratory and autonomic function. Although 10% of patients with GBS are left with substantial residual neurologic deficits, the majority improve and resume their premorbid lifestyles; plasmapheresis and IVIG have been shown to enhance recovery.

Advances in the management of GBS, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 175.4.

TABLE 175.4

ADVANCES IN MANAGEMENT BASED ON MAJOR CONTROLLED CLINICAL TRIALS OF PLASMAPHERESIS AND INTRAVENOUS IMMUNOGLOBULIN IN GUILLAIN–BARRÉ SYNDROME

References	Purpose	Results
44	Compared PE with supportive care	PE showed beneficial effect in time to improve one clinical grade, time to independent walking, and outcome.
53	Compared various PE treatment schedules in three severity groups	Mild group: 2 PEs more effective than none. Moderate group: 4 PEs more effective than 2 PEs. Severe group: 6 PEs not more beneficial than 4 PEs.
50	(a) To determine effect of PE initiated within 17 d onset and (b) to compare albumin and FFP as replacement fluids	PE beneficial when administered early. No significant difference between albumin and FFP but albumin preferred due to less risks.
54	To determine whether IVIG is as effective as PE	IVIG is as effective as PE and may be superior.
55	Compared IVIG with PE, and combined regimen of PE followed by IVIG	PE and IVIG are equivalent in efficacy when treatment is given within the first 2 weeks of symptoms. The combination of PE followed by IVIG was not more beneficial.

IVIG, intravenous immunoglobulin; FFP, fresh-frozen plasma; PE, plasmapheresis.

CHAPTER 176 ■ MYASTHENIA GRAVIS IN THE INTENSIVE CARE UNIT

ISABELITA R. BELLA AND RANDALL R. LONG

Few physicians have more than a passing acquaintance with myasthenia gravis, although it is by no means rare. The key to handling the emergent problems associated with myasthenia is simply the management of airway and ventilatory support with the same care as in any other instance of respiratory failure (see Chapters 1, 58, and 59). With respiration under control, the treatment of the underlying disease can be unhurried and orderly, and in most patients, it is successful. This chapter reviews briefly the pathogenesis, clinical spectrum, and diagnosis of myasthenia gravis and focuses on the intensive care setting, including management of the patient in crisis and in the perioperative period.

PATHOGENESIS

Myasthenia gravis is an autoimmune disorder of neuromuscular transmission [1]. Circulating antibodies react with components of acetylcholine receptors within postsynaptic muscle membrane and activate complement-mediated lysis of the muscle membrane, accelerate receptor degradation, and block receptors (i.e., interfere with normal receptor activation by acetylcholine) [2]. The result is fewer receptors that can be activated at affected neuromuscular junctions, causing weaker muscular contraction. Electrophysiologic study of myasthenic neuromuscular junctions discloses miniature end-plate potentials that are diminished in amplitude [3]. These observations have been clearly linked to the receptor alterations and an altered postsynaptic response to normal quantal transmitter release from the presynaptic nerve terminals. Understanding of this underlying pathophysiology has, in turn, enabled rational approaches to treatment. Various immunosuppressive therapies and acetylcholinesterase inhibitors are primary therapeutic options in managing myasthenia gravis (see later).

EPIDEMIOLOGY

Myasthenia gravis is not rare; its prevalence in Western populations is approximately 1 in 20,000 [4]. The overall female to male ratio is approximately 3:2, although there are two distinct sex-specific incidence peaks, with the incidence among women peaking in the third decade and that among men in the fifth to sixth decades. A mild familial predisposition has been noted, although Mendelian inheritance does not apply.

CLINICAL SPECTRUM

The clinical spectrum of myasthenia gravis is characterized as much by its diversity as it is by its common themes. It may range from a mild and relatively inconsequential disease over a normal lifetime to a fulminant incapacitating disorder. The course of given individuals may also vary widely. The clinical hallmarks of the disease are weakness and exaggerated muscle fatigue. The specific muscles involved and the severity of weakness are highly variable, between individuals and within the same individual over time.

Ocular muscles are most frequently involved; diplopia is common, and various patterns of ophthalmoparesis are seen.

Bulbar muscles are also frequently affected, leading to varying combinations of facial paresis, dysarthria, and dysphagia. Ptosis is common, but the pupils are never affected. Limb muscle involvement may vary from very isolated weakness to generalized (usually proximal) weakness and fatigability. Respiratory muscle weakness is unfortunately not rare, and respiratory insufficiency and the inability to handle oral and upper airway secretions are the critical problems that bring myasthenics to the intensive care setting. Myasthenia should also be considered in any patient who cannot be weaned from ventilator support after an otherwise uncomplicated surgical procedure.

Approximately 15% to 20% of myasthenics have only ocular and eyelid involvement. Longitudinal studies indicate that if an individual manifests only oculomotor weakness for more than 2 years, there is little chance of later limb or respiratory weakness. Although several clinical classification schemes have been devised for categorizing myasthenics according to the distribution and severity of their disease, it is preferable to emphasize the fact that myasthenics often fluctuate over time, with variability rather than constancy being the norm. Some factors contributing to fluctuations of strength are recognizable (see later); many fluctuations appear to be random occurrences.

DIAGNOSTIC STUDIES

The diagnosis of myasthenia gravis is clinically suggested in patients who present with chronic ocular, bulbar, or appendicular weakness, variable over time, with preservation of normal sensation and reflexes. More restricted presentations require a much broader differential diagnosis. Myasthenia gravis should always be considered in the differential diagnosis of isolated ocular or bulbar weakness. Again, prominent muscular fatigability and temporal fluctuation are key features of the disease. Normal pupils, normal sensation, and normal reflexes are to be expected and are helpful in diagnosing myasthenia gravis when coincident with an acute or subacute paralytic illness.

Once the diagnosis of myasthenia gravis is suggested, confirmation rests on the exclusion of other diseases and supporting clinical and laboratory studies. It is important to stress that although abnormal tests may be diagnostic, normal test results do not exclude the diagnosis.

Edrophonium Test

Edrophonium hydrochloride (Enlon; formerly "Tensilon") is a fast, short-acting parenteral cholinesterase inhibitor. It reaches peak effect within 1 minute after intravenous injection and persists to some extent for at least 10 minutes. Myasthenic weakness typically improves transiently after administration of 4 to 10 mg (0.4 to 1.0 mL). The edrophonium test may be blinded, with drug or normal saline being injected. Whether drug or placebo, a 0.2-mL test dose is given to screen for excessive cholinergic side effects, such as cardiac arrhythmia, gastrointestinal hyperactivity, or diaphoresis. A crash cart should always be available, and patients with known cardiac disease and elderly patients warrant electrocardiographic monitoring. The remaining 0.8 mL is given after 1 minute. Interpretation of the test depends on identifying and observing an unequivocal baseline muscular deficit that can be improved following the injection of edrophonium. Ptosis and ophthalmoparesis, if present, are semiquantifiable and well suited; if respiratory compromise is present, monitoring maximum inspiratory pressure (MIP) or vital capacity is useful. As a general rule, positive responses are dramatic; if there is any doubt about the positivity of the test, it should be considered negative. False-positive edrophonium tests are quite rare; false negatives are common. In children, the appropriate test dose is 0.03 mg per kg, one-fifth of which may be given as a test dose.

Neostigmine is a longer-acting parenteral cholinesterase inhibitor that sometimes affects a more obvious clinical response. It is also typically associated with more obvious autonomic side effects. The 1.5-mg test dose (0.04 mg per kg in children) should therefore be preceded by 0.5 mg of atropine; both may be given subcutaneously.

Serological Testing

Recognition of the immune nature of myasthenia gravis has provided a relatively sensitive and highly specific diagnostic study. Approximately 85% of myasthenics have detectable serum antibodies, which bind to acetylcholine receptors (AChR) [5]. The sensitivity drops to 70% in those with purely ocular myasthenia [6]. The antibodies themselves constitute a heterogeneous group, reacting against various receptor subunits. Although the actual antibody titer is of little significance, correlating poorly with the severity of disease or clinical response to therapy, the presence of antibodies is a strong indication of the disease. A normal test does not exclude the diagnosis, especially in the patient presenting with predominantly ocular symptoms and signs. Of note, these antibodies have also been found in a small percentage of patients with Lambert–Eaton myasthenic syndrome, autoimmune liver disorder, and patients with lung cancer without neurologic disease [6].

Among seronegative myasthenic patients, from 30% to 70% may be found to have antibodies directed against muscle-specific tyrosine kinase [MuSK], an enzyme that catalyzes acetylcholine receptor aggregation in the formation of neuromuscular junctions [7]. Animal models have also recently shown that MuSK antibodies may reduce acetylcholine receptor clustering and thus impair neuromuscular transmission [8]. Patients who have antibodies to MuSK are often young women (onset of symptoms before 40 years of age) with prominent bulbar involvement [9] and neck or respiratory muscle weakness [7]. They tend to have more severe disease requiring aggressive immunosuppressive treatment [9] and have a higher frequency of respiratory crisis compared to seronegative or AChR-positive myasthenics [10]. Unlike patients with antibodies to AChR, there appears to be a correlation between MuSK antibody levels and disease severity, with antibody levels often decreasing after various immunosuppressive treatments except thymectomy [11].

Striated muscle antibodies that react with muscle proteins titin and ryanodine receptor have also been found, mainly in patients with thymoma and in those with late onset myasthenia (onset of symptoms > 50 years of age) [12]. Thus, they may be helpful in the detection or recurrence of thymoma. In addition, they tend to be associated with more severe disease, and therefore may aid in prognosis [12].

Myasthenics also have an increased incidence of other autoantibodies, including antithyroid antibodies, antiparietal cell antibodies, and antinuclear antibodies, although routine screening for these is not part of the diagnostic evaluation for suspected myasthenia gravis.

Electromyographic Studies

The electromyographic hallmark of myasthenia gravis is a decrement in the amplitude of the muscle potential seen after exercise or slow repetitive nerve stimulation. The decrement should be at least 10% and preferably 15% or more. Routine motor and sensory conduction studies are normal, as is the conventional needle examination. The more severely

affected patient is more likely to show a decremental response; responses are most consistently elicited from facial and proximal muscles. If a significant decrement is observed, exercising the muscle briefly for 10 seconds transiently reverses the decrement [13]. Single-fiber electromyography is relatively sensitive, documenting increased jitter [14]—variability in the temporal coupling of single fibers within the same motor unit. Increased jitter, however, is far from specific; most peripheral neurogenic diseases also lead to increased jitter.

MISCELLANEOUS STUDIES

Myasthenia gravis may be associated with either malignant thymoma or thymic hyperplasia. Once a diagnosis is established, chest imaging should be obtained. Because there is also a significant association with thyroid and other autoimmune diseases, appropriate screening studies are indicated in the newly diagnosed myasthenic. Muscle biopsy has no role in the evaluation of myasthenia, unless there is a strong consideration of neurogenic or inflammatory weakness.

CRITICAL CARE OF THE MYASTHENIC PATIENT

Patient in Crisis

Crisis refers to threatened or actual respiratory compromise in a myasthenic patient. It may reflect respiratory muscle insufficiency or inability to handle secretions and oral intake, but it is typically a combination of both. With currently available treatments, myasthenic crisis is not common. An occasional patient presents with fulminating disease; crisis management then coincides with initial evaluation and institution of therapy. Otherwise, crisis may be precipitated by other illnesses, such as influenza or other infections, or by surgery.

General Measures

The respiratory function of any acutely deteriorating or severely weak myasthenic should be monitored compulsively. When the weakening myasthenic reaches a point at which increased respiratory effort is required, fatigue often prevents the effective use of secondary muscles, and respiratory failure rapidly ensues. Arterial blood gas values and even oxygen saturation are poor indicators of incipient failure in the face of respiratory muscle compromise. Forced vital capacity (FVC) and MIP are better indices and should be serially charted. The FVC should be assessed with the patient both sitting and supine, because diaphragmatic paresis may be accentuated in the supine position. MIP measurement requires special care if the patient also has significant facial weakness. An FVC less than 20 mL per kg or an MIP greater than (i.e., not as negative as) −40 cm H_2O suggests impending failure and usually warrants intubation. If a downward trend is noted (greater than 30% decrease) [15], elective intubation should be considered even sooner, unless there is a realistic expectation of rapid reversal.

Acute deterioration in a myasthenic always warrants consideration of contributing circumstances or concurrent illness that may accentuate the underlying defect in neuromuscular transmission. The major considerations are listed in Table 176.1 and discussed later.

The possibility of cholinergic crisis in patients receiving anticholinesterase drugs (e.g., pyridostigmine), although no longer common, should not be overlooked. The presence of fasciculations, diaphoresis, or diarrhea should alert the clinician to this possibility. In the past, the importance of differentiating between myasthenic crisis and cholinergic crisis was stressed. Edrophonium testing was used to differentiate between the two; abrupt deterioration after a conventional 10-mg test dose indicated overdosage with cholinesterase inhibitors. One had to be adequately prepared for deterioration and increased respiratory secretions. Because oftentimes it is very difficult to determine the response and because of the potential side effects with overdosage of anticholinesterase drugs of increased pulmonary secretions, many authors now recommend discontinuation of cholinesterase inhibitors at the time of crisis [2,16,17] and reinstituting them when patients are stronger. This assumes that adequate respiratory monitoring and support are in effect. A brief holiday from cholinesterase inhibition also often results in an enhanced response to therapy when reinstituted.

TABLE 176.1

CONDITIONS THAT MAY UNDERLIE INTERIM DETERIORATION IN MYASTHENIC PATIENTS

Intercurrent infection; occult infection should be excluded
Electrolyte imbalance (Na, K, Ca, P, Mg)
Cholinergic crisis: if any doubt, discontinue cholinesterase inhibitors
Thyrotoxicosis, hypothyroidism
Medication effects (see Table 176.2)

Intercurrent infection is often associated with increased weakness in the myasthenic patient. There should be a comprehensive search for systemic infection in the deteriorating patient, particularly the patient receiving immunosuppressive therapy. Any infections should be treated aggressively. Both hypothyroid and hyperthyroid states are often associated with increased weakness. Again, there is an increased association between thyrotoxicosis and myasthenia gravis. The manifestations of electrolyte imbalance may be enhanced in myasthenics. Otherwise, insignificant electrolyte effects on transmitter release or muscle membrane excitability may be amplified at the myasthenic neuromuscular junction. Potassium, calcium, phosphate, and magnesium alterations should be corrected. Myasthenia gravis may also impart enhanced sensitivity to a number of medications that have only minimal effects on neuromuscular function in normal individuals. Aminoglycoside antibiotics, beta-blockers, and many cardiac antiarrhythmics may have adverse effects. Anticholinergics, respiratory depressants, and sedatives of any kind should be avoided or used only with great caution. *Neuromuscular-blocking agents should never be administered to myasthenics in the intensive care unit (ICU) setting*, because they often have profound and prolonged effects. This increased sensitivity occasionally results in postoperative failure to wean in an undiagnosed mild myasthenic who has undergone surgery for an unrelated problem. Table 176.2 provides a comprehensive listing of medications that may further impair neuromuscular transmission in myasthenic patients.

Some attention should also be given to the general environment in which the myasthenic is managed. The typical noisy, brightly illuminated ICU is not conducive to rest and sleep, which are necessities for the myasthenic patient in whom fatigue may be critical.

Special consideration must be given to respiratory care of the myasthenic. Incentive spirometry should be avoided, because muscular fatigue outweighs any potential benefit, even in the postoperative patient. Careful attention to respiratory toilet is key and can be complicated by cholinesterase inhibitors, which increase respiratory secretions. Atropine may be used to minimize this effect, but its other autonomic side effects, such as ileus, constipation, and delirium, may limit longer-term use.

TABLE 176.2

MEDICATIONS THAT MAY ACCENTUATE WEAKNESS IN MYASTHENIC PATIENTS

Antibiotics	Neuromuscular blockers and muscle relaxants	Antiarrhythmics and antihypertensives	Antirheumatics	Antipsychotics	Others
Amikacin	Anectine (succinylcholine)	Lidocaine	Chloroquine	Lithium	Opiate analgesics
Clindamycin	Norcuron (vecuronium)	Quinidine	d-Penicillamine	Phenothiazines	Oral contraceptives
Colistin	Pavulon (pancuronium)	Procainamide		Antidepressants	Antihistamines
Gentamicin	Tracrium (atracurium)	Beta-blockers			Anticholinergics
Kanamycin	Benzodiazepines	Calcium blockers			
Lincomycin	Curare				
Neomycin	Dantrium (dantrolene)				
Polymyxin	Flexeril (cyclobenzaprine)				
Streptomycin	Lioresal (baclofen)				
Tobramycin	Robaxin (methocarbamol)				
Tetracyclines	Soma (carisoprodol)				
Trimethoprim/ sulfamethoxazole	Quinamm (quinine sulfate)				

THERAPY IN MYASTHENIC CRISIS

Therapeutic agents used in the critical care setting parallel those available to the patient with milder myasthenia gravis. Immunosuppressive therapies are the major considerations. Any myasthenic in crisis, if not already receiving immunosuppressive therapy, requires it. Symptomatic therapy with cholinesterase inhibitors is now primarily used on a shorter-term basis, pending response to immunomodulating therapies. Plasmapheresis, intravenous human immune globulin, corticosteroids, and longer-term immunosuppressants and cholinesterase inhibitors are discussed individually.

Plasmapheresis

Recognition of the role of immunoglobulins in the pathogenesis of myasthenia gravis stimulated early, uncontrolled clinical trials of plasmapheresis as soon as efficient pheresis technology became available [18]. The results have been quite favorable, prompting the National Institutes of Health Consensus Conference to support its use despite the lack of controlled trials [19]. Most patients demonstrate a significant clinical response within 48 hours of initiation of plasmapheresis, although the response is short lived unless therapy is continued on an intermittent basis. The rapid response from plasmapheresis can be crucial in the face of crisis, providing a short-term reprieve during which alternative therapy can be initiated or any intercurrent medical problems resolved. Approximately 50 mL per kg should be exchanged per session [20], approximating 60% to 70% of total plasma volume. Plasma removed is replaced by an equal volume of normal saline and 5% albumin, adjusted to maintain physiologic concentrations of potassium, calcium, and magnesium. The usual course of treatment includes three to seven pheresis sessions at 24- to 48-hour intervals. Many patients develop increased sensitivity to cholinesterase inhibitors after plasmapheresis; dosage should be correspondingly reduced. The major potential complications of plasmapheresis include hypotension, arrhythmia, and hypercoagulability due to hemoconcentration. Coincident cardiovascular disease is a relative contraindication to plasmapheresis. Although plasmapheresis is too invasive to be used for long-term therapy in the majority of patients, periodic plasmapheresis has been beneficial in some patients with moderate to severe myasthenia refractory to immunosuppressive agents [21]. Selective removal of acetylcholine receptor antibodies using immunoadsorption columns may also be a promising alternative to plasmapheresis, but further clinical studies are required [22].

Intravenous human immune globulin also frequently leads to rapid yet transient improvement in myasthenics [23]. Intravenous immunoglobulin (IVIG) is a therapeutic option in the event of crisis or in the perioperative period, particularly if the patient's cardiovascular status limits plasmapheresis. Although IVIG and plasmapheresis were found to be equally efficacious in some trials [24], others have reported that plasmapheresis was more efficacious than IVIG; however, complications occurred more often with plasmapheresis [25]. The customary dose is 400 mg per kg per day for 5 consecutive days. More recently, a total dose of 1 gram per kilogram was reported to be equally efficacious to 2 gram per kilogram, although there was a trend toward slight superiority of the higher dose [26]. Maximal improvement occurs by the second week after therapy, and the therapeutic response usually persists for several weeks. Patients should be pretreated with acetaminophen and diphenhydramine to prevent flu-like symptoms that commonly occur during infusion. In addition, adequate hydration will help reduce the potential complication of thrombosis. Renal function should be checked prior to initiation of therapy, as renal failure may occur in those with renal insufficiency. Likewise, an IgA level should be obtained as patients with IgA deficiency may develop anaphylaxis.

Longer-Term Immunosuppression

Corticosteroids have proven to be an effective long-term therapy for almost all myasthenics whose clinical manifestations cannot be well managed with low doses of cholinesterase inhibitors. Despite potential side effects associated with corticosteroid therapy, a response rate of greater than 80% supports its use [27]. Side effects can be minimized with appropriate precautions. Carbohydrate metabolism, electrolytes, blood pressure, and diet should be closely monitored; bisphosphonates (e.g., alendronate sodium, 70 mg weekly), calcium (500 to 1,000 mg per day), and vitamin D supplementation (at least 800 to 1,000 IU per day) as well are prudent to minimize osteopenia. Screening for tuberculosis exposure with skin testing and chest radiographs should be done before initiation of therapy. Occult infection must be excluded in the deteriorating myasthenic.

Recommendations regarding corticosteroid preparation, dose, and regimen vary. Approximately one-third of patients may become transiently weaker before they improve, if given high doses of prednisone initially [3]. Initiation with relatively low doses of prednisone and increasing in a stepwise manner has been advocated by some clinicians to minimize interim deterioration, especially if the patient is not intubated [16]. The authors prefer to begin with 15 to 25 mg of prednisone or its equivalent as a single daily dose, increasing the dose by 5 mg every second or third day until a dose of 1 mg per kg per day is reached. In the critical care setting, concurrent plasmapheresis or IVIG may offset initial steroid-related deterioration; high doses of corticosteroids (1 mg per kg per day) can be initiated in this situation, enabling a more rapid response. Oral corticosteroids are preferable since there is a risk of developing acute steroid-induced myopathy in patients with myasthenia who are given high doses of intravenous corticosteroids [17,28].

Once maximal response is obtained, usually within 1 to 2 months, patients may be gradually shifted to alternate-day therapy by concurrently reducing the off-day dose and increasing the on-day dose, with a 10-mg shift made once each week. Some individuals note a definite off-day adverse effect; this can usually be countered with a 10-mg alternate-day dose. Once stabilized on alternate-day therapy, the on-day dose can be tapered by 5 mg per month. Many patients can be maintained in remission with as little as 20 to 25 mg of prednisone every other day (or alternating with 10 mg). Only rare patients remain in remission if therapy is discontinued, and overenthusiastic tapering of steroids is an all too common precipitant of unnecessary disability or even crisis. Myasthenia sometimes remits spontaneously, and if the patient has undergone thymectomy (see later), the probability of remission increases appreciably, making discontinuation of therapy a more realistic option.

Azathioprine is often used as an alternative agent for longer-term immunosuppression. It is effective in 70% to 90% of patients with myasthenia gravis [2] and is often initiated in patients with an insufficient response to corticosteroids, as a steroid-sparing agent, or in patients in whom corticosteroids are contraindicated [3]. Azathioprine is limited by a relatively long delay before its effects are clinically evident, up to 6 to 12 months, but its side-effect spectrum compares favorably with steroids over a time frame of many years. If a patient tolerates a 50-mg per day test dose, the daily dose can be increased by 50 mg each week up to 2 to 3 mg per kg per day. The dose is reduced if the white blood cell count is less than 3,000 per mm^3; an elevated mean corpuscular volume can also be used to assess adequate response [4,29]. In up to 10% of patients, an influenza-like reaction characterized by fever, malaise, and myalgias occurs within the first few weeks of therapy and resolves after discontinuing the drug [2,29]. Patients should be screened for thiopurine methyltransferase (TPMT) deficiency; those homozygous for TPMT mutations cannot metabolize azathioprine and therefore should not receive the drug. Concurrent treatment with allopurinol should also be avoided as it interferes with the degradation of azathioprine, thereby increasing the risk of bone marrow and liver toxicity [29].

Cyclosporine appears to be as effective as azathioprine in the treatment of myasthenia gravis [30] and is used mainly in patients who are intolerant or refractory to azathioprine. Onset of clinical improvement is quicker than with azathioprine, with most patients noticing improvement after 1 to 3 months, and becoming maximal around 7 months [31]. Its major limitations are renal toxicity and hypertension, which are seen in about one-quarter of patients. To minimize side effects, the starting dose of 5 mg per kg per day can be given in two divided doses 12 hours apart, followed by adjustments to maintain a predose trough level in the range of 100 to 150 ng per L. Subsequent adjustments can be made depending on creatinine levels and clinical improvement, with the aim to reduce the dose as much as possible once maximal improvement is obtained [31]. Renal function (blood urea nitrogen and creatinine) must be continually monitored. Significant hypertension and preexisting renal disease are contraindications to the use of cyclosporine.

Another agent from the realm of transplant medicine, mycophenolate mofetil (CellCept), has also been used effectively for longer-term therapy. Several case series, retrospective analysis, and a small placebo controlled, double-blind trial suggested that mycophenolate mofetil is beneficial in patients with myasthenia gravis [32–34]. Because it is better tolerated than other immunosuppressants, it has become widely used. Recently, however, two large double-blinded randomized controlled trials failed to show any benefit of mycophenolate mofetil over placebo in patients with myasthenia gravis [35,36]. One study showed that mycophenolate mofetil was not superior to placebo during a steroid taper [35], while the other study showed no benefit in taking mycophenolate mofetil with 20 mg prednisone compared to taking prednisone alone [36]. Several factors have been proposed to explain these surprisingly negative results including the short duration of the trials, selection of generally mildly affected patients, and the unexpected significant response to low-dose prednisone [2]. Further studies are warranted to establish the role of mycophenolate mofetil in myasthenia. Despite this, mycophenolate mofetil is still widely used in the treatment of myasthenia gravis. The standard dose is 1,000 mg twice a day, but doses up to 3,000 mg per day may be used. Monthly complete blood counts should be performed to monitor for any evidence of myelosuppression.

In refractory cases in which it has proven difficult to achieve or maintain remission, high-dose cyclophosphamide has proven effective [2]. However, it has significant side effects including bone marrow toxicity, hemorrhagic cystitis, teratogenicity, and increased risk of infections and malignancies. Oral dosage ranges from 1 to 5 mg per kg per day [16]. Recently, Drachman and colleagues reported dramatic clinical improvement by "rebooting the immune system" in patients with refractory myasthenia using high-dose cyclophosphamide 50 mg per kg per day for 4 days, followed by granulocyte colony-stimulating factor; clinical improvement lasted several years in some patients [37].

Several case series have reported a beneficial response of rituximab in patients with refractory myasthenia gravis and in those with MuSK myasthenia gravis [38]. Patients tolerated the treatment without significant side effects, making this a promising drug for the future.

Cholinesterase Inhibitors

Cholinesterase inhibition was the mainstay of pharmacotherapy for myasthenia gravis before the advent of immunosuppressive therapies and thymectomy. Many patients are now maintained in remission on corticosteroids or other immunosuppressive agents, while others, in particular, those with mild nonprogressive or purely ocular disease, require only treatment with an oral anticholinesterase drug, such as pyridostigmine (Mestinon). If an acutely deteriorating patient has been taking a cholinesterase inhibitor, the possibility of cholinergic crisis should be entertained. Overdosage of cholinesterase inhibitors may produce weakness accompanied by muscarinic symptoms such as increased pulmonary and gastric secretions, bradycardia, nausea, vomiting, diarrhea, and nicotinic symptoms such as fasciculations [2,17]. Many authors advocate discontinuing anticholinesterase therapy during myasthenic crisis to minimize secretions, avoid potential exacerbation of weakness due to overdosage of cholinergic medications, and allow

easier assessment of response to other therapies [16,17]. It is reasonable to reinstitute anticholinesterase therapy when patients are stronger, starting at a low dosage and gradually increasing the dose until there is clear benefit [16].

The use of intravenous anticholinesterase therapy is controversial. Infusion of intravenous pyridostigmine at 1 to 2 mg per hour during crisis was found in one small retrospective study to be comparable to plasmapheresis [39]. However, intravenous therapy carries the risk of dangerous side effects such as cardiac arrhythmias, myocardial infarction (due to coronary vasospasm), airway obstruction, and increased pulmonary secretions [17,40]. It is therefore more prudent to hold cholinergic drugs until the patient is able to take them orally or through a nasogastric tube [17]. If intravenous anticholinesterase therapy is deemed necessary, neostigmine and pyridostigmine preparations are available in parenteral forms. One milligram of neostigmine given intravenously is roughly equivalent to 120 mg of pyridostigmine taken by mouth. Intravenous pyridostigmine is approximately 1/30th to 1/60th the dose of oral pyridostigmine.

PERIOPERATIVE MANAGEMENT OF THE MYASTHENIC PATIENT

An intercurrent problem requiring surgical intervention was a common source of major morbidity and mortality for myasthenics before the 1960s. Subsequent developments in critical care techniques, especially respiratory care, and in therapy of the underlying disease have dramatically improved this situation. Perioperative management must be compulsive, yet myasthenia gravis should rarely preclude surgical treatment that is otherwise indicated.

Preoperative Considerations

Myasthenia gravis is a major variable in surgical management, whether the surgery is elective or emergent. A neurologist (preferably the neurologist who has been managing the patient) should be considered an integral member of the operative team. If the procedure is elective, the patient's myasthenic status should be optimized before anesthesia and surgery. Pulmonary functions should be reviewed in detail; if respiratory or bulbar muscle function is compromised, therapy adjustments should be undertaken to improve the patient's status. All therapeutic options should be considered, with the possible exception of corticosteroids. If the patient is not receiving steroids, it is prudent to forego or delay this treatment until after surgery, because corticosteroids may increase the risk of infection and retard wound healing. If the patient is already receiving corticosteroids, therapy should be continued, with a short-term increment in dose to compensate for the added stress of anesthesia and surgery. Plasmapheresis or intravenous human immune globulin is often useful in the preoperative setting, providing a transient therapeutic benefit through the preoperative and postoperative periods. Once dose and regimen are optimized, cholinesterase inhibitors may be continued up to the time of surgery. They should then be discontinued because they stimulate respiratory secretions.

It is crucial that all physicians involved in perioperative management of the myasthenic are aware of the particular medications that may accentuate the underlying defect in neuromuscular transmission. It is appropriate to post a warning regarding specific medications on the patient's chart, in a manner analogous to that for medication allergies. Neuromuscular blockade should be avoided during surgery unless absolutely essential; if required, the shortest-acting agents should be used at minimal doses. Accentuated and prolonged effects should be anticipated. Aminoglycoside antibiotics should also be avoided when alternatives are available. There is no clear consensus in favor of any one halogenated anesthetic agent; ether adversely affects neuromuscular transmission. Again, close attention to metabolic homeostasis cannot be overemphasized.

Postoperative Care

Postoperative care of the myasthenic patient should not differ greatly from that of other patients, provided preoperative and intraoperative management has been successful. The patient's status before surgery is often the best indicator of the postoperative course. Intubation and mechanical ventilatory support must be continued until the patient is alert and responsive and demonstrates and maintains adequate pulmonary function. Serial pulmonary functions indicate when the patient can be extubated. An FVC greater than 20 mL per kg and MIP less than (i.e., more negative than) -40 cm H_2O are minimum requirements. If needed, cholinesterase inhibitors may be resumed as a continuous intravenous infusion until bowel function is restored and oral intake allowed. Increased sensitivity to cholinesterase inhibitors is the norm after surgical procedures, especially thymectomy. Resumption at a rate of no more than one-half the preoperative equivalent is often sufficient. Subsequent adjustments should reflect clinical indices. The myasthenic whose neuromuscular function deteriorates during the postoperative period is the exception. In all probability, an intercurrent reversible factor underlies the deterioration. The spectrum of metabolic, infectious, and pharmacologic issues discussed previously should be reviewed.

Thymectomy

After several decades of controversy, there is a consensus that thymectomy favorably alters the natural history of myasthenia gravis, especially in younger patients, independent of the presence or degree of thymic hyperplasia [41]. Thymectomy should be considered early in the course of myasthenia, except in elderly, frail patients. Thymectomy remains an elective procedure, however. The myasthenic with marginal respiratory or bulbar function should be optimally treated before surgery. The perioperative management considerations discussed earlier apply to prethymectomy and postthymectomy management. Some controversy persists regarding the appropriate thymectomy procedure. Most centers favor the transsternal approach. Although more invasive, this approach facilitates recognition and removal of all thymus tissue and avoids postoperative respiratory compromise. There are some proponents of transcervical mediastinoscopic thymectomy; in experienced hands, this remains an alternative. Thymectomy by conventional thoracotomy has no place in the treatment of myasthenia.

CONCLUSION

Respiratory failure is no longer the source of major morbidity and mortality in myasthenia gravis that it once was. When it does occur, appropriate ventilatory support and airway protection provide time for resolution of any intercurrent problems and therapy of the underlying myasthenia. Plasmapheresis and immunosuppression are usually successful; extended intensive care stays should be rare occurrences. Treatment of myasthenia gravis with steroids, immunosuppressive agents, and thymectomy usually enables these patients to lead essentially normal lives.

CHAPTER 177 ■ MISCELLANEOUS NEUROLOGIC PROBLEMS IN THE INTENSIVE CARE UNIT

JING JI, ANN L. MITCHELL AND NANCY M. FONTNEAU

A wide variety of neurologic problems may confront the physician in the intensive care unit (ICU), including several important disorders for which basic information is not readily available. These include

- Suicidal hanging, electrical shock, acute carbon monoxide poisoning, and decompression sickness, which present so blatantly that the diagnosis is rarely in question, yet the range of clinical manifestations and their management may be unanticipated.
- Cerebral fat embolism, which is often not initially suspected if other surgical or medical issues take precedence.
- Singultus (hiccups), which is an all too common secondary problem that may further weaken the severely ill patient.

- Compression neuropathies, which may complicate prolonged bed rest.

SUICIDAL HANGING

Hanging is the second most common means of committing suicide in the United States [1]. Introduced in fifth-century England, hanging proceeded to become the official form of execution. Early on, there was no exact procedure, and most hangings resulted in slow strangulation [2]. Changes in techniques, such that the victim dropped at least his height and the hangman's knot being placed in the submental location, produced a consistently fatal bilateral axis-pedicle fracture, resulting in complete herniation of the disc and severance of the ligaments between C2 and C3 [3]. This injury causes almost immediate death by destroying the cardiac and respiratory centers, lacerating the carotid artery, and injuring the pharynx [2,3].

Suicidal hangings are rarely so expert, and death usually results from strangulation due to interruption of cerebral blood flow [4]. A minimal amount of compression occludes the jugular veins, while an increased force occludes the carotid arteries [5,6]. A much larger force is necessary to arrest blood flow in the vertebral arteries [5]. Pressure on the jugular veins from the noose results in venous obstruction and stagnation of cerebral blood flow, causing hypoxia and loss of consciousness [3]. Cervical muscle tone then decreases, allowing airway obstruction and arterial compression, further worsening hypoxia [3]. In addition, external compression of the carotid bodies or vagal sheath can increase parasympathetic tone, whereas pressure on the pericarotid area stimulates sympathetic tone; either can result in cardiac arrest [4,5]. The altered autonomic tone may also cause a release of catecholamines, resulting in neurogenic pulmonary edema, as well as affect the respiratory smooth muscle tone, causing respiratory acidosis and a further insult to cerebral oxygenation [3].

If blood flow is quickly restored, full recovery can often be expected. If the blood flow is interrupted for more than a few minutes, however, hypoxia causes cell death and cytotoxic and vasogenic edema, with increased intracranial pressure. There is selective vulnerability of the cerebral cortex (particularly the pyramidal cell layer), the globus pallidus, thalamus, hippocampus, and the cerebellar Purkinje cells to anoxia and ischemia.

Diagnosis

Although the diagnosis is rarely in doubt, the patient may show a range of findings, varying from rope burns to coma. In the immediate posthanging period, the patient most commonly shows evidence of an altered level of consciousness, ranging from restlessness, delirium, or violence to lethargy, stupor, or coma. Seizures, and rarely status epilepticus, may occur [4,5]. Hyperthermia may be present because of hypoxic damage to the hypothalamus [6]. Injury to the neck blood vessels occurs in 40% of patients, resulting in carotid dissection, thrombus formation, and distal ischemic infarcts [7]. Venous occlusion may lead to venous congestion, venous ischemia, and hemorrhage [8]. Development of the acute respiratory distress syndrome may result from central nervous system (CNS) catecholamine release, causing constriction of the pulmonary venules [3]. In incomplete hanging, the patient may also show signs of laryngeal and pharyngeal edema, resulting in hoarseness, dysphagia, and stridor [3,8]. Although infrequent in suicidal hangings, fracture of the odontoid and injury to the spinal cord may occur.

Careful neurologic examination should be performed, with particular attention to alterations in the level of consciousness and evidence of spinal cord injury, such as paraparesis, quadriparesis, or urinary retention. There should be frequent monitoring of vital signs for evidence of autonomic instability and stridor. Initial laboratory evaluations should include radiographs of the cervical spine, arterial blood gas determination, electrocardiogram, and cardiac monitoring. CT angiogram should also be considered if suspicious for dissection of the carotid artery [9].

Neuroimaging of the brain may be quite variable, from a normal head computed tomography (CT) scan in many patients, to evidence of edema, hemorrhage, and ischemia. Due to decreased blood flow and the resultant hypoxia, edema may be seen in the white matter tracts [10]. Subcortical and subarachnoid hemorrhages may result from venous occlusion, while ischemic insults may result from venous or arterial occlusion, particularly in the areas of greatest vulnerability: the basal ganglia, cortex, thalamus, and hippocampus [11].

Treatment

The patient may appear dead but might still be resuscitable. Patients quickly lose consciousness with hanging attempts, but may still have cardiac and respiratory function or can quickly regain these with prompt cardiopulmonary resuscitation (CPR). The goals of treatment are to maintain an adequate level of cerebral oxygenation, to decrease the raised intracranial pressure, and to monitor and treat any cardiac arrhythmias or respiratory distress that may develop. In hangings, the mechanical trauma induced by strangulation can also cause hemorrhage and edema in the paratracheal and laryngeal areas and result in a delayed but significant airway obstruction at any time within the first 24 hours. Endotracheal intubation may be required if there is evidence of hypoxia due to acute respiratory distress syndrome, airway obstruction, or increased intracranial pressure [8].

Other concerns in victims of hangings include fractures and thrombi. A fracture of the odontoid requires immediate neurosurgical or orthopedic intervention to stabilize the cervical spine and protect the cord from injury. A carotid thrombus requires prompt vascular intervention to remove the clot and restore patency and blood flow. In addition, assessing the patient for other evidence of self-inflicted injuries and intoxications is also warranted, as is a complete psychiatric evaluation once the patient is able to cooperate.

Course

The prognosis for recovery is not immediately apparent with the first neurologic examination. Many patients have made a full recovery despite an initial Glasgow Coma Scale (GCS) score of 3 [4]. However, the fatality rate for suicidal hangings may range from 60% to 70% [12]. Indicators for a good recovery include a hanging time of less than 5 minutes, a heartbeat present at the scene or in the emergency room, CPR initiated at the scene, a GCS score greater than 3, and an incomplete circumferential ligature [4]. Predictors of a poorer prognosis include evidence of cardiopulmonary arrest, a spontaneous respiratory rate less than 4 per minute, need for intubation, and neurogenic pulmonary edema [5].

Other neurologic sequelae can become manifest either in the immediate posthanging period or after a relatively asymptomatic latent period. The individual may show evidence of a confusional state, a circumscribed retrograde amnesia, Korsakoff's syndrome, or even progressive dementia [8]. Transient hemiparesis, aphasia, abnormal movements, motor restlessness, and myoclonic jerks also can characterize this period [8]. Ear numbness may result from injury to the greater auricular nerve [13]. Three more severe outcomes have also been observed: (a) comatose state with minor neurologic improvement

and death; (b) early neurologic recovery, followed by cerebral edema with uncontrollable uncal herniation and severe morbidity or mortality; and (c) complete neurologic recovery, followed by delayed encephalopathy and death [3]. Most patients who survive recover to variable degrees.

ELECTRICAL INJURIES

Approximately 4,000 injuries and 1,000 deaths from electrical shock occur annually in the United States. Most fatalities occur in the workplace, but one third result from contact with household current [14]. Approximately 400 people per year are affected by lightning strikes, with one-third of victims dying due to their exposure [15].

Pathophysiology

Electrical and lightning injuries are exceedingly variable and dependent on a number of factors. Current flowing between two potentials, or amperage, is equal to the voltage divided by the resistance to current flow (I = V/R). Current is generated by either an electrical source or a lightning strike. Current may be direct (DC), as with lightning, or alternating (AC), as with most household appliances. Alternating current has a tendency to produce tetanic contractions that prevent voluntary release from the current source, thus prolonging the electrical contact time and increasing the potential for injury. Higher voltages, such as those that occur with lightning or with contact with high-voltage conductors, produce more severe injuries than those due to low voltages. Wet skin and tissues high in water content provide low resistance to current flow and are at a higher risk for injury, while tissues high in fat and air, such as hollow organs, provide high resistance. Nerves and blood vessels have lower than expected resistances, and thus are more sensitive to electrical injury than their water content would suggest [16]. Other variables that affect the severity of damage include the current pathway (i.e., whether it involves the heart, diaphragm, spinal cord, or brain), the area of current contact and exit, and the duration of contact [16].

In addition, lightning injuries are classified according to the type of exposure [17]. "Direct strikes" involve direct contact between the lightning bolt and the highest point of the victim, often the head. "Side flash" involves the spread of electricity from the lightning bolt to a nearby object and then to the patient. Side flash victims are typically exposed to less voltage and current than with a direct strike. Finally, "stride current" involves the spread of electricity from the lightning bolt to the ground and then through contact points in the patient. Stride current patients are more likely to experience spinal cord injuries, as the current crosses through the spinal cord from one limb to another.

Neurologic Complications of Electrical and Lightning Injuries

Neurologic sequelae of electrical injuries affect both the central and peripheral nervous systems, with both immediate and long-term difficulties.

Immediate Effects

Immediate neurologic effects of electrical injuries are noted throughout the neuraxis. Ten percent to 50% of patients experience a brief loss of consciousness, as well as headache, retrograde amnesia, and confusion [18]. Patients with electrical and lightning injuries to the head may also suffer subarachnoid or parenchymal hemorrhages, particularly in the basal ganglia and brainstem [19]. In patients who suffer cardiac or respiratory arrest, posthypoxic encephalopathy may develop in "watershed" areas of the cerebral cortex. Less commonly, patients may present with cerebral infarction or a temporary cerebellar syndrome [19].

Catecholamine release may result in autonomic dysfunction, as evidenced by transitory hypertension, tachycardia, diaphoresis, vasoconstriction of the extremities, and fixed and dilated pupils [20]. Thus, lightning strike victims should receive full resuscitative efforts despite pupillary changes, as these may not indicate brainstem dysfunction. Lightning strike victims may also suffer "keraunoparalysis," a self-limited paralysis more often involving the lower extremities, accompanied by a lack of peripheral pulses, pale and cold extremities, and variable paresthesias [19]. Keraunoparalysis is presumably due to localized vasospasm from catecholamine release.

Acute spinal cord injuries are also seen, particularly with stride current injuries. The spectrum of spinal cord injuries includes paralysis, spasticity, autonomic dysfunction, and, later, chronic pain and pressure ulcers [19]. Acute neuropathies are typically not seen with lightning strikes, but may be seen with electrical injuries in association with compartment syndromes, local burns, or vascular injury [21]. Both electrical and lightning strike victims are vulnerable to the subacute development of cataracts, while lightning strike patients are peculiarly susceptible to tympanic membrane rupture, vertigo, and hearing loss [22,23].

Delayed Effects

Delayed effects of electrical and lightning injuries may also span the neuraxis. Recognized neuropsychiatric effects include depression, posttraumatic stress disorder, fatigue, irritability, and memory and concentration difficulties [24]. Movement disorders have also been described, such as transient dystonias, torticollis, and parkinsonism [19]. Delayed ophthalmologic and otologic consequences include cataracts, conductive and sensorineural hearing loss, and vertigo [22,23]. Delayed autonomic dysfunction may manifest as reflex sympathetic dystrophy, presenting as a limb with burning pain, cutaneous vasoconstriction, swelling, and sweating [20]. Prolonged and permanent spinal cord abnormalities may become manifest in the delayed development of a myelopathy or a motor neuronopathy [14,25]. Peripheral neuropathies may result from compression due to scarring and fibrosis from the original injury or delayed ischemia due to vascular occlusion [26]. Peripheral neuropathies are more likely to occur in areas directly involved by the electrical current, but may also occur in limbs that were not seemingly in the current path [27].

Evaluation

Initial evaluation of the electrical- or lightning-injured patient involves assessment of the scene and evaluation of safety. Disconnect electrical sources before evaluating the patient. Contrary to conventional mythology, lightning-strike victims are not electrically charged and may be examined immediately.

Assessment of cardiopulmonary status is essential, as many victims suffer cardiopulmonary arrest and may recover well if CPR is initiated promptly. Cardiac arrhythmias and asystole commonly accompany these injuries, as does respiratory arrest due to passage of current through the brainstem respiratory centers. Stabilization of the spine is also essential, due to potential spinal cord injuries and fractures from falls.

Neurologic Examination

The neurologic examination should begin with assessment of the level of consciousness. Initially, many patients are

comatose, but this is often brief and followed by a period of confusion and amnesia, lasting hours to days [28]. Seizures are uncommon. The cranial nerve examination may reveal fixed and dilated pupils, blindness, papilledema, partial hearing loss, and tinnitus. Rupture of the tympanic membranes may also be present with lightning injuries to the head. Evaluation of the motor system for focal weakness and reflex changes may indicate cerebral injuries, myelopathy, or neuropathy. Cerebral lesions, due to hemorrhage or infarction, may result in contralateral hemiparesis. Spinal cord injuries are more common in the cervical region and produce paraparesis or quadriparesis. Peripheral nerve injuries in the immediate assessment are typically located in areas of extensive burns. Sensory loss is less frequent than motor deficits and is maximal in burned areas.

Laboratory Evaluation

Laboratory evaluations should be focused on the known complications of electrical and lightning injuries. Serial determinations of electrolytes, renal function, and hematocrit are essential for assessing adequate fluid replacement. Serum creatine kinase and urinary myoglobin are useful measures of muscle necrosis. Arterial blood gases may reveal a metabolic acidosis. Electrocardiogram (ECG) and cardiac monitoring are used in patients with cardiopulmonary arrest or with known current pathways through the thorax, as delayed cardiac arrhythmias may develop. Radiologic examinations of the long bones, spine, and skull are indicated when fractures or deep burns are suspected based on the history and physical examination. Magnetic resonance imaging (MRI) or myelography may be used to assess spinal cord damage if signs of myelopathy are present. Cranial imaging is indicated when there is prolonged alteration of consciousness and may reveal intracranial hemorrhages, cerebral edema, or the effect of diffuse cerebral hypoxia. The electroencephalogram (EEG) is also useful to rule out status epilepticus in patients with prolonged unconsciousness. The EEG background may remain slow even when the mental status has returned to baseline. Nerve conduction studies and electromyography may be useful in localizing and following axonal and demyelinating electrical injuries to the peripheral nerves and plexi, although they are not generally used in the acute evaluation.

Management

Evaluation and treatment of medical concerns are essential for good neurologic recovery. Efforts should focus on circulatory volume, hydration status, renal function, acidosis, and electrolyte balance. Because high-voltage electric shock victims usually have myoglobinuria secondary to burns and deep tissue injury, their fluid needs are similar to those of crush injuries. Central venous pressure monitoring is usually needed, and urine output should be maintained at greater than 50 mL per hour. Alkalinization of the urine and osmotic diuresis with mannitol also help to prevent myoglobin nephropathy.

Extensive burns due to direct current or clothing ignition are best treated in specialized burn units. At times, skin grafts are required. Debridement of necrotic muscle and fasciotomy are sometimes necessary to prevent secondary ischemia from a compartment syndrome. Amputation is required if there is significant necrosis. In these patients, arteriography may assist in identifying the level of viability. Tetanus prophylaxis and prevention of superinfection are also needed. Spine and long-bone fractures require stabilization.

Recurrent seizures are treated with phenytoin (18 to 20 mg per kg loading dose followed by 5 to 7 mg per kg per day). Other antiepileptics, such as levetiracetam, could also be considered. Because fluid restriction is contraindicated, patients with signs of increased intracranial pressure require osmotic diuresis with mannitol. Intracranial pressure monitoring may be useful in patients with cerebral edema. Specific treatment for electrical spinal cord injuries is not available, and early institution of physical therapy is recommended. In patients with cardiac arrest, the hypothermia protocol could be considered.

Prognosis

Prognosis is difficult to ascertain for electrical injuries to the nervous system. Patients with deficits at presentation frequently recover fully, whereas those with delayed onset of neurologic deficits may have syndromes that progress over months to years.

CARBON MONOXIDE POISONING

Carbon monoxide is a colorless, tasteless, odorless gas that may give no warning of its presence. It is normally present in the atmosphere in a concentration of less than 0.001%, but a concentration of 0.1% can be lethal [29]. Carbon monoxide is found in automobile exhaust, fires, water heaters, charcoal-burning grills, methylene chloride, volcanic gas, and cigarette smoke. It is also endogenously formed from the degradation of hemoglobin, resulting in baseline carboxyhemoglobin saturation between 1% and 3% [29]. Smoking can raise the endogenous level to 6% to 7% saturation [29]. Carbon monoxide poisoning may occur in the acute and chronic setting. For further information on the pathogenesis, diagnosis, and treatment of carbon monoxide poisoning, see Chapter 64.

Diagnosis

It is important to consider carbon monoxide poisoning in the differential diagnosis of any individual who presents with an altered state of consciousness or headache, particularly in the setting of a long car ride or other exposure to poorly ventilated and incompletely combusted fuel. Of note, the carboxyhemoglobin levels are not indicative of the severity of toxicity and depend on factors such as duration of exposure, comorbid conditions, and ambient carbon monoxide concentration [30]. With mild intoxication, symptoms may include a mild headache, dyspnea on exertion, and fatigability [29]. With increasing levels of toxicity, more severe symptoms may include impaired motor dexterity, blurry vision, irritability, weakness, nausea, vomiting, and confusion [29]. At its most severe, carbon monoxide exposure may cause tachycardia, cardiac irritability, seizures, respiratory insufficiency, coma, and death [29]. In addition, there can be evidence of rhabdomyolysis, flame-shaped superficial retinal hemorrhages, and, occasionally, a cherry-red discoloration best appreciated in the lips, mucous membranes, and skin [29,31].

Furthermore, carboxyhemoglobin levels do not correlate well with the development of delayed neurologic sequelae [32]. In mild carbon monoxide intoxication, in which there is no loss of consciousness and carboxyhemoglobin levels are less than 5% in nonsmokers or less than 10% in smokers, only headache and dizziness at or before presentation were found to correlate with an increased incidence of delayed sequelae, including asthenia, headache, or decreased memory [33].

A head CT scan may be normal early on or show signs of cerebral edema as inferred from narrowed ventricles and effacement of the cerebral sulci. The degree of CT abnormalities does not predict the clinical course [34]. MRI findings may reveal diffuse, confluent diffusion-weighted imaging (DWI), fluid-attenuated inversion recovery, and T_2 (time for

63% of transverse relaxation) hyperintensities bilaterally in the periventricular white matter, centrum semiovale [35,36], basal ganglia, particularly involving the globus pallidus, and the hippocampus [37]. The electroencephalogram usually demonstrates diffuse slowing but is generally of little prognostic value.

Treatment

The criteria for hospital admission include coma, loss of consciousness, or neurologic deficit at any time; any clinical or electrocardiographic signs of cardiac compromise; metabolic acidosis; abnormal chest radiograph; oxygen tension less than 60 mm Hg; and carboxyhemoglobin level greater than 10% in individuals with pregnancy, greater than 15% in those with cardiac disease, or greater than 25% in all other patients [31].

All patients should be treated with 100% oxygen as soon as the diagnosis of carbon monoxide poisoning is even considered. It should be administered through a tight-fitting nonrebreathing mask or after endotracheal intubation in severely sensorium-compromised patients. The administration of 100% oxygen can shorten the half-life of carbon monoxide from 4 to 5 hours to approximately 1 hour [30]. Oxygen should be administered until the carboxyhemoglobin level normalizes [29]. (See Chapters 62 and 64 for a discussion of hyperbaric oxygen therapy.)

Administering 100% oxygen and possibly hyperbaric oxygen therapy are also useful in treating acute cerebral edema, as is mechanical hyperventilation and maintaining fluid and electrolyte homeostasis. Steroids have not been effective in cerebral postanoxic states and may increase the risk of oxygen toxicity seizures if hyperbaric oxygen therapy is being considered [31].

Course

The delayed appearance of neurologic sequelae found in many posthypoxic states occurs with particular frequency and severity after carbon monoxide poisoning. Up to 30% of patients may succumb to the initial exposure and 25% may develop a progressive encephalopathy resulting in a persistent vegetative state, with a 50% mortality rate [34]. Later sequelae may include seizures, cortical blindness, scotomas, Korsakoff's psychosis, irritability, hemiplegia, chorea, and peripheral neuropathy.

Between 10% and 30% of patients develop delayed neurologic sequelae, and there are no guidelines to indicate which patients are at greatest risk [31]. Although there seems to be a rough correlation between duration of initial unconsciousness and increasing age with the development of delayed neurologic sequelae, even patients with mild toxicity can progress to develop the tardive signs [30]. The post–carbon monoxide syndrome begins 7 to 30 days after the initial insult and is characterized by gait disturbances, incontinence, and memory impairment, as well as signs of parkinsonism, mutism, and frontal lobe disinhibition [29,30,38]. The development of isolated cognitive impairment has considerable variability in the literature. Some report memory dysfunction, impaired attention, and affective disorders in moderate to severe carbon monoxide exposure, while other studies suggest that mildly exposed individuals have no cognitive impairments compared to matched controls in neuropsychiatric testing [30,39,40].

On average, 75% of affected individuals largely recover within a year of the insult, although 20% of these individuals continue to show evidence of mild to moderate impairment of memory and extrapyramidal function [41]. Although the specific cause of the delayed syndrome is unknown, it does correlate temporally with the pathologic findings of cerebral white matter demyelination found in the chronic stages of the illness as opposed to the largely gray matter edema, ischemia, and hemorrhagic necrosis found in the acute stage [42]. There is no specific treatment for the delayed neuropsychiatric syndrome, although symptomatic treatment, including cognitive therapies and dopamine agonists, may be of benefit in the short term [41].

DECOMPRESSION SICKNESS

Decompression sickness ("the bends") occurs when gases dissolved in body fluids come out of solution, forming bubbles in tissues and venous blood. Situations in which decompression sickness arises include rapid ascent to the surface by tunnel workers or scuba divers, decompression or rapid ascent in an airplane, and high-altitude flying with inadequate cabin pressurization. In these situations, nitrogen and other inert gases that supersaturate the tissues under high pressure are released as bubbles under conditions of decreased pressure. As the bubbles coalesce, they may cause local tissue ischemia because of compression or venous obstruction. The microcirculation is further compromised by capillary endothelial edema; by activation of platelets, coagulation factors, and complement; and by hemoconcentration due to fluid extravasation [43,44]. Nitrogen, the largest component of inspired air, is lipophilic, and thus gas bubbles are more likely to form in the bone marrow, fat, and spinal cord. Additionally, gas bubbles may result in barotrauma to the pulmonary beds, releasing further air emboli into the venous circulation [43,44].

Symptoms of decompression sickness are variable. In most cases, the onset is within 6 hours of decompression, but may be seen later at 12 to 24 hours [43]. Fulminant cases present earlier. Any organ system can be affected, and symptoms range from a pruritic skin rash ("the creeps"), cough ("the chokes"), and joint pain to paraplegia, vertigo, altered level of consciousness, seizures, shock, and apnea.

Almost 80% of patients with decompression sickness have neurologic symptoms. The most frequent neurologic presentation is with paresthesias, which may be diffuse or focal, and result from gas bubble formation in the skin, joints, peripheral nerves, or spinal cord. Weakness, ranging from monoparesis to quadriplegia secondary to spinal cord involvement, may also occur. Cerebral symptoms are infrequent and range from headache and lethargy to vertigo, visual disturbances, paralysis, and unconsciousness [43,44]. Vertigo, hearing loss, tinnitus, nausea, and vomiting are relatively common complaints, resulting from rupture of the cochlear and semicircular canal membranes.

Air embolism is a more serious decompression illness, and its onset is usually within 5 minutes of decompression. It probably results from tearing of the lung parenchyma secondary to overinflation as the gases in the lungs expand during ascent [43]. The gas escapes into the pulmonary vein and may embolize into large vessels [43]. Venous gas bubbles are effectively filtered by the lungs, but arterial embolism may also result from gas passing through a patent foramen ovale. Based on their buoyancy, the emboli often produce neurologic symptoms by floating into and occluding cerebral arterioles. Unconsciousness and stupor are the most frequent symptoms. Death from cardiopulmonary arrest may also occur. In most patients, improvement in symptoms accompanies the redistribution of the gas emboli to the venous circulation [43].

Recompression is the definitive treatment for decompression diseases. The patient should be transported in a pressurized aircraft to the nearest decompression chamber with minimal delay. (See Chapter 61 for a more detailed discussion of the management and therapy for decompression syndrome.) The Divers Alert Network also maintains a 24-hour phone consultation

service to assist with diving accidents, reached at (919) 684-9111.

Remarkable recovery may occur after recompression. Delay in treatment can limit its effectiveness, but recompression should be attempted even up to 2 weeks after the onset of symptoms. Relapses requiring repeated hyperbaric treatment may occur [45]. Patients with long-term sequelae from decompression illnesses should not be re-exposed to conditions that allow their recurrence.

CEREBRAL FAT EMBOLISM SYNDROME

Fat embolism syndrome is characterized by diffuse pulmonary insufficiency with hypoxemia, neurologic dysfunction, and petechiae occurring 12 to 48 hours after trauma [46,47]. At least subclinically, fat embolism is present after all fractures involving the long bones. It is clinically recognized in 0.5% to 2% of patients with long bone fractures and in 5% to 10% of patients who have sustained multiple fractures [48,49]. There are also reports of fat embolism syndrome occurring in the setting of orthopedic procedures, such as hip arthroplasty, intramedullary rods, and leg lengthening procedures [48,50]. There is an increased risk associated with a patent foramen ovale [49].

Pathogenesis

The two main pathogenetic hypotheses of fat embolism syndrome are the mechanical and chemical theories. The mechanical theory posits that physical disruption of bone and blood vessels at the fracture site allows free fat globules to enter venous sinusoids and then to embolize to the lungs [46]. The chemical theory proposes that a trauma-induced catecholamine surge results in lipid mobilization from the fat stores or the coalescence of chylomicrons into fat globules [46,51]. The fat emboli in the circulation may then be broken down by lipases in the lungs or systemic circulation, generating free fatty acids [46,47,52]. The toxic fatty acids stimulate the release of inflammatory mediators, increasing permeability of capillaries, generating acute respiratory distress syndrome (ARDS) and cerebral vasogenic edema [46,47]. Furthermore, the inflammatory mediators may increase platelet adhesion and coagulation [52]. Fat emboli, in conjunction with increased platelet adhesion, may arrest blood flow, resulting in cerebral ischemia and hemorrhage [47,52].

Cerebral fat emboli and ischemia, rather than cerebral anoxia, produce the neurologic damage seen in this condition. The brain is edematous and shows a leptomeningeal inflammatory reaction and cortical surface petechiae. Microscopically, there are fat emboli and ball, ring, and perivascular hemorrhages. The fat emboli are more prevalent in the gray matter, but the hemorrhages are more common in the centrum semiovale, internal capsule, and cerebral and cerebellar white matter [53]. Electron microscopy reveals intravascular fat vacuoles, breakdown of endothelial walls, swollen neurons, and glia [53].

Diagnosis

Characteristically, there is a symptom-free interval of 12 to 48 hours between the inciting trauma and the onset of fat embolism syndrome [46]. Altered consciousness or development of neurological deficits after a lucid interval following trauma should alert the physician to the possibility of fat embolism. The syndrome may present as a spectrum of disability, from subclinical presentations with only a decreased arterial partial pressure of oxygen (PaO_2), decreased platelets or hemoglobin, to a fulminant presentation. Gurd's diagnostic criteria for fat embolism syndrome include one or more major criteria (respiratory insufficiency, neurologic dysfunction, or petechial rash), four or more minor criteria (fever, tachycardia, retinal changes, jaundice, or renal changes), and one or more laboratory criteria (fat macroglobulinemia, decreased hemoglobin or platelets, or increased erythrocyte sedimentation rate) [47]. An alternative diagnostic scheme was proposed by Schonfeld [47], assigning a numerical score to similar criteria with a score of 5 or more suggestive of the diagnosis.

Sudden onset of fever, tachycardia, and tachypnea often herald onset of the syndrome. Respiratory distress and hypoxemia with an oxygen tension less than 60 mm Hg is common and may be the initial or only laboratory abnormality. The chest radiograph may be unremarkable in one-half of the cases, but fine stippling or hazy infiltrates of both lung fields should be sought as they are consistent with fat embolism syndrome [51].

Petechiae are present in 50% to 60% of clinically recognized cases and are most often found on the lower palpebral conjunctivae, neck, anterior axillary folds, and anterior chest wall [47]. There is an associated thrombocytopenia, believed to be caused by the consumption of platelets with their aggregation around the embolic fat droplets, and a progressive anemia with hemoglobin levels commonly less than 9.5 g per 100 mL [51]. Retinal fat emboli and lipuria are each in evidence in more than 50% of patients [51]. The retinal emboli appear as small rosaries of microinfarcts surrounding the macula of both eyes, which over the course of the following 10 to 14 days evolve into yellowish, fatty plaques [51].

The CNS manifestations range from confusion to coma, and although they almost always accompany respiratory insufficiency, they can be the initial and sometimes only symptomatic manifestation of fat embolism syndrome [47]. Impaired consciousness is the earliest recognizable sign. The symptoms can begin with restlessness and confusion and may evolve gradually or abruptly to stupor and coma. Coma, especially if it develops abruptly, portends a poor prognosis [46]. Focal or generalized seizures can occur and may antedate the onset of coma [47]. Decerebrate rigidity is found in up to 15% of cases, and pyramidal signs of hyperreflexia and extensor plantar responses are found in 30% to 70%. Focal neurologic signs, such as aphasia and hemiparesis, are usually restricted to patients with more severe disturbances of consciousness [47].

Neuroimaging of cerebral fat embolism syndrome reveals diffuse vasogenic and cytotoxic edema, as well as areas of hemorrhage and infarct. The most common finding on head CT is evidence of diffuse brain edema, as shown by small ventricles and flattened sulci [54]. Brain MRI performed within 48 hours of a neurologic change may reveal signs of cerebral fat embolism syndrome even earlier than CT. The DWI sequence can exhibit a "starfield" appearance, with dot-like hyperintensities, both patchy and confluent, in border zone areas of territorial gray matter, deep white matter, and basal ganglia [54]. The DWI changes are suggestive of cytotoxic edema. Later, T_2 hyperintensities appear as small subcortical foci in gray and white matter, indicative of vasogenic edema; an increased number of T_2-weighted hyperintensities correlates with a decreased Glasgow Coma Scale [55]. These T_2-weighted hyperintensities disappear with resolution of the neurologic symptoms [56]. The later MRI appearance of brain atrophy and residual multiple infarcts may be present, particularly in patients with a poorer outcome.

Treatment

Rapid immobilization of fractures and their early definitive management decreases the likelihood of fat embolism syndrome [51]. Sequential clinical examinations, chest

radiographs, and arterial blood gas determinations in patients believed to be at high risk may help identify early on those needing more aggressive care. These patients should have early and expedient replacement of fluids and blood and administration of 40% oxygen by mask [51].

The support of respiration and maintenance of arterial oxygen levels greater than 70 mm Hg sometimes requires intubation and mechanical ventilation. Placement of a central venous pressure line is useful in monitoring the patient for shock. Steroids have been advocated as treatment to blunt the inflammatory response, to help preserve vascular integrity, and to minimize interstitial edema formation, but there are as yet no controlled trials demonstrating a consistent benefit. A brain CT or MRI is indicated to assess whether there are any direct cerebral traumatic injuries accounting for neurologic symptoms.

Prognosis

Mortality in fat embolism syndrome can reach 10% to 20%, but recent improvements in management have lessened this rate [57]. Twenty-five percent of patients experience permanent neurologic deficits [53]. A favorable prognosis is more likely with normal muscle tone, active deep tendon reflexes, and retention of appropriate pain response [47]. If patients survive the pulmonary insufficiency, neurologic dysfunction is typically reversible [47]. A worse prognosis is portended by coma, severe ARDS, pneumonia, or congestive heart failure [46].

SINGULTUS (HICCUPS)

Hiccups are usually a benign and self-limited condition. Prolonged hiccups can produce fatigue, sleeplessness, weight loss, depression, difficulty in ventilation, and, in postoperative patients, wound dehiscence [58–60]. In intubated patients, persistent hiccups may result in hyperventilation, leading to a respiratory alkalosis [58].

Pathophysiology

Hiccups result from a sudden reflex contraction of the diaphragm, causing forceful inspiration, which is arrested almost immediately by glottic closure, producing the characteristic sound. Afferent pathways include the vagus and phrenic nerves and thoracic sympathetic fibers (T_6 to T_{12}). The efferent pathway includes the phrenic nerve to the diaphragm, the vagus nerve to the larynx, and the spinal nerves to the accessory muscles of inspiration. Although central control of this reflex is not well defined, it probably involves lower brainstem and upper cervical spinal levels, including the respiratory center, phrenic nerve nuclei, medullary reticular formation, and hypothalamus [61].

Etiology

Hiccups may result from a multitude of causes, due to injury or irritation of the afferent or efferent pathways or disease within the central control mechanism. Hiccups most frequently result from irritation of the stomach wall or diaphragm, leading to impulses along the phrenic and vagus nerves. Abdominal disorders causing hiccups include gastric ulceration, gastric distention, gastroesophageal reflux, hiatus hernia, cholecystitis, peritonitis, subdiaphragmatic abscess, ileus, and bowel obstruction. Thoracic disorders that precipitate hiccups include esophagitis, pericarditis, myocardial infarction, pneumonia, and neoplasm. More proximally along the course of the nerves, neck masses, such as neoplasm and goiter, may also result in hiccups. Brainstem neoplasm or ischemia, multiple sclerosis, arteriovenous malformations, and meningoencephalitis are CNS causes. Perioperative causes include neck extension, intubation, visceral traction, and intraoperative manipulation of efferent or afferent nerves [58]. Metabolic disorders, such as uremia, electrolyte abnormalities, alcohol intoxication, diabetes mellitus, and general anesthesia, have also been implicated [58,61]. Medications, most frequently corticosteroids and benzodiazepines, may also induce hiccups [62,63]. Recently, hiccups have been reported in four patients with Parkinson's disease, and dopamine agonists appeared to play a causative role [64,65]. Some patients have idiopathic or psychogenic hiccups.

Evaluation

A history of gastrointestinal, cardiac, pulmonary, or CNS complaints or surgery may assist in determining the etiology of intractable hiccups. The physical examination should rule out inflammation or neoplasm in the thorax, abdomen, CNS, and neck. Chest and abdominal radiographs are obtained routinely, and fluoroscopic evaluation of the diaphragm is sometimes needed. Radiographic or endoscopic evaluation of the gastrointestinal tract is sometimes warranted. If the CNS is implicated, cranial CT or MRI may be useful. Electrocardiography is required. Other investigations include determinations of electrolytes, renal function, glucose, creatine kinase (if myocardial infarction is suspected), and a toxicology screen for alcohol and barbiturates. Lumbar puncture is required if there is a suspicion of CNS infection. Electromyography may be useful if surgical therapy for hiccups is contemplated. Careful review of medications for potential causative agents is indicated.

Management

Initial management includes identification and treatment of disorders that may cause hiccups, such as inflammation, infection, or gastric dilatation. When this is unsuccessful, nonpharmacologic and pharmacologic treatments are available for intractable hiccups.

Nonpharmacologic therapies alter the reflex arc responsible for hiccups. Pharyngeal stimulation may resolve hiccups, either by nasogastric intubation, swallowing dry granulated sugar, or by the introduction of a red rubber catheter through the mouth or nares, followed by a jerky to-and-fro movement [58]. Pharyngeal stimulation tends to be a temporary measure. Counterstimulation of the vagus nerve by pressure on eyeballs, rectal massage, or irritating the tympanic membrane may also alleviate hiccups [61]. Breathing into a paper bag, gasping with fright, Valsalva maneuver, and supramaximal inspiration possibly abolish hiccups by interrupting the stimulus for respiration or increasing the carbon dioxide concentration [66]. Case reports of acupuncture therapy also document effectiveness for refractory hiccups [59].

If nonpharmacologic therapies are ineffective, drug therapy should be initiated. Baclofen 5 mg orally three times a day, increased to 10 mg three times a day, has been effective in decreasing and potentially eliminating hiccups [61]. Alternatively, chlorpromazine taken 25 to 50 mg orally or intramuscularly three or four times a day has also been effective. If this is ineffective in 2 to 3 days, then a slow intravenous infusion of chlorpromazine 25 to 50 mg in 500 to 1,000 mL of normal saline is indicated. Although hypotension may result from intravenous (IV) administration, chlorpromazine may be most effective by this route [67]. If IV chlorpromazine is ineffective, it should be discontinued and 10 mg of metoclopramide given orally four times per day. Other medications used in refractory

patients include haloperidol (5 mg three times per day), anticonvulsants (e.g., gabapentin, phenytoin, carbamazepine, and valproic acid), amitriptyline, nifedipine, nimodipine, and amantadine [67].

Most patients respond to mechanical or drug therapy. In refractory cases, transcutaneous stimulation of the phrenic nerve, transesophageal diaphragmatic pacing, vagus nerve stimulation, phrenic nerve block or ablation, or microvascular decompression of the vagus nerve may be useful [60,67–70]. Because there are multiple efferent pathways involved, hiccups may remain even after phrenic nerve ablation.

COMPRESSION NEUROPATHIES

Compression neuropathies are common in the general population. In the ICU population, several nerves are particularly at risk, compression of which may result in delayed morbidity. The ulnar nerve may be compressed in the condylar groove posterior to the medial epicondyle when the arms are positioned in a flexed, pronated, or semipronated fashion, or when the flexed elbows are used by the patient for repositioning. Ulnar nerve palsy causes weakness of the intrinsic muscles of the hand and numbness of the fourth and fifth fingers. The peroneal nerve is also at risk where it courses around the fibular head. The everted immobile position of the leg in severely weak or paralyzed patients contributes to its vulnerability. Other compression neuropathies and brachial plexopathy may result from positions assumed during prolonged coma before hospitalization. Hematomas resulting from clotting disorders, anticoagulation, local injection, arterial puncture, or phlebotomy may also compress the peripheral nerves and plexi. Evaluation of compression neuropathies includes an EMG to localize the lesion. Proper positioning of the limbs to avoid compression of these nerves between the bed and bony prominences is key to prevention.

CHAPTER 178 ■ SUBARACHNOID HEMORRHAGE

WILEY HALL, MAJAZ MOONIS AND JOHN P. WEAVER

Intracranial hemorrhage after rupture of saccular aneurysms accounts for 6% to 8% of all strokes affecting young adults. Intracranial aneurysms are found in approximately 5% of the population at autopsy and rupture at a rate of 4 to 10 per 100,000 population per year, with a 25% mortality during the first 24 hours [1]. Current mortality rates vary between 35% and 50%. Up to 30% die within the first 2 weeks, and 45% die within 30 days after the initial event. Fifty percent of the survivors are left with significant neurologic impairment [2–4]. As a rule, intensive care medical and surgical interventions are necessary in the management of these cases [5,6].

Subarachnoid hemorrhage (SAH) represents a potentially highly treatable form of stroke. Presently, the usual care of an aneurysmal SAH patient includes early aneurysm repair to limit rebleeding, a calcium channel antagonist to ameliorate cerebral injury secondary to vasospasm, intravascular volume maintenance to address any blood volume deficit, and some form of hemodynamic manipulation. Improvements in functional outcome are due to early intervention, supportive intensive care management, and modern methods of treatment, including cerebral protection, interventional neuroradiology, cerebrospinal fluid (CSF) manipulation, and hemodynamic management [5,6].

PATHOGENESIS

Saccular, or berry, aneurysms must be distinguished from other types of intracerebral aneurysms such as traumatic, dissecting, mycotic, and tumor-related aneurysms. Saccular aneurysms lack the normal muscular media and elastic lamina layers [7]. Eighty-five percent of saccular aneurysms are located in the anterior circulation; 15% are in the posterior circulation [8]. Common sites for aneurysms are at the junction of the anterior cerebral and anterior communicating arteries, the origin of the posterior communicating artery, the middle cerebral artery trifurcation, and at the top of the basilar artery. Less common are those located at the cavernous carotid, the internal carotid bifurcation, the distal anterior cerebral, and the proximal basilar arteries. Twelve percent to 31% of patients have multiple aneurysms. Nine percent to 19% have aneurysms located at identical sites bilaterally (mirror aneurysms), and multiple aneurysms may occur within families [9]. Systemic diseases such as polycystic kidney, Marfan's syndrome, Ehlers–Danlos syndrome, pseudoxanthoma elasticum, fibromuscular dysplasia, and coarctation of the aorta are associated with an increased incidence of intracerebral aneurysms [10,11].

It is unclear at present whether aneurysms have a congenital/hereditary origin or result from subsequent degenerative mechanisms. Supporting a congenital theory for aneurysm occurrence, individuals with a single primary relative with an intracranial aneurysm are at a 1.8 fold increased risk of intracranial aneurysm; those with two primary relatives have a 4.2 fold increased risk. Supporting the degenerative theory, there is an increased incidence of intracranial aneurysms in patients with hypertension, cigarette abuse, and alcohol abuse, and in the majority of cases, a family history of aneurysms is absent [11–14].

Risk of Rupture in Unruptured Intracranial Aneurysms

Ideally, the goal of treatment would be to prevent SAH, which carries a high mortality and morbidity. With increasing

use of magnetic resonance angiography (MRA) and high-resolution computed tomography angiography (CTA), incidental or asymptomatic small aneurysms are increasingly recognized before rupture. It is important to estimate the risk of aneurysmal rupture in these cases, which depends on critical size, location, or morphology of the aneurysm itself.

Data from a large, multicenter, prospective study—the International Study of Unruptured Intracranial Aneurysms [15]—suggests that the critical size associated with increased risk of rupture is 10 mm. Patients with unruptured intracranial aneurysms who have not had a prior SAH have a lower risk of aneurysmal rupture than with those in whom another aneurysm has previously ruptured. The annual risk of rupture of unruptured intracranial aneurysms smaller than 10 mm in patients with no previous SAH is 0.05% per year, compared with 0.5% per year in those with a prior SAH. In addition to size, aneurysm location was also predictive of subsequent rupture. Basilar tip aneurysms had the highest risk of rupture [15].

Data from the International Study of Unruptured Intracranial Aneurysms study conflicts with the experience at many centers that the majority of SAHs are attributable to aneurysms less than 10 mm. A smaller study [16] prospectively examining 118 consecutive patients with intracranial aneurysms found that, of 83 ruptured aneurysms, 81.9% and 59% were under 10 and 7 mm, respectively. Mean height and width were 6.7 and 6.1 mm. Seventy-two unruptured aneurysms were found to have similar size distributions, and mean height and width were 5.7 mm. The lack of conclusive evidence regarding prevalence of unruptured intracranial aneurysms in the general population and the absence of a screening tool that is sensitive, cost-effective, and safe enough makes optimal management of unruptured intracranial aneurysms a continuing challenge.

SYMPTOMS

The signs and symptoms of intracranial aneurysms result from their expansion or rupture. Aneurysmal expansion can lead to localized headache, facial pain, pupillary dilatation and ptosis from oculomotor nerve compression, and visual field defects from optic nerve or chiasm compression. Warning leak or "sentinel" hemorrhage occurs in approximately 20% of patients and is characterized by nuchal rigidity or meningismus that usually lasts at least 48 hours. The event is misdiagnosed in 20% to 40% as muscular-tension headache, migraine, sinusitis, viral syndrome, aseptic meningitis, or malingering [17]. Evidence of aneurysmal expansion or warning leak must be regarded with a high index of suspicion because such events precede major hemorrhage. Neurologic and functional outcomes are greatly improved if the patient is treated while neurologically intact before hemorrhage [18].

Aneurysmal rupture typically produces severe headache which is maximal at onset and is associated with neck pain, nausea, vomiting, photophobia, and lethargy. At the time of rupture, patients may lose consciousness and may demonstrate abducens nerve palsy, subhyaloid hemorrhages, or papilledema, reflecting the acute rise in intracranial pressure (ICP) that may transiently equal mean arterial pressure [19]. Other focal symptoms may also develop. Early seizures after SAH (8% to 11%) reflect a rise in ICP and are not indicative of the site or severity of rupture [20,21].

CLINICAL GRADING AND PROGNOSIS

The clinical grading scale developed by Hunt and Hess [22] is useful in estimating the patient's prognosis (Table 178.1). Grades I and II at presentation have a relatively good prognosis, whereas grades IV and V have a poor prognosis, and grade III an intermediate prognosis. The Glasgow Coma Scale is also useful in predicting outcome after early surgical intervention [23].

TABLE 178.1

HUNT AND HESS GRADING SCALE[a]

Grade	Symptoms
I	Asymptomatic or minimal headache and slight nuchal rigidity
II	Moderate-to-severe headache, nuchal rigidity, no neurologic deficit other than cranial nerve palsy
III	Drowsiness, confusion, or mild focal deficit
IV	Stupor, moderate-to-severe hemiparesis, possibly early decerebrate rigidity, and vegetative disturbances
V	Deep coma, decerebrate rigidity, moribund appearance

[a]Serious systemic diseases, such as hypertension, diabetes, severe arteriosclerosis, chronic obstructive pulmonary disease, and severe vasospasm, result in placement of the patient in the next less-favorable category.

DIAGNOSTIC EVALUATION

If SAH is suspected, an urgent noncontrast head CT should be obtained to identify, localize, and quantify the hemorrhage. CT imaging is 98% to 100% sensitive in the first 12 hours after SAH, declining to under 85% sensitive 6 days following a hemorrhage [6]. A lumbar puncture is indicated if the CT is nondiagnostic. CT scan may be negative in up to 35% of patients with sentinel leaks [24]. CT angiography (CTA) is the preferred study in the emergent surgical setting, and is often used when the presence of a large parenchymal clot makes delay for conventional arteriography unacceptable. CTA uses a contrast-enhanced high-speed spiral (helical) CT performed with reconstruction of the axially acquired data into angiographic images. CTA can demonstrate aneurysms of 2- to 3-mm size with sensitivities of 77% to 97% and specificities of 87% to 100% [25,26].

Traumatic lumbar puncture and SAH are distinguished by xanthochromia, demonstrated by spectrophotometric analysis of a centrifuged sample of the CSF [27]. Cell counts remain uniform in all tubes of CSF in a true SAH, and blood clots do not form. The CSF protein is usually elevated and glucose may be very slightly reduced. Opening pressure at the time of lumbar puncture may reflect the elevation of ICP.

Four-vessel cerebral angiography is necessary to localize the aneurysm, define the vascular anatomy, and assess vasospasm and the possible presence of multiple aneurysms. It should be performed within 24 hours after initial hemorrhage. If angiography does not reveal an aneurysm, magnetic resonance imaging and angiography can be performed to reveal aneurysms larger than 3 mm. If these studies are also negative, angiography is repeated in 1 to 3 weeks because acutely, intraluminal thrombus and vasospasm can interfere with angiographic visualization of aneurysms [6,28,29].

GENERAL MEDICAL MANAGEMENT

Complications of SAH are fatal in 25% of cases [15,27]. General preoperative medical management should include provisions for quiet bed rest, head elevation to improve cerebral

venous return, good pulmonary toilet to avoid atelectasis and pneumonia, and prophylaxis against thrombophlebitis with pneumatic boots. Patients should receive stool softeners. Nausea and vomiting can be controlled with antiemetics. Pain control is best accomplished with agents such as morphine or fentanyl. Mean arterial pressures higher than 100 mm Hg should be lowered gently until repair of the aneurysm can be achieved, but agents that can depress consciousness such as α-methyldopa should be avoided. Blood pressure is managed with beta-blocking agents; these agents may also reduce the risks of cardiac arrhythmias.

After SAH there may be a salt-wasting diuresis. Suggested mechanisms include an increase in circulating atrial natriuretic peptide. This syndrome is distinguished from the syndrome of inappropriate antidiuretic hormone by urine output and urine chemistry; both may result in hyponatremia. Accordingly, fluid input and output must be followed closely along with serum electrolytes and osmolality.

Seizures have been reported to occur in up to 18% of patients with SAH at onset, and are less common in hospitalized patients, recently reported at 4% [30]. The need for prophylactic anticonvulsants is controversial, and phenytoin remains the most common anticonvulsant used, though recent studies suggest a worse cognitive outcome with its use [31]. Levetiracetam is sometimes substituted if hepatic enzymes rise or suspected drug fever occurs, but data on its efficacy in this setting is as yet unavailable.

Elevation of ICP must be treated promptly with an agent such as mannitol. The use of dexamethasone for cerebral edema is restricted to patients with postoperative edema due to retractor manipulation, and is used to blunt headache caused by meningeal irritation; it has been reported anecdotally to shorten the course of hydrocephalus after SAH as well.

CARDIAC FUNCTION AFTER SUBARACHNOID HEMORRHAGE

Cardiac dysrhythmias may complicate care following SAH; a variety of mechanisms have been proposed. Increased levels of circulating catecholamines influence the α-receptors of the myocardium and can result in prolonged myofibril contraction, eventually causing myofibrillar degeneration and necrosis. An alternative theory of myocardial injury suggests that coronary artery spasm is the mechanism for the myocytolysis. SAH is the most frequent neurologic cause for electrocardiographic changes, which include large upright T waves and prolonged QT intervals (on average, approximately 0.53 seconds). In addition, prominent U waves, inverted T waves, and minor elevation or depression of the ST segment can occur. Despite ST-T changes, the incidence of myocardial ischemia remains low [32,33]. Pathologic Q waves are not common in SAH and suggest the need for further investigations for myocardial infarction. Patients with coronary artery vasospasm have a worse prognosis [34]. Arrhythmias are very common: a prospective study of 120 patients performed by using Holter monitoring indicated a 90% incidence of ventricular and supraventricular arrhythmias in the first 48 hours of hospitalization [35]. These do not appear to account for significant mortality.

NEUROLOGIC COMPLICATIONS

Aneurysmal rebleeding, hydrocephalus, and cerebral vasospasm with ischemia are the three major neurologic complications after SAH.

Rebleeding is a serious and frequent neurologic complication of SAH, carrying a mortality rate from 50% to 70% [5,6,9]. The peak incidence of rebleeding occurs during the first day after SAH, and a secondary peak occurs 1 week later. The rerupture risk for an untreated ruptured aneurysm is 23% at 2 weeks, 35% to 42% at 4 weeks, and 50% within 6 months [29]. Clinically, patients suffer with increasing headache, nausea, vomiting, depressed level of consciousness, and the appearance of new neurologic deficits. Occasionally, seizures occur, but they have not been shown to be a cause of rebleeding. Attempts to prevent rebleeding by drug-induced hypotension and bed rest have not been successful [36]. Antifibrinolytics decrease the rate of rebleeding, but older studies associate their use with increased incidence of ischemic insults from vasospasm [37,38]. Modern approaches including early aneurysm repair and intravascular therapy for vasospasm may ameliorate these issues, but antifibrinolytics are not strongly recommended [6].

Hydrocephalus can develop acutely within the first few hours after SAH because of impaired CSF resorption at the arachnoid granulations or intraventricular blood causing obstruction of CSF outflow. Clinically significant hydrocephalus developing subacutely over a few days or weeks after SAH is manifested by the loss of vertical gaze and progressive lethargy. Patients may appear to be abulic. Ventricular CSF drainage may be indicated if the clinical neurologic examination deteriorates or for any obtunded patient with hydrocephalus. CSF drainage is limited in patients with unprotected aneurysms because there is a danger of rerupture associated with abrupt decreases in ICP. A delayed form of hydrocephalus manifested by cognitive changes and gait disorders may be observed several weeks after the SAH; in these cases, a ventriculoperitoneal shunt may be indicated [5].

Stroke due to vasospasm is a major cause of morbidity and mortality in the postoperative period. Several controlled studies have shown an important role for the calcium antagonist nimodipine in ameliorating neurologic deficits caused by vasospasm. Beneficial effects are probably related to calcium channel–blocking properties, interfering with steps in the ischemic cascade [39–41]. The neurologic outcome and mortality rates of SAH patients prophylactically treated with nimodipine are improved 25% to 50% over control subjects. Fewer infarcts are noted in these patients, although there is no difference in the incidence or extent of arteriographic vasospasm [42–44]. The only adverse effect is mild transient hypotension. Current recommendations are to administer 60 mg of nimodipine orally every 4 hours for a 21-day course beginning at the onset of SAH.

ANEURYSM REPAIR

After acute angiography, patients should undergo aneurysm repair as soon as possible [44–46]. Many centers delay repair in patients who present overnight until the following day to allow approach by a well-rested team. Hemorrhages associated with large parenchymal clots are approached urgently. Delays of longer than 1 to 2 days are no longer common.

Aneurysms may be excluded from the systemic circulation by open surgical or endovascular approach. Open surgery offers definitive repair under direct visualization. The potential benefit of decreased hemorrhage burden in the subarachnoid space following irrigation has been suggested as a means to decrease vasospasm incidence, but this has not been well studied. Endovascular repair offers a less invasive approach, allowing obliteration of aneurysms which may be inaccessiuble to open surgery. Endovascular repair may also be of advantage in higher grade hemorrhages where cerebral edema complicates craniotomy, or in cases where late presentation or diagnosis increases the risk of open surgery. The choice of repair modality is best decided by a team approach combining experts from both interventional neuroradiology and vascular neurosurgery.

SURGICAL MANAGEMENT

Current surgical management necessitates craniotomy for clip occlusion of the aneurysmal neck, using mild systemic intraoperative hypotension, temporary proximal occlusion, and microsurgical techniques [47–49]. Unique problems that dictate the use of specialized techniques include vertebral-basilar system aneurysms, giant aneurysms (greater than 25 mm), and multiple aneurysms. Moreover, some giant aneurysms can be isolated from the intracerebral circulation with an antecedent arterial bypass from the superficial temporal artery, or saphenous vein graft from the cervical or petrous carotid artery. Internal carotid proximal occlusion may still be an effective way to reduce intra-aneurysmal pressure and reduce the occurrence of subsequent hemorrhage in certain aneurysms, but endovascular techniques have mostly replaced surgery to accomplish this treatment.

Postsurgical arteriograms are obtained by most neurosurgeons to assess successful clip placement or to diagnose vasospasm. The availability of portable digital angiography has made the possibility of intraoperative angiography quite practical. Barrow et al. [50] reported a series of 115 procedures with intraoperative arteriography in which 19 studies resulted in an altered surgical plan, presumably saving reoperation. Selection criteria currently rely on the operative difficulty of clip placement, visualization of clip placement, and surgical judgment.

HYPOTHERMIA AND INTRAOPERATIVE CEREBRAL PROTECTION

Hypothermia is a well-known cytoprotective strategy used in cardiac surgery. Animal investigation has demonstrated that a moderate decrease in brain temperature is associated with decreased concentrations of tissue neurotransmitters that might otherwise promote cascades of secondary neuronal and vascular injuries. In addition, the cerebral metabolic rate of oxygen uptake decreases as temperature falls; below 28°C cerebral electrical activity is minimal. While moderate hypothermia (31°C to 34°C) is commonly used as an adjunct to pharmacologic methods for neuroprotection during routine aneurysm surgeries [51,52], larger trials failed to detect an impact on outcome [53].

Deep hypothermia (22°C to 18°C) under barbiturate anesthesia with a short (10- to 15-minute) circulatory arrest is used rarely for reconstruction of giant aneurysms [54]. Previous bleeding disorders, predisposition to hemorrhage, and prior cardiopulmonary disease are all relative contraindications to deep hypothermia; this remains a high-morbidity procedure with fewer than 50% of patients achieving a good outcome. Reported complications include postoperative hemorrhage, deep vein thrombophlebitis, and pulmonary embolism.

INTERVENTIONAL NEURORADIOLOGY

The development of endovascular techniques has allowed increasingly safe and precise access to the cerebral vasculature. Endovascular balloon occlusion, coil technologies, angioplasty, and intraoperative arteriographic definition of vascular reconstruction represent technical advances that have improved outcomes. Endovascular therapy may be used to treat aneurysms by occlusion of the parent artery or by selective occlusion of the aneurysm.

The technique of endovascular balloon occlusion allows the fluoroscopically directed placement of a detachable silicone occlusive balloon within the aneurysmal sac [55]. In recent years, the devices have been abandoned for direct treatment of saccular aneurysms because of complications, including rupture, embolic events, and incomplete aneurysm obliteration. They are used, however, for the treatment of cavernous carotid fistula resulting from a ruptured aneurysm of the intracavernous carotid, and for parent artery occlusion. Temporary occlusion with neurologic monitoring of the patient's condition, electroencephalogram, cerebral blood flow (CBF), and transcranial Doppler (TCD) measurements are used before permanent proximal occlusion.

The most common endovascular approach to aneurysm occlusion is achieved by placing detachable platinum-alloy microcoils into the aneurysm sac. A low positive direct electric current transmitted through the guidewire detaches the coil from the stainless steel microcatheter by electrolysis and promotes intra-aneurysmal electrothrombosis by the attraction of local blood components. Clinical reports demonstrate a relatively high success rate for aneurysm obliteration and lower morbidity and mortality than balloon or free-coil embolization [56–58]. Advanced endovascular techniques, including stent-assisted coiling, balloon remodeling, and multicatheter techniques, allow aneurysms of various morphologies to be treated [59,60].

The International Subarachnoid Aneurysm Trial presented level I evidence supporting endovascular repair of ruptured aneurysms over surgical approach in most patients. The trial reported a 30.9% death or dependency rate in patients undergoing surgical repair, compared with 23.5% in those treated via endovascular approach. Higher rebleed rates at 1 and 4 years in the endovascular group did not offset the improvement in functional outcome [61,62]. The International Subarachnoid Aneurysm Trial was limited by a paucity of posterior circulation aneurysms, possibly because of evolving belief that these aneurysms are better approached via an endovascular approach and thus a perceived lack of clinical equipoise. Aneurysms with ratios of neck size to dome size greater than 0.5 and those with arterial branches arising from their domes or bases may be best treated surgically in most centers due to limitations in endovascular techniques.

POSTOPERATIVE MANAGEMENT

Care following repair of the ruptured aneurysm centers on limiting sequelae of SAH. Patients are monitored in the intensive care unit for evidence of vasospasm and hydrocephalus. Meticulous care to avoid pneumonia, deep venous thrombosis, and skin breakdown are mandatory. Nimodipine is continued for 21 days after hemorrhage [44]. Hypertensive, hypervolemic, hemodilution ("triple-H" or HHT) therapy has not been shown to prevent vasospasm, but is utilized when vasospasm is present to prevent infarction [44,63,64]. Maintenance of hematocrit above 30% is common, but evidence supporting its necessity in patients without evidence of coronary ischemia is lacking.

Cerebral vasospasm is a major cause of morbidity and mortality in patients recovering from SAH. Although noted angiographically in more than 70% of patients, it causes clinically evident symptoms due to cerebral ischemia in only 36% [65]. This difference probably reflects the adequacy of collateral circulation in the individual patient and the degree of vessel narrowing. Unlike rebleeding, the clinical presentation of vasospasm occurs progressively over a period of hours to days. It is rarely seen before the third day after hemorrhage, with a peak between days 4 to 12, and may rarely occur as long as 3 weeks after SAH [5,6]. The neurologic deficits are correlated with the areas of brain supplied by the narrowed arteries. Vasospasm is identified by angiography and noninvasively by TCD techniques.

TCD techniques are now widely used at most cerebrovascular centers. This simple bedside test is sensitive to the onset of cerebral vasospasm as arterial blood flow velocity increases with progressive vessel narrowing. Because the middle cerebral artery has little collateral circulation, diagnosis of vasospasm by TCD measurements is best validated in this vascular territory; TCD has an overall sensitivity of 68% to 94%, specificity of 86% to 100%, positive predictive value of 57% to 95%, and negative predictive value of 80% to 90% [66]. Fewer studies have documented sensitivity of TCD diagnosis for posterior circulation vasospasm [67]. This sensitivity is clinically useful because an elevated blood flow velocity is often detected before the occurrence of ischemic complications of vasospasm. More aggressive treatment aimed to increase cerebral perfusion pressure and improve circulation rheology can be instituted before the onset of neurologic impairment. Use of TCD for large groups of patients has allowed daily charting of the velocity changes that occur with the vasospasm syndrome. The time course of vasospasm onset and duration makes TCD a good tool to stratify patients into risk groups [68].

The amount of blood in the subarachnoid space and its location may predict the degree and location of delayed cerebral ischemic events. In theory, the pathogenesis of spasm is related to products of local erythrocyte breakdown that may be spasmogenic. Potential inducers of spasm include oxyhemoglobin, angiotensin, histamine, serotonin, prostaglandin, and catecholamines [4]. Vasospasm may occur because of endothelial structural changes caused by an inflammatory response, depression of vessel wall respiration, or damage from prolonged active arterial wall contraction. Other theories include impairment of normal vasodilatation, the mechanical effects of arterial compression by clot, and development of a proliferative vasculopathy. Pathologic specimens of affected vessels demonstrate intimal proliferation and medial necrosis. Thus, the pathogenesis of cerebral vasospasm is a complicated multifactorial process. Vasospasm occurs more frequently in patients with a poor clinical grade, thick focal blood clots, or a diffuse layer of blood in the subarachnoid space.

Modern multimodality monitoring of brain tissue oxygen tension and microdialysis of the interstitial space offers the promise of early diagnosis of vasospasm. Early case series suggest that brain tissue chemistry may change up to several days before the onset of vasospasm, best detected by detection of alterations in tissue lactate, lactate/pyruvate ratio, glutamate and other proteins using bedside microdialysis [69–71].

HYPERDYNAMIC THERAPY

Circulatory manipulation is a routine treatment for regional ischemia with predictable benefit [65,72]. Selection criteria for treatment include increasing blood flow velocity signals by TCD measurement, focal deficit, and global impairment of consciousness without hydrocephalus. While there is no proven preventative treatment for cerebral vasospasm, the current mainstay of therapy is hypervolemic hypertensive therapy or HHT. The aim is to augment cerebral perfusion and rheology by raising systolic blood pressure, cardiac output, and intravascular volume. Progress in this area has been predominantly in the area of small cohort studies of intermediate variables, CBF, and systemic blood volume [73–75]. A number of authors have demonstrated that elevation of systemic arterial pressure produces a significant increase in the regional CBF [76–78]. Typically, 20 to 30 mm Hg elevation of the mean arterial pressure increases CBF by 15 to 25 mL per minute per 100 g. In contrast, recent studies have failed to demonstrate a beneficial effect of hemodilution therapy on oxygen delivery in patients with vasospasm [79]. Vasopressors are used to keep systolic blood pressures 20 to 40 points higher than pretreatment levels, and plasma volume is maintained with normal saline and occasionally with albumin, hetastarch, or Plasmanate. This therapy is continued for 48 to 72 hours or until serial imaging studies improve before it is gradually withdrawn under close observation. Risks of therapy include myocardial infarction, congestive heart failure, dysrhythmias, and hemorrhagic infarcts. This treatment can be used most aggressively in the postoperative period because of the risks of aneurysmal rerupture before surgery. Early surgery and careful cardiac monitoring for congestive heart failure are necessary for the prevention of significant complications.

Angioplasty is another proven technique for treatment of cerebral vasospasm [80–82]. Higashida et al. [81] developed a soft silicone balloon that is navigated into the basilar, posterior cerebral (P1), middle cerebral (M1, M2), and anterior cerebral (A1, A2) arteries and provides appropriate pressures to dilate these vessels. Patient selection criteria for treatment include the presence of arteriographic vasospasm without infarction in a patient with a repaired aneurysm. A correlation of symptoms with the anatomy of the vascular narrowing is helpful but not always present because altered mental status is often the presenting symptom of vasospasm. Failure of calcium antagonist prophylaxis or complications of hypertensive hypervolemic therapy are appropriate indications for considering this procedure. Most successful angioplasties are performed in the first 48 hours after onset of major symptoms because the procedure is much less effective as a "salvage" technique after cerebrovascular reserve is depleted and vascular fibrosis occurs. Observations in a rabbit SAH model demonstrated that the initial vessel narrowing is related to vasospasm with subsequent anatomical fibrosis during the next 5 to 7 days, when it accounts for more than 60% of the caliber changes [83]. This identified the timing and extent of alteration of vessel inelastic elements in the production of vasospasm. Thus, angioplasty should be most effective early on before maximal fibrosis occurs. Angioplasty has also been used to treat catheter-induced spasm. Several groups have reported SAH patients who benefited from intra-arterial infusions of papaverine, verapamil, and nicardipine [84–86].

THROMBOLYSIS OF THE SUBARACHNOID SPACE

The degradation of hemoglobin in the cranial subarachnoid space produces a histologic and arteriographic picture consistent with vasospasm, and the severity of spasm/ischemia appears to relate to the amount of blood in the CSF space. Thus, there has been a longstanding interest in removing this spasmogen. A reduced incidence of vasospasm after intrathecal treatment with recombinant tissue-type plasminogen activator within the first 24 hours of onset of SAH, and a drop in the resistance to CSF outflow has been noted after experimental treatment with tissue plasminogen activator [87,88]. The use of intrathecal tissue plasminogen activator has been reported in 109 patients, with one hemorrhagic death due to an epidural hematoma, four nonfatal cases of epidural and intracerebral hematoma, and one extradural hematoma [89]. Arteriographic follow-up demonstrated a decreased incidence of arteriographic vasospasm.

FREE RADICAL SCAVENGERS IN SUBARACHNOID HEMORRHAGE

Free iron from the blood can lead to lipid peroxidation and free radical generation. Free radical scavengers may be useful in preventing further damage [90]. A controlled study in 208 patients using a free radical scavenging agent, nizofenone, demonstrated improvement based on functional recovery,

especially in patients with delayed ischemic symptoms, moderate severity of preoperative deficits (Hunt and Hess grades II or III), and diffuse high-density areas in pre- and postoperative CTs [91]. The nonglucocorticoid 21-aminosteroid tirilazad mesylate has been shown to inhibit lipid peroxidation and protect cell membranes by scavenging destructive-free radicals, but positive results of a European trial were not reproduced in a large multicenter North American trial [92–94]. In a post hoc subgroup analysis of the highest dose group, however, mortality was improved from 33% in the vehicle group to 5% in the patient subgroup that included men with admission grades IV and V.

RECOMMENDATIONS

The current literature for unruptured aneurysms has level IV and level V evidence and can support grade C recommendations. Patient factors, biases, and personal preferences influence treatment decisions and should be taken in consideration. Recommendations for ruptured aneurysms are more definite.

1. Management of unruptured intracranial aneurysms.
   a. In general, small incidental aneurysms less than 10 mm require follow-up rather than surgical intervention. Younger patients may require more aggressive management. Small aneurysms in this group may also be treated if there is rapid enlargement, daughter sac formation, or there is a history of familial intracranial aneurysms.
   b. Irrespective of size, coexisting or remaining aneurysms in patients with a previous history of SAH warrant consideration for aneurysm repair.
   c. Patients with basilar tip aneurysms 7 mm or more in diameter have a higher incidence of rupture and treatment should be considered.
   d. Decisions on approach to repair should be made by a team including a vascular neurosurgeon and an interventional neuroradiologist.
2. Management of ruptured aneurysms.

2.1 Aneurysms preferentially treated with surgical clipping include the following:
   a. Patients with poor vascular anatomy for endovascular approach
   b. Acutely ruptured aneurysms with symptomatic intracranial hematoma
   c. Recurrent aneurysms after coil embolization

2.2 Aneurysm preferentially treated by endovascular embolization with detachable coils
   a. Medically unstable patients
   b. Patients with poor neurologic condition (e.g., grade 4 or 5, established vasospasm, or severe brain swelling)
   c. Aneurysms with significant calcification
   d. Residual aneurysms after unsuccessful surgery

2.3 Patients should be monitored for vasospasm postoperatively using clinical examination and TCD if available.
   a. Hyperdynamic therapy is therapeutic but not preventive for vasospasm.
   b. Endovascular therapies for vasospasm should be employed when medical therapies fail.
   c. The calcium channel antagonist nimodipine should be given for the first 21 days following SAH.

3. Giant aneurysms greater than 2.5 cm should be approached on an individual basis. Location, accessibility, and collateral circulation all influence the decision to treat surgically or with endovascular management [15,95,96]. Patients are best approached on an individual basis with direct collaboration between neurosurgeon and interventionalist prior to repair.

CHAPTER 179 ■ MENTAL STATUS DYSFUNCTION IN THE INTENSIVE CARE UNIT: POSTOPERATIVE COGNITIVE IMPAIRMENT

JOAN M. SWEARER AND SHASHIDHARA NANJUNDASWAMY

Cognitive dysfunction following major surgery is one of the common reasons neurologists are asked to evaluate postoperative patients in the intensive care unit (ICU): patients whose memory and intellectual abilities seem impaired when they otherwise appear to have recovered from the immediate effects of surgery. It is a major concern for the family, patient, and physician when a patient is found not to be intellectually the same on awakening following surgery as he or she was before.

There has been extensive research on cognitive dysfunction following major cardiac surgery and a growing literature from noncardiac surgery. In a literature review of cognitive decline following cardiac surgery published between 1985 and 2005, Newman et al. [1] reported that the incidence of decline noted within the first perioperative week varied from 50% to 70%. The incidence fell to 30% to 50% after 6 weeks, and to 20% to 40% at 6 months and 1 year. Differences in methods between studies (e.g., patient sampling, specific tests used, testing intervals, definitions of cognitive decline) make it difficult to compare the studies in literature reviews and meta-analyses directly. Despite these differences, increased age has been the most consistent factor associated with cognitive dysfunction; prolonged cardiopulmonary bypass has also been noted as a risk factor [1,2].

In a study of major noncardiac surgery [3], 1,064 patients aged 18 years and older completed neuropsychological testing before surgery, at hospital discharge, and 3 months after surgery. At 1 year postsurgery patients were contacted to determine survival status. At hospital discharge 36.6% of the young (18 to 39 years), 30.4% of the middle aged (40 to 59 years), and 41.4% of the elderly (60 years and older) had evidence of postoperative cognitive decline. At 3 months cognitive dysfunction was present in 5.7% young, 5.6% middle aged, and 12.7% elderly patients. Increased age, lower educational level, history of premorbid cerebral vascular accident (with no residual impairment), and cognitive decline at discharge were found to be independent risk factors for postoperative dysfunction at 3 months. Patients with postoperative cognitive decline were at increased risk of death in the first year postsurgery.

Although it is clear from these and other studies that postoperative cognitive decline can occur in elderly patients undergoing both major cardiac and noncardiac surgery, the precise pathophysiologic mechanisms have yet to be elucidated.

MENTAL STATUS EXAMINATION IN THE INTENSIVE CARE UNIT

The primary objectives of a mental status evaluation in the ICU are to screen for the presence of postoperative cognitive decline, to analyze both the nature and extent of the impairment, and to evaluate improvement or worsening over time. Cognitive changes may be obvious when there are gross deficits in learning, memory, attention, or concentration. The decline can also be subtle, with problems in initiative and planning ("executive" functions).

Many mental status screening tests are available [4–7], but none have been specifically developed for, or standardized in, the ICU. A brief screening test may provide a general impression of the patient's mental status, but the clinician must be able to assess areas of relative strength and weakness in greater depth. The following is offered as an outline for a mental status evaluation in the ICU [8–10].

Behavioral Observation and Patient Variables

Determination of the patient's level of wakefulness and arousal is the essential first step in a mental status examination: levels may range from deep coma to stupor, obtundation, normal alertness, hyperalertness, and manic states. Any further interpretation of mental status test results depends on full alertness, and is severely limited if arousal is not normal.

Test performance is also substantially influenced by the patient's ability to sustain attention. A patient who is easily distractible will perform poorly on most cognitive tests. Lack of motivation and effort during testing can have deleterious effects on test performance, and may lead to an overestimation of cognitive impairment. Abnormalities in mood and affect, and behavioral disturbances such as psychosis, disinhibition,

hyperactivity, or impulsivity will also negatively impact the patient's test performance.

Other patient variables that can influence test performance include demographic variables (e.g., premorbid cognitive abilities, age, gender, education, cultural background) and medical and psychosocial history (e.g., psychiatric history, social history, present life circumstances). A history from family members is extremely useful in assessing the patient's premorbid abilities.

Finally, test performance is compromised by postoperative pain, use of analgesic and sedating medications, limitations in arm/hand mobility, and possible sensory loss (e.g., hemianopia) or motor impairment (e.g., hemiparesis). Assessment of mental status becomes challenging, and the results uncertain, if the patient is on a ventilator.

Attention

The patient's span of attention can be assessed at the bedside using digit span, which also depends on immediate verbal recall. Repetition of digits both forward and backward should be evaluated. Both tests consist of increasingly longer strings of random number sequences that are presented aloud to the patient. The average score obtained by adults is seven digits forward and five digits backward.

Perseverance or the ability to sustain behavioral output can be measured at the bedside by mental tracking tests. Reciting the alphabet and counting from 1 to 40 by 3s are relatively easy mental tracking tests. Examples of more discriminating tracking tests include serial subtraction of 3s from 100 to 70 and reciting the months of the year backward.

Resistance to interference and response inhibition can be tested with motor sequencing tasks. Examples include the "go-no-go" test (when the examiner taps once, the patient taps twice, but when the examiner taps twice the patient does not tap [11]); and alternating sequences (e.g., copying a sequence of script such as "m n m n m n" [12]). Patients with impaired attention may perseverate on one element of the task rather than alternate between the sequences.

Speech and Language Functions

Speech output should be assessed for fluency (rate and effort of speech), articulation (normal or dysarthric), phrase length, prosody (melody, rhythm, inflection), content (semantics and syntax), and paraphasias (substitutions of rhyming alteration of words). Output can be observed in verbal responses to open-ended questions or by having the patient verbally describe a complex visual scene, such as a photograph ("propositional speech"). Disorders of repetition can be elicited by having the patient repeat phrases that vary in grammatical complexity (e.g., "no ifs, ands, or buts").

Auditory comprehension can be assessed at the bedside in a number of ways. Examples include pointing to named objects, such as body-part identification (e.g., "Point to your left thumb") and following multistage oral commands. Speech comprehension can also be assessed by asking "yes/no" questions such as "Do cows fly?"

Common objects (e.g., watch, pen, eyeglasses) can be used to test naming to confrontation. Component parts (e.g., lens, frame) may detect more subtle naming deficits. Oral reading and comprehension can be tested by having the patient read a brief passage from a newspaper, and then asked "yes-no" questions about its content.

Spontaneous writing and writing to dictation are excellent screening tests for aphasic writing deficits. Comprehension can also be assessed by having the patient follow written directions (e.g., "Point to the ceiling"). Word-list generation by specific category (e.g., animals, items found in supermarket or hardware store) and by specific initial letter is sensitive to both language and attentional sequencing disorders.

Memory Functions

Memory functions include immediate memory span, learning capacity and retention, and retrieval of previously learned information (recent and remote). Immediate memory span is commonly assessed with a digit span forward test (described previously). The ability to learn new information can be investigated in a number of ways. For example, three or four unrelated words are presented and the patient is instructed to remember them. After 5 minutes of other testing, the patient is asked to recall the words. Nonverbal learning can be assessed in a similar fashion using line drawings of simple geometric figures or by pointing to three or four objects in the room and asking the patient to recall them a few minutes later.

Remote memory can be tested by asking questions about political figures (e.g., naming the three previous presidents), dates of major world events (e.g., years of World War II), and personal history (e.g., name of high school attended).

Visuospatial and Visuoconstructive Abilities

Visuoconstructive ability is tested by having the patient copy simple figures (e.g., cube, daisy, interlocking pentagons). Spatial planning can be assessed with clock drawing. The patient is asked to draw the face of a clock and to fill in all the numbers. Left-sided visual inattention or hemispatial neglect is suggested if the patient places all the numerals on one side of the clock, or omits all numerals normally on one side. Capacity to process number/time relationships can be tested by having the patient "set the time to 10 minutes past 11 o'clock."

Executive Functions and Other Cognitive Abilities

Interpretation of proverbs (e.g., "the early bird catches the worm") evaluates concept formation or capacity for abstract thought. Ability to generate abstract thought can be assessed also by asking how word pairs are alike. An example of an easy similarity test pair is "broccoli–cauliflower"; a more difficult pair is "fish–dandelion." Mental arithmetic problems (e.g., "How many quarters are in $1.50?") test reasoning ability as well as immediate memory and concentration. Unfortunately, there are no reliable tests of judgment. Patients may be able to describe an appropriate response to how they would handle a small emergency, but may not behave so in a real emergency.

MENTAL STATUS DYSFUNCTION IN THE INTENSIVE CARE UNIT

Acute Confusional State (Delirium)

Delirium is a very common cause of mental dysfunction in postoperative patients in the ICU. The hallmark features of delirium are inattentiveness, confusion, and psychomotor agitation, although hypoactive delirium is also recognized. An alteration in sleep–wake pattern is evident. Fever, sepsis, metabolic and endocrine disturbances, as well as medication use or withdrawal,

or alcohol withdrawal, are among the causes of delirium; this is discussed in more detail in Chapter 197.

Focal Syndromes

Stroke is another adverse neurologic outcome from surgery—especially cardiac surgery [13] or endovascular procedures, such as angioplasty—and is usually recognized by the presence of focal or lateralizing deficits of sudden onset (see Chapter 173). Focal cognitive deficits include aphasia, apraxia, and agnosia; focal motor weakness and/or sensory loss may not be evident if the stroke involves more of the temporal–parietal areas due to low perfusion-border zone ischemia. Wernicke's type of receptive aphasia presents with a speech disturbance when the ischemic zone involves the posterior temporal lobe. In this condition, the patient speaks fluently but unintelligibly, is unable to comprehend speech, and can become agitated.

Postoperative Cognitive Decline/Dysfunction

As previously noted, changes in memory and concentration are often seen in the ICU in the initial postoperative period. These changes can, however, persist well beyond the immediate postoperative period when the effects of anesthesia and analgesia directly affecting cognitive functions have clearly worn off. Most mental status changes improve, but may continue following discharge, even weeks, months, and years later, with associated impaired quality of life and mortality [14,15].

Elderly patients undergoing major cardiac (e.g., coronary artery bypass grafting, thoracic vascular surgery) and major noncardiac (e.g., orthopedic, abdominal) surgery are at the greatest risk for postoperative cognitive decline. Other individual features that increase the risk of mental status dysfunction include previous cerebrovascular disease, previous and undetected cognitive impairment or dementia, and cardiovascular risk factors such as hypertension, diabetes, and peripheral vascular disease [1,2,16–18].

Intraoperative risk factors include surgical technique (e.g., duration of cardiopulmonary bypass, duration of aortic cross-clamping), hypotension, manipulation of diseased aorta, and the effects of general anesthesia and hypothermia. To assess these factors requires close scrutiny of the operative record, and of the anesthesia chart. Atherothromboembolic phenomena (microemboli) and hypoxia with watershed area injury secondary to hypoperfusion are possible causative mechanisms of postoperative cognitive dysfunction due to intraoperative events during surgery [1].

A number of postoperative factors can also affect cognitive status in the ICU, including the use of analgesics, degree of physical discomfort, and depression [16]. These factors may produce short-term but self-limited cognitive change. Nevertheless, they should be taken into account when assessing the mental status of a patient in the ICU.

SUMMARY

Testing for mental status dysfunction of a patient in the ICU can be a complex and difficult task. Interpretation of test results can be confounded by premorbid patient characteristics (e.g., presence of a dementing illness presurgically) and the patient's current status (e.g., drowsiness in the context of high-dose analgesics, sedatives, and other medications). Mental status testing should not be attempted if arousal is abnormal or if the patient is too ill. The approach to testing should be flexible and targeted to the individual patient's complaints and level of functioning. Postoperative cognitive changes range from obvious deficits in concentration and memory to subtle deficits in executive functions. Evidence of abnormality during a screening evaluation warrants a thorough neurologic evaluation.

CHAPTER 180 ■ NEWLY ACQUIRED WEAKNESS IN THE INTENSIVE CARE UNIT: CRITICAL ILLNESS MYOPATHY AND NEUROPATHY

DAVID A. CHAD

Although preexisting neuromuscular disorders (such as myasthenia gravis and the Guillain–Barré syndrome) may cause severe weakness leading to an intensive care unit (ICU) admission, two of the most common causes of *newly acquired weakness arising in the ICU setting* are critical illness myopathy and critical illness polyneuropathy [1,2]. Critical illness myopathy is probably the major contributor to severe ICU-acquired weakness, causing most instances of failure to wean from a respirator in patients with severe systemic diseases in the ICU, while critical illness polyneuropathy affects 70% to 80% of patients with severe sepsis and multiorgan failure [3]. Even experienced clinicians have great difficulty distinguishing between the myopathy and the polyneuropathy of intensive care, especially because the two conditions often coexist in an individual patient [4–6]. In the sections that follow, we discuss each disorder and comment on the differential diagnosis of severe weakness arising in the ICU setting.

CRITICAL ILLNESS MYOPATHY

Diagnosis

The hallmark of critical illness myopathy is weakness that is typically diffuse in distribution, affecting both limb and neck muscles [7]. As is typical of most myopathic disorders, weakness tends to have a proximal predominance in the limbs, but it may also involve distal muscles profoundly. Tendon reflexes tend to be depressed but present, and on occasion, may be absent, possibly due to a generalized reduction in membrane excitability that occurs in sepsis [8]. There may be facial muscle involvement, and rarely, extraocular muscles are affected [9]; other muscles supplied by cranial nerves are usually spared. A serious and common complication of the myopathy is failure to wean from a ventilator due to marked weakness of the diaphragm. Although the majority of affected patients are adults, severe myopathic muscle weakness may occur in children who receive organ transplants [10].

Risk Factors

Critical illness myopathy develops in up to one-third of patients treated for status asthmaticus in the ICU; and in this population, intravenous corticosteroids and neuromuscular blocking agents are considered major risk factors [11]. Occasionally, the myopathy develops in patients who have received high-dose corticosteroids alone, without neuromuscular blocking agents, or in patients who have received neither corticosteroids nor neuromuscular blocking agents, but the latter group typically has severe systemic illness with multiorgan failure and sepsis [8]. Overall, critical illness myopathy accounts for 42% of weakness among patients in the surgical and medical ICU setting [12].

Laboratory Studies

Serum creatine kinase (CK), electromyography (EMG), and muscle biopsy are the most important and revealing studies in the diagnosis of ICU-acquired muscle weakness. An elevated CK level helps to support the diagnosis of a myopathic cause of weakness in an ICU patient, but in the myopathy of intensive care, the CK rise, which is found in about 50% of affected patients, only occurs early in the course of the illness, peaks within a few days of onset, and then declines back into the normal range [7].

EMG Studies

With nerve conduction studies, motor responses are typically low-amplitude or absent, while sensory responses are relatively preserved, with amplitudes that are > 80% of normal in two or more nerves (sensory responses may be reduced, however, when ICU polyneuropathy coexists; see following discussion). Sensory responses may also be reduced initially in association with sepsis and increase during clinical recovery [8]. Needle electrode examination shows fibrillation potential activity in resting muscle in some patients. On voluntary muscle activation, motor unit potentials are short in duration and polyphasic in form with early recruitment, but when there is severe weakness or encephalopathy due to sepsis, the patient may be unable to contract muscles sufficiently to permit analysis of motor unit potentials. An interesting observation made of patients with critical illness myopathy, and demonstrated by direct muscle stimulation, is that the condition leads to electrical inexcitability of the muscle membrane [13,14] so that the ratio of nerve-evoked muscle action potential to direct stimulation of muscle is close to 1. In contrast, when weakness stems from severe neuropathy, the ratio of nerve-evoked response to muscle-stimulation–evoked response is less than 1 (and close to 0).

Muscle Biopsy

With a fairly stereotypic clinical presentation, and EMG results typical of a myopathy—often with fibrillation potential activity—the muscle biopsy is usually not necessary to establish the diagnosis of ICU myopathy. When the diagnosis is uncertain, and especially when diseases with specific therapies—such as the Guillain–Barré syndrome—are considered, a muscle biopsy may prove helpful. Biopsy shows muscle fiber atrophy, especially involving the type II fibers; a variable degree of muscle fiber necrosis, the absence of any inflammatory cells; and the hallmark of the disorder: features of a disrupted

intramyofibrillar network that manifests as patchy or complete reduction in myosin–adenosine triphosphatase reactivity in nonnecrotic fibers due to a loss of myosin that may be confirmed immunocytochemically or by electron microscopy [8]. There is a spectrum of histopathological severity ranging from a relatively mild myopathy without major structural damage (designated a cachectic myopathy) to a more severe myopathy with selective thick filament loss, and extending to the most severe manifestation of myopathy characterized by pronounced necrotizing features [6].

Pathophysiology

Myosin loss and muscle fiber necrosis probably contribute to persisting weakness. Myosin loss is characteristic of critical illness myopathy, and is essentially pathognomonic of the disorder. Corticosteroids may cause the loss of myosin, but other factors trigger the process, such as an abnormal neuromuscular junction caused by pharmacologic blockade in ICU patients [7]. Consistent with this hypothesis is the observation that a patient with myasthenia developed loss of myosin thick filaments after receiving high-dose corticosteroids [15], and that in an animal model of dexamethasone treatment plus denervation, there was a severe preferential depletion of thick filaments, leading to a reduction in muscle fiber size [16]. Some patients who are not exposed to administered corticosteroids or neuromuscular blocking agents, but who are systemically ill, often with metabolic acidosis, can also develop the myopathy of intensive care. Acidosis may stimulate glucocorticoid production, lead to an increase in muscle protein degradation, and trigger thick filament loss [7]. Finally, as noted earlier, muscle membrane inexcitability is noted in some patients with the disorder. In an animal model of ICU-related myopathy (rats treated with corticosteroids for 7 to 10 days after denervation of muscle in one leg), intracellular recordings in individual muscle fibers demonstrate that many fibers become unable to generate action potentials [17]. Paralysis appears to be due to abnormal inactivation of sodium channels, which suggests that the myopathy of intensive care may be, in part, an acquired disease of ion channel gating.

Treatment

The treatment of critical illness myopathy is essentially symptomatic: treating the underlying systemic illness and to the extent possible, discontinuing or minimizing corticosteroids and neuromuscular blocking agents. There is emerging evidence that intensive insulin therapy might have a role in reducing the incidence of both critical illness myopathy and critical illness polyneuropathy [18], but hypoglycemia remains a major concern. The experience using this modality was based on specific subgroups, which could limit the applicability of the conclusions, and the diagnosis of myopathy was based on EMG criteria alone and did not include information about clinical measures of muscle strength.

Outcome

If patients survive systemic illness, recovery occurs over weeks to months, depending on severity of the myopathy. In patients whose disease severity was pronounced, a recovery period of many months is to be expected along with the need for tracheostomy and long-term ventilatory support; although some motor recovery ultimately occurs in such patients, it is likely that they will be left with residual long-term muscle weakness and atrophy with compromise in daily function and problems with ambulation [19].

CRITICAL ILLNESS POLYNEUROPATHY

Diagnosis

Patients with critical illness polyneuropathy develop a sensorimotor axon-loss polyneuropathy [20]. Although distal muscles may be affected to a greater extent than proximal muscles, more commonly there is generalized flaccid weakness with depressed or absent reflexes. There is usually distal sensory loss, but pain and paresthesias are not typical features. The cranial nerves are generally spared. Many patients with critical illness polyneuropathy have a concomitant encephalopathy stemming from their underlying multiorgan system failure or sepsis, or both [21].

Risk Factors

Approximately 50% of patients admitted to the ICU with sepsis and multiorgan failure for at least 2 weeks will be found to have EMG evidence for an axon-loss polyneuropathy.

Laboratory Studies

EMG Studies

The most important diagnostic test is the EMG. Nerve conduction velocities are normal or only mildly reduced [21], but the amplitudes of sensory and motor responses are reduced, or even absent. This pattern is typical for axon-loss polyneuropathies rather than demyelinating neuropathies and is helpful in distinguishing critical illness polyneuropathy from the Guillain–Barré syndrome, in which, typically, myelin loss leads to slowing of nerve conduction velocities, conduction block and prolonged distal latencies, and delayed late responses (see following discussion). On needle electrode examination, there are typically features of acute denervation—fibrillation potentials and positive sharp wave activity—and reduced recruitment of motor unit potentials; as in many axon-loss polyneuropathies, there may be more pronounced changes seen in distal compared to more proximal muscles.

Pathophysiology

The polyneuropathy appears to be a complication of the systemic inflammatory response syndrome (SIRS) triggered by sepsis, severe trauma, or burns [22]. It may be induced by impaired microcirculation leading to reduced nerve perfusion and endoneurial edema which leads in turn to nerve hypoxia; the neuropathy may also result to a degree from the deleterious effects of cytokines produced by activated leukocytes [23]. There is also evidence that the acute polyneuropathy in critically ill patients stems in part from an abnormality in nerve excitability, caused by increased sodium channel inactivation (similar to what is found in the myopathy of intensive care), without actual nerve damage. This may underlie the reversibility of weakness that occurs in some affected patients [24].

Treatment

Treatment is essentially symptomatic and supportive and comprises attempts to stabilize underlying critical medical and

surgical conditions with vigorous treatment of sepsis. A recent study reported a 44% reduction in the incidence of critical illness polyneuropathy in mechanically ventilated critically ill patients who received intensive insulin therapy (IIT) to maintain the blood glucose levels between 4.4 and 6.1 mmol per L [23]. A Cochrane review makes clear, however, that the methodology of this and other studies limits the conclusions regarding the role of IIT in patients with either critical illness myopathy or neuropathy, or both [18].

Outcome

Recovery of sensory and motor function occurs over weeks to months, depending on the severity of the neuropathy. In some of the instances of very slow recovery over months, long-term ventilatory support may be required, even after the underlying critical illness has resolved [19].

DIFFERENTIAL DIAGNOSIS

Certain well-known peripheral neuropathies, neuromuscular junction disorders, and myopathies may present with acutely evolving weakness and simulate critical illness myopathy or polyneuropathy [1,2,25]. Among the acute and severe polyneuropathies, the most common is the Guillain–Barré syndrome, discussed in detail in Chapter 175. In brief, two-thirds of patients have had a preceding viral or bacterial syndrome (especially a *Campylobacter jejuni*-related diarrheal illness), an inoculation, or recent surgery. Most patients present with rapidly progressive areflexic paralysis that typically starts in the legs and spreads proximally, and involves the diaphragm in 25% of cases and the facial muscles in more than 50% of individuals. Most have EMG features of an acquired demyelinating polyneuropathy with slowing of nerve conduction velocity, conduction block, prolonged distal latencies, and prolonged or absent late responses, distinguishing Guillain–Barré syndrome from critical illness polyneuropathy. In most patients with Guillain–Barré syndrome, the cerebrospinal fluid (CSF) examination shows an elevation in protein without increased white cells by the second week of the illness, helping to distinguish Guillain–Barré syndrome from critical illness polyneuropathy, in which the CSF findings are normal. Guillain–Barré syndrome, an immune-mediated disorder, responds to plasma exchange or to intravenous γ -globulin, making early recognition essential in an effort to start treatment early and reduce morbidity.

A rare cause of severe neuropathic weakness is acute intermittent porphyria that may present with attacks of abrupt onset of abdominal pain, psychiatric disturbance, and polyneuropathy. It is generally triggered by drugs that induce the hepatic cytochrome-P450 system (diazepam, theophylline, barbiturates); it is characterized by weakness of the bulbar muscles and the diaphragm, has prominent dysautonomia, and EMG findings reveal features of a severe axon-loss polyneuropathy. Diagnosis is suggested by the presence of urinary porphyrin precursors, notably δ-aminolevulinic acid. The neuropathy responds to oral or parenteral carbohydrate loading and to intravenous hematin.

The most important neuromuscular junction disorder causing acute weakness is myasthenia gravis, described in Chapter 176. In brief, in this immunoglobulin-G immune-mediated postsynaptic condition, in which there is a loss of acetylcholine receptors, most individuals present with ocular muscle weakness (manifested as ptosis and diplopia) and generalized weakness with a fatigable component. More than 90% of patients have antibodies to the acetylcholine receptor, and abnormal EMG findings, with a decremental motor response during repetitive nerve stimulation at 2 to 3 Hz. The acute weakness (defined as myasthenic crisis when respiratory muscles are involved) responds well to plasma exchange or intravenous γ -globulin.

Another neuromuscular junction disorder is prolonged neuromuscular blockade by muscle relaxants. It is virtually always seen in the population of patients with renal or hepatic failure, is often associated with elevated levels of the metabolite of vecuronium (3-desacetylvecuronium), and tends to improve after infusion of acetylcholinesterase inhibitors. Botulism is a presynaptic disorder characterized by rapidly progressive, diffuse, symmetrical weakness with a proximal predominance, dysarthria and dysphagia, respiratory involvement, and a prominent autonomic component including dilated pupils, bradyarrhythmia, orthostatic hypotension, and urinary retention. Management consists of supportive care and administration of trivalent antitoxin.

THE DIAGNOSTIC CHALLENGE: DISTINGUISHING CRITICAL ILLNESS MYOPATHY FROM CRITICAL ILLNESS POLYNEUROPATHY

Favoring the diagnosis of myopathy would be severe generalized weakness, with failure to wean from mechanical ventilation (the latter more likely to be associated with ICU myopathy rather than neuropathy [26]), preservation of reflexes and sensation, a transient rise in CK, and an EMG picture of relatively preserved sensory responses with low or absent motor responses and early recruitment of small, polyphasic motor unit potentials, often with fibrillation potential activity. Favoring a polyneuropathy would be the clinical findings of demonstrable sensory loss and areflexia, and the EMG findings of absent or low motor amplitudes in the company of absent or low sensory responses, along with fibrillation potentials and reduced recruitment of motor unit potentials. Clinically, a polyneuropathy might easily be missed because, in many patients, careful sensory examination is impossible in the ICU setting, especially if there is a coexisting encephalopathy. Further confounding the distinction, reflex loss can occur in either critical illness polyneuropathy or myopathy, fibrillation potentials may be found in both disorders, and voluntary motor unit potentials may not be elicitable either because of inability to activate muscles due to encephalopathy or from severe weakness.

In the final analysis, it may be difficult to distinguish one disorder from another in an individual case: ICU-related myopathy and polyneuropathy arise in a common setting, share the clinical features of severe generalized weakness with areflexia, may have a similar underlying acquired sodium channelopathy (affecting multiple sodium channel isoforms in both nerve and muscle [24]), and cannot always be reliably differentiated by EMG testing. Although a biopsy may be helpful in ambiguous situations, truly distinctive features of either disorder may be difficult to discern. It is likely that in many patients *both* disorders are present in varying degrees [27] and in fact have a combined syndrome of critical illness myopathy and polyneuropathy and may be considered to have critical illness polyneuromyopathy [5] or critical illness myopathy and neuropathy [6]. Personal and collective experience [14,25,28] suggests that in ICU patients with the *most profound weakness and failure to wean,* ICU myopathy probably plays the predominant role.

CHAPTER 181 ■ IMMUNOSUPPRESSION IN SOLID-ORGAN TRANSPLANTATION

AMIT BASU, ARTHUR J. MATAS AND ABHINAV HUMAR

Clinically successful solid-organ transplantation required breakthroughs in our understanding of immunology and immunosuppressive therapy. Alexis Carrel, in the early 1900s, described what was to become the modern method of vascular suturing; experimental transplants soon followed [1], but the first successful clinical transplant was not done until five decades later. During that interval, it gradually became apparent that early rapid destruction of allografts was due to an immune process, which came to be known as *rejection*.

Organ transplantation has now become commonplace as the results have improved remarkably with the use of more potent and specific immunosuppressive agents. Progress in nonrenal transplantation has especially accelerated with the use of newer and more potent immunosuppressive agents. Besides the developments in techniques and immunosuppression protocols, progress in tissue typing and cross matching, and in preservation and transportation of harvested organs have played major roles in the rapid development of organ transplantation.

This chapter reviews the clinical use and the adverse reactions associated with commonly used immunosuppressive agents.

PHARMACOLOGIC AGENTS

Calcineurin Inhibitors

Cyclosporine (CSA) and tacrolimus (TAC), although structurally dissimilar, have a similar mechanism of action. Both drugs interfere with the cellular pathway for cytokine production and proliferation. Early events in the T-cell activation process are associated with a rise in the levels of intracellular calcium. The protein calcineurin has been validated as part of the calcium-dependent signal transduction pathway of interleukin-2 (IL-2) production in T cells [2]. CSA and TAC bind to two intracellular receptors, CypA and FKBP12, respectively; these receptors are found in virtually all cell types. The resulting receptor complex binds to calcineurin, blocking its phosphatase ability and thereby stopping the production of IL-2 [2].

The two calcineurin inhibitors (CNIs) currently used are described separately in the following sections.

Cyclosporine

CSA was isolated from a soil sample in Norway and produced by the fungus *Tolypocladium inflatum*. The first formulation of CSA that was approved by the U.S. Food and Drug Administration (FDA) was Sandimmune®; this was modified in the early 1990s by the microemulsion (ME) formulation called Neoral®. In 2000, the first generic versions of CSA were launched. CSA has remained a major component of many transplant regimens.

Pharmacokinetics. CSA is a lipophilic decapeptide, consisting of several amino acids in a ring structure. The original oral formulation (Sandimmune®) is in an olive-oil vehicle, which is necessary to promote absorption [3]. Absorption of Sandimmune® is erratic and it requires the presence of bile in the upper small intestine for absorption. Because many liver transplant recipients require diversion of bile to external drainage, absorption of Sandimmune® is problematic for them [4]. Absorption is also complicated by the presence of food and the length of drug therapy. Neoral® self-emulsifies in water, making absorption much more reliable and much less dependent on the presence of bile.

Studies comparing the two formulations showed these advantages with the ME: a more consistent and linear elimination of CSA; higher area-under-the-curve (AUC) values, leading to reduced dose requirements; reduced effects of diet, and, especially for liver recipients, much better absorption [4]. The side effect profiles were unchanged. The ME has become the primary formulation for CSA. CSA is generally considered a narrow-therapeutic-range drug, so whether generic versions can be used without additional pharmacokinetic study has been controversial.

The oral bioavailability of the ME formulations is approximately 30%. The average half-life of CSA ranges from 6 to 9 hours, with a t_{max} (ME) of approximately 1 hour. CSA is highly bound in plasma to red blood cells. It is extensively metabolized by the liver to multiple metabolites via the cytochrome P450 3A4 enzyme system; however, most of the metabolites are considered essentially inactive. Significant liver impairment can slow the clearance of CSA by the body. Because very little drug is eliminated by the kidney, renal failure does not change CSA elimination [3].

CSA is available as an oral soft gelatin capsule (Neoral®, Sandimmune®), as an oral solution (Sandimmune®, Neoral®), and as an intravenous (IV) preparation (Sandimmune®). To convert to IV use, the IV dose must be calculated as one-third of the daily oral dose. The IV dose can be administered over 6 hours; however, a continuous infusion is usually desired to minimize toxicity.

Adverse Events. The extensive side effect profile of CSA has long been a reason for attempts at minimizing drug exposure. Of most concern is its acute and chronic nephrotoxicity. Acute nephrotoxicity from CSA initially is characterized by vasoconstriction of the intrarenal arterioles, resulting in a reduced glomerular filtration rate. This mechanism of vasoconstriction is not well understood, but may be a result of increase in the vasoactive substance endothelin I [5], the activation of the renin-angiotensin system resulting in increased levels of angiotensin II [6], and possibly a decrease in production of nitric oxide [7]. CSA may also affect prostacyclin levels and induce vasoconstriction by increasing thromboxane A_2 [3].

CSA-induced thrombotic microangiopathy (TMA) was first reported in liver allograft recipients, then in kidney and heart recipients [8]. TMA can present as a full-blown syndrome consisting of hemolytic anemia, thrombocytopenia, neurologic abnormalities, fever, and renal failure. Pathogenic mechanisms include a direct cytotoxic effect on endothelial cells, reduction in prostacyclin synthesis leading to vasoconstriction, platelet aggregation, and thrombus formation. CSA reduces the generation of activated protein C from endothelial cells and increases thromboplastin production from mononuclear and endothelial cells, thus contributing to a prothrombotic effect. Discontinuation of CSA is an important step in management along with plasmapheresis and fresh frozen plasma replacement. TAC or sirolimus (SRL) can be substituted as immunosuppressive agents, although TMA can occur with both these agents.

In heart and lung transplant recipients, the effect of CSA on long-term kidney function has been significant. Kidney biopsies of their native kidneys reveal wrinkling and thickening of the glomerular basement membrane, with some kidneys exhibiting microthrombotic angiopathy and fibrosis. Clinical findings showed that several of these recipients had advanced to end-stage renal disease requiring dialysis; others developed significant proteinuria [9]. However, a study of kidney recipients showed that the incidence of rejection correlated with poorer long-term graft function; higher CSA levels were associated with better, not worse, graft function [10]. Whether or not higher CSA levels are to blame for chronic CSA nephrotoxicity is still a matter of discussion. Transforming growth factor-B type 1 (TGF-B type 1) and platelet-derived growth factor, both fibrogenic cytokines, are produced in increasing amounts by human renal proximal tubular cells by increasing concentrations of CSA [11]. An increase in the activation of the renin-angiotensin system has been linked with the morphological changes that occur in chronic CSA nephrotoxicity by experimental studies [12], and angiotensin II receptor blockers reduce these changes.

Hypertension is another significant adverse event with CSA. Most patients receiving CSA develop hypertension, sometimes requiring multiple drug therapy. The mechanism for CSA-induced hypertension is primarily related to small-vessel vasoconstriction. The renal vasoconstriction may be affected, in part, by increased endothelin production. Patients also develop sodium retention and lower plasma renin levels [13]. Treatment of hypertension has focused on calcium-channel blocker use, because calcium-channel activation induces endothelin vasoconstriction and increases blood pressure. Calcium-channel blockers, such as diltiazem, nifedipine, and amlodipine, have been shown to decrease renal vascular resistance and improve glomerular filtration rate. Given these beneficial renal effects, calcium-channel blockers have been used to try to reduce chronic nephrotoxicity associated with CSA. Clinical evidence of a salutary effect has been conflicting, and further study is needed.

CSA has been associated with several neurologic toxicities, including headaches, tremors, seizures, and encephalopathy. In most instances, but not always, these effects are seen with higher CSA levels. A decrease in dosage may prevent serious tremors and headaches. Reversible posterior leukoencephalopathy can occur after CSA use and affects the posterior white matter and the frontal lobes and gray matter as well [14]. It manifests with confusion, coma, cortical blindness, cerebellar syndrome, hemiplegia, and flaccid paralysis or various combinations of these features. This neurological syndrome and brain imaging abnormalities usually resolve within 2 weeks of stopping CSA, or after dosage reduction if blood levels were high [15]. Hypertrichosis and gingival hyperplasia can reduce patient compliance to CSA. Many patients develop hair growth on their backs and arms; although not life threatening, these cosmetic changes can have emotional and physical repercussions, potentially resulting in graft loss if noncompliance ensues. Electrolyte imbalances may occur with CSA, including hyperkalemia, hyperuricemia, and hypomagnesemia. Patients usually need diet instruction and sometimes electrolyte replacement to control these changes. CSA can increase cholesterol and triglyceride levels, sometimes requiring treatment with lipid-lowering medications [3].

Drug Interactions. CSA is metabolized by the cytochrome P450 3A4 enzyme system that is found not only in the liver but also in the cells lining the intestine; so CSA levels can be increased or decreased by changes in gut absorption or in liver metabolism [16]. Some centers try to manipulate the interaction, intentionally using compounds that inhibit CSA metabolism to decrease the dosage required and, thus, the cost [17]. This practice is controversial, because any change in the interacting drug used affects CSA levels. CSA interactions may also occur with medications that change gut motility and with other nephrotoxic agents [16]. Table 181.1 lists the drugs that affect CSA metabolism, efficacy, and nephrotoxicity.

Clinical Use. CSA was and continues to be extensively used in organ transplantation, especially renal transplant, although now a different CNI, tacrolimus, has become the more commonly used primary immunosuppressive agent [18]. When CSA is used, it is often the ME formulation (Neoral®),

TABLE 181.1

SIGNIFICANT DRUG INTERACTIONS (CYCLOSPORINE, TACROLIMUS, SIROLIMUS)

Inhibitors of metabolism	Inducers of metabolism	Additive nephrotoxicity (cyclosporine and tacrolimus only)
Verapamil	Rifampin	Aminoglycosides
Diltiazem	Phenobarbital	Salicylates
Fluconazole	Phenytoin	Nonsteroidal anti-inflammatory agents
Itraconazole	Carbamazepine	
Ketoconazole	St. John's wort	
Erythromycin		Amphotericin B
Azithromycin		Vancomycin
Clarithromycin		
Grapefruit juice		
Fluvoxamine		
Nefazodone		
Atorvastatin		

although patients with stable allograft function from earlier years may still be using Sandimmune. As Sandimmune® and ME formulations are not considered bioequivalent by the FDA, one cannot be substituted for the other without careful monitoring of doses and serum concentrations. Most centers initiate CSA therapy at 4 to 8 mg per kg per day orally, starting the day after transplant. If the transplanted kidney shows signs of acute tubular necrosis posttransplant, some centers may delay the initiation of CSA. Anti–T-cell preparations may be used during this time to provide T-cell suppression if CSA cannot be started [3]. Because of the better bioavailability of the ME formulation, the need for IV CSA has decreased but still may be necessary if the patient has significant diarrhea or cannot tolerate any oral or nasogastric medications.

Therapeutic Drug Monitoring. Monitoring CSA levels is vital. Maintaining the appropriate levels in the first 6 months posttransplant has a significant effect on graft survival [19]. Monitoring CSA is a challenge because of the differences in bioavailability between patients, the narrow therapeutic range, and the number of compounds available that affect CSA blood concentrations. Several different assays are currently in use to measure CSA. The various methods used today measure whole-blood CSA levels and include radioimmunoassay (RIA), high-performance liquid chromatography (HPLC), and monoclonal antibody assays. HPLC only measures the parent compound of CSA, whereas radioimmunoassay and the monoclonal assays measure CSA plus several metabolites. When deciding whether a blood concentration is appropriate, it is important to know which assay the laboratory is using.

Traditionally, trough concentrations (C0) of CSA have been used to determine the appropriateness of a dosing regimen. Earlier studies were performed with the Sandimmune® formulation, which had quite variable dose-response curves. After the use of the ME preparation became standard, several studies suggested that measuring the AUC would be more predictive of toxicity and rejection (compared with the C0) [20]. AUC monitoring requires more blood samples per measurement, and it is therefore more costly and impractical in clinical practice [20]. A monitoring strategy measuring AUC for the first 4 hours after dosing (AUC 0 to 4 hours) correlates well with clinical outcomes, although it still requires multiple blood samples [21]. A blood sample taken 2 hours after intake of Neoral® (C_2) is the most accurate one-point predictor for AUC 0 to 4 hours and shows less variability than either C0 or C_1. In retrospective analysis, the risk of acute rejection is reduced in patients in whom C_2 were greater than 1,500 µg per L in the 2 weeks following transplantation [22].

In a prospective study, 45% of C_2-monitored patients failed to reach the target levels by day 5 posttransplantation compared with 2.5% of Co-monitored patients [23]; this may explain why the theoretical benefit of C_2 monitoring in the early posttransplant period is not borne out. Due to the lack of prospective evidence showing an advantage for C_2 monitoring in the early posttransplant period, trough levels (C0) remain the standard.

Tacrolimus

With the success of CSA, researchers studied soil samples from around the world, looking for another compound that might turn out to display immunosuppressive properties. TAC, initially known as FK-506, was isolated from a soil sample in Tsukuba, Japan, in May 1984, from the fungus *Streptomyces tsukubaensis* [24]. It has a completely different chemical structure from CSA, yet its effect on the lymphocyte is remarkably similar. A few differences have been found on the cellular level between CSA and TAC. The FKBP12-TAC complex is 10 to 100 times as potent as CSA, possibly due to greater affinity for its binding protein [24,25].

Pharmacokinetics. The pharmacokinetics of TAC are similar to CSA. TAC has an extremely lipophilic, macrocytic lactone structure. Its oral bioavailability ranges anywhere from 4% to 93% (average 25%), with variable dose-response curves between patients. Because of this poor oral bioavailability, the IV dose should be calculated at approximately one-third of the oral daily dose [26]. One significant difference between CSA and TAC is that with TAC the presence or absence of bile in the digestive tract does not significantly alter absorption. This was a problem with Sandimmune® and a reason that TAC was initially studied in the liver transplant population. TAC binds extensively to erythrocytes and exhibits the same temperature-dependent properties as CSA. The metabolism is also similar to CSA, with the cytochrome P450 3A4 system as the primary metabolic pathway. The many metabolites for TAC are still being studied. Less than 1% of active drug is excreted through the urine. The average elimination half-life ranges from 8 to 20 hours, depending on the population studied [26].

TAC is available as a 0.5-mg, 1.0-mg, and 5.0-mg capsule, formulated as a solid dispersion in hydroxymethylcellulose. A suspension can be compounded if necessary for pediatric or nasogastric administration. An IV preparation is solubilized in alcohol and a surfactant. It is available as a 5 mg per mL concentration that must be diluted and administered as a continuous infusion to avoid toxicity [26].

Adverse Events. The adverse event profile of TAC is similar to CSA in many respects. TAC appears to have the same nephrotoxicity seen with CSA, and the mechanism also appears to be the same. However, in one study, mean or median serum creatinine levels in renal transplant recipients were lower in TAC-treated patients, with 5 years follow-up, than in patients treated with cyclosporine ME (or standard formulation) [27]. As with CSA, the nephrotoxicity of TAC is concentration dependent, making drug level monitoring equally important [28].

Hypertension has also been reported with TAC. However, the 5-year follow-up results from the U.S. randomized trial indicate that significantly fewer TAC than CSA recipients were receiving antihypertensive treatment (80.9% vs. 93%, $p < 0.05$) [27]. Immunosuppression with TAC-based regimens is associated with better lipid profiles than is immunosuppression with CSA-based regimens [29]. Neurotoxicity appears to be somewhat worse than with CSA. In randomized trials, liver recipients had more trouble with the neurotoxicity of TAC versus CSA, even when controlling for previous liver failure–induced encephalopathy [30]. Headache, tremor, neuropathy, seizures, blindness, coma, and various other neurologic complaints have been seen with TAC [30]. Patients usually recover when the drug is stopped. The incidence of hyperkalemia appears to be similar to that with CSA, although hypomagnesemia is more likely to occur with TAC-treated patients [31].

TAC-associated TMA has a reported incidence between 1% and 4.7% [32]. All patients have an elevated serum creatinine, but do not always show signs of hemolysis. Renal allograft biopsy provides a conclusive diagnosis. Treatment consists of reduction or discontinuation of TAC, anticoagulation, and/or plasmapheresis with fresh frozen plasma exchange and leads to resolution of TMA in most instances. Rarely, there may be loss of kidney function or patient death.

The incidence of posttransplant diabetes mellitus (PTDM) was significantly higher among TAC-treated patients than CSA-treated patients (9.8% vs. 2.7%) according to a meta-analysis [33]. Many patients with PTDM have reversal of diabetes mellitus, with eventual discontinuation of insulin. In a U.S. trial combining TAC with mycophenolate mofetil (MMF) and corticosteroids, the 10-year incidence was 6.5%, and the 1-year prevalence was 2.2% [34]. TAC does not appear to cause hypertrichosis or gingival hyperplasia, but instead is associated

with hair loss. Sometimes these differences become important enough to cause a change in therapy.

Drug Interactions. TAC is metabolized through the same pathway as CSA and has been subject to the same interactions with the cytochrome P450 3A4 system. If the medication is known to alter P450 3A4 activity, it probably alters TAC concentrations. Drugs that cause nephrotoxicity also have the same additive effects with TAC as with CSA (Table 181.1).

Therapeutic Drug Monitoring. As with CSA, careful blood concentration monitoring is required; TAC also has a narrow therapeutic range. TAC is extensively bound to erythrocytes, so whole-blood trough measurements have become the standard for drug monitoring. The primary assay used currently is an automated microparticle enzyme immunoassay, available from Abbott Laboratories (Abbott Park, IL). Several generations of this assay have been used, with the current assay more sensitive at lower drug concentrations. The current suggested therapeutic range for TAC is 5 to 20 ng per mL; however, this range is still controversial and under study [25].

Clinical Use. Because TAC does not require bile to be absorbed, its use has attracted a great deal of interest in liver transplantation. Sandimmune® required bile in the small intestine, and if the bile drainage was being diverted it was almost impossible to obtain adequate CSA blood levels. TAC provided a possible advantage in liver transplantation, so the first major trials were in liver recipients.

The U.S. Multicenter FK-506 Liver Study Group compared the efficacy and safety of a CSA-based regimen (using Sandimmune®) versus a TAC-based regimen in adult and pediatric liver recipients at 12 different centers in the United States [30]. Recipients were randomized to CSA in combination with Azathioprine® (AZA) and steroids, or to TAC in combination with steroids. The investigators looked at patient and graft survival rates as well as the incidence of acute rejection, steroid-resistant rejection, and refractory rejection. At 1 year posttransplant, patient and graft survival rates were similar between the two groups, but TAC was associated with fewer episodes of all categories of rejection. The TAC group did have an increased incidence of adverse events, including nephrotoxicity, neurotoxicity, and hyperglycemia. Follow-up studies using lower doses of TAC have shown a reduction in these adverse events [35,36].

TAC is usually initiated at a dose of 0.05 to 0.10 mg per kg per day. Some centers use a standard starting dose of 2 mg BID, and adjust doses based on the blood concentration. As with CSA, TAC may be delayed after a kidney transplant in the case of graft dysfunction, and started when the kidney is recovering from acute tubular necrosis.

In studies of TAC and CSA in kidney recipients, results have been similar to those with liver recipients (i.e., same graft and patient survival rates, fewer rejection episodes) [37]. This pattern has also been seen in higher-risk patient populations, such as black recipients [38]. Other transplant categories with historically higher rates of rejection, such as pancreas transplant recipients, have seen benefit with TAC-based immunosuppressive regimens [31]. TAC continues to be the primary maintenance immunosuppressive agent in heart, lung, and bowel recipients, and was approved by the FDA for heart transplantation in 2006 [39–42].

Antiproliferative Agents

Antiproliferative agents have been part of transplant protocols since the first transplant was performed in the 1960s. Early antiproliferative agents included radiation, azaserine, and actinomycin D. AZA, developed in the early 1960s, was part of the first successful transplant series reported in 1963. It continues to be used today in maintenance immunosuppressive regimens and for autoimmune diseases. Cyclophosphamide was used when AZA use was not possible, but because of side effects it has never been considered a suitable alternative. A major advance in antiproliferative agents has been the development and use of MMF, released for clinical use in 1995. MMF is now a component of most new transplant regimens, with AZA having been used in transplants performed before 1995.

Azathioprine

Pharmacology. AZA is actually a prodrug of 6-mercaptopurine, an antineoplastic agent used in leukemia regimens. It acts by the inhibition of purine synthesis in the de novo pathway. This purine inhibition leads to the inhibition of the mixed lymphocyte reaction, and to a lesser extent, the antigen–antibody reaction [43].

Pharmacokinetics. AZA is rapidly absorbed after oral administration, with peak levels occurring 1 hour after ingestion. The large first-pass effect after oral administration means that IV doses must be multiplied by a factor of two. AZA is metabolized by xanthine oxidase through several steps to 6-thiouric acid and excreted into the kidneys. Although the half-life of the parent drug is relatively short, the pharmacodynamic effects of the parent drug and metabolites far outlast the time that AZA is present in the bloodstream [43].

Adverse Events. AZA is relatively well tolerated by most patients. The most common side effect is myelosuppression due to suppression of purine synthesis by AZA. The myelosuppression is usually limited to the white blood cells, but occasionally red cell aplasia is observed. Most patients can tolerate this effect by reducing the daily dosage, although some need to discontinue the drug entirely. Liver function tests must be regularly monitored: AZA has been reported to cause hepatic necrosis and liver failure. Pancreatitis or a skin rash may indicate an allergic reaction, in which case AZA may need to be stopped. Hair loss is bothersome to some patients but is reversible. Gastrointestinal (GI) disturbances, including nausea and vomiting, are mild and usually tolerable [43].

Drug Interactions. Severe pancytopenia has been reported when AZA and allopurinol are used together. It is recommended that AZA doses be reduced by 75% if allopurinol is added to the patient's drug regimen. With the development of MMF, the management of this interaction has become easier, as MMF (which is metabolized differently than AZA) can be substituted for AZA when allopurinol is indicated [43].

Clinical Use. AZA is available as a 50-mg tablet that can be split, if necessary. A compounded suspension of 5 mg per mL can be used if tablets are not an option. AZA is also available IV. Most recipients are maintained on a dose of 1.0 to 2.5 mg per kg per day. AZA has an important historical role in transplantation, but its use has declined as newer agents have been introduced. Most likely, recipients currently on AZA were transplanted before 1995 and have done well on that initial regimen. Some centers switched all their recipients when MMF became available, but many are still maintained on AZA due to a significant cost advantage over MMF.

Mycophenolate Mofetil

MMF was approved by the FDA in 1995 to prevent rejection in kidney recipients. Its use has grown to include liver, heart, lung, and pancreas recipients. It has been a major addition to

the immunosuppressive arsenal. Many centers have replaced AZA with MMF in their current protocols.

Pharmacology. MMF is also a prodrug, quickly metabolized to the active compound, mycophenolic acid (MPA). MPA acts as a noncompetitive inhibitor of inosine monophosphate dehydrogenase, thereby blocking de novo purine synthesis and proliferation in the T and B lymphocytes [44]. In vitro and in vivo data from rodent models of chronic allograft nephropathy suggest that MMF also decreases vascular smooth muscle cell proliferation, offering theoretical treatment possibilities for the morphology seen in chronic rejection [45].

Pharmacokinetics. Oral MMF is rapidly hydrolyzed in the bloodstream by esterases to MPA, with no measurable parent compound in serum [46]. The oral bioavailability for MPA approaches 100%, so the IV to oral conversion ratio is 1:1. IV administration of MMF provides measurable blood levels of the parent compound during infusion, with levels becoming immeasurable 12 minutes after the end of the infusion. Peak concentrations occur approximately 1 hour after IV or oral administration (but IV has a slightly higher peak than oral) [47]. MPA is subsequently glucuronidated in the liver to inactive metabolic mycophenolic acid glucuronide (MPAG). Enterohepatic cycling recirculates a significant percentage of MPAG secreted in bile back to MPA, displaying a secondary peak in plasma MPA concentration [48]. MPAG is eventually excreted, primarily in the urine; only 6% of MPAG is excreted in the feces [44].

Adverse Events. MMF can cause significant GI problems, including nausea, vomiting, diarrhea, abdominal pain, and gastroesophageal reflux. Persistent diarrhea not accompanied by fever may be associated with an erosive enterocolitis causing malabsorption of nutrients that has been attributed to a toxic action of the acyl MPAG metabolite on absorptive cells [49]. Occurrence of these side effects has more frequently been linked to the MMF dose rather than to the plasma concentration of parent compound or its metabolites. Dividing the total daily dose into four doses instead of two has been effective in reducing GI problems in some recipients. An alternative, enteric-coated form of MPA—mycophenolate sodium (EC-MPS)—has been developed to mitigate the GI toxicities. Patients who had GI intolerance on MMF administration required fewer dose changes of EC-MPS, and showed reduced symptom burden, better functioning, and improved health-related quality of life [50]. Neutropenia and thrombocytopenia can also occur with MMF, requiring a dosage reduction [44]. At 2 g per day, the occurrence rate in the major trials was comparable to AZA. Teratogenic trials of MMF in rabbits showed changes in offspring at doses equivalent to those given to humans. No human teratogenic trials have been performed (but the manufacturer recommends that female patients wait at least 6 weeks after stopping MMF before trying to conceive). Female healthcare workers are also advised by the manufacturer to not open capsules for fear of aerosolization of the drug. It is also recommended that IV MMF be administered using standard chemotherapy precautions [51].

Drug Interactions. MMF is not metabolized by the cytochrome P450 system; therefore, interactions with MMF only affect its absorption, enterohepatic cycling, or renal excretion. As discussed earlier, a significant percentage of the AUC for MMF comes from enterohepatic cycling. Cholestyramine, a bile acid resin, decreases cholesterol by interfering with its enterohepatic cycling. The mixture of cholestyramine and MMF decreases the total AUC by 40%, so the combination of these two drugs is not recommended [51]. Antacids appear to reduce absorption of MMF by 20%, so adjusting dosing times, if possible, is recommended. Ganciclovir and acyclovir compete with MPAG for secretion by the kidney, and animal studies have suggested a possible interaction [51].

Recipients treated with CSA in combination with MMF display lower MPA concentrations than do patients who are not receiving CSA [52]. However, coadministration of MMF with TAC tends to increase MPA levels due to the lack of CSA inhibitory effects, and also possibly due to the inhibition of the uridine diphosphate—glucuronosyl transferase that generates MPAG [53].

Clinical Use. The success of MMF has allowed it to generally replace AZA in many transplant centers. The results of three major trials were instrumental. The U.S., Tricontinental, and European trials compared MMF, in combination with CSA and steroids, with conventional immunosuppression. The U.S. and Tricontinental trials randomized patients to MMF at a low (2 g per day) or high dose (3 g per day) versus AZA, whereas the European study used a placebo instead of AZA [54–56]. All three trials saw significantly reduced rejection in the MMF arm at 6 months posttransplant. The low-dose and high-dose arms demonstrated significantly fewer rejection episodes and clinically significant reductions in the severity and treatment of rejection episodes. Whether long-term MMF changes survival rates is still controversial. The 3-year data from the U.S. trial periods do not yet show a statistically significant difference in patient or graft survival [53].

The high dose (3 g per day) was associated with more side effects in all three trials. Patients on the high dose developed more infections and had a higher rate of GI intolerance and marrow suppression [54–56]. FDA approval of MMF was at a starting dose of 2 g per day, given as a divided dose of 1 g twice daily. In recipients who develop GI or hematologic toxicity, the dosage should be reduced or MMF should be withheld for a few doses. Dividing the daily dose into more than two doses per day can also be beneficial. Recipients may need to discontinue MMF or convert to EC-MPS for GI intolerance.

The major trials used the less effective oil-based form of CSA. A European study using the ME-CSA formulation (Neoral®) showed only modest, insignificant reductions in acute rejection episodes with MMF compared with AZA, questioning the value of using the costlier MMF [57]. These findings which are drawn on low immunologic risk patients ought to be applied cautiously in other situations.

A subgroup analysis of the higher immunological risk African-American patients enrolled in the U.S. pivotal trial showed that the benefit for African-American versus Caucasian recipients was restricted to the MMF 3 g dose versus the MMF 2 g dose or azathioprine cohorts [58]. Thus, African-American recipients should receive 3 g per day unless they are unable to tolerate that dose.

In a multicenter trial, using a combination of TAC with MMF, a MMF dose of 2 g per day reduced the incidence of acute rejection episodes compared with MMF 1 g per day or AZA—the low acute rejection rate of 8.6% using a combination with MMF 2 g per day suggest that a combination with TAC produced superior results to a combination with CSA [59].

Therapeutic Drug Monitoring. Based on initial pharmacokinetics studies, MMF doses have not been calculated on a milligram per kilogram basis [47]. However, there exists a rationale to implement therapeutic drug monitoring for MMF, as pharmacokinetic variability of MMF has been documented due to differences in hepatic/renal function, concurrent drug administration, and the presence of diarrhea, but not to ethnicity [60]. It is the MPA parent compound and not the parent drug MMF that is readily measured in plasma by HPLC, owing to its high predose concentration (C0). Full MPA AUC monitoring with at least seven samples is impractical on a

routine basis. Concentration monitoring is most useful early after transplantation when absorption may be slow and incomplete, and clearance more rapid than at 3 months [61].

Sirolimus

The newest immunosuppressive agent to be released by the FDA belongs to a class of compounds known as the mammalian target of rapamycin (mTOR) inhibitors. Sirolimus (SRL), formerly known as rapamycin, was approved in September 1999 to prevent rejection in kidney recipients. It is produced by *Streptomyces hygroscopicus*, a fungus isolated from a soil sample found on Easter Island (Rapa Nui). SRL is the first mTOR inhibitor to be approved in the United States. A derivative of rapamycin, everolimus, was approved by the FDA in August 2004.

Pharmacology. SRL binds to FKBP-12, the same binding protein as TAC. It was initially thought that SRL and TAC could be antagonistic, given that they shared the same binding protein. Further research revealed, however, that the target of SRL is not calcineurin, but rather the target protein mTOR [62]. The inhibition of mTOR prevents cell-cycle progression from G1 to S in T lymphocytes; thus, SRL blocks the rejection pathway at a later stage than CSA or TAC [63].

SRL, because of its inhibition of lymphocyte proliferation at a later stage, may work synergistically with CSA or TAC. Median effect analysis of the pooled data to demonstrate immunosuppression synergy between CSA and SRL shows that administration of SRL allows a twofold reduction in CSA exposure, and conversely CSA allows a fivefold reduction in SRL dose to achieve the same immunosuppressive efficacy [64]. However, SRL reduces the exposure to TAC when the two drugs are coadministered [65].

Pharmacokinetics. SRL is rapidly absorbed, but the systemic bioavailability of the current formulation is approximately 15%. Food can affect systemic absorption, and SRL should be taken consistently with a meal. SRL is extensively distributed among blood components, but unlike CSA or TAC the distribution does not appear to be temperature dependent [66,67]. Only a small fraction of SRL remains unbound. It is extensively metabolized, with seven major metabolites currently identified. The primary pathway for metabolism is the cytochrome P450 3A4 enzyme system. SRL has a much longer half-life than CSA or TAC, with an average terminal half-life of approximately 60 hours. This extended half-life allows it to be dosed on a once-a-day basis. Hepatic impairment can extend the elimination half-life, so patients with mild to moderate liver disease may require dosage adjustment [67].

SRL is currently available as a 2 mg and 1 mg tablet and as a 1 mg per mL suspension. The tablets should not be crushed. For administration, the suspension should be mixed only with water or orange juice; no other liquids have been tested. No IV formulation is commercially available [68].

Adverse Events. SRL has a different profile of adverse events than other immunosuppressive drugs. In one study, SRL used alone in kidney recipients resulted in a lower serum creatinine level and a higher glomerular filtration rate, compared with CSA [68]. SRL use is not entirely bereft of adverse effects on the kidney. TMA has been found to occur with the use of SRL in the absence of CNI use [69]. Proteinuria is a common manifestation of SRL toxicity in patients converted from CNI for renal impairment. Pre-existing renal damage may be necessary before proteinuria manifests [70]. In such cases, proteinuria resolves when patients were converted back to CNI and SRL was stopped [71]. Delayed recovery from ischemia–reperfusion injury has been observed in registry analysis [72] and this occurs due to inhibitors of cell proliferation by SRL affecting tubular repair [73].

Hypertriglyceridemia and hypercholesterolemia are dose-related adverse events of SRL that may be exacerbated by the use of steroids or CNI [74,75]. Their effect appears to peak after 1 month of SRL therapy; in some recipients, lipid levels decreased to near baseline concentrations after 1 year. Fifty-three percent of SRL-treated patients required lipid-lowering agents compared with 24% in the CSA group. The increase in lipids seen with mTOR inhibitors is a long-term concern.

SRL causes dose-dependent thrombocytopenia and leukopenia, particularly during initial therapy; their incidence is variable and usually self-limiting. Significant decreases in platelet or white blood cell counts can be treated by decreasing the dosage. Occurrence of leukopenia and thrombocytopenia correlates with SRL trough concentrations greater than or equal to 16 ng per mL [76]. The incidence of anemia is also increased with the use of mTOR inhibitors. In the global study of primary use of SRL in renal allograft recipients, anemia was observed in 16% of recipients taking 2 mg per day and 27% of recipients taking 5 mg per day of SRL [77].

During clinical trials, other adverse events associated with SRL included hypertension, rash, acne, hypokalemia, diarrhea, aphthous ulcers, and arthralgias [67]. Thirty-one cases of interstitial pneumonitis were reported by the FDA [78], which can occur any time after initiation of SRL treatment and can progress to respiratory failure. A mortality of 12% was noted in this report, although early recognition with immediate discontinuation of SRL should reduce mortality.

Other adverse effects that occur with de novo SRL use in kidney recipients include wound healing problems and lymphoceles [79]. A systemic program based on patient selection with body mass index < 32 kg per m^2, the use of closed suction drains, modifications of surgical technique, and avoiding a loading dose of SRL led to a reduction in wound complications and in the incidence of lymphoceles.

Drug Interactions. Most of the drug interactions that have been reported for SRL are related to P450 enzyme inhibition or induction—the same list of drugs that interact with CSA and TAC. Any compound that can affect P450 metabolism may also affect SRL metabolism. As mentioned earlier, significant changes in exposure to TAC or CSA can occur when prescribed along with SRL.

Patients taking SRL have a much higher exposure to MPA, the active constituent of MMF, than do patients taking CSA and MMF [80]; a similar drug interaction is recognized for TAC as well.

Clinical Use. The phase II trials conducted in Europe were among the earliest that used SRL as a principal immunosuppressant. Pooled data from two of these studies showed significantly higher glomerular filtration rates in patients receiving SRL as compared to CSA [81]. A systematic review of randomized trials in which mTOR inhibitors were used in place of CNI as initial therapy after kidney transplantation revealed no difference in the incidence of acute rejection at 1 year, but the serum creatinine was lower in patients receiving mTOR inhibitors [82]. The two large phase III studies of SRL, one conducted in the United States [83] and the second worldwide [77], revealed much about how best to use SRL and its drawbacks. There was a higher incidence of lymphocele formation and wound infection in the SRL arm compared with the control arm. It was also found that the renal function of patients on a combination of SRL and CSA was worse than patients on CSA alone. Regarding the combination of SRL with TAC, registry data suggest poorer graft survival compared to the combination of TAC with MMF [84]. Phase III studies indicated that the combination of either 1.5 mg per day or 3 mg per day of everolimus was better than MMF in the prevention of acute renal allograft rejection when combined with CSA and steroids after kidney transplantation.

The combination of everolimus/CSA was associated with poorer renal function than MMF/CSA combination [85].

Inhibitors of mTOR are potentially attractive agents for use in the maintenance phase of the posttransplant course in patients with CNI toxicity and as a later addition to CNI to enhance immunosuppression in response to acute rejection. A randomized controlled trial suggests that conversion to SRL with impaired graft function results in a rapid improvement in measured glomerular filtration rate at 3 months that was sustained at 2 years; patients remaining on CNI experience deteriorating graft function [86]. Time for conversion in such patients is unclear, but early rather than late conversion is probably best, before the structural changes associated with interstitial fibrosis/tubular atrophy become extensive [87].

Inhibitors of mTOR are known to prevent tumor cell growth. Temsirolimus, an SRL derivative, has been used in phase I/II clinical trials of advanced renal carcinoma, breast cancer, prostate cancer, pancreatic cancer, glioblastoma, and lymphoma. A multivariate analysis of posttransplant malignancies in renal allograft recipients showed a lower incidence of malignancy in patients taking mTOR inhibitors alone or in combination with CNI compared to those taking CNI alone [88]. SRL has been also found to be effective in the treatment of posttransplant lymphoproliferative disorder (PTLD) [89] and Kaposi's sarcoma [90].

Therapeutic Drug Monitoring. Drug level monitoring is extremely important, especially in newer protocols that may not contain CNI or steroids. Making an accurate assay commercially available has been difficult, hindering use of the drug in some instances. Research is ongoing to determine the best assay system. HPLC has been studied and is being used in several centers with good success to date [75]. An immunoassay is also available for SRL therapeutic drug monitoring.

Initial therapeutic drug monitoring of SRL has correlated well with trough concentrations and allograft rejection, such that trough concentrations are generally accepted as a good measure of SRL activity. The therapeutic range is still being debated, but the general agreement is that concentrations between 5 and 15 ng per mL will prevent rejection and toxicity in most patient populations. Higher-risk patients may need to achieve higher trough concentrations [75].

Corticosteroids

Steroids have been a part of transplantation since its inception. It soon became clear, however, that the toxicities of steroids could overshadow their benefits. The role of steroids in transplantation is changing, as experience is gained in the use of newer immunosuppressive medications that are serving to limit corticosteroid use.

Pharmacology

Steroids have many different effects on the immune system. They inhibit T-cell proliferation, T-cell–dependent immunity, and the expression of various cytokines, especially IL-2, IL-6, interferon-γ , and tumor necrosis factor-α (TNF-α) [91]. They also suppress antibody formation and the delayed hypersensitivity response found in allograft rejection [92].

Clinical Use

For years, steroids have been part of any immunosuppressive regimen to prevent and treat rejection. For use in standard immunosuppression, recipients typically begin on a high initial dose [anywhere from 1 mg per kg to 500 mg IV of methylprednisolone (MP)] on the day of the transplant, and then taper over weeks to months to their final maintenance dose. Most centers maintain recipients on 5 to 10 mg daily or every other day. PRED is the oral drug of choice in most programs; however, if IV dosing is required, MP is the drug of choice. The true ratio of MP to PRED potency is 0.8 to 1.0, although for most recipients that difference is small enough to allow a one-to-one conversion [93].

Steroids at high doses have successfully reversed rejection episodes [94]. Most centers use 500 mg to 1 g of IV MP for three doses to reverse a suspected or documented rejection episode. Recipients should be advised that the typical adverse effects for steroids may be magnified at these higher doses. Many centers use three doses of IV MP for mild to moderate rejection episodes. Antibody therapy is used for steroid-resistant rejection or high-grade rejection.

Adverse Effects

Steroid use is associated with a number of problems, acute and long-term. Acute toxicities of corticosteroids include sodium retention, glucose intolerance, mental status changes, and increase in appetite, acne, and gastritis. Most of these problems are magnified with higher doses and are reduced or eliminated once the dosage is reduced. The long-term side effects are costly to treat and reduce quality of life. A cost estimate for the incidence of cataracts, hypertension, osteoporosis, and diabetes in transplant recipients was in the range of $2,500 to $7,500 per patient over 10 years [95]. Graft loss due to rejection is being replaced by death with function, a term referring to recipients who die with a functioning graft. Cardiovascular disease has become one of the leading causes of death with function. Hypertension, hyperlipidemia, and steroid-induced diabetes may be partly responsible for increasing the risk of cardiovascular death. Accordingly, many transplant centers are switching to steroid-withdrawal/steroid-free protocols for many of their recipients.

Steroid Withdrawal Protocols. A meta-analysis of trials where steroid withdrawal had been done in the first year after kidney transplantation showed that although the risk of acute rejection was more than twofold when steroids were withdrawn, there was no significant difference in the incidence of graft failure [96]. Although four of the trials used MMF/CSA and two used MMF/TAC, no attempt was made to differentiate steroid-sparing potential of CSA and TAC. The European TAC/MMF study group randomly assigned immunologically low-risk patients who had undergone transplantation 3 months earlier to continue triple therapy (TAC, MMF, and steroids), withdraw steroid, or withdraw MMF. Incidence of acute rejection was similar in all three groups at 6 months [97] suggesting TAC enables more effective steroid sparing than CSA. Graft and patient survival and the incidence of acute rejection were similar between groups at 3 years, and serum creatinine levels remained stable [98].

A 3-year analysis of a large trial was done of 300 patients receiving basiliximab induction, CNI, and MMF or SRL in which patients were assigned to have steroids withdrawn on day 2 or to continue steroids. No difference was noted in graft function, patient and graft survival, biopsy proven acute rejection, or chronic allograft nephropathy between the two groups [99]. Use of MMF and SRL, with a CNI, may allow safe withdrawal of steroids earlier.

BIOLOGIC IMMUNOSUPPRESSION

Various antibody preparations, both of polyclonal and monoclonal origin, are currently used in clinical immunosuppression. Polyclonal antibodies directed against lymphocytes were developed first and have been used in transplantation since the 1960s. Monoclonal antibody techniques were discovered later, and, in turn, allowed for the development of biologic agents

such as OKT3, which target specific subsets of cells. A number of different monoclonal antibodies (mAbs) are currently under development or in various phases of clinical testing; several have been tested and are now in clinical use. Many are directed against functional secreted molecules of the immune system or their receptors, rather than against actual groups of cells.

One disadvantage of early murine-based antibody preparations such as OKT3 is the potential for the development of antimouse antibodies by the recipient—antibodies that may then limit further use of the agent. To address this problem, recent efforts have focused on the development of so-called humanized versions of mAbs. One option is to replace the constant Fc portion of the parental murine antibody with a human Fc component, thus creating a chimeric antibody. These mAbs may be further humanized to preserve only the original complementarity-determining region, the hypervariable region of the antibody that determines antigen specificity. The remainder of the original murine mAb molecule is replaced by human immunoglobulin G. The advantages of these humanized mAbs are a very long half-life, reduced immunogenicity, and the potential for indefinite and repeated use to confer effects over months rather than days [100]. Biologics are used as rescue agents in 20% of all acute rejection episodes, whilst 50% to 70% of patients undergoing kidney transplantation receive biologic induction [18].

Polyclonal Antibodies

Polyclonal antibodies are produced by immunizing animals, such as horses or rabbits, with human lymphoid tissue; allowing for an immune response; removing the resulting immune sera; and purifying the sera in an effort to remove unwanted antibodies. What remain are antibodies that recognize human lymphocytes.

Polyclonal preparations consist of a wide variety of antibodies and detect specificities include many T cell molecules involved in antigen recognition (CD3, CD4, CD8, and TCR), adhesion (CD2, lymphocyte function antigen [LFA]-1, and intracellular adhesion molecule [ICAM]-1), and costimulation (CD28, CD40, CD80, CD86, and CD154), and non-T cell molecules (CD16 and CD20), and class I and class II major histocompatibility complex (MHC) molecules.

After administration of these antibodies, the transplant recipient's total lymphocyte count should fall and hence these are known as depleting antibodies. Lymphocytes, especially T cells, are then lysed, cleared from the circulation, and deposited into the reticular endothelial system. Alternatively, their surface antigen may be masked by the antibody. Polyclonal antibodies have been successfully used to prevent rejection and to treat acute rejection episodes. Two main polyclonal antibody agents are available for clinical use in the United States: ATGAM and Thymoglobulin.

The broad reactivity with adhesion molecules and other receptors upregulated on activated endothelium has led to preferential use of polyclonal antibodies in situations with prolonged ischemia times where endothelial activation and ischemic reperfusion injury is expected [101].

ATGAM®

ATGAM® is obtained by immunizing horses with human thymocytes. It is generally administered at a dose of 10 to 15 mg per kg, in a course lasting 7 to 14 days. ATGAM® must generally be infused into a central vein, because infusion into a peripheral vein is often associated with thrombophlebitis. To avoid the cytokine release syndrome, recipients should be premedicated with MP and diphenhydramine hydrochloride. Side effects include fever, chills, arthralgia, thrombocytopenia, leukopenia, and a serum sickness–like illness. These side effects are more likely related to the release of pyrogenic cytokines such as TNF-α, IL-1, and IL-6 which result from cell lysis due to antibody binding to targeted cellular surface receptors [102]. Increased infection rates are associated with all immunosuppressants, but certain infections, such as cytomegalovirus, are more common after the use of ATGAM® and other antibody preparations [103].

Thymoglobulin (ATG-R)

Thymoglobulin is obtained by immunizing rabbits with human thymocytes. Initial kidney transplant studies show ATG-R® to be statistically superior to ATGAM® in preventing acute rejection episodes and in reversing acute rejection episodes [104,105].

ATG-R® induction and reduced maintenance immunosuppression has been used in closely followed patients and resulting in graft and patient survivals comparable to standard triple immunosuppression [106]. Administration before reperfusion is advocated to maximize antiadhesion molecule effects.

Comparison studies showed that OKT3 reversed a slightly higher number of rejection episodes than ATG-R® in kidney recipients, but both were efficient treatments. First-time use of ATG-R® was associated with fewer side effects than OKT3 [107]. The side effect profiles of ATG-R® and ATGAM® are similar. With ATG-R®, leukopenia and thrombocytopenia may be quite significant. If a significant drop in platelets or white blood cells is noted, the dosage should be halved or the drug temporarily withheld.

Monoclonal Antibodies

The hybridization of murine antibody–secreting B lymphocytes with a nonsecreting myeloma cell line produces mAbs. A number of mAbs are active against different stages of the immune response. OKT3® has been the most commonly used mAb, but the last few years have seen the introduction and wide use of a number of chimeric and humanized mAbs. Chimeric antibodies preserve the specificity of the original antibody better, whereas humanized antibodies are less likely to be neutralized [108]. Both strategies are effective in preventing antibody clearance.

OKT3

On binding to CD3, OKT3® mediates complement-dependent cell lysis and antibody-dependent cell cytotoxicity leading to rapid clearance of T cells from the peripheral circulation [100]. Pan-T cell activation before their elimination results in systemic cytokine release, and a marked cytokine release syndrome which results in most of the adverse effects associated with OKT3®.

Along with T cell depletion, the overall effect of OKT3® is likely to be due to interrupted T cell receptor (TCR) binding and internalization, disrupted trafficking, and cytokine-mediated regulatory changes.

The standard dose of OKT3® is 5 mg per day given IV, although smaller doses may be as effective. Efficacy can be measured by monitoring CD3-positive cells in the circulation. If OKT3® is effective, the percentage of CD3-positive cells should fall to, and stay below, 5%. Failure to reach this level indicates either an inadequate dose or the presence of antibodies directed against OKT3®. Human antimouse antibodies may develop in at least 30% of patients, and render OKT3® ineffective, allowing for the reappearance of CD3-positive cells in the circulation. This scenario is more common with retreatment using OKT3® or with prolonged treatment.

OKT3® is highly effective and versatile. Most commonly, it is used to treat biopsy proven acute rejections in patients who have failed 3 days of therapy with high-dose MP [109]. OKT3® has also been used as induction therapy to prevent acute rejection and as primary treatment for acute rejection associated with vasculitis (Banff 2 or 3) [110]. Use of OKT3® as an induction agent has declined due to its side-effects' profile. Significant, even life-threatening, side effects may be seen with OKT3®. They may occur when cytokines (e.g., TNF, IL-2, and interferon) are released by T cells into the circulation. These side effects usually occur relatively soon after infusion of OKT3®, and they tend to be most severe after the first and second dose, generally abating by the third or fourth dose. Premedication with IV steroids and agents such as diphenhydramine hydrochloride is important to try to minimize these side effects. The most common symptoms are fever and chills, which generally occur within 30 to 60 minutes after the infusion. Generally, only symptomatic treatment is needed. If fever persists beyond the third dose, then an infectious cause should be sought.

The most serious side effect with OKT3® is a rapidly developing, noncardiogenic pulmonary edema that can be life threatening. The risk of this side effect significantly increases if the recipient is fluid overloaded before beginning OKT3®. Pulmonary edema may develop even in euvolemic patients. If patients are fluid overloaded, they should undergo dialysis or ultrafiltration to remove excess volume before they begin OKT3®.

OKT3® is associated with a wide spectrum of neurologic complications. The most common side effect is headache. Aseptic meningitis has also been reported, albeit usually self-limiting. In this situation, a lumbar puncture demonstrates leukocytosis, but the fluid is sterile. Encephalopathy, ranging from mild to severe, has also been described. If severe encephalopathy develops, OKT3® should be discontinued.

Nephrotoxicity occurring with OKT3® therapy is usually self-limiting, and the recipient improves after the first few doses. Allograft thrombosis has also been reported [111]. Late adverse events reported with OKT3® include infections (especially with cytomegalovirus) and lymphomas.

Anti–Interleukin-2 Monoclonal Antibodies

IL-2 is an important cytokine necessary for the proliferation of cytotoxic T cells. Several mAbs have been developed to target the IL-2 receptor, but currently only one agent is available for clinical use: basiliximab (Simulect®). Daclizumab (Zenapax®) was recently withdrawn from clinical use. Binding of these agents to the IL-2 receptor results in blockade of IL-2–mediated responses. Both are humanized antibodies; with basiliximab, the constant region of the antibody is of human origin; the variable region is of murine origin. Therefore, 75% of the antibody is of human origin.

Because major portions of these agents are of human origin, they tend to have much longer half-lives than does OKT3®. Also, unlike OKT3®, they are not associated with a first-dose reaction. The CD25 component of the IL-2 receptor is primarily focused on naive T cell early activation. Based on this effect, clinical trials in kidney recipients have shown these agents to be effective in preventing acute rejection [112]. It is not indicated for the treatment of established acute rejection episodes, however. For basiliximab, two IV doses of 20 mg (one administered preoperatively and the other on postoperative day 4) are recommended.

Comparable outcomes have been seen in studies comparing basiliximab and polyclonal antibodies and maintenance immunosuppression regimens consisting of CSA, MMF, and steroids [113]. Steroid-free maintenance regimens have also been used in kidney transplantation with anti-CD25 induction [114]. CNI monotherapy or avoidance is not facilitated by the use of anti-CD25 preparations [115]. In all clinical trials to date, basiliximab has been shown to be remarkably safe, with minimal side effects ascribed directly to its use.

Alemtuzumab (Campath-1 H®)

The CD52-specific humanized monoclonal antibody alemtuzumab has the advantages of ease of administration, consistency of monoclonal antibodies, and the benefits of humanization. Alemtuzumab rapidly depletes CD-52 expressing lymphocytes centrally and peripherally resulting from bulk T cell depletion with lesser depletion of B cells and monocytes [116].

Although alemtuzumab depletes all T cell subsets, its action is selective for naive cell types [117]. The T cells that are not depleted exhibit a memory phenotype and are most susceptible to CNI. Maintenance regimens using CNI do best following alemtuzumab induction.

Alemtuzumab facilitates reduced maintenance immunosuppression requirements without an increase in infections or malignant complications in kidney, pancreas, lung, and liver transplantations as compared to historical controls [118–123].

With the increasing use of alemtuzumab as an induction agent, there has been increase in its use as an agent for treating steroid-resistant rejection. There have been anecdotal reports of its use in this setting [124]; additional studies are needed to define its role for this indication.

Rituximab (Humanized Anti-CD-20)

This is a chimeric monoclonal antibody specific for CD20, a cell surface glycoprotein involved in B cell activation and maturation. Rituximab rapidly clears CD20+ cells from the circulation. CD20+ cells are precursors to antibody producing plasma cells, but do not produce antibody themselves; neither do they have a direct effector cell role in rejection. Presence of CD20+ infiltrates has been used as a marker for resistant acute rejection [125]. These cells also have a role in intragraft antigen presentation.

Rituximab has been used as an induction agent in lieu of recipient splenectomy in patients undergoing donor desensitization with plasmapheresis and/or intravenous immunoglobulin [126].

Use of rituximab in high-grade rejection remains investigational. Rituximab has a role in the treatment of Banff 2 and 3 rejection and in reducing antibody formations [127].

The most important indication for the area of rituximab in organ transplantation is as a primary treatment of PTLD—somewhere between immunosuppression withdrawal and the aggressive use of chemotherapy.

FUSION PROTEINS

These are made by the fusion of a single receptor targeting a ligand of interest with a secondary molecule, which is typically the Fc portion of an IgG molecule. Fusion proteins can be composed of humanized components limiting their immune clearance and allowing prolonged administration.

Costimulation-Based Agents

Costimulatory molecules alter the threshold for activation of naive T lymphocytes without having a primary activating or inhibitory function. Fusion proteins have been developed that act by blocking costimulation pathways. The two costimulatory receptors on T cells are CD28 and CD152; these serve

reciprocal roles—CD28 facilitates a T cell response, whereas CD152 reduces it.

The fusion proteins that act by inhibiting costimulation-based pathways, and have been studied in renal transplantation, inhibit CD28 and CD152 signaling and this leads to immunosuppression.

Belatacept (investigative name LEA29Y) is a second-generation costimulation-blockade agent that has two amino acid substitutions that give slower dissociation rate for binding to the ligands of CD28. It prolongs the onset of acute rejection in nonhuman primates and synergizes with basiliximab and other clinically available agents. The BENEFIT study reported the primary outcomes from a randomized, phase III study of belatacept versus CSA in kidney transplant recipients [128]. At 12 months, belatacept regimes demonstrated superior renal function and similar patient/graft survival versus CSA, despite an increase in acute rejection in the early posttransplant period. Belatacept is a promising, nonnephrotoxic option in kidney transplant recipients and is being developed with the aim of providing CNI avoidance [129]. It is intended for use as an induction agent as well as for maintenance immunosuppression.

OTHER IMMUNOSUPPRESSIVE AGENTS

Leflunomide and Malononitrilamide (MNA)

The potential of overimmunosuppression resulting from the long half-life (15 to 18 days) of leflunomide has been partly overcome by the shorter half-life (6 to 45 hours) of one of its synthetic analogues also known as FK778. Leflunomide and its analogues have strong antiproliferative effects on T lymphocytes and B lymphocytes. Inhibition of pyrimidine synthesis by a direct-leflunomide–mediated inhibition of dihydro-orotate dehydrogenase leads to suppression of DNA and RNA synthesis. This group of medications also acts through inhibition of tyrosine kinase. FK778 and leflunomide possess antiviral effects and have been used successfully to treat cytomegalovirus [130] and BK virus nephropathy [131] in renal transplant patients.

FK778, in combination with TAC and corticosteroids, was used in a phase II multicenter study involving 149 renal transplant patients [132]. Patients receiving FK778 experienced fewer acute rejection episodes, but there was no effect on graft survivals at week 16.

Janus Kinase 3 Inhibitors

Janus kinase 3 (JAK3) is essential for the signal transduction from the cytokine receptors of several cytokines to the nucleus. Being expressed only on immune cell makes it an important target for developing new immunosuppressants. Several JAK3 inhibitors are available, but CP-690559 is the most potent and selective JAK3 inhibitors. In vivo effects of CP-690550 include reduction in natural killer cell and T cell numbers, whilst CD8+ effector memory T cells were unchanged [133]. A randomized, pilot study compared CP690550 (15 mg BID [CP15] and 30 mg BID [CP30], $n = 20$ each) with TAC ($n = 21$) in de novo kidney transplant recipients [134]. Patients received an IL2R antagonist, MMF, and steroids. Coadministration of CP-690550 30 mg BID with MMF was associated with overimmunosuppression. At a dose of 15 mg BID, the efficacy/safety profile was comparable to TAC, although there was higher rate of viral infection. Although, further dose ranging evaluation of CP-690550 is needed, it may become an important component of CNI avoidance regimens.

IMMUNOSUPPRESSIVE STRATEGIES

Immunosuppressive strategies must take into account the risk of an acute rejection episode, the consequences of an acute rejection episode, the side effects of the immunosuppressive agents, and the consequences of graft loss. The relative importance of each factor may vary depending on the organ transplanted. For example, for kidney recipients, an acute rejection episode is a major risk factor for chronic rejection; strategies must minimize the incidence of acute rejection. For liver recipients, an acute rejection episode usually is easily reversed and has little long-term significance; therefore, lower initial doses of immunosuppression can be used and then increased in those patients who suffer a rejection episode. Dialysis provides a backup if a kidney graft fails, whereas there is no recourse (other than a retransplant) for failure of many other solid-organ grafts. Therefore, particularly for heart and lung recipients, early aggressive immunosuppressive strategies are warranted.

Thus, no single approach applies uniformly across all organs to posttransplant immunosuppressive therapy. Immunosuppressive agents can be categorized according to their use:

Induction—those used for a limited interval at the time of transplant;

Maintenance—those used long term for maintenance of immunosuppression; and

Antirejection—those used for a short time or in high doses to reverse an acute rejection episode.

Considerable overlap exists among these categories, however. For example, the monoclonal and polyclonal antibodies can be used for induction or rejection treatment; PRED is used in high doses for induction or antirejection therapy but in low doses for maintenance therapy; and, in some situations, the doses of maintenance therapy drugs (e.g., TAC) are increased to treat rejection.

Finally, many transplant programs individualize immunosuppression depending on the perceived immunologic risk of rejection and graft loss for that recipient. For example, for kidney recipients, immunosuppressive protocols at a single center may vary for human leukocyte antigen–identical living donor recipients, nonidentical living donor recipients, low-risk cadaver donor recipients, and high-risk (e.g., blacks, those with a high panel-reactive antibody or delayed graft function, retransplant) recipients.

Induction

All recipients (except for identical-twin kidney recipients) require immunosuppressive therapy at the time of transplant. Many transplant centers begin with the same immunosuppression that is used for long-term maintenance. Other centers begin using induction therapy with polyclonal (e.g., Thymoglobulin, ATGAM) or monoclonal (e.g., basiliximab, OKT3, alemtuzumab) antibodies. The goal of induction immunosuppression is to provide powerful immunosuppression peritransplant, decrease the overall incidence of rejection, and permit delay in introducing other maintenance agents such as the CNI.

Prospective randomized studies have shown a decreased incidence of acute rejection episodes with early posttransplant induction therapy. The drugs are expensive, however, and a

TABLE 181.3

ADVANCES IN IMMUNOSUPPRESSION OF SOLID-ORGAN TRANSPLANTATION

1. Major emphasis has been in the area of reduction of toxicities of immunosuppressive agents/combinations.
2. With the increasing use of tacrolimus, steroid-free protocols have been used successfully.
3. Use of depletional antibodies like alemtuzumab has allowed the successful use of tacrolimus monotherapy.
4. To circumvent nephrotoxicity of CNIs, several nonnephrotoxic agents like sirolimus, mycophenolate, belatacept, and JAK3 inhibitors have been developed. Use of IL-2 receptor blockers as induction therapy along with combination of nonnephrotoxic agents might one day lead to successful CNI-free immunosuppression.
5. Use of rituximab in the treatment of B-cell (CD20+)–mediated rejection.

CNIs, calcineurin inhibitors.

long-term benefit has not been well documented for low-risk recipients. As a consequence, some centers use induction for all recipients, other centers use it for no recipients, and still others individualize depending on rough calculations of immunologic risk. More recently, the advantages of steroid- or calcineurin-sparing protocols have been touted, so many centers use short-term induction with IV antibodies in an attempt to lower the doses of other immunosuppressive drugs.

One perceived advantage of antibody induction is the ability to use lower doses of CNIs early posttransplant. A frequent concern is perioperative renal function (of the kidney graft for kidney recipients; of the native kidneys for liver, heart, or lung recipients). Because CNIs are nephrotoxic, delaying their introduction until renal function has recovered may be beneficial.

Maintenance Therapy

First Six Months

With the introduction of multiple new agents in the 1990s, immunosuppressive protocols have become more varied. Table 181.2 illustrates the many combinations currently used for long-term posttransplant maintenance therapy. At most centers, CINs (CSA or TAC) form the basis of immunosuppressive protocols. These drugs have been used as monotherapy and/or in combination with PRED or an antimetabolite. Prospective randomized trials have shown a lower incidence of acute rejection when MMF replaces AZA in these combination protocols [54–56]. Similar trials have shown a lower incidence of acute rejection in SRL versus AZA-treated recipients [83]. Additional studies are needed to determine the relative benefits and risks of MMF versus SRL.

Of interest, CNI-free protocols have been devised. The major goal of such protocols is to avoid the nephrotoxicity associated with use of CNIs. The combination of SRL and MMF has been used to achieve these results. Although nephrotoxicity can be avoided, relatively high doses of both drugs need to be used; as discussed previously, they each have their own side effects. In other randomized trials of CNI-free protocols, belatacept [128] and JAK3 inhibitors [133] have been used.

Considerable debate exists as to whether CNI should be used as monotherapy or combined as double or triple therapy for early posttransplant immunosuppression. Preconditioning with alemtuzumab (Campath 1-H) followed by TAC monotherapy has been successfully used in kidney transplantation with low acute rejection rates [121]. It is important to note that for all protocols, monitoring drug levels and maintaining CNI levels within a specified drug range seem critical to prevent acute rejection episodes early posttransplant.

Late Posttransplant

It is unclear whether all agents used for maintenance therapy in the early posttransplant period need to be continued late posttransplant. Meta-analyses have shown no risk to stopping AZA or CNI late posttransplant [135,136]. Meta-analyses of studies of PRED withdrawal in kidney recipients have shown an increased risk of rejection, however, and an increased risk of graft failure in recipients who stopped PRED [136,137]. In addition, single-center studies have shown no impact of stopping MMF in the late posttransplant period.

CONCLUSIONS

Since 1992, following the introduction of a number of new immunosuppressive agents, short-term graft and patient outcomes have improved considerably. However, the side effect of immunosuppressive agents continues to present a major problem. With the increasing use of TAC, steroid-free protocols were used successfully. Development of depleting monoclonal antibodies like alemtuzumab has led to the use of TAC monotherapy as maintenance immunosuppression. In kidney transplantation, long-term outcomes have been affected by the nephrotoxicity of CNI. In nonrenal transplant recipients, CNI toxicity has led to renal insufficiency and failure in a significant number of instances. Development of nonnephrotoxic agents like SRL, MMF, belatacept, and JAK3 inhibitors and their use in combination will some day lead to the successful use of CNI-free immunosuppression. A summary of some of the advances in the field of immunosuppression is shown in Table 181.3.

Another major advantage of the availability of several immunosuppressive agents is that immunosuppression can now be tailored for the individual patient. Those having drug-specific toxicity can be switched to another drug with similar efficacy but differing side effects.

ACKNOWLEDGMENT

We are grateful to Melissa Connell for assistance with the manuscript.

CHAPTER 182 ■ CRITICAL CARE PROBLEMS IN KIDNEY TRANSPLANT RECIPIENTS

MARK L. STURDEVANT AND RAINER W.G. GRUESSNER

INTRODUCTION

A kidney transplant (KTx) remains the most definitive and durable solution for patients reaching end-stage renal disease (ESRD). A successful transplant, as compared with dialysis, can provide a higher quality of life for a longer period at an overall lower cost for the more than 104,000 patients currently awaiting a KTx on the United Network for Organ Sharing waiting list [1,2]. In 2006, in United States KTx centers, the cumulative 1-year graft survival rate was 91.3% for deceased donor recipients and 96.4% for living donor recipients; an analysis of recipients transplanted in 2002 revealed a 5-year graft survival rate of 68.9% for deceased donor recipients and 81.5% for living donor recipients. The half-life graft survival time now projected for deceased donor recipients is approximately 10 years; for living related donor recipients, almost 18 years, depending on the human leukocyte antigen (HLA) match [3–5]. Despite these encouraging results, the waiting list continues to expand, and the living and deceased donor pools have fallen further behind; this divergence results in recipients who can be subjected to the ill effects of uremia and dialysis for more than 5 years pretransplant. Critical care providers therefore face a cohort of patients with a higher acuity of illness than seen even a decade ago. This chapter discusses the salient points of critical care that KTx recipients must receive to optimize their outcomes.

PRETRANSPLANT EVALUATION

Thoughtful patient selection and a thorough pretransplant evaluation of transplant candidates are essential for optimal transplant outcomes; because hypertension, diabetes mellitus, and cardiovascular disease are ubiquitous in this group, risk stratifying is helpful. The pretransplant evaluation should be exhaustive (covering gastrointestinal, pulmonary, neurologic, genitourinary, and infectious disease concerns). The cardiovascular examination is the most important and possibly the most unreliable. Candidates at increased risk for coronary artery disease or cardiac dysfunction, especially those with diabetes, should undergo noninvasive cardiac stress testing. For those with reversible cardiac ischemia, coronary angiography is mandatory to elucidate the need for percutaneous coronary artery balloon dilation or even coronary artery bypass.

The problem lies in the most troublesome deficiency in noninvasive testing—that is, the suboptimal sensitivity for cardiac death and infarction. In a meta-analysis, the sensitivity of the pretransplant cardiac perfusion study for myocardial infarction was only 0.7; for cardiac death, only 0.8 [6,7]. Therefore, the onus remains on transplant physicians to have a high suspicion for life-threatening cardiovascular disease in this patient population; even uremic young adults (< 40 years old) should be heavily scrutinized, because more than 90% of them who

had renal insufficiency during childhood will have significant cardiac or carotid disease.

Even with an aggressive approach to pretransplant evaluation, cardiac complications occur in 6% of recipients during the first-month posttransplant [6]. Candidates with a history of stroke or transient ischemic attacks (TIAs) require a carotid duplex ultrasound to exclude critical carotid stenoses. Pulmonary function testing should be assessed in candidates with a history of pulmonary disease such as emphysema or asthma. Also, at least one group reported an abnormally high prevalence of pulmonary hypertension (40%) in recipients who were undergoing hemodialysis (HD) via an arteriovenous fistula [8].

Up to 10% of the HD population has antihepatitis C antibodies; therefore, all KTx candidates should be screened, and abnormal liver function test results should stimulate a more thorough evaluation [9]. Cholecystectomy should be considered for candidates with symptomatic cholelithiasis.

Gastrointestinal disease, ranging from gastritis and peptic ulcer disease to colonic diverticulosis, is more common in patients with ESRD. Liberal use of bidirectional endoscopy is justified in this population, and colonoscopy is mandatory in all candidates 50 years and older. Recurrent urinary tract infections or a history of bladder dysfunction mandates a urologic evaluation.

Candidates with a personal or family history of hypercoagulability should undergo a thrombophilia evaluation. If appropriate pretransplant evaluations are readily performed, therapeutic measures can begin in a timely manner to avoid many potential complications (some life threatening).

PERIOPERATIVE CARE

Pretransplant Preparation

Proper pretransplant preparation in the days before the operation is essential for optimal graft and recipient outcome. Ideally, HD-dependent patients can undergo their routine HD session the day before their KTx; appropriate electrolyte panels should be checked within hours of anesthesia induction. Dialysis catheter sites require examination for infection; for recipients on peritoneal dialysis, culture and Gram stains of their peritoneal fluid should be obtained. Each recipient should undergo a repeat history and physical examination, electrocardiogram (ECG), chest x-ray (CXR), and laboratory examination within days before their transplant, to detect any interim health derangements since their last physician visit. A medication list review is mandatory to confirm the cessation of some drugs (e.g., warfarin) and the continuation of others (e.g., beta-blockers), which may affect intraoperative and postoperative outcomes. Bowel preparation occurs at some centers the evening before the operation.

Intraoperative Care

The type of invasive monitoring during the KTx should reflect the nature and degree of the individual recipient's comorbidities. A central venous catheter is often introduced to facilitate monitoring of central venous pressure (CVP), thereby helping to guide intraoperative and postoperative fluid management (particularly in high-risk recipients). Continuous arterial blood pressure monitoring is considered mandatory at most centers, given the high prevalence of hypertension in this population as well as the importance of optimizing the blood pressure at the time of reperfusion. The indications for pulmonary artery pressure monitoring are more controversial, but it may be justifiable for those with significant cardiac dysfunction (e.g., ejection fraction < 30%), valvular abnormalities, or known pulmonary artery hypertension. A 20-Fr 3-way Foley catheter is placed in the bladder, which is then filled with saline and antibiotic solution. Compression stockings and sequential compression devices provide deep venous thrombosis prophylaxis.

Communication between the anesthesia and surgical teams is paramount during the KTx. Adequate intravascular volume, especially at the time of reperfusion, is critical to allow the graft to function immediately. The importance of immediate graft function, with avoidance of acute tubular necrosis (ATN) and of delayed graft function (DGF), cannot be overstated: both ATN and DGF have been found to be predictive of increased patient mortality [10]. CVP should be in the range of 10 to 15 mm Hg. Systolic blood pressure, ideally, should be greater than 120 mm Hg at the time of graft reperfusion. Vasopressors (except for low-dose dopamine) should be avoided in lieu of volume expansion. Mannitol at 1 g per kg, when combined with optimal volume expansion, has been shown to decrease the incidence of ATN; it is given concurrently with furosemide at many centers [11]. After the ureteral anastomosis is completed, urine output is measured frequently, which helps guide volume resuscitation in the immediate postoperative period.

Immediate Postoperative Care

Recipients with a higher acuity of illness may require admission to the intensive care unit (ICU) for optimal monitoring; however, the vast majority can receive appropriate care on a solid-organ transplant ward. Serial complete blood counts, coagulation profiles, and chemistries should be obtained; myocardial ischemia should be excluded with serial troponin measurements in the appropriate subgroup of recipients with cardiac risk factors. CXR and ECG are obtained in the immediate postoperative period. Electrolyte abnormalities (hyperkalemia, hypokalemia, hypomagnesemia, and hypocalcemia) are common and should be corrected.

For recipients with initial graft function, fluid management consists of equivalent replacement of urine output, which is measured hourly; if cardiac dysfunction is not present, urine output can initially be replaced milliliter for milliliter. For recipients with high-output diuresis (≥ 500 mL per hour), 1% dextrose with 0.45% normal saline solution should be administered; potassium replacement may also be necessary, but should not exceed 0.3 mEq per kg per hour intravenously; serum potassium levels should be serially monitored. For recipients with cardiac dysfunction and high-output diuresis (≥ 500 mL per hour), the volume of fluid replacement should be lower than urine output (i.e., 0.5 mL of replacement for 1 mL of urine). In general, within 24 hours posttransplant, urine output in recipients with initial high-output diuresis is frequently appropriate for the recipient's weight and kidney function; fluid replacement is then converted to a continuous rate of 100 to 150 mL per hour. If initial urine output is less than 500 mL per hour, fluid replacement in nondiabetic recipients should consist of 5% dextrose with 0.45% normal saline solution. In diabetic recipients, 0.45% normal saline solution should be used.

Most KTx recipients are cared for on a surgical ward dedicated to solid-organ transplantation. ICU monitoring may become necessary if complications develop, at any time and at any stage posttransplant. The higher susceptibility of transplant recipients to complications is related to their comorbidities, immunosuppression intensity and duration, and immediacy of graft function. Thus, deceased donor recipients, with their accompanying higher DGF rate and increased immunosuppressant load, are more prone to complications than are living related donor recipients. Deceased donor recipients are also more likely to have felt the effects of prolonged uremia and dialysis, as compared with living donor recipients.

Many risk factors directly correlate with the incidence and severity of posttransplant complications. Between 15% and 30% of high-risk transplant recipients require specific critical care.

CRITICAL EVALUATION OF DYSFUNCTIONAL GRAFTS

Early graft function is affected by numerous factors, such as the quality of the donor (i.e., living vs. deceased), cold and warm ischemia times, and the recipient's volume status and medical stability. Urine output is the most readily apparent parameter to gauge graft function in the initial hours posttransplant, but it may be influenced by a residual effect of diuretics infused during the operation or of urine produced by the recipient's native kidneys. A consistent, downward trend in the serum creatinine level and brisk diuresis (> 100 to 200 mL per hour) confirm that the graft is functioning well.

Monitoring the function of an initially delayed or slow functioning graft is more difficult, because urine output is minimal, and the creatinine level may remain at baseline. Doppler ultrasound plays a vital role in surveillance of the newly transplanted kidney and is the most helpful modality in evaluating a dysfunctional graft. Intensivists must be aware of the medical and surgical complications that can occur in the early posttransplant period and that can result in an abrupt change in graft function; graft salvage is only possible with an efficient, expeditious evaluation leading to rapid therapeutic maneuvers.

Medical Complications Leading to Early Graft Dysfunction

Acute Tubular Necrosis

ATN is the most common cause of impaired kidney function immediately posttransplant. Although ATN is rare in living related donor recipients, its incidence averages 35% in deceased donor recipients. It may occur immediately after revascularization or, in grafts with initial diuresis, have a more delayed presentation; dysfunction may last from several days to several weeks. In deceased donor grafts, ATN is usually secondary to prolonged ischemia times, but may also occur in recipients with negative immunologic factors, for example, a high panel-reactive antibody percentage directed against HLAs, a retransplant, and a poor HLA match between donor and recipient. Donor factors such as age, underlying disease (e.g., hypertension), and use of vasopressors (during both procurement and the transplant operation) also contribute to ATN. As stated before, ATN has a detrimental effect not only on later graft function, but also on overall graft survival and postoperative morbidity [12].

Recipients with ATN have a higher incidence of acute rejection, which ultimately lowers graft survival rates by subjecting the kidney to higher rates, and more aggressive progression, of chronic allograft nephropathy [13]. ATN must be differentiated from a vascular catastrophe (renal artery or vein thrombosis) and early acute rejection. Thrombosis should be excluded within 24 hours posttransplant with a Doppler ultrasound to confirm vascular patency. For recipients with ATN, HD frequently must be reinstituted; after a few days to several weeks, kidney function recovers in more than 95% of recipients.

Acute Rejection

A complete discussion of acute kidney graft rejection is beyond the scope of this chapter, however, *acute antibody-mediated rejection* may lead to a rapid decline in early graft function and is therefore relevant. Alloantibodies may form in recipients with a history of blood transfusions, pregnancies, or previous organ transplants; these antibodies can be detected by cross-matching pretransplant, which may, in fact, preclude the transplant. Fortunately, desensitization protocols are in place at many centers that may allow highly sensitized KTx candidates to proceed with a transplant. They do, however, remain at much higher risk for rejection; when these preformed antibodies target capillary endothelium, the complement system may be activated, ultimately resulting in a rapid deterioration of graft function. Only a kidney graft biopsy can confirm the diagnosis; performing the biopsy via an open approach minimizes potential bleeding complications [14,15].

Recurrence of Kidney Disease

Most acute kidney diseases rarely recur, but *focal segmental glomerulosclerosis* (FSGS) and *hemolytic uremic syndrome* (HUS) deserve special mention for their ability to cause profound, early graft dysfunction. Posttransplant nephrotic range proteinuria (i.e., > 3.5 g per day) in a recipient with known FSGS should prompt an immediate biopsy, which will likely show diffuse foot process effacement [16]. When graft dysfunction is accompanied by signs of microvascular trauma (i.e., low haptoglobin levels, elevated lactate dehydrogenase levels, and the presence of schistocytes on blood smears), HUS should be suspected. It may be recurrent or de novo: calcineurin inhibitors (CNIs) (i.e., tacrolimus, cyclosporine) have been long implicated as a causative agent [17].

Surgical Complications Leading to Early Graft Dysfunction

Hemorrhage from the venous or arterial anastomosis is rare. Most postoperative bleeding emanates from small vascular tributaries in the renal hilum or from diffuse hemorrhage in the retroperitoneal dissection field. In the confined retroperitoneal space, bleeding usually tamponades, so reexploration is seldom required. Subcapsular bleeding, albeit less common, is considerably more morbid and can lead to significant and irreversible kidney damage if not quickly recognized and controlled. Bleeding should be suspected if recipients are tachycardic, hypotensive, or oliguric, or if they require several units of blood in the early posttransplant period.

Although the incidence of *vascular thrombosis* is low (0.7% to 5%), it almost invariably results in graft loss [18]. Any sudden change in urine output or creatinine levels in the first several weeks posttransplant should prompt urgent Doppler sonography. The best opportunity for graft salvage occurs if the thrombosis is discovered while the patient is in the recovery room; after several hours, salvage is unlikely and nephrectomy is usually necessary.

Causative factors for *renal artery thrombosis* include unidentified intimal flaps, perfusion or preimplantation arterial or graft damage, size discrepancy between donor and recipient vessels, hypotension or hypoperfusion (especially in pediatric recipients with adult donors), and technical difficulties in kidneys with multiple arteries [18]. Other arterial complications include aneurysms and stenosis. Aneurysms may be anastomotic (pseudoaneurysm) or infected (mycotic). Magnetic resonance angiography can usually confirm the diagnosis without exposing the kidney to nephrotoxic contrast; conventional angiography is reserved for equivocal cases. Aneurysms require surgical repair, which can result in graft loss. For recipients with iliac or renal artery stenosis, percutaneous balloon dilation is the treatment of choice; if unsuccessful, surgical repair is necessary.

Renal vein thrombosis, a complication in 0.3% to 4.2% of KTx recipients, may be caused by kinking of the anastomosis, intimal injury during organ procurement, pressure on the vein

secondary to a fluid collection (i.e., lymphocele, urinoma, or hematoma), compartment syndrome, and extension of an iliofemoral thrombosis [19]. Renal vein thrombosis usually occurs within the first few posttransplant days and may be characterized by sudden onset of pain and graft swelling, hematuria, and, in the case of iliofemoral thrombosis, an edematous leg. The diagnosis is confirmed by Doppler ultrasound, which will show a pulsatile renal artery (with reversal of blood flow) running into the hilum of an enlarged kidney, possibly surrounded by hematoma. If thrombosis is complete, nephrectomy is necessary, although recovery of function after surgical embolectomy or thrombolytic therapy has been report. If thrombosis is incomplete, immediate thrombectomy is recommended (or, as an alternative, urokinase, and heparin treatment).

Urologic complications are rarely life threatening, but can add significant morbidity and can lead to inferior graft survival rates if not handled in a systematic manner. The incidence of urologic complications ranges from 5% to 14% in most KTx series [20].

Hematuria from the distal ureter or the cystostomy suture line generally ceases within the first 12 to 24 hours posttransplant, but it may result in clot formation in the bladder, especially in grafts with poor initial diuresis. Bladder clots or debris may lead to obstructive uropathy, which presents with a sudden cessation of urine output; obstructive uropathy is the most common cause of new-onset anuria in the immediate postoperative period and should be readily remedied with catheter irrigation. If anuria persists, emergent Doppler ultrasound will (1) confirm renal artery and vein patency and (2) rule out a large retroperitoneal hematoma causing hydronephrosis or a retroperitoneal compartment syndrome. Persistent hematuria due to a bleeding diathesis or technical error in the ureteroneocystostomy may lead to the formation of large bladder clots, which may present with suprapubic pain and "bladder spasms" or with frequent Foley catheter occlusions; if continuous bladder irrigations do not restore diuresis, manual hematoma evacuation is performed via a 20-Fr 6-eye Foley catheter. If hematuria is caused by a posttransplant biopsy, with subsequent clot formation in the renal pelvis, temporary percutaneous placement of a nephrostomy tube may be necessary. Most hematuria-related complications require close urine output monitoring, but rarely ICU admission.

Urine leaks most commonly occur at the ureteroneocystostomy anastomosis and can present in the first few postoperative days (technical error) or during the first several weeks (ureteral necrosis). Symptoms and signs of a urine leak may include graft swelling and tenderness, fever, wound drainage, oliguria, scrotal or labial edema, and ipsilateral thigh swelling. Diagnostic studies that confirm the diagnosis include nephroscintigraphy, retrograde cystography, or pelvic computed tomography (CT) scans. Perirenal fluid collections can be aspirated and sent for fluid creatinine level testing to confirm the diagnosis. Minor urine leaks may spontaneously resolve after several weeks with Foley catheter decompression. Recipients with significant leaks in the early postoperative period are best served by immediate exploration and reimplantation of the ureter. Other investigators advocate for an initial percutaneous maneuvers, namely, a percutaneous nephrostomy and stent placement for 4 to 8 weeks; success rates up to 90% have been reported in some centers with this approach [21,22].

Ureteral stenosis becomes evident months posttransplant and may be secondary to rejection, ischemia, infection, or a tight ureteroneocystostomy. Recipients usually have an elevated creatinine level and hydronephrosis (visualized on ultrasound). A percutaneous nephrostomy elucidates the location and degree of the stenosis and is typically followed by a balloon dilatation with a temporary stent tube. If balloon ureteroplasty and stenting fail, operative repair is required (but fortunately only in the vast minority of recipients). A localized distal ureteral stenosis can be repaired by reimplanting the transplanted ureter, but most stenoses require a ureteroureterostomy (to the native ureter) or an ureteropyelostomy (native ureter to the graft's renal pelvis) because of extensive adhesions and lack of graft mobility [22].

Lymphoceles or hematomas can cause compression of the iliac veins (leading to leg edema or deep venous thrombosis) as well as compression of the ureter (leading to hydronephrosis and impaired graft function). Lymphoceles are a collection of lymph in the retroperitoneal space secondary to disruption of lymphatic vessels along the external iliac artery. The incidence can be decreased with careful ligation of the lymphatic vessels during dissection of the iliac vessels. Symptomatic lymphoceles can be diagnosed by ultrasound and treated with percutaneous drainage. Recurrent lymphoceles are approached laparoscopically [23] or, less commonly, by open laparotomy, to create a peritoneal window for decompression of the lymph leak.

NON-RENAL POST-TRANSPLANT COMPLICATIONS

Cardiovascular Complications

The incidence of *cardiac complications*, the most common cause of death posttransplant [24], depends on the extent of underlying cardiac disease, on the efficacy of the preoperative cardiac evaluation, and on the function of the newly transplanted kidney. Correction of uremia by immediate posttransplant graft function improves the cardiac index, stroke volume, and ejection fraction [25]. In contrast, recipients with ATN experience persistent uremia and oliguria, which may lead to perioperative fluid overload and congestive heart failure if immediate HD is not performed to correct fluid retention and electrolyte derangements. Recipients with diabetes, hypertension, and significant coronary disease are more likely to develop cardiac complications if there is no urine output immediately posttransplant; therefore, such recipients require perioperative ICU monitoring, especially if their left ventricular function is poor (e.g., ejection fraction < 30%). Pulmonary artery catheter (PAC) placement to optimize hemodynamics might be prudent, especially in diabetic recipients with coronary artery disease.

Myocardial infarction is uncommon in the perioperative period. It is mostly seen in diabetic recipients with preexisting coronary artery disease who have complicated posttransplant courses with resultant hypotension. ICU admission, serial troponin evaluations, and close monitoring of their hemodynamic parameters are mandatory, especially when complicated by postoperative ATN. Although uncommon in the early posttransplant period, myocardial infarction is one of the major causes of death long-term in transplant recipients. In diabetic recipients, the duration of their diabetes and the presence of preexisting coronary artery disease have an impact on the incidence and severity of posttransplant myocardial infarction, which is the main cause of death in this subgroup. Data suggest that maintaining the hematocrit above 30% is prudent in diabetic recipients: doing so is associated with a 24% decrease in cardiac morbidity in the initial 6 months posttransplant [26].

The incidence of *pericarditis* in the early posttransplant period is 1% to 3% [27]. It has been attributed to infections (e.g., cytomegalovirus [CMV]), fluid overload, and certain medications (e.g., minoxidil). The main factor, however, is uremia. Most episodes of viral or uremic pericarditis occur during the first 8 weeks posttransplant. In contrast, the less frequent bacterial pericarditis develops later, often in recipients with advanced septic complications. Bacterial pericarditis usually requires, besides antibiotic treatment, surgical or ultrasound/CT–guided drainage. Pericardiocentesis is mandatory if cardiac failure, hypotension, or cardiac tamponade develops. Recipients with clinical symptoms of pericarditis require ICU monitoring.

Although *hypertension* is the most common long-term complication posttransplant, with an incidence of up to 50%, it may also require aggressive management immediately posttransplant. Overzealous perioperative hydration may lead to postoperative exacerbation of baseline hypertension. Abrupt cessation of antihypertensive medications should be avoided as well; however, most clinicians do advocate removal of angiotensin-converting enzyme (ACE) inhibitors from the perioperative regimen. CNIs, a part of virtually every immunosuppressive regimen, may also lead to hypertension, especially when they reach toxic levels. The pathophysiology of CNI-induced hypertension has not been fully elucidated, but appears to be multifactorial. CNIs directly lead to systemic vascular constriction by reducing prostacyclin and nitric oxide production while increasing serum levels of endothelin-1; this imbalance favors widespread constriction. Afferent arteriole vasoconstriction in the kidney leads to diminished glomerular filtration, which enhances sodium retention and exacerbates hypertension. Calcium-channel blockers appear to be superior at obviating the renal vasoconstriction induced by CNIs [28–30].

More intensive blood pressure monitoring is warranted in recipients with systolic blood pressure greater than 180 mm Hg or diastolic pressure greater than 100 mm Hg. Treatment often is simply to restart their home regimen, which is typically a combination of calcium-channel blockers, vasodilators, and diuretics. Unless a strong contraindication is noted, perioperative β-blockade is mandatory in this high-risk cohort of surgical patients in order to minimize perioperative cardiac events [31]. Consensus has not been reached on the optimal antihypertensive regimen, given that many drugs interfere with kidney function and CNI metabolism; treatment is based on each individual's response. ICU monitoring and intravenous (IV) antihypertensive infusions (e.g., titration with sodium nitroprusside) may be required, but early posttransplant hypertension can usually be controlled with appropriate oral antihypertensive medications [32].

Hypotension, either intraoperatively or immediately posttransplant, is the single most detrimental nonimmunologic event associated with an increased incidence of graft loss or severe dysfunction. Intraoperative hypotension is usually related to volume depletion or anesthetic agents. Intravascular volume status is assessed most accurately via CVP monitoring, before unclamping, to avoid poor graft perfusion. Posttransplant hypovolemia, especially in recipients with immediate graft function, is often caused by inadequate fluid replacement and should be treated accordingly. Cardiac dysfunction and bleeding must be excluded in recipients with early posttransplant hypotension. Induction immunosuppression (e.g., Thymoglobulin) may lead to hypotension, which is readily reversed by slowing the infusion rate.

As compared with the general population, uremic recipients are more prone to *deep venous thrombosis* (DVT) posttransplant. The incidence of DVT ranges from 1% to 4%. DVT has been linked both to high-dose corticosteroid therapy early posttransplant and to "rebound" hypercoagulability, which is attributed to overcorrection of impaired platelet aggregation and thrombin generation (both associated with uremia). Thrombophilic events of concern within the first few weeks posttransplant include decreased fibrinolytic activity and an increase in plasminogen activation inhibitors. Other risk factors for the development of DVT are postoperative immobilization, increased blood viscosity from posttransplant erythrocytosis, cyclosporine use, and posttransplant hematoma and lymphocele formation (both of which diminish the venous return from the leg and may result in stasis and ultimately thrombosis).

In contrast, neither transient marked elevation nor moderate sustained elevation of hemoglobin levels per se seem to be directly associated with an increased incidence of thromboembolic complications; DVT rarely occurs during periods of peak hemoglobin elevation. Elevated hemoglobin levels (in combination with increased whole blood viscosity, iron deficiency, or hypertension), as well as older recipient age and diabetes, contribute to the occurrence of thrombotic events posttransplant. Aggressive therapeutic phlebotomy to maintain the hematocrit level at less than 55% has been recommended in such recipients. The diagnosis is made clinically and confirmed by Doppler ultrasound to assess the extent of DVT and the potential involvement of the kidney graft in the thrombotic event. Because the kidney is a "high-flow" organ, DVT usually stops at the level of, or distal to, the renal vein anastomosis. About two-thirds of the time, DVT occurs on the graft side.

Once the diagnosis of DVT has been established, standard therapy is systemic heparinization followed by warfarin administration for 3 to 6 months. If DVT occurs in the immediate postoperative period, when heparinization can cause major bleeding, an inferior vena cava filter is an appropriate alternative. Surgical intervention is indicated only if phlegmasia cerulea dolens develops. Venous thrombectomy (with or without creation of a temporary arteriovenous fistula) and, if necessary, fasciotomy are the treatments of choice in that rare situation [33–35].

Pulmonary embolism is rare (< 1%) after a KTx, yet more common than in the uremic nontransplant population. In kidney recipients, especially those who were uremic pretransplant, the coagulation system is activated and enhanced during the first-week posttransplant, which may explain the overall higher incidence of pulmonary embolism. In general, quick recovery posttransplant lowers the rate of pulmonary embolism. Pulmonary embolism as a result of DVT occurs in fewer than 1% of kidney recipients, but, if it does occur, the mortality rate is about 40%.

Pulmonary Complications

Most KTx recipients do not require ventilator support postoperatively, but prolonged support may be indicated in case of pulmonary dysfunction secondary to intraoperative fluid overload, cardiac dysfunction, or underlying lung disease.

Pulmonary edema usually is the result of overresuscitation intraoperatively and is more likely to occur in recipients who underwent inadequate pretransplant HD and/or overzealous volume infusion accompanied by a poorly functioning graft. As discussed previously, poor early graft function requires much more precise fluid management to optimize volume status for the graft, without placing the recipient at unacceptable risk for cardiopulmonary complications. Chest radiography in the recovery room to assess pulmonary status should be routine, particularly when anti-CD3 murine monoclonal antibody (OKT3) is given intraoperatively; fluid-overloaded recipients can respond to their first dose of OKT3 with flash pulmonary edema [36,37]. Fortunately, few modern immunosuppressive regimens include OKT3 for induction; its primary role is to combat acute rejection. Recurrent pulmonary edema may be an atypical manifestation of a kidney graft renal artery stenosis.

Pulmonary hypertension (PHT), a known risk factor for death in liver transplant recipients, has now been found to be an independent risk factor for inferior rates of patient survival after a KTx. KTx recipients with known PHT may require ICU care postoperatively, often guided by PAC monitoring [38].

Acute respiratory distress syndrome (ARDS) affects 0.2% of all KTx recipients. It is more likely in recipients with poor initial graft function and in those receiving antithymocyte globulin for induction of immunosuppression. Not surprisingly in this population with a higher acuity of illness, the mortality rate of KTx recipients with ARDS is prohibitive at well over 50% [39].

Metabolic Complications

Hyperkalemia is a frequent perioperative derangement, making serial serum potassium determinations necessary. Surgical trauma and transfusion of banked blood might cause intraoperative hyperkalemia, which can be corrected with intravenous glucose and insulin, thereby driving extracellular potassium into the cells. Posttransplant, hyperkalemia can develop immediately in recipients with ATN and later in those with poor graft function due to severe acute or chronic rejection. Hyperkalemia is frequently secondary to physiologic abnormalities or to medications that decrease potassium excretion in the urine. Such abnormalities include a decrease in the glomerular filtration rate (GFR), injury to distal tubules (which are a major site of potassium secretion in the nephron), and a decrease in plasma aldosterone levels. CNIs cause vasoconstriction of the afferent arterioles and direct damage to distal tubules, leading to hyperkalemia and decreased GFR. Medications that decrease potassium excretion include trimethoprim–sulfamethoxazole (TMP–SMX) (which blocks sodium and potassium exchange in distal tubules), ACE inhibitors, angiotensin-2 receptor-antagonists, and nonsteroidal anti-inflammatory agents (which suppress plasma aldosterone levels leading to higher potassium levels). Hyperkalemia can also be a drug-related side effect (e.g., impeded intracellular potassium entry by a beta-blocker). Therapeutically, a potassium-binding ion exchange resin (e.g., Kayexalate®) can be given or, if a rapid decrease of serum potassium is required, IV glucose, insulin, and bicarbonate infusions. Recipients with hyperkalemia due to poor graft function eventually require HD.

Copious diuresis (> 500 mL per hour) immediately posttransplant may result in *hypokalemia,* which requires appropriate potassium replacement. Recipients requiring more than 0.3 mEq per kg per h should be placed on a cardiac monitor.

Less frequently, *hypomagnesemia* and *hypophosphatemia* occur in recipients with high-output diuresis initially. Hypomagnesemia is secondary to drug-related renal wasting (e.g., cyclosporine, tacrolimus, diuretics, aminoglycosides, and amphotericin B), poor dietary intake, and malabsorption from the gastrointestinal tract. Hypophosphatemia is secondary to renal wasting of phosphate, caused by secondary hyperparathyroidism, glucocorticoids (which inhibit the tubular reabsorption of phosphate), and antacids (which bind phosphate in the gastrointestinal tract).

Infectious Complications

A comprehensive review of the role of infectious diseases after a KTx is beyond the scope of this chapter, except for infections known to develop in the immediate posttransplant period (e.g., 1 to 4 weeks). Infections do not occur at random, but rather according to a timetable. Bacterial infections caused by nosocomial pathogens or recipient colonizers tend to occur early posttransplant, affecting the anatomic sites breached during the transplant operation itself, namely, the lungs, blood (indwelling vascular catheters), superficial wounds, and perinephric (deep) space [40].

As compared with all other solid-organ transplant recipients, KTx recipients have the lowest incidence of *pneumonia*; still, it develops in about 16% of KTx recipients and carries with it a mortality rate of 10% to 13%. In the first posttransplant month, 90% of the pneumonic processes are bacterial, particularly staphylococcal and nosocomial Gram-negative species; fungal infections (i.e., *Candida, Aspergillus*) are more frequent when the recipient is on a more intensive immunosuppressive regimen or underwent prolonged antibiotic therapy. Dual fungal and bacterial infections or superinfections have an associated mortality rate as high as 100% [41–43].

Bacterial pneumonias frequently cause fever, along with other expected clinical signs and symptoms making the diagnosis straightforward; however, in the early posttransplant phase it may be difficult to exclude noninfectious thoracic processes (i.e., pulmonary edema, atelectasis, infiltrates). If the CXR reveals abnormal patterns of infiltration, chest CT may be helpful in delineating the cause of the pneumonia. No consensus has been reached on the role of bronchoalveolar lavage (BAL) in the diagnostic evaluation, but it seems prudent for recipients with pneumonia who do not respond to antimicrobial therapy in 48 to 72 hours. No disagreement exists on the degree and rapidity with which to treat a presumed pneumonia; broad-spectrum antibiotics should be initiated immediately to cover the most common culprits mentioned earlier. Antifungals should be considered when appropriate: surveillance cultures should be obtained and reviewed to exclude the presence of multidrug-resistant (MDR) bacteria, for example, methicillin-resistant *Staphylococcus aureus*, vancomycin-resistant enterococci, extended-spectrum beta-lactamase, and MDR *Pseudomonas* or *Klebsiella* [42,43].

The most common posttransplant infectious complication is a *urinary tract infection* (UTI), with an incidence of more than 30% during the initial 90 days posttransplant. UTIs lead to pyelonephritis and bacteremia in more than 10% of immunosuppressed KTx recipients. Gram-negative bacilli are the cause 70% of the time, but *Enterococcus*, *Staphylococcus*, and *Candida* should also be considered as possible etiologic agents. Risk factors for UTI include a history of graft dysfunction, prolonged bladder catheterization, neurogenic bladder, and ureteral surgical complications, including stent placement [44]. Treatment consists of prompt antibacterial therapy even in the cases of asymptomatic bacteruria; for persistent cases, removal of stents and a more thorough evaluation (e.g., voiding cystourethrogram, CT scan) are indicated.

A KTx, a clean-contaminated operation, carries with it a *wound infection* rate of 1% to 6%. This low rate is due to thorough pretransplant skin preparation with chlorhexidine, intravenous administration of a prophylactic antibiotic, irrigation of the urinary bladder with an antibiotic solution, and meticulous attention to hemostasis. If wound infections occur, they are treated according to standard surgical principles of drainage and antimicrobial therapy; exploration and debridement may be necessary for deep-space infections [45].

Most patients undergoing a KTx are HD-dependent and therefore have an indwelling catheter, arteriovenous fistula, or arteriovenous graft, all of which can lead to a *bloodstream infection*. The current national practice guidelines call for goal infection rates of less than 10% at 3 months after catheter placement; unfortunately, most centers fall short of that goal. Catheters should be removed when no longer required. Staphylococcal species and gram-negative bacilli are the most likely pathogens and should be treated aggressively with IV antibiotics and possibly catheter removal [46,47].

Infective endocarditis is rare but may occur in recipients with severe septicemia or longstanding immunosuppression [48]. Cardiac valve vegetations noted on an echocardiogram in recipients with persistent bacteremia confirms the diagnosis; prolonged antibiotic therapy is required.

Viral infections play a prominent role in the intermediate to late posttransplant period, predominantly the herpesvirus genus, for example, CMV, Epstein–Barr virus (EBV), herpes simplex virus (HSV), and varicella-zoster virus (herpes zoster virus [HZV]). Primary HSV infections are rare, but mucocutaneous reactivations of HSV in the early posttransplant period are relatively common, occurring in up to 30% of adult recipients and 8% of pediatric recipients. OKT3 use is associated with an even higher risk of reactivations. HSV is diagnosed by

direct immunofluorescent antibody staining, by Tzanck preparation, or by culture of tissue and body fluids. Serodiagnosis is possible if immunoglobin M (IgM) is detected or if a fourfold rise in IgG titers is noted. Symptomatic HSV infections are common with orofacial (virus resides latently in the sensory ganglia) or genital lesions; occasionally, conjunctivitis or corneal ulceration may develop. Topical application of 5% acyclovir ointment accelerates healing and shortens the duration of viral shedding; oral acyclovir (200 mg five times per day) is also effective. If disseminated disease occurs (e.g., hepatitis, meningoencephalitis), IV acyclovir (5.0 mg per kg every 8 hours for 7 to 14 days) is necessary.

CMV infections and disease, while rare during the first posttransplant month, deserve special mention because they affect a large proportion of KTx recipients at some point in their first posttransplant year. In just the initial 100 days posttransplant, up to 60% of recipients develop CMV infections (e.g., viremia), and 25% actually suffer from invasive CMV disease of one or more organ systems. Such infections are associated with chronic graft rejection and decreased graft and patient survival rates. The highest risk of developing CMV infections, up to 60%, is in the donor-seropositive, recipient-seronegative (D+ R−) group; the lowest risk, 20% to 40%, is in the D+ R+ and D− R+ groups. CMV infections may occur as primary infections (e.g., D+ R−) or as a reactivations (e.g., with a seropositive recipient after inception of immunosuppression). CMV superinfections (both primary infections plus reactivations, by separate strains of CMV) in the D+ R+ group are associated with the worst graft and patient survival rates among the various groups [49–52].

Success has been achieved in preventing CMV infections with prophylactic 9-[(1,3-dihydroxy-2-propoxy)methyl] guanine (DHPG) in parenteral (ganciclovir) or enteral (valganciclovir) forms. The efficacy of oral DHPG (valganciclovir) was found to be equal to that of oral ganciclovir in preventing CMV disease in high-risk recipients [50]. CMV disease, which is potentially (yet rarely) fatal, has not been eliminated. Symptoms include fever, malaise, headache, myalgia, and arthralgia; leukopenia occurs in more than 70% of infected recipients. CMV infections can present as neuritis, gastritis, or colitis; colitis often causes gastrointestinal tract bleeding. CMV infections can also cause retinitis, hepatitis, pancreatitis, adenopathy, hepatosplenomegaly, and nephritis, frequently during the first 6 months posttransplant.

The gold standard for diagnosis of active CMV disease continues to be growth in tissue culture; however, identification of viremia allows for much earlier diagnosis (< 48 hours) and prompt treatment. Two techniques are currently in clinical use: (1) a quantitative polymerase chain reaction assay and (2) an antigenemia assay based on identification of the late structural protein pp65. Both techniques are felt to be equally efficacious in quantifying the viral load of CMV in the serum.

When the diagnosis of CMV disease is established, treatment is initiated with IV DHPG (5 mg per kg every 12 hours if creatinine < 1.5 mg per dL, with dose adjusted according to graft function; and 1.2 mg per kg every 48 hours if the recipient is on dialysis). Dose reduction or temporary cessation of DHPG is indicated if leukopenia (white blood cell count < 3,000 cells per mm^3) or thrombocytopenia (platelet count < 100,000 per mm^3) occurs. DHPG is administered IV for 14 days; the addition of CMV hyperimmune globulin is indicated for recalcitrant and life-threatening cases. Oral DHPG treatment is frequently continued for up to 6 months. For recipients with concurrent CMV and acute rejection, simultaneous treatment is an option: IV ganciclovir should be given at the time of rejection treatment, or if possible, 1 to 2 days before increasing immunosuppression. Since cell-mediated immunity is markedly impaired during CMV infections, superinfections by other opportunistic pathogens are a risk. Graft dysfunction (e.g., glomerulopathy) during or after active CMV infections has been described. Recipients in the D+ R− (high-risk) group should receive prophylactic oral DHPG for at least 6 months posttransplant. Currently, oral DHPG is standard for CMV prophylaxis posttransplant and continues for 3 to 6 months.

Varicella-zoster virus, also called HZV, usually presents as dermatomal skin lesions. The diagnosis is frequently made on physical examination alone. HZV can be cultured, and direct immunofluorescent antibody staining or Tzanck preparation can be used. HZV requires systemic therapy with acyclovir, usually over a 7-day period. Varicella-zoster immune globulin is used in seronegative recipients.

EBV infections have been associated with mononucleosis-like symptoms and with fulminant, widespread posttransplant lymphoproliferative disease (PTLD), a form of B-cell lymphoma. Recipients of a kidney from a seropositive donor can seroconvert. Symptoms include EBV-related malaise, fever, headaches, and sore throats. PTLD usually occurs months to years posttransplant in heavily immunosuppressed recipients. Immunosuppression impairs the ability of virus-specific cytotoxic T lymphocytes to control the expression of EBV-infected transformed B cells, leading to polyclonal and monoclonal proliferation of lymphocytes (which constitutes PTLD). Treatment entails cessation of immunosuppression accompanied by anti-CD-20 antibodies (rituximab), and antiviral therapy (e.g., ganciclovir, acyclovir, or anti-CMV immune globulin). Suboptimal responses necessitate conventional lymphoma treatment.

Other viruses causing morbidity after a successful KTx are adenoviruses and influenza viruses (involving the respiratory tract), papovaviruses (progressive multifocal leukoencephalopathy), and hepatitis viruses (in particular hepatitis C). Recipients are also at high risk for developing human papillomavirus infections, which can lead to cancer of the cervix (e.g., invasive squamous cell cancer).

Fungal infections, both local and systemic, are frequent (in up to 14% of KTx recipients), and can occur early posttransplant. Most fungal infections are secondary to *Candida* and *Aspergillus* species. The most common source of *Candida* infections is translocation of organisms from the gastrointestinal tract, followed by infected intravascular catheters. Early posttransplant, *oropharyngeal candidiasis* is the most common fungal infection; it can be prevented and treated with oral nystatin or clotrimazole solutions.

Systemic fungal infections are particularly noted in recipients who are on significant immunosuppression or broad-spectrum antibacterials or who have had multiple rejection episodes and poor graft function; if such infections occur as superinfections, they are associated with a high mortality rate. Patients with cerebral, pulmonary, or visceral involvement, such as meningitis, pneumonia, or endocarditis (most frequently caused by *Candida* or *Aspergillus* species), require reduction or even temporary cessation of immunosuppression [53].

Given their favorable safety profile, the azole antifungals (e.g., fluconazole) are the preferred empiric therapy for fungal infections; however, for life-threatening fungemia, some clinicians favor the echinocandins caspofungin, the newer azole agents or amphotericin B, especially when a *Candida* species other than *Candida albicans* is suspected [54]. Liposomal amphotericin B preparations are now a more palatable option because of their improved safety profile in regards to nephrotoxicity. *Candida* can also cause an uncommon but life-threatening complication: a mycotic pseudoaneurysm. This complication is typically treated with graft nephrectomy, with or without ligation of the external iliac artery, followed by IV amphotericin B. *Cryptococcus* and *Aspergillus* can cause severe pulmonary and cerebral infections requiring systemic amphotericin B. *Pneumocystis jiroveci*, which manifests as interstitial pneumonia, usually late posttransplant [55]. Since the practice of

TMP–SMX prophylaxis was initiated, the incidence of pneumocystic pneumonia (PCP) has decreased significantly. PCP is still seen in heavily immunosuppressed recipients and should be considered in anyone with fever, dyspnea, and nonproductive cough. The CXR will reveal interstitial infiltrate; BAL or lung tissue biopsy (using staining techniques or monoclonal antibodies conjugated with fluorescein) is needed for diagnosis. Therapy consists of IV TMP–SMX (with the dose adjusted according to kidney function) and, in case of sulfa hypersensitivity, pentamidine or dapsone. PCP, like most other severe infections, requires reduction or temporary cessation of immunosuppression.

Mycobacterium tuberculosis infects about 1% of KTx recipients because of prior infections, reactivations, or disseminated disease. Fever, malaise, night sweats, and weight loss usually occur. The diagnosis should be made clinically, because only one-fourth of recipients have a positive tuberculin skin test. Sputum and blood samples should be used to identify acid-fast bacilli and a BAL may be necessary to obtain an appropriate sample. Treatment includes a 2- to 3-drug regimen lasting at least 6 months. Potential agents include isoniazid, rifampin, pyrazinamide, ethambutol, and ciprofloxacin. Despite aggressive treatment, the mortality rate can be high.

Gastrointestinal and Pancreaticobiliary Complications

The incidence of posttransplant gastrointestinal tract complications is 5% to 25%. They are a major cause of morbidity and mortality in the KTx population.

In the *upper gastrointestinal* tract, the most common problem is peptic ulcer disease and its associated complications (bleeding, perforation); evidence suggests a higher prevalence of *Helicobacter* infection in the uremic population. However, the overall incidence of upper gastrointestinal tract complications in KTx recipients has declined considerably over the last two decades, mainly because of the development and ubiquitous use of H_2 blockers and proton-pump inhibitors. Historically, severe upper gastrointestinal tract bleeding episodes occurred in more than 10% of KTx recipients, with a mortality rate of up to 65%; most of these bleeding episodes developed in the early postoperative period, half in the first 3 months [56–58].

Prophylactic gastric operations (various forms of vagotomy) became very popular in the 1970s for patients with chronic kidney failure listed for KTx, in an attempt to decrease the morbidity and mortality rates of peptic ulcer disease posttransplant. With the advent of H_2 blockers (e.g., cimetidine, ranitidine) and inhibitors of the H+–K+ adenosinetriphosphatase (ATPase) enzyme system (e.g., omeprazole, pantoprazole), prophylactic gastric operations are no longer performed [59–62].

If severe upper gastrointestinal tract bleeding occurs despite prophylactic treatment and cannot be controlled by conservative means (including gastroscopy with submucosal injection of epinephrine), the same surgical options (resection, vagotomy) apply as for nontransplant patients. Angiographic embolization for acute hemorrhage has been advocated, and, for anatomic reasons, usually requires embolization of two arteries. The risk of embolization is development of (gastric) necrosis and infection. Patients with severe upper gastrointestinal tract bleeding require ICU monitoring; it is important to stabilize them before they undergo emergency gastric procedures, which have a high mortality rate posttransplant. If extensive gastroduodenal surgery is performed, reduction of immunosuppression is mandatory and postoperative ICU monitoring recommended. An unexpectedly high incidence of CMV infections has been observed in apparent peptic ulcers in KTx recipients. Diagnostic and immunohistochemical improvements have made it easier to detect tissue-invasive CMV infections; for such recipients, DHPG and possibly anti-CMV immune globulin are initiated [63].

The impact of hypercalcemia on the pathogenesis of peptic ulcer disease and on its therapeutic consequences is controversial. Hypercalcemia due to hyperparathyroidism may aggravate peptic ulcer disease. Immediate and permanent cessation of gastric bleeding has been noted after subtotal parathyroidectomy in KTx recipients.

The most common *small bowel* complication is intestinal obstruction. Most kidney grafts are placed retroperitoneally (except in children and in recipients of a simultaneous pancreas-KTx), so obstruction is often related to previous intra-abdominal procedures (e.g., native nephrectomy, splenectomy), infections, or PTLD in the small bowel and mesentery. Obstruction in the early postoperative period may be due to incarceration of small bowel through a peritoneal tear made during retroperitoneal dissection. The same therapeutic principles apply as for nontransplant patients.

The incidence of complications of the *lower gastrointestinal tract* in KTx recipients is 1% to 10%. Colonic perforation and lower gastrointestinal tract hemorrhage are the two most common complications in the immediate posttransplant period and carry considerable morbidity and mortality if not recognized and treated expeditiously.

Colonic perforation, occurring in 1% to 2% of all KTx recipients, is due to (in descending order) diverticulitis, ischemic colitis, and CMV colitis; rarely, stercoral ulceration, fecal impaction, or an undetermined forms of colitis can result in perforation as well. The use of sodium polystyrene sulfonate, given orally or as an enema, has been implicated as a cause of perforation, but only in sporadic case reports, so the practice continues at most centers. About 50% of all colon perforations occur within the first month posttransplant, with a 20% to 38% mortality rate; risk factors for death include age older than 40 years, long-term HD, and exploration more than 24 hours from the time of initial symptoms. Peritoneal signs, the hallmark of hollow organ perforation, are frequently absent in immunosuppressed KTx recipients, mandating a high index of suspicion, liberal use of imaging studies, and a low threshold for exploration; in general, a diverting colostomy has been associated with better outcomes [64–73].

KTx recipients are more susceptible to *colonic diverticulitis* and tend to more readily perforate, as compared with nontransplant patients; KTx recipients with polycystic kidney disease are at even higher risk [74–76]. Steroids are thought to be responsible for the difference in the incidence of diverticulitis between transplant recipients and nontransplant patients; steroids not only mask symptoms but also impair the host's ability to localize and contain the perforation. Furthermore, steroids adversely affect colon wall microcirculation and weaken peritoneal defense mechanisms. Historically, diverticular perforations have been associated with prohibitive (50% to 100%) mortality rates, but a series showed a marked decrease in mortality (12.5%), thanks to increased awareness of the problem and prompt surgical intervention. Recipients with sigmoid diverticulitis require resection of the sigmoid colon, with creation of a colostomy and Hartmann pouch; at least one group of investigators advocates a primary anastomosis and a loop colostomy in appropriate cases. Some transplant surgeons advise a pretransplant partial colectomy for KTx candidates who experience a single episode of documented diverticulitis; however, no consensus has been reached.

Ischemic colitis has been associated with impaired blood flow to the colonic wall, stenosis or occlusion of the inferior mesenteric artery, insufficient vascular collateralization, previous retroperitoneal surgery, immunosuppressive and antibiotic therapy, and diseases such as vasculitis and

thrombophilia. Other causative factors are (intermittent or temporary) hypotension and irregular blood volume distribution. Often, however, no explanation is apparent, especially in young KTx recipients with normal mesenteric vessels. Ischemic colitis may be segmental or pancolic; at laparotomy, features suggestive of inflammatory bowel disease may be identified that microscopically lack the typical lesions of Crohn's disease [77,78].

Pseudomembranous colitis caused by the *Clostridium difficile* species is being increasingly recognized, to enhanced surveillance; it can progress to toxic megacolon and perforation. The diagnosis is confirmed via stool toxin assay and culture, or with visualization of the classic pseudomembranes on endoscopy. Such recipients are usually treated conservatively, with metronidazole (250 mg four times daily for 10 days) or oral vancomycin (125 mg every 6 hours for 10 days).

Neutropenic enterocolitis causes mucosal ulceration of the bowel wall. It is associated with profound neutropenia and invasion by clostridial organisms (e.g., *Clostridium septicum*). The course of neutropenic enterocolitis is often progressive, requiring treatment with metronidazole and possibly surgical intervention [79]. *Infectious colitis* is frequently due to CMV infections, which may cause lower gastrointestinal tract hemorrhage; at stated before, CMV rarely is clinically active within the first posttransplant month. Infectious colitis can also be bacterial (e.g., mycobacteria), viral (e.g., herpes), and fungal (e.g., *Candida*) infections. The diagnosis is obtained via endoscopic biopsy and stool cultures, with treatment starting with appropriate and early empiric antimicrobial agents. Surgical intervention is not desirable, given the increased morbidity and mortality rates.

Cecal volvulus is a rare complication but requires prompt surgical intervention [80]. If gangrene is not evident, a cecopexy can be performed; if a perforation has occurred, resection and creation of a colostomy are imperative.

The incidence of posttransplant *acute colonic pseudo-obstruction (Ogilvie's syndrome)* is 1.5% [81]; it causes paralytic colonic ileus resulting in cecal dilation. Usually, it responds to nonoperative therapy consisting of bowel rest and nasogastric decompression, neostigmine, and possibly endoscopic colonic decompression. Like fecal impaction and stercoral ulceration, Ogilvie syndrome can cause colonic perforation, thus necessitating surgical resection. In general, survival rates in recipients with colonic perforation can be improved with early diagnosis and prompt treatment. As with treatment for septicemia, immunosuppression should be markedly reduced. Of interest, rejection in recipients with severe infection is not common. Once the recipient's condition improves, immunosuppression should cautiously be restarted.

Lower gastrointestinal tract *hemorrhage* is most commonly due to opportunistic colitis. Gastrointestinal tract lesions thought to be peptic, particularly when associated with upper gastrointestinal tract bleeding, are frequently the result of CMV infections [82]. Fungal ulceration has also been described as a source of lower gastrointestinal tract hemorrhage, because proton-pump inhibitors, H_2 blockers, and antacids promote fungal overgrowth due to achlorhydria. Another cause of lower gastrointestinal tract bleeding is the ulcerogenic effect of steroids and their tendency to impair the reparative mechanisms of the bowel wall. In addition, conditions such as uremia and diabetes result in colonic distention and impaction, because of autonomic neuropathy; both contribute to the pathogenesis of colonic ulcers. In recipients with lower gastrointestinal tract bleeding, colonoscopy must be undertaken urgently, so that treatment is not delayed. To prevent fungal superinfection dissemination, empiric fluconazole is initiated.

KTx recipients are exposed to numerous risk factors for pancreatitis: (1) immunosuppressants (e.g., corticosteroids, azathioprine, cyclosporine) and diuretics (e.g., furosemide, thiazide diuretics); (2) hypercalcemia with or without hyperparathyroidism [83]; (3) infections (e.g., CMV, HSV) [84]; (4) previous episodes of pancreatitis (uremia); and (5) cholelithiasis (i.e., related to cyclosporine). Therefore, it is hardly surprising that 1% to 6% of recipients suffer a posttransplant episode of pancreatitis. The mortality rate appears to be highest if pancreatitis develops after the first three posttransplant months [85]. Steroids increase the viscosity of pancreatic secretions (theoretically leading to obstruction and dilation of the pancreatic duct) and speed epithelial duct proliferation and peripancreatic fat necrosis. An equally serious side effect of steroids is that they mask abdominal pain during episodes of pancreatitis, thus delaying the diagnosis. Hypercalcemia secondary to tertiary hyperparathyroidism is also considered a major causative factor; excessive serum calcium concentration accelerates the conversion of trypsinogen, promoting pancreatic autodigestion. Infections, especially CMV, are a well-documented cause of posttransplant pancreatitis, but bacterial infections causing pancreatitis have also been reported. The term *rejection pancreatitis* arose from speculation that the host forms antibodies that are reactive not only with the graft (vascular rejection), but also with antigens on the surface of pancreas cells (vascular pancreatitis). Biliary tract disease and alcoholism, the most frequent causes of pancreatitis in nontransplant patients, are of minor importance in KTx recipients [86–89].

The diagnosis of pancreatitis depends mainly on an observed increase in the serum amylase or lipase level. However, hyperamylasemia in uremic recipients is not uncommon (30%), because of reduced amylase clearance in light of insufficient kidney function. The amylase/creatinine clearance ratio appears to be a more sensitive index of pancreatitis in KTx candidates with kidney dysfunction. The degree of hyperamylasemia is not a prognostic factor. A contrast-enhanced CT scan may be helpful in both staging pancreatitis and excluding necrotizing pancreatitis. For the edematous form of pancreatitis, conservative treatment is usually successful. Recipients with hemorrhagic or necrotizing pancreatitis require ICU monitoring, with specific attention to volume replacement and cardiovascular status. In such recipients, reduction of immunosuppression, use of broad-spectrum antibiotics, and ICU monitoring are imperative.

The role of early surgical intervention is still controversial. Recipients with infected pancreatic necrosis are best served with aggressive surgical therapy, including removal of all infected necrotic material, drainage and irrigation of the abdominal cavity, and a low threshold for relaparotomy. Overwhelming sepsis is the most common cause of death, so intensive management of infections is essential. Surgical intervention is also required if pseudocysts develop and do not resolve, although maturation of pseudocysts may take longer in KTx recipients. Pseudocyst complications, such as erosion or obstruction of adjacent vascular and hollow viscus structures, mandate early intervention. The mortality rate from complications of posttransplant pancreatitis appears to be higher than from other forms of pancreatitis. A rapid reduction of immunosuppression is necessary to minimize septic complications.

Pretransplant screening for *cholelithiasis* is variably performed at centers in the United States: the role of prophylactic cholecystectomy for asymptomatic cholelithiasis is controversial. Data generated over the past 15 years failed to strengthen a policy of mandatory pretransplant cholecystectomy for asymptomatic cholelithiasis. *Acute cholecystitis*, especially in uremic diabetic KTx recipients, should be considered if they have sepsis or abdominal pain without a source. *Acalculous cholecystitis* has become more common in recipients with a complicated posttransplant course (e.g., septicemia, multiorgan failure). This diagnosis is established clinically and, especially if recipients are intubated and on the ventilator, by serial ultrasounds and possibly biliary scintigraphy. A cholecystectomy is

desirable, but image-guided (ultrasound or CT) cholecystostomy may also be helpful if recipients are too ill to undergo a formal operation [90,91].

Neurologic Complications

Up to 30% of KTx recipients develop neurologic problems posttransplant. The incidence of life-threatening central nervous system (CNS)-related complications in the immediate posttransplant period is 1% to 5% [92–94]. Causative factors are the sequelae not only of the KTx itself, but also of the underlying kidney disease (more common in recipients with diabetes and hypertension) and of pretransplant conditions (e.g., uremia). *Cerebrovascular events* (e.g., infarct, TIA, hemorrhage) are the most frequent complications, usually peaking during the first few months posttransplant. Hypertension, atherosclerosis, diabetes, hyperlipidemia, hypercoagulability, and advanced age—all of which play a major role in the pathogenesis of these complications—are ubiquitous in KTx recipients. For those with strokes or TIAs, conservative treatment (heparinization, aspirin) is best, although carotid endarterectomy can benefit those with ulcerated carotid lesions or with severe but accessible stenoses. The prognosis of intracerebral hemorrhage is poor; posttransplant hypertension is one of the major causative factors and therefore should be aggressively monitored and treated.

All CNS *infections* are considered life threatening, and often result in various degrees of disability. Infections are caused by bacteria (e.g., *Listeria monocytogenes*, *Pseudomonas* species), viruses (e.g., CMV, HSV), fungi (e.g., *Cryptococcus, Aspergillus, Mucor*), and parasites (*Toxoplasma*). *L. monocytogenes* is the most common infectious organism and usually causes meningitis. *Aspergillus* frequently manifests as brain abscesses. Rhinocerebral mucormycosis infection can cause cavernous sinus thrombosis and rapid death. Dissemination of CMV may include the CNS, although the overall incidence is low [95]. Acute polyradiculoneuritis has also been associated with CMV infections [96]. Similarly, dissemination of the VZV can involve the CNS [97] or facial nerve (Ramsay Hunt syndrome). It is crucial to diagnose and treat these infections early and aggressively. Intrathecal administration of antimicrobial drugs or drainage in recipients with brain abscesses may be necessary.

Seizures are associated with excessively high CNI serum levels and affect children at a higher frequency than adults; hypertension and hypomagnesemia may predispose recipients to seizure activity [97–101]. Treatment consists of CNI dose reduction and anticonvulsants; ICU monitoring is mandatory after such events. Other CNI-related complications, such as tremor, dysesthesia, ataxia, and psychologic disorders, usually do not require ICU monitoring. Tacrolimus, more frequently than cyclosporine, causes neurotoxicity in the form of tremor and headaches, both of which can be debilitating; it also can cause paralysis, quadriplegia, coma, and leukoencephalopathy (*posterior reversible encephalopathy syndrome* [PRES]). PRES, occurring in about 0.35% of KTx recipients, is diagnosed by brain magnetic resonance imaging [102]. Another drug-related complication is aseptic meningitis caused by OKT3; treatment consists of discontinuing OKT3 therapy and temporarily administering anticonvulsants.

In contrast to CNS-related problems, peripheral neurologic complications do not require ICU monitoring. Compressive *neuropathy* (involving the femoral nerve or the lateral femoral cutaneous nerve) is due to hematoma, ischemia, or retraction injury at the time of the KTx; all symptoms are confined to the ipsilateral side. This complication has a high degree of reversibility [103]. If a large hematoma is identified, reexploration and evacuation should be performed.

KTx, kidney transplantation.

CURRENT CHALLENGES IN KIDNEY TRANSPLANTATION

Despite the many advances in kidney transplantation, several challenges remain (Table 182.1). During the past decade the proportion of candidates on the active KTx waiting list > 50 years of age has increased from 44% to 58% and those with diabetes and hypertension have increased from 24% to 28% and 17 to 22%, respectively. To maintain excellent short-term outcomes, an exhaustive pretransplant cardiovascular evaluation followed by intense posttransplant critical care has become mandatory for this high-acuity cohort of patient [6,7].

Mortality on the waiting list continues to stimulate the adoption of innovative desensitization protocols to allow high-risk recipients an opportunity at transplant. This in turn must be met with equally innovative therapies if antibody-mediated rejection occurs in the early postoperative period. Attempts at modulating the complement system are underway to mitigate early posttransplant injury in the allograft [14].

CHAPTER 183 ■ SPECIFIC CRITICAL CARE PROBLEMS IN HEART AND HEART–LUNG TRANSPLANT RECIPIENTS

SARA J. SHUMWAY AND EIAS E. JWEIED

The advent of thoracic organ transplantation has brought new hope to patients who were previously doomed by end-stage cardiac, pulmonary, or combined cardiopulmonary disease. The first heart transplant was performed on December 3, 1967. Fourteen years passed before the first successful heart–lung transplant was performed on March 9, 1981. Heart–lung transplantation established the potential for lung transplantation as a viable therapeutic option, and the first successful single-lung transplant was performed in 1983 [1].

HEART TRANSPLANTATION

The United Network for Organ Sharing (UNOS) is a nonprofit organization that maintains the nation's organ transplant waiting list. Patients awaiting cardiac transplants are listed according to severity of illness. Organs are then allocated to those individuals who are severely ill and have waited the longest. Just more than 2,200 heart transplants are performed annually in the United States. There has been a decrease in candidate waiting times, with the average waiting time for a status 1A heart candidate of 50 days and a status 2 candidate of 309 days [2]. A status 1 heart candidate includes those individuals with highest medical urgency. These are patients who have support either via a total artificial heart, ventricular assist device (VAD), intraaortic balloon pump, or extracorporeal membrane oxygenation. It could also be an individual who has a mechanical assist device in place, either right or left support that is beginning to malfunction. It also includes individuals who are on continuous mechanical ventilation or on high-dose inotropic support and are unable to be weaned. Status 2 candidates are individuals who need a heart transplant but have not been defined as being in the most urgent status. They may be patients who are at home and taking heart-failure medications and are still active

and awaiting transplant but are not as critically ill as those individuals in the status 1 category. At any given time, UNOS has approximately 3,000 candidates listed for heart transplant, and most have been waiting for more than a year.

The number of heart transplants performed nationally depends on donor availability. In spite of this, the annual mortality rate on the waiting list has slowly declined during the last 10 years. In the middle to late 1990s, it was not uncommon to have anywhere between 700 and 800 people die from cardiac disease while awaiting a heart transplant. That number has been slowly decreasing to less than 400 each of the last 3 years [2]. This slow decrease is related to the evolution of left ventricular assist devices and their acceptance as a bridge to transplant.

Ninety percent of adult candidates listed for heart transplant have end-stage cardiac disease with some form of cardiomyopathy. Approximately 47% have idiopathic cardiomyopathy, and 35% have ischemic cardiomyopathy. The remaining 15% of heart transplant candidates have end-stage valvular disease, cardiomyopathy associated with congenital heart disease, or graft failure requiring retransplantation. Cardiac retransplantation represents approximately 4% of the adult heart transplant population annually [2,3].

Patient Selection

Many of the specific critical care problems seen in thoracic organ recipients can be reduced by careful patient selection. In well-compensated patients, a weeklong outpatient evaluation is performed. This applies to approximately 80% to 90% of patients seen at a cardiac transplant center. The other 10% to 20% are individuals who are desperately ill and undergo an urgent transplant evaluation.

The recipient assessment consists of a general evaluation, an assessment of the functional and hemodynamic status, and a psychosocial evaluation. All parts are equally crucial. One of the first assessments is an oxygen-consumption treadmill test. For those patients who are capable of performing this test, there are excellent data that demonstrate that a peak oxygen consumption of less than 12 mL per kg per minute is associated with a very poor 1-year survival rate without transplant. Individuals with a peak oxygen consumption of less than 15 mL per kg per minute should be considered for listing [4,5]. The assessment then proceeds with a general evaluation. The patient's medical history is examined to try to determine the cause of the patient's heart disease. General laboratory tests are performed, including a creatinine clearance. Individuals who have a creatinine clearance of less than 50 mL per minute do have a significant increase in the need for postcardiac transplant dialysis and a decrease in survival rate. Individuals with severely abnormal creatinine clearance would be excluded from heart transplant or considered for heart and kidney transplantation. Individuals with diabetes need further end-organ evaluation prior to listing to understand the full scope of their risk.

Nutritional status is also crucial. Those individuals with a body mass index less than 20 kg per m^2 or greater than 35 kg per m^2 would be asked to either gain or lose weight, respectively. Again, individuals at the extremes of the body mass index have an associated increase in postoperative mortality [6,7].

The hemodynamic evaluation consists of an echocardiogram to evaluate function and anatomy, and a cardiac catheterization. The cardiac catheterization includes evaluation of heart function by a right heart catheterization as well as a coronary angiogram. In this assessment, the patient's coronary anatomy is examined for potential intervention, and any abnormalities in the filling pressures, pulmonary capillary occlusion pressure, or pulmonary vascular resistance are identified.

Patients with heart failure and secondary pulmonary hypertension are a group who are of special interest. Pulmonary arterial and capillary wedge pressures are measured to determine the degree to which a patient has secondary pulmonary hypertension and whether or not it is reversible. The patient's hemodynamics should be optimized in the catheterization laboratory in an attempt to decrease the pulmonary arterial pressures to normal levels, and 100% oxygen, nitric oxide, and other pulmonary vasodilators can be used to test for reactivity in the pulmonary bed. The absolute exclusion criteria for heart transplantation are a pulmonary vascular resistance greater than 4 Wood units (WU) and, more importantly, a transpulmonary gradient greater than 15 mm Hg. Individuals with values outside these values would then be listed for heart–lung transplant, or be given a trial of pulmonary vasodilators.

The patient's ABO blood type and panel-reactive antibody (PRA) level is determined to quantitate the patient's preexisting antibodies and sensitization to the general population. If class II (locus D) is greater than 20%, it is recommended that a preoperative cross-match be performed. The patient's HLA typing is also done at that time, and if the PRAs are significantly elevated, the laboratory should be able to identify the particular human leukocyte antigen to which the individual is reacting. Sensitization can occur in many situations. It may occur because of pregnancy, between sexual partners, from prior transplantation, or with transfusions often associated with the placement of a ventricular assist device. Individuals who carry a high PRA level have been treated in the past with plasmapheresis, intravenous immunoglobulin, cyclophosphamide, and mycophenolate mofetil (MMF). There have been inconclusive results with each of these.

The psychosocial evaluation should be centered on evaluating not only the transplant recipient but also the family support for the patient. This needs to be performed by a social worker and, when indicated, other mental health professionals who have a keen understanding of the demands made on a postoperative cardiac transplant patient. Patients need to be medically compliant, have adequate neurocognitive function for the postoperative regimen, and adequate social support.

Once the evaluation has been completed, the patient is evaluated for any relative or absolute contraindication for heart transplant. Those relative contraindications include age greater than 70 years, previous chronic substance abuse, limited social support, limited adaptive ability, mild renal dysfunction, active peptic ulcer disease, cachexia, obesity, and cigarette smoking. It should be noted that to receive a heart transplant, individuals who smoke are required to go through a smoking-cessation program, and many transplant programs require them to sign a contract stating that they will not resume smoking prior to or after the transplant. They also are evaluated for chemical evidence of smoking during their waiting time [8].

Absolute contraindications to cardiac transplantation include ongoing substance abuse, refractory psychiatric conditions, suicidal behavior, severe personality disorder, issues with ongoing medical noncompliance, inadequate neurocognitive ability, irreversible hepatic or renal dysfunction, severe peripheral or cerebral vascular disease, systemic disease that limits rehabilitation, insulin-dependent diabetes with severe end-organ damage, and evidence of severe, fixed, secondary pulmonary hypertension [8–10].

Implantable Cardiac Assist Devices

The proliferation and success of ventricular assist devices probably represent the greatest advance in the treatment of end-stage heart failure and the field of heart transplantation of the past 10 years (Table 183.1). With an assist device implanted, patients who would otherwise not survive long enough to

TABLE 183.1

ADVANCES OF VENTRICULAR ASSIST DEVICES IN HEART FAILURE TREATMENT

Topic	Finding	Reference
Destination therapy trial with pulsatile pumps	Improved survival at one year with mechanical assist device vs. medical management for Class III and IV heart failure	[11]
Bridge to transplant trial with continuous flow pumps	HeartMate II provides effective support to transplant for at least 6 months with 75% survival	[12]
Improved survival with continuous flow pumps	Effective support, improved functional status and quality of life with 72% survival at 18 mo	[48–50]

receive a heart transplant are now living independently at home with reasonably good quality of life until a suitable organ becomes available. Today, at high-volume heart transplant centers, many if not most patients arriving for heart transplantation have an assist device already in place and it can be expected that in the coming years most if not all heart transplant recipients will have had one of these devices implanted by the time they receive an organ.

From their increased use, a corpus of terminology has evolved to categorize and describe the devices themselves, their use, and technical aspects of their function and performance. Most devices are designed to assist the left ventricle and hence are called left ventricular assist devices (LVADs). However, some models are made to be implanted in either ventricle and when implanted on the right side are referred to as a right ventricular assist devices (RVAD). When both ventricles are mechanically assisted, each with its own pump, the whole system together is referred to as a biventricular assist device, or BIVAD.

There are two broad categories of devices in use based on pump mechanism: pulsatile devices that employ some type of pneumatic pump, and continuous, or axial, flow devices that involve a spinning propeller. The cycles of the pulsatile device are measured in beats per minute (bpm) and that of the continuous flow pumps in revolutions per minute (rpm). Each device has an inflow cannula through which the patient's blood is drawn from the heart and into the pump and an outflow cannula that directs the blood back into the patients' circulation.

Further, for both pulsatile pumps and continuous flow pumps, there are two more classifications that can be described on the basis of the location of the pump when implanted: intracorporeal wherein the entire pump is implanted inside the body with the exception of the drive-line that powers the device and passes through an exit site on the abdomen; the other is paracorporeal, or extracorporeal, wherein the pump sits outside the body and the inflow and outflow cannulae enter and exit the skin on the upper abdomen just below the costal margin.

Most LVADs usually involve an inflow cannula placed in the apex of left ventricle and the outflow cannula in the ascending aorta. The only permanent RVAD approved for use in the United States is the Thoratec® Paracorporeal Ventricular Assist Device and its inflow cannula is placed in the right ventricular free wall and the outflow cannula is anastomosed to the pulmonary artery. The Levitronix® CentriMag (now owned by Thoratec®) is approved for temporary right ventricular assistance up to 30 days and its inflow cannula may be placed in either the right atrium or the right ventricle.

Lastly, there is a categorization of devices based upon the intended therapeutic goal for each particular patient. Bridge to transplant (BTT) indicates that the patient is or will become a heart transplant candidate and the device is intended to improve survival and other physiologic parameters until an organ is available. Destination therapy (DT) indicates that the patient is not a transplant candidate but the device is implanted to improve survival and quality of life for the remainder of the patient's life. Bridge to recovery refers to the patient who is expected to recover from heart failure and the device is used to sustain life until the time when it can be weaned off and explanted. Bridge to decision (BTD) refers to those patients for whom survival is not certain and a temporary assist device, such as the AbioMed BVS5000™ or the Levitronix® CentriMag, is used in the critical care setting to prolong life until it can be determined whether the patient ought to be implanted with a long-term device as those used in BTT or DT patients or be disconnected from the BTD device and allowed to expire.

The superior efficacy of VADs over optimal medical management in improving survival in end-stage, New York Heart Association Class 3 or 4 heart failure patients was proven in the REMATCH trial: patients implanted with the Thoratec® HeartMate VE had a 52% survival at one year compared to 25% in the medically managed group [11]. Subsequently the Food and Drug Administration (FDA) approved the HeartMate XVE for destination therapy. The Thoratec® HeartMate II continuous flow pump demonstrated efficacy in bridge to transplantation with 75% survival at 6 months postimplantation and 68% survival at 1 year [12]. It received approval by the FDA in April 2008 for bridge to transplantation and was subsequently approved for destination therapy in January 2010. Smaller devices such as the Jarvik 2000 Flowmaker™ and the HeartWare™ VAD are currently under investigation in the United States with more than two dozens other devices presently in development (Fig. 183.1).

Knowing how these devices work and how these patients are managed will be an important part of the pretransplantation care of the recipient, and indeed any critically ill patient who is admitted with one of these devices. Almost all of these patients will arrive anticoagulated on warfarin. It will be important not to begin administration of plasma and cryoprecipitate until the plan to proceed with the transplant is certain. Administration of blood products without completing the transplant will only sensitize the recipient and increase the PRAs for any subsequent transplant offers [13]. The postoperative course is often complicated by bleeding. Drains for the VAD pocket are necessary and pericardial effusions are more common.

Several studies have examined posttransplant survival and recent studies have shown that recipients of ventricular assist devices have had equal or better posttransplant outcomes [14,15]. One exception is the patient who had VAD-related sepsis prior to transplantation as these patients had a trend to slightly poorer posttransplant survival than those patients who did not have an infection [16].

Donor Criteria

The donor evaluation begins with the pronouncement of brain death. The local organ procurement agency will obtain consent

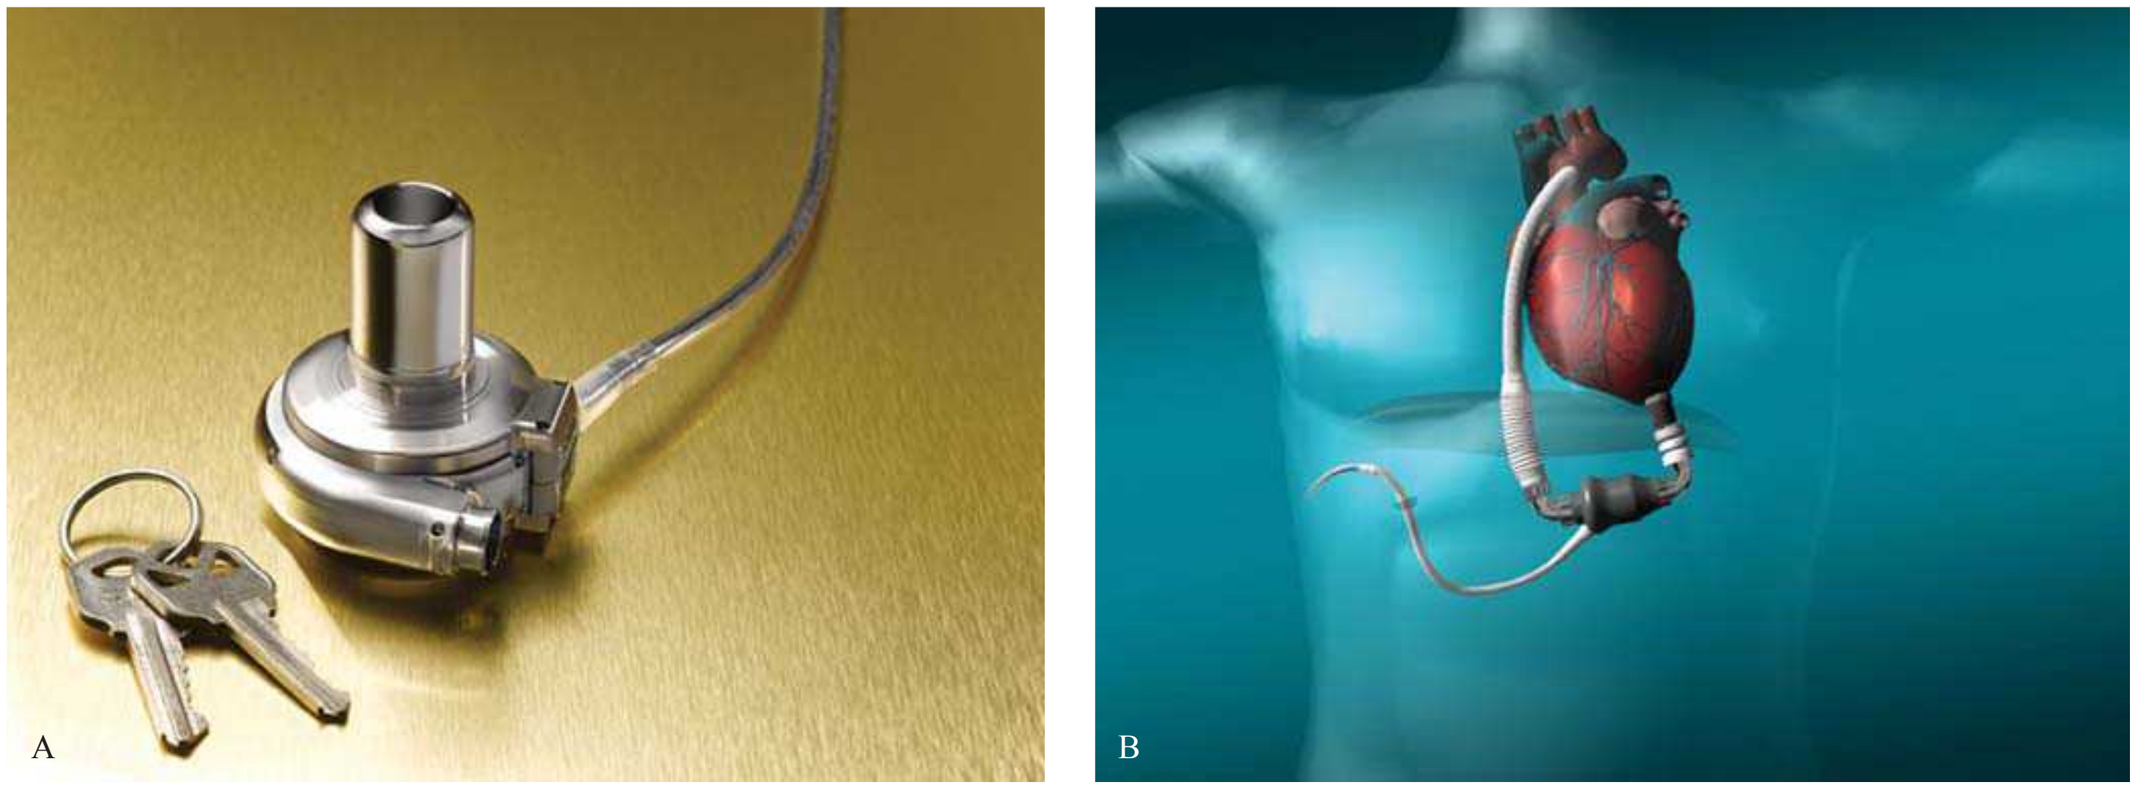

FIGURE 183.1. Continuous flow ventricular assist devices. **A:** HeartWare ventricular assist device. [Reprinted with permission from HeartWare™.] **B:** HeartMate II ventricular assist device. [Reprinted with permission from Thoratec®.]

for donation from the family and proceed with the donor evaluation and support. The donor evaluation consists of taking a general history of any illnesses or risk factors such as heart disease, hypertension, diabetes, or cigarette smoking. Specifics are gathered surrounding the time and mode of death to determine whether there is any potential cardiac injury, down time, cardiopulmonary resuscitation, or cardioversion. The organ-procurement professionals will proceed with a hemodynamic evaluation of the patient. This consists of at least measuring central venous pressures and, potentially, full hemodynamic profiles if pulmonary artery catheter measurement capability exists at the donor hospital. Once the donor is stabilized hemodynamically, further studies are performed. The initial stabilization phase should include endocrine support with the administration of levothyroxine and corticosteroids, reduction of inotropic support if it is appropriate, and, potentially, diuresis or transfusion if needed. A surface echocardiogram is then performed to make sure the heart is structurally normal and that function is normal. A 12-lead electrocardiogram is also obtained. It is not uncommon to find subtle ST changes in individuals who are brain-dead. It is generally accepted that a cardiac catheterization will be necessary in male donors more than 40 years old and female donors more than 45 years old, but catheterization should also be performed in younger donors if the donor has a significant history of hypertension, cigarette smoking, diabetes, or alcohol abuse. Cardiac enzymes need to be carefully evaluated and correlated to any severe hemodynamic instability, the use of cardiopulmonary resuscitation, as well as the time of herniation [17].

A number of studies have demonstrated correlations between elevations of troponin and early graft failure [18,19]. In one study, a cardiac troponin I value greater than 1.6 μg per L was a predictor of early graft failure, with a sensitivity of 73% and a specificity of 94% [18]. These data should be analyzed closely with the patient's hemodynamic function and echocardiographic findings.

A transplant center may request that a second echocardiogram be performed if the first echocardiogram was performed shortly after herniation. Catecholamine-induced left ventricular dysfunction can improve significantly in a short period of time and not preclude excellent short- and long-term outcomes. One must also take into consideration the ischemic time that will be incurred with procurement and travel time. The majority of transplant centers are willing to accept an ischemic time up to 4 hours for adult donors but no more than 6.

Operative Techniques

Donor Operation

Once the donor has been prepared and the abdominal team has started their procedure, the median sternotomy incision is performed. If lungs are being harvested, both pleural spaces are also opened for inspection of both lungs. During this inspection, one should palpate the coronaries to discern any calcifications and also palpate the aortic root for calcifications. External evaluation of the heart is not a reliable evaluation of function unless there is something grossly abnormal, such as severe bruising from a myocardial contusion or a dilated right ventricle. Once it is determined that the heart is appropriate for transplantation and all of the other organ teams are ready, the donor is heparinized and cannulated. The heart is cannulated with a cardioplegia cannula in the ascending aorta. If the lungs are being harvested, a pulmonary artery cannula will be placed in the main pulmonary artery. Once all teams are ready, the aorta is cross-clamped and the flush solution is given. Between 1 and 2 L of cold cardioplegic solution are administered. The heart is vented via the left atrial appendage, excised, and is then submerged in ice slush saline, packaged sterilely, and placed in a cooler for rapid transport to the recipient center.

Recipient Operation

Once the recipient is prepared and draped, the median sternotomy incision is made and the heart is dissected free of any adhesions, and then cardiopulmonary bypass is established.

The recipient is placed on total cardiopulmonary bypass, before the cross-clamp is applied the aorta, and the heart is excised along the atrioventricular groove. The great vessels are divided just above their respective semilunar valves. The anastomoses are performed in the following order: left atrial, right atrial or inferior vena caval, pulmonary arterial, aortic, and, if bicaval anastomoses are being performed, superior vena caval

[20]. Temporary pacing wires are left on the donor right atrium and right ventricle. The organ is reperfused and, once it has recovered, separated from bypass. On separation from bypass, the appropriate inotropic support is administered. Typically, the patient may require dopamine or epinephrine and milrinone for postoperative support. Isoproterenol is used to maintain an appropriate heart rate if bradycardia is a problem or the heart is paced. The pulmonary artery catheter should be floated through the new heart so that pulmonary artery pressures can be monitored closely and any signs of right heart failure can be detected early.

Postoperative Care

The immediate postoperative management of a heart transplant recipient is by and large not unlike that of other cardiac surgery patients. Drips and temporary pacing leads are modified to optimize cardiac index and end-organ perfusion. Typical inotropes used are epinephrine, dopamine, dobutamine, and milrinone. A pulmonary artery catheter is used with continuous mixed venous oximetry and preload is optimized with either volume or diuretic. Usually patients come out of the operating room on Isuprel (isoproterenol) to stimulate the heart rate and/or the temporary pacemaker set to a back-up rate of 90 to 100 bpm or higher. The ideal heart rate for these patients in the first few days postoperatively is 100 to 120 bpm. After the first several days, the heart rate is allowed to drift to its baseline as the cardiac index allows. Occasionally, patients exhibit a distributive shock immediately postoperatively characterized by low systemic vascular resistence and vasopression or neosynephrine are used to treat it.

Ventilatory management varies from patient to patient. The ideal patient who is hemodynamically stable and has no signs of surgical bleeding can be extubated within a few hours. Sometimes patients with right ventricular failure due to pulmonary hypertension need to be treated with inhaled nitric oxide or epoprostenol (Flolan®) and thus mechanical ventilation is continued.

Patients who have had a ventricular assist device placed as a bridge to transplant frequently have had two or more prior sternotomies and arrive to the hospital on Coumadin. These patients have a tendency to bleed more postoperatively and one should keep a low threshold to return to the operating room for exploration if bleeding persists.

Serious ventricular failure after cardiac transplantation is unusual and can be related to poor donor-organ selection, poor graft preservation, a long ischemia time, or rejection due to the presence of preformed antibodies. Early rejection is often heralded by atrial fibrillation and the manifestation of arrhythmias should prompt an immediate work-up and treatment. Plasmapheresis can be very effective in removing preformed antibodies responsible for humoral rejection. Inotropes and pulmonary vasodilators are also often used to manage the right heart failure that frequently accompanies rejection, with the addition of an intra-aortic balloon pump if necessary. In cases of severe graft dysfunction, ventricular assist devices can support the patient until either the donor heart recovers or retransplantation takes place.

Immunosuppression

Balanced triple-drug immunosuppression is still the most commonly used protocol, consisting of calcineurin inhibitors, an antimetabolite, and corticosteroids (Table 183.2). The calcineurin inhibitors include cyclosporine and tacrolimus. Cyclosporine is largely recognized as the agent that moved cardiac transplant from a feasible medical option to an acceptable medical treatment. The physicians at Stanford University performed a randomized control trial in cardiac transplant patients that demonstrated that cyclosporine immunosuppression improved 1-year survival to 80% from the mid-50% range [21]. Patients receiving either cyclosporine or tacrolimus have similar survival rates in heart transplantation, both long and short term [22–24]. However in a controlled clinical trial by Kobashigawa et al. in 2006 studying 343 de novo cardiac transplant patients, tacrolimus in combination with either mycophenolate or sirolimus had fewer occurrences of grade 3 A or greater rejection or hemodynamic compromise rejection at 1 year when compared to cyclosporine and mycophenolate [25]. In addition, median serum creatinine and triglyceride levels were lowest in the tacrolimus and mycophenolate group. Cyclosporine is well known to also cause postoperative hypertension, nephrotoxicity, hepatotoxicity, gingival hyperplasia, hypertrichosis, and tremor. Tacrolimus also causes nephrotoxicity and many of the other side effects of cyclosporine but to a lesser extent, in particular, posttransplant hypertension and gingival hyperplasia.

The antimetabolites include MMF and azathioprine. These inhibit purine synthesis and thus block proliferation of both T and B cells. They are complimentary to the calcineurin inhibitors. Kobashigawa et al. [26] demonstrated considerable benefits to MMF over azathioprine when coupled with cyclosporine in transplants performed in 1998. MMF is current the most widely used antimetabolite in heart transplantation [24].

Corticosteroids remain a cornerstone of therapy. There are multiple regimens for early corticosteroid reduction to avoid the serious side effects of corticosteroids. These include systemic hypertension, obesity, osteoporosis, and glucose intolerance. In spite of the negative side effects, in 2004 approximately 75% of patients were still taking corticosteroids 1 year following their transplants [27]. Monotherapy consisting of tacrolimus is currently being studied in heart transplant recipients. In one study, 75% of recipients were successfully converted to monotherapy [28] and other prospective randomized clinical trials are currently underway to evaluate these findings.

The use of IL-2 receptor blockade has become more prevalent during the last 4 to 5 years. These proliferation signal inhibitors, sirolimus and everolimus, block the activation of the T cell via the engagement of the IL-2 receptor. They have shown promise in significantly reducing the severity of cardiac allograft vasculopathy, the main threat of long-term graft survival. But they remain only a compliment to the calcineurin inhibitors that are still more effective in preventing acute rejection.

Outcomes

The registry of the International Society for Heart and Lung Transplantation (ISHLT) has reported on survival after cardiac transplantation in adult patients transplanted from 2004 to 2008, with survival rates of 85% to 89% at 1 year [29]. The UNOS/OPTN (Organ Procurement and Transplantation Network) database also report survival rates at 1 year of 87.7%. These data were from patients transplanted from 1997 to 2004 [2].

Over the years, the average survival rate for cardiac transplant patients improves. The median survival in patients who were transplanted between 1982 and 1988 was 8.1 years, and that has increased to 9.8 years for individuals transplanted between 1994 and 1998. A significant improvement that has occurred during the current era is the 1-year survival for cardiac retransplantation, which is markedly better than that reported in past eras. The 1-year survival for these patients is 82.4% [2].

TABLE 183.2

BALANCED TRIPLE-DRUG IMMUNOSUPPRESSION PROTOCOL[a]

Drug	Perioperative	Maintenance	Taper	Maintenance	Withdrawal
Corticosteroids					
Methylprednisolone	10 mg/kg intraoperatively or perioperatively; 125 mg IV q8 h three doses postoperatively				
Prednisone	0.5 mg/kg IV/PO qd in two divided doses	0.5 mg/kg IV/PO qd in two divided doses	Decrease dose by 5 mg/d until total daily dose is 0.3 mg/kg/d	1st mo: 0.3 mg/kg/d 2nd mo: 0.2 mg/kg/d 3rd mo: 0.1 mg/kg/d 4th mo: 0.05 mg/kg/d (or 2.5 mg PO qd)	5th mo: total steroid withdrawal (if no rejection for the past 3 mo)
Calcineurin inhibitors					
Tacrolimus	0.05 mg/kg PO preoperatively; 0.1 mg/kg PO qd in two divided doses; dose target levels 0–1 mo, 10–15	Dose target levels 2–6 mo, 10–12 7–12 mo, 10–12 12+ mo, 8–12			
Cyclosporine	2 mg/kg PO preoperatively; 1 mg/kg IV over 24 h., then 3–5 mg/kg PO qd in two divided doses (based on renal function); dose target levels 0–1 mo, 200–250	Dose target levels 2–6 mo, 150–225 7–12 mo, 125–175 12+ mo, 100–125			
Antimetabolite					
Mycophenolate mofetil	1,000 mg PO preoperatively; 2–3 g IV/PO qd in two divided doses; dosage to keep white blood cell count > 4.0	2–3 g PO qd in two divided doses			
Azathioprine	34 mg/kg PO preoperatively; 3 mg/kg IV/PO qd postoperatively	1–3 mg/kg PO qd			

[a]Data from Refs. [21–25].
IV, intravenously; PO, orally.

General Complications of Heart Transplantation

Right Heart Failure and Pulmonary Hypertension

Frequently acute right heart failure in the postoperative heart transplant patient is secondary to pulmonary hypertension. As mentioned, patient selection is crucial in identifying those recipients with fixed pulmonary hypertension. Those with a pulmonary vascular resistance ≥4 WU, a systolic pulmonary artery pressure ≥60 mm Hg or a transpulmonary gradient ≥15 mm Hg that does not reverse with vasodilator therapy such as inhaled nitric oxide or a prostacyclin analogue such as epoprostenol should not receive a heart transplant. Despite this, there are still recipients who will have some degree of pulmonary hypertension that will cause right heart strain post-transplantation.

Though right heart failure is frequently accompanied by pulmonary hypertension, other causes include donor selection, poor preservation, or prolonged ischemia time. The main principles of management in all cases of right heart failure are to preserve coronary perfusion, optimize RV preload, and reduce afterload by using high inspired oxygen concentrations, inhaled nitric oxide, and prostacyclin [30]. Intravenous milrinone or dobutamine followed later by oral sildenafil are also mainstays

TABLE 183.3

ISHLT CARDIAC BIOPSY GRADING FOR ACUTE CELLULAR REJECTION

Grade	
0R	No rejection
1R, mild	Interstitial and/or perivascular infiltrate with up to 1 focus of myocyte damage
2R, moderate	Two or more foci of infiltrate with associated myocyte damage
3R	Diffuse infiltrate with multifocal myocyte damage ± edema, ± hemorrhage, ± vasculitis

ISHLT, International Society for Heart and Lung Transplantation. Data from Stewart S, Winters GL, Fishbein MC, et al: Revision of the 1990 working formulation for the standardization of nomenclature in the diagnosis of heart rejection. *J Heart Lung Transplant* 24:1710, 2005.

of therapy. Finally, in severe cases of right heart failure in the acute postoperative setting, a temporary right ventricular assist device is used to bridge the heart to recovery. The need for mechanical assistance typically lasts only a few days to a week and a low threshold should be kept for implanting a device.

Rejection

Surveillance for rejection in the heart transplant recipient by evaluating endomyocardial biopsies of the right ventricle obtained via the right internal jugular vein is performed frequently during the first year and eventually lessens to two to three times per year. There are four types of rejection: hyperacute, acute cellular, acute humoral, and chronic. The grading scale for rejection was recently revised to simplify it and because there appeared to be little clinical difference between grade 1A and 1B rejection in the old classification and also there was evidence of a benign clinical course for grade 2 rejection in the old classification as well [31]. The new grading system is shown in Table 183.3.

The mainstay of treatment is pulse corticosteroids administered intravenously for 3 days, with or without a subsequent taper. In the case of hemodynamically significant rejection or suspected acute humoral rejection, ultrafiltration, and intravenous immunoglobulin are administered to lower circulating antibodies. The addition of methotrexate or cyclophosphamide also should be considered. Photopheresis has been used to treat patients who have preexistent high levels of PRAs [32]. Late chronic rejection manifests as cardiac allograft vasculopathy, is thought to be due to a combination of humoral and cellular rejection, and is the greatest threat to long-term survival. When a patient has no other options to treat chronic, unrelenting rejection, the last resort is retransplantation.

Infection and Pneumonia

Patients who have undergone thoracic organ transplantation are susceptible to bacterial, fungal, and viral infections. The most morbid viral infection that occurs in thoracic organ transplant recipients is caused by cytomegalovirus (CMV) [33]. Transmission of CMV by a donor organ is very common and hence prophylaxis with ganciclovir is used in CMV-mismatched thoracic transplant recipients. Patients who are seronegative at the time of transplantation and receive a graft from a seropositive donor sustain the highest rate of infection and exhibit the most severe form of CMV disease. Ganciclovir is the treatment of choice.

Pulmonary complications occur in approximately a third of heart transplant recipients [33,34] and is the most common infectious complication in heart transplant recipients. In the first 6 months, hospital acquired bacterial pneumonia is the most common pulmonary complication followed by Aspergillus pneumonia. The overall mortality associated with pneumonia is 35% to 55% and accounts for 40% of all cause mortality. A heightened vigilance for pulmonary infection is critical and the presence of yeast- or mold-positive sputum should be aggressively treated. Risk factors for pulmonary complications are older recipient age, moderate to severe rejection, and development of CMV antigenemia in a previously CMV-seronegative recipient [33].

Coronary Allograft Vasculopathy

The development of coronary allograft vasculopathy can lead to myocardial infarction and sudden death in the cardiac transplant recipient. Routine annual coronary angiography with intravascular ultrasound is performed to permit an accurate assessment of the time of onset and rate of progression of coronary artery disease. Graft atherosclerosis occurs in 30% to 40% of transplant recipients after 3 years and in 40% to 60% of patients by 5 years after transplantation [35]. It remains the major obstacle to long-term survival in cardiac transplant recipients. A correlation between CMV infection and accelerated allograft atherosclerosis has also been identified [36]. Immunologically mediated endothelial damage has been proposed as a stimulus for the development of graft atherosclerosis. Treatment can be temporizing in the form of angioplasty for focal lesions; however, when the disease involves tapering of the distal vessels, only cardiac retransplantation can ultimately treat the problem.

Renal Failure

Renal failure in the perioperative period is often transient, and it may be the direct result of nephrotoxic immunosuppressive drugs. Mild impairment of renal function preoperatively is acceptable as long as the risk of severe renal impairment during the postoperative period is recognized as a possible complication. The lowest acceptable level for creatinine clearance in a potential thoracic organ transplant recipient is 50 mL per minute. For suitable patients, combined heart and kidney transplant can be considered. It is also possible for a patient to be listed for a kidney transplant following thoracic organ transplantation.

Posttransplant Lymphoproliferative Disease

Posttransplant lymphoproliferative disease is a common cause of late death following solid-organ transplantation. It is more commonly seen in the pediatric population and is associated with exposure to the Epstein–Barr virus (EBV). Those at greatest risk for posttransplant lymphoproliferative disease are individuals who are EBV-seronegative before transplant who convert after their transplant. Those individuals who are EBV seropositive before transplant are at a lesser risk but are not risk free. Management includes vigilant monitoring of the patient's EBV status, EBV polymerase chain reaction testing, and regular examinations of lymph node beds for enlargement. Therapy once this problem occurs has not been standardized and runs the gamut of antiviral agents, reduction of immunosuppression, anti-CD20 antibodies (such as rituximab), chemotherapy, and radiation therapy. Many of these have been used in combination.

Gastrointestinal Problems

Approximately 40% of patients experience gastrointestinal complications post-transplant. The majority is related to drug side effects, most notably MMF that can cause nausea, vomiting, and diarrhea [37]. These are most often managed with dose adjustments. Serious complications of the alimentary tract following heart and heart–lung transplantation have been well documented and remain a major source of morbidity and mortality [38]. For that reason, patients with active peptic ulcer disease or diverticular disease are not considered for thoracic organ transplantation, at least until these problems have resolved. Mild liver dysfunction as evidenced by elevation of serum transaminase values and hyperbilirubinemia may occur in patients receiving high doses of cyclosporine. This is a chemical hepatitis that usually responds to a decrease in the dosage. Other immunosuppressants such as azathioprine have been implicated in a similar process. Hepatitis may also be secondary to hepatitis B, CMV, herpes simplex virus, hepatitis A, or hepatitis C.

Biliary tract disease is common in the thoracic organ transplant population. In a series of heart transplant recipients, the incidence of cholelithiasis ranged from 30% to 39%, which is more than twice that expected for age- and gender-matched controls [39]. The primary cause of this problem is thought to be gall bladder stasis and the side effects of specific immunosuppressants [40].

Cardiac Retransplantation

Cardiac retransplantation represents a small fraction of the transplants that are performed annually (the UNOS/OPTN database: 3% to 5% annual retransplant rate) [2]. According to the ISHLT database, approximately 2% of all adult heart transplants internationally are retransplants. In the pediatric heart transplant population, this rate is approximately 6% of all transplants. Current 1-year survival for heart retransplant is 82%, closely approaching the 1-year survival of the original transplant [3]. The primary indications for retransplantation appear to be early graft failure, and in later time periods, chronic rejection or graft atherosclerosis.

HEART–LUNG TRANSPLANTATION

Heart–lung transplants are performed almost exclusively in patients with surgically uncorrectable congenital heart disease and Eisenmenger's physiology [41]. Patients with unrelated severe cardiomyopathy and pulmonary disease may also be candidates for heart–lung transplants. With the difficulty of obtaining a heart–lung block and the outcomes of these procedures, many surgeons repair the congenital heart defect and transplant only the lungs [42]. More and more patients with primary pulmonary hypertension are being treated with bilateral single-lung transplant rather than with heart–lung transplant.

There has been a constant decline in the number of heart–lung transplants performed since the mid-1990s, both nationally and internationally, with fewer than 90 heart–lung transplants being performed annually in the current era [2].

Donor Criteria and Organ Procurement

The donor criteria are similar to the criteria used for heart (as listed previously) and lung transplantation (see Chapter 189). The procurement of the heart–lung block entails simultaneous use of techniques that are otherwise used to procure these same organs separately.

Operative Technique: Heart–Lung Transplant

From the outset, the recipient is placed on cardiopulmonary bypass. The recipient heart is excised first, and then each lung is removed. The phrenic neurovascular bundles are protected bilaterally [39]. The left recurrent laryngeal nerve is also at risk for damage in the region of the ligamentum arteriosum. For that reason, some surgeons leave a portion of the main and left pulmonary artery in situ. The tracheal anastomosis is performed first. Although it can be wrapped with omentum, it does not need to be, because the coronary–bronchial collateral circulation is generally excellent. Performance of the right atrial anastomosis or bicaval anastomoses is followed by the aortic anastomosis. Large aortopulmonary collaterals and bronchial vessels can develop in patients with chronic cyanosis and Eisenmenger's physiology. Extreme care must be taken during the operative procedure in these patients to avoid postoperative bleeding.

Postoperative Care

Postoperative care of patients who have had heart–lung transplantation can be quite complex. Potential complications from the heart or the lungs can arise. The standard postoperative care most closely resembles that of a lung transplant patient, and is discussed in a separate chapter. Postoperative bleeding can be quite profound in this subset of patients, even with careful operative control of collateral vessels.

Outcomes

As of 2009, the current registry reports from ISHLT demonstrate a 1-year survival rate of only 75% for individuals undergoing a heart–lung transplant. The average survival for this group who were transplanted between 1982 and 2003 was 3.2 years. Because of the significant mortality rate that occurred within the first year after the transplant, the conditional half-life was higher at 9 years [27]. Early mortalities were due to technical complications, graft failure, and non-CMV infections accounting for 73% of the deaths. Mortality that occurred beyond the first year was attributed to chronic lung rejection with bronchiolitis obliterans, whereas cardiac rejection or coronary vasculopathy played a minimal role.

In the field of heart–lung transplantation, it was initially thought that endomyocardial biopsy would be the appropriate diagnostic test to detect rejection [43,44]. However, with two organ systems involved, the lungs often reject despite normal findings on endomyocardial biopsy [45]. Transbronchial biopsy reveals what is occurring in the lungs during the perioperative period and, later, complications in the lung grafts may be suggested when there are changes on chest radiograph or in pulmonary function studies, and should be evaluated with transbronchial biopsy [46]. Treatment of recurrent lung rejection consists of pulse corticosteroids with or without a taper. Alternate therapies including lympholytic agents, photopheresis, methotrexate, or cyclophosphamide may be used for refractory cases of rejection [47].

CONCLUSION

The discipline of heart transplantation has recently passed its 40th anniversary, and many major advances have been made.

In spite of the changes that have occurred in recipient criteria, the greater number of potential recipients coming to transplant who are more than 60 years of age, on inotropic support, or using mechanical assist, the outcomes of heart transplantation have improved with each passing year. The field has also enjoyed seeing a decrease in candidate waiting times on the list and the evolution of cardiac assist devices to improve candidates for heart transplant. Clearly, knowledge of cardiac transplant is directly related to the duration of experimental and clinical experience. It is expected that, as understanding continues to expand, long-term survival of transplant recipients will increase.

CHAPTER 184 ■ CARE OF THE PANCREAS TRANSPLANT RECIPIENT

ROBERT M. ESTERL JR, GREGORY A. ABRAHAMIAN, DAVID E.R. SUTHERLAND AND RAJA KANDASWAMY

Type 1 diabetes mellitus has two treatments: (a) exogenous insulin administration or (b) beta cell replacement by pancreas or islet transplantation. The former is burdensome to the patient and gives imperfect glycemic control, predisposing to secondary complications of the eyes, nerves, kidneys, and other systems. The latter, when successful, establishes a constant euglycemic state but requires major surgery—at least for the pancreas transplant—and immunosuppression to prevent rejection, predisposing to complications as well, often compounded by those that are preexisting from diabetes.

The Diabetes Control and Complications Trial [1] showed that intensive insulin therapy (multiple injections per day with doses adjusted by frequent blood sugar determinations) decreased, although rarely normalized, glycosylated hemoglobin levels (HbA1C) and reduced the rate of secondary complications [2]. The threshold for totally eliminating the risks of secondary diabetic complications was perfect glycemic control, an objective that cannot be achieved by even the most sophisticated exogenous insulin-delivery devices available today. Pancreas transplantation induces insulin independence in diabetic recipients without the risk of hypoglycemia and can ameliorate secondary complications. With major advances in the area of management of pancreas transplantation (Table 184.1), the success rate has progressively increased during the past five decades [3]. Today's recipients have a high probability of achieving insulin independence for years, if not indefinitely.

Historically, islet transplants have been less successful than pancreas transplants for a variety of reasons, but the gap is narrowing. In the late 1990s at the University of Alberta, insulin independence was achieved by sequential transplantation of islets from multiple donors and the use of a steroid-free, nondiabetogenic, immunosuppressive regimen [4]. In another series from the University of Minnesota with a similar immunosuppressive regimen, single-donor islet transplants induced insulin independence [5]. In this series, the donors had a high body mass index and the recipients had a low body mass index, so that the net number of islets transplanted per unit weight was similar in the Alberta and Minnesota series. Islet transplants can succeed with strict donor and recipient selection, but are not yet able to supersede pancreas transplants as the mainstay of beta cell replacement. Until islet transplants can consistently succeed from a single donor, regardless of recipient size or insulin requirements, an integrated approach is likely; large donors will be used for islet transplants to recipients with low insulin needs and the remaining donors (the majority) for pancreas transplants to recipients with average- or high-insulin requirements. This strategy will maximize the number of recipients who receive allogeneic beta cells and eliminate surgical complications for at least a subset of patients.

Although short-term islet-graft survival appears promising (even with single donors) [6], long-term graft function after islet transplants (even with multiple donors) continues to be a major impediment to rapid progress. In the University of Alberta series, only 10% of islet transplant recipients were insulin independent at 5 years posttransplant [7].

The main trade-off for recipients of beta cell allografts is the need for immunosuppression. A successful graft makes the recipient euglycemic and normalizes glycosylated hemoglobin levels, but the combined risks of immunosuppression and a major pancreas transplant surgery must be weighed against the long-term risks of imperfect glycemic control with exogenous insulin injection and of development of secondary complications. A randomized prospective trial has not been done to weigh these risks. The burden of daily management of diabetes with the need for multiple sticks to monitor blood sugar levels and to inject insulin tilts the balance in favor of a pancreas or islet transplant for many diabetic patients. Furthermore, antirejection strategies are continually being modified to decrease the complications of immunosuppression. Nevertheless, only a few institutions perform pancreas transplants soon after the onset of diabetic disease [8]; most institutions delay pancreas transplantation until the recipient becomes uremic and needs a kidney transplant.

The main indications for pancreas transplants in patients with normal kidney function are progressive diabetic complications, glycemic lability, and hypoglycemic unawareness, the latter of which may emerge years after the onset of diabetes, particularly in patients with autonomic neuropathy. However, even for nonlabile diabetic patients who attempt tight control by intensive glucose monitoring, the diabetes literature shows a high rate of secondary complications that are just as morbid [9] as complications of chronic immunosuppression in pancreas transplant recipients. Thus, for patients who wish to avoid a lifetime of insulin injections and glucose monitoring and prefer the risks of immunosuppressive complications to the secondary complications of diabetes, a pancreas transplant can be an attractive alternative therapy.

Most pancreas transplant candidates have advanced diabetic nephropathy and require a kidney transplant also. The risks of immunosuppression are already assumed because of the kidney transplant, so a simultaneous or sequential pancreas transplant does not pose significant additional risks other than surgical ones [8]. Although most pancreas transplants are performed in type 1 diabetics with impending or chronic renal failure, some pancreas transplants occur in renal allograft recipients who meet the criteria for type 2 diabetes who want to eliminate the need for exogenous insulin [10].

PANCREAS TRANSPLANT RECIPIENT CATEGORIES

Pancreas transplant candidates are divided into three categories: uremic (need a kidney transplant), posturemic (have a functioning kidney transplant), and nonuremic (do not need a kidney transplant, at least yet). For candidates who are

TABLE 184.1

MAJOR ADVANCES IN THE MANAGEMENT OF PANCREAS TRANSPLANTATION

Topic	Change	References
Organ donation	1) Increased donor pool due to use of organs from donors after cardiac death with comparable graft survival rates to recipients of organs from brain-dead donors 2) Greater application of the expanded donor for pancreas organs	[50,84–90]
Preservation fluids	Improved pancreas preservation fluids/techniques	[92–115]
Pancreas transplant operation	1) Shift from bladder to enteric drainage of pancreatic exocrine secretions 2) Shift from systemic to portal venous drainage 3) Shift toward deceased pancreas transplant after living kidney transplant 4) Increased application of islet cell transplant 5) Increased laparoscopic living donor kidney and segmental pancreas organ procurement	[11,13,14,37,40, 85,124–137]
Immunosuppressive regimens	1) Tacrolimus and mycophenolate mofetil have replaced cyclosporine and azathioprine with improved graft survival 2) Increased use of depleting antibody to encourage innovative immunosuppressive strategies (steroid withdrawal or avoidance, calcineurin withdrawal, monotherapy)	[132–138]

uremic, the options are to receive kidney and pancreas transplants either simultaneously in the same operation or sequentially in separate operations. Which option to take is usually based on the availability and suitability of living and deceased donors for one or both organs at that particular time.

Accordingly, there are three broad categories of pancreas transplants: simultaneous pancreas kidney (SPK) transplant, pancreas after kidney (PAK) transplant, and pancreas transplant alone (PTA).

1. SPK transplants: Most SPK transplants are performed with both organs from the same deceased donor. Because a large number of patients wait on the UNOS list for a kidney organ, unless priority is given to SPK candidates, waiting times tend to be long (years). To avoid two operations and long waiting times, a simultaneous kidney and segmental pancreas transplant from a living donor can be done, but only a few centers offer this option. With successful islet transplantation from a living donor [11], a simultaneous living donor islet-kidney transplant may become a viable option in the future. If a living donor is willing or is medically suitable to give a kidney organ only, another option is a simultaneous living donor kidney and deceased donor pancreas transplant [12]. For this option, the living kidney donor and the recipient must be available at a moment's notice, because the deceased donor pancreas must be transplanted soon after procurement. Alternatively, a recipient of a scheduled living donor kidney transplant could receive a simultaneous deceased donor pancreas organ if it became available fortuitously. If not, and only a living donor kidney is transplanted, the recipient becomes a PAK candidate.
2. PAK transplants: For diabetic patients who have already received a kidney transplant from a living or deceased donor, a PAK transplant can be performed. Most PAK transplants today are performed from a deceased donor in a patient who previously received a living kidney transplant. Although a PAK transplant requires that a uremic diabetic patient undergoes two operations to achieve both a dialysis-free and insulin-independent state, the two transplants done separately are "smaller" procedures than a combined transplant. The time interval between the living donor kidney transplant and the deceased donor pancreas transplant depends on several factors, including recipient recovery from the kidney transplant and donor availability, but the outcomes are similar for all time intervals greater than 1 month duration. Because of the lack of priority of patients who wait for a SPK versus a kidney alone, the PAK is now becoming the most popular pancreas transplant category at many institutions [13,14].
3. PTA: For recipients with adequate kidney function, a solitary pancreas transplant can be performed from either a living or deceased donor. Because the waiting time for a solitary deceased pancreas is relatively short at the present time, living donor solitary pancreas transplants are done infrequently, but are typically indicated if a candidate has a high panel-reactive antibody and a negative cross-match to a living donor. PTA candidates have problems with glycemic control, hypoglycemic unawareness, and frequent insulin reactions but fairly normal renal function. A successful PTA not only obviates these problems, but also probably improves the quality of life, and may ameliorate secondary diabetic complications, thus increasing the applicability of PTA [13–15].

Although the numbers of SPK transplants have remained fairly constant for nearly two decades, the numbers of solitary pancreas transplants (PAK and PTA) have nearly quadrupled [16]. From 2004 to 2008, the most common category of pancreas transplant was the SPK (73%), followed by the PAK (19%) and the PTA (9%); in the PAK category, 76% of the kidney organs came from living donors [3]. Although rare, pancreas transplants can also occur as multiorgan transplants in patients with unique medical problems [17].

HISTORICAL PERSPECTIVES, EVOLUTION, AND IMPROVEMENTS IN PANCREAS TRANSPLANTS

The first clinical pancreas transplant was performed at the University of Minnesota in 1966 [18]. The number of transplants remained low during the 1970s, but progressively increased in the 1980s, due to the introduction of cyclosporine.

By the end of 2008, more than 30,000 pancreas transplants were reported to the International Pancreas Transplant Registry (IPTR) from more than 1,000 centers worldwide, including more that 22,000 in the United States and more than 8,000 outside the United States [3]. In 2010 more than 3,700 patients wait for a pancreas transplant on the UNOS list, and more than 1,200 pancreas transplants have been done annually in the United States [17].

The early history of pancreas transplants involved various surgical techniques, many of which were developed to manage pancreatic exocrine drainage [19]. The first clinical pancreas transplant was performed by Kelly et al. as a duct-ligated, segmental graft at the University of Minnesota in December 1966 [18,20]. In 1973, Lillehei described a series of 13 pancreas transplants at the University of Minnesota where he used enteric drainage (ED) of pancreatic secretions via a cutaneous duodenostomy and a roux-en-y-duodenojejunostomy [20,21]. In the 1970s, Gliedman reported the first segmental pancreas transplant (and then a series of 11 pancreas transplants) with a pancreatic duct–ureter anastomosis for exocrine drainage [20–23]. This technique did not have widespread popularity because of leakage from the pancreatic duct–ureter anastomosis and the cut surface of the pancreas [20].

From the mid-1970s to mid-1980s, segmental pancreas transplants predominated due to a historical belief that the pancreas organ was less antigenic than the duodenal stump [20,21]. With segmental pancreas transplants, two techniques were popularized to manage pancreatic exocrine secretion, including open intraperitoneal drainage by Bewick in 1976 and the University of Minnesota in 1978 [20,24] and synthetic polymer pancreatic duct injection by Dubernard in 1978 [20,25]. In 1983, Sollinger reported the use of direct bladder drainage (BD) to manage pancreatic exocrine secretions in a segmental pancreas graft [26], and the next year he described a series of 10 segmental pancreas transplants with BD that had very few surgical complications, so BD became the predominant technique (Fig. 184.1) [20,27]. In 1982, Groth and Tyden described a segmental pancreas transplant followed by a series of whole-organ pancreas transplants with ED (Fig. 184.2) [28] and this technique ended the predominance of segmental pancreas transplants [20,29].

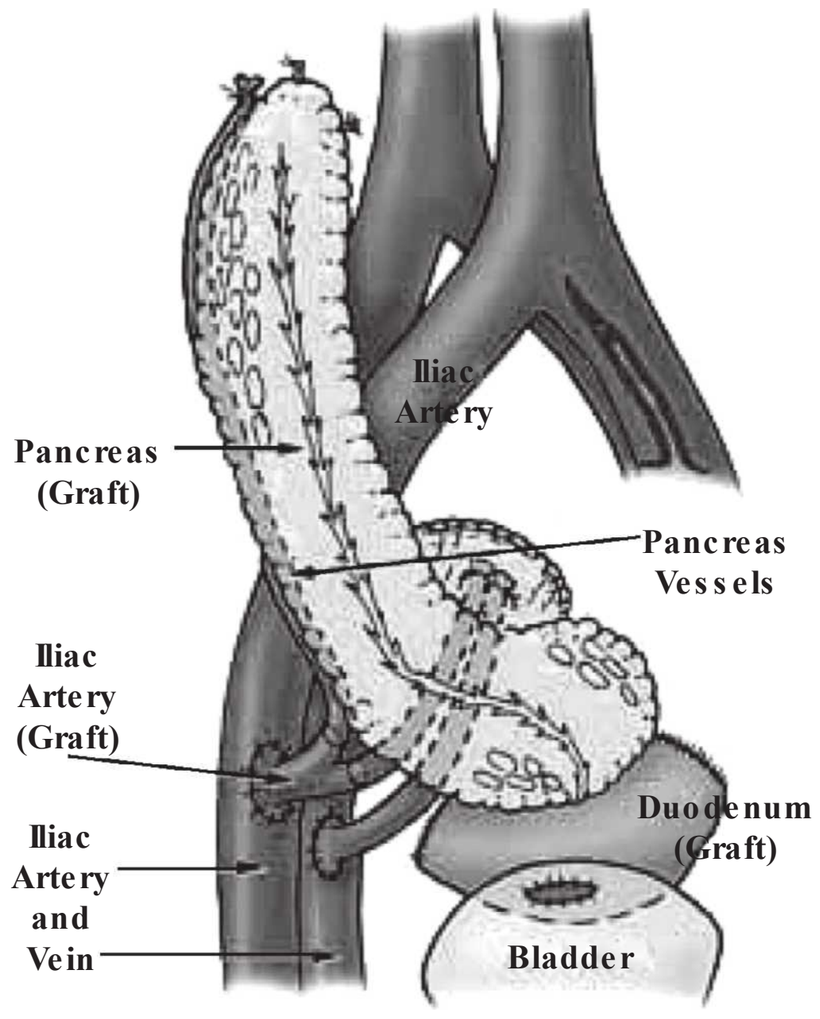

FIGURE 184.1. Bladder-drained pancreaticoduodenal transplant alone from a cadaveric donor.

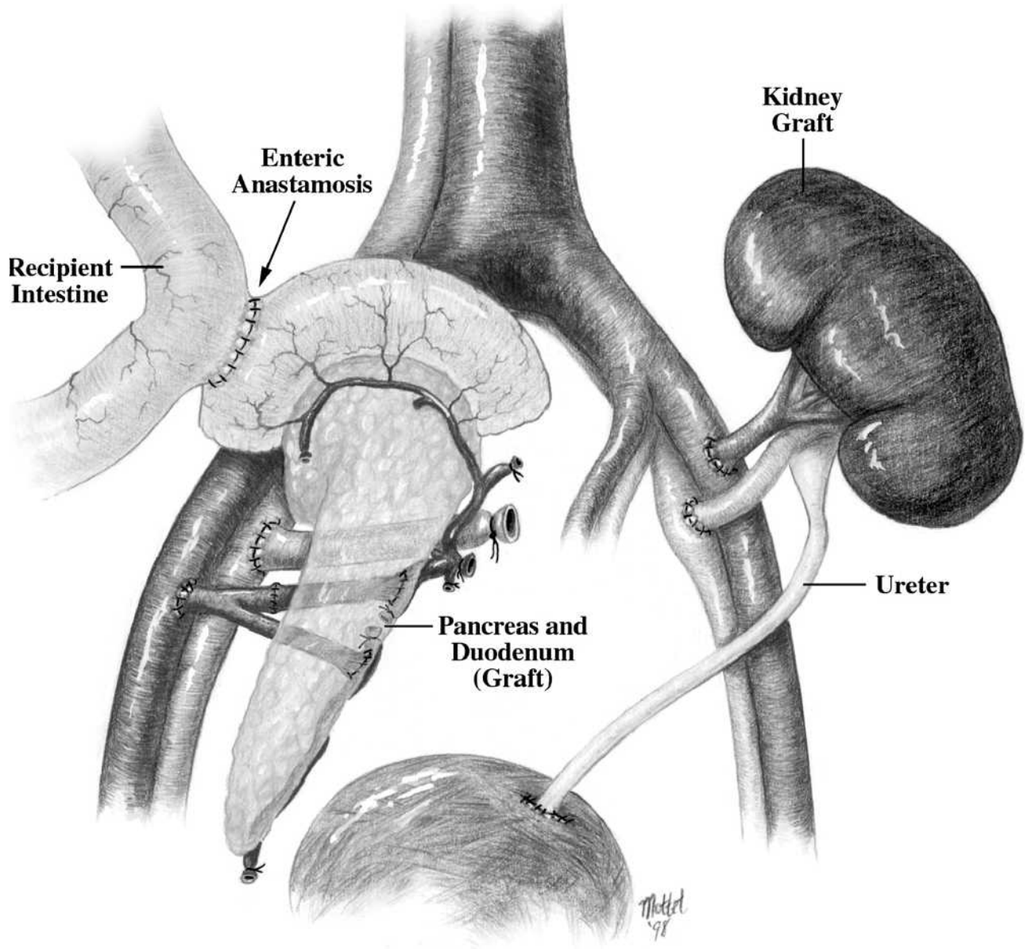

FIGURE 184.2. Enteric-drained simultaneous pancreas and kidney transplant from a cadaveric donor with systemic venous drainage.

In 1987, Nghiem et al. described a whole-organ pancreas transplant with BD via a duodenal stump, a technique that took on widespread acceptance in both Europe and the United States. BD was especially appealing because urinary amylase levels could be tracked to monitor rejection and pancreatitis [20,30]. In mid-1980s, Starzl revived ED of the whole-organ pancreas transplant described by Lellehei 20 years previously [20,31]. In the mid-1980s to the mid-1990s, although BD was popular, urinary complications including cystitis, urethritis, hematuria, metabolic acidosis, and volume depletion led to enteric conversion of whole-organ pancreas transplants in a technique first described by Tom in 1987 [20,32].

Venous drainage of the pancreas has also evolved over the years. Portal drainage was used with segmental grafts in the 1980s [33–36]. In 1989, Mühlbacher described the first case of whole-organ pancreas transplantation with portal venous drainage and exocrine BD [37]. Until 1990s systemic venous drainage had been the norm, until portal drainage gained widespread popularity with ED [38,39] as opposed to BD [37]. By 2004, about 20% of SPK transplants had portal drainage, most commonly to the superior mesenteric vein (Fig. 184.3) and 80% of SPK had ED of pancreatic exocrine secretions [40].

Before standard techniques were developed to procure liver and pancreas grafts with intact blood supplies, segmental pancreas grafts were commonly used. Currently, whole-organ pancreaticoduodenal grafts predominate, although segmental grafts are still used for living donor pancreas transplants. The first living donor pancreas transplant was performed at the University of Minnesota in 1979 [41]. The early series of living donor pancreas transplants consisted of solitary pancreata because the rejection rates for deceased donor pancreata were so high [42]. In the 1990s, living donor pancreas transplants were predominantly performed in combination with a kidney from the same donor (Fig. 184.4) [43–45]. More recently, laparoscopic living donor segmental pancreatectomy has gained popularity [46]. Another approach, as previously mentioned, is to perform a living donor kidney transplant simultaneously with a deceased donor pancreas transplant [12].

Immunosuppressive regimens have made great strides over the years. Most immunosuppressive protocols use antibody

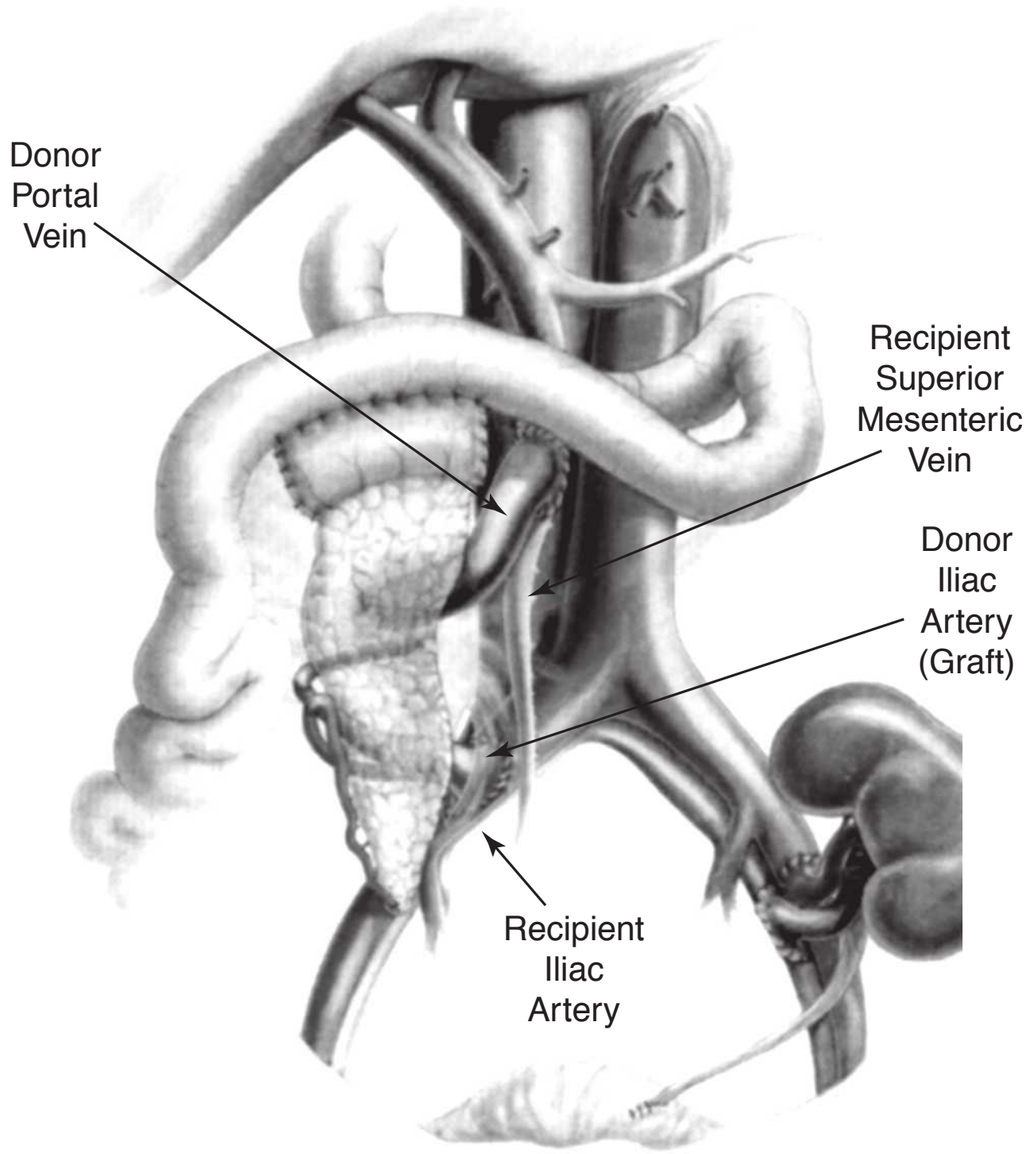

FIGURE 184.3. Enteric-drained simultaneous pancreas and kidney transplants with portal venous drainage of the pancreas graft via the superior mesenteric vein.

induction, followed by maintenance therapy with tacrolimus in combination with mycophenolate mofetil [40]. In the late 1990s and early 2000s some centers such as Northwestern University pushed for steroid-free regimens for pancreas transplants [20]; in fact, of the nearly 25,000 pancreas transplants reported to the IPTR, a third of those in the last 5 years were done with a steroid-free immunosuppressive regimen [20,40]. Today there are more than 140 pancreas transplant centers and 25 islet cell transplant centers in the United States [17]. Some centers have reported extensive experience, including more than 1,000 SPK transplants at the University of

TABLE 184.2

SUMMARY OF AMERICAN DIABETES ASSOCIATION RECOMMENDATIONS FOR INDICATIONS FOR PANCREAS TRANSPLANTS

Indication for pancreas transplants
1). Imminent or established end-stage renal disease in patients who have had, or plan to have, a kidney transplant
2). History of frequent, acute, and severe metabolic complications (e.g., hypoglycemia, hyperglycemia, ketoacidosis)
3). Incapacitating clinical and emotional problems with exogenous insulin therapy
4). Consistent failure of insulin-based management to prevent acute complications
5). Islet cell transplants hold significant potential advantages over whole-gland transplants but the procedure is experimental and should be performed only within the setting of controlled research studies

Wisconsin [17], and more than 1,900 pancreas transplants of all categories at the University of Minnesota [17]. Since 1980, the IPTR has collected data from all centers in the world [47] and remains an excellent resource for outcome analysis. In addition, the US Transplant Scientific Registry of Transplant Recipients (SRTR), administered through the Arbor Research Collaborative for Health, provides detailed scientific analysis of national, regional, state, and center-specific pancreas graft and patient survival [48].

INDICATIONS AND CONTRAINDICATIONS FOR PANCREAS TRANSPLANTS

The indications for a pancreas transplant have evolved and expanded over the years as the results have improved. The position statement of the American Diabetes Association [49] on indications for a pancreas transplant (Table 184.2) is fairly conservative. A pancreas transplant is also indicated for patients who have developed secondary complications of diabetes including retinopathy, cardiovascular disease, nephropathy, and neuropathy. The progression of many of these complications is halted by a functioning pancreas graft.

With a functioning pancreas transplant improvements with sensory, motor, and autonomic neuropathy and paresthesias have been reported [19,50–55]. Patients with abnormal cardiorespiratory neurologic reflexes have reduced death rates after functioning pancreas transplants [50,56]. There is increased nerve conduction velocity in SPK recipients with functioning pancreas transplants versus those with failed pancreas grafts [51,57,58]. Uremic patients who undergo SPK transplants have improved symptoms of gastroparesis than in patients who have kidney transplants alone [52,59].

Similarly a successful pancreas transplant halts the progression of diabetic changes in the new kidney transplant, and several studies have demonstrated improvement of nephropathy after PTA [50–52]. One study showed that long-term normoglycemia due to a functioning pancreas transplant led to reversal of characteristic diabetic glomerular lesions that occurred in nonuremic PTA recipients who had established nephropathy [52,60]. In addition to improvement in glomerular architecture, this group also showed a reversibility of cortical

interstitial expansion and reabsorption of atrophic renal tubules 10 years after PTA [52,61]. These changes in renal architecture may explain the reduction in blood pressure, albuminuria, and nephrotic range proteinuria that some PTA recipients demonstrate [52,62,63], but creatinine clearance can still deteriorate.

Several recent reports have shown stabilization or amelioration of diabetic retinopathy with a functioning pancreas transplant [50–52]. Ramsey et al. reported reduced deterioration in advanced retinopathy with a functioning pancreas transplant at 3 years [52,64]. Wang et al. reported regression of diabetic retinopathy in 43% of SPK recipients versus 23% of kidney transplant alone recipients, although nearly 50% of both groups showed no benefit but follow up was short at 1 year [50,65]. Giannarelli et al. examined 33 type 1 patients who received a pancreas transplant versus 36 type 1 patients who had medical therapy only, and noted that stabilization or amelioration of diabetic retinopathy was 91% versus 43%, respectively [51,66].

Several studies have examined the effects of pancreas transplantation on vasculopathy and cardiovascular risk factors. Severe and advanced vascular disease may be unaffected by a functioning pancreas transplant [50,51]. One series documented improvement in conjunctival microcirculation in 12 SPK patients when compared with five kidney transplant alone recipients [52,67], and other series reported improvement in carotid artery intima-media thickness (which correlates with decreased cardiovascular events) within 2 years of pancreas transplantation [50,52,68,69]. SPK transplants have also shown to improve cardiovascular risk factor profiles, progression of coronary atherosclerotic lesions, left ventricular systolic and diastolic function, and endothelial function [50–52,70–76]. Atherosclerosis regresses in nearly 40% of recipients with a functioning pancreas transplant and this fact may explain improved quality of life and patient survival benefit after pancreas transplantation [50,51,70]. Fiorina et al. demonstrated normalization of left ventricular diastolic function at 4 years after a functioning pancreas graft [50,51,77], which leads to reduction in cardiovascular events [74]. Rates of myocardial infarction and pulmonary edema were lower in SPK recipients than in kidney transplant alone patients, although the kidney alone patients tended to be quite older and the follow up period was short [50,78–80]. Echocardiographic findings 2 years after pancreatic transplantation showed improvement in left ventricular shape and function when compared with kidney transplantation alone. Stabilization [50,56] and even improvement [50,81] in cardiac autonomic dysfunction can occur after pancreas transplantation. A pancreas transplant should really be offered early, before the onset of these complications of diabetes, to interested patients who understand the risks of a significant operation and immunosuppression versus the benefit of insulin independence and freedom from diabetic complications.

Although the most subjective outcome after pancreas transplantation, improved quality of life may be the most important [52]. One study compared the quality of life of diabetic patients who underwent SPK transplants with a kidney transplants alone, and noted that SPK recipients reported improved quality of life in regard to chronic symptoms, effects of kidney disease, cognitive function, pain, physical activity and overall health [82]. Data regarding quality of life in PTA recipients is lacking.

Relative and absolute contraindications include those for any other transplant, such as extremes of age, prohibitive cardiovascular and pulmonary risk, severe hepatic disease, malignancy, active acute and chronic infections, AIDS, severe persistent coagulation disorder, noncompliance, and serious psychosocial problems. Candidates with advanced vascular disease have increased risks of surgical complications, yet, those patients who do well after pancreas transplantation, greatly benefit from stabilization of their cardiovascular risk.

PRETRANSPLANT EVALUATION

The pretransplant workup should include a detailed medical, surgical, and psychosocial evaluation. Cardiac risk assessment is mandatory because diabetes is a major risk factor for coronary artery disease (CAD). Cardiologists vary on the type of test to screen for CAD in pretransplant diabetic patients. Coronary angiograms are performed in most candidates, especially those over 45 years of age. Noninvasive tests are not very sensitive for CAD and are poorly predictive for subsequent postoperative events in long-standing diabetic patients. With the use of iso-osmolar radiographic contrast, there does not seem to be an increased risk of contrast-induced nephropathy in patients with chronic kidney disease [83]. In selected patients (i.e., young, healthy patients with short-duration diabetes) dobutamine stress echocardiograms are used for cardiac evaluation with acceptable results. Once significant CAD is detected, aggressive treatment by angioplasty, stenting, or revascularization is recommended. Revascularized transplant candidates have significantly fewer postoperative cardiac events, as compared with those who received medical therapy alone. The minimum cardiac evaluation should include an ECG, chest radiograph, echocardiogram, and cardiac stress test [50].

A detailed examination must be done to rule out vascular insufficiency in the lower extremities. If such vascular insufficiency is found, it too may need pretransplant correction with angioplasty, endarterectomy, or revascularization, because the transplant operation, often involving an anastomosis to the iliac artery, may further diminish lower extremity blood flow.

Pulmonary function tests are indicated in chronic smokers and patients with a history of chronic pulmonary disease. Postoperative intensive care unit monitoring and perioperative bronchodilator therapy may be indicated in some patients. Liver function tests should be done to rule out hepatic insufficiency and viral hepatitis. The diagnosis of viral hepatitis (especially hepatitis C) is associated with worse long-term outcome after extrahepatic transplantation. Abnormal liver function tests or the diagnosis of viral hepatitis should be followed up with a liver biopsy to rule out cirrhosis. The presence of cirrhosis is a contraindication for pancreas transplant (unless the patient is a candidate for a rare multiorgan transplant). A gastrointestinal evaluation must be done to rule out autonomic dysfunction. Significant symptoms of gastroparesis would prompt a gastric emptying study. Some immunosuppressive medications may worsen gastrointestinal dysfunction (mycophenolate mofetil can have significant gastrointestinal side effects). A prokinetic agent may be indicated to treat gastroparesis. A urologic examination is especially important for bladder-drained recipients because bladder dysfunction predisposes to graft pancreatitis.

CADAVERIC DONOR SELECTION

Pancreas donor selection criteria are not standardized, but instead vary from center to center. Absolute contraindications are the obvious ones applied to most solid organs: active hepatitis

B, hepatitis C (unless the recipient has hepatitis C), human immunodeficiency virus, non-CNS malignancy, surgical or traumatic damage to the pancreas, duodenum or spleen, history of diabetes mellitus, pancreatitis, and extremes of age (less than 10 or more than 60 years). Prolonged intensive care unit stay and duration of brain death have been associated with an increased risk of pancreas graft failure [84]. Other studies have shown that donor age is important. Even middle-aged donors (> 45 years old) are associated with pancreas graft failure and increased complications [85–87]. Small donors (< 28 kg) have been used for pancreas transplantation with good outcomes [88]. Obesity in the deceased donor is a common cause for refusal of solid-organ pancreas donation, and donors with a BMI > 35 kg per m^2 are virtually never used for solid-organ pancreas transplants [50]. Older and obese donors (> 50 years old and > 30 kg per m^2) are probably more suitable for islet cell than for solid-organ pancreas transplantation [50]. Donors after cardiac death are being used increasingly to expand the donor pool. One survey showed equivalent patient and graft survival at 1, 3, and 5 years in SPK transplant recipients from donors after cardiac death compared with ideal donors after brain death [89]. In general, a pancreas from a so-called marginal donor is associated with good outcome if the pancreas is found to be normal on gross inspection [89,90].

In nearly 3,200 consecutive pancreas donors procured between 2000 and 2005 Vinkers et al. determined the influence of a "preprocurement pancreas suitability" score on the acceptance or refusal of deceased pancreas organs [91]. The investigators assigned a weight for several pre-procurement factors including age, BMI, length of ICU stay, cardiac arrest as cause of death, serum sodium, amylase and lipase levels, and need for vasopressor support to develop a donor score. When the donor score was ≥ 17, pancreata from these deceased donors were three times more likely to be refused by transplant centers. Donor scoring systems such as this one may provide more objective information about the quality of a deceased pancreas organ to promote wider pancreas donor acceptance.

Pancreas Preservation

University of Wisconsin solution was first used for pancreas preservation in a preclinical model in 1987 [92]. As with most solid organs, in vivo flush followed by simple storage in cold University of Wisconsin solution is still the gold standard for pancreas preservation. In the original canine model, pancreata were preserved for up to 96 hours [93], but in clinical transplantation, pancreas cold preservation exceeding 24 hours has been associated with increased graft dysfunction. Even less than 24 hours, it is evident that the longer the cold ischemia time, the greater the technical complication rate. Therefore, every effort should be made to minimize the cold ischemia time to optimize graft function and to minimize complication rates. The two-layer method (TLM) using University of Wisconsin solution and perfluorochemical [94] has been used in clinical whole pancreas transplantation but more commonly for islet preservation. This method improves pancreas oxygenation, allowing for longer preservation time while providing a mechanism for repair of ischemic damage due to cold storage [95–97]. Some studies show that TLM improves islet yields, islet viability, islet morphology, rates of successful islet isolations and transplants, and islet yields from marginal donors [97–104]. Other studies report that TLM has no effect or is even detrimental for pancreas preservation, and show no difference in islet yields, islet viability or islet transplant outcomes when pancreas organs were preserved with the TLM versus University of Wisconsin solution [97,98,105,106]. More prospective, randomized, controlled trials are needed before the TLM becomes routine procedure.

Three main preservation solutions for pancreas transplantation are available today, including University of Wisconsin solution, Celsior, and histidine–tryptophan–ketoglutarate solution (HTK) [97,98]. HTK has been increasingly used in pancreas transplantation, and its advantages include lower viscosity, less potassium, lower cost and no need for "on-shelf" cold storage, but it requires more solution to flush organs in the multiorgan donor (8 to 12 L of HTK solution vs. 4 to 6 L of Celsior vs. 4 to 6 L of University of Wisconsin solution) [97]. In pancreas transplantation, there have been only one retrospective study [107] and two prospective randomized studies [108,109], which compare University of Wisconsin solution with Celsior and both solutions give similar results. Several reports [110–114] have compared HTK with University of Wisconsin solution and most reports have described equal suitability for perfusion and organ preservation in clinical pancreas transplantation. In an analysis of the UNOS pancreas transplant database from 2004 to 2008, Stewart et al. [115] noted that HTK preservation was associated with a 1.5-fold higher odds of early (< 30 days) pancreas graft loss when compared with University of Wisconsin solution, and was independently associated with increased pancreas graft loss in SPK and PTA recipients, especially when cold ischemia times were ≥ 12 hours. Further prospective, randomized studies will be necessary to determine which perfusion and preservation solution provides the best short-term and long-term pancreas graft survival.

HLA Matching

The impact of HLA matching on outcome varies. HLA matching appears to have little effect on patient, kidney, or pancreas graft survival after SPK transplantation, [116,117], although increased acute rejection rates have been reported with poorer matches [118–120]. For PAK and PTA transplants the data are mixed, ranging from studies showing no impact [121] to registry data showing that higher HLA A and B mismatches are associated with increased immunologic graft loss [117]. Pancreata have been successfully transplanted across rare positive T cell cross-matches, and intravenous immunoglobulin and plasmapheresis have been used to neutralize or eliminate the antibody [50]. A positive T cell cross-match is much more of a risk for immunologic graft loss than is a positive B cell cross-match (especially in a primary pancreas transplant recipient) [50,122].

Anesthetic Considerations in Recipient

A patient with brittle diabetes and secondary complications (e.g., CAD, autonomic neuropathy) can pose special problems for the anesthesiologist. Dysautonomic response to drugs or hypoxia can lead to significant morbidity and even death. It is well documented that long-standing diabetes poses a challenge to the anesthesiologist during intubation. Awareness of these risks and use of an experienced anesthesiology team might help decrease the morbidity and mortality. A major operation such as a pancreas transplant or combined kidney-pancreas transplant is often prolonged and can be associated with significant blood loss. Prompt replacement with blood or colloid solutions should be instituted to avoid hypoperfusion after significant blood loss, because pancreas hypoperfusion can lead

to thrombosis. In the intra- and peri-operative period, careful blood glucose monitoring is essential, and continuous intravenous (IV) insulin therapy may be necessary to maintain tight control of blood glucose levels. Blood glucose levels may be high in the immediate postoperative period due to high dose steroids, so continuous IV insulin therapy may be required to control hyperglycemia. Perioperative beta-blockade should be considered for long-standing diabetic patients with a cardiac history.

BACK TABLE PREPARATION OF THE DONOR PANCREAS

Back table preparation of the pancreas organ is necessary before implantation, including these steps:

1. Donor splenectomy (taking care to avoid injury to the pancreatic tail)
2. Shortening the donor duodenum without damage to the main or accessory pancreatic duct (especially important with BD to minimize bicarbonate loss)
3. Ligation of the mesocolic and mesenteric stumps on the anterior aspect of the pancreas
4. Excision of excessive lymphatic and ganglionic tissue in the periportal area
5. Reconstruction of the splenic and superior mesenteric arteries with a donor Y graft including the iliac artery bifurcation (to provide for a single-arterial anastomosis in the recipient)
6. Some mobilization of the portal vein
7. Ligation of the bile duct stump

RECIPIENT OPERATION

Several techniques have been described for the recipient operation [123]. The techniques vary based on whether a solitary pancreas transplant (PTA, PAK) or a combined transplant (SPK) is done. Most SPK transplants are performed through a midline intra-abdominal approach although some are performed through bilateral iliac retroperitoneal incisions.

The major surgical considerations for pancreas transplants include the following:

1. Choice of exocrine secretion of the pancreas, ED versus BD: The 2004 IPTR noted that 81% of SPK, 67% of PAK, and 56% of PTA transplants had ED of pancreatic exocrine secretions [40]. ED is much more physiologic and eliminates the complications of BD (e.g., acidosis, pancreatitis, urinary tract infections, hematuria, urethritis, urinary stricture, urinary disruption). Between 10% and 20% of BD recipients ultimately undergo enteric conversion at 6 to 12 months because of such complications. BD, however, allows for direct measurement of urinary amylase as a marker of exocrine function. A decrease in urinary amylase is sensitive, but not very specific, for acute rejection of the pancreas [40]. Hyperglycemia is a late event in rejection, and a decrease in urinary amylase occurs early in rejection. Thus, rejection episodes may be detected earlier with BD than with ED.

   In clinical practice, the choice of exocrine drainage varies. Some groups always use ED, some always use BD, and others determine the choice of exocrine drainage based on the individual recipient's anatomic constraints and the risk of bowel/urologic complications. Patient and graft survival are similar with both techniques [85,124], but BD is associated with higher rates of urinary tract infections, in addition to urologic and metabolic complications [125,126]. ED is likely to predominate as the major technique in the future, as immunologic strategies to eliminate rejection are further refined. ED usually occurs as an anastomosis between the donor duodenal stump and the recipient proximal jejunum, but graft placement behind the right colon can allow for direct duodenoduodenostomy [125,127].
2. Choice of venous drainage, portal or systemic: The 2004 IPTR reported that in enteric-drained pancreas transplants, 20% of SPK, 23% of PAK, and 35% of PTA cases had venous drainage to the portal vein [40]. Portal drainage is more physiologic than systemic drainage. Theoretically, portal drainage preserves the first-pass metabolism of insulin in the liver. Therefore, pancreas recipients with portal venous drainage will have lower systemic insulin levels than recipients with systemic venous drainage. In one study [128] that compared portal with systemic venous drainage in SPK recipients, there were no significant differences in patient, kidney or pancreas allograft survival rates or early graft loss by pancreatitis or thrombosis. There were no significant differences in early endocrine function, although HbA1C was lower at 6 and 12 months in the portal-drained group.

   Portal venous drainage is difficult to perform with BD unless there is a venous extension graft [37]. However, portal venous drainage is likely to increase in popularity, given some reports that rejection rates are lower in this category [124,129]. Recent modifications include a retroperitoneal portal-enteric drainage technique behind the right colon [130].
3. Choice of graft, whole-organ or segmental: Almost all deceased donor pancreas transplants performed today are whole-organ grafts. Segmental grafts have little role to play in this group, except when a rare anatomic abnormality is noted such that the head of the pancreas cannot be used. A rare instance of a split deceased donor pancreas organ transplanted into two different recipients has been described [131]. All living donor pancreas transplants use segmental grafts (body and tail), which are still capable of maintaining normoglycemia in the recipient.

POSTOPERATIVE CARE

After an uncomplicated pancreas transplant, the recipient is transferred to the postanesthesia care unit or the surgical intensive care unit. Centers that have a specialized monitored transplant unit (with central venous and arterial monitoring capabilities) transition the postoperative recipients through the postanesthesia care unit to the transplant unit. Other centers transfer patients directly to the surgical intensive care unit for the first 24 to 48 hours. Care during the first few hours post transplant is similar to care after any major operative procedure. Careful monitoring of vital signs, central venous pressure, oxygen saturation, urine output, and laboratory parameters is crucial. The following factors are unique to pancreas recipients and should be attended to:

1. Blood glucose levels: Any sudden, unexplained increase in blood glucose levels should raise the suspicion of graft thrombosis. An urgent ultrasound must be done to assess blood flow to the graft. Some centers believe that maintenance of tight glucose control (less than 150 mg per dL) using an IV insulin drip is important to "rest" the pancreas in the early postoperative period.

2. Intravascular volume: Because the pancreas is a "low-flow" organ, intravascular volume must be maintained to provide adequate perfusion to the graft. Central venous pressure monitoring is used to monitor intravascular volume status. In some cases, such as patients with depressed cardiac function, pulmonary artery catheter monitoring may be required during the first 24 to 48 hours. If the hypovolemia is associated with low hemoglobin levels, then packed red cell transfusions should be given; otherwise, crystalloid (and sometimes colloid) replacement should be used to treat hypovolemia.
3. Maintenance IV fluid therapy: The choice of IV fluid therapy can be 5% dextrose in 0.45% normal saline, as long as IV insulin is used to maintain tight blood glucose control, or 0.45% normal saline to maintain acceptable urine output. In SPK recipients, whose IV fluid rate is based on urine output, dextrose should be eliminated if the urine output is high (more than 500 mL per hour), because hyperglycemia may cause an osmotic diuresis leading to worsening hypovolemia. Maintenance IV fluid for BD recipients should also include HCO_3 10 mEq per L to account for the excess HCO_3 loss, or sodium lactate can be used as an alternative.
4. Antibiotic therapy: Broad-spectrum antibiotic therapy (with strong Gram-positive and Gram-negative coverage) and antifungal therapy are instituted in the perioperative period. Antiviral prophylaxis is similar to that for other solid organs and is driven by cytomegalovirus (CMV) status.
5. Anticoagulation: At the University of Texas Health Science Center at San Antonio all pancreas recipients receive enteric-coated aspirin 81 mg started on first postoperative day and continued indefinitely. Recipients of solitary pancreas transplants or "high-risk" SPK transplants also receive an intraoperative dose of heparin (2,500 units), followed by a postoperative regimen of low-dose, continuous IV heparin at 300 units per hour for 24 hours, then 400 units per hour for 24 hours, then 500 units per hour for 5 postoperative days, at which time the IV heparin is discontinued and warfarin begins for 6 months. The partial thromboplastin time for heparin and the international normalized ratio for warfarin are not measured because these drugs are "low dose". Our experience is that therapeutic doses of heparin lead to excessive postoperative hemorrhage that requires reduction in heparin dose, and sometimes red cell transfusion or reoperation.

Immunosuppression

Immunosuppression is essential to thwart rejection in all allotransplant recipients. Before the advent of cyclosporine in the early 1980s, dual therapy with azathioprine and prednisone was the mainstay of immunosuppression for pancreas transplants. From the early 1980s to the mid-1990s, cyclosporine was introduced for maintenance therapy and resulted in significant improvement in immunologic outcomes. Since the mid-1990s, tacrolimus and mycophenolate mofetil have replaced cyclosporine and azathioprine as the primary maintenance immunosuppressive medications. In a prospective, randomized, multicenter study of tacrolimus versus cyclosporine in SPK recipients, Saudek et al. noted that 3-year patient and kidney graft survival were comparable but pancreas graft survival was superior in the tacrolimus-treated cohort (89% tacrolimus vs. 74% cyclosporine) [132]. In addition, with antibody induction steroids have been successfully withdrawn or even avoided in some cases [133,134]. The use of rapamycin in combination with tacrolimus has also allowed for steroid withdrawal or avoidance in some pancreas recipients [135,136]. Specific immunosuppressive regimens vary among different transplant programs. The immunosuppressive protocols for pancreas transplantation for the University of Texas Health Science Center at San Antonio in Table 184.3.

Antibody induction has become mainstay protocol for pancreas recipients. The debate continues as to which antibody preparations are best in pancreas transplant recipients [137]. The administration of depleting agents such as rabbit antithymocyte globulin (rATG) or alemtuzumab has increased dramatically in the last few years, while the use of IL-2 inhibitors has decreased, with the rationale that depleting antibodies provide good immunosuppressive coverage for innovative immunosuppressive strategies including steroid withdrawal or avoidance, minimization of calcineurin inhibitors and even monotherapy in pancreas transplant patients [138]. When combined with steroid withdrawal, minimization of calcineurin inhibitors may require prolonged antibody therapy, which may increase the risk of infection [138].

Results

Outcomes after pancreas transplants have consistently improved over the years. The 2008 SRTR report [48] described pancreas transplant graft and patient survival over the decade from 1997 to 2008. Unadjusted graft survival rates for SPK, PAK, and PTA recipients were 84%, 78%, and 75%, respectively, for year 2006, whereas patient survival rates were similar in all 3 groups (SPK 95%, PAK 97%, PTA 98%) [62]. Those recipients who received SPK transplants experienced the best unadjusted long-term graft survival rates: 73% at 5 years and 53% at 10 years. Graft survival rates for PAK and PTA recipients were statistically lower than SPK recipients, with 5-year rates of 54% and 51%, respectively, and 10-year rates of 35% and 26%, respectively.

The latest report from the IPTR [40] focused on United States pancreas transplants from 2000 to 2004, and included more than 3,800 SPK, more than 600 PAK, and 290 PTA cases. One-year patient survival rates for all three categories were more than 95%. One-year pancreas graft survival rates were higher for SPK (85%) than for PAK (78%) and PTA (76%) recipients. Graft loss from rejection at 1 year was low in all three categories (2% SPK, 8% PAK, 10% PTA). In the majority of all transplants, ED was used for duct management, and of the ED transplants, portal venous drainage was used in 25% of cases. Although overall graft function did not vary with ED or BD, the PTA group had a higher immunologic graft loss rate in ED versus BD cases. BD may result in earlier diagnosis of rejection because of the ability to monitor decreased urinary amylase levels as a marker. Nevertheless, the late rejection rate was higher in the PTA than in other categories.

Donor and Recipient Causes of Pancreas Complications

Donor and recipient factors can influence the postoperative course after pancreas transplantation. In a study of 210 SPK transplants between 1995 and 2007, donor-specific risk factors correlating with postoperative pancreas-related complications included donor age, need for vasopressor support, need for preprocurement blood transfusions, and asystolic events > 10 minutes [139]. Increasing donor age and BMI were associated with greater need for postoperative interventions. Graft preservation with HTK solution was associated with significantly higher postoperative complications, as was preexisting cardiac disease in the recipient. The choice of immunosuppression had a significant effect on pancreas-related complications,

UNIVERSITY OF TEXAS HEALTH SCIENCE CENTER AT SAN ANTONIO STANDARD IMMUNOSUPPRESSION-PANCREAS PROGRAM

SPK[a]	PAK[b] and PTA[c]	Rejection
Antithymocyte globulin 1.5 mg/kg: Three doses QOD First dose intraoperatively Give methylprednisolone 250 mg before first dose 100 mg before second dose Give premeds before all doses— diphenhydramine and acetaminophen Monitor ALC[d], platelet count	**Antithymocyte globulin** 1.5 mg/kg: Three doses QOD First dose intraoperatively Give methylprednisolone 250 mg before first dose 100 mg before second dose Give premeds before all doses— diphenhydramine and acetaminophen Monitor ALC, platelet count	Methylprednisolone Day 0–4: 1,000 mg IV[h] Resistant rejection Antithymocyte globulin 1.5 mg/kg IV up to 7 days Give methylprednisolone 250 mg IV before first dose 100 mg before second dose Give premeds before all doses— diphenhydramine and acetaminophen Monitor ALC, platelet count
Tacrolimus 5 mg po[e] b.i.d.[f] Start when creatinine < 4 mg/dL If tacrolimus is delayed continue ATG[g] until tacrolimus levels are therapeutic Levels 8–10 ng/mL for 3 mo Then 5–8 ng/mL	Tacrolimus 5 mg po b.i.d. Start postoperatively If tacrolimus is delayed continue ATG until tacrolimus levels are therapeutic Levels 8–10 ng/mL for 3 mo Then 5–8 ng/mL	
Mycophenolate 500 mg po b.i.d. until ATG is removed, then 1 g po b.i.d.	Mycophenolate 500 mg po b.i.d. until ATG is removed, then 1 g po b.i.d.	

Round up antithymocyte globulin dose to the nearest 25 mg.
ALC Levels: if zero, hold antithymocyte globulin; if 0.1, give half dose antithymocyte globulin; if 0.2 or above, give full dose.
ATG requires "premeds" with methylprednisolone for first three doses, and diphenhydramine and acetaminophen for all doses.
[a]SPK, simultaneous pancreas kidney.
[b]PAK, pancreas after kidney.
[c]PTA, pancreas transplant alone.
[d]ALC, absolute lymphocyte count.
[e]po, orally.
[f]b.i.d., twice daily.
[g]ATG, antithymocyte globulin.
[h]IV, intravenously.

which were greater after induction therapy with rATG versus daclizumab, and maintenance immunosuppression with tacrolimus/rapamycin or cyclosporine/mycophenolate mofetil versus tacrolimus/mycophenolate mofetil. The duration of the pancreas transplant operation and the presence of elevated C reactive protein were associated with significantly more postoperative complications that required interventions. In another study, donor obesity (BMI > 30 kg per m^2) was associated with greater risk of graft thrombosis and deep wound infections [140]. Another trial [141] noted that technical failure of the pancreas graft occurred more commonly when (1) the donor BMI was > 30 kg per m^2, (2) the cause of donor death was other than trauma, (3) the preservation time was > 24 hours, (4). the duct management was ED versus BD, and (5) recipient BMI was > 30 kg per m^2. In other study [142], multivariate analysis showed that technical failure of a pancreas transplant appeared to be the most significant risk factor for kidney graft loss. This evidence underscores that careful donor and recipient selection in addition to improved preservation and surgical techniques play important roles to minimize complications after pancreas transplantation [143].

Surgical Complications

Prevention of surgical complications has critical implications not only on pancreas graft and patient survival, but also on financial impact associated with postoperative care. Early diagnosis and management of surgical complications can limit morbidity; delayed diagnosis, and treatment of pancreas complications can lead not only to pancreas graft loss but also kidney graft loss [143,144]. Common surgical complications in pancreas transplants will now be addressed:

1. Hemorrhage: Postoperative hemorrhage is a frequent reason for early re-laparotomy in pancreas transplant recipients. Hemorrhage can occur from the pancreatic parenchyma, from poorly ligated mesenteric or splenic vascular stumps or from the anastomosis in an enteric-drained or bladder-drained pancreas transplant. The incidence of hemorrhage ranges from 6% to 7% [85], and this risk increases with the use of anticoagulation in the immediate postoperative period. Frequent physical examination and monitoring of hemoglobin help to detect early hemorrhage. Heparin may be temporarily suspended to stabilize the patient. Packed cells should be administered if the recipient has symptomatic anemia. If hemorrhage continues, early operative intervention is indicated. If hemorrhage slows down or ceases, heparin should be resumed at a lower rate and judiciously increased as tolerated.
2. Thrombosis: Thrombosis post transplant ranges from 5% to 6% [85], and remains the most common cause of early pancreas graft failure. The risk increases after segmental

pancreas transplantation because of the small caliber of vessels [145]. Most pancreas transplant thromboses are due to technical causes. Diagnosis is suspected by sudden hyperglycemia and confirmed by sonogram, CT angiogram, formal angiogram, or MRI, which reveals pancreas graft thrombosis. Aggressive anticoagulation will not prevent pancreas transplant thrombosis due to technical reasons. A short portal vein requiring an extension graft or atherosclerotic arteries in the pancreas graft increases the risk for thrombosis. In the recipient, a narrow pelvic inlet with a deeply placed, poorly immobilized iliac vein, atherosclerotic disease of the iliac artery, a technically difficult vascular anastomosis, kinking of the vein by the pancreas graft, significant hematoma formation around the vascular anastomosis, hypovolemia, and a hypercoagulable state are some of the factors that increase the risk for thrombosis. The most common form of hypercoagulable state in the Western population is factor V Leiden mutation. Its incidence ranges from 2% to 5% but may be as high as 50% to 60% in patients with a history (self or family) of vascular thrombosis [146]. Other causes of hypercoagulable state include antithrombin III deficiency, protein C or S deficiency, activated protein C resistance and anticardiolipin antibodies [147]. The transplant surgeon must have a high incidence of suspicion of these hypercoagulable states and treat them aggressively to prevent pancreas graft thrombosis. Thrombosis is diagnosed by sudden hyperglycemia and by imaging studies that show nonpatent pancreatic vessels. Thrombosis usually necessitates transplant pancreatectomy.

3. Duodenal stump leaks: The incidence of duodenal stump leaks ranges from 6% to 7% [85]. A leak from the anastomosis of the duodenum stump to the bowel almost always leads to re-laparotomy. Gross peritoneal contamination due to an enteric leak usually necessitates a graft pancreatectomy. The diagnosis is made by elevated pancreatic enzymes in a patient who has clinical signs of acute abdomen. A plain abdominal radiograph may show free air, and an abdominal CT scan may show free air and extravasation of contrast into the free peritoneal cavity. The differential diagnosis is pancreatitis, abdominal infection, or acute severe rejection. A roux-en-Y anastomosis to the duodenal stump may be a preferred technique, if the risk of leak is thought to be increased during the initial pancreas operation. Other novel techniques such as a venting roux-en-Y-pancreatic duodenojejunostomy have been used in selected recipients [148].

   Small duodenal stump leaks in bladder-drained recipients are usually managed nonoperatively with prolonged catheter decompression of the urinary bladder. The diagnosis of duodenal stump leak is made using plain or CT cystography. Large leaks may require operative intervention, including primary repair, enteric conversion, or even transplant pancreatectomy if there is significant compromise of the duodenal stump.
4. Major intra-abdominal infections: The incidence of significant intra-abdominal infections requiring reoperation ranges from 3% to 4% [85]. Performance of the enteric anastomosis with associated contamination predisposes to this higher rate of intra-abdominal infection, where fungal and Gram-negative organisms predominate. With the advent of percutaneous procedures to drain intra-abdominal abscesses, the incidence of reoperations is fast decreasing. If the infection is uncontrolled or widespread, then graft pancreatectomy followed by frequent washouts may be necessary.
5. Renal pedicle torsion: Torsion of the kidney has been reported after SPK transplants [149,150]. The intraperitoneal location of the kidney (allowing for more mobility) predisposes to this complication. Additional risk factors are a long renal pedicle and a marked discrepancy between the length of artery and vein. Prophylactic nephropexy to the anterior or lateral abdominal wall is recommended with intraperitoneal transplants to avoid this problem. The colon can be mobilized and re-approximated over a kidney transplant in order to prevent torsion also.
6. Others: Other surgical complications that may require re-laparotomy include wound dehiscence, incisional hernia, severe pancreatitis (sometimes hemorrhagic or necrotic), pseudocysts, pseudoaneurysms, arteriovenous (AV) fistula in the graft, severe painful rejection and bowel obstruction [151]. The overall incidence of re-laparotomy for these complications decreased from 32% in the 1980s to 19% in the 1990s, and the mortality rate in recipients requiring re-laparotomy decreased from 9% to 1% over that same period. Improved antibiotic prophylaxis, surgical techniques, immunosuppression, and advances in interventional radiology have all contributed to this decrease [85].

Nonsurgical Complications

1. Pancreatitis: The incidence of posttransplant pancreatitis varies based on the type of exocrine drainage. Bladder-drained recipients with abnormal bladder function are at increased risk of pancreatitis secondary to incomplete bladder emptying and urinary retention causing resistance to flow of pancreatic exocrine secretions. Other causes of pancreatitis include drugs (corticosteroids, azathioprine, cyclosporine), hypercalcemia, viral infections (CMV or hepatitis C), and reperfusion injury after prolonged ischemia. Pancreatitis is usually manifested by an increase in serum amylase and lipase with or without local signs of inflammation. An abdominal ultrasound or CT scan may identify an enlarged, edematous, hypoechoic pancreas transplant. The treatment usually consists of catheter decompression of the bladder for a period of 2 to 6 weeks, depending on the severity of pancreatitis. In addition, octreotide therapy may be used to decrease pancreatic secretions. The underlying urologic problem, if any, should be treated. The patient should be placed on NPO status and total parenteral nutrition should be administered if the pancreatitis is severe. If repeated episodes of pancreatitis occur, enteric conversion of a bladder-drained pancreas transplant may be indicated.
2. Rejection: The incidence of acute rejection ranges from 15% to 30% and immunologic graft loss from 2% to 15% for all types of pancreas transplants at 1 year [3]. The diagnosis is usually based on increased serum amylase and lipase levels in all pancreas transplant patients, and decreased urinary amylase levels in bladder-drained recipients. A sustained drop in urinary amylase levels from baseline should prompt a pancreas biopsy to rule out rejection. In enteric-drained recipients, one has to rely on serum amylase and lipase levels only. A rise in serum lipase levels has shown to correlate well with acute rejection in the pancreas transplant. Other signs and symptoms include tenderness over the graft, unexplained fever, and hyperglycemia (which is usually a late finding). Diagnosis of rejection can be suspected by a hypoechoic, enlarged graft by ultrasound or an enlarged, edematous graft by abdominal CT scan. Diagnosis of rejection can be confirmed by a percutaneous pancreas biopsy [152]. In cases in which percutaneous biopsy is not possible due to technical reasons, empiric therapy for rejection may be started. Rarely, open biopsy is indicated, and transcystoscopic biopsy of a bladder-drained pancreas graft, which was used in the past, has been largely abandoned. Finally, in SPK recipients, isolated pancreas transplant rejection portends a worse renal allograft survival than in patients who experience no rejection [153].

3. Others: Other findings include infectious complications such as CMV, extra-abdominal bacterial or fungal infections, posttransplant malignancy such as posttransplant lymphoproliferative disorder, and other rare complications such as graft-versus-host disease. Many catheter infections are due to Gram-positive organisms, with methicillin resistant coagulase negative isolates quite common [154]. The diagnosis and management of these complications is similar to those of other solid-organ transplants.

Radiologic Studies

1. Ultrasonography: This is the most frequent study used in pancreas recipients. Noninvasive, portable, and relatively inexpensive, it provides prompt information regarding blood flow to the pancreas, the presence of arterial or venous stenosis or occlusion, thrombosis, pseudoaneurysms, AV fistulae, resistance to blood flow within the pancreas (suggestive of either rejection or pancreatitis) and peripancreatic fluid collections.
2. CT scan: A CT scan provides more detail of pancreatic and surrounding anatomy. Use of oral, IV, and bladder contrast (in bladder-drained recipients) is recommended. Thus, a CT cystogram can be combined with an abdominal CT scan. A CT scan is frequently used as a guide in pancreas biopsies or in placement of percutaneous drains for intra-abdominal infection.
3. Fluoroscopy: A contrast cystogram can be performed under fluoroscopy and can be used instead of, or in addition to, a CT cystogram to look for a bladder leak. The combination of the tests increases the sensitivity for detecting bladder leaks.
4. Magnetic resonance angiogram (MRA): An MRA is done if vascular abnormalities are suspected on the ultrasound. MRA provides accurate information about pancreatic vascular patency, but it is inferior to standard angiography in providing fine vascular detail.
5. Angiography: This is the gold standard test for evaluating arterial anatomy in and around the pancreas. However, it is rarely employed, except in cases in which angiographic intervention (such as angioplasty, stenting of a stenotic segment, or coiling of an AV fistula or pseudoaneurysm) is planned. Contrast nephropathy is feared in a solitary pancreas recipient with renal dysfunction, and reasonable alternatives (such as ultrasound) are available.

FUTURE DIRECTIONS

In type 1 diabetic patients with kidney dysfunction, an SPK or PAK transplant is the standard of care. A PTA, however, is less common because the long-term risks of diabetes are weighed against the long-term risks of immunosuppression. A successful pancreas transplant can improve existing neuropathy and nephropathy in diabetic recipients and the survival after a solitary pancreas transplant is better than remaining on the waiting list [155]. As the risks of immunosuppression decrease with novel methods of tolerance and immunomodulation, the balance will tilt in favor of an early transplant. The limiting factor will then be the organ shortage, which could be alleviated if xenotransplantation is able to overcome its current barrier of hyperacute rejection.

The application of islet transplants is rapidly growing. Recent successes suggest that islet transplants can provide all the benefits of pancreas transplants without the risks of major operation. Improvements in islet isolation, islet viability, islet functionality, islet implantation, and immunotherapy will improve islet outcomes, so that only one donor will be necessary to achieve insulin independence [156]. Xenotransplantation of islets may be more readily achievable using encapsulation than with other organs. Prolonged diabetes reversal after intraportal xenotransplant in primates has been documented [157] and may pave the way for human xenotransplant trials. Also, stem cells from numerous sources (e.g., bone marrow, adipose, or cord blood) may be manipulated to differentiate into islets in order to provide a rich supply for transplantation, and islet transplants can be combined with immunomodulation and tolerogenic strategies to minimize or eliminate immunosuppression [156]. This combination would provide for minimally invasive islet cell transplants for all type 1 diabetic patients without the need for long-term immunosuppression. The only scenario that would be better would be the thwarting of autoimmunity before the onset of isletitis, thereby preventing type 1 diabetes mellitus in the first place.

CHAPTER 185 ■ MANAGEMENT OF THE ORGAN DONOR

CHRISTOPH TROPPMANN

In 2009, nearly 10,000 patients on the national organ transplant waiting list in the United States died or were de-listed because they had become too ill before a suitable donor organ became available [1]. Almost assuredly, this number underestimates the actual magnitude of the problem. Many patients with end-stage organ failure are currently not even considered for transplantation (and consequently are not listed) because of the strict recipient selection criteria that are being applied—in part as a result of the severe, ongoing organ shortage. The widening gap between available deceased donor organs and the number of patients waiting is a result of the explosive, increased use of organ transplantation therapy over the past 30 years (Tables 185.1 and 185.2), with which the deceased donor pool has not kept pace [1,2] (Fig. 185.1).

The single most important factor that has been identified in this equation is the failure to maximize the conversion of potential deceased donors to actual donors, primarily because of the inability to obtain consent for organ retrieval. The rates of consent granted by families of potential deceased donors range from 0% to 75% and appear to vary widely among geographic regions and ethnic groups [10–12]. The national average is only 54% [12]. Lack of dissemination and poor presentation of information to the public, misperceptions in the general population regarding the beneficial nature of organ transplantation and the necessity of organ retrieval from deceased donors, and inappropriate coordination of the approach to families of potential donors contribute to the stagnation of the organ supply [11–13].

The role of physicians who care for critically ill patients in altering the current situation is crucial. It is their responsibility to seek early referral to an organ procurement organization (OPO) and to ensure that families are adequately approached, thus laying the foundation for obtaining consent (Table 185.3). In the United States alone, approximately 250,000 additional life years could be saved annually if consent for potential deceased donors could be increased to 100% [14]. Intensive care and emergency medicine physicians are obligated ethically and morally to provide the best possible outcome for a very ill

TABLE 185.1

NUMBER OF SOLID ORGAN TRANSPLANTS FROM DECEASED DONORS PER YEAR IN THE UNITED STATES: 1982 VERSUS 2009

Organ	1982	2009
Kidney	3,681	11,296
Liver	62	6,101
Pancreas	38	1,233
Heart	103	2,211
Heart–lung	8	30
Lung	—[a]	1,659
Intestine	—[a]	178

[a]No lung or intestinal transplants were performed in 1982.
Data from references [1–4].

TABLE 185.2

ONE-YEAR GRAFT SURVIVAL RATES (DECEASED DONORS): 1982 VERSUS 2008

Organ	1982[a] (%)	2008 (%)
Kidney	80	91
Liver	35	82
Pancreas	23	86
Heart	65	87
Lung	—[b]	82
Intestine	—[b]	68

[a]Results without cyclosporin A–based immunosuppression.
[b]No lung or intestinal transplants were performed in 1982.
Data from references [4–8] (1982) and [1,2] (2008).

TABLE 185.3

IDENTIFICATION OF POTENTIAL ORGAN DONORS: GUIDELINES FOR REFERRAL TO THE LOCAL ORGAN PROCUREMENT ORGANIZATION

Clinical triggers	All severely neurologically injured patients on a ventilator with any of the following conditions: Head trauma Cerebral hemorrhage Primary brain tumor Hypoxic insult (including prolonged CPR, near drowning, drug overdose, poisoning, cerebral edema, seizures, and asphyxiation injuries)
Referral guidelines	Refer all patients who meet clinical triggers regardless of age and underlying/associated diagnosis Refer all patients who meet clinical triggers *prior* to approaching the family regarding end-of-life decisions Refer patients prior to brain death evaluation Refer patients if the family raises the subject of donation Coroner case status does *not* constitute an exclusion criterion

patient. However, after a potential donor has been identified, they are also obligated to seek the best possible outcome for patients with end-stage failure of a vital organ waiting for a transplant by attempting to ensure that organ donation occurs. It is becoming increasingly evident that implementation of critical pathways and standardized donor management protocols play an important role in this context [15–25).

DONOR CLASSIFICATION

Brain-Dead Deceased Donors

This is by far the most common donor type (currently 90% of all donors belong in this category) [2]. In most Western developed countries, brain death is legally equated with death. The diagnosis of brain death rests on the irreversibility of the neurologic insult and the absence of clinical evidence of cerebral *and* brainstem function. The details of the clinical examination that is required to unequivocally establish brain death are described later in this chapter. Organ procurement proceeds only after brain death has been diagnosed and death has been declared.

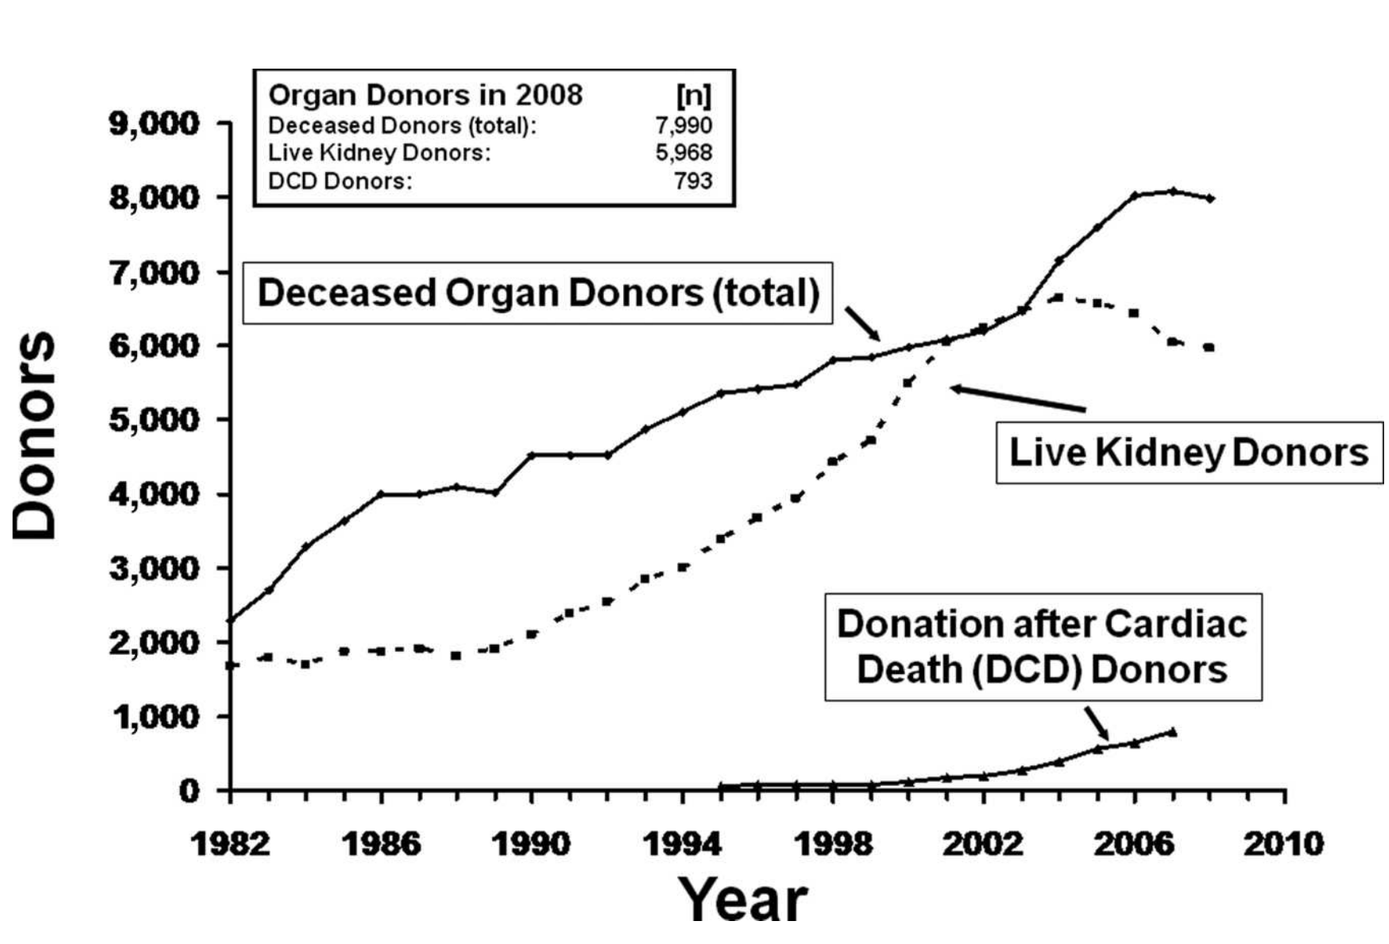

FIGURE 185.1. Evolution of the number of deceased organ donors and living kidney donors between 1982 and 2008 in the United States. (Data from references [1–4,9].)

Donation after Cardiac Death Donors (Formerly Known as Non–Heart-Beating Donors)

Increases in this donor category are to be expected over coming years (Fig. 185.1) [1,2,24,26,27]. Most frequently, families of unconscious patients with severe irreversible traumatic or cerebrovascular brain injury, who do not fulfill the formal criteria of brain death, decide to forgo any further life support treatment and wish to donate the organs of their family member. Time and place of death are therefore controlled. The prospective donor is brought to the operating room and life support treatment is discontinued. Organ procurement is initiated once death has been pronounced by a physician not belonging to the organ recovery and transplant team [26].

An alternative, by far less common scenario—uncontrolled death—involves a patient who expires, for example, in the emergency room following massive trauma or a sudden cardiovascular event. In the interest of minimizing warm ischemia time, flushing cannulas would then have to be inserted and possibly even perfusion of internal organs with cold preservation solution would already have to be started while consent to proceed with organ donation is obtained from the patient's family. Issues that specifically surround this category of donation after cardiac death (DCD) donors have generated considerable debate within the medical community. These issues include ethical concerns centered on when to stop the resuscitation effort and whether it is ethical to perform a procedure (i.e., insertion of flushing cannulas) that presumes consent before actually obtaining it from the family. Other considerations that pertain to both controlled and uncontrolled death DCD donors and that have undergone intense debate, too, include establishing a definition of death after discontinuing life support (there is no commonly accepted definition of, for example, the minimal duration of asystole after the patient expires following withdrawal of support before death can be pronounced; this is currently subject to considerable interinstitutional variation), the possibility of the patient at least temporarily surviving the withdrawal of support systems (backup plans must be clearly defined by each individual institutional DCD donor protocol), and the conflict between providing optimal care for the patient and promoting suitable organ procurement and maintaining donor organ viability [28,29]. Nevertheless, these concerns must be contrasted with the right of self-determination and the final wishes of a competent patient family. Further debate by the medical community and general public is crucial to resolving these complex moral and ethical issues [28,29]. Without such thorough consideration, the deceased donor concept and the donation system that is currently in place might be harmed or discredited.

CURRENT STATUS OF SOLID-ORGAN TRANSPLANTATION

The increased number of solid-organ transplant procedures performed during the last 30 years has been paralleled by a significant improvement in outcome with regard to patient and to allograft survival (Table 185.2). This phenomenon has been attributed to a variety of factors that include (a) the introduction in the early 1980s of the powerful immunosuppressive agent cyclosporin A, followed almost a decade later by tacrolimus, mycophenolate mofetil, and other new immunosuppressants; (b) the availability of antilymphocyte antibody preparations to prevent and treat rejection episodes (e.g., antilymphocyte and antithymocyte globulin); (c) improvements in organ preservation (e.g., use of University of Wisconsin solution); (d) thorough preoperative patient screening for the presence of existing disease processes; and (e) increasing sophistication in the postoperative intensive care of regular as well as high-risk recipients. In addition, the availability of potent, yet nontoxic, antibacterial, antifungal, and antiviral agents has allowed opportunistic infections in immunocompromised transplant patients to be treated more effectively. In combination with refinement of surgical techniques, these factors have led to increasing success of solid-organ replacement therapy.

Thus, transplantation has become the treatment of choice for many patients with end-stage failure of the kidneys, liver, endocrine pancreas, heart, lungs, and small bowel. Successful hand, arm, larynx, and face transplants from deceased donors have also been reported [30–33]. Criteria for potential recipients have been expanded over the past five decades to include infants, children, and individuals previously thought to be at higher risk for complications (e.g., diabetics, elderly patients). Currently, the only patients who are excluded from undergoing transplantation are those with malignancies (metastatic or at high risk for recurrence), uncontrolled infections, those who are unable to withstand major surgery, or those who have a significantly shortened life expectancy due to disease processes unrelated to their organ dysfunction or failure.

Kidney

Currently, patients undergoing kidney transplants from deceased donors exhibit excellent graft survival rates (91% and 68% at 1 and 5 years, respectively) [1,2]. Renal transplantation dramatically improves life expectancy and quality of life, decreases cardiovascular morbidity, and rehabilitates the recipients from a social perspective. Kidney transplants are also less expensive from a socioeconomic standpoint than is chronic hemodialysis. For pediatric patients with chronic renal failure, a functioning renal allograft is the only way to preserve normal growth and ensure adequate central nervous, mental, and motor development.

Liver

Patients with end-stage liver failure die unless they receive a transplant. Liver transplants are an effective treatment for many patients, pediatric and adult, regardless of the cause of liver failure: congenital (i.e., structural or metabolic defects), acquired (i.e., due to infection, trauma, or intoxication), or idiopathic (e.g., cryptogenic cirrhosis, autoimmune hepatitis). A dramatic improvement in graft survival occurred after the introduction of cyclosporin A (Table 185.2). Currently, there are no reliable means to substitute, even temporarily, for a failing liver other than with a transplant. Extracorporeal perfusion, using either animal livers or bioartificial liver devices (e.g., hepatocytes suspended in bioreactors), may someday bridge the gap between complete liver failure and a liver transplant, but these therapeutic modalities are still investigational and are far from becoming standard clinical tools. Use of hepatocyte and stem cell transplants to treat fulminant liver failure and to correct congenital enzyme deficiencies is also in the preliminary stages of study.

Small Bowel

Small bowel transplants are being performed increasingly in patients with congenital or acquired short gut, especially if liver dysfunction occurs because of long-term administration of total parenteral nutrition and if difficulty in establishing or

maintaining central venous access occurs. If liver disease is advanced, a combined liver–small bowel or, in highly selected cases, a multivisceral transplant (liver, stomach, small bowel, with or without pancreas) can be performed. Current results are encouraging, and a further increase in the number of small bowel and multivisceral transplants can be expected over the next decade [1,2,34].

Pancreas and Islet

Primary prevention of type 1 insulin-dependent diabetes mellitus is not possible at present, but transplantation of the entire pancreas or isolated pancreatic islets can correct the endocrine insufficiency once it occurs. Glucose sensor systems that *continuously* monitor blood sugar levels coupled with real-time command of an insulin delivery system (implantable pump) are not yet available for routine clinical use. Development of bioartificial and hybrid biomechanical insulin-secreting devices is in the experimental stages. The only effective current option to *consistently* restore continuous near-physiologic normoglycemia, however, is a pancreas transplant [35–37]. Good metabolic glycemic control decreases the incidence and severity of secondary diabetic complications (neuropathy, retinopathy, gastropathy and enteropathy, and nephropathy). Most pancreas transplants are performed simultaneously with a kidney transplant in preuremic patients with significant renal dysfunction or in uremic patients with end-stage diabetic nephropathy. Selected nonuremic patients with brittle type 1 diabetes mellitus (with progression of the autonomic neuropathy to the point of hypoglycemic unawareness, and with repetitive episodes of diabetic ketoacidosis) can benefit from a solitary pancreas transplant (without a concomitant kidney transplant) to improve their quality of life and to prevent the manifestation and progression of secondary diabetic complications. Evidence suggests that a successful pancreas transplant can achieve these goals in uremic and in nonuremic recipients and decrease mortality [35]. Islet transplants are undergoing intensive clinical investigation. Results of transplanting alloislets from deceased donors are encouraging in the short term [36]; however, long-term results have been relatively disappointing [37]. Nonetheless, with further progress to be expected, islet transplants may become a routine form of therapy for patients with complicated diabetes within the next 10 years.

Heart

Heart transplants are the treatment of choice for patients with end-stage congenital and acquired parenchymal and vascular diseases and are recommended generally after all conventional medical or surgical options have been exhausted. After a widely publicized start in 1967, poor results were observed over the ensuing decade. In the 1980s, however, the field of cardiac transplantation experienced dramatic growth (Table 185.1) because of significant improvements in outcome, probably most directly related to immunosuppressive therapy and to refinements in diagnosis and treatment of rejection episodes [38]. Mechanical pumps, such as ventricular assist devices or the bioartificial heart, serve only to bridge the time between end-stage cardiac failure and a transplant and are by no means a permanent substitute for the transplant itself.

Heart–Lung and Lung

Heart–lung and lung transplants are effective treatment for patients with advanced pulmonary parenchymal or vascular disease, with or without primary or secondary cardiac involvement. This field has evolved rapidly since the first single-lung transplant with long-term success was performed in 1983 (Table 185.1). The significant increase in lung transplants is mainly due to technical improvements resulting in fewer surgical complications, as well as to the extremely limited availability of heart–lung donors. Previously, many patients with end-stage pulmonary failure would have waited for an appropriate heart–lung donor. Currently, they undergo a single or a bilateral single-lung transplant instead [39]. Bilateral single-lung transplants are specifically indicated in patients with septic lung diseases (e.g., cystic fibrosis, α_1-antitrypsin deficiency) in which the remaining native contralateral lung could cross-contaminate a single transplanted lung. Double en bloc lung transplants have been abandoned because of technical difficulties related to the bronchial anastomotic blood supply. Mechanical ventilation or extracorporeal membrane oxygenation can be used as a temporary bridge to this type of transplant, but use of these modalities does not obviate the need for organ replacement therapy.

CURRENT STATUS OF ORGAN DONATION

The once steady increases in most types of organ transplant procedures have considerably slowed or reached a plateau over the last several years. This is due to an insufficient augmentation of the donor pool (Tables 185.1 and 185.2; Fig. 185.1). The 55-mile-per-hour speed limit, stricter seat belt and helmet laws, and improved trauma care have all had a significant impact on the number of available brain-dead organ donors [1]. As a consequence, substantial nationwide changes in cause-of-death patterns for brain-dead donors were observed between 1988 and 2008. Head trauma deaths decreased from 34% to 16% of total deaths, whereas cerebrovascular deaths increased from 29% to 41% [1,2]. In 2008, the three leading causes of death among brain-dead donors in the United States were cerebrovascular accidents, blunt head injuries, other cardiovascular events (e.g., myocardial infarctions), followed by gunshot or stab wounds, and other miscellaneous causes [1,2].

To improve organ availability in the face of the donor crisis, the United States Department of Health and Human Services (DHHS) launched at the beginning of the new millennium several national Organ Donation and Organ Transplantation Breakthrough Collaborative initiatives [24,26,40,41]. These were designed to develop and share best practices among donor hospitals, organ procurement organizations, and transplant centers throughout the United States. The initiatives called on the participants to reach a 75% conversion rate (the number of actual donors divided by the number of potential donors) and a 3.75 organs-transplanted-per-donor average yield rate [24,26,40,41]. In large part due to these initiatives and other ongoing national efforts, an encouraging increase of the number of deceased donors in the United States has been observed over the past decade (Fig. 185.1) [1,2,24,26]. Most recently, however, the number of organ donors in the United States has begun to stagnate again (Fig. 185.1) [1,2].

A positive trend that has started to take place is the increasing number of DCD donors (Fig. 185.1) [2,24]. These donors constitute currently 10% of the overall deceased donor pool [2]. Further increases over the coming years are to be expected as the overall organ donor shortage will continue to worsen. In DCD donors, refined surgical techniques allow for fast insertion of cannulas and perfusion of vital organs while these are rapidly excised. Innovative approaches, such as withdrawal of care in the ICU (rather than in the operating room), in the presence of the donor's family, may further increase acceptance of DCD donation among potential donors' families

and health care personnel [26,29]. Moreover, refinements of organ perfusion and preservation techniques, including maintenance of the DCD donor on extracorporeal membrane oxygenation (ECMO) until organ recovery can occur, and placement of the recovered organs on pulsatile perfusion pumps during the transport and preservation phase, result in less ischemic organ injury, and allow for better organ preservation and increased use of DCD donor organs, too [24,42–44]. Currently, kidneys and livers are the organs most commonly recovered and transplanted from DCD donors [2].

According to estimates, there are at least 10,500 to 13,800 *potential* brain-dead donors in the United States per year [12]. In 2010, however, there were only 7,944 *actual* deceased organ donors in the United States [1]. In a recent study, the overall consent rate (the number of families agreeing to donate divided by the number of families asked to donate) was 54% in the United States, and the overall conversion rate was 42% [12]. The single most important reason for lack of organ retrieval from 45% to 60% of the potential donor pool is the inability to obtain consent [12,24]. Several studies have shown that family refusal to provide consent and the inability to identify, locate, or contact family members to obtain consent within an appropriate time frame are the leading causes for the nonuse of many potential donors [10–13,24]. A public opinion survey showed that 69% of respondents would be very or somewhat willing to donate their organs, and 93% would honor the expressed wishes of a family member [45]. However, only 52% of these individuals had communicated their wishes to their family. Moreover, 37% of respondents did not comprehend that a brain-dead person should be considered dead and unable to recover, and 59% either believed or were unsure whether or not organs can be bought and sold on the "black market." Also, 42% did not realize that organ donation does not cause any financial cost to the family of the deceased in the United States [45].

Correcting these misperceptions and attempting to increase awareness of the importance of organ transplant must remain the focus of public educational campaigns [24,29]. The family's knowledge of the patient's previous wishes is central to decision making [10,11,13]. Such efforts can be successful, especially among minorities, in whom mistrust and the perception of inequitable access to medical care and organ transplant therapy have led to disappointingly low organ donation and recovery rates [24,46]. It is very important that adequate communication, empathy, and an informative, humane approach to the family of the deceased occur to ensure reasonable consideration of donation. Families are more likely to donate if they are approached by an organ procurement organization coordinator, view the requestor as sensitive to their needs, and experience an optimal request pattern [11,13,21,22]. Educational efforts to enhance organ donation must therefore also be directed at health care professionals and medical students, whose views and knowledge of these issues are often inconsistent and limited [29,47]. Physicians, too, need to be better trained to recognize and refer potential organ donors and to not discuss organ donation until a member of the local organ procurement organization has approached their families [11,13,21,22].

OPTIONS TO INCREASE ORGAN AVAILABILITY

Mechanisms that might serve to increase the number of available organs for transplantation include (a) optimization and maximal use of the current actual donor pool; (b) increasing the number of living donor transplants, including the provision of incentives for live donation; (c) use of other unconventional and controversial donor sources, such as anencephalic donors and executed prisoners; and (d) xenotransplants (e.g., use of animal organs as a potentially unlimited supply for transplantation into humans, particularly after genetic engineering) [48]. The first two mechanisms are of current practical interest, whereas the last two are likely to continue to confront critical care and transplant physicians, nurses, and the lay population over the next years in the form of an ongoing, public debate.

Optimal Use of the Current Donor Pool

As a result of the ongoing organ shortage, transplant surgeons have attempted to refine procurement techniques so that maximal use of the available donor pool occurs [49] (Fig. 185.2). For example, currently more than 85% of all deceased donors are multiple-organ donors. On average, more than three organs are recovered and transplanted from each deceased donor [1,2,24,40,41] (Fig. 185.2). Extension of the organ preservation time by a variety of techniques, including new preservation solutions and pulsatile perfusion preservation, has facilitated allocation of organs to geographically distant transplant centers [44].

Marginal donors—elderly patients, patients with a history of hypertension, poisoning victims, patients with significant organ injury (e.g., liver laceration due to blunt injury), or complications of brain death (e.g., hypotension, oliguria or anuria, disseminated intravascular coagulation)—are now used almost routinely for recovery of kidneys and of extrarenal organs [1,2,24]. Procurement techniques also have been adapted to

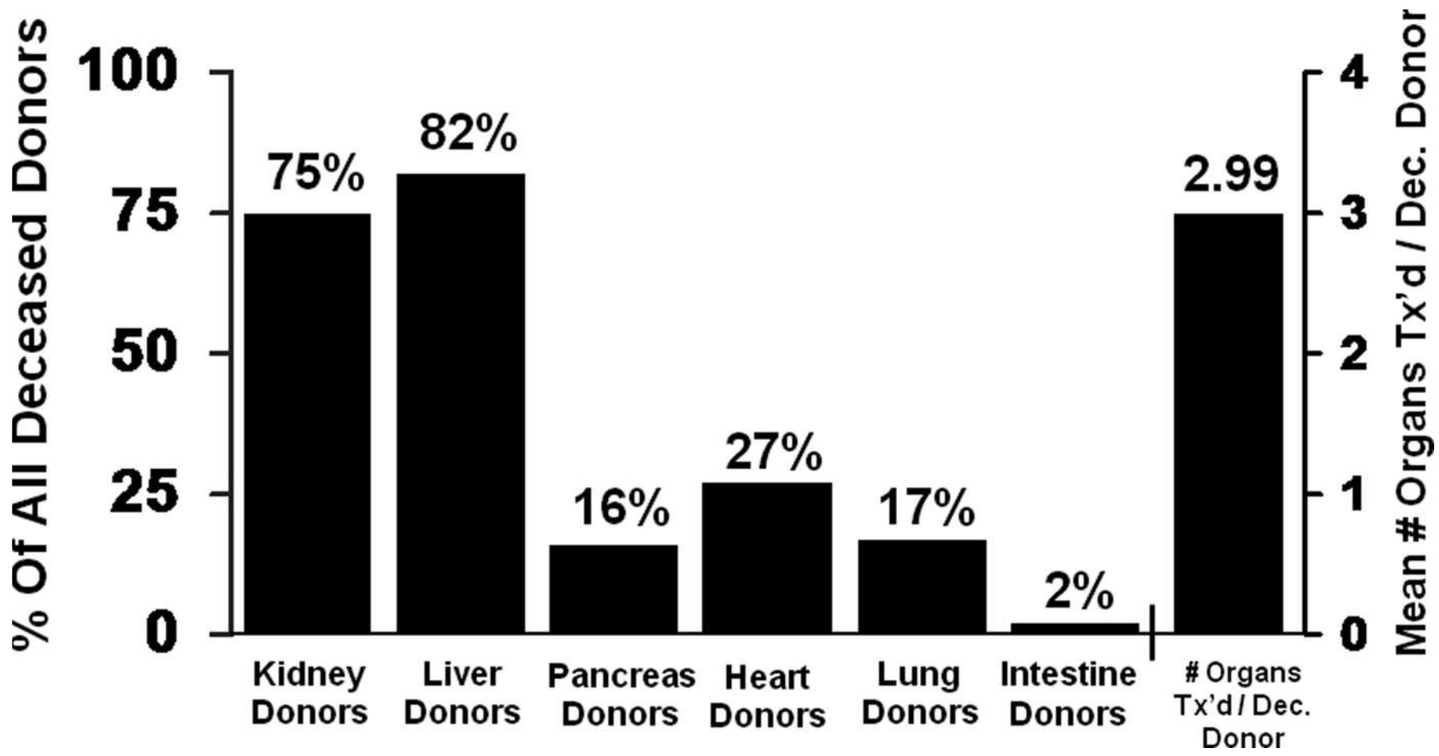

FIGURE 185.2. Organ transplantation rates (by organ) from 8,085 deceased donors (100%) in the United States (2007). The last bar represents the mean number of organs transplanted per deceased donor ("organ yield"). Tx'd, transplanted; Dec., deceased. (Based on data from references [1,2].)

facilitate use of older donors with significant aortic atherosclerosis [50]. Organs with anatomic abnormalities (e.g., multiple renal arteries or ureters, horseshoe kidney, annular pancreas) also are being used routinely. Improvements in operative technique permit the en bloc transplantation of two kidneys from very young donors that would have been too small to be used separately in one recipient [51,52]. Similarly, transplantation of both kidneys from an *adult* donor into one recipient is done to avoid discarding suboptimal kidneys with an insufficient individual nephron mass. To maximize the use of livers, adult donor livers can be split and the two size-reduced grafts transplanted into two recipients (e.g., a pediatric and an adult recipient). A similar principle has also been proposed for the pancreas and has been reported on at least one occasion [53].

Explanted livers from patients undergoing liver transplantation for hepatic metabolic disorders that cause systemic disease without affecting other liver functions (e.g., familial amyloidotic polyneuropathy, hereditary oxalosis) can be used for transplanting other patients ("domino transplant") who are not candidates for deceased livers because of graft shortage (e.g., cirrhotic patients with hepatocellular carcinoma confined to the liver who are not in the group with good expected survival) [54]. The combination of split-liver and domino transplantation can even result in transplantation of three adult patients with one deceased donor graft [55].

The advent of single-lung transplants has made it possible to distribute the heart and lungs of one donor to three recipients. Formerly, transplanting a heart–lung bloc into one recipient was the treatment of choice for end-stage pulmonary disease. If the native heart of a heart–lung recipient is healthy, a domino transplant can be performed: The heart–lung recipient donates his or her heart to another patient in need of a heart transplant. Again, as an attempt to optimize use of scarce donor resources, the reuse of transplanted hearts, kidneys, and livers has been reported [56]. However, all these methods allow only for better use of organs from the existing donor pool. The cornerstone for an effective increase in the number of organ donors remains heightened awareness and education of the public, physicians, and other health care professionals to improve consent and conversion rates [11–13,24,29].

Living Donors

The use of living donors, traditionally limited to kidney transplants, has been expanded to the pancreas, liver, small bowel, and lung [1,2]. In the past, most living donors were genetically related to the recipient—siblings, parents, and adult children. The use of living unrelated kidney donors, who are either emotionally related to the recipient (e.g., spouses, close friends), or emotionally unrelated to the recipient (nondirected, "altruistic" donors) has considerably increased over the past 15 years as a result of the organ shortage [1,2]. In 2008, the 5,968 live donor kidney transplants constituted 34% of all kidney transplants that were done that year [1] (Fig. 185.1). In order to increase that proportion even further, paired-kidney-exchange programs and living donor chain transplants have been implemented [57,58]. In that setting, the supply of organs is increased for instance by exchanging kidneys from living donors who are ABO or cross-match incompatible with their intended recipients, but ABO or cross-match compatible with another donor-recipient pair [donor A would provide a kidney to (ABO or cross-match compatible) recipient B, and donor B would provide a kidney to (ABO or cross-match compatible) recipient A] [57,58]. In cases when paired kidney exchange or donor chain transplants are not available or feasible, it is alternatively possible to precondition the intended recipient of an ABO or cross-match incompatible kidney (by use of plasmapheresis and/or intravenous immunoglobulin and pharmacologic intervention) to still facilitate a successful living donor kidney transplant.

Currently, there is considerable public debate on providing incentives for living kidney donation [59–62]. The debate centers on concerns that reimbursement might lead to the commercialization of organ donation, with the inherent risk of turning potential donors and transplantable organs into a commodity [60–62]. In the United States, those in support of compensating live donors stress that an OPTN-run transparent system of paid living donation would ensure that donors are compensated fairly, eliminate transplant tourism to other countries, greatly diminish the currently existing black market for organs in those countries, and emphasize any potentially interested donor's autonomy—while increasing the organ supply [59,60]. In any case, paid living donation, while a reality in certain regions of the world, remains currently unlawful in the United States and most, if not all, Western Countries.

Even when assuming that (i) public attitudes toward living donation will continue to evolve favorably (Fig. 185.1), (ii) innovative approaches as described above will be increasingly used, and (iii) other alternative means for finding living donors, such as donor solicitation via the internet would ultimately be fully embraced by the transplant community and society, only modest increases of the absolute number of living donors could be expected [60,61,63–66]. Compared with renal transplantation, the proportion of living donor transplants for extrarenal organs is much smaller (less than 5% for liver and less than 0.5% for pancreas, lung, and small bowel) [1]. Thus, living donor transplants will continue to help alleviate the organ shortage for certain organs (kidney, liver) to some extent, but will never be able to completely compensate, even under the best circumstances, for the severe lack of deceased donors.

Other Human Donor Organ Sources

The potential for financial compensation or other rewards for deceased donor families (e.g., compensation for funeral expenses) has been considered as a means to increase donation rates [66].

Certain countries (e.g., China) use organs from executed prisoners. Use of this group would contribute only very small numbers of donors in the United States, and this concept has been rejected by the transplant community here [67]. Likewise, the use of anencephalic babies for solid-organ transplantation would not significantly alleviate the organ shortage because only a few babies fulfill all brain-death criteria. Proposals to use organs from executed prisoners or anencephalic babies would engender a very passionate, emotional debate that could have a negative impact on public opinion and thereby decrease overall organ availability [68]. Therefore, these options are not being actively explored.

Xenotransplantation

Xenotransplantation of organs and tissues from animals into humans offers a potentially unlimited supply of donors [69]. Several attempts have received significant public attention [70], but numerous practical problems remain before this procedure could become clinical reality. Ethical concerns regarding the use of animal organs for transplantation have also been raised [71]. Immunologic concerns include hyperacute rejection (mediated by circulating, preformed natural antibodies), which occurs in vascularized solid-organ transplantation between virtually all discordant species. Also, the biocompatibility of protein synthesized by an animal liver and the human organism is not fully established, and infectious diseases (e.g., caused by retroviruses) could be transmitted using nonhuman primates or pigs

as donors. Genetic engineering of animals before their use as donors to overcome the immunologic barriers is an area of intensive investigation. Significant experimental progress in this area could fundamentally change the field of organ transplantation.

Presumed Consent Laws

Presumed consent laws have been implemented in many areas of the world, most notably in several countries in Europe. These laws permit organ procurement unless the potential donor has objected explicitly. A permanently and easily accessible registry of objectors is a prerequisite for such a system. Emphasis is placed on an individual's decision, and family input is limited. In the United States, presumed-consent legislation does not have broad support, and it is uncertain whether the public could reach a consensus on this issue. Moreover, presumed consent would not alleviate the problem of insufficient donor identification and referral [12].

The beneficial impact that such laws can have became evident in Spain. In that country, presumed consent laws coupled with the creation of a decentralized network of mostly hospital-based, specifically trained transplant coordinators (most of them physicians in intensive care units) in the early 1990s led not only to more efficient identification of eligible deceased donors but also to higher consent rates. Accordingly, the annual donation rate in Spain rose from 14.3 donors per million population (pmp) in 1989 to 34.2 pmp in 2008 (United States, 2008: 26.3 pmp) [72–74]. Interestingly, a similar approach (without the presumed consent component) using in-house coordinators at some hospitals the United States did yield greater consent and conversion rates, too, and underscored the advantages that such a system could have, if implemented at a larger scale [75].

REGULATION AND ORGANIZATION OF ORGAN RETRIEVAL AND ALLOCATION

In the early 1980s, the introduction of new immunosuppressive agents engendered a rise in organ transplant activity. Tissue matching (e.g., by use of living-related donor-recipient combinations) became less important, and the use of brain-dead donors increased (Fig. 185.1). In the wake of these developments, consolidation and national regulation of the organ-sharing and allocation organizations, which had previously functioned mainly at a local and regional level, became necessary.

In the United States, the National Organ Transplant Act (NOTA) of 1984 called for a national system to ensure equitable access to transplant therapy for all patients, a major component of which was fair organ allocation. The federal government commissioned a task force on organ transplantation to define such an allocation system. This task force, whose members were appointed by the U.S. Department of Health and Human Services, resolved that human organs are a "national resource to be used for public good" and recommended the creation of a national Organ Procurement and Transplantation Network (OPTN) [3]. In 1986, the U.S. Department of Health and Human Services awarded the OPTN contract to the United Network for Organ Sharing (UNOS). Pursuant to the contract, UNOS was asked to design a network to achieve balance in the goals of equity in organ access and distribution and in optimal medical outcome [76]. In 1986, the Omnibus Budget Reconciliation Act mandated that only hospital members of the OPTN could perform Medicare- and Medicaid-reimbursed transplant procedures. In 1988, the Organ Transplant Amendments reaffirmed the federal interest in equitable organ allocation by locating authority in UNOS as opposed to local transplant organizations.

The national OPTN is currently still operated by the nonprofit UNOS and is accountable to the U.S. Department of Health and Human Services. All patients on waiting lists of a transplant program are registered with UNOS, which maintains a centralized computer system linking all OPOs and transplant centers. The United States has been divided into 11 regions for organ procurement, allocation, and sharing purposes (Fig. 185.3). Organs are registered, shared, and allocated through use of the central UNOS computer, which generates a list of recipients for each available organ. Patients awaiting deceased transplantation are ranked according to UNOS policies, based on medical and scientific criteria such as blood type, tissue type, length of time waiting on the list, age (pediatric vs. adult), level of presensitization (percentage of panel reactive antibody), and medical status. National sharing of 0-antigen (A, B, and DR HLA loci) mismatched kidneys is mandated. In

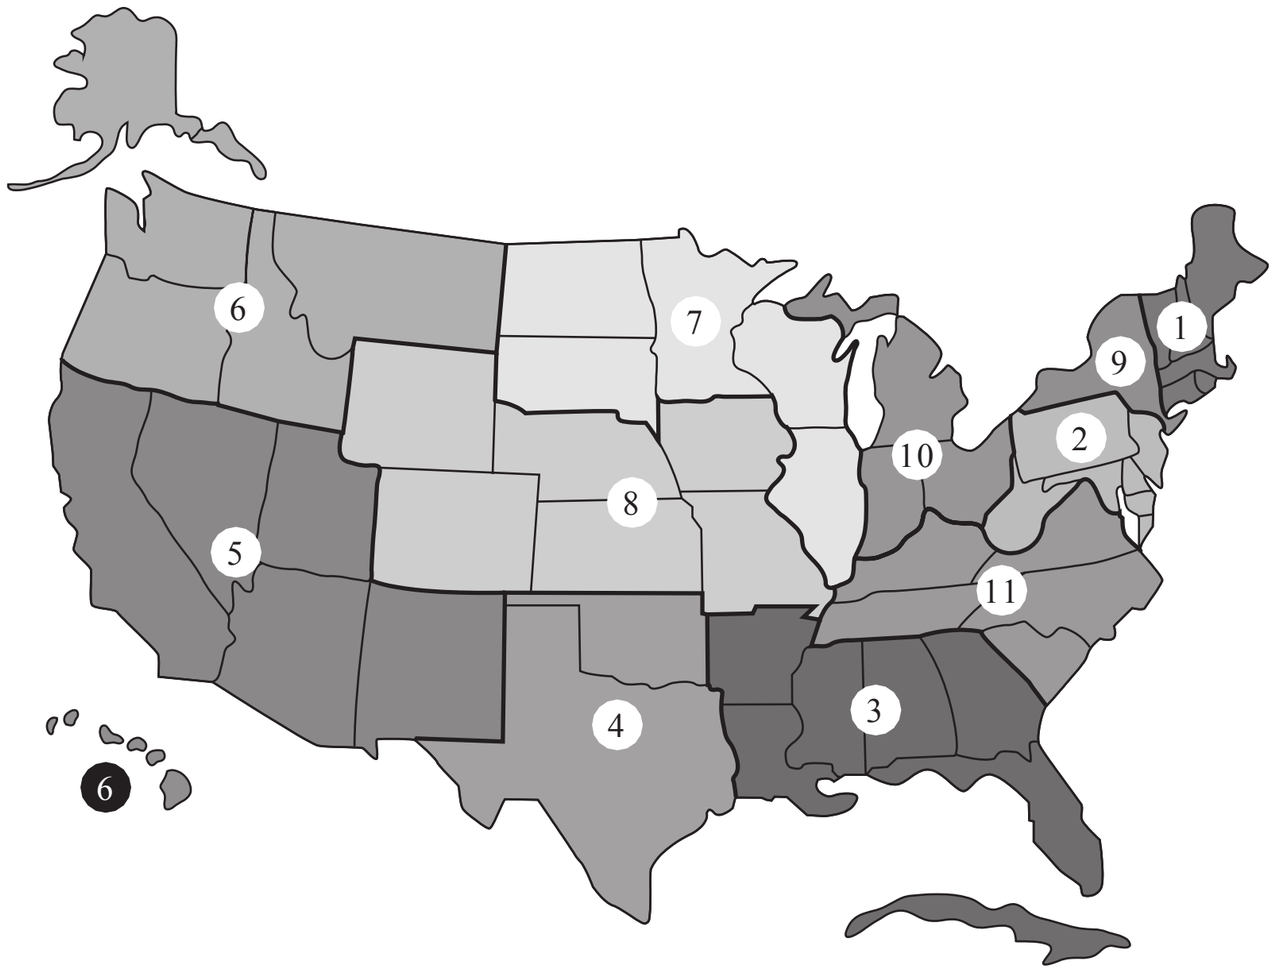

FIGURE 185.3. United Network for Organ Sharing (UNOS) regions in the United States (24-hour access number: 1-800-292-9537). The United States has been divided into 11 regions for organ procurement, allocation, and sharing purposes.

all other cases, and for all other organs, allocation first takes place locally. If no suitable local recipients are available, organs are allocated regionally or nationally [1,76].

LEGAL ASPECTS OF ORGAN DONATION AND BRAIN DEATH

Uniform Anatomical Gift Act

The Uniform Anatomical Gift Act, adopted in 1968 and in force throughout the United States, allows any adult individual (over age 18 years) to donate all or part of the body for transplantation, research, or education. That act provides also the legal basis for procurement of organs from both DCD and brain-dead (vide infra) donors. Explicit consent, which can be revoked at any time, is required. The act also permits legal next of kin to give consent for donation [77]. Donor cards or driver's licenses, on which individuals indicate their consent to postmortem organ donation, are promoted by many states but are legally nonbinding and thus serve ultimately only as a tool to heighten public awareness. In most instances, consent from the next of kin is still sought. Therefore, educational efforts must urge potential donors to make their wishes known to their next of kin [11,13].

Uniform Determination of Death Act

Over the past four decades, brain death has legally become equated with death in most Western developed countries. *Brain death* means that all brain and brainstem function has irreversibly ceased, and circulatory and ventilatory functions are maintained temporarily. The recognition of brain death became possible only after substantial advances in intensive care medicine (e.g., cardiovascular support, prolonged mechanical ventilation). The first classic description of brain death was published in 1959 in France and termed *coma dépassé* (beyond coma). An ad hoc commission of the Harvard Medical School defined brain-death criteria in the United States in 1968 [78]. These criteria were judged by some as being too extensive and too exclusive. In 1981, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research formulated the Uniform Determination of Death Act, which established a common ground for statutory and judicial law related to the diagnosis of brain death. The commission stated that "an individual who has sustained... irreversible cessation of all functions of the entire brain, including the brainstem, is dead," and left the criteria for diagnosis to be determined by "accepted medical standards."

Those standards were defined in a related report to the President's Commission on the diagnosis of death by 56 medical consultants in 1981 [79]. The guidelines in that report have now been accepted as the standard for determining brain death in the United States. They are as follows: "Cessation is recognized when (1) all cerebral functions and (2) all brainstem functions are absent. The irreversibility is recognized when (1) the cause of the coma is established and is sufficient to account for the loss of brain functions, (2) the possibility of the recovery of any brain functions is excluded, and (3) the cessation of cerebral and brainstem function persists for an appropriate period of observation and/or trial of therapy" [79]. Confusion regarding this well-founded and accepted medicolegal concept of the equivalence of brain death and death of a human persists to this date among physicians, other health care professionals, and the general public [11,13]. Specifically, in the field of transplantation, it should be unequivocally clear to the potential donor's family and anyone involved in the patient's care that the time of death is the time at which the diagnosis of brain death is established and not the time of cardiac arrest during the organ retrieval. Providing education targeted specifically at these groups and society at large is of paramount importance to optimize consent rates [11,13].

Required Request

Required request laws have now been enacted in all states in the United States. They obligate hospitals to notify an OPO of potential donors and to offer the option of donation to the families of potential donors (brain-dead or DCD donors).

Clinical Diagnosis of Brain Death

The clinical diagnosis of brain death rests on three criteria: (a) irreversibility of the neurologic insult, (b) absence of clinical evidence of cerebral function, and, most important, (c) absence of clinical evidence of brainstem function [79–81] (Table 185.4). Irreversibility is established if structural disease (e.g., trauma, intracranial hemorrhage) or an irreversible metabolic cause is known to have occurred. Hypothermia, medication side effects, drug overdose, or intoxication need to be ruled out when testing for brain death. Plasma concentrations of sedative or analgesic drugs sometimes correlate poorly with cerebral effects. Therefore, residual effects of those drugs can be excluded only by passage of time, if any doubts exist. The observation period (the waiting time between two sequential brain-death examinations) should be at least 6 hours for structural causes and preferably 12 to 24 hours for metabolic causes, drug overdose, or intoxication [80]. Even with potentially reversible metabolic alterations (e.g., hepatic or uremic encephalopathy), recovery has not been described after duration of the brain-death state for more than 12 hours. Clinical testing of cerebral and brainstem function is detailed in Table 185.4 [79–82]. It should be noted that brain-death criteria are more stringent for very young pediatric patients, particularly newborns, in whom criteria for brain death also include demonstration of the absence of blood flow on cerebral flow studies.

After brain death, the pupils become fixed in midposition because sympathetic and parasympathetic input is lost. Decerebrate (abnormal extension) and decorticate (abnormal flexion) responses to painful stimuli imply the presence of some brainstem function and are incompatible with the diagnosis of brain death. In contrast, spinal cord–mediated tendon reflexes, automatic stepping, and other spinal cord–generated movements (which can occur during apnea testing) are compatible with the presence of brain death [83]. The occurrence of these movements can be quite distressing if observed by the next of kin; therefore, it is advisable that they not be present during the apnea test. Very rarely, ascending acute reversible inflammatory polyneuropathy (Guillain–Barré syndrome) can simulate brain death and inhibit all motor functions, including pupillary reactions and brainstem reflexes. The typical clinical history, coupled with evidence of progressive weakness, yields the correct diagnosis and precludes a diagnosis of brain death being established [80].

The American Academy of Neurology has stated that special confirmatory tests are not necessary to diagnose brain death in the vast majority of cases. Only in equivocal or questionable circumstances do tests demonstrating absence of intracranial blood flow or the presence of an isoelectric electroencephalogram need to be performed [80,81]. The most sensitive and specific test for assessing intracranial blood flow is four-vessel cerebral arteriography. All other adjunctive tests are

TABLE 185.4

BRAIN DEATH CRITERIA AND CLINICAL DIAGNOSIS OF BRAIN DEATH

Irreversible, well-defined etiology of unconsciousness
Structural disease or metabolic cause
Exclusion of hypothermia; hypotension; severe electrolyte, endocrine, or acid-base disturbance; and drug or substance intoxication
Sufficient observation period (at least 6 h) between two brain death examinations
No clinical evidence of cerebral function
No spontaneous movement, eye opening, or movement or response after auditory, verbal, or visual commands
No movement elicited by painful stimuli to the face and trunk (e.g., sternal rub, pinching of a nipple, or fingernail bed) other than spinal cord reflex movements
No clinical evidence of brainstem function
No pupillary reflex: pupils are fixed and midposition; no change of pupil size in either eye after shining a strong light source in each eye sequentially in a dark room
No corneal reflex: no eyelid movement after touching the cornea (not the conjunctiva) with a sterile cotton swab or tissue
No gag reflex: no retching or movement of the uvula after touching the back of the pharynx with a tongue depressor or after moving the endotracheal tube
No cough reflex: no coughing with deep tracheal irrigation and suctioning
No oculocephalic reflex (doll's eyes reflex): no eye movement in response to brisk turning of the head from side to side with the head of the supine patient elevated 30 degrees
No oculovestibular reflex (caloric reflex): no eye movements within 3 min after removing earwax and irrigating each tympanic membrane (if intact) sequentially with 50 mL ice water for 30 to 45 seconds while the head of the supine patient is elevated 30 degrees
No integrated motor response to pain: no localizing or withdrawal response, no extensor or flexor posturing
No respiratory efforts on apnea testing ($PaCO_2$ > 60 mm Hg or 20 mm Hg higher than the normal baseline value): The patient is preoxygenated with an FIO_2 of 1.0 for 10–15 min, preferably with an arterial line in place for rapid blood gas measurements, while adjusting ventilatory rate and volume such that the $PaCO_2$ reaches □40–45 mm Hg. After a baseline arterial blood gas value is obtained and the patient is disconnected from the ventilator, O_2 at 6–8 L/min is delivered through a cannula advanced 20–30 cm into the endotracheal tube (cannula tip at the carina). Continuous pulse oximetry is used for early detection of desaturation, which does not usually occur when using this protocol. In most cases, a $PaCO_2$ > 60 mm Hg is achieved within 3–5 minutes after withdrawal of ventilatory support; at this point, the patient should be reconnected to the ventilator (or earlier, should hemodynamic instability, desaturation, or spontaneous breathing movements occur). Obtaining an arterial blood gas sample immediately before reinstitution of mechanical ventilation is mandatory. If there is no evidence of spontaneous respirations before reinstitution of mechanical ventilation in the presence of a $PaCO_2$ > 60 mm Hg or an increase of > 20 mm Hg from the normal baseline value, the criteria for a positive apnea test are met.
Other points
Spinal reflexes, such as deep tendon reflexes and triple flexion responses, can be preserved and do not exclude the diagnosis of brain death
Shivering, goose bumps, arm movements, reaching of the hands toward the neck, forced exhalation, and thoracic respiratory-like movements are possible after brain death and are likely due to neuronal impulse release phenomena of the spinal cord, including the upper cervical cord. All these findings are compatible with the diagnosis of brain death.
Confirmatory tests should be used in cases in which the observation period needs to be shortened (e.g., unstable donors), in equivocal situations in children younger than 1 year old, or if one of the potential pitfalls (Table 185.6) cannot be ruled out (demonstration of absence of intracranial circulation by angiographic contrast or radioisotopic flow studies, transcranial Doppler ultrasonography, or electrocerebral silence documented by an electroencephalogram).

$PaCO_2$, partial arterial carbon dioxide pressure; FIO_2, fraction of inspired oxygen.
From references [79–82].

less sensitive (e.g., digital subtraction angiography, transcranial Doppler ultrasonography), are less specific (e.g., brainstem acoustic evoked potentials), measure only hemispheric flow (e.g., radioisotope angiography), or are indirect (e.g., computed tomography, echoencephalography). If either hemispheric neuronal function (electroencephalogram) or hemispheric flow is assessed, reliable clinical testing of the brainstem must be performed to confirm the diagnosis. The use of a brain-imaging modality, positron emission tomography (using ^{18}F-fluorodeoxyglucose to assess brain metabolism), to diagnose brain death is currently not universally recommended [80]. The decision whether to accept ^{18}F-fluorodeoxyglucose–positron emission tomography as a confirmatory test for determination of brain death is awaiting the results of further studies.

Four-vessel cerebral arteriography is indicated in all conditions that can temporarily cause an isoelectric electroencephalogram (e.g., extreme intoxication). If the indication for cerebral arteriography is unclear, the benefits must be weighed against the potential risks of transporting an unstable patient, hypotension after contrast injection, and the nephrotoxic effects of injection of contrast media that potentially may affect early renal allograft function [82]. Confirmatory tests may serve to shorten the waiting period between the two brain-death examinations, should donor hemodynamic instability occur. Certain potential pitfalls exist in clinical brain-death testing, and the diagnosis should not be considered to have been established until these all have been excluded (Table 185.5). If these cannot be excluded, confirmatory testing is mandatory [80,81].

In summary, the diagnosis of brain death can be established by performance of routine neurologic examinations, including cold caloric and apnea testing on two separate occasions,

TABLE 185.5

PITFALLS IN CLINICAL BRAIN DEATH TESTING AND POTENTIAL REMEDIAL MEASURES[a]

Pitfalls	Remedial measure(s)
Hypotension, shock	Institute fluid resuscitation, use of pressor agents
Hypothermia	Use warmed fluids, ventilatory warmer
Intoxication or drug overdose	If measurable, check drug levels and toxicology screens or increase waiting time between brain death examinations
Neuromuscular and sedative drugs, which can interfere with elicitation of motor responses	Discontinue muscle relaxants and mood- or consciousness-altering medications, increase waiting time between brain death examinations
Pupillary fixation, which may be caused by anticholinergic drugs (e.g., atropine given during a cardiac arrest), neuromuscular blocking agents, or preexisting disease	Discontinue anticholinergic medications and muscle relaxants, increase waiting time between brain death examinations, obtain careful patient history
Corneal reflexes absent due to overlooked contact lenses	Remove contact lenses before brain death examination
Oculovestibular reflexes diminished or abolished after prior use of ototoxic drugs (e.g., aminoglycosides, loop diuretics, vancomycin) or agents with suppressive side effects on the vestibular system (e.g., tricyclic antidepressants, anticonvulsants, and barbiturates) or due to preexisting disease	Obtain careful medication history and patient history

[a]If one of the listed conditions cannot be ruled out, confirmatory testing (cerebral flow studies or electroencephalography) is necessary before brain death is declared.

coupled with prior establishment of the underlying diagnosis and prognosis in most cases. More sophisticated tests are required in cases in which the diagnosis cannot be unequivocally established. However, brain death must be diagnosed in accordance with local regulations and state laws. Details on the locally prevailing regulations are available through the state medical board or the local OPO.

ORGAN DONATION PROCESS

The three key elements leading to successful organ donation are (a) early referral of potential donors, (b) a well-coordinated approach in informing and dealing with the potential donor's family to request and obtain consent, and (c) appropriate critical care therapy of the donor [11,13,15,16]. The optimal course of events for both brain-dead and DCD donors is summarized in Table 185.6.

Early Donor Referral

Early referral of any potential donor to the local OPO minimizes the loss of transplantable organs due to unexpected cardiac arrest and death, hemodynamic instability, serious nosocomial infection, or complications related to intensive care [16,84,85]. For example, an inverse correlation exists between the duration of mechanical ventilation and the suitability of the donor for lung donation.

The evidence is substantial that brain death eventually leads to cardiac arrest, even when cardiorespiratory support is maintained [84,86]. Cardiac arrest occurs in 4% to 28% of potential donors in the maintenance phase. Although approximately 50% of all potential donors die within 24 hours without appropriate support, as many as 25% are not recognized for 48 hours or longer, with identification occurring only at the time of cardiovascular death [86].

The previously outlined clinical guidelines for referral to the local OPO should be applied to any neurologically severely injured patient after admission to the hospital or intensive care unit (Table 185.3). Early contact with the OPO is essential as the latter will provide assistance with further screening and the evaluation of any patient who might potentially become a donor.

Donor Evaluation

General Guidelines

During the initial contact with the OPO, the physician should provide the potential donor's name, age, sex, height, weight, and blood type. Also needed are the date of admission and diagnosis, the nature and extent of any trauma, a concise medical and social history, and the time of brain death (if applicable). Whether local investigative agencies (e.g., medical examiner, coroner) need to be notified also should be specified. The current medical status, including vital signs, urine output, cardiorespiratory status, medications, and culture results, must be communicated. Basic laboratory results should be obtained: arterial blood gas determinations; blood urea nitrogen, creatinine, and electrolyte values; hemoglobin, hematocrit, white blood cell and platelet counts, and tests for serum amylase, total bilirubin, alkaline phosphatase, alanine aminotransferase,

TABLE 185.6

ORGAN DONATION ALGORITHM[a]

1. Early identification of the potential donor by the critical care physician or health care professional (Table 185.3)
2. Early contact with the local or regional OPO for medical, legal, and logistic assistance. If the local OPO's address or phone number is unknown, a 24-h access number to UNOS is available: 1–800-292–9537.
3. Completion of the preliminary screening by the OPO if necessary in consultation with the transplant surgeon for decisions regarding marginal donors

4a. For potential DCD donors: await family decision regarding withdrawal of care. Proceed only if family decides to do so.

4b. For potential brain-dead donors: brain death diagnosis and confirmation (Tables 185.4 and 185.5), certification of death. Family notification and explanation of brain death with its legal and medical implications. Sufficient time for acceptance must be allowed.

5. Request for organ donation. Must be made after, in clear temporal separation, from step 4a or 4b.
6. After consent for organ donation is obtained, the focus switches from treatment of elevated intracranial pressure and cerebral protection to preservation of organ function and optimization of peripheral oxygen delivery (Table 185.8).
7. All remaining laboratory and serologic studies as well as any further studies and tests required in equivocal situations are performed at this point (e.g., coronary angiography for older or marginal heart donors).
8. Final organ allocation by the OPO and UNOS, coordination of the organ recovery operation, notification of the abdominal and thoracic surgical teams. Modification of the final steps may become necessary under special circumstances, for example, in hemodynamically unstable donors.
9. For DCD donors: Support is withdrawn and death is certified (in the ICU or in the operating room).
10. Organ recovery operation (brain-dead and DCD donors).

[a]Steps 4, 5, and 9 should not involve physicians who are part of the transplantation team.
OPO, organ procurement organization; UNOS, United Network for Organ Sharing; DCD, donation after cardiac death.

and aspartate aminotransferase; coagulation profile (including prothrombin time or International Normalized Ratio [INR]); and urinalysis and urine culture should be available, along with electrocardiogram and chest radiograph results. In the case of potential lung donors, chest circumference and radiographic thoracic measurements, as well as the results of an oxygenation challenge [partial arterial oxygen pressure (PaO_2) measurement after ventilation for 10 minutes with a fraction of inspired oxygen (FIO_2) of 1.0], are helpful.

The OPO provides further procedural, administrative, legal, and logistic help. Most importantly, the OPO coordinates how the family is approached. All further testing [including HLA-tissue typing; serologic screening for cytomegalovirus (CMV), for hepatitis A, B, and C viruses, for human immunodeficiency virus (HIV), and for human T-cell lymphotropic virus type I and syphilis; and blood, sputum, and urine cultures] is then coordinated through the OPO if the donor passes the preliminary screening tests. The organ allocation process begins only after the family has decided to withdraw support (DCD donors) or brain death has been declared and consent has been obtained. If prospective tissue typing is to be done, performing a surgical inguinal lymph node biopsy at the donor hospital may be necessary—after consent for organ donation has been obtained but before proceeding with the actual organ recovery several hours later.

The medical status and the life expectancy of the potential recipient without the organ transplant are taken into account when the final decision about transplantation of a specific donor organ is made. The ultimate decision regarding the use of a donor organ is made by the transplant surgeon. At this point, the transplant center may need to obtain further tests to assess the functional status of one or more organ systems. For example, if the heart is to be retrieved, an echocardiogram is usually obtained. In selected donors, coronary angiography is performed. Pulmonary status can be further assessed by bronchoscopy after considering the results of the chest radiograph, oxygenation challenge, and sputum cultures. For potential liver donors who might have fatty liver disease, a percutaneous bedside liver biopsy can be performed. If concern over the suitability of organs arises, direct inspection by the transplant surgeon is necessary at the time of the organ procurement operation. In some cases, an open biopsy (e.g., for kidney or liver) and frozen section pathologic analysis obtained at the time of organ recovery also help in the final decision making. Direct inspection also is important in organ donors who suffered a blunt injury to the head and trunk (e.g., motor vehicle accident). Under these circumstances, intra-abdominal organs have been used successfully despite the presence of parenchymal tears or subcapsular hematomas in either the liver or kidney. Significant injuries to the pancreas preclude its use.

In summary, *each* patient with a severe neurologic injury should be referred to the local OPO as a potential donor, regardless of type of brain injury (e.g., trauma, stroke), history, age, or medical condition (Table 185.3). With few exceptions (vide infra), organ donation should never be excluded a priori because of the clinical situation, the results of imaging studies, or the magnitude of an injury, without first having contacted the local OPO (24-hour access number: 1–800-292–9537).

Organ-Specific Considerations

The use of kidneys from older donors, donors dying of cardiovascular disease, or donors requiring large doses of inotropic drugs for cardiovascular support entails a higher rate of delayed or diminished graft function and is associated with decreased graft survival [87,88]. Nevertheless, organs from these so-called marginal donors are routinely used, given the current prolonged periods (greater than 6 years) that some recipients may wait for available organs, during which their medical condition may deteriorate. Marginal donor kidneys benefit from preservation on a pulsatile perfusion pump, which was shown to improve quality of early graft function and long-term outcomes [44]. In equivocal cases (e.g., donors with elevated baseline serum creatinine levels or a history of hypertension), renal biopsies at the time of organ recovery may quantify the amount of preexisting donor arteriosclerosis or glomerulosclerosis. The critical shortage of organs has led to increasing relaxation of exclusion criteria, with satisfactory long-term results in many recipients. Donor organ function is more important than donor biologic age.

Livers from donors with an abnormal liver enzyme or coagulation profile can frequently still be transplanted. Elevated hepatic enzyme levels may reflect transient hepatic ischemia at the time of resuscitation. The trends observed in the results of serial hepatic enzyme levels are more important than absolute values. Abnormal coagulation test results may be due to disseminated intravascular coagulation (commonly a result

of brain injury, not primary hepatic dysfunction). Significant donor hypernatremia (e.g., > 155 mg per dL), as commonly observed in under resuscitated brain-dead donors with significant diabetes insipidus, is a risk factor for primary liver graft nonfunction posttransplant. Aggressive intervention prior to procurement is warranted and will ultimately allow for safe transplantation of liver grafts from these hypernatremic donors. The decision to use a liver from a marginal donor has to be made on the basis of relatively crude information. Often, only direct inspection, with or without a biopsy of the liver, at the time of organ recovery provides a final answer and may be the only way to assess a donor with a history of significant ethanol intake. Severe hepatic steatosis is one of the most significant factors predictive of early posttransplant hepatic dysfunction or failure.

In general, donors older than 55 years of age are not considered for pancreas donation. However, donors with hyperglycemia [caused by peripheral insulin resistance, particularly after brain death (see "Endocrine Therapy" section) or hyperamylasemia (which can be a consequence of severe head injury without actual pancreatitis)] [89] are not to be excluded a priori from pancreas donation, because these factors do not necessarily influence posttransplant outcome [90]. A pancreas transplant registry analysis suggested a slightly higher incidence of graft thrombosis for pancreata that had been procured from donors treated with desmopressin (vs. those that did not) [91]. Clearly, further study is necessary to confirm or refute these findings and determine their clinical significance. Currently, the only absolute contraindications to pancreas donation are a history of impaired glucose tolerance or insulin-dependent diabetes mellitus, direct blunt or penetrating trauma to the pancreas, or the finding of acute or chronic pancreatitis at the time of the donor operation.

Regarding heart donation, an important criterion is good donor heart ventricular function immediately before retrieval, as judged by the cardiac surgeon at visual inspection during organ recovery. Ideally, no potential heart donor should be excluded solely on the basis of echocardiographic wall motion abnormalities, a borderline or abnormal ejection fraction, inotropic medication requirements, or heart murmurs, arrhythmias, or other electrocardiographic changes (which often occur in brain-dead individuals in whom no cardiac disease is present) [16].

Risk factors associated with poorer outcome after lung transplantation include a history of smoking, aspiration, purulent secretions observed during bronchoscopy, an abnormal chest radiograph, or an unsatisfactory oxygenation challenge (PaO_2 less than 300 mm Hg after 10 minutes of ventilation with FIO_2 of 1.0 and PEEP of 5 cm H_2O) alone or in combination in lung donors. However, even lungs obtained from such marginal donors have been successfully transplanted [92]. Bronchoscopy often is performed as a final confirmatory test in the operating room by the transplant surgeon immediately before retrieval. Direct intraoperative inspection of the lungs determines whether significant contusions are present, which could preclude use of the organs.

In conclusion, the traditional donor criteria have been considerably expanded over recent years, for both thoracic and abdominal organs, due to the ongoing, severe donor shortage.

Transmission of Infectious Diseases

Transmission of bacterial or fungal infection through organ transplantation can be due to contamination of the organ itself during organ procurement or storage. Published evidence suggests that organs transplanted from bacteremic donors do not transmit bacterial infection or result in poorer recipient outcomes [93]. However, potential donors who exhibit or develop active bacterial or fungal infection that is unresponsive to adequate source control and antibiotic therapy or who have evidence of severe systemic sepsis with positive blood cultures (even without a primary source) should be rejected. Similarly, active tuberculosis is a contraindication to organ donation. Positive urine cultures do not preclude renal donation. Donors with serologic evidence of syphilis have been successfully used.

Absolute contraindications to donation include evidence of significant *acute* viral infections (e.g., viral encephalitis, systemic herpes simplex virus infections, acute viral hepatitis A, B, or C), seropositivity for HIV, and the acquired immunodeficiency syndrome. Individuals known to be at high risk for acquiring such diseases (e.g., intravenous [IV] drug users, prostitutes, or residents of sub-Saharan Africa) are only accepted as donors on a case-by-case basis.

Potential donors that test positive for the hepatitis B virus (HBV) surface antigen (HBsAg) or HBe antigen are usually precluded from donating [16,94]. Serologic positivity for the hepatitis B core antigen antibody (HBcAb) does not constitute an absolute contraindication to proceed with donation [94]. Acceptable organs from donors with any type of serologic evidence of HBV are usually only transplanted into recipients that have demonstrated immunity against HBV (i.e., HBsAb-positivity). Selected recipients may also receive HBV immunoglobulin or lamivudine, or both, beginning at the time of transplant [94]. Ideally, however, all potential organ transplant recipients should receive HBV immunization during the pretransplant evaluation [16].

The use of hepatitis C (HCV)–seropositive donors for selected recipients has become routine [16,95]. For adequate identification of HCV-positive donors, many OPOs now routinely perform nucleic acid testing (by polymerase chain reaction [PCR]) for HCV–RNA. HCV-infected livers and kidneys transplanted into HCV-infected recipients do not convey a worse outcome than HCV-negative grafts [16,95]. In essence, exclusion of all HCV-positive donors would increase the organ shortage while preventing what would appear to be relatively limited disease transmission. As is the case for HBV serology–positive donors, the final decision regarding the use of an HCV serology–positive donor must be made on an individual basis by each transplant surgeon. Factors that are taken into account in such circumstances include the likelihood of disease transmission, the recipient's current medical and serologic status, and whether the organ to be transplanted is life-saving (e.g., liver, heart) [16,95].

CMV also can be transmitted by donor tissue, particularly to CMV-seronegative patients. Effective prophylaxis against and treatment of CMV disease have become a reality with the advent of effective antiviral agents such as ganciclovir and valganciclovir. Positive CMV serologies do not preclude organ donation but have been used to identify high-risk donor-recipient combinations (CMV-seropositive donor–CMV-seronegative recipient) where prophylaxis should be used and careful surveillance for CMV disease is important.

Transmission of Malignancy

Transmission of malignancy via donor organs is very rare [16]. Because donor selection is particularly important in this regard, donors with most types of cancer should not be used. The exceptions are those with low-grade skin malignancies, such as basal cell carcinoma and most squamous cell carcinomas; carcinoma in situ of the uterine cervix; or primary brain tumors, which rarely spread outside the central nervous system (CNS; e.g., grade I astrocytomas, benign meningiomas, and hemangioblastomas, but not medulloblastomas and glioblastomas) [16,96]. It is important to ensure that a CNS tumor does not represent a focus of metastatic disease from the

primary site. Metastases from choriocarcinomas, bronchial or renal malignancies, and malignant melanomas may present as what appears to be a primary brain tumor or may bleed and be mistaken for an intracranial hemorrhage because of an arteriovenous malformation or a ruptured aneurysm. Previous treatment of a neoplasm, menstrual irregularities after a pregnancy or a spontaneous abortion in women of childbearing age (suggestive of a choriocarcinoma), or evidence of lesions at other sites in the patient with a purported primary CNS malignancy should preclude organ donation. Donors with primary brain tumors should not be used if they have undergone radiotherapy, chemotherapy, ventriculoperitoneal or ventriculoatrial shunting, or craniotomies, because these treatments either are associated with high-grade malignancies or create potential pathways for the systemic dissemination of tumor cells [16,96].

If a potential donor has had successful cancer treatment in the past, the transplant surgeon must weigh the small potential risk of transmitting micrometastases against discarding a potentially life-saving organ. In general, patients with a history of malignancy with little propensity to recur after therapy (e.g., small, noninvasive lesions treated by complete surgical excision) are considered as organ donors, particularly if they have remained without evidence of recurrence for more than 5 years. Patients who have experienced invasive cancer in which a substantial risk of late recurrence exists (e.g., breast cancer, malignant melanoma), particularly if a large lesion was initially present and chemotherapy or radiation therapy was used, should probably not be considered for donation. Similarly, patients with a history of leukemia or lymphoma should not be considered as donors.

Required Request for Organ Donation and Consent

After the OPO determines the suitability of a potential donor, the next important steps are the brain-death examination (when applicable) and the legally required request for organ donation (Table 185.6). Those steps should *not* involve any of the physicians associated with the transplant team, as this would represent a potential conflict of interest. In 1987, federal required-request legislation became effective and has since been adopted by every state in the United States. Required-request laws mandate that the family of a potential organ donor be offered the option of organ donation. The hospital must notify the local OPO of the presence of a potential organ donor. Several studies have shown that consent rates are highest when an OPO coordinator—rather than a member of the patient's ICU team such as a physician or a nurse—approaches the family about organ donation [11–13,75].

Brain-Dead Donors

For brain-dead donors, it is of the utmost importance to ensure that (a) the family understands and accepts the concept of brain death, including its legal and medical equivalence with death; (b) the request for organ donation is *not* made at the same time that brain death is explained (unless the family voiced the wish to consider donation earlier during the hospitalization); and (c) the approach and request be made by an OPO representative (rather than a member of the potential donor's care team). Sufficient time must be given to the next of kin to begin coping with this information and to accept the loss of the family member. Only then, in clear temporal separation from the explanation of death, should the subject of organ donation be broached and an appropriate request be made [11,13]. As a case in point, within one region of the United States, consent rates were 18% when the discussion of death and the request for donation were combined but rose to 65% when these issues were discussed separately [97]. Also, the family must be informed that after declaration of brain death and consenting to organ donation, all hospital costs relating to donation will be paid by the OPO.

DCD Donors

Families of patients with severe, irreversible brain injuries who do not fulfill the formal criteria of brain death might decide to forgo any further life-sustaining treatment. Only then can the subject of organ donation be broached with the family. As discussed earlier, it is paramount that the approach to the family and the request for organ donation be made by an OPO representative [26,98,99].

Consent

Driver's licenses and signed donor cards are not considered legally binding documents for the purpose of organ donation. Thus, the family's wishes under such circumstances are virtually always honored, even if they are contrary to the donor's wishes expressed on a driver's license or donor card. The Uniform Anatomical Gift Act of 1968 specifies the legal next-of-kin priority for donors over age 18 years in the following order: (a) spouse, (b) adult son or daughter, (c) either parent, (d) adult brother or sister, and (d) legal guardian [79]. Similarly, the order of priority for donors under age 18 years is as follows: (a) both parents, (b) one parent (if both parents are not available and no wishes to the contrary of the absent parent are known), (c) the custodial parent (if the parents are divorced or legally separated), and (d) the legal guardian (if there are no parents). In part in response to the aforementioned dilemma, nearly all states in the United States have now created state donor registries where residents can register their decision to donate (usually on-line) to ensure that they can donate their organs [24]. Such initiatives help to relieve families of making an often difficult decision on the donor's behalf. In contrast to driver's licenses and signed donor cards, an individual's decision to donate that is documented in a state donor registry cannot be overridden by the family [24].

PERIOPERATIVE CRITICAL CARE MANAGEMENT OF THE BRAIN-DEAD ORGAN DONOR

Although some of the critical care issues that pertain to brain-dead organ donors have been met by significant clinical and basic research interest (e.g., hormonal changes and hormonal replacement therapy), there is an overall lack of randomized, controlled studies that could lead to a more evidence-based approach to the care of these patients. The level of evidence provided by these studies is mainly low. It is therefore important to acknowledge that some of the following recommendations may undergo substantial revision as additional, new evidence emerges (Tables 185.7 and 185.8).

Pathophysiology of Brain Death

The majority of our knowledge of the pathophysiologic changes during and after brain death has been derived from experiments performed using animal models. Hemodynamic instability during the phase of impending brain herniation is the result of autonomic dysregulation secondary to the progressive

TABLE 185.7

MAINTENANCE THERAPY ENDPOINTS IN THE BRAIN-DEAD ORGAN DONOR

Variable	Therapeutic endpoint
Systolic blood pressure	100–120 mm Hg or mean arterial pressure ≥ 60 mm Hg
Central venous pressure	8–10 mm Hg
Urine output	100–300 mL/h
Core temperature	> 35°C
Partial arterial oxygen pressure	80–100 mm Hg
Systemic arterial oxygen saturation	95%
pH	7.37–7.45
Hemoglobin	10–12 g/d
Hematocrit	30–35%

loss of central neurohumoral regulatory control of vital functions. The continuous increase in intracranial pressure with worsening brain ischemia leads to severe systemic hypertension (Cushing's response) and frequently is associated with tachyarrhythmias. This process is mediated by an increase in sympathetic activity and an excess of circulating catecholamines ("autonomic storm") [100–102]. A brief period of transient bradycardia associated with the hypertensive response can be seen in the early phase of brain herniation (Cushing's reflex).

During the phase of increased sympathetic activity, there is evidence that coronary blood flow is significantly impaired, resulting in cardiac microinfarcts. Furthermore, decreased hepatic perfusion due to increased intrahepatic shunting has been demonstrated as a result of the excessive sympathetic activity. Neurogenic pulmonary edema is thought to develop during the autonomic storm phase secondary to the temporary elevation of left atrial pressures over the level of pulmonary arterial and alveolar capillary pressures. This causes massive transudation of fluid from the microvasculature into the alveoli and interstitial hemorrhage [100–102]. Within approximately 15 minutes after brain herniation and brain death, catecholamines decrease to below baseline values.

The resting vagal tone is abolished because of destruction of the nucleus ambiguus, eliminating all chronotropic effects of atropine administered after brain death. The total carbon dioxide production after brain death is low, because of the absence of cerebral metabolism and the presence of hypothermia and decreased muscle tone. The subsequent chronic maintenance phase of brain-dead donors is frequently characterized by hypotension, resulting mainly from complete arterial and venous vasomotor collapse with significant peripheral venous pooling.

An increasing body of experimental evidence also shows that brain death leads to activation of proinflammatory and immunoregulatory pathways [102–106]. In small animal brain-death models, messenger ribonucleic acid and protein expression within peripheral solid organs were significantly increased for cytokines (e.g., interleukin-1β, interleukin-6, tumor necrosis factor-α, interferon gamma, tumor growth factor-β), chemokines (e.g., RANTES), adhesion molecules (e.g., P- and E-selectin), and vasoconstrictors (e.g., endothelin) [102–106]. Importantly, brain death has also been associated with enhanced expression of immunoregulatory molecules such as major histocompatibility complex class I and II proteins [103]. Consistent with these findings, increased immunogenicity and accelerated rejection were noted in kidneys and hearts transplanted from brain-dead rodents [102].

Routine Care and Monitoring

Regular nursing care must be continued after brain death. Frequent turning to prevent decubitus ulcers, skin care, dressing changes, urinary and intravascular catheter care, and catheter site care must be meticulous to minimize the risk of infection. Other indwelling devices should be removed, if possible (e.g., ventriculostomies and ventriculoatrial or ventriculoperitoneal shunts, which may have been inserted in certain patients for monitoring or treating of elevated intracranial pressure). Any urinary and intravascular catheters that may have been inserted under suboptimal, emergent conditions without appropriate aseptic technique at the time of original injury should be replaced. A nasogastric tube should always be inserted for gastric decompression and prevention of aspiration.

Arterial lines should be inserted preferentially into peripheral arteries of the upper extremities because femoral arterial line readings can become inaccurate from surgical manipulation of the abdominal aorta during organ procurement. Similarly, central venous catheters should not be inserted through the femoral vein because dissection and manipulation of the interior vena cava occur during organ procurement. In addition, venous catheters inserted through the femoral vein can cause iliac vein thrombosis. This increases the risk of pulmonary embolization, particularly during surgical venous dissection. Thrombosis can also render the iliac veins unsuitable for use in vascular reconstruction, which may be necessary for some types of abdominal or thoracic organ transplants.

The following parameters must be determined routinely and frequently for all organ donors using various monitoring devices: core temperature (esophageal, rectal, or indwelling bladder catheter temperature probes), heart rate (continuous electrocardiographic monitoring), systemic blood pressure (arterial catheter), central venous blood pressure (subclavian or internal jugular central venous catheter), arterial oxygen saturation (pulse oximetry), and hourly urine output (Foley catheter). Use of a pulmonary artery catheter for measurement of pulmonary arterial and left ventricular wedge pressure and central venous oximetry is not routinely necessary; its use should be reserved for selected unstable donors whose volume status is uncertain or who exhibit persistent acidosis with evidence of tissue hypoperfusion. Laboratory parameters also must be checked regularly, including arterial blood gas, serum electrolytes, blood urea nitrogen, creatinine, lactate, and liver enzyme values; total bilirubin; and hemoglobin, hematocrit, platelet count, and coagulation tests. Testing is adapted to the individual clinical situation—frequent electrolyte determinations if diabetes insipidus has been diagnosed, lactate monitoring in acidotic donors, and repeated coagulation profiles in the presence of disseminated intravascular coagulation.

If infection is suspected, blood, urine, sputum, cerebrospinal fluid, and wound drainage cultures must be obtained. Routine surveillance cultures (usually blood and urine cultures) may be required, depending on the protocol of the local OPO and the organ type. Blood cultures should be obtained using peripheral venipuncture, rather than arterial or central venous catheters, to avoid contamination. Prophylactic antibiotics only should be administered immediately before the retrieval procedure. Any source of infection should be identified, characterized from a microbiologic standpoint, and treated.

General Management Goals

The most important overall goal in the management of brain-dead multiple-organ donors is to optimize organ perfusion and tissue oxygen delivery. Organ viability and function after transplantation are closely correlated with adequacy of resuscitation

TABLE 185.8

MANAGEMENT OF THE DECEASED ORGAN DONOR: SELECTED EVIDENCE PUBLISHED 1993–2009[a]

Study design	Study	Outcome	No. of cases	Level of evidence	Reference
Effect of standardized medical and institutional donor management protocols and pathways					
Individual case control study	Effect of critical donor pathway (including hormonal resuscitation protocol component)	Significant increase of organs procured, organ quality unchanged	270	3b	[15]
Case series	Aggressive hemodynamic monitoring, intervention, and hormonal resuscitation in marginal donors	High organ recovery rates from marginal donors	52	4	[17]
Individual case control study	Impact of hospital-based OPO coordinators on conversion rates	Higher donor conversion rate in hospitals with hospital-based OPO coordinators	NA	4	[75]
Retrospective cohort study	Effect on intensive lung donor management protocol on organ yield	Increased lung yield in the intensive early donor management group	182	4	[23]
Effect of donor pretreatment—Single pharmacologic agents					
Retrospective cohort study	Effect of catecholamine administration to brain-dead donors on graft survival	Catecholamine use associated in dose-dependent manner with significantly better kidney graft survival	3,890	4	[108]
Retrospective cohort study	Effect of dopamine administration on quality of early graft function in the recipients	Lower recipient delayed graft function rates and faster creatinine decrease in the dopamine group	254	4	[107]
RCT	Effect of continuous low-dose dopamine infusion in stable donors with normal renal function on early recipient graft outcomes	Decreased posttransplant need for > 1 dialysis session; no effect on rejection and short-term graft survival	265	2b	[109]
Individual case control study	High-dose steroids and aggressive management for marginal lung donors	No graft survival differences for lungs from marginal vs. standard donors	194	3b	[154]
RCT	Effect of high-dose continuous steroid infusion in liver donors on posttransplant outcomes	Improved posttransplant clinical reperfusion parameters (liver enzymes, bilirubin) and less early liver rejection for grafts from the steroid group	100	2b	[153]
RCT	Effect of intensive lung donor management protocol + (steroids or T3 or [steroids + T3] or placebo) on prerecovery lung quality and lung yield	No effect of pharmacologic pre-recovery interventions on lung yield; significantly less extravascular lung water accumulation in steroid groups	60	2b	[23]
Retrospective cohort study	Effect of donor desmopressin use on pancreas graft thrombosis rates (UNOS recipient database)	Higher thrombosis rates in pancreas grafts from donors that had received desmopressin	2,804	4	[91]
Retrospective cohort study	Effect of use of individual drugs on organ yield (UNOS donor database)	Favorable impact of steroids or desmopressin, but not T4, on organ yield	15,601	4	[123]
RCT	Effect of low-dose vasopressin vs. saline on donor hemodynamics and inotrope use	Increase in blood pressure and decrease in inotrope use in vasopressin group	24	2b	[110]
RCT	Effect of T3 infusion (limited to the duration of the organ procurement operation) vs. no T3	No differences for posttransplant liver graft function	25	2b	[124]
RCT	Effect of T3 infusion (within > 5 h of organ recovery) vs. none on donor hemodynamics and adenine nucleotide concentration measured in graft biopsy tissue	No differences in hemodynamics and adenine nucleotide levels	52	2b	[145]
Effect of donor pretreatment—Combination hormonal replacement therapy					
Retrospective cohort study	Requirements for adrenergic support of donors receiving thyroxin + steroids + insulin vs. steroids only vs. no hormonal therapy	Less adrenergic support required in donors receiving thyroxin + insulin + steroids	119	4	[127]
Individual case control study	Effect of T3 + steroids + insulin on need for inotropic support and organ yield in unstable donors	Hormonal treatment improved hemodynamics of unstable donors and resulted in similar organ yield as in stable donors	47	4	[127]

(*continued*)

TABLE 185.8

CONTINUED

Study design	Study	Outcome	No. of cases	Level of evidence	Reference
Retrospective cohort study	Impact on organ yield of (T3 or thyroxin) + steroids + vasopressin vs. none	Increased kidney, liver, pancreas, heart, and lung yield rates in donors that received hormonal replacement therapy	10,292	4	[20]
Retrospective cohort study	Impact of (T3 or thyroxin) + steroids + vasopressin vs. all other (> 3 hormones) hormonal replacement regimens on heart yield and early heart graft function	Increased number of transplanted hearts and improved early heart graft function	4,543	4	[19]
RCT	Effect of intensive lung donor management protocol and (steroids or T3 or [steroids + T3] or placebo) on lung quality and yield	No effect of steroids + T3 on donor lung quality and yield	60	2b	[23]
Retrospective cohort study	Effect of steroids + T4 on organ yield (UNOS donor database)	No effect of steroids + T4 on organ yield	15,601	4	[123]

[a]Levels of evidence (range: 1A [highest]—5[lowest]) were assigned based on current guidelines published by the Oxford Centre for Evidence Based Medicine (www.cebm.net).

and hemodynamic stability during the organ donor maintenance phase.

The events associated with the cause of brain death (e.g., hemorrhagic shock, cardiac arrest) can lead to significant physiologic abnormalities. Head injury preceding brain death is known to induce a hypermetabolic response, equivalent to that observed after a second- or third-degree burn involving approximately 40% of the total body surface area. Significant metabolic stress and impairment of organ perfusion occur during brain herniation, and both events are related to excessive catecholamine release. Any additional circulatory compromise in the time period afterward potentiates the deleterious consequences of these previous adverse events. Posttransplant organ function can be negatively affected by such episodes of cardiovascular dysregulation, particularly in such ischemia-sensitive organs as the heart and liver. For example, even with optimal heart donor management the recipient often needs inotropic support and may exhibit subendocardial myocyte necrosis on biopsy specimens obtained during the early posttransplant period [18,102]. Anticipating these changes associated with brain death and providing optimal management should they occur during the organ donor maintenance phase, as well as optimizing organ function, are of utmost importance [18].

Parameters associated with adequate tissue perfusion in stable donors in the absence of lactic acidosis are listed in Table 185.7. They include systolic blood pressure of 100 to 120 mm Hg, central venous pressure of 8 to 10 mm Hg, oxygen saturation of the arterial blood greater than or equal to 95%, core temperature greater than or equal to 35°C, and hematocrit of 30% to 35% [15,25], the latter balancing the slightly decreased oxygen transport capacity of the red blood cell mass with the beneficial effects of low viscosity on blood flow. Maintaining adequate hemoglobin concentration is also essential in preparation for organ recovery, in which hemodynamic stability throughout the operation is crucial, especially if blood loss occurs.

The use of vasopressors should be minimized if at all possible because of their splanchnic vasoconstrictive effects. Efforts to elevate blood pressure beyond the normal range can adversely affect outcome and should be avoided: High doses of vasopressors can cause arrhythmias and increase myocardial oxygen consumption, and pulmonary edema after excessive fluid administration can render lungs unsuitable for transplantation. After the lung, the pancreas is the organ most prone to tissue edema. Normal central venous pressure and low positive end-expiratory pressure (PEEP) help maintain an adequate perfusion gradient across the hepatic microcirculatory bed (i.e., that between the portal vein and hepatic artery on one side and the inferior vena cava and right atrium on the other).

Selective use of pulmonary artery catheterization must be considered in donors who do not respond to routine management and continue to exhibit hypotension or persistent lactic acidosis after adequate volume loading, particularly in those in whom this occurs despite use of moderate doses of dopamine. Determining pulmonary artery and capillary wedge pressures, cardiac output and index, pulmonary and systemic vascular resistive indices, oxygen availability and consumption, and other parameters helps to differentiate the cause of instability. Appropriate therapy can then be administered (e.g., fluid balance correction or PEEP adjustments, additional inotropic support, preload or afterload reduction). Once the hemodynamic instability has resolved, pulmonary artery catheters should be removed promptly to eliminate the inherent risks of infection, induction of arrhythmias, and mechanical endomyocardial damage.

A potential management conflict exists when the lungs are to be procured in combination with other organs from the same donor. Maintaining a central venous pressure of 8 to 10 mm Hg usually represents an acceptable compromise between the need for sufficient hydration to maintain adequate perfusion and good diuresis versus the dangers of provoking pulmonary edema in potential lung donors. Overall, optimizing hemodynamic parameters is paramount during the donor maintenance phase. Hypotension must be treated aggressively by proper fluid management, while minimizing the use of vasopressors. Hypertensive crises and tachyarrhythmic episodes require prompt intervention. PEEP that exceeds 5 cm H_2O should be used with caution, because hypotension may ensue.

Cardiovascular Support

Hypotension is the most common hemodynamic abnormality seen in brain-dead organ donors. The usual cause is hypovolemia, due to a combination of vasomotor collapse after brain death and the effects of treatment protocols to decrease intracranial pressure, which require minimizing hydration and use of osmotic diuretics (Tables 185.9 and 185.10). After brain death is declared, adequate volume resuscitation of the donor can require several liters of fluid. Until a euvolemic state is achieved, dopamine (greater than 3 µg per kg per minute) can be used temporarily; the dose should be titrated to maintain an adequate systolic blood pressure [15,25]. Infusion rates greater than 10 µg per kg per minute have been associated with increased rates of acute tubular necrosis and decreased renal allograft survival. High infusion rates also lead to decreased perfusion of other organs due to splanchnic vasoconstriction.

Dopamine is also the drug of choice if hemodynamic instability persists after fluid resuscitation and adequate volume loading. Use of isoproterenol and dobutamine should be avoided in this context because of their vasodilatory effects. Drugs with α-adrenergic agonist effects such as phenylephrine (IV infusion 0.15 to 0.75 µg per kg per minute) should be added only if hypotension persists in the face of euvolemia and titration of the dopamine infusion up to 15 µg per kg per minute. α-adrenergic agonists can cause severe peripheral vasoconstriction and reduce renal and hepatic perfusion; for this reason they must be used judiciously. Once these drugs are used, the need for their continued use must be frequently reassessed. Similar considerations apply to the use of epinephrine and norepinephrine (IV infusion up to 0.05 µg per kg per minute) [25]. For the majority (> 80%) of donors, adequate hemodynamic goals can be achieved with volume resuscitation and low-to-moderate doses of a single vasopressor agent (dopamine). Interestingly, recent studies have suggested a beneficial impact on early graft function and on graft survival of administration of catecholamines, and in particular of dopamine, to brain-dead patients [107–109]. Several potential mechanisms have been invoked to explain these observations, including a favorable modulatory effect on ischemia-reperfusion and on the upregulation of adhesion molecules that results from the inflammatory state induced by brain death [107–109]. Low-dose arginine vasopressin can serve as an additional or alternative vasopressor. It enhances vascular sensitivity to catecholamines, and may thus allow minimizing their dose and side effects [110–112]. Effective arginine vasopressin doses for improving hemodynamic stability range from 0.01 to 0.1 units per minutes, given as continuous intravenous infusion [111,112].

Measurement of urine output alone as a means of assessing adequacy of fluid resuscitation is notoriously unreliable in brain-dead donors. The presence of a systolic blood pressure between 100 and 120 mm Hg, a central venous pressure between 8 and 10 mm Hg, and the absence of metabolic acidosis (with or without infusion of a small amount of dopamine) with concurrent adequate urine output (at least 1 to 2 mL per kg per hour) are usually better indirect indicators of donor stability and sufficient oxygen delivery to organs and tissues. It is important to remember, however, that the use of vasoconstrictor or inotropic agents does not serve to replace adequate fluid resuscitation. Thus, proper fluid management remains the cornerstone of successful donor management.

When attempting to determine the etiology of hypotension in an organ donor, underlying cardiac disease (e.g., coronary artery disease, valve defects) and factors related to the cause of brain death (e.g., myocardial infarction, cardiac tamponade, or myocardial contusion) must be included in the differential diagnosis. Electrolyte abnormalities such as hypophosphatemia, hypocalcemia, hypokalemia, and hypomagnesemia are common in brain-dead organ donors. The presence of these entities must also be considered when hemodynamic instability is encountered, and frequent testing and correction of these significant electrolyte imbalances are important. Hypophosphatemia and hypocalcemia can decrease myocardial contractility and provoke hypotension [113]; hypokalemia and hypomagnesemia can impair hemodynamics by causing arrhythmias.

As a general rule, medications that possess rapid reversibility and a short half-life should be chosen to treat arrhythmias or hypertension. Hemodynamic instability can be pronounced after brain death, with wide swings between the extremes of hypotension and hypertension, rendering the brain-dead donor more susceptible to cardiovascular drug effects. Hypertension

TABLE 185.9

DIFFERENTIAL DIAGNOSIS OF HYPOTENSION IN THE BRAIN-DEAD ORGAN DONOR

Diagnosis	Common underlying cause(s)
Hypovolemia	See Table 185.10
Hypothermia	Loss of central temperature control, administration of room-temperature intravenous fluids and blood products, heat loss during laparotomies and thoracotomies
Cardiac dysfunction	Arrhythmia (ischemia, catecholamines, hypokalemia, hypomagnesemia) Acidosis Hypo-oxygenation Excessive positive end-expiratory ventilatory pressure Congestive heart failure due to excessive fluid administration Hypophosphatemia Causes related to the injury leading to brain death (cardiac tamponade, myocardial contusion) Myocardial sequelae of autonomic storm Preexisting cardiac disease
Drug side effect or overdose	Long-acting beta-blocker, calcium channel antagonist, antihypertensive agent
Hypocalcemia	Transfusions, hypomagnesemia (e.g., secondary to osmotic diuresis), acute renal failure

TABLE 185.10

DIFFERENTIAL DIAGNOSIS OF HYPOVOLEMIA IN THE BRAIN-DEAD ORGAN DONOR

Arterial and venous vasomotor collapse due to loss of central neurohumoral control
Dehydration (fluid restriction to treat head injury)
Insufficient resuscitation after the injury leading to brain death (e.g., ongoing hemorrhagic shock with coagulopathy after polytrauma)
Polyuria
Osmotic diuresis (mannitol, hyperglycemia)
Diabetes insipidus
Hypothermia
Administration of other diuretics
Massive third spacing in response to the original injury
Decreased intravascular oncotic pressure after excessive resuscitation with crystalloid fluids

can be treated with short-acting vasodilatory agents (e.g., nitroprusside) or a rapidly reversible β-adrenergic antagonist (e.g., esmolol hydrochloride), because hypertension usually is associated with increased circulating catecholamines. Other drugs, such as calcium channel blockers (e.g., verapamil, nifedipine) or longer-acting beta-blockers (e.g., labetalol, propranolol), should be avoided because of their negative inotropic effects and the inability to titrate them precisely. Bradyarrhythmias during the early phase of brain herniation are part of Cushing's reflex and do not usually require any treatment, unless they are associated with hypotension and asystole. Because of the lack of chronotropic effects by atropine after brain death, use of either isoproterenol or epinephrine is required to treat hemodynamically significant bradyarrhythmias.

Tachyarrhythmias are associated with the increased catecholamine release that occurs during and immediately after brain herniation. Administration of short-acting beta-blockers (e.g., esmolol hydrochloride) serves not only to treat arrhythmias but also to mitigate hypertension during the autonomic storm. Use of additional short-acting IV antiarrhythmics (e.g., lidocaine) may become necessary if tachyarrhythmias do not resolve after beta-blocker therapy. Calcium channel blockers (e.g., verapamil) must be avoided under these circumstances because of their negative inotropic effects. Cardiac glycosides (e.g., digoxin) also should not be used because they can induce and potentiate bradyarrhythmias and tachyarrhythmias, and they also have splanchnic vasoconstrictive side effects.

Cardiac arrest occurs in up to 25% of all donors during the maintenance phase after brain death and should be treated by routine measures, with the exception that isoproterenol or epinephrine must be substituted for atropine [84,86]. No intracardiac injections should be given during cardiopulmonary resuscitation because they can render the heart unsuitable for transplantation.

Respiratory and Acid–Base Maintenance

Use of endotracheal suctioning should be minimized during the treatment of cerebral edema to avoid any unnecessary stimulation that would increase intracranial pressure. In contrast, after brain death is declared, vigorous tracheobronchial toilet is important, with frequent suctioning using sterile precautions. Percussion and turning for postural drainage are instituted as well. Even if the lungs are unsuitable for donation, it is important to minimize the risk of atelectasis and infection. Preventing atelectasis facilitates oxygenation and may obviate the need for detrimental high levels of PEEP. Steroids administered to some patients as part of the treatment for increased intracranial pressure predispose to pulmonary infectious complications. The presence of pneumonia can preclude donation of the lungs as well as other organs, depending on its severity and association with systemic sepsis. Routine respiratory care of all donors also includes the use of 5 cm H_2O PEEP to increase alveolar recruitment and prevent microatelectasis [15,25].

In potential lung donors the endotracheal tube should not be advanced more than several centimeters into the trachea, to prevent damage to areas that may become part of an anastomosis. A sample of sputum should be obtained for Gram's stain and cultures to exclude the presence of infection. The samples can be obtained using bronchoscopy, a procedure that is often routinely performed before lung donation. Peak end inspiratory airway pressures should be less than 30 cm H_2O. Traditionally, tidal volumes of 10 to 12 mL per kg have been recommended. However, it is not clear at present to what extent the evidence supporting lung protective strategies for many regular ICU patients—that is, tidal volumes of 6 to 8 mL per kg—also applies to the management of the often injured lungs of brain-dead donors as well [25,114,115]. For now, though, it appears prudent to apply pulmonary management principles that have proven beneficial for general ICU patients also to potential organ donors. For potential lung donors, the lowest FIO_2 that is capable of maintaining a PaO_2 of greater than 100 mm Hg should be selected. If oxygenation is insufficient, PEEP should be increased rather than increasing the FIO_2. High levels of PEEP negatively affect cardiac output, which should be carefully monitored in this setting. If hypotension occurs, PEEP should be reduced. Under these circumstances, use of pulmonary artery catheterization generally should be considered to balance PEEP requirements against those of organ perfusion. In contrast, to correct insufficient arterial oxygenation in non–lung donors, an increase in FIO_2 is preferred over high levels of PEEP [25].

The etiology of pulmonary edema in organ donors can be cardiogenic, neurogenic, aspiration induced, a result of trauma or fluid overload, or a combination of these factors. Neurogenic pulmonary edema usually precludes lung or combined heart–lung donation, but not donation of other organs (e.g., heart, kidney, liver, and pancreas). The treatment for pulmonary edema is supportive and should be directed at maintaining adequate arterial oxygenation without using high levels of PEEP. Fluids must be administered carefully to maintain organ perfusion while avoiding exacerbation of the edema. Excessive use of crystalloid fluids during the initial resuscitation after brain death is declared can render the lungs unsuitable for transplantation. If large amounts of fluid are required, colloids (e.g., albumin solutions) or blood transfusions (if the hemoglobin is less than 8 g per dL) should be considered in addition to the infusion of crystalloid solutions [15].

Respiratory alkalosis can develop in brain-dead organ donors secondary to mechanical hyperventilation as part of the treatment protocol for elevated intracranial pressure. After brain death, the arterial pH should be adjusted to normal values because alkalosis has many undesirable side effects, such as increased cardiac output, systemic vasoconstriction, bronchospasm, and a shift to the left of the oxyhemoglobin dissociation curve [15]. The latter decreases oxygen unloading in the tissues and impairs oxygen delivery, thereby diminishing tissue oxygenation and metabolism. Lactic metabolic acidosis is frequent in brain-dead donors; it should be treated by compensation with a slight respiratory alkalosis until the underlying abnormality has been corrected (e.g., dehydration, tissue ischemia). Administration of sodium bicarbonate should be contemplated only if the increased minute ventilation necessary to induce respiratory alkalosis leads to a decrease in cardiac output. In either situation, the most important aspect of managing metabolic acidosis is to treat the underlying cause. In rare cases, this may require pulmonary artery catheterization to assess the adequacy of hydration, cardiac output, and tissue oxygen delivery.

Renal Function and Fluid and Electrolyte Management

Maintaining adequate systemic perfusion pressure and brisk urine output (greater than 1 to 2 mL per kg per hour), while minimizing the use of vasopressors, contributes to good renal allograft function and reduces the rate of acute tubular necrosis after transplantation. If the urine production is still insufficient (e.g., less than 0.5 mL per kg per hour) after adequate volume loading, loop diuretics (furosemide, ethacrynic acid, bumetanide) or osmotic diuretics (mannitol) can be considered to initiate diuresis. Nephrotoxic drugs (e.g., aminoglycosides) and agents that may exert adverse effects on renal perfusion (e.g., nonsteroidal anti-inflammatory drugs) are contraindicated. Cephalosporins, monobactams, carbapenems,

and quinolones are examples of less nephrotoxic but effective antibiotics that can be used if infection occurs.

Polyuria in brain-dead donors is a frequent finding. It can be due to diabetes insipidus, osmotic diuresis (induced by mannitol administered to decrease elevated intracranial pressures or hyperglycemia), physiologic diuresis due to previous massive fluid administration during resuscitation after the original injury with return of third-space fluid into the intravascular space, or hypothermia. Diabetes insipidus often heralds brain death in head-injured patients. It is the most frequent cause of polyuria during the organ donor maintenance phase. Found in up to 80% of all brain-dead bodies [82], it is related to insufficient blood levels of antidiuretic hormone (vasopressin), resulting in the production of large quantities of dilute urine. Diabetes insipidus should be suspected when urine volumes exceed 300 mL per hour (or 7 mL per kg per hour) in conjunction with hypernatremia (serum sodium greater than 150 mEq per dL), elevated serum osmolality (greater than 310 mOsm per L), and a low urinary sodium concentration. In addition to hypernatremia, other electrolyte abnormalities frequently observed during diabetes insipidus include hypokalemia, hypocalcemia, and hypomagnesemia. The appropriate replacement of these electrolyte losses can be guided by urinary electrolyte determinations, which easily allow calculation of the amount of the electrolyte to be replaced. Because diabetes insipidus is so common, mannitol administration should be discontinued after brain death is declared. Other supportive care of patients with diabetes insipidus includes replacing urine output milliliter for milliliter with free water (e.g., 5% solution of dextrose in water IV). Once urine output due to diabetes insipidus exceeds 300 mL per hour, desmopressin (desamino-8-d-arginine vasopressin), a synthetic analog of vasopressin, or arginine vasopressin, should be administered. Desmopressin has a long duration of action (6 to 20 hours) and a high antidiuretic–pressor ratio, avoiding any undesirable splanchnic vasoconstrictive effects that can occur with administration of normal- and high-dose arginine vasopressin [25,110,116]. For example, doses of 1 to 2 µg desmopressin are administered intravenously every 8 to 12 hours to achieve a urine output less than 300 mL per hour [116]. Desmopressin can also be effectively administered subcutaneously, intramuscularly, and intranasally. Vasopressin IV infusion can be started at 0.5 units per hour and titrated up to 6 units per hour, targeting a urine output of 0.5 to 3 mL per kg per hour and a serum sodium of 135 to 145 mEq per L [25,110]. Compared to desmopressin, arginine vasopressin is easier titrated and adds beneficial hemodynamic effects.

During the initial resuscitation phase after brain death is declared, infusion solutions with low sodium content should be used. Subsequently, maintenance fluid should consist of 5% dextrose in 0.45% sodium chloride with 20 mEq potassium added to each liter, administered at a rate of 2 mL per kg per hour during the maintenance phase if urine output is adequate (greater than 1 to 2 mL per kg per hour). If the urine output is greater than 2 mL per kg per hour, IV fluids should be administered at a rate equal to the urine output during the previous hour (IV intake = urine output). If the serum sodium concentration exceeds 150 mEq per dL, the maintenance fluid should consist of 5% dextrose solution with 20 mEq potassium added to each liter. Should the hourly fluid administration rate exceed 500 mL per hour, the dextrose concentration of the maintenance fluid should be decreased to 1% to avoid excessive hyperglycemia. IV maintenance fluids administered to brain-dead organ donors must always contain glucose, which is important to maintain intrahepatic glycogen stores that appear to be associated with normal liver allograft function in the early posttransplant period. The sodium content of certain IV fluids and plasma expanders (e.g., albumin solutions) also must be taken into consideration in hypernatremic patients.

The use of blood transfusions and other blood products should be minimized in organ donors, as in other patients. If transfusion or blood component therapy is necessary, CMV-seronegative blood products or leukocyte filters, or both, should be used whenever possible [15]. All blood must be screened for HIV, HBV, and HCV, and seropositive units should not be used.

Endocrine Therapy

According to previous studies, pituitary hormone blood levels do not uniformly decrease after brain death. Diabetes insipidus develops in approximately 80% of brain-dead donors as a result of low or absent blood levels of vasopressin [82]. These findings are a direct consequence of brain death, which abolishes vasopressin production in the hypothalamic nuclei (supraoptic and paraventricular nuclei) and vasopressin storage and release in the posterior pituitary. In contrast, near normal levels of anterior pituitary hormones, such as thyroid-stimulating hormone, adrenocorticotropic hormone, and growth hormone, have been documented after brain death in some studies [117–120]. Their persistence is probably due to the preservation of small subcapsular areas in the anterior pituitary, the blood supply of which is derived from small branches of the inferior hypophyseal artery. The latter arises from the extradural internal carotid artery, which is relatively protected from increases in intracranial pressure [121]. Recent clinical evidence, however, suggests deficient adrenal cortisol secretion after dynamic stimulation in brain-dead donors, irrespective of the level of pituitary dysfunction [122].

The principle of pharmacologic replacement therapy for deficient posterior pituitary vasopressin after brain death is well established [15,25,110,111,116]. A UNOS database analysis demonstrated a significant association between desmopressin use in donors and organ yield (Table 185.8) [123]. Low-dose vasopressin has been shown to exert beneficial hemodynamic effect in brain-dead donors (Table 185.8) [110,111]. In contrast, controversy still exists regarding the benefits of supplementation with hormones synthesized by organs under anterior pituitary control (i.e., triiodothyronine [T3], thyroxine [T4], and corticosteroids) (Table 185.8) [15,19,20,21,25,123–133]. Initially, the presence of low T3 blood levels was demonstrated after brain death in animal experiments [134]. Administration of exogenous T3 to donor animals improved a variety of metabolic parameters before and after organ preservation [135–137], as well as organ function after transplantation [138]. These findings suggested possibly positive effects of T3 also in human donors. A limited number of uncontrolled clinical trials suggested favorable influences of donor pretreatment with thyroid hormone on hemodynamic and metabolic parameters during the donor maintenance phase [86,139,140] and on outcome after heart transplantation [141–143]. But a number of other investigators failed to observe a significant benefit of thyroid hormone administration on biochemical and hemodynamic donor parameters and on posttransplant outcomes (Table 185.8) [23,123,124,132,144–146].

The latter outcomes could be explained at least in part by the findings of some studies which have suggested that the low T3 levels in human donors do not correlate with the presence of hemodynamic stability [147,148] or outcome after transplantation [149–152] to begin with. The typical thyroidal hormonal pattern after brain death consists of decreased T3, normal or decreased thyroxine, and normal thyroid-stimulating hormone. This pattern is not consistent with acute insufficiency of the hypothalamic–pituitary–thyroid axis or clinically overt hypothyroidism, but is similar to changes observed in other groups of critically ill individuals [130]. Thyroid hormone administration to such patients may not only be ineffective but

may theoretically even be detrimental in some cases [130,131]. In summary, there is no conclusive evidence to date that supplementation of organ donors with thyroid hormone *alone* yields a significant clinical benefit.

By contrast, evidence for the potential benefits of routine administration of corticosteroids *alone* is emerging [23,123,153,154]. Normal human serum adrenocorticotropic hormone and cortisol levels have been demonstrated after brain death in some studies [117–120], while others have observed dysfunction of the hypothalamic–pituitary–adrenal axis in patients with traumatic brain injury [119]. Clinically, however, administration of high-dose steroids was noted to stabilize and improve lung function, leading to higher probability of lung recovery from brain-dead patients that had previously not been considered for lung donation, to increase organ yield and to lead to improved outcomes after liver transplantation [15,123,153–156].

Published retrospective evidence suggests that institution of empiric donor management protocols that incorporate *combination* treatment with arginine vasopressin, high-dose corticosteroids, thyroid hormone, and insulin may stabilize and improve cardiac function in brain-dead donors and may result in increased probability of kidney, heart, liver, lung, and pancreas recovery and transplantation and may improve posttransplant outcomes (Table 185.8) [17,19–20,126–129]. These and other findings have served as the basis for recommendations from a national U.S. consensus conference held in 2001 that include: T3: 4 µg bolus, 3 µg per hour continuous infusion; arginine vasopressin: 1 unit bolus, 0.5 to 4.0 units per hour continuous infusion (titrate SVR to 800 to 1,200 using a PA catheter); methylprednisolone 15 mg per kg intravenous bolus, repeat every 24 hours; and insulin continuous intravenous infusion at a minimum rate of 1 unit per hour (titrate blood glucose to 120 to 180 mg per dL) [16,18]. However, given the uncertainty regarding potentially adverse side effects and the absence of high-level evidence, large prospective randomized trials are necessary before routine administration of hormonal combination therapy can be recommended for all donors—particularly because, for example, excellent lung procurement rates from marginal donors and good posttransplant outcomes have also been described in the current era without hormonal supplementation (Table 185.8) [157]. Moreover, the optimal dose and combination, and the contribution of each individual hormone to the observed overall outcome remain yet to be studied and elucidated. The above-mentioned findings have stimulated national prospective multicenter trials that investigate the optimal timing and outcome of combination hormone replacement therapy. Although these trials are ongoing, it appears prudent to reserve routine *combination* hormone replacement therapy for hemodynamically unstable donors that require substantial catecholamine doses (e.g., dopamine > 10 µg per kg per min) or have an ejection fraction of less than 45% [16,18,25].

Although brain death is not associated with primary pancreatic endocrine dysfunction, hyperglycemia is frequent in brain-dead donors. Hyperglycemia can be caused by increased catecholamine release, altered carbohydrate metabolism, steroid administration for treatment of cerebral edema, infusion of large amounts of dextrose-containing IV fluids, or peripheral insulin resistance. Treating hyperglycemia in brain-dead donors appears to be important with regard to pancreatic islet cell function. Experimental evidence suggests that high glucose levels may produce transient or irreversible damage to beta cells in the pancreatic islets, in vitro and in vivo [158,159]. This glucose toxicity was attenuated during in vivo experiments by correcting hyperglycemia [160]. Clinical studies in pancreas transplant recipients have demonstrated that donor hyperglycemia is a risk factor for decreased graft survival [90]. It was not established in these studies, however, whether donor hyperglycemia was indicative of marginal or insufficient beta-cell mass or whether impaired pancreatic graft function was related to islet cell dysfunction as a result of hyperglycemia.

Hyperglycemia in and of itself is known to cause insulin resistance [161]. Studies in brain-dead donors have suggested that a state of hyperinsulinemia coupled with peripheral insulin resistance exists, as evidenced by elevated C-peptide–glucose molar ratios [162]. For all the above reasons, it is prudent to maintain blood glucose levels in donors between 120 and 180 mg per dL [163]. Insulin should be administered as needed according to the blood glucose values to mitigate any potential adverse effects of hyperglycemia on pancreatic islets, which could impair glucose homeostasis after transplantation [163]. If hyperglycemia persists despite initial bolus insulin therapy, continuous IV insulin infusion should be instituted to facilitate titration of glucose levels. As in many other critical care patients, good glycemic control is also good standard practice for brain-dead donors, since it acts to prevent ketoacidosis and osmotic diuresis, both of which can be significant problems in the management of brain-dead donors, and since it may contribute to improved overall organ recovery and transplantation rates [164].

Hypothermia

After brain death, the body becomes poikilothermic because of the loss of thalamic and hypothalamic central temperature control mechanisms, and hypothermia usually ensues [165]. Systemic vasodilation causes additional heat loss. Hypothermia can be aggravated by administering room-temperature IV fluids and cold blood products. Adverse effects of hypothermia include decreased myocardial contractility, hypotension, cardiac arrhythmias, cardiac arrest, hepatic and renal dysfunction, and acidosis and coagulopathy [166–168]. Therefore, donor core temperature must be maintained at or above 35°C. It is usually sufficient to use humidified, heated ventilator gases; warmed IV fluids and blood products; and warming blankets to achieve rewarming and to maintain an adequate body temperature. Rewarming with peritoneal dialysis or bladder irrigations generally should not be performed in organ donors.

Coagulation System

Coagulopathy and disseminated intravascular coagulation are common findings in brain-dead donors, particularly after head injuries. Pathologic activation of the coagulation cascade occurs when brain tissue, which is very rich in tissue thromboplastin, comes in contact with blood after trauma. Massive blood transfusions can produce dilutional thrombocytopenia, and subsequent ongoing hemorrhage, hypothermia, and acidosis are all able to trigger or further aggravate coagulopathy. Clinical findings can include pathologic bleeding, abnormal prothrombin time, thrombocytopenia, hypofibrinogenemia, and increased levels of fibrin/fibrinogen degradation products. Treatment of coagulopathy entails use of blood components such as platelets, fresh-frozen plasma, or cryoprecipitate and correction of the underlying pathophysiology (e.g., hypothermia, acidosis, surgical hemorrhage). ε-Aminocaproic acid should not be used because of its potential for inducing microvascular thrombosis, thereby rendering organs potentially unsuitable for transplantation.

Other Aspects

Brain death may also adversely affect the donor's nutritional status. Experimental studies have suggested a hypercatabolic state and decreased hepatic intracellular ATP levels [169].

Moreover, a suboptimal organ energy and redox status along with the inflammatory changes that result from the chemokine and cytokine release associated with brain death may exert a deleterious influence on the magnitude of, and recovery from, ischemia-reperfusion injury and on posttransplant organ function in the recipient. Appropriate nutritional support of the donor may be able to prevent depletion of micro- and macronutrients and may attenuate oxidative stress and ischemia-reperfusion injury. However, currently there is no clinical data available that would directly support routine nutritional supplementation of brain-dead donors [169].

Various pharmacologic donor pretreatment protocols to optimize donor and transplant outcomes have been reported. The clinically beneficial effects of administration of catecholamines, vasopressin (or its analogue desmopressin), and of steroids on both donor and posttransplant outcomes have already been discussed in detail above (Table 185.8) [23,107–109,123,153,154]. In other studies, verapamil mitigated the adverse impact of elevated cytosolic calcium levels on renal allograft function [170] after donor hemodynamic instability. Finally, donor pretreatment with immunosuppressants may have a favorable impact by preventing upregulation of proinflammatory pathways and increased expression of major histocompatibility complex molecules that have been demonstrated to occur after brain death [102,103,104]. The latter pretreatment modalities, however, must be investigated more extensively before they can be routinely applied.

Multiple-Organ Donor Operation

After consent is obtained, the OPO schedules and organizes the organ recovery operation. Often, several surgical teams from different locations participate; their transportation and the preparation of the recipients in the various hospitals must be meticulously coordinated. After certification of death according to the state laws occurs, the brain-dead donor is brought to the operating room. Full cardiovascular and ventilatory support is maintained throughout the operation, until the organs are flushed and cooled. The principles of brain-dead donor management should be reviewed with the anesthesiologist, unless he or she is familiar with the specific clinical aspects of cardiovascular and ventilatory support for brain-dead organ donors. Hemodynamic stability must be maintained during the surgical organ retrieval, which is the equivalent of a combined major abdominal and thoracic operation and can last up to several hours. Transient tachycardia and hypertension may occur while the surgical incision is being made; they most likely reflect spinal reflexes causing vasoconstrictive responses and adrenal stimulation. Subsequently, consideration must be given to the increased heat loss caused by the wide abdominal and thoracic incisions and the duration of the surgery. Vecuronium or pancuronium should be used to inhibit reflex muscular contractions [83]. Tubocurarine should not be used in brain-dead donors because of its association with hypotension as a consequence of histamine release and ganglionic blockade. Maintenance fluid administration throughout the operation must take into account the significant intraoperative fluid losses resulting from extensive dissection with evaporation and blood loss, transsection of lymphatic channels, and massive third-space fluid loss.

All organs to be recovered are completely mobilized, and their vascular pedicles are dissected free. At the end of the operation, systemic heparinization occurs and cannulas are inserted (depending on the organs to be procured) into the abdominal aorta, inferior vena cava, portal vein, aortic arch, and pulmonary artery. Only then is circulatory and respiratory support terminated. The organs are flushed in situ with preservation solution to remove blood and to cool the organs to a temperature of 4°C to 7°C. Simultaneously, topical external cooling is provided by the application of sterile ice slush. The organs are then individually removed, by dividing the remaining attachments and vascular pedicles, and then packaged [49]. Storage in preservation solution at 4°C to 7°C in a cooler surrounded by crushed ice allows maximal preservation times of 4 to 6 hours for heart and lungs, approximately 30 hours for livers and pancreata, and about 40 hours for kidneys. These preservation constraints are taken into consideration as organs are allocated. Critical care of the donor ends when controlled cardiac arrest occurs at the completion of the surgical organ recovery. This finality is ephemeral, however, because it results in the start of new lives for the recipients after a successful organ transplant.

PERIOPERATIVE CRITICAL CARE MANAGEMENT OF THE DONATION AFTER CARDIAC DEATH ORGAN DONOR

Preoperative Care of the Potential DCD Donor (Prior to Obtaining Consent for Organ Donation)

Therapy in those patients must remain primarily aimed at treating the underlying pathology (e.g., head trauma, cerebrovascular accident). Any premature (i.e., prior to the family having made the decision to withdraw care and prior to obtaining consent) change of therapeutic objectives would be unethical and may lead to lower consent rates, thereby further exacerbating the current donor organ shortage [26,28,98].

Preoperative Care of the Actual DCD Donor (After Having Obtained Consent for Organ Donation)

Once consent to proceed with organ donation has been obtained, the focus switches from cerebral protection to preservation of organ function and optimization of peripheral oxygen delivery [26,98]. Maintenance therapy endpoints in DCD donors are identical to those that apply for brain-dead organ donors (Table 185.7). Since DCD donors usually do not exhibit the same pathophysiologic characteristics as brain-dead donors, general management principles for DCD donors are more akin to those that apply to non-brain–dead patients in the ICU that are described elsewhere in this book. Organ-specific considerations (e.g., use of catecholamines) are the same as those described below for brain-dead donors.

Preterminal and Intraoperative Care of DCD Donors

Maintenance therapy as outlined above is continued until support is withdrawn and the patient is extubated (either in the ICU or in the operating room). Any additional premortem interventions (e.g., surgical: insertion of femoral cannulas in preparation of organ recovery; pharmacologic: administration of intravenous heparin, opioids, and phentolamine) must occur in strict accordance with local OPO/hospital DCD protocols and policies [26,98,171–174]. Death is then pronounced by a physician (usually the patient's intensive care physician) not belonging to the organ recovery and transplant team according

to criteria that are specified by the local OPO/hospital DCD protocol.

Next, after an additional 2-to-5-minute waiting time, surgical organ recovery begins [26,173,174]. For DCD donors, the use of a rapid procurement technique is mandatory in order to minimize warm ischemia time, particularly when highly ischemia-sensitive organs such as the liver, pancreas, or lungs are to be recovered as well [49].

Disposition of the patient, if death does not occur within a specified waiting time post withdrawal of support, is determined by the local protocol (e.g., return of patient to a nonintensive care hospital floor for comfort care only).

CHAPTER 186 ■ DIAGNOSIS AND MANAGEMENT OF REJECTION, INFECTION, AND MALIGNANCY IN TRANSPLANT RECIPIENTS

TUN JIE, DAVID L. DUNN AND RAINER W.G. GRUESSNER

Allograft rejection in transplant recipients is the side effect of the complex and intricate mammalian immune system, which is intended to defend the host against pathogens. The history of solid-organ transplantation has demonstrated that graft survival depends on manipulating the immune system. However, any modification of the host's defense mechanism can bring unwanted consequences, such as infection and malignancy. Throughout the development of solid-organ transplantation during the 1960s, it became clear that suppressing the immune system of the prospective host would be required for sustained graft function. In the infancy of this field, acute rejection (AR) and graft loss were the rule rather than the exception.

Subsequently, however, successful antirejection treatment and, more important, the ability to markedly reduce the incidence of rejection through preventive strategies allowed solid-organ transplantation to develop beyond its status as a sparingly performed investigational therapy. Specifically, successful allogeneic renal transplantation was achieved using a combination of a high-dose corticosteroid and azathioprine [1]. Contemporaneous observations of those early transplant recipients demonstrated that nonselective immunosuppressive therapy prolonged graft (and patient) survival yet led to an increased susceptibility to infection, often with unusual, opportunistic pathogens [2]. Furthermore, immunosuppressed transplant recipients also had an increased susceptibility to malignancy [3].

In the nearly 50 years since the report of the initial 12 recipients treated for rejection of allogeneic renal grafts, solid-organ transplantation has flourished beyond the expectations of any but the most wildly optimistic pioneers in the field. Kidney, liver, heart, and lung transplants are now standard-of-care therapies for end-stage renal, hepatic, cardiac, and pulmonary disease, respectively. Pancreas and pancreatic islet-cell transplants restore the beta-cell function in patients with diabetes mellitus. Even the small bowel has been successfully transplanted as a treatment for patients with short gut syndrome. Such strides have been made possible by the accumulated advances in organ procurement, preservation, surgical techniques, tissue typing, immunosuppressive therapy, and the use of antibacterial, antifungal, and antiviral agents for both prophylaxis and treatment of posttransplant infection. Table 186.1 lists some of the major advances in the management of rejection, infection, and malignancy in transplant recipients.

Yet even with the expanded immunosuppressive armamentarium of the twenty-first century, it remains difficult to adequately suppress the host immune system (to allow acceptance and even tolerance of the graft) without oversuppressing immune function (and thereby leaving the host vulnerable to opportunistic infection and malignancy). This chapter reviews the complications (namely, graft rejection, infection, and malignancy) of solid-organ transplantation on either side of that delicate balance. Special attention is directed toward opportunistic infections and unusual malignancies that occur in the immunosuppressed patient population.

REJECTION

Unlike the nonspecific innate immune system seen in all living organisms, the adaptive immune system—a unique property of jawed vertebrates—is an evolutionarily more advanced, efficient, "specific," and versatile host defense mechanism against invasion of pathogens. However, a side effect of the ability of the host immune system to recognize and attack "nonself" tissues is rejection of grafted tissues posttransplant. That side effect was observed clinically for centuries before Medawar demonstrated that it was an intrinsic property of the host immune system in response to foreign tissue [4]. The exogenous modulation of the host immune system to allow sustained graft function has proceeded along with—and often preceded—our understanding of the physiologic mechanism of rejection and tolerance.

Integral to our understanding of rejection is its immunologic basis. The immunologic disparity among members of the same species of mammals that leads to lack of recognition of "self" tissue and to rejection of nonself tissue is based on the differences in cell surface molecules that are expressed. In humans, these major histocompatibility antigens were first identified in leukocytes, and hence are termed *human leukocyte antigens* (HLAs). HLAs are subdivided into two classes: class I (HLA-A, -B, and -C), expressed on the surface of all nucleated cells, and class II (HLA-DR, -DQ, and -DP), expressed on the surface of *antigen-presenting cells* (APCs). The recognition of nonself tissue occurs via two distinct immunologic pathways: *direct* and *indirect allorecognition*. Direct allorecognition consists of recipient T-helper cells recognizing donor HLA disparity expressed on the donor cell surface. Indirect allorecognition consists of recipient APCs (generally thought to be activated macrophages, dendritic cells, and B lymphocytes) phagocytosing donor cellular debris, including HLAs, which are then processed and re-presented on the APC surface to be recognized by recipient T- helper cells (CD4+ lymphocytes).

In either pathway, costimulation signals between CD4+ T-helper lymphocytes and CD8+ cytotoxic T lymphocytes trigger a cascade of immunologic events. Interleukin (IL)-2, a crucial and early signal in immune activation, is secreted by activated CD4+ T-helper lymphocytes, engendering increased T-cell responsiveness, clonal expansion of alloreactive T lymphocytes, and acquisition of the cytolytic phenotype by host T lymphocytes. Direct allorecognition leads to a more immediate and vigorous immune response against foreign tissue, but, in both pathways, additional helper T lymphocytes are recruited and secrete a wide array of cytokines (e.g., IL-1, interferon-γ, tumor necrosis factor-α), facilitating the further recruitment of

TABLE 186.1

MAJOR ADVANCES IN MANAGEMENT OF REJECTION, INFECTION, AND MALIGNANCY IN TRANSPLANT RECIPIENTS

Topic	Major advances	Reference
Graft rejection	Desensitization protocols for patients with DSA	[6,32,33]
	Flow cytometry, Luminex-based cross-match	[7,8]
	Induction therapy and biologics reduce rejections	[10–16]
Fungal infection	Caspofungin and voriconazole	[99–102,104]
Viral infection	PCR for CMV and EBV detection	[114,115]
	Preemptive CMV therapy	[120–124,194]
	Liver transplants for patients with HBV or HCV	[137–142]
	Improved outcomes for recipients with HIV	[144–147]
Malignancy	Chemotherapy and rituximab beneficial for PTLD	[170,179,195]
	HHV-8 and posttransplant Kaposi sarcoma	[185–187]
	Liver transplant for patients with HCC	[191–193]

DSA, donor-specific antibody; PCR, polymerase chain reaction; CMV, cytomegalovirus; EBV, Epstein–Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; PTLD, posttransplant lymphoproliferative disease; HHV, human herpes virus; HCC, hepatocellular carcinoma.

cytotoxic T lymphocytes, natural killer cells, and B lymphocytes. Then, B lymphocytes begin to secrete antibody directed against the allogeneic tissue in ever-increasing quantities. Infiltration of the graft by such effector cells, the binding of antibody, and the activation of complement lead to rejection in its various forms (vide infra), which, if unchecked, results in graft loss (Fig. 186.1). Donor-recipient mismatches between HLAs may produce an immune response by either the direct or indirect pathways; however, minor non-HLA mismatches typically produce an immune response by the indirect pathway only.

Clinically, rejection is classified according to the temporal relation of graft dysfunction to the transplant operation and the histologic features seen in rejected tissue. The three main types of rejection are *hyperacute (HAR)*, *acute (AR)*, and *chronic (CR)*. Each type is mediated by a different host immune mechanism. Consequently, each type poses different problems for clinicians and researchers.

Hyperacute Rejection

HAR occurs within a few minutes to a few hours after the reperfusion of the graft posttransplant. Preformed antibodies directed against antigens presented by the graft mediate activation of complement, activation of endothelial cells, and formation of microvascular thrombi, leading to graft thrombosis and loss [5]. The process is irreversible; currently, no treatment is available. Because HAR is mediated by circulating preformed antibodies normally directed against ABO system (comprising the four main blood types, i.e., A, B, AB, and O) antigens or against major HLA antigens, thorough screening of potential transplant recipients should prevent nearly all HAR.

The panel-reactive antibody (PRA) assay is a screening test that examines the ability of serum from potential transplant recipients to lyse lymphocytes from a panel of HLA-typed donors. A numerical value, expressed as a percentage, indicates the likelihood of a positive cross-match to the donor population. Therefore, patients lacking preformed antibodies to random donor lymphocytes are defined as having a PRA of 0% and have a very low probability of eliciting a positive lymphocyte cross-match to any donor. The finding of a higher PRA identifies patients at high risk for a positive cross-match and thus for HAR and for subsequent graft loss. Most often, such patients were previously sensitized by childbirth, blood transfusions, or a prior transplant.

Pretransplant, cross-match testing is performed to identify preformed antibodies against class I HLAs (T-lymphocyte cross-match testing) and class II HLAs (B-lymphocyte cross-match testing). A strong positive class I-HLA cross-match immediately pretransplant is ordinarily an absolute contraindication to renal and pancreas transplants. At most centers, heart and liver transplants are performed without a cross-match, unless the recipient is highly sensitized or has previously received a graft possessing major antigens in common with the current donor (i.e., donor-specific antibody [DSA]). A positive B-lymphocyte crossmatch indicates preformed antibodies directed against class II HLAs and is a relative, but not absolute, contraindication to a transplant. Recent studies confirmed the

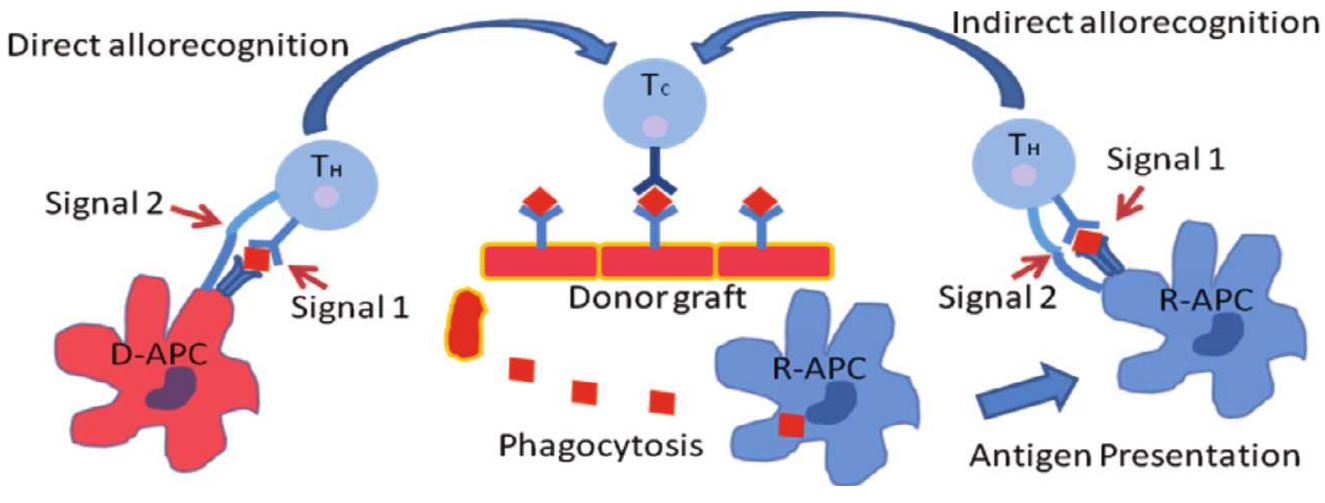

FIGURE 186.1. Direct, indirect pathways of allorecognition. Signal 1 is delivered through the T-cell receptor after engagement by a peptide–HLA complex. Signal 2, also known as costimulatory sign, is delivered by an array of cell-surface molecules on the T helper cell and the antigen-presenting cell (APC). D-APC, donor APC; R-APC, recipient APC; TH, T helper lymphocyte; Tc, cytotoxic T lymphocytes.

efficacy of plasmapheresis followed by administration of immune globulin to reduce PRA levels and to convert strongly positive crossmatch results to weakly positive or negative results, thereby allowing organs to be transplanted across what were previously considered as strong immunologic barriers [6].

Crossmatch testing is a vital tool to identify the presence of antibodies against potential donor antigens and to assess the risks of posttransplant rejection and subsequent graft loss. Ironically, cross-match testing methods are not standardized. Since the mid-1960s, cross-match testing was based on the complement-dependent cytotoxicity (CDC) assay. The CDC assay was further refined by adding a wash step and an antihuman globulin (AHG) step, to increase its sensitivity and specificity. Then, with the introduction of technology based on flow cytometry (FC), the presence of recipient antibody on the surface of donor lymphocytes could be detected independent of complement binding. The FC method further enhances the sensitivity of crossmatch and, since the late 1980s, has been adopted by an increasing number of transplant centers [7].

The latest development in anti-HLA antibody screening was the introduction of Luminex® technology, using HLA-coated fluorescent microbeads and FC. This method in theory pinpoints the DSAs in sera of recipients with high PRA levels. Since all transplant donors are HLA typed nowadays, a negative cross-match for recipients with high PRA levels can be ensured by avoiding the selection of donors carrying unacceptable antigens (virtual cross-match) [8].

The main concerns with these new developments in antibody typing and crossmatch testing are between-center test variability and the thresholds of defining false-negative results (results that could deny recipients with high PRA levels a chance for a potential lifesaving transplant). Currently, it is up to an individual transplant center to implement its own HLA typing and cross-match policy, depending on the center's experience and clinical outcomes.

Although screening has all but eliminated HAR as a clinical problem, active investigation is nonetheless directed at dissecting the underlying pathophysiologic mechanisms of HAR. Another research focus is on the similar rapid rejection of xenoreactive antigens that serve as a barrier to the development of xenotransplantation.

Acute Rejection

AR is the most common form of graft rejection in modern clinical transplantation. It may develop at any time, but is most frequent during the first several months posttransplant. Rarely, it occurs within the first several days posttransplant, a process termed *accelerated acute rejection* (AAR), most likely a combination of amnestic immune response driven by sensitized memory B lymphocytes and activation of the direct allorecognition pathway. Under such circumstances, the donor antigen exposure often occurred in the distant past, so the level of circulating DSAs would have been too low to be detected by conventional crossmatch techniques. Once challenged by the same donor antigens introduced by the organ transplant, dormant memory lymphocytes reactivate, replicate, and differentiate. Within several days, large numbers of antibodies are directed against the donor tissue and result in graft rejection.

Cellular rejection and antibody-mediated rejection (AMR) are not mutually exclusive in AR. Histologically, AR generates an infiltration of activated T lymphocytes into the graft, resulting in gradually progressive endothelial damage, microvascular thrombosis, and parenchymal necrosis. Pathologic grading schemes have been developed regarding the extent to which AR involves vascular damage, cellular infiltration, or a combination of both. Vascular AR is thought to be mediated by the presence of DSAs, albeit not in sufficient numbers to cause HAR. C4 d, a complement split product detected immunohistochemically in the capillaries of biopsied graft specimens, is highly correlated with AMR [9]. Without intervention, AR inevitably progresses to graft loss. The clinical presentation of AR varies markedly, depending on the specific organ, on the level of immunosuppression, and on the attendant reduction of inflammation in the affected tissues.

Unless the host immune system is suppressed pharmacologically, a transplant inevitably leads to AR. A combination of immunosuppressive agents is typically used chronically to prevent AR, including a lymphocyte antagonist (usually a calcineurin inhibitor [CNI] such as cyclosporine or tacrolimus) and an antiproliferative agent (such as azathioprine or mycophenolate mofetil), with or without corticosteroids. Antilymphocyte antibody therapy is often added during induction of immunosuppression or for treatment of "steroid-resistant" AR.

In the last decade, immunosuppression for transplant recipients has been undergoing a paradigm shift. Since the mid-1990s, the use of antibody induction in solid-organ transplant recipients has increased from 25% to more than 60% [10]. In particular, monoclonal antibodies such as basiliximab and daclizumab (both anti-CD25 [IL-2 receptor]) as well as alemtuzumab (Campath-1 H, anti-CD52) were proven to be effective induction agents in preventing AR in renal or pancreas transplantation [11–13]. Furthermore, strategies such as corticosteroid avoidance and CNI-reduced or CNI-free maintenance immunosuppression were shown to be equivalent to traditional triple-drug maintenance [14–16]. Nonetheless, all immunosuppressive agents carry some risk of toxicity and adverse reactions that may complicate therapy (Table 186.2).

Chronic Rejection

CR remains a common yet poorly understood clinical problem, with slightly different manifestations in each type of graft. Over time, the accumulation of microvascular injury in a graft degrades graft function, with eventual graft loss. This process appears to be mediated by multiple mechanisms, likely including both immune and nonimmune factors. Evidence for the contribution to CR of immune factors includes the observation that AR episodes significantly increase the likelihood of CR as well as the correlation, observed in renal transplant recipients, between a poor response to AR treatment and the subsequent development of CR [17]. A similar association between a poor response to AR treatment and the subsequent development of CR has been observed in liver transplant recipients, although reversible AR has little impact. Nonimmune factors likely also contribute to the development and progression of CR, including the toxic effects of immunosuppressive medication and cumulative injury from infection such as that caused by cytomegalovirus (CMV) [18] and polyomavirus [19]. CR nearly always eventuates in graft loss, although the rapidity of the process varies considerably.

Renal Grafts

Current reports indicate that about 10% to 25% of renal transplant recipients experience an episode of AR. Because most episodes are clinically silent, the diagnosis of AR must be considered in recipients whose serum creatinine, blood urea nitrogen, and urinary output values have normalized and whose graft function has been stable in the outpatient setting, but whose serum creatinine and blood urea nitrogen values subsequently rise while their urinary output decreases. The presence of hypovolemia, drug nephrotoxicity (e.g., high calcineurin levels), ureteral obstruction or leak, lymphocele, or vascular anastomotic complications should be excluded, and the diagnosis of

TABLE 186.2

IMMUNOSUPPRESSIVE MEDICATIONS, MECHANISMS OF ACTION, AND COMMON SIDE EFFECTS

Medications	Mechanisms of action	Side effects
Corticosteroids	Upregulate IκB Decrease IL-1, TNF-α, IFN-γ Exert anti-inflammatory effect	Cushing syndrome
Azathioprine	Act as an antimetabolite	Marrow suppression GI, liver toxicity
Mycophenolate mofetil	Specifically affect lymphocytes Act as an antimetabolite	Marrow suppression GI intolerance
Cyclosporine	Act as a calcineurin inhibitor Downregulates IL-2	Nephrotoxicity Neurologic symptoms
Tacrolimus (FK506)	Calcineurin inhibitor Downregulate IL-2, IFN-γ	Nephrotoxicity Neurotoxicity Diabetogenic
Sirolimus (rapamycin)	Block IL-2R, IL-4, IL-6, platelet-derived growth factor signaling	Impaired healing Hypertriglyceridemia
Antilymphocyte globulin	Act as a cytolytic antibody Block and deplete T cells	Leukopenia Thrombocytopenia "Serum sickness"
OKT3	Act as a cytolytic antibody Block T-cell receptor Deplete T cells	Cytokine release Aseptic meningitis
Daclizumab (or basiliximab)	Blocks IL-2R Inhibit T-cell activation	Minimal impact

GI, gastrointestinal; IFN, interferon; IL, interleukin; OKT3, ornithine–ketoacid transaminase-3.

AR should be established via histologic examination of a percutaneous graft biopsy specimen. Rarely, tenderness and swelling in the area of the graft occur, and occasionally fever or other signs of systemic inflammation, although such findings used to be common.

As discussed earlier, most AR episodes occur in the early posttransplant period. Among the subset of recipients who experience delayed graft function, up to 30% exhibit evidence of AR on biopsy [20]; 20% of recipients who require dialysis posttransplant have AR [21]. Intriguingly, up to 30% of recipients with well-functioning grafts also have AR, per early posttransplant protocol biopsies, but whether such findings are clinically important and whether mild episodes should invariably be treated remain controversial [22]. Recent studies have provided data that may allow prediction of individual risk of AR, with the potential for individualizing immunomodulatory therapy. For example, donor IL-6 genetic polymorphism is strongly associated with an increased incidence of AR posttransplant [23], and recipients with elevated levels of serum C-reactive protein (CRP), presumably indicative of systemic inflammation, have a higher rate of AR and a shorter time to AR than those with lower CRP levels [24]. Other biomarkers (such as soluble CD30, gene expression assays on peripheral blood samples, urinary proteomics, and T-lymphocyte subset analysis) were shown to be predictive for rejection or transplant tolerance, and are currently undergoing various clinical investigations [25].

The diagnostic workup for AR includes studies that may identify alternative causes of recipient graft dysfunction (Table 186.3). It is vital to consider alternative diagnoses, particularly in the early postoperative period, including vascular problems with the arterial or venous anastomoses, ureteral obstruction, or urinary leak. Other common causes of apparent graft dysfunction include the acute tubular necrosis associated with delayed graft function, hypovolemia and attendant prerenal azotemia, and the nephrotoxic effects of cyclosporine and tacrolimus. To rule out the vascular and ureteral problems discussed previously, a duplex ultrasound study of the renal graft is commonly obtained. Several ultrasound findings may suggest the diagnosis of AR: increased size of the graft, increased cortical thickness, enlargement of the renal pyramids, and decreased

TABLE 186.3

BASIC WORKUP OF RECIPIENTS WITH GRAFT DYSFUNCTION OR ACUTE REJECTION

History and physical examination	Establish and order differential diagnosis
Doppler ultrasound	Rule out vascular surgical complication Rule out leak (e.g., biliary, ureteral)
Serum chemistry	Evaluate relative blood urea nitrogen and creatinine, amylase, bilirubin Detect and treat electrolyte abnormalities
Drug levels	Evaluate for potential drug toxicity Detect inadequate drug levels
Blood cell count, cultures	Evaluate for potential infection
Graft biopsy	Firmly establish and grade graft rejection

graft renal artery blood flow [26]. The diagnosis of AR is clearly established by percutaneous allograft biopsy and histologic examination. Biopsy is generally safe when performed by experienced practitioners; however, complications include bleeding, hematoma and arteriovenous fistula formation, and ureteral or major vascular injury.

Rejection is graded according to a standardized histologic classification scheme, the modified Banff Criteria, which may be used to guide therapy [27]. Fine-needle aspiration biopsy has been used by some centers to establish the diagnosis of AR; however, some consider the loss of microstructural data, as compared with traditional core biopsy, to be a weakness of the technique. In particular, the diagnoses of acute vascular rejection and CR are difficult to make using fine-needle aspiration biopsy.

The treatment of AR in renal transplant recipients varies between centers. High-dose methylprednisolone (500 to 1,000 mg per day or every other day [2 to 3 doses] is common) is often the initial approach. Corticosteroid-resistant AR, or AR that is histologically graded as severe or vascular, is often treated with potent depleting antilymphocyte antibodies such as murine monoclonal IgG2a antibody (OKT3) or polyclonal antithymocyte globulin (antithymocyte gamma globulin, Thymoglobulin). Alemtuzumab was selectively used to treat AR in some centers [28]. Since some AR episodes occurred while the recipients were on stable immunosuppression, their maintenance therapy was switched from cyclosporine to tacrolimus or from azathioprine to mycophenolate mofetil. Most AR episodes are reversible with current therapies; however, as noted previously, the long-term outlook for preservation of graft function is lessened with each episode, especially when the posttreatment serum creatinine level does not return to the pre-AR baseline.

CR in renal transplant recipients is a persistent clinical problem and appears to be multifactorial, with immunologic and nonimmunologic factors driving the gradual loss of graft function. As described earlier, minimizing the frequency and severity of AR episodes is important in decreasing the likelihood of eventual CR. Nonimmunologic factors thought to contribute to CR include (a) episodes of infection, particularly due to CMV and BK virus (*vide infra*); (b) the nephrotoxicity of CNI therapy; (c) ischemia-reperfusion injury and delayed graft function in the peritransplant period; and (d) innate cell senescence within the graft [29]. Attention is being directed toward identifying inflammatory activity within the graft, in response to both immune and nonimmune insults that may contribute to the development of CR. One of the leading causes of kidney retransplants is CR. It remains a formidable problem that is still poorly understood.

Hepatic Grafts

The hepatic graft is considered to be immunologically "privileged" in that evidence of some degree of immune tolerance occurs in a substantial number of liver transplant recipients over time. Despite that observation, all forms of rejection can occur posttransplant. At one time, it was thought that HAR did not occur in the hepatic graft; this idea is now known to be incorrect, as anti-HLA antibody-mediated HAR has been described in liver transplant recipients [30,31]. Unlike the renal graft, the hepatic graft undergoes HAR over a number of days, not minutes to hours, probably secondary to its ability to absorb a large amount of antibody before the onset of the significant microthrombosis and vascular damage seen in HAR. A more delayed form of antibody-mediated rejection is seen in up to 33% of patients who undergo liver transplants across ABO-incompatible blood groups [32], but even this barrier appears surmountable with the use of plasmapheresis along with aggressive immunosuppression [33].

AR remains an important clinical problem in liver transplantation; even with the use of standard multiagent immunosuppression, the incidence of AR ranges from 30% to 80%. In two large, multicenter trials, double therapy with a CNI and steroids resulted in a 60% to 80% incidence of AR [34,35]. Triple therapy with Neoral® or Sandimmune®, along with azathioprine and prednisone, resulted in a 30% to 45% incidence of AR [36]. Substitution of mycophenolate mofetil for azathioprine further reduced the incidence of AR to 26% [37]. The latest liver transplant regimen, consisting of two doses of a monoclonal anti-IL2 receptor (basiliximab) as induction therapy and dual maintenance therapy with a CNI and mycophenolate mofetil, was shown to lessen the severity of rejection without increase the infection rate [38,39].

The diagnosis of AR in liver transplant recipients is normally suggested by elevated levels of transaminases, bilirubin, or alkaline phosphatase. Among patients with T-tube drainage (which is increasingly uncommon), the biliary drainage may be seen to thicken, darken, and decrease in amount. The suspicion of AR mandates graft biopsy and studies to eliminate other possible causes of early hepatic graft failure. Duplex ultrasonography and, in some cases, cholangiography are increasingly being replaced by magnetic resonance imaging. Biopsy findings are classified, according to a standardized set of criteria, as *mild*, *moderate*, and *severe*, with clear implications for prognosis [40]. AR is normally treated with high-dose corticosteroids, but 5% to 10% of cases are steroid-resistant; such recipients are then treated with an antilymphocyte antibody. Interestingly, in large population studies, the incidence of AR is associated with improved long-term patient survival rates [41], albeit thought to be due to the higher incidence of AR in younger, healthier recipients. Even adjusting for recipient characteristics, AR has not been clearly associated with either decreased graft or patient survival rates; however, frequent AR episodes are a risk factor for subsequent CR, so continued pursuit of immunosuppressive strategies that reduce the risk of AR is imperative.

CR in liver transplant recipients is characterized by vascular obliteration and bile duct loss ("the vanishing duct syndrome"). Seen in 5% to 10% of recipients, it is more common in those with vasculitic findings during AR episodes; if larger vessels are not seen on biopsy, the diagnosis of CR may be misread as AR. The incidence of CR appears to be decreasing, perhaps as a result of changes in immunosuppressive regimens [42]. In addition to multiple AR episodes, other factors associated with an increased risk of CR include CMV infection, chronic hepatitis, increased donor-recipient histocompatibility differences, and increased ischemia time. CR does not always herald graft loss; long-term patient survival and even regeneration of bile ducts have been described. Tacrolimus has been used to salvage grafts in recipients with CR on cyclosporine-based immunosuppression, with a 73% success rate [43].

Pancreas Grafts

At most centers, patients undergoing a pancreas transplant alone or a simultaneous pancreas–kidney transplant receive more potent immunosuppression than do renal transplant recipients, thanks to initial studies demonstrating a higher rate of AR after those two types of pancreas transplant [44]. Overall success rates continue to improve: the risk of AR has been reduced by standardized induction therapy with antilymphocyte antibody preparations, and it may be further reduced with mammalian target of rapamycin (mTOR) inhibitors and/or with IL-2 receptor monoclonal antibodies [45].

Establishing the diagnosis of AR in pancreas transplant recipients may be difficult. Hyperglycemia is a late finding that only occurs with substantial loss of functional islet-cell mass.

By the time hyperglycemia is seen, it may be too late to retain a functional graft. Clinical findings may include fever and graft tenderness; however, pancreas graft rejection is often clinically silent.

For pancreas grafts transplanted along with a renal graft, a rising creatinine level is often used as a surrogate marker of rejection, with antirejection therapy aimed at both the pancreas graft and the renal graft. However, isolated pancreas graft rejection is observed in up to 20% of simultaneous pancreas–kidney transplant recipients who have AR [46].

In pancreas transplant recipients with exocrine bladder drainage, a decreasing urinary amylase level may be used as a marker of graft rejection [47]. Other possible markers of rejection (serum anodal trypsinogen, serum amylase, soluble HLA, and analysis of glucose-disappearance kinetics during a brief glucose tolerance test) have been examined but have failed to gain wide acceptance.

The diagnosis of pancreas graft rejection is confirmed by biopsy, which may be performed percutaneously or, in bladder-drained recipients, through a cystoscopic, transduodenal approach. Complications (bleeding, arteriovenous fistula formation, graft pancreatitis) have been described, but most biopsies do not lead to complications. Pancreas transplant recipients with early evidence of graft dysfunction should undergo Doppler ultrasonography to rule out graft thrombosis, which occurs in up to 10% to 20% of them [48].

Treatment of AR for pancreas transplant recipients is similar to that for renal or liver transplant recipients. High-dose corticosteroids are given initially, but a low threshold is maintained for possibly switching to antibody-based therapy, given the relatively common steroid resistance. Most AR episodes are reversed with treatment.

Cardiac Grafts

Rejection in heart transplant recipients is a major obstacle to long-term success and accounts for up to a third of the deaths. All forms of rejection are seen in heart transplant recipients. Albeit rare, HAR due to preformed antigraft antibodies occurs within minutes to days; it manifests with rapid deterioration of cardiac function, with prolonged need for inotropic support. In recipients whose grafts fail to recover rapidly, an attempt to reverse HAR by plasmapheresis may be made, but success is uncommon, and an immediate retransplant is usually required.

AR in heart transplant recipients is common and usually occurs in the first 3 to 4 months posttransplant. At one time, the diagnosis was made on the basis of the development of congestive heart failure or the elaboration of electrocardiographic abnormalities. However, the present-day use of protocol endomyocardial biopsies has eliminated such late findings of AR, except in noncompliant recipients. Most centers use frequent percutaneous transjugular right ventricular endomyocardial biopsies as part of a standardized surveillance protocol. Biopsies are evaluated histologically, according to an international grading system [49], and therapy is directed accordingly.

Several investigators have developed noninvasive approaches to establishing the diagnosis of AR, including electrocardiographic frequency analysis, nuclear scintigraphic techniques, and echocardiography; however, no approach has attained sufficient sensitivity to eliminate the need for protocol biopsies. The need for continued endomyocardial biopsies later than 1 year posttransplant is controversial, and many centers discontinue performance of biopsies at 1 year unless indicated on clinical grounds.

The treatment of AR is based on histologic findings. Bolus steroid therapy is used in lower-grade rejection without hemodynamic compromise; oral prednisone therapy for mild AR also has been used with success [50]. Salvage therapy with an antilymphocyte antibody agent is most common in recipients with histologic findings of more severe rejection, in recipients with steroid-resistant rejection, and in recipients with signs of hemodynamic compromise. In a series of 100 of such high-risk recipients, AR was reversed in 90% of those treated with 10 to 14 days of OKT3 [51]. However, other investigators have had markedly lower rates of success with OKT3 in the treatment of steroid-resistant rejection [52]. Methotrexate also has been used to reverse AR that fails to respond to steroids or that is refractory to OKT3.

Other approaches include switching from cyclosporine-based to tacrolimus-based immunosuppression as rescue therapy in recipients with refractory AR, a strategy that was proved to be safe and efficacious [50]. Photopheresis has been used in the treatment of recipients with T-cell lymphoma and autoimmune disease. Studies of photopheresis and triple-drug immunosuppression have provided evidence of a decrease in the total number of AR episodes, as compared with triple-drug immunosuppression alone [50]. Of note, photopheresis has reversed refractory high-grade rejection in small numbers of heart transplant recipients [53].

CR manifests in heart transplant recipients as cardiac allograft vasculopathy (CAV), an entity that is the major cause of late-term morbidity and mortality. The pathologic findings of CAV include progressive intimal thickening in a concentric manner, which begins distally within the cardiac vasculature. It is associated with the loss of response to endogenous (and pharmacologic) vasodilators [50]. CAV is thought to be immunologically mediated, because HLA donor-related matching is clearly associated with reduced rates of CAV [54]. Nonimmunologic mechanisms are also thought to be involved; identifiable risk factors for CAV include hyperlipidemia, donor age older than 25 years, recipient weight gain, CMV disease, preexisting donor or recipient coronary artery disease, and increasing time posttransplant [50]. Another nonimmunologic risk factor for CAV is ischemic time during the peritransplant period. As in other solid-organ transplant recipients, the use of mycophenolate mofetil is associated with a reduction in the incidence of CR in heart transplant recipients [55].

Lung Grafts

The lung graft is highly prone to rejection—nearly all lung transplant recipients experience at least 1 AR episode. The clinical difficulty posed by rejection is in distinguishing it from other causes of decreased graft function, most commonly infection.

HAR of the lung graft [56] is mediated by recipient preformed antibodies to the donor graft, in a fashion similar to other organs. The clinical manifestation is similar to the more common ischemia-reperfusion injury, which, unlike HAR, usually resolves. HAR of the lung graft is rare and only described in case reports. To date, we know of no lung transplant recipients who have survived HAR. It must be prevented via initial cross-match testing and exclusion of immunologically unsuitable donor organs.

Most AR episodes occur during the first 3 to 6 months posttransplant. Some recipients experience symptoms, including fever, cough, and dyspnea, but many are asymptomatic. Early diagnosis of AR in lung transplant recipients is essential: untreated AR can lead to respiratory insufficiency or failure, and repeated AR episodes are associated with an increased risk of bronchiolitis obliterans and eventual graft failure [57].

The diagnosis of AR is made by transbronchial biopsy, although less invasive techniques continue to be assessed [58]. Bronchoalveolar lavage (BAL) is also performed to rule out

infection before increasing immunosuppression; infection and rejection may occur simultaneously in up to 25% of lung transplant recipients with AR [59]. Early diagnosis of AR may be aided by spirometry; decreases in timed forced expiratory volume, in pulmonary capillary blood volume, and in the diffusing capacity of the lungs for carbon monoxide are associated with AR and should prompt investigation. Radiography is not ordinarily helpful. The histologic findings of AR include lymphocytic infiltrates into the perivascular and interstitial spaces; AR is graded according to histologic findings [60].

The initial treatment of AR in lung transplant recipients typically entails high-dose corticosteroids; if they are not successful, anti–T-cell antibody therapy is tried next. Many recipients initially respond to the steroid pulse therapy, yet it may not completely clear their AR, and secondary episodes are common, so additional therapy may be required. For that reason, surveillance bronchoscopy with transbronchial biopsies and BAL are common after initial treatment [61].

CR in lung transplant recipients is extremely common, affecting up to 40% of recipients at 2 years posttransplant and up to 70% of recipients after 5 years [62]. The mean time to diagnosis of graft dysfunction posttransplant is 16 to 20 months. A definitive histologic diagnosis of early bronchiolitis obliterans may be difficult to obtain, so it must be established largely on clinical grounds. Radiography, again, is not specific. Typical presenting symptoms are cough, progressive dyspnea, and loss of exercise tolerance. The use of home spirometry can point to the diagnosis based on a 20% reduction in timed forced expiratory volume on successive measurements [63]. Factors associated with accelerated bronchiolitis obliterans include multiple episodes of AR, CMV pneumonitis/infection, *Pneumocystis jiroveci* pneumonia (PCP), and episodes of airway ischemia [62,64].

Many different therapies have been tried for recipients with bronchiolitis obliterans, but with little success. Increases in immunosuppression, antilymphocyte antibody therapy, and inhaled cyclosporine have all been tried. Ultimately, the progress of bronchiolitis obliterans is inexorable, with continued loss of graft function and subsequent death. A lung retransplant is the only viable option [65].

INFECTIONS

The suppression of the host immune response is required to establish and maintain a functioning solid-organ graft. The development of immunosuppressive therapies has been impressive, leading to the widespread use of solid-organ transplantation as the primary therapy for a number of organ failure syndromes. This success comes at a price, however, and the successful immunosuppression that allows engraftment leaves the host with an increased susceptibility for a number of serious infectious complications. Up to 80% of solid-organ transplant recipients experience an infectious complication during the first year posttransplant, and infections remain a major cause of morbidity and mortality in the transplant population [66].

The range of potential pathogens that can cause disease in the immunosuppressed host is prodigious. Not only are the common endogenous and nosocomial flora involved, but also "opportunistic" or "atypical" pathogens must be considered in the differential diagnosis of a solid-organ transplant recipient who has evidence of infection. In considering the epidemiology of infectious complications posttransplant, the clinician must assess several factors, including the time posttransplant, the organ transplanted, the type and degree of immunosuppression, the need for antirejection therapy, and the potential occurrence of surgical complications.

The greatest risk of infections corresponds with the period of most intense immunosuppression, which is characteristically during the first 6 to 12 months posttransplant and after antirejection therapy, particularly for repeated AR episodes. Rubin et al. have characterized periods posttransplant during which certain infection patterns may be seen [67]. Infectious complications in the first month posttransplant are typically caused by endogenous or nosocomial flora that would cause disease in an immunocompetent host [68], including (a) bacterial surgical site infections; (b) postoperative or ventilator-associated pneumonia; (c) urinary tract infections (UTIs) associated with prolonged indwelling urinary catheters; (d) intraabdominal infections related to surgical complications; and (e) central venous catheter infections [67,68].

The period between 1 and 6 months posttransplant is typically the time of greatest immunosuppression and, subsequently, the time most opportunistic infections occur. They are frequently caused by fungal or especially viral pathogens that may become activated after lying dormant in the host or may be transferred from the donor with the graft [69,70]. Knowledge of the characteristic patterns of maximal frequency for a number of specific viral pathogens within that 5-month window may be helpful to the clinician in establishing the diagnosis [71].

These infection patterns may be categorized into an *early cluster* of viral agents occurring with peak frequency between 2 and 3 months posttransplant and a *late cluster* more commonly occurring between 4 and 9 months posttransplant. The early cluster includes CMV, adenoviruses, hepatitis B virus (HBV) and hepatitis C virus (HCV), and human herpes virus (HHV)-6 [67–69,71–74]. The late cluster includes varicella zoster and polyoma viruses [19,75]. Epstein–Barr virus (EBV) may cause disease throughout the first year posttransplant [76].

The opportunistic fungi can similarly be observed to cluster with *Candida* and *Aspergillus* species (spp), causing infections in the first 2 to 3 months posttransplant [77,78], whereas *Cryptococcus*, histoplasmosis, coccidioidomycosis, and *P. jiroveci* most often occur later during the first year [79,80].

After the first 6 to 12 months, most transplant recipients exhibit patterns of infectious disease morbidity that are similar to those of the general population, with frequent respiratory infections secondary to pneumococcal infections and influenza, as well as uncomplicated UTIs. However, opportunistic infections can occur anytime. Increased immunosuppression secondary to AR treatment may slightly increase transplant recipients' susceptibility to, and alter the temporal pattern of, various pathogens. When assessing immunosuppressed transplant recipients for infectious diseases, the clinician must maintain a high index of suspicion at all times. The typical localizing signs of infection and inflammation may be blunted, or even absent, because of the anti-inflammatory action of immunosuppressive regimens.

An important component of the solid-organ transplant process is the preoperative assessment of both the recipient and the donor for any underlying infections, or any disease processes that predispose to infections, that could manifest subsequent to administration of exogenous immunosuppression. For the donor, the most important evaluation is the determination of CMV and EBV status, because those two agents are most easily transmitted to a seronegative recipient. Cultures of organ preservation fluid are routinely positive, but appropriate antiviral therapy can ordinarily prevent positive cultures from causing clinically significant disease [81]. For the recipient, a thorough pretransplant history and physical examination are essential to minimize the risk of infectious complications secondary to a latent or indolent infectious process. Routine viral studies should be obtained, vaccinations updated, and prophylaxis administered where indicated (e.g., gut decontamination in liver transplant candidates with end-stage liver disease or prophylactic antibiotics in patients with cystic fibrosis).

Bacterial Infections

In the first 30 days posttransplant, bacterial infections are common. Even in the immunocompetent patient population, bacterial infections are common complications of surgery. The risk of a nosocomial bacterial infection is related to the site of surgery as well as to the continued presence of any catheters, lines, endotracheal tubes, or other breaks in the skin. The most common sites of infection are the urinary tract, the surgical site, the lungs, and the bloodstream. The risk of nosocomial bacterial infections is directly related to host factors (including underlying diseases such as diabetes or cirrhosis, obesity, and chronic pulmonary disease) as well as to technical and management factors (including the length and technique of the operation, the development of a hematoma or seroma, and the need for prolonged urinary catheterization, mechanical ventilation, or central venous catheterization).

Particularly in renal transplant recipients and in bladder-drained pancreas transplant recipients, the urinary tract is a common site of bacterial infections. Bacteriuria may be detected in up to 83% of renal transplant recipients [82], with an attendant increased risk of systemic sepsis and wound infection. The most common pathogens are Gram-negative aerobes, enterococci, and *Candida* spp. The risk factors associated with an increased incidence of UTIs include prolonged catheterization, hemodialysis, and antibiotic prophylaxis in excess of 48 hours [83]. The use of ureteral stents in renal transplant recipients, though it may help reduce ureteral complications, is associated with an increased rate of UTIs [84]. The use of prophylactic trimethoprim-sulfamethoxazole (TMP-SMX) is common in renal transplant recipients, primarily to decrease the risk of UTIs. Long-term prophylaxis helps reduce the incidence of infections due to several opportunistic pathogens, including *P. jiroveci*, *Toxoplasma gondii*, *Listeria monocytogenes*, and *Legionella pneumophila* [85].

Diagnosis of a UTI in transplant recipients is based on clinical suspicion and on urinalysis and culture results. The typical findings of dysuria, hesitance, and frequency may be absent; the only clinical manifestations might be a minimal fever or an elevated white blood cell count. Treatment is often empiric and, because of the risk of bacteremia, should consist of intravenous administration of a third-generation cephalosporin or a quinolone, particularly during the first months posttransplant. Once the causative microbe has been identified and antimicrobial sensitivity data are available, treatment can be refined.

In recipients of solid-organ grafts besides the kidney and bladder-drained pancreas who do not require a long duration of urinary catheterization, an increased risk of bacterial or fungal UTIs is not seen.

Infections of the surgical site are potentially a source of major morbidity and, occasionally, graft loss and mortality in solid-organ transplant recipients. Surgical site or wound infections are classified according to the structures involved. Infections above the fascia are superficial, infections below the fascia are deep, and combined infections involve elements of both the superficial and the deep compartments of the wound [68].

In all solid-organ transplant recipients, immediately before their operation begins, a single dose of an antibiotic should be administered, to decrease the risk of surgical site infections. In pancreas, bowel, lung, and liver transplant recipients, significant degrees of wound contamination may occur, so antibiotics are typically administered for 24 to 72 hours posttransplant, although data to support that practice are lacking. In renal transplant recipients, the surgical site infection rate is very low (1% to 2%) and is comparable to the wound infection rate for other clean-contaminated procedures in immunocompetent patients [86].

However, other transplant procedures are associated with higher rates of infection. The wound infection rate after heart transplants is typically below 8%, which is comparable to the rate for other high-risk cardiac procedures [87]. The rate of wound infections is slightly higher after lung and heart–lung transplants [88]. The rate after liver transplants of superficial wound infections is 6% to 8%; of deep wound infections (most commonly an intra-abdominal abscess secondary to a biliary leak), 15% to 20% [69]. The rate of wound infections after pancreas transplants is high: 10% to 40%, superficial; 15% to 22%, deep; and 8%, combined [89]. Such wound infections confer substantial morbidity, are associated with mortality in some cases, and require a very aggressive approach to diagnosis and therapy.

Pathogenic microbes are predictable, according to the type of operation. In renal transplant recipients, wound infections are caused by the endogenous flora of the skin (Gram-positive aerobes) and the bladder (Gram-negative aerobes), with occasional *Candida* spp and enterococci.

In heart transplant recipients, wound infections are almost invariably due to skin flora such as *Staphylococcus aureus* and *Staphylococcus epidermidis*, although some fungal and atypical pathogens are found.

Lung transplants introduce respiratory flora and the potential for grave infections with *Pseudomonas aeruginosa*.

In liver transplant recipients, wound infections are typically associated with either skin or biliary flora, although any preexisting cirrhosis and end-stage liver disease may result in colonization with drug-resistant nosocomial pathogens.

In pancreas transplant recipients, wound infections are invariably polymicrobial, with gram-positive, fungal, and resistant Gram-negative pathogens frequently present. Treatment generally requires opening of the wound, reexploration, and/or administration of broad-spectrum antimicrobial therapy (with a carbapenem or extended-spectrum penicillin, a β-lactamase inhibitor, and vancomycin) and often antifungal coverage.

Wound infections are often subtle, and findings may be limited to fever, elevated white blood cell count, or wound drainage with a deceptively innocuous appearance. Any wound drainage should be examined by Gram stain and culture; any suspicion or evidence of infections should result in opening of the superficial wound. Additionally, imaging should be undertaken to rule out infections in the deep surgical space; if a fluid collection is identified, percutaneous drainage or prompt exploration is needed. Prolonged, broad-spectrum antimicrobial therapy is used, and immunosuppression is minimized in the face of potentially life-threatening infections.

The development of postoperative pneumonia varies with the type of transplant and is associated with a high mortality rate (20% to 60%) [90]. Renal transplants are associated with the lowest incidence of postoperative pneumonia (1% to 2%); lung transplants, the highest (22%). The most common pathogens are Gram-negative aerobes, staphylococci, and *Legionella* spp. Frequently, *Candida* spp or CMV may be identified along with bacterial pathogens, particularly in the first 2 to 3 months posttransplant. Such findings are clinically significant, and active CMV pneumonitis is a significant risk factor for the development of bacterial pneumonia [90,91].

Several risk factors may predispose solid-organ transplant recipients to the development of pneumonia, including prolonged mechanical ventilation, thoracic surgery, pulmonary edema, and intense immunosuppression or AR treatment. Lung transplant recipients are at increased risk, because of their lungs' preexisting colonization with endogenous flora as well as the loss of the mucociliary clearance function associated with denervation [88]. Those with cystic fibrosis have an additional risk, because their lungs and sinuses are universally colonized with highly drug-resistant flora such as *Pseudomonas aeruginosa* and *Burkholderia cepacia* [92]. The evaluation of

suspected pneumonia in lung transplant recipients should be thorough, including bronchoscopy with biopsies and BAL to rule out rejection, as described above. Pleural effusions should be drained and cultured, because the progression of an infected effusion to empyema in lung transplant recipients is associated with a very high mortality rate.

Bacteremia in the transplant population, as in the general hospital population, may occur secondary to seeding along a vascular access device or as a result of hematogenous spread from another source; or, it may be primary (without a source being identified). UTIs, wound infections, and pneumonia are risk factors for the development of bacteremia, as is prolonged vascular catheterization. Additional risk factors include receiving a deceased donor graft, leukopenia, and antirejection therapy. Bacteremia in immunosuppressed patients may present as fever, leukocytosis, leukopenia, or hypotension without other significant manifestations. Consequently, routine blood cultures should be part of any workup for fever in this population. Suspicion of bacteremia should prompt removal and culture of intravascular devices and a search for a source of other sites of infection. The mortality rate of bacterial sepsis and septic shock in transplant recipients exceeds 50%. Consequently, the use of broad-spectrum antimicrobial therapy, an aggressive approach to source control, and the minimization of immunosuppression are indicated.

Several atypical bacterial infections occur in the solid-organ transplant recipients, including mycobacteria such as *Mycobacterium tuberculosis*, *Nocardia* spp, and *Listeria monocytogenes*. Such infections are associated with high rates of morbidity and mortality. Mycobacterial infections are 50 to 100 times more frequent in the transplant population than they are in the general population and are fatal in 30% of cases. Most mycobacterial infections occur within the first 6 to 12 months posttransplant and are associated with intense immunosuppression and antirejection therapy [93]. Infections are typically due to reactivation of latent disease or transmission with the transplanted graft. Their diagnosis is complicated by the typical lack of reaction to skin testing seen with immunosuppression. Consequently, a high index of clinical suspicion is needed. If mycobacterial pulmonary infection is suspected bronchoscopic evaluation with biopsy, acid-fast staining, and culture should be performed. Treatment consists of multidrug therapy with isoniazid, ethambutol, pyrazinamide, and rifampin. Prophylaxis should be considered in patient populations in whom infections are common, in patients with a history of significant exposure without subsequent therapy, and in patients with a history of serious or inadequately treated infections.

Nontuberculous mycobacteria (NTM) such as *Mycobacterium avium complex*, *M. ulcerans*, and *M. xenopi* are environmental mycobacteria that rarely caused disease in humans until the AIDS epidemic two decades ago. NTM infections typically manifest as insidious pulmonary or soft tissue infections in immunosuppressed patients. If NTM infections are suspected, repeat isolations by bronchoscopy or tissue biopsy are required to improve the chance of diagnosis. In addition to acid-fast staining, a special culture for an atypical mycobacterium should be obtained. Besides long-term antimicrobial treatment, wide debridement of the infected site is often required to eradicate such infections [94].

Listeria monocytogenes infection may be associated with pneumonia, bacteremia, or, most ominously, cerebromeningitis in the transplant population. In renal transplant recipients, *Listeria* spp have been associated with a 26% mortality rate. Consequently, if listeriosis (pulmonary or meningitis) is suspected in any immunosuppressed patients, a thorough evaluation must be performed. Empiric therapy for meningitis should include appropriate coverage, such as ampicillin plus an aminoglycoside [95]. The extended-spectrum penicillins also provide adequate coverage.

Nocardial infections most commonly manifest with pulmonary symptoms and signs, but disseminated disease may involve the skin, eyes, and brain, alone or in combination. The clinical manifestations are nonspecific and comprise fever, chills, malaise, occasional cough, dyspnea, headache, or mental status change. Such infections have a mortality rate of 25% to 50% and must be aggressively diagnosed and treated [96]. The diagnosis is made by microscopic examination of sputum or lung (or occasionally brain) biopsy tissue, or by aspiration of a skin nodule using routine, Kinyoun, and Ziehl-Neelsen staining. Treatment consists of high-dose intravenous TMP-SMX, generally in combination with an aminoglycoside, such as amikacin, with continued treatment with oral TMP-SMX, preferably for life. Concurrently, immunosuppression should be curtailed, particularly during treatment of aggressive, disseminated infections.

Fungal Infections

Solid-organ transplants are associated with a significant risk of fungal infections. In the era of broad-spectrum antibacterial prophylaxis and empiric therapy, the incidence of fungi as pathogens is increasing, as is the incidence of azole drug-resistant fungal infections. Fungal infections are most common after liver and pancreas transplants, for which the incidence approaches 40% [97]. But they are less common after renal transplants (only 5%). Nonetheless, all fungal infections are serious infections, with an attendant mortality rate, associated with invasive disease, of 30% to 50%. As described previously, most fungal infections occur during the first 3 to 4 months posttransplant, when immunosuppression is greatest. The source of most fungal pathogens is the oral cavity, the gastrointestinal (GI) tract, or the environment.

The most common fungal pathogens are the *Candida* spp [98]. Candidal overgrowth of the oral and GI tract is common, and prophylaxis consisting of topical nystatin or clotrimazole is often used. Risk factors associated with invasive candidal disease include diabetes, neutropenia, intense immunosuppression, and prolonged administration of antibacterial antibiotics, particularly broad-spectrum agents. Long-term TMP-SMX prophylaxis has not been associated with fungal infections. Despite prophylaxis, invasive candidiasis does occur, most often in transplant recipients with a perforation of the GI tract, an anastomotic breakdown, a deep surgical-site infection, or a concomitant GI infection, such as CMV gastroenteritis or colitis.

Increasing use of triazoles such as fluconazole has led to more frequent isolation of resistant *Candida* species, such as *C. glabrata* and *C. krusei*. Even apart from this observation, most invasive candidal infections should be treated with amphotericin B or the newer agents like echinocandins (see later), because of the attendant morbidity and mortality in the immunosuppressed population [99]. Caspofungin is an echinocandin that acts to block the synthesis of 1,3-β-d-glucan, an essential element of the fungal cell wall. It is well tolerated, with a side effect profile that compares favorably to amphotericin B. Note that caspofungin and amphotericin B appear to act in an additive manner, and cross-resistance has not been identified [100]. Clinical trials of caspofungin versus amphotericin demonstrated equivalent outcomes in the treatment of candidemia [101]. In solid-organ transplant recipients, caspofungin will be an important drug in treating serious fungal infections, particularly because it lacks the nephrotoxicity of amphotericin. Two of the more recently released triazole drugs, itraconazole and voriconazole, also possess activity in vitro against *Aspergillus* spp; the combination of voriconazole and caspofungin has been shown to enhance clinical efficacy [102].

Aspergillosis occurs in 1% to 4% of transplant recipients, most commonly after liver and lung transplants. Half of such patients go on to develop disseminated disease, with a mortality rate in excess of 80% [78,103]. Most patients with aspergillosis present with what appears to be a bacterial pneumonia. In high-risk lung or liver transplant recipients, or in lower risk patients whose supposed pneumonia fails to respond to appropriate antibiotic therapy, an aggressive diagnostic approach is warranted. The diagnosis of aspergillosis is established initially by microscopic examination of samples obtained via bronchoscopy and BAL for the presence of filamentous hyphae. Agents approved by the U.S. Food and Drug Administration (FDA) against invasive aspergillosis include liposomal amphotericin B, itraconazole, voriconazole, posaconazole, and caspofungin. Dissemination to the central nervous system (CNS) may result in brain abscesses, which in the past were nearly uniformly fatal, but more recently have been successfully treated with newer antifungal agents (such as voriconazole) and neurosurgical resection [104].

Infections due to a number of other fungi occur in solid-organ transplant recipients, including *Cryptococcus neoformans, Coccidioides immitis, Blastomyces dermatitidis, Histoplasma capsulatum*, and *Zygomycetes*, *Mucor*, and *Rhizopus* spp. Infections caused by those fungi occur in specific settings and present as specific syndromes that should be considered by the clinician caring for immunosuppressed patients.

Cryptococcus neoformans is the second leading cause of invasive fungal infections in liver transplant recipients. This pathogen may cause pneumonia or meningitis, and patients with pulmonary disease often have CNS involvement as well. It is recommended that immunocompromised patients with cryptococcal infection should undergo lumbar puncture even if asymptomatic neurologically. Skin nodules are occasionally seen. The diagnosis is confirmed by India-ink staining and by testing for cryptococcal antigen in cerebrospinal fluid or sputum. Treatment consists of amphotericin B followed by oral fluconazole [105].

Coccidioides immitis is endemic in the southwestern United States and in Mexico. Between 7% and 9% of solid-organ transplant recipients residing in that area develop coccidioidomycosis, with an associated mortality rate of 25% in pulmonary cases and of up to 70% in disseminated cases [80]. The presentation of disease is variable, as multiple organ systems may be involved. The diagnosis must be made by microscopy, antigen detection, or tissue culture. Lifelong fluconazole prophylaxis for solid-organ transplant recipients who reside in endemic areas is advocated in some centers, though long-term outcome data are lacking. A reduction of calcineurin inhibitor dosage can be an adjunct benefit. The treatment is prolonged amphotericin B administration or azole therapy [106].

Histoplasmosis and blastomycosis infections occur in endemic areas of the American Midwest and in the Mississippi and Ohio River valleys. Invasive disease, either reactivation of latent fungi or a new infection, occurs in up to 2% of solid-organ transplant recipients, with the highest incidence in those areas. Invasive disease spreads from the lungs to the skin and bone marrow. Biopsy and samples for culture analysis may be obtained from skin lesions or from a bone-marrow aspirate. Amphotericin B or itraconazole are appropriate therapeutic agents [79].

Mucor and *Rhizopus* spp in the *Zygomycetes* class are soil fungi that, when inhaled, may cause a highly morbid, invasive rhinocerebral infection in profoundly immunosuppressed patients and in diabetic patients with poor glycemic control [107]. The diagnosis is established by biopsy; treatment is surgical debridement with adjuvant antifungal therapy (amphotericin B with the occasional addition of 5-flucytosine, itraconazole, or rifampin). The mortality rate associated with those types of infections is in excess of 50%.

Pneumocystis jiroveci pneumonia (PCP) is a common cause of pneumonia in immunosuppressed patients. PCP is associated with profound defects in cellular immunity and normally is seen with CD4-positive T-cell counts lower than 200 per μL [108]. Those indices are often seen with OKT3 therapy for AR. Prophylaxis with TMP-SMX or atovaquone (if sulfa allergic) makes PCP a rare entity; however, transplant recipients who have a respiratory illness but did not receive prophylaxis (e.g., because of allergy or noncompliance) should be evaluated promptly for PCP. Untreated PCP has a very high mortality rate. The diagnosis is typically established by bronchoscopy and BAL, with methenamine silver staining of washings, or by transbronchial biopsy. Normal findings should not delay further evaluation and therapy (the characteristic alveolar and interstitial changes seen on a chest radiograph are late findings). Even before the diagnosis of PCP is established, empiric therapy is normally started with intravenous TMP-SMX or inhaled pentamidine. Dapsone is used in patients with a sulfa sensitivity. Concurrent CMV infection is common, so CMV diagnostic studies should be undertaken in patients whose PCP fails to respond promptly to appropriate therapy.

Viral Infections

Viral infections have increasingly been recognized as important causes of morbidity and mortality in solid-organ transplant recipients. Viruses that are endemic and of little clinical concern in the general patient population may produce overwhelming infections in the host with suppressed cellular immunity. The recent appreciation of the immunomodulatory effect of several opportunistic viral pathogens gives even more reason for continued development of effective prophylaxis, diagnosis, and treatment modalities for this class of infectious agents. Immunosuppressed transplant recipients may develop serious viral infections by reactivation of latent virus, by transmission of the virus via the donor graft or via blood transfusion, or by exposure to the virus in the environment.

Pathogens known as the HHVs are important in the solid-organ transplant population (Table 186.4). Those viruses commonly cause disease during periods of intense immunosuppression, particularly early posttransplant and after antirejection therapy. They include many of the most important viral pathogens facing immunosuppressed patients, including CMV, EBV, the herpes simplex viruses (HSVs), and the varicella zoster virus (VZV).

CMV infections affect 30% to 75% of solid-organ transplant recipients, primarily within 2 weeks to 3 months posttransplant. The highest risk for CMV infections is in a CMV-seronegative recipient receiving a graft from a CMV-seropositive donor (the D+/R− graft) [109]. Lung and heart–lung transplant recipients have the highest rate of CMV disease (50% to 80%). Pancreas and pancreas–kidney transplant recipients have a rate of 50%; kidney, heart, or liver transplant recipients, 8% to 35% [110].

The most severe CMV disease is a primary infection in the D+/R− population. A superinfection (due to concurrent reactivation of an endogenous strain and transmission of a serotypically distinct strain of CMV) is typically intermediate in severity, whereas reactivation of latent disease is most often comparatively mild [111]. The range of clinical disease is vast: from asymptomatic infections (detected solely by a change in anti-CMV titer or by shedding of virus or viral DNA in blood, urine, or sputum) to tissue-invasive disease (which may affect the lungs, liver, or intestine). A typical mild infection produces a mononucleosis-like syndrome, including fever, malaise, and

TABLE 186.4

HUMAN HERPES VIRUSES (HHVs)

Virus	Eponym	Clinical syndromes
HHV-1	Herpes simplex virus-1	Mucocutaneous disease Primarily oral–labial symptoms Ocular keratitis Herpes simplex virus encephalitis
HHV-2	Herpes simplex virus-2	Mucocutaneous disease Primarily genital symptoms Ocular keratitis
HHV-3	Varicella zoster virus	Chickenpox, shingles Pneumonitis, encephalitis
HHV-4	Epstein–Barr virus	Infectious mononucleosis Hepatitis, pneumonitis Posttransplant lymphoproliferative disease Burkitt lymphoma
HHV-5	Cytomegalovirus	Mononucleosis, pneumonitis Hepatitis, gastroenteritis, retinitis
HHV-6	Roseola (6B)	Childhood febrile exanthema Mononucleosis, encephalitis Pneumonitis, disseminated disease
HHV-7		No clear clinical entities
HHV-8	Kaposi agent	Cutaneous lymphomas

myalgias, often accompanied by leukopenia. More severe disease clinically manifests with differing signs and symptoms, depending on the site(s) of invasive infection. GI ulceration with occasional hemorrhage is seen in GI disease. CMV pneumonitis may produce respiratory insufficiency and failure. CMV hepatitis may lead to liver failure and to severe pancreatitis can occur. CMV retinitis may produce vision changes, leading to blindness.

Formerly, the presence of CMV was suspected in patients who developed a viral prodrome, with a fourfold increase in anti-CMV titer or by direct observation of CMV inclusion bodies in biopsy specimens. Retrospective confirmation was on the basis of culture analysis that took 2 to 3 weeks. Those inadequate diagnostic techniques have been supplanted by the rapid "shell-vial" culture, in which virus is grown in culture with fibroblasts and examined by immunofluorescence microscopy after incubation with anti-CMV immunofluorescence-linked monoclonal antibodies [112].

A rapid antigenemia assay is also available that measures the levels of the pp65 CMV antigen in sample fluid, but accurate results depend on a normal white blood cell count [113]. Most recently, the polymerase chain reaction has been used to measure viral copy number in peripheral leukocytes and, like the antigenemia assay, may permit very early diagnosis of subclinical CMV infections in at-risk patients [114]. Investigators differ in their preference between those two techniques [115], but both are clearly useful. Overall, the new techniques allow substantiation of CMV infections with greater than 90% to 95% sensitivity and specificity within 24 to 48 hours.

Given the high prevalence and significant morbidity of CMV disease, prophylaxis with ganciclovir, valacyclovir, or valganciclovir for 3 to 6 months posttransplant is common, particularly in high-risk patients. Additional prophylaxis routinely is begun with initiation of antirejection therapy. Several randomized clinical trials have shown ganciclovir prophylaxis to be superior to acyclovir prophylaxis in preventing both reactivation and primary CMV disease in solid-organ transplant recipients [116–119].

A second approach to this problem is the close monitoring of at-risk patients with protocol antigenemia or polymerase chain reaction assays followed by empiric (so-called preemptive) therapy with ganciclovir, if levels rise above a predetermined threshold. This approach, though somewhat more cumbersome, has led to reductions in the burden of CMV disease in liver transplant recipients [120]. Prophylaxis, surveillance with empiric therapy, or a combination of both based on calculated risk is currently practiced in most transplant centers. However, in kidney transplant recipients, surveillance monitoring with preemptive therapy has not been shown to be superior to treatment based on symptomatic disease [121], and, consequently, the main focus in this population is on prophylaxis. Ganciclovir prophylaxis is used for lung, heart–lung, and heart transplant recipients as well [122–124], but data on surveillance, preemptive therapy, and efficacy in such recipients are limited.

Traditionally, treatment of established CMV infections consists of intravenous ganciclovir, followed in most cases by oral ganciclovir. Oral valganciclovir alone can achieve similar clinical outcomes [125]. Anti-CMV immune globulin is available and is commonly added to ganciclovir for the treatment of serious, life-threatening invasive CMV infections, although studies of this agent have been limited to its use in prophylaxis and are equivocal in showing efficacy [126]. Foscarnet (trisodium phosphonoformate) is used in those rare instances where ganciclovir-resistant strains of CMV are isolated. The data that clearly establish the efficacy of foscarnet in treating CMV disease are limited to CMV retinitis; efficacy equivalent to ganciclovir was observed, but foscarnet was associated with a higher rate of adverse effects (e.g., nephrotoxicity) [127].

The HSVs (HSV-1 and HSV-2) commonly cause mucocutaneous disease of the oropharynx (HSV-1) and the genitalia (HSV-2). In profoundly immunosuppressed patients, they may cause disseminated disease, including hepatitis, encephalitis, and pneumonitis. Most such infections are thought to be reactivation of latent virus [128], and the highest risk is in lung and heart transplant recipients. The diagnosis is established by identification of the virus by immunofluorescent monoclonal antibody staining or by Tzanck smear. Culture and rising anti-HSV antibody titers provide evidence as well. Treatment consists of acyclovir; most epidermal lesions respond to oral therapy, but any evidence of disseminated disease requires high-dose intravenous acyclovir and minimization of immunosuppression.

Infections associated with EBV are commonly detectable in solid-organ transplant recipients. The most common manifestations include the typical mononucleosis-type syndrome, pneumonitis, and hepatitis [129]. The diagnosis of EBV infections is made by detection of heterophile immunoglobin M antibodies in serum or by following titers of antibodies to viral capsid antigen or to early antigens. Polymerase chain reaction is also used to monitor viral activity and response to therapy. Treatment consists of acyclovir (or ganciclovir, when a CMV infection is also suspected). Severe invasive disease mandates a reduction in immunosuppressive therapy. The most important aspect of EBV, however, is its association with posttransplant lymphoproliferative disorders (PTLDs) (vide infra).

VZV commonly emerges from latency in immunosuppressed transplant recipients and causes an episode of shingles [75]. More rarely, VZV may cause disseminated infections, such as pneumonitis and encephalitis. The highest risk of disseminated VZV disease is in pediatric transplant recipients who have not been exposed to VZV (e.g., chickenpox); this type of

primary infection is associated with a high mortality rate (11%) [130]. Fortunately, the introduction of the varicella vaccine has markedly reduced this type of disease; the vaccine is recommended pretransplant for all pediatric and nonimmunosuppressed transplant candidates [131]. VZV infections are treated with acyclovir; with severe disseminated disease, immunosuppression is reduced [132]. No evidence supports the efficacy of anti-VZV immune globulin for treating severe VZV disease in immunocompromised patients, though it may be considered in nonimmunocompromised individuals.

The role of HHV-6 as a cause of clinical disease is not yet clearly established in solid-organ transplant recipients. Considerable evidence, primarily in bone marrow and stem cell transplant recipients, points to an association between HHV-6 and CNS syndromes, pneumonitis, and a mononucleosis-like immunosuppressive syndrome that may predispose to other opportunistic infections [133]. An association between HHV-6 activation with severe CMV disease has been reported, but understanding causality in this context is difficult. Treatment of neurologic diseases related to HHV-6 includes ganciclovir and foscarnet, either alone or in combination [133]. HHV-7 is not yet clearly associated with clinical syndromes that pose major problems in solid-organ transplant recipients. HHV-8 is linked to the development of Kaposi sarcoma in transplant recipients (vide infra).

Viral hepatitis is a significant problem, particularly in liver transplant recipients, who may have developed end-stage liver disease as a result of HBV or HCV infections. Primary HBV or HCV infections may occur during the transplant operation itself, because of donor graft or blood transfusion transmission.

Would-be donors positive for hepatitis B surface antigen (HBsAg) and/or anti-hepatitis B core antibodies (HBcAbs) are often excluded from donating any organ or tissue [134]. Organs other than the liver have been transplanted from isolated HBcAb-positive donors, without evidence of transmission, but the risk for transmission is unknown [135]. HCV-positive donors are normally excluded from donating any organ [136], except to status-1 patients whose death is imminent or to patients who already have such infections. Liver transplant candidates with HBV or HCV disease are transplanted; currently, their graft and patient survival rates, particularly in the short term, are comparable to those for recipients without HBV or HCV disease. At one time, HBV disease was a contraindication to a liver transplant; however, the use of lamivudine and HBV-immune globulin (HBIG) has significantly reduced the burden of recurrent HBV disease [137,138] and has allowed hundreds of patients with end-stage liver disease secondary to HBV to undergo successful transplants. The optimal duration of HBIG treatment is debatable.

However, the development of recurrent viral disease in patients with HCV is inevitable and may be clinically significant, depending on the severity of the disease [139]. Up to 25% of transplant recipients accelerate to cirrhosis within 5 to 10 years posttransplant, likely related to immunosuppressive therapy and rejection [140]. The care of transplant candidates with HCV includes extending the donor pool, tailoring antiviral treatment pre- and posttransplant, and offering a living donor transplant [141]. The idea of neutralizing human monoclonal antibodies against HCV is currently under clinical investigation [142].

As discussed previously, many of the HSVs are associated with invasive hepatitis, which may progress to fulminant disease. Hepatitis may also be caused by adenovirus infections in solid-organ transplant recipients. Several other viruses cause significant morbidity and mortality in this patient population. Adenoviral infections, though more common in hematopoietic cell transplant patients, do occur in solid-organ transplant recipients. Invasive adenoviral infections most commonly manifest as pneumonitis or hepatitis, both of which carry a poor prognosis [143].

Primary infections with HIV via an organ transplant from an HIV-positive donor have been described; HIV-positive status is ordinarily a contraindication to either donating or undergoing a transplant [144]. However, solid-organ transplant recipients infected with HIV have been identified and have enjoyed long-term survival posttransplant [145], given the success of long-term multidrug therapy for HIV. With the introduction of highly active antiretroviral therapy (HAART), the transplant community has now recognized HIV infections as a chronic condition. In fact, end organ failure develops in HIV-positive individuals as they age and/or from the side effects of their antiviral treatments. Short-term outcomes in HIV-positive transplant recipients have been promising [146]: the HIV load remains suppressed, CD4-positive T-lymphocyte counts are stable, and the risk of opportunistic infection is acceptable. However, major challenges in the care of HIV-positive transplant recipients include high graft rejection rates and multiple drug interactions between HAART and maintenance immunosuppression [147].

The polyomavirus, including BK, JC, and SV40, is a ubiquitous pathogen that has no clinical significance in immunocompetent hosts. BK virus (BKV) is tropic-specific for human transitional and renal tubular epithelial cells. After primary infection, which often occurs in early life, BKV establishes lifelong latency in the host's renal cells. Reactivation takes place when the host's immune system is weakened, such as during pregnancy or posttransplant immunosuppression. The diagnosis is made by detecting free viral particles in the urine, blood, or intranuclear viral inclusion-bearing cells (decoy cells) in urine cytology specimens. BKV nephropathy (BKN) has been increasingly recognized as an important entity in kidney transplant recipients since the mid-1990s; currently, it is seen in 1% to 9% of them within the first year posttransplant [148]. In advanced BKN, the graft failure rate has been reported as high as 60% [149]. Depending on the severity of renal tubule injury, clinical presentations of BKN can include fatigue, fever, mild hydronephrosis, or marked graft dysfunction. In bone marrow transplant recipients, hemorrhagic cystitis has been described. The diagnosis of BKV reactivation is made by urinary cytology, quantitative PCR analysis to measure the viral load in urine or plasma, and kidney biopsy [150]. The mainstays of caring for patients with BKN are to reduce immunosuppression and to closely monitor disease progression. Given the lack of specific antiviral agents against BKV, low-dose cidofovir or leflunomide has been used, with some success, in patients with persistent BKN [151,152].

Human papilloma viruses may cause disease through the development of tissue-specific growth leading to benign or malignant processes, including cervical cancer, cancer of the vulva and perineum, condyloma acuminatum, laryngeal polyposis, and nonmelanotic skin cancer (vide infra). Respiratory syncytial virus may produce a fulminant pneumonia in both adult and pediatric transplant recipients. The diagnosis is made by nasopharyngeal washing. More severe cases should be treated with ribavirin.

Parasitic Infections

Several common parasitic infections are seen in immunosuppressed solid-organ transplant recipients. *Toxoplasma gondii* presents as a brain abscess with neurologic changes [153]. It is seen late posttransplant, whereas a brain abscess in the early posttransplant period is more likely to be fungal [154]. Heart transplant recipients seem to be at greatest risk, possibly due to the presence of *T. gondii* cysts in donor myocardial tissue. If the heart donor was seropositive for *T. gondii*, the recipient

normally undergoes prophylactic treatment with pyrimethamine and sulfadiazine for 3 to 6 months posttransplant. Treatment of *T. gondii* infections consists of pyrimethamine and sulfadiazine; the mortality rate is high in transplant recipients who exhibit CNS disease.

MALIGNANCY

Solid-organ transplant recipients have a markedly increased risk of developing malignancy posttransplant. An extensive data collection tracks the epidemiology of tumors in transplant recipients; it was initiated and is maintained by the Israel Penn International Transplant Tumor Registry [155]. The increased incidence of malignancy is multifactorial, probably due to a combination of the activation of latent viruses with oncogenic potential, the direct oncogenic effect of immunosuppressive drugs such as cyclosporine, and, perhaps, environmental factors. Strong but indirect evidence points to the loss of immunologic surveillance as a mechanism of increased oncogenesis. The most common neoplasms in solid-organ transplant recipients are skin cancers, PTLD, lung cancer, Kaposi sarcoma, and carcinoma of the cervix. Of those neoplasms, lung cancer appears to occur at the same frequency as in the general population; the other neoplasms occur at increased frequency in solid-organ transplant recipients. PTLD presents the greatest challenge in terms of attendant high morbidity and mortality rates.

Posttransplant Lymphoproliferative Disorder

The term *PTLD* encompasses a very broad range of pathologies, from simple lymphoid hyperplasia to very aggressive monoclonal B-cell lymphomas. EBV infections play a central causative role. In particular, primary EBV infections posttransplant (EBV D+/R− match) and immunosuppression markedly increase the risk of PTLD [156]. Other risk factors include active CMV disease [157], CMV D+/R− match [158], increasing intensity of immunosuppression [159,160], and, possibly, HCV infections [161] and recipient cytokine gene polymorphisms [162].

PTLD is least common in adult kidney transplant recipients and most common in pediatric small-bowel transplant recipients. It is most common early posttransplant, concurrent with the most intense immunosuppression and with the use of anti–T-cell therapy for AR, particularly repeated courses. However, a subset of PTLD occurs late (several years) posttransplant. These late-occurring neoplasms appear to be related more to patient age, duration, and intensity of immunosuppression, and type of graft than to the more typical risk factors seen in early onset disease.

The clinical presentation of PTLD varies widely, as might be expected from the wide range of pathology encountered with this entity. Many patients experience fever, sweats, and myalgias as the only symptoms. Weight loss, diarrhea, and upper respiratory infection symptoms also are common; some, but not all, patients have lymphadenopathy. CNS involvement, which occurs in up to 20% of patients [163], often manifests as mental status changes. GI disease may be silent or may present as abdominal pain, GI bleeding, perforation with peritonitis, or bowel obstruction. Intrathoracic PTLD has a characteristic radiographic appearance of multiple circumscribed pulmonary nodules, which may or may not be accompanied by mediastinal lymphadenopathy. PTLD in the graft itself can present very similarly to AR; because the therapeutic approach to those two entities is diametrically opposed, a correct diagnosis on biopsy is essential.

Biopsy of suspected lesions is the gold standard in establishing the diagnosis of PTLD. Biopsy specimens are histologically graded (based on cell morphology and nodal architecture) and assessed for clonality (polyclonal or monoclonal) and for the presence of an EBV genome and copy number. Specific cell marker studies are required to establish the cell of origin, but most lesions are EBV positive and of B-cell lineage. Pathologists familiar with PTLD as well as with graft rejection and opportunistic infections should review the biopsy results. Consensus conference standards for the grading and classification of PTLD are used [164]. Histologic classification currently uses the Harris standard formulation [165]. EBV serology does not typically add to the diagnostic workup of PTLD, with many false-negatives in patients with established primary EBV infections [166,167]. Similarly, peripheral cytology is not helpful in making the diagnosis [168]. If PTLD is suspected, patients should undergo imaging of the head, thorax, and abdomen. Fluorodeoxyglucose-positron emission tomography (FDG-PET)/CT scanning has been increasingly used as a diagnostic and/or staging tool and in follow-up studies of PTLD patients [169].

Currently, there is little information to provide direction regarding optimal prophylaxis against PTLD. Clearly, it is important to identify, and closely monitor, high-risk patients (e.g., children; liver and small-bowel transplant recipients; EBV-negative transplant recipients, particularly those with an EBV-positive donor; and transplant recipients on intense antilymphocyte therapy for rejection). Similarly, OKT3 therapy should not be used in high-risk patients without a definitive diagnosis of AR on biopsy. Both antiviral agents and passive immune transfer with anti-EBV immune globulin have been proposed as prophylaxis against PTLD, but data supporting those approaches are lacking. Several trials are ongoing to establish the best prophylactic approach [170]. Intriguingly, the improvements in baseline immunosuppression preventing AR appear to decrease the frequency of PTLD, likely as a byproduct of reducing the frequency of antilymphocyte antibody therapy [171].

Treatment of established PTLD depends on each patient's clinical situation and histologic diagnosis. With few trials to guide therapy, a graded, individualized approach is taken. Ordinarily, immunosuppression is reduced to minimal levels, and specific therapy is directed at the neoplasm. In 25% to 50% of patients, PTLD regresses after their immunosuppression is reduced [172].

Surgical intervention is clearly indicated for patients with GI PTLD that manifests as aggressive disease (e.g., viscus obstruction or perforation). Surgical debulking of the tumor burden has also been used in amenable cases [173], as has radiotherapy [174]. Isolated CNS disease initially should be treated with external beam irradiation.

Medical approaches to treating PTLD include (a) antiviral medications (e.g., acyclovir, ganciclovir) [175]; (b) interferon-α2b [176]; (c) immunoglobulins [75,175]; (d) standard, low-dose, and high-dose chemotherapy protocols [177,178]; and (e) most recently, monoclonal antibodies directed against B-cell surface markers, such as CD19 and CD20 (rituximab) [179]. In unusual cases, immunomodulatory therapy with adoptive transfer of cytotoxic T cells sensitized to EBV has been attempted with some success [180].

Late-onset PTLD, occurring more than 1 to 2 years posttransplant, often does not respond to the reduction in immunosuppression and to the medical therapy typically used in patients with early-onset disease. Often EBV-negative, late-onset PTLD is difficult to treat because of side effects, including infectious complications of the aggressive chemotherapy that is often required. Similarly, CNS involvement may be a marker for PTLD that is potentially refractory to therapy, possibly because of the relatively privileged immune site. Treatment options include intrathecal administration of interferon-α and anti–B-cell

antibody therapy along with local radiotherapy, but the prognosis remains guarded [163,181].

Skin Cancer

The most common neoplasms associated with transplants and immunosuppression are nonmelanotic skin cancers. These lesions increase in frequency with sunlight exposure and with increasing time posttransplant. Often-quoted studies show a prevalence of 66% in transplant recipients in Australia after 24 years of surveillance [182] and 40% after 20 years in the Netherlands [183]. Those figures correlate to a 4- to 21-fold increase in prevalence in transplant recipients, as compared with the immunocompetent population, with synergistic increases seen in the areas of highest sunlight exposure.

Most skin cancers in transplant recipients are squamous cell carcinomas. Many recipients develop multiple lesions, and the age at onset is markedly lower than in the general population. The incidence of melanomas is also higher representing 4.8% of skin cancers in kidney transplant recipients, as compared with 2.7% in the general population [155]. Even nonmelanotic squamous cell carcinomas behave more aggressively in transplant recipients, with lymph node metastasis and a 6% mortality rate due to disseminated disease [184]. On identification of skin lesions, prompt surgical extirpation should be undertaken. Solid-organ transplant recipients are instructed to avoid direct exposure to sunlight for any prolonged period and to liberally use sunblock. Clearly, close dermatologic counseling and follow-up are warranted in this patient population.

Kaposi Sarcoma

Kaposi's sarcoma (KS) is a multicentric, vascularized, nodular neoplasm that may affect the skin, visceral tissues (such as the lungs and GI tract), or both. Endemic in the Mediterranean region and Middle East, it is strongly associated with either endogenous or exogenous immunosuppression, as a result both of AIDS and of immunosuppressive therapy. The incidence of this disease in U.S. transplant recipients is 0.4%, which represents a 20-fold increase over the basal rate in the population at large [155]. That figure rises to 1.6% in Italian kidney-transplant recipients and up to 4.0% in Saudi Arabian transplant recipients [185,186]. Recently, human herpes virus (HHV)-8 has been implicated as a causal agent in KS. One small series showed HHV-8 seropositivity pretransplant to be a relative risk factor for development of KS posttransplant [187].

Cutaneous KS is readily identified by clinical appearance and biopsy. But patients with only visceral KS often present with more advanced disease, usually GI bleeding or viscus perforation, sometimes dyspnea related to pulmonary disease. Immunosuppression should be reduced to the extent possible, after which about 30% to 55% of patients will experience remission. Chemotherapy is reserved for patients with visceral KS and for those who do not experience remission after their immunosuppression is reduced. However, of patients with visceral KS, 45% to 50% die of it. Viral studies and antiviral therapy do not yet have any well-established role in fighting this neoplasm, but anecdotal evidence indicates that certain patients may respond to antiviral agents (e.g., ganciclovir).

Cervical Cancer

The rate of development of cervical intraepithelial neoplasia is elevated by 10- to 14-fold in solid-organ transplant recipients and may approach 50% [188,189]. Cervical carcinoma was seen in 10% of all women with posttransplant cancer in the Transplant Tumor Registry [155]. Close surveillance by pelvic examination and Papanicolaou smear is essential in this population, given the increased incidence of disease. In transplant recipients with more advanced cervical cancer, a functioning graft poses complications in selecting and carrying out appropriate therapy. Limited data are available to guide therapy.

Transmitted and Recurrent Malignancy

Case reports have described patients who received grafts that harbored malignant cells, leading to the development of malignancy. Transmission to transplant recipients of renal cell carcinoma, metastatic cancer of the breast or lung, and melanoma has been reported. Currently, cancer or recent history of cancer is a contraindication to organ donation, with the possible exception of some low-grade skin cancers, noninvasive CNS neoplasms, and small, limited, extirpated cancers that are not likely to recur or spread. Nonetheless, some grafts are found to contain foci of neoplasia, which develop into a clinically significant cancer in recipients. This finding emphasizes the need for a thorough examination of donors during organ procurement, particularly considering the present trend toward the use of older donors.

Patients with a history of malignancy clearly are at risk for recurrent disease posttransplant, presumably due to the use of immunosuppression. Data from the Transplant Tumor Registry show a 21% recurrence rate, with the highest rates seen in patients with multiple myeloma (67%), nonmelanotic skin cancer (53%), bladder cancer (29%), soft-tissue sarcoma (29%), renal cell cancer (27%), and breast cancer (23%) [190]. Tumors were least likely to recur if more than 5 years had passed between cancer treatment and the transplant.

Liver transplants to treat patients with primary, well-circumscribed liver tumors represent a special case. In this population, liver tumor size and the number of liver tumors are considered indicative of the likelihood of disease recurrence and patient survival posttransplant [191,192]. Adjuvant techniques, such as cryoablation and radiofrequency ablation, to reduce the tumor burden pretransplant have been used, but currently the data are insufficient to clearly define the ability of adjuvant techniques to reduce posttransplant morbidity and mortality secondary to disease recurrence. Risk factors for recurrence include tumor size > 6 cm, number of nodules > 5, and vascular invasion per the final pathology report [193]. Clearly, tumor biology dictates the risk of disease recurrence and needs to be further characterized, representing an interesting, perhaps promising experimental arena.

SUMMARY

Over the past several decades, advances in the field of solid-organ transplantation have been significant, such that the primary limitation to further expansion may be considered to be logistic, related to organ availability. Dramatic improvements in medical care and technology have broadened the pool of potential recipients to include those who would have been considered too sick, with too much comorbidity, even a few years ago. Until medical science is able to develop immunosuppression without side effects, the predominant challenges in transplantation will remain the prevention, detection, and treatment of rejection; the prophylaxis, diagnosis, and treatment of infections; and the prevention, detection, and treatment of malignancy. Those clinical problems have only grown in the nearly six decades since the first successful kidney transplant was performed, and they promise to become even more complex throughout the twenty-first century.

CHAPTER 187 ■ CRITICAL CARE OF THE LIVER AND INTESTINAL TRANSPLANT RECIPIENTS

RUY J. CRUZ JR, WILLIAM D. PAYNE AND ABHINAV HUMAR

INTRODUCTION

The field of liver transplantation has undergone remarkable advances in the last two decades. From an essentially experimental procedure with poor results in the early 1980s, it has progressed to become the accepted treatment of choice for patients with acute and chronic end-stage liver disease. One-year survival rates have increased from 30% in the early 1980s, to more than 85% at present. The major reasons for this dramatic improvement in outcome include improved surgical and preservation techniques, better immunosuppressive regimens, more effective treatment of rejection and infection, and improved care during the critical perioperative period. The field of intestinal transplantation has also made tremendous strides in the last 20 years, though perhaps has not enjoyed the degree of success seen with liver transplantation. Nonetheless, results continue to improve and it is approaching success rates that are not dramatically inferior compared with liver transplantation.

Despite the improved results, both liver and intestinal transplantation remain major undertakings, with potential for complications affecting every major organ system. This chapter focuses on the critical care of these challenging and complicated patients, including preoperative selection and evaluation, intraoperative care, postoperative care, and management of potential complications.

LIVER TRANSPLANTATION

History

The origins of modern clinical liver transplantation date back to the late 1950s, when the surgical techniques were perfected in the dog model [1]. The first human liver transplant was performed by Starzl in 1963 [2], but not until 1967 was the first successful such transplant performed [3]. Little progress was made in the field over the next decade. It remained a dangerous procedure, reserved for terminal patients.

In the early 1980s, liver transplantation proliferated for a variety of reasons, the most important being the introduction of cyclosporine [4]. At that time, it was the most specific immunosuppressive agent and allowed for a dramatic rise in all organ transplants. Patient survival rates for liver recipients on cyclosporine more than doubled. In the late 1980s, the introduction of University of Wisconsin (UW) preservation solution extended the cold preservation time of the cadaver liver from 8 to 24 hours [5].

As the success of liver transplantation grew, so did the indications and the number of people awaiting a transplant. With each passing year, there was an ever increasing disparity between the number of transplants performed and the number of patients awaiting transplant. In 1988, there were approximately 1,500 transplants performed and 3,000 patients awaiting a transplant. In 2008, according to the UNOS Database, 6,319 liver transplants were performed in the United States, while 16,584 patients were listed waiting for an available/suitable organ (UNOS/OPTN, www.optn.transplant.hrsa.gov/, accessed August, 2009) [6].

Given this increasing disparity between the number of actual and potential recipients, recent attempts have been made to expand the donor pool. Some of this increase in donors has been achieved by the use of livers that are considered marginal and would not have been used for transplant a decade ago. Recently, the use of organs from donors after cardiac death (also referred as nonheart beating donors) has emerged as an important source of organs in response to the significant growth of the waiting list. Donation after cardiac death (DCD) involves those donors who present a severe neurological injury and/or irreversible brain damage but still have minimal brain function. In 2000, only 11 centers used DCD livers, increasing to 62 centers in 2007 [7–9].

Innovative surgical procedures have also been used in order to increase the donor pool. These procedures include, but are not limited to, living donor liver transplantation, split-liver transplantation, and dual liver transplantation. Living donor transplants involve transplanting a lobe or part of a lobe from a healthy donor into a potential recipient. Split-liver transplantation involves dividing a cadaver liver into two functional grafts, which can be transplanted into two recipients. Dual liver transplantation involves the use of two lobes (usually two left lobes) from two living donors that are implanted into one adult recipient. These procedures are helping expand the donor pool, but are also associated with unique problems.

Proper allocation of the scarce resource of a deceased donor liver graft has always been an important issue in the development of the field. Recent effects have focused on directing organs to individuals with the greatest need, rather than those with the longest waiting time. In the United States, this lead to the development and adaptation in 2002 of the MELD (Model for End-Stage Liver Disease) and PELD (Pediatric End-Stage Liver Disease) scoring systems [10].

Preoperative Evaluation

A liver transplant is indicated for liver failure, whether acute or chronic. Liver failure is signaled by a number of clinical symptoms (e.g., ascites, variceal bleeding, hepatic encephalopathy, malnutrition) and by biochemical liver test results that suggest impaired hepatic synthetic function (e.g., hypoalbuminemia, hyperbilirubinemia, coagulopathy). The cause of liver failure often influences its presentation. For example, patients with acute liver failure generally have hepatic encephalopathy and coagulopathy, whereas patients with chronic liver disease most commonly have ascites, gastrointestinal (GI) bleeding, and malnutrition.

A host of diseases are potentially treatable by a liver transplant. Broadly, they can be categorized as acute or chronic, and then subdivided by the cause of the liver disease (Table 187.1). Chronic liver diseases account for the majority of liver transplants today. The most common cause in North America is chronic hepatitis, usually due to hepatitis C, less commonly to hepatitis B. Chronic alcohol abuse accelerates the process, especially with hepatitis C. Progression from chronic infection to cirrhosis is generally slow, usually 10 to 20 years. Chronic hepatitis may also result from autoimmune causes, primarily in women; it can present either acutely over months or insidiously over years [11]. Alcohol often plays a role in end-stage liver disease (ESLD) secondary to hepatitis C, but it may also lead to liver failure in the absence of that viral infection. In fact, alcohol is the most common cause of ESLD in the United States. Such patients are generally suitable candidates for a transplant as long as an adequate period of sobriety can be documented. Most of the centers in the United States require a minimum of 6 months of demonstrated abstinence and an adequate evaluation and treatment period for alcohol addiction. In spite of this strict pretransplant screening the rate of alcohol use after transplant can reach 42% in the first 5 years after transplant [12]

TABLE 187.1

DISEASES POTENTIALLY TREATABLE BY A LIVER TRANSPLANT

Cholestatic liver diseases
Primary biliary cirrhosis
Primary sclerosing cholangitis
Biliary atresia
Alagille's syndrome
Chronic hepatitis
Hepatitis B
Hepatitis C
Autoimmune hepatitis
Alcohol liver disease
Metabolic diseases
Hemochromatosis
Wilson's disease
α_1-Antitrypsin deficiency
Tyrosinemia
Cystic fibrosis
Hepatic malignancy
Hepatocellular carcinoma
Neuroendocrine tumor metastatic to liver
Fulminant hepatic failure
Others
Cryptogenic cirrhosis
Polycystic liver disease
Budd–Chiari syndrome
Amyloidosis

Cholestatic disorders also account for a significant percentage of transplant candidates with chronic liver disease. In adults, the most common causes are primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC). PBC, a destructive disorder of interlobular bile ducts, can progress to cirrhosis and liver failure over several decades. It most commonly affects middle-aged women. PSC, a disease characterized by inflammatory injury of the bile duct, occurs mostly in young men, 70% of whom have inflammatory bowel disease [13]. In children, biliary atresia is the most common cholestatic disorder. It is a destructive, inflammatory condition of the bile ducts; if untreated, it usually results in death within the first 1 to 2 years of life.

A variety of metabolic diseases can result in progressive, chronic liver injury and cirrhosis, including hereditary hemochromatosis (an autosomal recessive disorder characterized by chronic iron accumulation, which may result in cirrhosis, cardiomyopathy, and endocrine disorders including diabetes), α_1-antitrypsin deficiency (which may result in cirrhosis at any age, most commonly in the first or second decade of life), and Wilson's disease (an autosomal recessive disorder of

copper excretion, which may present as either fulminant hepatic failure or chronic hepatitis and cirrhosis) [14].

Hepatocellular carcinoma (HCC) may be a complication of cirrhosis from any cause, most commonly with hepatitis B, hepatitis C, hemochromatosis, and tyrosinemia. In 2007, almost 15% of all liver transplants in the United States were performed in patients with a diagnosis of HCC. HCC patients may have stable liver disease, but are not candidates for hepatic resection because of the underlying cirrhosis; they are best treated with a liver transplant. The best transplant candidates are those with a single lesion less than 5 cm in size or with no more than three lesions, the largest no greater than 3 cm in size (known as the Milan criteria). Transplantation outside of these criteria is usually associated with higher recurrence rates, though some centers have shown acceptable 5-year survival in patients that have tumors that slightly exceed the Milan criteria [15,16].

Currently, in the United States, only the patients within Milan criteria are eligible for priority listing for liver transplantation. The amount of waiting list time for patients with HCC remains a critical factor in the success of liver transplantation, as long waiting times may lead to disease progression. Recently downstaging treatment, with transarterial chemoembolization and radiofrequency ablation, has emerged as a possible option for those patients who slightly exceed Milan criteria [17].

A host of other diseases may lead to chronic liver failure and are potentially amenable to treatment with a transplant, including Budd–Chiari (obstruction of the hepatic veins secondary to thrombus, which leads to hepatic congestion, ascites, and eventually liver damage) and polycystic liver disease (in which a large number of cysts, depending on their size, can lead to debilitating symptoms).

Acute liver disease, more commonly termed fulminant hepatic failure (FHF), is defined as the development of hepatic encephalopathy and profound coagulopathy shortly after the onset of symptoms, such as jaundice, in patients without preexisting liver disease. The most common causes in the Western world include acetaminophen overdose, acute viral hepatitis, various drugs and hepatotoxins, and Wilson's disease; often, however, no cause is identified [18]. Treatment consists of appropriate critical care support, giving patients time for spontaneous recovery. The prognosis for spontaneous recovery depends on the patient's age (those younger than 10 and older than 40 years have a poor prognosis), the underlying cause, and the severity of liver injury (as indicated by degree of hepatic encephalopathy, coagulopathy, and kidney dysfunction) (Table 187.2) [19,20]. A subset of patients may have delayed onset of hepatic decompensation that occurs 8 weeks to 6 months after the onset of symptoms. This condition is often referred to as subacute hepatic failure; these patients rarely recover without a transplant.

TABLE 187.2

ADVERSE PROGNOSTIC INDICATORS FOR PATIENTS WITH ACUTE LIVER FAILURE

(I) Acetaminophen toxicity
pH < 7.30
Prothrombin time > 100 sec (INR > 6.5)
Serum creatinine > 300 µmol/L (> 3.4 mg/dL)

(II) No acetaminophen toxicity
Prothrombin time > 100 sec (INR > 6.5)
Age < 10 or > 40 y
Non-A, non-B hepatitis
Duration of jaundice before onset of encephalopathy > 7 d
Serum creatinine > 300 µmol/L (> 3.4 mg/dL)

TABLE 187.3

INDICATIONS FOR A LIVER TRANSPLANT EVALUATION IN PATIENTS WITH CHRONIC LIVER DISEASE

Clinical indications
- Refractory ascites
- Spontaneous bacterial peritonitis
- Recurrent or severe hepatic encephalopathy
- Hepatorenal syndrome
- Significant weakness, fatigue, or progressive malnutrition
- Recurrent cholangitis or severe pruritus
- Progressive bone disease

Biochemical indications
- Serum albumin < 3.0 g/dL
- Serum INR > 1.7
- Serum bilirubin > 2 mg/dL (> 4 mg/dL for cholestatic disorders)

Indications for Transplant

Chronic Liver Disease. The simple presence of chronic liver disease with established cirrhosis is not an indication for a transplant (Table 187.3). Some patients have very well-compensated cirrhosis with a low expectant mortality. Patients with decompensated cirrhosis, however, have a poor prognosis without transplant. The signs and symptoms of decompensated cirrhosis include the following:

1. *Hepatic Encephalopathy (HE):* In its early stages, HE may begin with subtle sleep disturbances, depression, and emotional liability. Increasing severity of HE is indicated by increasing somnolence, altered speech, and at the extreme end, coma. Evaluation of the severity of HE is based on the West Haven criteria of altered mental status. A common finding on physical examination is asterixis, an ability to maintain position, which is most commonly tested by having the patients outstretch their arms and hold them in dorsiflexion. However, other simple tests (such as tongue protrusion, dorsiflexion of the foot, or asking the patient to grasp the examiner's fingers) can also trigger the asterixis. Blood tests often reveal an elevated serum ammonia level. HE may occur spontaneously, but is more commonly triggered by a precipitating factor such as infections, GI bleeding, use of sedatives, constipation, diuretics, electrolyte imbalance, or excessive dietary protein intake. The purpose of treatment is to correct the precipitating factor in combination with pharmacological management including nonabsolvable disaccharides (i.e., lactulose), and antibiotics such as neomycin, rifaximin, and metronidazole.
2. *Ascites:* Ascites is generally associated with portal hypertension. The initial approach to the management of ascites is sodium restriction and diuretics. If this approach is not successful, patients may require repeated large-volume (4 to 6 L) paracentesis. A better option to diuretic-resistant ascites requiring frequent paracentesis is transjugular intrahepatic portosystemic shunting (TIPS). A potential complication of TIPS is progression of liver failure or disabling encephalopathy. Patients with signs of far-advanced liver disease such as hyperbilirubinemia, HE, and renal dysfunction are generally not good candidates for TIPS.
3. *Spontaneous Bacterial Peritonitis (SBP):* This complication of chronic liver failure generally signals advanced disease. Anaerobic Gram-negative bacteria (*Escherichia coli, Klebsiella pneumoniae*) account for 60% of the cultured organisms; Gram-positive cocci account for the remainder. Diagnosis is confirmed if a tap of the abdominal fluid shows

a polymorphonuclear neutrophil (PMN) count of > 250 per mL. If a traumatic tap is performed (red cells > 10,000 per mL), the PMN count should be corrected, subtracting 1 PMN for every 250 red cells. Treatment is generally with a third-generation cephalosporin. The recurrence rate of SBP at 1 year is up to 70%; therefore, prophylaxis with antibiotics (norfloxacin or ciprofloxacin) is highly recommended. The long-term prognosis of patients who develop SBP is extremely poor with mortality rates of 50% to 70% at 1-year follow-up [21].

4. *Portal Hypertensive Bleeding:* The likelihood of patients with cirrhosis developing varices ranges from 35% to 80%. About one-third of those with varices will experience bleeding. The risk of recurrent bleeding approaches 70% by 2 years after the index bleeding episode. Each episode of bleeding is associated with a 30% mortality rate. Thus, urgent treatment of the acute episode and steps to prevent rebleeding are essential. Endoscopy is indicated to diagnose and treat the acute bleed with either band ligation or sclerotherapy. Other therapies include vasoactive drugs such as octreotide or vasopressin, balloon tamponade, TIPS, and emergency surgical procedures (such as a portosystemic shunt or transection of the esophagus). Generally, patients whose endoscopic procedure fails should undergo emergency TIPS, if feasible, to control bleeding. Beta-blockers have been shown to be of value in preventing the first bleeding episode in patients with varices and in preventing rebleeding.
5. *Hepatorenal Syndrome (HRS):* In patients with advanced liver disease and ascites, HRS is characterized by oliguria (< 500 mL of urine per day) in association with low urine sodium (< 10 mEq per L). It is a functional disorder; the kidneys have no structural abnormalities, and the urine sediment is normal. The differential diagnosis includes acute tubular necrosis, drug nephrotoxicity, and chronic intrinsic renal disease. HRS may be precipitated by volume depletion from diuresis, SBP, or agents such as nonsteroidal antiinflammatory drugs. Patients may require dialysis support, but the only effective treatment is a liver transplant.
6. *Others:* Other signs and symptoms of decompensated cirrhosis include severe weakness and fatigue, which may sometimes be the primary symptoms. Such weakness can be debilitating, leading to the inability to work or even to carry out day-to-day functions. It may be associated with malnutrition and muscle wasting, which at times may be quite severe. Biochemical abnormalities and loss of synthetic function in advanced ESLD are associated with a low-serum albumin, a high-serum bilirubin, and a rise in the serum international normalized ratio (INR).

The severity of illness and prognosis of patients with chronic liver disease can be estimated by a number of different scoring models including the Childs–Pugh–Turcotte score and the MELD score. The latter is now widely used in the United States for the allocation of organs. It is based on a predicted 3-month mortality for patients awaiting a liver transplant, and uses 3 laboratory values to generate a score which determines priority. The three laboratory values used are serum bilirubin, serum creatinine, and INR. The format is as follows:

$$\begin{aligned}\text{MELD Score} = {} & 0.957 \times \log_e(\text{creatinine mg per dL}) \\ & + 0.378 \times \log_e(\text{bilirubin mg per dL}) \\ & + 1.120 \times \log_e(\text{INR}) \\ & + 0.643\end{aligned}$$

For pediatric patients, the scoring system is somewhat different. The PELD (pediatric end-stage liver disease) score is calculated using the following factors: serum bilirubin, albumin, and INR, the age of the patient (additional points if < 1 year old), and if the patient has growth failure [22].

Acute Liver Disease. Patients with FHF should be considered for transplant if they have any one of a number of poor prognostic indicators that predict a low likelihood for spontaneous recovery of liver function (Table 187.2). Generally, FHF patients are more acutely ill than chronic liver failure patients, and thus require more intensive care pretransplant. FHF patients have more severe hepatic parenchymal dysfunction, as manifested by coagulopathy, hypoglycemia, and lactic acidosis. Infectious complications are more common, as is their incidence of kidney failure and neurologic complications, especially cerebral edema.

Coagulopathy is usually secondary to the impaired hepatic synthesis of clotting factors. A component of consumption, as a result of disseminated intravascular coagulation (DIC), may also be associated with FHF. Close attention should be given to the serum glucose level, which is more likely to be decreased in FHF patients. Intravenous (IV) glucose should be administered at a sufficient rate to maintain euglycemia.

The prevalence of bacterial infection in FHF patients is very high, a reflection of the loss of the liver's immunologic functions. The respiratory and urinary systems are the most common sources. In addition, almost one-third of FHF patients develop some form of fungal infection, usually secondary to *Candida* species [23]. Sepsis is generally a contraindication to a transplant; if it is unrecognized pretransplant, the outcome posttransplant is poor.

Multiple organ dysfunction syndrome, characterized by respiratory distress, kidney failure, increased cardiac output, and decreased systemic vascular resistance, is a well-described complication of FHF. It may be due to impaired clearance of vasoactive substances by the liver. Mechanical ventilation and dialysis support may become necessary pretransplant. Hemodynamic abnormalities may manifest as hypotension and worsening tissue oxygenation.

Cerebral edema is substantially more common in FHF patients. As many as 80% of patients dying secondary to FHF have evidence of cerebral edema. The pathogenesis is unclear, but it may be due to potential neurotoxins that are normally cleared by the liver. Diagnosis may be problematic; patients are often sedated and ventilated, making clinical examination difficult. Radiologic imaging is neither sensitive nor specific. Several centers have tried intracranial pressure (ICP) monitoring; therapy (e.g., mannitol, hyperventilation, thiopental) can then be directed to achieve an adequate cerebral perfusion pressure. ICP monitoring also helps predict the likelihood of neurologic recovery posttransplant. Sustained cerebral perfusion pressures of less than 40 mm Hg have been associated with postoperative neurologic death. Disadvantages of ICP monitoring include the risks of performing it in patients with severe coagulopathy; it is also a possible source of infection and may precipitate an intracranial hemorrhage.

Contraindications for Transplant

The indications for a liver transplant are numerous (and are increasing), but the numbers of absolute contraindications are few (and have decreased with time). There are no specific age limits for recipients; their mean age is steadily increasing. Patients must have adequate cardiac and pulmonary function. Other contraindications, as with other types of transplants, include uncontrolled systemic infection and malignancy. HCC patients with metastatic disease, obvious vascular invasion, or significant tumor burden are not good transplant candidates. Patients with other types of extrahepatic malignancy should be deferred for at least 2 years after completing curative therapy before a transplant is attempted.

Currently, the most common contraindication in the United States to a liver transplant is ongoing substance abuse. Before considering patients for a transplant, most centers require a documented period of abstinence, demonstration of compliant behavior, and willingness to pursue a chemical dependency program.

Unique to patients with chronic liver disease, a transplant may be contraindicated in the presence of severe hepatopulmonary syndrome or pulmonary hypertension. Hepatopulmonary syndrome is characterized by impaired gas exchange, resulting from intrapulmonary arteriovenous shunts. These shunts may lead to severe hypoxemia, especially when patients are in the upright position (orthodeoxia). A transplant may be contraindicated if intrapulmonary shunting is severe, as manifested by hypoxemia that is only partially improved with high inspired oxygen concentrations. Pulmonary hypertension (mean pulmonary artery pressure > 25 mm Hg in the setting of portal hypertension) is seen in a small proportion of patients with established cirrhosis. Its exact cause is unknown [24]. Diagnosing pulmonary hypertension pretransplant is critical, because major surgical procedures in the presence of nonreversible pulmonary hypertension are associated with a very high risk of mortality. The initial screening is usually performed with transthoracic Doppler echocardiography (TTE) which can estimate pulmonary arterial systolic pressure when tricuspid regurgitation is present. TTE presents a sensitivity of 97% and specificity of 77% in diagnosing pulmonary hypertension in the setting of liver failure. In patients with elevated pulmonary arterial systolic pressure (> 50 mm Hg), a more invasive assessment (right heart catheterization) is recommended. It has been shown that perioperative mortality is directly proportional to the mean pulmonary artery pressure (mPAP) and pulmonary vascular resistance. For these reasons, most transplant centers consider a mPAP greater than 35 mm Hg to be an absolute contraindication for transplant. If the mPAP can be lowered below that value using medications (epoprostenol, sildenafil), the patient can still be considered for transplant [24].

Another absolute contraindication for liver transplantation, in case of acute liver failure, is a presence of unresponsive cerebral edema with sustained elevation of intracranial pressure (> 50 mm Hg) and a persistent decrease in cerebral perfusion pressure (< 40 mm Hg).

Intraoperative Care

A detailed description of the operative procedure and anesthetic management is beyond the scope of this chapter. A basic understanding of the intraoperative course is necessary, however, to aid in postoperative care and monitoring for possible complications.

The operation itself may be divided into three phases: preanhepatic, anhepatic, and postanhepatic. The preanhepatic phase involves mobilizing of the recipient's diseased liver in preparation for its removal. The basic steps include isolating the supra- and infrahepatic vena cava, portal vein, and hepatic artery, and then dividing the bile duct. Given existing coagulopathy and portal hypertension, the recipient hepatectomy may be the most difficult aspect of the procedure. The anesthesia team must be prepared to deal with excessive blood loss during this time.

Once the above-named structures have been isolated, vascular clamps are applied. The recipient's liver is removed, thus beginning the anhepatic phase. This phase is characterized by decreased venous return to the heart because of occlusion of the inferior vena cava and portal vein. Many centers routinely employ a venous bypass system during this time: blood is drawn from the lower body and bowels via a cannula in the common femoral vein and portal vein, and returned through a central venous cannula in the upper body. Potential advantages of bypass include improved hemodynamic stability, reduction of bleeding from an engorged portal system, and avoidance of elevated venous pressures in the renal veins. However, many centers do not routinely use venovenous bypass (VVB). Very few randomized trials have measured specific clinical outcomes with or without VVB. In one randomized trial, postoperative renal function and the need for hemodialysis or hemofiltration were no different between liver recipients with versus without VVB [25]. This, combined with the potential complications of VVB (air embolism, thromboembolism, hypothermia, hemodilution, cannula and incision-related morbidity, trauma to vessels, and incremental costs), have led some centers to adopt a selective use for VVB—reserving it for patients without portal hypertension or for those patients who demonstrate hemodynamic instability with a trial of caval clamping [26].

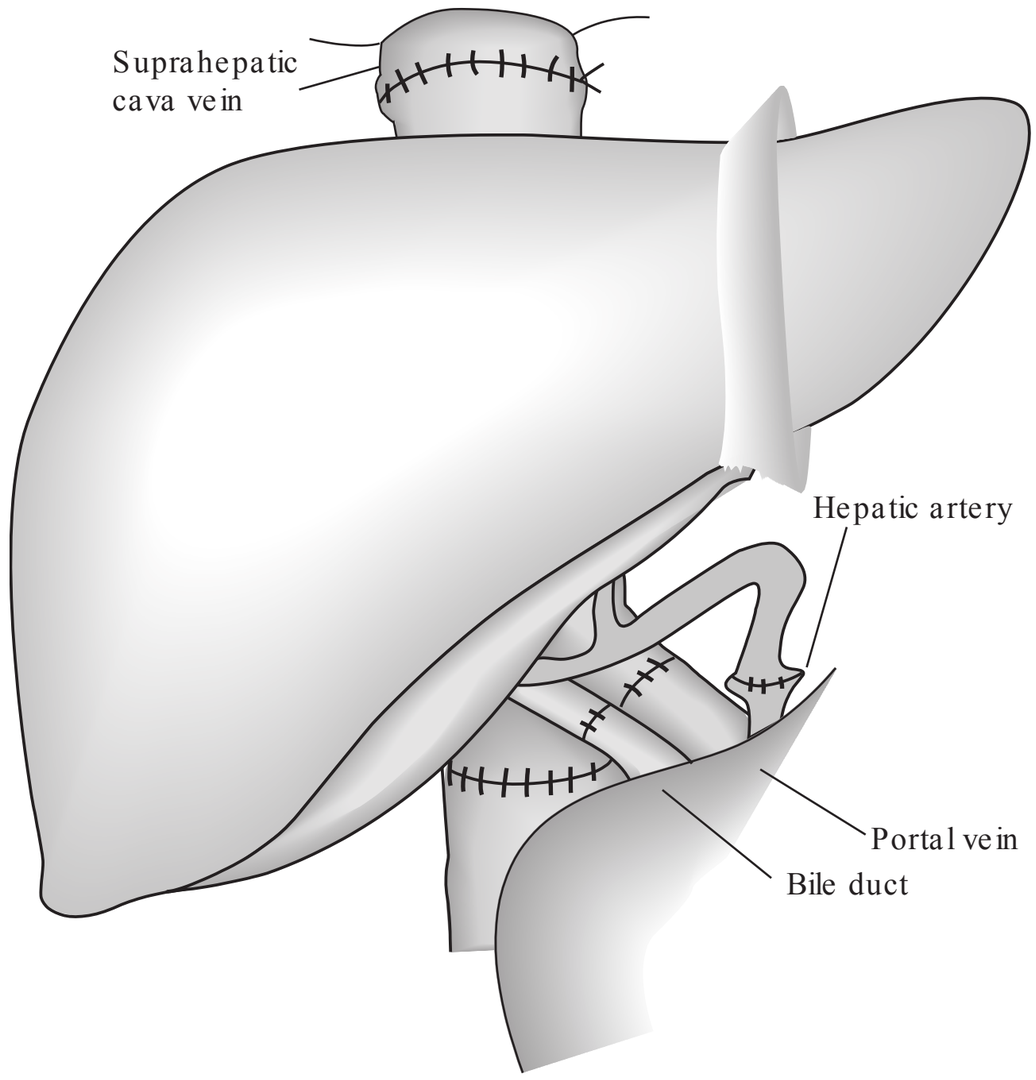

FIGURE 187.1. Illustration of standard liver transplant procedure with replacement of the recipient's inferior vena cava. Typical vascular and biliary anastomoses are shown.

With the recipient liver removed, the donor liver is anastomosed to the appropriate structures to place the new liver in an orthotopic position (Fig. 187.1). The suprahepatic caval anastomosis is performed first, followed by the infrahepatic cava and the portal vein. The portal and caval clamps may be removed at this time, allowing reperfusion of the new liver. Either before or after this step, the hepatic artery may be anastomosed.

With the clamps removed and the new organ reperfused, the postanhepatic phase begins, often characterized by marked changes in the patient's status. The most dramatic changes in hemodynamic parameters usually occur upon reperfusion, with hypotension and the potential for serious arrhythmia. Severe coagulopathy may also develop because of the release of natural anticoagulants from the ischemic liver or active fibrinolysis. Both epsilon aminocaproic acid and aprotinin have been used prophylactically to prevent fibrinolysis and decrease transfusion requirements [27]. Electrolyte abnormalities, most commonly hyperkalemia and hypercalcemia, are often seen after reperfusion; they are usually transient and respond well to treatment with calcium chloride and sodium bicarbonate. After reperfusion of the liver, the final anastomosis is performed, establishing biliary drainage. The recipient's remaining common

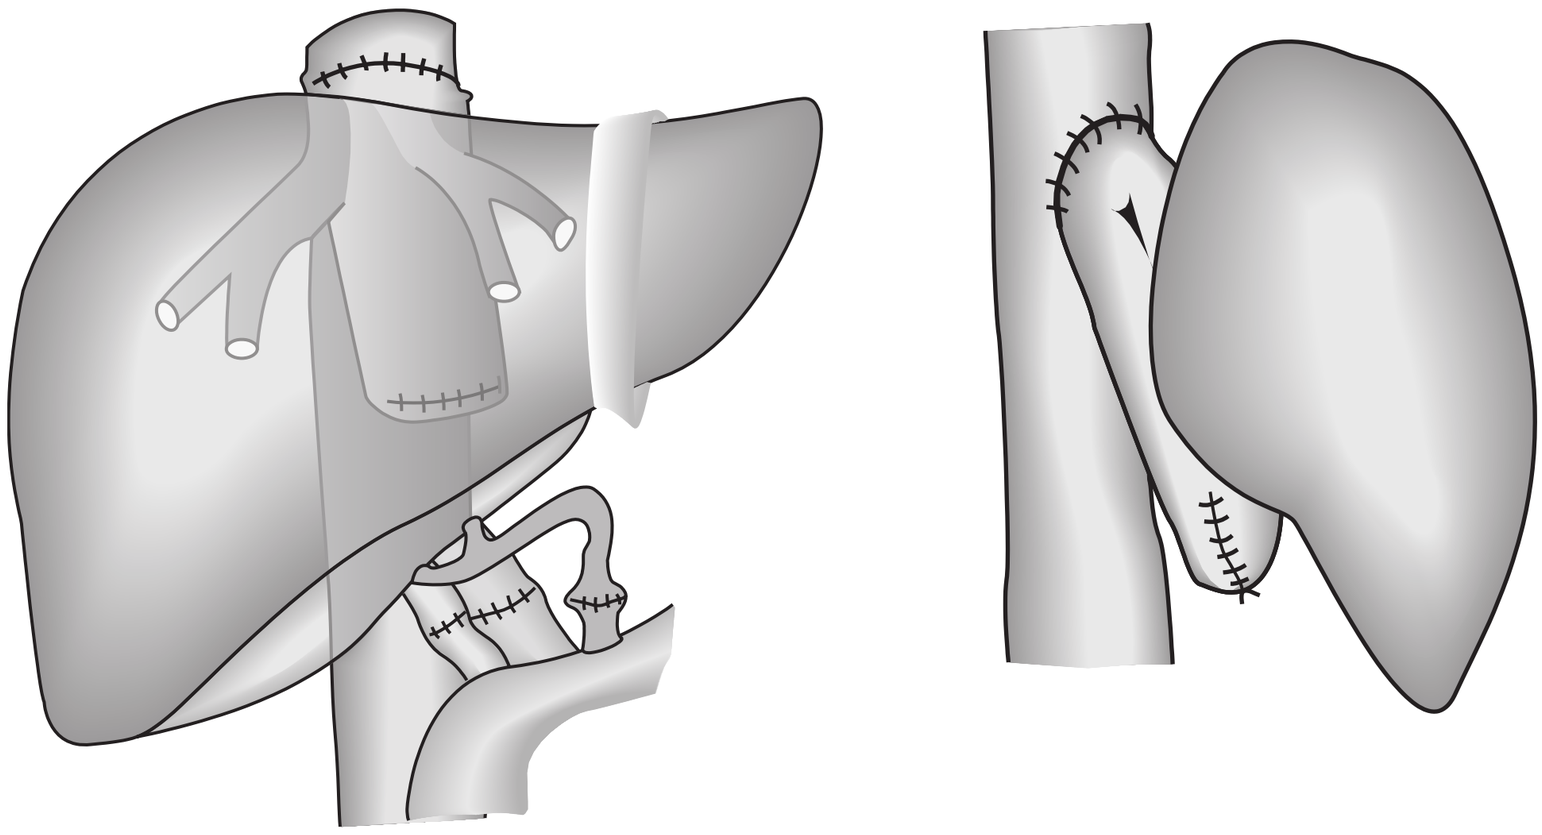

FIGURE 187.2. Illustration of "piggyback" liver transplant procedure with preservation of the recipient's inferior vena cava.

bile duct (choledochoduodenostomy) or a loop of bowel (choledochojejunostomy) may be used.

Several variations of the standard operation have been described, including the "piggyback technique." Here the recipient's inferior vena cava is preserved, the infrahepatic donor cava is oversewn, and the suprahepatic cava is anastomosed to the confluence of the recipient hepatic veins (Fig. 187.2). With this technique, the recipient's cava does not have to be completely crossclamped during anastomosis—thus allowing blood from the lower body to return to the heart uninterrupted, without the need for VVB. In spite of the potential advantages of the "piggyback technique," this procedure is precluded, for obvious reasons, in patients with tumors involving retrohepatic vena cava or main hepatic veins.

The surgical procedure for children does not differ significantly from that for adults. However, the size of the recipient is a significantly more important variable and has an impact on both the donor and the recipient operations.

For pediatric patients (especially infants and small children), the chance of finding a size-matched cadaver graft may be very small: the vast majority of cadaver donors are adults. Accordingly, pretransplant mortality used to be very high in pediatric patients. As a result, three procedures evolved from the principle that a liver is made up of several self-contained segments, each with its own vascular inflow, vascular outflow, and biliary drainage. As a result of these three procedures (namely, reduced-size liver transplants, living related liver transplants, and split-liver transplants), pediatric waiting list mortality rate is now very low.

Reduced-Size Liver Transplants

The earliest efforts involved tailoring a whole-cadaver graft on the back table to fit the recipient. A portion of the liver, such as the right lobe or extended right lobe, was resected and discarded. The remaining left lateral segment was then used for transplant. Reduced-size liver transplant (RSLT) significantly reduced waiting times for children, but negatively affected the adult recipient pool.

Living Donor Liver Transplant

Living donor liver transplant (LDLT) is a natural extension of RSLT. Usually, the left lateral segment from an adult is used (Fig. 187.2), providing sufficient liver tissue for children up to 25 kg. Advantages include the ability to perform the transplant before the recipient deteriorates clinically and the ability to select an ideal donor. The main disadvantage, obviously, is the risk to the donor.

Split-Liver Transplants

With this technique, an adult cadaver liver is divided into two functional grafts: the left lateral segment (which can be transplanted into a child) and the remaining right trisegment (which can be transplanted into an adult). Most split-liver transplants (SLTs) are now performed in vivo: the liver is divided in the cadaver, in a similar fashion to the LDLT procedure. SLT overcomes the disadvantages of both LDLT and RSLT while increasing the donor pool.

Because the severe shortage of organs, partial transplants, either a living donor transplant or a deceased donor split-liver transplant, are being increasingly used for adult recipients also. Usually, in LDLTs for pediatric recipients, the left lateral segment is used; for adult recipients, however, this would be inadequate liver mass and so usually the right lobe is used. Split-liver transplants from deceased donors involve dividing the donor liver into two segments, each of which is subsequently transplanted.

The greatest advantage of a LDLT is that it avoids the waiting time seen with deceased donor organs. In the United States, over 16,500 people are now waiting for liver transplants, but only 6,000 transplants are performed every year (UNOS/OPTN, www.optn.transplant.hrsa.gov/, accessed August, 2009) [6]. Approximately, 15% to 25% of the candidates will die of their liver disease before having the chance to undergo a transplant. For those who do end up receiving a transplant from a deceased donor, the waiting time can be significant, resulting in severe debilitation. With a LDLT, this waiting time can be bypassed, allowing the transplant to be performed before the recipient's health deteriorates further. In 2007, 266 LDLTs were performed in the United States, accounting for 4% of the total liver transplants performed that year.

A partial hepatectomy in an otherwise healthy donor is a significant undertaking, so all potential donors must be very carefully evaluated. Detailed medical screening must ensure that the donor is medically healthy; radiologic evaluation must ensure that the anatomy of the donor's liver is suitable; and a psychosocial evaluation must be done to ensure that the donor is mentally fit and not being coerced. The decision to donate should be made entirely by the potential donor after careful consideration of the risks and of the potential complications, with no coercion from anyone.

The overall incidence of donor complications after living donor liver donation ranges from 5% to 10%. There is also a small risk (<0.5%) of death [28,29]. Of note, mortality is higher for adult-to-adult donation (0.24% to 0.4%) compared with adult-to-child donation (0.09% to 0.2%). This is explained by the fact that adult-to-child donation usually removal of a smaller portion of the liver. Bile duct problems are the most worrisome complication after donor surgery. Bile may leak from the cut surface of the liver or from the site where the bile duct is divided. That site may later become strictured. Generally, bile leaks resolve spontaneously with simple drainage. Strictures and sometimes bile leaks may require an ERCP and stenting. If the above measures fail, a reoperation may be required. Intra-abdominal infections developing in donors are usually related to a biliary problem. Other complications after donor surgery may include incisional problems such as infections and hernias. The risk of deep venous thrombosis (DVT) and pulmonary embolism (PE) is the same as for other major abdominal procedures.

The recipient operation with LDLTs is not greatly different from whole-organ deceased donor liver transplants. The hepatectomy is performed in a similar fashion—the cava should be preserved in all such cases, because the graft will generally only have a single hepatic vein for outflow. This is then anastomosed directly to the recipient's preserved vena cava. Outflow problems tend to be more common with partial versus whole transplants, especially with right lobe transplants (which, again, are usually used for adult recipients). Various methods have been described to improve the outflow of the graft, such as including the middle hepatic vein with the graft, reimplanting accessory hepatic veins, and reimplanting large tributaries that drain the right lobe into the middle hepatic vein [30–32]. Inflow to the graft can be reestablished by anastomosing the donor's hepatic artery and portal vein branch to the corresponding structures in the recipient.

Another method to increase the number of liver transplants is to split the liver from a deceased donor into two grafts, which are then transplanted into two recipients [33]. Thus, a whole adult liver from such a donor can be divided into two functioning grafts. The vast majority of split-liver transplants have been between one adult donor and two pediatric recipients. Splitting one adult liver for two pediatric recipients has no negative impact on the adult donor pool, but it does not increase it either. Adults now account for the majority of patients awaiting a transplant—and the majority of patients dying on the waiting list. Therefore, if split-liver transplants are to have a significant impact on waiting list time and mortality, they must be performed so that the resulting two grafts can also be used in two adult recipients [34]. The worry is that the smaller of the two pieces would not be sufficient to sustain life in a normal-sized adult. However, with appropriate donor and recipient selection criteria, a small percentage of livers from deceased donors could be split and transplanted into two adult recipients.

Recently, the use of organs from donors after cardiac death (also referred as non-heart–beating donors) has emerged as an important source of organs in response to the significant growth of the waiting list. DCD involves those donors who present a severe neurological injury and/or irreversible brain damage but still have minimal brain function. Therefore, DCD offers the patient and the family the opportunity to donate when criteria for brain death will not have been met [7–9]. Two different types of DCD are described. Controlled DCD involves planned withdrawal of ventilatory and organ-perfusion support, most often in the operating room with a surgical team readily available (Maastricht III). In contrast, uncontrolled DCD sustains an unexpected cardiopulmonary arrest and either fails to respond to resuscitation or is declared dead on arrival to the hospital (Maastricht I, II, and IV). The number of DCD liver allografts has gradually increased, and now represents approximately 5% of all liver transplants performed in the United States. In 2000, only 11 centers used DCD livers, increasing to 62 centers in 2007 [8].

Because of the constant imbalance between the number of available organs and the number of candidates for liver transplant, organs that were previously thought to be associated with an unacceptably high risk of initial poor function have been used to increase the donor pool. These organs obtained from the so-called expanded criteria donors have been used with an increase rate of primary nonfunction (PNF).

In 2006, a retrospective study using characteristics of more than 20,000 donors identified several factors that were associated with an increase risk of graft loss. These factors were used to generate a "donor risk index," which is directly related to a predicted rate of graft survival. Six donor/graft characteristics are as follows: (1) donor age over 40 (particularly over 60), (2) donation after cardiac death, (3) African American race, (4) shorter in height, (5) cerebrovascular accident as cause of death and (6) use of partial grafts, were significantly associated with graft failure. In parallel to the recipient risk score (i.e. MELD score) the donor risk index may help to optimize the donor/recipient matching. However, the potential benefit of utilization of this score in organ allocation remains to be determined [35].

Postoperative Care

The postoperative course can range from smooth to extremely complicated, depending mainly on the patient's preoperative status and the development of any complications. The care of all such patients involves (1) stabilization and recovery of the major organ systems (e.g., cardiovascular, pulmonary, renal); (2) evaluation of graft function and achievement of adequate immunosuppression; and (3) monitoring and treatment of complications directly and indirectly related to the transplant.

Initial Stabilization

The initial care immediately posttransplant should be performed in an intensive care unit (ICU) setting. Recipients generally require mechanical ventilatory support for the first 24 to 48 hours. The goal is to maintain adequate oxygen saturation, acid base equilibrium, and stable hemodynamics. Guidelines for extubation are no different from the standard postoperative patient: a level of consciousness sufficient to protect the airway and the ability to maintain adequate oxygenation and ventilation. As well, there should be some indication of function of the new graft prior to attempting extubation. After extubation, it is crucial to continue with aggressive physiotherapy, deep breathing exercises, and ambulation to reduce the typically high incidence of respiratory complications.

Continuous hemodynamic monitoring should be maintained via an arterial line and pulmonary artery catheter. Information obtained should be used to ensure adequate perfusion of the graft and vital organs. The preoperative hyperdynamic circulatory state will often persist into the postoperative period. Later, as hepatic function improves, the cardiac index progressively declines and the SVR increases toward normal values. However, the myocardial dysfunction that is often seen early in the reperfusion phase may persist, with decreased compliance and contractility of the ventricles. The cause of this myocardial depression is unclear, but may be related to the release of vasoactive substances after reperfusion of the ischemic liver and decompression of the portal circulation. The usual treatment is to optimize preload and afterload, and inotropic agents such as dopamine or dobutamine.

To assess for possible bleeding, serial hematocrits should be measured initially every 4 to 6 hours. Coagulation parameters

(prothrombin time, partial thromboplastin time, thrombin time) need to be carefully monitored because of frequent coagulopathy, most likely related to intraoperative blood loss and temporary ischemic damage in the revascularized new liver. Other laboratory values to monitor include serum transaminases and serum bilirubin. Normalization of these values, along with improvement in mental status and renal function, are valuable indicators of good graft function.

Fluid management, electrolyte status, and renal function require frequent evaluation after surgery. Most liver recipients have an increased extravascular volume but a reduced intravascular volume. Attention should be given to the potassium, calcium, magnesium, phosphate, and glucose levels. Potassium may be elevated because of poor renal function, residual reperfusion effect, or immunosuppression medications. Diuretics may be required to remove excess fluid acquired intraoperatively, but may result in hypokalemia. Magnesium levels should be kept more than 2 mg per dL to prevent seizures and phosphate levels between 2 and 5 mg per dL for proper support of the respiratory and alimentary tracts. Marked hyperglycemia may be seen secondary to steroids, and should be treated with insulin. Hypoglycemia is often an indication of poor hepatic function.

Nasogastric suction is initially required until normal bowel function resumes (usually 48 hours); patients with a choledochojejunostomy may need more time. Some form of prophylaxis for GI bleeding should be maintained as the physiologic stress after a liver transplant may lead to gastric erosions and ulcerations. The GI tract can be used for nutrition by postoperative day 3 to 5. However, for patients with prolonged ileus or significant intestinal edema—especially if they were malnourished preoperatively—total parenteral nutrition (TPN) should be instituted early.

As soon as the patient enters the ICU, prevention, prophylaxis, and close monitoring of possible infections should begin. Given the magnitude of the operation, the often poor pretransplant medical status, and the need for immunosuppression, it is not surprising that more than 50% of liver recipients develop some infection. Close attention must be given to all invasive monitoring lines, which should be changed every 5 to 7 days. Aggressive pulmonary toilet is needed: the lung is a common source of infection. Perioperative antibiotics with activity against biliary tract pathogens should be employed. All recipients should also receive trimethoprim–sulfamethoxazole to reduce the likelihood of infections secondary to *Pneumocystis* or *Nocardia*. Prophylaxis is also indicated against fungal infections (most commonly *Candida* and *Aspergillus*) and viral infections (most commonly CMV [cytomegalovirus] and herpes virus).

Graft Function and Immunosuppression

A crucial aspect of postoperative care is the repeated evaluation of graft function, which in fact begins intraoperatively, soon after the liver is reperfused. Signs of hepatic function include good texture and color of the graft, evidence of bile production, and restoration of hemodynamic stability. Once the patient arrives in the ICU, evaluation of hepatic function is continued based on clinical signs and laboratory values. The patient who rapidly awakens from anesthesia and whose mental status progressively improves likely has a well-functioning graft. Laboratory values that corroborate good function include normalization of the coagulation profile, resolution of hypoglycemia and hyperbilirubinemia, and clearance of serum lactate. Adequate urine production and good output of bile through the biliary tube (if present) are also indicators of good graft function. Serum transaminase levels will usually rise during the first 48 to 72 hours secondary to preservation injury, and then should fall rapidly over the next 24 to 48 hours.

Induction immunosuppression posttransplant varies from center to center. Many use a triple immunosuppressive regimen based on cyclosporine or tacrolimus, prednisone, and azathioprine or mycophenolate mofetil. Some centers also use antilymphocyte antibody for induction therapy, either for all recipients or only for those with renal dysfunction. The newer humanized monoclonal antibodies (basiliximab or daclizumab) are also being used, usually as part of regimens that involve the withholding of calcineurin inhibitors or steroids [36].

Posttransplant Surgical Complications

Given the magnitude of the operation, surgical complications posttransplant are not uncommon. One important aspect, then, of postoperative care is to be aware of any complications so that they may be quickly recognized and treated. Surgical complications related directly to the operation include postoperative hemorrhage and problems with any of the five anastomoses (five vascular and one biliary).

Postoperative Hemorrhage. Bleeding is common in the postoperative period, and is usually multifactorial. Previously, it has been reported that 15% of patients required a reoperation for bleeding control after transplant. Currently, with the improvement of postoperative treatment of coagulopathy in the ICU, the incidence of reoperation has dropped to 5%. A large raw surface is created during the recipient hepatectomy, often in a patient with significant vascular collaterals secondary to portal hypertension. A number of small persistent bleeding sites may often result. This may be compounded by an underlying coagulopathy resulting from deficits in one or more of the main systems of hemostasis: coagulation, fibrinolysis, and platelet function.

Large volume intraoperative blood transfusions and poor postoperative liver function secondary to ischemic damage of the liver can lead to severe coagulation defects. As liver function improves, coagulation parameters normalize. Fresh frozen plasma (FFP) and cryoprecipitate are used, as needed, until graft function is adequate. Thrombocytopenia is seen in virtually all recipients posttransplant, with lowest levels on postoperative day 3 and 4, then returning to normal by day 7. Platelets are transfused, as needed, for platelet counts less than 50×10^9 per L (depending on the degree of ongoing bleeding), but counts may not increase, because of ongoing deposition of platelets in the spleen. Hyperfibrinolysis, often a problem intraoperatively during the reperfusion phase, may persist into the early postoperative period. Aprotinin, a serine protease inhibitor, may be administered intraoperatively; it decreases hyperfibrinolysis-triggered bleeding in some recipients.

Blood loss should be monitored through the abdominal drains and with serial measurements of hemoglobin and central venous pressures. If bleeding persists despite correction of coagulation deficiencies, an exploratory laparotomy should be performed. Reexploration is especially important if increasing abdominal pressure is evident which may compromise respiratory or renal function. Bleeding complications are generally higher in recipients of reduced-size, split-liver, or living related grafts, because the cut surface of the liver is an additional source of potential blood loss.

Vascular Complications. The incidence of vascular complications after liver transplant is 5% to 10%. Thrombosis is the most common early event; stenosis, dissection, and pseudoaneurysm formation are less common. Any of the four vascular anastomoses may be involved, but the hepatic artery is most common [37].

Hepatic artery thrombosis (HAT) has a reported incidence of 3% to 5% in adults and about 5% to 8% in children. Several risk factors have been reported for early HAT CMV mismatch

(seropositive donor liver in seronegative recipient), retransplantation, use of arterial conduits, prolonged operation and cold ischemic times, low recipient weight, severe rejection, variant arterial anatomy, and low-volume transplantation centers. Technical factors that disturb laminar flow of the blood in the arteries (such as intimal dissection, tension on the anastomosis, and kinking of the artery) are also implicated in the development of HAT. Thrombosis rates are higher after split-liver and living related transplants, because of the smaller caliber of vessels and the sometimes complex arterial reconstruction required [38,39].

After HAT, liver recipients may be asymptomatic or they may have severe liver failure secondary to extensive necrosis. Those with thrombosis early postoperatively, especially adults, have the most dramatic signs and symptoms: marked elevation of serum transaminase levels, septic shock, HE, and overall rapid deterioration. Ultrasound with Doppler evaluation is the initial investigation of choice, with more than 90% sensitivity and specificity. Prompt reexploration with thrombectomy and revision of the anastomoses is indicated if the diagnosis is made early. If hepatic necrosis is extensive, a retransplant is indicated. CT or MRI scans may be helpful in determining the extent of necrosis. Some centers have used implantable Doppler probes performing continuous flow monitoring in patients with high risk for development of HAT.

HAT may also present in a less dramatic fashion. The donor bile duct receives its blood supply from the hepatic artery. Thrombosis may therefore render the common bile duct ischemic, resulting in a localized or diffuse bile leak from the anastomosis, or more chronically a diffuse biliary stricture. Late thrombosis may be asymptomatic, especially in children, because of the presence of collaterals (which provide sufficient arterial inflow) along the biliary anastomosis.

Thrombosis of the portal vein is far less frequent (compared with the hepatic artery), occurring in fewer than 2% of recipients. It may be related to a technical factor such as narrowing of the anastomosis or excessive length of the portal vein with kinking. Recipients who require a venous conduit secondary to underlying portal vein thrombosis are also at higher risk for portal vein thrombosis. As with HAT, clinical presentation can vary. Early postoperatively, portal vein thrombosis may result in severe liver dysfunction. Tense ascites and variceal bleeding may be seen secondary to acutely elevated portal and mesenteric venous pressures. If these symptoms develop postoperatively, urgent ultrasound with Doppler evaluation is performed to assess the patency of the portal vein. If the diagnosis is made early, operative thrombectomy and revision of the anastomosis may be successful. If thrombosis occurs late, liver function is usually preserved due to the presence of collaterals. In this case, a retransplant is not necessary, and attention is diverted toward relieving the left-sided portal hypertension.

Complications of the hepatic veins (such as thrombosis and stenosis) are rare, with an incidence of less than 1%. Recurrence of Budd–Chiari syndrome and technical factors such as narrowing of the anastomosis are the most common causes. Presentation is usually with massive ascites and graft dysfunction. Again, ultrasound Doppler will usually demonstrate the problem. The risk of thrombosis is higher in recipients of a left lateral segment, either from a living donor or as part of a split-liver graft. This segment may be quite mobile, and if it is not properly aligned, it may twist on the anastomosis, obstructing flow [40].

Biliary Complications. Complications of the biliary system continue to be common after liver transplantation. The incidence is 10% to 25% with an associated mortality of less than 5% [41]. This incidence may be even higher in partial transplant recipients and recipients of DCD livers. Biliary complications manifest as either a leak or an obstruction. Timing will often determine type and clinical outcome of the complication. Bile leaks tend to occur early postoperatively and often require surgical repair, while obstruction usually occurs later and can often be managed with radiologic or endoscopic techniques.

Most bile leaks occur within the first 30 days posttransplant. Most centers have abandoned the use of external T-tube stents because a leak may occur from the T-tube site when it is removed. In whole liver transplant recipients, biliary leaks occur most commonly at the anastomotic site. The area around the anastomosis has the most tenuous blood supply: both the donor common bile duct (CBD) and the recipient portion of the CBD are supplied by end arteries. Excessive dissection or cauterization around the donor or recipient CBD can further disrupt the blood supply, leading to ischemic complications. Another important cause of biliary tract complications is hepatic artery thrombosis: the donor CBD receives its blood supply from the hepatic artery. With any biliary tract complication, the hepatic artery should be carefully assessed to document patency. Other causes of leaks include poorly placed sutures, excessive number of sutures, and tension on the anastomosis. With partial transplants, the cut surface of the liver represents the most common site for a bile leak.

Clinical symptoms of a bile leak include fever, abdominal pain, and peritoneal irritation. Bile in the abdominal drains is highly suspicious for a leak, but absence of bile in the drains does not preclude the diagnosis. Blood tests may demonstrate an elevation of the white blood cell count, bilirubin, and alkaline phosphatase; unfortunately, no laboratory test is pathognomonic. Ultrasound may demonstrate a fluid collection, but often cholangiography is required for diagnosis. This is simple to perform if an external biliary stent is in place. In the absence of an external stent, options include magnetic resonance cholangiography (MRC), endoscopic retrograde cholangiography (ERC), or percutaneous transhepatic cholangiography (PTC).

Many recommend operative treatment for all early bile leaks. The anastomosis is revised, or for small leaks, additional sutures are placed at the leak site. If there is undue tension in recipients with a CDC, the biliary anastomosis is converted to a CDJ. The increasing popularity of treating nontransplant biliary leaks with endoscopically placed stents has led to their use for transplant-related leaks.

Biliary obstruction is usually secondary to stricture and occurs later in the postoperative period. It is most common at the anastomotic site and is likely related to local ischemia. Nonanastomotic strictures usually have a worse prognosis; they are associated with hepatic artery thrombosis, prolonged cold ischemic times, and ABO-incompatible donors [42]. Patients sustaining biliary obstruction usually present with cholangitis or cholestasis, or both. Ultrasound can be misleading in making the diagnosis, since ductal dilatation may not be seen; however, it is still a crucial test in order to exclude potential hepatic arterial flow complication (which is a potential cause of bile duct stricture). Cholangiography (T-tube cholangiography, ERC, MRC, or PTC, depending on the type of BD reconstruction performed) is always necessary for diagnosis of BD stricture. The treatment is usually not an operation, but rather by percutaneous on internal balloon dilatation and stent placement across the site of stricture. If these initial options fail, surgical revision is required.

Wound Complications. Wound complications, very common in liver transplant recipients, can be a source of significant morbidity. In the general surgical population, risk factors for wound complications have been well described, including a lengthy operative procedure, bowel or biliary contamination, blood transfusions, poor nutritional status, and steroid administration. All of these risk factors are generally present in liver recipients.

The most common problems with the wound are infections and hematomas. Direct bacterial contamination of the wound may occur from bile or bowel contents if a CDJ is performed. Wound hematomas can easily result from large abdominal wall collaterals, compounded by underlying coagulopathy. Wound infections will usually present after postoperative day 5. The infection may be obvious, with fever, chills, erythema, and purulent drainage from the wound. But at times, signs and symptoms may be minimal. Treatment is the same as for nontransplant patients: opening the wound, serial dressing changes, and allowing healing by secondary intention. IV antibiotics should be used with significant cellulitis or systemic symptoms. Necrotizing fasciitis has also been reported, and requires rapid, aggressive debridement plus high-dose IV antibiotics.

Posttransplant Medical Complications

Given the underlying illness and the need for powerful immunosuppression, it is not difficult to see why a significant percentage of liver recipients develop some medical complication before discharge. Medical complications seen early posttransplant may be due to immunosuppression, to residual effects of the liver failure, or to unrelated factors. Almost any organ system may be involved.

Nontechnical Graft Dysfunction. The vascular and biliary complications described earlier can all lead to poor liver function postoperatively. Hepatic dysfunction not related to technical complications may also be seen during this time. Causes may include PNF of the graft, acute rejection, and infection.

PNF is a devastating complication, with a mortality rate of more than 80% without a retransplant. By definition, it is a syndrome that results from poor or no hepatic function from the time of the transplant procedure. Most centers now report the incidence to be less than 5%.

The cause of PNF is unknown, but several retrospective studies have attempted to identify donor risk factors that may predict development of this syndrome. Donor factors that have been associated with PNF include advanced age, increased fat content of the donor liver, longer donor hospital stay before organ procurement, prolonged cold ischemia (> 18 hours), and reduced-sized grafts [43].

Early prediction of PNF is valuable in identifying patients that will need a retransplant. It is also important to rule out conditions that may mimic PNF such as hepatic artery thrombosis, accelerated acute rejection, and severe infection. Intraoperative clues may indicate poor graft function. PNF should be considered in recipients who do not stabilize soon after reestablishment of hepatic perfusion, or who have ongoing hemodynamic instability, worsening acidosis and coagulopathy, poor bile production, or poor liver graft color. Upon arrival to the ICU, recipients who do not regain consciousness, or who have increasing renal dysfunction, continued hemodynamic instability, increasing prothrombin time, or persistent hypoglycemia may have PNF. An AST > 5,000 IU per L, Factor VIII < 60% of normal, PT > 20 seconds at 4 to 6 hours postreperfusion, in association with poor bile production, may all suggest PNF.

Unfortunately, no medical treatment is effective for PNF. IV prostaglandin E1 (PGE1) has some useful effect [44], but further evaluation is necessary. Its mechanism of action is presumably a vasodilatory effect on the splanchnic circulation, resulting in enhanced blood flow to the new liver. PGE1 is also immunomodulatory and may lessen the risk of graft rejection. Recipients with suspected PNF should probably be started on a continuous infusion and listed for an urgent retransplant. The starting dose is 0.005 µg per kg per minute, which is increased, as tolerated per blood pressure measurements, to a maximum of 0.03 µg per kg per minute. Ultimately, such recipients do better with a retransplant. However, if a retransplant is to positively influence outcome, it must be done before multiorgan failure develops. In one series of 15 liver recipients with PNF, all those who sustained organ failure in four or more systems died despite a retransplant [45].

Rejection is very common after a liver transplant; 20% to 30% of recipients will have at least one bout at some point posttransplant. Most acute rejection episodes are not seen until at least 1 week posttransplant. Rejection episodes during the first posttransplant week may be seen in recipients of ABO-incompatible grafts, or those with a very strongly positive preoperative cytotoxic cross-match. With current immunosuppressive drugs, signs and symptoms of acute rejection tend to be fairly mild. Most commonly, the serum bilirubin and/or transaminase levels are elevated, which may be completely asymptomatic or may involve mild accompanying symptoms such as fever and malaise. The differential diagnosis must include mechanical complications (such as vascular thrombosis and bile leaks), and underlying sepsis. Ultimately, a histologic assessment of the graft is required to confirm the diagnosis of acute rejection, most commonly via a percutaneous liver biopsy. Mild rejection episodes can usually be treated simply by increasing the level of maintenance immunosuppression. Episodes that are judged to be moderate or severe by histology are usually treated with high-dose IV corticosteroids.

Neurologic Complications. Neurologic complications posttransplant are common, affecting more than 20% of liver recipients. Complications generally manifest as decreased level of consciousness, seizures, or focal neurologic deficits.

Decreased level of consciousness is usually due to oversedation from drugs that have accumulated over days because of impaired hepatic or renal clearance. Benzodiazepines and narcotics are common culprits, but unresponsiveness may also be secondary to calcineurin neurotoxicity. This tends to be more common in patients with previous hepatic encephalopathy.

Multiple metabolic abnormalities are frequent posttransplant, and may diminish alertness. A poorly functioning or nonfunctioning graft with resulting liver failure can lead to hepatic encephalopathy. Other evidence of liver failure is also frequent, such as a marked elevation of liver enzymes, prothrombin time, and ammonia levels. Flumazenil, a benzodiazepine receptor antagonist, improves HE for a short time [46]. It may thus be a useful diagnostic tool when HE is suspected, postoperatively. Renal failure and sepsis may also contribute to a metabolic encephalopathy. After significant periods of perioperative hypotension, a decreased GCS may indicate hypoxic-ischemic encephalopathy. This may be a difficult diagnosis to make, since imaging studies are often normal. Nonspecific abnormalities may be seen on EEG. The clinical scenario is characterized by an initial insult, then a prolonged recovery period, often characterized by decreased alertness.

Central pontine myelinolysis (CPM) is an uncommon cause for failure to awaken posttransplant [47]. Typically, it is seen with marked fluctuations in serum sodium levels and osmolality, or in recovered alcoholics. CT is often normal, but MRI may demonstrate characteristic abnormalities in the pons. Careful attention to shifts in the serum sodium and osmolality may decrease the risk of CPM.

FHF patients, especially those with severe HE and evidence of cerebral edema preoperatively, invariably have a period of diminished level of consciousness posttransplant. Intraoperatively, during the reperfusion phase, their intracranial pressure (ICP) often increases. If untreated and severe, this increase may lead to neurologic death, which is often not diagnosed until in the ICU. Usually, however, the effects of cerebral edema linger over a period of 7 to 10 days postoperatively, with eventual recovery. ICP monitoring pre- and intraoperatively may be of value in detecting cerebral edema and marked elevations of pressure.

Liver recipients, who have an initially normal neurologic course postoperatively, followed by sudden clinical deterioration, should be evaluated for an intracranial hematoma. Predisposing factors include underlying coagulopathy and systolic hypertension.

Postoperative seizures usually occur de novo, tend to be of the generalized tonic clonic variety, and are most common during the first 2 weeks posttransplant. Causes are numerous. Electrolyte abnormalities (such as hyponatremia, hypocalcemia, and hypomagnesemia) and medications, are the most common causes. Structural abnormalities such as intracranial hemorrhage and cerebral infarction may be responsible. Infectious processes (such as meningitis, encephalitis, and a brain abscess) should also be considered.

Immunosuppression medications may sometimes cause significant neurologic changes after transplantation. Several neurotoxic effects have been associated with use of cyclosporine, including tremors, headache, mental status changes, seizures, focal neurological deficits, and/or visual disturbances. Tacrolimus produces neurologic disorders similar to those seen in patients using cyclosporine, but more frequently. Posterior reversible encephalopathy syndrome (PRES) is a rare but serious complication of immunosuppressive therapy after solid organ transplantation (0.5%). In addition to the neurologic symptoms, which range from headaches to mental status changes, this syndrome is associated with a characteristic imaging feature of subcortical white matter lesions on magnetic resonance imaging. The changes in the subcortical white matter are secondary to potentially reversible vasogenic edema. These imaging findings predominate in the territory of the posterior cerebral artery. PRES typically develops in the first 2 months after liver transplantation (90%). A prompt diagnosis of this rare entity with a temporary discontinuation of the calcineurin inhibitor offers the best chance of avoiding long-term sequelae [48].

Cardiovascular Complications. A number of cardiovascular complications (including arrhythmia, ischemia, changes in blood pressure and cardiac arrest) can be seen intra- and postoperatively. They may occur in liver recipients with previously normal cardiac status or in those with underlying comorbid cardiac conditions. The latter group is becoming more important as the increased success of liver transplantation has led to expanded indications and older recipients.

Most intraoperative cardiovascular complications are seen immediately after reperfusion of the liver. About 30% of recipients experience a transient decrease in blood pressure during this phase, which has been termed the postreperfusion syndrome (PRS). This syndrome is defined by a decrease in the mean arterial pressure of at least 30% for 1 minute within the first 5 minutes after reperfusion, accompanied by a decrease in the heart rate and SVR and an increase in the CVP and PCWP. The exact cause of the myocardial depression and decreased contractility seen with PRS is unclear, but is likely multifactorial. Hyperkalemic, cold, acidotic fluid washed out from the graft, combined with existing abnormalities such as hypocalcemia and acidosis, may be the main culprits. Myocardial depressant factors may also be released from the ischemic graft on reperfusion. The effect is generally short-lived; left ventricular function is usually normal within 5 minutes. Some recipients, however, experience extreme bradycardia and hypotension, leading to cardiac arrest; this is rare and small doses of inotropic agents are usually effective. Arrhythmias, such as ventricular tachycardia and ventricular fibrillation, have also been described in the early reperfusion phase.

The incidence of postoperative myocardial ischemia is 5% to 13%. As the age of transplant candidates has increased, so has the likelihood of silent coronary artery disease, leading to perioperative ischemia. Candidates with risk factors and a high probability of coronary artery disease should undergo a pretransplant coronary assessment. Poor exercise tolerance often precludes a formal stress test. Pharmacological stress testing with either dipyridamole thallium imaging or dobutamine echocardiography, may be better. Candidates with positive tests should undergo coronary angiography, with a view toward revascularization procedures (PTCA, CABG) as indicated.

A rare postoperative complication is acute right ventricular failure secondary to severe pulmonary hypertension, but deaths have been reported [49]. The pulmonary hypertension in these recipients was likely present pretransplant. It is an uncommon complication of portal hypertension, affecting less than 1% of patients. The exact cause is unclear, though portal hypertension is the strongest predisposing factor. Histologically, the predominant lesion is a nonspecific plexiform arteriopathy. Pretransplant right heart catheterization may be necessary to establish the diagnosis; severe pulmonary hypertension may contraindicate transplantation.

Pulmonary Complications. The pulmonary system is one of the most common sites of complications posttransplant; infectious and noninfectious pulmonary complications may be seen. Infectious complications predominate after the first posttransplant week, but noninfectious complications (such as pulmonary edema, pleural effusions, atelectasis, and ARDS) predominate prior to that.

Mechanical ventilation, generally short-lived, is required immediately posttransplant in almost all liver recipients. Most patients can be extubated within the first 48 hours. Those with significant preoperative lung disease, malnutrition, or early postoperative pulmonary and hepatic complications tend to require prolonged intubation.

Atelectasis is very common posttransplant, as it is after other major abdominal operations. Significant preoperative ascites and pleural effusions are predisposing factors. Poor nutrition, decreased level of consciousness, and poor lung compliance are other contributing factors. Treatment is generally successful with chest physiotherapy and PEEP, with therapeutic bronchoscopy reserved for recipients with large areas of collapse or persistent atelectasis. Diaphragmatic dysfunction may also be seen posttransplant, with resultant right-sided atelectasis and decreased vital capacity, which may prolong the need for ventilatory support. The cause of this dysfunction is probably a crush injury of the right phrenic nerve, which can occur during surgery when the suprahepatic caval clamp is applied [50]. Usually, the nerve and diaphragmatic function completely recover, but it may take up to 9 months posttransplant.

Pleural effusions are noted in a large number of recipients. The right side is more commonly involved. Usually transudative in origin, pleural effusions may be related to sympathetic fluid accumulation from the operative diaphragmatic dissection or preoperative ascites. Typically, these effusions resolve spontaneously within 1 to 2 weeks. Thoracentesis may be needed to rule out an empyema or hemothorax. If the effusion is large enough to compromise respiratory status, therapeutic thoracentesis or insertion of a small pigtail catheter for drainage should be performed.

All of the above conditions may manifest with arterial hypoxemia postoperatively. A less common cause of hypoxemia is the presence of intrapulmonary vascular dilatations (IPVD). These vascular abnormalities are sometimes seen in patients with chronic liver disease, associated with portal hypertension and spider angiomas of the skin. Common clinical findings are dyspnea, cyanosis, clubbing, exercise desaturation, and orthodeoxia. Two techniques are generally used to confirm intrapulmonary vascular dilatation: transthoracic contrast-enhanced echocardiography, and perfusion body scan with

99mTechnetium-labeled macroaggregated albumin (99mTc-MAA). During transthoracic contrast-enhanced echocardiography, IV injections of microbubbles (diameter < 90 μm) are used to visualize intrapulmonary shunts. The timing of the appearance of the microbubbles in the left side of the heart makes the distinction between intracardiac and intrapulmonary shunts. Whole-body scan with 99mTechnetium-labeled macroaggregated albumin allows not only the detection of IPVD, but also its quantification. In normal individuals the macroaggregates (> 20 μm in diameter), are normally trapped in the pulmonary circulation. In the presence of cardiac right-to-left shunts or intrapulmonary vascular dilatation, the uptake of 99mTc-MAA in other organs, such as the brain, kidneys, spleen, and liver, can be visualized. The major disadvantage of this technique is the inability to differentiate between intracardiac shunts and IPVD [51,52].

The combination of chronic liver disease, IPVDs, and severe hypoxemia or a markedly increased alveolar arterial oxygen gradient has been termed the hepatopulmonary syndrome (HPS). HPS is reversed in 60% to 90% cases after liver transplantation, and can be documented by a perfusion lung scan [52]. Hypoxemia, requiring supplemental oxygen, can be corrected as early as 6 to 12 months after surgery; however, an increased recovery time is shown in older patients, patients with a preoperative $PaO_2 \leq 52$ mm Hg and/or $AaPO_2 \geq 66$ mm Hg, or if the liver disease is a result of alcohol abuse [51,52].

Patients with significant hypoxemia pretransplant should be investigated for IPVDs. For those with a good response to 100% O_2, the transplant may proceed: the recipient has a good chance for improvement postoperatively. But for those with a poor response, pretransplant pulmonary angiography and embolization might be beneficial. Recipients with documented IPVDs and severe hypoxemia postoperatively may also benefit from embolization, especially if they have large discrete IPVDs.

Renal Complications. Some degree of renal dysfunction is very common after transplant, affecting almost all liver recipients. About 10% have renal failure severe enough to require dialysis. Impairment may already have been present pretransplant, or may develop early or late in the posttransplant period. Early diagnosis, identification of the cause, and appropriate interventions are necessary. Renal failure, whether pre- or posttransplant, increases the mortality rate associated with the procedure.

Postoperative renal problems that may have been present pretransplant are most commonly due to hepatorenal syndrome (HRS) or acute tubular necrosis (ATN). Usually, such problems will improve posttransplant, but recipients with severe pretransplant renal dysfunction are at greater risk for persistent renal impairment posttransplant. Those with prolonged renal impairment pretransplant, or those who are dialysis-dependent and not likely to regain kidney function after a liver transplant, should be considered for a simultaneous liver–kidney transplant. Obtaining a kidney biopsy pretransplant may help determine the reversibility of the underlying renal disease and hence the need for a combined transplant.

Intraoperatively, periods of hypovolemia and hemodynamic instability may contribute to postoperative renal dysfunction secondary to ATN. Such periods can be minimized by invasive cardiac monitoring to maintain adequate blood volumes and cardiac output. A rapid infusion technique is crucial, at times, to allow the anesthesiologist to keep pace with ongoing volume losses. Some surgeons argue that venovenous bypass (VVB) reduces renal vein pressures during the anhepatic phase when the cava is clamped, thus reducing the risk of postoperative renal dysfunction. Several centers routinely use VVB though there is no significant evidence to show a decreased incidence of postoperative renal failure. Several centers have adopted a selective policy, reserving VVB for liver recipients who meet certain criteria, such as hemodynamic instability with caval clamping or preexisting renal dysfunction. Intraoperative administration of verapamil or furosemide has been tried, but there is no good evidence of any significant renal benefit.

Postoperative renal dysfunction is often multifactorial. The cause may be prerenal, renal, or postrenal. Postrenal causes are rare and are usually easy to rule out. Prerenal and renal causes account for the vast majority of dysfunction [53].

Hypoperfusion of the kidneys will lead to a prerenal picture characterized by a low urine output, decreased sodium in the urine (< 10 mEq per L), and a fractional excretion of sodium of less than 1%. Hypoperfusion is most common with systemic hypovolemia, often due to ongoing blood loss within the abdomen. Third-space fluid losses into the area of dissection or from bowel wall edema (related to the portal vein clamping) may also lead to intravascular volume depletion and prerenal azotemia. Renal hypoperfusion may also be due to significantly raised intra-abdominal pressure, as with tense ascites or a large volume of intraperitoneal blood and clots.

True HRS will give a picture similar to other prerenal causes, as it is believed to result from renal arterial vasoconstriction. Low sodium and a low fractional excretion of sodium again characterize urinary electrolytes. Generally, HRS is present pretransplant, especially in patients with fulminant hepatic failure or acute deterioration of chronic liver failure. Classically, HRS is considered to be functional, so kidney function should fully recover posttransplant. HRS can be divided into two types (1 and 2) based on prognosis and clinical characteristics. In HRS-1, an abrupt deterioration in the renal function occurs and often develops after a precipitating event (particularly spontaneous bacterial peritonitis). HRS-2 is characterized by a steady or slowly progressive course that occurs mostly in an outpatient setting in patients with refractory ascites. Survival of patients with HRS-1 is shorter than that of patients with HRS-2. The full recovery of kidney function is usually achieved after transplant; however, renal recovery may be delayed, especially in patients with HRS-2 and if some degree of ATN was superimposed. New onset of HRS posttransplant occurs with PNF or severe graft dysfunction, and may indicate the need for an urgent retransplant [54].

Renal causes are most commonly secondary to ischemic ATN, drug nephrotoxicity, or preexisting renal disease. Urinary electrolytes generally reveal a salt-wasting picture, with a high urinary sodium level (> 30 mEq per L) and a fractional excretion of sodium > 1%. On microscopic urinalysis, granular casts may be identified in the presence of ATN. The cause of ATN in liver recipients is usually ischemia and sustained hypoperfusion of the kidneys. ATN may start preoperatively, especially in acutely ill patients, or may develop secondary to hemodynamic instability intraoperatively. In one study, the predictors of acute renal failure in the immediate postoperative period were poor preoperative clinical conditions (worse Child score), elevated basal creatinine value pretransplant, transfusion of a large volume of blood products, and intraoperative hypotension [53,54]. ATN may also be seen with sepsis and multiple organ dysfunction.

Nephrotoxicity secondary to drugs is also very common. Most liver recipients have some drop in the creatinine clearance posttransplant secondary to cyclosporine or tacrolimus, both of which have significant nephrotoxic properties. Acute renal failure may be more common with high drug levels and with intravenous formulations. These immunosuppressive agents may also worsen existing renal dysfunction. Nephrotoxicity may also be secondary to other drugs, most commonly the aminoglycosides and amphotericin B.

Once renal dysfunction is adequately diagnosed, therapy can be guided appropriately. Invasive monitoring with an arterial line and a pulmonary artery catheter is helpful to optimize hemodynamic parameters and renal perfusion. Hypovolemia

should be treated with volume replacement and blood products as necessary. Blood pressure should be kept in the normal range, as determined from preoperative values. For decreased cardiac output secondary to myocardial depression, inotropic agents such as dopamine or dobutamine are indicated. If increased SVR is the main problem, a peripheral vasodilator may be of benefit. Other interventions would depend on the cause of renal dysfunction. Tense ascites can be relieved with paracentesis, while nephrotoxic drugs should be discontinued or their dosage lowered.

Once cardiovascular parameters have been optimized and compounding factors dealt with, efforts should be made to establish diuresis. Prognosis is generally better in recipients with nonoliguric (as opposed to oliguric or anuric) renal failure. The role of diuretic therapy is unclear. Recipients who were on chronic diuretic therapy pretransplant may have "diuretic dependence," and require its continued use posttransplant to maintain urine output. They should be adequately volume-loaded before diuretics are initiated, otherwise renal failure may be exacerbated. A loop diuretic such as furosemide is often the first-line agent. Its delivery to the afferent artery of the kidney depends, in part, on its binding to albumin. Therefore, in recipients with significant hypoalbuminemia, infusion of albumin may be necessary to maximize the effect of the diuretic.

If renal function does not improve, artificial renal support may become necessary. Options include regular hemodialysis or continuous venovenous hemofiltration (CVVH). Intermittent hemodialysis may not be feasible for acutely ill postoperative patients because of the hemodynamic instability it often causes. CVVH imposes a less significant stress on the hemodynamic system. Indications for CVVH or hemodialysis include (1) significant volume overload with evidence of pulmonary edema, (2) persistent or worsening hyperkalemia, and (3) persistent or worsening metabolic acidosis.

In patients with chronic hepatitis C virus (HCV) infection who have undergone a liver transplant, kidney dysfunction can be also associated with type II mixed cryoglobulinemia. Mixed cryoglobulinemia is a systemic vasculitis secondary to circulating immune complex deposition in the small vessels, and is usually triggered by the hepatitis C virus infection. The principal clinical manifestations of glomerular disease (usually membranoproliferative glomerulonephritis, MPGN) are the presence of proteinuria and microscopic hematuria, with impaired kidney function. The diagnosis of HCV-related MPGN is usually made by positive tests for serum HCV antibodies and HCV RNA, high concentrations of cryoglobulins, positive rheumatoid factor assays, and low levels of complement [55].

Infectious Complications. Infections are common after all organ transplants, but the incidence is highest after liver transplantation. More than two-thirds of recipients will experience at least one infective episode. Several factors account for this very high incidence: (1) the length and magnitude of the operation, (2) the high potential for biliary and enteric contamination, and (3) the poor overall medical condition of many recipients.

The incidence of infections has not changed significantly since the early days of liver transplantation. What has changed is the mortality rate. Early series reported mortality rates of 25% to 50% associated with infections. More recent studies, however, suggest that infection-related deaths in most centers are now less than 10%. A better understanding of the immunosuppressed state, identification of risk factors, and more effective means of treatment and prophylaxis have all contributed to an improved prognosis. Nonetheless, infections remain the most common cause of early mortality posttransplant and a significant source of morbidity. Identification of risk factors, preventive measures and effective prophylaxis, rapid diagnosis, and prompt and appropriate treatment are all crucial.

The preoperative workup should include evaluation for any infective diseases. Serologic testing should assess the transplant candidate's CMV, HIV, and hepatitis (B and C) status. Latent infections (such as tuberculosis) that may be reactivated with immunosuppression must be ruled out. Focus should be on active infections that would require treatment pretransplant or even preclude a transplant. Candidates with chronic liver failure are prone to infections such as spontaneous bacterial peritonitis, cholangitis, pneumonia and fungal infections, all of which should be treated appropriately and documented as improved pretransplant. The urgency of the transplant will often determine the length of treatment.

Once the transplant has occurred, efforts should be instituted to prevent infections. Perioperative antibiotics effective against biliary tract pathogens are important. Other prophylactic regimens with proven benefit include trimethoprim–sulfamethoxazole for *Pneumocystis* pneumonia (other options include dapsone, atovaquone, and pentamidine), acyclovir or ganciclovir for CMV and other herpes family viruses, and nystatin or fluconazole/voriconazole for antifungal prophylaxis. Preventive measures that should be followed are no different than for similar, nontransplant patients in a critical care setting: attentive care to indwelling arterial and venous lines, change of central catheters every 7 days, and aggressive pulmonary toilet.

Any postoperative fever should prompt an urgent, thorough evaluation for infection, including culture of blood, urine, sputum, and ascitic fluid, as indicated. A CXR to rule out a pulmonary source should be performed, then bronchoscopy and lavage to evaluate any suspicious infiltrates. A thorough examination with close attention to the wound is important. A wound infection will require opening of the wound and serial dressing changes. If no obvious source of infection is found, a CT scan of the abdomen to look for fluid collections is warranted. A diagnostic aspiration can then be performed to rule out an abscess. If the recipient has a persistent high temperature or toxic appearance, antibiotics should be started, even without identification of the infective source. Generally, a wide-spectrum antibiotic with activity against biliary pathogens is the agent of first choice. Of note, an elevated temperature may also be seen with other conditions, such as acute rejection, graft-versus-host disease, and drug reactions.

Infections posttransplant are broadly categorized into those occurring early (within 1 month) and later. Regardless of the timing, bacterial, viral, or fungal pathogens may be responsible. The relative incidence of these various pathogens differs at different times posttransplant.

Bacterial and fungal organisms account for most infections during the first month. The immunosuppressed state is a risk factor, but these infections are more related to surgical complications, initial graft function, and morbid conditions that existed pretransplant. Risk factors include prolonged surgery, large-volume blood transfusions, PNF requiring a retransplant, and reoperations for bleeding or bile leaks. Common sites for these infections, in decreasing order of frequency, are the abdomen, the respiratory tract, blood, wounds, and the urinary tract.

After the first month, the immunosuppressed state becomes the main risk factor for infection. Immunosuppressive drugs depress cell-mediated immunity, leading to opportunistic infections with viral, fungal, and parasitic pathogens. The risk increases as immunosuppression increases, especially when acute rejection episodes are treated with bolus high-dose steroids or antilymphocyte agents. Bacterial infections generally decline after the first month, except in recipients who have had prolonged ICU stays because of surgical complications or respiratory failure. Other predisposing factors for late bacterial infections are a biliary stricture and hepatic arterial thrombosis.

Bacterial infections usually involve the abdominal cavity, including the wound. Bacterial pathogens often originate from either the biliary tree or from the small bowel. A choledochojejunostomy (CDJ) for biliary drainage is associated with a higher rate of infection than is a duct-to-duct biliary anastomosis. Contamination may occur either at the time of surgery, or later because of biliary complications such as a leak or stenosis. Abdominal infections usually manifest as cholangitis, abscesses (intra- or extrahepatic), peritonitis, or wound infection. Cholangitis often develops with an underlying biliary stricture and may lead to a subsequent ascending infection with development of intrahepatic abscesses. Hepatic artery thrombosis may also lead to ischemia of the allograft and development of intrahepatic abscesses secondary to necrosis of the liver. Peritonitis and an extrahepatic abscess often signal the presence of a bile leak. If an intra-abdominal infection is suspected, a CT scan should be done, with aspiration and culture of any identified fluid collections. If a biliary stent is present, it can be used to evaluate for the presence of a leak or stricture. In the absence of a stent, a nuclear medicine study or cholangiography (percutaneous or endoscopic approach) may be necessary to evaluate the biliary tree. Therapy involves drainage of the abscess, management of any identified biliary complications, and IV antibiotics directed at the most likely pathogens: aerobic Gram-negative bacilli (*E coli*, *Enterobacter, Pseudomonas*), some aerobic gram-positive cocci (group D *Streptococcus*), and anaerobes.

Fungal infections are a major cause of morbidity and death after all solid-organ transplants. Liver transplants are associated with the highest incidence of fungal infection, with some studies reporting an incidence of about 20%. The cause may be contamination from the biliary tract or small bowel during surgery. Most fungal infections are seen during the first 2 months posttransplant. Risk factors include preoperative renal dysfunction, prolonged duration of surgery, a retransplant, other reoperations, and CMV infection [56]. The vast majority of early fungal infections are secondary to *Candida* or *Aspergillus* species. Less common pathogens include *Cryptococcus* and *Trichosporon*, which are generally seen later in the transplant course because of chronic immunosuppression.

Viral infections generally are not seen until after the first posttransplant month. Common pathogens include CMV, Epstein–Barr virus (EBV), herpes simplex virus (HSV), and the hepatitis viruses (B and C). The mortality rate is generally not as high as with fungal and bacterial infections, yet viral pathogens account for significant morbidity. CMV is the most common pathogen involved. Its presentation ranges from asymptomatic infection to tissue-invasive disease. Asymptomatic infection is characterized by the shedding of virus in urine or saliva plus a change in the recipient's serostatus. CMV disease is suggested by the presence of the virus in the blood and by systemic symptoms such as fever, malaise, arthralgia, and leukopenia, with or without specific end-organ involvement (liver, lungs, bowel, eyes). Tissue-invasive CMV disease (TI-CMV) indicates organ involvement and presents as hepatitis, gastroenteritis, retinitis, or pneumonia.

The introduction and widespread use of IV ganciclovir has significantly altered the prognosis of CMV disease, which now is an uncommon cause of death posttransplant. Treatment with this drug at 10 mg per kg per day for 14 to 21 days posttransplant is effective, with minimal toxicity. Neutropenia may be seen, but usually responds to dose reduction or temporary discontinuation of the drug. If neutropenia remains a problem, then colony-stimulating factor (G-CSF) can be used. IV ganciclovir is also effective prophylaxis against CMV infections. Many different prophylaxis regimens are currently used, including high-dose oral acyclovir for 12 weeks posttransplant and, more recently, newer drugs such as oral ganciclovir, valacyclovir, and valganciclovir.

Viral hepatitis and liver transplantation are closely linked; hepatitis C is a common indication for a transplant. In the vast majority of liver recipients, however, disease eventually recurs in the new graft, representing a persistence or recurrence of preexisting infection. The risk of recurrence is now significantly lower for hepatitis B (versus C), but the former has a significantly worse prognosis. The risk of recurrence for hepatitis B depends in part on pretransplant replicative state. Recipients positive for hepatitis B viral DNA or hepatitis B e antigen have a higher risk of recurrence. Those with fulminant hepatitis B or coexisting hepatitis delta infection have lower recurrence rates. Once infection recurs, the course is characterized by rapid progression and eventual cirrhosis. A retransplant is generally not effective because of the very high recurrence rate in the second graft, especially if disease recurred in the first graft shortly posttransplant. Fortunately, recurrence rates are now very low due to the routine use of infection prophylaxis regimens which include long- and short-term administration of hepatitis B immunoglobulin with or without use of antiviral agents such as lamivudine [57].

Almost all patients transplanted for hepatitis C develop recurrent infection. The prognosis associated with recurrent hepatitis C is not as poor as with recurrent hepatitis B. Many liver recipients will show some histologic evidence of mild hepatic inflammation in the graft by 3 to 6 months posttransplant. However, only about 20% of them progress to cirrhosis requiring a retransplant. Unfortunately, prophylaxis regimens to prevent recurrent hepatitis C are not effective, and so recurrence of hepatitis C liver disease after transplant is becoming an increasingly important problem [58].

Gastrointestinal Complications. GI complications may occur as the direct result of a technical complication from the operation. Bile or enteric leaks from anastomoses can lead to generalized peritonitis or intra-abdominal abscesses. Other GI complications may result from the stress of the operation, an infection, or drug toxicity. Upper GI bleeding is usually secondary to peptic ulcer disease, persistent bleeding from esophageal varices, stress gastritis, or CMV gastroenteritis. Bleeding from gastric and esophageal varices usually settles quickly posttransplant. Persistent bleeding should trigger an assessment of the portal vein to rule out thrombosis or stenosis, which may be the underlying factor. If the recipient recently received sclerotherapy for variceal bleeding, the possibility of postsclerotherapy esophageal ulceration should be considered. Diffuse gastritis secondary to surgical stress is uncommon today, thanks to routine prophylaxis posttransplant with antacids, H2 antagonists, or proton pump inhibitors. Peptic ulcer disease remains a possible cause of upper GI bleeding. High-dose steroids seem to have some causal relationship to its development. Its incidence seems to be highest in the first month posttransplant, perhaps related to the time when steroid doses are generally highest. Ulcerations in the upper GI tract may also be due to infection. Severe esophagitis secondary to *Candida* can progress to frank ulceration with bleeding. Ulcerations may also be of viral origin, most notably CMV. Other unusual causes of GI bleeding are hemobilia after liver biopsy (incidence of 0.03%) and bleeding from the Roux-en-Y anastomosis in patients who required choledochojejunostomy.

Lower GI bleeding posttransplant is often secondary to colitis, which is of infectious origin. Usually, opportunistic pathogens such as CMV, *Clostridium difficile*, and fungi (e.g., *Candida*) are responsible. Ulcers of noninfectious origin may also cause colonic bleeding, related to the high-dose steroids used in induction therapy.

Bowel perforation is a devastating complication associated with a high mortality rate. A high index of suspicion is required. The typical signs and symptoms associated with acute peritonitis, such as a high temperature and severe pain, may be masked

or hidden by the effects of steroids. Perforation may be of the small or large bowel, with the latter associated with a higher mortality rate. Inadvertent or unrecognized injury to the bowel wall during the operation may later present as a perforation. Perforations may also be spontaneous; these are more common in children, generally occur 7 to 14 days posttransplant, and may be related to the high-dose steroids. As with perforation in nontransplant patients, early diagnosis with prompt reexploration is the best option. The leak can be repaired with irrigation of the abdominal cavity to decrease the degree of contamination.

INTESTINAL TRANSPLANTATION

Intestinal transplants have been performed in the laboratory for years. The first human intestinal transplant was performed in 1966. But it remained essentially an experimental procedure, with dismal results, well into the 1980s. Newer immunosuppressive drugs and advances in the surgical techniques have played a significant role in the successes with the procedure since the mid-1990s. Although intestinal transplants remain the least frequently performed of all transplants, graft survival rates have significantly improved and now approaching those seen with other types of extrarenal transplants. As the early problems with technical graft losses have diminished, immunologic and infectious issues have emerged as the main challenges facing the field today [59].

There are several reasons why the number of intestinal transplants has not increased as dramatically as the other transplants. As with kidney failure patients, a medical alternative exists for patients with intestinal failure, namely, long-term total parenteral nutrition (TPN). Unlike kidney failure patients, however, patients with intestinal failure have no survival advantage with a transplant (vs. medical therapy). Immunologically, the small intestine is the most difficult organ to transplant. It is populated with highly immunocompetent cells, perhaps explaining the reason for the high rejection rates and the need for higher levels of immunosuppression. Moreover, the intestinal lumen is filled with potential infective pathogens, which can gain access to the recipient's circulation if there is any breakdown of the mucosal barrier (which can occur with an acute rejection episode).

Pretransplant Evaluation

Intestinal failure is defined as the inability of the intestine to maintain nutrition or fluid and electrolyte balance without parenteral support. This most commonly results from extensive resection of the small bowel with resultant short bowel syndrome (SBS). Currently intestinal transplant is indicated for patients suffering from irreversible SBS who present with life-threatening complications secondary to the TPN or underlying disease. Traditional criteria for intestinal transplant in patients with SBS on TPN include (i) thrombosis of two major venous access sites, (ii) recurrent line infections and sepsis requiring hospitalization (more than two episodes per year), (iii) imminent liver failure related to TPN, and (iv) severe and frequent electrolyte imbalance and/or dehydration in spite of TPN [60]. At present, patients who are stable on TPN without such complications are generally not considered intestinal transplant candidates, because their estimated annual survival rate may be higher with TPN. However, as results continue to improve with transplant, this may be altered.

Other uncommon indications for intestinal transplant in patients with intestinal failure but without SBS are (i) severe myopathy or neuropathy of the GI tract (hollow visceral myopathy, total intestinal aganglionosis, pseudo-obstruction syndrome), (ii) gut malabsorption syndromes (microvillus inclusion disease, radiation enteritis, selective autoimmune enteropathy), (iii) neoplastic syndromes involving the root of the mesentery (neuroendocrine and desmoid tumors—usually associated with familial adenomatous polyposis or Gardener's syndrome), and (iv) diffuse portomesenteric thrombosis with high risk of GI bleeding [61].

The causes of intestinal failure are different in adult versus pediatric patients. In infants, gastroschisis (21%), volvulus (18%), and necrotizing enterocolitis (12%) account for more than half of the cases. On the other hand, mesenteric vascular thrombosis (22%), Crohn's disease (13%), and trauma (13%) are the most frequent causes of intestinal failure in the adult population [62,63]. Based on data from the International Intestinal Transplant Registry, approximately 60% of the recipients receiving an intestinal transplant had an underlying diagnosis of short bowel syndrome [59]. The development of SBS depends not only on the length of bowel resected, but also on the location of the resection, on the presence or absence of the ileocecal valve, and on the presence or absence of the colon. As a rough guideline, most patients can tolerate resection of 50% of their intestine with subsequent adaptation, avoiding the need for long-term parenteral nutritional support. Loss of greater than 70% of the intestine (considered ultra short gut syndrome), however, usually necessitates some type of parenteral nutritional support. The development of TPN-induced liver failure is much more rapid in children when compared to adults. For these reasons pediatric patients should be considered early for intestinal transplantation before development of irreversible liver injury [64].

The pretransplant evaluation is not too different from that for other transplants. A clear understanding of the anatomy of the patient's GI tract is essential. An upper GI tract series and abdominal CT scan are always necessary in order to plan GI tract reconstruction during the transplant. Hepatic function should be evaluated carefully and a transjugular or percutaneous liver biopsy is often required. If there is evidence of significant liver dysfunction and cirrhosis, a combined liver-intestine or multivisceral transplant may be indicated [65]. Patients with thrombotic disorders need specific hematologic tests to define hypercoagulable states (such as protein C and S deficiency, prothrombin G20210 A and factor V Leiden mutation, and hyperhomocysteinemia). A full abdominal visceral angiography and a comprehensive evaluation of upper and lower central venous system is mandatory in high-risk patients and those with thrombotic disorders. Absolute contraindications such as malignancy, active infection, marked cardiopulmonary insufficiency must be ruled out [62,63,66].

Recently, there has been an increased interest in performing isolated intestine procedures in recipients with early liver failure as there is mounting evidence to suggest that TPN-associated liver disease may be reversed with successful isolated intestine transplant [67,68]. Therefore, early referral of such patients is warranted to see if attempts can be made to salvage the liver.

Surgical Procedure

The indication for transplant and the choice of organs to include in the composite graft are defined by the baseline disease, recipient's anatomy, associated disease (such as diabetes, exocrine pancreatic insufficiency, and renal failure), and functional quality of other abdominal organs. The three most common types of transplants involving the small intestine include isolated intestinal transplantation, combined liver–intestine transplant, and multivisceral transplants [61–63].

The isolated intestine is the graft of choice for patients with irreversible gut failure that is limited to the small bowel. The

vascular anastomoses are based on the superior mesenteric vessels. The outflow is usually achieved with the anastomosis of the superior mesenteric vein to the native superior mesenteric vein or splenic vein; however, in some cases a systemic drainage (inferior vena cava) is required. Systemic drainage will lead to certain metabolic abnormalities, but there is no good evidence to suggest that such abnormalities are of any obvious detriment to the recipient. In patients with combined pancreatic dysfunction (i.e., cystic fibrosis, type I diabetes and chronic pancreatitis) the inclusion of the pancreas should be considered. In living donation or in case of severe donor-to-recipient size mismatch (cadaveric adult to pediatric donation), a 200-cm length of the distal small bowel is used; inflow to the graft is via the ileocolic artery, and outflow via the ileocolic vein [61–63,69].

For a combined liver and intestinal transplant, the graft is usually procured intact with an aortic conduit, which contains both the celiac and superior mesenteric arteries. The common bile duct can be maintained intact in the hepatoduodenal ligament along with the first part of the duodenum and whole pancreas. Doing so avoids a biliary reconstruction in the recipient. A partial pancreatectomy, keeping a small rim of the head of the pancreas is also an alternative technique to avoid hilar dissection; however, this procedure has been abandoned by most centers, due to high risk of complications (i.e., pancreatitis and pancreatic fistulas). During the liver–small bowel transplant, the native stomach, duodenum, pancreas, and spleen are left intact and a portocaval shunt is always required for outflow reconstruction of the native organs [61–63].

The third type of transplant including the small bowel is the multivisceral transplant. In general, multivisceral grafts are those which contain a donor stomach, pancreas, and intestine. The common indications for multivisceral transplant include, but are not limited to, hollow visceral myopathy or neuropathy, pseudo-obstruction syndrome, extensive GI polyposis and total symptomatic splanchnic vascular thrombosis. The surgery encompasses the complete splanchnic evisceration and en bloc transplantation of stomach, duodenum, pancreas, liver, and small bowel (full multivisceral transplant). In some occasions, the right and transverse colon can also be included. In patients with preserved liver function, the native liver can be preserved (so called modified multivisceral transplant). In patients with established or impending renal failure, a renal graft (usually right kidney) can also be included in the multivisceral or liver–intestine allografts.

Several factors should be considered in appropriately matching the donor and recipient. Usually ABO-identical grafts are used; ABO nonidentical but compatible grafts are usually avoided because of the higher risk of graft-versus-host disease. Donors should usually be smaller than the recipients, as the latter usually have shrunken peritoneal cavities, and so a smaller graft may be more appropriate because of space constraints. Selective decontamination of the gut (amphotericin B, polymyxin B, and gentamicin) through a nasogastric tube should be attempted in all the donors. CMV enteritis can be a devastating problem in intestinal transplant recipients, and so, if possible, CMV seronegative recipients should receive organs from seronegative donors. Similar viral matching should be performed for EBV, if possible, because of the risk for PTLD [62,69–71].

The recipient operation varies, depending on the graft being implanted. The recipient's surgery is usually a complex procedure due to the presence of abdominal adhesions, stomas, gastrojejunostomies tubes, contracted abdominal cavity, and, in some cases, considerable portal hypertension (patients requiring combined allografts). Generally, arterial inflow to the graft is achieved using the recipient's infrarenal aorta to perform an end-to-side anastomosis (usually an interposition arterial graft is required). This technique is used for all the abovementioned grafts. The venous drainage is achieved either into the portal system or into the inferior vena cava. In full multivisceral or liver–intestine allografts, the venous drainage is established by piggy-back technique or by interpositioning the retrohepatic caval portion.

GI continuity can be achieved by a number of different methods. Commonly the proximal anastomosis of isolated intestine or liver–intestine is a side-to-side jejunojejunostomy. In multivisceral allografts (full or modified), the proximal anastomosis is performed between the stomach to the native esophagus or stomach stump. In multivisceral transplantation a pyloroplasty should be always performed to avoid delayed gastric emptying.

Gastrojejunostomy tubes are usually used permitting gastric decompression and enteral feeding in the early postoperative period. A Bishop–Koop enterostomy (chimney) or loop ileostomy are used to decompress the terminal ileum and to facilitate enteroscopies and biopsies, which is the only reliable method to monitor the allograft and diagnose acute rejection. Finally, the remaining recipient large intestine is anastomosed with the allograft roughly 20 cm proximal to the end ileostomy. Of note, cholecystectomy is performed in all the cases.

Postoperative Care

The early posttransplant care is, in many ways, similar to that of other transplant recipients. Initial care is usually in a critical care setting, so that fluid, electrolytes, and blood product replacement can be carefully monitored. Serial hemoglobin measurements are performed to look for any evidence of bleeding. Serum pH and lactate should also be monitored to look for evidence of intestinal ischemia or injury. In patients who received liver-intestine or multivisceral allografts, pancreatic enzymes and liver function tests should be assessed daily to track the organ functional status. Broad-spectrum antibiotics are routinely administered given the high risk for infectious complications. Routine prophylaxis should also be administered against CMV and EBV infection, especially in the seronegative recipient. Most centers usually use IV ganciclovir with or without the addition of CMV immunoglobulin. The gut decontaminant solution is given enterally, until the enteral feeding is started. Protozoal prophylaxis (i.e., *Pneumocystis* pneumonia) with trimethoprim–sulfamethoxazole should be started in the first week after transplant [62,63].

Immunosuppression should be initiated immediately after surgery. A number of different immunosuppressive protocols have been described. Most centers use lymphoid depleting agents, including Thymoglobulin or alemtuzumab for induction therapy, followed by a tacrolimus-based maintenance regimen [70,71].

Regardless of the protocol, intestinal transplants clearly have a high risk of rejection (incidence of 30% to 50% in the first 90 days after the transplant). It is very important to differentiate enteritis (mostly caused by *Clostridium difficile*, adenovirus, cytomegalovirus and calicivirus) from rejection, since both conditions may be characterized by diarrhea (or increased stoma output), abdominal pain, and low-grade fever. Therefore, careful evaluation of an intestinal biopsy by an experienced pathologist is always necessary. In addition to routine and regular endoscopy and biopsy, other noninvasive markers of intestinal rejection have been described. Recently studies have shown that several molecules, such as calprotectin and citrulline (measured in the stools and blood, respectively), are reliable markers of moderate and severe intestinal rejection [66]. Acute rejection episodes are often associated with infections. Rejection results in damage to the intestinal mucosa, leading to impaired mucosal barrier function and bacterial translocation. Therefore, advanced rejection can be very difficult to treat.

The switch from parenteral to enteral nutrition is gradual and usually occurs in the first 2 weeks after transplant. Antidiarrheic or prokinetic agents are used to modulate the stoma output after transplant, once rejection or enteritis is ruled out.

Short-term results have improved dramatically, mainly due to improvements in surgical technique and in immunosuppression [61,69,71]. Nonetheless, intestinal transplants are still associated with a high complication rate. Potential complications include enteric leaks with generalized peritonitis or localized intra-abdominal abscesses, graft thrombosis, respiratory infections, and life-threatening hemorrhage.

Infectious complications are, unfortunately, very common in intestinal transplant recipients. There are several factors that contribute to this. The intestinal graft itself is a significant source of bacteria, and any process which compromises containment of these bacteria (such as rejection or anastomotic leak) can lead to a systemic infection. Because of the higher risk of rejection, and the consequences associated with rejection, intestinal transplant recipients generally receive higher levels of immunosuppression compared with other organ recipients, usually in a greater immunosuppressed state. Bacteria can translocate from the graft directly into the peritoneal cavity itself, leading to bacterial peritonitis. Bacteria can also spread directly into the portal circulation, and subsequently disseminate to other sites. Besides bacterial infections, viral infections with CMV, EBV, or adenovirus are also more common in intestinal transplant recipients.

Outcomes

According to the UNOS Database, 1,785 intestinal transplants have been performed in the United States since 1990 (UNOS/OPTN, www.optn.transplant.hrsa.gov/, accessed August, 2009). Currently, only eight Medicare-approved centers in the United States perform intestinal/multivisceral transplant. However, 29 centers throughout the country are listed in the International Intestinal Transplant Registry as active small bowel transplant centers [59,60].

Over the past 15 years, there has been a remarkable improvement in short-term patient and graft survival. This is a result of combination of advances in surgical techniques, immunosuppressive strategies, and postoperative management. The 1-year graft and patient survival rates are now about 80%, with no significant difference between the different types of allografts. In spite of the significant improvement of short-term survival, the 5-year survival rate has remained stable at approximately 60%, and the presence of the liver in the composite allograft (liver–intestine and full multivisceral transplants) is associated with a significant improvement in the long-term survival. The most common causes of graft loss and patient death are quite similar and include rejection, technical failure, and infection/sepsis. Other causes of graft loss and death are post-transplant lymphoproliferative disorders (lymphomas), graft-versus-host disease, and pancreatitis (in combined allografts) [61,70,71].

SUMMARY

Care of liver and intestinal transplant recipients, before, during, and after surgery is a significant challenge. The potential is great for an array of complicated medical and surgical problems. Despite dramatic advances in the field, these procedures remain major undertakings with the possibility of complications affecting every major organ system. A systematic approach is necessary to prevent, minimize, and manage these complications. Intensive medical care in an ICU setting may be necessary even pretransplant, especially in patients with fulminant hepatic failure or severely decompensated chronic liver disease. Optimizing the overall medical status of the transplant candidates with chronic liver failure is essential to minimize the likelihood of postoperative problems. Immediately posttransplant, intensive monitoring—with diligent attention to all organ systems—is necessary to ensure a successful outcome. A thorough knowledge of potential complications is required to allow for rapid diagnosis and appropriate treatment.

Improvements in the care of these patients during the critical perioperative period, along with better immunosuppressive regimens, have allowed for remarkable advances (Table 187.4). A liver transplant is the only real treatment of choice for patients with acute and chronic end-stage liver disease. Most centers now report 1-year patient survival rates of about 85% and 5-year survival rates of more than 70%. Intestinal transplants are becoming an increasingly used option for patients with intestinal failure. As results continue to improve, this will become an alternative option to long-term maintenance therapy with TPN. For both liver and intestinal transplants, the future will likely see further improvements in results (with refinements in surgical and preservation techniques and with newer drugs to treat rejection and infections). Care of these patients in the critical perioperative period, however, will remain a crucial aspect of ensuring a successful outcome.

TABLE 187.4

MAJOR ADVANCES OR CHANGES IN THE LIVER TRANSPLANTATION FIELD OVER THE LAST 10 YEARS

Topic	Change	Reference
Allocation system	MELD/PELD utilized widely in the United States with evidence-based analysis showing it to improve patient survival	[10]
Indications for transplant	Extended tumor criteria outside of Milan criteria with equivalent results—for example, UCSF criteria	[16,17]
Surgical technique	Growth in adult-to-adult living donor transplant Donor morbidity for above estimated at 30%–35%	[28,29]
Increasing the donor pool	Increasing use of marginal donors nonheart beating donors, and split livers to expand the donor pool	[7,33,34]
Viral recurrence	Effective prophylaxis regimens to significantly decrease the risk of hepatitis B recurrence after transplant Hepatitis C recurrence becoming an increasing problem	[57,58]

CHAPTER 188 ■ HEMATOPOIETIC CELL TRANSPLANTATION

PAUL A. CARPENTER, MARCO MIELCAREK AND ANN E. WOOLFREY

GENERAL PRINCIPLES

Hematopoietic cell transplantation (HCT) typically is performed in patients with life-threatening disorders of the hematopoietic system. The procedure has considerable risks of transplant-related morbidity and mortality with a substantial proportion of patients requiring intensive medical care [1,2] (Fig. 188.1). Thus, knowledge of the basic principles of the transplant procedure and an understanding of potential complications including their differential diagnosis are important for improving the outcome of critically ill patients after transplantation.

HCT is potentially curative treatment for diseases including leukemia, lymphoma, myelodysplasia, multiple myeloma, aplastic anemia, hemoglobinopathies, and congenital immune deficiencies. In selected cases, HCT may also have a role in the treatment of solid tumors such as germ cell tumors, renal cell cancer, and breast cancer, and as a type of immunosuppression for patients with life-threatening autoimmune diseases (Table 188.1). In preparation for HCT, high-dose chemotherapy alone, or combined with irradiation therapy, is used to eradicate the underlying disease and to induce transient immunosuppression in the recipient to prevent graft rejection, a possible complication mediated by immunologic host-versus-graft reactions after allogeneic HCT. High-dose chemoradiation is followed by intravenous infusion of the graft, which contains hematopoietic stem cells (HSCs) that home to the bone marrow and reconstitute the hematopoietic system of the patient. In contrast to autologous HCT, allogeneic HCT requires prophylactic immunosuppressive therapy after transplant to prevent or mitigate graft-versus-host disease (GVHD), an inflammatory syndrome that primarily affects the skin, gastrointestinal (GI) tract, and liver.

Classification

HCT can be categorized according to the source of stem cells, the type of donor, or the intensity of the preparative regimen. The type of HCT used in an individual patient is a complex decision based on the patient's age, diagnosis, disease stage, prior treatments, donor availability, and presence of comorbidities.

Stem Cell Source

HSCs capable of reconstituting hematopoiesis in recipients given myeloablative therapy can be obtained from bone marrow, peripheral blood, or umbilical cord blood (UCB). The stem cell products obtained from each of these sources are characterized by distinct kinetics of engraftment and recovery of immune function after transplantation. These features may affect the risks of developing infectious complications and GVHD during the posttransplant period.

Bone Marrow. Bone marrow was historically the most common source of stem cells for HCT but is now used very infrequently for autologous HCT. Bone marrow is harvested from the iliac crest under general anesthesia, from appropriate volunteer donors. Engraftment after bone marrow transplant is evidenced by rising neutrophil and platelet counts and occurs between 3 and 4 weeks after transplant.

"Mobilized" Peripheral Blood. Growth factor–mobilized peripheral blood stem cells (PBSC) are the predominant source of HSC for allogeneic HCT in adults and are almost always used as HSC rescue for autologous HCT [3]. PBSCs are recognized on the basis of their expression of the CD34 surface marker and can be collected from the blood by a semiautomated procedure called leukapheresis. To promote peripheral blood mobilization of PBSC for autologous HCT, patients typically receive chemotherapy followed by administration of G-CSF, which has the benefit of chemotherapy-mediated tumor debulking prior to stem cell collection [4]. For allogeneic HCT, PBSCs are mobilized from healthy donors using growth factor alone.

Engraftment after PBSC transplantation occurs approximately 1 week earlier compared with bone marrow transplantation, which is likely related to the greater proliferative potential of stem and progenitor cells in PBSC. PBSC allografts contain approximately 10 times more T cells than marrow, which influences the development of GVHD, graft rejection, and rate of relapse for malignancies after HCT [5]. Randomized studies of allografts donated from HLA-matched siblings have shown a higher risk for relapse and lower risk for chronic GVHD among recipients of marrow compared with PBSC [3,6].

Umbilical Cord Blood. UCB contains HSC sufficient for reconstitution of hematopoiesis, which can be collected from the placenta and umbilical cord immediately after delivery of a baby. UCB banking has increased the likelihood of donor availability for patients with rare HLA haplotypes. T cells contained in UCB are immunologically naive, which allows for less stringent HLA matching between donor and recipient. The number of HSC contained in a typical UCB unit is several orders of

BOOP, bronchiolitis obliterans with organizing pneumonia; DAH, diffuse alveolar hemorrhage; GVHD, graft-versus-host disease; HHV6, human herpes virus 6; HSV, herpes simplex virus; IPS, idiopathic pneumonia syndrome; SOS, sinusoidal obstruction syndrome.

TABLE 188.1

INDICATIONS FOR ALLOGENEIC OR AUTOLOGOUS TRANSPLANTS

Allogeneic	Autologous
High-risk acute leukemia Acute myeloid leukemia Acute lymphoblastic leukemia	High-risk lymphoma Non-Hodgkin's lymphoma Hodgkin's lymphoma
Chronic leukemia Chronic myeloid leukemia Chronic lymphocytic leukemia	Multiple myeloma
Juvenile myelomonocytic leukemia	Solid tumors Neuroblastoma Poor-risk breast cancer Poor-risk sarcoma
Chronic myelomonocytic leukemia	Investigational Other poor-prognosis tumors Refractory autoimmune disorders
Myelodysplastic syndromes	
Bone marrow failure syndromes Severe aplastic anemia	
Severe immunodeficiency syndromes	
Inborn errors of metabolism	
Hemoglobinopathies Thalassemia major Symptomatic sickle cell disease	

magnitude lower compared with typical bone marrow or PBSC harvests. The smaller number of HSC may result in delayed engraftment, increased risk for graft rejection, and infection [7,8]. Recent studies have shown that infusion of two UCB units increases the total number of HSC, which seems to decrease the risk of graft rejection, thus giving adults as well as children the option of UCB transplantation [9].

Donor Type

Autologous. Transplantation of HSC donated by the patient is termed autologous HCT. Most commonly, autologous PBSC are cryopreserved and then thawed and reinfused once the high-dose preparative therapy has been completed. High-dose chemoradiation is given to kill tumor cells that may not be susceptible to conventional-dose cytotoxic therapy. The success of the autologous transplant procedures relies exclusively on the tumor-eradicating potential of the preparative regimen [10]. The effect the conditioning regimen has on extrahematopoietic tissues determines the dose-limiting toxicity of the procedure. Relapse after autologous HCT may occur from tumor cells that have survived the conditioning therapy or from those that contaminated the graft, although the former mechanism appears to be more important.

Syngeneic. Transplantation of HSCs donated from identical (monozygotic) twins is termed syngeneic HCT. When there is no genetic disparity between donor and recipient, the biology of the transplant is similar to autologous HCT. Compared with allogeneic HCT from HLA-matched related or unrelated donors, relapse rates are higher after syngeneic HCT, which has been attributed to the absence of malignancy-eradicating graft-versus-host reactions.

Allogeneic. Transplantation of HSCs cells donated by another individual is termed allogeneic HCT. Allogeneic HCT requires

availability of an HLA-compatible related or unrelated donor. Because of the inheritance pattern of HLA haplotypes, the statistical likelihood of two siblings being genotypically HLA identical is 25%. Donor-recipient HLA genotypic identity is associated with the lowest risks for immunologically mediated complications such as graft rejection and GVHD [11]. For approximately 70% of patients who do not have an HLA-identical sibling donor, a search for a suitable unrelated donor can be considered. HCT from HLA-matched unrelated donors, however, has traditionally been associated with higher risks of transplant-related morbidity and mortality compared with HCT from HLA-identical related donors. Use of unrelated donors who are matched using molecular HLA typing methods can improve outcomes considerably, and, for some diseases, survival of patients with unrelated grafts has approached that with HLA-identical sibling grafts [12,13].

The worldwide development of donor registries has increased the number of available HLA-matched unrelated donors and umbilical cord blood units for patients without suitable related donors. Another alternative source of HSC is a haploidentical relative, such as a parent, defined by the inheritance of one identical haplotype and mismatching of one or more HLA loci with the noninherited haplotype. Over the past decade, technological advances have improved the outcome for recipients of HLA-disparate grafts. When more than a single HLA antigen disparity is present, depletion of T cells from the graft is necessary to prevent life-threatening GVHD. Depletion of T cells from the marrow may be accomplished ex vivo by using immunologic or physical methods to target T cells for removal. Because T cells play an important role in establishment of the graft, early immune reconstitution, and tumor control, T-cell depletion has been associated with higher rates of graft failure, opportunistic infections, and relapse. Strategies to selectively deplete alloreactive T cells remain an active area of research.

Intensity of the Preparative Regimen

Myeloablative

In myeloablative HCT, the preparative regimen ablates the hematopoietic system of the patient and leads to transient but profound myelosuppression with pancytopenia. The transplanted hematopoietic cells reconstitute the ablated hematopoietic system in the recipient. High-dose chemotherapy regimens, with or without doses of total body irradiation (TBI) that exceed 6 Gy, combine different drug combinations that have nonadditive toxicities with radiation. The aim of high-dose therapy is to overcome the genetic heterogeneity of tumors by employing agents with different mechanisms of action. Although the myeloablative regimens used for autologous HCT typically consist of drugs that provide maximum tumor eradication with tolerable toxicity to the patient, regimens used for allogeneic HCT also must provide sufficient recipient immunosuppression to prevent graft rejection. Myeloablative preparative regimens are associated with substantial risks of transplant-related toxicity and mortality, particularly among older or medically ill patients [14].

Nonmyeloablative

Nonmyeloablative preparative regimens for allogeneic HCT are mainly immunosuppressive and aimed at preventing graft rejection. The underlying malignancy is eliminated through the ensuing immunologic graft-versus-tumor effects, provided the tumor expresses antigens that make it a target for immune attack. Compared with myeloablative allogeneic HCT, the extrahematopoietic toxicity from nonmyeloablative preparative regimens is considerably milder, an important consideration for older patients or those with comorbidities [15,16]. Typical post-HCT complications such as GVHD and infections, however, are not prevented by nonmyeloablative conditioning but may have a delayed onset.

Epidemiology

Current estimates of annual numbers of HCT are 45,000 to 50,000 worldwide. During 2006, 16,000 transplants were registered with the Center for International Blood and Marrow Transplant Research (CIBMTR), of which one-half were allogeneic. Allogeneic HCT is most commonly performed in adults using PBSC grafts. In contrast, children now predominantly receive cord blood or marrow grafts (NMDP Web site: http://www.marrow.org/). PBSC is less used in children because of the difficulties harvesting PBSC from young children and because of the increased risk of chronic GVHD.

Risk Factors for Transplant-Related Morbidity and Mortality

The likelihood of developing transplant-related complications depends on patient's age, the intensity of the preparative regimen, the type and stage of the underlying disease, and the presence of comorbidities. Prognosis is most heavily influenced by the underlying disorder. Patients with chronic malignancies and nonmalignant disorders, such as aplastic anemia, have a higher likelihood of survival compared to those with aggressive malignancies, who have a greater tendency to relapse following HCT. Mortality caused by the transplant procedure, and not from disease relapse, termed transplant-related mortality, ranges from 15% to 40% for allogeneic HCT recipients compared to 5% to 10% for autologous HCT recipients. HLA disparity between donor and recipient increases the risk of transplant-related mortality owing to the greater likelihood of developing GVHD and graft rejection. The risk for mortality increases significantly with age, although improvements in supportive care and donor selection and the introduction of nonmyeloablative preparative regimens have increased the proportion of patients older than 60 years who benefit from allogeneic HCT. Recent studies have demonstrated that pretransplant assessment of comorbidities using simple but transplant-specific comorbidity scoring systems has improved the ability to predict subsequent transplant-related mortality and survival [14,17].

TRANSPLANT-RELATED COMPLICATIONS

Transplanted-related complications include infections, regimen-related toxicity (RRT), and complications associated with alloreactivity. More intense conditioning regimens and higher degrees of donor-recipient HLA disparity are associated with greater risk for infection. Regimen-related toxicities include profound cytopenias and organ damage that follow myeloablative conditioning. The complications seen after allogeneic HCT that may occur irrespective of the intensity of the conditioning regimen include rejection, GVHD, and hemolysis.

Regimen-Related Pancytopenia

Reconstitution of hematopoiesis after HCT occurs in an orderly pattern; in general, neutrophil recovery occurs first, followed by recovery of platelets and red blood cells. The tempo of hematopoietic reconstitution varies according to the type

of HSC product, being earlier after PBSC grafts and later after UCB grafts, compared with marrow grafts. Transfusions of platelets and red blood cells often are needed until there is marrow recovery. Transfusion of red blood cells should be determined by the clinical condition of the patient, including hemodynamic stability and presence of active hemorrhage. Red blood cell transfusions generally are indicated when the hemoglobin falls below 8 g per dL. Platelet transfusions are indicated when the platelet count falls below 10,000 cells per μL to minimize the risk for spontaneous bleeding [18,19]. Transfusions thresholds should be increased before invasive procedures or in patients with bleeding to a level appropriate for any other intensive care unit (ICU) patient [18]. Platelet consumption may be increased in patients with fever, disseminated intravascular coagulation (DIC), or splenomegaly. Patients who have become alloimmunized to platelet antigens demonstrate poor response to platelet transfusions and may achieve higher platelet counts by limiting the number of donor exposures, controlling fever or DIC, using platelet products that are less than 48 hours old, or use of nonpooled (single-donor) or HLA-matched platelets [20,21].

Precautions should be taken in preparation of blood products for transfusion into HCT patients because passenger lymphocytes pose a risk for generating GVHD and latent viruses may be transferred through leukocytes. Except for the stem cell graft, all other components should be irradiated at a dose of 1,500 to 3,000 cGy to inactivate or eliminate contaminating lymphocytes. Depletion of leukocytes or use of blood components that test seronegative for cytomegalovirus (CMV) is effective for prevention of CMV transmission to CMV-seronegative recipients [21]. Removal of white blood cells from platelet and red blood cell products also decreases the risk for alloimmunization of the patient [22].

Regimen-Related Toxicity

High-dose cytotoxic chemotherapy with or without doses of TBI exceeding 6 Gy may severely disrupt mucosal integrity and has the potential to cause RRT in the skin, GI tract, liver, bladder, lung, heart, kidney, and nervous system. RRT occurs predominantly within the first 3 to 4 weeks after conditioning [23] and is more common after myeloablative than nonmyeloablative conditioning. RRT increases the risk for opportunistic infection, which is already high because of concomitant profound immunosuppression and regimen-related cytopenias. This section will focus on the noninfectious complications of individual organs specifically attributable to conditioning toxicity. Opportunistic infection or, after allografting, GVHD must strongly be considered as etiologies for organ dysfunction in the differential diagnosis of RRT. These alternative diagnoses are covered elsewhere under the appropriate subsection.

Skin

Generalized skin erythema is common after doses of TBI exceeding 12 Gy but is self-limiting and rarely associated with skin breakdown. Regimens that contain cytosine arabinoside (Ara-C), thiotepa, busulfan, etoposide, and carmustine may also cause erythema. Hyperpigmentation typically follows the inflammatory dermatitis, with skin folds often being particularly noticeable. Skin biopsies during the first 3 weeks after transplant often show nonspecific inflammatory changes irrespective of cause, making them frequently unhelpful in distinguishing between RRT, drug allergies, or acute GVHD [24].

Gastrointestinal Tract

Mucositis. Most patients who receive high-dose conditioning regimens develop mucositis. Symptoms include inflammation, desquamation, and edema of the oral and pharyngeal epithelial tissue that typically presents within the first several days after HCT and usually resolves by the third week. Anorexia, nausea, or other intestinal symptoms that persist after day 21 are more likely to be caused by GVHD or infection. Severe mucositis places patients at risk for aspiration and occasionally airway compromise, indicating the need for endotracheal intubation. Damage to the mucosa of the lower GI tract results in secretory diarrhea, cramping abdominal pain, and anorexia, and it facilitates translocation of intestinal bacteria with sepsis [23,25].

Mucositis is treated supportively with total parenteral nutrition, administration of intravenous fluids, and intravenous narcotics for pain control. It is important to recognize an iatrogenic narcotic bowel syndrome, characterized by abdominal pain and bowel dilatation, which occasionally may be a side effect of efforts to control painful symptoms of mucositis or sinusoidal-obstruction syndrome [26].

Acute Upper Esophageal Bleeding. The combination of mucositis, thrombocytopenia, and severe retching may result in a Mallory–Weiss tear, or esophageal hematoma [27]. The latter condition may have associated symptoms of dysphagia and retrosternal pain, and can be diagnosed by computed tomography (CT) scan. These conditions are treated supportively with transfusions to maintain platelet counts of greater than 50,000 per μL and optimal management of nausea and vomiting.

Liver

Sinusoidal Obstruction Syndrome. Sinusoidal obstruction syndrome (SOS; formerly referred to as veno-occlusive disease) develops in 10% to 60% of patients and is a clinical diagnosis based on the triad of tender hepatomegaly, jaundice, and unexplained weight gain usually within 30 days after HCT and in the absence of other explanations for these symptoms and signs [28,29]. It is more likely to be severe in patients with cirrhosis or fibrosis of the liver, or those with a history of hepatitis or liver irradiation (greater than 12 Gy), or chemotherapy-induced SOS [29,30].

Elevations of total serum bilirubin and serum transaminases are sensitive but nonspecific markers for SOS, and urinary sodium levels are typically low. A hepatobiliary ultrasound may show hepatomegaly, ascites, and dilatation of the hepatic vein or biliary system [31]. Doppler ultrasonography may show attenuation, or diagnostic, reversal of hepatic venous flow, but absence of this pattern does not exclude SOS [32]. If the diagnosis remains unclear, a transvenous liver biopsy may be helpful, and simultaneous measurement of hepatic venous pressure showing a gradient of greater than 10 mm Hg is highly specific for SOS [33].

Other causes of jaundice after HCT seldom lead to renal sodium avidity, rapid weight gain, or hepatomegaly. Cyclosporine, methotrexate, and total parenteral nutrition are iatrogenic causes of hyperbilirubinemia, although rarely cause levels greater than 4 mg per dL [34]. Combinations of illnesses that may mimic SOS are cholangitis lenta (cholestatic effects of endotoxin [35], especially when combined with renal insufficiency); cholestatic liver disease with hemolysis and congestive heart failure; GVHD and sepsis syndrome.

Once SOS is established, mathematical models can be used to predict prognosis, based on rates of increase in serum bilirubin and weight according to the elapsed time after transplantation [29,36]. The treatment for the 70% to 85% of patients who are predicted to have a mild or moderate course is largely supportive, with attention to management of sodium and water balance to avoid fluid overload [29]. Diuretics must be used judiciously to avoid depletion of intravascular volume and renal

hypoperfusion. Paracentesis is indicated if the degree of ascites threatens respiratory function. There is no universally effective therapy for severe SOS. However, multiple studies, including a recent large international multicenter phase II clinical trial, have demonstrated 30% to 60% complete remission rates with defibrotide, even among patients with severe SOS [37]. There is no support for insertion of peritoneovenous shunts and limited support for use of portosystemic shunts to reduce ascites [38]. Liver transplantation has been successful in a small number of patients [39].

Lung

Pulmonary complications occur in 40% to 60% of patients after HCT [40,41]. Noninfectious pulmonary problems that may occur within 30 days from the transplant include idiopathic pneumonia syndrome (IPS), diffuse alveolar hemorrhage, pulmonary edema [42] due to excessive sodium and fluid administration or associated with SOS, or acute cardiomyopathy induced by cyclophosphamide, and sepsis with adult respiratory distress syndrome (ARDS) [43]. These complications occur more frequently in older patients, those who receive higher-dose conditioning regimens, and those with allogeneic donors, particularly HLA-disparate donors [44]. Although the incidence of life-threatening pulmonary infections has decreased over the past decade due to the introduction of routine antimicrobial prophylaxis, pulmonary complications continue to be a leading cause of death.

Idiopathic Pneumonia Syndrome. IPS is defined as a noninfectious inflammatory lung process that may be triggered by TBI and chemotherapies such as carmustine or busulfan. IPS has been reported in 5% to 10% of patients and occurs with a median onset of 2 to 3 weeks after myeloablative HCT [44,45]. Contributing factors to IPS lung injury may be release of inflammatory cytokines due to alloreactivity or sepsis. The clinical symptoms cannot be distinguished from infection, and may include fever, nonproductive cough, and tachypnea. Hemoptysis is infrequent and more likely related to indicate invasive fungal disease or diffuse alveolar hemorrhage. Radiographic imaging shows diffuse interstitial or multifocal intra-alveolar infiltrates. Arterial blood gases show hypoxemia and the alveolar–arterial oxygen gradient is increased. In the occasional patient who is not too ill to attempt lung function studies, a new restrictive pattern or a reduced diffusing capacity is characteristic. Measurements of pulmonary artery occlusion pressure or echocardiography may be useful to rule out cardiogenic pulmonary edema. Bronchoalveolar lavage or lung biopsy is necessary to exclude bacterial, fungal, or viral infection because *IPS is a diagnosis of exclusion*. Multifocal bronchiolitis obliterans with organizing pneumonia (BOOP) may mimic late-onset IPS and has been more commonly associated with chronic GVHD.

Management of IPS is mainly supportive, including judicious diuresis to decrease pulmonary edema, transfusions of blood components to reverse bleeding diathesis, support of oxygenation, and administration of antibiotics to prevent superinfection with mold and bacteria, particularly in patients receiving high-dose glucocorticoids. Effective therapy for idiopathic pneumonia has not been demonstrated. High-dose glucocorticoids (1 to 2 mg per kg) have been reported to have an adjunctive role in treatment of diffuse alveolar hemorrhage or idiopathic pneumonia, but their efficacy has not been validated in controlled studies [46]. In a recent study of 15 patients who had IPS after allogeneic HCT, combination treatment with soluble tumor necrosis factor receptor (etanercept) and glucocorticoids resulted in an encouraging day-28 survival rate of 73% [47]. More than half of the patients included in this study had required mechanical ventilation at therapy onset. Long-term survival, however, did not appear to be superior compared with historic controls.

The mortality associated with IPS after myeloablative HCT is 50% to 70% [45,48]. Aggressive management, including initiation of mechanical ventilation to identify and treat reversible causes of respiratory failure, is a reasonable approach for most HCT recipients with diffuse or multifocal pulmonary infiltrates. When hemodynamic instability or sustained hepatic and renal failure develop, survival is extremely unlikely. Withdrawal of mechanical ventilation may be appropriate in specific situations.

Acute Respiratory Distress Syndrome. An ARDS-like syndrome also has been described as a presenting feature of acute GVHD, typically early-onset (hyperacute) GVHD. ARDS has an extremely high mortality rate in the transplant population; recovery depends on aggressive treatment of associated infections and support of respiratory and cardiac function [49,50]. The diagnosis of ARDS often is complicated by presence of other illnesses, such as SOS, hemorrhage, or disseminated intravascular hemolysis, which can cause difficulties in fluid management and indicate the need for pulmonary artery catheterization.

Diffuse Alveolar Hemorrhage. Diffuse alveolar hemorrhage may be a manifestation of diffuse alveolar damage. However, the erosion of blood vessels by fungal organisms always needs to be considered [51]. Hemorrhage occurs more frequently in older patients and those with malignancy, severe mucositis, or renal failure [52]. Bloody bronchoalveolar lavage (BAL) fluid with hemosiderin-laden macrophages is characteristic of diffuse alveolar hemorrhage.

Heart

Cardiac complications occur in 5% to 10% of patients after HCT, but death from cardiac failure is uncommon [53,54]. Cardiac injury with hemorrhagic myocardial necrosis is a rare but known adverse effect of high-dose cyclophosphamide, one of the most commonly used chemotherapy agents in conditioning regimens. Acute cardiac failure due to cyclophosphamide has a case mortality rate exceeding 50%. Risk factors for cyclophosphamide cardiotoxicity include use of doses equal to or greater than 120 mg per kg, an underlying diagnosis of lymphoma, prior radiation to the mediastinum or left chest wall, older age, and prior abnormal cardiac ejection fraction [54,55]. Patients who had prior cumulative anthracycline exposures of 550 mg per m^2 doxorubicin equivalents are at an increased risk for developing heart failure. Signs and symptoms of congestive heart failure may occur within a few days of receiving cyclophosphamide, while anthracycline-related cardiomyopathy may have a delayed onset. The electrocardiogram (ECG) may show voltage loss or arrhythmia, and echocardiography may reveal systolic dysfunction, pericardial effusion or tamponade [56]. Older age and a history of abnormal ejection fraction are other factors that predispose to cardiac toxicity [54]. Management includes attention to fluid and sodium balance, afterload reduction, and inotropes.

Kidney and Bladder

Acute Renal Failure. Acute renal failure (ARF), defined by doubling of baseline serum creatinine, occurs in 30% to 50% of all patients during the first 100 days after HCT, and most often during the first 10 to 30 days [57,58]. Occasionally, ARF develops during conditioning or infusion of HSC, as a consequence of tumor or red-cell lysis. ARF occurs most frequently in the setting of SOS and is characterized by low urinary sodium concentration and high blood urea nitrogen to creatinine ratio, similar to the hepatorenal syndrome. Renal hypoperfusion, caused by

acute hemorrhage, sepsis, or high-volume diarrhea, may result in ARF. Nephrotoxic drugs like cyclosporine, tacrolimus, all amphotericin products, and aminoglycosides frequently cause renal insufficiency.

Thrombotic microangiopathy (TMA), endothelial damage caused by chemoradiotherapy, cyclosporine, tacrolimus, or sirolimus, occurs in 5% to 20% of patients, more frequently in allograft recipients [59]. The hallmark of thrombotic microangiopathy is red blood cell (RBC) fragmentation (schistocytes) associated with increased RBC turnover (increased reticulocytes; elevations of serum lactate dehydrogenase and indirect bilirubin) without evidence for immune-mediated hemolysis or disseminated intravascular coagulation. The syndrome ranges from subclinical hemolysis to a life-threatening hemolytic syndrome, the latter being seen more frequently when sirolimus therapy is combined with cyclosporine or tacrolimus (calcineurin inhibitors, CNIs) and immediately following conditioning with busulfan and cyclophosphamide. High-therapeutic or supratherapeutic serum levels of CNIs or sirolimus are more prone to be associated with TMA [60]. Management involves careful assessment of volume status and discontinuation or adjustment of the drug levels of the offending agent(s). The use of plasma exchange has been associated with high mortality rates in most series [61] with recent exceptions [62], and may be skewed by selection bias because only the sickest patients are likely to receive the treatment. For this reason, determination of any survival benefit attributable to plasma exchange in the absence of a controlled study is impossible.

Hypertension. Hypertension develops in approximately 60% of patients after HCT, more often in patients given CNIs for GVHD prophylaxis. Glucocorticoid therapy also contributes to the development of hypertension. Uncontrolled hypertension may lead to fatal intracerebral bleeding in thrombocytopenic patients. Therefore, hypertension should be anticipated and controlled medically. Most patients respond to conventional antihypertensive therapy, such as a calcium channel blocker, angiotensin-converting enzyme inhibitor, or beta-blocker. Correction of hypomagnesemia, which often confounds CNI therapy, may improve control of hypertension [63].

Hemorrhagic Cystitis. High-dose cyclophosphamide is commonly used for conditioning, and one of its toxic metabolites, acrolein, accumulates in the urine and may cause a hemorrhagic chemical cystitis during the conditioning regimen or later after HCT [64,65]. Measures to prevent hemorrhagic cystitis include aggressive fluid hydration to increase urine volume that dilutes and minimizes contact of acrolein with the mucosa, and administration of the drug mesna, which provides free thiol groups to detoxify acrolein. Viral infections, particularly adenovirus and BK virus, also have been implicated in the development of hemorrhagic cystitis [66] and the diagnosis is established by viral culture or polymerase chain reaction (PCR) test of a urine sample [66]. Unless there is evidence of disseminated infection, viral cystitis is managed with supportive therapy, including aggressive hydration and platelet transfusions. Intravesicular infusions of ε-aminocaproic acid or prostaglandins have been reported to improve outcome of severe hemorrhagic cystitis [67]. Severe hemorrhagic cystitis caused by BK virus that proves refractory to supportive therapy may respond to therapy with cidofovir [68].

Central Nervous System

Noninfectious complications include cerebrovascular events and encephalopathies due to metabolic, toxic, and immune-mediated causes. Focal symptoms are more indicative of infectious or cerebrovascular mechanisms, while diffuse symptoms such as delirium or coma may have metabolic causes. Fever is not necessarily associated with central nervous system (CNS) infections. Infection should be considered as the cause of any neurologic symptom and should prompt evaluation, including obtaining CT or magnetic resonance imaging (MRI) scans of the head and a sample of cerebrospinal fluid for appropriate cultures, cytochemistry stains, and PCR tests should be undertaken.

Cerebrovascular Events. Thrombocytopenia poses a risk for intracranial hemorrhage, which usually presents as abrupt onset of focal neurologic deficit or mental status changes [69]. Patients with sickle cell disease have a predisposition to CNS hemorrhage after HCT and should be managed carefully by ensuring sufficient platelet and magnesium levels and strict control of hypertension [70]. Ischemic stroke is an unusual complication after HCT but has been reported in patients with *Aspergillus* infections, hypercoagulable states, or TMA [59,71].

Toxic Encephalopathies. Conditioning with high-dose busulfan or carmustine may cause encephalopathy and seizure prophylaxis with phenytoin is usual. High-dose cytarabine may cause cerebellar dysfunction, encephalopathy, and seizures. High-dose cyclophosphamide can be associated with the syndrome of inappropriate antidiuretic hormone (SIADH), rarely causing acute decline in the serum sodium that may prompt seizures. Fludarabine, used frequently in nonmyeloablative conditioning, may cause an encephalopathy.

A rare syndrome of encephalopathy and hyperammonemia without other chemical evidence of liver failure has been reported after HCT [72]. Contributing factors may include hypercatabolism induced by conditioning, glucocorticoids, or sepsis, and high nitrogen loads associated with parenteral nutrition or intestinal hemorrhage. The syndrome is difficult to reverse and has a high mortality rate. Treatment involves hemodialysis and administration of ammonia-trapping agents, such as sodium benzoate or sodium phenylacetate.

Related to a tendency to accumulate in nervous tissues due to their lipophilic characteristics, CNIs can cause a range of neurologic toxicities [73]. Tremor develops in most patients. Seizures have been reported in up to 6% of patients and may present in association with headaches, tremor, or visual disturbances [74]. Seizures should be managed with anticonvulsant therapy and cessation of the drug. When CNIs are essential for management of GVHD, substitution of one agent for the other, or reinstitution of the offending agent at a lower dose, may be feasible [75]. A unique and usually reversible syndrome of cortical blindness has been reported as a complication of cyclosporine treatment; hypertension and hypomagnesemia are thought to be predisposing factors [76]. Toxicity due to calcineurin inhibitor therapy may occur with "therapeutic" drug levels, and clinical suspicion is often confirmed by MRI scans that show multifocal areas of signal hyperintensity on T2 (time for 63% of transverse relaxation) and fluid-attenuated inversion recovery (FLAIR) sequences, most often in the occipital lobe white matter.

Glucocorticoid therapy may be associated with psychosis, mania, or delirium in a dose-dependent fashion. Seizures or altered sensorium may be associated with the use of sedative-hypnotic drugs and have been reported as adverse side effects of many of the commonly used antibiotics and antiviral agents. Metabolic encephalopathy may be associated with Gram-negative sepsis, hypoxic encephalopathy with IPS, and hepatic encephalopathy due to SOS or GVHD.

Treatment of metabolic encephalopathies should be directed at the underlying problem, and offending drugs have to be discontinued. In patients with CNI neurotoxicity, temporary discontinuation of the CNI and the restarting at a lower dose is usually successful. Short-term phenytoin for seizure prophylaxis may be indicated.

Infection

Conditioning regimens and GVHD severely impair host defense mechanisms, and the process of immune reconstitution necessarily requires many months for completion. Together these factors place patients at high risk for acquisition of severe infections. Proper medical care of patients after HCT includes measures to monitor and prevent infection, as it is a leading cause of death.

Prevention of infection is of vital importance to the success of HCT procedures. Hospitalized patients should be housed in single rooms that have positive-pressure airflow and ventilation systems with rapid air exchange and high-efficiency particulate air filtration [77]. Strict visitation, hand washing, and isolation policies should be instituted to prevent introduction or spread of communicable disease. A daily program of skin and oral care should include bathing all skin surfaces with mild soap, brushing teeth with a soft brush, frequent rinsing of the oral cavity with saline, and good perineal hygiene. The diet should exclude foods known to contain bacteria or fungi, and patients should avoid exposure to dried or fresh plants or flowers. Caregivers should be trained in the proper handling of central venous catheters.

Immunologic reconstitution after HCT can broadly be categorized into three phases, which are characterized by a spectrum of opportunistic infections. Advances in management of antimicrobial prevention of opportunistic infections after HCT are outlined in Table 188.2.

Before Engraftment Period

The period before engraftment (less than 30 days posttransplant) is characterized by neutropenia and oral and gastrointestinal mucosal damage. The most common infections are bacterial and fungal. The use of indwelling central venous catheters

Infection	Recommendations for prophylaxis (strength of recommendation)[a]	
	All patients	**Patients with chronic GVHD**
Bacteria	Broad-spectrum antibiotic(s) during period of neutropenia (ANC < 500/μL). Choices include a single agent, such as levofloxacin or ceftazidime, or a combination of agents, such as piperacillin. [CIII] Patients with hypogammaglobulinemia: Intravenous immunoglobulin administered at 1- to 4-week intervals depending on level. [CIII]	Penicillin VK twice daily for encapsulated organisms. [BIIb] Alternatives: TMP/SMX daily, azithromycin three times per week. [CIII] Patients with hypogammaglobulinemia or repeated sinopulmonary infections: Intravenous immunoglobulin administered at monthly intervals depending on level. [CIII]
Fungi	Fluconazole from start of conditioning to day 75 (allogeneic HCT) or day 30 (autologous HCT). [AIa]	Mold active agents, such as posaconazole when prednisone dose is ≥ 1 mg/kg. [AI]
PCJ	TMP/SMX is the drug of choice and starts 1–2 wk before transplant until 48 h before HCT, then from engraftment until 6 months after HCT if no chronic GVHD. Alternatives: dapsone, atovaquone, pentamidine. [AIb]	TMP/SMX in a variety schedules. [AIb]
HSV (seropositive patients)	Acyclovir prophylaxis from start of conditioning until day 30. Alternatives: valacyclovir. [AI]	Not indicated
VZV (seropositive)	Acyclovir prophylaxis from start of conditioning until 1 year after HCT for those with a history of natural infection. Alternative: valacyclovir. [AIa]	Acyclovir from start of immune suppression until completion. Alternatives: valacyclovir. [AIa]
CMV (seropositive)	Ganciclovir prophylaxis or preemptive therapy based on plasma CMV DNA detection by PCR between engraftment and day 100. Foscarnet is an equally effective alternative to ganciclovir for preemptive therapy. [AI]	Valganciclovir therapy based on plasma CMV DNA detection by PCR until dose of prednisone is < 1 mg/kg. [BIII]
CMV (seronegative)	Preferential use of preemptive therapy with ganciclovir or foscarnet as outlined for seropositive patients. [BII]	Not indicated

[a]Evidence-based grading system adapted from Couriel D, Carpenter PA, Cutler C, et al: Ancillary therapy and supportive care of chronic GVHD: NIH Consensus Development Project on criteria for clinical trials in chronic GVHD: V. Ancillary Therapy and Supportive Care Working Group Report. *Biol Blood Marrow Transplant* 12:375–396, 2006.
Recommendations are "A," should always be offered; "B," should generally be offered; "C," optional; "D," should generally not be offered. Evidence is "level I" if it is derived from ≥ 1 properly designed randomized, controlled trial; "level II" if it is derived from ≥ 1 well-designed clinical trial without randomization, from cohort or case-controlled analytical studies, or from multiple time series or dramatic results from uncontrolled experiments; and "level III" if it is derived from opinions of respected authorities based on clinical experience. Qualifiers, "a," indicates that evidence is directly from study(s) in GVHD, or "b" if the evidence was derived indirectly from study(s) in analogous or other pertinent disease.
ANC, absolute neutrophil count; CMV, cytomegalovirus; DS, double strength; GVHD, graft-versus-host disease; HCT, hematopoietic cell transplantation; HSV, herpes simplex virus; IgG, immunoglobulin G; IV, intravenous; max, maximum dose; MTX, methotrexate; PCJ, *Pneumocystis jiroveci* pneumonia; PCR, polymerase chain reaction; SMX, sulfamethoxazole; TMP, trimethoprim; VK, V potassium; VZV, varicella zoster virus.

heightens the risk of blood infections with organisms that colonize the skin, such as coagulase negative *staphylococci* or *Candida spp.*, and gastrointestinal mucosal damage increases the risk of infections with enteric organisms, such as *Escherichia coli*. *Clostridium difficile* toxic colitis can be a common infection in transplant patients, particularly those patients in intensive care units. Patients with a history of prolonged neutropenia prior to HCT are at risk for developing fungal infections involving the skin, lung, sinuses, which typically are a mold such as *Aspergillus*, or the liver and spleen, typically *Candida* spp. The most likely viral infection in this period is herpes simplex virus. Fever of unknown origin also occurs commonly during the neutropenic period. Prophylactic systemic antibiotics conventionally are administered to reduce the risk of bacteremia during the neutropenic period, although improvement in survival has not been demonstrated [77,78]. Administration of growth factors, such as granulocyte colony-stimulating factor, shortens the duration of neutropenia, but there is little evidence for improvement in outcome [79].

Following Engraftment Period

The period following engraftment (30 to 100 days posttransplant) is characterized by skin and mucosal damage and compromised cellular immunity related to GVHD and its treatment. Viral (CMV) and fungal (*Aspergillus, Pneumocystis jiroveci*) infections predominate during this period. Gram-negative bacteremias related to GVHD-associated mucosal damage and Gram-positive infections due to indwelling catheters remain a risk. Other causes of fever of unknown origin after engraftment include occult sinusitis, hepatosplenic candidiasis, and pulmonary or disseminated *Aspergillus* infection.

Late Phase

The late phase (greater than 100 days posttransplant) is characterized by a persistently impaired cellular immunity in patients with chronic GVHD. Patients with chronic GVHD are highly susceptible to recurrent bacterial infections, especially from encapsulated bacteria, including *Streptococcus pneumonia, Haemophilus influenzae*, and *Neisseria meningitides* (functional asplenia). Bronchopulmonary infections, septicemia, and ear, nose, and throat infections occur. Common nonbacterial infections at this time include varicella zoster, CMV, *P. jiroveci*, and *Aspergillus*.

Evaluation and Treatment

Signs and symptoms of infection may be diminished in patients who are neutropenic or receiving immunosuppressive drugs [80]. Thus, preemptive antibiotic therapy should be instituted promptly for any fever during the neutropenic period, because infections can progress rapidly to a fatal outcome [81]. The febrile patient should be examined thoroughly for source of infection, including the oral cavity, perianal tissue, and skin surrounding the central venous catheter. Cultures should be obtained of blood, urine, and stool if diarrhea is present, and chest radiograph should be performed. Antibiotic therapy should provide empiric coverage for the most common organisms, Gram-positive bacteria that colonize the skin and oral cavity, as well as the less common but more virulent Gram-negative bacteria that arise from the GI tract [78,80,81]. Broad-spectrum antibiotic therapy should be continued through the duration of neutropenia, even if fever resolves. If fever persists, the antibiotic regimen should be broadened after 4 days to provide empiric treatment of fungi. *C. difficile* infection should be considered in patients with diarrhea and can be treated with oral metronidazole.

Evaluation of persistent fevers after granulocyte recovery should consider occult sources of bacterial infection, such as sinuses, perirectal tissue, or central venous lines, as well as viral or fungal etiologies. Removal of the central venous catheter is occasionally required. Viral infections must be considered in patients with GI symptoms and may involve the esophagus, upper and lower intestines, or liver [82]. The diagnosis is established by biopsy or brushings taken from the center of the lesions so as to include infected endothelial cells and submucosal tissue. Host immunosuppression associated with GVHD and its treatment predisposes patients to a variety of opportunistic infections. Patients with active chronic GVHD should receive prophylaxis for *P. jiroveci* pneumonia with trimethoprim–sulfamethoxazole and for encapsulated organisms with daily trimethoprim–sulfamethoxazole, penicillin, or azithromycin. Infectious causes of pulmonary infiltrates must be differentiated from noninfectious causes to ensure prompt institution of appropriate therapy [48,83].

BAL should be performed without delay to establish the etiology of diffuse infiltrates, unless clearly related to pulmonary edema [84]. BAL specimens should be assayed for the presence of common nosocomial bacteria as well as *Legionella*, *Mycobacteria*, and *Nocardia; P. jiroveci*; fungi other than *P. jiroveci* pneumonia; respiratory viruses; and herpes group viruses by cultures and immunocytochemical stains. Focal pulmonary infiltrates that occur after HCT are most frequently caused by infection, particularly fungal infection [85]. Evaluation of a focal infiltrate should include a CT scan to delineate the number and extent of infiltrates. BAL should be performed as a first step because the procedure is minimally invasive and historically has produced a diagnosis in 50% of patients with fungal lesions using standard diagnostic approaches, although the predictive value of negative results was poor [84]. At some centers, the increasing use of more diagnostic approaches like galactomannan antigen testing [86] or, ongoing development of molecular methods to detect fungi or viral pathogens (e.g., human metapneumovirus [87,88]) continues to improve the yield of BAL. As a result, the number of lung biopsies performed at these centers has declined. Transbronchial biopsy is not recommended because it has not been shown to improve sensitivity in these situations, and often thrombocytopenia precludes the ability to perform the procedure safely. Percutaneous fine-needle aspiration is indicated for diagnosis of peripheral infiltrates that cannot be evaluated by BAL. Fine-needle aspiration has a sensitivity of approximately 67% for diagnosis of fungal infection, but it has a poor negative predictive value. If the diagnosis is not ascertained after BAL or fine-needle aspiration, a biopsy is required [89]. Specimens should be evaluated histologically and undergo testing for bacteria, fungi, and viruses by appropriate cultures and immunocytochemical stains as noted previously. Surgical resection of a solitary fungal lesion may improve the chances for cure [90].

Opportunistic Infections

Pneumocystis jiroveci **Pneumonia.** Inadequate cell-mediated immunity poses a risk for development of *P. jiroveci* pneumonia infection after HCT [91]. Recommendations for prevention of PJP are found in Table 188.2 [77,92].

Fungal Infections

Factors that predispose to invasive yeast infections include neutropenia, mucosal barrier disruption, and broad-spectrum antibiotics that promote colonization of the GI mucosa [93]. Candidal infections generally occur within the first 3 weeks after HCT, coinciding with the period of neutropenia, although a second period of risk occurs during treatment for chronic GVHD. Invasive candidiasis may involve the liver and spleen, with potential for dissemination to kidneys or rarely, the CNS

[94,95]. The diagnosis of invasive candidiasis is difficult because blood cultures are negative in approximately one half of the cases with organ involvement. Recommendations for prevention of candidiasis are found in Table 188.2. Fluconazole is effective for treatment of the most common *Candida* spp, *C. albicans* and *C. tropicalis* [96,97] (see Table 188.2), but does not prevent or treat infection with *C. glabrata*, *C. krusei*, or *C. parapsilosis*. Removal of the central venous catheter should be considered when *Candida sp*. is isolated from blood cultures. Fungal vegetations on heart valves are possible and echocardiography is often considered. Lipid-complexed amphotericin products, echinocandins, or other azoles may be useful alternatives [98].

Invasive mold infections develop in up to 20% of patients after HCT [99]. The incidence of *Aspergillus* infections is highest within the first month after HCT, and there is a second peak incidence during chronic GVHD. *Aspergillus* infections have been difficult to diagnose by standard methods, and more than 20% of the cases have been diagnosed only at autopsy. Cultures of BAL fluid are negative in 50% of pulmonary disease; therefore, the diagnosis frequently requires a biopsy of affected tissues [85]. The *Aspergillus* Galactomannan Enzyme Immunoassay detects a polysaccharide secreted from *Aspergillus hyphae* and is a useful screening tool, with a sensitivity of 65% and specificity of 95% [100]. High-risk patients, those with severe GVHD treated with high-dose corticosteroids, should be given prophylaxis with agents like voriconazole or posaconazole which is active against aspergillosis and certain other molds. Because invasive aspergillosis is associated with a high mortality rate, documented or suspected infections should be treated aggressively with voriconazole, lipid-complexed amphotericin products, or combination therapy [101,102]. Surgical removal of infected tissue should be restricted to cases of circumscribed disease [103].

Viral Infections

Cytomegalovirus. Protection from exposure by use of seronegative or leukocyte-reduced blood components has reduced the incidence of CMV infection among seronegative patients [21], whereas ganciclovir has been shown to be an effective agent for prevention of CMV disease in seropositive patients [104–106] (see Table 188.2). Ganciclovir should be initiated as prophylaxis after engraftment, with careful monitoring of the patient for marrow suppression, a side effect that can lead to life-threatening infection (Table 188.2) [107]. A reasonable alternative is to monitor for CMV reactivation with serum PCR assays, followed by prompt institution of ganciclovir when the CMV copy number reaches a positive threshold [108–110]. Generally, surveillance CMV PCR testing is performed weekly from transplant day 0 through day 100; however, monitoring generally is continued for CMV positive patients on high-dose corticosteroids.

Although prophylaxis greatly reduces the risk for CMV disease, severe pneumonitis, gastroenteritis, hepatitis, or bone marrow failure continue to occur in a small proportion of patients [111]. The diagnosis of CMV pneumonitis can be established in most patients by PCR assay or rapid shell vial culture of BAL fluid [112]. CMV enteritis is often indistinguishable from GVHD clinically, and the diagnosis relies on endoscopic evaluation [113]. CMV enteritis appears as ulcerations of the esophagus, stomach, or intestines. Viral cultures and histologic stains of the affected tissue are used to establish the diagnosis. Treatment of CMV infection includes ganciclovir (foscarnet or cidofovir are acceptable alternatives) in combination with immune globulin [114,115]. Foscarnet can be used in place of ganciclovir if significant marrow toxicity occurs or drug resistance is identified.

Herpes Simplex Virus. Herpes simplex virus (HSV) is the most common cause of infectious mucositis after HCT and may cause life-threatening encephalitis, hepatitis, or pneumonia in immunocompromised patients [116–118]. HSV pneumonitis or hepatitis is associated with high mortality rates; although less serious, HSV mucositis produces severe local pain and swelling. Acyclovir prophylaxis has been shown to be very effective for prevention of HSV reactivation in seropositive patients and for treatment of established disease [119,120] (see Table 188.2).

Varicella Zoster Virus. Varicella zoster virus (VZV) causes life-threatening disease in immunocompromised patients, as a primary infection or reactivation of endogenous virus [121]. Exposed seronegative patients should receive VZV immune globulin within 96 hours if available, and acyclovir should be administered from days 3 to 22 after exposure [122]. Among seropositive patients, VZV reactivation occurs in approximately 40%, with the highest incidence around 5 months after HCT [121,123]. Prophylaxis with acyclovir is recommended for seropositive patients until 1 year after HCT or until complete discontinuation of immunosuppressive therapy for chronic GVHD immunity [124] (see Table 188.2). VZV infection typically causes local skin involvement, but it can disseminate in immunocompromised patients, resulting in pneumonitis, esophagitis, pancreatitis, hepatitis, or encephalitis [125–128]. VZV hepatitis may present as a syndrome of fever, severe abdominal pain, and elevated aminotransferase levels, and because it is associated with a high mortality rate, should be treated presumptively with high-dose acyclovir [128]. For localized infection, a short course of intravenous acyclovir for 24 to 48 hours can be followed by oral valacyclovir for the duration of therapy.

Respiratory Viruses. Respiratory viruses may spread quickly within HCT patient populations, causing epidemics of life-threatening infection. Respiratory syncytial virus (RSV), influenza, and parainfluenza are the most frequently encountered respiratory viruses in these situations [129]. Symptoms of upper respiratory infection should prompt cultures of nasopharyngeal secretions, careful monitoring for progression of disease, and isolation to prevent spread to other patients. Patients in the period before engraftment are at greatest risk for progression to lower tract disease with RSV. Once lower-tract disease occurs, however, mortality is high regardless of engraftment status [130]. If lower-tract disease is suspected, BAL should be performed to obtain samples for viral fluorescence antibody and PCR tests and viral cultures [131].

Adenovirus. Adenovirus and polyoma BK virus are common causes of hemorrhagic cystitis after HCT [66]. When disseminated, adenovirus can cause hemorrhagic enterocolitis, interstitial pneumonitis, myocarditis, nephritis, meningoencephalitis, or severe hepatitis [132]. Adenoviral infections occur more commonly in children and after allogeneic grafts [133]. Patients with poor T-cell function, such as recipients of T cell–depleted grafts or those receiving intensive immune suppressing therapies, are at greatest risk for disseminated infection. Disseminated infections are often difficult to detect by viral cultures, and PCR assays may be more useful [134]. The most promising treatment results have been reported after administration of cidofovir, although renal insufficiency is a potential side effect [135]. Polyoma BK virus should be considered in the differential diagnosis of renal insufficiency in patients on chronic immune suppression, and can be diagnosed by renal biopsy.

Epstein-Barr Virus. Epstein–Barr virus (EBV) seropositive immunocompromised patients are at risk for development of life-threatening lymphoproliferative disease (LPD) after HCT

[136]. The risk for EBV–LPD is highest among patients who receive T-cell–depleted grafts or who are given intensive immune suppression for treatment of GVHD [137]. The diagnosis is made by biopsy of enlarged nodes or affected tissue. A presumptive diagnosis can be made in high-risk patients who have clinical symptoms and elevated plasma or cellular EBV DNA copy number [138]. The mainstay of therapy is reduction or elimination of immunosuppressive therapy to allow reconstitution of EBV-specific T-cell immunity. However, it may not be feasible to eliminate immunosuppression therapy without risking a flare of life-threatening GVHD. Some studies have shown encouraging results with mAb directed against CD20, which targets EBV-infected B cells [139]. EBV–LPD that develops in recipients of T cell–depleted grafts may be ameliorated by infusion of donor T lymphocytes [140].

Graft Rejection

Graft rejection presents as failure to recover hematopoiesis after transplantation, termed *primary graft failure*, or as the loss of an established donor graft, termed *secondary graft failure*. Persistence of neutropenia (an absolute neutrophil count of more than 100 cells per μL) after day 26 is associated with increased risk of early mortality [141]. Although the molecular and cellular mechanisms are not completely understood, graft rejection appears to be mediated preferentially by recipient T cells [142]. Another described mechanism includes rejection mediated by host natural killer cells which, to some extent, can be overcome by the preparative regimen. Finally, alloimmune antibodies in sensitized recipients may cause rejection in mice but their role in humans is controversial. Donor HLA disparity stimulates strong alloreactive immune responses in the immunocompetent recipient and increases the risk for graft rejection. Donor T cells counteract the rejection responses of host alloreactive cells that have survived the conditioning regimen [143]. Higher stem cell doses facilitate engraftment, particularly when T cell–depleted grafts are used [144,145].

Quantitation of donor engraftment (donor chimerism), using PCR-based techniques to detect donor-specific variable nucleotide tandem repeats (VNTR) sequences, may be helpful in determining whether the graft has been rejected, in which case the peripheral blood T cells will be primarily of host origin, or whether the donor graft is not functioning, in which case the cells will be of donor origin. In the latter case, other causes of graft suppression should be considered, including relapse, medications such as ganciclovir or trimethoprim–sulfamethoxazole, mycophenolate mofetil, or viral infections such as CMV, human herpes virus 6, or parvovirus B19. In either case, graft failure after myeloablative conditioning is a life-threatening complication because autologous reconstitution is uncommon and results in death from hemorrhage or infection. A range of cellular therapies have been used to overcome rejection ranging from donor lymphocyte infusions in the case of declining donor T-cell chimerism, possibly combined with immunosuppressive therapy. In fulminant rejection, retransplantation is necessary, using the same or another donor. Conditioning should preferentially differ from that used at the first transplant to avoid unnecessary toxicity, and a high graft cell dose should be targeted [142].

Graft-Versus-Host Disease

The most significant immunologic barrier to successful HCT is the graft-versus-host reaction, which can result in life-threatening inflammation and tissue destruction. Donor T cells that recognize disparate recipient alloantigens are the central mediators of GVHD. The most important alloantigens are those encoded by the major histocompatibility complex, or HLA system, although non-HLA antigens may certainly be involved. Despite the significance of GVHD as a complication of HCT, patients who develop GVHD have lower relapse rates than patients without GVHD, and this can also be explained by an immunologically mediated graft-versus-tumor (GVT) effect that helps eradicate the underlying malignancy.

Acute Graft-Versus-Host Disease

The incidence and severity of acute GVHD are determined primarily by the degree of HLA disparity and influenced by the nature of GVHD prophylaxis [146–148]. Severe acute GVHD (grades III to IV) develops in 15% of recipients transplanted from HLA-identical sibling donors, and in a greater proportion of those given unrelated or mismatched grafts. Acute GVHD typically begins abruptly at 2 to 4 weeks after myeloablative HCT and generally occurs before day 100, but the onset may be delayed after nonmyeloablative HCT. The clinicopathologic syndrome is consistent with various combinations of inflammatory dermatitis, enteritis, and hepatitis, which reflect the pathophysiology of T-cell activation with generation of cytotoxic lymphocytes and elaboration of inflammatory cytokines that cause tissue damage. The severity of acute GVHD in the three main target organs (skin, liver, and GI tract) is staged 1 through 4 based on accepted criteria that primarily include the extent of rash, magnitude of hyperbilirubinemia, and volume of diarrhea. The various combinations of skin, liver, and GI involvement can then be used to assign an overall grade of GVHD: grade I being mild, and grade IV being life threatening [149,150] (Table 188.3). When cellular injury is severe, GVHD of the skin may manifest with bulla formation and skin ulceration. In the GI tract, symptoms range from mild anorexia, to nausea and vomiting, or to severe bloody diarrhea with cramping periumbilical pain.

Chronic Graft-Versus-Host Disease

Chronic GVHD (CGVHD) occurs in approximately 30% to 60% of transplant recipients, more often when the donor is not an HLA-identical sibling and when there is a history of acute GVHD [151]. There is a higher risk for developing CGVHD with growth factor–mobilized PBSC grafts compared to marrow grafts [152]. CGVHD also is more likely when the recipient or donor is older or CMV seropositive, or in a male patient who receives HSC from a multiparous female donor. Risk factors for mortality at the time of diagnosis of CGVHD include: platelet counts less than 100×10^9 per L, greater than 0.5 mg per kg per day prednisone, serum total bilirubin greater than 34 μmol per L, older recipient, prior acute GVHD, older donor, and graft-versus-host HLA mismatching [153,154].

CGVHD is defined without reference to time after HCT, but by the presence of hallmark CGVHD features, which resemble autoimmune diseases such as systemic sclerosis, Sjogren's syndrome, primary biliary cirrhosis, wasting syndrome, bronchiolitis obliterans, immune cytopenias, and chronic immunodeficiency [155] (Table 188.4). Simply stated, the distinction of chronic from acute GVHD requires the presence of at least one diagnostic clinical sign of CGVHD or presence of at least one distinctive manifestation confirmed by pertinent biopsy or other relevant tests. The overall severity of CGVHD is determined by a 0- to 3-point score (none, mild, moderate, severe) that reflects the clinical effect of CGVHD on the patient's functional status in any number of different organs. CGVHD frequently involves the skin, liver, eyes, mouth, upper respiratory tract, lungs, and esophagus. Less frequently, serosal surfaces, lower GI tract, female genitalia, or fascia are involved. Major causes of morbidity include scleroderma, contractures, ulceration, keratoconjunctivitis, strictures, obstructive pulmonary disease, and weight loss. Uncontrolled chronic GVHD

TABLE 188.3

CLASSIFICATION OF GRAFT-VERSUS-HOST DISEASE

Acute GVHD organ staging			
Organ	**Stage**	**Scores**	**Description**
Skin	1		≤25% body surface area with maculopapular rash
	2		25%–50% body surface area with maculopapular rash
	3		≥50% body surface area with maculopapular rash or erythroderma
	4		Generalized erythroderma with bullae
Liver	1		Bilirubin 2.0–3.0 mg/dL
	2		Bilirubin 3.0–5.9 mg/dL
	3		Bilirubin 6.0–14.9 mg/dL
	4		Bilirubin rise to ≥15 mg/dL
GI tract			Stage is assigned according to a total GI score based on volume of diarrhea, presence of bloody stool, and abdominal pain or cramping
	1		Total GI score of 1
	2		Total GI score of 2
	3		Total GI score of 3–4
	4		Total GI score of 5–7
GI scoring			Diarrhea volume averaged over 3 d Adult (mL/d), child[a] (mL/kg/d)
		+1	>500–999, >10–20
		+2	1,000–1,499, >20–30
		+3	>1,500, >30
		+2	Score additional 2 points for presence of abdominal pain or cramping
		+2	Score additional 2 points for presence of bloody stools

Acute GVHD overall grade	Skin stage	Liver stage	GI stage
I	1–2	0	0
II	3 or	1 or	1
III		2–3	2–3
IV	4 or	4 or	4

[a]Children < 17 years of age who are < 1.73 m^2.
GI, gastrointestinal; GVHD, graft-versus-host disease.
Adapted from Martin PJ, Nelson BJ, Applebaum FR, et al: Evaluation of a CD5-specific immunotoxin for treatment of acute graft-versus-host disease after allogeneic marrow transplantation. *Blood* 88(3):962–969, 1996, with permission.

interferes with immune reconstitution and is strongly associated with increased risks of opportunistic infections and death.

Confirming the Diagnosis of Graft-Versus-Host Disease

Unlike CGVHD, the clinical signs of acute GVHD are not considered sufficiently pathognomonic to establish the diagnosis, especially when there is isolated organ involvement. However, the combination of rash, nausea, and voluminous diarrhea, occurring at the time of, or early after, neutrophil engraftment makes the diagnosis very likely. The differential diagnosis involves ruling out other causes of rash, diarrhea or liver toxicity as listed in Table 188.5. Tissue biopsies of the skin, liver, or stomach are recommended to confirm a histologic diagnosis of GVHD and, most importantly, to exclude opportunistic infection; however, the interpretation of biopsies performed within 3 weeks of myeloablative therapy may be problematic because it is difficult to separate cellular injury induced by chemoradiotherapy from GVHD. The gastric antral mucosa provides the most sensitive site for evaluation of intestinal GVHD and is preferred over duodenal and rectal biopsy because there is less risk for bleeding complications. The histologic hallmark of GVHD-induced cellular injury is apoptosis, observed in epidermal basal keratinocytes, bile duct or intestinal crypt epithelial cells, and often associated with infiltration by lymphocytes [156–158]. Biopsy is unnecessary to confirm the presence of chronic GVHD if at least one diagnostic feature is present, but histologic confirmation or other pertinent testing is necessary when CGVHD features are only distinctive or suggestive (see Table 188.4).

Prevention of Graft-Versus-Host Disease

GVHD prevention strategies are almost always incorporated into the overall treatment plan, and these include optimizing the choice of allogeneic donor and stem cell product based on known risk factors for GVHD, T-cell depletion of the donor HSC graft as discussed earlier, or, most commonly, post-transplant immunosuppression. Adjunctive therapy with ursodeoxycholic acid may improve liver function and a randomized placebo-controlled multicenter study demonstrated that prophylaxis with ursodeoxycholic acid reduced hepatic problems, severe acute GVHD, and improved survival after allogeneic HCT [159].

TABLE 188.4

CLASSIFICATION OF SYMPTOMS AND SIGNS OF CHRONIC GRAFT-VERSUS-HOST DISEASE

Organ or site	Diagnostic	Distinctive[a]	Common[b]
Skin	Poikiloderma Lichen planus-like features Sclerotic features Morphea-like features Lichen-sclerosis–like features	Depigmentation	Erythema Maculopapular rash Pruritus
Nails		Dystrophy Longitudinal ridging, splitting, or brittle features Onycholysis Pterygium unguis Nail loss[c]	
Scalp and body hair		New onset of scalp alopecia Scaling, papulosquamous lesions	
Mouth	Lichen-type features Hyperkeratotic plaques Restriction of mouth opening	Xerostomia Mucocele Mucosal atrophy Pseudomembranes[c] Ulcers[c]	Gingivitis Mucositis Erythema Pain
Eyes		New onset dry, gritty, or painful[d] Cicatricial conjunctivitis Keratoconjunctivitis sicca[d] Confluent punctate keratopathy	
Genitalia	Lichen-planus–like features Vaginal scarring or stenosis	Erosions[c] Fissures[c] Ulcers[c]	
GI tract	Esophageal web Esophageal strictures or stenosis in upper to mid third[c]		Anorexia, nausea vomiting, diarrhea, Failure to thrive
Liver			Bilirubin > 2 × ULN Alk Phosp > 2 × ULN AST/ALT > 2 × ULN
Lung	Bronchiolitis obliterans based on lung biopsy	Bronchiolitis obliterans based on PFTs + radiology[d]	BOOP
Muscles, fascia, joints	Fasciitis Joint stiffness or contractures secondary to sclerosis	Myositis or polymyositis	
Features acknowledged as part of chronic GVHD symptomatology if the diagnosis is already confirmed			
Skin	Sweat impairment, ichthyosis, keratosis pilaris, hypopigmentation, hyperpigmentation		
Hair	Thinning scalp hair, typically patchy, coarse, dull not explained by endocrine or other causes, premature gray hair		
Eyes	Photophobia, periorbital hyperpigmentation, blepharitis		
GI tract	Exocrine pancreatic insufficiency		
Muscles/Joints	Edema, muscle cramps, arthralgia, or arthritis.		
Hematology	Thrombocytopenia, eosinophilia, lymphopenia		
Immune	Lymphopenia, hypo- or hypergammaglobulinemia, autoantibodies (AIHA, ITP)		
Other	Pericardial/pleural effusions, ascites, peripheral neuropathy, nephrotic syndrome, myasthenia gravis, cardiac conduction abnormality, or cardiomyopathy		

[a] Seen in chronic GVHD but are insufficient alone to establish the diagnosis.
[b] Seen in both acute and chronic GVHD alone to establish a diagnosis of chronic GVHD.
[c] In all cases must exclude infection, drug effects, malignancy, or other causes.
[d] Diagnosis of chronic GVHD requires biopsy or radiology confirmation (or Schirmer's test for eyes).
AIHA, autoimmune hemolytic anemia; ALT, alanine aminotransferase; AST aspartate aminotransferase; BOOP, bronchiolitis obliterans with organizing pneumonia; GI, gastrointestinal; ITP, idiopathic (immune) thrombocytopenic purpura; PFTs, pulmonary function tests; ULN, upper limit of normal range for age.
Modified from Filipovich AH, Weisdorf D, Pavletic S, et al: National Institutes of Health consensus development project on criteria for clinical trials in chronic graft-versus-host disease: I. Diagnosis and Staging Working Group report. *Biol Blood Marrow Transplant* 11(12):945–956, 2005, with permission.

TABLE 188.5

DIFFERENTIAL DIAGNOSIS OF ACUTE GRAFT-VERSUS-HOST DISEASE (AGVHD)

AGVHD manifestation	Differential diagnosis
Rash	Drug reaction Allergic reaction Infection Regimen-related toxicity
Diarrhea	Infection (viral, fungal) Narcotic bowel syndrome (opiate withdrawal)
Abdominal pain	Acute pancreatitis Acute cholecystitis (biliary sludge, stones, infection) Narcotic bowel syndrome (opiate withdrawal)
Elevated liver enzymes	Sinusoidal obstruction syndrome Medication toxicities (e.g., cyclosporine) Cholangitis lenta (sepsis) Biliary sludge syndrome Viral infections (CMV, EBV, hepatitis B) Hemolysis

CMV, cytomegalovirus; EBV, Epstein–Barr virus.

Postgrafting Immunosuppression. In the absence of T-cell depletion, posttransplant immune suppression must be administered to control donor alloreactive T cells. Standard prophylaxis regimens deliver a 6-month course of cyclosporine or tacrolimus combined with a short course of methotrexate administered intravenously on the 1st, 3rd, 6th, and 11th days after HCT [147]. After myeloablative conditioning, methotrexate toxicity may exacerbate RRT in high turnover cells such as in oral and intestinal mucosae and hepatocytes. Some patients, particularly those with the C677T polymorphism in the methylene–tetrahydrofolate reductase gene, have more severe mucositis and slower platelet engraftment when given methotrexate [160]. Variations of CNI plus methotrexate include CNI plus mycophenolate mofetil [147,161]. or, tacrolimus and sirolimus, with or without methotrexate [162–164]. Steady-state serum CNI and sirolimus levels require monitoring. Dose reductions should be made when toxicities emerge or when serum trough levels exceed the upper limit of the therapeutic range.

Treatment of Graft-Versus-Host Disease

Despite GVHD prophylaxis regimens, 30% to 80% of allogeneic HCT recipients develop acute GVHD and require additional therapy with glucocorticoids.

Acute Graft-Versus-Host Disease. Glucocorticoids have been the mainstay of primary therapy for acute GVHD. Initial starting doses have been recently calibrated to the severity and extent of organ involvement as demonstrated by one large retrospective study [165]. This approach requires further validation, particularly for grades III and IV acute GVHD. For the one third of patients who develop GVHD without liver involvement, and whose GI symptoms are defined as stage 1 (anorexia, nausea, or vomiting with peak stool volume less than 1,000 mL per day), with or without rash involving less then 50% of the body surface, treatment may reasonably begin at 1 mg per kg per day methylprednisolone (or oral equivalent) combined with topical and minimally absorbed glucocorticoids (beclomethasone or budesonide). When there is liver involvement, or when intestinal and skin GVHD is greater than defined above, methylprednisolone is typically begun at a dose of 2 mg per kg per day for 14 days, by which time rash, diarrhea, abdominal pain, and liver dysfunction usually remit and a glucocorticoid taper is considered appropriate. In patients with GI hemorrhage, surgery very rarely is indicated, and the mainstay of therapy is initiation of immune suppression, along with the infusion of appropriate blood components [166,167]. Several studies, including a randomized trial, have shown no benefit for administration of doses greater than 2 mg per kg per day of methylprednisolone [168,169]. The results of a recent multicenter randomized phase II trial suggested that response and early survival after standard therapy with prednisone might be improved by adding mycophenolate mofetil [170]. A follow-up phase III study to more definitively evaluate this finding is imminent.

Chronic Graft-Versus-Host Disease. In practice, systemic therapy is considered when chronic GVHD is present in more than two organs, or there are moderate to severe abnormalities of a single organ with functional impairment (Table 188.6). In contrast, systemic therapy is generally not warranted for patients with mild abnormalities of one or two organs that do not cause functional impairment. For example, jaundice, or marked elevations of liver enzymes or skin manifestations that are not extensive. However, mild chronic GVHD does warrant systemic therapy when either thrombocytopenia or steroid treatment is present at diagnosis.

Standard primary therapy for clinical extensive CGVHD usually begins with glucocorticoids and extended administration of a CNI. After newly diagnosed CGVHD manifestations have been controlled by daily glucocorticoids, the judicious use of glucocorticoids at the lowest effective dose and alternate-day administration can minimize steroid-related side effects. The median duration of systemic immunosuppression for the treatment of CGVHD approximates 2 to 3 years [153]. Longer therapy tends to be required for recipients of peripheral blood stem cells, male patients with female donors, multiple organ

TABLE 188.6

INDICATION FOR SYSTEMIC IMMUNOSUPPRESSION AT DAY 80

Global severity of chronic GVHD	High-risk features[a]	Systemic therapy
None	Yes	None[b]
Mild (< 3 sites[c], no lung)	No	No
Mild	Yes	Yes
Moderate[d] (or mild lung) or severe[e]	Yes or no	Yes

[a] Less than 100,000 platelets/μL, progressive onset (on prednisone).
[b] Need to balance risks and benefits of graft-versus-tumor against risks of developing more severe chronic GVHD based on the coexistence of risk factors, including unrelated or mismatched-related donor, female donor, and peripheral blood stem cell transplant.
[c] No clinically significant functional impairment (score ≤ 1 in each site).
[d] At least one site functionally impaired without major disability (Score 2) or 3 or more sites without clinically significant functional impairment (each with score ≤ 1).
[e] Major disability at any site (score 3, or score ≥ 2 in lung).
GVHD, graft-versus-host disease.

TABLE 188.7

THERAPY OPTIONS FOR STEROID-REFRACTORY ACUTE GRAFT-VERSUS-HOST DISEASE

Therapy	Comments
Systemic	
Polyclonal	
Antithymocyte globulin (ATGAM,[a] Thymoglobulin[b])	Delayed use appears to be very ineffective. Skin responds best.
Monoclonal	
Anti-CD3 (OKT3,[c] visilizumab[d,e])	Currently used infrequently.
Anti-IL2 (daclizumab,[d] basiliximab[f])	Depletes conventional and regulatory T cells.
Anti-TNFα (infliximab[f])	Consider early for refractory lower GI tract.
Anti-CD52 (alemtuzumab[d])	Depletes T & B cells (lower risk EBV PTLD)
Anti-CD2 (alefacept[g])	Depletes memory T cells; needs further study.
Fusion proteins	
Anti-IL2 (denileukin diftitox)	Anti-T cell but also depletes regulatory T cells.
Anti-TNFα (etanercept)	
Macrolides and antimetabolites	
Tacrolimus	Inhibits conventional and regulatory T cells
Sirolimus	Inhibits conventional but not regulatory T cells.
Mycophenolate mofetil	Enteric coated formulation may minimize toxicity but liquid formulation not available
Extracorporeal photopheresis	Mechanism includes facilitation of regulatory T cells Particularly effective in skin, infrequently associated with opportunistic infections.
Mesenchymal stem cells	Mechanism poorly understood but thought to modulate tissue repair.
Topical	
Glucocorticoids	
Budesonide	Useful as steroid-sparing agent in lower GI tract.
Beclomethasone[e]	Useful as steroid-sparing agent in upper GI tract
PUVA	Useful for skin only involvement.

[a]Equine.
[b]Rabbit.
[c]Murine.
[d]Humanized.
[e]Not commercially available.
[f]Chimeric murine–human.
[g]Human IgG1-fusion protein.

involvement at the onset of CGVHD, graft-versus-host HLA mismatching, and hyperbilirubinemia.

Within 3 years of primary therapy, just over one quarter of the patients have resolved CGVHD, 1 out of 10 patients will continue primary therapy beyond 3 years and one-third require secondary treatment with a variety of other immunosuppressive agents [171]. The remaining patients develop recurrent malignancy or die from nonrelapse causes. Infection from a broad array of pathogens is the major cause of nonrelapse mortality, followed by progressive organ failure from CGVHD involvement. Therefore, antibiotic prophylaxis to prevent infection (Table 188.2) and supportive care to minimize morbidity and prevent disability are critically important components of CGVHD management [172].

Steroid-Refractory Graft-Versus-Host Disease. Glucocorticoids often fail to control acute GVHD manifestations such that 40% to 60% of patients have steroid-refractory (SR) acute GVHD. SR-GVHD has been defined operationally as the progression of acute GVHD symptoms beyond 3 days after starting methylprednisolone. Persistence of GVHD beyond 7 to 14 days also should be considered failure of response. The prognosis of acute GVHD can be related to its overall severity (grade) and response to glucocorticoids [173,174]. It is of no surprise that grade III and IV SR acute GVHD, especially with visceral involvement, requires urgent initiation of effective secondary therapy.

Unfortunately, there is no generally accepted therapy for SR acute GVHD. A full review of the various secondary GVHD therapies is beyond the scope of this review but various approaches are listed in Table 188.7 together with a summary of outcomes (Table 188.8). Polyclonal antithymocyte globulins (ATG), and more recently monoclonal antibodies, are generally used to treat life-threatening visceral manifestations where urgent control of GVHD is necessary. Unfortunately, longer term survival has been unusual when visceral manifestations are severe [175–179]. However, early administration of ATG within 14 days of primary therapy was reported in one study to be associated with improved survival [180]. It has remained difficult to improve the survival after SR-refractory acute GVHD because progressive organ dysfunction is often irreversible, and because second-line therapies constitute a "second hit" to an immune system that has already been impaired by cumulative exposure to high-dose prednisone. In this regard, high daily prednisone doses increase the risk for CMV viremia [181]. Similarly, invasive aspergillosis occurs more frequently in patients

TABLE 188.8

ADVANCES IN THERAPY OPTIONS FOR STEROID-REFRACTORY ACUTE GRAFT-VERSUS-HOST DISEASE (AGVHD)

Treatment	Study design/results	Comments	Reference
Antithymocyte globulin (equine ATG)	Single-arm Phase II studies (N = 29–79) from 1980 to 1999. CR/PR 30% overall (59%–72% for skin), OS 5%–32%.	Responses considerably better in skin than visceral organs. OS worse in visceral or more severe GVHD. One study found OS better if ATGAM given within 14 d of primary therapy (46% vs. 19%, p = 0.05).	[175,180,190,191]
Antithymocyte globulin (rabbit ATG)	Single-arm Phase II (N = 36). 89% had mostly three-system Grade III/IV GVHD. CR/PR 59% overall (96% skin, 46% GI, 36% liver. OS 6%.	Very poor survival. Infections, including 25% EBV PTLD rate, were major problems.	[176]
Daclizumab	Single center Phase I/II (N = 13–57) from 1990s to 2006. CR/PR 51%–92% overall. OS 25%–46%.	Well tolerated. Responses better in children and in skin GVHD. Significant morbidity and mortality due to infections. Patient selection and aggressive antiviral and fungal prophylaxis advised.	[179,192,193]
Denileukin Diftitox	Single center Phase I/II (N = 32). CR/PR 71% overall. OS 30%.	Reversible transaminitis in 22% at MTD. OS 58% (7/12) if achieved CR.	[178]
Infliximab	Single center retrospective (N = 21–32) from 1998 to 2004. CR/PR 59%–82% overall. CR 19%–62%. OS 38%–46% at □1 year.	Well tolerated and active, particularly for GI tract. Better response if age < 35 y and longer interval between HCT and infliximab treatment. High rates of opportunistic infection.	[194–196]
Etanercept	Single center retrospective (N = 13 with AGVHD) from 1995 to 2005. CR (N = 4)/PR (N = 2) 46% overall. OS 67% at median 429 d (range: 71–1,007 d); includes 8 other patients with cGVHD.	Well tolerated. Responses most common in GI tract (64%). CMV reactivation (48%), bacterial (14%) and fungal (19%) infections occurred.	[197]
Psoralen and ultraviolet A (PUVA)	Single center retrospective (N = 103) from 1994 to 2000. CR 24% by intention to treat. OS 51%.	Generally well tolerated but 8 discontinued because of toxicity. CR 37% if tolerated PUVA for 6 wk. PUVA was steroid sparing; 57% did not require additional therapy for skin GVHD.	[198]
Extracorporeal photopheresis (ECP)	Single-center or multicenter phase II or retrospective (N = 21–77) from 1992 to 2006. CR/PR 50%–60%. OS 48%–57%	Best responses in skin (60%–82%) then liver (61%–67%). GI responses variable (0%–75%). Poor Grade IV responses < 15%. AEs during ECP: cytopenias. OS 59%–91% among CRs vs. 11%–12% for non-CRs.	[199–203]
Mycophenolate Mofetil	Single-center retrospective (N = 19–36). CR/PR 42%–72%. OS 16% □–37% □□	Commonest AEs: mild-to-moderate cytopenias. (□at 2 y, □□at 5 y including 12 additional patients with cGVHD)	[204,205]
Sirolimus	Single center pilot trial (N = 21) from 1996 to 1999. High loading dose and/or high maintenance dosing of sirolimus. CR/PR 28% □. OS 34%	□Frequent expected toxicities (cytopenias, hyperlipidemia, HUS) associated with high-serum concentrations likely limited the efficacy. CR/PR 67% among 18 who received ≥ 6 doses.	[206]
Pentostatin	Prospective phase I, single center (N = 23). CR/PR 76%. OS 26% at a median of 85 d (5–1,258 d).	Universal lymphopenia and late infections were dose-limiting. Best responses in skin. Suggested dose for phase II was 1.5 mg/m^2/d × 3 d.	[207]
Mesenchymal stem cells (hMSCs)	European multicenter phase II (N = 55) from 2001 to 2007 of up to 5 doses hMSCs. CR/PR 71%. OS 36% at 2 y. U.S. multicenter phase III hMSC vs. placebo (N = 260). Durable CR 35% vs 30% (p = NS)	No infusion toxicities. OS 53% for CRs in the European study. U.S. study found that hMSCs did not improve durable CR rates (primary endpoint) but hMSCs did improve durable liver CRs (29% vs. 5%, p = 0.046, N = 61) and GI responses (88% vs. 64%, p = 0.018, N = 71)	[208], written communication, Osiris press release

cGVHD, chronic graft-versus-host disease; CMV, cytomegalovirus; CR, complete response; EBV, Epstein–Barr virus; GI, gastrointestinal; HCT, hematopoietic cell transplantation; HUS, hemolytic uremic syndrome; MTD, maximally tolerated dose; NS, not significant; OS, overall survival; PR, partial response; PTLD, posttransplant lymphoproliferative disorder.

who develop CMV disease and in patients receiving higher doses of prednisone [182]. After nonmyeloablative HCT, high dose prednisone therapy at the time of diagnosis of mold infection has been associated with an increased risk for mold infection-related death [183].

When CGVHD becomes refractory to steroids, in contrast to SR acute GVHD, secondary therapy generally avoids potent antibody therapies unless the manifestations overlap with the disease features typically associated with severe acute GVHD. The time to complete resolution of classical CGVHD manifestations is in the order of weeks to months, and total duration of therapy spans months to years. Therefore, secondary therapies for SR-CGVHD must try to avoid profound T-cell depletion and must generally be more easily delivered chronically in the outpatient setting. Ideally, second-line agents should promote transplantation tolerance so that the morbidity associated with prolonged use of glucocorticoids and other immunosuppressive agents can be minimized.

Promising new agents or strategies that warrant further controlled clinical trials include sirolimus, extracorporeal photophoresis, rituximab, and the platelet-derived growth factor receptor, imatinib, which is of particular interest for the treatment of sclerotic GVHD. A number of ancillary measures that are used with topical intent are often used to target specific organ involvement [172].

Hemolysis

RBC hemolysis may be encountered after HCT and may include more than one etiology. Thrombotic microangiopathy may present as mild hemolysis with RBC fragmentation (schistocytes) or as a more severe form, with thrombocytopenia, renal insufficiency, fever, and altered mental status, similar to hemolytic uremic syndrome (HUS) or thrombotic thrombocytopenic purpura (TTP) [59,184]. Predisposing factors include: endothelial cell injury triggered by chemotherapy, radiation, or immunosuppressive therapy (e.g., CNIs) [59,185]. Drugs such as fludarabine, antithymocyte globulin, or infections with mycoplasma also may produce hemolysis. Unlike the preceding etiologies, hemolysis mediated by major or minor blood group incompatibilities is only seen in recipients of allografts.

Major ABO incompatibility occurs in 30% of allograft recipients and is defined by the presence of isohemagglutinins within recipient plasma that are directed against donor A or B antigens. *Minor* ABO incompatibility also occurs in 30% of recipients and is defined by presence of isohemagglutinins within the donor plasma directed against recipient A or B. *Bidirectional* ABO incompatibility may be present as in the case of a type A recipient and type B donor or vice versa. After successful donor engraftment, the conversion of recipient to donor blood type may take weeks to months because of the relatively long half-life of red blood cells.

Major ABO incompatibility poses a serious risk of severe hemolytic reactions at the time of infusion of the HSC product if preventative steps are not taken. Immediate hemolytic reactions are more likely in the presence of high-level isoagglutinin titers. Therefore, red blood cells are most commonly removed from the graft before infusion to avoid life-threatening hemolysis. Delayed recovery of donor hematopoiesis or hemolysis may occur because recipient plasma cells continue to produce isohemagglutinins for up to several months after HCT [186]. In this case, the diagnosis relies on detection of a positive direct antiglobulin test and the presence of isohemagglutinins directed against donor-type red blood cells. Management of major ABO incompatibility includes the transfusion of group O red blood cells, donor-type platelets, and donor-type plasma until isohemagglutinins against donor-type red blood cells disappear. In the rare cases of ongoing hemolysis due to persistence of donor-directed isohemagglutinins, additional therapy with immunosuppressive agents, erythropoietin, plasma exchange, anti-B-cell antibodies (rituximab), or plasma exchange may be considered [187].

Minor ABO incompatibility poses a risk for mild and self-limited hemolysis at the time of infusion. Delayed hemolysis, seen more commonly after PBSC transplantation, is mediated by clonally expanded donor "passenger lymphocytes" and can present as an abrupt and potentially fatal hemolytic transfusion reaction typically at 1 to 2 weeks after HCT [188,189]. In contrast to major ABO incompatibility, pretransplant donor isohemagglutinin titers do not predict the severity of hemolysis following minor ABO-mismatched HCT. The diagnosis relies again on the detection of a positive direct antiglobulin test and the presence of isohemagglutinins directed against recipient-type red blood cells. To prevent hemolysis, plasma should be removed from the donor HSC product if donor hemagglutinin titers are high. Emergence of donor-derived RBC and isohemagglutinin titers should be monitored after allogeneic HCT. Management of minor ABO incompatibility after HCT includes supportive care with judicious fluid management aimed at preventing acute renal failure, and the transfusion of group O red blood cells and recipient type platelets and plasma. There is no convincing evidence to support the use of plasma exchange.

CHAPTER 189 ■ CRITICAL CARE OF THE LUNG TRANSPLANT RECIPIENT

LUIS F. ANGEL AND STEPHANIE M. LEVINE

Over the past three decades, lung transplantation (LT) has become a successful therapeutic option for patients with end-stage pulmonary parenchymal or vascular disease. In the early era of LT, the primary complications associated with the procedure were dehiscence and impaired healing of the bronchial anastomosis and early graft failure; these complications occurred in most patients who survived for more than 1 week. Improvements in donor and recipient selection and surgical techniques, the development of new immunosuppressive drugs, and better management of complications, such as primary graft dysfunction (PGD), rejection, and infections have all contributed to advancing the field (Table 189.1). Despite these advances, LT is still associated with numerous complications, often requiring intensive care management.

According to the 2009 report of the International Society for Heart and Lung Transplantation (ISHLT), more than 2,700 lung transplants were performed in 2007 alone. The ISHLT Registry reports that the 1-year survival rate for lung transplant recipients is 79%, the 3-year rate is 64%, and the 5-year rate is 52% [1]. There has been an improvement in median survival in the recent years to 5.7 years over the 4.7 years found in previous years. The most common cause of mortality is PGD in the

TABLE 189.1

MAJOR ADVANCES OR CHANGES IN LUNG TRANSPLANTATION OVER THE PAST FIVE YEARS

Topic	Change	Reference
Transplant procedures by indication	More BLT procedures performed for COPD	[1]
Allocation system	Organs allocated by necessity, not time on waiting list	[7]
Increasing the donor pool	Increasing the use of marginal/extended donors	[15–18]
Primary graft dysfunction	No proven benefit of inhaled nitric oxide administered prophylactically for the prevention of PGD	[31]
	New staging system for PGD	[26]
Immunosuppression	Possible benefit from inhaled cyclosporine	[59]
Rejection	Revision of the staging system for bronchiolitis obliterans syndrome	[62]
Infection prophylaxis	PCR used to monitor for CMV infection following transplant	[74]
	Effective antifungal prophylactic regimens available	[81]
	Twelve months of oral valganciclovir is effective for CMV prophylaxis	[76]
Revision of staging of pathologic rejection	Restaging of lymphocytic bronchiolitis	[58]

BLT, bilateral lung transplantation; CMV, cytomegalovirus; COPD, chronic obstructive pulmonary disease; PCR, polymerase chain reaction; PGD, primary graft dysfunction.

first 30 days following transplantation, non-cytomegalovirus (CMV) infection in the first year following transplantation, and chronic rejection at all subsequent time intervals.

INDICATIONS

Single-lung transplantation (SLT) is performed for obstructive nonsuppurative lung disease, such as emphysema resulting from tobacco use or α_1-antitrypsin deficiency. It is also indicated for fibrotic lung diseases such as idiopathic pulmonary fibrosis (29%), familial pulmonary fibrosis, drug- or toxin-induced lung disease, occupational lung disease, sarcoidosis, limited scleroderma, lymphangioleiomyomatosis, eosinophilic granuloma, and other disorders resulting in end-stage fibrotic lung disease [1].

The most frequent indications for bilateral lung transplantation (BLT) are suppurative pulmonary lung disease, cystic fibrosis and bronchiectasis (31%) and severe chronic obstructive pulmonary disease (COPD) resulting from tobacco use (26%), or α_1-antitrypsin deficiency (8%). In addition, more than 90% of transplant centers prefer to perform BLT when patients have idiopathic pulmonary hypertension (5%) [1].

Heart–lung transplantation (HLT) is performed at only a few transplantation centers and should be reserved for patients who cannot be treated by LT alone. The most frequent indications for HLT are Eisenmenger syndrome with a cardiac anomaly that cannot be corrected surgically and severe end-stage lung disease with concurrent severe heart disease. HLT is discussed in more detail in Chapter 183.

GUIDELINES FOR RECIPIENT SELECTION

There has been a revision of the original consensus-based guidelines for the selection of lung transplant candidates [2]. Any patient with end-stage pulmonary or cardiopulmonary disease with the capacity for rehabilitation can be considered for transplantation. The patient should have untreatable end-stage pulmonary disease, no other significant medical illness, have a limited life expectancy, and be psychologically stable and compliant.

Age

The 2006 international guidelines for the selection of transplant candidates [2] now suggest an age limit of 65 years regardless of procedure type. Although this is somewhat arbitrary, numerous patients with end-stage pulmonary disease are young to middle-aged, and there is a relative lack of available donors.

Relative Contraindications

Transplantation is not contraindicated in patients with systemic diseases that are limited to the lungs such as scleroderma, systemic lupus erythematosus, polymyositis, and rheumatoid arthritis. These cases should be considered on an individual basis. Osteoporosis has become a significant problem in the post-transplant period, and preexisting symptomatic osteoporosis has also been identified as a relative contraindication to transplantation.

Patients with active sites of infection are not considered to be good transplant candidates. Treated tuberculosis and fungal disease pose a particular problem but are not contraindications for LT. Many centers will not consider performing a transplant in a patient who is chronically colonized with a resistant organism (e.g., *Burkholderia species*, methicillin-resistant Staphylococcus, atypical mycobacterium, or Aspergillus) and it is recommended to try to eradicate these organisms in the pre-transplant period and to consider each patient on an individual basis. However, if considered, these patients should be candidates only for BLT procedures since the remaining colonized

lung could pose a serious threat to the new graft in the case of an SLT. This issue is of particular concern in cystic fibrosis patients who are often infected with drug resistant organisms. Both *Burkholderia cenocepacia* (specific strains) and *Burkholderia gladioli* are of concern due to poor posttransplant outcomes [3].

A requirement for invasive mechanical ventilation is a strong relative contraindication to transplantation, although LT has been performed successfully in small numbers of mechanically ventilated patients with CF, and other end-stage lung disease [4,5]. In one small series there was a longer time on postoperative mechanical ventilation and a longer ICU stay following LT. Rates of PGD, survival, and total hospital stay were similar to those in patients undergoing LT not on mechanical ventilation [4]. Recently venoarterial extracorporeal membrane oxygenation (ECMO) has been used in end-stage lung disease patients during transplantation with good short-term function and survival rates [5]. In a large review of the United Network Organ sharing (UNOS) database of patients undergoing LT on mechanical respiratory support 586 on mechanical ventilation and 51 on ECMO as a bridge to LT, the authors found that patients on mechanical ventilation or ECMO have lower survival rates following LT compared to those not requiring support [6]. Noninvasive ventilatory support is not considered a relative contraindication to transplantation

To be considered for transplantation, patients should have an ideal body weight of > 70% or ≤ 130% predicted (BMI 18 to 30 kg per m^2). Those patients with poor nutritional status may be too weak to withstand the surgical procedure; those patients who are obese make more difficult surgical candidates and may have higher mortality rates than nonobese patients.

Pretransplant low-dose therapy with corticosteroids has been proven to be acceptable for patients who cannot have therapy with corticosteroids completely discontinued. Initial data implicated corticosteroids as a cause of tracheal bronchial dehiscence. Currently, transplant programs will consider patients who can be maintained in the long term on a regimen of prednisone of ≤ 20 mg per day and may consider patients who are receiving higher doses.

Prior thoracotomy or pleurodesis was once considered to be a relative contraindication to transplantation due to increased technical difficulties and increased bleeding. Despite this, transplantation can be successfully performed in these patients.

Absolute Contraindications

The 2006 international guidelines [2] identified several absolute contraindications to LT including major organ dysfunction (i.e., renal creatinine clearance of ≤ 50 mg per mL per minute), HIV infection, hepatitis B antigen positivity, and hepatitis C with biopsy-documented liver disease. Active malignancy within the prior 2 years is also a contraindication to transplantation. For patients with a history of breast cancer greater than stage 2, colon cancer greater than Duke A stage, renal carcinoma, or melanoma greater than or equal to level 2, the waiting period should be at least 5 years. Restaging is suggested prior to transplant listing.

Severe nonosteoporotic skeletal disease, such as kyphoscoliosis, is often an absolute contraindication to transplantation, primarily because of the technical difficulties encountered during surgery.

Drug abuse and alcoholism are considered to be contraindications to transplantation because patients with these conditions are at high risk for noncompliance. Patients who continue to smoke despite having end-stage pulmonary disease are not candidates for LT. Transplant centers require patients to abstain from cigarette smoking, alcohol use, or narcotics use for 6 months to 2 years before being considered for lung transplant evaluation.

The patient must be well motivated and emotionally stable to withstand the extreme stress of the pretransplant and perioperative period. A history of noncompliance or significant psychiatric illness is an absolute contraindication

DONOR ALLOCATION AND SELECTION

Until the spring of 2005, as established by the United Network of Organ Sharing, lungs were allocated primarily by time on the waiting list, and not by necessity. In the spring of 2005, the system for donor allocation for lungs was revised, and assigned priority for lung offers became based on a benefit or need-based Lung Allocation Score [7]. The LAS is calculated using the following measures: (1) waitlist urgency measure (i.e., the expected number of days lived without a transplant during an additional year on the waitlist); (2) posttransplant survival measure (i.e., the expected number of days lived during the first year posttransplant); and (3) the transplant benefit measure (i.e., the posttransplant survival measure minus waitlist urgency measure) [8]. Although it is still too early to determine the long-term effects that this new allocation system will have on LT, it appears that many of the goals of the system (decreased waiting list deaths, and times, prioritizing patients by urgency rather than time on the list) are being accomplished, with comparable survival rates except in those with the very high LAS scores (> 46 in one study) [9,10]. There appears to be a stepwise decline in posttransplant survival as the LAS score increases. In patients with high LAS scores there was also higher morbidity including requirements for dialysis, infections, and longer lengths of stay [11]. Since the implementation of the LAS, the distribution of patient diagnoses on the list, and those transplanted, has also shifted from a majority of COPD patients to an increasing number of patients with pulmonary fibrosis. In addition, sicker patients are being transplanted.

Donor lungs are first distributed locally, then regionally, and finally nationally. Currently, the average time spent on the waiting list is approximately 18 to 24 months, and therefore close management of the listed transplant patient is required. Despite this close attention, a small percentage of patients die while awaiting transplantation.

A shortage of donor organs remains the primary factor limiting the number of LTs performed. Contributing to this shortage is the estimate that lungs for transplantation are procured from only 19% of multiorgan donors [12]. The vast majority of transplanted lungs are from brain-dead donors. A small number of LT procedures involving living related donors and non–heart-beating lung donors (also called donation after cardiac death [DCD]) have been performed at institutions specializing in these procedures [13]. In a small group of DCD donors lung transplant recipients, rates of PGD, acute rejection, bronchiolitis obliterans, and 2-year survival rates were comparable to those of lung transplant recipients from cadaveric donors during the same period. Graft function was better preserved in the DCD recipients [14].

The usual donor selection criteria are age younger than 60 to 65 years, no history of clinically significant lung disease, normal results from a sputum Gram stain, and a limited history of smoking (less than 20 pack-years). In addition, the lung fields should be clear as demonstrated by chest radiograph, and gas exchange should be adequate as demonstrated by a partial pressure of arterial oxygen (PaO_2) more than 300 mm Hg, while receiving fractional inspired oxygen (FIO_2) equal to 1, or a PaO_2/FIO_2 ratio of more than 300 with a positive end expiratory pressure (PEEP) of 5 cm H_2O. Bronchoscopy is also

part of the evaluation of the donor. The main goal of the endobronchial evaluation is to rule out gross aspiration or purulent secretions in the distal airways.

Lungs from extended donors (i.e., those who do not meet all of the criteria listed earlier) are now more frequently being transplanted in an attempt to expand the donor pool [15–18], and some centers are actively engaged in developing protocols for optimizing marginal donor lungs, thereby rendering them transplantable. By instituting a protocol including educational and donor management interventions, and changing donor classification and selection criteria, a single-organ procurement organization was able to increase the percentage of lungs procured from 11.5% to 22.5% with an increase in the number of procedures performed, without adverse recipient outcomes [15].

Donors are excluded from potential lung donation if there is evidence of active infection, human immunodeficiency virus, hepatitis, or malignancy. Donor and recipient compatibility is assessed by matching A, B, and O blood types and chest wall size. Human leukocyte antigen (HLA) matching is not routinely performed in LT except in patients with history of preformed donor-specific antibodies.

SURGICAL TECHNIQUES

Initially, double-lung transplantation was the procedure of choice; the anastomosis was placed at the level of the trachea. However, the rate of ischemic airway complications was prohibitive. Now, SLT or BLT (essentially sequential SLT) with anastomoses at the level of the mainstem bronchi is the preferred surgical technique. At the time of cardiac harvest, the donor lung is usually removed through a median sternotomy. The pulmonary veins are detached from the heart with a residual 5-mm cuff of left atrium. The pulmonary artery is transected from the main pulmonary trunk, and the mainstem bronchus is transected between two staple lines. During transportation to the recipient site, the partially inflated donor lung graft is placed into preservation solution, usually a low-potassium dextran solution with extracellular electrolyte composition or a modified Euro-Collins solution with an intracellular electrolyte composition at 4°C.

For SLT, the recipient surgery is performed through a posterolateral thoracotomy or sternotomy, or vertical axillary muscle-sparing minithoracotomy. Most centers start with the bronchial anastomosis, without a vascular anastomosis of the bronchial circulation of the recipient and donor lungs. Initially, most transplant procedures involved an end-to-end anastomosis, which was wrapped with a piece of omentum or pericardial fat with an intact vascular pedicle for assistance in bronchial revascularization. Subsequently, a telescoping technique was recommended, with the recipient and donor bronchi overlapping by approximately one cartilaginous ring. This procedure allowed the recipient's intact bronchial circulation to supply the donor bronchus. More recently, most anastomoses are performed with an end-to-end single suture in the membranous portion and a single or continuous suture in the cartilaginous portion, without omental wrap, and telescoping is performed when the donor and recipient bronchi differ in size and there is a natural, unforced telescoping of both bronchi [19,20].

After the bronchial anastomosis has been performed, the donor pulmonary veins are anastomosed end-to-end to the recipient's left atrium, and the pulmonary arteries are attached with an end-to-end anastomosis.

BLT is usually performed through a transverse thoracosternotomy (clamshell incision) or a median sternotomy followed by sequential single-lung procedures. Cardiopulmonary bypass may be required for patients with pulmonary hypertension or those who cannot tolerate single-lung ventilation or perfusion and who experience marked hypoxemia or hemodynamic instability. Although center specific, an increasing number of cases (nearly 50% of LT procedures at some institutions) are performed with the use of cardiopulmonary bypass.

GENERAL POSTOPERATIVE MANAGEMENT

After LT, patients usually remain intubated, require mechanical ventilation, and are transferred to the ICU. Most patients are ventilated in a volume-control mode, although in recent years some transplant centers have changed to pressure-control ventilation, or airway pressure release ventilation. In general, low tidal volume ventilation strategies are used. Airway pressures are kept as low as possible so that barotrauma and anastomotic dehiscence can be avoided. Many institutions use routine pharmacologic sedation. Patients are generally maintained with tidal volumes of 6 to 8 mL per kg postoperatively. At most institutions, a low level of PEEP (5.0 to 7.5 cm H_2O) is applied immediately after lung expansion in the operating room and is continued after transplantation. Early extubation is one of the main goals after LT, and lung transplant recipients who do not experience complications are extubated within the first 12 to 24 hours postoperatively if they meet the commonly accepted weaning criteria. Some centers may attempt to extubate immediately postoperatively [21]. Both postural drainage and chest physiotherapy can be routinely employed without concern for mechanical complications at the anastomosis, and patients should perform incentive spirometry soon after extubation.

Certain patient populations require special ventilator management. Most patients with idiopathic pulmonary hypertension undergo BLT; however, at a few centers some patients undergo SLT for pulmonary hypertension with an increased risk of reperfusion pulmonary edema because nearly all of the perfusion is going to the newly implanted lung.

Patients with obstructive lung disease can encounter problems if the delivered tidal volume or the required levels of PEEP are high. Occasionally, clinically significant acute native lung hyperinflation can occur and can compromise the newly transplanted lung and lead to hypotension and hemodynamic instability. To reduce this problem, some transplant centers avoid PEEP for patients undergoing SLT for obstructive disease. However, the problem is magnified when patients experience reperfusion injury or pneumonia after transplantation; in such cases the compliance of the transplanted lung is decreased and higher PEEP is required for maintaining oxygenation. As a consequence, the more compliant emphysematous lung becomes overexpanded and can herniate toward the contralateral hemithorax [22]. Attempts to prevent this possible complication by using selective independent ventilation with a double-lumen endotracheal tube have been tried. Lung hyperinflation is associated with a significantly longer stay in the intensive care unit (ICU), a longer duration of mechanical ventilation, and a trend toward higher mortality [23].

Pain control is usually provided by opiates, usually fentanyl, administered intravenously or morphine sulfate via an epidural catheter with a patient-regulated pain-control system.

Because many patients are nutritionally depleted before transplantation as a result of their underlying disease, postoperative nutrition is important. Ideally, enteral nutrition should be provided as soon as tolerated.

Antibiotics are routinely administered for the first 48 to 72 hours after transplantation. Antibiotic regimens include broad-spectrum antibiotic coverage for both Gram-negative

and Gram-positive bacteria. Most centers advocate empiric anaerobic coverage. Gram stains and cultures of sputum from the donor and the recipient may be used when available to guide the choice of appropriate antibiotics. Many centers routinely use antifungal agents such as inhaled amphotericin B, voriconazole, or itraconazole postoperatively. Most transplantation programs administer ganciclovir and, more recently, valganciclovir for CMV prophylaxis if either the patient or the donor is CMV-positive before surgery.

Immunosuppression is begun preoperatively with tacrolimus or cyclosporine and corticosteroids. Corticosteroids are administered in the operating room as intravenous methylprednisolone 0.5 to 1 g (usually administered at the time of reperfusion) and then at doses of 1 to 3 mg per kg daily for the next 3 days, followed by 0.8 mg per kg daily and then conversion to an equivalent oral dose. In the past, lympholytic medications, such as intravenous antithymocyte globulin (ATG) at 1.5 mg per kg daily for 3 to 5 days or muromonab-CD3 (Orthoclone OKT3) at 5 mg per day for the first 5 to 10 days, were used as induction therapy after transplantation; however, more recently the use of these medications has been limited. Some centers currently use interleukin (IL)-2 receptor blockers (e.g., basiliximab) for induction. A retrospective registry analysis of the impact of induction therapy on survival following LT showed a survival advantage with the use of interleukin-2- receptor antagonists in both SLT and BLT recipients and in BLT recipients treated with ATG [24]. After the transplantation procedure, most patients begin a triple immunosuppression protocol with a combination of prednisone, a calcineurin agent, tacrolimus or cyclosporine, and a cell cycle inhibiting agent, mycophenolate mofetil or azathioprine [25].

POSTOPERATIVE PROBLEMS

Primary Graft Dysfunction

Perhaps the most serious problem in the postoperative period after LT is PGD [26]. It is estimated that as many as 80% of patients will experience some degree of PGD and as many as 15% of cases can be severe [27]. A 2005 consensus conference attempted to standardize the grading of PGD on the basis of gas exchange and the presence of radiographic infiltrates (Table 189.2). When the acute lung injury definition of acute respiratory distress syndrome (ARDS)—a PaO_2/FIO_2 ratio of less than 200 is used to define the most severe form of PGD (grade 3), the reported incidence is 10% to 25%. PGD

TABLE 189.2

GRADING OF THE SEVERITY OF PRIMARY GRAFT DYSFUNCTION

Grade	PaO_2/FIO_2	Radiographic infiltrates consistent with pulmonary edema
0	> 300	No
1	> 300	Yes
2	200–300	Yes
3	< 200	Yes

Adapted from Christie JD, Carby M, Bag R, et al: Report of the ISHLT Working Group on Primary Lung Graft Dysfunction part II: definition. A consensus statement of the International Society for Heart and Lung Transplantation. *J Heart Lung Transplant* 24(10):1454–1459, 2005, with permission.

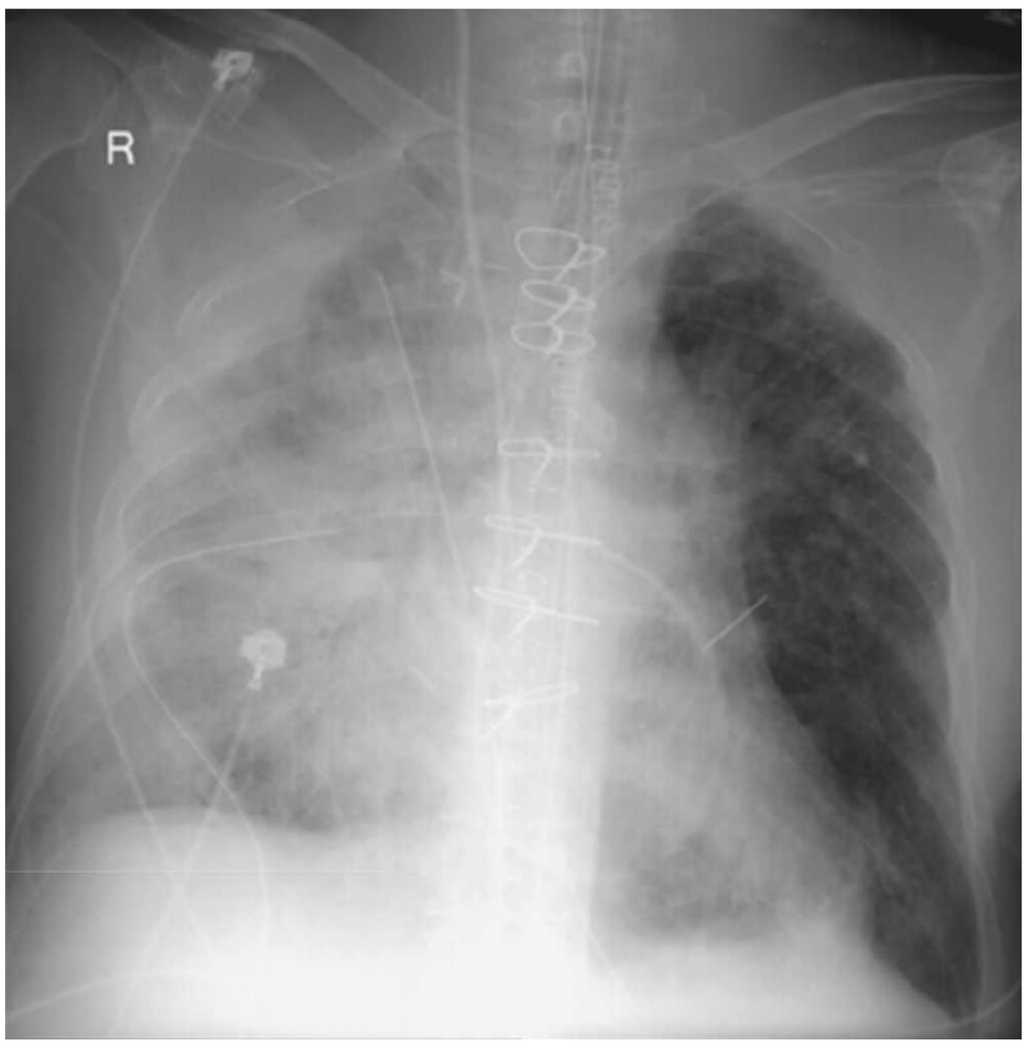

FIGURE 189.1. Severe primary graft dysfunction in the transplanted lung following a right single-lung transplant for idiopathic pulmonary fibrosis.

is a diagnosis of exclusion; the condition usually occurs hours to 3 days after LT, whereas rejection and infection are more common after the first 24 hours. A stenosis at the venous anastomosis presents with similar signs and symptoms, but this diagnosis can be excluded by transesophageal echocardiography. However, because the timing of these disorders may vary, differentiation may be difficult [26].

PGD can persist to various degrees for hours to days after LT. Clinically, PGD is characterized by the appearance of new alveolar or interstitial infiltrates on radiographs, a decrease in pulmonary compliance, an increase in pulmonary vascular resistance, and a disruption in gas exchange. Radiographic findings in these patients include a perihilar haze, patchy alveolar consolidations, and, in the most severe form, dense perihilar and basilar alveolar consolidations on air bronchograms (Fig. 189.1). Pathology reports from biopsy specimens, autopsies, or lung explants removed during retransplantation indicate diffuse alveolar damage. PGD usually stabilizes over the next 2 to 4 days and then begins to resolve, or worsens with all cause mortality rates at 30 days exceeding 40% in some studies.

PGD is managed supportively with diuretics and mechanical ventilation, often with protective ventilatory strategies [28]. Because endogenous nitric oxide (NO) activity decreases after LT, there are several reports of the successful use of inhaled NO for hypoxemia and for pulmonary hypertension as a consequence of graft dysfunction after transplantation [29–32]. However, in one randomized, placebo-controlled trial (84 patients), the prophylactic inhalation of NO 10 minutes after reperfusion and for a minimum of 6 hours, was not shown to be beneficial for hemodynamic variables, reperfusion injury, oxygenation, time to extubation, length of intensive care or hospital stay, or 30-day mortality [31]. A similar study beginning NO at the onset of ventilation supported these findings [30]. The use of artificial surfactant replacement has also been examined [33–35]. An open randomized prospective trial studying the use of instilled bovine surfactant immediately after establishment of the bronchial anastomosis, showed improved oxygenation and decreased PGD, shortened intubation time, and enhanced

TABLE 189.3

POSSIBLE RISK FACTORS FOR PRIMARY GRAFT DYSFUNCTION AFTER LUNG TRANSPLANTATION

Recipient characteristics
Pulmonary hypertension
Diffuse parenchymal lung disease diagnosis
Body mass index > 25 kg/m^2
Operative factors
Cardiopulmonary bypass during surgery
Prolonged ischemic time for the organ
Methods/techniques of preservation and reperfusion
Blood product transfusions
Donor characteristics
Female gender
African American race
Age < 21 y or > 45 y
Prolonged mechanical ventilation
Aspiration pneumonia
History of tobacco use
Trauma
Hemodynamic instability after brain death

Adapted from references [27,43–48].

early post-LT recovery in the treatment group, although an unusually high incidence of PGD was found in the control group [34]. The use of ECMO for severe early graft dysfunction [36] has also been described, with a hospital survival rate of 42% in an analysis of the Extracorporeal Life Support Organization registry study [37]. High-frequency oscillatory ventilation and independent lung ventilation have been used in some cases. Retransplantation has also been performed, but the outcome for patients undergoing retransplantation for PGD has been very poor.

Severe PGD usually leads to compromised short-term outcomes, including increase in the duration of mechanical ventilation and lengths of stay, poor 1-year survival rates (40% for patients with PGD in one single-center study), and compromised function among survivors [38,39]. Long-term outcomes, such as pulmonary function and the incidence of bronchiolitis obliterans, are also impacted, and more severe PGD and longer duration of PGD significantly increases the development of bronchiolitis obliterans syndrome (BOS) [40,41].

Although the mechanisms of PGD have not been completely delineated, several contributing factors have been postulated, including the disruption of lymphatics, bronchial vasculature, or nerves, and lung injury occurring either during preservation of the graft or after reperfusion [42]. Multiple risk factors (Table 189.3) may be associated with the development of PGD [27,43–48]. Some have borne out in multivariate analysis. Donor variables include: female gender, African American race, donor age less than 21 years and more than 45 years, prolonged mechanical ventilation, aspiration pneumonia, history of tobacco use, trauma, and hemodynamic instability following brain death. The technique used for graft preservation and the perfusion solution (e.g., Eurocollins), the use of cardiopulmonary bypass, prolonged ischemic times, and blood product transfusions may also be risk factors for PGD. Recipient factors contributing to PGD include: a diagnosis of pulmonary hypertension, elevated pulmonary artery pressures at the time of transplant, body mass index (BMI) > 25 kg per m^2, and diffuse parenchymal lung disease. Humoral rejection has recently been postulated to be a risk factor for PGD [48]. Since the institution of the LAS, some studies have shown an increase in the incidence of PGD [49] but others have not supported this finding [50].

Intensive Care Unit Outcomes

Few data are available for predicting outcomes and length of ICU stay after LT. It is known that the duration of mechanical ventilation is prolonged and the ICU mortality increased for patients who experience PGD [38]. One study found that an immediate postoperative PaO_2/FIO_2 ratio of less than 200 predicted an ICU stay of 5 days or more [51]. In another study, poor nutritional status (BMI below the 25th percentile) in patients remaining in the ICU for more than 5 days was associated with a higher ICU mortality rate [52]. In this same study, a preoperative diagnosis of pulmonary hypertension or restrictive lung disease and BLT rather than SLT were associated with longer ICU stays. Another study examined the value of intravascular volume status and central venous pressure (CVP) in predicting ICU outcomes; the results indicated that a CVP higher than 7 mm Hg after transplantation was associated with a longer duration of mechanical ventilation, longer ICU and hospital stays, and higher 2-month mortality rates [53].

Among patients requiring prolonged ICU stays, those who underwent tracheostomy were more likely to have undergone BLT, to have required cardiopulmonary bypass during the procedure, to have experienced postoperative pneumonia, to have had more significant reperfusion injury at 48 hours, to have had longer initial periods of mechanical ventilation, and to have required reintubation more often [54].

Late Complications Requiring Admission to the Intensive Care Unit

The number of lung transplant recipients who are admitted to the ICU is expected to increase as the number of long-term survivors increases. The postoperative mortality rate has decreased because of improved surgical techniques and perioperative care, and approximately 90% to 95% of patients are discharged alive after transplantation. However, after this immediate posttransplantation period, lung transplant recipients are more likely than some other solid-organ transplant recipients to experience infection or rejection that often requires readmission to the ICU.

Nearly 25% of lung transplant recipients require an ICU admission after the initial hospital discharge. The most common admission diagnoses are respiratory failure and sepsis. These patients frequently require mechanical ventilation (53%), and the mortality rate is generally close to 40%. Prognostic factors for mortality include higher acute physiology and chronic health evaluation (APACHE) scores, a forced expiratory volume in one second (FEV_1) lower than the patient's best posttransplantation FEV_1, nonpulmonary organ dysfunction, low-serum albumin level, and longer duration of mechanical ventilation [55]. Patients admitted with a diagnosis of BOS who require mechanical ventilation are at the highest risk of mortality. The long-term survival of patients who recover from the ICU stay is also compromised; however, a high percentage of patients (50%) can still enjoy long-term survival after an ICU admission.

Airway Complications

Because of the lack of revascularization of the bronchial circulation, anastomotic complications, such as bronchial

dehiscence, bronchial stenosis, and bronchial infection, are the main airway complications reported in the first few weeks to months after LT. The incidence of anastomotic complications has decreased as surgical techniques have improved and surgeons have gained experience with the procedure. The reported incidence of this complication ranges widely: some studies report it to be as high as 33%; others, as low as 1.6%. However, in reality, most recent series suggest a range of 7% to 18% [56], with a related mortality rate of 2% to 4%. Risk factors for airway complications include ischemia of the donor bronchus during the posttransplant period, due to loss of bronchial blood flow (only the pulmonary vessels are revascularized during LT surgery), surgical techniques for the anastomosis, length of the donor bronchi, acute rejection, and bronchial infections.

Airway complications can be classified as early or late. Early airway complications usually occur during the first 4 to 12 weeks after transplantation and manifest themselves as a partial or complete anastomotic dehiscence or a fungal (usually *Aspergillus* or *Candida* species) or bacterial (usually *Staphylococcus* or *Pseudomonas* species) anastomotic infection. These conditions can subsequently result in anastomotic strictures or bronchomalacia. Clinically, bronchial dehiscence may cause prolonged air leaks in the early posttransplantation period. In some cases, the dehiscence may also lead to infection or the formation of peribronchial abscesses or fistulas. The results of chest radiographs and computed tomography (CT) scans are usually nonspecific; however, the appearance of extraluminal air on chest CT scans is very sensitive and specific for the diagnosis of anastomotic dehiscence. Bronchoscopy is the preferred diagnostic method for evaluating the bronchial anastomosis. This procedure may be performed routinely (surveillance bronchoscopy) or because of pulmonary symptoms, usually during the first 6 months after transplantation. During this period, the anastomosis should be evaluated carefully, the integrity of the mucosa should be assessed, and specimens from a bronchial wash or brush should be sent for cultures and cytologic examination. If there is any evidence of infection, antibiotics and antifungals (usually inhaled amphotericin with or without itraconazole or voriconazole) should be administered based on culture results.

Late bronchial anastomotic complications, including stenosis (most common), bronchomalacia, and development of exophytic granulation tissue are often the result of infection or dehiscence during the early weeks after transplantation. These complications manifest themselves as cough, shortness of breath, wheezing, dyspnea on exertion, and worsening obstruction as documented by pulmonary function testing. The characteristic flow volume loop demonstrates a concave appearance in both the inspiratory loop and the expiratory loop. Bronchial strictures or stenoses may also be seen on chest radiographs or CT scans, or by bronchoscopy. Therapeutic options for anastomotic complications include balloon dilation of a stricture, stent placement, cryotherapy, argon beam coagulation, laser procedures, and, rarely, surgery.

Rejection

Graft rejection is categorized clinically according to the time of onset after transplantation and the histopathologic pattern. The three types of rejection are hyperacute, acute, and chronic. Hyperacute rejection is mediated by preexisting alloantibodies that immediately bind to the donor vascular epithelium and lead to vessel thrombosis because of complement activation. This was thought to be a rare complication after LT. However, humoral or antibody mediated rejection is currently an area of active research in the field of LT [57]. Humoral rejection is characterized by local complement activation or the presence of antibody to donor HLAs and may be a risk factor for BOS. Treatment of humoral rejection includes plasmapheresis, intravenous immunoglobulin and/or rituximab, a monoclonal antibody against the CD-20 antigen.

Acute Rejection

As many as 50% to 55% of patients experience acute rejection during the first postoperative month, and as many as 90% will experience at least one episode of acute rejection within the first year [57]. Acute rejection usually occurs between 10 and 90 days after LT. It is not uncommon (20% of lung transplant recipients) for a single patient to experience either recurrent (more than two episodes) and/or persistent (failure to resolve with standard therapy) rejection. Acute rejection usually does not occur as frequently after the first postoperative year. Risk factors for acute rejection are poorly defined, but HLA mismatches may be correlated with its occurrence.

Clinically, acute rejection manifests itself as cough, shortness of breath, malaise, and fever. Occasionally, the presentation is asymptomatic; 68% of transplantation centers advocate surveillance bronchoscopy for the detection of this condition, although outcome data are not available [25]. Physical examination may detect rales or wheezing. The usefulness of chest radiography depends on the time since transplantation. Typically, during the first month the results of chest radiography can be abnormal in as many as 75% of rejection episodes; however, the results of radiography are abnormal in only 25% of rejection episodes that occur more than 1 month after transplantation. The most common radiographic patterns associated with acute rejection are a perihilar flare, and alveolar or interstitial localized or diffuse infiltrates with or without associated pleural effusion. In addition, CT may show ground glass opacities, septal thickening, and volume loss. New pleural fluid or increases in the amount of pleural fluid produced during the second to sixth week after LT is common among patients with acute lung rejection. The characteristics of the fluid are consistent with those of an exudate: the total lymphocyte count is often more than 80% of the total number of white blood cells.

Physiologic findings during periods of acute rejection include hypoxemia and deterioration in pulmonary function. Pulmonary function abnormalities are characterized by at least a 10% to 15% decline in FEV_1 from baseline and/or at least a 20% decline in forced expiratory flow (FEF) over 25% to 75% of expired vital capacity. Once again, these changes are nonspecific and can also be seen with infectious processes and graft complications.

Because clinical criteria alone cannot differentiate acute rejection from infection and less common graft complications, transbronchial biopsy (TBBx) with BAL has become the primary diagnostic procedure. The sensitivity of diagnosing acute rejection by TBBx ranges from 61% to 94%, and the specificity ranges from 90% to 100%. A histologic grading system for acute pulmonary rejection was proposed in 1990 and revised in 1996 and 2007 [58]. Pathologically, acute rejection is characterized by perivascular, mononuclear lymphocytic infiltrates with or without airway inflammation; histologically, it is graded from A_0 to A_4 on the basis of the degree of perivascular inflammation. In addition, the airway can be involved by lymphocytic bronchitis or bronchiolitis, which is graded from B_0 to B_x [58]. As rejection progresses, the perivascular lymphocytic infiltrates surrounding the venules and arterioles become dense and extend into the perivascular and peribronchiolar alveolar septa. Severe rejection may involve the alveolar space; parenchymal necrosis, hyaline membranes, and necrotizing vasculitis have been described [58]; and respiratory failure requiring mechanical ventilation can occur.

Once acute rejection has been diagnosed, treatment consists of augmenting the level of immunosuppression. Intravenous methylprednisolone (10 to 15 mg per kg daily for 3 days)

followed by an increase in the maintenance regimen of prednisone regimen to 0.5 to 1 mg per kg daily, with tapering over the next several weeks, is a standard treatment regimen. Maintenance immunosuppression should also be augmented. Typically, symptoms resolve in days, and histologic follow-up 3 to 4 weeks later should demonstrate resolution. Recurrent or persistent acute rejection may require conversion in the baseline immunosuppressive regimen. Lympholytic therapy, methotrexate, photophoresis, total lymphoid irradiation, and aerosolized cyclosporine have been used with varied success [59].

Obliterative Bronchiolitis

Chronic rejection has been equated with the histologic finding of obliterative bronchiolitis (OB); it is a primary cause of morbidity and mortality after LT and the leading single cause of death more than 1 year after transplantation [1]. The incidence of OB ranges from 35% to 50% at various centers. OB has been defined clinically by an obstructive functional defect and histologically by obliteration of terminal bronchioles. OB generally occurs in a mean of 16 to 20 months after LT, but it has been reported as early as 3 months after transplantation. More than 50% of recipients will experience some degree of OB by 5 years after transplantation [1].

The causes of and risk factors for OB remain unclear. Several possible causes have been proposed, including uncontrolled acute rejection, lymphocytic bronchiolitis, CMV pneumonitis, CMV infection without pneumonitis, community acquired respiratory viruses, gastroesophageal reflux disease, PGD, antibody-mediated rejection, HLA-A mismatches, total HLA mismatches, absence of donor antigen-specific hyporeactivity, non-CMV infection, older donor age, and bronchiolitis obliterans with organizing pneumonia [40,41,60–63]. The most consistently identified risk factor is acute rejection, particularly in those patients who experience recurrent, high-grade episodes of acute rejection.

Clinically, OB can manifest itself as an upper respiratory tract infection and can be mistakenly treated as such. Other patients exhibit no clinical symptoms, but pulmonary function testing demonstrates gradual obstructive dysfunction. FEV_1 has been the standard spirometric parameter used for diagnosis, but midexpiratory flow rates may be a more sensitive parameter for early detection.

Typically, chest radiographs are not helpful in the diagnosis of OB because their results are unchanged from the results of baseline posttransplantation radiographs. High-resolution CT scans may show peripheral bronchiectasis, patchy consolidation, decreased peripheral vascular markings, air trapping, mosaicism, tree-in-bud changes, and bronchial dilation; these findings may aid in the diagnosis of OB [64]. Air trapping on end-expiratory high-resolution CT scans has been shown to be a sensitive (91%) and accurate (86%) radiologic indicator of OB, but it may not be able to provide an early diagnosis of this disorder. As with acute rejection, TBBx is used to diagnose OB, but primarily to exclude other diagnoses. The classic pathologic finding is constrictive bronchiolitis. Unfortunately, the sensitivity of TBBx for diagnosing OB is low (range: 15% to 87%), and the diagnosis of OB is often made by exclusion. OB is graded physiologically on the basis of the degree of change in pulmonary function (FEV_1) from baseline [61,62]. Because of the variability in obtaining bronchioles by TBBx, the ISHLT has established a staging system for BOS [62]. This staging is based on a reduction in FEV_1 of more than 20% from baseline after transplantation and is associated with a decrease in the FEF 25% to 75%, with or without the pathologic documentation of OB.

Once OB has been diagnosed histologically or clinically by excluding alternative diagnoses, treatment involves administering high-dose methylprednisolone followed by a tapering course of oral corticosteroids. Lympholytic depleting agents such as ATG, OKT_3, alemtuzumab, and basiliximab can be considered if there is no clinical response to corticosteroid treatment. Therapy may stabilize pulmonary function, but it only rarely results in substantial improvement. Alternative immunosuppressants such as sirolimus have also been associated with stabilization of pulmonary function when used as rescue treatment for BOS. Methotrexate, total lymphoid radiation, aerosolized cyclosporine, photophoresis, and newer immunosuppressants have been used to treat refractory cases of OB. Inhaled cyclosporine may be added for cases of lymphocytic bronchiolitis. Several studies have shown stabilization and/or improvement in BOS when a macrolide agent, such as azithromycin or clarithromycin is added to the regimen, likely due to the immunomodulating effects [65–67].

Infection, including bronchiectasis, frequently complicates intensive immunosuppression for OB and may result in death. Pseudomonas is a common offender, and aerosolized aminoglycoside antibiotics or suppressive quinolone treatment may be considered. Because most cases of OB can only be stabilized, strategies directed at prevention, early diagnosis, and treatment are necessary for the preservation of lung function. Retransplantation has been performed with varied results. Survival rates are somewhat lower than those after the initial transplantation and are superior when performed for the indication of BOS (1 year 62% and 5 year 45%), than for PGD [68,69].

Infectious Complications

Infections are an important cause of early and late morbidity and mortality after transplantation and are the leading single specific cause of death during the first year after transplantation [1]. The incidence of infection is significantly higher among recipients of lung transplants than among recipients of most other solid organ transplants; this higher incidence may be related to the continuous exposure of the allograft to the environment. Other predisposing factors include a diminished cough reflex because of denervation, poor lymphatic drainage, decreased mucociliary clearance, recipient-harbored infection, and, occasionally, transfer of infection from the donor organ. Nosocomial infections, such as urinary tract infections, ventilator-assisted pneumonia, and infections at the site of the surgical wound or the vascular access, also occur during the early postoperative period. However, in most circumstances the allograft is the primary site of infection.

Bacterial Infections

Bacterial pneumonia is the most common life-threatening infection that develops during the early postoperative period. Its incidence during the first two postoperative weeks is reported to be as high as 35% [70–72]. Common organisms include *Pseudomonas aeruginosa* and *Staphylococcus species*. The incidence of perioperative bacterial pneumonia has been reduced to as low as 10% by prophylaxis with broad-spectrum antibiotics, usually an antipseudomonal cephalosporin and clindamycin, and by routine culture of the trachea of both the donor and the recipient at the time of transplantation. Prophylactic antibiotics are usually discontinued after 3 days if the results of cultures are negative; the antibiotics are tailored to the cultured organisms if the results are positive. For transplant recipients with bronchiectasis, postoperative bacterial prophylaxis is usually continued for 14 days. The incidence of bacterial pneumonia is high during the first 6 months after transplantation but decreases thereafter, although a second late peak in incidence often occurs when immunosuppression is augmented for the treatment of chronic rejection. During the early posttransplantation period, bacterial infection due to Staphylococcus or, less

commonly, Pseudomonas can develop at or distal to the site of the anastomosis.

It is often difficult to distinguish pneumonia from other early graft complications, such as reperfusion injury, pulmonary edema, rejection, and other causes of infection. In addition, differentiating between colonization and invasion may be difficult and often requires invasive procedures such as bronchoscopy with BAL, quantitative sterile brush sampling, or TBBx.

Other Infections

Atypical pneumonias, including those due to Legionella, mycobacteria, and Nocardia, are uncommon during the first month after transplantation but occur among 2% to 9% of recipients of lung or heart–lung transplants. At transplantation centers that routinely administer prophylaxis with trimethoprim–sulfamethoxazole during the first year after transplantation and reinitiate it when immunosuppression is augmented, the incidence of Pneumocystis pneumonia is less than 1%.

Most opportunistic infections occur within 6 months after transplantation. Sustained immunosuppression leading to a decrease in cell-mediated immunity predisposes the patient to infection with opportunistic organisms such as Aspergillus, Mycobacterium, Nocardia, and geographically endemic fungi.

Viral Infections

Viral infections are a primary cause of morbidity and mortality among long transplant recipients. During the first 6 months after transplantation, CMV accounts for most of the viral infections among these patients [72,73]. The typical time period for the development of CMV infection is 30 to 150 days postoperatively; the incidence of illness (i.e., infection and disease) is approximately 50%. Risk factors for CMV disease depend on the serology of the donor and the recipient and on the use of high-intensity immunosuppressive therapy, including cytolytic therapy. Approximately 15% to 35% of CMV-positive patients who receive grafts from either CMV-positive or CMV-negative donors experience CMV disease, whereas approximately 55% of CMV-negative patients who receive a graft from a CMV-positive donor may experience CMV disease. Most studies indicate that CMV pneumonitis contributes to the development of chronic rejection [62].

CMV can cause a wide spectrum of disease, ranging from asymptomatic infection, such as shedding of the virus in the urine or BAL, to widespread dissemination. The most common presentation of CMV among lung transplant recipients is pneumonitis, but the infection may also present as gastroenteritis, hepatitis, or colitis. CMV pneumonitis can often be confused with acute rejection. Clinical findings of CMV pneumonitis include fever, cough, flu-like illness, hypoxemia, an interstitial or alveolar infiltrate, and leukopenia. A definitive diagnosis of invasive disease requires cytologic or histologic changes in cell preparation or tissue. Therefore, diagnosis often requires flexible bronchoscopy with TBBx and BAL; this combination can detect 60% to 90% of CMV pneumonias. Currently, plasma-based polymerase chain reaction (PCR) assays are used to screen patients and to detect CMV infection [74]. The risk of CMV pneumonitis after LT is usually related to the serum concentration of CMV DNA, and this measure is used in many programs for the preemptive management of CMV [75].

The pathologic hallmark of CMV infection is a cytomegalic 250-nm cell containing a large central basophilic intranuclear inclusion. This inclusion is referred to as an "owl's eye" because it is separated from the nuclear membrane by a halo. Identifying CMV cytologically is very specific (98%) but lacks sensitivity (21%) for detecting the presence of infection. Other pathologic findings in the lung parenchyma of patients with CMV pneumonia include a lymphocytic and mononuclear-cell interstitial pneumonitis.

Ganciclovir (oral or intravenous) and oral valganciclovir are currently the mainstays of therapy for invasive CMV disease [73]. Bone marrow toxicity is one of the primary limiting side effects of ganciclovir therapy and may necessitate conversion to an alternative agent such as foscarnet. Most centers also use CMV-specific hyperimmunoglobulin to treat CMV disease.

Prophylaxis against CMV infections has become an important strategy at most transplantation centers. Initially, some centers attempted to match CMV-negative recipients with CMV-negative donors; however, the limited donor supply did not allow the continuation of this practice. The use of CMV-negative blood products is advocated. Prophylaxis with ganciclovir or valganciclovir seems to be effective in delaying the onset of CMV infection. Most centers give prophylaxis to all patients except CMV-negative recipients who receive grafts from CMV-negative donors. Prophylaxis is usually recommended for at least 90 days, particularly for CMV-negative recipients of grafts from CMV-positive donors. A recent randomized, controlled, multicenter study examined the efficacy of extending valganciclovir prophylaxis from the standard 3 months to 12 months in at risk (either donor or recipient CMV positive) patients. The investigators found a significant reduction in CMV infection, disease, and disease severity without increased ganciclovir resistance or toxicity in those patients receiving the longer course of therapy [76]. For patients at highest risk of infection, CMV hyperimmunoglobulin may be added to the regimen. Preemptive strategies, such as initiating treatment when a high level of CMV DNA is detected by PCR, may also delay and decrease the severity of CMV infection and may become the standard of care.

Other viruses that affect lung transplant recipients include herpes simplex virus (early after transplantation), community acquired respiratory viruses, such as respiratory syncytial virus, other paramyxoviruses (such as parainfluenza), influenza virus, metapneumovirus, and adenovirus [77]. Some transplantation programs initiate prophylaxis with acyclovir for herpes infection after the discontinuation of ganciclovir.

Fungal Infections

Fungal infections are more common among recipients of lung transplants than among recipients of other solid-organ transplants [78,79]. The overall incidence of invasive fungal infection after LT ranges from 15% to 35%. Such infections usually develop during the first few months after transplantation. Fungal infections carry the highest morbidity and mortality rates of all infections after transplantation; mortality rates can range from 40% to 70%.

Aspergillus species such as *A. fumigatus, A. flavus, A. terreus*, and *A. niger* can be colonizing organisms, can cause an infection that suggests an indolent, progressive pneumonia, or can cause an acute fulminant infection that disseminates rapidly. Aspergillus can invade blood vessels and may appear as an infarct on chest imaging or present with hemoptysis. The radiographic findings of pulmonary aspergillosis include focal lower-lobe infiltrates, patchy bronchopneumonic infiltrates, single or multiple nodules with or without cavitation, thin wall cavities, and opacification of the entire lung graft. High-resolution CT scans may reveal a halo sign that is believed to be pathognomonic for angioinvasive fungal infections such as aspergillosis [80]. Other manifestations of Aspergillus infection include pseudomembranous tracheobronchitis, often at and distal to the site of the anastomosis. Diagnosing invasive aspergillosis requires identifying organisms within tissues. These organisms can appear as septate hyphae that branch at acute angles and can be detected on hematoxylin-eosin and methenamine silver stains.

Survival rates for patients with Aspergillus infection have been improved by the early initiation of broad-spectrum azoles (such as voriconazole or itraconazole), high-dose amphotericin, or both, sometimes with the addition of an echinocandin, and a reduction in immunosuppressive therapy. Surgical resection may rarely be required to maximize cure rates in patients with aspergillosis. A lipid formulation of amphotericin B should also be considered for the management of invasive fungal infections among patients who cannot tolerate conventional amphotericin B or who experience nephrotoxicity with conventional amphotericin B, and among patients with progressive fungal infection despite therapy with conventional amphotericin. Prophylaxis with the azoles (voriconazole or itraconazole) for 3 to 6 months, and/or with amphotericin or aerosolized amphotericin, has shown promise in decreasing the incidence of Aspergillus infection after transplantation [81].

Candidal infections may occur during the early postoperative period but usually do not cause invasive disease. *Candida* species can cause a variety of syndromes among lung transplant recipients; these syndromes include mucocutaneous disease, line sepsis, wound infection, and, rarely, pulmonary involvement. Fluconazole and caspofungin have emerged as effective alternatives for treating infections caused by *Candida albicans*, but amphotericin B may still be considered for widespread disease. Fluconazole appears to be less active against other *Candida* species such as *C. glabrata* and *C. krusei*.

Less common causes of fungal infections among lung transplant recipients include *Cryptococcus neoformans* and the dimorphic fungi (*Coccidioides, Histoplasma*, and *Blastomyces*). Amphotericin B or the newer broad-spectrum azole agents are the initial therapeutic choices for treating serious infections with the invasive mycoses. The dose, duration of therapy, and alternative therapies differ depending on the organism.

Immunosuppression

After LT, a typical regimen for the maintenance of immunosuppression consists of tacrolimus at a dose of approximately 0.1 mg per kg orally every day in two divided doses (adjusted to maintain a serum concentration of 8 to 15 ng per mL), or cyclosporine 5 mg per kg orally every day in two divided doses (with dose adjusted to maintain serum concentrations of 250 to 350 ng per mL), and mycophenolate mofetil at a dose of 1 to 3 g daily, or azathioprine 1 to 2 mg per kg daily (adjusted to maintain a leukocyte count higher than 4,000 to 4,500 per mm^3), and prednisone approximately 0.5 mg per kg daily for the first month and then tapered by 5 mg per week over the next few months to a final maintenance dose of 5 mg per day. A minority of transplantation programs completely discontinue the administration of prednisone approximately 1 year after transplantation. The role of sirolimus after LT remains to be established. It is recommended that sirolimus not be used in the early perioperative period due to impaired wound healing.

Physicians caring for transplant recipients must be aware of the numerous drugs that can interact with tacrolimus and cyclosporine. For example, the azoles cause a significant increase in the serum concentrations of cyclosporine and tacrolimus. Likewise, discontinuing azole agents without increasing the dose of cyclosporine or tacrolimus can cause an acute and life-threatening decrease in the therapeutic concentrations of these drugs. Interactions with macrolide antibiotics, calcium channel blockers, and gastric motility drugs have also been reported. The concentrations of cyclosporine and tacrolimus are decreased by rifampin and anticonvulsants.

All immunosuppressants are associated with toxicity and drug interactions [82]. The details of these complications are discussed in a separate chapter.

Miscellaneous Complications

Another possible complication of LT is postoperative hemorrhage requiring reexploration. One of the early clues to this diagnosis is radiographic evidence of a hemothorax or what appears to be a retained clot, or a large volume of blood draining from the thoracostomy tubes. This complication may occur more frequently among patients who require cardiopulmonary bypass with its attendant requirement for anticoagulation or among patients with pleural adhesions from previous procedures such as pleurodesis or diagnostic or therapeutic lung surgery. Persistent air leaks can occasionally occur but are unlikely unless the bronchial anastomosis loses its integrity, because the lung parenchyma is normally not entered during a routine LT procedure [83].

In addition to the bronchial anastomotic complications discussed earlier, vascular anastomotic complications can occur. A stenosis at the venous anastomosis is indicated by radiographic evidence of pulmonary edema and infiltrates; this condition can be confused with PGD and is usually diagnosed by transesophageal echocardiography. A stenosis at the arterial anastomosis is suggested by unexplained gas exchange abnormalities and pulmonary hypertension.

Phrenic nerve dysfunction and diaphragmatic paralysis, which occur in conjunction with other types of cardiothoracic surgery, occur after LT with an incidence of 3% to 9.3% and are associated with a prolongation in the number of days for which mechanical ventilation is required, an increase in the length of stay in the ICU, an increase in the use of ICU resources, and an increase in the need for tracheostomy [84]. An inability to wean the patient from mechanical ventilation may indicate phrenic nerve dysfunction; the diagnosis can be confirmed by phrenic nerve conduction studies. For patients who do not require ventilation, the diagnosis of phrenic nerve dysfunction can be made with a fluoroscopic "sniff test." If the injury is the result of stretching of the phrenic nerve or trauma to the nerve during the surgical procedure but the nerve is not completely transected, a slow recovery can be anticipated. Complete transection is rare, but the damage is permanent. Diaphragmatic plication or pacing can be performed in some cases.

Pleural effusions can develop and/or persist following LT. The characteristics of these effusions are usually lymphocyte predominant exudates and can be associated early on with severing of the lymphatics (i.e., chylous effusion) or with rejection. A single-center study of a large number of lung transplant patients found that 27% of pleural effusions in these patients required drainage. 96% of the effusions were exudates, 27% of patient had infected pleural effusions with organisms such as fungal pathogens (specifically Candida most commonly), followed by bacterial etiologies. These infected effusions were characterized by high lactate dehydrogenase levels and neutrophilia [85]. Other causes of pleural effusions include heart failure, pulmonary embolism, and trapped lung. Rarely pleurodesis or decortication may be required.

Lung transplant recipients also experience gastroparesis, severe gastroesophageal reflux resulting in aspiration pneumonia, and an increased incidence of gastrointestinal emergencies [86]. These conditions include colonic perforation, small-bowel obstruction, diverticulitis, CMV colitis, megacolon, prolonged ileus, ischemic bowel, and pancreatitis [87]. Gastroesophageal reflux may be more severe among transplant recipients with cystic fibrosis.

Renal insufficiency is also a frequent complication among lung transplant recipients. This complication results from a combination of infections leading to sepsis and acute tubular necrosis, or from medication-related renal toxicity.

Cardiac arrhythmias, especially supraventricular arrhythmias such as atrial fibrillation, commonly develop in the perioperative period [88].

In one series of lung transplant recipients, the incidence of deep venous thrombosis and pulmonary embolism was reported to be 8.6%. This complication was believed to be related to alterations in coagulability leading to a hypercoagulable state or hypercoagulability due to their underlying disease [89,90].

Posttransplant lymphoproliferative disease (PTLD) and other malignancies can occur among lung transplant recipients. The incidence of PTLD after LT reportedly ranges from 1.8% to 9.4% [91]. PTLD comprises a heterogenous group of lymphoid proliferations, usually of the B-cell form, that are strongly associated with the Epstein–Barr virus (EBV). Patients for whom the results of pretransplantation serological studies are negative for EBV but who receive an organ from an EBV-positive donor and experience seroconversion are at a higher risk of PTLD. Clinically, PTLD usually occurs during the first year after transplantation; it involves the allograft and manifests itself as radiographic findings of solitary or multiple pulmonary nodules. Treatment includes reducing the level of immunosuppression, institution of antiviral therapy, and administering the anti-CD20 monoclonal antibody rituximab. In some cases, chemotherapy or surgery may be indicated.

Significant advances have been made in the field of LT since its inception more than 30 years ago, allowing this procedure to be a successful therapeutic option for patients with end-stage parenchymal or vascular lung disease. However, despite these improvements, numerous complications, many of which are managed by critical care professionals, can arise in this group of patients, and the unique aspects of their care are important.

SECTION XV ■ METABOLISM/NUTRITION

DOMINIC J. NOMPLEGGI

CHAPTER 190 ■ NUTRITIONAL THERAPY IN THE CRITICALLY ILL PATIENT

DOMINIC J. NOMPLEGGI

The nutritional management of critically ill patients has changed dramatically over the past 10 years. Changes in the areas of nutritional assessment, guidelines for total energy provided, disease-specific feeding, and immune-enhancing enteral nutrition have been the most prominent. The rationale for nutrition support comes from the knowledge that critically ill patients are prone to develop malnutrition, which is known to be associated with serious complications such as sepsis and pneumonia, leading to a poor outcome and even death [1].

Although guidelines continue to be in evolution, there are sufficient data on clinically proven principles and methods of nutrition support to permit practical and useful recommendations for the specific problems and questions confronted by the intensivist.

The Society of Critical Medicine and the American Society for Parenteral and Enteral Nutrition convened an expert panel to review all available data in the literature to establish guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient [2]. These recommendations concluded that now after more then 30 years of investigation, nutrition *support* in critically ill patients, once regarded as adjunctive care designed to preserve lean body mass, maintain immune function, and avoid metabolic complications should now be considered nutrition *therapy* specifically aimed at attenuating the metabolic response to stress, prevent oxidative injury and improve the immune response [2]. Table 190.1 does not list all of the recommendations of the panel but summarizes all the recommendations supported by randomized trials.

WHAT IS MALNUTRITION AND HOW DO WE RECOGNIZE IT?

Malnutrition in ICU patients is common and can be present on admission or develop as a result of the metabolic response to injury. This response to injury can lead to changes in substrate metabolism, causing alterations in body composition and nutrient deficiencies that become clinically evident [3]. During starvation, the body uses fat and muscle protein as a source of energy in order to preserve visceral protein [4]. Mobilization of fat for fuel is an important adaptive response for survival because glucose stores, in the form of glycogen, provide only 1,200 kcal in the first 24 hours of starvation. The body attempts to use muscle protein rather than visceral protein because visceral protein is essential for vital functions of the body. Skeletal muscle mass decreases steadily, and its rate of loss exceeds that of weight loss [5]. Because these changes are difficult to assess, intensivists have had to resort to a variety of tools such as clinical, anthropometric, chemical, and immunological parameters that reflect altered body composition [6].

Nutritional Assessment

It is not known how long a critically ill patient can tolerate lack of nutrient intake without adverse consequences, but because critical depletion of lean tissue can occur after 14 days of starvation in severely catabolic patients, it is recommended that nutrition support be instituted in patients who are not expected to resume oral feeding for 7 to 10 days [7]. A recent study conducted by the European Society of Intensive Care Medicine (ESICM) surveyed intensivists from 35 countries using a 49-item questionnaire to determine how they cope with these issues and to assess the current practice of nutritional management in intensive care units (ICUs) [8].

In the ESICM study, 45% of the patients were fed within 24 hours and 47% between 24 and 48 hours of admission to the ICU [8]. The need for nutritional support is determined by the balance between endogenous energy reserves of the body and the severity of stress. The best clinical markers of stress are fever, leukocytosis, hypoalbuminemia, and a negative nitrogen balance.

The purpose of nutritional assessment is to identify the type and degree of malnutrition to devise a rational approach to treatment. Percentage weight loss in the patient's past 6 months, serum albumin level, and total lymphocyte count are readily available, commonly used measures to assess nutritional status. A 10% or 10-lb weight loss over the previous 12 months is an indicator of protein calorie malnutrition. This results from inadequate caloric intake. Hypoalbuminemic malnutrition or kwashiorkor is due to severe stress or profound malnutrition. Albumin is not a very sensitive indicator of malnutrition in ICU patients because its synthesis is influenced by numerous factors other than nutritional status such as protein losing states, hepatic function, and acute infection or inflammation [9]. Normal concentrations of albumin are unattainable in many critically ill patients because of large fluid shifts and inadequate synthesis to meet demands. Hypoalbuminemia should be viewed as a marker of injury and not as an indicator of impaired nutrition. Most critically ill patents have a combination of the two. The protein calorie malnutrition can be easily treated by supplying adequate caloric intake. The hypoalbuminemic malnutrition is most effectively treated by nutrition support and treatment of the stresses that led to this severe catabolic condition.

Traditionally, weight loss of 10 lb or 10% of usual weight is clinically important, weight loss of 20% to 30% suggests moderate protein calorie malnutrition, and greater than 30%, severe protein calorie malnutrition. Unfortunately, in many critically ill patients, total body weight is often an insensitive parameter because of progressive total body salt and water retention. Anthropometrics (i.e., measurement of triceps skinfold thickness and midarm muscle circumference) are reasonably accurate even in the presence of excess body water because edema accumulates to a lesser extent in the upper extremities

TABLE 190.1

SUMMARY OF EVIDENCE-BASED GUIDELINES FOR NUTRITION SUPPORT

- Enteral Nutrition (EN) is preferred over parenteral nutrition (PN) for critically ill patients who require nutrition support.
- Bowel sounds are not required for the initiation of enteral feeding.
- Immune modulating enteral formulations should be used for critically ill patients on mechanical ventilation but with caution in patients with severe sepsis.
- Patients with ARDS and severe acute lung injury require enteral feeding containing anti-inflammatory lipids (i.e., omega-3 fish oil, borage oil) and antioxidants.
- Antioxidant vitamins and trace minerals, specifically containing selenium, should be given to all critically ill patients receiving nutrition therapy
- EN regimens not containing glutamine should be supplemented with glutamine in burn, trauma and mixed critically ill patients.
- Protocols to promote moderately strict control of serum glucose levels (110–150 mg/dL) when providing nutrition support are recommended.

Adapted from McClave SA, Martindale RG, Vanek VW, et al: Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient: Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.) *J Parent Enteral Nutr* 33:277–318, 2009.

[10]. However, they are difficult to perform in critically ill patients, time consuming, and not routinely performed. The general appearance of the patient, with emphasis on evidence of temporal, upper body, and upper extremity wasting of skeletal muscle mass, provides a quick, inexpensive, and clinically useful measure of nutritional status. For the reasons above, clinicians have found that body mass index may be a more practical way to assess nutritional status. As presented in Chapter 191, Driscoll suggests that a patient weight less than 85% of the ideal body weight (IBW) or BMI less than 18.5 indicates moderate malnutrition. Severe malnutrition would be considered likely if weight is less than 75% of IBW or BMI is less than 16 kg per m^2. Thus, a greater sense of urgency to intervene with nutrition support is present under these conditions and should be undertaken within several days of the acute injury.

Malnutrition is closely correlated with alterations in immune response as measured by skin test reactivity and total lymphocyte count. A total lymphocyte count less than 1,000 per mm^3 is indicative of altered immune function and is associated with decreased skin test reactivity. Loss of delayed cutaneous hypersensitivity to common antigens is a measure of impaired cellular immunity, which has consistently been found to be associated with malnutrition [9].

Subjective global assessment (SGA) is a method for evaluating nutritional status that uses clinical parameters like history, physical findings, and symptoms [11,12]. The SGA determines whether (a) nutritional assimilation has been restricted because of decreased food intake, maldigestion, or malabsorption, (b) any effects of malnutrition on organ function and body composition have occurred, and (c) the patient's disease process has influenced nutrient requirements [7].

As stated by the advisory committee convened by the National Institutes of Health, the American Society for Parenteral and Enteral Nutrition, and the American Society for Clinical Nutrition, "there is no 'gold standard' for determining nutritional status because (a) there is no universally accepted clinical definition of malnutrition, (b) all current assessment parameters are affected by illness and injury, (c) it is difficult to isolate the effects of malnutrition from the influence of the disease on clinical outcome, and (d) it is not clear which of the commonly used nutrition assessments techniques is the most reliable because of the paucity of comparative data" [7].

According to the ESICM questionnaire, the critical care community appears to most commonly assess nutritional status using the SGA and laboratory parameters [8]. Although there are no data to attest to the reliability of this approach in critically ill patients, serum albumin, stress level, weight loss in excess of 10% of ideal body weight, and SGA have been shown to be reasonable markers of nutritional status in noncritically ill hospitalized patients. Until future studies show otherwise, weight loss, serum albumin, and SGA are likely to be reliable parameters to follow in patients who are not volume overloaded. They are simple to measure, generally accepted, and commonly used.

HOW MUCH SHOULD YOU FEED?

Macronutrients

Body cell mass is the major determinant of the total caloric requirement. Energy needs can be estimated or measured directly using indirect calorimetry. Because estimated energy requirements have been shown to be adequate in most patients, direct measurement is usually reserved for patients in whom estimating energy needs are difficult or when patients do not appear to respond to therapy (e.g., worsening respiratory function, continued weight loss, or a decrease in prealbumin levels, a more sensitive marker of protein synthesis than albumin).

The general principle of macronutrient support is to provide enough energy to promote anabolic functions and avoid caloric overload. Caloric requirements of 25 to 30 kcal per kg should be based on the usual body weight and are adequate for most patients [2,9]. If patients are not responding to therapy as indicated by the parameters listed above, or if they are in a severe catabolic state as occurs in multiple trauma or burns patients, they may need 30 or even 40 kcal per kg.

Protein

The usual protein requirement has been estimated to be 1.2 to 1.5 g per kg per day for actual body weight. Nitrogen retention can be monitored and protein adjusted to support protein synthetic functions. Protein should be reduced when the blood urea nitrogen rises to 100 mg per dL or an elevated ammonia level is associated with clinical encephalopathy to limit the impact of the uremia and to avoid worsening encephalopathy associated with elevated ammonia levels [9].

Carbohydrates

Generally patients will need about 25 to 30 kcal per kg per day to meet there energy requirements. Approximately 20 kcal per kg per day of the actual body weight can be provided as carbohydrate. Levels of carbohydrate above 30 kcal per kg per day increase the risk of hyperglycemia. Hyperglycemia should be avoided because it is associated with abnormalities in granulocyte adhesion, chemotaxis, phagocytosis and intracellular killing, and poor clinical outcomes.

Hyperglycemia is a major contributing factor to postoperative infection. Blood sugars greater than 220 mg per dL on postoperative day 1 have been associated with a fivefold increased risk of serious infection [13]. A recent study in patients requiring total parenteral nutrition (TPN) to determine whether

the frequency of hyperglycemia and infectious complications can be reduced by an underfeeding strategy (1,000 kcal with 70 g per kg as protein) provision of 1.5 g per kg of protein in conjunction with 25 kcal per kg was not associated with more hyperglycemia or infections than deliberate underfeeding. However, a regimen of 25 kcal per kg in conjunction with 1.5 g per kg of protein did provide significant nutritional benefit in terms of nitrogen balance as compared with hypocaloric TPN [14]. This suggests that it is not a hypocaloric low carbohydrate formula that protects against infection but rather the avoidance of hyperglycemia. Alternatively, TPN can be adjusted and regular insulin given, as needed, to maintain a blood glucose level from 110 to 150 mg per dL [2].

Fat

Usually no more than 15% to 20% of total calories per day should be provided as fat. This will avoid infectious complications that may be due to dysfunction of the reticuloendothelial system, which has been associated with the administration of excess lipids [15]. Omega-6 polyunsaturated fatty acids should be provided in doses adequate to prevent essential fatty acid deficiency (at least 7% of total calories). Medium-chain triglycerides (MCT) can be administered with long-chain triglycerides (LCT). MCTs are more water soluble and require less lipase activity and bile salts for absorption. Patients with malabsorption, pancreatic insufficiency, and chronic liver disease can absorb them more easily. The ratio of MCT to LCT depends on the route of administration and product availability [9].

Electrolytes, Micronutrients, and Fluid

Potassium, magnesium, phosphate, and zinc should be provided in amounts necessary to maintain normal serum levels. The absolute requirements for vitamins, minerals, and trace elements have not yet been determined. Normal serum and blood levels of vitamins have been established but may vary with the laboratory in which the measurement is obtained [9]. In general, patients should receive 25 mL of fluid per kg actual dry body weight to avoid dehydration. Three milliliters of trace elements injection 5 (Multitrace-5®) and 10 mL of multiple vitamin infusion (Infuvite Adult®) will provide adequate vitamins, trace elements, and minerals and should be added to TPN daily. The required daily allowance (RDA) for all vitamins and minerals are usually provided in 1,000 to 1,500 mL of most enteral formulas. If the patient is receiving less than a liter of enteral feeding, vitamin supplementation may be necessary. Spot electrolyte measurements (aliquots of urine, ostomy, nasogastric, or fistulous output) may be very helpful in determining proper replacement. If the total daily volume of the lost fluid is measured, the daily loss of any electrolyte in that fluid can be estimated using the following equation: mmol per L × volume output per 24 hours (in liters) = mmol per 24 hours (e.g., 20 mL of urine contains 100 mmol per L, the daily urine output is 2 L; therefore, the 24 hour urine sodium output is 200 mmol).

WHICH ROUTE OF ADMINISTRATION?

Enteral Feeding

Enteral feeding has been shown in clinical studies to reduce infection and preserve gut integrity, barrier, and immune function. It is the preferred route of nutrient administration because it is more physiologic, safer, and less expensive than parenteral feeding. Current recommendations support initiation of enteral nutrition as soon as the patient is hemodynamically stable [2]. The only contraindication is a nonfunctioning gut. For example, intragastric feeding requires adequate gastric motility. Gastric residuals should be checked hourly and a volume greater than 200 mL necessitates modification of the infusion rate to minimize reflux and aspiration. Supplemental parenteral nutrition to meet caloric requirements or small bowel feeding to potentially decrease the risk of aspiration will be necessary until normal gastric function returns. Gastric atony and colonic ileus do not preclude enteral feeding but may require gastric decompression and small bowel feeding.

Initiation of enteral feeding does not require active bowel sounds or the passage of flatus or stool. Small bowel feedings can be given in the presence of mild or resolving pancreatitis and low output enterocutaneous fistulas (less than 500 mL per day) [2,8]. Recently, even patients with severe acute pancreatitis (acute physiology and chronic health evaluation [APACHE] II score 12 to 13) receiving enteral nutrition were found to have significantly fewer total complications and septic complications than patients receiving parenteral nutrition [16]. Worsening abdominal distention or diarrhea in excess of 1,000 mL per day requires a medical evaluation. If distention is present, enteral feedings should be discontinued. If no infectious cause for the diarrhea is found, antidiarrheals can be administered and feedings continued [9]. Nasogastric feeding is appropriate for most patients except those with a history of aspiration pneumonia associated with reflux. Those patients should be fed postpylorically or via a G-tube to minimize nasogastric tube-associated reflux of gastric contents and aspiration. Although there are some recent data suggesting it is just as safe to feed patients with severe pancreatitis intragastrically, the bulk of existing evidence favors feeding intrajejunally to minimize pancreatic stimulation [17].

Standard isotonic polymeric formulations can meet most patients' nutritional needs. The use of elemental formulas should be reserved for patients with severe small bowel absorptive dysfunction. The "American Gastroenterological Association Medical Position Statement: Guidelines for the use of enteral nutrition" has concluded that disease or organ-specific specialty formulations generally are more expensive and have a limited clinical role, and they will require more data to justify their practicality and effectiveness [18].

There are numerous issues that arise when providing enteral nutrition to critically ill patients. We provide guidelines to help the readers of this review overcome the problems that often arise when administering enteral tube feeding.

In general, most complications associated with the use of feeding tubes relate to placement, displacement, or malfunction of the tubes. It is important to remember that these tubes require frequent maintenance to avoid complications. The position of nasogastric or nasoenteric feeding tubes placed at the bedside should be confirmed endoscopically or radiographically before use because clinical assessment is unreliable. The use of promotility drugs has not been shown to be consistently beneficial and although they can increase the volume of feeding the overall impact is small [2,9]. Excessive force during insertion, which can result in malposition, should be avoided. Tubes need to be flushed regularly to avoid clogging with medications or tube feeding. Cycled tube feeding is recommended, if possible, to facilitate this. Little is known about compatibility of most medications with tube feeding and, therefore, medications should not be mixed with tube feedings since this can lead to precipitation of the medication with blockage of the tube and decreased absorption of the medication.

Placement of tubes across the gastroesophageal junction or pylorus can lead to incompetence of the sphincter, reflux, and aspiration. In patients at risk for or with a history of aspiration associated with reflux we recommend percutaneously

placed gastric or jejunal feeding tubes. Gastric tubes are preferred because the smaller caliber of the jejunal tubes makes them likely to clog with administration of anything except liquid medications. Percutaneously placed tubes that fall or are pulled out should be replaced cautiously. Unlike noncritically ill patients who usually have had their feeding tubes in place long term, critically ill patients are likely to have had their tube placed recently or may have impaired healing and, therefore, may not have a fully developed cutaneous fistula. For these reasons we recommend confirming placement with a contrast-enhanced radiograph before use when replacing these tubes at the bedside.

Elevating the head of the bed 30 degrees and checking for gastric residuals to avoid increases in the volume of the gastric contents, which can lead to hypersecretion and reflux of gastric contents, is also recommended.

Stress gastritis, also known as stress-related erosive syndrome (SRES), is a term used to describe gastrointestinal mucosal injury associated with serious systemic disease. Most patients at risk cannot have oral feedings. Histamine H_2 receptor antagonists (H2RAs) have been shown to protect against significant gastrointestinal hemorrhage. There are less data on the efficacy of proton pump inhibitors (PPIs). A reasonable suggestion has been to wait 6 to 12 hours between stopping parenteral H2RAs before starting to feed and initiating therapy with a PPI [19].

Parenteral Feeding

Parenteral nutrient administration is recommended when the gastrointestinal tract is nonfunctional or inaccessible or enteral feeding is insufficient. Although parenteral nutrient admixtures are not as nutritionally complete as enteral formulations, nutritional goals are achieved more often with the former than the latter. This is usually attributable to a variety of barriers. A recent study of four university-based ICUs at two hospitals found that physicians ordered a daily volume of enteral feeding that was 66% of the requirement, but because only 78% of the ordered volume was infused, patients received only 52% of target calories. Sixty-six percent of the time the reasons given for stopping the infusion were determined to be avoidable. Half the patients whose tube feedings were checked every 4 hours had their feedings held for residual volumes less than 200 mL, when the guideline for stopping the tube feeding was a residual of greater than 200 mL [20]. Protocols for delivery of enteral feeding can avoid this.

Parenteral nutrition is associated with an increased risk of infectious complications, especially line infection, and increased cost. Strict adherence to protocols emphasizing aseptic techniques and limiting central line interruption can decrease complications. Peripheral indwelling central catheters or central subclavian or internal jugular lines should be considered and implanted permanent lines should be avoided [9]. Management of infected temporary lines is easier and has fewer complications.

HOW DO YOU PREVENT COMPLICATIONS AND MAXIMIZE BENEFITS?

Anticipating potential complications leads to early recognition, minimizes the impact of the complications, and improves outcome. Adherence to general guidelines for energy requirements, mentioned above, should help avoid overfeeding. Overfeeding can lead to a number of problems, such as cholestatic liver disease, hyperglycemia, increased infections, and worsening hypercapnic respiratory failure. When there is doubt, expired gas analysis can be used to assess caloric requirements. A respiratory quotient (R/Q) greater than 1 generally indicates overfeeding. R/Q is the quotient of mL CO_2 produced per mL O_2 consumed. Increased CO_2 production will cause a rise in the R/Q from 0.80, a normal, average steady state. Reducing total calories (glucose and fat) may benefit patients with chronic lung disease fed parenterally who develop worsening hypercapnia. Assessment of nitrogen balance (the difference between nitrogen produced and nitrogen eliminated in urine and stool) every 5 to 7 days may be useful for adjusting the protein dose. Prerenal azotemia from excessive protein administration is an indication to decrease nitrogen intake. Patient outcome following acute renal failure (creatinine greater than twice normal) does not improve with the administration of specialized formulations.

Monitoring triglycerides and adjusting continuous fat infusion to keep triglycerides less than 500 mg per dL will avoid hypertriglyceridemia. Monitoring of prealbumin because of its short half-life (i.e., 2 days) can be used to assess response to feeding in the ICU setting. Monitoring of fluid and electrolytes is essential particularly in patients receiving TPN to avoid volume overload. Deficiencies in potassium or calcium can lead to cardiac arrhythmias. Hypophosphatemia can precipitate rhabdomyolysis, severe muscle weakness, and respiratory failure. Hypomagnesemia can cause muscle weakness and even seizures. Zinc deficiency can lead to impaired wound healing, diarrhea, and cutaneous anergy. Routine monitoring of vitamins and minerals in patients on short-term parenteral nutrition support is not useful because deficiencies are usually only associated with long-term therapy. Monitoring on a selected case basis when there are clinical signs or symptoms of a vitamin deficiency (e.g., hyperkeratosis [vitamin A], megaloblastic anemia [folate/vitamin B_{12}]) is more practical. Although liver enzymes should be monitored weekly to determine if biliary or liver disease has developed, specialized formulations are not indicated unless there are signs of encephalopathy [9].

WHAT IS THE IMPORTANCE OF PROVIDING SPECIAL KEY NUTRIENTS?

Effects of special nutrients on regulation of the processes of inflammation and repair and immune function have been the object of many recent studies. Although specialized nutrients added to parenteral or enteral formulas have been shown to modulate a variety of cellular responses, their precise clinical utility is still unresolved. For example, arginine is an amino acid that participates in a variety of metabolic processes, including synthesis of nitrous and nitric oxide, compounds known to protect the liver from damage in a murine model of endotoxin-induced hepatic necrosis [21], urea synthesis, lymphocyte proliferation, and wound healing. Other studies have shown that diets rich in fish oils increased survival in guinea pigs challenged with endotoxin [22,23].

The branched chain amino acids leucine, isoleucine, and valine are essential amino acids required for protein synthesis. Although improvement in nitrogen balance can be observed when these are given in combination with other essential amino acids in doses of 0.5 to 1.2 g per kg per day, their efficacy in improving patient outcomes remains to be defined [9,24].

The importance of glutamine to normal cellular function and its unique function in amino acid metabolism, in both health and disease, has recently been elucidated [25]. The skeletal muscle-free amino acid pool is 61% glutamine, and accelerated mobilization of glutamine occurs during catabolic states. In such states, glutamine depletion occurs despite

administration of standard parenteral amino acids, which do not contain glutamine because of their instability in aqueous solution. In rats, decline of the intracellular pool of glutamine in skeletal muscle has been shown to correlate with skeletal muscle protein degradation. The majority of glutamine released from skeletal muscle is taken up by intestinal cells. Rat studies have shown that glutamine-supplemented parenteral nutrition improves gut mucosal metabolism and nitrogen balance in sepsis and also increases villus height and mucosal thickness in starved rats, suggesting that mucosal barrier defense is improved [26,27]. However, in humans, a randomized trial of glutamine supplementation in parenteral nutrition detected no difference in infectious complications or median length of hospital stay between groups [28].

Addition of specialized key nutrients to enteral formulas to enhance immune function has been suggested for the reasons outlined earlier. A meta-analysis of 12 studies that used either of the two most common commercially available enteral feeding preparations enriched with the "immunonutrients" arginine and omega-3 fatty acids concluded that they had no effect on mortality [29]. However, significant reductions in infection rates, ventilator days, and hospital length of stay in patients fed these formulas are sufficient to justify their use. These benefits were most pronounced in surgical patients, although they were present in all groups of patients [29]. Although the relative efficacy of any single immune-enhancing component versus its combination with another is impossible to state on the basis of the presently available evidence [30], commercially available formulas fortified with "immunonutrients" are clearly beneficial and we recommend their use [2].

Although the administration of growth hormone can attenuate the severe catabolic state induced by the metabolic response to injury, surgery, and sepsis, two randomized placebo-controlled clinical trials found that in-hospital mortality, length of stay in the ICU, and duration of mechanical ventilation were greater in patients receiving growth hormone [31].

In summary, nutrition support should be considered essential to the treatment of any critical illness. We have provided some useful guidelines for the nutritional assessment, estimation of energy requirement, route of nutrient delivery, estimations of the effectiveness of nutrition provided in critically ill patients, and also suggested some practical points to simplify delivery and avoid associated complications related to parenteral and enteral feeding.

CHAPTER 191 ■ PARENTERAL AND ENTERAL NUTRITION IN THE INTENSIVE CARE UNIT

DAVID F. DRISCOLL AND BRUCE R. BISTRIAN

Nutritional and metabolic support during acute illness is an integral part of the clinical care of critically ill patients. The significance of such interventions is predicated on three main factors: (a) degree of metabolic stress; (b) dysfunction of major organ systems; and/or (c) presence of protein-calorie malnutrition (PCM). In the first case, metabolic stress can arise from a variety of sources including, for example, severe injuries sustained by major trauma such as closed head injury, multiple long-bone fractures, third-degree burns of greater than 25% body surface area, and severe sepsis and stress of lesser intensity such as thoracoabdominal surgery, pulmonary infection, systemic infection, or any source of active systemic inflammation. Often, more than one form of metabolic stress may be present that can accentuate and/or dysregulate the injury response. Concerning the second factor, metabolically stressed patients may develop acute failure of vital organs during the critical care period or have underlying chronic end-organ dysfunction. Acute or chronic disease, particularly of the cardiopulmonary, renal, or hepatic system, often further complicates the clinical course and requires modification of nutritional support during critical illness, especially in the elderly [1]. Finally, the presence of preexisting or the likely early development of PCM is key to identifying those patients who will derive the greatest clinical benefits from nutritional and metabolic support therapy.

Approximately 35 years ago, the prevalence of PCM in hospitalized general medical and surgical patients was reported to be as high as 50% of all adult admissions to a large teaching hospital [2,3]. More recent reports continue to document high rates of malnutrition in hospitalized patients [4–9]. When moderate to severe PCM accompanies severe metabolic stress, an increase in nutrition-related complications can be expected to occur, including wound dehiscence, nosocomial infections, and severe fluid, electrolyte, and acid–base disturbances. During stress, substantial catabolism of both endogenous and exogenous protein and energy occurs coincident with the injury response. In support of the metabolic response to injury, the breakdown of body protein, principally from muscle and connective tissue stores, supports amino acid and energy needs to mount various beneficial components of the systemic inflammatory response by the release of amino acids for accelerated synthesis of such proteins as leukocytes, hepatic acute phase and cellular proteins, and wound tissue, and gluconeogenesis for the optimization of energy requirements for such tissues as cardiac, leukocytes, and fibroblasts. An assessment of the degree of this response can be estimated by application of the catabolic index [10]. However, if protein calorie malnutrition complicates injury or infection, the systemic inflammatory response is less intense than that found in normally nourished individuals with a similar degree of injury. Consequently, the degree and duration of the metabolic response, with respect to nitrogen breakdown, is greatly diminished. In terms of the degree of catabolism, for example, a malnourished elderly patient with significant catabolic injury could manifest nitrogen losses that may be as a much as 50% less than normally nourished younger counterparts with the same injury [1]. Although this might imply a less severe catabolic response sparing lean tissue, the pathologic consequences are more severe as a result of the muting of the beneficial aspects of the systemic inflammatory response, and these adverse effects tend to occur sooner. Moreover, the time course to intervene with nutritional and metabolic support to limit the likelihood of nutrition-related complications is also shortened by as a much as 50% (i.e., 5 to 7 days) in the moderate to severely malnourished versus normally nourished individuals (i.e., 7 to 10 days) with the same metabolic stress. Ultimately, the consequences of ongoing depletion of the metabolically active body cell mass in the malnourished reduce the ability to recover from acute illness, can be associated with severe deficiencies in minerals that are typically found in muscle (potassium, magnesium, and phosphorus), and often lead to severe impairments in immunocompetence, wound healing, and organ repair.

Once the decision to provide nutrition support is made, parenteral or enteral nutritional therapies are available options. In every case, if the gastrointestinal tract is functional and the patient is hemodynamically stable, enteral nutrition (EN) should be instituted. However, if significant malnutrition also exists and a prolonged recovery is anticipated, it should be recognized that the time frame to achieve eucaloric intakes for EN often takes much longer due to associated gastrointestinal intolerance, compared with parenteral nutrition (PN). As central venous access is generally necessary during critical illness, EN support can often be supplemented with PN [11] so as to avoid the prolongation of caloric deficits during acute illness, which are particularly of concern in initially malnourished patients or the most critically ill with closed head injury, multiple trauma, major burns, and severe sepsis. In such patients it appears that early feeding within the first 72 hours, whether by enteral, parenteral, or the combination, has the greatest impact on outcome in terms of mortality. Although mild decrements in energy balance in the critical care setting may well be tolerated and in certain circumstances appropriate, at least 1 g of protein per kg and 15 kcal per kg advancing to 1.5 g protein per kg and 20 to 25 kcal per kg as soon as possible should be the goal to avoid adverse, nutrition-related outcomes. Moreover, intensive metabolic support (i.e., the provision of electrolytes and acid–base therapy) can also be accomplished efficiently through the PN admixture. The amount of parenteral nutrients can be gradually reduced as the patient is transitioned to EN coincident with remission of the stress response and return of full gastrointestinal tolerance to tube feeding. Thus, in the intensive care unit (ICU), nutrition support is often provided to patients using both enteral and parenteral means, especially during the acute care period. The purpose of supplying both EN and PN where appropriate should not be motivated by attempts to meet protein and energy needs as soon as possible, but rather as a means of providing trophic stimulation to enterocytes and hopefully a quicker transition to full enteral feedings, while PN is used to treat severe metabolic disorders such as hypokalemia, hypophosphatemia, and metabolic alkalosis, that can only be safely and effectively addressed by the

intravenous route of administration. The greatest challenge facing the critical care clinician is to appropriately identify those patients who are in greatest need of nutrition support therapy and to provide it in a manner that is both effective and does not produce iatrogenic complications.

CLINICAL CONSEQUENCES OF DELAYING NUTRITION SUPPORT

Although at times it is difficult to pinpoint the cause and effect of nutrition-related complications during critical illness, it should be intuitively obvious that withholding nutrition will ultimately lead to death from starvation. This message was poignantly illustrated in the deaths of Maze prisoners in Belfast, Ireland, as detailed in a report from Leiter and Marliss [12] in 1982. Ten Irish Republican Army prisoners went on a hunger strike that led to their deaths over a period of 45 to 73 days of fasting. All were young lean males and the critical weight loss that resulted in death was approximately 35% calculated from the first day of the fast. It is also generally acknowledged that patients who approach 35% to 40% losses from their ideal or usual body weight through inadequate nutritional intake are at greatest risk of malnutrition-related death. Presumably, at these extreme levels of body mass depletion, both the size and function of vital organs of the viscera are considerably diminished. At some critical point, presumed to be when fat stores become limited, protein catabolism now coming from both skeletal and visceral organs accelerates. If one discontinues providing life-sustaining needs for energy, the loss of a critical mass of body protein is ultimately reached and death from organ failure is imminent.

The effects on the vital organs can be catastrophic, since oxygen consumption of the visceral organs is much higher than that of resting skeletal muscle. The imbalance between loss of skeletal muscle and visceral organ mass initially favoring visceral organs has also been suggested to explain the higher energy expenditures per body weight seen in severely depleted hospitalized patients (average of approximately 70% of ideal body weight) as a result of an approximate 10-fold difference in resting oxygen consumption between skeletal muscle compared to visceral tissues such as the liver [13]. During starvation (with adequate water intake), and in the absence of metabolic stress, a normally nourished, thin individual can survive for periods of approximately 6 to 10 weeks. In terms of total body nitrogen, it is estimated that the loss of 350 to 500 g of nitrogen is potentially lethal. In terms of body mass index (BMI), which is weight in kg per height in meters squared, it is generally considered that a BMI less than 13 kg per m^2 in males and less than 11 kg per m^2 in females is incompatible with life [14]. However, the rapidity of weight loss is also a factor, since lesser degrees of semistarvation (i.e., smaller energy deficits) are better tolerated. Table 191.1 depicts the relationship of BMI with nutritional status.

By way of comparison, the metabolically stressed patient experiences greater catabolism coincident with acute illness and can lose as much as 30 g of nitrogen per day, representing about 1 kg of lean tissue from the breakdown of lean body mass. Generally, the majority of these losses can be measured in a 24-hour urine collection as urea nitrogen and used for nitrogen balance estimation. Nitrogen balance studies assess the difference between dietary protein (nitrogen) intake and nitrogen excretion. Healthy individuals consuming an adequate diet in terms of essential nutrients including protein (0.8 g protein per kg per day) and sufficient energy to provide energy balance will be in zero nitrogen balance. That is the nitrogen in is equaled by the nitrogen out in urine (mostly) and feces, reflecting no net change in lean body mass. Net nitrogen losses in patients receiving parenteral or enteral feeding can vary from 0 to 30 g per day, depending on the extent of the injury response and the level of feeding. With the systemic inflammatory response, the utilization of protein to maintain lean body mass is impaired, making the daily requirement increase to about 1.5 g protein per kg per day. Similarly, energy requirements increase, which are offset to some degree by the reduction in physical activity characteristic of the hospitalized patient. With the development of renal dysfunction, the proportionate amounts of nitrogen found in the urine become substantially less, with a concomitant rise in blood urea nitrogen (BUN). In general, in a 70-kg male every 5 mg% change in BUN represents 2 g of nitrogen catabolized and not excreted, and 1.5 g of nitrogen for a 60-kg female, based on average total body water of 60% and 50% for males and females, respectively. Protein intakes must be adjusted to limit the rise in BUN, but nutrition efficacy should not be sacrificed to renal function beyond a reduction to the 1 g protein per kg for other than very brief periods. Renal replacement therapy such as dialysis or hemofiltration should be considered in those circumstances. Once the BUN becomes stable, even if elevated by impaired renal function, a 24-hour urine urea nitrogen excretion represents the amount catabolized over that period. The catabolic index (CI) (CI = 24-hour urine urea nitrogen − [0.5 × dietary nitrogen + 3]), adjusts for the effects of dietary intake and obligatory nitrogen loss on urinary urea nitrogen excretion. The catabolic index is the difference between measured and predicted urine urea nitrogen excretion. For example, the major catabolic stresses that produce the highest nitrogen losses and catabolic indices include burns, head injury, severe sepsis, and multiple trauma. The clinical application of nitrogen balance and CI assessments are illustrated in Table 191.2.

There are potential clinical scenarios that may affect the accuracy of nitrogen balance studies. This is especially true in patients with renal dysfunction that may reduce nitrogen output and could erroneously suggest an improvement in nitrogen balance. A correction of the nitrogen balance study can be applied to account for the nitrogen losses that do not appear in the urine, but result in an increase in the BUN concentration. Assuming nitrogen intake remains constant, two important pieces of data are required to correct for the nitrogen losses not appearing in the urine and include the patient's BUN and body weight at the beginning and end of the 24-hour collection period. These are important because most of the urea is distributed in total body water. A clinical example that applies to this method of correction appears in Table 191.3.

In terms of lean body mass, each gram of nitrogen lost represents approximately 30 g of (hydrated) lean tissue (hydration ratio: approximately 4 or 5 to 1). For patients with daily

BODY MASS INDEX AND NUTRITIONAL STATUS

Body mass index	= weight in kg ÷ (height in m)^2
Assumptions:	weight: 75 kg; height: 1.84 m
BMI	= 75/(1.84)^2
	= 22.2
Body mass index	Nutritional status
≥ 30	Obese
≥ 25 − < 30	Overweight
20 − < 25	Normal
< 18.5	Moderate malnutrition
< 16	Severe malnutrition
< 13	Lethal in males
< 11	Lethal in females

TABLE 191.2

CLINICAL APPLICATION OF THE NITROGEN BALANCE AND CATABOLIC INDEX ASSESSMENTS[a]

Nitrogen balance	$= \frac{\text{protein intake (g)}}{6.25} - (24\text{ h UUN} + 4)$ $= \frac{105\text{ g}}{6.25} - (20 + 4)$ $= -7.2\text{ g}$
Catabolic index	= UUN (g) − ($^1/_2$ × dietary nitrogen + 3) = 20 g − (0.5 × 16.8 g + 3) = 8.6 (severe stress)
< 0 no significant stress	
0–5 significant stress	
> 5 severe stress	

[a]Assumptions: 70 kg male; 105 g protein intake; 20 g UUN over 24 hours.
UUN, urine urea nitrogen.

nitrogen losses of 30 g, which represents the highest catabolic nitrogen loss in the absence of dietary protein intake, approximately 1 kg of lean tissue would be lost each day. Such losses cannot be sustained for protracted periods, and under these circumstances, nutrition support is clearly indicated within the first 24 to 36 hours even in the previously well-nourished patient to address this extraordinary rate of loss. Using cumulative nitrogen deficits of 350 to 500 g, a sustained loss of this magnitude could theoretically result in death in approximately 2 to 3 weeks, although catabolic rates usually diminish in the later weeks of injury. For the severely malnourished patient of 75% ideal body weight, one can estimate the critical survival period to be in the range of 1.5 to 2 weeks under the same circumstances. Finally, a cumulative caloric deficit of 10,000 kcal or more during acute illness has been associated with significant morbidity and mortality in the surgical ICU [15]. However, it is likely that the associated protein deficit played the larger role, since normal individuals have more than 150,000 stored calories as fat, which always makes up the greater proportion of the caloric deficit. A study in the medical ICU has shown that intakes of less than 25% of requirements were associated with a higher rate of bloodstream infections [16].

Of course, projections of survival or complications are estimates and may be highly variable depending on other factors (i.e., nutritional status, metabolic stress[es], end-organ function, and so forth). Moreover, in the clinical setting, such high outputs of nitrogen over long periods will not likely be sustained, as medical and surgical therapies will usually be successful in reducing the stress response. Furthermore, both the rate of reduction in lean body mass and the intensity of the systemic inflammatory response diminish as PCM develops. Such patients will invariably receive calories (dextrose) and electrolytes from various parenteral infusions, so that some form of supplementation is given, which also slows the loss of lean tissue. Consequently, the outcome of death from the total lack of nutrition support is rare. However, nutrition-related complications, such as impaired wound healing and immunocompetence leading to nosocomial infection, are the common proximate causes of increased morbidity and mortality under such circumstances.

IDENTIFYING PATIENTS IN NEED OF NUTRITION SUPPORT

In the ICU setting, it is often difficult to identify those patients who are at greatest risk of developing nutrition-related

TABLE 191.3

NITROGEN BALANCE CORRECTION IN RENAL DYSFUNCTION[a]

Prenitrogen balance data	
BUN = 31 mg/dL; weight = 70 kg; 105 g protein intake	
Prestudy	
Total body water @70 kg	= 42 L
Total BUN @31 mg/dL	= 42 L × 310 mg/L (or 310 mg/L) = **13,020 mg or 13 g**
Postnitrogen balance data	
BUN = 51 mg/dL; weight = 74 kg; 105 g protein intake; 24 h UUN = 20 g	
Poststudy	
Total body water @74 kg	= 42 L + 4 L = 46 L
Total BUN @51 mg/dL (or 510 mg/L)	= 46 L × 510 mg/L = **23,460 mg or 23.5 g**
Nitrogen balance	$= \frac{\text{protein intake (g)}}{6.25} - (24\text{ h UUN} + 4)$ $= \frac{105\text{ g}}{6.25} - (20 + 4)$ $= -7.2\text{ g}$
Corrected N-balance	= 13.02 g − 23.5 g urea nitrogen (blood) = −10.5 g not excreted in urine = −10.5 g (BUN) + (−7.2 g UUN) = **−17.7 g**

[a]Assumptions: Total body water = 60% (for males).
BUN, blood urea nitrogen; UUN, urine urea nitrogen.

complications due to preexisting malnutrition. Such patients are often volume overloaded due to massive administration of parenteral fluids from multiple drug therapies and often acute volume resuscitation, as well as maintenance intravenous therapy to support intravascular volume. This fluid retention and weight gain is often compounded by the hormonal consequences of the systemic inflammatory response such as enhanced insulin, aldosterone, and antidiuretic hormone secretion, which favor salt and water retention. Consequently, the weight of the patient is artificially high, and major efforts of the ICU team are often directed at reducing volume intake in order to mobilize third-space fluids. A weight history may be difficult to obtain or overlooked entirely because of more acute clinical issues. Moreover, an accurate patient weight is also important to optimize drug therapy. Under these circumstances, a moderately to severely malnourished patient may escape detection by the primary care team, and only be recognized as malnourished after fluid homeostasis is achieved, or worse, a potentially preventable nutrition-related complication, such as wound breakdown, occurs. Clearly, at this point, the opportunity to minimize such complications from expert nutrition support has passed, and the course toward rehabilitation may be long and costly.

To avoid this scenario, a more substantial effort must be undertaken to identify the patients at greatest risk. Nutrition screening programs on admission, especially by dieticians, can greatly assist in identifying these patients, but many patients, especially acute admissions for emergent care, may escape this surveillance process. In these cases, the premorbid weight is very important and should be obtained if at all possible. It will at least provide a baseline prior to the numerous medical and surgical maneuvers that may take place over the ensuing 24 to 48 hours that could dramatically change the patient's weight in the critical care setting.

If the admission weight is not obtained, then the clinician may need to estimate the patient's body weight from available hospital data. Estimations may be made based on the most recent weight recorded, and then backtracked through the medical chart using the intake and output records to reconstruct the original weight history. For critically ill patients, such records are usually reliable, and a reasonable estimate may be made. This estimate may be confirmed by subsequent discussions with the patient or family. When confirmed, the body weight can then be compared to standard measures for population-based body weight for height tables such as the ideal body weight or the BMI. A patient weight less than 85% of the ideal body weight (IBW) or BMI less than 18.5 indicates moderate malnutrition. Severe malnutrition would be considered likely if weight is less than 75% of IBW or BMI is less than 16 kg per m^2. Thus, a greater sense of urgency to intervene with nutrition support is present under these conditions and should be undertaken within several days of the acute injury. If the patient is deemed well nourished, then intervention may be delayed unless the systemic inflammatory response is severe (i.e., major third-degree burns, closed head injury with a Glasgow Coma Score less than 8, multiple trauma with very high acute physiology and chronic health evaluation [APACHE] or injury severity scores, severe pancreatitis with a positive CT scan and more than three Ranson criteria, and so forth). Then, because the systemic inflammatory response is likely to endure beyond 1 week, very early nutritional support is indicated. The serum albumin level, which reflects the presence of a recent systemic inflammatory response, is not often helpful in this setting because the invariable systemic inflammatory response and common disturbances in volume status make hypoalbuminemia universal. However, severe hypoalbuminemia (less than 2.4 g per dL) usually reflecting a greater degree and/or longer duration of systemic inflammation identifies a population at much greater nutritional risk. Finally, if the weight-based data are not reliable, a formal nutrition support consult or indirect calorimetry may be indicated.

NUTRITIONAL REQUIREMENTS

Protein

The amount and type of protein administered to the critically ill depend on the clinical circumstances of each patient. Nevertheless, there is an upper limit to the quantity of protein that can be given based on net protein utilization during metabolic stress. In general, providing protein in amounts above 1.75 g per kg per day exceeds the capacity of the body to use the administered protein to increase synthesis [17,18]. Amounts above this level of intake are essentially completely converted to urea and serve no nutritional purpose. At intakes ranging between 0.6 to 1.75 g per kg per day, each increment of intake increases net protein synthesis at a cost of increasing the proportion going to ureagenesis. In patients with nitrogen accumulation disorders (of either renal or hepatic origin), a compromise must often be made between greatest rates of net protein synthesis and lowest rates of urea or ammoniagenesis. For example, as the BUN increases, especially above 100 mg%, the risk of uremic complications increases, including bleeding, or, increasing the production of ammonia in encephalopathic patients. Generally, the optimal protein intake in critically ill patients is given at twice the recommended daily amount (approximately 0.8 g per kg per day) of normal adults, at approximately 1.5 g per kg per day. With renal impairment, at least 1 g per kg should be provided and greater amounts given if tolerated or dialysis is initiated. In patients with liver failure at least 1 g per kg of standard protein should be provided and up to 1.5 g per kg if tolerated. This is done recognizing the overall impairments in protein utilization that accompanies metabolic stress, as well as the heightened needs during catabolism.

The type of protein administered varies with the patient's condition and the route of administration. For PN support, standard protein mixtures are given in their monomeric form as individual crystalline amino acids and levorotatory isomers, which comprise the essential amino acids (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine) and the nonessential amino acids (alanine, aminoacetic acid, arginine, cysteine, proline, serine, and tyrosine). In standard amino acid formulations, the branched-chain amino acids (leucine, isoleucine, and valine) comprise approximately 18% to 25% of the amino acid profile. Collectively, they are available in commercial intravenous solutions in concentrations ranging from 3% to 15%. On average, for every 6.25 g of the amino acids in the mixture, 1 g of nitrogen is available, although this number is lower with a number of the specialized amino acid formulas. The caloric value of protein is 4.1 kcal per g, and such calories should be counted in critically ill patients when tracking energy intakes.

Specialized amino acid mixtures have evolved that include selected profiles. For example, renal formulations have been devised that principally provide the essential amino acids (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine), while hepatic formulations have eliminated or reduced aromatic amino acids (phenylalanine, tryptophan, and tyrosine) and the sulphur-containing amino acid methionine and increased the proportion of branched-chain amino acids (BCAAs) (isoleucine, leucine, and valine). However, the routine use of these expensive formulations in these conditions over conventional or standard amino acid mixtures has not been convincingly demonstrated, and in certain cases when used to meet full protein needs, may be harmful [19]. For patients with nitrogen accumulation

disorders, the use of branched-chain enriched amino acid formulas in the range of 45% to 50% of the total amino acid profile have been shown to improve protein utilization when total amino acid intakes are given in the 40- to 70-g range and may reduce the risk of encephalopathy when compared to a standard formula. Finally, other attempts at modifying the profiles of amino acid mixtures, such as the extemporaneous preparation by the hospital pharmacy of sterile glutamine in total parenteral nutrition (TPN), have shown some benefits in selected settings but they require a considerable level of parenteral compounding expertise. In addition, in order to safely provide this compounded sterile preparation, ongoing quality assurance measures as outlined by the *United States Pharmacopeia* must be performed and therefore such practices are subject to Federal Drug Administration oversight [20]. A glutamine-containing dipeptide formulation, which is commercially available in Europe, has been the subject of some positive trials, but its ultimate place in the care of the critically ill is not yet established.

For EN support, protein is typically provided in either an oligomeric form as protein hydrolysates containing various peptides ranging from di- and tripeptides to polymers of eight or more, or as whole protein usually provided as casein or in its polymeric form as, for example, casein hydrolysates. Less commonly, they can even be provided as the individual amino acids. Most formulations contain a fixed amount of protein in the range of 30 to 40 g per L and thus for fluid-restricted patients in the ICU cannot meet the protein needs of most patients. Alternatively, more concentrated enteral formulae exist that may be used, or the clinician may opt to add protein modules to conventional products to increase protein density. However, in either case, both approaches result in higher osmolarities that may affect gastrointestinal tolerance.

Carbohydrate

The amount and type of energy provided to improve the utilization of the prescribed protein intake also varies with the individual patient. As well, there are physiologic limits to the amounts given, beyond which significant complications are more likely. For most patients, providing 25 kcal per kg per day is sufficient to support the protein synthetic response to metabolic stress. This is the total energy expenditure of most critically ill, postoperative patients. Amounts above 30 kcal per kg per day exceed the energy expenditure of most hospitalized patients except those with severe burns, closed head injury, and multiple trauma where measured caloric expenditures are usually 30 to 40 kcal per kg. However, providing nutritional support in amounts greater than 30 kcal per kg leads to higher rates of hyperglycemia in both types of patients; in the postoperative setting, due to overfeeding, and in the trauma unit, due to the severity of systemic inflammatory response. Although better glycemic control through the use of insulin would be one way to reduce the infectious risk in the latter instance, it is interesting to note that in several trials of immune-enhancing diets that improved outcomes and reduced infection rates have been seen at energy intakes at 30 kcal per kg or less, in diets that are likely to have been hypocaloric [21]. For carbohydrates, the physiologic limits are linked to the normal endogenous hepatic production rates for glucose, which approximate 2 mg per kg per minute or about 200 g per day for a 70-kg healthy adult [22]. This is the amount of glucose needed by the body to meet the obligate needs of tissues dependent on glucose (i.e., brain, renal medulla, red blood cells, and so forth), and it is derived from body stores of glycogen (glycogenolysis) or made from noncarbohydrate sources such as from protein breakdown to gluconeogenic amino acid precursors (gluconeogenesis). Glycogen stores are limited and therefore can be rapidly depleted during acute metabolic stress (i.e., within 24 hours) [23]. Thus, the major source of glucose in the hypocaloric state following stress comes from gluconeogenesis, and higher amounts than usual are produced to support the metabolic response to injury, accelerated by the hormonal milieu produced by the increased secretion of catecholamines, glucagon, cortisol, and growth hormone [24]. The judicious provision of nutrition support is designed to attenuate the extent of protein breakdown without exacerbating significant changes in nutritional and metabolic homeostasis. Similar to the case with protein, as carbohydrate intake increases net oxidation occurs, but with an increasing proportion going to nonoxidative pathways (glycogen synthesis and particularly de novo lipogenesis). However, glycogen synthesis is limited by available storage capacity of about 500 g in normal adults and perhaps 1,000 g in a critically ill patient receiving TPN, with its resultant very high insulin levels. There is effectively no limit for fat storage. The optimal balance is at intakes at about 400 g per day, with maximal glucose oxidized of 700 g per day. Thus, in a 70-kg adult, glucose to amino acid of 2:1 TPN formula providing glucose at 400 g per day and 1.5 g of protein per kg per day represents about 25 kcal per kg per day.

For PN, glucose is the only reasonable carbohydrate fuel or energy source that is widely available for intravenous administration. Generally, it is provided as a monohydrate and its caloric equivalent is therefore 3.4 kcal per g rather than 4 kcal per g for its anhydrous form. It is commercially available in a variety of concentrations ranging from 2.5% to 70% in sterile water for injection. Glucose is the primary energy source of any PN admixture prescribed for central venous alimentation and typically is given in final admixture concentrations from 10% to 25%. Higher concentrations can be given, but are associated with an increase in the number of dextrose-associated complications if the amounts given are too large.

For EN, carbohydrates may be given in a number of chemical forms. For example, they can be given as the monosaccharide, glucose, frequently found in monomeric or elemental formulas. Alternatively, in less refined formulas, carbohydrates may be provided as oligosaccharides, such as hydrolyzed cornstarch, or more complex polysaccharides, such as corn syrup, are frequently used. The selection of a particular enteral formula is largely based on a number of clinical factors such as gastrointestinal function, fluid status, and end-organ function.

Fat

Lipids serve as an alternative energy source that is used to substitute for a portion of the carbohydrate calories. PN support prescribed in this fashion, it is referred to as a total nutrient admixture, all-in-one or 3-in-1 mixed-fuel system [25]. As with protein and carbohydrates, the amount and type of lipids used will vary depending on the clinical condition of the patient. For the most part, long-chain triglycerides (LCTs) derived from vegetable oils have been the principal source of lipid calories used in the clinical setting. Specifically, soybean oil, which is rich in polyunsaturated omega-6 fatty acids, has been extensively used, especially for intravenous nutrition. It is a major source of the essential fatty acids, linoleic, and alpha linolenic acids. However, ill-considered prescribing habits, where either excessive quantities or infusion rates have been used, have led to clinically significant adverse effects such as immune dysfunction and pulmonary gas diffusion abnormalities in critically ill patients. The excessive administration of intravenous lipid emulsions (IVLE) can accumulate in the liver and impair Kupffer cell function, thus interfering with a major component of the reticuloendothelial system [26,27]. In addition, lipid injectable emulsions are composed of various oils that serve as prostaglandin precursors that are immunosuppressive,

especially those of the n6 series such as PGE_2, which suppresses lymphocyte proliferation and natural killer cell activity [28], and can reverse hypoxic vasoconstriction in patients with adult respiratory distress syndrome [29]. In contrast, the oxidation and subsequent plasma clearance of lipids is significantly improved when IVLEs are given over 24 hours versus briefer intervals [30]. Impaired plasma clearance of lipids can result in fat overload syndrome and is a particularly significant clinical issue in children [31–42]. Fat overload syndrome can result from the administration of a stable fat emulsion over brief intervals [29,30,43–47] or from more modest doses of lipid that might be physicochemically unstable [48]. In fact, a review of the literature regarding *stable* fat emulsions has concluded that virtually all of the adverse effects associated with LCTs have occurred when the infusion rate exceeds 0.11 g per kg per hour [49]. For a 70-kg adult this limit would be approximately 13 hours for 500 mL of 20%, which makes 3-in-1 admixture infusions safer and easier to administer as a continuous infusion over 24 hours rather than as a separate "IV piggyback" over a brief period, which would require an infusion rate almost twice as fast. In addition, piggyback infusion of lipids is not recommended beyond 12 hours [50].

Recent reports regarding the clinical significance of unstable fat emulsions have emerged. On December 1, 2007, the United States Pharmacopeia (USP), which is recognized by the Food and Drug Administration (FDA) as the official compendium for drug standards, was the first pharmacopeia worldwide to establish globule size limits for intravenous lipid emulsions [51]. This is notable because intravenous lipid emulsions had been used clinically in the United States for more than 30 years (and Europe for more than 45 years), when most drugs have official USP specifications within 5 years of FDA approval [52]. The USP limits specified two size limits: (i) mean droplet size (MDS < 0.5 µm) and (ii) large diameter tail, expressed as the percent of fat globules > 5 µm ($PFAT_5 < 0.05\%$). The primary motivation for these limits was to avoid the development of microvascular pulmonary embolism from an excessive population of large-diameter fat globules indicating instability of the emulsion.

Around the time the USP announced its intentions to adopt these limits in 2004 [53], a major lipid emulsion product also changed its conventional packaging from glass to plastic containers. With this change in packaging, the lipid emulsion product now failed the large-diameter globule limits of the USP [54]. Lipid emulsions failing USP limits were also shown to produce less stable emulsions when packaged in syringes for neonates [55], when mixed in TPN admixtures [56] and when used in a multichamber bag premixed for TPN therapy [57]. Moreover, lipid emulsions not meeting pharmacopeial limits were also shown to be associated with significant hypertriglyceridemia in premature neonates when compared to lipid emulsions meeting USP limits [58], although this has not been confirmed in a randomized clinical trial. Finally, in animal studies lipid emulsions failing USP limits were shown to be hepatotoxic [59]. A recent study intended to explore the extent of physiologic damage from the infusion of unstable lipid emulsions produced evidence of hepatic accumulation of fat associated with oxidative stress, liver injury and a low-level systemic inflammatory response [60].

Triglyceride clearance is maximal at serum triglyceride levels of up to about 400 mg per dL, and patients who initially have serum triglycerides at this level will tolerate even lesser amounts of fat without adverse consequences. In patients who have normal serum triglyceride levels at initiation of TPN, serum triglyceride levels are usually not monitored. For those with levels greater than 200 mg per dL it is reasonable to check the triglyceride again after a stable regimen has been attained with lipids below 0.11 g per kg per hour. Stable levels below 400 mg per dL are acceptable while receiving lipid emulsions.

For PN therapy, soybean oil emulsions continue to dominate the United States market. However, there are a number of different lipid compositions presently available in Europe and under investigation in the United States [61]. They include various mixtures of soybean oil with medium-chain triglycerides (MCTs), olive oil, and fish oil. In nearly every case, soybean oil is included in sufficient proportions to provide adequate amounts of the essential fatty acids [62].

For EN therapy, a number of the lipid types available for parenteral use in Europe are widely available in the United States for enteral administration in complete nutritional diets. Typically, they contain 30% to 40% of the total calories as fat and often contain blends of corn and soy oil. However, in the more specialized enteral formulas, MCTs, fish oil, and even structured lipids are available. Moreover, in some of these products the fat content is either severely restricted (i.e., 3% to 10% of total calories for the fat-intolerant patient) or may be as high as 55% for the patient with pulmonary compromise.

Volume

The maintenance of fluid homeostasis is an important goal in critical care. At times, many patients in the ICU become severely volume-overloaded as a consequence of parenteral fluid administration and the fluid-retentive state characteristic of critical illness [63–65]. For this reason, when assessing fluid status, it is important to bear in mind the usual contribution of water to body weight or total body water (TBW) of the patient under normal, unstressed conditions. In normal adults, TBW comprises approximately 50% to 60% of body weight. As lean body mass is hydrated in a ratio of approximately 4 parts water to 1 part protein, lean tissue is a significant component of TBW. In the clinical setting, acute changes in weight over short intervals primarily reflect net changes in TBW which almost never reflect lean tissue gains in the hospital setting. For example, a 10% increase in weight over 24 to 48 hours represents a proportional increase in TBW and may be associated with adverse clinical consequences, such as greater ventilator dependence, impaired cardiovascular function, and disturbances in electrolyte homeostasis. Even when the patient is considered euvolemic, the contributions to volume from nutrition support are generally limited to approximately 25 mL per kg per day, as other reasons for fluid administration are usually indicated.

Depending on the volume assessments by the primary care team, the amount of nutrition support that may be provided by either PN or EN may be affected. The most significant effect occurs when volume restrictions are imposed. When this happens, hypocaloric nutrition is usually provided due to the limitations associated with caloric density. Caloric or macronutrient density is the sum total of calories from protein, carbohydrates, and fat, expressed in kilocalories per milliliter (kcal per mL). Generally, the caloric density of typical formulations routinely prescribed for either PN or EN support is approximately 1 kcal per mL, but special forms of each therapy are available that reasonably allow up to 1.5 kcal per mL to be formulated. However, most enteral formulations are commercially available in fixed concentrations and therefore are less easily manipulated to the specific needs of the critically ill patient than with the PN admixture. For example, with a 1,000 mL fluid restriction allotted for PN support, the increased macronutrient density could be achieved to attain eucaloric nutrition for adult patients weighing up to 60 kg (25 kcal per kg). Of course, these special dosage forms are generally more expensive than conventional products, and the cost-to-benefit ratio has not been fully demonstrated. The usual parenteral formula provided when fluid restriction is necessary is a more standard PN admixture [66], providing 70 g of amino acids and 210 g of glucose (A7D21) approximating 1,000 kcal in a 1 L final volume when

[a]Calories from the hypocaloric regimen consists of 1 g/kg/day of protein and 15 kcal/kg/day total or approximately 50% to 60% of needs. Hypocaloric regimens that are intended as permissive underfeeding are often intended for patients whose present weight is within 10% of ideal body weight.
[b]Assumes a stock bottle of 15% amino acids at 4.1 kcal/g.
[c]Assumes a stock bottle of 70% hydrated dextrose at 3.4 kcal/g.
[d]Assumes a stock bottle of 20% lipid emulsion at 9 kcal/g and providing approximately 20% of total calories.
[e]Final concentration of nutrient in 1,000 mL of total parenteral nutrition fluid.
From Driscoll DF: Formulation of enteral and parenteral mixtures, in Pichard C, Kudsk KA (eds): *Update in Intensive Care Medicine*. Brussels, Springer-Verlag, 2000, pp 138–150, with permission.

compounded from the standard 10% amino acid (700 mL) and 70% dextrose (300 mL) stock solutions, and is usually given for short periods of up to 10 days. Such a formula offers a compromise of the usual desired protein and caloric goals and may provide for a clinical outcome not distinguishable from higher protein, eucaloric regimens [67]. Tables 191.4 and 191.5 provide examples of PN formulations that may be used in the acute critical care setting in adult patients who are fluid restricted (i.e., 1,000 mL for TPN), whose regimens are often hypocaloric for clinical and practical reasons (see Table 191.4), as well as for goal amounts of nutrients in TPN in the absence of fluid restrictions [68]. A recent analysis of highly concentrated TPN admixtures, using a 16% crystalline amino acid solution containing lipid injectable emulsions in eucaloric amounts, showed them to be stable for up to 30 hours with a net fluid savings of approximately 20% compared with conventional 10% amino acids [69]. Patient-specific PN therapy for pediatric patients (premature, neonate, infant, and adolescent) may be devised using specific practice guidelines [70].

Electrolytes

There are seven key electrolytes that must be monitored and provided as necessary in nutritional admixtures. In some cases, certain electrolytes must be given in *standard* quantities as part of the recommend dietary allowance, while others are given in *variable* amounts and replaced according to the clinical needs of the patient. However, in both cases, the daily requirements can be highly variable especially during acute illness for a variety of reasons, including drug therapy [71,72]. As well, in all cases certain electrolytes may be deliberately omitted because of retention disorders associated with certain disease states. This, of course is more difficult to accomplish with enteral formulas that contain fixed amounts of nutrients and electrolytes. Nevertheless, avoiding the consequences of wide fluctuations in serum electrolyte concentrations that may assume clinical significance in the critical care setting is an important and necessary goal.

[a]Calories from the eucaloric and euvolemic regimen consists of 1.5 g/kg/day of protein and 25 mL/kg/day respectively. Eucaloric and euvolemic regimens are in conformance with the ASPEN Guidelines for safe total parenteral nutrition formulations and intended for patients whose present weight is within 10% of ideal body weight.
[b]Assumes a stock bottle of 15% amino acids at 4.1 kcal/g.
[c]Assumes a stock bottle of 70% hydrated dextrose at 3.4 kcal/g.
[d]Assumes a stock bottle of 20% lipid emulsion at 9 kcal/g and providing approximately 25% of total calories.

Standard Additives

Calcium. Approximately 98% of total body calcium is present in the skeleton. Thus, the extracellular concentration in plasma is but a fraction of total calcium stores and is tightly regulated by parathyroid hormone. As absorption of calcium from the gastrointestinal tract diminishes because of impaired absorption or decreased or absent intake, and serum levels begin to fall, the parathyroid glands sense these changes and secrete parathormone that promotes calcium mobilization from bone to restore normal serum concentrations. However, critical illness disturbs normal calcium homeostasis and mild depressions of total and free calcium concentrations are common [73]. The parenteral equivalent of the recommended dietary allowance (pRDA) for adults is about 25% of the oral recommended dietary allowance (RDA) or 200 mg (10 mEq or 5 mmol) of elemental calcium daily. Higher amounts may be used if needed when seeking to maintain calcium at the lower limit of normal, but this does increase the risk of incompatibility with phosphate salts that could produce fatal pulmonary emboli [74–76]. Therefore, if higher amounts are needed, it may be necessary to use fat emulsion-free formulas that allow greater amounts of calcium and phosphate to be infused safely. The other alternative, separate infusions of calcium should be done with great care especially if given by the peripheral veins, as extravasation injury can be severe [77–79]. In addition, the separate administration of parenteral calcium may be incompatible as a coinfusion with other common infusions applied in the critical care setting such as sodium bicarbonate. Moreover, if parenteral calcium is given intermittently and the same intravenous line is to be used for other medications, it should be flushed with saline or other suitable parenteral fluid (i.e., D_5 W) immediately following termination of the calcium infusion. Parenteral forms of calcium are commercially available in three forms, including the gluconate, acetate, and chloride salts. Of these, the gluconate form is preferred in PN admixtures, as it is least capable of forming insoluble products. However, for immediate delivery of calcium in emergency situations such as severe hypocalcemia, the chloride form is the best form for bioavailability reasons, although it is the most reactive salts with respect to compatibility with nutrient formulas and therefore should not be employed when compounding TPN formulas.

Magnesium. Another predominant intracellular cation, magnesium, plays a pivotal role in calcium metabolism. For parathyroid hormone to be secreted in response to hypocalcemia, magnesium is required [80]. In certain instances, corrections of serum magnesium concentrations have been sufficient to normalize hypocalcemia [81]. Such responses have been viewed as an indication of the extent of magnesium deficiency [82]. Furthermore, similar to calcium, hypomagnesemia is commonly seen in critical illness, and the goal is similar (i.e., to maintain levels at about the lower limit of normal). The pRDA is about 33% of the oral RDA or 120 mg (10 mEq or 5 mmol) for elemental magnesium per day. The only parenteral form of magnesium available is as the sulfate salt.

Phosphorus. Phosphorus is an essential element involved in numerous life-sustaining metabolic processes. For example, if omitted from a PN admixture, a life-threatening hypophosphatemia may ensue within days of initiating therapy. Like magnesium and calcium, it is too predominantly found in the intracellular compartment. However, because its gastrointestinal absorption is highly efficient, the pRDA for phosphorus is the same as its oral RDA at 1,000 mg (30 mmol) daily. The use of milliequivalent units to describe phosphorus concentrations in a solution is often mistakenly applied. At this time, the only parenteral form of phosphorus commercially available in the United States is a mixture of inorganic salts of monobasic ($H_2PO_4^-$) and dibasic (HPO_4^-) phosphate ions. Milliequivalents are defined as the molecular weight (in mg) divided by the valence of a single ion, which is determined by the pH of the final solution. As the pharmaceutical dosage form is a mixture of two ions and has a finite yet variable pH range, the dosage form cannot be accurately described in mEq units. However, because sodium and potassium are the accompanying anions, it has become traditional to order them in terms of mEq units where, for example, 30 mmol of phosphorus is found in about 40 mEq of the commonly available formulations.

Variable Additives

Sodium. Sodium is often prescribed in daily amounts ranging from 60 to 100 mEq each day. However, certain clinical conditions preclude the use of sodium beyond minute quantities (i.e., 0 to 20 mEq per day) such as found with florid congestive heart failure, end-stage liver disease, and during attempts to reduce massive volume overload characterized by extensive third-spacing of fluids by volume restriction and active diuresis. In contrast, patients with severe sodium deficits can require daily amounts that may be as much as three to four times higher than typical quantities given to those without sodium restrictions. There is limited to no impact of sodium amounts on nutritional efficacy. Parenteral forms of sodium are available as chloride, acetate, and phosphate salts.

Potassium. Potassium is often prescribed in daily amounts ranging from 40 to 80 mEq each day. As described earlier, there are extreme clinical conditions that may require either severe restriction or expansion of the daily dose so that ranges of potassium intake may be from 0 to 400 or more mEq per day. For instance, a severe amphotericin-induced renal loss of potassium of 100 mEq per L with a 4 L urine output can be managed by placing an equivalent amount in the parenteral formula so long as close monitoring of potassium in the serum and urine output is provided. In all cases, serum potassium concentrations should be closely monitored, as the safe clinical range is narrow and levels outside may produce severe and even life-threatening cardiovascular complications. Like sodium, parenteral forms of potassium are available as chloride, acetate, and phosphate salts.

Chloride. Chloride salts are widely used in nutrition support. Most often they are provided as sodium and potassium salts and quantitatively constitute the majority of anions present in nutritional formulations. In the past, an emphasis on chloride salts with parenteral crystalline amino acid formulations had tended to produce an iatrogenic metabolic acidosis. However, these formulations have since been revised and balanced with an appropriate amount of acetate ions. Thus, it is not necessary to include the inherent concentrations of chloride and acetate present in amino acid products in the additive calculation for the final PN admixture.

Acetate. Acetate salts are primarily used when clinically indicated for the treatment of metabolic acidemia. They are the only suitable alkalinizing salt for use in nutritional formulations. With respect to alkalinizing power, acetate is equivalent to bicarbonate, but this requires cellular metabolism to be effective. Bicarbonate salts should never be used in PN admixtures as they can form insoluble carbonates with calcium ions that are present in most nutritional admixtures and as such could result in the formation of fatal pulmonary emboli [83].

Trace Minerals

To provide a balanced nutritional formulation, trace minerals are generally included in most nutritional formulations. These

include chromium, copper, manganese, selenium, and zinc. In addition, iodine, and molybdenum may also be present in certain formulations. However, for most acute situations, the absence of trace minerals for brief periods (days to weeks) will not produce clinically significant adverse effects. In contrast, the absence of trace minerals in the patient receiving long-term PN support may lead to significant deficiency [84]. However, since manganese is excreted in bile, there is some concern about manganese overload when chronically provided to patients receiving long-term home TPN. Iron is a special case, since hypoferremia is an invariable consequence of the systemic inflammatory response. Furthermore, large amounts of parenteral iron supplementation may worsen septic states. For this reason, iron is not usually provided in TPN formulas during critical illness and when provided to nonseptic patients in home, PN should only be provided when clinically necessary, since iron overload can result in patients with short gut syndromes who have substantial enteral intake. Iron is incompatible in fat emulsion-containing formulas.

Vitamins

Multivitamins are an essential component of all nutritional formulations. This is particularly true for PN formulations. During the national vitamin shortage that occurred in the summer of 1988, three patients died as a result of receiving vitamin-free PN in a matter of 3 to 5 weeks [85]. Ultimately, the cause of death was related to acute thiamine deficiency producing a refractory lactic acidosis. As a water-soluble vitamin, thiamine is an important cofactor in the entry of pyruvate into the Krebs cycle as well as facilitating the processing of glucose within the Krebs cycle. In the absence of thiamine, pyruvate cannot enter the Krebs cycle and is therefore converted to lactic acid. The administration of hypertonic dextrose, the major energy component of PN therapy, accelerates the consumption of thiamine and thus accentuates the clinical course of the condition. Therefore, multivitamins are an essential part of any nutrition support regimen.

The Food and Drug Administration has mandated a change in the composition of adult parenteral multivitamins after nearly 30 years of clinical use [86]. The concentrations of four vitamins (thiamine, pyridoxine, ascorbic acid, and folate) were increased by 50% to 100% of previous amounts and for the first time, vitamin K has been added at 150 mcg per vial. This latter addition may well have some impact on therapeutic doses of warfarin for full anticoagulation as well as for low-dose warfarin therapy for home TPN patients. Lastly, with respect to enteral feeding formulas, the RDA for vitamins is generally met when caloric intakes are between 1,500 to 2,000 kcal per day.

Immunonutrients

There have been a number of nutritional additives that have been alternatively given in supraphysiologic amounts in an effort to improve outcome. The main ones would include lipids composed of high concentrations of the unsaturated long-chain fatty acids (LCFA) containing n3 or n9 fatty acids, medium-chain saturated fatty acids (MCFA), and certain "conditionally essential" amino acids. Historically, soybean oil, containing polyunsaturated fatty acids (PUFAs), rich in the 18-carbon essential (cannot be synthesized endogenously) n6 fatty acid linoleic acid and n3 fatty acid alpha linolenic acid, has been the main source of fat used in lipid injectable emulsions. These fatty acids are the precursors to the true "necessary" fatty acids, arachidonic and eicosapentaenoic acids from the n6 and n3 families, respectively, whereas the n9 fatty acid, oleic acid is nonessential (i.e., can be synthesized endogenously) [87].

Unfortunately, however, the n6 fatty acids from soybean oil can be proinflammatory and potentially detrimental when provided in large amounts to the critically ill, especially in patients with adult respiratory distress syndrome [29,44–45,88–92]. Therefore, substitution of a portion of the conventional n6 fatty acids with alternative lipid fuels such as the n3 fatty acids (20- and 22-carbon PUFAs) from fish oil, or 18-carbon monounsaturated n9 fatty acids from olive oil, or saturated MCFAs from coconut oil (mostly comprises 8- to 10-carbons), may modulate the proinflammatory response. Thus, one benefit of these alternative lipid sources is a reduction in the intake of the highly vasoactive n6 PUFA precursors to ones with less pronounced effects on eicosanoid metabolism by changing the fatty acid composition of cell membranes. The n6 PUFAs produce proinflammatory eicosanoids (i.e., prostaglandins, prostacyclins, thromboxanes, leukotrienes) and increase the responsiveness of cytokines (i.e., interleukin [IL]-1, IL-6, and TNF) which subsequently lead to an increased systemic inflammatory response. Meanwhile, the n3 and n9 lipids lead to eicosanoids that are less proinflammatory and even antiinflammatory. Another benefit is related to a unique metabolic action of the substituted lipid(s) that may have favorable clinical implications. In the case of MCFAs, their metabolism is independent of carnitine transport into the mitochondria with rapid oxidation and less interference with the reticuloendothelial system (RES), while olive oil may be better tolerated with respect to liver function in certain patients receiving conventional soybean oil–based formulations [93].

Of the amino acids used in clinical nutrition, arginine and glutamine have been shown to exert favorable immune effects in patients receiving nutrition support. Arginine has been shown to stimulate T-cell function and wound healing, but may be harmful in certain patients under certain conditions depending on dose [94,95]. Thus, its role in immune enhancement has not been clearly defined, and it is most often given as part of a complex nutritional formula containing other potential immunonutrients. Nonetheless, there appears to be a correlation of demonstrable benefits at doses exceeding 4% of the total energy intake [95]. Glutamine is the most abundant amino acid in the human body, and it is an important nutrient for rapidly dividing immune cells such as lymphocytes and macrophages. Despite its abundance, serum and tissue glutamine concentrations fall during critical illness, which largely reflects its diverse needs during acute metabolic stress. Its role in clinical nutrition is also not well defined, and in a large clinical trial in ICU patients, no differences in outcomes were noted between groups receiving 20 g per L versus a conventional enteral formula that was isonitrogenous and isocaloric [96]. Data with parenteral glutamine tend to be more positive in the critically ill, which may reflect the prominent first pass clearance of enteral glutamine limiting systemic appearance of the amino acid.

DIFFERENCES BETWEEN ENTERAL AND PARENTERAL NUTRITION

Nutrition support may be provided in a variety of ways ranging from noninvasive approaches such as dietary counseling for food and oral supplements to invasive forms of therapy. Of the interventional approaches to nutrition support, these can be accomplished by aseptic placement of intravascular catheters (i.e., PN), or by extravascular devices placed into the gastrointestinal tract (i.e., EN). Each invasive form of nutrition support

has its advantages and disadvantages, and the selection of either approach must be individualized.

Routes of Administration

Enteral Nutrition Options

Like PN therapy, EN can be delivered in a variety of ways with some distinct advantages of one access route over the other. The options include gastric, duodenal, and jejunal placement of various enteral feeding catheters. The simplest technique is the nasogastric placement of a feeding tube into the stomach. However, this approach is often associated with the greatest degree of gastrointestinal intolerance. A higher degree of successful feeding is likely with fluoroscopic, endoscopic, or surgical placement of the feeding catheter beyond the ligament of Treitz. Furthermore, enteral feeding catheters placed in the upper jejunum may even allow feeding in patients with severe pancreatitis [97]. However, placement of feeding tubes in the jejunum postinjury rarely occurs spontaneously and generally requires fluoroscopic or endoscopic assistance, which is expensive and delays feeding.

Parenteral Nutrition Options

PN may be provided by either peripheral or central venous access. Peripheral venous access is clearly less invasive and has minimal complications. The most significant complications are related to maintenance of the patency of the venous catheter and thrombophlebitis and the limited use of each venipuncture site for a relatively short duration. Most peripheral vein catheters will last between 48 to 72 hours from the time of the initial insertion, and therefore a systematic rotation of other infusion sites must be performed. Ultimately, however, the number of viable peripheral venipuncture sites is limited and generally of little practical value in the ICU setting. Moreover, due to the osmolarity limits of these low-flow blood vessels, very large fluid volumes are required to approach protein and energy requirements for most patients, which is not practical in the ICU setting. Peripherally inserted central (venous) catheters (PICCs) generally last longer and can even be used to provide hypertonic PN admixtures. However, the inability to change catheters over guidewires for PICCs for suspected infections, and a greater likelihood of mechanical complications makes this a less desirable alternative to a central venous catheter.

By far, central venous catheterization is most commonly used to deliver PN therapy. Invariably, central venous access is necessary for virtually all patients requiring ICU care, so the delivery of PN therapy does not introduce unique clinical risks associated with catheter placement (i.e., pneumothorax, catheter malposition, catheter infections, and so forth). In addition to supplying nutrition support, the PN admixture can also be used as a vehicle to provide intensive metabolic support such as replacement of large amounts of electrolytes and correction of acid–base balance, which otherwise could not be accomplished by peripheral vein or EN therapy, largely due to osmolarity limitations. Moreover, it has also been used as a vehicle for selected pharmacotherapies, which can also assist in reducing excess fluid intakes associated with multiple diluents (i.e., D_5W, saline, and so forth) used to deliver drugs [98].

Parenteral Versus Enteral Nutrition and Complications

Approximately 15 years ago, there was a significant push toward the use of EN over PN as being a safer mode of nutrient supplementation. The principal benefit purportedly associated with the use of EN is reduced infectious complications compared with PN support in the critically ill. Three key investigations conducted in trauma patients were largely responsible for promoting enteral over PN, showing that patients receiving the latter mode of nutrition support had significantly higher rates of infectious complications [99–101]. In addition, this association appeared to be subsequently confirmed by meta-analysis [102]. However, as eloquently pointed out by Jeejeebhoy [103] in 2001, studies such as these are significantly flawed in that the groups receiving PN have significantly higher energy intakes that are associated with significantly higher blood glucose levels, which predisposes them to nosocomial infections. Higher energy intakes are easily obtainable via PN, whereas they are more difficult to achieve with EN during acute illness due to gastrointestinal intolerance [104].

Subsequently, Simpson and Doig [105] conducted a more sensitive approach to meta-analysis comparing studies of parenteral versus EN only in the critically ill. Previous systematic reviews of the risks and benefits of nutrition support have relied on a composite scales technique that combines certain dimensions of the quality of the selected trial used in the metaanalysis into a combined summary score. Consequently, important differences in methodologic quality (i.e., concealment of allocation, appropriate blinding, and analysis according to the intention-to-treat principle) may be overlooked, making well-conducted studies appear poorly conducted [106]. In contrast, the approach by Simpson and Doig in assessing parenteral versus EN, using the intent-to-treat principle, applied a component scale technique and demonstrated increased infectious complications with PN, but more importantly, reduced mortality by 50% compared with enteral feeding. This impressive benefit was also shown to be largely the effect of early feeding, since a post hoc analysis of TPN versus early enteral feeding showed no difference in mortality [105]. The latter finding was in contradistinction to previous analyses applying the composite scales approach in assessing the benefits and risks of PN [102,107]. Finally, the seminal publication by Van den Berghe et al. [108] in 2001 showed a significant morbidity and mortality benefit in surgical ICU patients receiving adequate nutrition either enterally, parenterally, or by combination when blood glucose levels were aggressively managed with the intravenous infusion of insulin, and the clinical significance of hyperglycemia in nutritional support was clearly established. Two groups of patients were studied ($n = 1{,}548$) to receive either "intensive" or "conventional" insulin therapy concurrent with PN. Blood glucose management assigned to the "intensive" insulin therapy group was treated with an insulin infusion if levels were above 110 mg%, whereas in the "conventional" insulin therapy group, insulin was initiated at levels above 215 mg%. The standard infusion consisted of 50 units of insulin in 50 mL of 0.9% sodium chloride solution (1 U per mL), and the maximum insulin dose was arbitrarily set at 50 U per hour for all groups. Hypoglycemia was defined as a blood glucose determination of 40 mg% or less. Within 24 hours, on average, all patients received approximately 1 g of protein and 19 kcal per kg per 24 hours, respectively. Significant reductions in in-hospital morbidity (e.g., renal and hepatic function, bloodstream infections, polyneuropathy) and mortality were observed in the "intensive" versus "conventional" insulin therapy group, where, for example, control of the morning blood glucose levels for all patients were significantly different between groups (103 ± 33 mg% vs. 153 ± 19 mg%, respectively). Additional significant clinical benefits (e.g., days on ventilator, lower TISS-28 scores) were also noted for those patients with ICU stays exceeding 5 days.

A follow-up study by Van den Berghe et al. [109] in 2006 was conducted, but this time it was performed in medical ICU patients receiving EN. Unfortunately, the nutrition support data were not as clearly presented as in the 2001 study,

but inferences are made as to how it was supplied. The nutritional goals stated from the outset was 22 to 30 kcal per kg per 24 hours (with approximately 20% to 40% of energy as fat calories) and protein at between 0.5 to 1.5 g per kg per 24 hours, with EN beginning as early as possible, once the patient was hemodynamically stable. Subsequently, in the results, two figures are shown that give more details about the success of achieving the stated nutritional goals during this study. One depicts the "total intake of nonprotein calories (kcal per 24 hours)" versus "day" showing that by days 3 and 4 of the study a steady amount of calories (between approximately 1,500 to 1,600 calories per day) were achieved over the 14-day profile. The other depicts the "fraction of kilocalories administered by enteral route" versus "day" showing achievement of 50% of total calories via EN at day 7 and roughly 70% by day 12 of the 14-day profile. The slow progression of enteral nutritional support is expected in critically ill patients, as contrasted from their previous PN study showing rapid advancement of protein and calories [108]. No significant improvements in mortality were noted, but morbidity (e.g., acute renal failure, days on ventilator) was reduced for patients receiving "intensive" insulin therapy. Of note, for the patients staying in the ICU for less than 3 days (n = 433) ("and for whom data were censored after randomization") [109], 56 deaths occurred in the "intensive" versus 42 deaths in the "conventional" insulin infusion group. Moreover, although the severity of hypoglycemia was similar between groups, hypoglycemia was more common in the "intensive" insulin treatment group. A subsequent logistic regression analysis revealed hypoglycemia to be an independent risk factor for death, prompting the investigators to speculate "that the benefit from intensive insulin therapy requires time to be realized" [109]. For patients staying 3 days or more, the mortality benefits seen in the previous study [108] were similarly observed and may support their theory of a time-dependent benefit of aggressive blood glucose management. From a nutritional perspective, the slow progression of protein and calories via the enteral route suggests significant caution in applying aggressive insulin therapy in medical ICU patients receiving EN support only, since parenteral glucose may make hypoglycemia less likely.

A closer evaluation of the manuscript and the table provided in a supplemental appendix reveals that rather marginal amounts of protein and adequate calories were given to the "intention-to-treat group (n = 1,200)" at approximately 40 g of protein and 1,200 kcal daily, whereas in the "long-stayers (in ICU 3 days or more)," approximately 50 g of protein and 1,500 kcal daily were given. It is also obvious from this table that the parenteral infusions were glucose only and not TPN, and that the protein intake in the first 72 hours was about 10 g protein per day. Thus, these critically ill patients did not receive early, adequate feeding, which should be the goal in the critically ill. Furthermore, this less than optimal nutritional therapy was provided at a rather high cost in terms of hypoglycemia with an incidence of 25.1% versus 3.9% in the intensive versus conventional treatment in the long stayers in the ICU.

In conclusion, much of the increase in morbidity related to PN and EN is due to hyperglycemia, which can be significantly reduced by intensive insulin therapy. The level of glycemia necessary to accomplish this goal, whether < 110 mg per dL or only < 150 mg per dL, is not yet defined. Surgical patients being adequately fed may benefit from the lower range, but a recent large study of intensive insulin therapy alone without full feeding in mixed populations of medical and surgical patients have significantly lower mortality with looser control of < 180 mg per dL versus tighter control (81–108 mg per dL) [110]. A possible interpretation is that to accomplish early, adequate feeding requires some parenteral feeding in many critically ill patients who also may serve to minimize the risks of hypoglycemia when employing tighter glucose control.

Tolerance

Enteral Nutrition

Tolerance to nutrition support interventions is highly variable and principally depends on the clinical condition of the patient and the mode of administration. In general, critically ill patients are least able to tolerate all forms of nutrition support. This is particularly true with EN and often limits the amount of protein and calories that can be provided, as gastrointestinal intolerance to feeding is common. As well, a number of other factors associated with ICU care can also interfere with its efficacious delivery [111]. The use of specialized formulations that provide elemental forms of the macronutrients, or are of reduced osmolarity, or of low fat content, may reduce the degree of gastrointestinal intolerance. Moreover, the use of antimotility agents will benefit some patients as well. Nevertheless, despite these preventive measures, gastrointestinal intolerance cannot be successfully managed in all patients. Other maneuvers, such as diluting the enteral feeding formula rarely alleviate the problem and generally should not be undertaken. Rather, providing monomeric or oligomeric formulations with reduced fat content at full strength, given at low rates (i.e., 20 mL per hour) and slowly advanced (i.e., 10 mL per hour every 6 to 12 hours as tolerated) will define those patients who will likely succeed with EN. As a general rule, patients who suffer multiple trauma excluding head injury are usually more tolerant of enteral feeding and allow quicker advancement than those critically ill patients who have closed head injury, sepsis, or are postoperative. Consequently, the time course to achieve eucaloric nutrition is usually longer than with PN.

Parenteral Nutrition

In contrast, patients receiving PN will physically tolerate large amounts of nutrients when given by intravenous administration. The "physiologic brake" that obviously limits EN is not readily apparent. Metabolic abnormalities, such as hyperglycemia and electrolyte and acid–base disturbances, can be easily ascribed to the consequences of the metabolic response to injury, rather than recognizing the contribution of overly aggressive PN support. Furthermore, these iatrogenic metabolic abnormalities are often addressed independently from the PN admixture, such as by separate infusions of insulin, fluid, electrolytes, and so forth, without modifying the PN regimen. The net effect of parenteral overfeeding can unnecessarily complicate the critical care of such patients and lead to significant increases in morbidity and even mortality. However, once metabolic homeostasis is achieved, the time course to reach eucaloric nutrition support is usually brief compared with EN therapy.

Fixed Versus Variable Amounts of Nutrients

Enteral Nutrition

There is limited opportunity to manipulate the contents of EN formulations as these products are premade as "complete" commercial products. Of course, they may be modified by the addition of various nutrient modules, but cannot easily be specifically tailored to the patient, especially during acute illness. For example, a number of electrolyte additives may precipitate the complex feeding formulas and cause clogging of the feeding tube. The addition of other components to the enteral formulation increases the osmolarity, which is an important consideration for enteral feeding, as well as increasing the risk of incompatibilities [68]. Thus, the flexibility of enteral therapy is limited, which may make it difficult to achieve the proper

balance of nutrients during severe metabolic stress. Once the stress response remits and major organ function improves, this becomes a less pressing concern.

Parenteral Nutrition

Major stability issues associated with PN admixtures preclude the manufacture of ready-to-use commercial products. Of these, the interaction between certain amino acids with dextrose forming oxidized end products, known as the Maillard reaction is generally acknowledged [70]. The use of multicompartment bags offer a possible alternative to these reactions, but as with enteral products, they too become clinically limiting in the unstable patient in the acute care setting. Thus, PN admixtures are most often made extemporaneously from individual commercial ingredients (i.e., amino acids, dextrose, lipids, electrolytes, and so forth) by qualified pharmacy personnel. The introduction of automated compounding devices and their subsequent widespread use has made the practice of patient-specific admixtures a relatively easy task [112]. Thus, even the sickest of ICU patients can receive some form of nutrition support by the prescribing of unique and specifically designed formulations to support the protein synthetic response to injury.

Costs

Enteral Nutrition

Historically, EN formulations have been a fraction of the cost of PN admixtures as they are ready-to-use and largely comprised of polymeric forms of macronutrients. However, with refinements in these products to construct oligomeric or monomeric forms of protein and carbohydrates, the so-called elemental formulas, the costs have increased substantially. Moreover, the addition of novel nutrients, such as omega-3 fatty acids, glutamine, arginine, and others to produce nutritional supplements that may have pharmacologic effects, particularly with respect to immune function, has increased costs that now exceed most PN formulations per kcal. Although the data are promising for these innovative formulations in terms of their potential to reduce length of stay and possibly infectious complications, the full extent of these claims have not been fully substantiated.

Parenteral Nutrition

By historical comparison, PN was always more expensive than EN therapy. There were many good reasons for this [113], considering the product had to be specially compounded under aseptic conditions to be suitable and safe for intravenous administration. As the methods of commercial production improved and became more efficient and competition increased, the costs of PN therapy have significantly declined. Compared with specialized formulas that contain immunonutrients or certain concentrated enteral products, the present costs of PN therapy are equal or in many cases less expensive. In contrast, for conventional, polymeric EN supplements, the cost of the formulations is still substantially less than PN formula costs. However, the placement of an enteral feeding tube and components (pumps, sets, and so forth) are dedicated to the provision of nutrition support, whereas central venous lines are already being used for the provision of intravenous fluids, medications, and blood tests. Therefore, additional costs of even conventional EN therapy must be considered.

Complications

The complications or adverse patient events associated with parenteral and EN include mechanical, septic, and metabolic misadventures [114]. For example, mechanical complications of invasive nutrition support are often associated with the misplacement of various types of feeding access devices (i.e., vascular injury or pneumothorax). With experienced clinicians, the incidence of such complications is substantially reduced and clinically acceptable at about 1% to 2%.

Metabolic and associated septic complications are more common and can have a significant impact on patient outcome. Severe disturbances in fluid, electrolyte, and acid–base homeostasis are commonly associated with high rates of morbidity and mortality in the ICU. This is especially true in patients with significant heart disease [115]. As well, septic complications in association with hyperglycemia and infections in critically ill patients receiving parenteral or EN are at least equally significant, if not even more so [116]. Therefore, a more modest provision of energy intake (i.e., approximately 25 total kcal per kg per day) should be the overall goal of therapy by whatever route of delivery and is most likely to succeed, and with this, fewer nutrition-related complications are likely. However in the first 3 to 7 days of enteral and PN providing at least 50% of the estimated energy requirement along with protein intake of at least 1 g per kg may be a reasonable compromise meeting the definition or early, adequate feeding while lowering the risk of metabolic and infectious complications.

Appropriate Application of Nutrition Support

Nutrition support does not improve outcome in operative patients who are well nourished, no matter what route of administration it is given. A number of examples appear in the medical literature supporting this contention. For example, a randomized clinical trial of perioperative nutrition support only found significant improvement in the malnourished group irrespective of feeding mode [117]. Heslin et al. [118] reported no benefit with enteral tube feeding in patients with gastrointestinal cancer without significant weight loss. In fact, the routine provision of EN in well-nourished patients may cause significant impairments in ventilatory function and mobility [119]. Finally, an extensive review of the literature has corroborated the lack of benefits in the standard prescription of nutrition support in patients who initially are well nourished and undergoing moderate stress as following major thoracoabdominal surgery [120]. There is reasonable support for early and adequate feeding in the most critically stressed even when initially well-nourished such as those with closed head injury, severe multiple trauma, major third degree burns, and severe sepsis, not to prevent the development of malnutrition but presumably to limit the severity of the systemic inflammatory response.

In contrast, invasive feeding in the malnourished patient is likely to be effective in a variety of clinical scenarios. This is particularly true during acute metabolic stress, where ongoing catabolism results in significant daily losses of body protein. Patients with weight loss classified as moderate (i.e., 10% or more) or severe (i.e., 20% or more) from usual or IBW are most susceptible to nutrition-related complications such as infection or wound dehiscence. The absence of nutritional intervention in this vulnerable population for protracted periods of time (i.e., greater than 7 to 10 days) may have a significant impact on outcome. Moreover, even the initially well-nourished patient cannot sustain the protein synthetic response to injury for long periods. For example, in a randomized study of the effects on outcome of postoperative feeding with TPN, those who were inadequately fed for 14 days had a significant increase in morbidity and mortality [121]. Patients who suffer multiple traumas, major burns, or closed head injury are a unique group. Although generally well nourished at the outset, the severity of catabolic response and the likely duration

of substantially longer than 7 days make early nutritional intervention within the first few days beneficial.

MONITORING PARAMETERS FOR NUTRITION SUPPORT

Electrolytes

During critical illness, severe electrolyte disorders are common and are primarily the result of various concomitant etiologies, including changes in (a) the function of major organ systems, especially the kidneys; (b) fluid balance affecting intravascular volume and the hormonal milieu produced as a result of the metabolic response to severe stress(es); (c) intra- or extracellular shifts of ions associated with acid–base disturbances; and (d) multiple drug therapies. Renal dysfunction has profound effects on electrolyte balance by influencing the absorption and excretion of most notably, sodium, potassium, magnesium, phosphorus, and titratable acids. As renal function declines, the excretion of these electrolytes decreases and the PN admixture must be adjusted accordingly. For example, in some cases, electrolytes are significantly reduced, while in other circumstances they are entirely omitted from the daily admixture. As well, chloride ions are often substituted with alkalinizing anions such as acetate to combat the metabolic acidosis associated with renal failure.

Fluid overload is a common finding in critically ill patients related to intraoperative support of renal blood flow and function, acute volume resuscitation with crystalloids in the ICU, and the administration of multiple intravenous medications that may produce its own set of complications. For example, acute increases of 10% or greater above usual body weight over short intervals clearly reflect a significant expansion of total body water that may impede the weaning of the patient from mechanical ventilation. Thus, clinical efforts to return to the patient's premorbid weight, such as by aggressive diuretic therapy and concentrating intravenous medications in the least diluent volume possible, are often used. In certain severe circumstances, the use of colloids for acute volume expansion, followed by aggressive diuretic therapy as a "push–pull" method of fostering diuresis is undertaken to achieve a net negative fluid balance. More recently, the use of hemofiltration procedures to accomplish this goal has proven quite effective. Despite "third-spacing" of fluids, the consequences of the antidiuretic and antinatriuretic responses of stress often present as a hyponatremia and can be mistakenly treated by the parenteral administration of sodium salts in an effort to correct the serum sodium concentration. However, given that sodium essentially distributes in total body water, one can easily calculate that, in fact, the patient is both fluid and total body sodium overloaded. Hence, clinical maneuvers to address the problem should be directed at increasing both sodium and free water losses, with gradual restoration of serum sodium concentrations. A clinical example of this estimation appears in Table 191.6.

The acute intra- or extracellular shifting of electrolytes is primarily the result of the effects of changes in acid–base homeostasis and serum insulin concentrations. In the former case, serum potassium concentrations are most affected by changes in acid–base status. Potassium is predominantly an intracellular ion whose concentration in the intracellular compartment is much higher than its extracellular concentration. When arterial pH falls below normal, potassium shifts to the extracellular compartment and hyperkalemia occurs, and conversely, metabolic alkalosis produces hypokalemia.

Insulin also has a profound effect on the shifting of potassium, magnesium, and phosphorus between the intra- and extracellular environments. In fact, the life-threatening refeeding syndrome that occurs in severely malnourished patients is associated with the shifting of these electrolytes from the extracellular to the intracellular compartments [122]. In the atrophic heart muscle characteristic of severe malnutrition (i.e., greater than 30% below ideal body weight), severe reductions of serum potassium (i.e., less than 3 mEq per L) and serum phosphorus (i.e., less than 0.2 mg per L) related to feeding may have life-threatening electrophysiologic consequences [123].

Finally, critically ill patients commonly receive multiple drug therapies intravenously for a variety of clinical reasons and include, for example, cardiovascular agents, vasopressors, diuretics, anesthesia/sedation therapy, crystalloids, colloids, antibiotics, anticoagulants, and so forth. These can cause clinically significant effects by altering intended drug actions (i.e., toxic synergism, reduced drug effects) or by addition of substantial diluent volumes (i.e., greater than 500 mL), worsening a fluid-overloaded state. The clinical care of acutely ill patients with severe fluid and electrolyte disorders can be optimally managed through intensive metabolic monitoring and selective manipulations of PN admixture components [71,72,123].

TABLE 191.6

ESTIMATING TOTAL BODY SODIUM IN THE ACUTE CARE SETTING[a]

Premorbid total body sodium	
Total body water @70 kg	= 42 L
Total body sodium	= 42 L × 140 mEq/L
	= **5,880 mEq**
Present total body sodium	
Total body water @91 kg	= 42 L + (91 kg − 70 kg)
	= 63 L
Total body sodium	= 63 L × 130 mEq/L
	= **8,190 mEq**
Excess total body sodium	
8,190 − 5,880	= **2,310 mEq**

[a]Assumptions: Premorbid weight = 70 kg male; presently = 91 kg; serum sodium = 140 mEq/L (normal); presently = 130 mEq/L; total body water = 60% (for males).

Insulin and Glucose Homeostasis

Notwithstanding its regulatory role in glucose homeostasis in terms of glucose production and breakdown in the liver, as well as its facilitated transport of glucose into muscle and other obligatory tissues, insulin is a complex hormone that exhibits numerous metabolic effects that may be of significant clinical consequences in critically ill. The mechanisms by which abnormally elevated blood glucose concentrations in critically ill patients produce metabolic dysfunction have been described [124]. With respect to infectious risk, the ability of mononuclear (macrophages and monocytes) and polymorphonuclear neutrophils to exert phagocytic, oxidative bursts, and killing functions is significantly impaired. Thus, infections of the bloodstream, lungs, and superficial wounds (i.e., any surgical incision site, intra-, and extravascular catheter sites, or other topical sites of injury) are significantly increased following periods of hyperglycemia.

Glucose homeostasis is best achieved when parenteral insulin is given in an effective manner. A review of the methods of administration employed emphasize that the route of insulin delivery should be commensurate with the means of

administration of carbohydrate calories [125]. In the acute phases of critical illness, patients receiving PN should receive intensive insulin therapy [108]. Once, stabilized (i.e., patients receiving the largest source of glucose as parenteral calories), insulin should be given in the TPN admixture in amounts sufficient to cover the caloric intake from this source over 24 hours. When exclusive PN therapy is given, 24-hour glucose intake may account for as much as 150 to 300 g per L daily (510 to 1,020 kcal), requiring substantial amounts of insulin in the admixture, and can be effectively accomplished [125]. As well, in some cases supplemental "low-volume, full-strength" EN may provide 50 to 150 g per 24 hours (170 to 510 kcal), which should be managed with subcutaneous insulin provided based on blood glucose determinations taken on a regular basis and algorithm-based insulin doses.It should be emphasized that, the insulin should be administered subcutaneously as an intravenous dose has a serum half-life of approximately 5 to 7 minutes. The same principles may be applied to patients receiving substantial amounts of glucose in the peritoneal dialytic regimens, where insulin is often best provided in the dialysis solution. Thus, in some cases, such as a patient undergoing both peritoneal dialysis and PN or EN, insulin is given via multiple routes to cover the administration of glucose from various sources to link the insulin administration to the source of exogenous glucose. When hyperglycemia is severe due to severity of the stress response or severity of insulin deficiency (type 1) or insulin resistance (type 2), it is reasonable to employ continuous intravenous insulin and close blood glucose monitoring to quickly establish glucose homeostasis, whatever the source of exogenous glucose.

Goals of Nitrogen Balance

Achieving positive nitrogen balance is an unrealistic goal in the critically ill early in the clinical course. Rather, the principal aim of nutritional intervention is to support the protein synthetic response to injury and, therefore, narrow the negative nitrogen gap (where output exceeds input) that occurs during severe metabolic stress. Even when the metabolic stress has subsided, it should be recognized that nutritional rehabilitation of the moderate to severe malnourished patient occurs at a limited rate equivalent to approximately 1 kg of body weight per week and generally much of this repletion will occur outside the hospital after discharge. This estimation is based on a maximum rate of repletion of a positive nitrogen balance (i.e., approximately + 5 g per day) that represents 150 g of lean tissue (hydrated protein) and a calorically equivalent amount of fat (13 g) per day. Weight increases above this rate of repletion can only reflect increases in total body water.

Finally, it should be mentioned that when expending the effort to obtain a 24-hour urine collection, additional laboratory measurements should be performed on this specimen such as for the determination of creatinine excretion and certain electrolytes (sodium, potassium, chloride). In this way, important additional clinical information may be provided including creatinine clearance, urea clearance, fractional excretion of sodium, and quantification of electrolyte losses, among other possible data that may be used in the clinical and nutritional/metabolic care of critically ill patients.

EVIDENCE-BASED GUIDELINES FOR NUTRITION SUPPORT THERAPY

In 2009, the Society of Critical Care Medicine (SCCM) and the American Society for Parenteral and Enteral Nutrition (ASPEN) developed and copublished "Guidelines for the Provision and Assessment of Nutrition Support Therapy in the Adult Critically Ill Patient" [126,127]. The last statement of the introduction of this document is noteworthy: "*Delivering early nutrition support therapy, primarily using the enteral route, is seen as a proactive therapeutic strategy that may reduce disease severity, diminish complications, decrease length of stay in the ICU, and favorably impact patient outcome.*" Of the 12 categories or conditions (sections A through L), nine sections related to EN, two sections on PN, and one section (L) relating to end-of-life situations. It is the authors' opinion that this document is unfortunately biased against the potential utility of PN in many circumstances. The assessment system applied in the guidelines consisted of "Levels of Evidence" and "Grades of Recommendation." "Levels of Evidence" were from I to V, with "Level I" being the strongest evidence and "Level V" being the weakest evidence. The "Grades of Recommendation" were from A to E, with "A" being the highest and "E" being the lowest. If, for example, one scores the grades according to a quality point average (QPA) as applied in education with A = 4.0, B = 3.0 . . . E = 0.0, the evidence is poor for both EN and PN. For example, in the SCCM/ASPEN 2009 guidelines, the QPA for all EN sections was 1.21 and the QPA for all PN sections was 1.25. We selected three controversial statements in the guideline:

A3. "EN is the preferred route of feeding over parenteral nutrition (PN) for the critically ill patient who requires nutrition support therapy. Grade B"

The statement is correct, and fits Dr. Dudrick's original thesis "if the guts works, use it," but the principal rationale for its preference, that is, reduced infectious morbidity is misidentified. Although previous studies have shown this association to be true, the premise overlooks the importance of blood glucose control and caloric intake in these studies. Invariably, the PN group in many of the supporting studies received significantly more calories than the EN group and consequently, had higher blood glucose values that clearly increase infectious complications. This is not surprising since EN is often not well tolerated in eucaloric amounts as PN, and is frequently interrupted for various clinical maneuvers or diagnostic tests in the critical care setting. As well, the insulin required to maintain glucose homeostasis is greater for parenteral compared to enteral glucose. Furthermore, the data supporting this statement was essentially derived before the subsequent eras of reduced energy provision and tight glucose control in the critically ill.

G1. "If the patient is deemed to be a candidate for PN, steps to maximize efficacy (regarding dose, content, monitoring, and choice of additives) should be used. Grade C"

In accordance with the thesis of "do no harm," it would seem intuitively obvious that the safety and efficacy of PN would be accomplished by optimizing the formulation. A "Grade C" recommendation diminishes the importance of dosing nutrients, which unfortunately, is associated with a long history of overfeeding and its attendant complications. In the same section (G6), the use of extemporaneously prepared parenteral glutamine is given the same "Grade C," despite the fact that such an additive is classified as a "HIGH RISK" compounded sterile preparation by the United States Pharmacopeia [20].

H3. "Serum phosphate levels should be monitored closely and replaced appropriately when needed. Grade E"

The literature is replete with data on the importance of serum phosphate levels is the critically ill, especially with respect to the risks associated with hypophosphatemia on myocardial performance and respiratory function [128]. Moreover, the provision of hypertonic glucose in a PN admixture

produces a supraphysiologic increase in serum insulin levels that will cause significant intracellular shifts that may produce life-threatening hypophosphatemia in susceptible patients. A "Grade E" recommendation is inappropriate in this circumstance. Also in 2009, the European Society of Parenteral and Enteral Nutrition (ESPEN) produced "Guidelines on Parenteral Nutrition: Intensive Care" [129]. Seventeen statements (categories or conditions) are included and there are three Grades of Recommendation (A, B, C) with the strongest evidence being "Grade A" versus the weakest evidence with a "Grade C." Only two statements received "Grade A." We selected three controversial statements in this guideline.

Under "Requirements"

> "During acute illness, the aim should be to provide energy as close as possible to the measured energy expenditure in order to decrease negative energy balance. Grade B"

In the ICU setting, particularly during the early phases of critical illness, hypocaloric regimens often seem to be most prudent. Maintenance of normal blood glucose values should take precedence over energy balance in most critical care settings, and then once achieved, judicious increases in calories can commence.

> "In the absence of indirect calorimetry, ICU patients should receive 25 kcal/kg/day increasing to target over the next 2–3 days. Grade C"

As already stated, caloric intakes in the ICU should be advanced slowly after the initial provision of 50% of energy and 1.0 to 1.2 g protein per kg to avoid hyperglycemia and infectious morbidity. As stated earlier, for most patients, providing 25 kcal per kg per day is sufficient to support the protein synthetic response to metabolic stress. The guideline, as stated, implies that 25 kcal per kg per day is the starting point, when in fact, for most adult patients, it is the target range [130], and is gradually reached after initiating lesser amounts of calories from the outset.

Under "Amino Acids"

> "When PN is indicated in ICU patients the amino acid solution should contain 0.2–0.4 g/kg/day of l-glutamine (e.g., 0.3–0.6 g/kg/day alanyl-glutamine dipeptide). Grade A"

Although there is a commercial product in Europe that is available to provide glutamine supplementation, a recommendation of Grade A seems to be overly optimistic. This is especially true given the recent assessment of l-glutamine in the ICU of an "area of uncertainty" from one of the leading investigators in the field [130]. Thus, such a recommendation seems premature at this time.

At this time, the data is unclear for several reasons. First, the guidelines and methods of assessment must be standardized between organizations. Second, "mining of data" from past studies, many of which are significantly flawed with respect to design and endpoints, cannot yield meaningful guidelines, despite the use of statistical tools, such as meta-analyses. Third, critically ill patients are not homogenous. As recently pointed out, EN is contraindicated in 10% to 15% of ICU patients; there are very few well-designed, randomized controlled studies of PN efficacy, and preexisting malnutrition, combined with numerous pathophysiologic factors in ICU patients which greatly complicate the role of nutrition support [130].

Thus, it seems that to definitively address the evidence for nutrition support therapy in the ICU setting will require designing better studies in the future rather than the current methods to rehash old data from a previous era using statistical tools. A major emphasis should clearly be on the design (randomized controlled trial, sufficient power, APACHE score, etc.) and specific endpoints for future studies to answer the question of the impact of nutritional therapy in the critically ill on morbidity and mortality and clinical outcome. For example, multicenter studies should focus on the potential role of early (within 72 hours of ICU admission) and adequate energy (> 50%, but < 110% of energy requirements) and protein (at least 1.2 g per kg per day) by whatever means necessary (enteral, parenteral, or both). Only then can we have a true understanding of the role of nutrition support therapy in the critically ill.

CONCLUSIONS

Nutritional and metabolic support is an essential component of the clinical care of critically ill patients. However, if applied in an overly aggressive manner without thought to the nutritional status, amounts of nutrients, route of administration, and the clinical condition of the patient, significant iatrogenic complications may occur and little clinical benefit can be expected. Thus, nutritional support of the critically ill must be carefully integrated into the overall clinical care of the patient, with specific and measurable outcome measures in order to obtain the maximum benefits of this important therapy.

CHAPTER 192 ■ DISEASE-SPECIFIC NUTRITION

MICKEY M. OTT, BRYAN R. COLLIER AND DOUGLAS SEIDNER

INTRODUCTION

In the critically ill patient, the constant barrage of multiple physiologic derangements quickly leads to malnutrition. The hypermetabolic response to stress changes the nutritional requirements of these individuals, but failure of the various organ systems complicates the issue. Renal, hepatic, and pulmonary function must be considered when prescribing nutritional therapy in the intensive care unit (ICU). This chapter will discuss the metabolic abnormalities associated with these disease processes, the nutritional assessment of the patient in organ failure, and propose evidence-based guidelines for nutritional support in these disease-specific populations.

RENAL FAILURE

Despite many recent advances in medical therapy, management of the critically ill patient with renal failure remains a challenging endeavor. Acute renal failure (ARF) is associated with an overall mortality rate of 50% to 90%, depending on its derivations and comorbid conditions [1]. Hypotension and hypovolemia, secondary to excessive fluid losses, inadequate fluid replacement, or decreased cardiac output are the leading causes of renal failure in the ICU. Factors such as shock or sepsis and exposure to nephrotoxic drugs or blood transfusions can also predispose patients to renal dysfunction. Early diagnosis and restoration of circulating blood volume to the kidneys may decrease the risk of permanent damage; however, the course to renal recovery is often a complicated one. The patient in chronic renal failure (CRF) is also at increased risk for morbidity, as these patients will likely present with protein-calorie malnutrition at baseline. Moreover, the nutritional support of the patient on dialysis will offer a unique challenge to the critical care physician.

Malnutrition and Hypermetabolism

In general, renal failure is characterized by altered nutrient metabolism, defective metabolic waste excretion, inadequate nutrient intake, and excessive nutrient losses. Approximately 10% to 70% of patients with CRF undergoing maintenance dialysis are severely malnourished [2,3]. In these patients, malnutrition is most often the result of poor dietary intake secondary to uremia-induced gastroparesis, poor-tasting highly restrictive diet prescriptions, and medications with gastrointestinal side effects. Diminishing creatinine clearance levels have been linked to a spontaneous decline in the dietary protein intake of CRF patients as well [3,4]. In addition, patients with acute renal failure and critical illness represent by far the largest group receiving supplemental nutrition [5].

The dialysis dose also plays a significant role in the development of malnutrition. The protein catabolic rate of patients undergoing dialysis can be calculated to estimate daily protein intakes of these individuals [6]. In a 1983 investigation by Acchiardo et al., daily protein intakes of less than 0.8 g per kg, as measured by protein catabolic rate, correlated with an increased morbidity and mortality rate compared to patients with greater protein intakes [7]. A subsequent study by Lindsey and Spanner demonstrated a strong linear relationship between dialyzer urea clearance, duration of dialysis, and volume dialyzed (collectively expressed as Kt/V) and protein catabolic rate [8]. It is suggested by this correlation that an adequate dose of dialysis is influential on sufficient nutrient intake and the prevention of malnutrition in chronic dialysis patients [9].

Critical illness imposes an even greater metabolic stress and nutritional demand on the patient with renal dysfunction. Protein-calorie malnutrition (PCM) is reportedly present in 25% to 60% of individuals undergoing continuous renal replacement therapy (CRRT) within the intensive care unit [10]. It is important to note that the increased energy expenditure seen in these patients is a direct result of the hypermetabolic response to infection and injury and not of the renal failure itself. Indirect calorimetry has been used to show that the intensity of renal dysfunction has no direct bearing on energy expenditure [11]. Renal failure is, however, the root of several metabolic alterations that often interfere with nutritional status and overall stability of the critically ill patient.

Metabolic Abnormalities

Common metabolic abnormalities associated with ARF include glucose intolerance, impaired lipolysis, increased protein catabolism, decreased protein synthesis, fluid and electrolyte imbalance, and metabolic acidosis (Table 192.1). Although renal excretion of insulin is diminished, insulin resistance coupled with the stress of sepsis or injury can lead to significant hyperglycemia in this patient population. Decreased activity of lipolytic enzymes, such as hepatic triglyceride lipase and lipoprotein lipase, may reduce clearance of parenterally infused triglycerides by as much as 60% in ARF patients versus controls with intact renal function [12]. Adequate energy provision may thus be hindered by altered carbohydrate and fat metabolism. Nonprotein calorie requirements in ARF patients are best met with formulas providing mixed substrates in the ratio of 50% to 70% as carbohydrate and 30% to 50% as fat [13].

TABLE 192.1

METABOLIC RESPONSES TO ACUTE RENAL FAILURE

Nutrient	Metabolic abnormalities
Glycemic	Diminished metabolism of insulin and glucagon Glucose intolerance (hyperglycemia) Peripheral insulin resistance Increased glycogenolysis and gluconeogenesis
Lipid	Increased lipolysis with reduced clearance of serum lipids Hypercholesterolemia Hypertriglyceridemia
Protein and amino acid	Increased catabolism of skeletal muscle and visceral proteins Diminished amino acid uptake Reduced insulin-mediated protein and amino acid synthesis Azotemia
Fluid and electrolyte	Anuria Anasarca Ascites Altered serum concentrations of sodium, phosphorus, or potassium Hypocalcemia Metabolic acidosis

Data compiled from references [8,12,17,19,26].

Several factors contribute to increased protein catabolism and overall negative nitrogen balance in ARF patients. In accordance with the metabolic response to injury, patients with renal failure experience an increase in gluconeogenesis, leading to the breakdown of skeletal muscle proteins for use as energy and for synthesis of acute-phase proteins. Metabolic acidosis, frequently seen in renal failure, can trigger skeletal muscle protein breakdown as well. Reduction in muscle protein synthesis in this population has been linked to diminished cellular uptake of glucose and amino acids secondary to insulin resistance, altered cellular ion transport mechanisms, and defective intracellular synthesis [14,15].

Varying protein and energy provisions also influence protein catabolism and nitrogen balance in ARF patients. A 1996 investigation of 40 ICU patients with ARF receiving continuous venovenous hemofiltration revealed that at levels of protein administration above 1.5 g per kg per day, increasing energy provisions are associated with an increase in protein catabolism [16] (Fig. 192.1). Increasing energy provisions had a protein-sparing effect at lower levels of protein administration. Net nitrogen balance was also examined in this population (Fig. 192.2). Protein administration rates of 1.5 to 2.0 g per kg per day were associated with a positive net nitrogen balance,

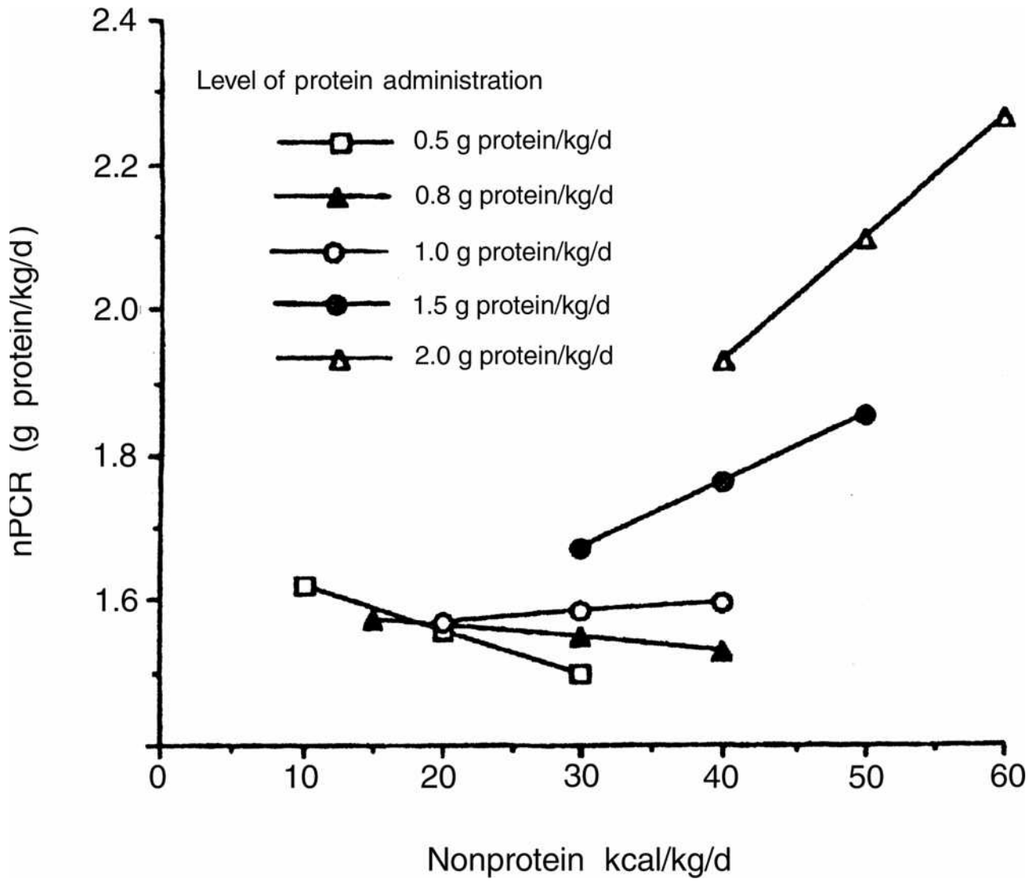

FIGURE 192.1. Effect of varying energy and protein provisions on protein catabolism. At higher levels of protein administration (> 1.5 g/kg/d), increasing energy provisions are associated with increased net protein catabolic rate (nPCR). At lower levels of protein administration (< 0.5 g/kg/d), increasing energy provisions promote protein sparing. [Adapted from the American Society for Parenteral and Enteral Nutrition (ASPEN) and Macias WL, Alaka KJ, Murphy MH, et al: Impact of nutritional regimen on protein catabolism and nitrogen balance in patients with acute renal failure. *JPEN J Parenter Enteral Nutr* 20(1):56–62, 1996, with permission. ASPEN does not endorse the use of this material in any form other than its entirety.]

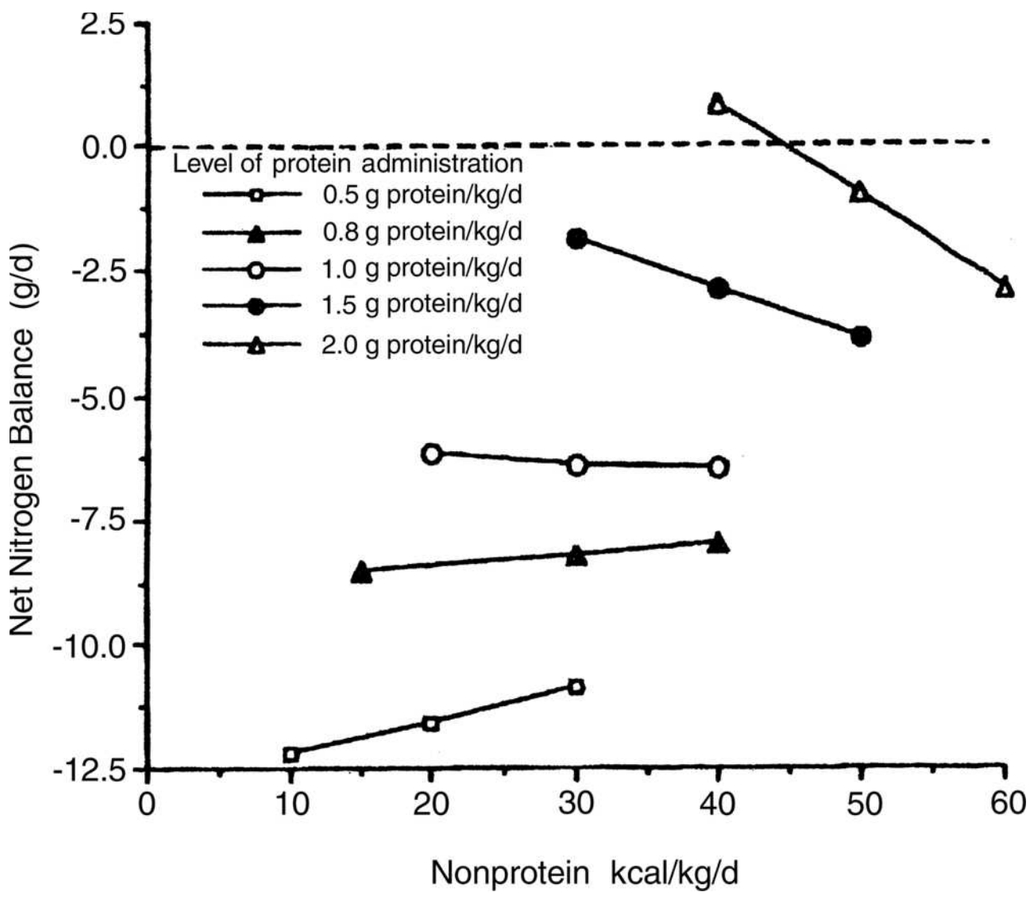

FIGURE 192.2. Effect of varying protein and energy provisions on nitrogen balance. Higher levels of protein administration (> 1.5 g//kg/d) in combination with lower energy provisions (25–35 kcal/kg/d) promote a more favorable net nitrogen balance. [Adapted from the American Society for Parenteral and Enteral Nutrition (ASPEN) and Macias WL, Alaka KJ, Murphy MH, et al: Impact of nutritional regimen on protein catabolism and nitrogen balance in patients with acute renal failure. *JPEN J Parenter Enteral Nutr* 20(1):56–62, 1996, with permission. ASPEN does not endorse the use of this material in any form other than its entirety.]

although at these elevated levels of protein provision, lower-energy administration rates were necessary to prevent protein catabolism and promote more favorable nitrogen balance. Final nutrient recommendations were for 1.5 to 1.8 g protein per kg per day with energy levels between 25 to 35 kcal per kg per day in critically ill ARF patients on continuous venovenous hemodialysis (CVVHD) [5,16].

Close monitoring of fluid status is crucial to the maintenance of adequate intravascular volume and renal perfusion. Fluid is typically restricted to 1.0 to 1.5 L per day in nondialysis anuric or oliguric patients. Concentrated enteral or parenteral formulas are often required to meet daily nutrient needs under these circumstances. Dialysis, with special emphasis on CRRT, allows for a liberalization of fluid provisions to thereby permit an adequate supply of protein and energy to the renal patient. In the ICU setting, ARF patients tend to be severely volume overloaded with fluid shifting to the extravascular space secondary to hypoalbuminemia. Even while on some form of CRRT, maintenance of fluid balance is challenging in these patients and importance should be given to adequate protein provision for repletion and reversal of the effects of low serum albumin levels. In CRRT, there is a loss of at least 0.2 g amino acids per liter of ultra filtrate (up to 10 to 15 g amino acids per day), and of 5 to 10 g per day of proteins. Vitamins are also lost in significant amounts; however, there does not appear to be lipid losses across the filter [5].

Serum electrolyte levels fall within a wide range of highs to lows depending on renal excretion, extent of catabolism, and type and duration of dialysis [17]. Increased catabolism of skeletal muscle protein releases phosphorus, potassium, and magnesium into the bloodstream, leaving elevated serum electrolyte values. Because of this, parenteral nutrition (PN) formulations for renal patients are often made with low levels of these cations. A 1998 case report demonstrated the dangers of undershooting electrolyte needs in a frequently malnourished CRF population [18]. Introducing a carbohydrate load parenterally or even enterally to a malnourished patient stimulates insulin release and cellular anabolism, thereby enhancing intracellular ion transport [19]. The subsequent decline in serum electrolyte levels with resulting clinical complications is referred to as the *refeeding syndrome*. This case study reported four CRF patients who developed significant hypophosphatemia after starting PN due to inadequate electrolyte provisions in combination with intracellular shifts [18]. It is thus recommended that dextrose infusions be started gradually and serum electrolytes be monitored closely to correct for potential abnormalities in this population. Depressed serum ionized calcium levels are a common result of hyperphosphatemia and uremia. Supplementation is most often necessary to prevent release of calcium from the bone. Multivitamin preparations standard to enteral and parenteral formulas are adequate for most ARF and CRF patients. Support exists in the literature that vitamin C should not exceed 30 to 50 mg per day, because inappropriate supplementation may result in secondary oxalosis. If signs of vitamin A or other toxicities are observed, daily provision may need to be withheld. The kidney normally excretes trace elements; however, excess accumulation in renal failure is unlikely as gastrointestinal tract losses also occur. The micronutrient milieu may also be affected by the mode and dose of renal replacement therapy. Recent data show that prolonged CRRT results in selenium and thiamine depletions despite supplementation at recommended amount [5].

Standard daily doses of trace elements may be safely given to most patients in renal failure. Iron deficiency anemia is a commonly documented finding among end-stage renal disease patients. Recent research has focused on anemia and carnitine, an amino acid with a central role in long-chain fatty acid oxidation. Deficiency of carnitine has been associated with dialysis, and supplementation of l-carnitine has led to the improvement

of hematocrit levels in HD patients [20]. Metabolic acidosis in this population is a result of diminished acid excretion, increased protein catabolism, and daily protein intake [21]. Bicarbonate should be given enterally or intravenously to maintain pH more than 7.2 or serum bicarbonate more than 17 mEq per L. When supplementing by PN, sodium or potassium acetate is given because bicarbonate forms an insoluble precipitate with calcium in PN solutions.

Nutrition Assessment

The identification of malnutrition and timely initiation of nutrition support in critically ill patients with renal failure may not only reduce their degree of protein depletion but also increase their chances for survival [1]. Unfortunately, common measures of nutritional status, such as serum albumin, serum transferrin, weight changes, and anthropometrics tend to fluctuate with the alterations in fluid balance inherent to this patient population. Despite this, serum albumin is considered the strongest laboratory predictor of mortality for hospitalized patients with renal failure [22]. Daily monitoring of weight and intake and output records can help to assess fluid balance in these individuals. It is essential to use a dry weight (i.e., free of edema or ascites) when examining alterations in weight status. The dry or adjusted body weight of a renal patient may then be used to more closely estimate daily nutrient needs.

Continuous Renal Replacement Therapy (CRRT) Versus Intermittent Hemodialysis (HD)

It is commonly thought that dialysis therapy can be relied on to correct many of the metabolic derangements associated with acute and chronic renal failure. This may be true under most circumstances; however, research and patient care experience have shown that patients receiving intravenous (IV) nutrition are at greater risk for fluctuating serum chemistries despite regular dialysis treatments [1,18]. HD can also increase the risk of hypotension and may add to the hemodynamic instability of the ICU patient by limiting the removal of adequate fluid. CRRT is useful for 24-hour-per-day clearance of nitrogenous wastes, metabolic by-products, and excess fluids. CRRT is often preferable to HD in the critical care setting because it reduces the risks for fluid and electrolyte disorders and hypotension while allowing for more liberal fluid and nutrient provisions. In patients with severe fluid intolerance, slow continuous ultrafiltration may be necessary. Protein losses can be as high as 10 to 13 g per HD session versus 5 to 10 g per day in CRRT [23,24]. Amino acids can be added to the hemodialysate solution to promote retention of nitrogen balance [25]. Consideration should be given to typical glucose content of the dialysate, as this may make a significant contribution to the caloric load of patients already exhibiting some form of glucose intolerance. Dialysate of CRRT is approximately 1.5% glucose, thereby contributing up to 600 glucose calories during a 10-L per day dialysis infusion [26].

Enteral and Parenteral Formulations

A wide array of enteral nutrition products has been designed for patients in varying stages of renal disease (Table 192.2). Formula selection depends largely on the individual's fluid allowance [27]. For predialysis ARF patients in need of short-term enteral nutrition, a formula containing only essential amino acids and histidine with little or no vitamins, minerals, and electrolytes may be appropriate. Products with reduced levels of protein, phosphorus, potassium, magnesium, and vitamin A are useful for patients with chronic renal insufficiency, yet not on dialysis. Moderate protein formulas with low electrolyte content are often indicated for patients receiving intermittent dialysis treatments. All enteral products designed for use in renal dysfunction are concentrated in volume (2 kcal per mL) to aid in fluid management. It is best to initiate tube feedings at a slow rate in this population and advance the feeding rate gradually to prevent osmotic diarrhea. Because patients on CRRT demonstrate improved clearance of nitrogenous wastes, fluid, and electrolytes, standard enteral formulas may be used. In this case, selection likely depends more on accompanying clinical conditions than on renal status. For example, a low-carbohydrate formula may be more appropriate for the CRRT patient with glucose intolerance than the typical calorically dense renal formulas.

Delayed gastric emptying related to dialysis treatment, diabetes, high blood urea nitrogen levels, hyperglycemia, or postoperative gastrointestinal complications can lead to enteral feeding intolerance in patients with renal failure. PN is indicated when the enteral route cannot safely be used to fully meet daily nutritional requirements. In general, standard amino acid solutions can be used. When fluid volume restriction is necessary, concentrated 15% amino acids solutions are helpful. A parenteral amino acid solution of equal amounts of essential amino acids and standard amino acids at a dose of 1 g per kg

per day may be given in cases of severe intolerance to standard mixtures despite intensive dialysis. Patients receiving enteral or parenteral preparations using essential amino acids as the sole source of nitrogen have demonstrated conflicting results concerning improvement in nitrogen balance and overall recovery of renal function [14,28,29]. Also, nonessential amino acids may become conditionally essential for protein synthesis and ammonia detoxification when the patient is under the stress of certain disease states. Thus, the use of formulations containing only essential amino acids should be reserved for less than 2 weeks of treatment in quantities less than 0.5 g per kg per day for patients with worsening renal function who are unable to begin dialysis.

Intradialytic parenteral nutrition (IDPN) is another means of nutritional support designed for use in malnourished HD patients unable to meet full protein and energy requirements by the oral or enteral route. IDPN may offer some advantages over PN in that dedicated vascular access is not needed and administration is done during dialysis therapy to avoid fluid overload. On the other hand, IDPN alone cannot provide adequate daily nutrition; it places the patient at high risk for hyperglycemia with insulin resistance, and expenses of the treatment are comparable to PN [30]. Several trials have attempted to demonstrate the efficacy of IDPN with favorable results; however, limitations in study design have left health care professionals wary of supporting its use in clinical practice [31]. A recent prospective study of 16 malnourished HD patients receiving IDPN revealed a significant weight gain after 6 months of IDPN treatment [32]. No control group was used in this study and no other outcome variables (i.e., morbidity, mortality) were adequately evaluated. At present IDPN should not be used as a substitute for total PN, especially in the critical care setting.

Summary of Nutritional Recommendations

Primary efforts of the caregiver should be directed toward management of the various nutritional and metabolic disorders commonly associated with renal failure. Adequate nutrient provision may optimize renal function, improve nutritional status, and raise the chances of survival in ARF patients [33]. Protein and energy requirements are largely dependent on the underlying causes of renal failure in the critically ill patient. ARF secondary to sepsis or severe injuries places a far greater nutrient demand on patients than that of nephrotoxic drug-induced ARF. The Harris–Benedict equation is used to calculate basal energy requirements, which is then multiplied by an activity and stress factor to determine total energy expenditure. Estimates of total energy expenditure in a critically ill population are typically between 30 and 45 kcal per kg per day. Increasing energy above this does not improve nitrogen balance [34]. Patients with a prolonged stay in the ICU may benefit from the more accurate predictions of energy expenditure afforded by indirect calorimetry [35]. Nondialyzed patients with ARF require a protein restriction of less than 0.5 g per kg of essential amino acids or 0.6 to 1.0 g per kg per day of mixed protein sources. However, such severe restrictions should not be imposed for longer than 2 weeks, and importance should be given to adequate energy provision for protein sparing. Patients receiving intermittent HD require 1.2–1.5 g per kg per day of mixed protein sources, whereas those undergoing CRRT can tolerate protein levels of up to 2.5 g per kg per day. Serum electrolytes should be monitored daily with additives adjusted on an individual basis. Standard vitamins and trace minerals can safely be provided to renal failure patients in the ICU. Fluid allowances for nondialyzed or HD patients are based on 24-hour urine output with an additional 500 mL for insensible losses. Those undergoing CRRT should be permitted additional fluid for provision of full nutritional support. A summary of recommendations supported by randomized controlled trials is included in Table 192.3.

TABLE 192.3

NUTRITION SUPPORT IN ACUTE KIDNEY INJURY

Increasing energy intake from 30 to 40 kcal/kg/d does not improve nitrogen balance and results in elevated levels of triglycerides and blood sugars [34].
Protein intake of 2.5 g/kg/d is recommended to achieve positive nitrogen balance in patients on CRRT.
Indirect calorimetry can improve the accuracy of energy provision in patients on CRRT.

LIVER FAILURE

As the central regulatory organ of the body, the liver is responsible for the metabolism, storage, activation, transport, and synthesis of many vital nutrients. Biochemical reactions fundamental to carbohydrate metabolism such as glycogenesis and gluconeogenesis are carried out in the liver. Albumin, transferrin, prealbumin, and prothrombin are a few of the major serum proteins generated in the liver. Fatty acid oxidation as well as the production of bile salts, triglycerides, and cholesterol for lipid absorption and transport is part of the normal hepatic function. The liver is also responsible for the catabolism of various potentially toxic substances including ammonia, alcohol, and acetaminophen. Liver damage can lead to the disruption of many of these processes; however, due to the large capacity for hepatic reserve, dysfunction is not usually seen until 80% to 90% of the liver cells have been injured [36].

A number of insults can initiate the cellular degeneration of acute or chronic liver disease. Viral infection, alcohol use, medications or other hepatotoxic agents, cardiac shock, chronic cholestasis, metabolic disorders, and autoimmune diseases are all potential instigators of liver injury. The damage can be so sudden and severe that it results in fulminant hepatic failure (FHF), a rare disease involving extensive liver necrosis and often culminating in death. Complications of FHF include metabolic abnormalities such as hypoglycemia or acidosis, hemodynamic instability, cerebral edema, sepsis or immunosuppression, and the hepatorenal syndrome. The presence of hepatic encephalopathy (HE), manifested by several neurologic, behavioral, and neuromuscular changes, may be able to predict the prognosis of FHF depending on the severity of the impairment [37]. Treatment of FHF often involves nutritional intervention; however, no controlled studies have been done to assess the benefits of nutrition therapy in this population.

Patients with acute hepatitis tend to be highly catabolic in the setting of severe gastrointestinal distress. Nausea, vomiting, and anorexia with occasionally concurrent acute pancreatitis may preclude the ability for oral intake. Short-term nutrition support is often necessary until causes of the acute injury to the liver have been identified and treated.

The end stage of most chronic liver diseases is the development of cirrhosis. Cirrhosis is characterized by repeated episodes of necrosis, followed by regrowth and formation of connective scar tissue. The resulting disruption of normal hepatic structure increases resistance of blood flow to the liver. Portal hypertension, esophageal varices with gastrointestinal bleeding, and ascites often stem from altered hepatic circulation in cirrhotic patients. Clinical evidence of cirrhosis can progress from elevated serum transaminases and jaundice to

hypoalbuminemia and HE. Malnutrition has been documented in up to 100% of hospitalized patients with alcoholic liver cirrhosis [38]. It is important to note that the presence of esophageal varices or ascites does not preclude the use of small bowel nasoenteric tube feeding in malnourished cirrhotic patients [39]. Several controlled trials using enteral nutrition in this population have demonstrated improvements in liver function tests, nutritional status, nitrogen balance, length of hospitalization, and overall prognosis [40–42]. The achievement of positive nitrogen balance did not have a negative impact on encephalopathy, azotemia, edema, or ascites among the study groups.

Malnutrition and Metabolic Alterations

Malnutrition in acute and chronic liver disease is the result of a combination of factors. A decrease in oral intake is common in the patient with prolonged gastrointestinal distress, early satiety secondary to ascites, or excessive alcohol consumption. Maldigestion and malabsorption leading to steatorrhea is often seen with cholestasis or chronic pancreatitis. Malnutrition in liver failure is also closely linked to the presence of severe metabolic derangements characteristic of hypercatabolic states of organ injury. Impaired glycogen synthesis and storage as well as decreased hepatic degradation of stress hormones lead to the preferential use of lipid and protein reserves for gluconeogenesis [43]. Insulin resistance and glucose intolerance are usual complications of early liver failure. Hypoglycemia can occur in decompensated cirrhosis or FHF as a result of hepatic glycogen depletion and impaired gluconeogenesis.

Hepatic steatosis with concurrent depletion of adipose tissue stores is a frequent consequence of the imbalance between lipid uptake, fatty acid oxidation, and the release of lipoproteins by the damaged liver. It is important to note that hepatic steatosis is often preventable by avoiding overfeeding. Lipids are the primary source of energy in enteral nutrition supplements designed for use in liver failure patients. IV lipids are also metabolized well by critically ill patients with hepatic failure when given in amounts not to exceed the energy needs of the individual patient. A recent study by Druml et al. found no significant difference in uptake, hydrolysis, or oxidation of a 20% IV lipid emulsion in septic patients with hepatic failure versus in healthy controls [44].

Altered protein metabolism is by far the most challenging aspect of providing nutrition therapy to the critically ill patient with liver disease. Cirrhosis has long been established as a catabolic disease, with unremitting protein degradation and inadequate resynthesis leading to depletion of visceral protein stores and muscle wasting [45]. Under ordinary circumstances, the skeletal muscle collects circulating branched-chain amino acids (BCAAs) for the synthesis of glutamine and alanine, amino acids that are released into the bloodstream and taken up by the liver for use in hepatic gluconeogenesis. Glutamine is also a carrier for ammonia, a potentially toxic by-product of protein metabolism. Ammonia is normally converted into urea by the liver and excreted by the kidneys. As liver function declines, uptake of serum glutamine is diminished and the degradation of ammonia into urea is impaired. In this case, excess serum glutamine and ammonia is diverted to renal pathways for direct excretion by the kidneys.

Adequate protein intake is therefore essential in the liver patient not only for the provision of energy by gluconeogenesis but also for the preservation of skeletal muscle mass and the prevention of HE. The clinical practice of protein restriction in patients with liver damage is common, for fear of precipitating or worsening central nervous system changes associated with HE. Several protein-related theories have been proposed regarding the development of HE, although it is of significance that the occurrence of encephalopathy has not been observed to directly correlate with protein intake in cirrhotic patients [46]. IV protein solutions with higher concentrations of BCAAs have been developed for use in liver disease based on the following hypothesis. As the use of BCAAs by skeletal muscle increases, serum levels decrease, thereby leaving an imbalance of BCAAs and aromatic amino acids at the blood–brain barrier. With less opposition from BCAA, aromatic amino acids readily cross into the central nervous system to form "false neurotransmitters." The false neurotransmitters compete with actual neurotransmitters for binding sites and disrupt normal central nervous system function to cause symptoms of HE [47].

Elevated serum ammonia concentrations have also been implicated in the pathogenesis of HE. Ammonia metabolites such as glutamine in cerebrospinal fluid have been correlated with the severity of encephalopathy [48]. Plauth et al. evaluated differences in serum ammonia levels between enterally and parenterally fed cirrhotic patients' status post–transjugular intrahepatic portosystemic shunt placement [49]. The small intestinal metabolism of enterally fed glutamine was found to produce significantly greater serum ammonia levels than the direct systemic infusion of parenterally fed glutamine. This suggests that PN may allow for a safer way to provide protein to encephalopathic patients. Enteral or parenteral administration of glutamine, however, is not recommended in patients with moderate to severe liver disease [50].

Zinc plays an important role in the regulation of nitrogen metabolism and zinc deficiency has been implicated in the pathogenesis of hepatic encephalopathy. Zinc supplementation therefore would seem to be a potential target for therapy and many studies have tried to address this question with conflicting results. To date there is no clear evidence of a beneficial effect for zinc supplementation for patients with hepatic encephalopathy [51].

Enteral and Parenteral Formulations

As mentioned previously, enteral and parenteral formulas for use in liver failure are designed to normalize plasma amino acid concentrations and improve encephalopathic symptoms. Hepatic enteral nutrition products are generally calorically dense, enriched with BCAAs, and of low-to-moderate fat content (Table 192.4). IV solutions for use in hepatic failure consist of 8% amino acids with 36% of total amino acids provided as BCAA (e.g., valine, isoleucine, and leucine) and only 2% as aromatic amino acids (e.g., tryptophan, phenylalanine, and tyrosine). These include Aminosyn-HF (Hospira, Inc., Lake Forest, IL), Hepatasol (Clintec Nutrition, Deerfield, IL), and HepatAmine (B. Braun Medical, Inc., Irvine, CA). Several leaders of nutrition-related research have published studies, reviews, and meta-analyses on the topic of oral or enteral BCAAs and HE, although consensus is still lacking among them [52–54]. Differences in the degree of encephalopathy, duration of treatment, type of control therapy, and amount of BCAAs supplied have limited the ability to draw distinct conclusions. Numerous research trials have also been conducted in an attempt to demonstrate clinical benefits of BCAA-enriched PN. A meta-analysis of seven such trials concluded that encephalopathy and survival rates were significantly improved among patients treated with BCAAs versus the control groups treated mainly with large doses of dextrose and lactulose or neomycin [55]. It should be noted, however, that improvement in encephalopathy did not always correlate with changes in serum amino acid levels. Other factors may have influenced mental status and mortality in these patients. A Cochrane Review from 2003 looked at 11 randomized trials (556 patients) regarding the effect of BCAA on hepatic encephalopathy [56]. Compared to the control regimens, the BCAA arms showed improvement

in encephalopathy at the end of the treatment. There was no effect on survival. Given the lack of follow-up, poor quality, and the small sample size of these studies, however, the reviewers concluded that there is no convincing evidence that BCAA have a beneficial effect on patients with hepatic encephalopathy [57]. In one large, randomized trial by Muto et al, oral BCAA given to patients with cirrhosis improved the combined rate of death and progression to liver failure [56]. Iwasa et al. showed improvement in regional cerebral blood flow in patients with cirrhosis treated with BCAA [58]. In regards to PN, few published studies exist to date comparing BCAA-enriched TPN to parenteral solutions containing standard amino acids [59–61]. No differences in outcome were noted in each of these studies.

Nevertheless, recommendations for clinical practice may be made from the evidence at hand. A primary focus in the management of HE should be on treatment of the underlying causes [9]. Dehydration, infection, electrolyte abnormalities, gastrointestinal bleeding, acid–base imbalances, and medications have been implicated in the occurrence of encephalopathy among critical care patients. In most acute cases, mental status improves with correction of precipitating abnormalities. Use of lactulose or neomycin, or both, for bowel cleansing and sterilization is the first line of treatment for hyperammonemia. The practice of restricting dietary protein in cirrhotic patients, especially those with HE, may seem prudent given the clear relationship between serum ammonia levels and poor outcomes. However, Cordoba et al. showed in a randomized controlled trial that restricting protein intake during encephalopathy had no beneficial effect [62]. When nutrition support is needed, a standard protein formula can be initiated at doses of 0.6 to 0.8 g per kg per day [63]. Restriction of protein is only necessary until the causes of encephalopathy have been identified and treated. To maintain nitrogen balance, nutrition support should be advanced as tolerated to goals of 1.0 to 1.5 g per kg per day in critical care situations [64]. BCAA-enriched formulas are solely reserved for use in severe encephalopathy refractory to standard treatment, but evidence for their role as a first choice is mounting.

Nutrition Assessment

Traditional parameters of nutritional status such as weight loss and depletion of visceral protein stores are frequently masked among liver failure patients by the presence of ascites or edema. Serum albumin, prealbumin, and transferrin levels are more reflective of disease-related intravascular volume expansion and increased protein catabolic rate than the severity of nutritional deficit. Despite this, albumin remains an important marker of PCM among liver patients. Because the upper extremities tend to escape the fluid retention often seen in liver patients, mid-arm muscle circumference and triceps skinfold measurements are considered to be the most accurate tools for nutrition assessment in this population. Recent investigations have centered on the detection of those nutritional parameters most predictive of survival, indicative of PCM, and responsive to treatment in liver failure patients. A prospective study of 271 mildly to severely malnourished patients with chronic alcoholic hepatitis revealed significant improvements in visceral proteins and mid-arm muscle mass in response to intensive nutrition therapy along with oral administration of oxandrolone, an androgenic anabolic steroid [46]. Severe reduction in mid-arm muscle circumference and triceps skinfold measurement, suggestive of muscle mass and body fat depletion were found to be independent predictors of survival in a study of 212 hospitalized cirrhotic patients. In this study, Alberino et al. also advised the inclusion of upper-arm anthropometry to improve prognostic accuracy of the Child-Pugh score, a commonly used classification of the severity of liver disease [65]. A comprehensive analysis of all available data, including physical examination, anthropometric measurements, and laboratory values, may therefore be the best determinant of nutritional status in liver disease.

Summary of Nutritional Recommendations

In devising a plan for nutritional management of the critically ill patient with liver disease, one must consider the etiology of the disease, associated complications and metabolic abnormalities, and concurrent disease processes (Table 192.5). Despite the inherent difficulties in obtaining an accurate dry weight, the Harris-Benedict equation with stress factors may be used in most liver patients to estimate basal energy expenditure. Requirements for most patients are met with 25 to 35 kcal per kg per day or basal energy expenditure times 1.2 to 1.4, and standard protein doses of 1.0 to 1.5 g per kg per day [66]. Nonprotein calories are generally supplied in proportions of 50% to 70% carbohydrate and 30% to 50% fat in the setting of glucose intolerance. Patients demonstrating symptoms of persistent encephalopathy despite aggressive medical management require a temporary protein restriction of 0.6 to 0.8 g per kg per day pending treatment of underlying causes. If the patient does not respond to protein restriction, a BCAA-enriched formula should be used to promote nitrogen balance. Sodium and fluid restriction are indicated with ascites or edema. Recommended daily allowances of vitamins, minerals, and trace elements are usually sufficient in this population, although additional supplementation of thiamine and folate is customary in alcoholic cirrhosis. Pescovitz et al. document an elevated rate of profound zinc deficiency among patients with end-stage liver disease [67]. Supplementation of zinc in these cases may improve HE; however, efficacy of zinc as a routine therapy for encephalopathy is still controversial [68].

In the case of severe liver disease such as FHF, indirect calorimetry is a more accurate method of determining energy

TABLE 192.5

NUTRIENT REQUIREMENTS IN VARIOUS STAGES OF LIVER DISEASE

Degree of liver injury	Total energy (kcal/kg/d)	Protein or amino acids (g/kg/d)
Compensated cirrhosis	25–35	1.0–1.2 for maintenance, 1.2–1.5 for repletion
Decompensated cirrhosis	25–35	Begin with 0.6–0.8 of standard protein If improvement, advance to 1.2–1.5 as tolerated If refractory, supplement with BCAA until positive nitrogen balance is achieved
Fulminant hepatic failure	35–40	0.6–0.8, if improvement advance
Post–liver transplant	25–35	1.2–1.5

BCAA, branched-chain amino acids.

requirements. Because patients in FHF have limited gluconeogenesis capacity, nutrition support should be initiated peripherally with 10% dextrose to limit the possibility of hypoglycemia and limit catabolism. To provide more substantial dextrose concentrations parenterally, central access is required. Fluid restriction is often necessary to prevent exacerbation of cerebral edema. However, with the use of peripheral 10% dextrose solution, large volumes are required to achieve nutritional goals. Protein administration should begin with 0.6 to 0.8 g per kg per day of a standard amino acid solution. Standard protein provisions should be advanced as tolerated to 1.2 to 1.5 g per kg per day if the encephalopathy improves. If the patient remains in negative nitrogen balance with severe encephalopathy, BCAA formulas should be used and advanced as tolerated to achieve positive nitrogen balance. Protein requirements in FHF are 1.5 to 1.75 grams per kg per day, and basal energy requirements in FHF are 35 to 40 kcal per kg per day provided as a mixture of carbohydrate and lipid substrates. A summary of recommendations supported by randomized controlled trials is included in Table 192.6.

TABLE 192.6

NUTRITION SUPPORT IN LIVER DISEASE: SUMMARY OF CONTROLLED TRIALS

Cirrhosis and severe malnutrition:

Total enteral tube feeding, compared to a regular diet, improves liver function and reduces mortality in hospitalized patients [40].

Alcoholic liver disease:

Protein calorie malnutrition correlates significantly with mortality, clinical severity of the liver disease, and biochemical liver dysfunction [42].

Supplemental enteral tube feeding, in addition to an oral diet, results in more rapid improvement of liver function in hospitalized patients [102].

Hepatic encephalopathy (acute):

Branched-chain amino acid enriched nutrition support leads to a more rapid resolution of hepatic encephalopathy, but has no affect on mortality [56].

Normal protein intake is well tolerated and results in less protein breakdown when compared to low protein intakes [62].

Note: Studies did not specifically focus on patients in the critical care setting and most were small in size.

Liver Transplantation

Currently, the best therapy for unsalvageable liver failure is liver transplantation [50]. It is important to note that not only must the nutritional status of the liver transplant recipient be considered, but also that of the donor. There is evidence to suggest that infusion of large quantities of dextrose can restore glycogen stores, that feeding the donor patient improves protein synthesis, that fish oils may increase hepatic energy content, and that glutamine offers some graft protection in ischemia-and-reperfusion injury [69,70].

Liver transplant candidates should undergo a comprehensive nutritional assessment to uncover signs of poor nutritional status. Once moderate-to-severe PCM has been established, nutrition support should be initiated to promote improved postoperative outcomes [50,71]. Nutrition support is also of value in the immediate posttransplant period. Hasse et al. randomized 50 posttransplant patients to receive standard enteral nutrition or parenteral electrolyte solutions until oral diets were tolerated [72]. A decreased incidence of infection and faster recovery of nitrogen balance was found in the enterally fed group during the first 21 days after undergoing orthotopic liver transplantation. Posttransplant patients are often faced with impaired glucose tolerance and hyperlipidemia, although standard lipid infusion is generally well tolerated and necessary to maintain glycemic control in this population. Tight blood glucose control with special emphasis on the increased risk for hypoglycemia may help reduce the chances for postoperative septic complications. Energy requirements are estimated using the Harris-Benedict equation multiplied by stress factors of 1.2 to 1.3, with protein needs estimated at 1.2 g per kg per day. No specific advantages have been found with regard to the use of BCAA-enriched amino acids solutions or fat emulsions containing medium- and long-chain triglycerides in this population [72].

PULMONARY FAILURE

Optimal functioning of the pulmonary system is essential to the maintenance of adequate nutritional status. Through the process of gas exchange, the lungs and supporting respiratory structures provide oxygen to vital tissues for nutrient metabolism. The respiratory system also plays a major role in regulation of acid–base balance. Pulmonary injury or insufficiency can lead to malnutrition and dependence on mechanical ventilation in the critically ill patient. Acute respiratory distress syndrome (ARDS), characterized by severe progressive

hypoxemia and mechanical ventilation, is a frequent result of trauma, sepsis, or surgery in the critical care setting. The patient with chronic obstructive pulmonary disease (COPD) may also undergo periods of acute exacerbation requiring intensive care. Malnutrition has been documented in up to 60% of this population, with the highest incidence occurring in the mechanically ventilated. In a 1996 study by Vitacca et al., nutritional prognostic indicators such as weight loss and percentage of ideal body weight were able to significantly predict the need for mechanical ventilation among hospitalized COPD patients. Decreased survival rates have been observed in malnourished, critically ill COPD patients as well [73,74].

Malnutrition may result from a variety of factors inherent to the pulmonary disease process. Hyperinflation of the lung with an associated decrease in abdominal volume often leads to anorexia, early satiety, and tube feed intolerance. Oral intake may also be hindered by dyspnea and fatigue during meal times. Significant weight loss is found in 20% to 40% of patients with forced expiratory volume in 1 second (FEV_1) of less than 50% [75]. Energy expenditure is reported to be up to 20% above normal in COPD due to the increased work of breathing [76]. Patients with significant COPD spend 430 to 720 kcal per day in the task of breathing, whereas normal subjects use only 36 to 72 kcal per day toward the same goal [9]. Impaired gas exchange with inadequate delivery of oxygen to body tissues has been implicated as a cause of malnutrition in COPD [77]. Increased levels of tumor necrosis factor, an inflammatory mediator, may additionally lead to alterations in energy expenditure and the development of anorexia in this population [78].

Effects of Malnutrition on Pulmonary Function

Just as pulmonary disease influences the onset of malnutrition, poor nutritional status may significantly impair several structural and functional components of the respiratory system [79]. Respiratory muscles display reduced efficiency and endurance during nutrition deprivation due to loss of muscle mass and depletion of energy reserves. Impaired respiratory muscle function eventually results in decreased ventilatory drive and inefficient gas exchange or hypercapnia and hypoxemia. Severe hypophosphatemia, often seen during rapid refeeding of malnourished patients, also adversely affects respiratory muscle function resulting in decreased delivery of oxygen to the tissues [80]. Hypoalbuminemia, associated with critical illness and malnutrition, decreases osmotic pressure, leading to the expansion of extracellular fluid and increased interstitial lung fluid or pulmonary edema. A reduction in pulmonary functional reserve capacity accompanies fluid retention in the lungs [81]. Immunity from respiratory tract infection relies heavily on the preserved integrity of the pulmonary system. Nosocomial pneumonia is the most common fatal infection among hospitalized individuals. Malnutrition in the setting of critical illness not only impairs immune response but also damages specific pulmonary defense mechanisms. Decreased secretion of immunoglobulin A, reduced alveolar macrophage recruitment, increased bacterial adherence to respiratory epithelium, and a weakened lung matrix are all potential outcomes of malnutrition leading to increased risk of pneumonia and mortality in the critically ill patient [9].

Nutritional Assessment

As previously mentioned, common indicators of nutritional status have correlated with the duration of mechanical ventilation and mortality in hospitalized COPD patients. Several recent studies have focused on uncovering specific parameters most predictive of nutritional status and outcome in this population. A large-scale, prospective study conducted by Landbo et al. observed strong associations between low body mass index (BMI) and increased mortality in subjects with severe COPD [82]. In a similar study, Hallin et al. demonstrated that patients who were under weight (BMI < 20) had a lower FEV_1 and a higher risk of dying within the next 2 years following their hospital admission [83]. It is unclear, however, if nutritional support in the chronic COPD patient can improve these outcomes.

In regard to defining nutritional status, Faisy et al. compared changes in bioelectrical impedance analysis with various anthropometric and biologic parameters among ICU patients with COPD and acute respiratory failure [84]. Bioelectrical impedance analysis more accurately detected severe alterations in nutritional status in those patients requiring mechanical ventilation, whereas anthropometric data were inconclusive. Low serum albumin levels were also significantly associated with increased mortality among patients in this study. Weight changes, serum albumin levels, and bioelectrical impedance analysis, if available, are thus used as valuable tools in assessment of nutritional status and prediction of outcome in patients with severe respiratory insufficiency.

An accurate measure of energy expenditure is of utmost importance in the nutritional care of the patient with pulmonary disease. Underfeeding, with the consequence of malnutrition, may increase risk of infection, prolong ventilator dependence, delay wound healing, and increase overall hospital morbidity and mortality. An overestimation of energy needs is associated with several metabolic, hepatic, and respiratory complications, including increased carbon dioxide production with inability to wean from mechanical ventilation (Table 192.7). McClave et al. demonstrated an inverse correlation between the degree of feeding in mechanically ventilated adults and the amount of air inspired and expired over the period of 1 minute [85]. Patients receiving greater than 100% up to 300% of nutritional needs as estimated by indirect calorimetry showed significant decreases

TABLE 192.7

POTENTIAL COMPLICATIONS OF OVERFEEDING

System	Complications
Metabolic	Hypermetabolism Hyperglycemia Increased lipogenesis Fluid overload Hypophosphatemia Hypokalemia Hypomagnesemia
Hepatic	Hepatic steatosis Cholestatic liver disease Elevated serum transaminases
Respiratory	Increased carbon dioxide production Hypercapnia Increased minute ventilation Increased ventilatory drive Decreased oxygen saturation Increased respiratory quotient Weakened respiratory muscles Difficulty weaning from mechanical ventilation

Data compiled from references [8,56,70,77,79,83,94,95].

in minute ventilation, whereas those receiving less than 100% of their caloric requirements had significant increases in minute ventilation. Ventilatory settings may be adjusted to account for minor discrepancies in provision of nutrient requirements without much setback; however, this study also revealed that only approximately 25% of hospitalized patients actually receive calories within 10% of energy requirements [86,87].

Indirect calorimetry is a clinical tool by which measurements of respiratory gas exchange are used to determine energy requirements and substrate utilization for a given subject. It continues to be the gold standard for establishing nutritional goals. Several researchers have examined the benefits of using indirect calorimetry over predictive equations to assess energy expenditure in critically ill patients with acute respiratory failure [85,87,88]. Flancbaum et al. found poor correlation between various predictive formulas and indirect calorimetry measurements. A 1997 review by Brandi et al. concluded that although several sources of error exist, indirect calorimetry remains the most appropriate measure of energy expenditure in mechanically ventilated patients. Recommendations were also made to obtain several measurements throughout the course of a patient's illness to more closely approximate nutritional requirements under fluctuating metabolic states. In cases in which indirect calorimetry is not available or not feasible, the Harris-Benedict equation may be used to estimate resting energy expenditure (REE), which is then multiplied by a stress factor of 1.3 to 1.5 to approximate energy requirements in this population.

Nutrient Requirements and Nutrient Impact on Pulmonary Function

Substrate utilization as assessed by indirect calorimetry is the ratio of oxygen consumed to carbon dioxide produced on metabolism of various macronutrients. This ratio is referred to as the respiratory quotient (R/Q). The oxidation of fat, protein, and carbohydrate produces an R/Q of 0.7, 0.8, and 1.0, respectively. Ideally, the R/Q of a given patient should approximate 0.85 to reflect metabolism of mixed substrates. When carbohydrate or total calorie provisions exceed energy requirements, R/Q levels rise above 1.0 to suggest fat synthesis. An R/Q of less than 0.7 is indicative of inadequate nutrition support with breakdown of bodily fat and protein stores. This information is useful for the adjustment of fuel mixtures within the nutrient prescription to avoid potentially harmful effects of over or underfeeding the ventilator-dependent patient.

The provision of carbohydrate in excess of 5 mg per kg per minute in severely stressed patients increases carbon dioxide production ($\dot{V}CO_2$) and may delay weaning from mechanical ventilation. Jih et al. reported the case of a septic ARDS patient who developed increased respiratory distress and hypercapnic acidosis in response to hypercaloric carbohydrate infusion [89]. Hypercapnia resolved as carbohydrate and total calories were decreased to levels consistent with indirect calorimetry measurements of REE. Talpers et al. maintain that total caloric intake has more of an impact on respiratory function in mechanically ventilated patients than excessive carbohydrate calories [90]. No difference in ($\dot{V}CO_2$) was observed upon variation in carbohydrate provisions with consistent total caloric intake (1.3 × REE). In contrast, increasing total caloric provisions (1.5 to 2.0 × REE) with fixed carbohydrate content led to a significant progressive increase in ($\dot{V}CO_2$). Administration of PN at a calorie level equal to indirect calorimetry measurements did not increase ($\dot{V}CO_2$) or ventilatory demand in a 1994 analysis of mechanically ventilated patients by Kiiski and Takala [91]. In many cases, sustained hyperglycemia in the critically ill mechanically ventilated patient signifies a need for decrease in carbohydrate or total calorie provisions rather than an incremental increase in insulin dosage.

The substitution of fat for carbohydrate calories may lower R/Q and decrease ($\dot{V}CO_2$) to ease weaning from the ventilator [92]. The use of IV fat emulsions (IVFE) is not without its drawbacks, however. Rapid infusion of IVFE may adversely affect gas exchange by decreased rate of clearance, deposition of lipid particles within the reticuloendothelial system, and subsequent reduction in pulmonary diffusion capacity. This effect is most often seen in patients with existing pulmonary dysfunction and with rates of lipid administration more than 1 kcal per kg per hour [93]. Immune function is also compromised by rapid infusion of IVFE in patients with pulmonary insufficiency. Specific omega-6 polyunsaturated fatty acids, including linoleic acid, serve as precursors for synthesis of vasoconstrictive prostaglandins and proinflammatory eicosanoids. The resulting activation of pulmonary neutrophils limits bacterial clearance from systemic circulation and increases uptake of bacteria into the lungs [94]. Inflammatory cells, possibly activated by lipids, release phospholipase A[2] and platelet-activating factor, enhancing edema formation, inflammation, and surfactant alterations [95]. Specialized enteral formulas designed to decrease production of proinflammatory agents and enhance immune function in pulmonary patients are discussed in the following section.

Battistella et al. examined the effects of withholding IVFE for 10 days in 57 polytrauma patients requiring total PN [96]. Results indicated a significantly greater length of ICU and hospital stay, longer duration of mechanical ventilation, and higher incidence of infection in patients receiving IVFE. It is, however, impossible to fully assign the differences to the withholding of lipids, as this group did not receive extra calories to account for the absence of lipid. The group with IVFE received 25% more total calories, which could have contributed to the increase in adverse outcomes in this group of patients. Clinical experience has shown that IVFE may be given safely in the range of 20% to 40% of nonprotein calories infused over a period of 12 to 24 hours in the critically ill patient [9].

Protein requirements in critically ill patients with pulmonary failure are elevated in accordance with the hypercatabolism of stressed states. Consequences of protein malnutrition, including loss of diaphragmatic muscle mass, are significant enough to warrant 1.5 to 2.0 g per kg per day of protein depending on the need for repletion [97]. Unfortunately, an increase in ventilatory drive and minute ventilation may be seen with protein infusion. BCAA formulas, in particular, may result in severe respiratory distress [98]. It is therefore recommended that protein provisions be advanced slowly with close attention to respiratory function in mechanically ventilated patients.

Enteral and Parenteral Nutrition

The use of enteral nutrition or PN is necessary in nearly every patient that requires prolonged ventilator support. However, the use of PN in the patient with pulmonary failure has become increasingly scrutinized. Plurad et al. showed that the administration of PN was independently associated with late onset ARDS [99]. In general, parenteral nutrition should be avoided in this patient population. In those patients in whom PN must be used secondary to inability to use the gastrointestinal tract, there is new evidence to suggest that omega-3 fatty acids-supplemented parenteral nutrition may be better than standard formulas [100]. Currently, these formulas are not available in the United States.

Although the intubated and sedated patient is at increased risk of aspiration, enteral nutrition is clearly the preferred route of feeding due to improved outcomes, lower costs, decreased

[b]Abbott Nutrition (Columbus, OH).
MCT, medium-chain triglycerides; N/A, data not available; Na, sodium; NPC:N, nonprotein calorie to nitrogen ratio; PO_4, phosphorus.

risk of sepsis, and improved preservation of gut mucosal barrier. Proposed mechanisms by which risks for aspiration may be reduced include timely weaning of the patient off pressor support, maintenance of the patient in a semirecumbent body position, and the use of transpylorically placed feeding tubes [80,101]. Gastric feedings may work equally as well if gut motility is intact. Kearns et al. [102] found no clear difference between the use of small bowel and gastric feeding tubes in the prevention of ventilator-associated pneumonia [102]. Despite this, small bowel tube placement remains the preferred method of feeding for improved nutrient intake in a population frequently hindered by gastric ileus.

Standard enteral formulas may be used in most patients with pulmonary dysfunction, however, current recommendations advise that specialized nutritional support is indicated in the critically ill who are unable to consume an oral diet within 5 to 10 days [103]. Fluid and sodium-restricted tube feedings are often necessary until the risk for pulmonary edema resolves. Enteral products designed specifically for use in pulmonary disease should be reserved for patients with existing COPD and increasing difficulty weaning off the ventilator (Table 192.8). These formulas are typically nutrient dense with moderate to high levels of fat (40% to 60%). Akrabawi et al. examined the effects of a moderate fat (Respalor; 41% fat) (Novartis Nutrition, Minneapolis, MN) versus high fat (Pulmocare; 55% fat) (Abbott Nutrition, Columbus, OH) enteral formula on gastric emptying times and pulmonary function in 36 patients with COPD [104]. Although no differences were found in pulmonary function between the two feedings, gastric emptying times were significantly enhanced with the moderate-fat meal. This implies possible benefits, including improved tolerance and overall increased nutrient intake and absorption with the use of a moderate-fat enteral nutrition product providing 30% of total fat as medium-chain triglycerides.

A specialty enteral feeding was designed to counteract the inflammatory cascade and improve oxygenation in the patient with ARDS. This product (Oxepa, Abbott Nutrition, Columbus, OH) is supplemented with eicosapentaenoic acid and gamma-linolenic acid, two fatty acids with anti-inflammatory properties. Gadek et al. compared the effects of this specialized enteral formula (Oxepa) with a control feeding (Pulmocare) in 98 critically ill patients with ARDS [105]. The two formulas differed only in terms of lipid composition and increasing levels of antioxidants in the experimental product. Significant beneficial effects on oxygenation (partial arterial pressure of oxygen/fraction of inspired oxygen: 203 vs. 168), minute ventilation, duration of mechanical ventilation (11 vs. 16.3 days; $p = 0.011$), and length of ICU stay (12.8 vs. 17.5 days; $p = 0.016$) were demonstrated in patients fed the specialized diet compared with controls. Further studies are necessary to clearly identify the benefits of these specialized formulas, but based on the recommendations by several nutritional organizations, these formulas should be chosen in patients with ARDS [106,107].

Immunonutrition has also received substantial recent attention. Possible advantages include reduced duration of mechanical ventilation and decreased incidence of pulmonary infection among the critically ill. Atkinson et al. conducted a prospective, double-blind, controlled trial on the use of IMN Impact (Nestle, Minnetonka, MN), an enteral formula supplemented with arginine, purine nucleotides, and omega-3 fatty acids [108]. Three hundred and sixty-nine ICU patients were randomized to receive IMN Impact or an isocaloric, isonitrogenous enteral feed. There was no difference in hospital mortality rate between the two groups. Those patients receiving more than 2.5 L of IMN Impact within 72 hours of ICU admission ($n = 50$ IMN Impact vs. $n = 51$ control formula) had a significant reduction in median duration of mechanical ventilation (6.0 vs. 10.5 days; $p = 0.007$) and median length of hospital stay (15.5 vs. 20.0 days; $p = 0.03$). Mendez et al. found opposite effects when comparing an immune-enhancing formula (Perative, Abbott Nutrition, Columbus, OH) with an essentially isonitrogenous, isocaloric standard feeding [109]. Overall mortality was again identical between the two groups; however, those receiving immunonutrition remained longer on the ventilator (16.4 vs. 9.7 days) and in the hospital (32.9 vs. 22 days) than the control group. It is important to note that Perative does not contain purine nucleotides and delivers omega-3 fatty acids in the form of canola oil rather than fish oils. A recent review of 23 clinical trials involving immune-enhancing formulas concluded that immunonutrition has established a reduced need for ventilation and a decreased risk of infectious complications in malnourished postsurgical ICU patients with known COPD [110]. According to the most recently published guidelines, the use of specialized enteral formulas with anti-inflammatory profiles is now recommended in patients with ARDS with the potential to improve outcomes [107].

Summary of Nutritional Recommendations

Sustained nutrition therapy in mechanically ventilated patients has demonstrated several benefits including increased serum albumin, reduced anasarca, improved respiratory function, and facilitated weaning from the ventilator. Overfeeding can be highly detrimental to the ventilator-dependent critically ill

patient. However, it appears that more often than not, nutritional requirements for these patients are underestimated. Daily energy needs are best determined by indirect calorimetry; although, approximations may be made with predictive equations and stress factors of 1.3 to 1.5 × REE or 25 to 30 kcal per kg. Careful monitoring of intake and output, weight changes, and respiratory status is required when indirect calorimetry is not available. Protein needs generally range between 1.5 to 2.0 g per kg per day, with cautious advancement to goal levels. Carbohydrate dosages should not exceed 5 mg per kg per minute provided as 60% to 80% of nonprotein calories. A conservative dose of fat emulsion is recommended in the range of 20% to 40% of nonprotein calories infused over 12 to 24 hours. Enteral feedings with roughly 30% fat, 50% carbohydrate, and 20% protein are generally well tolerated, provided nutrient requirements are not exceeded. Modified and immune enhanced formulas are gaining favor, but should be reserved for those with ARDS and obvious difficulties weaning off the respirator. Maintenance of fluid balance is also of primary importance in the critically ill patient with pulmonary insufficiency. Concentrated parenteral solutions and enteral formulas should be used as necessary. Sodium restriction is indicated in patients with pulmonary edema or congestive heart failure. Hypophosphatemia may be avoided by gradual advancement of nutrition support in severely malnourished patients. Serum phosphorus, potassium, and magnesium levels should be monitored routinely and deficiencies should be corrected aggressively in the critically ill patient. A summary of recommendations supported by randomized controlled trials is included in Table 192–9.

TABLE 192.9

NUTRITION SUPPORT IN PULMONARY DISEASE

Early enteral nutrition (within 24–48 h admission) decreases infectious complications, including pneumonia.
Enteral formulas with anti-inflammatory lipid profiles and antioxidants improve oxygenation, decrease duration of mechanical ventilation, and shorter intensive care unit length of stay in acute respiratory distress syndrome or acute lung injury [105].
Enteral formulas that provide immunonutrition (arginine, glutamine, nucleic acids, omega-3 fatty acids, antioxidants) decrease duration of mechanical ventilation, organ failure, hospital and intensive care length of stay, and mortality [108, 111].

Note: Early enteral nutrition is not a part of this chapter but a general concept that has been indirectly related to decrease pneumonia.

SECTION XVI ■ RHEUMATOLOGIC, IMMUNOLOGIC, AND DERMATOLOGIC PROBLEMS IN THE INTENSIVE CARE UNIT

NANCY Y.N. LIU

CHAPTER 193 ■ RHEUMATOLOGIC DISEASES IN THE INTENSIVE CARE UNIT

NANCY Y.N. LIU AND JUDITH A. STEBULIS

Patients with established rheumatologic diseases are rarely admitted to the intensive care unit (ICU) because of their inflammatory joint disease. However, since many of these diseases include systemic involvement, organ system failure and complications of therapy are common reasons for ICU admission. Other musculoskeletal problems frequently encountered in the intensive care setting include (a) patients whose underlying rheumatic diseases may pose certain problems in the planning and execution of certain critical care procedures, such as endotracheal intubation or (b) patients in whom acute rheumatic syndromes develop during their hospitalization.

ACUTE RHEUMATIC DISEASES IN THE INTENSIVE CARE SETTING

Several acute musculoskeletal disorders occur with increasing frequency in selected populations of hospitalized patients, including those in the ICU. The most common is crystal-induced arthritis due to monosodium urate, calcium pyrophosphate dihydrate, basic calcium phosphate (BCP)-hydroxyapatite, or calcium oxalate crystals. Two other acute arthritides include septic arthritis from bacteremia and spontaneous hemarthrosis due to complications from anticoagulation therapy or bleeding diathesis.

Gout

Pathogenesis

Gout is characterized by initial intermittent attacks of mono- or polyarticular arthritis in the setting of prolonged hyperuricemia. Over many years, attacks become more frequent and chronic arthropathy may develop. Acute gout is triggered by precipitation or shedding of monosodium urate crystals in the joint space or nearby soft tissues, provoking an intense inflammatory reaction. Regardless of a primary or secondary etiology of hyperuricemia, marked fluctuations in serum urate levels increase the risk of acute gout.

Although the specific triggering event that initiates an isolated attack may be difficult to define, many factors produce serum urate fluctuations and result in an increased incidence of secondary gout in ICU patients. A reduction in glomerular filtration rate from either intrinsic renal disease or decreased effective arteriolar blood volume will result in reduced filtered load of urate, hyperuricemia, and an increased risk of gout. In addition, a reduction in effective arteriolar blood volume results in enhanced tubular reabsorption of urate. Since organic acids such as lactic acid, β-hydroxybutyric acid, and acetoacetic acid may competitively inhibit the renal tubular secretion of uric acid, conditions in which these acids accumulate will also lead to hyperuricemia. Mechanisms of hyperlacticacidemia in the critically ill patient are multiple.

Drug-induced hyperuricemia is a common cause of gout in both hospitalized and nonhospitalized patients. Diuretic therapy decreases effective arteriolar blood volume and also may directly inhibit renal tubular secretion of uric acid. Although thiazide diuretics are the most commonly implicated cause of hyperuricemia and gout, other diuretics including furosemide, acetazolamide, ethacrynic acid, and diazoxide are also potential culprits. Furosemide and diazoxide may also induce hyperlacticacidemia.

In addition to diuretics, other drugs associated with hyperuricemia include low-dose salicylates (less than 2.0 g per day), pyrazinamide, levodopa, α-methyldopa, and cyclosporine. Because of the uricosuric effect of radiocontrast media, a contrast study might precipitate an attack of acute gout. Finally, a hyperuricemic patient who undergoes any surgical procedure is at risk for postoperative gout.

Clinical Features

Gout is easily identifiable and treatable. Classically, the patient with acute gout complains of sudden onset of an exquisitely painful joint that involves one or more sites in an asymmetric pattern. The attack is sometimes accompanied by low-grade fever, particularly in a polyarticular presentation. The great toe is involved in more than 50% of the initial acute attacks and in 90% of acute attacks at some time in the course of the disease. Other common sites of involvement in order of observed frequency include insteps, ankles, knees, wrists, fingers, and elbows. Periarticular sites of urate deposition in bursae, tendons, and soft tissues may be similarly inflamed during an acute attack. On examination, the involved area is erythematous, swollen, warm, and exquisitely painful on palpation, and sometimes with joint motion. The overlying erythema and edema often extends beyond the joint capsule and can mimic cellulitis or bursitis. The presence of lymphangitis or lymphadenopathy and the absence of pain on joint motion are more consistent with cellulitis. Bursitis can be distinguished from true arthritis since full joint extension is preserved in bursitis, and the region of erythema is not within the borders of the joint compartment. If clinical suspicion of joint infection is low then diagnostic arthrocentesis should be avoided until a therapeutic trial of appropriate antibiotics for cellulitis has been completed. Otherwise, there may be a risk of introducing organisms into a sterile joint. However, if motion is restricted or if radiography suggests an effusion, a diagnostic arthrocentesis should be performed before the institution of any therapy.

The diagnosis of gout is confirmed when aspirated synovial fluid or soft tissue site reveals negatively birefringent monosodium urate crystals within polymorphonuclear neutrophils (PMNs) under polarizing light microscopy. Gouty synovial fluid is inflammatory, with more than 2,000 leukocytes

per μL, occasionally as high as 100,000 per μL, and PMNs predominate in the cell differential. Since gout and septic arthritis have similar clinical features and rarely coexist, aspirated synovial fluid should always be Gram stained for microorganisms and cultured. Elevations in erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and peripheral leukocytosis cannot distinguish gout from other inflammatory states. Serum urate may be normal during an acute attack, while an elevated level does not confirm the diagnosis without crystal identification.

Therapy

Once the diagnosis of acute gout is established, the immediate aim of therapy is to terminate the attack by interruption of the inflammatory response. Long-term management (e.g., prevention of recurrent attacks, sequelae of tophaceous disease or renal stones) need not be considered in the ICU setting. In fact, the initiation or discontinuation of any drugs that alter urate levels (i.e., allopurinol, febuxostat, probenecid, or salicylates) may prolong the acute attack. Asymptomatic hyperuricemia should not be treated.

Corticosteroids. Systemic and intra-articular steroids are effective for the treatment of gout. Intravenous (IV) methylprednisolone (100 to 150 mg IV daily for 1 to 3 days) or intramuscular triamcinolone acetonide (60 to 80 mg daily for 1 to 3 days) is the preferred agent in critically ill patients [1]. Oral prednisone may also be effective in doses of 20 to 30 mg twice per day initially and tapered over 7 to 14 days with decrements of 10 mg every two days [1]. Potential complications of steroid treatment include hyperglycemia, fluid retention secondary to mineralocorticoid effects, and hypothalamic-pituitary-adrenal suppression. Intra-articular corticosteroid injections are an excellent choice for acute gouty arthritis if few joints are involved since systemic side effects are avoided. Steroid injections provide rapid resolution of symptoms, usually within 12 to 24 hours, but if infection is suspected, corticosteroid injection should be delayed until culture results are available. Intra-articular corticosteroids are quite effective in small joints if performed by physicians skilled in these injections. Dosing ranges from 10 to 60 mg methylprednisolone or equivalent triamcinolone, depending on the size of the joint involved.

Adrenocorticotropic Hormone. Adrenocorticotropic hormone (ACTH) has been used for more than 40 years for the treatment of gout. Dosing regimens vary, starting at 40 to 80 IU intramuscularly, subcutaneously, or intravenously 1 to 3 times a day until symptoms abate. Adverse effects include mild hyperglycemia and fluid overload. Although the overall safety profile and efficacy of ACTH are excellent, its use is limited by its lack of availability and prohibitive cost. Its anti-inflammatory effects are result of interruptions of microtubule function in multiple cell types but particularly PMNs' function in chemotaxis, adhesion, phagocytosis, and production of cytokines.

Colchicine. Colchicine is one of the established treatments for gout. Its main mechanism of action involves formation of a reversible complex with the tubulin subunit of microtubules leading to reduced activation and migration of PMNs. Oral colchicine is absorbed in the small intestine and excreted in the bile and urine, reaching a peak serum level in 2 hours. Gastrointestinal side effects, most notably diarrhea, occur in up to 80% of patients, resulting in electrolyte imbalances and fluid losses. In the critically ill patient, oral colchicine may not be feasible and is potentially toxic. Renal and hepatic insufficiencies are risk factors for colchicine related neuromyopathy and bone marrow suppression. In addition, potential drug–drug interactions, including macrolide antibiotics, HMG-CoA reductase inhibitors, fibric acid derivatives, verapamil and diltiazem, and cyclosporine may potentiate colchicine toxicities.

A recent study reports equal efficacy in reducing pain of acute gout with low dose colchicine (1.2 mg orally followed in 1 hour by another 0.6 mg orally) to traditional oral loading of colchicine (1.2 mg orally followed by 0.6 mg every hour for 6 hours) [2]. In addition, the gastrointestinal side effects are significantly reduced with the low dose regimen. Thus, if an ICU patient with an acute onset of gout has normal renal and hepatic function and is able to take oral colchicine, the low dose regimen is a reasonable choice. However, if there is renal insufficiency, dose adjustment is necessary and colchicine is probably best avoided if creatinine clearance is less than 10 mL per minute. A more appropriate use of oral colchicine is the prevention of subsequent attacks once the acute attack is treated. Dosages of 0.6 mg orally once or twice a day have been effective (again dose adjustment is necessary based on GFR) [3]. The most common side effects include nausea, diarrhea, and proximal myopathy with elevated creatinine kinase levels. The risk of myotoxicity correlates with a creatinine clearance of less than 50 mL per minute.

Intravenous colchicine has been used in the past for acute gout. However, due to numerous deaths and inappropriate use of the intravenous route, the United States Food and Drug Administration has recommended the discontinuation of production of intravenous colchicine since 2008 and it is unavailable at this time.

Nonsteroidal Anti-inflammatory Drugs. Nonsteroidal anti-inflammatory drugs (NSAIDs) are effective in the treatment of acute gout. However, the mechanism of action involves prostaglandin inhibition, which can interfere with gastric mucosal integrity and worsen renal function by reducing renal perfusion in the setting of volume contraction. NSAIDs may also cause other side effects, including decreased coronary flow and mental status changes. Although the cyclooxygenase-2 inhibitor agents offer the possibility of fewer adverse events, their safety profile is based on outpatient experience. Serious adverse effects with these newer agents have been reported. Given the fact that many patients in the ICU have some degree of renal disease and are at risk for gastrointestinal bleeding, NSAIDs are rarely a first-line agent in the treatment of gout in the ICU.

Other Microcrystalline Arthropathies

Although gout is the best-defined and most common crystalline arthropathy, several other crystalline-induced syndromes may mimic gout and cause potential diagnostic confusion. These include calcium pyrophosphate dihydrate (CPPD), BCP-hydroxyapatite, or calcium oxalate crystals.

Pathogenesis

The pathophysiology of these entities appears to be similar to that of gouty arthritis, involving a complex series of biochemical reactions that lead to an inflammatory response within the involved joint or periarticular region. Similar to gout, each of these disorders may be more common in a specific subset of ICU patients.

The acute, self-limited form of CPPD deposition (also known as *pseudogout*) may be precipitated by surgery of any type and is related to downward fluxes in serum calcium levels that lead to crystal shedding into intra-articular spaces. Attacks commonly occur several days postoperatively and often involve the knee or wrist. Severe medical illnesses, such as ischemic heart disease, cerebral infarction, and thrombophlebitis, may also provoke attacks of CPPD arthritis.

Patients on chronic intermittent peritoneal dialysis have a high incidence of acute arthritis that is secondary to CPPD or

BCP-hydroxyapatite deposition in articular cartilage. In contrast, chronic hemodialysis patients are at risk for acute arthritis from calcium oxalate crystals.

Clinical Features

Clinically, each of the above crystalline arthropathies is indistinguishable from acute gout. The presence of radiographic calcification in hyaline or articular cartilage of the involved joint (i.e., chondrocalcinosis) suggests the diagnosis of pseudogout, but the diagnosis is confirmed by visualizing weakly positively birefringent, rhomboid-shaped CPPD crystals within synovial fluid PMN under polarizing microscopy. Calcium oxalate crystals, likewise, are positively birefringent, but they are pleomorphic, bipyramidal, or rod-like in shape. Smaller BCP-hydroxyapatite crystals, however, are not visible under polarizing microscopy, and a presumptive diagnosis is made given the clinical setting, the exclusion of other diagnoses, and the occasional presence of periarticular, amorphous calcifications on radiographs.

Therapy

Therapeutic options are limited in the ICU patient if NSAIDs are contraindicated. Isolated joints can be aspirated and injected with corticosteroids once infection is excluded. Alternatively, a regimen of tapering corticosteroids similar to acute gout is effective. Pseudogout may also respond dramatically to colchicine in dosing similar to gout. Low dose colchicine is also used to prevent recurrent attacks in patients who have frequent events.

Septic Arthritis

Joint infection is the most critical diagnosis to establish and treat in any ICU patient who develops acute mono- or oligoarthritis. A delay in the diagnosis and treatment of septic arthritis may lead to destruction of articular cartilage and loss of joint function. Furthermore, a diagnosis of septic arthritis may help identify and initiate early treatment of the source of septicemia, such as endocarditis (see Chapter 80).

Pathogenesis

Risk factors for development of septic arthritis include diabetes mellitus, age over 80, skin infections, rheumatoid arthritis (RA), intravenous drug abuse, alcoholism, recent joint surgery, low socioeconomic status, and presence of prosthetic joints [4]. In addition, patients in the ICU often have multiple invasive procedures, indwelling lines, or catheters that are potential portals of infection. Whether or not these predisposing factors exist, acute septic arthritis usually develops from hematogenous seeding from another site of infection. Direct inoculation or local extension from adjacent soft tissue infection or osteomyelitis is less common. Prosthetic joints or damaged joints from rheumatoid or osteoarthritis are particularly susceptible to hematogenous seeding. Once an infection is established within a joint, a complex cascade of physiologic responses occurs that leads to a severe inflammatory reaction with subsequent cartilage degradation and bone destruction. The rapidity and severity of this process depends on the virulence of the organism and the length of time delay before appropriate antibiotics are started.

Clinical Features

Clinically, septic arthritis may be indistinguishable from crystalline arthritis or other inflammatory joint diseases. The presentation is often acute and monoarticular with physical findings of warmth, swelling, tenderness, and erythema within the confines of the joint margins, and markedly limited joint motion. The knee, hip, shoulder, elbow, and ankle are the most common joints involved. Atypical joints such as the sternoclavicular, symphysis pubis, or sacroiliac joints are common sites of infection in younger patients, or those with a history of intravenous drug use. Polyarticular infections may occur in 20% of the cases in reported studies [4], particularly in patients with rheumatoid arthritis. Fever is a variable finding and when present, it may be low grade.

High clinical suspicion remains essential to the diagnosis of septic arthritis. Unless physical examination indicates extra-articular features (e.g., cellulitis), any ICU patient with an acutely swollen, painful joint needs a diagnostic arthrocentesis to exclude infection. In the case of suspected cellulitis, appropriate antibiotics should be administered and arthrocentesis performed only if symptoms or findings do not improve within 48 hours. The diagnosis of septic arthritis is supported by an elevated white blood cell count (WBC), ESR, and CRP, but these studies cannot reliably differentiate infection from other inflammatory processes. Conversely, the absence of fever or normal ESR or CRP cannot exclude septic arthritis. Thus, synovial fluid analysis can confirm septic arthritis and identify organisms on Gram's stain or in culture. The fluid should be transferred immediately to the laboratory, both anaerobic and aerobic cultures should be ordered routinely, and special requests for fungus or other organisms that require a special growth medium (e.g., *Neisseria gonorrhoeae*) are ordered if clinically indicated. In addition, synovial fluid analysis for WBC with differential and crystal search may support a diagnosis of infection before microbiology results are available. Although leukocyte counts under 20,000 per µL have been associated with septic arthritis, the WBC generally exceeds 50,000 per µL and on occasion may be as high as 200,000 per µL with a marked PMN predominance. A meta-analysis of various laboratory studies in septic arthritis suggests that the likelihood ratio of septic arthritis increases incrementally with higher synovial leukocyte counts [5]. However, since septic arthritis has been associated with WBC as low as 2,000 per µL to 50,000 per µL, the absolute number cannot differentiate septic arthritis from other inflammatory states such as rheumatoid, psoriatic, or crystalline arthritis.

Although initial radiographs of the infected joint are often normal, baseline x-rays are useful to identify preexisting joint abnormalities and for comparison to identify subsequent changes of septic damage. MRI imaging may be helpful to evaluate joints that are difficult to assess clinically (i.e. spine, sacroiliac, or hip), bone for underlying osteomyelitis, and soft tissue for sinus tracts. Classic late radiographic findings include juxta-articular osteopenia, joint-space narrowing, or subchondral bone loss.

Therapy

Once the diagnosis of septic arthritis is either strongly suspected on clinical grounds or documented by positive Gram's stain or culture, treatment requires adequate drainage in addition to appropriate antibiotics. *N. gonorrhoeae* is the most common cause of septic arthritis in patients under the age of 30, but overall, *Staphylococcus aureus (S. aureus)*, including methicillin resistant *S. aureus* (MRSA), is the most common organism in the immunocompetent patient, followed in frequency by *Streptococcal* species. Together, these Gram-positive organisms made up 91% of septic arthritis in a prospective study [6]. Gram negative and anaerobic organisms occur less frequently but must be suspected in patients at risk (elderly, immunocompromised, recent hospitalization or surgery, prior antibiotics, and possible urogenital or abdominal infections) [4]. In the critically ill patient with multiple risk factors, broad-spectrum antibiotic coverage against staphylococcus and streptococcus, Gram-negative bacteria, and pseudomonas should be initiated until culture results are available. Fungal or mycobacterial septic arthritis is often subacute or chronic and thus unlikely to be

initially considered but remains the possible cause if symptoms persist. *Candida* organisms have caused acute arthritis and the Gram stain may be positive before cultures are available. The duration of antibiotic therapy varies according to the clinical situation, but antibiotics should be continued intravenously for at least 2 weeks. Further route and duration of therapy depend on the specific type and sensitivity of identified organism and the patient's clinical response. However, the length of treatment is usually at least 4 weeks for nongonococcal septic arthritis. Please refer to Chapter 77 for appropriate antibiotic treatment and dosing for presumptive or identified infectious organisms.

Drainage of the infected joint either with serial percutaneous needle aspirations or surgical intervention is also crucial. Since there are no prospective studies comparing these options, controversy exists regarding the optimal approach. The physical removal of inflammatory cells, cellular debris, lysosomal enzymes, and bacterial byproducts reduce the potential damage to the joint. Prosthetic joints and other native joints such as hip, shoulder, wrist, finger, sacroiliac or sternoclavicular joints require immediate surgical intervention, while native septic knees may respond to serial percutaneous needle aspiration. Arthroscopy or arthrotomy has the advantage of more complete debridement of fibrin, infected synovium, and loculations. However, percutaneous drainage may be the only option in a critically ill patient who is unstable for surgery. Indications for surgical intervention include initial delay in diagnosis, established joint damage from RA or osteoarthritis, failure to sterilize the joint fluid after 3 to 5 days of antibiotics, difficult percutaneous aspirations due to loculations, or infection with Gram-negative bacterium. Thus, the ideal approach is to consult both the orthopedist and rheumatologist at the time of diagnosis to decide on optimal management.

The affected joint should be immobilized in functional position in the first few days. Once antibiotics are given and drainage has been performed, early physical therapy with passive range of motion and graduation to active range of motion will improve outcome [7].

Finally, since septic arthritis usually occurs as a consequence of bacteremia from a distant primary source of infection, investigation for these sites must be pursued. Unless an obvious site of local inoculation is present, cultures from blood, urine, sputum, indwelling lines, and catheters should be obtained before the institution of antibiotics. In addition, imaging studies such as echocardiography, tomography (CT), or gallium scanning might locate the source of infection.

Septic Arthritis in the Prosthetic Joint

Although rates of prosthetic joint infections (PJI) are generally quite low, 0.8% to 1.9% and 0.3% to 1.7% for knees and hips, respectively [8], RA patients have an increased risk of developing infected prosthetic joints. Risk factors are similar for native septic arthritis discussed previously as well as a history of prior infection of prosthetic joint at the same site or revision arthroplasty. Early infection, usually within 3 months of surgery, is usually due to *S. aureus* or more virulent organisms from direct inoculation at the time of surgery; chronic infections with less aggressive bacterium including coagulase-negative staphylococci occur often months to years after the replacement. Bacteremia with seeding of a prosthetic joint can occur anytime. Causative organisms for PJI are predominantly Gram-positive cocci (65%); aerobic Gram-negative bacilli and anaerobes contribute 10%, while 20% are polymicrobial infections [8].

Clinical features of acute PJI include localized pain, fever (occurring in < 50%), and elevation of ESR, while more chronic infections may present with only pain and loosening of hardware on radiograph. CRP elevation of more than 5 mg per L has a sensitivity of 95% and specificity of 62% in the diagnosis of PJI [9]. Plain radiographs cannot distinguish aseptic periprosthetic loosening from infection. Computed tomography and magnetic imaging may be distorted by ferromagnetic prostheses. The imaging of choice for the diagnosis of PJI is indium-111 labeled WBC in combination with technetium-99m-labeled sulfur colloid bone scan [10]. Synovial fluid studies are as useful in prosthetic joint infections as native joint infections. However, a synovial fluid WBC more than 1,700 cells per µL from the prosthetic knee joint or more than 4,200 cell per µL from the prosthetic hip joint with predominantly PMNs on the differential is enough to suggest infection [8]. If aspiration is not done before surgery, then intraoperative sampling of multiple periprosthetic tissue sites will increase the yield of an organism. Culture of the removed prosthesis may also provide additional microbial information.

Treatment of suspected PJI should initially cover both Gram-negative and Gram-positive organisms with a regimen such as vancomycin and an aminoglycoside until microbiology results and antibiotic sensitivities are available (see Chapter 77). Initial infectious disease consultation will help guide therapy.

Antibiotics alone without surgical intervention, however, are rarely successful. If the patient is a surgical candidate, options include: (1) resection arthroplasty, (2) one or two stage surgery with prosthesis removal and reimplantation, or (3) surgical debridement with retention of prosthesis with or without long-term oral antibiotic suppression. The first option is rarely performed unless the patient has failed previous surgical attempts at eradicating the infection or is likely to have minimal functional improvement after replacement. Chronic PJI requires resection arthroplasty with one or two stage exchanges. The latter usually entails removal of the infected prosthesis, treatment with antibiotics with or without an antibiotic loaded spacer for a period of 6 to 12 weeks, and then subsequent reimplantation. Debridement with retention of the infected prosthesis is an option only if (i) age of the prosthesis is less than 3 months; (ii) symptoms have been present for less than 3 weeks; (iii) absence of sinus tract communicating with joint space; (iv) no radiographic evidence of prosthetic loosening; (v) infection not involving *S. aureus, Pseudomonas aeruginosa*, enterococcus, fungal or multidrug resistant organisms; and (vi) absence of comorbidities such as diabetes and rheumatoid arthritis [11]. Prolonged oral antibiotics (3 months for hips and 6 months for knees) are recommended in patients treated with debridement with implant retention [8].

Hemarthrosis

In the absence of an underlying inherited disorder of coagulation, hemarthrosis in the intensive care setting is most likely a complication of anticoagulation therapy, most frequently described in patients receiving an oral anticoagulant (sodium warfarin). Since hemarthrosis may occur spontaneously in an anticoagulated patient, a history of trauma is often absent. Clinically, a patient develops a monoarticular, painful, swollen, warm, and tense effusion. A prolongation of coagulation parameters suggests the diagnosis, but diagnostic arthrocentesis is essential to confirm the diagnosis of hemarthrosis and exclude septic arthritis, crystalline disease, or other causes. When performed aseptically and carefully, arthrocentesis is safe and free of significant long-term morbidity. It is unnecessary to reverse the anticoagulant state prior to arthrocentesis.

A precise definition of hemarthrosis has not been established, but the diagnosis is suggested by a synovial fluid hematocrit exceeding 3%. Causes of hemarthrosis other than anticoagulation include trauma (especially with intra-articular fracture), blood dyscrasias, Charcot joint, synovial tumors such as pigmented villonodular synovitis or other primary or metastatic neoplasms, myeloproliferative disease, CPPD

arthropathy, septic arthritis, sickle cell trait or disease, and scurvy.

Despite the fact that hemophiliac patients with repeated hemarthrosis have significant joint abnormalities, an isolated episode of spontaneous hemarthrosis has a benign prognosis. Treatment of hemarthrosis from hemophilia or other bleeding diathesis is discussed elsewhere (see Chapters 108,109, and 114). Management of spontaneous hemarthrosis from anticoagulation consists of immobilization, analgesia, and if possible, temporarily reducing or correcting clotting parameters with fresh frozen plasma if the patient is not at high risk of thromboembolism. If the patient is at high risk (i.e., prosthetic valve), allowing the INR to drift toward the lower therapeutic range is one option. Arthrocentesis may reduce the pressure of joint distension. Once the hemarthrosis improves, close monitoring of coagulation parameters to values within the therapeutic range minimizes the chance of recurrence.

ASPECTS OF RHEUMATIC DISEASES COMPLICATING INTENSIVE CARE PROCEDURES

Difficult endotracheal intubations may be encountered in patients with RA, juvenile idiopathic arthritis (JIA), ankylosing spondylitis (AS), or systemic sclerosis (SSc). Involvement of the cervical spine, temporal mandibular joints, or oral aperture may limit adequate positioning, visualization, or successful endotracheal intubation with conventional techniques. The use of fiberoptic intubation, laryngoscopy, or blind nasotracheal intubation may suffice in some instances (see Chapter 1), although a tracheostomy may be required for satisfactory tracheal cannulation (see Chapter 15), particularly in emergent situations. Potentially more serious neurological sequelae are anterior atlantoaxial subluxation or a staircase cervical subluxation that involves many cervical vertebrae.

The prevalence of atlantoaxial instability in RA patients is estimated to be anywhere from 23% to 60% depending on the subpopulation studied and is associated with duration and severity of disease [12]. This instability also occurs in certain subgroups of patients with JIA and ankylosing spondylitis. Although the majority of patients with cervical spine involvement are asymptomatic, forced manipulation of the neck (e.g., during intubation, endotracheal suctioning, nasogastric tube placement, bronchoscopy, or endoscopy) may precipitate symptoms and signs of spinal cord compression.

Cervical instability and dislocations most commonly occur at the atlantoaxial (first and second cervical vertebrae) junction due to laxity or erosion of the transverse ligament caused by synovitis. Subsequently, the odontoid (superior peg of the second cervical vertebra) moves more freely and can protrude posteriorly, particularly during neck flexion, and compress the spinal cord, lower medulla, or vertebrobasilar arteries. Fracture or erosive destruction of the odontoid may allow the atlas (first cervical vertebra) to slide posteriorly on the second cervical vertebrae, a process termed posterior atlantoaxial subluxation. Destruction of the lateral atlantoaxial joints and of the bones of the foramen magnum may allow the axis to sublux cephalad, so-called vertical subluxation. Symptoms suggestive of cervical myelopathy include Lhermitte's sign, neck pain radiating up to the occiput, paresthesias in the hands or feet, loss of arm or leg strength, and urinary incontinence or retention.

Patients at risk are identified with lateral cervical spine radiographs in flexed and extended views. The normal distance between the odontoid process and the arch of the atlantis is less than 4 mm. If this distance is exceeded, care should be taken to avoid sudden or forced neck flexion during any intensive care procedure. A soft cervical collar to maintain the neck in slight extension helps prevent sudden forced flexion and is a reminder to all caregivers that any neck manipulation should proceed with caution. Open-mouth posterior-to-anterior views will exclude odontoid fracture and severe subluxation, but MRI scanning is the best imaging procedure to exclude cord compression.

In patients with ankylosing spondylitis where multilevel cervical fusion exists, large anterior cervical osteophytes can prevent adequate visualization of the larynx or successful endotracheal intubation. Fixed cervical flexion deformities can hinder appropriate neck positioning for intubation. The ankylosed spine is often osteoporotic and brittle. Minor forces in flexing or extending the neck can result in inadvertent fracture. Thus, plain radiograph imaging with lateral views before any procedure can help establish potential barriers to endotracheal intubation and the need for fiberoptic nasotracheal intubation [13].

Patients with JIA (and RA more rarely) may have established micrognathia due to temporomandibular joint disease that restricts lower jaw motion and limits access to the oropharynx. Micrognathia may also cause upper respiratory tract obstruction and sleep apnea, both of which occur more commonly in patients with JIA. In contrast, patients with systemic sclerosis (SSc) may have facial tissue fibrosis and atrophy that reduce the oral aperture and make orotracheal intubation impossible. In these situations, early awareness of the need for nasotracheal intubation will prevent potential complications in routine or emergency endotracheal intubation.

Nearly 50% to 75% of patients with longstanding RA have involvement of the cricoarytenoid joints on CT scans, but only half have symptoms [14]. These synovial joints allow adduction and abduction of the vocal cords. Symptoms of cricoarytenoid involvement include throat pain, sensation of a foreign object in the throat, odynophagia, dysphagia, hoarseness, shortness of breath, and stridor. As a result of acute or chronic inflammation, the vocal cords may become fixed in a position of adduction, resulting in upper airway obstruction and respiratory failure. The diagnosis may be made and distinguished from recurrent laryngeal nerve paralysis, tumor, and thyroiditis by visualizing the vocal cords either by indirect laryngoscopy or fiberoptic nasopharyngoscopy. In the patient with chronically restricted motion of the cricoarytenoid joints, a superimposed insult, like an upper respiratory tract infection or trauma from intubation, may cause sufficient soft tissue swelling to cause laryngospasm or airway obstruction. Treatment of life-threatening airway obstruction includes establishing an airway by cricothyroidotomy or tracheostomy, high-dose systemic corticosteroids, systemic antirheumatic therapy, and topical aerosolized corticosteroids.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic, autoimmune, inflammatory disorder that affects synovial joints and extra-articular organ systems. The patient with RA may require admission to the ICU because of airway obstruction due to cricoarytenoid arthritis or atlantoaxial subluxation (discussed previously); septic arthritis; respiratory distress from large pleural effusions or parenchymal lung disease; cardiac dysfunction due to pericardial, myocardial, or endocardial involvement; necrotizing vasculitis; or mononeuritis. The approach to the RA patient in the ICU includes knowledge of the diverse complications of rheumatoid disease and the potential toxicities of RA medications including NSAIDs, corticosteroids, traditional disease modifying agents, and the newer biologic agents.

Pathogenesis

Rheumatoid arthritis is characterized by chronic synovial inflammation with subsequent articular cartilage and bone

destruction in a genetically susceptible host. The initial triggering antigen, whether exogenous or self, has not been identified, but the subsequent CD4 T-cell activation initiates the process of recruitment of other cells to the joint space, including macrophages, neutrophils, and B cells. Fibroblast-like and macrophage-like synovial cells perpetuate synovial inflammation through elaboration of cytokines that have paracrine and autocrine activity. In addition to cytokines, the products of several cell types also induce adhesion molecules and stimulate angiogenesis. Activated synovial cells also release metalloproteinases responsible for degradation of articular cartilage and erosion of bone.

Joint Infections Complicating Rheumatoid Arthritis

One indication for admission of the RA patient to an ICU is sepsis, particularly involving joints. RA patients are more susceptible to developing septic arthritis, often polyarticular and more severe than in patients without RA. A variety of factors, including immunosuppressive drugs, general debility, immobility, and cutaneous ulcers predispose the rheumatoid patient to developing bacterial infections in other sites, which hematogenously seed inflamed rheumatoid joints. Normal protective mechanisms, PMN leukocyte bacterial killing, PMN chemotaxis, and complement and serum bactericidal activity are all decreased in the rheumatoid joint. Although joint sepsis after arthrocentesis or intra-articular steroid injection is a rare complication, infection has been reported in this context and may be more resistant to treatment.

A delay in diagnosing joint sepsis in RA patients may also contribute to their increased morbidity and mortality. Other factors include: 1) masking of joint pain and inflammation by NSAIDs, corticosteroids, and immunosuppressive agents; 2) generalized debility and malnutrition; and 3) attributing the joint inflammation to RA rather than infection by the patient or physician. Failure to recognize septic arthritis complicating RA may have disastrous effects. When a single or few joints are more inflamed than others in a rheumatoid patient, joint sepsis should be excluded by arthrocentesis, Gram's stain, and cultures of synovial fluid, blood, and other appropriate sites guided by the patient's signs and symptoms. Inspection of the skin for a possible portal of bacterial entry and a thorough general examination are of the utmost importance.

The microbiology of septic arthritis complicating RA includes a wide range of organisms, but in approximately 80% of cases, the organism is *S. aureus*. Streptococcal species are also common pathogens. Gram-negative organisms (*Pseudomonas aeruginosa*, *Escherichia coli*, *Proteus mirabilis*, and others), anaerobes, fungi, mycobacterium, and polymicrobial infection, have all been reported as causes of septic arthritis in the rheumatoid joint.

Management of septic arthritis in a rheumatoid patient is identical to patients without RA. However, the septic rheumatoid joint more frequently fails percutaneous needle aspiration. Early surgical drainage with synovectomy may be the preferred treatment since there is more proliferative synovitis and an increased tendency for loculations to develop in this population.

Pulmonary Involvement in Rheumatoid Arthritis

The respiratory system in the patient with RA can be involved in numerous ways, including upper airway, bronchi, pleura, parenchyma, vasculature, and diaphragmatic muscles. Pulmonary infections are common, particularly in the patient with poor mucociliary clearance, ineffective cough, on immunosuppressive therapy, or with associated Sjögren's syndrome. Table 193.1 summarizes respiratory tract involvement in RA and other connective tissue disorders. In addition, certain antirheumatic drugs are associated with potential pulmonary toxicities. Angioedema and bronchospasm induced or aggravated by aspirin or other NSAIDs is most common followed by hypersensitivity pneumonitis from methotrexate or sulfasalazine, or interstitial fibrosis from methotrexate.

Pleural Disease

Pleuritis and interstitial disease are the most common pulmonary manifestations of RA, and the former is most common in a subset of male patients who are seropositive and have nodules. Although involvement may be asymptomatic, acute febrile pleurisy or large pleural effusions impairing respiratory function may occur and result in ICU admission. The differential diagnoses of the pleural effusions include malignancy, pulmonary infarction, viral or bacterial infection, tuberculosis, and empyema. Infectious empyema occurs with increased frequency in patients with preexisting rheumatoid pleural effusions and should be suspected in debilitated, anemic, or hypoproteinemic patients who have been treated with corticosteroids and have persistent fever and pleural effusions. In patients on anti–tumor necrosis factor alpha (anti-TNF-α therapies), reactivation of (or new infection with) tuberculosis is of major concern and needs to be excluded with pleural biopsy.

Pleural effusions and sterile empyemas associated with RA are exudative and have characteristic features: elevated lactic dehydrogenase (often > 700 IU per L), total protein (> 4 g per dL), low glucose (< 40 mg per dL), and pH < 7.2. Other characteristics include clear yellow to green-yellow appearance, white blood cell count of 100 to 7,000 cells per μL (predominantly lymphocytes), reduced complement levels, cholesterol crystals, and immune complexes [15]. Chylous effusions may occur if necrotic subpleural nodules rupture into the pleural space.

Once infections including tuberculosis and malignancy are excluded, symptomatic pleural effusions are managed with NSAIDs and thoracentesis. In recurrent pleuritis or sterile empyema, intrapleural corticosteroids, systemic corticosteroids in moderate doses, and additional disease modifying agents are recommended. Rarely, surgical pleurodesis or decortication is required if chronic adhesive fibrothorax develops. There are no prospective trials to evaluate the efficacy of many of these recommendations [15]. High-dose corticosteroid therapy may not be effective and carries an increased risk of an empyema.

Lung Disease

ILD occurs in up to 40% to 60% of patients with RA depending on the subpopulations studied and screening tests used to make the diagnosis. In a prospective European study of newly diagnosed RA patients, the annual incidence was 4 in 1,000 patients but over 20 years, mortality was over 75% in those patients with interstitial lung disease, with the majority of deaths due to ILD [16]. Thus after infection, pulmonary disease is the second most common cause of mortality in RA patients. Pathologically, usual interstitial pneumonia(UIP) is more common than nonspecific interstitial pneumonitis (NSIP). Lymphocytic interstitial pneumonitis (LIP), organizing pneumonia (OP), and acute interstitial pneumonia are less common.

Symptoms include dyspnea on exertion, cough, and chest discomfort. Physical and laboratory findings include dry crackles, diminished diffusion capacity, and restrictive physiology, as well as desaturation with exercise. Chest radiographs may show an interstitial pattern, but high-resolution CT scanning (HRCT) is a more sensitive test in assessing pneumonitis and fibrosis. Bronchoalveolar lavage (BAL) is not particularly helpful except to rule out infection, while thoracoscopy guided lung biopsy provides the best pathologic details. Treatment of ILD due to RA is extremely challenging. Some patients may respond

TABLE 193.1

RESPIRATORY INVOLVEMENT IN CONNECTIVE TISSUE DISEASES

	Common	Rare (< 10%)
Upper airway involvement		
Cricoarytenoid arthritis	RA	SLE
Laryngeal nodules	RA	
Bronchial tree		
Obliterative bronchiolitis		RA
Bronchiectasis	SSc	RA, SS, SLE
Follicular or constrictive bronchiolitis		RA, SS
Bronchiolitis obliterans with organizing pneumonia	RA	SLE, PM/DM
Parenchyma		
Interstitial lung disease	RA, SSc, SS, PM/DM	SLE
Acute pneumonitis		SLE, PM/DM
Bronchiolitis obliterans with organizing pneumonia	RA	PM/DM
Cryptogenic organizing pneumonia		RA, SLE, PM/DM, SSc
Rheumatoid nodules ± cavitation	RA	
Aspiration	SSc, PM/DM	RA
Drugs: methotrexate, sulfasalazine, minocycline		
Infections	All	
Pleura		
Pleuritis	RA, SLE	
Pleural effusions	RA, SLE	
Pleural thickening	RA	SLE
Respiratory muscle disease		
Myositis	PM/DM	RA
Diaphragm dysfunction	PM/DM	SLE
Vascular		
Pulmonary hypertension	SSc	SLE, RA, PM/DM, APS
Vasculitis	SLE	PM/DM, RA
Diffuse alveolar hemorrhage		SLE, RA, PM/DM, APS
Pulmonary Embolism	APS, SLE	

RA, rheumatoid arthritis; SLE, systemic lupus erythematosus; SSc, systemic sclerosis; SS, Sjogren syndrome; PM/DM, polymyositis/dermatomyositis; APS, antiphospholipid syndrome.

to corticosteroids alone but the progressive nature of the disease may require treatment with cytotoxic agents although it is unclear which immunosuppressant is most effective [17]. In those patients with ground glass opacities on HRCT scanning, IV cyclophosphamide is being used increasingly, although no large controlled trial exists to support this approach. Case reports on the use of biologic agents are conflicting.

Other less common manifestations of rheumatoid lung disease may require treatment in the ICU when patients develop respiratory distress. These include bronchiolitis obliterans with organizing pneumonia (BOOP), obliterative bronchiolitis (OB), cryptogenic organizing pneumonia, pulmonary vasculitis, spontaneous pneumothorax, and lung toxicity secondary to antirheumatic therapy. It is particularly important to distinguish BOOP from ILD and OB, and only lung biopsy will provide histological distinction.

Obliterative alveolitis is often characterized by the abrupt onset of dyspnea and a dry cough with inspiratory crackles, sometimes with a mid-inspiratory squeak, a clear chest radiograph or finding of hyperinflation, irreversible airflow obstruction at low volumes on pulmonary function testing, mild-to-moderate arterial hypoxemia with a respiratory alkalosis, and progressive obliteration of small airways (1 to 6 mm in diameter) with constrictive bronchiolitis [18]. The prognosis is generally poor with a fairly rapid rate of progressive airflow obstruction. Despite the lack of adequate therapeutic trials, when patients present with rapidly progressive deterioration, recommendations based on expert opinion include bronchodilators and inhaled and oral corticosteroids (1 to 1.5 mg per kg per day). Macrolides, pulse intravenous cyclophosphamide, or etanercept (with methotrexate) may be considered as second-line therapy [18]. Progression to respiratory failure is common. In contrast, BOOP is more responsive to corticosteroid therapy.

Rarely, chronic vasculitis may involve pulmonary as well as bronchial arterioles and result in pulmonary hypertension and cor pulmonale. Therapy consists of corticosteroids in combination with cytotoxic agents (see Chapter 196).

Although pulmonary manifestations of RA are frequent, they are rarely the primary reason for admission to the ICU. Infectious pneumonia is particularly frequent and the major cause of mortality in rheumatoid patients. Since the advent of TNF-α agents, atypical infections and reactivation of tuberculosis have been of great concern.

Rheumatoid Cardiac Involvement

RA may involve all structures of the heart as a result of granulomatous proliferation or vasculitis. Pericarditis, myocarditis,

endocarditis (valvulitis), coronary arteritis, aortitis, and cardiac conduction abnormalities have all been reported. Cardiac involvement may be the principal reason for intensive care hospitalization, or may complicate the course of the rheumatoid patient hospitalized in the ICU for other medical or surgical problems.

Pericarditis, the most common of the rheumatoid cardiac manifestations (approximately 50% by autopsy studies) rarely causes impairment of left ventricular function. However, constrictive pericarditis or a large pericardial effusion may rarely cause cardiac tamponade. The pericardial fluid has the same characteristics as pleural fluid (see the section Pulmonary Involvement in Rheumatoid Arthritis). Pericarditis generally responds to the administration of 30 to 40 mg prednisone per day over a several-week period. Corticosteroids alone are less likely to be effective in the setting of cardiac tamponade. Pericardiocentesis should be performed early if tamponade is suspected (see Chapters 7 and 35) or if there is a question of septic or suppurative pericarditis. Aspiration of pericardial fluid may temporarily improve cardiac function, but often the viscosity of the fluid, loculations, and thickness of the pericardium necessitate pericardiectomy. In cases of constrictive pericarditis, pericardiectomy is the only effective therapy.

The myocardium may be affected by granulomatous inflammation and by vasculitis. Cardiac conduction abnormalities, including complete heart block, may develop because of subcutaneous nodules. Arteritis may affect the coronary arteries and the aorta. In patients with active systemic vasculitis, coronary arteritis may be the cause of myocardial infarction. Involvement of the aorta, either by rheumatoid granulomas or inflammation of the aortic vasa vasorum, may result in dilatation of the aortic root and aortic valvular insufficiency.

Rheumatoid arthritis patients die prematurely from cardiovascular events that include (i) ischemic heart disease, often silent; (ii) congestive failure, often in the setting of preserved ejection fraction; and (iii) sudden death. When compared to non-RA patients, these increased cardiovascular complications are not explained by traditional risk factors alone. Other factors, including poor primary or secondary preventive care and comorbid conditions along with the chronic inflammatory or immunologic state contribute to premature cardiac deaths [19]. Thus, in the ICU setting, silent cardiovascular disease with atypical presentations must be considered in the rheumatoid patient.

Rheumatoid Vasculitis

The vasculitis that complicates RA is a panarteritis with mononuclear cell infiltrates in all layers of the involved blood vessels, fibrinoid necrosis in active lesions, and thrombosis associated with intimal proliferation. Rheumatoid vasculitis tends to occur in patients with severe deforming RA, subcutaneous nodules, and high-titer rheumatoid factor, and in patients with Felty's syndrome. The clinical features of rheumatoid vasculitis are variable and include palpable purpura, cutaneous ulceration including pyoderma gangrenosum, distal arteritis ranging from fingernail-fold infarcts and splinter hemorrhages to digital gangrene, and arteritis of major organs including the bowel, kidneys, heart, lungs, liver, spleen, pancreas, and components of the nervous system in a manner similar to polyarteritis nodosa. Severe necrotizing forms of rheumatoid vasculitis, manifested as digital gangrene, intestinal bleeding or perforation, myocardial or renal infarction, and mononeuritis multiplex, are associated with a poor prognosis and are treated aggressively in a manner similar to that of polyarteritis and Wegener's granulomatosis (see Chapter 196) with high-dose corticosteroids, cytotoxic agents, and occasionally plasmapheresis.

Neurologic Complications of Rheumatoid Arthritis

All components of the nervous system can be affected by RA. The brain and meninges, spinal cord, peripheral nerves, and muscles may be involved with granulomatous inflammation in the form of rheumatoid nodules or vasculitis; the spinal cord and cranial and peripheral nerves may also be compressed by skeletal and soft tissue structures, and the nervous system may be affected by hyperviscosity syndrome and medications.

Spinal cord compression is one of the most common neurologic complications in patients with RA is discussed in previous section. Manifestations that require immediate intervention include the sensation of anterior instability of the head during neck flexion, drop attacks, loss of urinary bladder and anal sphincter control, dysphagia, vertigo, hemiplegia, dysarthria, nystagmus, changes in level of consciousness, and peripheral paresthesias without evidence of a peripheral cause. Although RA patients may have radiographic evidence of cervical subluxation without symptoms, once signs of cord compression become apparent, myelopathy may progress rapidly. For patients with manifestations of spinal cord and brainstem compression, surgical reconstruction of normal alignment and stabilization are treatments of choice. For the nonsurgical candidate, a firm collar can be used in an effort to immobilize the neck and prevent further subluxation.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by excessive autoantibody production and immune complex deposition in multiple organ systems. The clinical result of these varied immune abnormalities is a disease with tremendous variation in signs and symptoms that range from arthralgias, rash, and fatigue to life-threatening renal, central nervous system (CNS), cardiac, pulmonary, or hematological manifestations. Diagnosis of SLE is based on the clinical criteria set forth by the American College of Rheumatology [20]. Mortality of SLE patients admitted to the ICU is much higher than the general ICU population (47% vs. 27%) [21]. In the ICU patient with established SLE, it is essential to differentiate problems caused directly by SLE activity from those with secondary causes such as infections, drug-induced lupus, NSAID-induced renal dysfunction, aseptic meningitis, and corticosteroid-induced psychosis. Diseases associated with SLE include avascular necrosis, hypertensive encephalopathy, pseudotumor cerebri, amyloidosis, myasthenia gravis, and thrombotic thrombocytopenic purpura. In ICU patients without a prior history of autoimmune disease, SLE should be considered in the differential diagnosis of patients presenting with acute renal failure, seizures, myocarditis, acute pulmonary deterioration, hemolytic anemia, or thrombocytopenia.

Renal Disease

Renal involvement is the major cause of disease-related mortality in SLE patients. The frequency of renal involvement ranges from 38% to nearly 80% depending on definition, but clinical lupus nephritis (LN) occurs in approximately 50% of the patients. Advances in diagnostic and therapeutic modalities have dramatically improved the survival of lupus patients with renal disease. Glomerulonephritis and progressive renal failure, however, remain major sources of morbidity and mortality. LN constitutes approximately 3% of all end-stage renal failure in

patients on dialysis or requiring transplantation. Recent data from one transplant group with predominantly white patients found no difference in overall 15-year patient survival (80%) and graft survival (69%) in SLE patients compared with controls [22]. Early graft thrombosis occurred more frequently in patients with antiphospholipid antibodies (APAs) and recurrence of LN was around 8% [23].

Classification of lupus-associated glomerulonephritis (GN) is based on histopathologic, immunofluorescent, and electron microscopic changes according to the 2003 revised classification by the International Society of Nephrology and the Renal Pathology Society (ISN/RPS) classification [24]. The classification includes: Class I: mesangial GN; Class II: mesangial proliferative GN; Class III: focal proliferative GN; Class IV: diffuse proliferative GN with two subclasses, segmental and global; Class V: membranous GN; and Class VI: advanced sclerosing GN. Renal lesions are commonly pleomorphic, vary from one glomerulus to another, and temporally transition from one class to another over time. The tubulointerstitium and vasculature are often involved. Semiquantitative scoring to define activity and chronicity may provide information on prognosis and guidelines for therapeutic options. In particular, the presence of proliferative lesions and chronic lesions are associated with greater mortality.

The clinical manifestations of renal involvement vary from rapidly progressive renal failure with attendant fluid overload, to congestive heart failure or accelerated hypertension, and are common events precipitating an ICU admission. A sudden deterioration in an SLE patient's renal function warrants careful consideration of other causes of acute renal insufficiency (see Chapter 73) before attributing the deterioration to active SLE. In particular, hypovolemia, drug-induced interstitial nephritis or renal insufficiency, renal vein thrombosis, and contrast-induced acute tubular necrosis must be excluded. Physical examination may reveal evidence of SLE activity in other organ systems. Laboratory studies should include routine tests to assess renal status and fluid balance, and immunologic studies, including double-stranded DNA (dsDNA) antibody, total hemolytic complement, third (C3) and fourth (C4) complement components, and ESR. Active serologies suggest SLE flare, but normal values do not exclude active disease.

Management of LN depends on the patient's renal histopathology and functional parameters. Thus, a patient with mesangial glomerulonephritis with normal creatinine clearance requires no specific therapy, whereas a patient with increasing azotemia, active urinary sediment, and impaired clearance requires aggressive therapy. It is now established that in patients with severe glomerulonephritis (ISN/RPS class III or IV), the combination of high dose prednisone with monthly intravenous pulse cyclophosphamide (IVCY) for 6 months followed by quarterly infusions for additional 6 months stabilizes renal function and improves survival. This regimen is the standard for comparison in all other LN drug trials [25,26]. In the past few years, several trials in different populations have documented the equivalency of mycophenolate mofetil (MMF) up to 3 g per day to monthly IVCY as induction therapy for class III, IV, or V LN [27]. More recently, a large international trial conducted by the ALMS group (Aspreva Lupus Management Study) confirmed this equivalence of both induction regimens at the end of 24 weeks with a response rate of 56% in each group [28]. However, only 8% from either treatment group reached complete remission. This study also supported the racial and ethnic differences in LN and the response to therapy reported in other studies. Patients of Hispanic and African descent had a much better response to MMF than IVCY (60% vs. 38%), while whites and Asian patients responded equally to either regimen. The risk for gonadal failure was less with MMF but other toxicities such as infections were similar. Given the currently available evidence, it appears that MMF and IVCY are equivalent induction therapies for severe LN. Durability of remission is being assessed in a continuation of the ALMS trial in which responders were randomized to either MMF or azathioprine (AZA) for maintenance therapy [28]. Another recent study demonstrated better efficacy and fewer long-term toxicities in maintenance therapy with AZA or MMF rather than the traditional quarterly IVCY after initial monthly IVCY induction [29].

In an acutely ill ICU patient with LN and/or other organ system involvement, IVCY along with pulse IV methylprednisolone at 500 to 1,000 mg daily for 3 days may be the regimen of choice since many of the studies have not stratified for disease severity. The protocol for administration of IVCY therapy is outlined in Table 193.2. Dose adjustments for renal insufficiency are outlined and subsequent monthly dosing is based on nadir white blood cell counts. Another option for IVCY induction is the low dose regimen from the Euro-Lupus Nephritis Trial, which demonstrated equal efficacy and less gonadal toxicity between low dose IVCY (500 mg every 2 weeks for six doses) and high dose IVCY (500 to 750 mg per M^2 with maximum of 1,500 mg, monthly for 6 months, followed by every 3 month infusion until a year) [30]. Both groups then received AZA at 2 mg per kg per day for maintenance. The long-term outcomes measured by death, end-stage renal disease, and doubling of serum creatinine were similar in both groups after 10 years [31].

TABLE 193.2

INTRAVENOUS CYCLOPHOSPHAMIDE THERAPY (IVCY)

1. Initiate IV hydration at 200–500 mL/h
   Normal or $^1/_2$ NS for 1 L over 1–2 h if CrCl > 50 mL/min and depending on cardiac status. (If medical status prevents adequate hydration, MESNA can be substituted—see below.)
2. Antiemetic treatment:
   a. Ondansetron, 8 mg IV < 30 min (or PO < 60 min), prior to CY and then 8 mg every 8 h for 24 h
   b. Granisetron, 1–2 mg IV < 30 min (or < 60 min PO) prior to CY and then every 12 h PO for 24 h
3. MESNA (for CrCl < 50 mL/min or inadequate prehydration due to cardiopulmonary status)
   Give 60% of total CY dose in divided doses: Infuse over 15 min 20% of CY dose (mixed in 50 mL of D_5 W) 30 min prior to CY and repeat same doses 4 and 8 h following CY.
4. Cyclophosphamide: Initial dose is 500–750 mg/M^2 in 250 mL NS over 60 min. Subsequent dose is based on nadir WBC obtained at days 7, 10, 14 after infusion.
   Dose adjustments
   a. CrCl 10–50 mL/min: 75% of CY dose
   b. CrCl < 10 mL/min: 50% of CY dose
   c. Hemodialysis patients: 50% of CY dose after dialysis
   d. Subsequent month dose: increase or decrease by 10%–20% of previous dose
5. Posthydration fluid is identical to prehydration. Monitor adequate urine output and encourage frequent voiding for 24 h after IVCY. In patients without indwelling Foley catheter, avoid CY infusion after 4 pm to reduce prolonged bladder contact with CY metabolites over night.

CY, cyclophosphamide; D_5 W, dextrose 5% in water; IV, intravenous; MESNA, sodium 2-mercaptoethane sulfonate, NS, normal saline; PO, by mouth; WBC, white blood cells.

Membranous GN (Class V), which constitutes 20% of LN, is less aggressive than Class IV GN. While renal survival rate is at 80% at 10 years, it is still associated with significant comorbidities of hyperlipidemia, cardiovascular and thromboembolic diseases [32]. Angiotensin-converting enzyme (ACE) inhibitors have been used successfully to reduce proteinuria. Treatment with corticosteroids, AZA, and cyclosporine has been studied in small series. More recently, the pooled subset of Class V patients from two prospective randomized studies on treatment of GN demonstrated equivalent efficacy and safety profile of MMF and IVCY [33]. Adjunctive renoprotective therapies that include aspirin, statins, ACE inhibitors, or angiotensin receptor blockers should also be instituted.

Advances in biologic therapies for RA and psoriatic arthritis have also stimulated investigations for SLE. Initial open label studies and case reports suggest promising results with the use of rituximab (RTX), an anti-CD20 B-cell depleting monoclonal antibody, for reducing SLE activity. Surprisingly, a randomized trial comparing RTX to placebo with a background of MMF for active proliferative LN revealed no additional benefit, and another study on active nonrenal SLE was also negative [34,35]. Trials of other potential therapies are underway, including a human monoclonal against B-lymphocyte stimulator (BLyS).

Neuropsychiatric Disease

Neuropsychiatric systemic lupus erythematosus (NPSLE), which encompasses involvement of the central, peripheral, and autonomic nervous systems along with psychiatric syndromes, occurs in 25% to 80% of SLE patients depending on the criteria applied or methods used for diagnosis. Although NPSLE was considered a poor prognostic indicator in the older literature, it does not seem to have significant impact on survival rates. Active CNS disease contributed primarily or secondarily to death in only small percentage of patients.

Neuropsychiatric manifestations of SLE can be classified into central versus peripheral nervous system involvement. Due to the limitations of the ACR classification criteria of CNS involvement, an ad hoc neuropsychiatric lupus nomenclature committee of the American College of Rheumatology defined 19 manifestations that included 12 in the CNS and 7 in the peripheral nervous system [36] (Table 193.3). The wide range of prevalence for the more diffuse CNS syndromes (cognitive dysfunction, anxiety, acute confusional states, and psychosis) and headache is due to the definition, criteria, or diagnostic parameters used in reported studies. This proposed nomenclature attempts to define the spectrum of NPSLE but is not a substitute for clinical diagnosis. An individual SLE patient may have multiple neuropsychiatric manifestations and these can develop prior to the formal diagnosis of SLE or during an inactive disease state. Frank psychosis is relatively rare, estimated at 5%. Often, it is difficult to separate active lupus psychosis from other causes such as functional disorders, uremia, illicit drugs, metabolic disturbances, medications, or infections.

Focal central nervous system disease, including seizures that occur in 15% to 35% of SLE patients, can antedate the diagnosis of SLE or develop any time during the disease course. Grand mal seizures are the most common, but essentially all types have been reported. Secondary causes of seizures must be sought since in several prospective studies of SLE patients with neurologic events, a majority of seizures were due to associated infection, uremia, hypertension, and metabolic abnormalities.

Cerebrovascular accidents (5% to 18%) include infarctions secondary to intracranial hemorrhage or arteritis, thrombosis from lupus anticoagulant (LAC) or APA-associated hypercoagulable states, or embolism from Libman-Sacks endocarditis. Movement disorders including chorea, ataxia, and hemiballismus are rare (< 1%) [37]. Transverse myelitis is an unusual but devastating complication of SLE characterized by acute or subacute paraplegia or quadriplegia associated with sensory level deficit and loss of sphincter control. Cerebrospinal fluid (CSF) analysis reveals pleocytosis, low CSF glucose, and high CSF protein. T2-weighted magnetic resonance imaging (MRI) usually demonstrates increased signal intensity and cord edema. Meningitis, usually infectious, may develop in SLE patients. However, aseptic meningitis can be idiopathic or secondary to administration of ibuprofen or AZA.

Peripheral nervous system syndromes include cranial neuropathies (4% to 49%) such as facial palsies and ocular muscle dysfunction. Pure sensory or motor abnormalities based on electromyography/nerve conduction studies (EMG/NCS) occur in up to 47% but plexopathy, Guillain-Barré syndrome, and autonomic neuropathy are rare.

The differentiation of NPSLE from other CNS disorders is difficult and remains a process of elimination. CSF pleocytosis and low glucose require exclusion of infections. Electroencephalography generally reveals diffuse brain wave slowing, but focal activity suggests seizures. Serum antiribosomal P antibodies are associated with lupus psychosis. The gold standard for imaging the central nervous system in SLE is conventional MRI with gadolinium. CT scans are less sensitive and should be reserved for patients in whom MRI is contraindicated or for emergent situations to document bleed, infarct, cerebral edema, or masses. Focal lesions in the subcortical white matter

TABLE 193.3

NEUROPSYCHIATRIC MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

Central nervous system
Diffuse neuropsychiatric syndromes
Cognitive dysfunction (50%–80%)
Anxiety disorders (7%–70%)
Mood disorders (14%–57%)
Psychosis as defined by *DSM-IV* related to medical condition (5%–8%)
Acute confusional state (4%–7%)
Focal neurological syndromes
Headache (24%–72%): range from migraine, tension, or benign intracranial hypertension
Seizures (15%–35%): grand mal, petit mal, temporal lobe, focal
Cerebrovascular disorders (5%–18%): infarcts, transient ischemic attacks
Movement disorders (< 1%): chorea
Transverse myelitis (< 1%)
Demyelinating syndrome (< 1%)
Aseptic meningitis (< 1%)
Peripheral nervous system
Peripheral neuropathy
Polyneuropathy (3%–28%)
Mononeuropathy, single or multiplex
Plexopathy (< 1%)
Cranial neuropathies (4%–49%)
Acute inflammatory demyelinating polyradiculoneuropathy (Guillain-Barré syndrome) < 1%
Autonomic neuropathy (< 1%)
Myasthenia gravis (< 1%)

Adapted from The ACR nomenclature and case definitions for neuropsychiatric lupus syndromes. *Arthritis Rheum* 42:599–608, 1999; Hanly JG. Neuropsychiatric lupus. *Rheum Dis Clin N Am* 31:273, 2005.

are the most common MRI findings and correlate with ischemic changes. Changes in the gray matter that brighten on T2-weighted imaging suggest more acute events and may improve with therapy. However, it is often difficult to distinguish acute from chronic MRI lesions, and subcortical lesions are found in up to 50% of patients without any neuropsychiatric symptoms. Angiography is invasive and rarely results in an accurate diagnosis of active CNS lupus. Since the sensitivity of MRI in patients with cognitive or affective symptoms is low, additional imaging with single-photon emission computerized tomography (SPECT), which measures functional cerebral blood flow, is attractive. Although sensitivity is high (positive in 86% to 100% of patients with major NPSLE manifestations), specificity is low since nearly half of SLE patients without neuropsychiatric involvement have positive SPECT scans [38]. Magnetic resonance angiography is not sensitive enough to delineate the smaller vessels involved in NPSLE. Newer imaging techniques such as magnetic resonance spectroscopy, magnetic transfer imaging, and perfusion and diffusion weighted imaging are still viewed only as research tools and their roles in assessment of NPSLE remain to be determined.

Management of SLE patients with neuropsychiatric manifestations should focus on specific neurologic symptoms. Non-SLE causes of CNS disease, including infections, uremia, hypertension, metabolic disturbances, hypoxia, or drug toxicities, must be identified and treated appropriately. If steroid psychosis is suspected, a brief doubling of the steroid dose for 3 days may exclude the possibility of a diffuse CNS syndrome. If no improvement or evidence of active lupus is noted, the steroid dose should be tapered. Seizures are treated with appropriate anticonvulsant medications. Status epilepticus is treated with anticonvulsants and high-dose steroids. Psychotic patients should receive antipsychotic agents. High-dose steroids have been recommended for neuropsychiatric lupus; dosages range from 1.0 to 1.5 mg per kg per day, or its equivalent. In severe cases, pulse IV methylprednisolone in a dose of 1,000 mg per day for 3 days is preferred. As for immunosuppressive agents, few prospective studies of treatment of NPSLE have been performed. A recent Cochrane database review of therapy for neuropsychiatric lupus found only one controlled clinical trial that suggested better outcomes with monthly IVCY than steroids alone [39,40]. Limited case reports of rituximab therapy in NPSLE suggest efficacy but no randomized studies are available. Transverse myelitis has been treated successfully with pulse methylprednisolone, IVCY, and plasmapheresis.

Pulmonary Disease

The pleuropulmonary manifestations of SLE are common and can involve the pleura, parenchyma, vasculature, diaphragm, or airways (see Table 193.1). Acute pulmonary symptoms can be the initial presentation of SLE that results in an ICU admission, while the prevalence of long-term lung damage (11.6% by 10 years of disease duration) can contribute to the SLE morbidity and mortality [41].

Pleuritis with or without effusions has been reported in 30% to 50% of patients with SLE, depending on the method of study (i.e., clinical history, radiograph findings, or autopsy findings) [42]. Pleural effusions are usually small and bilateral, but massive collections can occur. Thoracentesis is indicated when the etiology of the fluid is uncertain or if respiratory compromise is present. Pleural fluid is characteristically exudative with high protein, pH more than 7.35, and glucose normal or slightly decreased in contrast to the uniformly low glucose and pH seen in rheumatoid pleural effusions. White blood cell counts are elevated and consist predominantly of PMNs. The presence of lupus erythematosus cells on Wright stain is infrequent but highly specific for SLE. Antinuclear antibodies (ANAs) are frequently present in pleural fluids. Mild pleuritis usually responds to NSAIDs or low-dose corticosteroids (0.5 mg per kg per day prednisone or its equivalent). The latter is used only after infection has been excluded.

Acute lupus pneumonitis (ALP), although uncommon (0% to 14%), can be life threatening [42] and may be the initial presentation of SLE. It cannot be differentiated from other forms of bronchopneumonia, and thus infectious etiologies should be excluded by appropriate studies. Clinically, patients present with fever, severe dyspnea, tachypnea, and hypoxemia. Chest radiographs reveal patchy alveolar infiltrates, usually basilar in location. Mortality is as high as 50%. Transbronchial brushings with biopsies and bronchoalveolar lavage may help distinguish infections from acute immunologically mediated pneumonitis. High frequency of anti-SSA/SSB antibodies has been associated with ALP. Given the poor prognosis, therapy requires high-dose corticosteroids (1 to 2 mg per kg per day) or pulse IV methylprednisolone (1,000 mg IV daily for 3 days) along with broad-spectrum antibiotics until final cultures return. Case reports suggest the use of IVCY, plasmapheresis, or immunoglobulins in patients who respond poorly to steroids.

Pulmonary hemorrhage is a rare but potentially fatal complication. Patients characteristically present with acute dyspnea, tachycardia, severe hypoxemia, rales, sudden drop in hematocrit, and hemoptysis. Rarely, diagnosis is delayed due to the absence of hemoptysis. BAL provides the most reliable confirmation with the presence of bloody fluid, hemosiderin-laden macrophages, purulent sputum, and absence of pathogenic organisms on culture and Gram stain. Pathologic findings include intra-alveolar hemorrhage sometimes associated with interstitial pneumonitis or capillaritis. Immunopathologic studies may reveal granular deposition of immunoglobulin G (IgG) in alveolar septal walls and pulmonary vessels, thus suggesting a possible immune complex–mediated process. Therapy is generally aggressive with IV methylprednisolone at 1,000 mg daily for 3 days followed by tapering high-dose oral (1 mg per kg per day) corticosteroids. The addition of IVCY should be considered in patients who are critically ill or fail pulse corticosteroids. Plasmapheresis has been added in case reports, but whether it offers any additional benefit is unclear. Mortality remains high at 80% despite such treatment. (See Chapter 53 for an in-depth discussion of intrapulmonary hemorrhage and pulmonary-renal syndromes.)

The prevalence of ILD is less than 3% in several studies and may occur before or after ALP. Patients usually present with dyspnea on exertion, productive cough, pleuritis, and rales. Pulmonary function tests reveal a restrictive pattern and marked reduction in diffusing capacity. High-resolution thin-section CT may differentiate earlier-stage alveolitis from end-stage fibrosis. The presence of dense alveolar opacities or "ground-glass" appearance suggests active inflammation and may guide therapy. Treatment for ILD is challenging, and there are no prospective randomized trials. Therapy for symptomatic disease begins with high-dose corticosteroid therapy and again, IVCY or AZA has been used in clinically progressive ILD.

Pulmonary arterial hypertension (PAH) in SLE is less common in SLE than other connective tissue diseases and is estimated at 0.9% [43]. Pathologically, changes of intimal thickening and fibrosis, medial hypertrophy, altered elastic laminae, and periadventitial fibrosis have been similar to changes seen in idiopathic pulmonary hypertension. Necrotizing arteritis has been reported. Patients usually present with severe dyspnea on exertion and fatigue. Patients with PAH have a greater frequency of Raynaud's phenomenon than SLE patients without PAH (75% vs. 25%) [44]. In addition, the prevalence of APAs is higher in SLE-associated PAH than in other connective tissue diseases with PAH (47% vs. 19%) [45]. Because symptoms often develop late in the clinical course, assessment with Doppler

echocardiography is useful to monitor for progressive disease requiring therapy.

Therapy for primary pulmonary hypertension is evolving rapidly with the use of IV prostacyclin (epoprostenol), a prostacyclin analog (iloprost), and endothelin-receptor antagonist (bosentan). IV prostacyclin has provided significant benefit in idiopathic PAH, and these therapies have been applied to PAH secondary to systemic sclerosis and less so SLE (also see the section Systemic Sclerosis). Sildenafil (a phosphodiesterase isoenzyme 5 inhibitor that enhances endothelial nitric oxide and cyclic GMP, resulting in selective pulmonary, bronchial, and coronary artery vasodilation) is effective for lupus-related PAH [46]. Calcium channel blockers are ineffective. A retrospective, open-labeled study compared the use of IVCY alone versus IVCY with vasodilator therapy in patients with SLE-related PAH. The patients given IVCY alone had less severe PAH (New York Heart Association, Class II/III) and 50% responded [47]. It is postulated that there may be a role of immune or inflammatory mechanisms in PAH associated with connective tissue disorders. This is an intriguing but yet not proven pathogenesis.

Pulmonary embolism and peripheral vasoocclusive disease are well-known risks in SLE. One prospective study documented the risk of deep vein thrombophlebitis at approximately 12%, with a 9% risk for pulmonary embolism. The risk of thromboembolic events is increased in patients with LAC and APAs (see "Antiphospholipid Syndrome" section).

Other rare pulmonary syndromes occur in SLE. Dyspnea from shrinking lung syndrome can be either acute or chronic and has a prevalence of 0.9% [42]. Postulated mechanisms include myopathy of respiratory skeletal muscles or diaphragm, phrenic neuropathy, or pleural inflammation. Pulmonary function tests reveal reduced total lung volumes with a restrictive pattern while chest radiographs reveal low lung volumes. Acute reversible hypoxemia, possibly secondary to pulmonary leukocyte aggregation, has been described in acutely ill SLE patients. Patients present with severe hypoxemia, hypocapnia, and increased alveolar-arterial PO_2 gradient without obvious parenchymal lung disease. Treatment with high dose glucocorticoids improves oxygenation. Cricoarytenoid or laryngeal involvement causing upper airway obstruction varies from 0.3% to 30% [42]. Bronchiectasis is common but usually clinically asymptomatic.

Cardiac Disease

Cardiovascular involvement in SLE ranges from 29% to 66%. This tremendous range reflects whether data is based on clinical parameters or pathologic findings at autopsy. Often, the latter studies document significant findings in the heart without clinical correlation. However, a multisite international SLE cohort study confirmed that circulatory disease (including cardiac, arterial, and cerebral vascular disease) is the major cause of mortality [48].

Pericardial disease is by far the most common cardiac manifestation of SLE (see Chapter 35) but less common than lupus pleuritis. Subclinical pericarditis is often documented only at autopsy. Pericarditis usually presents in association with other organ system activity, rather than as an initial manifestation of SLE. Classic symptoms include an anterior or substernal pleuritic chest pain that is characteristically relieved by leaning forward. A pericardial rub may be heard. Although objective radiographic, electrocardiogram (ECG), and echocardiographic findings of pericarditis are similar to idiopathic pericarditis, some patients may have relatively normal findings.

Life-threatening complications of pericarditis include cardiac tamponade and constriction. Both entities are rare; the incidence of tamponade is reported at 1% to 2.5% while constriction is described in case reports [49]. Since hemodynamically significant pericarditis is rare, pericardiocentesis fluid data are limited. Typically, pericardial fluid is exudative with high protein and normal-to-low glucose, compared with serum. The total WBC counts from various reports have ranged from 544 to 199,600 cells per μL, with predominantly PMN cells. Thus, suppurative pericarditis becomes a significant and important differential in SLE patients with pericarditis. Other reported pericardial fluid features include low or absent complement levels, lupus erythematosus (LE) cells on Wright stains, and positive ANA titers, but none of these findings can differentiate infectious from lupus pericarditis. Constrictive pericarditis may develop after successful treatment of pericarditis with or without corticosteroids.

Once other causes of pericarditis, including uremia, drugs, or viral infections, have been eliminated, hemodynamically stable but symptomatic pericarditis can be successfully treated with NSAIDs or, occasionally, moderate dose (15 to 30 mg per day) oral corticosteroids. If fever is present and the etiology of the pericardial effusion is not clear, a diagnostic pericardiocentesis may be necessary to rule out bacterial or opportunistic infections. Hemodynamically compromising effusions require pericardiocentesis and high-dose IV corticosteroids (e.g., equivalent of 1 mg per kg per day of prednisone). IVIg has been used for the treatment of life-threatening pericarditis. If effusions recur despite the use of high-dose steroids, repeat drainage, pericardial window, or even pericardial stripping may be required.

Another common cardiac manifestation of SLE is valvular heart disease involving the mitral, aortic, or tricuspid valves, often asymptomatic and picked up on echocardiography. Thickened leaflets are common findings but nonbacterial, verrucous lesions (Libman-Sacks endocarditis) may result in embolic events, secondary infectious endocarditis, or valvular insufficiency or stenosis. At autopsy, 15% to 60% of SLE patients have lesions composed of immune complexes, fibrin, platelets, and fibrotic changes on the ventricular surface of the mitral valve (and less commonly, aortic valve), ventricular endocardium, chordae tendineae, and papillary muscle. Clinically, the presence of these lesions does not correlate with murmurs. Prevalence varies from 11% by transthoracic echocardiogram to 43% by transesophageal approach [50]. If significant valvular dysfunction occurs, valve repair or replacement may be required, but complications include rapid calcification of the repaired valve or bioprosthesis. Ongoing anticoagulation is recommended in some cases.

Since the mid-1980s, the presence of Libman-Sacks endocarditis has been associated with the presence of APAs in SLE and primary antiphospholipid syndrome (APS). However, other studies have not confirmed this association in all patients. Whether valvular lesions associated with APA are different in morphology and location remains unclear. Lifelong anticoagulation is indicated if thromboembolic events occur.

Myocardial involvement in SLE is the least frequent manifestation of cardiac disease and should be categorized as primary or secondary. Primary myocarditis is rare, clinically occurring in 2.1% to 14.0% of SLE patients [51]. M*yocarditis* has been defined as unexplained tachycardia, congestive heart failure, ventricular arrhythmias, conduction defects, ST- or T-wave changes, or cardiomegaly without evidence of valvular or pericardial disease. Congestive heart failure from myocarditis is rare and is estimated to occur in 4% of cases. In most studies cardiac function was evaluated by echocardiography, thallium stress tests, and, rarely, invasive hemodynamic studies. Secondary myocardial dysfunction in SLE includes systemic hypertension, valvular disease, pulmonary disease, coronary artery ischemia (see following discussion), drug toxicity, and amyloidosis. These secondary causes are often more important than true lupus myocarditis. Management of patients with evidence of carditis rests on distinguishing primary from secondary

disorders. In the rare patient who does have myocarditis from SLE, high-dose corticosteroids are indicated. Data regarding the use of immunosuppressive agents is scarce.

Primary coronary artery involvement in SLE includes embolic events, thromboses, or a true vasculitis of the vessels as opposed to secondary changes of premature atherosclerosis. Coronary arteritis is rare and difficult to distinguish from atherosclerosis on arteriographic studies unless repetitive studies are performed. In a prospective study of 100 SLE patients, 5% of those with clinical ischemic symptoms responded to increases in steroid dosage, suggesting active arteritis [51]. This can occur in the absence of extracardiac SLE activity. Thrombosis associated with APAs may contribute to myocardial ischemia.

Myocardial infarction from accelerated atherosclerosis, however, occurs more frequently in SLE patients and especially in the age group between 35 to 44 years. Circulatory diseases including heart disease, arterial disease, and cerebral vascular events is the major cause of death in a large multinational SLE cohort, with a standardized mortality ratio (ratio of deaths observed to deaths expected) of 1.7 [48]. SLE patients in the Nurses' Health Study had a more than twofold age adjusted relative risk for cardiovascular disease [52]. Another large lupus cohort reports 9% to 10% incidence of atherosclerotic disease [53]. The mean age of these patients was 48 years, and lupus was quiescent at the time of angina or myocardial infarction. Subclinical atherosclerotic disease is estimated at 37% to 43% of SLE patients based on arterial calcifications by ultrasound or electronic beam CT. Traditional risk factors are more prevalent in the SLE population but SLE is also an additional major risk. Other identified factors include hyperlipidemia, older age at SLE onset, duration of SLE, hypertension, and duration of corticosteroid use.

The management of SLE patients with acute myocardial ischemia initially should be similar to any patient with atherosclerotic coronary artery disease. However, the etiology of the ischemia must be determined since management of coronary arteritis differs from management of atherosclerotic disease. Evidence of extracardiac SLE activity may be helpful. Laboratory tests, including ANA, anti-dsDNA, complement levels, complete blood count with differential and platelet counts may provide some indicators of SLE activity. LAC and APAs should be checked. ECG, echocardiogram, and thallium stress tests do not distinguish arteritis from atherosclerosis. Coronary arteriogram may be helpful in separating thrombosis and vasculitis from atherosclerosis. However, arteriographic distinction of the latter two may be difficult. If arteriography reveals thrombosis without evident atherosclerosis and the presence of APAs is documented, therapy should consist of anticoagulation and antiplatelet medications.

Conduction abnormalities and arrhythmias due to SLE are usually clinically insignificant. The incidence of atrioventricular nodal block is estimated at 5%. Sinus tachycardia without underlying pathology (fever, dehydration, congestive heart failure, thyroid disease, drug abuse) may be a subtle manifestation of lupus activity. If acute conduction disease is suspected clinically to be secondary to myocarditis or arteritis, a short trial of corticosteroids could be initiated in the hemodynamically compromised patient.

Hematologic Disease

Hematological abnormalities constitute one of the major criteria for SLE. These include hemolytic anemia, thrombocytopenia, leukopenia, and lymphopenia. Anemia is present in 50% of SLE patients, with anemia of chronic disease being the most common etiology [54]. Other causes of anemia include iron deficiency (from menses, gastrointestinal bleeding, or poor iron absorption), autoimmune hemolytic anemia (AIHA), drug induced (cyclophosphamide or AZA), pure red cell aplasia, and chronic renal insufficiency. Rarely, other syndromes including thrombotic thrombocytopenia purpura and macrophage activation syndrome have been reported in SLE patients who have more than two cell lines affected [55].

Only 8% to 28% of lupus patients develop AIHA sometime during the course of their disease. While 18% to 65% of SLE patients have a positive direct Coombs assay, significant hemolytic anemia develops in only 10% [54]. The presence of warm IgG autoantibodies and complement on the red cell surface is characteristic of SLE AIHA. Clinically, AIHA is accompanied by an elevated reticulocyte count and indirect bilirubin and decreased haptoglobin levels. Severe hemolytic anemia, defined as hemoglobin less than 8 g per dL, is often associated with concomitant seizures, nephritis, serositis, and other cytopenias [56]. In addition, 74% of patients with AIHA will have APAs. Over 75% to 96% of patients with AIHA respond rapidly to high-dose corticosteroids (60 to 100 mg per day prednisone orally or with intravenous methylprednisolone at 1.5 mg per kg per day) [57,58]. Prednisone is tapered slowly after 3 weeks, based on laboratory results. If active hemolysis persists after 3 weeks, other therapeutic modalities include danazol, dapsone, immunosuppressive agents, and splenectomy; however, splenectomy induces permanent remission in fewer than 50% of patients. Combination of high-dose steroids and danazol, 800 to 1,200 mg per day, is an alternative treatment for severe AIHA, with subsequent gradual steroid tapering. One retrospective study of SLE patients treated for AIHA suggests that danazol was most effective in long-term treatment [58,59]. The efficacy of IVIg is short term and not sustained. Uncontrolled trials or case reports with AZA, cyclophosphamide, plasmapheresis, or rituximab have shown therapeutic response.

Leukopenia, defined as a total white blood cell count of less than 4,000 per μL, occurs in 50% to 60% of SLE patients, but associated infectious complications are rare unless CD4 counts are below 200. In the febrile, severely neutropenic patient, granulocyte-stimulating factor has been used. *Lymphopenia*, defined as counts lower than 1,500 per μL, is seen in 84% of SLE patients during active disease.

Thrombocytopenia, or platelet counts lower than 100,000 per μL, is observed in 20% to 40% of SLE patients and is severe (less than 50,000 per μL) in 10% of patients. Idiopathic thrombocytopenic purpura (ITP) may be the initial presentation of SLE. In evaluating any patient with thrombocytopenia, underlying causes including drug toxicities, ineffective thrombopoiesis, congestive splenomegaly, dilutional effects, and abnormal platelet destruction by disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), vasculitis, drug-induced infection, or hematological excluded. The pathologic mechanism is usually antiplatelet antibodies, with resultant splenic sequestration and decreased platelet life span, although there is association with elevated APA as well. A bone marrow biopsy is helpful in distinguishing various forms of thrombocytopenia. SLE-associated ITP is characterized by an increased number of megakaryocytes.

Once TTP, HUS, DIC, and drug toxicities are excluded, therapy of severe SLE-associated ITP (less than 50,000 per μL) is similar to that of idiopathic autoimmune thrombocytopenia. Corticosteroid therapy at 1 mg per kg per day is the recommended initial therapy. Subsequent tapering is guided by platelet counts. Administration of IVIg may result in a rapid increase in platelet counts. Recommended doses range from 0.4 to 1.0 g per day or 6 to 15 mg per kg per day for 4 to 7 days, but success at maintaining platelet counts is variable. Splenectomy is an option for patients who fail medical therapy, although sustained remission is seen in only 64% of patients

after splenectomy [60]; thus, the long-term benefit of splenectomy is still questioned. For refractory disease, danazol, 800 to 1,200 mg per day alone or in conjunction with corticosteroids, has been effective in several studies [58]. Immunosuppressive agents include various combinations of vincristine or vinca-loaded platelets, cyclophosphamide, and AZA. Anecdotal evidence and open case reports suggest that rituximab (RTX) is effective for intractable disease [61].

Lupus anticoagulant (LAC) interferes with the activation of prothrombin activator complex (factors Xa and V, Ca^{2+}, and phospholipid) of the intrinsic and extrinsic pathways. The laboratory findings are markedly prolonged partial thromboplastin time and normal or mildly prolonged prothrombin time that cannot be corrected by mixing with normal plasma. In addition, patients may also have false-positive reactions in the test for syphilis (VDRL). (Please see the section Antiphospholipid Syndrome for clinical details.) Although many SLE patients have both LAC and APA, subsets of patients have only one or the other laboratory abnormality.

Gastrointestinal Disease

The gastrointestinal involvement in SLE is not frequently considered because many gastrointestinal symptoms can be attributed to complications of drug therapy, particularly salicylates, NSAIDs, corticosteroids, hydroxychloroquine, and AZA. SLE-related gastrointestinal disease varies from of 8% to 22% and includes serositis, mesenteric vasculitis or thrombosis, pancreatitis, cholecystitis, inflammatory bowel disease, protein losing enteropathy, intestinal pseudo-obstruction, and pneumatosis intestinalis [62,63].

The most serious but rare (< 1%) gastrointestinal complication of SLE is mesenteric vasculitis or thrombosis with subsequent large or small intestinal ischemia. The severity and extent of involvement vary and symptoms may be chronic or acute in presentation. Intestinal involvement ranges from segmental edema or ulcerations to perforations. Evaluation should include plain films, paracentesis (to rule out perforation or bacterial peritonitis), CT scans, or angiography. Although features of dilated bowel, bowel wall edema or enhancement, or edema of the mesentery or its vessels are nonspecific, multiple vessel involvement, often in the areas of ileum and jejunum, is found in SLE mesenteric vasculitis [64]. However, angiographic results may be normal due to small vessel disease. Direct visualization with endoscopy or colonoscopy may also provide useful information.

Lupus peritonitis is less devastating but often quite dramatic in presentation. Peritoneal fluid may be present, and is usually transudative and sterile with a low cell count. Other causes of ascites must be ruled out, including constrictive pericarditis, nephrotic syndrome, and spontaneous bacterial peritonitis. Pancreatitis attributed to active SLE is rare and more often related to usual causes of pancreatitis in non-SLE patients (e.g., drugs, hepatobiliary infection, alcohol, etc.) [63]. In a recent report, protein losing enteropathy and intestinal pseudo-obstruction were the most common gastrointestinal manifestations in hospitalized SLE patients [62].

Management of the SLE patient with abdominal pain does not differ significantly from that for non-SLE patients. In patients with mild to moderate pain with a chronic course, medications and intercurrent disease should be considered first as the cause of pain and surgical consult obtained. If no etiology is found, peritonitis should be considered and treated with a moderate increase in steroids. In patients who present acutely, supportive care should be started and appropriate laboratory and imaging studies performed. Paracentesis should be done to exclude perforated viscus or infection. A therapeutic trial of high-dose steroids can then be instituted if mesenteric vasculitis is suspected. Rapid (12 to 48 hours) response usually is consistent with vasculitis or peritonitis, although complete response is often delayed; if a patient deteriorates clinically, exploratory laparotomy is necessary. If studies suggest mesenteric vasculitis, IVCY may be necessary along with the corticosteroids.

Drug-Induced Lupus

The syndrome of drug-induced lupus (DIL) should be considered in ICU patients if systemic symptoms of fever, arthralgias, arthritis, pleuropericarditis, or, less commonly, rash develop. Because many ICU patients receive medications that potentially induce SLE (Table 193.4), the diagnosis must be excluded. Although some medications, particularly procainamide, hydralazine, and TNF-α inhibitors, produce positive ANA tests, this does not necessarily imply that drug-induced lupus is present. Symptoms typically develop several months after the institution of the offending medication. Although CNS and renal manifestations are rare, case reports of more atypical drug-induced lupus have been reported. Males and females are equally susceptible. DIL is more common in older patients, except for minocycline related DIL. Laboratory values reveal an elevated ESR, mild leukopenia or thrombocytopenia, and positive ANA; antihistone antibodies are present in 90% of patients; and specific antibodies to dsDNA and Smith (Sm) antigen are uncommon. However, TNF-α inhibitors such as etanercept or infliximab have been associated with anti-dsDNA, anti-Ro, anti-Sm, and antineutrophil cytoplasmic antibodies (ANCA) [65]. Discontinuation of the offending medication results in gradual diminution of symptoms that may last as long as a year. NSAIDs or low-dose steroids may control the symptoms, and in patients with severe organ system involvement, treatment is similar to idiopathic lupus.

Most rheumatologists believe that patients with idiopathic SLE who require hydralazine, procainamide, isoniazid, phenytoin, beta-blockers, or other medication that can potentially induce lupus can take these medications. TNF-α inhibitors, however, are relatively contraindicated in SLE. It is advisable to document the clinical and serologic status of the patient before starting the medication.

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid syndrome (APS) is defined by vascular thrombosis or pregnancy complications in the presence of moderate-to-high titer IgG or IgM anticardiolipin antibodies (APAs), lupus anticoagulant (LAC), or high titer anti-β_2 glycoprotein-I antibody, documented at least twice 12 or more weeks apart (Table 193.5). Other features often associated with APS, but not included in the classification criteria, include livedo reticularis, skin ulcers, endocardial disease, thrombocytopenia, Coombs-positive hemolytic anemia, and false-positive tests for syphilis [66]. Primary APS occurs in the absence of other connective tissue disease. When APS is associated with SLE or other connective tissue disorders, it is referred to as *secondary APS*. Patients with *catastrophic APS* (CAPS) present with acute multiorgan failure from occlusive vasculopathy of small vessels in the kidney, lungs, brain, heart, adrenal glands, and liver. Large vessel occlusions have also been reported.

The LAC, APAs, and anti-β_2 glycoprotein-I antibody all bind to negatively charged phospholipids. How these antibodies induce thrombosis remains unknown, but interaction with endothelial cells, coagulation factors, and platelets, and complement activation, all play a role. Thromboses and emboli occur in all vessel sizes and organ systems. Nonthrombotic associations include valvular lesions similar to Libman-Sacks, hemolytic anemia, thrombocytopenia, and livedo reticularis.

TABLE 193.4

MEDICATIONS ASSOCIATED WITH DRUG-RELATED LUPUS

Type	Definite	Possible	Rare[a]
Cardiovascular	Methyldopa Hydralazine Procainamide Quinidine Practolol Diltiazem	Captopril Beta-blockers Hydrochlorothiazide Amiodarone Ticlopidine	Reserpine Minoxidil Chlorthalidone Clonidine HMG CoA inhibitors Spironolactone Disopyramide Prazosin
Anticonvulsants or neurologic medications		Phenytoin Mephenytoin Primidone Carbamazepine Trimethadione	Levodopa Ethosuximide Valproate
Psychiatric	Chlorpromazine	Lithium carbonate	Lamotrigine
Antibiotics	Isoniazid Minocycline	Sulfonamides Nitrofurantoin Rifampin	Streptomycin Tetracycline Penicillin Nalidixic acid Griseofulvin, terbinafine
Endocrine		Methimazole Propylthiouracil, Methylthiouracil Glyburide	Tolazamide
Rheumatic	Penicillamine TNF-α inhibitors	Sulfasalazine	Gold salts Allopurinol *p*-Aminosalicylic acid NSAIDs: tolmetin, ibuprofen, sulindac, diclofenac, tolmetin
Others	Interferon gamma	Danazol, dapsone	Psoralen Quinine Leuprolide acetate Promethazine Timolol eye drops Olsalazine, mesalamine Zafirlukast Interleukin 2 Docetaxel

[a]Rare: usually case reports.

The APS manifestations that most likely require ICU admission are cerebrovascular disease, pulmonary embolism, major abdominal or extremity arterial or venous thrombosis, myocardial infarctions, severe valvular disease (insufficiency or thrombotic valvular vegetations), and intracardiac thrombosis. Renal manifestations of APS include hypertension, proteinuria, acute or subacute renal insufficiency, and end-stage renal failure [67]. The classic renal lesion is thrombotic microangiopathy, but the entire renal vasculature can be affected: renal artery lesions can cause renal artery stenosis, cortical ischemia, and infarct, while thrombosis of the renal vein and inferior vena cava result in nephrotic range proteinuria. Hemodialysis patients with APS are at increased risk of vascular access thrombosis. CAPS, which occurs in less than 1% of APS, is the most serious and devastating subset with multisystem small vessel thromboses occurring within a short time period, usually less than 1 week [68]. Differentiation from TTP and DIC is imperative but sometimes difficult since microangiopathic hemolytic anemia or elevated fibrin split products are sometimes present in CAPS. Precipitating factors include infection, surgery, malignancy, subtherapeutic anticoagulation, and SLE flares. Mortality is high, nearly 48%, with death most often associated with renal, pulmonary, splenic, or adrenal involvement, or underlying SLE [69].

APS patients with *venous* thrombosis are treated with heparin anticoagulation followed by conversion to warfarin with an international normalized ratio (INR) target of 2.0 to 3.0. Lifelong anticoagulation is supported by a high incidence of recurrent thrombosis when warfarin is discontinued. A prospective trial comparing two intensities of warfarin for prophylaxis suggests that moderate dose (INR 2.0 to 3.0) is comparable to high dose (INR 3.1 to 4.0) in preventing further thrombosis and equal in bleeding complications [70]. However, in this study, only 24% of patients had arterial thrombosis and thus controversy still exists as to whether high intensity warfarin (INR 3.1 to 4.0) is necessary for patients with arterial clots. In APS patients with recurrent thrombosis despite therapeutic anticoagulation, treatment options include standard dose warfarin plus an antiplatelet agent, high intensity warfarin, unfractionated heparin, or low-molecular-weight heparin. For CAPS, combination therapy with high-dose corticosteroids, high intensity anticoagulation, and IVIg or plasmapheresis has the

TABLE 193.5

MODIFIED SAPPORO CLASSIFICATION CRITERIA FOR ANTIPHOSPHOLIPID SYNDROME

Clinical criteria
1. Vascular thrombosis involving any size vessel (arterial, venous, or capillary)
2. Pregnancy complications
   a. Three or more sequential spontaneous miscarriages before 10 weeks gestation (without obvious causes)
   b. One or more unexplained death of normal fetus beyond 10 weeks gestation
   c. Preterm delivery of normal fetus < 34 weeks due to preeclampsia, eclampsia, or placental insufficiency

Laboratory criteria (measured at least on two occasions, 12 weeks apart)
1. Moderate-to-high titer IgM or IgG anticardiolipin antibodies by ELISA
2. Lupus anticoagulant defined by guidelines from International Society on Thrombosis and Hemostasis
3. High titer (> 99 percentile) IgM or IgG anti-β_2 glycoprotein-I antibody by ELISA

Diagnosis is based on the presence of one clinical and one laboratory criteria. The laboratory finding should not be less than 12 weeks or more than 5 years apart from the clinical event.

Adapted from Miyakis S, Lockshin MD, Atsumi T, et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome. *J Thromb Haemost* 4(2):295–306, 2006.

best survival data [68]. There is no evidence to support anticoagulation as primary prevention in individuals who have antiphospholipid antibodies or LAC without thrombotic manifestations [71].

Other causes of hypercoagulability associated with venous thrombosis include deficiencies of protein C, protein S, plasminogen, and antithrombin III; factor V Leiden; prothrombin mutation and homocystinemia; nephrotic syndrome; and paraneoplastic syndrome. In patients with arterial thromboses, homocystinemia, and other nongenetic causes including cocaine use, valvular heart disease, atrial myxoma, and arterial stenosis should be excluded.

SYSTEMIC SCLEROSIS

SSc, or scleroderma, is an immune-mediated disease characterized by progressive fibrosis of the vasculature and viscera resulting in end-organ damage in the skin, heart, lungs, kidneys, and gastrointestinal tract. There are two subsets of scleroderma: (a) limited cutaneous disease, often associated with the anticentromere antibody and (b) systemic/diffuse disease, associated with the presence of antitopoisomerase 1 (SCL-70) or anti-RNA polymerase. Both subsets have potential end-organ complications that result in ICU admission, including severe digital ischemia from Raynaud's phenomenon, respiratory failure, cardiac dysfunction, or renal insufficiency. The following discussion is limited to these areas.

Severe Raynaud's Phenomenon

Although primary Raynaud's phenomenon (RP) is common in the general population (up to 5%), severe secondary RP associated with connective tissue disease often is more difficult to treat and digital ulceration or gangrene may occur in 25% of SSc patients. Dihydropyridine-type calcium channel blockers, usually nifedipine, reduce the frequency and severity of RP attacks, and are considered first-line therapy [72]. Bosentan, a dual endothelin receptor antagonist, is effective in reducing the number of new digital ulcers [73,74]. Limited evidence suggests that sildenafil, a phosphodiesterase inhibitor, reduces the frequency and severity of attacks and promotes healing of digital ulcers [75,76]. Topical nitrates, ACE inhibitors, and α-adrenergic receptor blockade are additional therapies with modest benefit. Intravenous prostacyclin (epoprostenol) or iloprost (a prostacyclin analog) are effective in patients with severe digital ischemia refractory to other therapies (Table 193.6) [77]. Oral prostanoids are less effective. Use of intravenous prostaglandins should be avoided in patients with pulmonary hypertension unless closely monitored. Chemical sympathectomy with lidocaine provides short-term pain relief, but surgical digital sympathectomy is a last alternative when medical therapies fail.

Pulmonary Disease

Pulmonary involvement in SSc is now the major cause of death (more than 50%). The prevalence of lung disease ranges from 25% to 90% [78]. Clinically significant disease from interstitial fibrosis or pulmonary arterial hypertension (PAH) is estimated at 40% (see Table 193.1).

Exertional dyspnea, cough, and basilar crackles are the predominant clinical features of ILD. Radiographs may reveal pulmonary fibrosis in 33% to 40%, with a characteristic basilar reticulonodular or honeycombing pattern [78]. High-resolution CT scans (HCRT) are more sensitive in documenting the reticular and ground glass opacities of ILD when plain radiographs are relatively normal. Pulmonary function tests may reveal abnormalities even before radiographic or clinical findings. The classic pattern is restrictive, with decreased total lung capacity and forced vital capacity. These findings correlate with fibrosis of the chest wall, diaphragm, and pleura. A decrease in diffusing capacity (D_LCO) may occur in either ILD or pulmonary hypertension and has been reported in isolation without other pulmonary function test abnormalities. Patients with ILD may develop secondary PAH, but the degree of PAH is disproportionate to the degree of ILD.

Prevention of progressive fibrotic disease is the goal of treatment for SSc-associated ILD. In one study, the extent of disease on CT was predictive of mortality and FVC decline, suggesting that patients with more advanced CT abnormalities should be treated [79]. Patients with less extensive disease should be monitored closely and treated if there is evidence of radiographic progression or decline in pulmonary function. BAL cellularity does not predict disease progression or response to treatment, and currently has a limited role in the evaluation of ILD, but is useful to rule out infection [80]. A randomized, placebo controlled study of oral cyclophosphamide (1 mg per kg per day titrated to maximum of 2 mg per kg per day) found small but statistically significant improvement in forced vital capacity (FVC), skin score, and subjective symptoms [81]. Another randomized, placebo controlled study of IVCY (0.5 to 0.7 g per M^2 monthly) demonstrated improvement in FVC [82]. Although there are no controlled trials to compare efficacy of oral versus intravenous CY, the IV route is most practical initially in the critically ill ICU patient. Debate exists as to whether concomitant high-dose prednisone or prednisolone provides additional benefit. Case reports and small open studies of mycophenolate mofetil are encouraging, but larger studies are needed.

Isolated PAH is more common in limited scleroderma, but also occurs in patients with diffuse disease, with a prevalence of 12% to 15% [83]. Pulmonary vasospasm and

TABLE 193.6

DRUG THERAPY FOR SEVERE RAYNAUD'S AND PULMONARY HYPERTENSION IN SSC

Drug	Route of administration	Pulmonary arterial hypertension[a]	Severe digital ischemia[a]	Side effects
Epoprostenol	Continuous, intravenous	2 ng/kg/min titrated to 11 ng/kg/min [90]	2 ng/kg/min titrated up to 4–8 ng/kg/min over 5 d [77]	Catheter related; flushing, nausea, jaw pain, diarrhea, depression
Iloprost	Inhalant	5 µg 6–9 times/d [116]	Ineffective	Flushing, jaw pain, ? syncope
Iloprost[b]	Intravenous		0.5–2 ng/kg/d for 6 h for over 3–5 d [117]	Infusion site pain, headache, nausea, diarrhea, vomiting, jaw pain
Treprostinil	Continuous infusion, or subcutaneous	2 ng/kg/min titrated up to 40 ng/kg/min [118]	2 ng/kg/min titrated up to 40 ng/kg/min (case reports)	Jaw pain, headache, diarrhea, nausea, infusion site pain
Treprostinil	Inhalant	6–18 µg 4 times/d		
Bosentan	Oral	125 mg b.i.d. [84,85]	62.5 mg b.i.d. then increased to 125 mg b.i.d. [73,74]	Hepatotoxicity, anemia, edema, male infertility, teratogenicity
Ambrisentan	Oral	5–10 mg/d [86]		Hepatotoxicity, anemia, edema, male infertility, teratogenicity
Sitaxsentan[b]	Oral	100 mg/d [87,88]		Hepatotoxicity, anemia, edema, male infertility, teratogenicity
Sildenafil	Oral	20 mg t.i.d. to 80 mg t.i.d. [89]	50 mg b.i.d. [75,76]	Headache, diarrhea, dyspepsia, flushing

[b]Not currently available in the United States.

endothelial cell activation with subsequent arterial wall proliferative changes contribute to the development of PAH. Symptoms include exertional dyspnea, fatigue, reduced exercise tolerance, chest pain, syncope, and lower extremity edema, but patients may be asymptomatic until the disease is advanced. The most sensitive tests are decreased diffusing capacity, often with preserved lung volumes, and Doppler echocardiography showing increased pulmonary pressures and right atrial and ventricular hypertrophy. Right heart catheterization is the gold standard for confirmation of suspected PAH and allows vasodilator trials to assess the degree of pulmonary vascular responsiveness to iloprost or epoprostenol, inhaled nitric oxide, or adenosine. General measures include the use of supplemental oxygen for hypoxic patients, diuretics for management of volume overload, and digoxin for atrial arrhythmias. Anticoagulation is recommended for advanced PAH, but controlled studies have not been done.

Treatment for PAH has recently advanced with oral agents in addition to intravenous or subcutaneous prostacyclin (epoprostenol, iloprost, and treprostinil). Bosentan, a dual endothelin receptor A and B antagonist, maintains vasodilation in the pulmonary arterial bed and clearance of endothelin, improves exercise tolerance, reduces symptoms, and stabilizes hemodynamics [84,85]. Bosentan is currently approved by the FDA for treatment of New York Heart Association (NYHA) class II, III, and IV PAH. Ambrisentan, a selective endothelin-A receptor antagonist, recently has been approved for treatment of NYHA Class II and III PAH [86]. Sitaxsentan is another selective endothelin-A antagonist only approved in Europe [87,88]. Sildenafil, a phosphodiesterase-5 inhibitor, increases vascular smooth muscle cyclic guanosine monophosphate (cGMP) with subsequent vasodilation, improves hemodynamic measures, and improves exercise capacity at doses of 20 mg to 80 mg three times a day [89]. Since these oral agents cause fewer side effects and eliminate the need for intravenous or subcutaneous delivery, they now are the preferred initial drugs of choice for treatment of PAH. Intravenous prostacyclin, epoprostenol, and a subcutaneous prostacyclin analog, treprostinil, are approved for treatment of NYHA class III and IV PAH, and epoprostenol has approval for use in SSc PAH [90]. Given the problems associated with the need for continuous delivery and the associated adverse effects, both agents are reserved for patients who have failed oral therapy. Inhaled prostacyclin, iloprost, 2.5 to 5.0 µg dosed six to nine times per day, also has been approved for the treatment of NYHA class III and IV PAH. Combination therapy with inhaled iloprost, intravenous or subcutaneous prostacyclin, and oral agents may provide even greater benefit, but controlled studies are not available. Table 193.6 summarizes the current therapies available for treatment of PAH.

Surgical interventions include atrial septostomy or transplantation. The former is viewed as a bridge to transplantation since it creates a right-to-left shunt to reduce right heart pressures. However, with recent advances in medical therapy, time to transplantation has been prolonged in the PAH population.

Cardiac Disease

Cardiac involvement in SSc may be a primary process within the heart or secondary to other major organ involvement (i.e., pulmonary, renal, vascular, thyroid). Primary cardiac disease in SSc includes pericardial disease, myocardial disease, conduction abnormalities, and arrhythmias. Because the most common symptoms are dyspnea, orthopnea, atypical chest pain, palpitations, fatigue, and dizziness, the clinical manifestations of cardiac disease can be confused with those of other organ systemic involvement. Recent studies have also shown an increased burden of atherosclerotic coronary disease in SSc [91].

Pericardial disease is the most common cardiac manifestation, and as in SLE, asymptomatic pericardial disease based on autopsy series or echocardiographic data has a much higher prevalence than symptomatic disease (33% to 71% vs. 7% to 20%). Pericardial effusions are usually small and do not

influence prognosis. Larger effusions (> 200 mL), however, are associated with poor prognosis. Pericardial tamponade with hemodynamic compromise is rare. Pericardiocentesis is rarely required unless the patient is hemodynamically compromised or febrile and an infectious etiology must be excluded. Pericardial fluid tends to be serous with a wide range of leukocyte counts and with normal complement levels. Corticosteroids are rarely required for treatment.

Myocardial involvement is the most common cardiac finding in patients with SSc at autopsy, ranging from 12% to 89%; however, symptomatic disease occurs less frequently than pericarditis. Pathologically, the most common findings are patchy, focal myocardial fibrosis equally distributed in both ventricles and all three layers of the heart [92]. Autonomic cardiac neuropathy may also contribute to cardiac morbidity in SSc patients.

Clinically, myocardial disease may result in cardiomyopathy, left ventricular diastolic dysfunction, congestive heart failure, angina, conduction abnormalities, or malignant arrhythmias. A high percentage of SSc patients without cardiac symptoms have an abnormal resting ECG, chest radiograph, Holter monitor, or echocardiogram. Electrophysiological studies reveal a high incidence of reentrant supraventricular tachyarrhythmias and atrioventricular conduction delays. Ventricular tachycardia occurs in 10% to 13% of patients and may be the cause of sudden death. Advanced myocardial fibrosis, rather than selective fibrosis of the conduction system, appears to be responsible for conduction abnormalities and arrhythmias.

Evaluation of acutely ill SSc patients for suspected heart disease should include a routine ECG and chest radiograph. Doppler echocardiography provides information regarding the pericardium, valvular function, systolic and diastolic ventricular function, chamber size, wall thickness, and the presence of pulmonary hypertension. Nuclear scanning may reveal subclinical myocardial disease; cardiac catheterization is useful for accurate assessment of pulmonary arterial pressures but is otherwise unremarkable unless the patient has arteriosclerosis. Negative endoyocardial biopsies cannot exclude myocardial fibrosis since the pathologic process tends to be patchy.

Treatment of SSc cardiac disease is tailored to the specific syndrome. Pericarditis can be treated with NSAIDs or low-dose corticosteroids. Diuresis should be pursued with caution in patients with large pericardial effusions. Renal failure has been reported in patients after vigorous diuresis, presumably secondary to hypovolemia superimposed on low cardiac output resulting in decreased renal cortical blood flow. Congestive heart failure is treated as outlined in Chapter 33. However, if echocardiography reveals evidence of diastolic dysfunction, ACE inhibitors or calcium channel blockers may be more appropriate than inotropic agents. A high index of suspicion for coronary artery disease and aggressive management of modifiable risk factors are important aspects of therapy for all patients.

Renal Disease

In addition to cardiac and pulmonary involvement in diffuse scleroderma, significant morbidity and mortality result from renal disease. The onset of accelerated to malignant hypertension accompanied by signs of microangiopathic hemolytic anemia, hyperreninemia, and rapidly progressive renal failure describes a syndrome referred to as *scleroderma renal crisis* (SRC). SRC may develop in up to 15% to 20% of patients with diffuse scleroderma [93]. SRC typically occurs early in the course of disease in patients with diffuse disease, often in the setting of other organ system involvement. Predictors for development of SRC include high skin score, large joint contractures (wrists, elbows, knees), enlarged cardiac silhouette, and prednisone use [93].

Although the pathophysiology of SRC is unknown, several factors contribute to its evolution. The primary event is endothelial cell injury, leading to intimal proliferation and luminal narrowing. Combined with other contributing factors such as vasospasm, decreased renal blood flow leads to increased renin release and clinical development of malignant hypertension and SRC. Moderate-to-high dose corticosteroid use is associated with the development of SRC, possibly because of the inhibition of prostacyclin production. Microangiopathic hemolytic anemia and thrombocytopenia develop with associated elevation of fibrin degradation products, decreased haptoglobin, elevated reticulocyte count, and the presence of urinary hemosiderin. The urinary sediment contains small amounts of protein (< 2.5 g per 24 hours) but typically no red blood cell casts.

The diagnosis of SRC should be strongly considered in the SSc patient with accelerated hypertension. Symptoms of malignant hypertension include headache, confusion, altered vision, and seizures. However, SRC may occur rarely in normotensive patients. Examination of peripheral blood smears for microangiopathy rapidly confirms the syndrome of SRC in a hypertensive patient. Virtually all patients with SRC have elevated plasma renin activity, although serial tests of renin levels in patients with scleroderma are not predictive of the onset of this syndrome.

Since the advent of aggressive management with ACE inhibitors, conservation or improvement in renal function is possible. It is now clear that this class of drugs is the standard of care in SRC. Short-acting ACE inhibitors should be started and titrated upward every 6 to 12 hours. Blood pressure should be controlled within 48 hours. Additional antihypertensives, including calcium channel blockers, can be added. In many patients treated with ACE inhibitors, there may be a transient reduction in glomerular filtration rate and a rise in serum creatinine. In a large prospective observational study of patients with SRC who were treated with ACE inhibitors, 61% had good outcomes (defined as no or temporary dialysis) and only 4% progressed to renal failure or dialysis [94]. In patients with good outcomes after the initial renal crisis, continuing ACE inhibitors indefinitely may provide further benefit to maintain renal function. Survival data of patients with good outcomes after SRC are similar to those of SSc patients without renal crisis. SRC accounts for only 8% of deaths in SSc, but in a retrospective review of SSc patients, those patients with SRC had a long-term survival of only 50% [93]. There is no evidence to support the use of ACE inhibitors for primary prevention of SRC.

Gastrointestinal Disease

Gastrointestinal tract involvement is common in SSc, affecting 50% to 80% of patients. The most common physiologic abnormalities, esophageal dysmotility and decreased lower esophageal sphincter (LES) pressure, are manifested by symptoms of dysphagia and heartburn, respectively. Pathologically, impaired microvascular perfusion initially alters myoelectrical function of the smooth muscle layer and later, hypoperfusion results in fibrotic changes in muscularis, submucosa, and lamina propria [95]. Although dysphagia and heartburn can be treated symptomatically, serious complications include strictures and Barrett's esophagus.

Gastric involvement is less common but can include gastroparesis with symptoms of early satiety, bloating, and vomiting. Telangiectasias are a common source of gastrointestinal blood loss, and gastric antral vascular ectasia (GAVE) may present with acute bleeding and antedate the diagnosis of SSc.

However, other causes of gastrointestinal bleeding also must be excluded.

Small and large intestinal involvement usually occurs concomitantly and results in malabsorption with symptoms of bloating, cramping, and intermittent or severe diarrhea. Hypomotility due to progressive smooth muscle atrophy and fibrosis results in bacterial overgrowth. In addition, adynamic ileus or pseudo-obstruction may occur. Although barium studies reveal wide-mouth sacculations or diverticula on the antimesenteric border, most patients have relatively few symptoms. Fecal incontinence and constipation are common but underreported. Rare complications include obstruction due to fecal impaction, megacolon, and volvulus. Pneumatosis cystoides intestinalis (PCI), or intramural air-filled cysts in the small or large intestines, may be found incidentally or cause abdominal pain, diarrhea, or bloody rectal discharge. Rupture of these cysts results in pneumoperitoneum without peritonitis.

Primary biliary cirrhosis is the most common liver disease associated with SSc. Up to 18% of patients with primary biliary cirrhosis have SSc, usually the limited cutaneous form, whereas 8% of all SSc patients have antimitochondrial antibodies. The liver disease most often follows the diagnosis of SSc but can precede it.

Treatment of gastroesophageal dysmotility and reflux includes modifications in eating and high-dose proton pump inhibitors. Treatment for GAVE includes various therapeutic endoscopic procedures such as cautery, sclerotherapy, and laser ablation. Prokinetic agents, including metoclopramide and macrolide antibiotics, have been reported to be useful in treatment of esophageal, gastric, and intestinal disease. Intestinal malabsorption has been treated with antibiotics, low-residue diets, medium-chain triglycerides, fat-soluble vitamins, and total parenteral nutrition. Octreotide improves intestinal peristalsis in pseudo-obstruction, and in combination with erythromycin may have additive benefits [96]. An investigational 5-HT4 receptor agonist, prucalopride, improves symptoms and gut transport in SSc [97]. Prucalopride recently was approved for use in Europe, but is not yet available in the United States. Cisapride, another 5-HT4 receptor agonist, is severely restricted in the US because of concerns regarding severe cardiac arrhythmias. PCI is usually managed conservatively without surgery, but both malabsorption and PCI are poor prognostic indicators [98].

IDIOPATHIC INFLAMMATORY MYOPATHIES

Polymyositis (PM), *dermatomyositis* (DM), and *inclusion body myositis* (IBM), the most common acquired inflammatory myopathies, are characterized by progressive symmetric proximal muscle weakness and elevated muscle enzymes. Each subtype also has unique clinical and histologic features. In both PM and DM, other organ system involvement is common. DM has classic skin findings including a heliotrope rash on the upper eyelids, scaly erythematous patches called Gottron's papules overlying the MCP and PIP joints and the extensor surfaces of the knees and elbows, and erythema typically in a V shape and mantle distribution on the neck and chest. PM and IBM have no skin manifestations. Both PM and DM may have pulmonary, cardiac, or gastrointestinal involvement. IBM differs from PM/DM in many ways including older age at onset, more indolent course with poor response to treatment, more frequent asymmetric and distal muscle involvement, and often only mild creatinine kinase elevation. The diagnosis of PM/DM is based on criteria established by Bohan and Peter [99]: symmetric proximal muscle weakness, typical rash of DM, elevated serum muscle enzymes, myopathic changes on electromyography, and characteristic muscle biopsy abnormalities. Muscle biopsy is usually required to establish the diagnosis and exclude other causes of muscle weakness. The biopsy should be taken from a muscle that is weak on exam, usually the quadriceps or deltoid. Obtaining the biopsy from a muscle contralateral to one with myopathic changes on EMG may improve the diagnostic yield. T2-weighted MRI with fat suppression can also be useful for identifying an actively inflamed muscle for biopsy [100]. A number of myositis-specific antibodies (MSAs) and myositis-associated antibodies (MAAs) have been identified that correlate with specific clinical presentations and may contribute diagnostic and prognostic information [101,102]. Anti–Mi-2, found in up to 10% of patients with myositis, is associated with classic DM, and is a marker for a more favorable prognosis. Antibodies against a signal recognition particle (SRP) occur in only 5% of myositis patients but are associated with acute, severe myositis with an overall poor prognosis. Table 193.7 summarizes the various clinical and laboratory features of these three idiopathic inflammatory myopathies.

Inflammatory myositis is also associated with other connective tissue diseases (SSc, SLE, mixed connective tissue disease), malignancy, inborn errors of metabolism, lipid storage disease, and mitochondrial myopathies, but these will not be discussed here. Numerous drugs can cause myopathy or myositis that is sometimes difficult to distinguish from inflammatory myositis. These drugs include lipid lowering agents, glucocorticoids, antipsychotics, antimalarials, colchicine, nucleoside reverse transcriptase inhibitors (NRTIs), alcohol, and cocaine. Bacterial infections (*S. aureus*, *Streptococcus pyogenes, Clostridium perfringens, Borrelia burgdorferi*) and viruses (coxsackievirus A and B, echovirus, influenza A and B, adenovirus 2 and 21, hepatitis B and C, and HIV) can cause a myopathy that may be confused with PM or DM. Parasites including trichinosis, toxoplasmosis, cysticercosis, toxocariasis, and amebiasis may all cause myositis. Muscular dystrophies, neuropathic disease, and metabolic/endocrine diseases also need to be excluded in patients with muscle weakness.

PM and DM are primarily disorders of skeletal muscle, but involvement of the pulmonary, cardiac, articular, gastrointestinal, or vascular systems sometimes lead to catastrophic illness requiring support in an ICU. Moreover, organ dysfunction may occur in patients with overlap syndromes. Respiratory failure, cardiac abnormalities, or comorbidities related to immunosuppression are the most common reasons for ICU admission. A complete discussion of the presentation, diagnosis, management, and differential diagnosis is beyond the scope of this chapter but excellent reviews exist [103–105].

Pulmonary Involvement

Lung disease in PM/DM patients is common (20% to 30% of patients; see Table 193.1) and includes (a) respiratory insufficiency due to weakness of intercostal or diaphragmatic muscles; (b) aspiration pneumonia; (c) pneumonia from neither aspiration nor opportunistic infection; and (d) ILD. Pulmonary vasculitis, pleuritis, pulmonary edema, alveolar hemorrhage, secondary pulmonary hypertension, and bronchiolitis obliterans with organizing pneumonia have also been reported but are uncommon. Dyspnea, cough, and chest pain, are the usual symptoms.

Respiratory failure from intercostal muscle weakness or diaphragmatic dysfunction occurs in 7% of PM/DM patients. Thus, pulmonary mechanics (spirometry, inspiratory force) should be evaluated when respiratory symptoms develop. Serial measurements often predict impending respiratory failure that might necessitate intubation and mechanical ventilation. Management of respiratory failure resulting from muscle weakness is supportive (oxygen, mechanical ventilation) and

TABLE 193.7

FEATURES OF IDIOPATHIC INFLAMMATORY MYOPATHIES

	Polymyositis	Dermatomyositis	Inclusion body myositis
Mean age at onset	45	Childhood or 40	65
Sex (M:F)	1:2	1:2	2:1
Mode of onset	Insidious over months	Insidious over months	Insidious over years
Distribution of muscle involvement	Proximal >> distal symmetric	Proximal >> distal symmetric	Variable, may be primarily distal, asymmetric
Dermatologic findings (see text)	No	Yes	No
Raynaud's	Yes	Yes	No
Pulmonary disease	Yes	Yes	No
Cardiac disease	Yes, rare	Yes, rare	No
Arthritis	Yes	Yes	No
Gastrointestinal tract	Yes	Yes	Cricopharyngeal dysfunction
Creatine kinase	Highly elevated	Highly elevated-classic DM Normal-amyopathic DM	Normal or minimally elevated
Electromyogram/nerve conduction studies	Myopathic features	Myopathic features	Myopathic features but also some neurogenic changes
Histopathology	Endomysial CD8 cells, without vascular inflammation	Perivascular infiltrate of B and CD4 cells and late complements (C_{5-9}, membrane attack complex); perifascicular atrophy	Similar to PM but also presence of intracellular lined vacuoles and inclusions; EM with microtubular filaments
Autoantibodies	Jo-1 (20%), U1-RNP (10%), PM-Scl (10%), SRP (< 5%)	Jo-1 (5%); Mi-2 (10%); U1-RNP (5%); PM-Scl (0.5%)	Rare
Malignancy association	Yes (twofold increase)	Yes (sixfold increase)	No
Response to therapy	Good	Good	Poor

DM, dermatomyositis; EM, electron microscopy; PM, polymyositis; RNP, ribonuclear protein; Scl, scleroderma.

accompanied by therapy directed at the underlying myositis (see Chapter 49).

Bronchopneumonia occurs in up to 24% of PM/DM patients. Contributing factors include pharyngeal incompetence and poor airway protection with subsequent aspiration, iatrogenic immunosuppression, and often a weakened cough. Infectious agents include virulent bacteria and opportunistic organisms. Myositis occurring in the setting of acquired immunodeficiency further expands the possible spectrum of infectious agents. Hence, respiratory symptoms should be evaluated aggressively with chest radiographs and routine and specialized microbiologic techniques (culture for bacteria, mycobacteria, fungi, and smears for *Pneumocystis jiroveci*).

The most common type of parenchymal lung disease in PM/DM is ILD with a prevalence of 20% to 60%. Patients develop progressive dyspnea with or without a nonproductive cough and bibasilar rales. Ground glass opacities and reticulonodular infiltrates may be present on HRCT scans. Pulmonary function tests reveal decreased lung volumes and reduced diffusing capacity. Histopathology usually reveals nonspecific interstitial pneumonia (NSIP) or usual interstitial pneumonia (UIP). Patients with Jo-1 and other antiaminoacyl-tRNA synthetase antibodies have a high incidence of ILD, along with prominent arthritis, fever, Raynaud's phenomenon, and dry, cracking skin lesions referred to as *mechanic's hands*. Fulminant ILD has occurred in amyopathic DM without anti-Jo antibodies.

Myocardial Involvement

Cardiac and pulmonary diseases are the main prognostic factors for PM/DM mortality [106]. Up to 70% of patients have cardiac abnormalities on noninvasive testing, but clinically, few are symptomatic. Myocarditis may manifest as heart failure, arrhythmias, cardiac arrest, or myocardial infarction. It is difficult to diagnose since levels of creatine kinase and muscle brain fractions are elevated as a result of skeletal muscle inflammation. Cardiac troponin I is the most specific marker for myocardial involvement. Cardiac imaging techniques (echocardiogram, gallium citrate or indium-labeled antimyosin antibody detection, and scintigraphic studies) are insensitive and nonspecific for detecting myositis. Contrast enhanced cardiac MRI may provide more information, but large-scale evaluation of its sensitivity and specificity is lacking in PM/DM patients. The gold standard of diagnosis requires endomyocardial biopsy but is invasive. Although previous literature suggested an association of anti-SRP antibodies with myocarditis, recent studies contradict this.

The extent to which any cardiac abnormality is iatrogenic or arises as a complication of the disease is unclear. For example, steroid therapy accelerates atherosclerosis and may exacerbate hypertension, diabetes mellitus, and electrolyte disturbances. Similarly, hypoxia from pulmonary involvement contributes to arrhythmias, axis shifts, and strain patterns on ECG.

Other Organ System Involvement

The major gastrointestinal manifestation of inflammatory myopathies is weakness of the upper pharyngeal striated muscles, resulting in dysphonia, dysphagia, and regurgitation of fluids. Smooth muscle involvement of the distal esophagus is rare, and intestinal vasculitis, commonly seen in childhood dermatomyositis, is also uncommon.

Renal failure and its attendant metabolic abnormalities are the result of rhabdomyolysis, myoglobinemia, and subsequent

myoglobinuria. Myoglobinuric renal failure is rare but tends to occur in patients with acute or hyperacute presentations as a result of widespread muscle necrosis and release of sarcoplasmic materials, including myoglobin. Therapy is directed toward the underlying muscle disease while maintaining an adequate urinary output.

Malignancy

The relationship of PM/DM to malignancy has been established by several epidemiologic studies [107]. DM is associated with the highest risk (sixfold increase compared to age and gender-matched population), while PM has a twofold increase. The risk decreases with time but even at 5 years, the risk is still measurable. Identified risk factors include female sex, later age at diagnosis, cutaneous necrosis and leukocytoclastic vasculitis, and capillary damage. Malignancies commonly associated with DM/PM include breast, ovarian, lung, colon, gastric, pancreatic, nasopharyngeal, and non-Hodgkin's lymphoma [103].

Treatment

High-dose corticosteroids are the first-line therapy for PM/DM, although there are no clinical trials to support this approach. Treatment is usually begun with prednisone 1 to 1.5 mg per kg per day for 6 to 8 weeks, then tapered based on clinical response. In more severe cases (dysphagia, alveolitis, myocarditis, or impending respiratory failure from muscle weakness), IV methylprednisolone may be given at a dose of 1,000 mg daily for 3 days followed by the usual high-dose oral corticosteroid regimen. In steroid responsive patients, a steroid-sparing agent (methotrexate, AZA, mycophenolate mofetil, tacrolimus, cyclophosphamide, or cyclosporine) may be added to facilitate steroid tapering, but efficacy is based on small case series or clinical experience as no randomized clinical trials have been done. IVIg is recommended for patients with severe weakness refractory to steroids based on proven efficacy in a randomized, placebo-controlled trial in patients with DM [108]. Therapy for progressive or severe ILD usually requires the use of corticosteroids and cyclophosphamide. Cyclosporine and tacrolimus can be used in refractory cases. A number of case reports suggest that rituximab can be effective for PM/DM resistant to other therapies, and a placebo-controlled trial is underway. There is conflicting data regarding the use of TNF inhibitors; anecdotal reports suggest benefit for some patients with PM/DM, but lack of efficacy and a high frequency of disease flares were reported in one open-label pilot study [109].

Therapy for IBM is more difficult since it responds to steroids poorly and slowly. IVIg and methotrexate have not been effective in double-blind, placebo-controlled trials. Current recommendations include a trial of steroids if muscle biopsies reveal significant inflammation and physical therapy to help maintain strength and function.

DRUGS USED IN RHEUMATIC DISEASE

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are the cornerstone of therapy in patients with rheumatic diseases. Numerous NSAIDs with variable dosing regimens are currently available. In the intensive care setting, however, comorbidities are often present in the acutely ill patient, and thus limit their use. Potential NSAID toxicities (gastrointestinal bleeding, exacerbation of cardiac and renal dysfunction) may far outweigh their benefits. NSAIDs are contraindicated in patients who are anticoagulated, further restricting their use in critically ill patients.

Corticosteroid Therapy

Although NSAIDs are the drugs of choice in the initial treatment of nonseptic inflammatory joint disease, corticosteroids are more effective for the vasculitides and inflammatory, multisystem autoimmune diseases such as SLE. The physiology and mechanism of action of corticosteroids are beyond the scope of this chapter.

Exogenous corticosteroids at a dose equivalent to prednisone 5.0 to 7.5 mg per day inhibit the hypothalamic-pituitary-adrenal axis. Thus, patients who are on corticosteroids chronically require increased stress doses when situations such as surgery, sepsis, trauma, or other serious medical complications occur. Several corticosteroid preparations are available, which differ in potency, half-life, and mineralocorticoid activity. In the ICU, the most commonly used corticosteroids are hydrocortisone, methylprednisolone, and prednisone. There are few indications to use the long-acting corticosteroids, such as dexamethasone, in patients with rheumatic diseases. At physiologic concentrations, corticosteroids are primarily bound by transcortin, but at higher levels, plasma concentrations of albumin-bound and free corticosteroid are increased. In hypoalbuminemic patients, a greater percentage of corticosteroid is free, thus increasing the anti-inflammatory effects and the toxicities. Since corticosteroids are metabolized in the liver, the concomitant administration of drugs that increase hepatic microsomal enzyme activity (phenytoin, barbiturates) also accelerates corticosteroid metabolism.

The dosage and mode of administration of corticosteroids depend on the clinical situation. In rheumatoid arthritis patients without evidence of vasculitis, joint symptoms usually can be controlled with less than 10 mg per day of prednisone. In contrast, a patient with newly diagnosed DM requires high-dose prednisone (1 to 1.5 mg per kg per day) to achieve disease control. The more usual situation in the ICU is the patient with multisystem involvement from SLE or vasculitis. In these patients, high-dose parenteral methylprednisolone can be initiated at 50 to 100 mg per day.

For acutely ill patients who fail conventional high-dose steroids (i.e., 1.0 to 1.5 mg per kg per day), pulse IV methylprednisolone at 1,000 mg per day infused over 60 minutes and repeated daily for 3 consecutive days may be more effective. Pulse IV methylprednisolone may produce minor side effects, such as metallic taste, facial flushing, transient hypertension, and hyperglycemia. More significant (but rare) toxicities include seizures, anaphylaxis, intractable hiccups, arrhythmias, hemiplegia, psychosis, and sudden death. In four reported deaths, patients were receiving furosemide concurrently. Theories on the mechanism of death include an electrolyte imbalance resulting in cardiac arrhythmias, cardiovascular collapse due to hypovolemia and vasodilation, and anaphylaxis. Data are limited on the actual mechanism of action by pulse methylprednisolone in suppressing SLE or vasculitis activity. In addition, the long-term toxicities are unknown. Thus, these factors must be weighed against the patient's clinical status.

High-dose daily corticosteroids are usually continued for 4 to 6 weeks. If disease activity remains controlled, further tapering should be attempted. Switching to alternate-day steroids reduces hypothalamic-pituitary-adrenal axis suppression and reduces or prevents Cushing's syndrome. This regimen, however, does not prevent steroid-induced osteopenia. If the patient does not improve with high-dose or pulse corticosteroids, the addition of other immunosuppressive agents must be considered.

Immunosuppressive Therapy

Immunosuppressive agents were initially used in rheumatic diseases as steroid-sparing agents. However, convincing evidence exists that these agents can produce dramatic improvement or induce remission in many different rheumatic diseases. The most commonly used drugs include methotrexate, AZA, cyclophosphamide, leflunomide, and mycophenolate mofetil. Cytotoxic drugs should be initiated in patients with life-threatening or organ-threatening diseases that have failed to respond to conventional therapy. In addition, the patient should have reversible lesions rather than end-stage disease. Many of the drugs are teratogens contraindicated during pregnancy. Thus, in any patient starting cytotoxic therapy, pregnancy needs to be excluded. Active infection cannot be present at the start of cytotoxic therapy. Patients with a positive PPD require further evaluation and treatment for active versus latent tuberculosis. Once therapy is initiated, laboratory studies need to be monitored carefully.

The dosing of immunosuppressive agents for the different rheumatic diseases has been discussed in previous sections. In the ICU setting, adjustment to conventional dosing may be necessary based on renal or hepatic function since many of these agents are metabolized or excreted through the kidney or liver. Drug interactions such as allopurinol with AZA or trimethoprim with methotrexate are also important considerations.

Mechanism of Action and Metabolism

All immunosuppressive agents interfere with the cell cycle, and the cytotoxic effects occur through inhibition of cell division.

Azathioprine (AZA), a purine analog, prevents biosynthesis of the purine bases, adenine, and guanine. AZA is a prodrug that is metabolized in the liver to 6-mercaptopurine and then, through the enzyme thiopurine S-methyltransferase (TMPT), to its active metabolites. A genetic polymorphism of TMPT results in variable enzyme activity and predicts greater risk of myelosuppression in patients with low or absent levels. TMPT genotype testing is recommended before initiating AZA therapy [110]. Since 45% of the prodrug is renally excreted, the dose should be reduced in patients with renal insufficiency, but specific recommendations are not available. AZA should be avoided, or the dose markedly reduced, in patients taking allopurinol, which interferes with its metabolism by inhibiting xanthine oxidase.

Mycophenolate mofetil (MMF) is a reversible inhibitor of inosine monophosphate dehydrogenase, whose effects also result in reduced purine synthesis and consequent inhibition of T- and B-cell proliferation. The antiproliferative effects of MMF are relatively specific for lymphocytes. Other potential mechanisms of MMF-induced immunosuppression include induction of T lymphocyte apoptosis and inhibition of adhesion molecule expression. Most of the MMF dose (90%) is excreted renally and the remainder by enterohepatic elimination. Dose adjustment is necessary in patients with renal insufficiency.

Methotrexate (MTX) inhibits dihydrofolate reductase, thus reducing intracellular tetrahydrofolate levels and interfering with tetrahydrofolate dependent metabolic pathways, which include purine and pyrimidine metabolism. Potential mechanisms whereby MTX exerts an anti-inflammatory effect include increased extracellular adenosine concentrations, reduction of inflammatory cytokines (IL-1B and IL-6), inhibition of cyclooxygenase and lipoxygenase activity, and induction of apoptosis. MTX and its metabolites are excreted by the kidney. Methotrexate should not be used in patients whose estimated glomerular filtration rate is less than 30 mL per minute.

Leflunomide (LEF) selectively inhibits dihydroorotate dehydrogenase, an enzyme critical in the de novo synthesis of pyrimidine ribonucleosides. By reducing the pyrimidine pool and thus inhibiting DNA synthesis, LEF is postulated to modulate pathogenic T-cell proliferation and the subsequent inflammatory cascade. LEF has a very long half-life, is highly protein bound, undergoes enterohepatic recirculation, and is eliminated by the gastrointestinal tract and kidneys. It should not be used in patients with hepatic or severe renal impairment.

Cyclophosphamide (CY) is an alkylating agent that binds to DNA and prevents cell replication. CY is cytotoxic to both resting and dividing lymphocytes. It globally reduces T-cell function, and reduces B-cell numbers and antibody production. CY is metabolized by the liver to several active and inactive compounds that are also excreted in the urine. Dose adjustment is recommended for patients with renal insufficiency (Table 193.2.) Hepatic impairment does not appear to alter CY clearance. Hepatic and renal function should be monitored.

Toxicities

Toxicities common to all immunosuppressive agents include bone marrow suppression, infections, and gastrointestinal irritation. Bone marrow toxicity may occur anytime, as early as 1 or 2 weeks after institution of therapy. Leukopenia, especially granulocytopenia, is common. Anemia and thrombocytopenia may occur in conjunction with leukopenia but rarely alone. Infections secondary to immunosuppression occur with any drug but do not necessarily correlate with the degree of leukopenia, duration of drug therapy, or concomitant corticosteroid therapy. MTX and LEF are rated as pregnancy class X (contraindicated, risk outweighs benefits), and should not be used during pregnancy. AZA, rated as class D (positive evidence of risk), is considered safer than many other immunosuppressive agents during pregnancy based on literature in the transplant population. When the benefit of immunosuppression appears to outweigh the risks (e.g., in renal transplant recipients, active lupus, or inflammatory bowel disease), AZA is preferred over other immunosuppressive medications. We strongly recommend avoidance of CY and MMF (both pregnancy class D) during pregnancy except in life-threatening medical conditions in which no alternative therapy is available.

Specific toxicities of AZA include hypersensitivity hepatitis characterized by elevated transaminases and cholestasis that usually resolve after drug discontinuation, but irreversible damage has been reported. Pancreatitis has also been associated with AZA. Azoospermia, anovulation, and teratogenesis are unusual. TPMT levels do not predict these toxicities, in contrast to the known association of low enzyme level with risk of myelosuppression. It is uncertain whether neoplasia occurs at a greater incidence in rheumatic patients treated with AZA as compared to transplant patients. However, relative risk of lymphoproliferative disorders in RA patients receiving AZA is estimated at 2.2% to 8.7%.

The toxicity profile of MMF is similar to AZA and includes hepatitic abnormalities and myelosuppression. Gastrointestinal intolerance with nausea, vomiting, and diarrhea may improve over time and seldom requires drug discontinuation. A delayed release formulation is available that may improve GI tolerance. There is some evidence that MMF provides protection against fungal infections. As with other immunosuppressive medications, there may be an increased risk of malignancies, including lymphoma.

MTX's minor toxicities include nausea, vomiting, anorexia, diarrhea, and weight loss. Stomatitis occurs with variable severity. Alopecia, photosensitivity to ultraviolet light, urticaria, and cutaneous vasculitis may occur. Major hematological toxicities include megaloblastic anemia and, rarely, pancytopenia. Elevations in hepatitic enzymes also occur and require careful monitoring. Hepatic fibrosis is an infrequent but concerning complication. Acute interstitial pneumonitis is the most

common pulmonary toxicity associated with MTX. Other pulmonary toxicities include interstitial fibrosis, pleuritis, noncardiogenic pulmonary edema, and increased pulmonary nodulosis. Opportunistic infections, including *P. jiroveci* pneumonia, cryptococcosis, and disseminated herpes zoster, have occurred with low-dose weekly MTX therapy for RA. Small series have reported development of lymphoproliferative disorders in MTX-treated patients, and it is well established that RA patients are at greater risk for lymphoma. However, a study reviewing a national data bank for rheumatic disease in over 18,000 patients did not identify a significantly higher risk of lymphoma in patients treated with MTX [111]. Risk factors for MTX toxicity include renal insufficiency, viral infections, folic acid deficiency, and concurrent use of trimethoprim-sulfamethoxazole and probenecid. For a MTX overdose, folinic acid (leucovorin), in a dose equal to the MTX dose, should be given every 4 to 6 hours until the serum MTX level is no longer detectable.

Toxicities associated with LEF include diarrhea, alopecia, rash, hypertension, and peripheral neuropathy. Liver enzymes may be elevated but usually return to normal with dose reduction or drug discontinuation. In patients who experience severe side effects or who wish to become pregnant, elimination of LEF and its metabolites can be accelerated by the administration of cholestyramine, 8 g three times a day for 11 days.

The major side effects of CY are infertility, bladder toxicity, carcinogenicity, and bone marrow suppression. Oral and IV regimens induce gonadal dysfunction in men and women because of injury to germinal epithelium. Azoospermia in males and amenorrhea in premenopausal women is dose related and is usually permanent. The risk may be reduced by the induction of gonadal quiescence during CY treatment. Leuprolide was shown to preserve ovarian function in women treated with CY for LN [112]. Leuprolide was ineffective in men, but a small study has shown a reduced risk of azoospermia in men treated with testosterone [113]. Sperm banking is also recommended for men undergoing CY therapy. Cryopreservation of ova or embryos is usually not practical as it entails hormonal manipulation and significant delay in treatment. Hemorrhagic cystitis due to acrolein, a metabolite of CY, occurs in 20% to 30% of patients receiving oral CY. Bladder carcinoma occurs in 10% of patients who receive long-term CY therapy, even 20 years after exposure. IVCY may have fewer bladder complications than the oral regimen. Adequate hydration for all patients and concomitant use of sodium 2-mercaptoethane sulfonate (MESNA) during IVCY infusion in patients with renal insufficiency reduce the risk of hemorrhagic cystitis. The regimen is outlined in Table 193.2. Skin and hematologic malignancies and premalignant and malignant changes of the cervix are also associated with CY. Hepatotoxicity is rare, but nausea or vomiting with IVCY is common. Other toxicities include infections, cardiomyopathy, and pulmonary fibrosis. *P. jiroveci* pneumonia has also occurred in patients with autoimmune diseases treated with CY and steroids. PCP prophylaxis is recommended for all patients treated with CY.

Biological Modifiers

In addition to the above traditional immunosuppressive agents, this past decade has witnessed the development of multiple biologic modifiers for the treatment of rheumatic diseases including anticytokine therapies, T-cell costimulation blockade, and B-cell depletion (see Table 193.8). Biologic agents are increasingly used to treat rheumatoid arthritis (RA), psoriatic arthritis (PsA), and ankylosing spondylitis (AS). Use of biologic agents in other rheumatologic diseases is still in investigational stages. It is unlikely that the ICU physician will initiate any of these agents for therapeutic indications. However, if a patient is receiving one of these agents chronically, it is important for the

TABLE 193.8

BIOLOGIC AGENTS FOR THE TREATMENT OF RHEUMATIC DISEASES

Drug	Mechanism of action	Half-life	Side effects
Etanercept	Soluble p75 TNF-α receptor fusion protein	72–132 h	Injection site/infusion reaction, Tb reactivation, opportunistic infections, fungal and mycobacterial infections, demyelinating syndromes, drug-induced lupus, pancytopenia, aplastic anemia, hepatotoxicity, CHF, possible increased risk of lymphoma and nonmelanoma skin cancer
Infliximab	Chimeric anti-TNF-α monoclonal antibody	7–12 d	
Adalimumab	Human anti-TNF-α monoclonal antibody	10–20 d	
Golimumab	Human anti-TNF-α monoclonal antibody	14 d	
Certolizumab pegol	Human anti-TNF-α antibody Fab' fragment coupled to polyethylene glycol	14 d	
Abatacept	CTLA4-Ig soluble fusion protein, inhibits T-cell activation by blocking costimulatory signal	8–25 d	Infusion reactions, infections, COPD exacerbation, possible increased risk of lung cancer and lymphoma
Tocilizumab	Humanized IgG1 IL-6 receptor antibody	6–13 d	Infusion reactions, infections similar to TNF-α inhibitors, hypertension, hypercholesterolemia, elevated hepatotoxicity gastrointestinal perforation
Anakinra	Human recombinant IL-1 receptor antagonist	4–6 h	Injection site reactions, serious infections
Rituximab	B-cell depleting chimeric monoclonal CD20 antibody	19 d	Infusion reactions, PML, new or reactivated viral infections, including fulminant hepatitis B

TNF, tumor necrosis factor; Tb, tuberculosis; Fab, fragment antigen binding; CTLA4, cytotoxic T lymphocyte-associated antigen; CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; IL, interleukin; PML, progressive multifocal leukoencephalopathy.

ICU team to understand the mechanism of action and the potential complications or toxicities of these therapies [114].

Five biologic agents that inhibit TNF-α, one IL-6 inhibitor, and one IL-1 receptor antagonist are currently available to treat rheumatoid arthritis (RA). The TNF-α inhibitors are also used to treat psoriatic arthritis (PsA) and ankylosing spondylitis (AS). Because antigen-activated T cells initiate the cell-mediated immune response and the cytokines TNF-α, IL-1, and IL-6 promote the inflammatory processes in inflammatory joint diseases, these anticytokine therapies control signs and symptoms of inflammatory arthritis, and in RA and PsA, have been shown to retard the progression of joint damage.

Four TNF-α inhibitors (etanercept, infliximab, adalimumab, and golimumab) are currently approved in the treatment of moderate-to-severe RA, psoriatic arthritis, and ankylosing spondylitis. Certolizumab pegol, the newest of the TNF-α inhibitors, is currently approved for RA and is being studied for use in other types of inflammatory arthritis. Although TNF-α has many diverse cellular effects in RA and other inflammatory arthropathies, it acts as a potent inflammatory cytokine by binding to one of its receptors, p55 or p75, on chondrocytes, fibroblasts, and osteoclasts in the rheumatoid synovium and stimulates the production of metalloproteinases and other effector molecules that damage the joint. In addition, TNF-α–activated endothelial cells express adhesion molecules, which promote the ingress of PMN cells into the joint. Naturally occurring soluble TNF-α receptors, which theoretically should neutralize TNF-α, exist in high concentrations in rheumatoid synovial fluid but may be inadequate in concentration to neutralize TNF-α in this disease.

Etanercept, a fusion protein comprised of two recombinant p75-soluble TNF-α receptors combined with the Fc portion of human IgG, is administered in subcutaneous injections (25 mg twice a week or 50 mg weekly) alone or in combination with methotrexate. Adalimumab and golimumab are recombinant human IgG_1 monoclonal antibodies against TNF-α. Adalimumab is administered as a 40 mg subcutaneous injection every other week, and golimumab is given in a single monthly 50 mg subcutaneous injection. Infliximab, a chimeric (human and mouse) monoclonal antibody against TNF-α, is administered intravenously at starting doses of 3 mg per kg at weeks 0, 2, and 6, followed by maintenance infusion every 8 weeks. The dose can be titrated to response with maximal dosage of 10 mg per kg. Certolizumab is a human anti-TNF-α antibody Fab' fragment that is chemically linked to polyethylene glycol. Certolizumab is administered by subcutaneous injection at 2- or 4-week intervals. Methotrexate is recommended in combination with infliximab and adalimumab to reduce the frequency of neutralizing human/antichimeric antibodies or human/antihuman antibodies respectively. All five TNF-α inhibitors have been demonstrated in controlled studies to provide clinical benefit and, more importantly, halt the progression of joint damage in RA and PsA.

Short-term toxicities of etanercept, adalimumab, golimumab, and certolizumab include injection site reactions with local urticarial lesions that often resolve with subsequent repeated dosing. Mild hypersensitivity reactions with infliximab infusion occur in 20% of patients, but 2% will experience severe infusion reactions. There is an increased risk of serious infections in patients taking TNF-α inhibitors, including opportunistic, fungal, and mycobacterial infections. All patients should be tested for latent TB prior to initiating therapy with a TNF-α inhibitor and patients with known hepatitis B infection should not receive these drugs.

Demyelinating syndromes have been reported in patients treated with TNF-α inhibitors. Immunogenicity, low-titer anti-dsDNA antibody, and drug-induced lupus syndromes have been documented in patients treated with TNF-α inhibitors. Pancytopenia, aplastic anemia, elevated liver function tests, and exacerbation of preexisting or new onset congestive heart failure have all been reported. Long-term toxicities, including increased risk for malignancy, are an ongoing concern, although the data is inconclusive. Initial surveillance suggested a higher incidence of lymphoma and nonmelanoma skin cancers. Recent meta-analysis of published articles on TNF-α inhibitors suggests a higher rate of malignancy than patients in placebo or methotrexate groups [115]. However, other studies from large patient data bank registries from the United States and Europe have not shown increased malignancy rates associated with TNF-α inhibitors [111].

IL-1, produced by rheumatoid synovial macrophages, acts synergistically with TNF-α on synovial fibroblasts, chondrocytes, endothelial cells, and osteoclasts to promote influx of PMNs into the joint, release of metalloproteinases and collagenases from chondrocytes, and activation of osteoclastic bone resorption. IL-1 binds to two types of cell-surface receptors, but only type I is capable of intracellular activation. Anakinra, a human recombinant IL-1–receptor antagonist, competitively inhibits IL-1 binding to type 1 receptors and is approved for treatment of moderate-to-severe RA. Because of its short half-life, anakinra must be administered daily as a 100 mg subcutaneous injection. Toxicities include injection site reactions and an increase in serious infections. Due to the need for daily injections, modest benefit in RA, and the availability of other biologic agents, anakinra is seldom used for RA, although it remains an effective therapy for some cryopyrin-associated periodic syndromes.

IL-6, a proinflammatory cytokine expressed in RA synovial tissues, promotes the activation of B-cells, T-cells, and macrophages, and upregulation of endothelial adhesion molecule expression. IL-6 also stimulates osteoclast maturation and promotes bone erosion. Tocilizumab, a humanized IgG1 anti-IL-6 receptor antibody, is approved for treatment of RA in patients who fail to respond to DMARDs and TNF-α inhibitors. Tocilizumab is administered as a monthly IV infusion either alone or in combination with weekly methotrexate. The risk of serious infection is similar to the TNF-α inhibitors. TB has been reported, but there is insufficient data to quantify the risk. To date, there is no evidence of an increased incidence of malignancies in RA patients treated with tocilizumab, but long-term data is not available. In clinical trials, tocilizumab has also been associated with hypertension, hypercholesterolemia, elevated liver transaminases, and lower gastrointestinal perforation.

Rituximab (RTX), a chimeric monoclonal antibody to CD20 that results in depletion of mature B cells and disruption of T-cell activation, has been used for treatment of non-Hodgkin lymphoma (NHL). Rituximab is approved for treatment of RA in combination with methotrexate in patients who failed other disease modifying antirheumatic drugs (DMARDs) including anti-TNF-α therapies. Toxicities include infusion reactions with hypotension, fever, and nausea. Serious and potentially fatal viral infections, either new or reactivated, including reactivation of hepatitis B with fulminant hepatitis and hepatic failure, have been reported. There does not appear to be an increased risk of serious bacterial infections in RA patients treated with rituximab, but of the infections reported, respiratory tract infections are the most common. No opportunistic infections or tuberculosis, and no increased risk of malignancy have been reported in the limited follow up of treated RA patients. Data from the NHL database on rituximab has been reassuring in that serious adverse events were infrequent. However, there are case reports of progressive multifocal leukoencephalopathy (PML) in patients with RA and SLE.

Abatacept, a selective modulator of T-cell activation, is approved for the treatment of moderate-to-severe RA in patients who have an inadequate response to methotrexate, other DMARDs, or TNF-α inhibitors. In addition to cognate binding of the T-cell receptor to MHC/antigen on the antigen presenting cell (APC), T-cell activation requires a second costimulatory

TABLE 193.9

MANAGEMENT OF RHEUMATIC DISEASES: AVAILABLE TRIALS AND STRENGTH OF EVIDENCE

	Treatment recommendations	Strength of evidence[a]
Systemic lupus erythematosus (SLE): Lupus nephritis (LN)	Improved long-term preservation of renal function in proliferative glomerulonephritis with CY, AZA, or combination therapy when compared with high doses steroid alone [25]	A
	Combination therapy of IVCY with high-dose methylprednisolone improves renal outcome without significant toxicities [26]	A
	MMF is as effective as IVCY in induction of remission of class III and IV LN without differences in toxicity; MMF more effective than IVCY in patients of Hispanic or African origin [27,28]	A
	Low dose IVCY is equivalent to high dose IVCY efficacy for induction, sustained stabilization, toxicity profile over 10 years in LN (Class III, IV, V) [31]	A
	Short-term induction with IVCY followed by MMF or AZA for maintenance, if better at maintaining remission of lupus glomerulonephritis than long-term IVCY [29]	A
	MMF is equivalent to IVCY in induction of remission of Class V LN [33]	A
SLE: Neuropsychiatric (NSPLE)	IVCY is more effective than pulse methylprednisolone alone for severe NPSLE [39]	A
Antiphospholipid syndrome (APS)	High intensity warfarin therapy is not superior to moderate intensity warfarin therapy in patients with APS [70]	B
	Asymptomatic, persistently APA-positive individuals do not benefit from low-dose aspirin for primary thrombosis prophylaxis [71]	B
Systemic sclerosis (SSc): Raynaud's phenomena (RP)	Intravenous prostanoids are effective in healing digital ulcers in patients with SSc RP [77,117]	A
	Bosentan is effective in preventing new digital ulcers in patients with SSc RP [73,74]	A
	Sildenafil reduces the frequency and severity of attacks and promotes healing of digital ulcers in SSc RP [75,76]	B
SSc: Interstitial lung disease	Both IVCY and oral CY provide modest improvement in SSc lung function, dyspnea, and skin scores compared to placebo [81,82]	A
SSc: Pulmonary hypertension (PAH)	Continuous infusion of epoprostenol for SSc related PAH improves exercise capacity and hemodynamics compared to conventional therapy [90]	B
	Oral bosentan improves exercise capacity, dyspnea index, and functional class when compared with placebo in patients with PAH [84,85]	A
	Sildenafil improves exercise tolerance, functional class, and hemodynamics compared to placebo in patients with PAH [89]	B
	Ambrisentan improves exercise capacity, functional class, and hemodynamics in patients with PAH [86]	B
	Sitaxsentan improves exercise capacity, functional class, and hemodynamics in patients with PAH [87,88]	A

[a] *Strength of Evidence* (based on Ebell MH, Siwek J, Weiss BD, et al: Strength of Recommendation Taxonomy (SORT): A patient-centered approach to grading evidence in the medical literature. *Am Fam Physician* 69:548–556, 2004).
Level A recommendation is based on consistent and good-quality patient-oriented evidence; *Level B* recommendation is based on inconsistent or limited-quality patient oriented evidence.
APA, antiphospholipid antibody; AZA, azathioprine; IVCY, intravenous cyclophosphamide; MMF, mycophenolate mofetil.

signal delivered by binding of the T-cell CD28 receptor to an APC-bound B7 molecule. Abatacept (CTLA4-Ig) is a soluble fusion protein comprised of the extracellular domain of CTLA4 and the Fc portion of IgG1 that interferes with T-cell activation by binding to CD80 (B7-1) or CD86 (B7-2), thereby inhibiting the required costimulatory signal. Toxicities include hypersensitivity infusion reactions, infections, exacerbation of COPD, and potential concerns about malignancies including lymphoma and lung cancer.

An admitted ICU patient who has recently received one of these biologic agents should be approached as an immunocompromised host. Atypical or opportunistic infections are high on the differential if the patient is febrile. In addition, other toxicities of these drugs (although rare), including cytopenias, liver function abnormalities, atypical neurological symptoms, and congestive heart failure, may contribute to the patient's overall medical status. Given the critical nature of the illness that requires ICU care, it is prudent to postpone patients' scheduled doses of these biologic agents until their medical status is more stable. The biologic agents should not be used in patients with active infections. There are no well-controlled studies of the use of these agents in pregnant women. The TNF-α inhibitors and anakinra are rated pregnancy class B (no evidence of risk). Abatacept, rituximab, and tocilizumab are all class C (risk cannot be ruled out). Use of these biologic agents should be avoided during pregnancy unless no alternative therapies are available. Given the limited data on long-term toxicities of biologic therapies, vigilance in surveillance of toxicities is imperative and ongoing.

Advances in management of rheumatologic diseases, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 193.9.

CHAPTER 194 ■ ANAPHYLAXIS

FREDERIC F. LITTLE AND HELEN M. HOLLINGSWORTH

Anaphylaxis is the most severe and potentially fatal form of the immediate hypersensitivity reactions. The term *anaphylaxis* (antiphylaxis) is derived from the Greek and means "against protection" [1]. It describes the shock-like state that is caused by contact with a substance and contrasts with the term *prophylaxis*, which denotes a beneficial or protective state resulting from contact with a substance.

The clinical features of anaphylactic reactions are the physiologic sequelae of release of chemical mediators from tissue-based mast cells and circulating basophils and include a potential for life-threatening vascular collapse and respiratory obstruction [2,3]. A clinically and physiologically indistinguishable hypersensitivity reaction, which is called an anaphylactoid reaction, differs from anaphylactic reactions only because the chemical mediators are released by nonimmunologic mechanisms. Since the clinical features are indistinguishable, both will be referred to collectively as anaphylactic reactions [4].

Estimation of the annual incidence of anaphylactic reactions is hampered by complex coding and incomplete reporting. A recent European study estimated annual incidences of severe and fatal anaphylaxis at 1 to 3 per 10,000 and 1 to 3 per million, respectively [5]. Extrapolations from a comprehensive study of emergency department visits in a geographically defined U.S. population predict about 245,000 outpatient episodes of severe anaphylaxis annually. The additional cases consequent to medicines and radiocontrast media in hospitalized patients would at least equal the emergency room number. An estimated 1,500 people die of anaphylaxis per year, stressing the importance of prevention, as well as prompt diagnosis and treatment [6,7].

PATHOPHYSIOLOGY OF ANAPHYLACTIC REACTIONS

Mechanisms of Release of Chemical Mediators

In humans, anaphylaxis involves a series of steps that result in the release of chemical mediators from tissue-based mast cells and circulating basophils. First, contact with an antigen stimulates the generation of antibodies of the immunoglobulin E (IgE) class. Next, the IgE molecules bind by way of their Fc receptor to a glycoprotein receptor on the cell-surface membrane of tissue mast cells and blood-borne basophils, the so-called target cells. As many as 4,000 to 100,000 IgE molecules normally bind to a single target cell, and up to 100,000 to 500,000 in atopic individuals [8,9]. This binding may remain for weeks to months. When two IgE molecules with the same Fab binding (antigen recognition) specificity are in close proximity on the surface of mast cells and basophils, the cells are termed *sensitized*.

For subsequent antigenic exposure to stimulate the release of mediators from mast cells and basophils, the specific antigen must bind to the Fab portion of two IgE molecules fixed to the surface of the target cell. This bridging of two IgE molecules initiates a series of biochemical modifications called the activation–secretion response (Fig. 194.1). This sequence causes secretion of preformed primary mediators of anaphylaxis from cytoplasmic granules in target cells, including histamine, serotonin, eosinophil chemotactic factor of anaphylaxis (ECF-A), heparin, neutrophil chemotactic factor, and proteolytic enzymes that include tryptase [10].

The activation–secretion response also stimulates synthesis of kallikrein [11,12] and newly generated, secondary lipid mediators, which include platelet-activating factor (PAF) [1]; prostaglandin D_2 (PGD_2), a product of the cyclooxygenase pathway of arachidonic acid metabolism [12]; and leukotrienes C_4, D_4, and E_4 (LTC_4, LTD_4, and LTE_4), products of the lipoxygenase pathway of arachidonic acid metabolism. Several cytokines are also released after activation, including interleukins (IL-1, IL-2, IL-3, IL-4, IL-5, and IL-6), tumor necrosis factor, endothelin-1, and granulocyte-macrophage colony stimulating factor [13].

A variety of substances may induce IgE antibody formation and, on subsequent challenge, provoke anaphylactic reactions [14]. The most common substances are drugs, insect venoms, foods, and allergen extracts used in specific immunotherapy (SIT) [15,16]. These and other less common causes of IgE-mediated anaphylaxis are outlined in Table 194.1.

Non–IgE-mediated anaphylaxis occurs when certain ingested or infused substances cause direct mast cell and basophil activation. Clinically significant examples of non–IgE-mediated anaphylaxis are noted in Table 194.2. The administration of blood, serum, or immunoglobulins to patients who are IgA deficient can result in immune complex formation between donor IgA and recipient IgG anti-IgA antibodies [4,17]. These immune complexes fix complement causing activation of the complement cascade with release of the C3a and C5a complement fragments. C3a and C5a are anaphylatoxins and can directly activate mast cells and basophils.

Physiologic Properties of the Chemical Mediators of Anaphylaxis

The most important chemical mediators of anaphylaxis are histamine, cysteinyl leukotrienes (LTC_4, LTD_4, and LTE_4), PAF, and bradykinin. Physiologically, these substances increase arteriolar vasodilatation, enhance capillary permeability, recruit other inflammatory cells, and precipitate bronchoconstriction (reviewed in [18]). The contribution of multiple mediators other than histamine explains the limited benefit of antihistamines *alone* in treating anaphylaxis.

Histamine (reviewed in [19]) acts to (a) increase capillary permeability by stimulating terminal arteriolar dilatation and contraction of endothelial cells in postcapillary venules, which opens intercellular gaps, and, as a result, causes the development of urticaria and angioedema; (b) increase secretion from nasal and bronchial mucous glands; (c) stimulate

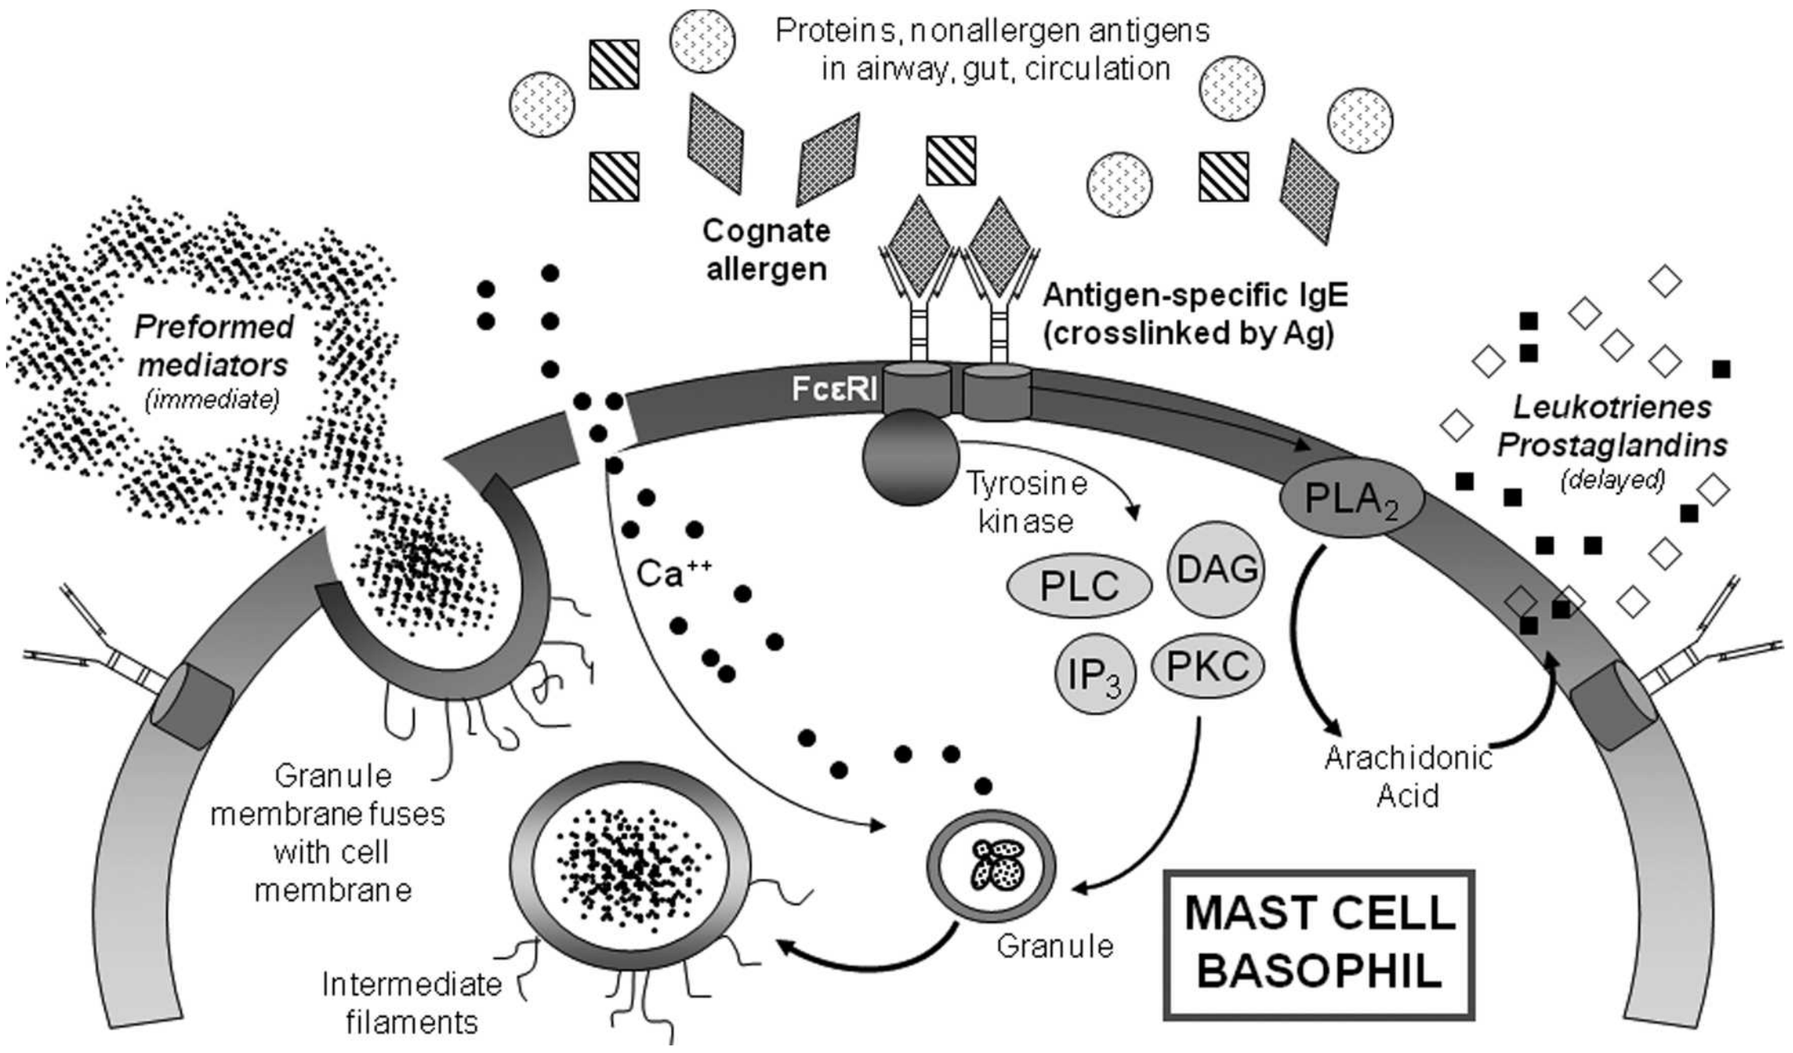

FIGURE 194.1. Chemical mediator release. When two IgE molecules are bridged by an antigen that is specifically recognized by those IgE molecules, a cascade of transmembrane and intracellular events is triggered. The end result is the extrusion of granule contents (mediators) into the extracellular space and elaboration of other, newly formed mediators. Tyrosine kinase appears to be an important intramembrane messenger that initiates the intracellular cascades. At least one cascade involves PLC, which mediates calcium influx into the cell and catalyzes hydrolysis of phosphatidylinositol into the secondary messengers 1,4,5-IP_3 and 1,2-DAG. IP_3 plays a role in calcium mobilization; DAG mediates production of arachidonic acid metabolites and activates PKC. PKC, in turn, participates in the fusion of granules within the cell membrane. PLA_2 mediates the conversion of membrane phospholipid into arachidonic acid, resulting in elaboration of prostaglandins and leukotrienes. Ag, antigen; DAG, diacylglycerol; IgE, immunoglobulin E; IP_3, inositol triphosphate; PKC, protein kinase C; PLA_2, phospholipase A_2; PLC, phospholipase C.

TABLE 194.1

CAUSES OF IMMUNOGLOBULIN E–MEDIATED ANAPHYLAXIS[a]

Type	Agent	Example
Proteins	Allergen extracts	Pollen, dust mite, mold
	Vaccines	Influenza
	Venoms	Hymenoptera
	Heterologous serum	Tetanus antitoxin [16], antithymocyte globulin, snake antivenom
	Others	Heparin, latex [113], thiobarbiturates, seminal fluid
Hormones		Insulin [140], ACTH, TSH [16] progesterone, salmon calcitonin
Haptens	Antibiotics	Beta-lactams [73], ethambutol, nitrofurantoin, sulfonamides [74], streptomycin, vancomycin [143]
Disinfectants		Ethylene oxide
Local anesthetics[b] [144]		Benzocaine, tetracaine, Xylocaine, mepivacaine
Others		Aminopyrine, sulfobromophthalein

[a]Numbers in brackets are reference citations.
[b]Precise mechanism not established.
ACTH, adrenocorticotropic hormone; TSH, thyroid-stimulating hormone.

TABLE 194.2

CAUSES OF NON–IMMUNOGLOBULIN E-MEDIATED ANAPHYLAXIS[a]

Complement activation
Blood product transfusion in IgA-deficient patient [17]
Hemodialysis with cuprophane membrane [145]
Direct release of chemical mediators of anaphylaxis
Protamine [146][b]
Radiographic contrast media [147]
Dextran [148][b]
Hydroxyethyl starch [149]
Muscle relaxants [150]
Ketamine [151]
Local anesthetics [144][b]
Codeine and other opiate narcotics [150,152]
Highly charged antibiotics, including amphotericin B [143]
Generation of leukotrienes
Nonsteroidal anti-inflammatory drugs [132]
Indomethacin [133]
Acetylsalicylic acid (aspirin) [153]
Sulindac [134]
Zomepirac sodium [135]
Tolmetin sodium [136]
Other
Antineoplastic agents (e.g., platinum-based [154,155])
Sulfiting agents
Exercise [120]
Idiopathic recurrent anaphylaxis [124,126]

[a]Numbers in brackets are reference citations.
[b]Precise mechanism not established.

contraction of smooth muscle; (d) enhance prostaglandin synthesis; (e) chemotactically modulate eosinophil migration; and (f) regulate parasympathetic afferent nerve stimulation (a process blocked by atropine), which increases airway resistance and decreases lung compliance. Studies of histamine infusion in normal human volunteers suggest that vasodilatation is mediated by both H_1 and H_2 receptors, whereas bronchoconstriction and tachycardia are mediated by H_1 receptors alone [20].

In anaphylaxis, LTC_4, LTD_4, and LTE_4 (a) induce a prolonged constrictive effect, on bronchial smooth muscle, which affects the peripheral more than the central airways, (b) increase vascular permeability, and (c) act as chemotactic agents for other inflammatory cells [21,22]. In fact, leukotrienes are far more potent bronchoconstrictors than histamine.

Two additional modulators of anaphylaxis are bradykinin, which appears to be activated by mast cell kallikrein and PAF. Bradykinin stimulates a slow, sustained contraction of bronchial and vascular smooth muscles while increasing vascular permeability and secretion from mucous glands [15]. PAF contributes to the pulmonary and cardiovascular manifestations of anaphylaxis by inducing platelet aggregation with release of serotonin, adenosine triphosphate, and lysosomal enzymes from preformed granules [23,24]. In addition, PAF is a potent chemotactic factor for eosinophils and can directly increase vascular permeability [25].

Thus, the physiologic consequences of chemical–mediator release in anaphylaxis are (a) an increased vascular permeability; (b) an increased secretion from nasal and bronchiolar mucous glands; (c) smooth muscle contraction in the blood vessels, the bronchioles, the gastrointestinal tract, and the uterus; (d) migration–attraction of eosinophils and neutrophils; (e) bradykinin generation stimulated by kallikrein substances; and (f) induction of platelet aggregation and degranulation. These events coordinate to increase the vascular permeability that in turn permits the access of a variety of plasma proteins (antibodies, complement, kinins, and coagulation proteins) to tissue sites, which further contributes to the observed inflammation. Substances such as PAF and Hageman factor potentially contribute to local coagulation abnormalities, which may also be seen in anaphylactic reactions [20].

CLINICAL AND LABORATORY FEATURES

Mast cells are concentrated in the skin, in the mucous membranes of the respiratory and gastrointestinal tracts, and in the perivenular tissue, while basophils are located in the bloodstream, all of which are potential sites of exposure to offending antigens (e.g., food, drugs, insect venom, and diagnostic agents) [26]. These sites are also most commonly involved in the manifestations of anaphylaxis. Urticaria, angioedema, respiratory obstruction, and vascular collapse are the most important clinical features of anaphylaxis, and these signs and symptoms are due to the direct effects of mast cell and basophil-derived mediators on affected organ systems. Other clinical manifestations may include (a) a sense of fright or impending doom, (b) weakness or dizziness, (c) sweating, (d) sneezing, (e) rhinorrhea, (f) conjunctivitis, (g) generalized pruritus and swelling, (h) cough, (i) wheezing, stridor, or breathlessness, (j) choking, (k) dysphagia, (l) vomiting or diarrhea, (m) abdominal pain, (n) incontinence, (o) uterine cramps, and (p) loss of consciousness.

Profound hypotension and shock may develop as a result of significant arteriolar vasodilatation, increased vascular permeability, cardiac arrhythmias [27,28], or irreversible cardiac failure [29], even in the absence of respiratory or other symptoms [3,30]. Furthermore, transient or sustained hypotension may result in local tissue ischemia, stroke, myocardial infarction, or death [30,31]. Intravascular coagulation, evidenced by a fall in the levels of factors V, VIII, fibrinogen, kininogen, and complement components, has also been described [32].

Anaphylaxis-induced fatalities most often result from involvement of the respiratory tract [31,33,34]. Structures throughout the respiratory tract may be affected, but respiratory failure is generally the result of upper respiratory tract obstruction due to laryngeal edema or obstruction of small airways due to bronchoconstriction, mucosal edema, and hypersecretion of mucus [35,36]. Intra-alveolar hemorrhage and acute respiratory distress syndrome have been reported [36,37].

The physical examination of a patient with anaphylactic shock often reveals a rapid, weak, irregular, or unobtainable pulse; tachypnea, respiratory distress, cyanosis, hoarseness, stridor, or dysphagia secondary to laryngeal edema; diminished breath sounds, crackles, cough, wheezes, and hyperinflated lungs due to severe bronchoconstriction; urticaria; angioedema or conjunctival edema (Table 194.3) [38]. Any patient may manifest only a subset of these findings, sometimes only cardiovascular collapse or only stridor and breathlessness.

Laboratory findings in anaphylaxis are varied. Biochemical abnormalities in anaphylaxis include elevation of serum histamine and tryptase levels, depression of serum complement components, and decreased levels of high-molecular-weight kininogen. Although these biochemical abnormalities codify our understanding of the pathophysiology of anaphylaxis, they are rarely evaluated in the management of clinically established anaphylaxis. As discussed in the next section, serum tryptase may be helpful retrospectively when the diagnosis is uncertain [39].

Although there have been no systematic reviews of electrocardiographic findings, reports describe disturbances in rate,

TABLE 194.3

CLINICAL MANIFESTATIONS OF ANAPHYLACTIC REACTIONS

System	Reaction	Symptoms	Signs
Respiratory tract	Rhinitis	Nasal congestion and itching	Mucosal edema
	Laryngeal edema	Dyspnea	Laryngeal stridor, edema of vocal cords
	Bronchoconstriction	Cough, wheezing, and sensation of chest tightness	Crackles, respiratory distress, tachypnea, and wheezes
Cardiovascular	Hypotension	Syncope, feeling of faintness	Hypotension, tachycardia
	Arrhythmias	Palpitations	ECG changes: nonspecific ST segment and T-wave changes, nodal rhythm, and atrial fibrillation
Skin	Urticaria	Pruritus, hives	Urticarial lesions
	Angioedema	Nonpruritic swelling of extremity or perioral, or periorbital region	Nonpruritic, frequently asymmetric swelling of extremity, perioral, or periorbital region
Gastrointestinal tract	Smooth muscle contraction, Mucosal edema	Nausea, vomiting, abdominal pain, and diarrhea	Abdominal tenderness, distention
Eye	Conjunctivitis	Ocular itching, lacrimation	Conjunctival inflammation

ECG, electrocardiogram.
Summarized from references [38] and [1].

rhythm, repolarization, and ectopy [40–42], as well as myocardial infarction [28,43]. Chest radiography may reveal hyperinflation caused by severe bronchoconstriction.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF ANAPHYLAXIS

Development of the characteristic clinical features of anaphylaxis shortly after exposure to an antigen or other inciting agent usually establishes the diagnosis of an anaphylactic reaction [2]. The setting is often suggestive as well: a patient who has just received an antibiotic injection or radiographic contrast media infusion or one who presents to the emergency room after a yellow jacket sting.

The clinical disorders that may be confused with anaphylaxis are sudden, acute bronchoconstriction in an asthmatic, vasovagal syncope, tension pneumothorax, mechanical airway obstruction, pulmonary edema, cardiac arrhythmias, myocardial infarction with cardiogenic shock, aspiration of a food bolus, pulmonary embolism, seizures, acute drug toxicity, hereditary angioedema, cold or idiopathic urticaria, septic shock, and toxic shock syndrome [15].

Initial laboratory testing often is not helpful. However, serum obtained during the acute episode can be assayed subsequently for tryptase and histamine. Total serum tryptase levels include both α- and β-tryptase. The former is increased in systemic mastocytosis and the latter can be elevated for up to 6 hours after suspected anaphylaxis onset [44]. However, the sensitivity of serum β-tryptase is suboptimal as levels can be normal after documented anaphylaxis, especially if caused by foods [45]. There may be a role for serial measurements in documenting the course of systemic mast cell and basophil degranulation [38]. Serum histamine is rarely assessed clinically because it must be obtained within the first hour after a reaction and requires special handling.

Retrospectively, measurement of antigen (allergen)-specific IgE antibodies by an ImmunoCAP (or similar assay, which have replaced radioallergosorbent tests [RAST]) may be helpful. Specific skin tests may also define allergic sensitivity. Skin testing must be done in a carefully controlled setting due to the risk of provoking another severe reaction. Cutaneous assessment for the presence of antigen-specific IgE may be negative for several days after a reaction, because mast cell and basophil degranulation at the time of the initial reaction may lead to a refractory period. This can be avoided by delaying testing for 4 to 6 weeks [46].

CLINICAL COURSE OF ANAPHYLACTIC REACTIONS

Clinical criteria that make the diagnosis of anaphylaxis "highly likely" have been codified [2]. The characteristic features of anaphylactic reactions are (a) the rapid onset of clinical manifestations that follow contact with or the administration of antigen and (b) the rapid progression of symptoms to a severe and potentially fatal outcome. Recognition of the early signs and symptoms of anaphylaxis and prompt treatment are imperative in preventing progression to irreversible shock and death [38].

The constellation of clinical symptoms as well as their severity and duration is variable but will depend to some extent on the mode of antigen exposure. Anaphylaxis may occur within seconds following parenteral introduction of antigen [32] and usually occurs within 30 minutes. In contrast, anaphylaxis that follows oral administration of an antigen may develop within minutes to several hours [47]. Generally, the more rapid the onset of symptoms, the more severe will be the reaction [1]. Mild systemic reactions often last for several hours, rarely more than 24 hours. Severe manifestations, such as laryngeal edema, bronchoconstriction, and hypotension, if not fatal, may persist or recur for several days. However, even severe manifestations may resolve within minutes of treatment. About 5% to 20% of patients will experience biphasic or protracted anaphylaxis, with signs and symptoms recurring up to 24 hours or persisting beyond 24 hours after initial presentation [38]. This highlights the need for close observation after initial response to treatment.

TREATMENT OF ANAPHYLAXIS

The key to successful treatment of anaphylaxis is prompt intervention to support cardiopulmonary function and prevent further exposure to the inciting stimulus when possible. The prompt administration of epinephrine is critical, and should be supplemented with aggressive use of vasopressors, fluid replacement, and medications as indicated to counteract the effects of released chemical mediators [38]. Injectable epinephrine, tourniquets, intravenous infusion materials and fluids, antihistamines, intubation equipment, a tracheostomy set, and individuals trained to use these materials should be available. Since symptoms of a systemic anaphylactic reaction may be followed by potentially fatal manifestations, patients must be serially examined and continuously monitored [38]. Many therapeutic and diagnostic agents frequently employed in intensive care settings (e.g., antibiotics, radiographic contrast) may induce anaphylactic reactions. Thus, the anticipation and the preparedness to deal with these potential reactions are very important.

Emergency Measures

The evaluation of individuals who are suspected of having anaphylaxis must be performed rapidly. The cause and mechanism of antigen exposure should be ascertained to assess how long the inciting antigen has been present and, when possible, to limit further absorption. A history of previous allergic reactions and former treatment may help to guide immediate therapy, obviating the need to try previously failed regimens in a life-threatening situation [48].

Supportive Cardiopulmonary Measures

Particular attention to the respiratory and cardiovascular systems is paramount and must include assessment for laryngeal edema and bronchoconstriction, as well as monitoring oxygenation, blood pressure, and cardiac rhythm [48].

Ensuring adequate ventilation and oxygenation is essential. Supplemental oxygen should be administered and pulse oximetry monitored. Intubation and assisted ventilation may be necessary in cases of severe bronchoconstriction, and ventilator management strategies such as those used for treatment of status asthmaticus may be necessary. These techniques are discussed in Chapters 48 and 58.

Although intubation is usually feasible, edema of the tongue, larynx, or vocal cords may obstruct the upper airway and preclude oropharyngeal or nasopharyngeal intubation. To ensure a patent airway in such instances, cricothyroidotomy or tracheotomy may be necessary (see Chapter 12) [49]. Cricothyroidotomy is preferred to tracheotomy when performed in an emergent situation, as the former is easier to perform and is usually safer [49]. Contraindications to cricothyroidotomy include a suspected neck fracture or a serious injury to the larynx or cricoid cartilage.

Close electrocardiographic monitoring is indicated because the sequelae of anaphylaxis and its therapy are both potentially arrhythmogenic [41]. Hypotension, acidosis, hypoxia, vasopressors, and bronchodilators are well-described predisposing factors for cardiac arrhythmias (see Chapter 42). Adequate intravenous access should be established as soon as possible, initially with two 18-gauge or larger peripheral catheters.

Pharmacologic Therapy

The mainstay of therapy is parenteral epinephrine (adrenaline), which acts on bronchial and cardiac β-receptors, causing bronchial dilatation and both chronotropic and inotropic cardiac stimulation. An equally important effect of epinephrine is stimulation of α-adrenergic receptors on blood vessels, which causes vasoconstriction. This is important in reversing anaphylaxis-induced hypotension and in delaying antigen absorption when infiltrated locally into an injection or sting site [48]. In addition, epinephrine increases the intracellular levels of cyclic adenosine monophosphate (AMP) and thereby inhibits the activation of tissue-based mast cells and circulating basophils [20,50,51]. Inhaled β_2-adrenergic agents, such as albuterol sulfate or salbutamol, complement the actions of epinephrine by reversing bronchoconstriction and reducing bronchial mucus secretion [52].

Antihistamines, particularly the H_1-receptor blocker diphenhydramine, are useful for treating cutaneous manifestations of anaphylaxis, but are slower in onset than epinephrine and not helpful for hemodynamic compromise. Thus, they are considered adjunctive therapy to epinephrine. Given their beneficial safety profile, they may be administered empirically unless there is a specific contraindication (e.g., known prior hypersensitivity). Glucocorticoids, although not immediately active in anaphylactic shock, are effective pharmacologic agents that are capable of increasing tissue response to β-adrenergic agonists as well as inhibiting basophil activation and phospholipase-mediated generation of LTC_4, LTD_4, and LTE_4 [53,54].

The guidelines for pharmacologic therapy of anaphylaxis are listed in Table 194.4.

Specific Therapy

Epinephrine. Epinephrine should be administered first to treat all initial manifestations of anaphylaxis [38,55]. When administered alone, it may reverse rhinitis, urticaria, bronchoconstriction, and hypotension. The failure to administer epinephrine or a delay in its administration may be fatal. There is compelling evidence, both from animal and human studies, that epinephrine is more rapidly absorbed when given intramuscularly (IM) rather than subcutaneously (SC) [56,57]. The IM route is definitely preferred for patients who are hypotensive (see below) or when adequate SC absorption is in doubt [58]. The dose is 0.2 to 0.5 mL of a 1:1,000 dilution (0.2 to 0.5 mg) and should be repeated in 5 to 15 minutes if improvement is equivocal, usually not more than three times [38,48]. Absorption of parenterally introduced antigens (e.g., stinging insect venom, vaccines) may be retarded by infiltrating the site with approximately half the dose of epinephrine. Tourniquet application proximal to the site of antigen exposure that is sufficient to occlude venous and lymphatic returns without interfering with arterial blood flow may also retard absorption of the antigen [1]. The tourniquet should be loosened for approximately 15 to 30 seconds every 10 to 15 minutes.

If shock develops, IM or SC epinephrine is unlikely to be absorbed. In this setting, epinephrine should be given intravenously: 1 mg (1 mL of a 1:1,000 solution or 10 mL of a 1:10,000 solution) diluted in 500 mL of D_5W and infused at a rate of 0.5 to 2.0 mL per minute (1 to 4 μg per minute) with continuous electrocardiographic monitoring. If intravenous access is not easily obtained, epinephrine should be given by endotracheal tube (10 mL of a 1:10,000 solution). If hypotension persists, continuous infusion of a pressor, such as norepinephrine, dopamine, or phenylephrine, is typically initiated (see Chapters 32, 148, and 157).

Volume resuscitation is also important, as described below. If no response to pressors and initial volume resuscitation occurs, the central venous pressure (CVP) may provide guidance regarding further fluid resuscitation. A CVP between 0 and 12 cm H_2O suggests that more intravenous fluids should be given, whereas a CVP more than 12 cm H_2O suggests that the hypotension may be based on myocardial failure. For

refractory hypotension, pulmonary artery catheterization (see Chapter 4) can help guide further fluid, inotropic, and vasopressor therapy, as outlined in Chapters 32,148, and 157.

Preexisting β-adrenergic blockade with noncardioselective or cardioselective agents is another potential cause of refractory anaphylactic shock [14,59]. In the presence of beta-blockade, anaphylaxis is characterized by bradycardia with or without atrioventricular nodal delay (in contrast to the usual tachycardia), profound and refractory hypotension, urticaria, and angioedema [59]. Whether beta-blockade truly increases the chance of developing anaphylaxis or just the severity is not known. Beta-blockade appears to increase anaphylactic mediator synthesis and release, as well as altering end-organ responsiveness. Although α-adrenergic agents may increase in vitro release of mast cell mediators in the presence of beta-blockade [60], the drug of first choice for treating anaphylaxis in the presence of beta-blockade remains epinephrine [59]. Dopamine, which has combined α, β, and dopaminergic activities, may be useful for shock refractory to epinephrine. The dose of β agonists will likely have to be more than usual to overcome the beta-blockade. Several case reports note the success with glucagon, often used in the treatment of beta-blocker overdose, in treating refractory shock. Glucagon appears to increase cardiac cyclic AMP independent of β-receptors and to increase heart rate despite beta-blockade [59,61].

Bronchodilators. Bronchoconstriction is treated with a nebulized short-acting β-agonist (typically albuterol 0.5 mL of 0.5% solution diluted in 3 mL of normal saline), often in addition to parenteral epinephrine, as described above. Nebulizer treatments should be repeated every 15 to 20 minutes until bronchoconstriction abates. In addition, a methylxanthine may be given: 250 to 500 mg of aminophylline may be infused over 20 minutes (see Chapter 48), although scientific data supporting this are limited. Methylxanthines are not recommended in hypotensive patients, as they may worsen hypotension and cause unpredictable cardiovascular toxicity [1]. Their exact mechanism of action is not well defined and they are not first-line agents in the treatment of bronchoconstriction.

Volume Resuscitation. Given the distributive nature of shock in anaphylaxis, aggressive volume resuscitation should accompany epinephrine (and other vasoactive medications) if hypotension develops. Prompt initiation of intravenous fluids is more important than whether the fluid is colloid or crystalloid. As noted earlier, refractory hypotension may warrant invasive hemodynamic monitoring to guide therapy.

Antihistamines. Parenteral administration of histamine receptor antagonists is preferred over oral administration. The H_1-receptor-blocker diphenhydramine (1 to 2 mg per kg up to 50 mg for an adult) can be given intravenously as a bolus [1]. The H_2-receptor-blockers cimetidine (300 mg for adult) or ranitidine (150 mg for adult) can be infused over 3 to 5 minutes [62]. Antihistamines are more effective in prevention than in treatment of full-blown anaphylaxis and should never be used as the primary therapy for anaphylactic shock. H_2-receptor-blocking antihistamines prevent the fall in diastolic blood pressure induced by experimental histamine infusion [54], and the H_2-blocker cimetidine has been reported to reverse refractory systemic anaphylaxis [62]. However, the evidence that H_2-receptor-blocking antihistamines are effective in the treatment of anaphylaxis is anecdotal.

Glucocorticoids. Although glucocorticoids are not of immediate clinical benefit, they help to reduce bronchoconstriction and laryngeal edema and provide blood pressure support when used in high doses and for prolonged attacks (see Table 194.4 for recommended doses). The generally recommended initial dose of aqueous hydrocortisone is 5 mg per kg to a maximum of 200 mg given intravenously, followed by 2.5 mg per kg to 200 mg given intravenously every 4 to 6 hours [1,4], for 24 to 48 hours.

Despite the theoretical basis for glucocorticoids preventing late recurrences of anaphylaxis, biphasic anaphylaxis has been reported to occur in 20% of anaphylactic reactions in spite of glucocorticoid therapy [63,64]. In this report, after an initial response to therapy, life-threatening symptoms recurred up to 8 hours later. Whether glucocorticoid therapy helped prevent recurrences after 8 hours, is not known. Because of the possibility of a late recurrence, patients should be monitored in the intensive care setting for 8 to 12 hours after resolution of symptoms. Roughly 30% of anaphylaxis cases may have protracted symptoms for 5 to 32 hours despite vigorous therapy including glucocorticoids [64]. One characteristic of patients with biphasic or protracted anaphylaxis is oral ingestion of the offending antigen. On this basis, it would be reasonable to include enteral activated charcoal and sorbitol in the therapy of such patients to reduce the absorption and duration of exposure to the antigen (see Chapter 117 on drug overdose).

TABLE 194.4

TREATMENT OF ANAPHYLAXIS IN ADULTS [2,38,156]

- Mandatory and immediate
  - General measures
    - Aqueous epinephrine (1:1,000), 0.2 to 0.5 mL IM; up to 3 doses at 1- to 5-min intervals
    - Tourniquet proximal to antigen injection or sting site
    - Aqueous epinephrine (1:1,000), 0.1 to 0.3 mL infiltrated into antigen injection or sting site (unless anatomic region with terminal circulation, e.g., fingertip)
  - For laryngeal obstruction or respiratory arrest
    - Establish airway: endotracheal intubation, cricothyroidotomy or tracheotomy
    - Supplemental oxygen
    - Mechanical ventilation
- After clinical appraisal
  - General measures
    - Diphenhydramine, 1.25 mg/kg to maximum of 50 mg, IV or IM
    - Aqueous hydrocortisone, 200 mg, or methylprednisolone, 50 mg, IV every 6 h for 24–48 h
    - Ranitidine, 150 mg, IV over 3–5 min
  - For hypotension
    - Aqueous epinephrine (1:1,000), 1 mL in 500 mL of saline at 0.5–2.0 mL/min, or 1–4 μg/min, preferably by a central venous line
    - Normal saline, lactated Ringer's, or colloid volume expansion
    - Glucagon, if patient is receiving beta-blocker therapy and hypotension is refractory, 1 mg/mL IV bolus or infusion of 1 mg/L of D_5W at a rate of 5–15 mL/min
  - For bronchoconstriction
    - Supplemental oxygen
    - Albuterol (0.5%), 0.5 mL in 2.5 mL of saline, by nebulizer
    - Aminophylline, only if patient *not* in shock and unresponsive to albuterol and epinephrine, 5 mg/kg to maximum or 500 mg IV over 20 min, then 0.3–0.8 mg/kg/h IV

D_5W, dextrose in 5% water; IM, intramuscular; IV, intravenous.

PREVENTION OF ANAPHYLACTIC REACTIONS

In view of the potential morbidity and mortality from anaphylactic reactions, prevention is of primary importance. Prevention includes obtaining a careful history to identify possible precipitants of anaphylaxis. Both physicians and patients should be aware of potential cross-reacting agents. For example, individuals with anaphylaxis secondary to aspirin are frequently sensitive to nonsteroidal anti-inflammatory drugs, such as ibuprofen, naproxen, ketorolac, and sulindac. Other preservatives, such as metabisulfite, ethylenediamine, and methylparaben, have been associated with anaphylactic reactions. It is therefore helpful to review the inactive ingredients contained in medications temporally associated with anaphylaxis [65].

Prevention of reactions to specific agents (e.g., antibiotics) is discussed below. In general, patients with a history of anaphylaxis should wear a Medic-Alert bracelet or necklace, which detail offending precipitants and potential cross-reacting agents. In addition, patients should be provided with and instructed in the use of anaphylaxis kits (e.g., EpiPen, Dey, Napa, CA) for prompt treatment in future reactions. Finally, consultation with an allergist can clarify the offending trigger (if unknown) and guide appropriate further evaluation and treatment plans. These three actions are the most relevant elements of post-anaphylaxis care from the intensive care perspective.

MANAGEMENT OF ANAPHYLAXIS TO SPECIFIC AGENTS AND PRECIPITANTS

Beta-Lactam Antibiotic Anaphylaxis

One of the most common causes of anaphylaxis in the United States is penicillin. Systemic reactions complicate approximately 1% to 2% of penicillin courses. Approximately 10% of the population will have positive skin tests to penicillin. Thus, a substantial portion of the population is at risk for developing anaphylactic reactions to the drug. About 10% of these reactions are life-threatening and 2% to 10% are fatal [16]. Seventy-five percent of the patients who die of penicillin anaphylaxis have experienced previous allergic reactions to the drug. As with other medications, the risk of a severe reaction is greater with parenteral administration than with oral administration [16]. On the other hand, about 80% of individuals who report penicillin allergy are found to be nonallergic on subsequent evaluation [66].

Skin testing for penicillin hypersensitivity with the major determinant benzylpenicilloyl-poly-l-lysine (BPO, PRE-PEN®, and ALK-Abello) and minor determinants benzylpenicillin (Pen-G), benzylpenicilloate, and benzylpenilloate is effective at detecting IgE-mediated sensitivity and thereby identifying individuals at risk for developing acute allergic reactions to penicillin [16]. The negative predictive value of skin testing when both major and minor determinants of penicillin are used is excellent for immediate hypersensitivity reactions to penicillin [66,67]. This testing does not evaluate other types of sensitivity, such as serum sickness reactions, morbilliform rashes, hemolytic anemia, and interstitial nephritis. In addition, it does not evaluate patients who may have specific allergy to a beta-lactam side chain of a penicillin derivative, for example, cephalosporins or carbapenems [68]. Cross-reactivity between beta-lactams and monobactams, for example, aztreonam, is rare. For critically ill patients, who need a beta-lactam drug and who have a history of beta-lactam antibiotic allergy, the best strategy is to use an alternate, non cross-reacting antibiotic or to proceed with a rapid desensitization protocol [69] (Table 194.5). A retrospective review of antibiotic desensitization for IgE-mediated allergy found that it was successful in 75% of patients [70].

TABLE 194.5

DESENSITIZATION SCHEDULE FOR BETA-LACTAM ANTIBIOTICS

Dose no.	Concentration of stock solution (mg/mL)[a]	Concentration of infused solution (mg/mL)[b]
1	0.0005	0.00001
2	0.005	0.0001
3	0.05	0.001
4	0.5	0.01
5	5	0.1
6	50	1
7	500	10

[a] Stock solution is prepared by solubilizing the antibiotic with nonbacteriostatic saline to a final concentration of 500 mg/mL. Dilutions of 1 mL of each preceding antibiotic dilution to 9 mL of diluent.
[b] One milliliter of stock solution is further diluted into 50 mL of saline and infused during 20 minutes.
From Borish L, Tamir R, Rosenwasser LJ: Intravenous desensitization to beta-lactam antibiotics. *J Allergy Clin Immunol* 80:314–319, 1987, with permission.

The incidence of anaphylactic reactions to cephalosporins is infrequent, but increasing [16,71]. Patients with a history of penicillin allergy have been reported to have allergic reactions to cephalosporins at a rate of 5.4% to 16.5%, compared with patients with a negative history, whose reaction rate was 1% to 2% [72,73]. The rate of cross-reactivity is lower with second- and third-generation than with first-generation cephalosporins. However, not all of these reactions reflect true cross-reactivity, as only 15% to 40% of patients with a positive history react to penicillin on subsequent testing [72,74]. In a study of 30 patients with immediate-type hypersensitivity reactions to second- and third-generation cephalosporins, 25 of 36 reactions were anaphylactic shock [75]. Only 13% of individuals had either a positive skin test or *in vitro* evidence of antigen-specific IgE to penicillin determinants, while all but three reactions were correlated with a positive skin test to culprit cephalosporins. Unfortunately, skin testing with cephalosporin derivatives is not reliable; severe allergic reactions have occurred in patients with negative cephalosporin skin tests and cephalosporin antigenic determinants for skin testing have not been standardized. On the other hand, patients with negative penicillin skin tests have no greater risk of allergic reaction to cephalosporins than the general population [73]. Several protocols for desensitization to cephalosporins have been outlined in a review [76]. Cross-reactivity between cephalosporins appears related to the degree of similarity of the R1 side chains, and 90% of patients allergic to second- and third-generation cephalosporins do not react to penicillin derivatives [71].

As noted earlier, monobactams (e.g., aztreonam) do not show cross-reactivity with penicillin, but do show some cross-reactivity with the cephalosporins (i.e., ceftazidime) [71]. Carbapenems (e.g., imipenem, meropenem), in comparison, have historically shown significant *in vivo* cross-reactivity with penicillin, and desensitization in penicillin-allergic patients was recommended when there was no reasonable alternative [77]. More recent reports in PCN skin test–positive patients have suggested that carbapenems can be given safely to young

[78,79] and adult [80] patients, who have negative skin tests to the proposed carbapenem. In urgent settings and/or where skin testing and graded challenge are not feasible, a desensitization protocol should be employed with the same precautions as if giving the patient penicillin [73].

Food Anaphylaxis

Food allergy occurs in approximately 6% of children and 3.7% of adults [47]; however, fatal anaphylactic reactions are much less common. Due to variable patterns of absorption, biphasic and/or prolonged anaphylaxis occurs in about 20% of cases. However, the delayed phase is rarely associated with a mild acute phase, where hypotension and bronchoconstriction are readily apparent [81]. A review of fatal and severe nonfatal anaphylactic reactions to foods revealed several important features of the fatal anaphylactic reactions: all occurred in patients with asthma, all were in a public setting rather than in the home, and all were associated with delayed administration of epinephrine [82]. The foods that caused these severe reactions were peanuts, cashews, milk, filberts, walnuts, and eggs. In another review of the causes of anaphylaxis, the five most common foods were pine nuts, peanuts, soy, shellfish, and other nuts [83]. A survey of food-related anaphylactic fatalities reported to an association registry confirmed the association between asthma and severe anaphylaxis; 90% of fatalities in this group were due to peanuts and tree nuts [34]. A methodical approach to the diagnosis and treatment of food hypersensitivity has been outlined by Sicherer and Sampson [47].

Processed foods may contain significant amounts of milk products, despite a lack of mention of this on the label ingredient lists [84]. This is important to remember in patients with milk allergy who appear to experience a cryptogenic anaphylactic episode. Standards for food labeling instituted in 2006 by the U.S. Food and Drug Administration have assisted patients with food allergy and their providers by requiring identification of possible trace allergen contaminants in processed foods. Other food additives, such as preservatives, have been implicated as causes of anaphylaxis [85].

Anesthetic Anaphylaxis

Immediate hypersensitivity reactions to local anesthetics are rare, despite them being one of the most commonly used groups of drugs in medicine [86,87]. Cell-mediated reactions that manifest as contact dermatitis are more common. Local anesthetics are divided into two classes: group I (para-aminobenzoic acid ester) consists of benzocaine, tetracaine, and procaine; group II (non–ester-containing) consists of Xylocaine, mepivacaine, dibucaine, and cyclomethycaine. Cross-reactivity between the two groups is very rare and cross-reactivity between the amides is also rare [88,89]. Skin testing, using a progressive challenge protocol, can help determine whether sensitivity exists and which drugs are likely to be safe in the future [87,89].

General anesthetics, such as neuromuscular blocking agents and thiobarbiturates, also cause anaphylaxis [90]. A skin test protocol has been described for evaluating patients with possible allergy to general anesthetics [91]. Other etiologies of perioperative anaphylaxis include allergy to antibiotics, latex, glutaraldehyde, and opioids.

Since neuromuscular blocking agents are used in intensive care units, anaphylaxis to these agents should be considered in the differential diagnosis of unexplained hypotension in the intensive care unit.

Radiocontrast Media Anaphylaxis

Radiocontrast dye studies are frequently necessary in critically ill patients, so it is important to know when a reaction is likely to occur and how to prevent it. Unfortunately, the likelihood of an anaphylactic reaction to radiocontrast dye cannot be predicted by pretesting with oral, conjunctival, or intradermal skin tests [92]. Although the overall adverse reaction rate ranges from 1% to 12% [93], patients with a history of a previous anaphylactic reaction to radiocontrast dye have a repeat reaction rate of 35% to 60% [94]. Patients with a general history of allergies, whether to inhalant allergens, foods, or medications, also have an increased reaction rate of serious reactions compared with nonallergic individuals [95]. The majority of contrast dye reactions are non-IgE mediated, although evidence is accumulating to suggest that an IgE-mediated mechanism may be contributory in some cases [96,97]. Although exceedingly rare, there have been several confirmed reports of anaphylactic reactions to iodinated oral contrast: Gastrografin (sodium and meglumine diatrizoate), Hypaque (sodium diatrizoate), barium sulfate, and gadolinium [98–102].

Nonionic, low-osmolal radiocontrast agents have largely replaced high ionic contrast media due to a decreased incidence of overall adverse reactions [103,104], although not all studies have found a reduction in life-threatening reactions or death [105,106]. Currently, for patients who have had a prior anaphylactic reaction to contrast media and who require a contrast study, the use of nonionic, low-osmolal contrast is recommended in addition to pretreatment with glucocorticoids, diphenhydramine with or without ephedrine [107], as outlined below. Iso-osmolal and noniodinated contrast are also being explored as alternatives to low-osmolal agents [107,108].

Pretreatment protocols have been developed for patients with a history of a prior anaphylactic reaction who require additional intravascular dye studies [92,94,109]. In one study of 192 procedures in patients with previous anaphylactic reactions to contrast media, pretreatment with prednisone, 50 mg orally at 13 hours, 7 hours, and 1 hour before the procedure, diphenhydramine, 50 mg orally or intramuscularly at 1 hour before the procedure, and ephedrine, 25 mg orally at 1 hour before the procedure resulted in a reaction rate of 3.1% [94]. A multicenter study of nonselected patients receiving intravenous contrast media reported a reaction rate of 5.4% in 2,513 patients given oral methylprednisolone, 32 mg at 12 hours and again at 2 hours before the procedure [109]. In this same study, a single dose of methylprednisolone, 32 mg 2 hours before the procedure, was no better than placebo, with a reaction rate of 9.4% in 1,759 patients. This finding raises the question of how to manage patients with a prior history of anaphylaxis requiring an urgent radiocontrast study. In a small study, nine such patients were treated with hydrocortisone, 200 mg intravenously immediately and every 4 hours until the procedure was completed, and diphenhydramine, 50 mg intravenously 1 hour before the procedure [110]. Roughly half of the patients received one dose of hydrocortisone, and the other half received two doses. No reactions occurred in these patients. Given that this study evaluated only nine patients, it remains unknown whether additional therapy with ephedrine or an H_2-receptor blocking agent, or both, would provide better protection.

Latex-Induced Anaphylaxis

Latex allergy, caused by sensitivity to *Hevea brasiliensis* proteins, can take several forms: contact dermatitis, asthma, urticaria, and anaphylaxis. Perioperative anaphylaxis caused by latex exposure has been described in several children with *spina bifida* and in patients with a history of multiple surgical

procedures [111]. In addition, latex allergy has become an occupational hazard in the health profession since the institution of universal precautions [112]. Sensitivity seems to be increased in atopic individuals with frequent exposure to latex. Unexplained perioperative or nosocomial urticaria, bronchoconstriction, or hypotension should raise concern for latex anaphylaxis. Mucosal and parenteral exposures have the highest risk of anaphylaxis.

Patients with latex allergy often have cross sensitivity with certain fruits and vegetables, including banana, kiwi, avocado, chestnut, papaya, potato, and tomato. Latex is found in a wide spectrum of health care products, including elastic thread, rubber bands, condom catheters, Foley catheters, surgical/examination gloves, enema bags, tubing on blood pressure cuffs, rubber stoppers on medication vials and intravenous line tubing, as well as some surgical drapes, drains, and gowns [113–116].

Establishing a diagnosis of latex allergy in a patient who is at high risk based on prior exposures or who may have had latex-induced anaphylaxis is important to guide future prevention efforts. However, skin test extracts are not yet commercially available in the United States and noncommercial latex extracts have been associated with systemic reactions. In addition, the specificity and sensitivity of noncommercial extracts may vary. A preferred alternative is serological testing by Phadia ImmunoCAP or the Siemens Immulite autoanalyzer; these tests have about 80% sensitivity [114,115].

The most important steps in prevention of future anaphylactic reactions to latex are careful patient education and in-hospital latex avoidance through the use of alert bracelets and latex-free kits [90]. Verbal and written information should be provided regarding potential sources of latex exposure and sources of latex-free gloves for patients to take to dentist and doctor visits. In addition, patients should understand the importance of alerting health care professionals who may care for them in the future and the need to carry an EpiPen kit in case of inadvertent exposure.

Stinging Insect Venom Anaphylaxis

Venom extracts for yellow jacket, white-faced hornet, yellow-faced hornet, wasp, honeybee, and fire ant are available for skin testing to confirm specific IgE mediation and for desensitization. Results with venom desensitization suggest more than 95% protection against anaphylaxis on subsequent stings [85]. The duration of desensitization therapy necessary for long-term protection is probably 5 years [117,118]. The geographic distribution of fire ants is expanding, making systemic allergic reactions to these insects a growing concern [119].

Exercise-Induced Anaphylaxis

Exercise-induced anaphylaxis syndrome is distinct from cold and cholinergic urticaria and exercise-induced asthma and usually occurs in individuals who engage in vigorous exercise [120,121]. A subgroup of these patients is allergic to a specific food, such as shrimp or celery, which acts as a cofactor; manifestations of anaphylaxis only occur if ingestion of the specific food is accompanied by exercise. Other potential cofactors include nonsteroidal anti-inflammatory drugs (NSAIDs), alcoholic beverages, and exposure to high pollen counts [122,123]. Typically, these patients can either ingest the food/NSAID or perform the exercise without adverse effect.

Anaphylaxis can be prevented by delaying exercise by at least 2 and preferably 4 hours after eating (48 hours after ingesting a food cofactor) and stopping exercise at the onset of pruritus. When NSAIDs are a cofactor, they should not be taken for at least 24 hours prior to exercise. Exercising with someone who is capable of administering epinephrine is also recommended. Antihistamines are occasionally of benefit in prevention.

Idiopathic Anaphylaxis

A group of patients has been described who experience recurrent anaphylaxis without an identifiable precipitant, the so-called *idiopathic anaphylaxis* [124]. In these patients, a careful review of all foods, preservatives, and drugs ingested prior to the episodes, as well as physical factors such as exercise, fails to reveal a cause for recurrent life-threatening anaphylaxis. These patients should be evaluated for possible systemic mastocytosis [125]. Maintenance therapy with antihistamines,

TABLE 194.6

MANAGEMENT OF ANAPHYLAXIS—QUALITY OF THE EVIDENCE

History of exposures and timing is the most important information to determine whether a set of symptoms was due to anaphylaxis and what tripper precipitated the event. (C)

The appropriate dose of epinephrine should be administered promptly at the onset of anaphylaxis. (A/D)

Intravenous infusion of crystalloid or colloid is essential for patients who are unstable or refractory to initial therapy with epinephrine. (B)

Specific situations

The extent of allergic cross-reactivity between penicillin and cephalosporins is low. (C)

Aztreonam cross-reacts with ceftazidime by shared R-group side chain. (B)

The three groups at increased risk for latex anaphylaxis are health care workers, children with *spina bifida* and genitourinary problems, and workers with occupational exposure to latex. (B)

Precautions for latex-allergic patients undergoing anesthesia include avoiding latex gloves, latex blood pressure cuffs, latex tourniquets, latex intravenous tubing ports, and rubber stoppers on vials. (B)

The greatest number of anaphylactic reactions in children has involved peanuts, tree nuts, fish, shellfish, milk, and eggs. (C)

Anaphylactic reactions to foods almost always occur immediately, but may recur hours later. (A)

Strength of recommendation

A. Directly based on meta-analysis of randomized controlled trials or from at least one randomized controlled trial or systematic review of randomized controlled trials/body of evidence.
B. Directly based on at least one controlled trial without randomization or at least one other type of quasi-experimental study or extrapolated recommendation from A.
C. Directly based on at least one other type of quasi-experimental or descriptive/comparative study or extrapolated recommendation from A or B.
D. Directly based on evidence from expert committee report or opinions or clinical experience of respected authorities or both.

Summarized from reference [38] and others.

oral glucocorticoids, and sympathomimetics has been shown to reduce the frequency and severity of episodes of this disorder [126,127].

Angiotensin-Converting Enzyme Inhibitor Angioedema

Severe, potentially life-threatening facial and oropharyngeal angioedema may occur in individuals with hypersensitivity to angiotensin-converting enzyme (ACE) inhibitors [128–130]. Onset of angioedema usually starts within the first several hours or up to a week after beginning therapy, but angioedema can develop after months to years of asymptomatic usage [128]. Subsequent episodes may occur after days to weeks of continued usage. A late onset of symptoms, 12 to 24 hours after the last dose, has been reported with the long-acting ACE inhibitors lisinopril and enalapril [130]. As with ACE-induced cough, cross-reactivity is the rule among different ACE inhibitors. The mechanism is unknown but is suspected to be related to an alteration in bradykinin metabolism or, possibly, an interaction with components of the complement cascade (e.g., complement 1-esterase inhibitor) [131].

Aspirin and NSAIDs

Acetylsalicylic acid (aspirin) and nonsteroidal anti-inflammatory agents cause urticaria, flares of urticaria in patients with chronic idiopathic urticaria, anaphylaxis, and aspirin-exacerbated respiratory disease (AERD) [132–136]. Most patients have either the urticaria/anaphylaxis pattern or the respiratory disease pattern, but a few patients have both. Some patients with the urticaria/anaphylaxis pattern appear to have sensitivity to a particular NSAID, but most have cross-sensitivity that is related to an abnormality of prostaglandin/leukotriene metabolism [137]. Desensitization protocols for patients with coronary artery disease, who need the antiplatelet effects of aspirin, have been published [138,139].

Miscellaneous Causes of Anaphylaxis

Insulin therapy has been associated with an increased risk of anaphylaxis, particularly when a patient on insulin therapy has a history of local wheal-and-flare reactions at the site of insulin injections and interrupts insulin therapy for more than 48 hours and then resumes it [16,140]. Anaphylaxis has also been described with recombinant DNA insulin [141] and to protamine in neutral protamine Hagedorn (NPH) insulin [142].

The injection of heterologous serum carries a significant risk of anaphylaxis. Human serum (homologous) should be used whenever available. If heterologous serum must be used (antitoxin for snake bites, passive rabies immunization in developing countries, and antilymphocytic serum for organ transplantation), patients are usually evaluated for cutaneous sensitivity by first performing a scratch test with antitoxin or normal horse serum. If there is no reaction, 0.02 mL of a 1:10 serum dilution can be injected intradermally. As with all skin testing, the physician must be prepared to treat any systemic reactions that arise [1].

Patients with mastocytosis appear to be at greater risk for developing anaphylaxis from Hymenoptera stings (even in the absence of IgE mediation) and from mast cell degranulating agents (see Table 194.2). These patients should carry an epinephrine kit during Hymenoptera season. Administration of diagnostic and therapeutic agents that might cause mast cell activation should be avoided in these patients.

The quality of evidence and recommendations for diagnosis and management of anaphylaxis are summarized in Table 194.6.

CHAPTER 195 ■ DERMATOLOGY IN THE INTENSIVE CARE UNIT

NIKKI A. LEVIN, DORI GOLDBERG, LAUREN ALBERTA-WSZOLEK, MEGAN BERNSTEIN AND ALEXIS C. PERKINS

INTRODUCTION

Patients in the intensive care unit (ICU) often present with cutaneous findings. Their reason for admission to the ICU may be primarily dermatologic, as in the case of toxic epidermal necrolysis (TEN) or pemphigus vulgaris, two diseases in which large areas of the epidermis are shed. Or they may have skin findings that provide diagnostic clues to their internal disease, as when a patient with systemic lupus erythematosus presents with a classic malar rash. Patients with life threatening infections, such as Rocky Mountain spotted fever and Meningococcemia, may present with characteristic skin lesions that suggest the correct diagnosis and allow prompt institution of lifesaving treatment.

Skin conditions in ICU patients are often iatrogenic, being caused by drugs (e.g., TEN, drug reaction with eosinophilia and systemic symptoms (DRESS), acute generalized exanthematous pustulosis (AGEP)), procedures (e.g., cholesterol emboli), dressings (e.g., contact dermatitis), or inattentive care (e.g., pressure ulcers). At other times, patients may have skin conditions which, although relatively minor, may complicate their ICU stay, put other patients and health care workers at risk (e.g., scabies), or make patients uncomfortable (e.g., miliaria, Grover's disease).

In this chapter, we give an overview of serious illnesses with prominent cutaneous findings, including drug reactions, exfoliative erythrodermas, infections, blistering disorders, vascular disorders, connective tissue disorders, and graft-versus-host disease (GVHD). In addition, we provide a brief description of more common but less serious dermatoses that may coexist in ICU patients, with suggestions for their management. We emphasize the importance of lesion morphology, that is, the shape, color, size, arrangement, and distribution of skin lesion in making a correct diagnosis. Table 195.1 provides a list of skin diseases arranged by morphology to assist in formulating a differential diagnosis.

Dermatologic consultation is often helpful for diagnosis and management of skin diseases in ICU patients. The dermatologic consultant may be able to help sort out multiple potential differential diagnoses by inspection of morphology, skin biopsy, or use of other diagnostic tests (skin scrapings for scabies, potassium hydroxide preparations for fungus, viral and bacterial cultures, direct fluorescent antibody tests for viral infections, etc.) Since morphology evolves with the natural course of disease and with attempted therapeutic measures, it is helpful to request consultation early in the course of cutaneous disease.

DRUG ERUPTIONS

Cutaneous drug reactions are frequently encountered in ICU patients. Certain drug reactions such as toxic epidermal necrolysis (TEN), Stevens–Johnson syndrome (SJS), DRESS, and acute generalized exanthematous pustulosis (AGEP) may be the primary cause for admission to the ICU. These reactions will be discussed in depth following a brief overview of more commonly occurring drug reactions. The exanthematous or morbilliform drug eruption is the most common (Fig. 195.1). It typically appears 7 to 14 days after introduction of the offending agent. Clinically it appears as symmetric macules that may become slightly papular on the trunk and upper extremities, and may become confluent with time. Low-grade fever and pruritus are sometimes present. The differential diagnosis includes viral exanthem, Kawasaki's disease, GVHD, and the more serious drug reactions discussed below (TEN, SJS, DRESS, and AGEP). Facial edema, mucosal lesions, blisters or sloughing of the skin, and laboratory abnormalities such as neutrophilia, eosinophilia, and elevated liver function tests may indicate the presence of a more serious drug reaction. Withdrawal of the causative drug is the most important treatment, although topical corticosteroids and oral antihistamines may be used for symptomatic relief. Exanthematous drug eruptions resolve without sequelae 1 to 2 weeks after the offending drug has been discontinued.

Toxic Epidermal Necrolysis/ Stevens–Johnson Syndrome

Toxic epidermal necrolysis (TEN) and Stevens–Johnson syndrome (SJS) are entities on a spectrum of severe cutaneous reactions that are most commonly caused by medications. They exhibit severe blistering and sloughing of the skin (Fig. 195.2) with mucosal involvement (Fig. 195.3), and may have high morbidity and mortality. The distinction between TEN and SJS is based on the percentage of skin involved with SJS being $< 10\%$, TEN being $> 30\%$, and SJS/TEN overlap being 10% to 30% of the body surface area affected. The cumulative annual incidence of these entities has been estimated at 1.89 per million people. SJS is more common in children, whereas TEN is more common in adults. TEN is more common in women, and the incidence increases with age and immunosuppression [1]. HIV infection increases the risk of SJS/TEN with the incidence of TEN in HIV patients receiving trimethoprim-sulfamethoxazole, 8.4 per 100,000 exposures as opposed to 2.6 per 100,000 exposures in non-HIV infected individuals [2]. There appears to be a genetic component to SJS/TEN, as multiple studies have demonstrated HLA alleles related to hypersensitivity to specific medications, however, at this time human leukocyte antigen (HLA) testing is not clinically useful due to its expense [2].

Ninety five percent of patients with TEN have a history of drug exposure and there is a clear relationship to a drug in 80% of cases. Only half of SJS cases are related to medications with the remainder being attributed to infections, including mycoplasma, which may present as mucositis without typical skin manifestations. The most common causative medications along with relative risks listed in parentheses include: trimethoprim-sulfamethoxazole (172), carbamazepine

TABLE 195.1

DIFFERENTIAL DIAGNOSIS OF SKIN ERUPTIONS BY MORPHOLOGY

Fever and rash
- Infectious disease (bacterial, fungal, viral)
- Rheumatologic disease (SLE, rheumatoid arthritis, juvenile rheumatoid arthritis, Still's disease, mixed connective tissue disease)
- Pustular psoriasis
- Drug eruption
- Leukemia/lymphoma
- Lofgren's syndrome (acute sarcoidosis with erythema nodosum, hilar adenopathy, fever, and arthritis)
- Sweet's syndrome
- Polyarteritis nodosa

Morbilliform (maculopapular)
- Drug eruption
- Viral exanthem
- Graft-versus-host disease
- Rickettsial infections

Generalized erythema
- Staphylococcal scalded skin syndrome
- Exfoliative erythroderma

Localized erythematous papules and plaques
- Psoriasis
- Seborrheic dermatitis
- Contact dermatitis
- Pityriasis rosea
- Tinea
- Scabies
- Dermatomyositis
- Lupus erythematosus
- Secondary syphilis
- Urticaria
- Still's disease
- Disseminated candidiasis
- Erythema nodosum
- Grover's disease

Annular (ring-shaped) erythematous lesions
- Tinea
- Erythema multiforme
- Urticaria
- Granuloma annulare
- Sarcoid
- Subacute cutaneous lupus
- Sweet's syndrome
- Erythema chronicum migrans (Lyme disease)
- Leprosy

Pustules
- Pustular psoriasis
- Steroid acne
- Folliculitis
- Acute generalized exanthematous pustulosis (AGEP)

Vesicles/Bullae
- Herpes simplex
- Varicella zoster
- Miliaria
- Bullous infections (impetigo, tinea, cellulitis)
- Erythema multiforme/Stevens–Johnson syndrome/TEN
- Pemphigus
- Paraneoplastic pemphigus
- Bullous pemphigoid
- Linear IgA dermatosis
- Epidermolysis bullosa acquisita
- Porphyria cutanea tarda
- Dermatitis herpetiformis

Purpura
- Vasculitis
- Purpura fulminans
- Calciphylaxis
- Heparin or Coumadin necrosis
- Cryoglobulinemia
- Cholesterol emboli
- Myeloproliferative disease
- Antiphospholipid syndrome

Ulcers
- Vasculopathy
- Infectious
- Neoplastic
- Bullous disorders
- Panniculitis
- Neuropathy
- Bites
- Aphthae
- Trauma

(90), NSAIDS (72), corticosteroids (54), phenytoin (53), allopurinol (52), phenobarbital (45), valproic acid (25), cephalosporins (14), quinolones (10), and aminopenicillins (6.7), with more recent reports implicating lamotrigine, rituximab, imatinib, lenalidomide [3]. The time from drug ingestion to clinical symptoms is generally 1 to 3 weeks, except for the aromatic anticonvulsants that can take up to 2 months to cause disease [4].

The cutaneous eruption may be heralded by a 1 to 3 day prodrome of fever and flu-like symptoms. The initial cutaneous finding is irregularly shaped erythematous to purpuric macules with irregular size and shape distributed on the face and trunk. This may evolve into flaccid blisters that may be easily enlarged with lateral pressure. The skin can become gray, which usually heralds full thickness epidermal sloughing. Mucosal involvement is present in 90% of patients with SJS and TEN, with the most common affected areas being the conjunctiva, oral cavity, and genitalia. Symptoms include severe skin pain and difficulty swallowing and urinating. Respiratory epithelium may also be involved with resultant dyspnea, pulmonary edema, and hypoxia.

The differential diagnosis includes staphylococcal scalded skin syndrome (SSSS), acute generalized exanthematous pustulosis (AGEP), severe acute GVHD, drug-induce linear IgA bullous dermatosis, and paraneoplastic pemphigus. The appropriate clinical setting and skin biopsy easily differentiate SJS/TEN from these entities. Two skin biopsies are recommended, one for frozen section and the other for routine H&E. Early lesions demonstrate necrotic keratinocytes, while advanced lesions reveal full-thickness epidermal necrosis, and a recent study indicates that the density of the dermal mononuclear cell infiltrate correlates with the severity of disease and mortality rate [5].

Prompt diagnosis and rapid cessation of the causative medication along with supportive therapy is the cornerstone of

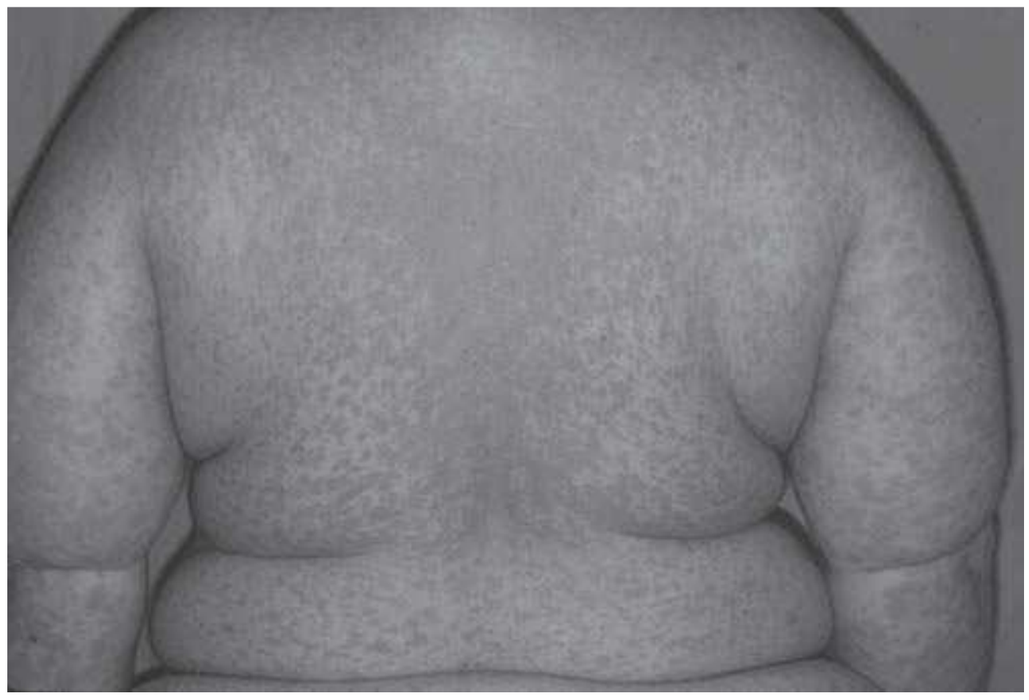

FIGURE 195.1. Morbilliform (maculopapular) drug eruption. Note the pink blanchable papules and plaques with areas of confluence over the trunk and extremities.

FIGURE 195.3. Stevens–Johnson syndrome. Bullae over the left top eyelid and erythematous and edematous plaques on the neck and shoulders. Note the erosions over the lips.

therapy. Careful monitoring of fluid volume, electrolytes, renal function, nutritional status, and evaluation for signs of sepsis should be performed. For extensive body surface involvement, care should be provided in an ICU with staff accustomed to caring for patients with fragile and denuded skin, usually a burn unit. Uninvolved skin should not be manipulated, while involved skin should be covered with Vaseline impregnated gauze and a topical antibiotic ointment. Debridement of necrotic skin may be followed by placement of artificial membranes or biologic dressings such as xenografts or allografts. Daily bacterial cultures should be performed of involved skin and mucosa as well as blood, urine, and any intravenous catheters, as sepsis is the most common cause of mortality in patients with SJS/TEN. Systemic antibiotics should not be started unless signs of sepsis are present because of the risk of selecting for antibiotic resistant organisms, and prophylactic use of antibiotics has not been shown to improve outcome [2]. Patients should be followed by an ophthalmologist to avoid conjunctival scarring. Currently, there is no gold standard systemic therapy for TEN/SJS. Intravenous immunoglobulin (IVIG) has been used, based on its ability to bind Fas receptors, thought to be a major mediator of apoptosis in TEN/SJS. Unfortunately, there are no randomized double-blind trials to support its use, and while some studies have shown mortality benefit with doses more than 1 g per kg per day, others have shown no benefit or even increased mortality associated with its use [6]. Systemic corticosteroid pulse therapy early in the disease course has been shown to have benefit in preventing ocular complications, and topical high potency corticosteroids appear to prevent corneal epithelial stem cell loss and scarring [7]. There is some emerging evidence that high dose (1.5 mg/kg/day) pulse corticosteroids decreased TEN-associated mortality [2]. Other systemic treatments have been tried, but none are recommended at this time [8].

The mortality rate for SJS and TEN is 5% and 30%, respectively, and is directly related to the percentage of skin involved. Risk of mortality can be predicted using the SCORTEN algorithm. One point each is assigned for the presence of the following seven criteria: age > 40 years, presence of malignancy, heart rate > 120, initial epidermal detachment > 10%, serum urea nitrogen > 10 mmol per L, serum glucose > 14 mmol per L, and serum bicarbonate < 20 mmol per L. The points are added and the predicted mortality based upon this total is 0 to 1 (3.2%), 2 (12.1%), 3 (35.8%), 4 (58.3%), and 5 or more (90%) [9]. Healing of sloughed epidermis usually takes 3 weeks and survivors may experience ocular scarring and visual loss. If the causative medication is reintroduced, the disease may recur in less than 48 hours. Notably, a patient who experiences TEN to one class of medication is not predisposed to TEN in response to other medication classes; however, cross-reactivity may be seen between related drug classes such as penicillins and cephalosporins.

FIGURE 195.2. Toxic epidermal necrolysis. Bullae and sheets of epidermal sloughing leaving behind red denuded areas are seen.

Drug Rash with Eosinophilia and Systemic Symptoms

Drug rash with eosinophilia and systemic symptoms (DRESS) is a potentially fatal hypersensitivity reaction to medication, most commonly anticonvulsants [10]. The incidence is between 1/1,000 to 1/10,000 exposures and it is thought to occur with higher frequencies in patients of African ancestry [11].

Although the etiology of DRESS is not understood completely, alteration in drug detoxification pathways and a causative role for human herpesvirus 6 have been proposed [12,13]. DRESS is most commonly caused by the aromatic anticonvulsants, including phenobarbital, phenytoin, and carbamazepine. Of note, these drugs may cross-react. Other common

causes include allopurinol, sulfonamides, minocycline, and dapsone.

In contrast to other drug reactions, DRESS may develop as late as 4 to 6 weeks after the offending medication has been introduced. DRESS has even been reported to occur more than 1 year after initiating allopurinol. The rash is usually morbilliform, though erythroderma, pustules, vesicles, and purpuric areas may also be present. High fever and edema of the face are hallmarks of this entity. Systemic involvement may include pharyngitis, lymphadenopathy, hepatosplenomegaly, peripheral eosinophilia, abnormal liver function tests, arthralgias, pulmonary infiltrates, and interstitial nephritis. Allopurinol and minocycline are associated with severe DRESS, the former frequently causing renal failure, and the latter causing pneumonitis [14]. Circulating atypical lymphocytes may also be present [11]. High eosinophil count and multiple medical comorbidities were poor prognostic factors in one series of 30 patients with DRESS [15]. Another study found that vitamin D deficiency was common among patients with DRESS, and that myocarditis is an underdiagnosed systemic manifestation, which may be detected by cardioselective biomarkers, echo, or cardiac MRI [16].

The differential diagnosis includes AGEP, SJS, TEN, Kawasaki's disease, and the hypereosinophilic syndrome. Histopathology of skin biopsies taken from patients with DRESS is variable and therefore not diagnostic [15]. The history of recent initiation of a suspect drug, the presence of atypical lymphocytes, peripheral eosinophilia, increased liver function tests, abnormal serum creatinine or urinalyses, and cutaneous eruption as described above, especially with facial edema, suggest the diagnosis of DRESS.

The most effective treatment is prompt diagnosis and cessation of the offending drug. Antipyretics may be used to treat the fever but they have no impact on disease outcome. Multiple independent case reports have suggested that systemic corticosteroid therapy may halt internal disease progression. Additionally, the disease has been reported to recur upon stopping corticosteroid treatment too soon. This has led many authorities to suggest treatment with systemic corticosteroids when there is internal involvement. However, no case control or randomized controlled trial data are available [17]. Thus, primary and secondary prevention of DRESS is of utmost importance. One must have knowledge of the most common causative drugs and an understanding of the cross-reactivity among the aromatic hydrocarbons. Mortality rates up to 10% have been reported and are primarily due to fulminant hepatitis.

Acute Generalized Exanthematous Pustulosis

Acute generalized exanthematous pustulosis (AGEP), also known as toxic pustuloderma [18] or pustular drug rash [19] is a very rare drug reaction that presents with fever, leukocytosis, and multiple pustules on a background of generalized erythema. There appears to be no sexual predilection and AGEP may occur at any age. Incidence rates have been estimated at 1 to 5 cases per million per year [20].

Drugs are responsible for at least 90% of AGEP cases. In a report of 97 cases from Europe, aminopenicillins (odds ratio [OR] = 23), macrolides (OR = 11), quinolones (OR = 33), hydroxychloroquine (OR = 39), calcium channel blockers (OR = 15), anticonvulsants (OR = 8), and corticosteroids (OR = 12) were the most common causative agents [21]. More recently, spider bites have been reported as triggers [22]. Patch testing with the offending agent is frequently positive reflecting the dominant role of T cells in the disorder.

The eruption is frequently sudden in onset and the majority of cases appear within 24 hours to several days of exposure to the offending agent. A fever of more than 38°C is followed by the appearance of tiny nonfollicular pustules on a background of generalized erythema and edema. Petechiae, purpura, vesicles, or target lesions may be present, and oral lesions may be observed in 20% of patients. The face and intertriginous areas are the most common presenting locations. Neutrophilia occurs in 90% and eosinophilia in 30% of patients. Liver function tests are usually normal and there is typically no systemic involvement, but lymphadenopathy is sometimes seen. The differential diagnosis includes pustular psoriasis, subcorneal pustular dermatosis, DRESS, and in severe cases, TEN. An acute onset and clinical history of a new drug favors AGEP over pustular psoriasis, whereas DRESS and TEN exhibit systemic involvement.

Discontinuation of the causative drug is the definitive treatment. Once the diagnosis is made and the causative drug is stopped, the pustules will resolve in less than 15 days with desquamation, and prognosis is excellent. Antipyretics may be used for symptomatic treatment of the fever and topical steroids may be used for symptomatic treatment of the rash, although neither will hasten the resolution of the eruption.

EXFOLIATIVE ERYTHRODERMA

Erythroderma (Fig. 195.4) is a rare, life-threatening skin condition characterized by erythema involving at least 90% of the body surface area with variable degrees of scaling [23–25]. While age at presentation varies with the underlying cause, patients are typically over 40 or 45 years. Male to female ratio and reported incidence are also variable, and there is no racial predilection [25–27].

The causes of erythroderma may be categorized into preexisting skin conditions (psoriasis, atopic dermatitis, contact dermatitis, and seborrheic dermatitis), drug reactions, malignancy, skin infections and infestations, and idiopathic etiology [23,25,27]. Over 60 topical and systemic medications have been implicated in erythroderma, including ACE inhibitors, anticonvulsants, penicillin, vancomycin, antifungals, and barbiturates [26,27]. Leukemias and lymphomas constitute up to 40% of malignancy-related erythrodermas. Cutaneous T cell lymphoma (CTCL) and Sezary syndrome represent most of these cases. Primary blood vessel malignancy and solid organ cancers are also reported in association with erythroderma [27]. SSSS, HIV seroconversion, superficial dermatophyte and candidal infections, scabies infestation, lupus erythematosus, sarcoidosis,

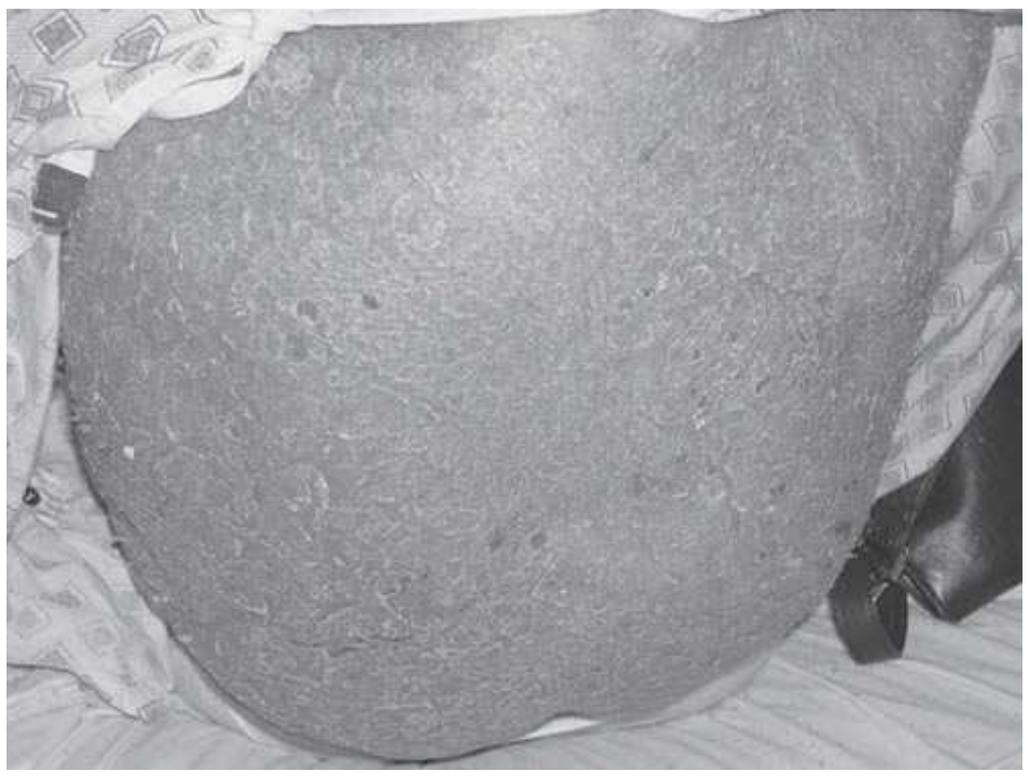

FIGURE 195.4. Exfoliative erythroderma. Widespread red blanchable erythema with scale.

and mastocytosis may rarely cause erythroderma as well. Up to 46% of cases have no identifiable trigger [23,26].

Varying degrees of scaling, which often begin at flexural surfaces, follow intense widespread erythema within 2 to 6 days. Erythroderma associated with psoriasis and atopic dermatitis has a more indolent course than the more rapidly progressive form linked to malignancy, drugs, and SSSS [26]. Along with intense erythema, patients may have fever, hyperkeratosis of the palms and soles, nail dystrophy, cheilitis, alopecia, edema of the face and legs, dermatopathic lymphadenopathy, hepatomegaly, and splenomegaly [25,26].

Erythrodermic patients have dramatic disturbances in the body's regulatory mechanisms. Increased cutaneous blood flow results in exaggerated heat and fluid losses with a compensatory increase in the body's basal metabolic rate. This, in conjunction with the shedding of 20 to 30 g per day of proteinaceous scale, can result in a hypoalbuminemia that exacerbates edema and nutritional deficits [26,27]. Complications include electrolyte imbalance, dehydration, high output cardiac failure, and secondary infections.

Identification of the underlying trigger is important in the evaluation and management of erythrodermic patients. Early examination of the skin with corroborating evidence from skin biopsy may be helpful in establishing the etiology, but in the majority of adult cases, the underlying dermatosis is obscured by widespread erythema and scaling. Skin biopsy has recently been shown to be more useful in detecting some underlying triggers for infantile and neonatal cases of erythroderma [28].

Erythroderma should be managed as a dermatologic emergency in the inpatient setting. Initial treatment, regardless of the underlying cause, consists of temperature regulation, hemodynamic support and monitoring, and skin care. Topical therapies include low-to-mid potency corticosteroids such as triamcinolone 0.025% to 0.1% cream under wet dressings. Tap water soaked gauze dressings may be changed every 2 to 3 hours, and tepid baths may provide additional relief. As the skin condition improves, emollients can be substituted for corticosteroids. Systemic corticosteroids can be helpful, but must be used with caution in atopic dermatitis and are contraindicated in infection and psoriasis. Additional therapy is targeted at the triggering disease and may include systemic retinoids, cyclosporine, or methotrexate in the case of psoriasis, and psoralen with UVA phototherapy in the case of CTCL [26,27]. Regardless of the underlying cause, relapses of erythroderma are common. Mortality rates range from 4.6% to 64% and are influenced by advanced age and comorbidities [25].

INFECTIONS

Toxic Shock Syndrome

Toxic shock syndrome (TSS) is an acute febrile illness caused by toxin-producing strains of *Staphylococcus aureus*, presenting with fever, rash, and hypotension and often progressing to multiorgan failure [29]. A similar syndrome caused by *Streptococcus pyogenes* has also been described, known as streptococcal toxic shock syndrome (STSS) [30]. TSS is rare and more often seen in young women (yearly incidence of 1/100,000 women of reproductive age) than men, most likely due to its association with tampon use. Predisposing factors for TSS include menstruation, recent childbirth or surgery, burn wounds, intravenous drug use, pneumonia, and influenza. STSS has an estimated yearly incidence of 10 cases/100,000 population and shows no gender predilection [29]. Pathophysiology of both entities involves massive release of cytokines due to bacterial toxins acting as superantigens.

Both TSS and STSS present with high fever, headache, nausea and vomiting, and myalgias and arthralgias. Hypotension, metabolic acidosis, acute renal failure, elevated transaminases, thrombocytopenia, leukocytosis, disseminated intravascular coagulation, cardiomyopathy, and acute respiratory distress syndrome (ARDS) are often seen. Most patients with TSS do not have an obvious localized *S. aureus* infection. In contrast, 80% of patients with STSS have a clinically evident painful streptococcal soft tissue infection, often necrotizing fasciitis, usually of an extremity [29].

Skin findings are especially prominent in TSS, which classically presents with generalized macular (sunburn-like) erythema, but a scarlatiniform rash with accentuation of the flexures can also be seen. Erythema of the palms and soles, conjunctivae, and mucous membranes is also observed. The patient may develop a bright red "strawberry" tongue. The eruption is followed 1 to 2 weeks later by desquamation, especially of the palms and soles.

The differential diagnosis includes Rocky Mountain spotted fever, meningococcemia, Kawasaki's disease, SSSS, scarlet fever, or a medication hypersensitivity reaction. Blood cultures are positive in 60% of cases of STSS, less often (< 15%) in TSS [29]. Diagnosis is on clinical grounds and requires four major criteria (fever > 38.9°C, diffuse macular erythroderma, desquamation 1 to 2 weeks later, hypotension, and poor peripheral perfusion) and at least three minor criteria (vomiting or diarrhea; severe myalgia or CPK twice normal; hyperemic mucous membranes; elevated urea or creatinine; elevated bilirubin, ALT, or AST; platelets $< 100 \times 10^9$/L; and disorientation or altered consciousness). TSS also has a specific T cell signature with early depletion of the V beta 2 subset followed by massive expansion, which can aid in early diagnosis [31]. Skin biopsy showing a neutrophilic and eosinophilic perivascular and interstitial infiltrate with scattered necrotic keratinocytes can be helpful.

Treatment is with supportive care (intravenous fluids and vasopressors), penicillinase-resistant antibiotics, and intravenous immunoglobulin (IVIG) or fresh frozen plasma (FFP). Nafcillin 1 to 2 g intravenously every 4 hours is the first line antibiotic for TSS and clindamycin 600 to 900 mg intravenously every 8 hours for STSS. As cases of TSS due to methicillin-resistant *S. aureus* (MRSA) are increasing in frequency, treatment with vancomycin (1 to 2 g IV every 24 hours) may sometimes be necessary [32]. In addition, prompt surgical exploration and drainage of suspected deep tissue infections is critical in cases of STSS in which necrotizing fasciitis may be present.

In one study of IVIG in STSS, 30 day survival improved from 34% to 67% and in the only randomized placebo controlled study of treatments for STSS, IVIG decreased mortality by 3.6-fold [33]. TSS has a case fatality rate of less than 5%, whereas mortality in STSS ranges from 30% to 70%, and significant morbidity, including renal failure, amputation, or hysterectomy may also occur [29,30].

Cellulitis and Erysipelas

Cellulitis is an acute bacterial infection of the skin and subcutaneous tissues. Erysipelas is a superficial form of cellulitis that is more indurated and well demarcated than other forms of cellulitis, in which the border between involved and uninvolved skin is indistinct. Cellulitis is common and more frequently affects men than women. The lower extremities are most often involved (73% of cases), followed by the upper extremities (19%), and head and neck (7%) [34].

Cellulitis is usually caused by group A beta-hemolytic streptococci or *S. aureus*, including MRSA [35], although it may also be caused by Group B streptococci, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and other bacteria, in

certain settings. Erysipelas is almost always caused by Group A streptococci. Predisposing factors for cellulitis include venous stasis disease, lymphedema, lower extremity ulceration, tinea pedis, and obesity. Bacteria on the skin surface enter through breaks in the skin and proliferate in the dermis and subcutaneous tissues, causing inflammation.

Patients with cellulitis present with erythema, swelling, warmth, and tenderness of a poorly demarcated area, usually on the leg, often in the setting of lower extremity swelling or dermatitis. If a line is drawn around the involved area, the area of redness is often seen to spread outward over hours to days. Patients frequently have tender local lymphadenopathy and/or lymphangitis. Fever or myalgias are sometimes present. In erysipelas, the skin is bright red and the borders are elevated and sharply demarcated from the uninvolved skin.

Cellulitis has a broad differential diagnosis, including contact dermatitis, superficial thrombophlebitis, deep venous thrombosis, necrotizing fasciitis, lipodermatosclerosis, and insect bites or stings [36,37]. One of the most commonly confused entities is simple stasis dermatitis, which is usually bilateral with scaling and hyperpigmentation of the distal lower extremities in addition to erythema and swelling. It is usually not tender unless ulceration is present.

Diagnosis of cellulitis and erysipelas is generally on clinical grounds. Blood cultures are of low yield (4% positive) unless the patient has signs of sepsis, and tissue cultures from needle aspirates are positive in only 10% to 20% of cases [38]. However, if the patient has an active ulcer, this may be cultured. Radiographic studies are usually unnecessary, although plain films or computed tomography (CT) may be of value to evaluate underlying osteomyelitis, and magnetic resonance imaging (MRI) may be used to differentiate cellulitis from necrotizing fasciitis [36]. If necrotizing fasciitis is strongly suspected, surgical debridement and intravenous antibiotics should be initiated immediately without waiting for radiologic or microbiologic studies.

Treatment of cellulitis is directed at the most likely bacterial causes, which are Streptococci and *S. aureus*. Initial treatment of the hospitalized patient is with beta-lactamase-resistant penicillins or cephalosporins such as cefazolin 1 g IV every 6 hours, nafcillin 1 to 1.5 g IV every 4 to 6 hours, or ceftriaxone 1 g IV every 24 hours. If MRSA is suspected, treatment is with vancomycin 1 to 2 g IV every 24 hours. As the cellulitis begins to resolve and the patient becomes afebrile, the patient may be converted to oral dicloxacillin or cephalexin 500 mg every 6 hours, for a total course of 7 to 14 days of antibiotics [36].

Local treatment of a cellulitic limb with elevation to reduce swelling and saline dressings to any open wounds may be helpful. Prognosis of patients with uncomplicated cellulitis is excellent but recurrences are common. Treatment of underlying tinea pedis with topical azole antifungals and of venous stasis or lymphedema with compression hosiery can help prevent recurrences [36].

Necrotizing Fasciitis

Necrotizing fasciitis (NF) is a rapidly progressive infection involving the subcutis and fascia that typically occurs in the elderly, diabetics, alcohol abusers, and those with chronic cardiac disease or peripheral vascular disease. It is increasing in frequency among young, previously healthy individuals. NF may occur *de novo*, after surgery, or after penetration or even blunt trauma. Injection drug use is not an infrequent cause of NF [39]. The extremity is the usual site of involvement. When NF originates in the scrotum, it is known as Fournier's gangrene. Most cases result from a polymicrobial infection. Pathogens may include Streptococci, *S. aureus*, enterococci, *Escherichia coli, Pseudomonas*, *Bacteroides, and* Clostridium *spp*. Community acquired MRSA has been reported more recently [40]. Invasive Group A *Streptococcus* is implicated in previously healthy patients. Other less frequent pathogens include *Pseudomonas aeruginosa*, *Aeromonas hydrophila*, and *Vibrio vulnificus, Haemophilus influenzae* type b.

The skin is initially shiny, erythematous, hot, tender, swollen, and tense. Pain is out of proportion to physical findings. Within 24 to 36 hours, skin color changes from red to dusky gray-blue, and bullae may develop. Deeper soft tissue may feel firm. With the destruction of cutaneous nerves, skin becomes anesthetic. The area becomes gangrenous by the fourth or fifth day, and patients appear toxic with fever, chills, tachycardia, shock, and leukocytosis.

NF may be difficult to differentiate from cellulitis, especially early in the course of disease. Features that suggest NF include: severe pain which may be out of proportion to physical findings, anesthesia of involved skin, rapid spread, edema and bulla formation, associated varicella infection, signs of shock, elevated creatine phosphokinase level, or NSAID use. NSAID use is implicated in disease progression through attenuation of signs and symptoms of inflammation that leads to a delay of diagnosis and treatment. MRI may help to discern extent of involvement. A newer tool called the laboratory risk indicator for necrotizing fasciitis uses a scoring system based on C-reactive protein, total white cell count, hemoglobin, sodium, creatinine, and glucose levels to help distinguish between necrotizing soft tissue infections and non-necrotizing infections, and in one retrospective study, was noted to predict mortality and amputation rate [41].

Early fasciotomy and immediate intravenous antimicrobial therapy based on initial Gram stain are crucial. Initial therapy usually involves a beta-lactam/beta-lactamase inhibitor. Hyperbaric oxygen therapy for anaerobic gram negative infection is controversial. Supportive care and attention to nutrition are important in optimizing postoperative wound healing. Even with early treatment, mortality may be between 20% and 40%. Poor prognostic factors include age over 50, diabetes, arteriosclerosis, delay of more than 7 days in diagnosis and surgical intervention, and infection involving the trunk rather than the extremity [42]. Other factors associated with mortality include STSS and immunocompromised state [39,43].

Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome (SSSS) is a blistering, desquamative skin condition caused by the exfoliative toxins of *S. aureus*. Infants and young children are the most commonly affected, likely due to their immature immune and renal function, resulting in a lack of antitoxin antibodies and accumulation of exfoliative toxin. A few cases have been reported in adults who generally have underlying renal impairment or immunosuppression [44,45].

Two toxins, ETA and ETB, have been detected in human disease, with the majority caused by ETA. These toxins bind to and cleave desmoglein-1, a desmosomal protein in the superficial epidermis critical for binding between keratinocytes. Cleavage of this protein causes separation between keratinocytes in the upper layers of the epidermis and also of the superficial epidermis from deeper layers, with resulting fragile blisters and denuded skin [44,45].

In the localized form of SSSS, bullous impetigo, *S. aureus* enters the skin through a break or tear and elaborates exfoliative toxin that results in the development of blisters. Further spread is prevented by antibodies to the toxin. In generalized SSSS, the focus of infection is at a distant site, such as an abscess, pneumonia, osteomyelitis, or endocarditis. Frequently, however, a focus of infection is not found. A lack of protective antibodies

allows the toxin to reach the epidermis by hematogenous spread and cause widespread skin disease [44–46].

Whereas bullous impetigo has no associated systemic symptoms, generalized SSSS is associated with a prodrome of fever, malaise, and generalized erythema. This is followed by the formation of large blisters with clear or purulent fluid that easily rupture, leaving extensive areas of denuded skin. The degree of skin involvement may vary from focal blistering to entire body exfoliation. Significant pain and tenderness, hypothermia, fluid losses, secondary infection with *Pseudomonas* and other species, bacteremia, and sepsis may complicate the disease course [44,45].

SSSS should be considered for any presentation of fever and diffuse skin erythema. While the main differential diagnosis is toxic epidermal necrolysis, other conditions to consider include pemphigus foliaceus, scalding or chemical burns, GVHD, and epidermolysis bullosa. A thorough evaluation should include determination of the degree of denudation, identification of the source of infection, determination of fluid status, and a search for signs of secondary infection. Culture and Gram stain of the skin and focus of infection may identify *S. aureus*, but alone do not confirm the diagnosis of SSSS. Enzyme-linked immunosorbent assay (ELISA) can detect production of exotoxin from isolated *S. aureus* species, but should be used as confirmation of SSSS only, as false negatives can easily result if the pathogenic strain of bacteria is not detected on culture. Blood cultures are frequently positive in adults with SSSS [44,45].

Skin biopsy is the most useful diagnostic test, since it further distinguishes between SSSS and TEN. SSSS shows cleavage in the mid-epidermis with minimal associated inflammation. In TEN, cleavage occurs at the dermo-epidermal junction and there is cellular necrosis of the epidermis. TEN can also be distinguished clinically by the presence of mucosal involvement, a finding that is not seen in SSSS. Pemphigus foliaceus, an autoimmune blistering disorder caused by autoantibodies against desmoglein-1, can be difficult to distinguish both clinically and by routine histology [44,45]. Direct immunofluorescence will demonstrate anti-desmoglein antibodies in the epidermis of pemphigus foliaceus patients [47].

Treatment of generalized SSSS is with intravenous antibiotics targeting penicillin-resistant *S. aureus*. Aminoglycosides may be added if there are signs of secondary infection. Analgesia, fluid resuscitation, and wound care are other key elements of treatment. Use of steroids is contraindicated [44,45].

Exfoliation continues for 24 to 48 hours after institution of appropriate antibiotics. MRSA must be considered in any patient not responding to therapy after this time. Although the disease is rarely fatal in children, mortality in adults, even with treatment, is upward of 50% to 60%, when there are serious underlying medical conditions [44,45].

Meningococcemia

Neisseria meningitidis is a major cause of meningitis and sepsis in the United States, with an annual incidence of approximately 1 in 100,000. Meningococcal disease is often rapidly fatal due to shock and multiorgan failure. The majority of cases occur in winter and early spring. Infants and teenagers have the highest rates of infection. Meningococcal disease often occurs in localized outbreaks such as in schools or military barracks [48]. Most affected patients are previously healthy, but those with HIV, immunoglobulin deficiencies, asplenia, or inherited and acquired deficiencies of terminal complement components C5–C9 are at increased risk [48,49].

N. meningitidis is an aerobic gram positive diplococcus that only infects humans. Thirteen serotypes have been identified, of which groups A, B, C, Y, and W-135 are the major pathogens. A vaccine against types A, C, Y, and W-135 is in use for high-risk individuals. The bacteria inhabit the respiratory mucosa and are spread person to person through respiratory secretions. They possess virulence factors that allow invasion through the respiratory epithelium and into the bloodstream. There, they damage endothelium directly and release lipopolysaccharide endotoxin, which provokes massive release of tumor necrosis factor alpha, interleukins-1 and –6, and interferon-gamma. These cytokines promote vascular permeability, hypotension, and eventually multiorgan failure and disseminated intravascular coagulation [48,49].

FIGURE 195.5. Meningococcemia. Purpuric papules and plaques, some of which have a dusky or gunmetal gray center.

Meningococcal disease may present in mild cases as a viral syndrome with fever, headache, nausea, vomiting, and arthralgias, but in fulminant cases, patients are severely ill with high fever, hypotension, and a hemorrhagic rash. Half of the cases will have meningitis with headache, stiff neck, and photophobia. Cutaneous findings are prominent in as many as 60% of patients with meningococcemia, with petechiae or purpura beginning at points of pressure on the trunk and extremities, but spreading to involve any body area. Urticarial and maculopapular lesions may also be observed early in the clinical course. As meningococcemia progresses, large areas of irregular gunmetal gray hemorrhage and necrosis may develop (Fig. 195.5) due to disseminated intravascular coagulation. In 10% to 20% of children with meningococcemia, purpura fulminans in combination with multiorgan failure and adrenal hemorrhage, the Waterhouse–Friderichsen syndrome, may occur [50].

The differential diagnosis of meningococcemia includes Rocky Mountain spotted fever, leukocytoclastic vasculitis, toxic shock syndrome, erythema multiforme, and other forms of bacterial sepsis. Diagnosis is usually based on blood or cerebrospinal fluid cultures, and in cases of meningococcal meningitis, gram staining of CSF is up to 90% sensitive. Newer polymerase chain reaction (PCR) tests for meningococcus are available, including the IS-1106, nspA, and ctrA TaqMan tests

[50,51]. Because meningococcal sepsis progresses rapidly and has a case fatality rate of up to 40%, treatment should never be delayed pending diagnosis.

Prompt treatment with an appropriate antibiotic is critical in treating meningococcal disease. First line treatment in adults 18 to 50 years of age is a broad-spectrum cephalosporin, such as ceftriaxone (2 g IV q12 hours). In adults over 50 years of age, ampicillin is given concomitantly. Once the diagnosis of meningococcemia is confirmed, patients in the United States may be switched to penicillin G (4 million units IV Q 4 hours), as penicillin-resistant strains have not been identified there [50]. Intensive supportive care with intravenous fluids, pressors, and ventilatory support is usually needed. Prognosis for untreated cases is very poor, with 70% dying before antibiotics were available. Overall case fatality of meningococcal disease is now around 10%, though it remains 40% for those with sepsis. Up to 19% of survivors have severe sequelae such as deafness or loss of a limb [48].

Rocky Mountain Spotted Fever

Rocky Mountain spotted fever (RMSF) is a life-threatening tick-borne febrile illness caused by the intracellular pathogen, *Rickettsia rickettsi*. Despite its name, RMSF is most commonly reported in the Southeast to Midwest states. Cases occur most often in the summer months, when humans are most likely to be exposed to ticks. RMSF is a rare disease, with an annual incidence of 2.2 cases per million [52]. The disease is most common in children, due to the relatively large amount of time they spend outdoors, where they are exposed to ticks.

RMSF is caused by *R. rickettsi*, a pleomorphic coccobacillary obligate intracellular parasite, which is transmitted to humans by the American dog tick (*Dermacentor variabilis*) in the Eastern United States and the wood tick (*Dermacentor andersoni*) in the mountain West.

R. rickettsi infects vascular endothelium and smooth muscle cells where it can replicate and spread to other cells, causing vascular and tissue injury. Vasculitis may occur in the gastrointestinal tract, lungs, kidneys, liver, heart, brain, and skin, leading to multiorgan failure. In addition, *R. rickettsi* promotes the coagulation cascade, leading to hypercoagulability and thrombocytopenia.

Most patients with RMSF present within 14 days of a tick bite with fever and severe headache. Rash usually occurs 2 to 5 days later. Roughly half of all patients will present with the classic triad of fever, rash, and headache. The rash of RMSF is initially blanching pink to red macules on the wrists and ankles, spreading to the palms and soles and then to the arms, legs, and trunk. The face is usually spared. Over several days, the rash becomes purpuric with areas of hemorrhage and necrosis [53]. In addition to fever and headache, patients frequently present with abdominal pain, nausea and vomiting, myalgias, and shortness of breath. Respiratory failure, myocardial edema, renal failure, liver dysfunction, and altered mental status may occur [54].

The differential diagnosis of RMSF includes other febrile illnesses with rash, such as ehrlichiosis, meningococcemia, toxic shock syndrome, measles, drug fever, idiopathic thrombocytopenic purpura, and various viral syndromes. In cases where no rash occurs, the differential diagnosis would include appendicitis, gastroenteritis, and other causes of acute abdomen. Several diagnostic tests are helpful, but in no case should treatment be delayed pending results once RMSF is suspected. The indirect fluorescent antibody test for *R. rickettsi* is 94% sensitive and specific but requires 7 to 14 days to become positive. Skin biopsy shows a lymphohistiocytic vasculitis with extravasation of red blood cells and occasional fibrin thrombi. *R. rickettsi* may be identified intracellularly by Giemsa staining. Nonspecific laboratory findings include thrombocytopenia and elevated transaminases.
