Seizures are often refractory to most conventional anticonvulsants [41]. Diazepam appears to be the most effective single agent, but its efficacy may be limited and large doses may be required. Animal data suggest sodium valproate may be effective [42]. Pyridoxine has dose-related effectiveness against convulsions and prevents lethality at doses from 75 to 300 mg per kg in canine models of INH toxicity [43]. In animal studies, when single-anticonvulsant regimens of pyridoxine, phenobarbital, pentobarbital, phenytoin, and diazepam were compared with the latter four anticonvulsants in combination with pyridoxine; pyridoxine was the only single agent that reduced the severity of convulsions and prevented death [41,43]. The combination of each of the other anticonvulsants with pyridoxine also prevented both convulsions and death. Therefore, pyridoxine, in conjunction with a benzodiazepine such as diazepam or lorazepam, is the preferred treatment for neurologic toxicity.

Intravenous pyridoxine therapy should be administered at the first sign of neurologic toxicity in milligram doses equal to the amount of INH ingested [8,10,44]. INH-overdosed patients treated with such pyridoxine doses exhibited no recurrent seizure activity, a decreased duration of coma, and prompt resolution of their metabolic acidosis [13]. If the amount of INH ingested is unknown, at least 5 g of pyridoxine should be administered [8,10]. In patients without seizures, the pyridoxine dose may be administered over 30 to 60 minutes. In those with seizure activity, it may be given as a bolus during 3 to 5 minutes. The pyridoxine dose should be repeated if seizures persist or recur. Intravenous diazepam or lorazepam should also be given [8,41]. As inadequate intravenous stores of pyridoxine in treating facilities have recently been documented, oral high-dose pyridoxine may be tried in the same doses as intravenous pyridoxine [45,46]. Seizures refractory to pyridoxine and diazepam have been successfully treated with thiopental-induced coma [47]. Reversal of prolonged INH-induced coma has been temporally associated with pyridoxine therapy [48].

Treatment of metabolic acidosis should be guided by arterial blood gas and electrolyte measurements. In most cases, intravenous sodium bicarbonate will not correct acid–base abnormalities until seizure activity is terminated [13]. Bicarbonate should be considered if the serum pH is lower than 7.2 or if the acidosis does not rapidly resolve after seizure control.

The role of forced diuresis in the management of INH overdose is unclear. Large amounts of INH recovered in the urine of some patients (43% to 58% of ingested doses) are offset by those reporting minimal recovery (6 to 144 mg) [11,49,50]. Peritoneal dialysis is somewhat effective but inefficient, whereas exchange transfusion is ineffective [49,51]. Hemodialysis and charcoal hemoperfusion increase the clearance of INH and decrease its half-life by 50%, but they have not been reported to remove significant quantities of INH (90 to 340 mg) [50,52].

Considering the rapid elimination half-life of INH and the efficacy of pyridoxine and benzodiazepine therapy, measures to enhance INH elimination are of limited use in the routine management of INH toxicity. However, patients with intractable acid–base disturbances, persistent seizures, or liver or renal dysfunction should be considered candidates for hemodialysis or charcoal hemoperfusion (if available). Unless the patient has experienced significant anoxia as a result of coma or seizures, neurologic recovery may be expected within 24 to 48 hours.

Prevention of peripheral neuropathy during chronic INH therapy can be accomplished by the administration of pyridoxine, 15 to 50 mg per day, in high-risk patients [19]. Peripheral neuropathy that develops during INH therapy is generally reversible on withdrawal of INH and treatment with high-dose pyridoxine (100 to 200 mg per day) [19]. However, the neuropathy may take months to a year or more to resolve, and in some cases, it may be permanent.

The management of INH-induced hepatotoxicity includes supportive care and cessation or reduction of INH administration. It is recommended that INH be discontinued in patients whose transaminase concentrations have risen to three times the upper limit of normal in the presence of jaundice or hepatitis symptoms or greater than five times the upper limit of normal if asymptomatic [27,30].

CHAPTER 138 ■ LITHIUM POISONING

KENT R. OLSON AND THANJIRA JIRANANTAKAN

Lithium was introduced in the nineteenth century for the treatment of gout. Apparently, toxicity was rarely encountered because of low recommended doses. In the 1940s, lithium chloride was briefly marketed as a salt substitute, but was withdrawn after several cases of serious intoxication and death resulted from its use. In 1949, its antimanic properties were reported, and lithium has found increasingly wide psychiatric use since its approval by the U.S. Food and Drug Administration in 1970 [1,2].

In patients with mania, lithium reduces hyperactivity, irritability, pressured speech, assaultive behavior, and sleeplessness. These effects may require several days of therapy, during which time alternate medications are used. Lithium is very effective in reducing the recurrence of episodes of manic–depressive bipolar disorder and is used to treat some patients with unipolar depression and schizophrenia. It induces neutrophilia (up to 1.5 to 2.0 times the normal leukocyte counts) by enhanced production of G-CSF (granulocyte colony-stimulating factor) and stimulation of pluripotential stem cell production. Lithium has been used to treat a variety of causes of neutropenia [1,3,4].

Lithium is available in conventional tablets or capsules containing 300 mg (8.12 mEq) of lithium carbonate or in sustained-release preparations containing 450 mg (12.18 mEq) of lithium carbonate. Liquid solutions of lithium citrate containing 8 mEq per 5 mL are also available [3].

PHARMACOLOGY

Lithium is the lightest alkali metal, occupying the same column in the periodic table as sodium and potassium, elements with which it shares some properties. However, it has no known normal physiologic role. The exact mechanisms of its therapeutic and toxic effects remain to be determined. Lithium affects ion transport and cell membrane potential by competing

with sodium and potassium and possibly other cations. However, unlike sodium and potassium, lithium does not produce a large distribution gradient and, therefore, cannot maintain a significant membrane potential. It is believed to enhance serotonin and acetylcholine effects, resulting in an indirect effect on the central nervous system (CNS). In addition, its inhibitory effects on second messengers, such as inositol phosphates, may reduce neuronal responsiveness to some neurotransmitters [1].

Lithium is readily absorbed from the gastrointestinal tract. The bioavailability of conventional tablets and capsules and the liquid solution is 95% to 100%; bioavailability is not affected by food. Normally, absorption is complete within 1 to 6 hours; peak levels are reached in 2 to 4 hours [1,3]. Sustained-release preparations are less predictably absorbed (60% to 90%), and peak levels may be delayed by more than 4 to 12 hours [3]. Overdose has resulted in delayed peak levels or secondary peak levels as long as 148 hours after ingestion [5]. In one case, esophagoscopy at 84 hours revealed a 5- to 6-cm tablet and hair bezoar in the stomach [6].

Lithium initially occupies an apparent volume of distribution of 0.3 to 0.4 L per kg (approximately that of intracellular water), but further distribution into various intracellular tissue compartments occurs during 6 to 10 hours, with the final volume of distribution being 0.7 to 1.0 L per kg. This explains why initial serum lithium levels may be very high, with few or no signs of toxicity. After a single dose, the equilibrium serum lithium concentration can be expected to increase by 1.0 to 1.5 mEq per L for each 1.0 mEq of lithium per kilogram of body weight. Steady-state tissue levels are achieved after 3 to 4 days of the therapy. Tissue distribution is uneven; whereas the cerebrospinal fluid lithium concentration is only 40% to 60% that of plasma, the saliva concentration may be two to three times greater than that of plasma. Lithium is not bound to serum proteins and freely crosses the placenta [1,3].

Lithium is not metabolized. More than 95% of absorbed lithium is excreted by the kidneys, with 4% to 5% eliminated in sweat and 1% in the feces. It is also excreted in breast milk. Eighty percent of renally filtered lithium is reabsorbed in the proximal tubule against a concentration gradient that does not distinguish lithium from sodium. Sodium depletion can result in as much as a 50% increase in lithium reabsorption. The usual renal clearance is 10 to 40 mL per minute, but it may be 10 to 15 mL per minute or less in the elderly and in patients with renal dysfunction or dehydration [3,7,8]. However, lithium excretion rate may be different in different types of renal failure. Some study demonstrated increased fractional excretion of lithium in patients with prerenal failure, but decreased fractional excretion in acute tubular necrosis (ATN) renal failure [9]. The elimination half-life averages 20 to 24 hours; in patients with chronic intoxication, it may be as long as 47.6 hours [10]. The very slow terminal elimination phase may last up to 10 to 14 days because of gradual lithium release from tissue storage sites such as a bone and the brain [1].

Therapeutic serum lithium concentrations are usually considered to be 0.80 to 1.25 mEq per L; prophylaxis against recurrent manic–depressive illness may be achieved with levels of 0.75 to 1.00 mEq per L. Drug levels should be drawn at least 10 to 12 hours after the last dose to allow for complete tissue distribution. Onset of therapeutic effects usually requires 5 to 21 days after initiation of daily drug administration. Therapeutic levels are achieved by administration of 600 to 1,200 mg of lithium carbonate (16 to 32 mEq of lithium) per day. Careful monitoring of lithium levels is essential because of its low toxic-to-therapeutic ratio [3].

Lithium intoxication primarily involves the CNS and kidneys, although a variety of other organ systems are also affected (Table 138.1). Lithium intoxication may follow an acute overdose or result from chronic accumulation because of either an increase in dosage or a decrease in lithium elimination by the kidneys. Most serious toxicity occurs in patients with chronic intoxication, especially in older patients and patients with renal insufficiency [11].

TABLE 138.1

COMMON FEATURES OF LITHIUM INTOXICATION

Feature	Number	Percentage of total
Confusion	19[a]	68
Agitation	17	61
Drowsiness	16[a]	57
Mutism	5	18
Coma (grades III–IV)	1	4
Convulsions	4	14
Hyperreflexia	22	79
Increased tone	16	57
Ankle clonus	4	14
Extensor plantar responses	3	11
Tremor	18	64
Ataxia	14	50
Dysarthria	10	36
Myoclonus	7	25
Vomiting	7	25
Diarrhea	4	14
Acute diabetes insipidus	3	11
Acute renal failure	2	7

[a]Excludes one patient who also took temazepam in overdose.
Reprinted from Dyson EH, Simpson D, Prescott LF, et al: Self-poisoning and therapeutic intoxication with lithium. *Hum Toxicol* 6:326, 1987, with permission.

Acute ingestion of at least 1 mEq per kg (40 mg per kg of lithium carbonate) in a person not previously taking lithium would be required to produce a potentially toxic serum lithium level. The acute toxic dose in a patient already taking lithium ("acute-on-chronic" overdose) depends on the prior lithium level (due to tissue soaking). The dose required to produce chronic intoxication depends on the individual's rate of renal elimination of lithium.

CLINICAL MANIFESTATIONS

Signs and symptoms of mild lithium intoxication include nausea, vomiting, lethargy, fatigue, memory impairment, and fine tremor. Moderate signs and symptoms of toxicity include confusion, agitation, delirium, coarse tremor, hyperreflexia, hypertension, tachycardia, dysarthria, nystagmus, ataxia, muscle fasciculations, extrapyramidal syndromes, and choreoathetoid movements. Patients with severe toxicity may also exhibit bradycardia, complete heart block, Brugada syndrome, coma, seizures, nonconvulsive status epilepticus, hyperthermia, neuroleptic malignant syndrome, serotonin syndrome, and hypotension [12–15]. Permanent sequelae include choreoathetosis, tardive dystonia, tremor, peripheral neuropathy, scanning speech, dysarthria, muscle rigidity, cognitive deficits, nystagmus, and ataxia [16–20].

Neurotoxic effects of lithium usually develop gradually and may become progressively severe over several days. Neurologic manifestations may worsen even as serum lithium levels are falling and may persist for days to weeks after cessation of the therapy, in part because of slow movement of lithium into and out of intracellular brain sites and possibly brain damage, such as demyelination caused by lithium [19].

Cardiovascular manifestations are nonspecific. The electrocardiogram changes are often similar to those seen with hypokalemia and may result from displacement of intracellular

potassium by lithium; U waves and flattened, biphasic, or inverted T waves can be seen with therapeutic doses and mild overdoses. Sinus and junctional bradycardia, sinoatrial and first- degree AV block, and QRS and QTc interval prolongation may be seen with severe intoxication [20,21]. Life-threatening dysrhythmias are rare. Patients with complete heart block during lithium treatment have been reported [12,13]. This lithium-associated cardiac toxicity is more common in patients older than 65 years with baseline EKG abnormalities, conduction abnormalities, use of renal toxic medication, and concomitant use of AV nodal–blocking agents [13]. Brugada syndrome precipitated by lithium has been reported [14]. Pulse and blood pressure abnormalities may be seen in moderate or severe poisoning, but they are usually not pronounced. Hypotension is more often due to dehydration, which can be a cause and a complication of lithium intoxication, than direct cardiotoxicity [20,21].

Chronic lithium therapy has several important effects on renal function, including impaired urinary concentrating ability, nephrogenic diabetes insipidus (NDI), and a sodium-losing nephritis [2]. These effects appear to be dose related and usually correct within several weeks of discontinuing the therapy [20]. Excessive water and sodium loss lead to increased proximal tubular reabsorption of lithium by transport mechanisms designed for sodium reabsorption. The accumulation of lithium may be enhanced by illnesses that result in decreased glomerular filtration rate, such as fever with sweating, gastroenteritis, and heart failure, or by diuretic drugs that enhance distal tubular sodium and fluid loss. Rising lithium levels may further aggravate nephrotoxicity. A patient who has remained stable with a satisfactory lithium serum level at a constant daily dosage for years may suddenly develop life-threatening intoxication within days of entering such a vicious cycle [2].

Metabolic abnormalities associated with lithium use include hypercalcemia, hypermagnesemia, nonketotic hyperglycemia, transient diabetic ketoacidosis, and goiter. Hypothyroidism is rare [20].

Lithium is teratogenic in rats, mice, and rabbits, and human fetal malformations have been described, including cardiac defects such as Ebstein's anomaly [22].

Several drugs may interact with lithium to alter its pharmacokinetics or directly enhance its toxicity. Diuretics may promote fluid and sodium depletion, leading to enhanced tubular lithium reabsorption. This effect appears to be much less apparent with furosemide than with thiazide diuretics. Aminophylline, urea, bicarbonate, and acetazolamide may decrease serum lithium levels by increasing the glomerular filtration rate. Nonsteroidal anti-inflammatory drugs, including the selective cyclooxygenase-2 inhibitor rofecoxib [23], may decrease the glomerular filtration rate and lithium elimination. Antipsychotic medications may have additive CNS depressant effects; in addition, lithium may enhance their dopamine-blocking and serotonergic effects and induce or aggravate rigidity and hyperthermia, possibly inducing neuroleptic malignant syndrome and serotonin syndrome [15,20]. Angiotensin-converting enzyme inhibitors (ACEIs) increase steady-state lithium concentrations by 36.1% and reduced lithium clearance by 25.5% resulting patients presented with lithium toxicity [24].

DIAGNOSTIC EVALUATION

The history should include the type of lithium preparation ingested, the amount(s) and time(s) of ingestion, and the nature of the symptoms. It is important to differentiate patients with acute lithium overdose from those with chronic intoxication resulting from excessive daily doses or impaired renal elimination.

The physical examination should focus on the vital signs, neurologic function, and cardiovascular status. All patients should have an electrocardiogram and laboratory evaluation, including serum electrolytes, glucose, blood urea nitrogen, creatinine, and serum lithium level. Lithium levels should be repeated at frequent (i.e., 2- to 4-hour) intervals after acute overdose until peak levels are observed. If the levels are elevated, they should be repeated until they fall below the toxic range and the patient becomes asymptomatic. Electroencephalography should be considered in patients who presented with coma to evaluate nonconvulsive status epilepticus [15].

Patients with chronic intoxication are typically brought to medical attention by a family member or therapist because of neurologic symptoms. There is usually a recent history of excessive fluid loss caused by gastroenteritis, other flulike illness, or excessive urination. The severity of chronic intoxication generally correlates with the serum lithium level [2,20]. In patients undergoing chronic therapy, mild neurotoxic effects may occur with serum lithium concentrations of less than 1.5 mEq per L. Steady-state concentrations of 1.5 to 3.0 mEq per L are associated with mild or moderate toxicity. Severe poisoning and death may occur with serum concentrations greater than 3 to 4 mEq per L [2,10,20].

After acute overdose, the predominant initial symptoms are nausea and vomiting [2]. Patients do not usually have significant neurologic manifestations despite high serum lithium levels during the first 12 hours or more after ingestion because lithium is taken up slowly by the brain and other tissues [10]. Serum lithium concentrations as high as 10.6 mEq per L without significant toxicity have been reported after acute overdose [25–27]. However, intoxication may develop during the subsequent 24 to 48 hours, even as serum levels fall [19,20,28]. Levels drawn shortly after acute or acute-on-chronic overdose cannot be used reliably to predict toxicity or guide therapy (Fig. 138.1) [2,10]. There does not appear to be any clinical variable that accurately predicts which patients will deteriorate. The use of cerebrospinal fluid levels to estimate brain concentrations more closely has been advocated [29]. However, cerebrospinal fluid concentrations do not reflect intracellular brain tissue levels or predict the level of coma (Fig. 138.2) [2,25,30].

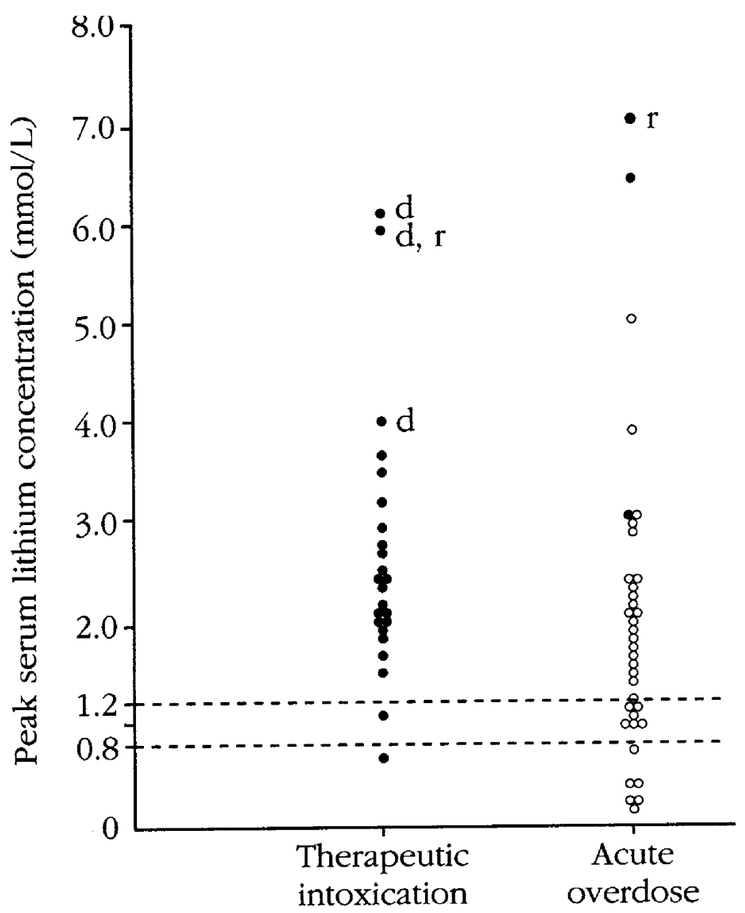

FIGURE 138.1. Lack of correlation between serum levels and toxic manifestations in patients with acute intoxication. d, diabetes insipidus; r, renal failure. [Reprinted from Dyson EH, Simpson D, Prescott LF, et al: Self-poisoning and therapeutic intoxication with lithium. *Hum Toxicol* 6:326, 1987, with permission.]

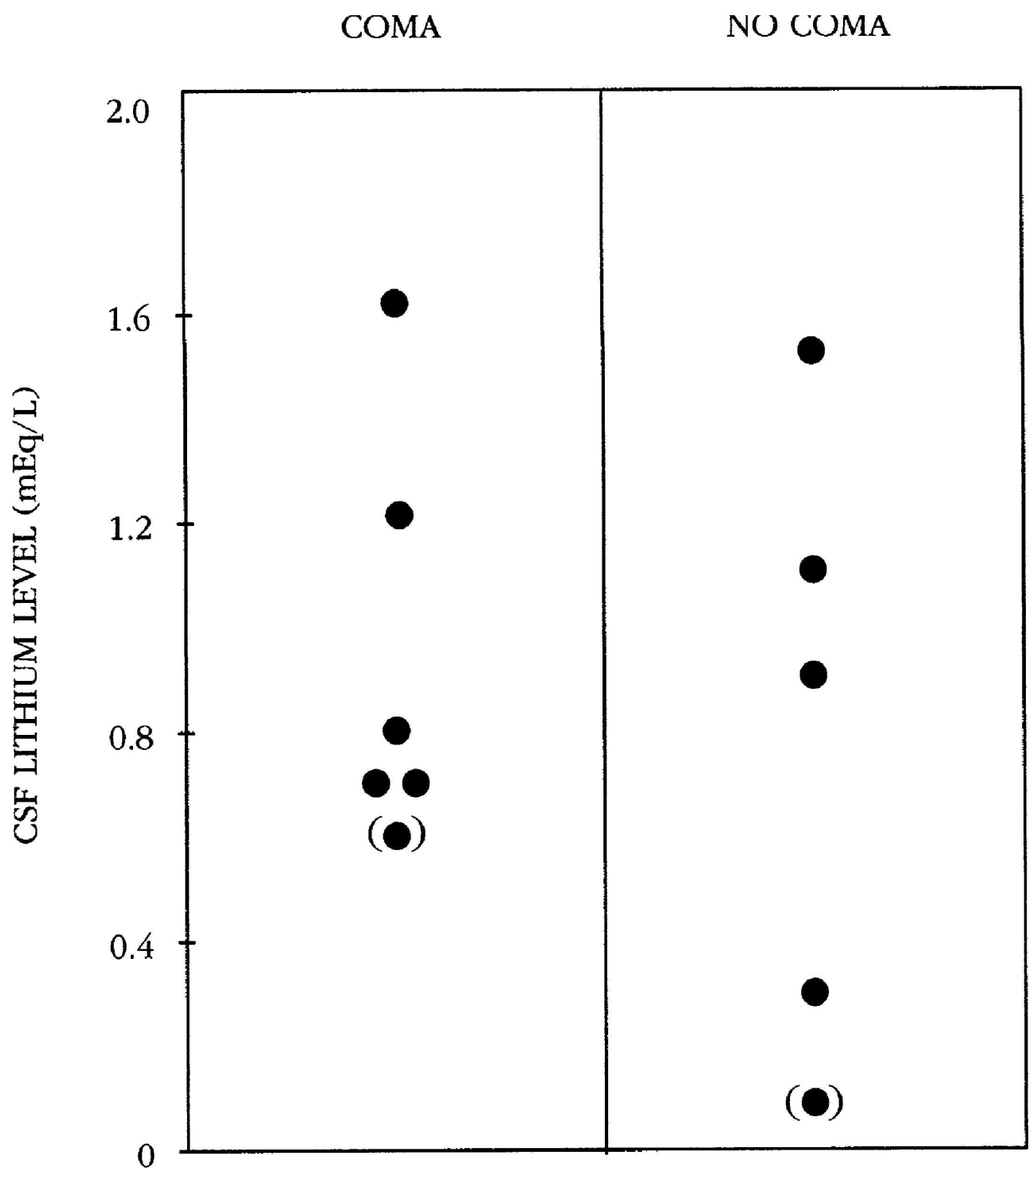

FIGURE 138.2. Cerebrospinal fluid (CSF) levels in patients with and without coma. [Reprinted from Lee BL, Brown CR, Becker CE, et al: Lithium overdose: factors that predict outcome in poisoned patients. *Vet Hum Toxicol* 28:505, 1986, with permission.]

Patients with acute-on-chronic overdose usually have a clinical course similar to those with acute ingestions. However, a smaller total dose may produce severe intoxication, depending on the preingestion therapeutic serum level.

Elevated blood urea nitrogen and creatinine reflect renal insufficiency and suggest that intoxication results from gradual accumulation of lithium rather than acute ingestion. Elevated creatinine may also be caused by cross-reactivity of the assay with creatine from muscle destruction and should prompt the measurement of serum creatine phosphokinase and urinalysis for myoglobinuria.

Patients with lithium-induced NDI usually have dilute urine with a low-measured osmolality relative to serum. The diagnosis is confirmed by lack of response to administered vasopressin by the inappropriately dilute urine [16].

Leukocytosis may be seen in patients taking lithium. It is a nonspecific finding and does not reflect severity of intoxication. A reduced or absent anion gap may occur with severe lithium carbonate intoxication [31], probably because the carbonate anion (but not the lithium cation) is measured and used in calculating the anion gap [32].

Plain radiographs of the abdomen may or may not reveal radiopaque lithium tablets after acute ingestion. A negative radiograph should not be used to rule out acute ingestion [33].

Conditions such as hypoxia, hypoglycemia, hypothermia or hyperthermia, electrolyte disturbances, CNS infection, head trauma, and intracranial bleeding should be included in the differential diagnosis of patients with lithium poisoning. In a patient with hyperthermia and rigidity who is also taking antipsychotic medications, neuroleptic malignant syndrome and serotonin syndrome should be considered (see Chapter 68). Other drug intoxications should be considered (see Chapter 68), especially if CNS symptoms appear shortly after an acute overdose.

MANAGEMENT

In patients with altered mental status, initial management should include (a) assessment and stabilization of the airway; (b) administration of oxygen; (c) assisted ventilation, if needed; (d) vascular access; and (e) administration of dextrose, naloxone, and thiamine. Diazepam or barbiturates should be administered to patients with seizures. Patient with nonconvulsive status epilepticus should be monitored by electroencephalography to confirm the resolution of seizure activity. If hyperthermia is present, immediate cooling measures should be instituted, including tepid sponging and fanning and neuromuscular paralysis, if needed. Hypovolemia, if present, should be treated with intravenous crystalloids. Cardiac dysrhythmias do not usually require treatment, but should respond to usual agents.

Asymptomatic patients with acute or acute-on-chronic overdose should be observed for a minimum of 6 hours after ingestion. Serial lithium levels should be obtained to confirm lack of significant absorption. Patients with mild overdoses can often be monitored and treated in the emergency department. Symptomatic patients, patients with a massive acute ingestion, and those whose levels continue to rise beyond 6 hours after ingestion should be admitted to an intensive care setting.

Lithium-induced NDI does not respond to vasopressin, but it has been reported to improve with hydrochlorothiazide, amiloride, carbamazepine, and indomethacin [20]. However, the gradual onset and the duration required of hydrochlorothiazide, carbamazepine, and amiloride therapy would limit their clinical usefulness. One case report suggests indomethacin may be acutely effective in treating lithium-induced NDI [34].

After acute ingestion, the gastrointestinal tract should be decontaminated as soon as possible to prevent continued absorption of lithium. Ipecac-induced emesis is not recommended because it yields poor return of gastric contents [35]. Gastric lavage can be performed, although there is little evidence for benefit [36]. Activated charcoal does not effectively bind lithium and should be given only if coingestion of another drug is suspected [37]. Whole-bowel irrigation (see Chapter 117) has been successful for large ingestions, especially if they involve sustained-release tablets [38]. If a tablet mass or concretion is suspected because of sustained high levels after 2 to 3 days, radiographic contrast studies, ultrasound, or gastroduodenal endoscopy and endoscopic removal should be considered [6]. Preliminary evidence in animals and human volunteers suggests that sodium polystyrene sulfonate (Kayexalate) binds lithium and may enhance its elimination [39,40]. One case report describes its use in a patient with acute-on-chronic lithium overdose [41]. There is no consensus at this point as to whether the administration of potassium with the polystyrene sulfonate enhances or decreases lithium excretion.

In most patients with mild or moderate intoxication, intravenous fluid therapy is effective in restoring and maintaining renal elimination of lithium. A crystalloid solution (half-normal or normal saline) aiming for urine output of 1 to 3 mL per kg per hour should be administered after an initial saline bolus (10 to 20 mL per kg), depending on the degree of dehydration. Serum electrolytes should be followed closely because hypernatremia may occur. To estimate the effectiveness of renal elimination, the lithium clearance can be estimated by obtaining simultaneous urine and serum lithium levels [42]:

Approximate renal lithium clearance = urine flow rate (mL/min) × urine lithium (mEq/L) / serum lithium (mEq/L).

Normal lithium clearance is 10 to 40 mL per minute. If the clearance is below normal in a patient without underlying cardiac or renal dysfunction, the rate of fluid administration should be increased because this suggests low renal perfusion secondary to dehydration. In human studies, water loading,

furosemide, thiazide, ethacrynic acid, ammonium chloride, and spironolactone did not increase lithium clearance. Sodium bicarbonate, acetazolamide, urea, and aminophylline were effective. However, clinical studies in patients with lithium intoxication treated by these agents have not been reported [7].

Hemodialysis is the most efficient method for removing lithium, achieving clearance rates of up to 100 to 150 mL per minute [2,30,42]. However, lithium is only slowly removed from intracellular tissue compartments, especially the brain, and rebound increases of serum lithium levels often occur within several hours after dialysis. Hemodialysis should be repeated frequently until the serum level drawn 6 to 8 hours after the last dialysis is 1 mEq per L or less [2]. However, despite repeated dialyses, patients with significant neurologic toxicity do not promptly improve. Recovery, if it occurs, may take several days to weeks [2,29,30].

The indications for hemodialysis are not well established. It is generally agreed that patients with severe clinical toxicity and those with renal dysfunction should undergo dialysis. Asymptomatic patients or those with mild-to-moderate intoxication who are otherwise healthy may be managed with intravenous fluids as long as they remain clinically stable or are improving and satisfactory lithium clearance (> 15 to 20 mL per minute) is achieved. Patients with chronic serum levels exceeding 2.5 mEq per L accompanied by symptoms and those with acute poisoning and peak levels exceeding 10 mEq per L (in which significant toxicity is expected to occur with subsequent tissue distribution) should also be considered for hemodialysis. However, some clinicians advocate hemodialysis for patients who have acute ingestion without prior lithium body burden and a serum lithium concentration greater than 4 mEq per L [43].

Continuous renal replacement therapy (e.g., venovenous or arteriovenous hemodiafiltration) has been reported to successfully remove lithium without the need for hemodialysis [44–47]. In one case, 14 hours of continuous arteriovenous hemodiafiltration was estimated to achieve lithium elimination equivalent to 5.75 hours of hemodialysis [48]. In another case report, clearances of up to 38 mL per minute were achieved with continuous venovenous hemodiafiltration [46]. Continuous renal replacement therapy removes lithium slowly, without rebound rises in levels seen with intermittent hemodialysis, and can also be performed in facilities without full dialysis capabilities.

CHAPTER 139 ■ METHYLXANTHINE POISONING

MICHAEL W. SHANNON†

The methylxanthines most commonly used in the clinical setting are theophylline and its ethylenediamine salt, aminophylline. Until recently, theophylline was used exclusively as a bronchodilator for the management of reversible obstructive pulmonary diseases and as a respiratory stimulant for the treatment of apnea of prematurity in neonates. During the 1980s, its use fell dramatically as more effective therapies for recurrent bronchospasm became available [1]. However, there has been renewed interest in theophylline as the scope of its pharmacologic benefits broadens. Potential uses for theophylline now include preconditioning of cardiac ischemia [2], treatment of bradycardia [3], amelioration of perinatal asphyxia [4], acute mountain sickness [5], bradycardia after spinal cord injury [6], protection from contrast-induced nephropathy [7], and treatment of attention-deficit hyperactivity disorder [8]. Recent clinical trials of theophylline for asthma have demonstrated substantial benefit, restoring interest in the drug for this indication [9–16]. Despite its renewed popularity, theophylline, with its potent pharmacologic actions, variable metabolic disposition in humans, and narrow therapeutic-to-toxic ratio, is a common cause of intoxication [1,17].

Caffeine and theobromine are other widely used methylxanthines. Caffeine is found in many pharmaceutical preparations (e.g., antisleep drugs), as well as in dietary supplements, including guarana and kola nut. Although severe toxicity from caffeine ingestion is uncommon, case reports of serious poisoning in children and adults are well documented [18–20]. Because caffeine and other xanthine derivatives are structurally similar to theophylline, signs and symptoms of toxicity resemble those seen in theophylline intoxication, and the approach to management is identical.

Three clinical circumstances account for most cases of theophylline poisoning: unintentional ingestions by children, intentional ingestions (suicide attempts) by adolescents or adults, and medication errors (miscalculation of dose, change in frequency of administration, lack of serum drug level monitoring, or an unrecognized drug–drug or drug–disease interaction) [1,21,22]. Most cases of theophylline intoxication result from chronic, unintentional overmedication.

PHARMACOLOGY

Theophylline is available commercially as a liquid, tablet, sustained-release capsule, or solution for intravenous administration. Overdose of sustained-release theophylline can lead to a marked delay in complete absorption, with peak serum theophylline concentrations occurring as long as 15 to 24 hours after ingestion [23]. Therapeutic serum theophylline concentrations range from 10 to 20 µg per mL.

A loading dose of 5 to 6 mg per kg of intravenous aminophylline should produce a serum theophylline level of 10 µg per mL in patients not currently taking theophylline. Maintenance dosages vary with age and underlying conditions (Table 139.1). For patients taking theophylline regularly, a loading dose increases the steady-state serum theophylline level. Typically, administration of 1 mg per kg of theophylline raises the serum drug concentration by 2 µg per mL. This relationship can also be used to predict the theophylline concentration after an overdose; the maximum possible drug concentration (in micrograms per milliliter) should be no more than twice the ingested or administered dose (in milligrams per kilogram).

Theophylline has a volume of distribution of 0.4 L per kg and is 40% to 65% bound to plasma proteins [24]. Its metabolism is almost exclusively by hepatic cytochrome P450 system; it is oxidized or demethylated in the liver by at least two isoenzymes (CYP1A2 and CYP3A4) [24]. Less than 15% of the drug is excreted unchanged in urine. At therapeutic doses, hepatic metabolism generally occurs by first-order elimination kinetics [25]. The drug exhibits saturable (Michaelis–Menten) kinetics in overdose leading to prolonged, unpredictable elimination rates. The elimination half-life of theophylline also varies widely with age: typical half-lives are 20 to 30 hours in

TABLE 139.1

INTRAVENOUS AMINOPHYLLINE MAINTENANCE DOSES

Age group	Infusion rate (mg/kg/h)
Newborn	0.3–0.4
1–6 mo	0.5–0.6
6 mo–9 y	1.0–1.2
9–16 y	0.9–1.1
Smoker age 12–50 y	1.0
Nonsmoker age 16–50 y	0.5–0.7
Older than 50 y	0.4–0.6
Cor pulmonale	0.3–0.5
Liver failure	0.1–0.5
Congestive heart failure	0.1–0.5

† Deceased.

TABLE 139.2

FACTORS AFFECTING SERUM THEOPHYLLINE CONCENTRATIONS

Drugs that *increase* theophylline clearance
- Barbiturates
- Carbamazepine
- Cigarette smoke
- Phenytoin
- Rifampin

Drugs that *decrease* theophylline clearance
- Cimetidine
- Ciprofloxacin
- Clarithromycin
- Fluvoxamine
- Erythromycin
- Norfloxacin
- Ofloxacin
- Zafirlukast

Conditions that *increase* theophylline clearance
- Cigarette smoking
- Cystic fibrosis
- Hyperthyroidism

Conditions that *decrease* theophylline clearance
- Hepatitis/cirrhosis
- Congestive heart failure
- Some viral infections

TABLE 139.3

PHYSIOLOGIC EFFECTS OF THEOPHYLLINE

Central nervous system
- Stimulation of cortical centers
- Stimulation of medullary respiratory center
- Nausea and emesis
- Cerebral vasoconstriction and decreased cerebral blood flow

Cardiovascular
- Positive inotropic and chronotropic effects
- Vascular smooth muscle relaxation

Pulmonary
- Bronchial smooth muscle relaxation
- Increased ventilation
- Stimulation of diaphragmatic and intercostal muscles

Gastrointestinal
- Increased gastric acid and pepsin secretion
- Relaxation of esophageal smooth muscle and possible reflux

Renal
- Increased blood flow and glomerular filtration rate
- Increased diuresis (< 48 h)

Endocrine
- Increased plasma catecholamines
- Augmented dopamine β-hydroxylase and rennin

Metabolic
- Lipolysis
- Gluconeogenesis and glycogenolysis

Musculoskeletal
- Augmented contractility
- Disturbances in depolarization (e.g., tremor)

premature infants, 4 to 7 hours in newborns, 3 to 4 hours in children 6 months to 18 years of age, and 8 to 9 hours in adults [24–27]. Many drugs, chemicals, and medical conditions affect the steady-state serum concentration and elimination half-life of theophylline (Table 139.2). The drugs that inhibit theophylline clearance are those that inhibit CYP1A2 and CYP3A4, including erythromycin, clarithromycin, ciprofloxacin, and cimetidine [24,28]. Drugs that increase theophylline clearance include barbiturates, carbamazepine, and the polyaromatic hydrocarbons of cigarette smoke (including passive smoke inhalation) [29,30]. Enzyme induction by these drugs can be temporary; if patients who smoke quit abruptly, theophylline clearance can fall to normal within days, leading to inadvertent theophylline intoxication unless dose is adjusted accordingly. Several disease states are also associated with a reduction in theophylline clearance, including congestive heart failure and liver disease [24,31]. Both hyperthyroidism and cystic fibrosis are associated with increased elimination of theophylline [32].

Theophylline has a variety of physiologic effects in therapeutic doses (Table 139.3). These effects include smooth muscle relaxation, mild central nervous system (CNS) excitation, and diuresis. Intoxication is associated with an array of other metabolic and clinical consequences. Although the effects of theophylline have been well characterized, their pharmacologic and pathophysiologic mechanisms remain poorly understood. Three primary cellular mechanisms of theophylline action have been theorized: inhibition of cyclic guanosine monophosphate or cyclic adenosine monophosphate (cAMP) activity, adenosine receptor antagonism, and adrenergic hyperstimulation (particularly at the beta-receptor) secondary to elevated levels of circulating plasma catecholamines [33–36]. Inhibition of calcium translocation and leukotriene production has also been postulated to be a fourth mechanism.

The physiologic changes seen with therapeutic doses of theophylline, including tachycardia, diuresis, bronchodilation, and CNS excitation, were thought to result from theophylline's inhibition of phosphodiesterase, the intracellular enzyme that inactivates cAMP, an important "second messenger" [37]. Such enzyme inhibition would lead to elevated intracellular cAMP concentrations, affecting a broad range of physiologic responses. However, this theory has been brought into question; in vitro data indicate that phosphodiesterase inhibition does not occur at therapeutic serum concentrations of theophylline, suggesting that increased cAMP activity is not a major mechanism of its therapeutic effects [38]. Whether the increased theophylline concentrations seen in the intoxicated patient are sufficient to inhibit phosphodiesterase activity is unknown.

Investigation has also been directed at the role of adenosine receptor antagonism as a mechanism of theophylline action. Adenosine is a nucleoside that promotes smooth muscle constriction, slows cardiac conduction, and acts as an endogenous anticonvulsant. With the structure of theophylline being similar to that of adenosine and with the drug having opposite physiologic actions, theophylline may be a simple competitive antagonist at bronchial and vascular smooth muscle, cardiac, and CNS sites. However, adenosine antagonism alone does not provide a complete explanation for theophylline's pharmacologic effects [39,40].

Additional data suggest that many of theophylline's actions can be accounted for by its stimulation of plasma catecholamines release [32,41]. Plasma concentrations of epinephrine, norepinephrine, and dopamine all rise significantly after theophylline administration [40]. With therapeutic doses, plasma catecholamine activity typically increases four- to sixfold. After theophylline intoxication, plasma catecholamine activity may rise to 30-fold [33,35]. Increased plasma catecholamines provide a ready explanation for many of the effects of theophylline seen after therapeutic doses and

potentially mediate many of the effects of theophylline intoxication. In all probability, the combined effects of adenosine receptor antagonism and catecholamine release are responsible for the predominant effects of theophylline intoxication.

Plasma catecholamines, particularly epinephrine, are capable of inducing hypokalemia, hyperglycemia, and metabolic acidosis. Epinephrine-induced hypokalemia appears to result from β_2-adrenergic receptor–linked stimulation of Na^+/K^+ adenosine triphosphatase. This leads to increased intracellular transport of potassium with preservation of total body potassium content [42]. Consistent with the theories of plasma catecholamine activity is the observation that theophylline-induced hypokalemia can be inhibited by pretreatment with propranolol or reversed by propranolol administration [43].

The CNS effects of theophylline intoxication include respiratory stimulation, vomiting, and seizures. These may result from disturbances in CNS cyclic guanosine monophosphate activity, adenosine antagonism, or adrenergic excess. Changes in neuronal transmembrane potentials by any of these mechanisms would lower excitation thresholds. Additionally, there are theories that theophylline inhibits CNS γ-aminobutyric acid receptor activity and stimulates *N*-methyl-d-aspartate and other excitatory neurotransmitters production. Theophylline administration has been associated with an abnormal electroencephalogram pattern in 34% of children and 12% of adults [44,45]. Cerebral vascular effects are also significant with theophylline and other methylxanthines because they are potent cerebral vasoconstrictors. This is the presumed mechanism of the efficacy of caffeine in the treatment of migraine headache. However, decreases in cerebral blood flow can be extreme, particularly during inhalational anesthetics administration [46]. In animal models, theophylline amplifies brain damage induced by seizures [47].

CLINICAL TOXICITY

Manifestations of theophylline intoxication can be classified into five categories: cardiac, CNS, gastrointestinal, musculoskeletal, and metabolic [1,17]. The cardiovascular effects of theophylline intoxication consist of rhythm and vascular disturbances. The hallmark (and first sign) of theophylline poisoning is sinus tachycardia, which occurs in more than 95% of cases. With more severe intoxication, unstable supraventricular tachydysrhythmias and ventricular dysrhythmias may occur. A common cause of death with severe theophylline intoxication is intractable ventricular dysrhythmias.

Blood pressure disturbances are also common. At lower ranges of intoxication, a mildly elevated blood pressure may be present, although severe hypertension is unusual in isolated theophylline poisoning. In severe cases of theophylline poisoning, hypotension with a widened pulse pressure is seen in the face of an increased cardiac index. Hypotension is caused by a marked fall in systemic vascular resistance [34].

The CNS effects of theophylline poisoning become prominent in severe overdose. The stimulatory actions of theophylline first produce hyperventilation with mild respiratory alkalosis. Significantly intoxicated patients develop agitation and anxiety. Vomiting, which can be severe, partly results from stimulation of the vomiting center of the medullary chemoreceptor trigger zone.

The most severe CNS manifestation of theophylline intoxication is seizures; these are a poor prognostic sign. Theophylline-induced seizures are typically tonic–clinic in nature and may be focal; they may be single, but are commonly multiple and typically resistant to conventional anticonvulsants. Seizures after theophylline intoxication are associated with a high frequency of adverse neurologic outcomes and a mortality that approaches 50% in elderly patients [48,49].

The gastrointestinal effects of theophylline poisoning consist of vomiting, diarrhea, and hematemesis. Vomiting results in part from hypersecretion of gastric acid and the enzymes gastrin and pepsin [50]. These acids and digestive enzymes are gastric irritants that can produce mucosal hemorrhage with hematemesis. Finally, theophylline is a potent relaxer of lower esophageal sphincter resting tone; this action facilitates the reflux of gastric contents.

Skeletal muscle tremor is a common feature of theophylline poisoning. These tremors are coarse; myoclonic jerks may also be present. Muscular hypertonicity also appears to be linked to theophylline's actions as a β_2-adrenoreceptor; this is evidenced by a similar syndrome occurring after excess administration of potent β_2-agonists (e.g., terbutaline).

A number of metabolic disturbances accompany theophylline intoxication: metabolic acidosis, hypokalemia, hyperglycemia, hypophosphatemia, hypomagnesemia, and hypercalcemia [26,51–55]. The resulting clinical picture can mimic diabetic ketoacidosis [56]. Metabolic acidosis may appear late and is typically modest; acidemia may not occur because of a superimposed respiratory alkalosis. Hypokalemia and hyperglycemia correlate strongly with the degree of intoxication after acute theophylline poisoning [57]. However, there are no obvious clinical consequences of hypokalemia. Hypercalcemia and hypophosphatemia are common, but not invariable, disturbances. Their cause is unclear, although theophylline (and epinephrine) has been shown to increase concentrations of parathyroid hormone, and correction of theophylline-induced hypercalcemia has been reported after propranolol administration [58].

Several studies have suggested that the metabolic and clinical consequences of theophylline intoxication vary, depending on whether the poisoning occurs through a single ingestion (or single intravenous overdose), chronic overmedication, or acute-on-therapeutic intoxication, in which the patient has maintained serum theophylline concentrations in the therapeutic range but then received a single toxic dose [18,22]. With *acute theophylline intoxication*, the patient ingests a single toxic dose of theophylline or inadvertently receives a toxic dose of intravenous aminophylline. The clinical course of acute theophylline intoxication strongly correlates with serum theophylline concentration. Serum theophylline concentrations of 20 to 40 µg per mL are associated with nausea, vomiting, and tachycardia. When theophylline concentrations are 40 to 70 µg per mL, premature ventricular contractions, agitation, and tremor appear. At theophylline concentrations greater than 80 µg per mL, life-threatening events, including severe cardiac dysrhythmias and intractable seizures, occur [16,59,60]. Hypokalemia can be profound after acute intoxication, with serum potassium concentrations falling to as low as 2.1 mEq per L. Serum glucose can be as high as 300 to 350 mg per dL.

In *chronic theophylline overmedication*, the patient ingests theophylline for at least 24 hours in doses or under conditions that exceed theophylline clearance. The result is a relatively slow rise in body "theophylline burden"-to-toxic concentrations. Victims of chronic overmedication are more likely to be neonates or elderly patients who have underlying cardiac disease or are taking/receiving medications that inhibit theophylline metabolism. These factors contribute to greater morbidity and mortality after chronic theophylline overmedication [18,30]. Signs of severe intoxication may occur with steady-state serum theophylline concentrations as low as 20 to 30 µg per mL. Seizures have occurred in patients with concentrations as low as 17 µg per mL. Patients with chronic theophylline overmedication are also less likely to have hypokalemia and hyperglycemia. The most striking feature of chronic theophylline overmedication is that there is *no significant correlation* between serum theophylline concentration and the appearance of life-threatening events [1,22,61,62]. Seizures and

dysrhythmias may appear with serum theophylline concentrations in the therapeutic or mildly toxic range [22,61]. As a result, serum theophylline concentration *should not be used* to predict the appearance of these events.

Patients who are chronically receiving theophylline in appropriate doses and then take or receive an acute overdose of theophylline develop *acute-on-therapeutic theophylline intoxication*. In these patients, clinical and metabolic consequences have features that are intermediate between those found with acute intoxication and chronic overmedication. Clinical manifestations are somewhat predicted by peak serum theophylline concentration, with life-threatening events usually not appearing until serum theophylline concentrations exceed 60 µg per mL. Metabolic disturbances are not as severe and have little or no correlation with serum theophylline concentration [1,21,22].

Patient age appears to be a significant risk factor for the development of life-threatening events after theophylline intoxication with those at extremes of age (i.e., neonates and elderly patients) [1,62]. For example, after chronic overmedication, patients older than 75 years have an almost 10-fold greater risk of a life-threatening event than do adolescents with comparable serum theophylline concentration [1,62]. There is evidence that in patients with chronic theophylline intoxication, age is a better predictor of major toxicity than serum theophylline concentration. Potential explanations for this observation include the differing pharmacokinetics found at extremes of age or the higher prevalence of significant underlying multisystem disease and use of multiple drugs in these patients.

DIAGNOSTIC EVALUATION

Essential laboratory studies to obtain in the patient with theophylline intoxication include serum theophylline concentration, serum electrolytes, blood urea nitrogen, creatinine, glucose, calcium, magnesium, phosphorus, liver function panel, and creatinine phosphokinase. Urine should be frequently evaluated for evidence of myoglobinuria. An electrocardiogram should be obtained; all patients with theophylline intoxication should be placed on continuous electrocardiogram monitoring. Arterial blood gas and complete blood cell count should be obtained as clinically indicated.

Sequential serum theophylline concentrations should be obtained every 1 to 2 hours until a plateau and subsequent substantive decline have been documented because delayed peaks in serum theophylline concentration may occur after an overdose. All abnormal laboratory studies should be serially monitored until all values have returned to normal.

MANAGEMENT

The management of theophylline intoxication consists of stabilization, decreasing absorption, and enhancing elimination. After acute ingestion, decreasing absorption is a primary concern. Treatment of chronic intoxication or intoxication after intravenous administration of theophylline generally focuses more on enhancing elimination.

Airway protection is paramount, and the threshold for tracheal intubation in the patient with seizures or other alterations in consciousness should be low. Assisted ventilation may be necessary if there is coingestion of a CNS depressant or if medications that depress respiratory drive, such as diazepam for seizures, are required for management.

If hypotension does not respond to an initial intravenous fluid bolus, propranolol may have a positive effect on blood pressure stabilization. If a vasopressor is also required, α-adrenergic agents such as phenylephrine or norepinephrine may be more efficacious; dopamine, which has some vasodilating properties at low doses, may be relatively ineffective.

Although no controlled clinical studies are available, there have been reports of success in treating tachydysrhythmias, particularly supraventricular tachycardias, with β-adrenergic antagonists, such as propranolol. Propranolol counters tachycardia, restores coronary blood flow, and interrupts the reentry phenomena that often underlie theophylline-induced dysrhythmias [33]. A potential hazard of propranolol administration is drug-induced bronchospasm; therefore, it should be used cautiously, if at all, in patients with significant reactive airways disease. Esmolol, an ultrashort-acting β_1-selective antagonist, has also been shown to be effective for select theophylline-induced tachydysrhythmias [63].

The antidysrhythmic agent adenosine has become the treatment of choice for supraventricular tachycardias and may be an important therapeutic addition in the management of theophylline-induced tachyarrhythmias. Having a significant effect on atrioventricular node conduction, adenosine can promptly reverse supraventricular tachycardias. Moreover, because of the evidence that adenosine and theophylline compete for the same receptor, adenosine may be a specific antidote for theophylline-induced supraventricular tachycardia. However, published clinical data in this regard are limited [64–66]. Amiodarone or lidocaine is the recommended treatment of ventricular irritability associated with hemodynamic compromise.

Seizures should be treated aggressively. High-dose benzodiazepine may be necessary for seizure termination. Phenytoin may be ineffective for theophylline-induced seizures [67], and in animal studies, it appears to contribute to theophylline-induced seizures. If seizures become prolonged, general anesthesia with a rapid-acting barbiturate, such as thiopental or pentobarbital, may be necessary. Neuromuscular blockade should be considered for seizures that are unresponsive to these modalities because significant morbidity may result from the rhabdomyolysis, hyperthermia, and acidosis of status epilepticus. There is some evidence that propranolol may help prevent or control theophylline-induced seizures [68].

Vomiting can be treated with the H_2-antagonist ranitidine, which reduces gastric acid hypersecretion [69,70]. Cimetidine administration is relatively contraindicated in theophylline poisoning because it inhibits theophylline metabolism. The dose of ranitidine is 50 to 100 mg given intravenously for adults and 0.1 to 0.5 mg per kg in children. Doses can be repeated every 6 to 8 hours. Metoclopramide also is an effective antiemetic that stimulates upper gastrointestinal motility and increases lower esophageal tone, without affecting theophylline clearance. The initial dose of metoclopramide is 0.5 to 1.0 mg per kg given intravenously for adults or 0.1 mg per kg for children (maximum, 1.0 mg per kg), although the risk of dystonia increases with increasing dose. Ondansetron is an alternative antiemetic, offering the advantage of effective antiemesis with no alterations in mental status and no risk of dystonic reaction. The phenothiazine antiemetics prochlorperazine and promethazine can lower seizure threshold and should not be administered.

Treatment of metabolic acidosis is aimed at maintaining a normal serum pH. For hypokalemia, it is important to emphasize that because hypokalemia's origin is predominantly the intracellular shift of potassium with minimal losses of total body potassium content through urine or vomitus, reversal of hypokalemia is best accomplished by lowering the theophylline concentration. Aggressive replacement of potassium may result in "overshoot" hyperkalemia [71]. Intravenous infusions of potassium chloride or potassium phosphate at 40 mEq per L in a saline solution should be adequate; intravenous boluses are usually not indicated. Hypophosphatemia, hypomagnesemia, hypercalcemia, and hyperglycemia rarely require correction.

Because vomiting is such a prominent feature of theophylline intoxication, there is rarely a need to perform gastric emptying. However, activated charcoal (see Chapter 117) is highly effective in reducing the absorption of theophylline and should be administered to all patients with recent ingestions. Whole-bowel irrigation (see Chapter 117) may be effective, particularly for sustained-release formulations, but its role in the treatment of theophylline intoxication remains undefined.

The repeated administration of activated charcoal (multiple-dose activated charcoal [MDAC]; see Chapter 117) is a valuable therapeutic measure for enhancing theophylline elimination [26,72–74]. Moreover, because MDAC acts through the principle of "gastrointestinal dialysis," it is effective even if theophylline intoxication occurs after intravenous administration of aminophylline [75]. MDAC is potentially as effective as hemodialysis in accelerating theophylline clearance [76,77]. However, it is not a substitute for hemodialysis in situations where rapid reduction in body theophylline burden is essential. All patients with significant theophylline intoxication should receive MDAC until the theophylline level is less than 15 µg per mL. Typical dosing is 1 g per kg charcoal every 4 hours (maximum, 50 g per dose). An effective alternative is 20 g every 2 hours [74]. Another alternative to bolus serial charcoal is administration via continuous nasogastric infusion at a rate of 0.25 to 0.50 g per kg per hour. Repeated vomiting, present in up to 80% of patients with theophylline intoxication [78], may delay or prevent successful MDAC administration. Aggressive antiemetic therapy is usually necessary.

In severely intoxicated patients or patients with moderate toxicity who are unable to tolerate MDAC, rapid removal of theophylline is essential. This is best accomplished by hemodialysis or hemoperfusion. If the need for extracorporeal drug removal is anticipated, a nephrologist should be involved early in management. Because of the time and personnel required to initiate extracorporeal drug removal, early notification can expedite the process once the decision has been made. Morbidity and mortality may be significantly lower if these procedures are undertaken before the onset of life-threatening disturbances. Indications for extracorporeal drug removal include hemodynamic instability or repeated seizures (regardless of serum theophylline concentration) and acute intoxication with a serum theophylline concentration greater than 80 µg per mL. Extracorporeal measures should be considered in patients younger than 6 months or older than 60 years with chronic intoxication and a theophylline concentration greater than 30 µg per mL.

Charcoal hemoperfusion has traditionally been considered the extracorporeal drug-removal method of choice for theophylline intoxication [79,80]. It reduces the elimination half-life of theophylline to as low as 0.7 to 2.1 hours [77], increasing clearance four- to sixfold [79]. However, hemoperfusion has significant risks, including hypotension, thrombocytopenia, red cell destruction, bleeding diathesis, and hypocalcemia. Also, there are few medical centers with the equipment and personnel needed to perform this procedure. The combination of scarce access to the procedure, increasing efficiency of hemodialysis, and the comparable efficacy of the two procedures has made hemodialysis the preferred procedure for treatment of severe theophylline intoxication [81].

Hemodialysis has many advantages over hemoperfusion. First, it is a technique that is widely available and relatively simple to perform. The need for administration of blood products is considerably less with hemodialysis. Dialysis can also increase theophylline clearance substantially, depending on the blood flow rates achieved by the device. Also, hemodialysis does not require the same degree of anticoagulation required by hemoperfusion, which lowers the risk of bleeding diathesis. Finally, the overall rate of complications is lower for hemodialysis than for hemoperfusion.

Peritoneal dialysis is an ineffective mode of drug removal in theophylline intoxication and is not recommended. Exchange transfusion, formerly thought to have no role in theophylline poisoning, has been used successfully in neonates with severe intoxication [82]. Other extracorporeal drug-removal methods, such as hemofiltration and plasmapheresis, have not been sufficiently evaluated, although there are case reports that these procedures have therapeutic value [83,84]. Hemofiltration, because it is a slow, passive, cardiac output-dependent technique, is unlikely to effect the rapid removal of theophylline that is necessary in severe intoxications.

CAFFEINE

Caffeine is a component of the three most popular beverages in the world: coffee, tea, and carbonated soft drinks. It is also used therapeutically as an antisleep aid and in many headache medications. Having a wide margin of safety and a relatively short elimination half-life—3 hours in adults, but 1 to 6 days in neonates—caffeine can be ingested daily in amounts as high as 1 g [85]. However, daily doses in this range are associated with unwanted adverse effects, including anxiety, jitteriness, and tachycardia.

The pharmacokinetic profile of caffeine resembles theophylline, with an important exception: whereas metabolism of theophylline (1,3-dimethylxanthine) produces inactive metabolites, caffeine (1,3,7-trimethylxanthine) undergoes 7-demethylation to form theophylline. Therefore, caffeine ingestion is invariably associated with measurable serum theophylline concentrations. After caffeine intoxication, serum theophylline concentration is a useful measure of toxicity. Many of the clinical manifestations of caffeine intoxication may in fact result from the effects of theophylline at its susceptible end organs.

The single ingestion of more than 1.5 g of caffeine (30 to 50 mg per kg in children) can produce serious adverse effects with the same manifestations found in acute theophylline intoxication [86]. Ingestions of more than 100 to 200 mg per kg are potentially lethal [85]. The five major disturbances occurring after caffeine intoxication are gastrointestinal, neurologic, metabolic, cardiac, and musculoskeletal [19]. Nausea and vomiting, with occasional hematemesis, predominate. CNS excitation may be manifested by anxiety, agitation, and seizures in severe cases. The same hypokalemia, hyperglycemia, and metabolic acidosis that appear after severe acute theophylline intoxication occur with caffeine poisoning. The most common cause of death after caffeine intoxication is intractable cardiac dysrhythmias [87]; severe acute overdoses have led to myocardial infarction [88]. Musculoskeletal effects can be prominent with caffeine intoxication; one feature is the appearance of severe rhabdomyolysis [89]. Life-threatening events after acute caffeine intoxication are associated with serum concentrations of more than 100 to 150 µg per mL. However, seizures after caffeine intoxication have occurred at serum concentrations as low as 50 µg per mL. Death has been reported with serum concentrations as low as 80 µg per mL. However, serum caffeine concentrations as high as 385 µg per mL have been associated with survival [90].

Management of caffeine intoxication follows the same principles as theophylline intoxication. Patient stabilization includes treatment of life-threatening seizures and cardiac dysrhythmias. Activated charcoal should be administered as soon as possible to provide gastrointestinal decontamination. Aggressive antiemetic therapy should be administered. MDAC is presumed to be equally effective for caffeine intoxication. Caffeine can be eliminated via hemodialysis; this procedure should be considered in those with seizures, cardiac dysrhythmias, or serum caffeine concentrations in excess of 100 µg per mL.

CHAPTER 140 ■ OPIOID POISONING

ROBERT P. DOWSETT AND LUKE YIP□

Natural opioids (e.g., morphine and codeine) are harvested from the seedpods of the poppy plant *Papaver somniferum*. Semisynthetic opioids (e.g., dextromethorphan, heroin, hydrocodone, hydromorphone, oxycodone, and oxymorphone) are derivatives of morphine, whereas synthetic opioids (e.g., buprenorphine, butorphanol, diphenoxylate, fentanyl, meperidine, methadone, nalbuphine, pentazocine, propoxyphene, and tramadol) are not.

Clandestine laboratories have produced potent opioids as new manufacturing methods have been developed to circumvent the use of controlled or unavailable precursor compounds. Because these drugs may contain a wide variety of active ingredients, adulterants, and contaminants, the clinical syndromes seen in the abuser may be only partly related to the opioid component.

PHARMACOLOGY

Opioids interact with central nervous system (CNS) receptors to produce their analgesic, euphoric, and sedative effects. Historically, on the basis of animal studies, three major opioid receptors designated *mu*, *kappa*, and *sigma* have been proposed [1]. The *sigma* receptor is no longer considered an opioid subtype because it is insensitive to naloxone, has dextrorotatory stereochemistry binding, and has no endogenous ligand. The International Union on Receptor Nomenclature recommends a change from the Greek alphabet to one similar to other neurotransmitter systems; receptors are denoted by their endogenous ligand (*o*piates *p*eptides) with a subscript denoting their order of discovery: *delta* to OP_1 *kappa* to OP_2, and *mu* to OP_3 [2] (Table 140.1).

Most opioid analgesics are well absorbed after parenteral administration, from the pulmonary capillaries and mucosal sites. Analgesia is promptly achieved after parenteral administration and within 15 to 30 minutes after oral dosing. Peak plasma levels are generally attained within 1 to 2 hours after therapeutic oral doses. However, acute overdose may produce decreased intestinal peristalsis, resulting in delayed and prolonged absorption. Therapeutic and toxic serum drug concentrations are not well established.

All opioids undergo hepatic biotransformation, including hydroxylation, demethylation, and glucuronide conjugation. Considerable first-pass metabolism accounts for the wide variations in oral bioavailability noted with drugs such as morphine and pentazocine. Only small fractions of the parent drug are excreted unchanged in the urine. Active metabolites can contribute to the toxicological profile of specific drugs.

All opioids elicit the same overall physiologic effects as morphine, the prototype of this group. A typical morphine dose (5 to 10 mg) usually produces analgesia without altering mood or mental status in a patient. Sometimes dysphoria rather than euphoria is manifest, resulting in mild anxiety or a fear reaction. Nausea is frequently encountered, and vomiting is occasionally observed. Morphine and most of its congeners cause miosis in humans. This effect is exacerbated after an overdose, resulting in profound pupillary constriction, predominantly a central effect. Cerebral circulation does not appear to be altered by therapeutic doses of morphine unless respiratory depression and carbon dioxide retention result in cerebral vasodilation.

Respiratory failure is the most serious consequence of opiate overdose. Opioid agonists reduce the sensitivity of the medullary chemoreceptors in the respiratory centers to an increase in carbon dioxide tension and depress the ventilatory

response to hypoxia. Even small doses of morphine depress respiration, decreasing minute and alveolar ventilation [3]. The peak respiratory-depressant effect is usually noted within 7 minutes of intravenous (IV) morphine administration, but may be delayed up to 30 minutes if the drug is intramuscularly administered. Normal carbon dioxide sensitivity and minute volume usually return 5 to 6 hours after a therapeutic dose [3].

Therapeutic opiate doses cause arteriolar and venous dilation and may result in a mild decrease in blood pressure. This change in blood pressure is clinically insignificant while the patient is supine, but significant orthostatic changes are common [4]. Hypotension appears to be mediated by histamine release [5]. Myocardial damage (necrotizing angiitis) in opiate overdose associated with prolonged hypoxic coma may be mediated by cellular components released during rhabdomyolysis, direct toxic effects, or hypersensitivity to the opioids or adulterants [6].

Heroin (diacetylmorphine) has two to five times the analgesic potency of morphine [7]. Virtually all street heroin in the United States is produced in clandestine laboratories and adulterated before distribution (Table 140.2). The purity of street heroin is between 5% and 90%. Physiologically, the effects of heroin are identical to those described for morphine [8]. Heroin can be administered intravenously, intranasally, or inhaled as a volatile vapor, and can be mixed with other drugs of abuse, typically amphetamine or cocaine ("speed ball"). The plasma half-life of heroin is 5 to 15 minutes. Heroin is initially deacetylated in the liver and plasma, and then renally excreted as a conjugate, with small amounts of morphine, diacetylmorphine, and 6-monoacetylmorphine [8]. Individual variation in sensitivity and tolerance makes correlation of serum levels with clinical symptoms difficult.

The initial heroin rush is probably due to its high lipid solubility and rapid penetration into the CNS [8]. The majority of its lasting effects are attributable to its metabolites 6-monoacetylmorphine and morphine [8]. Fatal overdoses with heroin have been reported with serum morphine concentrations of 0.1 to 1.8 μg per mL [9].

Codeine (methylmorphine) is formulated as a sole ingredient and in combination with aspirin or acetaminophen. Codeine is rapidly absorbed by the oral route, producing a peak plasma level within 1 hour of a therapeutic dose [10]. Usually 10% of codeine is metabolized to morphine by CYP2D6; this may be greatly increased in patients with duplicated or amplified CYP2D6 genes, resulting in opioid toxicity [11]. This pathway may be inhibited by quinidine [12]. Clearance of codeine by CYP3A4 may be inhibited by clarithromycin and voriconazole [11]. Codeine and morphine appear in the urine within 24 to 72 hours. However, only morphine is detected in the urine at 96 hours [10]. The effect of codeine on the CNS is comparable with, but less pronounced than that of, morphine. Fatal ingestions with codeine alone are rare. The estimated lethal dose in a nontolerant adult is 800 mg, with a serum codeine concentration of 0.14 to 4.8 mg per dL [13].

Fentanyl, a phenylpiperidine derivative, has a potency 200 times that of morphine. Legitimate use is limited to anesthesia, and it is known to be commonly abused by hospital personnel. Rapid IV administration may result in acute muscular rigidity primarily involving the trunk and chest wall, which impairs respiration. Although motor activity resembling seizures has been associated with fentanyl use, simultaneous electroencephalogram recording during fentanyl induction of general anesthesia failed to show epileptiform activity [14]. This suggests a myoclonic rather than epileptic nature of the observed muscle activity [14].

Fentanyl is available as a transdermal delivery system that establishes a depot of drug in the upper skin layers, where it is available for systemic absorption. After removal of the patch, drug absorption from the dermal reservoir continues with an apparent half-life of 17 hours, versus 2 to 4 hours with IV administration [15].

By manipulating the chemical structure of fentanyl, α-methylfentanyl (China white), 3-methylfentanyl, and parafluoro-fentanyl have been produced and distributed on the street as heroin substitutes. They are 200 to 3,000 times more potent than heroin [16]. α-Methyl-acetyl-fentanyl, α-methylfentanyl acrylate, and benzylfentanyl are 6,000 times more potent than morphine [17].

Meperidine, another phenylpiperidine derivative, is less than half as effective when given orally as compared to the parenteral route [18]. It appears to be a common drug of abuse among medical personnel, yet there are few reports of meperidine poisoning or fatalities [19]. Peak plasma levels are 30 minutes after intramuscular administration, and 1 to 2 hours after an oral dose [18]. The duration of action is 2 to 4 hours [18]. Meperidine is metabolized primarily by *N*-demethylation to normeperidine, an active metabolite with half the analgesic and euphoric potency of its parent and twice the convulsant property [20]. Excretion is primarily through the kidneys as conjugated metabolites [21]. Meperidine and normeperidine may be detected in either urine or serum [21]. The seizures reported with meperidine toxicity have been attributed to the accumulation of normeperidine, which has an elimination half-life of 14 to 24 hours [18,22].

A synthetic meperidine analog, methyl-phenyl-propionoxypiperidine has been used as a heroin substitute. Methyl-phenyl-tetrahydropyridine, a contaminant produced during the clandestine synthesis of this agent, led to an epidemic of Parkinsonism among IV drug abusers within days of repeated injections [23].

Diphenoxylate is structurally similar to meperidine. Diphenoxylate (2.5 mg) is formulated with 0.025 mg atropine sulfate (Lomotil) and used in the treatment of diarrhea. In therapeutic doses, the drug has no significant CNS effects. Symptoms arising from a toxic ingestion may be delayed because of decreased gastrointestinal (GI) motility and accumulation of the hepatic metabolite difenoxin, a potent opioid with a long serum half-life [24]. The ingestion of only six to eight Lomotil tablets may cause serious toxicity in children [24].

Methadone is used for chronic pain conditions and maintenance of opiate addicts. It is well absorbed orally, producing a peak plasma level within 2 to 4 hours [25]. It has a prolonged but variable duration of action; the half-life averages 25 hours, but may be as long as 52 hours during long-term maintenance therapy [25]. As little as 40 to 50 mg may produce coma and respiratory depression in a nontolerant adult [26]. A protracted clinical course is expected after an overdose [27].

Propoxyphene is structurally related to methadone. It is available alone or in combination with aspirin or acetaminophen. Oral administration is followed by rapid absorption, with peak serum levels occurring in 1 hour [28]. The plasma half-life of propoxyphene and its main active metabolite, norpropoxyphene, is 6 to 12 hours and 37 hours, respectively. Norpropoxyphene is the primary metabolite excreted in the urine [29]. It is believed to play a role in the prolonged clinical course after an overdose [30]. Blood levels in fatal overdose cases range from 0.028 to 42.7 mg per L [31].

Pentazocine is a synthetic analgesic in the benzomorphan class and has been involved in the drug abuse trade [32]. It has agonist as well as weak antagonist activity at the opioid receptors. It has one third the analgesic potency of morphine [32]. Orally administered, pentazocine achieves peak plasma levels within 1 hour and is extensively metabolized in the liver with the parent compound and metabolites detectable in either urine or plasma [32]. Pentazocine (Talwin), in combination with the antihistamine tripelennamine, was known on the street as *T's and Blues* and was used as a heroin substitute [33].

In an attempt to curtail pentazocine abuse, the oral preparation was reformulated to contain 0.5 mg naloxone (Talwin-NX). When Talwin-NX is parenterally administered, the effects of pentazocine are antagonized by naloxone, which has precipitated withdrawal in opiate-dependent individuals. Because the duration of action of pentazocine exceeds that of naloxone, delayed respiratory depression may occur.

Dextromethorphan, an analogue of codeine, is found in a large number of nonprescription cough and cold remedies. It is available as a single ingredient but usually formulated in combination with sympathomimetic and antihistamine drugs. Dextromethorphan is well absorbed from the GI tract, with peak plasma levels occurring 2.5 and 6.0 hours after ingestion of regular and sustained-release preparations, respectively. The therapeutic effect is 3 to 6 hours, with a corresponding plasma half-life of 2 to 4 hours. The predominant antitussive effect is attributed to the active metabolite dextrorphan [34]. Within the therapeutic dose, dextromethorphan lacks analgesic, euphoric, and physical dependence properties [35].

Hydromorphone and oxycodone are orally administered opioids used in the treatment of chronic pain conditions. A number of sustained-release formulations are available, and can result in prolonged poisoning in overdose. A formulation of hydromorphone has recently been withdrawn from the market because alcohol could accelerate the release of the drug [36]. The sustained-release properties of some formulations of oxycodone can be circumvented by crushing or dissolving the tablet, resulting in fatal narcotic overdoses in drug abusers [37].

Tramadol is structurally similar to morphine. It is a centrally acting analgesic with moderate affinity for *mu* receptors. The metabolite *O*-demethyl-tramadol appears to have a higher affinity than the parent compound. Most of the analgesic effects are attributed to nonopioid properties of the drug, probably by blocking the reuptake of biogenic amines (e.g., norepinephrine and serotonin) at synapses in the descending neural pathways, which inhibits pain responses in the spinal cord [38].

Buprenorphine is a partial agonist activity with high affinity to, and slow dissociation from, the *mu* receptor. It displaces other opioids and its dose–response curve has a ceiling effect, resulting in less respiratory depression in overdose, although apnea may still occur [39,40]. It has poor oral bioavailability and is administered sublingually. It is also formulated with naloxone that is active only if administered intravenously [41]. Other partial agonists include butorphanol and nalbuphine. They can precipitate opioid withdrawal (see Chapter 145) in those taking other opioids.

CLINICAL PRESENTATION

Miosis, respiratory depression, and coma are the hallmarks of opiate intoxication, with the magnitude and duration of toxicity dependent on the dose and degree of tolerance. The clinical effects of an overdose with any one of the agents in this class are similar. However, there are important differences between certain drugs. Overdoses resulting in toxicity often have a prolonged clinical course, in part because of opiate-induced decreased GI motility when taken orally and prolonged half-life of the drug or its active metabolite(s). Miosis is considered a pathognomonic finding in opiate poisoning, with the exception of meperidine, propoxyphene, pentazocine, and dextromethorphan use, in the case of a mixed overdose with an anticholinergic or sympathomimetic drug, or when severe acidemia, hypoxemia, hypotension, or CNS structural disorder is present.

CNS depression occurs in most severely intoxicated patients. However, codeine, meperidine, and dextromethorphan intoxications are remarkable for CNS hyperirritability, resulting in a mixed syndrome of stupor and delirium. In addition, patients with meperidine toxicity may also have tachypnea, dysphoric and hallucinogenic episodes, tremors, muscular twitching, and spasticity, whereas patients with dextromethorphan toxicity may also manifest restlessness, nystagmus, and clonus [22,42].

Pulmonary edema may complicate the clinical course of opioid overdose and appears more prevalent with heroin, morphine, codeine, methadone, and propoxyphene [13,43,44]. Pulmonary edema has occurred in postoperative patients who received naloxone and after naloxone therapy in overdose patients [45,46]. However, naloxone does not appear to alter the

Lung abscess	Respiratory arrest

vascular permeability of the lung directly [47]. Typically, the patient has a depressed consciousness and respiration. After naloxone administration, the patient awakens and over minutes to hours is noted to become hypoxic and develop pulmonary edema. Acute naloxone-induced withdrawal has been associated with massive CNS sympathetic discharge, which may be a precipitating factor in the development of neurogenic pulmonary edema [48]. It appears that the pulmonary injury is at the alveolar–capillary membrane, resulting in manifestations consistent with acute respiratory distress syndrome [49]. It does not appear to be an immune-mediated mechanism [50]. Pulmonary edema may present within 2 hours of parenteral heroin use, up to 4 hours after intranasal heroin use, and up to 24 hours after methadone overdose [51].

Patients with heroin-induced pulmonary edema typically have normal capillary wedge pressures and elevated pulmonary arterial pressures [52]. In contrast, elevated systemic, pulmonary arterial, and pulmonary capillary wedge pressures and total systemic vascular resistance are seen with pentazocine intoxication [53]. This effect is believed to result from transient endogenous catecholamine release [54]. Persistent pulmonary symptoms beyond 24 to 48 hours may indicate aspiration or bacterial pneumonitis, with atelectasis, fibrosis, bronchiectasis, granulomatous disease, or pneumomediastinum [55]. Adulterants in street drugs are potential pulmonary toxins [56]. Dyspnea, hypoxemia, and the presence of multiple reticulonodular infiltrates on chest radiograph may be caused by adulterants in the IV mixture. A summary of the potential pulmonary complications associated with opioid abuse is provided in Table 140.3.

Heroin toxicity may be associated with cardiac conduction abnormalities and dysrhythmias, which may be the result of metabolic derangements associated with hypoxia, a direct effect of the abused agent, or adulterants (e.g., quinine) in street drugs [57–59].

Leukoencephalopathy associated with inhalational abuse of heroin ("chasing the dragon") typically progresses for several weeks. Initially, cerebellar ataxia and motor restlessness may be followed by the development of pyramidal tract lesions, pseudobulbar reflexes, spastic paresis, myoclonic jerks, and choreoathetoid movements. A quarter of patients may progress to hypotonic paresis, akinetic mutism, and death [60].

Seizures and focal neurologic signs are usually absent after opiate intoxication [61] unless precipitated by severe hypoxia, an intracranial process (e.g., brain abscess and subarachnoid hemorrhage), proconvulsive adulterants, meperidine, propoxyphene, pentazocine (T's and Blues), or tramadol use [33,62–65]. Meperidine- and propoxyphene-related seizures may become more frequent in chronic drug abusers with renal insufficiency.

Disabling myoclonus has been reported after several days of fentanyl therapy by the transdermal delivery system [17].

The clinical course after propoxyphene overdose may be severe and rapidly progressive, with cardiac dysrhythmias, circulatory collapse, seizures, and respiratory arrest developing within 45 minutes [66]. Seizure may be focal or generalized [62]. Propoxyphene appears to be responsible for CNS toxicity (respiratory depression and seizures) and cardiac toxicity (QRS prolongation and dysrhythmias) [67], whereas norpropoxyphene contributed only to the cardiotoxicity in one animal study [68]. Cardiotoxicity may be exacerbated by hypoxia or adulterants (e.g., quinine) in street drugs. The minimum toxic dose reported is 10 mg per kg, and 20 mg per kg is considered potentially fatal, but tolerance develops with chronic use [69]. Doses of 1,000 to 2,000 mg can be ingested or injected, with minimal signs of intoxication in chronic propoxyphene abusers and heroin addicts [70].

Anxiety, dysphoria, and hallucinations are more common with pentazocine than with other opiate derivatives [32]. Acute toxicity in combination with tripelennamine results in the typical opiate intoxication syndrome as well as dyspnea, hyperirritability, hypertension, and seizures. It is believed that these effects may be directly related to tripelennamine [33].

Hypotension may occur after opiate overdose, although pentazocine intoxication may result in hypertension [33]. Heroin and propoxyphene toxicity may be associated with nonspecific ST-segment and T-wave changes, first-degree atrioventricular block, atrial fibrillation, prolonged QTc intervals, and ventricular dysrhythmias [57]. Cardiovascular findings may be exacerbated by hypoxia or adulterants (e.g., quinine) in street drugs.

Dextromethorphan abuse seems to be self-limiting because of adverse drug events, such as lethargy, somnambulism, and ataxia [71]. It is associated with a psychologic rather than physiologic dependence syndrome [72]. Recreation dextromethorphan abusers report increased perceptual awareness, altered time perception, euphoria, and visual hallucinations [71]. Long-term use may result in bromide toxicity [73]. Because dextromethorphan frequently appears in combination products, the contribution of these coingestants should be considered.

Methadone can produce bradycardia, QTc prolongation, and torsades de pointes. Bradycardia has been reported infrequently and is postulated to be because of methadone's structural similarity to verapamil [74,75]. QTc prolongation and torsades de pointes have been associated with mean daily methadone dose 397 ± 238 mg; mean QTc interval on presentation was 615 ± 77 ms. In one case series, the majority of patients were receiving a potentially QT-prolonging drug, 41% of the patients had hypokalemia, and 18% of the patients were found to have structural heart disease [76]. A proposed mechanism is inhibition of the cardiac potassium channel by the nontherapeutic (S)-methadone isomer [77]. This isomer is metabolized by CYP2B6; 6% of the population are slow metabolizers, resulting in elevated levels of (S)-methadone and increased QTc intervals [77,78].

The onset of anticholinergic and opioid effects may be significantly delayed after a diphenoxylate overdose [79]. Atropine effects (CNS excitement, hypertension, fever, and flushed dry skin) occur before, during, or after opioid effects. However, opioid effects (CNS and respiratory depression with miosis) may predominate or occur without any signs of atropinism. Cardiopulmonary arrest has been reported to occur 12 hours after ingestion of diphenoxylate [80].

Patients presenting after a tramadol overdose may exhibit lethargy, nausea, tachycardia, agitation, seizures, coma, hypertension, respiratory depression metabolic acidosis, acute hepatic failure, and acute renal failure [81]. Tramadol-associated seizures are brief, and significant respiratory depression is uncommon [65].

Interaction between meperidine and monoamine oxidase inhibitors (MAOIs), dextromethorphan and MAOIs, and tramadol and selective serotonin reuptake inhibitors may result in the serotonin syndrome [82–84]. Patients with severe serotonin syndrome exhibit rapid onset of altered mental status, muscle

rigidity, hyperthermia, autonomic dysfunction, coma, seizures, and death.

Rhabdomyolysis, hyperkalemia, myoglobinuria, and acute renal failure may complicate the clinical course of an acute opioid overdose [85]. Acute renal failure may be due to direct insult by the abused substance, adulterants in street drugs, and prolonged coma [58,85]. Chronic parenteral drug use may result in glomerulonephritis and renal amyloidosis and has been associated with concurrent bacterial infections [86]. Potential lethal acute infections have been linked to clostridia contamination [87].

Body packers or "mules" are people who transport large numbers of concentrated heroin packets in their GI tract from one country to another. If one of these packets ruptures, the amount of drug released can cause severe and prolonged toxicity [88]. They may also develop features of intestinal obstruction and, occasionally, intestinal perforation and peritonitis [89].

DIAGNOSTIC EVALUATION

Laboratory studies such as complete blood cell count, serum electrolytes, blood urea nitrogen, creatinine and creatine phosphokinase, urinalysis, arterial blood gas, electrocardiography, chest and abdominal radiography, head computed tomography, and lumbar puncture should be obtained as clinically indicated. Arterial blood gas usually reflects hypoventilation, respiratory acidosis, and metabolic acidosis [90]. If pulmonary edema develops, chest radiographs typically reveal bilateral fluffy alveolar infiltrates, occasionally unilateral in nature, and echocardiograms show normal cardiac function [43]. A markedly negative anion gap with hyperchloremia should raise the suspicion of bromide poisoning from chronic dextromethorphan use [73]. Chest radiographic findings of pulmonary edema usually resolve within 24 to 48 hours.

It is recommended that an ECG be obtained prior to commencing methadone therapy and within 30 days of commencement and then yearly to monitor the QTc interval [91].

Leukoencephalopathy associated with inhalational abuse of heroin appears as hypoattenuation in the affected white matter, although this may not be apparent until late in the disease. Magnetic resonance imaging typically demonstrates white matter hyperintensity on T2-weighted sequences. Affected areas are initially the occipital and cerebellar white matter, followed by involvement of the parietal, temporal, and frontal lobes. The cerebellar peduncles, splenium of the corpus callosum, posterior limb of the internal capsules, corticospinal tract, medial lemniscus, and tractus solitarius may also be involved [60].

Subdural abscess	HIV/AIDS

AIDS, acquired immunodeficiency syndrome; HIV, human immunodeficiency virus.

Quantitative serum opiate levels do not contribute to patient management. A urine toxicology screen may confirm the diagnosis, but is rarely necessary for acute patient management. Commercial opioid assays are unlikely to detect synthetic opioids. The metabolites of naloxone are chemically related to oxymorphone, but naloxone is not known to give false-positive immunoassay urine screens for opioid substances [92]. False-positive serology tests for syphilis have been reported among drug addicts [93]. Laboratory investigation should also include tests for infection in patients with fever (Table 140.4).

MANAGEMENT

A diagnosis of opioid poisoning should be considered in all comatose patients. However, the classic triad of opiate toxicity (coma, miosis, and respiratory depression) may not be apparent after a mixed overdose. Respiratory support is paramount in the management of patients with opioid toxicity; one should secure the airway and ventilate with 100% oxygen. Vascular access should be established. The patient should be placed on continuous pulse oximetry and cardiac monitoring. Vital signs should be monitored frequently.

Naloxone is a specific opiate receptor antagonist and can reverse the analgesia, respiratory depression, miosis, hyporeflexia, and cardiovascular effects of opiate toxicity [94,95]. The goal of naloxone therapy is to reestablish adequate spontaneous ventilation. The initial IV naloxone dose should be 0.1 mg if the patient is possibly opioid dependent; larger doses may precipitate acute opioid-withdrawal syndrome. Otherwise, an initial 2 mg dose can be administered. If there is history of an opiate exposure, a strong suspicion based on presenting signs and symptoms, or a partial response to the initial naloxone dose, repeated IV naloxone boluses up to 10 mg should be administered because methadone, pentazocine, propoxyphene, diphenoxylate, and sustained-release preparations of oxycodone and hydromorphone may not respond to the usual naloxone doses [96,97]. Despite its strong affinity to *mu* receptors, buprenorphine overdose can be treated effectively with normal doses of naloxone [40].

Intramuscular, intralingual, endotracheal, intraosseous, and intranasal routes of naloxone administration are acceptable alternatives when IV access is not readily available [96,98–100]. Repeat naloxone boluses may be required every 20 to 60 minutes because of its short elimination half-life (60 to 90 minutes). A continuous naloxone infusion should be considered in patients who have a positive response but require repeated bolus doses because of recurrent respiratory depression [100,101]. A therapeutic continuous naloxone infusion can be made by administering two third of the effective naloxone bolus dose per hour. The infusion is titrated to maintain adequate spontaneous ventilation without precipitating acute opioid withdrawal and empirically continued for 12 to 24 hours. The patient should be admitted to an intensive care or high-dependency setting for continuous monitoring. After the naloxone therapy is discontinued, the patient should be carefully observed for 4 hours for recurrent respiratory depression.

Naloxone is effective in reversing diphenoxylate-induced opioid toxicity. However, recurrence of respiratory and CNS depression is common [79]. All patients with significant diphenoxylate overdose should be observed in an intensive care setting for at least 24 hours.

Hypotension may respond to naloxone therapy but may require fluid resuscitation and vasopressors. Overzealous fluid resuscitation should be avoided because of the risk of pulmonary edema.

The management of seizures should follow present treatment guidelines and include benzodiazepines or barbiturates.

Adjunct naloxone therapy may be effective in propoxyphene, but not in meperidine- or tramadol-related seizures [102]. Seizures have been reported after naloxone administration for tramadol overdose [65].

The management of serotonin syndrome is primarily supportive (see Chapters 66 and 124). Sedation, paralysis, intubation and ventilation, anticonvulsants, antihypertensives, and aggressive rapid cooling may all be necessary. Some success has been obtained with the nonspecific serotonin antagonist cyproheptadine (4 to 8 mg every 8 hours orally) or olanzapine (sublingual 10 mg) [103,104].

GI decontamination should be considered for orally administered opioids after vital signs have been stabilized. The clinical benefits of multiple oral doses of activated charcoal are unproven, but it is potentially beneficial because of the prolonged absorption phase that is typically encountered with opiate overdoses. Repeat charcoal doses should not be used in the absence of active bowel sounds.

The management of pulmonary edema should include adequate ventilation, oxygenation, and positive-pressure ventilation as needed [105]. Inotropic agents and diuretics are of little value.

Bradycardia secondary to methadone administration responds to ceasing the drug; atropine has not been utilized [75]. If patients receiving methadone develop a QTc interval of more than 500 milliseconds, consideration should be given to reducing the dose or discontinuing the drug [91].

Asymptomatic body packers should be conservatively managed when the condition of packaging does not appear to be compromised. One proposed guideline involves the oral administration of a water-soluble contrast solution followed by serial abdominal radiographs (Table 140.5) [106]. Whole-bowel irrigation (WBI) with polyethylene glycol electrolyte lavage solution (PEG-ELS) has also been advocated on the basis of case reports [107].

Pruritus is a common opioid adverse drug event. It may be localized or general, and ranges from mild to severe. Antihistamines are usually ineffective, but naloxone has frequently been found to offer relief. Ondansetron has been reported to provide relief in refractory cases [108].

TABLE 140.5

MEDICAL MANAGEMENT FOR ASYMPTOMATIC BODY PACKERS

1. Administer an oral dose of water-soluble contrast (e.g., Gastrografin): 1 mL/kg[a]
2. Perform abdominal radiographs (supine and upright) at least 5 h after oral contrast administration
3. If radiographs are positive, perform daily abdominal radiographs, and after a spontaneous bowel movement
4. All bowel movements are checked for drug packets
5. The patient may be discharged after passage of two packet-free bowel movements *and* negative abdominal radiographs

[a]Patients are permitted to feed normally, and vascular access should be maintained.

Leukoencephalopathy associated with inhalational abuse of heroin has been reported to improve following the antioxidant ubiquinone (coenzyme Q10) administration in doses of 30 to 300 mg QID [109].

Nalmefene is also effective for the reversal of opioid-induced CNS effects and can be administered orally or intravenously. Its half-life and dose-dependent duration of action are 4 to 8 hours after IV administration [110]. The initial adult dose is 0.5 mg for those who are not opioid dependent and 0.1 mg for those suspected of having opioid dependency. If there is an incomplete response or no response, additional doses can be given at 2- to 5-minute intervals. A total dose of 1.5 mg may be necessary to exclude the possibility of opioid poisoning. The principal advantage over naloxone is its considerably longer duration of antagonistic action however; withdrawal syndromes precipitated by nalmefene use would also be prolonged.

Naltrexone is a potent, long-acting pure opiate antagonist that is effective orally. Its use is primarily limited as adjunctive therapy for opioid detoxification. Naltrexone may induce a withdrawal syndrome that lasts up to 72 hours.

CHAPTER 141 ■ PESTICIDE POISONING

WILLIAM K. CHIANG AND RICHARD Y. WANG

A pesticide is as an agent intended for killing, preventing, repelling, or mitigating any pest. With the increasing use, environmental contamination and reports of epidemic pesticide poisoning are inevitable [1–3]. The health consequences from the long-term and low-level exposure to these chemicals, such as carcinogenesis [4,5], teratogenicity [6], fertility [7], and neurologic sequelae [8,9], may be significant and immeasurable. In many countries in which there are limited regulations on pesticide usage, pesticide ingestion is one of the leading forms of suicide, and pesticide exposure is a major occupational risk [10–12]. Even in the United States, pesticide exposures remain a major public health problem [13]. The World Health Organization estimated that accidental and occupational pesticide poisonings worldwide account for 1.5 million cases and 28,000 deaths annually [14].

This chapter focuses on selected pesticides that are most clinically important. Some of the common pesticides are provided in Table 141.1. Organophosphate insecticides are covered in Chapter 128. Further information on the identification and toxicity of pesticide products may be obtained from sources such as material data safety sheets, *Hayes' Handbook of Pesticide Toxicology, Farm Chemicals Handbook*, and the pesticide label database (http://www.cdpr.ca.gov/docs/label/labelque.htm).

ORGANOCHLORINES

Organochlorines are commonly used as insecticides, soil fumigants, solvents, and herbicides. Human toxicity can result from either acute or chronic exposure. Contamination typically occurs during production and application of these agents. Infants and toddlers are at risk for toxicity from bioaccumulation in foodstuffs, excretion in breast milk, and concentration in fetal tissues [15–17]. These toxicants can cause a variety of systemic manifestations, but are most notable for their central nervous system (CNS) effects. Organochlorines can be divided into four structural categories: dichlorodiphenyltrichloroethane (DDT) and related agents, hexachlorocyclohexanes, cyclodienes, and toxaphenes.

DDT is a well-known organochlorine. It was a popular insecticide in the agricultural industry during the 1960s. The many environmental concerns related to the use of DDT, including carcinogenesis, bioaccumulation, and other health risks to humans and animals, led to the banning of its use in the United States as of 1972. DDT is no longer being produced in the United States. Dicofol (a miticide) and methoxychlor are structurally related to DDT. The cyclodienes include chlordane, heptachlor, endrin, aldrin, and dieldrin. The use of several of these insecticides in the United States was discontinued between 1988 and 1990. Some of the other organochlorines that are structurally related to the cyclodienes include endosulfan, chlordecone, kelevan, and mirex. Endosulfan is considered highly toxic and is registered for agricultural, but not residential, use in the United States [18]. Mirex and chlordecone (Kepone) are no longer being used in the United States.

Pharmacology

The organochlorines are well absorbed from the gastrointestinal (GI) tract. For example, death can occur within 2 hours of intentionally ingesting endosulfan, and most deaths associated with chlordane have been from oral exposures in children. The serum half-lives of these chemicals are long, varying from days to months, because of their high lipid solubility. This allows these agents to be stored in fatty tissues (e.g., brain), with the resultant delay in total body clearance. The organochlorines are known to concentrate in breast milk and fetal tissue. At delivery, it has been shown that fetal blood and tissue had higher concentrations of lindane (γ-hexachlorocyclohexane, Kwell) than maternal samples [16,17]. However, teratogenic effects have not been demonstrated in the limited number of animal studies performed [19].

Organochlorines are metabolized by the microsomal enzymes in the liver. Toxaphene, chlordane, DDT, and lindane can induce microsomal enzyme activity and affect not only their own metabolism but also the effects of coadministered medications [20].

Chlordane has several metabolites, such as heptachlor, oxychlordane, and heptachlor epoxide. Most of the available information on chlordane and metabolite tissue distribution is from case reports of accidental and suicidal exposures. Depending on the source, the elimination half-life of chlordane varies from 21 to 88 days [21,22]. Most of the chlordane and metabolites are excreted by the biliary system. On absorption into the body, aldrin is rapidly metabolized to the epoxide derivative, dieldrin. Because very little of aldrin remains, its toxicity is attributed to dieldrin. Dieldrin is stored in fatty tissues, and its elimination half-life in humans is approximately 369 days [23]. Endrin, an isomer of dieldrin, is rapidly metabolized in both humans and animals, with an elimination half-life of 2 to 6 days [24].

TABLE 141.1

COMMON PESTICIDES

- Inorganic and organometal pesticides
  - Aluminum phosphide
  - Antimony potassium tartrate
  - Arsenical pesticides
  - Barium carbonate
  - Boric acid
  - Calcium chloride
  - Copper sulfate
  - Elemental mercury
  - Elemental sulfur
  - Lead arsenate
  - Mercuric chloride
  - Methylmercury
  - Phosphorus
  - Sodium chlorate
  - Sodium dichromate
  - Thallium sulfate
  - Zinc chloride
  - Zinc phosphide
- Pyrethrins, pyrethroids, and plant-derived pesticides
  - Anabasine
  - Barthrin
  - Blasticidin S
  - Cartap
  - Chlordecone
  - Cyfluthrin
  - Cyfluthrinate
  - Cyhalothrin
  - Cypermethrin
  - Decamethrin
  - Deltamethrin
  - Fluvalerate
  - Fluvalinate
  - Nicotine
  - Phenothrin
  - Pyrethrins
  - Resmethrin
  - Ricin
  - Rotenone
  - Sabadilla
  - Strychnine
  - Tralocythrin
  - Tralomethrin
- Fumigants and nematocides
  - Acrylonitrile
  - Aluminum phosphide
  - Boron trifluoride
  - Carbon disulfide
  - Carbon tetrachloride
  - Chloropicrin
  - 1,2-Dibromoethane
  - 1,2-Dichloroethane
  - *p*-Dichlorobenzene
  - 1,2-Dichloropropane
  - 1,3-Dichloropropene
  - Epoxyethane
  - Hydrogen cyanide
  - Methylbromide
  - Naphthalene
  - 1,1,1-Trichloroethane
  - Trichloroethylene
- Synthetic organic rodenticides
  - ANTU
  - Brodifacoum
  - Chloralose
  - Difenacoum
  - Diphacinone
  - Fluoroacetamide
  - Fluoroethanol
  - Norbormide
  - Pyriminil
  - Sodium fluoroacetate
  - Warfarin
- Herbicides
  - Amitrole
  - Atrazine
  - Bromoxynil
  - Cycloate
  - Dicamba
  - Dichlobenil
  - 2,4-Dichlorophenoxyacetic acid
  - Diquat
  - Diuron
  - Ioxynil
  - MCPA
  - Mecoprop
  - Molinate
  - Phenmedipham
  - Paraquat
  - Propanil
  - Propazine
  - Pyrazon
  - Silvex
  - Simazine
  - TCA
  - 2,3,5-Trichlorophenoxyacetic acid
- Fungicides and biocides
  - Benomyl
  - Captafol
  - Captan
  - 1-Chloro dinitrobenzene
  - Dichloran
  - Diphenyl
  - Maneb
  - Organotins (tributyltin)
  - Quintozene
  - Tetrachlorophthalide
  - Thiabendazole
  - Thiram
  - Thiophanate-methyl
  - Zineb
  - Ziram
- Organochlorine insecticides
  - Aldrin
  - Chlordane
  - Chlorobenzilate
  - Chlordecone
  - DDT
  - Dicofol
  - Dieldrin
  - Endrin
  - Endosulfan
  - Ethylan
  - Heptachlor
  - Hexachlorobenzene
  - Isobenzan
  - Kelevan
  - Kelthane
  - Lindane (γ -hexachlorocyclohexane)
  - Mirex
  - Methoxychlor
  - TDE
  - Toxaphene
- Organophosphate insecticides
  - Azinphos-methyl
  - Carbophenothion
  - Carejin
  - Chlorfenvinphos
  - Chlorphoxim
  - Chlorpyrifos
  - Demeton
  - Demeton-methyl
  - Dialifos
  - Diazinon
  - Dicapthon
  - Dichlofenthion
  - Dichlorvos
  - Dicrotophos
  - Dimefox
  - Dioxathion
  - Edifenphos
  - Endothion
  - Fenitrothion
  - Fensulfothion
  - Fenthion
  - Fonofos
  - Formothion
  - Jodfenphos
  - Leptophos
  - Malathion
  - Merphos
  - Methidathion
  - Mevinphos
  - Mipafox
  - Monocrotophos
  - Naled
  - Oxydemeton-methyl
  - Parathion
  - Parathion-methyl
  - Phenthoate
  - Phorate
  - Phosalone
  - Phosphamidon
  - Phoxim
  - Pirimiphos-methyl
  - Schradan
  - Temephos
  - Thiometon
  - Trichlorfon
- Carbamates
  - Aldicarb
  - Bendiocarb
  - 4-Benxiothielyn-*N*-methylcarbamate
  - Bufencarb
  - Carbaryl
  - Carbofuran
  - Dioxacarb
  - Isolan
  - 3-Isopropyl phenyl-*N*-methylcarbamate
  - Landrin
  - Methomyl
  - Mexacarbate
  - Oxamyl
  - Phencyclocarb
  - Promecarb
  - Propoxur
- Miscellaneous pesticides
  - Azoxybenzene
  - Busulfan
  - Chlorambucil
  - Chlordimeform
  - Chlorfenxon
  - DEET
  - 5-Fluorouracil
  - Hexamethylmelamine
  - Metaldehyde
  - Methotrexate
  - Porfiromycin
  - Propargite
  - Thiotepa
- Nitro compounds and related phenolic pesticides
  - Binapacryl
  - Dinocap
  - 2,4-Dinitrophenol
  - Dinoseb
  - Pentachlorophenol
  - TCDD

ANTU, α-naphthylthiourea; DDT, dichlorodiphenyltrichloroethane; DEET, *N*-*N*-diethyl-*m*-toluamide; MCPA, 4-chloro-2-methylphenoxyacetic acid; TCA, trichloroacetic acid; TCDD, tetrachlorodibenzodioxin; TDE, 1,1-dichloro-2,2-bis(4-chlorophenyl)ethane.

TABLE 141.2

ORGANOCHLORINE LEVELS OF TOXICITY

High	Endrin, dieldrin, aldrin, endosulfan
Moderate	Chlordecone, heptachlor, chlordane, toxaphene, dichlorodiphenyltrichloroethane, hexachlorobenzene
Low	Methoxychlor, perthane, kelthane, chlorobenzilate, mirex

Organochlorines have several mechanisms of action. They alter sodium- and potassium channel movement across the neuronal membranes and can be considered axonal toxins. With DDT, sodium ion transport is facilitated and potassium transport is inhibited. This results in the spontaneous firing and prolongation of action potentials and repetitive firing after a stimulus. DDT also inhibits Na^+/K^+ adenosine triphosphatase and calmodulin activities, which reduces the rate of neuronal repolarization. This may account for some of the neurologic manifestations such as paresthesias, thought disturbances, myoclonus, and seizures. Cyclodienes, hexachlorocyclohexanes, and toxaphenes manifest neurotoxicity by inhibiting γ-aminobutyric acid receptor function in the CNS [25]. In the limbic system, lindane can directly excite neurons and result in agitation and seizures [25,26]. Abnormalities in respiratory rate patterns can result from direct medullary toxicity or pulmonary aspiration. The level of toxicity of the various organochlorines can be categorized into high, moderate, and low (Table 141.2).

Clinical Toxicity

Poisoning can result from ingestion, dermal absorption, or inhalation. Inadvertent human exposures to aldrin and dieldrin have resulted from pesticide spraying, which causes dermal and inhalational absorption. The use of lindane in home vaporizers has resulted in significant inhalation toxicity [27]. Agents such as dieldrin, lindane, and Kepone have good dermal penetration. Workers who directly handled lindane had health complaints of headaches, paresthesias, tremors, confusion, and memory impairment [28]. Also, seizures have been reported in occupational surveys among sprayers and applicators of aldrin and dieldrin [29,30]. As little as two total body applications on two successive days of 1% lindane (Kwell), a common scabicide, resulted in seizures in an 18-month-old child [31]. The peak concentration of lindane occurs 6 hours after dermal application; thus, delayed and prolonged manifestations of toxicity may occur from dermal absorption. Dermatitis can occur from the topical exposure to dicofol and methoxychlor [24]. Intradermal and subcutaneous injections of these agents can result in chemical dermatitis and sterile abscesses [32]. Dicofol and methoxychlor have minimal toxicity. Human volunteers ingesting up to 2 mg per kg per day of methoxychlor for 8 weeks did not demonstrate any ill effects [33].

Seizures are the most prominent CNS effect of these agents. The seizures occur soon after exposure, may present without a prodrome, and can be quite protracted in frequency [24,34–38]. Late-onset seizures may result from delayed GI or dermal absorption. Acute exposures to DDT present initially with tremors, nausea, vomiting, muscle weakness, and confusion, which may progress to seizures [39]. Among the organochlorines, both psychomotor agitation and CNS depression have been described. Chlordecone, mirex, and endosulfan are more likely to cause tremors and agitation than seizures. Kelthane, perthane, methoxychlor, and lindane are more likely to cause CNS sedation than excitation. Endrin is considered one of the most toxic of the chlordienes, with reports of hyperthermia and decerebrate posturing [24]. In 1984, an outbreak of endrin toxicity from contaminated foodstuffs occurred in Pakistan, where seizures resulted in a 10% mortality rate [36].

Neurologic symptoms resolve quickly because of rapid distribution of the organochlorines from blood to lipid stores. Because redistribution back into the blood pool can occur at a later time, continual observation of the patient for delayed toxicity may be warranted. Some of the long-term CNS effects (i.e., thought disturbances) after significant exposures may be due to direct chemical toxicity or anoxic encephalopathy from sustained seizures [40]. Chlordecone is a recognized neurotoxin, causing peripheral neuropathies [41].

Nausea, vomiting, and diarrhea may occur after ingestions, especially if petroleum distillates are part of the preparation. Pulmonary aspiration of these agents can cause tachypnea and significant respiratory distress, with resultant pulmonary edema [40]. When dicofol is heated or comes in contact with an acid, it decomposes to hydrogen chloride, which causes respiratory irritation [24]. Hypersensitivity pneumonitis may result from inhalational exposures when the organochlorine is mixed with pyrethrins.

Cardiac dysrhythmias, including ventricular fibrillation, have been reported from organochlorine exposure [42]. Halogenated hydrocarbons sensitize the myocardium to catecholamines, which results in a variety of rhythm disturbances. Cardiotoxicity can be exacerbated by either stress-provoking events or the exogenous administration of catecholamines. In severely ill patients, other causes of cardiac dysrhythmias, such as hypoxia and acidemia, should be considered.

Significant elevations in liver enzymes were reported in a group of 19 workers with a 10-year lindane exposure [43]. Animal studies with acute oral exposures to lindane have demonstrated fatty degeneration and necrosis of the liver [44]. From the few reports of human exposures to chlordane, there is little evidence of hepatotoxicity from this agent [21,45,46]. Microsomal enzyme induction has been demonstrated in animals that were orally administered chlordane. Long-term exposure among 233 workers with aldrin, dieldrin, endrin, and telodrin for 4 to 12 years was not associated with any significant elevation of hepatic enzymes or hepatic enzyme induction.

Hematologic dyscrasias, including aplastic anemia, leukopenia, leukocytosis, granulocytopenia, granulocytosis, eosinophilia, thrombocytopenia, and pancytopenia, have been reported after repeated lindane exposures [27,47]. However, all of the involved preparations also contained benzene, which can account for such findings. Megaloblastic anemia and bone marrow depression have been associated with chlordane exposures. DDT and toxaphene are suspected human carcinogens [48,49]. The risks for aldrin and dieldrin as human carcinogens could not be determined by the International Agency for Research on Cancer because of insufficient human and animal data [48].

Diagnostic Evaluation

Serum and urine concentrations of these organochlorines are commonly measured by gas chromatography or mass spectrometry. In an obvious exposure, these measurements are academic and would not alter clinical management. There are no correlations between concentrations in body tissues and specific health effects. If the diagnosis is in doubt, these measurements can at least confirm or rule out the insecticide exposure. Although blood is commonly sampled for the detection of these chemicals, adipose tissue or human milk may be used as well [50]. The laboratory should be consulted regarding the availability of analytical methods for biological specimens other

than blood. An acute exposure can be determined by a quantitative comparison of parent compound to metabolite. Because DDT and aldrin are rapidly metabolized on systemic absorption, their elevated concentrations in the blood would support a recent exposure.

Chlorinated hydrocarbons are radiopaque, and their radiopacity is directly related to the number of chlorine atoms per molecule. Thus, radiographs can assist in demonstrating aspiration pneumonia and gut burden.

Management

Rescue workers and health care providers must use proper equipment, such as gloves and gowns, to prevent unnecessary exposure to these chemicals when providing assistance to these patients [51]. Initial treatment of organochlorine exposure involves limiting further chemical absorption by the patient. The patient should be removed from the scene, disrobed, and thoroughly and repeatedly washed with soap and water. Washing should include hair and fingernails. The patient's clothing and leather goods must be placed in a plastic bag and discarded because of the tenacious binding of these agents to leather. All wash water should be contained and discarded in a secure fashion.

The role of gastric decontamination depends on the clinical presentation. Immediately after an intentional ingestion and in asymptomatic patients without spontaneous emesis, gastric aspiration should be carefully performed with a small nasogastric tube. Activated charcoal should be administered soon after ingestion (preferably within 1 hour) because it can limit further gut absorption and enhance elimination by interrupting enterohepatic or enteroenteric circulation [27]. Also, cholestyramine may interrupt enteric circulation and enhance elimination. Chlordecone and chlordane undergo enterohepatic circulation, and cholestyramine is indicated in symptomatic patients. In a controlled trial, cholestyramine was administered as 16 g per day to symptomatic factory workers exposed to chlordane. After 5 months, chlordane fecal elimination was shown to increase by 3.3 to 17.8 times, with neurologic symptoms improving as concentrations declined. Milk- and oil-based cathartics should be avoided because their high lipid solubility can enhance gut absorption. Hemodialysis is not effective in enhancing elimination of these chemicals because of their high volume of distribution and protein binding [52]. Hemoperfusion is probably of no benefit [52].

Organochlorine-induced seizures are managed with benzodiazepines and barbiturates. Phenytoin has not been demonstrated to be more effective as an anticonvulsant than barbiturates and it may actually increase the incidence of these seizures [53,54]. For uncontrolled status epilepticus, muscle paralysis and general anesthesia may be necessary. Aggressive seizure control is warranted to limit further development of CNS damage, metabolic acidosis, hyperthermia, rhabdomyolysis, and myoglobinuric renal failure.

Respiratory distress due to bronchospasm is managed with humidified oxygen and nebulized bronchodilators. Parenteral administration of adrenergic amines is not recommended because it may potentiate myocardial irritability. Early administration of steroids and prophylactic use of antibiotics for pulmonary aspiration have not been demonstrated to improve patient outcome. The early use of antibiotics may predispose to the selective growth of other bacterial organisms.

After appropriate decontamination, asymptomatic patients with an oral exposure can be observed for 6 hours and then discharged if their clinical status remains unchanged. Patients presenting with cardiovascular, CNS, or persistent respiratory manifestations should be admitted for further therapy and observation.

PYRETHROIDS

Pyrethrum is a collection of naturally occurring insecticide esters from the chrysanthemum flower. The pyrethrin I ester has the greatest insecticidal activity and is subject to rapid environmental degradation. To enhance its effectiveness in commercial use, synthetic alternatives known as pyrethroids were developed that are more resistant to decay. These compounds are present in consumer products, from flea and tick removers for pets to topical pediculicides.

Pharmacology

The pyrethroids (including pyrethrins) delay closure of the sodium channel during the end of depolarization, with resultant insect paralysis. Piperonyl butoxide is commonly added to commercial preparations to inhibit insects' ability to metabolize the pyrethroid and prolong activity. In mammals, these agents are relatively nontoxic because of the low concentrations and rapid mammalian metabolism. However, people who are allergic to ragweed may have hypersensitivity reactions to pyrethroids. The degree of this cross-sensitization has been reported to be as high as 46%. Pyrethroids have no effects on cholinesterase activity, and atropine and pralidoxime are not indicated in therapy.

Pyrethroids are readily absorbed from the GI tract. Dermal absorption varies depending on the type of agent and additive organic solvents. Systemic absorption is enhanced in the presence of petroleum distillates. These compounds are highly lipid soluble and largely metabolized by the mixed-function oxidase enzymes in the liver.

Clinical Toxicity

Poisoning from pyrethroids can result from inhalational, dermal, or oral exposures [42,44,55–57]. Nausea, vomiting, and diarrhea may occur after ingestion [44,57]. Neurologic manifestations and hypersensitivity reactions, including anaphylaxis, are the most common forms of systemic toxicity. Neurologic findings depend on the type and concentration of the pyrethroid and include paresthesias, muscle fasciculations, coma, and seizures [44,55,57]. Patients with an intentional ingestion of a mixture containing an organophosphate and a pyrethroid can present with predominant cholinergic manifestations [58].

Management

Treatment is very similar to that described for organochlorines (see previous discussion). GI decontamination may be appropriate, but there is no role for repeat-dose–activated charcoal and cholestyramine therapy because enterohepatic circulation has not been demonstrated for the pyrethroids. Hypersensitivity reactions, including anaphylaxis, should be managed with epinephrine, steroids, antihistamines, bronchodilators, and vasopressors, as indicated.

Asymptomatic patients with oral exposures can be observed for 6 hours and medically cleared of toxicity if their clinical status remains unchanged. Patients presenting with

cardiovascular, CNS, or persistent respiratory manifestations should be admitted for further therapy and observation.

ANTICOAGULANTS

Bishydroxycoumarin (dicumarol), the first anticoagulant, was isolated as the hemorrhagic agent in *sweet clover disease*, a bleeding disorder that resulted from the ingestion of spoiled clover silage. Numerous congeners, such as warfarin (3-α-acetonylbenzyl-4-hydroxycoumarin), have since been synthesized and used as a rodenticide. Typically, for the bait to be effective, the rodent must consume it for 3 to 10 days; however, continuous feeding for 21 days may be necessary to achieve 100% mortality. As rodents became increasingly resistant, warfarin derivatives were introduced and have supplanted warfarin. These "superwarfarins," or long-acting anticoagulants, include brodifacoum, difenacoum, and indanedione derivatives. The long-acting anticoagulants are 100 times more potent than warfarin and have a much longer half-life. Most anticoagulant rodenticide is packaged with cereal or other food products as bait, with the amount of rodenticide in the product varying from 0.025% to 0.005% per weight. Acute accidental or suicidal ingestion of a minimal amount of bait containing long-acting anticoagulants is unlikely to cause toxicity [59]. However, a "mouthful" of a long-acting anticoagulant ingestion in an adult human has been reported to cause significant coagulopathy [60–62].

Pharmacology

Warfarin and its derivatives are oxidized by mixed-function oxidases into inactive metabolites in the liver [63]. The plasma half-life of warfarin is 42 hours, with duration of action of 2 to 5 days [63]. The long-acting anticoagulants are concentrated in the liver and have extremely long half-lives; brodifacoum has a half-life of 120 days in dogs, 61 hours in rabbits, and 156 hours in rats [64–66]. The half-life of long-acting anticoagulants may be affected by the dose. The exact half-life of long-acting anticoagulants in humans is unknown, and because of significant interspecies variation, animal data cannot be extrapolated to humans. Case reports in human exposures have reported half-lives of 6 to 23 days for chlorophacinone and 16 to 39 days for brodifacoum [60,67–70]. Clinical coagulopathy may persist as long as 42 to 300 days [67–69,71–74].

These anticoagulants inhibit vitamin K 2,3-epoxide reductase and, to a lesser extent, vitamin K reductase. These enzymes are responsible for the cyclic regeneration of vitamin K [75,76]. Vitamin K is the active coenzyme responsible for activation of clotting factors II, VII, IX, and X, as well as anticoagulant factors protein C and protein S, by hepatic γ -carboxylation of the *N*-terminal glutamate residual of these proteins [75]. Once activated, vitamin K–dependent clotting factors can interact with calcium and phospholipids in the coagulation cascade [70]. Inhibition of vitamin K 2,3-epoxide reductase and vitamin K reductase depletes vitamin K and vitamin K–dependent clotting factors, resulting in coagulopathy and bleeding. The half-lives of vitamin K–dependent clotting factors are 7 hours for factor VII, 24 hours for factor IX, 36 hours for factor X, and 50 hours for factor II [63]. Because factor VII has the shortest half-life of the vitamin K–dependent clotting factors, increases in prothrombin time or international normalized ratio (INR) are not seen until 50% to 70% of factor VII is depleted. In a healthy person, this change occurs 24 to 48 hours after ingestion [59]. Clinical coagulopathy may not be evident for several days when the other vitamin K–dependent factors are also depleted, however [77,78].

Clinical Toxicity

The primary manifestation of poisoning is coagulopathy. The most common signs are cutaneous bleeding, soft-tissue ecchymosis, gingival bleeding, epistaxis, hematuria, and increased menstrual bleeding [61,79]. Gross hematuria, GI bleeding, hemoptysis, and peritoneal and diffuse alveolar bleeding may occur in patients with more serious poisoning [80–83]. Fatalities are uncommon and usually result from complications of intracranial hemorrhage [82,84].

Management

Gastric decontamination with activated charcoal should be initiated for acute ingestions. The most important laboratory studies are the prothrombin time and INR. Soon after an acute ingestion, values are expected to be normal; assays must be repeated at least 48 hours after exposure because of delayed coagulopathy [59]. Prophylactic vitamin K therapy can delay the onset of coagulopathy, but is not recommended as it may obscure the diagnosis and mandate prolonged coagulation profile monitoring, which might otherwise be unnecessary. Clotting factor analysis, particularly for factor VII, is a more sensitive and earlier indicator of coagulopathy [59]. Factor analysis does not offer more useful information in most patients with minimal ingestions, however. Occasionally, serum detection for warfarin and its derivatives has demonstrated unsuspected exposures in patients with coagulopathy of unknown cause [62,71]. In patients with coagulopathy, serial monitoring of warfarin derivative concentrations can assist in predicting the duration of coagulopathy and therapy [67].

The primary treatment of anticoagulant toxicity is vitamin K replacement [85,86]. Warfarin and its congeners have much less effect on human than on rat vitamin K reductase, thus allowing vitamin K rescue therapy for anticoagulant toxicity in humans. Because a single dose of vitamin K therapy cannot affect the prolonged toxicity of the long-acting anticoagulants, empiric vitamin K therapy is not recommended unless the patient has a coagulopathy. Vitamin K is not immediately effective in reversing coagulopathy; fresh-frozen plasma (FFP) administration is indicated in patients with significant bleeding diathesis (Table 141.3). Factor-specific concentrates have been demonstrated to decrease the time to correction of the INR in patients with a coagulopathy from warfarin toxicity faster than FFP [87]. The experience with these agents in the treatment of long-acting anticoagulant rodenticides, such as brodifacoum, is limited. Activated factor VII (FVIIa), FFP, and vitamin K have been used to treat brodifacoum toxicity [88,89]. In one of these instances, a product containing FVIIa and prothrombin complex concentrates (factor II, IX, and X) was used [88]. Some advantages of factor-specific concentrates over FFP include improved consistency in correction of the INR and decreased amount of fluid administered.

Only vitamin K_1 (phytonadione) should be used because the other forms (K_2, K_3, and K_4) are ineffective in the treatment of anticoagulant toxicity. Vitamin K_1 can be administered orally, subcutaneously, intramuscularly, and intravenously. Intravenous administration has been associated with anaphylactoid reactions and death [90–92]. Furthermore, it offers no real advantage over other routes of administration. Intramuscular injection may cause hematoma formation in patients with coagulopathy. Subcutaneous administration of vitamin K_1 is safe and effective. Oral vitamin K_1 may be simpler and just as efficacious [93]. The oral vitamin K_1 dose required to reverse coagulopathy is variable, but typically ranges from 100 to 300 mg per day, divided three to four times per day [61,66,80]. The amount

TABLE 141.3

TREATMENT GUIDELINES FOR COAGULOPATHY FROM LONG-ACTING WARFARIN-LIKE RODENTICIDES IN PATIENTS WITH NO UNDERLYING RISKS FOR THROMBOEMBOLISM

Active bleeding, major and life threatening

1. Factor replacement
   Fresh-frozen plasma (15 mL/kg)
   and
   Factor-specific concentrates, such as prothrombin complex concentrates (50 units/kg) or activated factor VII
   and
2. Vitamin K_1 intravenous (adult 10 mg, pediatrics 100 µg/kg by slow infusion)
3. Packed red blood cells for significant bleeding (i.e., anemia and hypotension)

No active bleeding and international normalized ratio (INR) ≥ 4.0

1. Vitamin K_1 intravenous (adult 10 mg, pediatrics 100 µg/kg by slow infusion)

Adapted from Leissinger CA, Blatt PM, Hoots WK, et al: Role of prothrombin complex concentrates in reversing warfarin anticoagulation: a review of the literature. *Am J Hematol* 83:137–143, 2008; and Watt BE, Proudfoot AT, Bradberry SM, et al: Anticoagulant rodenticides. *Toxicol Rev* 24:259–269, 2005.

of vitamin K therapy must be titrated to clinical response, however. The duration of vitamin K therapy and coagulopathy is also highly variable, ranging from 40 to 300 days. When the patient's INR has remained normal for several days after stopping the treatment, vitamin K therapy can be discontinued. The trend of the patient's concentration of clotting factors during this period may assist the determination of this clinical endpoint. Various methods have been proposed to decrease the duration of coagulopathy, including administration of hepatic enzyme inducers such as phenobarbital [64,66]. There is no good evidence to support any of these therapies, however.

STRYCHNINE

The use of strychnine as a pesticide dates back to the sixteenth century, when an extract of the Filipino St. Ignatius bean (*Strychnos ignatii*) was introduced as a rodenticide in Europe. Strychnine was used as a tonic, cathartic, and aphrodisiac as late as 1970, and resulted in numerous deaths [94]. It is also found as an adulterant in illicit drugs, such as cocaine and heroin. The only "legitimate" uses of strychnine today are as a pesticide and in research study of neural transmission [94,95].

Pharmacology

Strychnine is rapidly absorbed through the nasal mucosa and orally in the small intestine. It undergoes hepatic oxidative transformation to unknown metabolites [96], and only 10% to 20% is excreted unchanged in the urine within 24 hours. The half-life of strychnine in humans is 10 to 16 hours, and the volume of distribution is 13 L per kg [97,98].

Strychnine competitively antagonizes postsynaptic glycine receptors at the spinal cord and, to a lesser degree, at the brain stem, cerebral cortex, and hippocampus [95,99,100]. Strychnine-binding sites overlap, but are distinct from glycine-binding sites at the glycine receptor [100,101]. Glycine receptors at the cerebral cortex and hippocampus are of a subtype insensitive to strychnine and are minimally affected [95]. The action of glycine is similar to that of γ-aminobutyric acid in that it enhances chloride ionic channel conduction, resulting in hyperpolarization of postsynaptic membrane and an increased threshold for neurologic transmission [95,102]. The highest concentration of glycine receptors is found at the ventral horn motor neurons in the spinal cord [102]. Glycine antagonism reduces neuromuscular inhibition, including reciprocal inhibition between antagonistic muscles, resulting in contraction of both flexor and extensor muscle groups [103]. The pharmacologic effect of strychnine is quite similar to that of tetanus toxin, which inhibits the release of glycine at postsynaptic neurons in the spinal cord [102,104].

Clinical Toxicity

The onset of toxicity is usually within 15 to 30 minutes of exposure. The lethal dose in adults is typically 50 to 100 mg, but it may be as little as 5 to 10 mg in children [94,105]. Diffuse muscle contractions and spasms are the primary manifestations of strychnine toxicity. Facial muscle spasms result in risus sardonicus (the "sardonic smile") and trismus. Opisthotonos, abdominal muscle contractions, and tonic movements of the extremities may resemble convulsions. Because glycine has limited effects in the higher CNS centers, seizures are unlikely and mental status is normally preserved until the patient is hypoxic or moribund [94,105]. The extensor muscles appear to be more affected than the flexor muscles because they are the antigravity muscles and generally stronger [94,105]. Muscle contractions can be triggered or amplified by any stimulations, including auditory, tactile, and visual stimuli, and may lead to lactic acidosis, rhabdomyolysis, and hyperthermia [103,106]. Respiratory depression results from sustained chest and diaphragmatic muscle contractions and brain-stem depression. Death is related to respiratory depression, anoxia, and complications from significant muscle contractions [97,105]. The clinical manifestations of strychnine toxicity differ from tetanus infection in that the onset of symptoms in tetanus infection is more gradual and the duration of illness is more prolonged [104].

Management

Securing the airway, assisting breathing, and maintaining the circulatory system are the immediate goals in symptomatic patients. Electrolytes, acid–base changes, oxygenation saturation, renal function, urine output, and temperature must be monitored carefully in any symptomatic patient. GI decontamination should be performed in any case of suspected strychnine ingestion. Enhanced elimination by urinary manipulation has no effect because of minimal renal elimination [96]. Hemodialysis or charcoal hemoperfusion is ineffective because of the large volume of distribution.

Termination of muscle contractions prevents or reverses lactic acidosis, rhabdomyolysis, hyperthermia, and respiratory depression. Benzodiazepines are the initial agents of choice in attenuating musculoskeletal signs and symptoms [107–109]. Benzodiazepines enhance γ-aminobutyric acid effects in the spinal cord and may displace strychnine binding to glycine receptors [100,110,111]. Barbiturates also are reported to be useful in the treatment of strychnine toxicity. These agents may not be completely effective in patients with severe strychnine poisoning, however, and other agents such as propofol and adjunct nondepolarizing neuromuscular blockade may be required [98,105]. Strychnine toxicity usually resolves within

12 to 24 hours [96,103,112]. Supportive therapy should be continued until the patient is asymptomatic.

SODIUM MONOFLUOROACETATE

Sodium monofluoroacetate is frequently referred to as "compound 1080," the number assigned to the compound during its initial development. It is the primary toxic constituent in the South African gifblaar (*Dichapetalum cymosum*), but it is also present in other plants in South America and Australia. Fluoroacetate is highly toxic to all mammals, and its use was banned in the United States in 1972 because of human fatalities and indiscriminate extermination of nontarget species. The congener sodium fluoroacetamide (compound 1081), also used as a pesticide, has mechanisms and effects similar to those of fluoroacetate. Prior to compound 1080's ban in the United States in 1972, it was mostly used in livestock protection collars (tubular collars filled with pesticide, which is released when bitten by predators).

Pharmacology

Fluoroacetate appears to be minimally absorbed through skin but rapidly absorbed from the GI tract. It is metabolized to fluorocitrate in the tricarboxylic acid (TCA) cycle, with 12% of the ingested dose excreted in the urine [113]. In animals with relative resistance to monofluoroacetate, a hepatic defluorination system cleaves the carbon–fluoride bond to detoxify the compound [114].

Fluoroacetate is structurally similar to acetate and is incorporated into the TCA cycle with the assistance of acetyl coenzyme A. Fluoroacetate combines with citrate to form fluorocitrate in the TCA cycle [115]. Fluorocitrate inhibits aconitase and succinate dehydrogenase and disrupts the TCA cycle, halting cellular respiration and causing cell death [108,115,116]. Organs with high metabolic demands, such as the brain and heart, are immediately affected [117]. The lethal dose of sodium monofluoroacetate is 2 to 10 mg per kg [116].

Clinical Toxicity

The onset of poisoning occurs within 1 to 2 hours of exposure. Nausea and vomiting are followed by CNS and cardiovascular manifestations, which are the primary toxicities in humans [116,117]. The patient may present with agitation, lethargy, seizures, and coma [117–119]. Cardiovascular manifestations include tachycardia, premature ventricular contractions, ST-segment abnormalities, hypotension, ventricular tachycardia, and ventricular fibrillation [116]. Acute renal failure may be related to hypotension, rhabdomyolysis, and the direct toxic effects of monofluoroacetate on the kidney [117]. Fatality is related to CNS and cardiovascular toxicities [120,121]. Laboratory abnormalities include significant metabolic acidosis and hypocalcemia from the fluoride ion.

Management

General supportive measures are paramount and aimed at maintaining the airway, breathing, and circulation. Activated charcoal should be administered in all suspected oral exposures presenting within 1 to 2 hours after ingestion. Seizures should be treated with benzodiazepines or barbiturates. Hypocalcemia and prolonged QTc intervals may require calcium and magnesium supplementation. Various treatments have been tested in animals [122,123]. The most useful agent appears to be glyceryl monoacetate, which provides excess acetate as a substrate for the TCA cycle [122,124]. The clinical use of glyceryl monoacetate remains unproven, however.

ALUMINUM AND ZINC PHOSPHIDES

Aluminum and zinc phosphides are highly toxic insecticides and rodenticides commonly used as solid fumigants and grain preservatives. They are considered to be ideal pesticides for grain preservation because of the simplicity of application, low cost, and high efficacy without grain contamination. Although highly restricted in the United States, aluminum phosphide is widely available and commonly used for home grain storage in Asia and the Middle East. Typically, each pellet contains 3 g of 56% aluminum phosphide [125]. Aluminum phosphide has become one of the most common suicidal agents in India and other developing countries [10,125–128]. As little as 0.5 g can be fatal to an adult [129]. Phosphides are widely used in grain freighters and have emerged as the major maritime occupational health hazard [130]. Phosphine is slowly liberated when phosphides react with moisture in the environment.

Pharmacology

Phosphides react with water to form phosphine; the reaction is exothermic and it may be accelerated in the acidic environment of the stomach [126,131]. Phosphine is then readily absorbed in the stomach. Phosphine itself can also be absorbed through the lungs. There is limited information on the pharmacokinetics and metabolism of phosphine, although it is known to be partly eliminated through the lungs [131].

The exact mechanisms of toxicity have not been elucidated; the most likely mechanism is related to noncompetitive inhibition of cytochrome C oxidase. Also, phosphine increases the production of superoxide dismutase and lipid peroxidation [132]. As a cellular toxin, phosphine has deleterious effects on multiple organ systems, particularly organs with high metabolic demands.

Clinical Toxicity

Inhalation of phosphine gas results in immediate eye and mucus membrane irritation and early onset of pulmonary symptoms [126,129]. Oral ingestion of phosphides causes profound GI symptoms, including nausea, vomiting, and abdominal pain [125,129]. In these instances, esophageal lesions, such as ulcers, perforations, and strictures, can occur and they are typically associated with the ingestion of undiluted pellets [133,134]. Respiratory symptoms include cough, dyspnea, and chest tightness. Pulmonary edema and respiratory failure may be delayed for several hours after oral exposure to phosphides [125,135,136]. Hypotension and shock are expected within 6 hours in serious exposures. Fatalities are related to cardiovascular collapse from vasodilation and myocardial damage [137–139]. Various electrocardiographic changes have been reported, including ST-segment elevation and depression, QRS prolongation, bundle-branch blocks, atrioventricular nodal blockade, and supraventricular and ventricular tachycardia [140–142]. CNS effects lead to headache, lethargy, and encephalopathy [134]. Other manifestations include severe metabolic acidosis, hepatitis, and renal failure [137]. Mortality rates vary from 38% to 77% in suicidal ingestions [125,129,135,138,139].

Management

The patient should be immediately removed from the contaminated environment after the rescuer is adequately protected. Airway, breathing, and circulatory support are important in the immediate management. Activated charcoal should be mixed with sorbitol or magnesium citrate, rather than plain water, to reduce further liberation of phosphine in the GI tract [126]. Careful lavage with sodium bicarbonate (3% to 5% solution) or antacid has been advocated [143], but has not been adequately studied.

Cardiac monitoring and electrocardiography should be performed in suspected phosphine toxicity. Respiratory status should be monitored by continued clinical evaluation. Hypo- and hypermagnesemia have been reported with aluminum phosphide poisoning. Chest radiography, pulse oximetry, and arterial blood gases should be obtained as clinically indicated. The diagnosis may be suggested from a decaying fish odor released by substituted phosphines and diphosphines [126]. Silver nitrate–impregnated paper blackens in the presence of phosphine in the gastric fluid [144].

There is no antidote for phosphine poisoning. The mainstay of therapy is supportive care. Although intravenous magnesium therapy has been successful in treating various dysrhythmias [145–149], it has not been uniformly effective [150]. Magnesium therapy in phosphide poisoning should be considered in patients with dysrhythmias or hypomagnesemia.

METHYL BROMIDE

Methyl bromide (CH_3Br) is a colorless halogenated hydrocarbon gas primarily used as a fumigant for the control of nematodes, insects, rodents, fungi, and weeds. Methyl bromide has become one of the most widely used pesticides in the United States and worldwide since the abandonment of chlordane and acrylonitrile as fumigants [151,152]. Because methyl bromide causes ozone depletion in the stratosphere, the Montreal Protocol restricted its use in most developed countries since 2005. The United Nations proposed complete elimination of methyl bromide use worldwide by 2015. Methyl bromide was particularly popular in the food industry because it is extremely effective, is able to diffuse into any empty spaces, and does not leave any residues after proper ventilation. Space fumigation of fruits and tobacco can be performed in an airtight (fumigation) chamber. For soil fumigation, methyl bromide can be applied underground and sealed with an overlying tent or polyethylene cover. For structural fumigation, gas-proof tarpaulins are applied over the structure before the application of methyl bromide [153]. Methyl bromide is still used for the manufacture of chemicals such as aniline dyes. It has a musty and chloroform-like odor at high concentrations, but it is odorless at lower, but still very toxic, concentrations [154]. Because methyl bromide is heavier than air, it is particularly dangerous in an enclosed environment. Inadvertent exposures from accidents or inadequate ventilation have caused significant toxicities and fatalities [120,151,155–157].

Pharmacology

Methyl bromide is primarily absorbed through the lungs. Cutaneous absorption is minimal. Methyl bromide easily penetrates and is retained in cloth, rubber, and leather [153,158]. It is eliminated unchanged in the lungs, but a small proportion is metabolized to 5-methylcysteine and inorganic bromide; these are excreted in the urine [159].

The mechanism of toxicity is probably related to the methylation of sulfhydryl groups in different intracellular enzymes, as in heavy metal intoxication. Low concentrations of bromide can be detected in the serum after significant exposure to methyl bromide, but they do not correlate well with toxicity [151]. The symptoms of methyl bromide toxicity are distinctly different from those of bromide salt toxicity [160].

Toxic effects primarily involve the central nervous and pulmonary systems [151]. Although exposures to concentrations of 2,000 ppm or greater may produce immediate CNS depression and respiratory failure, symptoms may be delayed for 1 to 6 hours or longer with exposure to lower concentrations [153,157]. The current Occupational Safety and Health Administration permissible exposure limit for methyl bromide is 20 ppm [161].

Clinical Toxicity

Patients with mild toxicity may manifest dizziness, headache, confusion, weakness, nausea, vomiting, and dyspnea [120]. Initial or mild symptoms are frequently dismissed as viral symptoms [156]. Skin irritation and burns commonly underlie clothes and rubber gloves, where the methyl bromide gas is trapped [158]. After a significant exposure, the patient may present with tremor, myoclonus, and behavioral changes [121,162,163]. Severe toxicity may result in bronchitis, pulmonary edema, convulsions, and coma [151,157]. Fatality is related to pulmonary and CNS toxicities, although damage to different internal organs has been demonstrated [151,160,164]. Prolonged exposure to low concentrations of methyl bromide may cause subacute neurologic effects, such as headaches, confusion, behavioral changes, visual disturbance, and motor and sensory deficits [160,165–167]. Residual neurologic deficits may remain after significant acute or chronic exposure [160,164,168].

The essential laboratory studies in patients with methyl bromide intoxication are arterial blood gas or pulse oximetry monitoring. Chest radiography is useful in evaluating patients with pulmonary symptoms. Serum bromide concentrations may confirm exposure, but do not correlate with the severity of exposure. Serum bromide concentrations varied from 4.0 to 65.6 mg per dL in methyl bromide fatalities [151,160,169]. When the serum bromide concentration is significantly elevated, an elevated chloride concentration may be observed because of cross-reactivity in the analytical method [168].

Management

Treatment consists of supportive therapy, particularly of the airway, breathing, and circulation. Because methyl bromide is a gas, GI decontamination is not relevant. Clothing should be completely removed and the skin washed with soap and water to eliminate potential methyl bromide residues. Various compounds with sulfhydryl groups, such as dimercaprol and *N*-acetylcysteine, have been suggested as potential antidotes [158,162], but have not been demonstrated to be effective.

N,N-DIETHYL-M-TOLUAMIDE

N,*N*-diethyl-*m*-toluamide (diethyltoluamide, or DEET) was initially synthesized in 1954 and marketed as an insect repellent. Currently, DEET is the most effective and one of the most widely used insect repellents [170]. Use of DEET continues to increase with increasing public concern over Lyme disease and West Nile virus transmission. The concentration of DEET in the various products varies from 5% to 100%.

Pharmacology

DEET is well absorbed through the skin, with 48% of the applied dose absorbed within 6 hours. The plasma concentration peaks 1 hour after dermal application [171]. DEET is primarily metabolized in the liver, and 70% of the absorbed dose is excreted as metabolites within the first 24 hours. Another 10% to 15% is excreted unchanged in the urine [171]. DEET and its metabolites may accumulate in the fatty tissue, particularly after repeated applications.

The mechanism of DEET toxicity is unknown. Animals develop CNS symptoms similar to those reported in humans. Most reports of human poisoning involve children, likely because children absorb a higher ratio of DEET relative to their body weight. The initial theory suggested that patients with ornithine-carbamoyltransferase deficiency might be particularly susceptible to DEET toxicity [172]. However, recent reports have refuted this theory [173,174].

Clinical Toxicity

DEET may cause toxicity that is limited to skin irritation, contact dermatitis, skin necrosis, and urticaria [174–176]. Anaphylactic reactions have occasionally been reported with cutaneous application [176]. Manifestations of systemic poisoning vary from anxiety to behavioral changes, tremors, lethargy, ataxia, confusion, seizures, and coma [172–174,177–179]. Almost all of these case reports are related to application of concentrated DEET preparations or repeated application of lower concentration preparations [140,172,173,180].

Management

Treatment is largely supportive. Patients with dermal exposure should have their skin washed with soap and water to prevent further systemic absorption. Seizures may be treated with benzodiazepines. Neurologic workup may be required in many patients. The symptoms of DEET toxicity should be distinguished from those of Reye syndrome [172]. There is no antidote, and extracorporeal removal procedures are not helpful. Measures to prevent DEET toxicity may be the most important treatment. These include avoidance of concentrated DEET preparations. Products containing 20% to 30% DEET are adequate and safer than those with higher concentrations; concentrations of 10% or less are recommended for children. DEET should be applied only to exposed skin. An additional agent, such as permethrin, can be applied to clothing and may decrease the need of DEET [170]. The skin should be washed with soap when the insect repellent is no longer required, and the number of repeat applications should be limited.

PENTACHLOROPHENOL

Pentachlorophenol was first synthesized in 1841 and first used as a pesticide in 1936 [141]. It is primarily used as a wood preservative, however. Unlike other types of pesticide toxicity in adults, pentachlorophenol poisoning usually results from occupational exposure [142]. Occupational exposures to pentachlorophenol at wood-treating facilities frequently result from improper ventilation and inadequate engineering controls. Low-concentration, prolonged exposures to pentachlorophenol have been reported in log home residents from pentachlorophenol-treated wood [181]. Epidemics of infant poisoning have resulted from diapers improperly laundered with pentachlorophenol-containing antimicrobial soaps [182].

Pharmacology

Pentachlorophenol can be absorbed by the respiratory, oral, and dermal routes, although pulmonary absorption is the most efficient route. The volume of distribution is 0.35 L per kg and the pK_a is 5.0 [183]. Pentachlorophenol is primarily (74%) eliminated unchanged in the urine. A small proportion is oxidized to chlorohydroquinone, which is then eliminated in the urine. After a single oral exposure, the plasma half-life of pentachlorophenol is 27 to 35 hours [183]. Because of the low pK_a and significant renal elimination, pentachlorophenol elimination can be enhanced by urinary alkalinization [184].

The mechanism of toxicity of pentachlorophenol is similar to that of dinitrophenol: these agents uncouple oxidative phosphorylation by interfering with electron transport between flavoprotein and cytochrome P450.

Clinical Toxicity

Acute exposure results in headache, diaphoresis, nausea, vomiting, weakness, abdominal pain, and fever. With severe toxicity, significant hyperthermia (up to 108°F or 42.2°C), coma, convulsions, cerebral edema, and cardiovascular collapse may occur [141,185–187]. Laboratory studies may reveal a respiratory alkalosis and metabolic acidosis from significant exposures. Chronic exposures to pentachlorophenol have been reported to cause aplastic anemia, intravascular hemolysis, and pancreatitis [188–190]. Chloracne has also been reported from these exposures because of dioxin contamination in the product [186].

Management

Initial treatment includes oxygen supplementation, airway support, fluid resuscitation, and cardiac monitoring. Core temperature should be frequently monitored, and external cooling should be initiated immediately for significant hyperthermia. Seizures should be treated immediately with benzodiazepines or barbiturates to prevent further temperature increase and rhabdomyolysis. Fluid administration should be adequate to maintain a urine output of 1 to 2 mL per minute. Gastric decontamination (see Chapter 117) should be performed for oral exposure. The skin should be decontaminated with soap and water. Urinary alkalinization should be considered in patients with significant pentachlorophenol toxicity, although its clinical efficacy remains unproven [184].

PARAQUAT

Paraquat (1,1-dimethyl,4,4-bipyridyl dichloride) was developed in 1882 and for many years was used as an oxidation–reduction indicator. An electron donation to the compound forms a blue free radical; hence, paraquat was commonly called *methyl viologen*. The herbicidal properties of paraquat were discovered in 1955, and it was marketed as an herbicide in 1962. Today, paraquat is most commonly used as a nonselective contact herbicide in many countries. Paraquat can be applied safely when used according to the manufacturer's guidelines [191]. Typically, it is available as a 10% to 30% concentrated solution for agricultural use or as a 5% powder for domestic use. Once diluted, paraquat has limited absorption through the skin [192] and by aerosolization into the

respiratory system [193]. Paraquat is naturally inactivated in the soil and leaves little active residue in the environment. Despite its many desirable properties, however, the consequences of ingesting concentrated paraquat products are deadly. The median lethal dose of paraquat is 3 to 5 g in adults [194]. As little as a mouthful (10 to 15 mL) of a 20% solution of paraquat is fatal. Paraquat ingestion is a prevalent method of suicide in countries such as Taiwan, Japan, Malaysia, the West Indies, and Samoa [10].

Pharmacology

Although oral exposure to paraquat is the most common route of toxicity, less than 5% of the ingested amount is actually absorbed [195]. Any recent food ingestion may decrease the amount of systemic absorption. The peak plasma concentration is reached within 1 to 2 hours after ingestion. Paraquat is almost completely eliminated unchanged by the renal system [195]. Plasma paraquat concentrations decline rapidly after peak absorption because of tissue distribution. The terminal plasma half-life of paraquat is 12 hours with normal renal function, but it may be as long as 120 hours as renal function deteriorates [196]. The volume of distribution of paraquat estimated from kinetic study in one patient is 2.75 L per kg. Paraquat is particularly sequestered in the lungs and kidneys [195].

Dermal absorption of paraquat is minimal unless the exposure is prolonged with concentrated solutions [192]. Aerosolized paraquat particles have a diameter greater than 5 μm and do not reach the lower respiratory tree [193]. Concern about paraquat absorption from smoking marijuana is unfounded because much of the paraquat is pyrolyzed during the smoking process [197]. Paraquat toxicity from marijuana smoking has not been reported.

The primary organ of toxicity is the lung because of selective accumulation of paraquat. Paraquat is actively transported into type I and II alveolar cells through an existing transport system for endogenous polyamines. Paraquat and polyamines share a common structural property: they have two positively charged quaternary nitrogen atoms separated by a distance of 6 to 7 nm [198]. Diquat, another related herbicide with different structural features, is not selectively taken up and does not cause pulmonary toxicity [198,199]. Inside the cell, paraquat undergoes a single-electron reduction into paraquat free radical. This free radical reacts with oxygen to form superoxide free radicals, which then deplete nicotinamide adenine dinucleotide phosphate, leading to lipid peroxidation and subsequent cellular destruction [200,201]. Also, this mechanism of action is responsible for the phytotoxic property of paraquat. There is also evidence for direct inhibition of electron chain transfers in mitochondria [200].

Clinical Toxicity

The onset and severity of poisoning is largely determined by the amount of exposure. Patients who ingest more than 40 mg per kg usually die within hours to a few days [202]. These patients experience multiple organ failure, including acute respiratory distress syndrome, cerebral edema, myocardial necrosis, and hepatic and renal failure [202–205]. Death can be dramatic and may occur even before the development of significant chest radiographic abnormalities [202]. Patients who ingest 20 to 40 mg per kg of paraquat are most likely to die from pulmonary fibrosis, which progresses after a few days to a few weeks [206,207]. Ingestion of less than 20 mg per kg may lead to mild toxicity [202,206].

Paraquat is extremely corrosive to mucus membranes, and patients frequently complain of pain in the mouth, throat, esophagus, and abdomen [203,206]. The absence of significant ulcerations in the esophagus or stomach within the first 24 hours of exposure is a good prognostic indicator [203]. The development of renal failure is a poor prognostic indicator [196,203,208]. This phenomenon cannot be fully explained by the decreased elimination of paraquat in the body because most of the paraquat dose is eliminated within the first 24 hours, even in the setting of renal failure [196,209]. Conversely, renal failure may signify a large paraquat exposure. Almost all patients with renal failure from paraquat have significant pulmonary toxicity, but there are occasional reports of renal failure without significant pulmonary toxicity [205]. The prognosis for a patient with paraquat ingestion can be determined by the measurement of plasma paraquat concentration and its relation to time of ingestion [210]. The nomogram initially was presented by Proudfoot et al. [211] and subsequently refined by Hart et al. [210]. The availability of paraquat measurements depends on regional practice because the laboratory analysis is not routine. Although it is generally accepted that paraquat is not absorbed through the skin, it can be corrosive to the skin and nails [192]. Occasionally, dermal absorption and systemic toxicity may occur from prolonged exposure or exposure to concentrated products [212].

Management

It is critical to prevent systemic absorption of paraquat. Once ingested, it is rapidly absorbed and sequestered, frequently leading to death [205]. GI decontamination should be performed in any suspected paraquat ingestion. Orogastric lavage should be performed if the ingestion is within 1 to 2 hours. Fuller's earth (1 to 2 g per kg) or activated charcoal should be administered with a cathartic agent as soon as possible to bind any residual paraquat in the GI tract [213–215]. Multiple doses of oral adsorbents should be continued until there is evidence of adsorbent in the stool. This is done to prevent desorption of the paraquat. Any dermal exposure should be thoroughly washed with soap. Plasma and urine analytical methods to detect paraquat are useful to confirm the diagnosis and assess the prognosis; they are generally not useful in direct management of the patient. A rapid qualitative screen for paraquat exposure may be performed by the addition of sodium dithionite to urine under alkaline condition, however. A change in color to blue confirms paraquat's absorption [216]. Furthermore, prognosis may be predicted by the degree of color change: dark blue for poor prognosis and light blue for moderate-to-severe poisoning [217].

The treatment of paraquat toxicity consists of supportive care, particularly respiratory monitoring and support. Chest radiographs, judicious administration of supplemental oxygen, and monitoring for acute respiratory distress syndrome and impending respiratory failure are important in patients with significant exposure. Excessive oxygen supplementation may increase the formation of paraquat free radicals and worsen pulmonary toxicity [218]. Supplemental oxygen should be administered only when it is necessary and should be maintained at the minimal required level.

Experimental therapies for paraquat toxicity have been formulated using various strategies [200,208]. Forced diuresis does not have significant effects on paraquat elimination. Hemodialysis and charcoal hemoperfusion can increase elimination. In an animal model, the institution of charcoal hemoperfusion within 2 hours after paraquat ingestion decreased the fatality rate [219], and institution of hemoperfusion 2 hours after paraquat administration did not alter the paraquat concentration in the central compartment [220,221]. Clinically,

hemodialysis, charcoal hemoperfusion, and continuous arteriovenous hemofiltration have not altered mortality rates. There are significant limitations in applying extracorporeal procedures. Because the volume of distribution of paraquat is relatively large and paraquat is rapidly sequestered into tissue compartments, extracorporeal removal must be performed during peak absorption (within 2 hours after ingestion) to significantly decrease the paraquat body load. Because most patients present a number of hours after ingestion and the logistics of extracorporeal removal typically translate into an additional 1- to 2-hour delay, the amount of paraquat removed in most instances is insignificant.

Immunotherapy with monoclonal antibody fragments (Fab, Fv) against paraquat or against the active transport mechanism in the cells is intriguing [222,223]. More research is required to assess the value of this therapy, however. Various agents such as putrescine and spermidine [224,225] and β-adrenergic receptor blockers have been demonstrated to prevent active transport of paraquat into lung tissues but failed to provide any benefits in vivo.

Various antioxidants and free radical scavengers, such as vitamins C and E [201,208,226], deferoxamine [227], superoxide dismutase [228], clofibrate [208], selenium [229], glutathione peroxide, and *N*-acetylcysteine [230,231], have been tested against paraquat toxicity. To date, there has been no or insignificant improvement in animal models. A recent study using inhaled nitric oxide in rats demonstrated benefits in preventing pulmonary injuries and survival. Several studies have demonstrated increased patient survival with corticosteroids and cyclophosphamide therapy [232–238]. The use of methylprednisolone and cyclophosphamide to limit the acute inflammatory response from paraquat toxicity appears to decrease mortality in patients with moderate-to-severe poisoning from ingested paraquat on the basis of prospective controlled trials [237,238]. In a randomized-controlled trial, paraquat-poisoned patients with a predicted mortality of 50% or greater and less than 90% and treated with pulse-dose methylprednisolone and cyclophosphamide (Table 141.4) were less likely to die at 6 weeks than those who did not receive the treatment (mortality rate: 5/16, 31.3% vs. 6/7, 85.7%) (Table 141.5) [237]. All patients received GI decontamination and two sessions of charcoal hemoperfusion within 24 hours of hospitalization, which were completed prior to the initiation of the pulse-dose therapy. Methylprednisolone and cyclophosphamide do not appear to affect the mortality rate in patients with mild and fulminant paraquat poisonings [217,236]. Cyclophosphamide can cause a transient leukopenia (WBC < 3,000 per μL) in patients treated with the protocol [233,237]. Additional clinical trials at other centers are needed to verify that pulse-dose therapy with methylprednisolone and cyclophosphamide improves survival in patients with paraquat toxicity.

Other agents that may alter pulmonary fibrosis, such as colchicine [239], nonsteroidal anti-inflammatory agents, collagen synthesis inhibitors [240], and angiotensin-converting enzyme inhibitors [241], also require further study. Niacin, which increases nicotinamide adenine dinucleotide phosphate synthesis, has some protective effects in rats, but it is unclear if it is applicable to human toxicity [242].

Early lung transplantation has been unsuccessful because of toxicity to the transplanted lung from paraquat distributing from tissue stores [243,244]. A successful case of lung transplantation was performed in a patient 44 days after paraquat poisoning, however [245].

TABLE 141.4

TREATMENT GUIDELINES FOR PULSE-DOSE METHYLPREDNISOLONE AND CYCLOPHOSPHAMIDE IN PATIENTS WITH PARAQUAT TOXICITY [237][a]

Initial pulse-dose therapy
Cyclophosphamide 15 mg/kg/d administered as an infusion in 200 mL D5NS over 2 h for 2 d
Methylprednisolone 1 g/d administered as an infusion in 200 mL D5NS over 2 h for 3 d

After initial pulse-dose therapy
Dexamethasone 5 mg IV every 6 h until $PaO_2 \geq 80$ mm Hg or death

If $PaO_2 < 60$ mm Hg after initial pulse therapy, repeat pulse-dose therapy with
Methylprednisolone 1 g/d administered as an infusion in 200 mL D5NS over 2 h for 3 d, and

If WBC > 3,000 per μL at > 2 wk after initial pulse-dose therapy, add
Cyclophosphamide 15 mg/kg/d administered as an infusion in 200 mL D5NS over 2 h for 1 d

[a]Initiated after gastrointestinal decontamination and two sessions of charcoal hemoperfusion within 24 h of ingesting paraquat in patients with moderate-to-severe toxicity.

DIQUAT

Diquat (1,1′-ethylene-2,2′-dipyridylium ion) is a contact herbicide with action and structure similar to that of paraquat. Diquat and paraquat liberate hydrogen peroxide and oxygen free radicals, resulting in toxicity to plants and animals. The use of diquat is more limited and hence results in fewer intoxications than paraquat. Diquat is often formulated with paraquat.

Pharmacology

The kinetics of diquat are unknown in humans. In animal models, less than 10% of the oral dose is absorbed. More than 90% of the absorbed dose is eliminated unchanged by the kidneys. There are no known metabolites of diquat.

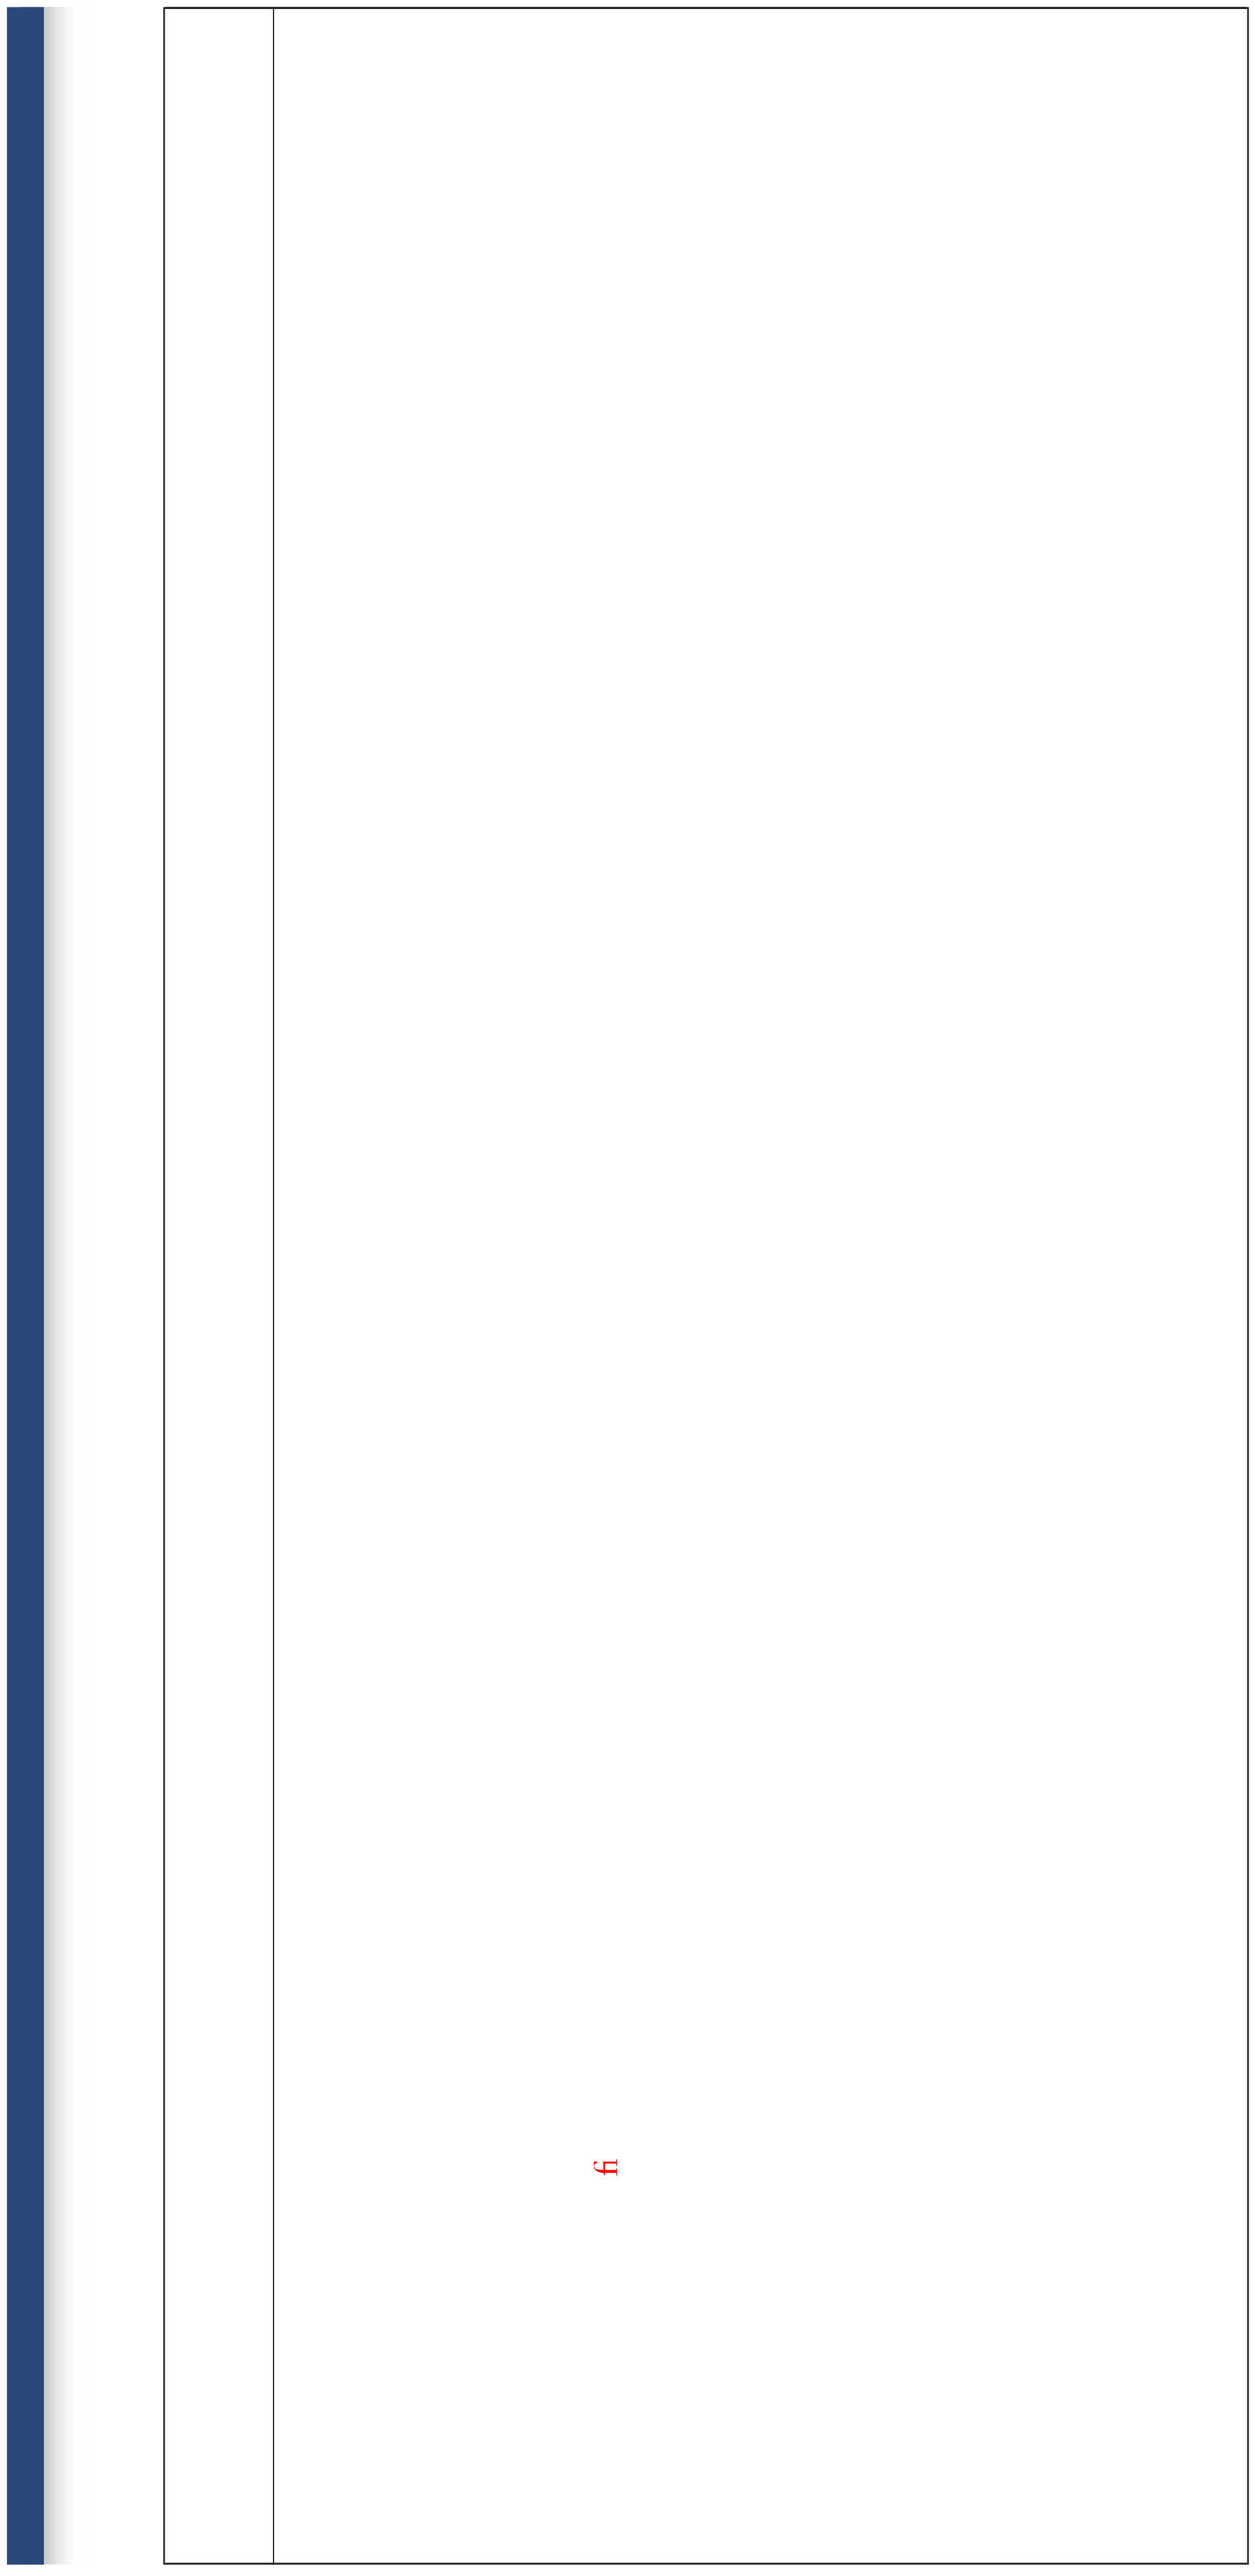
Although diquat is less toxic than paraquat, human fatalities have been reported with ingestion of 20 to 50 mL of a 20% solution [246]. Similar to paraquat, diquat causes multiple organ damage. Diquat normally spares the pulmonary system, however [246]. This is because diquat is not actively transported to and concentrated in the alveolar cells of the lungs [199].

Clinical Toxicity

Symptoms of diquat toxicity may be delayed several hours to 2 days [247]. Vomiting, abdominal pain, GI tract erosions, and paralytic ileus are common manifestations of toxicity [246,248,249]. Acute renal failure may be related to hypovolemia and the direct toxic effects. The effects of diquat on the CNS may result in lethargy, seizures, and coma [248,250]. Brain-stem infarctions may be specific to diquat toxicity. All patients who die have significant CNS manifestations before cardiovascular collapse [246,249].

Management

Treatment is largely supportive and similar to that for paraquat. Gastric lavage should be performed for any potential diquat ingestion within 2 hours. Fuller's earth or activated charcoal should be administered as soon as possible. Hemodialysis or



1510

hemoperfusion has not been demonstrated to be effective for the treatment of diquat toxicity [246,249,251,252].

CHLOROPHENOXY HERBICIDES

Chlorophenoxy herbicides are used to control broad-leaf weeds and woody plants. They exert their effects by mimicking the action of auxins (plant growth hormones) and cause overstimulation of plant growth. Numerous derivatives are available for agricultural and domestic use [253]. The most commonly used agents include 2,4-dichlorophenoxyacetic acid (2,4-D), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), and 2-methyl-4-chlorophenoxypropionic acid. Many preparations contain more than one chlorophenoxy herbicide or other types of herbicides. Despite extensive use of these agents, fatality and significant toxicity are limited. The chlorophenoxy herbicides are notorious because of dioxin contamination in Agent Orange, a 1-to-1 mixture of 2,4-D and 2,4,5-T used extensively in the Vietnam War, so named for the color of the drums used to store it. Agent Orange contained dioxin (2,3,7,9-tetrachlorodibenzodioxin), a contaminant in the synthesis of chlorophenoxy compounds and a potent teratogen in animals [254,255].

Pharmacology

In general, chlorophenoxy herbicides are well absorbed orally. They have small volumes of distribution, large renal excretion, and a low pK_a [253]. 2,4-D has a volume of distribution of 0.1 to 0.3 L per kg and a pK_a of 2.6 to 3.5 [256]. Oral doses of 5 mg per kg in human volunteers produce no ill effects. The peak serum concentration is achieved within 4 to 12 hours [257], 80% of the absorbed dose is eliminated unchanged in the urine, and 13% is eliminated as acid-labile conjugates. The plasma half-life is 18 to 40 hours and varies with urine pH; it may range from 4 to 220 hours [258]. The volume of distribution of 2,4,5-T is 6.1 L per kg. It is exclusively excreted unchanged in the urine, and the plasma half-life is 11 to 23 hours [259].

Various mechanisms of toxicity in humans are postulated. Uncoupling of oxidative phosphorylation has been demonstrated in vitro and may be responsible for a mild heat exhaustion syndrome [260,261]. Chlorophenoxy herbicides can interfere with the TCA cycle and cellular metabolism by forming analogues with acetyl coenzyme A [259,260]. There may be other direct toxic effects on skeletal muscles and peripheral nerves [262].

Clinical Toxicity

GI symptoms are common, and patients frequently experience nausea, vomiting, diarrhea, and abdominal pain [261,263,264]. Ulcerations may occur at the mouth and pharynx, but are uncommon elsewhere in the GI tract [260]. A mild heat exhaustion syndrome consisting of fever, diaphoresis, and hyperventilation can be seen [261,263]. The CNS is particularly affected, and patients may present with confusion, lethargy, convulsions, and coma [263,265]. Prolonged coma (up to 4 days) has been reported with 2,4-D toxicity [266]. Myotonia, rhabdomyolysis, and chronic muscle weakness are also reported [264]. Renal complications may result from rhabdomyolysis and myoglobinuria [267]. Hypocalcemia may occasionally be seen as a result of rhabdomyolysis and hyperphosphatemia [265,268]. Fatality is uncommon, and the cause of death remains unclear [258,260,264,268–270].

Management

Gastric decontamination with lavage should be performed within 1 to 2 hours of ingestion. Skin should be decontaminated with soap and water. Basic supportive therapies include the maintenance of good urine output (1 to 2 mL per kg per hour) with fluid resuscitation and external cooling for hyperthermia. Because of the low pK_a and renal elimination of chlorophenoxy herbicides, urinary alkalinization can significantly enhance renal excretion and decrease the plasma half-life of various chlorophenoxy herbicides [263]. Thus, it should be initiated in patients with significant toxicity by using a sodium bicarbonate infusion to titrate the urinary pH to 7.50 to 8.0. The patient's fluid status should be closely monitored because renal dysfunction may develop from chlorophenoxy herbicide toxicity. Although the utility of extracorporeal elimination of chlorophenoxy herbicides in poisoned patients has not been studied, hemodialysis may be useful for 2,4-D because of its small volume of distribution. Patients with renal insufficiency and significant toxicity would gain the most benefit from hemodialysis.

CHLORATE SALTS

Chlorate salts (sodium chlorate [$NaClO_3$] and potassium chlorate [$KClO_3$]) are nonspecific herbicides. They are also used in the manufacture of explosives, dyestuffs, tanning agents, and matches.

Pharmacology

Chlorates are strong oxidizing agents that result in hemolysis and methemoglobinemia. They have direct toxic effects on the kidneys and indirect nephrotoxicity from hemoglobinuria. Because chlorates are primarily eliminated by the kidneys, nephrotoxicity further enhances their toxicity. The acute lethal dose is 25 to 35 g [271].

Clinical Toxicity

GI symptoms are prominent within hours after an acute exposure and include nausea, vomiting, diarrhea, and abdominal pain [271–273]. Hemolytic anemia and methemoglobinemia result from the oxidizing effects. Both entities may result in a significantly decreased oxygen-carrying capacity and cellular hypoxia [272,274]. Cyanosis may be evident with significant methemoglobinemia. Acute renal failure typically develops within 48 hours after exposure [271,273,275]. Significant hyperkalemia from hemolysis is another potential fatal complication.

Management

Initial supportive care should be directed at the airway, breathing, and maintenance of circulation. Continuous cardiac monitoring should be initiated. Gastric decontamination should be performed within 2 hours after ingestion unless the patient already has significant vomiting. Laboratory studies should

include hemoglobin, serum electrolytes, blood urea nitrogen, creatinine, and methemoglobin concentrations. Electrocardiogram and arterial blood gas should be obtained as clinically indicated. Intravenous or oral sodium thiosulfate (2 to 5 g) has been advocated to inactivate the chlorate ion, but its efficacy has not been clinically proven [276]. Methylene blue should be administered for clinically significant methemoglobinemia, but it may not be effective in the setting of significant hemolysis because intact intracellular enzymes are required for its therapeutic effect [277]. Methylene blue is indicated in patients with a methemoglobin concentration of more than 20% or at a lower value in symptomatic patients with anemia. The initial dose is 1 to 2 mg per kg administered IV over 5 minutes and a response is anticipated within 30 minutes. Subsequent doses of methylene blue can be administered if there is an initial success, but it is withheld if no response is observed. Exchange transfusion may be required for refractory methemoglobinemia or significant hemolysis. Hemodialysis can remove chlorates and is recommended in patients with associated renal dysfunction [271,276].

CHAPTER 142 ■ PHENCYCLIDINE AND HALLUCINOGEN POISONING

FRANK F. DALY AND LUKE YIP[□]

PHENCYCLIDINE

Phencyclidine (phenyl-cyclohexyl-piperidine, or PCP) is a dissociative anesthetic chemically related to ketamine. PCP is a synthetic compound developed in the 1950s as an anesthetic–analgesic for animals and was used as a general anesthetic in man. However, there was an unacceptably high incidence of postoperative delirium and adverse drug events were not a deterrent for PCP abuse. Tables 142.1 and 142.2 show the slang, or street names, for both PCP and ketamine.

Pharmacology

PCP has acid and alkaloid forms. Both are odorless, nonvolatile, sold as "angel dust," and may be ingested or injected intravenously. PCP acid is a white crystalline substance sold as or incorporated into tablets. It deteriorates when heated and is not suitable for smoking. PCP alkaloid is a grayish–white amorphous powder smoked after incorporation into marijuana (e.g., "super grass," "super weed") or tobacco (e.g., "clickers," "primos") cigarettes. More often, the alkaloid is dissolved in a liquid hydrocarbon and applied to the wrapper of a tobacco cigarette. The ether-like or formaldehyde odor surrounding some patients who have used PCP is the smell of the volatile hydrocarbon used to dissolve PCP alkaloid.

Several analogs of PCP are occasionally used as street drugs (Table 142.3). Their pharmacologic actions are similar to those of PCP and cannot be distinguished clinically. In addition, street PCP samples may be contaminated with 1-piperidinocyclohexane-carbonitrile, a precursor of PCP that is more potent than PCP and capable of generating cyanide [1], although the clinical significance of this is unknown.

PCP has multiple mechanisms of action (Table 142.4), which helps to explain the varied signs and symptoms associated with PCP intoxication. It is well absorbed from the gastrointestinal (GI) and respiratory tracts. PCP is a weak base (pK_a 8.5), has a volume of distribution 6.2 L per kg, and is extensively protein-bound (65%) [2]. PCP concentrates in the brain, lungs, adipose tissue, and liver. The average serum half-life in controlled studies is 17 hours [2]. PCP is metabolized by the liver and excreted predominantly as inactive compounds [2–5]. Small amounts of PCP are excreted in perspiration, saliva, and gastric juice. PCP has been detected in umbilical and infant blood, amniotic fluid, and breast milk [6,7].

Clinical Toxicity

Drinking PCP, injecting intravenous PCP, or swallowing the remnants of a PCP-soaked cigarette has resulted in severe

intoxication within 1 hour. Clinical experience with PCP intoxication is derived from case reports [8–15] and small clinical series [16–20]. The hallmarks of PCP intoxication are nystagmus and hypertension. Nystagmus may be horizontal, vertical, or rotary. Patients may have systolic or diastolic hypertension. Hypertension usually resolves within 4 hours, but a significant number of patients may remain hypertensive for more than 24 hours.

Tachycardia is common, but heart rates more than 120 per minute are unusual. Hypothermia (< 36.7°C), hyperthermia (> 38.9°C), respiratory compromise, tachypnea, hypotension, and cardiac arrest are reported, but are uncommon.

Patients may present with delirium or normal sensorium. Lethargy, stupor, and unconsciousness are uncommon presentations. The most common behavioral effects are violent and agitated behavior, which may result in severe penetrating or blunt trauma. Patients may exhibit bizarre behavior such as driving less than 10 mph on the freeway, "playing bumper cars" on the freeway, sleeping on top of cars that are blocking traffic, lying down in a busy street, and wandering or acting wildly in public. Only 20% of PCP users report hallucinations or delusions. The visual hallucinations are typically concrete and realistic (e.g., blue fish). Patients may appear mute or may stare blankly.

The most common neuromuscular finding is rigidity of all extremities. It is often associated with jerky or thrashing movements, tremors, or twitching. Other musculoskeletal disturbances include oculogyric crisis, trismus, facial grimacing, circumoral muscle twitching, lip smacking or chewing movements, torticollis, tongue spasms, opisthotonos, and catalepsy. Patients may exhibit self-limited slow, writhing movements of the extremities or body. Athetosis and muscle stiffness may appear simultaneously. Intermittent athetoid movements may last for more than 10 hours. Rhabdomyolysis may occur, even in calm-appearing patients. Grand mal seizures and status epilepticus are uncommon.

The major autonomic effects are profuse diaphoresis, copious oral or pulmonary secretions, and urinary retention. Bronchospasm has been reported in patients who smoked or sniffed PCP. Pupillary size is usually normal, but miosis or mydriasis may be evident.

Clinically, acute PCP intoxication can be divided into major and minor clinical syndromes [20]. Major syndromes, representing moderate-to-severe PCP intoxication, are delirium, toxic psychosis, catatonic syndrome, and coma. They may include any of the effects previously discussed. Minor syndromes are lethargy or stupor, bizarre behavior, violent behavior, agitation, and euphoria. They represent mild PCP intoxication, and complications are rare.

Delirium is the most common presentation of PCP intoxication. Patients may be found wandering in traffic or appear intoxicated with ethanol. Patients exhibit signs and symptoms such as slurred, bizarre, or repetitive speech; ataxia; disorientation; confusion; poor judgment; inappropriate affect; amnesia of recent events; bizarre behavior; agitation; and violence. The duration of this syndrome often lasts for a few hours and rarely lasts more than 3 days, but has been reported to persist for 1 to 3 weeks.

Patients presenting with toxic psychosis often have a history of chronic PCP use (e.g., smoking) during the week before admission. This psychosis is characterized primarily by hallucinations, delusions, and paranoid ideation. Hallucinations may be auditory or visual, or both, and may involve seeing brilliantly colored objects, but objects are not distorted and there are no kaleidoscopic effects. Patients may be preoccupied with religious thoughts or have religious delusions. It is common for patients to have pressured speech, scream, or make animal sounds. Signs and symptoms persist for a median of 3 days (range, 1 to 30 days).

The catatonic syndrome manifests primarily as a combination of signs: posturing, catalepsy, rigidity, mutism, staring, negativism, nudism, impulsiveness, agitation, violence, and stupor. Stereotypies, mannerisms, grimacing, and verbigeration may also be present. Patients are typically mute, staring blankly, motionless, stiff, standing with extremities or head in bizarre positions, and unresponsive to noxious stimuli. Catatonic syndrome usually does not persist for more than 24 hours (range, 2 to 6 days), and most patients recover within 4 to 6 hours. The majority of patients emerging from catatonic syndrome are agitated or combative for several hours; the other patients emerge with delirium, lethargy, psychosis, bizarre behavior, or normal sensorium.

Patients with delirium and violent or bizarre behavior may subsequently lapse into coma. Coma may also occur abruptly and may last up to 6 days. Patients emerging from coma may exhibit delirium, catatonic syndrome, toxic psychosis, stupor, agitation, violence, bizarre behavior, or normal sensorium. The duration of the emergent phenomenon is variable.

TABLE 142.3

PHENCYCLIDINE ANALOGS USED AS STREET DRUGS

PCE (cyclohexamine)
PCPP (phenylcyclopentylpiperidine)
PHP (phenylcyclohexylpyrrolidine)
TCP (thienylcyclohexylpiperidine)

TABLE 142.4

PHENCYCLIDINE PHARMACOLOGY

Sites	Actions
N-methyl-d-aspartate receptor	Glutamate antagonist
D_2 dopamine receptor	Blocks dopamine reuptake Interferes with dopamine release
Serotonergic receptor	Antagonist
Cholinesterase	Antagonist
Nicotinic receptor	Antagonist
Muscarinic receptor	Anticholinergic effects may include tachycardia, mydriasis and urinary Cholinergic effects may include miosis salivation and diaphoresis Binds to receptors in the heart
Na^+ and K^+ channels	Antagonist
Presynaptic brain neurons	Increase catecholamine release

Data from references [53–63].

Violent, agitated, and euphoric patients typically have a clear sensorium. Patients with euphoria may report a sense of well being or feeling "spaced out," "freaked out," or "tingling all over." Such behavior usually lasts several hours.

Neonatal jitteriness, hypertonicity, and vomiting have been associated with maternal PCP abuse [21]. Chronic PCP intoxication has not been described, and there is no documentation of PCP flashbacks.

Diagnostic Evaluation

PCP intoxication is a clinical diagnosis. It is based on a history of possible PCP exposure associated with clinical findings consistent with PCP intoxication and the exclusion of other neuropsychiatric or behavioral disorders. The drug history should include the type of product, method of use, time of exposure, circumstances surrounding intoxication, and description of any effects witnessed by others or experienced by the patient. Particular attention should be paid to any abnormal behavior that might have resulted in occult trauma (e.g., jumps or falls).

The physical examination should focus on the vital signs, sensorium, behavior, and musculoskeletal, autonomic, and neurologic findings. A thorough examination should be performed to exclude occult trauma. Explosions in clandestine laboratories may lead to smoke or chemical inhalation, thermal or chemical burns, and blunt or penetrating trauma.

Laboratory tests should include complete blood cell count, serum electrolytes, blood urea nitrogen, creatinine, glucose, creatine phosphokinase (CPK), liver function tests, and urine analysis to include myoglobin. Common abnormal test results associated with PCP intoxication include hypoglycemia, elevated white blood cell count, serum CPK, serum glutamic oxaloacetic transaminase/serum glutamic pyruvic transaminase, and uric acid. Chest radiograph, electrocardiogram, arterial blood gas, computed tomography of the head, and lumbar puncture should be obtained as clinically indicated.

Serum or urine PCP levels can confirm the diagnosis of PCP intoxication but neither contributes to the patient management nor correlates with the severity of intoxication [22]. Rapid urine qualitative drug screens that detect PCP should be interpreted with caution. Dextromethorphan use may lead to false-positive PCP results on urine qualitative drug screens [23]. Diphenhydramine may interfere with PCP determination by gas–liquid chromatography [24].

Management

The immediate management is to assess and treat acute threats to the airway, breathing, and circulation. Close monitoring of the patient in a quiet area with limited stimuli may reduce the need for physical restraint or sedation and provide a safe environment for the patient, attending staff, and other patients. Routine gastric decontamination is not recommended.

Patients with major PCP intoxication syndrome or complicated minor PCP intoxication syndrome should be managed in an intensive care unit. These patients should receive supplemental oxygen, secure vascular access, and have their vital signs and cardiac rhythm continuously monitored. A core temperature should be obtained in all patients.

Hemodynamic effects of PCP usually do not require specific treatment. Abnormal vital signs should be managed in the context of the overall clinical status of the patient. Mild sinus tachycardia or hypertension not associated with psychomotor agitation or evidence of end organ damage usually does not require pharmacologic treatment. Treatment of psychomotor agitation using benzodiazepine sedation often results in improvement or resolution of sinus tachycardia and hypertension. Persistent significant hypertension despite resolution of psychomotor agitation, or if there is evidence of end organ damage, should be treated with intravenous nitroprusside or nitroglycerin titrated to effect. The use of β-adrenergic or calcium-channel antagonists to treat drugs of abuse-induced tachycardia or hypertension is not routinely recommended and may have deleterious effects.

Patients with hypotension should receive fluid resuscitation while alternative causes are considered (e.g., occult trauma). Persistent hypotension refractory to fluids necessitates a vasopressor such as norepinephrine or epinephrine. Pulmonary artery catheter hemodynamic monitoring may provide important data to guide pharmacologic intervention. Cardiac dysrhythmias should be managed according to current Advanced Cardiac Life Support guidelines.

Core temperature approaching or exceeding 104°F (40°C) is immediately life threatening and warrants aggressive management. Rapid-sequence induction, intubation, and ventilation may be required. Completely undress the patient, begin continuous monitoring of the patient's core temperature, and initiate active cooling measures. Active cooling should be terminated when the patient's core temperature approaches 101°F (38.3°C). Antipyretics (e.g., acetaminophen, aspirin, non-steroidal anti-inflammatory drugs) are not useful, and there is no good evidence that dantrolene, bromocriptine, or amantadine enhances the cooling process in patients with life-threatening hyperthermia.

The initial management of a patient with altered mental status should include assessment and treatment of all readily reversible causes such as hypoxia, hypoglycemia, opioid toxicity, and thiamine deficiency. Imaging studies of the head should be performed on patients with persistent altered mental status, followed by lumbar puncture as clinically indicated. Antibiotic and antiviral medications should be administered as soon as the diagnosis of meningitis or encephalitis is entertained.

Mild psychomotor agitation usually does not require active intervention, but sedation becomes necessary for patients whose behavior poses a danger to themselves or others. Haloperidol and chlorpromazine have been reported to be safe and effective in the management of patients with PCP intoxication who exhibit violent or bizarre behavior [20,25–27]. Benzodiazepines may be preferred treatment for patients with major or minor PCP syndromes; however, benzodiazepines lack anticholinergic and extrapyramidal side effects, do not lower seizure threshold, and have not been associated with hyperthermia or neuroleptic malignant syndrome. The dose of benzodiazepine should be titrated to achieve moderate sedation to obviate physical restraints. Occasionally, large doses (e.g., > 100 mg of diazepam) may be necessary to achieve safe gentle sedation. The patient's ability to protect the airway should be carefully monitored. Intubation and ventilation are rarely necessary.

Seizures should be treated with incremental doses of intravenous benzodiazepine. Cumulative high-dose benzodiazepine may be required. If seizure activity is not rapidly controlled, intravenous propofol or phenobarbital is indicated. Seizures refractory to sedative hypnotic drugs should be managed with non-depolarizing neuromuscular blockade and general anesthesia, along with continuous electroencephalogram monitoring.

Fluid management should address any electrolyte and acid–base abnormalities. Management of rhabdomyolysis should include treatment of psychomotor agitation and generous intravenous crystalloid fluids to maintain urine output of at least 2 to 3 mL per kg per hour to minimize the risk of acute tubular necrosis. The role of alkalinizing the urine to provide renal protection when rhabdomyolysis is present is controversial. As serum myoglobin levels are not usually rapidly available, serum CPK may be monitored noting that the clinically

important myoglobin serum peak may precede the CPK peak by several hours. Care should be taken to prevent dependent muscle injury.

Although urinary acidification can increase renal PCP excretion [9], the risks associated with urinary acidification outweigh potential benefits [10]. Hemodialysis is not indicated for enhanced drug elimination but may be necessary in patients with acute renal failure.

Patients with persistent suicidal ideation or psychosis should be referred to the psychiatric service.

HALLUCINOGENS

Psychedelic hallucinogens are primarily composed of synthetic indolamines (derivatives of tryptamine), phenethylamines (derivatives of amphetamine, see Chapter 144), and plant products. The psychedelic experience may precipitate homicidal acts [28–30], self-destructive behavior [31], accidental injuries, and acute or chronic psychosis. Physiologic effects vary from mild flushing to life-threatening alterations in vital signs, coma, seizures, and coagulopathy.

Pharmacology

Synthetic hallucinogens are sold as liquid, powder, tablets, capsules, microdots (dried drug residue) on printed paper, liquid-impregnated blotter paper, and as windowpanes (translucent 3 × 3 mm gelatin squares).

The routes of administration are oral, intranasal, sublingual, conjunctival, smoking, or intravenous injection. Blotter paper is chewed and swallowed, whereas microdot paper is usually licked. Windowpanes are usually placed under the tongue or in the conjunctival sac, and may also be swallowed.

The mechanisms of action for psychedelic hallucinogens are presumed to involve various neurotransmitters in the central nervous system. Psychedelic hallucinogen effects on thought and perception appear to primarily involve serotonin (5-hydroxytryptamine) neurotransmission. Serotonin modulates psychological and physiological processes such as affect, mood, personality, sexual activity, appetite, motor function, pain perception, sleep induction, and temperature regulation [32]. Serotonin causes vasoconstriction in all vascular beds except for coronary arteries and skeletal muscles, in which it causes vasodilation.

Tryptamine derivatives have been shown to act at presynaptic type 2 serotonin receptors (i.e., serotonin reuptake sites) [33]. Some of these compounds appear to be partial agonists or agonist–antagonists at these receptors.

Hallucinogens are readily absorbed from the GI tract, metabolized by the liver, and excreted predominately as pharmacologically inactive compounds. The clinical effects produced by different agents are very similar.

Lysergic acid (LSD, or "acid"), the most widely abused tryptamine derivative, was originally synthesized from an ergot alkaloid. The usual street form is a 1 cm^2 piece of blotter paper ("tabs"). At doses of 100 μg, LSD produces perceptual distortions and hallucinations.

Morning glory (*Ipomoea* and *Rivea* genera) seeds contain lysergic acid derivatives that are one tenth as potent as LSD. Users report that to achieve the desired hallucinogenic effect requires ingestion of 200 to 300 macerated seeds.

Psilocybin and psilocin are tryptamine derivatives found in *Psilocybe* and other hallucinogenic fungi ("magic mushrooms"). It is usually sold in the form of dried mushroom, capsules, or paper packets of brown powder. Pure psilocybin is available in capsules of white powder. The effective psilocybin dose is 5 to 15 mg, which is equivalent to ingestion of one to five large mushrooms. However, the clinical effects are dependent on a number of factors, including dose, method of preparation, and individual patient factors [34].

The toads of the genus *Bufo* secrete a mixture of hallucinogenic tryptamine derivatives and cardioactive compounds on their skin [35,36]. Toad licking has been popularized by the belief that hallucinogenic effects may be achieved by licking the skin of live toads.

Dimethyltryptamine (DMT) is an endogenous serotonin metabolite and is also found in the Yakee plant (*Virola calophylla*), which is native to the Amazon basin. Street DMT is available as liquid or yellow-tan powder that is sprinkled on tobacco, marijuana, or parsley and smoked. DMT is broken down in the GI tract; there is minimal systemic absorption after ingestion.

Mescaline, another amphetamine congener, is the psychedelic constituent of peyote (North American dumping cactus, *Lophophora williamsii*) and other cacti. Small segments of the crown of the cactus, known as "buttons" or "moons," may be swallowed whole or chopped into small pieces. Ground peyote may be smoked. The hallucinogenic dose of mescaline is 300 mg, corresponding to 6 to 12 buttons.

Clinical Toxicity

Acute psychedelic effects ("trip" or "tripping") are characterized by changes in sensory perception. They include euphoria or dysphoria; an increase in the intensity of sensory perception; distortions of time, place, and body image; visual hallucinations; synesthesias (i.e., "seeing sounds" and "hearing colors"); illusions; loss of spatial sense; and feelings of unreality. The visual hallucinations are characteristically nebulous, rapidly changing, and unreal (e.g., streaks and blobs of color or kaleidoscopic, multicolored shifting patterns). Visions and mystical experiences have been described [37]. Hallucinogenic drug effects may be variable, even in the same individual on different occasions. The person is usually awake and may appear hyperalert, but is often quiet, calm, withdrawn, depressed, uncommunicative, and oblivious to surroundings or preoccupied with internal stimuli. For some people, the psychedelic experience may be frightening or terrifying, which results in anxiety, agitation, violence, or panic (e.g., a "bad trip" or "bummer"). In general, tryptamine, amphetamine derivatives, and mescaline have clinical effects similar to those of LSD. The most common presentation is acute panic reactions. Patients typically present with anxiety, apprehension, a sense of loss of self-control, and frightening illusions.

The effects of LSD typically begin within 30 to 60 minutes, peak at 2 to 4 hours, and return to baseline within 12 hours. Accidental LSD ingestion by children has resulted in hyperactivity, tachycardia, and hyperventilation [38]; in one case, the reaction was described as "stark terror" [39]. The initial effects of morning glory seeds are listlessness, apathy, and irritability, followed by mild LSD-type effects. Severe psychedelic reactions have been reported [40–42]. Psilocybin effects usually last less than 4 hours but prolonged psychedelic effects have been reported after ingestion of 200 psilocybin mushrooms [43]. The effects of DMT are milder, occur sooner, and have shorter duration than those of LSD [44].

Hallucinogenic mushroom abuse has been associated with facial flushing, salivation, lacrimation, tachycardia, hypertension, mydriasis, nausea, vomiting, diarrhea, and hyperreflexia. Chills and myalgias may also occur [45].

Severe or life-threatening autonomic effects following hallucinogenic intoxication are rare and usually occur only after large doses. Manifestations include stupor or coma, bradycardia or tachycardia, shock or hypertension, severe hyperthermia, seizures, muscle rigidity, and coagulopathy.

No deaths directly attributable to the toxic effects of LSD have been reported. However, massive LSD overdose has resulted in severe autonomic effects such as coma, toxic psychosis, hyperventilation, respiratory arrest, hypertension, hyperthermia, tachycardia, athetosis, dystonic movements, and coagulopathy [46,47]. Serotonin syndrome has been associated with LSD use [48,49].

Intravenous injection of *Psilocybe* mushroom extract has resulted in systemic autonomic effects [45,50].

Persistent LSD effects rarely include prolonged psychotic reactions, depression, exacerbation of preexisting psychiatric illness, and hallucinogen-persisting perception disorder (flashbacks). Hallucinogen-persisting perception disorder is a chronic disorder that occurs after cessation of the acute intoxication and is characterized by recurrence of intrusive images. It can be triggered by stress, illness, and exercise. Flashbacks have been reported after LSD [51], morning glory seeds [41,42], and psilocybin [43] intoxication.

Diagnostic Evaluation

Psychedelic hallucinogen intoxication is a clinical diagnosis. It is based on a history of possible psychedelic hallucinogen exposure associated with clinical findings consistent with psychedelic hallucinogen intoxication. The drug history should include a history of prior drug abuse and psychiatric illness. Often, the name of the drug is not given but the route of intoxication and dosage form are described (e.g., "ate a paper," "chewed a button," "put acid in my eye"). Sometimes the only history is "on a trip."

Physical examination should focus on eliciting signs of autonomic disturbances, synesthesias, illusions, hallucinations, delusions, and abnormal behavior. Laboratory tests should include serum electrolytes, blood urea nitrogen, creatinine, glucose, CPK, and urinalysis. Urine toxicology screen may confirm the diagnosis of psychedelic hallucinogen intoxication and may be useful in patients with unexplained hallucinations. Quantitative hallucinogen drug levels are not clinically useful and do not contribute to patient management. Although laboratory tests are available for LSD and its metabolite [52], it is not part of most standard drug abuse screens. Electrocardiogram, arterial blood gas, imaging studies, and lumbar puncture should be obtained as clinically indicated.

Management

Management of psychedelic tryptamine is the same as for PCP. Patients should be placed in a quiet area with limited stimuli accompanied by a patient advocate. The advocate should provide reality testing and reassure the patient that it is a drug-induced experience and the adverse drug event will resolve within a few hours. This approach may not be practical or effective for severely disturbed or uncommunicative patients, and liberal intravenous benzodiazepine doses should be administered to achieve the desired effect. Depressed or withdrawn patients are unpredictable and should be kept under close observation. GI decontamination is unlikely to benefit a symptomatic patient and is not indicated. Cyproheptadine may be considered in patients exhibiting serotonin syndrome (see Chapters 66 and 124). Patients are expected to completely recover within 24 hours. Persistent signs and symptoms may be due to a psychiatric condition precipitated by the psychedelic drug, and the patient should be referred to the psychiatric service.

CHAPTER 143 ■ SEDATIVE–HYPNOTIC AGENT POISONING

ANDIS GRAUDINS

Sedative–hypnotics include benzodiazepines (BZDs), barbiturates, non-BZD nonbarbiturate agents (NBNBs), and some muscle relaxants. The barbiturates and "bromides" were the first to become available. In the 1960s, the NBNBs, such as meprobamate (Miltown), were introduced and became popular. NBNBs have been mostly supplanted by the BZDs, which have greater efficacy and a larger therapeutic ratio, and are currently one of the most widely prescribed classes of drugs (Table 143.1). BZDs and their derivatives are used to treat anxiety, depression, panic disorders, insomnia, musculoskeletal disorders, seizures, and alcohol withdrawal, and are used as adjuncts for anesthesia and procedural sedation.

BENZODIAZEPINES

Pharmacology

BZDs exert their therapeutic effect at specific BZD receptor sites in the central nervous system (CNS) [1]. The BZD receptor is located within the γ-aminobutyric acid-A (GABA-A) receptor supramolecular complex (GRSMC). Binding of GABA or GABA plus a BZD causes an allosteric change in the GRSMC. This results in an alteration in chloride-channel permeability, with an increase in chloride flux and hyperpolarization. GABA is an inhibitory neurotransmitter, and its receptors form an inhibitory bidirectional system with connections within many areas of the CNS. Once neurotransmission has been altered, there is a secondary effect on neurotransmitter release from the internuncial neurons. For the most part, activation of a GABA neuron leads to changes in dopamine release, although norepinephrine and acetylcholine may be involved. Serotonin effect is minimal except for neurons in the dorsal raphe [2]. Activation of GRSMC by a BZD potentiates synaptic GABA-mediated inhibition [3,4]. The GRSMCs are located throughout the brain and the spinal cord area. The BZD receptors are categorized as omega 1, omega 2, and omega 3. Each of the omega subtypes tends to cluster in particular areas of the CNS [2,5–7]. The omega-1 subtype predominates in the sensorimotor cortex and is predominantly sedative–hypnotic. The omega-2 subtype is concentrated in the limbic areas of the brain with mainly anxiolytic and anticonvulsant properties [2,3].

BZD absorption from the gastrointestinal (GI) tract depends on the properties and pharmaceutical formulation of each drug. Peak levels occur within 3 hours post-ingestion; intramuscular absorption can be erratic and delayed. Duration of action is dependent on the lipophilicity of each compound; the more

TABLE 143.1

Thiopental	

lipophilic, the shorter the duration of action. BZDs are highly protein-bound (85% to 99%). Their volume of distribution depends on lipid solubility and varies from 0.26 to 0.58 L per kg for chlordiazepoxide to 0.95 to 2.00 L per kg for diazepam. BZDs are metabolized by hepatic microsomal oxidation (N-dealkylation) and then glucuronidation [8,9]. They can be classified on the basis of elimination half-life (Table 143.2).

Fatality from pure BZD overdose is rare. Toxicity may vary between individual agents. Alprazolam overdose was found to result in more frequent intensive care unit admission, mechanical ventilation, and flumazenil use than other benzodiazepines [10]. A retrospective review of 1,239 overdose cases from one medical examiner's office revealed only two deaths solely related to diazepam overdose [11]. In chronic abusers, rapid clinical recovery after BZD overdose is believed to result from adaptation or tolerance to the depressant effect [12].

Clinical Presentation

Overdose commonly occurs as a part of polydrug ingestions. BZDs alone produce slurred speech, lethargy, ataxia, nystagmus, and coma. Loss of deep tendon reflexes and apnea are unusual except with a massive overdose. There are rare case reports of coma, cardiac arrest, acute respiratory distress syndrome, and pulmonary edema [12–15]. Abrupt cessation of BZDs after long-term use may result in a withdrawal syndrome [16,17] (see Chapter 145).

Diagnostic Evaluation

Recommended laboratory studies include serum electrolytes, blood urea nitrogen, creatinine, and glucose. Because BZDs may be involved in polydrug overdoses, serum acetaminophen levels and a 12-lead electrocardiogram (ECG) results should

TABLE 143.2

DURATION OF ACTION AND ELIMINATION HALF-LIFE ($T^{1}/_{2}$) OF BENZODIAZEPINES

Agent	Duration (h)	Elimination $t^{1}/_{2}$(h)	Peak effect (h)	Active metabolites
Ultra-short–acting	< 10			
Midazolam (Versed)		2–5	0.3–0.8	−
Temazepam (Restoril)		10	2–3	−
Triazolam (Halcion)		1.7–3.0	0.5–1.5	+
Brotizolam		5	1	−
Short-acting	10–24

also be obtained. Creatine phosphokinase (CPK), urine analysis, arterial blood gas, imaging studies, serum salicylate concentrations, and lumbar puncture should be obtained as clinically indicated. Quantitative BZD levels are not useful in the clinical management of overdose cases.

Management

The most important aspect of BZD overdose management is supportive care. Airway management should precede all interventions, and intubation is indicated if the patient cannot adequately maintain spontaneous ventilation or protect the airway. Vascular access should be established. The patient should be placed on continuous pulse oximetry and cardiac monitoring. Activated charcoal (1 g per kg) may be considered in awake patients if the presentation is within 1 hour of ingestion, but there is currently no evidence to suggest that administration changes outcome following simple BZD overdose and may in fact be harmful in patients who subsequently become sedated if the airway is unprotected. Charcoal administration is often not practical as many adult patients, presenting with deliberate self-poisoning, do so more than 2 hours post-ingestion [18]. Additionally, the risks of charcoal administration in a sedated patient with isolated benzodiazepine ingestion must be weighed against the low risk of morbidity and mortality seen with this type of poisoning. There is no evidence to suggest that repeat-dose charcoal enhances BZD elimination [19].

Flumazenil (Romazicon, Anexate) is a BZD antagonist that binds to the GRSMC omega-1 and -2 subtypes, competitively inhibiting BZD binding and thereby reversing BZD sedative and anxiolytic effects [20]. It may also reverse BZD-induced respiratory depression, obviating the need for intubation, but this effect is inconsistent. It does not fully reverse the amnestic effects of BZDs. Patients may appear awake and alert, but subsequent recall (e.g., of instructions) may be poor [21,22].

For most patients with pure benzodiazepine poisoning, supportive care with attention to airway and ventilatory status is all that is required to manage their overdose. It is uncommon for patients to require administration of flumazenil to treat sedation alone. This agent should never be considered in place of airway intervention in compromised patients. Adverse drug events associated with flumazenil use include anxiety, nausea, agitation, and crying. It should be avoided in patients who are suspected to be BZD-tolerant [23]. Flumazenil may precipitate an abrupt withdrawal syndrome with potential for seizures in these patients. This may occur after short-term use of benzodiazepines [24]. Flumazenil should also be avoided in patients with polypharmacy overdoses in whom reversal of BZD effect may unmask the epileptogenic effects of the other drugs (e.g., cyclic antidepressants, isoniazid, and cocaine). Flumazenil is contraindicated in patients with electrocardiographic evidence of cyclic antidepressant toxicity (e.g., prolonged QRS duration), as this finding is associated with a high risk of seizures [25]. Patients with a history of epilepsy are also at increased risk for seizures. Flumazenil has been suggested for both diagnostic purposes in undifferentiated coma and therapeutic purposes. Despite this, its role and indications remain unclear in the management of the BZD-poisoned patient [23]. Flumazenil does not reduce hospital length of stay or need for high-dependency monitoring. If administering flumazenil, the initial dose should be 0.05 to 0.1 mg. This can be repeated at 30-second intervals. In general, if there has not been any response after a total dose of 1 to 2 mg, the diagnosis of benzodiazepine poisoning is unlikely. In the uncommon situation where it may be used to reverse toxicity in deliberate self-poisoning, the aim is to titrate a flumazenil dose such that the patient is moderately drowsy and easily aroused, and *not* to have the patient completely awake, alert, and keen to self-discharge from hospital. Because flumazenil has a short half-life (approximately 50 minutes), it may be administered as an infusion in severe BZD poisoning, in a similar fashion to naloxone in severe opioid poisoning [26]. Seizures that result from flumazenil therapy may require treatment with large doses of BZDs or barbiturates (e.g., thiopental or phenobarbital).

Treatment of BZD withdrawal is similar to that for barbiturates and other nonbarbiturate sedative–hypnotics (see later discussion here and Chapter 145).

BARBITURATES

Barbiturates were the cornerstone of sedative–hypnotic therapy until the 1970s. Since then, the incidence of barbiturate overdose has declined, coincident with their diminishing use [27].

Pharmacology

Barbiturates depress the activity of all excitable tissues. They enhance GABA postexcitatory inhibition at the nerve terminal and appear to have a binding site on the GRSMC, leading to increased chloride flux. The CNS is most sensitive, with skeletal and smooth muscle depression evident at higher doses.

Barbiturates are available in all forms, although most toxicity results from ingestion. Barbiturates are divided into groups based on their duration of action. Ultra-short–acting barbiturates are highly lipid soluble and rapidly partition into the CNS, with subsequent redistribution to all tissues. When parenterally administered, they have rapid onset with less than 1-hour duration of effect; their predominant role is in induction of anesthesia.

Short- and intermediate-acting barbiturates are intermediate in lipid solubility and are used as anxiolytics and sedatives. Long-acting barbiturates have relatively low lipid solubility and are mainly used as anticonvulsants. Systemic toxicity tends to be a function of the drug's elimination half-life (Table 143.3).

Barbiturates are well absorbed from the GI tract; serum levels and symptoms are detectable within 30 minutes, and their peak effect occurs by 4 hours. Barbiturates are variably metabolized by the liver, with most of the highly lipid-soluble group excreted after glucuronidation. The longer-acting barbiturates rely more on urinary excretion for elimination (phenobarbital, 25% to 33%; barbital, 95%; primidone, 15% to 42%; phenylethylmalonamide a metabolite of primidone, 95%) [28]. As they are weak acids, renal elimination can be enhanced by urinary alkalinization. The kinetics of barbiturate elimination are mixed: first order at low concentrations and zero order at high ones [29]. Therapeutic serum drug levels are 10 to 40 µg per mL for phenobarbital and 1 to 5 µg per mL for the short-acting barbiturates. Toxic dosages are in the range of 6 to 10 g for the long-acting barbiturates and 3 to 6 g for the short-acting ones. Most patients demonstrate some degree of sedation with levels of 8 mg per kg. Tolerance rapidly develops, and chronic users may require 5 to 10 times the normal dose for sedation. Depending on the degree of tolerance, drug levels associated with coma range from 80 to 120 µg per mL for phenobarbital and 15 to 50 µg per mL for short-acting agents. Other sedatives (e.g., ethanol) have an additive effect and can result in toxicity at lower doses and blood concentrations [30].

Clinical Manifestations

The most common toxic scenario results from accidental or intentional oral barbiturate ingestion by a seizure patient or family member. Barbiturates may be involved in polypharmacy overdoses, particularly butalbital, a component of several common headache medications (e.g., Fiorinal).

TABLE 143.3

DURATION OF ACTION AND ELIMINATION HALF-LIFE ($t_{1/2}$) OF BARBITURATES

Barbiturate	Duration (h)	Elimination $t_{1/2}$ (h)
Ultra-short–acting	< 1/2	
Thiopental (Pentothal)		6–46
Thiamylal (Surital)		NA
Methohexital (Brevital)		1–2
Short-acting	3	
Hexobarbital (Sombulex)		3–7
Pentobarbital (Nembutal)		15–48
Secobarbital (Seconal)		19–34
Intermediate-acting	3–6	
Amobarbital (Amytal)		8–42
Aprobarbital (Alurate)		14–34
Butabarbital (Butisol)		34–42
Butalbital (Fiorinal, Esgic)		NA
Long-acting	6–12	
Barbital		48
Mephobarbital (Mebaral)		48–52
Phenobarbital (Luminal)		24–144
Primidone (Mysoline)		10–12

NA, not available.

Most patients present with some degree of sedation, which is evident within 30 minutes after ingestion of the agent. This may rapidly progress to coma, respiratory collapse, and hypotension. The patient may be mildly hypothermic from loss of autonomic function and decrease in overall muscle activity. The CNS depression is generalized, although there are many reports of focal findings [30,31]. Cardiovascular collapse with severe hypotension is believed to be due to direct myocardial suppression and vascular dilation, an indicator of serious toxicity. Dysrhythmias are rare. The gut becomes atonic, producing delayed absorption or ileus, which may then progress to bowel necrosis. Bullous skin lesions over pressure points occur in 6% of patients within 24 hours of ingestion [32,33]. The lesions are tense clean bullae surrounded by erythema, and the bullae fluid has detectable amounts of barbiturate. The presence of bullae is not pathognomonic for barbiturate poisoning. Bullae formation has also been reported following other sedative–hypnotics, tricyclic antidepressants, methadone, and carbon monoxide poisoning. Crystalluria has been reported [34].

Withdrawal symptoms may occur after 1 to 2 months of chronic use. Symptoms usually present after 2 to 7 days of abstinence or four to five elimination half-lives. Agitation, hyperreflexia, anxiety, and tremor are the most common symptoms, followed by confusion and hallucinations. In early withdrawal, up to 75% of patients experience seizures. Barbiturate withdrawal seizures appear to be more severe than ethanol withdrawal seizures. Transplacental tolerance occurs, with neonatal irritability noted for months after birth [35].

Diagnostic Evaluation

Serum phenobarbital concentration should be determined in situations where phenobarbital or primidone overdose is suspected. However, results of other serum barbiturate concentrations are generally not available in a clinically meaningful time. Recommended laboratory studies include complete blood cell count, serum electrolytes, blood urea nitrogen, creatinine, glucose, and liver function tests. Because barbiturates may be involved in polydrug overdoses, serum acetaminophen concentration, to exclude occult ingestion, and an ECG should also be obtained. CPK, urine analysis, arterial blood gas, imaging studies, and lumbar puncture should be obtained as clinically indicated.

Management

The most important aspect of barbiturate overdose management is supportive care. Early airway management is imperative, as up to 40% of patients may suffer from pulmonary aspiration. Frequent monitoring of all vital signs, including rectal temperature, is indicated. Vascular access should be obtained. The patient should be placed on continuous pulse oximetry and cardiac monitoring. A single dose of activated charcoal (1 g per kg) should be considered in large ingestions with appropriate airway protection.

Multiple-dose activated charcoal (MDAC) and urinary alkalinization can enhance the elimination of phenobarbital and possibly other barbiturates [36–38]. In a human volunteer study, MDAC was superior to urinary alkalinization in enhancing elimination of intravenously administered phenobarbital [39]. MDAC is recommended for all barbiturate overdoses, and urinary alkalinization is recommended for those involving long-acting agents such as phenobarbitone.

Hypotension should initially be treated with intravenous normal saline. Because its etiology is multifactorial, hypotension unresponsive to intravenous crystalloids challenge should be treated with dopamine or norepinephrine. Invasive hemodynamic monitoring and supportive therapy should be considered in severe or refractory cases. Cardiovascular instability unresponsive to conservative measures is also an indication for extracorporeal drug removal. Hemoperfusion (clearance, 100 to 300 mL per minute for phenobarbital) removes more drug than hemodialysis (clearance, 60 to 75 mL per minute), but more modern high-flow hemodialysis has the potential to be as effective as hemoperfusion, especially if combined with multiple-dose oral charcoal [40–42]. On completion of treatment, serum drug concentrations may rebound because of redistribution, and repeat hemodialysis/hemoperfusion may be necessary. Hypothermia requires rewarming. The patient should be monitored for development of aspiration pneumonia, acute respiratory distress syndrome, and electrolyte derangement.

Barbiturates suppress brain electrical activity, and an isoelectric electroencephalogram is not necessarily an indicator of poor prognosis; full recovery has been reported in patients with an isoelectric tracing.

Barbiturate withdrawal should be managed in a controlled environment with adequate resuscitation equipment available because seizures and cardiovascular collapse may occur. Because almost all sedative–hypnotic agents are cross-tolerant, barbiturate withdrawal can be treated with reinstitution of the same drug or another sedative–hypnotic (e.g., BZDs) in equipotent doses (Table 143.4). The goal in therapy is to suppress signs and symptoms of withdrawal. Patients should initially be given sufficient amounts of drug to induce sedation. Using an agent with a long duration of action (e.g., phenobarbital) maintains the serum concentrations, thereby limiting the side effects and cravings associated with falling levels. The dose is decreased by 10% every 3 days. If the equivalent phenobarbital dose is unknown, 120 mg can be administered orally or intravenously every 1 to 2 hours until withdrawal symptoms resolve or drowsiness ensues [17,43].

TABLE 143.4

SEDATIVE–HYPNOTIC EQUIVALENTS

Diazepam, 5 mg, is equivalent to	
Oxazepam	30 mg
Chlordiazepoxide	25 mg
Flurazepam	15 mg
Clorazepate	3.75 mg
Lorazepam	1 mg
Triazolam	0.5 mg
Alprazolam	0.25 mg
Phenobarbital, 30 mg, is equivalent to	
Pentobarbital	100 mg

Adapted from references [43,99].

Tolerance can be ascertained by the pentobarbital suppression test. The patient is given phenobarbital, 200 mg, every 2 hours until sedation occurs. If the initial 200 mg does not cause sedation, tolerance is present. If more than 1,200 mg is required to produce sedation, the patient will most likely experience withdrawal symptoms.

NONBENZODIAZEPINE, NONBARBITURATE SEDATIVE–HYPNOTICS

NBNB sedative–hypnotics include glutethimide (Doriden), ethchlorvynol (Placidyl), meprobamate (Miltown), chloral hydrate (Noctec), and the antispasmodic–muscle relaxants carisoprodol (Soma) and baclofen (Lioresal). Toxic effects and overdoses can be seen from legitimate and illicit use. Newer agents have also been introduced that vary in their toxicity in overdose. These include buspirone, an azaspirodecanedione that binds to 5-hydroxytryptamine receptors; zopiclone, a cyclopyrrolone with sedative–hypnotic activity; and zolpidem and alpidem, which are imidazopyridine sedative–hypnotic and anxiolytic agents, respectively. Many of these medications have a high abuse potential secondary to their ability to induce tolerance and dependence. In addition, a large percentage of those who use and abuse these medications have a history of psychiatric disorders and concurrent ethanol abuse.

Chloral Hydrate

Chloral hydrate was first introduced in 1869 and is still used for sedation in pediatric patients [44]. It is rapidly absorbed from the GI tract, with onset of action within 30 minutes. Chloral hydrate undergoes hepatic biotransformation by alcohol dehydrogenase. The principal metabolite trichloroethanol (TCE) has a longer half-life (4 to 12 hours) than the parent compound. When alcohol dehydrogenase is inhibited by 4-methylpyrazole, increased sedation is seen in 4-methylpyrazole–treated rats after chloral hydrate administration [45]. This suggests that the parent compound is more sedating than TCE and that the previously held belief that acute ethanol ingestion enhances TCE production and sedation may not be the case. However, acute chloral hydrate metabolism inhibition by ethanol may explain the additive effect of ethanol on chloral hydrate sedation ("Mickey Finn") [45]. The metabolism of chloral hydrate to TCE is age-related, with an increasing elimination half-life as the neonate ages to toddler [46]. In neonates, the glucuronidation pathway is still immature and chloral hydrate competes with bilirubin. In addition, renal clearance is limited due to immature kidney function. This can lead to direct hyperbilirubinemia in the neonate [46–48]. Saturation kinetics leading to prolonged elimination has been demonstrated in cases of overdose [49].

There has been a number of reports regarding pediatric chloral hydrate toxicity [49,50]. The lethal dose in adults is 5 to 10 g, but as little as 1.25 g has been fatal. Patients have survived reported doses as high as 36 g [51,52]. Toxicity develops within 3 to 4 hours after ingestion and is manifested by significant GI irritation, ranging from gastritis to perforation [53]. Other findings include CNS depression, pinpoint pupils, hypothermia, hypotension, and respiratory depression. Paradoxic CNS excitation, particularly in children, has been reported coinciding with peak plasma levels (1 to 3 hours) [48]. Myocardial depression results from decreased myocardial contraction and decreased refractory period. Cardiac dysrhythmias such as multifocal premature ventricular contractions, supraventricular dysrhythmias, and ventricular tachycardia have been reported [54].

Tolerance and addiction can develop in chronic abusers. The addicted patient may take very large doses of the drug and can suffer a withdrawal syndrome similar to that from alcohol [55]. Because this drug is hepatotoxic, the abuser may experience unexpected liver failure, leading to acute intoxication and death at doses that were previously tolerated [56].

The treatment of chloral hydrate poisoning is primarily supportive. All patients with a suspected ingestion should have an established intravenous line and continuous pulse oximetry and cardiac monitoring. Activated charcoal (1 g per kg) should be considered in symptomatic patients presenting early post-ingestion with appropriate airway protection. As chloral hydrate is radiopaque, large ingested amounts may be seen on abdominal radiographs.

Cardiac dysrhythmias may not respond to standard antidysrhythmics, such as lidocaine. Beta-blockers (e.g., propranolol 1.0 mg IV) may be of benefit [57]. Ventricular dysrhythmias may be partly due to TCE sensitization of myocardium to endogenous catecholamines similar to other halogenated hydrocarbons. Hypothermia can generally be treated with passive rewarming. Hemoperfusion may be considered in patients with prolonged coma, refractory dysrhythmias, or hypotension [58]. TCE clearance by hemodialysis varies between 120 and 162 mL per minute. In one patient who ingested 38 g, the half-life decreased from 35 to 6 hours after hemodialysis [58].

Ethchlorvynol

Ethchlorvynol is a hypnotic with muscle relaxant and anticonvulsant activities. Clinical effects are apparent within 15 to 30 minutes, and peak levels are seen in 1 to 2 hours. Ethchlorvynol is highly lipid-soluble and is stored in adipose tissue and the brain. It has a unique half-life, being 10 to 25 hours in therapeutic ingestions but up to 100 hours in very large overdoses. Ninety percent of the drug is metabolized by the liver. The patient may present with an altered sensorium ranging from dizziness to facial tingling, giddiness, excitement, dysarthria, ataxia, mydriasis, nystagmus, or areflexia after smaller doses. Severe overdose is characterized by profound and prolonged coma (more than 1 week), hypothermia, respiratory depression, hypotension, and bradycardia [59]. Comatose patients may have an isoelectric electroencephalogram. Seizures may occur after acute ethchlorvynol ingestion. A sometimes clinically useful property of ethchlorvynol is its aromatic and quite pungent odor, described as similar to that of a new car or plastic shower curtain. It may be detected on the patient's breath.

As in other medications of this group, chronic abuse of ethchlorvynol resulted in tolerance and dependence. Sudden

withdrawal can be confused with delirium tremens or an acute psychotic reaction [60].

Treatment is supportive. Hemoperfusion effectively clears the drug [61]. However, lipid redistribution of the drug means that repeated hemoperfusion may be necessary.

Glutethimide

The toxic dose of glutethimide is more than 3.0 g, with a usual fatal dose being 10 to 20 g. Glutethimide is highly lipid-soluble and displays two-compartment kinetics, with rapid intake in the brain followed by systemic distribution. Gastrointestinal glutethimide absorption is erratic, but its onset of action is 20 to 30 minutes [62]. Glutethimide is metabolized in the liver to an active metabolite, 4-hydroxy-2-ethyl-2-phenylglutarimide [62], which has a longer duration of action and is more potent than the parent compound [63]. It also stimulates the hepatic microsomal enzyme system and has considerable anticholinergic activity.

Acute glutethimide overdose is similar to that seen with barbiturates. Profound and prolonged coma is similar to that seen with ethchlorvynol. Glutethimide has been reported to produce thick and tenacious bronchial secretions. The most unique aspect of acute glutethimide intoxication is the fluctuating level of consciousness [63]. The reason for this is unclear, but theories include enterohepatic recirculation of the drug and its metabolites, prolonged absorption of the parent compound from an anticholinergic-induced paralytic ileus, and redistribution from adipose stores. Increased intracranial pressure, seizures, areflexia, and muscular twitching may be evident. Hypotension, hypothermia, persistent acidosis, and cardiac arrest have all been reported [63]. The chronic use of glutethimide leads to tolerance and addiction.

Glutethimide was frequently abused as a combination drug with codeine. Most preparations containing codeine also contained acetaminophen. This combination of glutethimide and Tylenol No. 3 or Tylenol No. 4 was called "loads" or "fours and doors."

The mainstay of treatment for glutethimide poisoning is supportive care. Because there may be significant anticholinergic-induced delay in gastric emptying, late administration of activated charcoal may be effective. Treatment with MDAC may increase glutethimide and 4-hydroxy-2-ethyl-2-phenylglutarimide elimination because of its known enterohepatic circulation. Case reports suggest that charcoal hemoperfusion may hasten recovery from coma, but this has never been examined in a controlled fashion [64].

Meprobamate and Carisoprodol

Meprobamate (e.g., Equanil, Miltown, Bamate, Neuramate) is an unusual member of this class of medications. It has antianxiety and muscle-relaxant effects in addition to sedative properties. Meprobamate is available in regular and sustained-release formulation. Toxicity can be seen in ingestions as small as 2.0 g and fatalities with as little as 12 g [65]. Survival has been documented with doses as high as 40 g.

Meprobamate is rapidly and completely absorbed after an oral dose [65]. Peak effect is seen in 3 hours, with a half-life of 10 hours. Most patients feel an effect for up to 36 hours. The drug is largely metabolized in the liver, induces microsomal enzymes, and its inactive metabolites are excreted in the urine. Very little of the drug is plasma protein-bound.

The clinical picture of meprobamate poisoning is similar to that of the other medications in this class, with predominately CNS and respiratory function impairment [65]. Hypotension is primarily mediated by a fall in systemic vascular resistance dysrhythmias, and palpitations [66]. Persistently elevated serum levels may indicate ongoing drug absorption from bezoar formation. Levels more than 20.5 mg per dL have been associated with CNS depression and coma. A withdrawal-abstinence syndrome beginning 1 to 2 days after cessation can occur even after chronic daily ingestions of as little as 1.6 g. Treatment of meprobamate poisoning is similar to that for the other medications in this class. MDAC may be of value after large ingestions because of potential for gastric concretion formation [67]. Hemoperfusion hastens drug clearance and should be considered in patients with cardiovascular compromise or failure to improve despite aggressive supportive treatment [68].

Carisoprodol (Soma, Rela) is a congener of meprobamate used as a muscle relaxant. Carisoprodol is metabolized in the liver and excreted in the urine, with an elimination half-life of 4 to 6 hours. Some of the ingested dose is metabolized to meprobamate by CYP2C19 [69]. The predominant side effect of the drug is drowsiness. Rarely seen idiosyncratic reactions include asthenia, transient quadriplegia, dizziness, ataxia, diplopia, agitation, confusion, and disorientation. Its toxicity and treatment are otherwise similar to those of meprobamate [70].

Baclofen

Although usually not considered a sedative or hypnotic drug, baclofen (Lioresal) toxicity may mimic that of sedative–hypnotics, and treatment is similar. Baclofen is a potent GABA-B agonist. Its primary use is as an antispasmodic agent, decreasing flexor tone and spasm in certain neurologic diseases. Therapeutic doses of baclofen are 15 to 60 mg per day. Baclofen is cleared by the kidney, with only a small portion hepatically transformed. Baclofen is well absorbed from the GI tract. Elimination is by first-order elimination kinetics, with a half-life of 2 to 6 hours after therapeutic dosing. Intrathecal baclofen is being used increasingly to treat intractable spasticity in children and in patients with spinal cord injury. Complications such as baclofen overdose and withdrawal syndrome may be related to pump malfunction, refilling mistakes, and programming mistakes related to adjustment of pump flow rate [71,72].

Hypotension and hypertension have been reported with baclofen toxicity [73]. Coma, seizures, severe myoclonus, apnea, and hypothermia may be evident [74]. Cardiac effects include prolonged PR and QTc intervals, junctional escape beats, premature atrial contractions with block, supraventricular tachycardia, and bradycardia [73]. Myoclonus and hyporeflexia have also been reported as well as seizure activity documented on EEG monitoring [71].

Management following baclofen either by the oral or intrathecal route intoxication is primarily supportive. Mechanical ventilatory support is often required after overdose [73]. Baclofen, in a large overdose, is more slowly absorbed from the GI tract than after a single therapeutic dose, suggesting that the administration of activated charcoal may be of benefit. Symptomatic bradycardia responds to atropine [75]. Hypotension commonly responds to intravenous fluids. Ventilatory assistance may be required for prolonged periods, averaging 3 to 7 days [76]. Patients have been observed to be persistently symptomatic up to 60 hours post-ingestion even when serum baclofen levels are undetectable [77]. Benzodiazepines should be used to control seizure activity or myoclonus.

Baclofen withdrawal syndrome (Chapter 145) may result after sudden cessation of oral baclofen therapy or in patients being treated with intrathecal baclofen where there may be pump failure and reduced baclofen delivery. Withdrawal may present with mental status changes, delirium,

hallucinations, hypertension, hyperthermia, myoclonus, hyperreflexia, seizure activity, and may mimic signs of serotonin syndrome or neuroleptic malignant syndrome in some cases [71,78]. A close evaluation of the baclofen pump is essential in these cases to identify any potential dosing errors or malfunction with the pump system. Treatment includes supportive care and reinstitution of baclofen therapy as soon as practicable, but may also require the acute use of high-dose parenteral benzodiazepines to attenuate symptoms and signs of neuromuscular hyperexcitability and seizure activity [78,79].

Buspirone

Buspirone is a serotonergic and dopaminergic active drug with minimal sedative–hypnotic effects during therapeutic dosing. It also has central acetylcholine and norepinephrine effects. Its mechanism of action is not fully understood, but it appears to interact with exogenous and endogenous BZD, binding at the GRSMC as well as 5-hydroxytryptamine receptors. At low doses, it is predominately anxiolytic, although it may take several weeks to reach this effect. At high doses, it can cause sedation similar to that seen with BZDs (20 mg per day), but the sedation is much less than that seen with an equivalent dose of the BZD. It is well absorbed orally, and peak serum levels occur within 1 to 2 hours. It is hepatically metabolized, with an elimination half-life of 2 to 3 hours.

Adverse drug events reported during therapeutic dosing include weakness, GI distress, dysphoria, headache, and dizziness. It may cause a withdrawal syndrome after prolonged use but does not cross-react with BZDs in treating BZD withdrawal. Flumazenil does not reverse buspirone effect.

Buspirone has been an uncommon drug in overdose settings. Serotonin syndrome has rarely been reported when buspirone has been added to therapy in patients prescribed selective serotonin reuptake inhibitor medications such as fluoxetine, fluvoxamine, and sertraline [80–82]. Supportive care is the mainstay of therapy after an overdose.

Zopiclone

Zopiclone is a non-BZD agent with sedative–hypnotic, anxiolytic, and muscle-relaxant properties but is predominately marketed as a hypnotic agent. It appears to bind to the GRSMC, possibly with its own binding site. It has been found to displace diazepam and flunitrazepam from their BZD binding sites. It is well absorbed orally, with peak plasma concentration within 30 to 90 minutes. It undergoes first-order kinetics of distribution and is extensively metabolized. Elimination occurs by the kidneys and lungs. Absorption is significantly affected by gastric emptying. Adverse drug events include a bitter taste in the mouth, and there is carryover sedation into the next day. There may be a morning-after amnesic effect. After chronic dosing, physical dependency and withdrawal have been reported. It may also potentiate the sedative effects of ethanol.

Isolated zopiclone poisoning commonly follows a similar benign course to that of benzodiazepine poisoning [83]. Patients with concurrent ethanol or other sedative ingestion may develop significantly greater sedation. Observation and supportive care is the mainstay of therapy. Isolated reports have noted mild to moderate and delayed onset (14 to 16 hours postingestion) methemoglobinemia (10 to 23%) following zopiclone overdose [84]. This may be related to production of large amounts of an N-oxide metabolite of the parent drug [84]. Zopiclone poisoning has been reported to respond to flumazenil [85].

Zolpidem and Alpidem

Zolpidem and alpidem are imidazopyridine agents used as hypnotic and anxiolytic agents, respectively. Both bind to the GRSMC, zolpidem at the omega-1 and alpidem at the omega-1/omega-3 receptor binding sites. Both agents are rapidly absorbed orally, highly protein-bound, and hepatically metabolized. Zolpidem has an elimination half-life of 2.5 to 5.0 hours and alpidem of 8 to 20 hours. Adverse drug events associated with zolpidem use include anxiety, dizziness, drowsiness, fatigue, headache, diplopia, diarrhea, tremor, and hangover effect with anterograde amnesia. Alpidem use has been associated with adverse drug events such as sedation, headache, dizziness, insomnia, nausea, and vomiting. Alpidem has been reported to increase serum hepatic transaminase levels. Tolerance, dependency, and subsequent withdrawal are possible. Coingestion with other sedative agents, including alcohol, will result in increased sedation.

The most common findings seen after zolpidem overdose include sedation and respiratory depression. Cardiovascular or ECG changes do not occur in isolated zolpidem toxicity. Death has been reported with the combination of overdose with zolpidem and other CNS depressants, although no deaths have been reported with zolpidem overdose alone [86]. Treatment of overdose is predominately supportive. Flumazenil has been used to reverse the effects of zolpidem in overdose [87].

γ-Hydroxybutyrate

γ-Hydroxybutyrate (GHB) was originally used as an anesthetic induction agent and subsequently found to be a naturally occurring GABA metabolite in the CNS. It does not interact with GABA-A receptors, and as a result, its effects are not antagonized by flumazenil [88]. The mechanism of action of GHB may result from its interaction with specific GHB receptors, GABA-B receptors, and by elevation of CNS dopamine and endorphin levels [88]. GHB can be administered orally or parenterally with clinical effects occurring within 30 minutes of ingestion. Metabolism is by succinate semialdehyde to succinate, which enters the Krebs cycle and is eventually metabolized to carbon dioxide and water. GHB is also excreted (2% to 5%) unchanged in urine [89].

γ-Hydroxybutyrate can be obtained illicitly by mail order in powder form and reconstituted to a liquid. GHB is commonly produced in illicit backyard laboratories in the United States. Recipes for its production can be found on the Internet. Production begins with γ-butyrolactone, which is treated with an alkali such as sodium hydroxide to open the lactone ring to produce GHB when heated. If the pH of the solution is not back-titrated with acid, it may result in a highly alkaline solution. Esophageal burns and subsequent stricture formation has been reported after ingestion of an alkali GHB solution [90]. GHB is abused for its hypnotic and euphoric effects recreationally and may also have been used as a date-rape drug. Many states in the United States have categorized GHB as a Schedule-1 controlled substance.

"Pine needle oil" contains 1,4-butanediol and has been reported to induce a similar toxicity to GHB. Alcohol and aldehyde dehydrogenase catalyze the conversion of 1,4-butanediol to GHB, resulting in a clinical syndrome similar to GHB toxicity. This reaction can be inhibited by ethanol, 4-methylpyrazole, and disulfiram [91]. Butanediol and γ-butyrolactone are freely available for legal purchase over the Internet in many countries. As both are metabolized to GHB when ingested and result in similar toxicity, they are often purchased instead of GHB to avoid legal prosecution [92].

Symptoms of GHB toxicity occur rapidly after ingestion and may be potentiated by alcohol and other sedative agents, including opioids. Death has resulted from mixed intoxication with opioids [93]. Drowsiness, euphoria, hallucinations, delirium, nausea, vomiting, hypothermia, seizures, and coma can be seen. Recovery from pure GHB poisoning is typically rapid with return of consciousness within a few hours of ingestion [94]. Mass exposures have been reported in the popular press, usually in the setting of a dance rave, party, or nightclub [95]. Chronic use can lead to tolerance and physical dependence. A withdrawal syndrome comprising anxiety, agitation, paranoia, and visual and auditory hallucinations has been reported [96].

Management of GHB intoxication is supportive. Airway protection and ventilatory support are the mainstay of therapy. Prolonged sedation may indicate coingestion of other sedative agents. Flumazenil (GABA-A receptor antagonist) and physostigmine (short-acting acetylcholinesterase) do *not* reverse sedation [97,98] and may result in unwanted toxic effects of the respective antidotal agent. Because GHB is usually ingested as a liquid formulation and has a rapid onset of action, activated charcoal is unlikely to be beneficial.

CHAPTER 144 ■ AMPHETAMINES

MICHAEL C. BEUHLER

INTRODUCTION

The term "amphetamine" includes a wide range of amine compounds with sympathetic-like effects. The simplest member of this group is amphetamine, but there are hundreds of molecules with related chemical structures that have similar clinical effects. This chapter will focus on the more important and commonly used licit and illicit members of this group.

Amphetamine and methamphetamine are the most well-known members of this class. **Amph**etamine or **a**lpha-**m**ethyl **phe**nylethylamine was first synthesized over 120 years ago, and it was widely used by many (including the U.S. military) as the stimulant Benzedrine, beginning in the 1930s. Restricting to

prescription decreased use slightly, but it has been continued to be used for both licit (Attention deficit hyperactivity disorder [ADHD], narcolepsy, and weight loss) and illicit reasons. Currently, Adderall® (a mixture of *l* and *d* amphetamine) and Vyvanse® (Lisdexamfetamine; metabolized to *d*-amphetamine) are two commonly used medicinal amphetamine preparations.

Methamphetamine (or N-methyl amphetamine) is undergoing a surge in United States and worldwide popularity. One reason for its popularity over amphetamine is its longer duration of action. Another reason is that the Drug Enforcement Agency has taken actions to limit the availability of precursor compounds for the synthesis of amphetamine, including the unrelated removal of phenylpropanolamine from the OTC market. Finally, synthesis can be conducted by individuals without specialized training using materials that are not difficult to obtain, resulting in a relatively pure product. Currently, Desoxyn® is a methamphetamine containing prescription preparation used for ADHD and obesity.

There are several other medicinal compounds that have clinical effects similar to amphetamines, with a select few discussed here. Ritalin® (methylphenidate) is commonly used in children for ADHD and is occasionally abused. Phenylpropanolamine (Dexatrim®) was used more extensively in the past as a decongestant and weight loss agent; in 2005 the FDA removed it from OTC sales due to concerns about increased stroke risk and it is no longer available as an Rx [1]. Ephedrine has been used extensively in the past in herbal weight loss/energy preparations as well as a decongestant in cough/cold preparations; but in 2004, the FDA prohibited the sale of dietary supplements containing ephedra (ephedrine and pseudoephedrine) over safety concerns. Additionally, in 2006, requirements regulating the sale of ephedrine were enacted in an attempt to limit its diversion for methamphetamine synthesis. Phentermine is an amphetamine derivative that is used for appetite suppression. Selegiline is an amphetamine derivative with selective monoamine oxidase inhibitor (MAOI)-B effects that is metabolized to l-methamphetamine. Propylhexedrine (Benzedrex® nasal inhaler), although not a true amphetamine, has sympathomimetic and vasoconstrictor properties and is occasionally abused.

Some amphetamine analogs with aromatic ring substitutions have direct affinity for serotonin receptors as well as increased inhibition of serotonin uptake, thereby exerting both sympathomimetic and serotonergic effects manifested by hallucinatory properties. One of the more popular compounds in this group is 3,4-methylenedioxy-methamphetamine (MDMA or Ecstasy). Other similar ring-substituted amphetamine compounds include 3,4-methylenedioxy amphetamine (MDA), 3,4-methylenedioxy-*N*-ethylamphetamine (MDEA or Eve), 2,5-dimethoxy-4-bromo-phenethylamine (2-CB; not strictly an amphetamine), para-methoxy amphetamine (PMA), 2,5-dimethoxy-4-methyl-amphetamine (DOM), and 2,5 dimethoxy-4-bromo-amphetamine (DOB; also the similar chlorine and iodine derivatives DOC and DOI exist). The 2,5 dimethoxy halogenated amphetamine derivatives (DOB, DOC, DOI) are common substitutions for LSD found on blotter paper in the United States [2].

Recent increases in clandestine methamphetamine production facilities ("meth labs") have resulted in concern for environmental contamination and bystander toxicity from laboratory chemicals. The vast majority of illicit amphetamine laboratories currently produce methamphetamine by reductive dehydroxylation of ephedrine or pseudoephedrine. Methamphetamine laboratories are often discovered after a chemical mishap or explosion and are a health risk due to the chemicals used, which include respiratory irritants and caustics [3]. Methcathinone is a potent, occasionally used amphetamine-like substance produced from the *oxidation* of ephedrine in amateur labs, instead of the usual *reduction* to methamphetamine; toxicity is similar except that cases of Parkinson-like neurotoxicity from manganese in the impure product have been reported.

There are two methods most commonly being utilized for methamphetamine synthesis. The one resulting in the cleanest product probably the more dangerous one is the Birch or "Nazi" method, which utilizes lithium metal as the reducing agent dissolved in anhydrous ammonia. The other method is the hydriodic acid method, which usually utilizes red phosphorus and iodine, as the availability of hydriodic acid is restricted.

Depending upon the illicit amphetamine purchased, there is a chance that it will contain one or more contaminants, or possibly be substituted by another sympathomimetic. Street purchased methamphetamine tends to be of better purity than cocaine, while MDMA is very commonly substituted or combined with other psychoactive substances. The exact "contaminants" or other chemicals present in street purchased amphetamines are highly variable based on drug, year, and location. Previously reported substitutions include acetaminophen, anesthetics (benzocaine, lidocaine, procaine), cocaine, caffeine, ephedrine, ketamine, lead (rare), talc, phencyclidine, piperazine compounds (benzylpiperazine and others), phenylpropanolamine, pseudoephedrine, strychnine, and quinine [4]. Depending on the quantity of the adulterant, it may contribute to the effect or toxicity of the sympathomimetic drugs.

Occasionally, an individual will ingest an amphetamine while it is wrapped in plastic or other non-permeable material. Body *packers* or "mules," are people who transport large quantities of specially prepared drug packets in their gastrointestinal (GI) tract. Each packet usually contains drugs in sufficient quantity and purity to cause life-threatening toxicity if rupture occurs. Body *stuffers* are people who quickly swallow ("stuff") drug-containing packets in an attempt to get rid of evidence and avoid arrest by the police. These packets are usually poorly prepared and are at increased risk of leakage and rupture, but often contain far less drug than a packet from a body packer. Rarely, individuals will ingest a plastic bag containing a drug with holes or a corner of the bag cut off in an attempt to produce a sustained release effect [5].

PHARMACOLOGY

Amphetamine and methamphetamine are similar in their pharmacokinetic properties and have similar physiological effects in humans [6]. They do not have significant direct effects at adrenergic or dopamine receptors; rather their effects are mediated by an increase in the concentration of synaptic dopamine and to a lesser extent, serotonin and norepinephrine. This increase occurs by several mechanisms. Amphetamine and methamphetamine enter the presynaptic cytoplasm by passive diffusion and uptake by biogenic amine uptake transporters. Amphetamine moves into the synaptic vesicles by diffusion and by the vesicular monoamine transporters (VMATs), subsequently causing release of stored dopamine and norepinephrine, most likely by collapsing the proton gradient as well as an effect on VMAT. This increases the cytosolic levels of these biogenic amines, which then results in increased synaptic levels due to increased reverse transport activity by the amine transporters, especially the dopamine transporter. Part of the mechanism of action of amphetamines' raising synaptic levels is also due to competitive inhibition of biogenic amines reuptake from the synapse into the presynaptic terminal. Finally, some amphetamines have MAOI activity, which inhibits the breakdown of dopamine, serotonin, and norepinephrine, with some (PMA for example) having significant MAOI activity [7,8].

The mechanism of action of MDMA toxicity includes a direct effect at some serotonin receptors, as well as some of the

indirect effects described above mediated by a release of serotonin. Additionally, human and animal studies have shown that MDMA produces a dose-related depletion of serotonin and serotonin transporter activity, and produces serotonergic neuronal degeneration [9]. Methamphetamine causes dopamine and serotonergic neuronal toxicity as well as a decrease in dopamine, VMAT, and serotonin transporter activity in the brain, at least in part by free radical injury [10,11].

Peak plasma concentrations of methamphetamine are reported within 4 hours for an insufflated dose, within 2 to 3 hours for a smoked dose and nearly immediate for an IV dose [12,13]; however levels do not correlate with the degree of clinical toxicity [14]. Methamphetamine and amphetamine have an *l* and *d* isomer; the *d* form is more potent in causing pleasurable CNS stimulation and persistent cardiovascular activation than the *l* form [15]. Most abused methamphetamine is the *d* isomer, having been synthesized from ephedrine or pseudoephedrine. However, the *d* form of methamphetamine has a shorter half-life (10 to 11 hours) than the *l* form (13 to 15 hours) [15,13]. The α-carbon on the amphetamine molecule protects it against MAO degradation. The majority of methamphetamine is either eliminated unchanged, N-demethylated to amphetamine (active) or hydroxylated to p-hydroxymethamphetamine (active) with contribution from cytochrome 2D6 [16,17]; amphetamine undergoes a similar metabolism, except that it is deaminated to an inactive metabolite as well as hydroxylated to p-hydroxyamphetamine (active). Excretion of both is increased in acidic urine, but this fact has no clinical utility as the risks of urinary acidification outweigh any potential benefits. Urine usually remains positive for 24 hours or longer in high dose chronic abusers [18]. The serotonergic amphetamine and amphetamine-like compounds (MDMA, PMA, 2-CB) are not metabolized to amphetamine or methamphetamine.

CLINICAL PRESENTATION

Methamphetamine toxicity has been reported following ingestion, inhalation (smoking), insufflation (intranasal), rectal, subcutaneous, intramuscular, and intravenous exposure [19]. The onset and duration of methamphetamine toxicity depends on factors such as dose, route of exposure, individual tolerance, pattern of use, ambient temperature, and crowding/stimulation level. Most people develop signs and symptoms within a few minutes of parenteral drug use, whereas signs and symptoms may be delayed for hours after ingestion with body packers and body stuffers. In most patients, the majority of sympathomimetic effects are expected to resolve within 24 to 36 hours post exposure [19]. Life-threatening toxicity is more common in drug abusers and in people who overdose with suicide intent, and it can also occur in body packers and body stuffers.

Methamphetamine toxicity usually results in a group of signs and symptoms known as the "sympathomimetic toxidrome," including hypertension, tachycardia, tachypnea, hyperthermia, diaphoresis, mydriasis, hyperactive bowel sounds, agitation, anxiety, and toxic psychosis. This pattern of symptoms is seen for other members of the amphetamine group as well as other sympathomimetics like cocaine and caffeine; but this pattern of symptoms can be variable depending on the sympathomimetic agent involved. For example, phenylpropanolamine has peripheral alpha vasoconstrictive effects that can result in a reflex bradycardia.

Airway and breathing abnormalities are uncommon with ingestion. Transient cough, pleuritic chest pain, and shortness of breath are common after insufflation or smoking. People present in illicit drug laboratory fires and explosions may have thermal injury to their oropharyngeal or upper airway. Insufflation or smoking methamphetamine may result in bronchospasm, pneumothorax, pneumomediastinum, pneumonitis, and noncardiogenic pulmonary edema. Noncardiogenic pulmonary edema and acute respiratory distress syndrome may be associated with multisystem organ failure. Tachypnea is common secondary to agitation or metabolic acidosis. Hypoventilation is rare but may occur secondary to intracranial pathology or the end stage of multisystem organ failure.

Many of the adverse cardiovascular effects result from increases in peripheral catecholamines, which result in a mismatch of oxygen consumption and delivery; there may be a direct cardiotoxic effect of methamphetamine as well. Palpitations and chest pain are common complaints. Acute myocardial infarction due to vasospasm, plaque rupture, and/or thrombosis can occur [20]. Life-threatening atrial or ventricular dysrhythmias, sudden death, and aortic dissection have been reported, with potential synergy if cocaine is also present [21,20]. Coronary artery disease and cardiomyopathy have been reported with chronic amphetamine abuse [14,22,23]. Peripheral vascular ischemia can result from oral sympathomimetic abuse but is uncommon unless an inadvertent intra-arterial injection occurs. Hypotension is unusual but may be secondary to dehydration, myocardial depression, intestinal ischemia, or sepsis.

There are several important findings that may be apparent on the Head-Eyes-Ears-Nose-Throat exam. Mydriasis is common and various forms of nystagmus have been reported. Patients who abuse and binge on sympathomimetic agents are often dehydrated and have dry mucous membranes. Nasal mucosal abnormalities, including nasal septal perforations, are well reported in patients who chronically insufflate cocaine and are possible with insufflation of other sympathomimetics. An increase in dental pathology has been noted in users of methamphetamines, manifested by a distinctive pattern of caries on the buccal smooth surfaces of the posterior teeth and the interproximal surfaces of the anterior teeth. The teeth may be loose, rotting, or crumbling, and are usually beyond salvage. The pathology of these changes is uncertain, but is believed to be due to a combination of decrease in salivation (xerostomia) along with increased ingestion of sugar- and acid-containing sodas, poor hygiene, poor nutrition, localized vasospasm, and bruxism, a side effect especially seen with MDMA. [24,25,26].

Central nervous system effects are the reason for abuse as well as often the reason for seeking care. Methamphetamine produces a euphoric and anorexic effect, with smoked and injected administration producing a greater "rush." The most common presenting symptoms include agitation and altered mental status; other symptoms include headache, hyperactivity, agitation, toxic psychosis, loss of consciousness, focal neurologic deficits, and seizures [27,19]. Hyperthermia may be more common and worse in patients with uncontrolled psychomotor agitation, especially when patients are physically but not chemically restrained. Altered mental status may be secondary to hypoglycemia or an acute intracranial process. Headache may be secondary to intracranial or subarachnoid hemorrhage [21,14,28,29]. Focal neurological deficit may be secondary to cerebral ischemia or infarction, vasospasm, or direct injection trauma. On arteriography, multiple occlusions or "beading" has been observed of the arteries; this is thought to represent some combination of local vasospasm or vasculitis [30,1,28]. Seizures may occur in association with and independent of intracranial hemorrhage or cerebral infarction. Prolonged methamphetamine (and probably MDMA) use may lead to cognitive decline represented by attention and memory changes [11].

Some abusers develop stereotyped, compulsive behavior such as cleaning or buttoning shirts; in some cases it has been observed that addicts compulsively take apart appliances, usually without reassembly. Psychosis from amphetamines is not uncommon and can present as paranoid delusions and

perceptual disturbances; these may persist long after the drug has been stopped and can result in homicidal or self-destructive behavior [31,32,19]. After binge use, patients may develop a withdrawal pattern of symptoms consisting of generalized fatigue, dysphoria, decreased level of consciousness, and profound lethargy.

One occasionally sees choreiform, ballistic, bruxism, torticollis, or athetoid involuntary movements with amphetamine and methamphetamine abuse [33]. These movements can be fast or slow and they can involve the facial, extremity, or trunk muscles. Ataxia may result if the trunk or limb movements are severe enough. These movements usually begin after prolonged abuse of amphetamine or methamphetamine and may become worse or reoccur with additional drug abuse. Usually, the symptoms resolve over several hours to a week following abstinence. However, they may only diminish in magnitude and persist for months or even rarely, years. The movements may be diminished with voluntary motor activity or during sleep. The mechanism for these movements is not well understood, and may involve a disruption of the normal dopamine neurotransmitter system [34].

Abdominal findings may include increased bowel sounds, bowel obstruction from body packing, and abdominal pain due to intestinal ischemia or bowel perforation [35,36]. Psychomotor agitation and seizures can result in rhabdomyolysis [37]. Hyperthermia and multisystem organ failure may result in coagulopathy and disseminated intravascular coagulation (DIC). Hepatic injury progressing to fatal fulminant liver failure can occur from MDMA without any preceding hyperthermia. Dehydration, increased anion gap metabolic acidosis associated with increased lactate, and hypokalemia are common in patients with significant sympathomimetic toxicity. Urinary retention has been reported from amphetamine toxicity. Acute tubular necrosis may occur secondary to hyperthermia, hypovolemia, hypotension, and rhabdomyolysis.

Diaphoresis with either warm or cool skin is common. Scarring and hyperpigmentation ("track marks") in areas above veins suggest chronic intravenous drug use. Skin popping, or subcutaneous injection of the drug can result in scabs, circular scars, and lesions in a variety of areas. Additional excoriations and rashes can result from skin picking and scratching. Abscesses and infection are not uncommon.

Medical complications from drug abuse include endocarditis, hepatitis, human immunodeficiency virus infection, cellulitis, septic emboli, abscesses, tetanus, and wound botulism. Methamphetamine abuse is associated with an increased risk of HIV infection both because of increase in risk taking behavior (IVDA, unprotected intercourse, untreated STDs) and probable enhancement of HIV infectivity [38].

Most of the time, the toxicity observed in the methamphetamine using patient is due to the drug and not from any adulterants. Adulterants are not usually present in large enough amounts, and methamphetamine is relatively pure and sufficiently toxic in its own right. However, some important exceptions should be noted. The addition of benzocaine has caused methemoglobinemia [39]. Intra-arterial injection of a drug may cause injury, possibly potentiated by any talc present. Talc pulmonary emboli have been reported as well, which probably contribute to pulmonary hypertension. Lastly, substitution is more of a problem with the ring-modified amphetamines (MDMA); the real substance present in the street purchased product is likely to be contaminated with or entirely be a piperazine (BZP and others), caffeine, methamphetamine, or some other substituted amphetamine such as PMA.

In addition to having some sympathomimetic qualities, nearly all of the ring-substituted amphetamines (MDMA, DOM) also have hallucinogenic properties likely due to their direct and indirect effect at serotonin receptors. The route of abuse for methylenedioxymethamphetamine (MDMA) is usually ingestion. Methylenedioxyamphetamine (MDA) is an analog of MDMA and has similar effects as MDMA. Serious autonomic reactions include many of the sympathomimetic symptoms discussed above as well as seizures, rigidity, dysrhythmias, and profound hyperthermia with grave consequences (rhabdomyolysis, renal failure, DIC) [40]. Given the increased serotonin levels produced, at least part of this toxicity should be characterized as serotonin toxicity/syndrome.

Some of the ring-substituted amphetamines have specific toxicities. There are several reports of hepatoxicity resulting in hepatomegaly, jaundice, and death caused by MDMA that did not stem from hyperthermia or shock liver; this probably resulted from an immunological component [41,40]. Hyperthermia is more common with the ring-substituted amphetamines, likely from contribution from serotonin toxicity and possibly from mitochondrial uncoupling [42]. Hyponatremia resulting in altered mental status, coma, seizures, cerebral edema, and death is also sometimes seen following MDMA use. This probably results from some combination of inappropriate antidiuretic hormone secretion (SIADH) and from excessive water drinking. SIADH may possibly be more commonly observed in young women from MDMA use, as there seem to be an inappropriately large number of cases in this group. The observed clinical toxicity from PMA or "death" includes hyperthermia, hypoglycemia, hyperkalemia, and prolonged QRS; the effects are similar to MDMA but may be more severe because its dose response curve is steep regarding elevating brain serotonin levels, PMA exposures are often unintentional, and it has significant MAOI activity [43,7,44]. Bromodimethoxyamphetamine (DOB) is highly potent, enough so that a dose (2 to 5 mg) can be found on a small piece of paper possibly being sold as LSD. Large doses of DOB have been reported to result in significant vasospasm that has resulted in seizures and deaths [45].

DIAGNOSTIC EVALUATION

Patients with amphetamine toxicity (sympathomimetic toxicity) should have frequent vital sign determinations including core or rectal temperature measurement, intravenous access, and continuous cardiac monitoring. Those with abnormal vital signs or mental status should have an electrocardiogram, complete blood cell count, electrolyte, blood urea nitrogen, creatinine, glucose, and arterial blood gas determinations. Patients with chest pain, dysrhythmias, or persistent pulse or blood pressure abnormalities should be evaluated for acute coronary or vascular syndromes. Patients with prolonged immobilization, uncontrolled psychomotor agitation, or hyperthermia should have serial CPKs to evaluate for rhabdomyolysis. Those that either have or have had significant hyperthermia or shock should also have liver injury and function tests (lactate dehydrogenase, aspartate aminotransferase, alanine aminotransferase, and coagulation profile) to evaluate for multisystem organ failure and DIC.

Several imaging studies may be warranted for an amphetamine toxic patient, depending on their clinical presentation. Those with respiratory symptoms or chest pain should have a chest radiograph and possibly a chest CT if there is concern for aortic dissection. Patients with headache or seizures should be evaluated for intracranial hemorrhage with computed tomography of the brain. Those with continued suspicion for subarachnoid hemorrhage with a negative CT scan should also have a lumbar puncture [28]. Plain and oral contrast abdominal radiographs may be helpful in detecting drug-containing packets in the GI tract of body packers, but their sensitivity is quite low for stuffers. Experience with abdominal CT and abdominal ultrasound for detection of stuffer packets is limited. A negative imaging study cannot be used to rule out drug packets in the GI tract.

The results of toxicology screening for most drugs of abuse rarely contribute to or alter patient management. However, in the case of sympathomimetic toxicity, the urine drug screen is reasonably sensitive to the recent use of methamphetamine/amphetamine as well as cocaine and can assist in differentiating these syndromes that can be important in management. If toxicology drug screening is essential, health care providers should contact their clinical laboratory to determine included substances as well as causes of false–positive and false–negative results. For example, the ability for immunologically based drug screens to detect MDMA (or similar ring-substituted amphetamines) is highly variable, but there are specific immunologically-based MDMA drug screens available.

A positive drug screen can confirm the presence of amphetamine or similar structured drug, whereas a negative drug screen is non-diagnostic. For amphetamines, the screen is typically reasonably sensitive for use within the last few days, but has terrible specificity. A sampling of some common substances that may cause a positive amphetamine screen are bupropion, chloroquine, clobenzorex, ephedrine, methylphenidate, phenelzine, phentermine, phenylpropanolamine, pseudoephedrine, selegiline, tranylcypromine, trazodone, and Vicks® inhaler [46,47,48]. One should remember that if the result of a toxicology screen is to be used for forensic purposes, the chain of custody should be maintained, and results will need to be confirmed using a more rigorous analytical method such as gas chromatography/mass spectrometry.

Toxicologic and nontoxicologic conditions that may have a similar presentation or that present concomitantly (Table 144.1) should be evaluated for and excluded. A serum lactate level may be helpful in patients with increased anion gap metabolic acidosis of unclear cause. An elevated lactate level would be expected in patients with compromised tissue perfusion (e.g., occurring with shock and intestinal or limb ischemia), in those with hypermetabolic states in which metabolic demands exceed available substrates, or in those with cellular dysfunction in whom normal substrates cannot be used. Other causes of increased anion gap metabolic acidosis (e.g., ethylene glycol, methanol, iron, salicylate) should be investigated when the lactate level is normal or near normal. The possibility of concomitant poisoning with by-products or impurities related to the illicit synthesis of methamphetamine (e.g., phenethylamine derivatives, caffeine, ephedrine, mercury, strychnine, or lead) would be rare, but should also be considered.

TABLE 144.1

DIFFERENTIAL DIAGNOSIS OF AMPHETAMINE TOXICITY

Toxicologic
β-Agonists toxicity (clenbuterol and others)
Black widow envenomation
Cocaine
Dextromethorphan
Methylxanthine toxicity (caffeine, theophylline)
Monamine oxidase inhibitor toxicity
Neuroleptic malignant syndrome
Piperazine compounds (benzylpiperazine and others)
Phencyclidine toxicity (PCP)
Bark scorpion envenomation (found mostly in AZ)
Salicylates
Serotonin toxicity
Strychnine
Withdrawal from sedative–hypnotics, including baclofen, barbiturates, benzodiazepines, clonidine, chloral hydrate, ethanol, γ-hydroxybutyrate, γ-butyrolactone, meprobamate, as well as from β-antagonists such as propofol
Nontoxicologic
Endocarditis
Encephalitis and meningitis
Heat stroke
Intracranial bleed or mass lesion
Pheochromocytoma
Sepsis
Thyrotoxicosis

MANAGEMENT

Patients who present with life-threatening effects from amphetamine toxicity or those that are at increased risk for developing them (such as a packer) should be managed in an intensive care unit (Table 144.2). The overall approach to these patients is aggressive supportive care with supplemental oxygen, sedation, fluid administration, and close monitoring while addressing the specific myriad complications that can occur.

The hemodynamic effects of amphetamines are primarily caused by release of catecholamines and not by a direct effect at receptors. Mild sinus tachycardia and hypertension not associated with psychomotor agitation or evidence of end organ damage usually do not require pharmacologic treatment. Treatment of psychomotor agitation utilizing appropriate benzodiazepine doses will often result in improvement or resolution of tachycardia and hypertension. If benzodiazepines do not provide adequate improvement, rate-related cardiac ischemia may be treated with a beta-blocker, preferably a short-acting and easily titratable agent such as esmolol, or a calcium-channel blocker, being cautious to exclude cocaine toxicity if a beta-blocker is being used. Patients with life-threatening dysrhythmias who are hemodynamically unstable should be cardioverted or defibrillated. Persistent hypertension, especially if there is evidence of end organ damage or hyperthermia, should be treated with benzodiazepines as well as phentolamine, nitroprusside, or nitroglycerin with careful dose titration.

Patients presenting with chest pain should be evaluated for acute coronary syndromes and managed accordingly [23]. Thrombolytic therapy or procedural coronary intervention may be indicated as per current guidelines. In these circumstances, cardiology consultation is recommended, especially since coronary vasospasm is a possibility. Other important potential causes of chest pain such as pneumothorax, pneumomediastinum, infection, septic emboli, and aortic dissection should be ruled out.

Hypotension should be treated with fluids, and patients assessed for comorbid potential life-threatening conditions such as dysrhythmias, acute coronary syndromes, pneumothorax, aortic dissection, hyperkalemia, GI hemorrhage, and sepsis. Persistent symptomatic hypotension that is refractory to

TABLE 144.2

INDICATIONS FOR ADMITTING PATIENTS TO AN INTENSIVE CARE UNIT

Acute coronary syndromes	Multisystem organ failure
Aortic dissection	Peripheral ischemia
Body packer or body stuffer	Persistent psychomotor agitation
Cerebral ischemia or infarction	Pneumothorax
Dysrhythmias	Rhabdomyolysis
Hyperthermia	Seizure
Intracranial bleed	
Myocardial infarction	

fluids necessitates treatment with a direct acting vasopressor such as norepinephrine, epinephrine, or phenylephrine. At times, the choice and dose of vasopressor should be guided by pulmonary artery catheter hemodynamic monitoring or bedside ultrasound.

Management of bronchospasm should include nebulized β_2 agonists (such as albuterol) and anticholinergic agents (such as ipratropium bromide). Noncardiogenic pulmonary edema and acute respiratory distress syndrome should be managed according to current guidelines. The benefit of corticosteroids in patients with sympathomimetic-induced bronchospasm, pneumonitis, and noncardiogenic pulmonary edema has not been well studied, but may be considered in patients with severe or persistent symptoms. Occasionally, pneumomediastinum and pneumothorax following smoking methamphetamine is observed. Patients with pneumothorax may require tube thoracostomy depending on the size of the pneumothorax. For a pneumomediastinum, the work up usually involves an oral contrast imaging study to rule out esophageal perforation, but surprisingly these commonly have a completely benign course.

The initial management of a patient with an altered mental status includes assessing and treating all readily reversible causes such as hypoxia, hypoglycemia, electrolyte abnormalities (especially hyponatremia), opioid toxicity, and thiamine deficiency. Imaging studies of the head should be performed on patients with persistent altered mental status, potentially followed by lumbar puncture if indicated. Mild agitation or anxiety may be treated with oral benzodiazepines. Psychomotor agitation that poses a danger to the patient or others requires more aggressive sedation. Incremental doses of intravenous benzodiazepine should be used to achieve the desired effect, noting that significant doses of benzodiazepines may be required. The role of antipsychotics for controlling agitation should be as an adjunctive therapy and not the primary means of control, but does appear to be safe and efficacious in adult and pediatric populations [19,49,50]. One should recognize the other clinical precautions that accompany the use of this pharmaceutical drug class (EKG changes, NMS, etc.). If agitation is severe, more aggressive measures such as sedation and paralysis may be required to protect the patient and the staff. Restraints should only be used during the relatively short time of gaining control of the agitation using pharmaceutical methods, as the restrained agitated patient is at risk for several adverse outcomes, including sudden death.

Patients presenting with seizures should be treated with incremental doses of intravenous benzodiazepines. If seizures are not rapidly controlled, intravenous propofol or phenobarbital is indicated usually along with intubation to secure the airway. The role for phenytoin is limited in the patient with toxicological causes of seizures and usually should be avoided. Seizures refractory to sedative–hypnotic drugs should be managed with non-depolarizing neuromuscular blockade and general anesthesia along with continuous electroencephalogram monitoring. The work up of seizures should include a CT scan to evaluate for potential physical causes. Patients with intracranial hemorrhage or cerebral infarction should have neurosurgery or neurology consultation as appropriate. As the etiology of the "beading" seen on angiography is uncertain, the role of calcium channel blockers (e.g., nimodipine) and/or steroids for such patients is equally uncertain.

Patients with peripheral vascular ischemia should be managed in conjunction with a vascular service. Intra-arterial administration of α-adrenergic receptor antagonists such as phentolamine may relieve localized arterial vasospasm; if multiple areas of vasospasm are observed, there may be a role for intravenous nitroprusside. This adverse effect may be observed more typically with some of the substituted hallucinogenic amphetamines such as DOB [45]. Accidental intra-arterial injection during intravenous abuse may lead to significant tissue destruction through emboli (e.g., talc and the other cutting agents), thrombosis, and vasoconstriction. There is no consensus on managing these patients although adequate fluid resuscitation, acetylsalicylate, and heparin appear to be reasonable; other interventions that have been used for intra-arterial injection accidents with heroin include intra-arterial phentolamine, thrombolytics, and dexamethasone.

Core temperature approaching or more than 104°F (40°C) should be aggressively managed, as the risk for multisystem organ failure exponentially rises with the temperature. One should undress the patient, initiate active cooling measures, and continuously monitor the patient's core temperature. Active cooling techniques include spraying the patient with cool water, draping with cold water soaked sheets along with large fans for evaporation, ice packs in the axilla and groin, or a cooling blanket possibly used *under* the patient while utilizing evaporative cooling from above. Active cooling should be terminated when the patient's core temperature approaches 101°F (38.3°C). Benzodiazepines are useful in decreasing motor agitation contributing to the hyperthermia. Paralysis and intubation would be a last resort to treating persistent rigidity associated hyperthermia. Antipyretics (e.g., acetaminophen, aspirin, nonsteroidal anti-inflammatory drugs) are not useful, and there is no evidence that dantrolene, bromocriptine, or amantadine enhance the cooling process in these patients with life-threatening hyperthermia.

Fluid management should address any electrolyte and acid–base abnormalities. Management of rhabdomyolysis should include generous intravenous crystalloid fluids to maintain urine output of at least 2 to 3 mL per kg per hour to minimize the risk of acute tubular necrosis. The role of alkalinizing the urine to provide renal protection when rhabdomyolysis is present is controversial, but may be performed if desired. As serum myoglobin levels are not usually rapidly available, serum CPK may be monitored instead. Although no longer recommended for amphetamine toxicity, urinary acidification would increase the urinary excretion of amphetamine but the risks outweigh any potential benefits.

The serotonergic amphetamines MDMA and like compounds can cause significant serotonin toxicity when combined with other pharmaceuticals that have serotonin effects such as SSRIs, MAOIs, and cocaine. Differentiating the degree of concomitant serotonin toxicity can be difficult, but the physical examination findings of myoclonus and hyperreflexia with the lower extremity reflexes more pronounced than the upper extremity reflexes would be strongly suggestive of serotonin toxicity. Treatment is benzodiazepines and supportive care, although cyproheptadine may be of some benefit; an adult dose for serotonin toxicity is 8 mg orally every few hours to a maximum of 32 mg/day. The hyponatremia arising from SIADH should be treated with water restriction and may require hypertonic 3% normal saline. These fluid requirements should be balanced with other fluid issues such as the possible presence of rhabdomyolysis.

The involuntary abnormal choreiform and athetoid movements following abuse may be the reason for presentation and can be a source of great anxiety for the patient. When the symptom onset is rapid and not present for a long period of time, antipsychotics such as haloperidol have theoretical benefit and may be efficacious [33]. When the involuntary movements have lasted for a long time, antipsychotics may be less effective. Sedatives have been observed to increase the movements in some patients. There has been some success in alleviating symptoms using centrally acting antimuscarinic drugs (e.g., benztropine) [34].

There is no consensus on management of asymptomatic body stuffers. Sometimes individuals claim to have ingested drug packets in an attempt to avoid going to jail, a technique which often works in the short term. The count of the number

of packets or the amount of drugs in the packet is usually unreliable. Even when bags or packets are ingested, they are rarely seen on imaging studies. An abdominal CT scan is more reliable than plain abdominal imaging, but false negatives do occur. GI decontamination using activated charcoal (AC) at a dose of 1 to 2 gram per kg should be considered for these patients. Multiple doses of AC have no proven benefit and may be harmful in potentially causing obstruction. The risks of forced AC administration usually outweigh any potential benefit when a patient will not voluntarily drink the AC. However, this risk/benefit ratio should be reassessed should a patient clinically deteriorate to the point of requiring intubation. Occasionally, whole bowel irrigation is also employed for these patients (see below). Given the lack of endpoint (i.e., passed packets) in most of these patients, they will require a period of sufficient observation. The safest approach to these patients would be admission for a minimum of 24 hours of close hemodynamic observation, with additional observation time should any unexplained increase in pulse or blood pressure occur. Note this observation period may not be sufficient for all patients; cases of toxicity have resulted from more than 36 hours from ingestion of a sealed baggie [5].

Asymptomatic body packers should also be conservatively managed. One proposed guideline involves the oral administration of a water-soluble contrast solution followed by serial abdominal radiographs (see Chapter 140, Table 140.5). Whole bowel irrigation (WBI) with isotonic polyethylene glycol electrolyte solution has also been advocated for GI decontamination based on case reports. Some clinicians advocate administering polyethylene glycol solution, 1 L per hour, to adults until there is no longer significant concern for retained packets in the GI tract. This is usually signaled by a clear rectal effluent, no radiographic evidence of drug packets in the GI tract, a negative rectal examination for any packets, and an accurate accounting of the number of ingested packets. It does appear that the packet count for body packers is sometimes more reliable than for body stuffers, but still may not be correct. Administration of multiple doses of cathartics is not considered whole-bowel irrigation and may result in severe fluid and electrolyte abnormalities [51,52,53,54].

Body packers and body stuffers who develop sympathomimetic toxicity should be suspected of having leakage or rupture of the drug packets in their GI tract [55]. In the case of a body packer, this is an absolute indication for emergent surgical intervention due to the massive amount of drug present. Surgical intervention is also indicated for patients with intestinal obstruction, ischemia, or perforation and may be indicated when packets fail to progress through the GI tract after conservative management. Endoscopic retrieval of packets retained in the stomach is rarely performed due to risk of rupture, but if implemented, it should be by an experienced endoscopist.

The proper management of patients exposed to methamphetamine laboratories varies depending on the exposure scenario and the type of laboratory. Many times, the only treatment required is adequate burn care as many of these patients present with thermal burns from a laboratory fire. The most dangerous components to a methamphetamine laboratory (besides the occasional armed psychotic inhabitant) are the possible gases: anhydrous ammonia, hydrochloric acid (HCl), and phosphine. Generally, the HCl and phosphine levels are only present in high enough levels to cause injury during the process of the "cook" [56,57]. All can cause significant pulmonary edema with the injury from phosphine potentially being delayed by several hours and anhydrous ammonia causing significant ocular and dermal injury as well. Methamphetamine laboratories also use caustics and solvents that on contact with skin or eyes can cause significant injury [3]. Variations in the synthesis methods, exposure duration, and preexisting conditions as well as chapter space make it difficult to give further exacting treatment recommendations. It should be noted that despite the subjective complaints, a minor transient exposure to a methamphetamine laboratory is unlikely to cause significant injury, and that unless gross contamination is present, a gentle cleaning with soap and water is adequate for nearly all exposures [58].

CHAPTER 145 ■ WITHDRAWAL SYNDROMES

PAUL M. WAX AND JENNIFER SMITH

As many as 25% of hospitalized adult patients at a university hospital may have a history of ethanol dependence and abuse [1]. Anticipation and recognition of early signs of sedative–hypnotic withdrawal in the sedative–hypnotic abuser allows timely treatment and prevents development of serious withdrawal manifestations, such as seizures, hyperthermia, and delirium. The management of withdrawal syndromes from γ-hydroxybutyrate (GHB) and baclofen may be particularly challenging. Recognition and treatment of the less life-threatening signs and symptoms of opioid withdrawal avoid unnecessary investigation of the frequently severe gastrointestinal symptoms and make the patient more comfortable and able to cooperate. Because ethanol and other sedative–hypnotic withdrawal may have life-threatening manifestations, patients with signs of significant withdrawal should be admitted to the intensive care unit (ICU) for stabilization and monitoring. In addition, drug-dependent patients admitted to the ICU for management of other serious medical or surgical problems may subsequently enter withdrawal in this substance-free environment [2].

Clinical withdrawal implies the presence of physical tolerance and dependency. Factors contributing to the development of dependency include dose of the drug, duration of effect, frequency of administration, and duration of abuse. Shorter-acting drugs require more frequent administration to produce dependency and are associated with more acute and severe withdrawal symptoms than longer-acting drugs. *Tolerance* is defined as a decreased physiologic response elicited by a given dose of the drug. A patient who chronically ingests large amounts of ethanol may not be sedated by a dose that would render a nondrinker comatose. A heroin abuser who has been drug-free during a year's imprisonment may suffer fatal respiratory depression from a dose of heroin that previously would have provided only mild sedation. This physiologic tolerance to drug effect that occurs with chronic use may arise from changes in drug metabolism, such as increased activity of hepatic microsomal enzyme systems and changes in drug effect at the cellular level [3]. Cross-tolerance occurs when the chronic ingestion of one substance decreases the response to a

second substance. Cross-dependency allows one drug to be substituted for another to prevent withdrawal symptoms. Ethanol, the barbiturates, and nonbarbiturate sedative–hypnotic agents are cross-tolerant and cross-dependent with one another but not with other sedating drugs such as opioids, neuroleptics, or antihistamines. These factors have important therapeutic implications.

ETHANOL WITHDRAWAL

Pathophysiology

Ethanol produces its toxic effects (relaxation, euphoria, disinhibition, slurred speech, ataxia, sedation, stupor, coma, and respiratory depression; see Chapter 119) through modulation of a variety of neuroreceptors and ion channels [4]. It acts, in part, by interacting with the γ-aminobutyric acid ($GABA_A$) receptor complex, potentiating inhibitory GABAergic receptor function by inducing chloride flux through the chloride channels of the receptor complex [5]. Ethanol also inhibits excitatory *N*-methyl-d-aspartate (NMDA) glutamate receptor function, contributing to impaired cognition and blackouts associated with chronic ethanol use [6]. Inhibition of NMDA receptor function changes intracellular calcium levels and, as a result, affects cell-signaling cascades, including phosphorylation [7]. Other neurotransmitter systems affected by ethanol include dopamine and serotonin [8]. Ethanol has been found to affect 5-hydroxytryptamine receptor function by increasing the potency with which agonists bind this receptor [4]. Ethanol consumption may also result in an increase in endogenous opiates, contributing to its euphoric effect [9]. In addition, ethanol may exert its effect by altering the lipid matrix of cell membranes [10]. Although it was not recognized until the 1950s that delirium was a manifestation of ethanol withdrawal rather than toxicity, it is now clear that the hallmarks of ethanol and other sedative–hypnotic intoxication are distinctly different from the manifestations of withdrawal from these agents [11,12].

Ethanol withdrawal produces a hyperadrenergic state characterized by intense sympathetic nervous system activation. This may be due in part to compensatory central nervous system (CNS) mechanisms that counteract the depressant effects of ethanol intoxication. During withdrawal, these compensatory mechanisms are unopposed, resulting in increased neural stimulation [13]. In support of this theory, elevated levels of plasma and urinary catecholamines have been associated with tachycardia, elevated blood pressure, and tremors observed in withdrawing patients [14]. A decrease in the inhibitory activity of presynaptic α_2-receptors has been demonstrated and may explain, in part, the increase in norepinephrine levels [15]. In addition, an increase in β-adrenergic receptors during withdrawal has been demonstrated [16]. One study showed an increase in plasma levels of the dopamine metabolite homovanillic acid in patients presenting with delirium tremens [17].

Compensatory changes in number and function of inhibitory $GABA_A$ receptors and excitatory NMDA glutamate receptors during chronic ethanol use may contribute to the CNS stimulation brought on by the cessation of ethanol. The abrupt withdrawal of the GABA-potentiating effects of ethanol leads to a disinhibition of neural pathways in the CNS [18]. During withdrawal, ethanol's enhancing effect on chloride flux is lost, resulting in a decrease in GABAergic functioning. Tachycardia, diaphoresis, tremors, anxiety, and seizures have been associated with this reduction in GABA-induced chloride flux [19]. Upregulation in NMDA glutamate receptors and changes in their receptor subunit composition increases calcium flux through these receptors [20]. This likely contributes to the excitotoxic neuronal cell death associated with ethanol withdrawal [21]. Repeated episodes of withdrawal increase the propensity for ethanol withdrawal seizures through altered $GABA_A$ and NMDA receptor function [22,23]. Because NMDA receptors mediate dopaminergic transmission, the increased NMDA receptor function that occurs during withdrawal may also lead to decreased dopaminergic and serotonergic transmission, contributing to alcohol craving [7].

Ethanol withdrawal occurs when a dependent patient suddenly stops drinking or drinks at a slower rate than previously. In either case, a significant drop in the serum ethanol level occurs. In chronic alcoholics, signs of withdrawal are commonly present even when their serum ethanol concentrations are higher than 100 mg per dL [24]. Patients admitted to the ICU with ethanol withdrawal often have a significant underlying disease that has led to an inability to maintain an ethanol intake adequate to prevent withdrawal. Alcoholic gastritis, hepatitis, pancreatitis, and pneumonia commonly precipitate decreased ethanol use and withdrawal. These patients typically present to the hospital after 24 to 48 hours of abdominal pain or fever and may be tremulous or have had a withdrawal seizure. Another type of ICU patient prone to withdrawal is one who has continued to imbibe ethanol nearly to the moment of arrival at the hospital. Intoxicated patients are prone to experience traumatic events and arrive in the operating room, recovery room, or ICU still intoxicated. A history of ethanol abuse or previous withdrawal may not be available in the postoperative or intubated patient when initial signs of withdrawal occur. Failure to recognize ethanol withdrawal in the seriously ill or injured patient may lead to prolonged complications [13].

Clinical Manifestations

Ethanol withdrawal results in a variety of signs and symptoms that vary in severity and duration. In their landmark article, Victor and Adams [12] described withdrawal as a tremulous–hallucinating–epileptic–delirious state. Although this description is often used to divide ethanol withdrawal syndrome into four stages, it is important to remember that the various manifestations of ethanol withdrawal form a progressive continuum of severity. A patient in ethanol withdrawal may exhibit one or more of these manifestations. The sequence of clinical events may be inconsistent. The severity of the withdrawal is often dose-dependent, with more severe reactions associated with heavier and longer periods of drinking [24]. It has been suggested that repeated withdrawal episodes produce a kindling effect, such that each subsequent withdrawal elicits increasingly more severe reactions [15,23,24].

Tremulousness and seizures are the most common clinical manifestations of ethanol withdrawal. They tend to occur early and are generally considered mild-to-moderate ethanol withdrawal symptoms. Delirium tremens is a late manifestation of ethanol withdrawal and constitutes the most serious clinical presentation. Although dramatic and life threatening, delirium tremens is but one aspect of ethanol withdrawal and affects 5% of withdrawal patients [25].

Mild ethanol withdrawal is usually characterized by a period of acute tremulousness (the "shakes"). It begins 6 to 8 hours after a reduction in ethanol intake [24,26]. Patients usually complain of tremulousness, nausea, vomiting, anorexia, anxiety, and insomnia. Physical examination reveals evidence of mild CNS and autonomic hyperactivity, which includes tachycardia, mild hypertension, hyperreflexia, irritability, and a resting tremor. Occasionally, significant tremor may not be appreciated despite the patient's complaint of feeling "shaky inside." Despite the fact that patients in delirium tremens have evidence of significant disorientation, this milder form of withdrawal is characterized by a clear sensorium,

although the patient may have a minor disorientation to time. Symptoms of mild ethanol withdrawal usually peak between 24 and 36 hours, and 75% to 80% of these patients recover uneventfully in a few days. Approximately 20% to 25% of patients presenting with mild ethanol withdrawal progress to serious withdrawal manifestations, which include seizures, hallucinations, or delirium tremens. However, it is impossible to reliably predict which patients will deteriorate [24].

Seizures that occur in alcoholics may or may not be due to ethanol withdrawal. Although ethanol withdrawal accounts for many of these seizures, other common causes include preexisting idiopathic and post-traumatic epilepsy [11,12]. Other complications of ethanol abuse not necessarily associated with withdrawal, such as hypoglycemia, hypomagnesemia, and hyponatremia, may also precipitate seizure activity [27]. Ethanol intoxication itself is not thought to be proconvulsant [28]. Alcoholic patients with a history of epilepsy appear to have a greater incidence of seizures than those without a preexisting seizure disorder. Failure to comply with anticonvulsant regimens may, in part, account for this. Brief abstinence (even overnight) may also lower the seizure threshold sufficiently to provoke seizures in susceptible patients. Because management strategies differ depending on whether the patient has a history of previous seizure disorder unrelated to ethanol withdrawal, differentiating between them becomes important [29].

Early studies showed that as many as 25% to 33% of patients in ethanol withdrawal demonstrate seizure activity [11,12]. Most ethanol withdrawal seizures ("rum fits") occur between 7 and 48 hours after cessation or relative abstinence from drinking [30]. Mild-to-moderate signs of withdrawal may precede the seizures, or the seizure may herald the onset of ethanol withdrawal. They are short, generalized, tonic–clonic seizures, 40% of which are limited to a single isolated event. Often a short burst of two to six seizures with normal sensorium between seizures occurs over a few hours. Patients with ethanol withdrawal seizures usually have normal baseline electroencephalograms, in contrast to those with underlying seizure disorders. Status epilepticus or recurrent seizure activity lasting longer than 6 hours is distinctly uncommon in ethanol withdrawal and suggests another diagnosis [31].

Ethanol-related seizures may foreshadow the development of delirium tremens. In one series of patients with ethanol withdrawal seizures, delirium tremens developed in 33% [32]. In some patients, postictal confusion blended imperceptibly into delirium tremens. Approximately 40% of patients in whom delirium tremens subsequently developed exhibited an initial clearing followed by the onset of delirium tremens 12 hours to 5 days later.

Disordered perceptions characterized by hallucinations and nightmares were noted in 25% of tremulous patients in early withdrawal by Victor and Adams [12]. The hallucinations were predominantly visual in nature, auditory only in 20% of cases, and rarely tactile or olfactory. Commonly described visual phenomena in this setting may include the graphic depiction of bugs crawling on the walls or bed [32].

A subset of hallucinating patients does not demonstrate tremulousness or other signs of sympathetic hyperactivity. Known as *acute alcoholic hallucinosis*, this uncommon clinical presentation (occurring in 2% of the patients of Victor and Adams) is a distinct manifestation of ethanol withdrawal that usually begins within 8 to 48 hours of cessation of drinking [12]. It is characterized by disabling auditory hallucinations, often of a persecutory nature. These patients display no evidence of formal thought disorder, have no personal or family history of schizophrenia, and are usually oriented to person and place. In most cases, symptoms last for 1 to 6 days, although they may persist for months and come to resemble chronic paranoid schizophrenia. These symptoms usually respond to therapy with cross-tolerant agents such as benzodiazepines [33].

Delirium tremens is characterized by a significant alteration of sensorium associated with dramatic autonomic and CNS hyperactivity. Only 5% of patients who exhibit any of the previously discussed manifestations of ethanol withdrawal progress to delirium tremens. Delirium tremens appears to be more common in patients with a history of significant withdrawal and a long history of ethanol use. Patients in whom delirium tremens develops may not have demonstrated earlier signs of withdrawal. Other patients who have had ethanol withdrawal seizures or hallucinations may deceptively improve before the onset of delirium tremens, which is rarely seen before 48 to 72 hours after cessation or reduction in drinking and may be delayed for as long as 5 to 14 days [12,26]. These patients are truly delirious, exhibiting disorientation, global confusion, hallucinations, and delusions. Speech is unintelligible. Psychomotor disturbances, such as picking at bedclothes, significant restlessness, and agitation, are common and often require the use of physical restraints. Autonomic disturbances, such as tachycardia, hypertension, tachypnea, hyperpyrexia, diaphoresis, and mydriasis, are present. Cardiac dysrhythmias may also occur [34]. Seizures rarely occur during delirium tremens [26]. Concomitant illness, trauma, seizures, or therapeutic drugs may mask or modify the typical presentation.

Mortality for delirium tremens varies with the presence of underlying disease. Higher mortality is associated with superimposed pneumonia, meningitis, pancreatitis, gastrointestinal bleeding, and major trauma. In the untreated patient without serious coexisting medical disease, mortality usually is a consequence of severe dehydration or hyperthermia, or both, precipitating cardiovascular collapse [35]. Before adequate therapeutic agents were available, a mortality rate of 24% to 35% was cited in the literature [36]. This had decreased to 5% to 10% with the use of barbiturates and paraldehyde [37]. The use of benzodiazepines and intensive supportive care and earlier recognition of withdrawal should further reduce mortality in the absence of significant underlying disease [18].

Diagnostic Evaluation

The differential diagnosis of ethanol withdrawal includes other causes of a hyperadrenergic state. Most importantly, ethanol-related hypoglycemia needs to be differentiated from withdrawal. Clinically, these two conditions may appear remarkably similar, although only hypoglycemia rapidly improves after intravenous (IV) glucose administration [38].

Intoxication with sympathomimetic agents such as cocaine or amphetamine shares many features with ethanol withdrawal, including signs and symptoms of adrenergic excess. Overdose of monamine oxidase inhibitors, phencyclidine, anticholingergic agents, and lithium, as well as neuroleptic malignant syndrome and serotonin syndrome, may all demonstrate marked agitation and confusion [39]. In the elderly patient, almost any therapeutic drug may be associated with delirium [40]. Withdrawal from other sedative–hypnotics, such as benzodiazepines, barbiturates, GHB, and baclofen, may precipitate a delirium-tremens-like state (see following discussion).

Significant underlying metabolic, traumatic, and infectious disorders should be excluded in the patient with altered mental status associated with ethanol withdrawal. Differentiation may require lumbar puncture, laboratory tests, and computed tomographic scan. These include CNS emergencies, such as intracranial bleeds, meningitis, and encephalitis; metabolic causes, including hypoxia, hypercarbia, sepsis, thiamine deficiency, and sodium and calcium abnormalities; and endocrine disturbances, such as thyroid storm and pheochromocytoma. Distinguishing between delirium tremens and hepatic encephalopathy may be difficult, especially because these conditions often coexist [41].

Management

A successful strategy in treating ethanol withdrawal must address several key goals: alleviation of symptoms, prevention of progression of withdrawal to a more serious stage, avoidance of complications, treatment of coexisting medical problems, and planning for long-term rehabilitation and drug independence [26]. Initial management involves securing the airway, breathing, and circulation. Patients with an altered level of consciousness require oxygen and IV administration of at least 100 mg thiamine and 50 g glucose. The latter two substrates are particularly important, as Wernicke's encephalopathy and hypoglycemia may be confused or coexist with ethanol withdrawal. Severely agitated patients may initially require physical restraints to prevent injury and facilitate sedation. Prolonged use of physical restraints without adequate sedation, however, may be detrimental because agitated patients quite often continue to struggle against their restraints. Such activity perpetuates the risk for hyperthermia, muscle destruction, and resultant myoglobinuric renal failure. Volume resuscitation, correction of electrolyte abnormalities, and vigilance in the diagnosis and treatment of coexisting medical and surgical disorders are vital in reducing morbidity and mortality in the patient with delirium tremens [37,42].

Achievement of adequate sedation is the cornerstone of successful treatment of ethanol withdrawal [43]. Sedation alleviates the excitatory manifestations of withdrawal, prevents progression to delirium tremens, and prevents common complications of agitation, including trauma, rhabdomyolysis, and hyperthermia. Although many agents have been used over the years, benzodiazepines have proved the most effective [43–47]. Benzodiazepines, unlike the neuroleptics, are cross-tolerant with ethanol and function as a replacement drug for the short-acting ethanol, increasing the affinity of GABA for the $GABA_A$ receptor [48].

Diazepam (Valium), chlordiazepoxide (Librium), and lorazepam (Ativan) are the most commonly used parenteral agents. All three drugs can easily be given intravenously to facilitate rapid sedation and titration of effect. Of these agents, only lorazepam has reliable intramuscular (IM) absorption [24,49]. Diazepam and chlordiazepoxide are long-acting agents with active metabolites that prolong their therapeutic effect, avoiding the need for frequent dosing that is associated with shorter-acting agents. Lorazepam, a shorter-acting agent, has no active metabolites and is better tolerated in the elderly and in patients with hepatic dysfunction, producing less sedation. Prolonged therapy (e.g., > 1 month) with high-dose IV lorazepam, however, has also been associated with acute tubular necrosis secondary to the polyethylene glycol used as the lorazepam diluent [50]. Continuous IV infusion of midazolam, a short-acting agent, has also been recommended in the treatment of delirium tremens [51]. However, this approach requires more vigilant monitoring and does not provide the advantages of a long-acting benzodiazepine that is gradually eliminated over several days. Midazolam infusion is also considerably more expensive than therapy with longer-acting agents [52].

The benzodiazepine of choice in the treatment of ethanol withdrawal remains controversial [53,54]. Although many investigators have suggested that lorazepam may be the preferred agent [13,37,55], long-acting benzodiazepines such as diazepam may be more effective in preventing ethanol withdrawal seizures and contributing to smoother withdrawal with less breakthrough or rebound symptoms [56,57].

Symptom-triggered benzodiazepine treatment for alcohol withdrawal is strongly encouraged [58]. The Clinical Institute Withdrawal Assessment for Alcohol (CIWA-A) scale is a reliable, validated scale to assess severity of alcohol withdrawal so treatment can be appropriately titrated and individualized. It includes subjective parameters such as anxiety, auditory and visual disturbances, headache, and nausea as well as objective parameters such as tremor, sweating, agitation, and clouding of sensorium. [59] The dose of benzodiazepines needed to achieve adequate sedation varies considerably depending on the patient's tolerance. Although oral therapy may be appropriate in patients with mild withdrawal, those with significant signs of withdrawal require IV treatment. Therapy with an IV benzodiazepine is titrated to the patient's needs by the use of frequent boluses until withdrawal symptoms subside. Using such a front-loading technique helps avoid undertreatment or excessive sedation [60,61]. For example, 5 to 20 mg of diazepam can be administered to the patient every 5 minutes until he or she is quietly asleep but can be easily awakened. Initial safe titration of benzodiazepines requires continual reevaluation by an observer at the bedside. In patients with moderate withdrawal symptoms, a study showed that using a symptom-triggered approach, instead of a fixed-schedule approach, resulted in the administration of less total medication and fewer hours of medication (9 hours vs. 68 hours) [62,63]. A recent study in a surgical ICU demonstrated that this symptom-orientated bolus-titrated approach decreases the severity and duration of alcohol withdrawal symptoms, resulting in reduced medication requirements, fewer days of ventilation, lower incidence of pneumonia, and shorter ICU stay [64].

Failure to obtain adequate sedation with standard doses of the chosen agent should not prompt a switch to an alternative benzodiazepine. Some patients require very high doses to achieve sedation; cases of patients receiving more than 1,000 mg diazepam during 24 hours have been reported [62]. Recent research into GABA receptor physiology suggests that resistance to large doses of benzodiazepines in some patients with alcohol withdrawal may be due to alterations in $GABA_A$ receptor subunits [65]. Chronic ethanol exposure produces upregulation of $GABA_A$ receptor α_4 subunits that are insensitive to benzodiazepines, and downregulation of benzodiazepine-sensitive α_1 subunits. If a patient with severe alcohol withdrawal does not respond to large doses of a benzodiazepine, administration of an alternative agent may be warranted. A drug such as a barbiturate, which acts on the $GABA_A$ receptor regardless of its specific α subunit composition, would be appropriate.

Recent research also suggests that changes in NMDA glutamate receptor physiology may be important in both clinical signs and symptoms of ethanol withdrawal and the excitotoxic neuronal cell death that may occur. In animal studies, NMDA receptor antagonists may attenuate the development of ethanol dependence if administered concomitantly, and may prevent withdrawal seizures and neuronal excitotoxicity if given during periods of withdrawal [20]. Patients who are refractory to high dose $GABA_A$ agonists may potentially benefit from addressing the glutaminergic as well as the GABergic manifestations of ethanol withdrawal. Options here are limited, but drugs such as propofol, which possess both GABA agonist and NMDA antagonist properties, may be particularly helpful.

Adequate early treatment with benzodiazepines usually suppresses significant manifestations of withdrawal and prevents progression to delirium tremens. If delirium tremens is already manifest, sedation with a benzodiazepine does not completely reverse mental status abnormalities. This may be a consequence of the incomplete cross-tolerance of benzodiazepine with ethanol or perhaps the lack of immediate reversibility of some of the CNS effects of withdrawal [66].

Barbiturates, particularly intermediate and long-acting agents such as pentobarbital and phenobarbital, are an alternative class of cross-tolerant sedative–hypnotic agents that can be used in the treatment of ethanol withdrawal [67]. Although excess sedation and a greater tendency to produce respiratory

depression may be more of a concern with barbiturates as compared with benzodiazepines, the drugs are still titrated until the patient is quietly asleep but easily awakened [68]. Phenobarbital dosages more than 20 mg per kg may be required. Withdrawal patients with idiopathic or post-traumatic epilepsy who require maintenance anticonvulsant levels may particularly benefit from this alternative strategy. Phenobarbital may also be useful for those patients who are resistant to benzodiazepine therapy.

Propofol, a sedative–hypnotic agent used for induction and maintenance of anesthesia, has been used successfully for treatment of severe ethanol withdrawal that is resistant to large doses of benzodiazepines (> 1,000 mg per day) [69–71]. Like ethanol, it acts as an agonist at the $GABA_A$ receptor and also inhibits the NMDA receptor. Its onset of action is rapid, it is easily titratable, and sedative effects wear off quickly after short-term use (< 72 hours). The fact that it addresses the glutaminergic as well as the GABAergic aspects of ethanol withdrawal may be one reason for its increased apparent effectiveness in patients resistant to standard therapy with benzodiazepines. Disadvantages of its use include high cost and prolonged sedation when it is used for extended periods [72]. No controlled trials have compared propofol and benzodiazepines for treatment of ethanol withdrawal.

Intravenous and oral ethanol have been used to suppress withdrawal and continue to be used by some medical practitioners, especially surgeons [73,74]. However, IV ethanol intensifies the biochemical abnormalities associated with ethanol metabolism, shifting energy production toward lactate and ketogenesis [75]. The use of ethanol in the treatment of ethanol withdrawal is not recommended [76].

The use of phenothiazines and butyrophenones to treat ethanol withdrawal has been associated with excessive fatalities [42,75,77]. These agents have been shown to lower the seizure threshold, induce hypotension, impair thermoregulation, and precipitate dystonic reactions [78–80]. These drugs have no role in the management of sedative–hypnotic withdrawal [81].

Beta-blockers and central adrenergic agonists have also been promoted as primary agents and as adjuncts to sedative–hypnotics in the treatment of ethanol withdrawal [82]. These agents do not prevent agitation, hallucinations, confusion, and seizures [46,67]. α_2-Receptor agonists such as clonidine and lofexidine act centrally to attenuate sympathetic outflow from the locus ceruleus [15,24]. Although α_2 agonists may help relieve mild withdrawal symptoms such as tremor, diaphoresis, and tachycardia [83,84], there is no evidence that they prevent delirium tremens [85]. A double-blind study comparing oral benzodiazepines (diazepam or alprazolam) to clonidine in the treatment of mild ethanol withdrawal showed that the benzodiazepines were significantly more efficacious in decreasing withdrawal symptoms [48]. A role for sympatholytic agents in management of seriously ill patients has not been demonstrated.

Valproate has been suggested as an alternative or adjunctive treatment for ethanol withdrawal. It appears to potentiate GABAergic neural transmission through a variety of mechanisms, including activation of glutamic acid decarboxylase. Although there is evidence that valproate may be effective in alleviating withdrawal symptoms, further research is needed before it can be recommended for use in ethanol withdrawal [86].

Baclofen is a $GABA_B$ agonist that appears to have a role in the treatment of alcohol withdrawal. In a randomized, controlled trial, it was comparable to benzodiazepines in relieving symptoms of moderate alcohol withdrawal in an outpatient setting [81]. It has also been shown to be more effective than placebo in controlling craving and in inducing abstinence from alcohol. The mechanism for this effect may be due to the influence of $GABA_B$ agonist on the mesolimbic dopamine pathway [82]. Baclofen has not been studied for use in the treatment of alcohol withdrawal in the intensive care setting.

Gamma-hydroxybutyric acid (GHB) is another $GABA_B$ agonist which recent research has suggested may have a role in the treatment of alcohol withdrawal. In randomized, controlled trials, it was comparable to benzodiazepines and clomethiazole in relieving symptoms of moderate alcohol withdrawal in an outpatient setting. Transient vertigo was the most commonly reported side effect, but also occurred with clomethiazole and benzodiazepine treatment. GHB may resolve withdrawal-associated symptoms of anxiety, agitation, and depression more quickly than benzodiazepines, possibly due to its action on dopaminergic and serotonergic neurotransmitter systems [87,88]. This method of treatment is not commonly used, and further study is warranted.

Magnesium sulfate has been suggested as a potential therapy for alcohol withdrawal, but no sound studies have been able to confirm that magnesium supplementation helps alleviate signs or symptoms of alcohol withdrawal, either in normomagnesemic or hypomagnesemic patients [89].

Adequate sedation of the patient with early signs of withdrawal prevents the development of ethanol withdrawal seizures and progression to delirium tremens. Patients who have had an ethanol withdrawal seizure are at risk for progression to delirium tremens and should be sedated with benzodiazepines or barbiturates, as previously discussed. A randomized, controlled trial evaluating patients presenting to the emergency department with ethanol withdrawal seizures and lacking other signs of moderate alcohol withdrawal showed that a one-time dose of lorazepam, 2 mg IV, was more effective than placebo in preventing recurrent ethanol withdrawal seizures [90]. No evidence has been shown to prove that phenytoin is efficacious in the treatment or prevention of ethanol withdrawal seizures [26,91]. Clinical studies failed to show any significant benefit of IV phenytoin when compared with placebo in the prevention of subsequent ethanol withdrawal seizures [92–94].

The use of anticonvulsants to prevent or treat ethanol withdrawal seizures should be limited to patients with an underlying seizure disorder who require maintenance anticonvulsant therapy [29]. These patients often seize at the onset of mild withdrawal secondary to poor compliance with their anticonvulsant regimen and require restoration of adequate serum levels with an anticonvulsant such as phenytoin. Patients who present with an apparent ethanol withdrawal seizure but do not have a history of either underlying seizure disorder or previous ethanol withdrawal seizures require a full seizure workup. For those rare patients in ethanol withdrawal in whom status epilepticus develops, aggressive anticonvulsant treatment is indicated and phenobarbital or phenytoin, or both, can be used in addition to the benzodiazepines. Because status epilepticus and seizures during delirium tremens are rare sequelae of ethanol withdrawal, their occurrence requires a search for underlying traumatic injuries and infection, regardless of any previous history of ethanol withdrawal seizures.

BENZODIAZEPINE WITHDRAWAL

Since their introduction in the early 1960s, benzodiazepines have replaced the barbiturates as the most widely prescribed sedative–hypnotic agents. Initially, these newer agents were not thought to have the same serious withdrawal problems associated with the barbiturates [95]. Subsequent experience has shown that withdrawal from benzodiazepines may be as severe as withdrawal from barbiturates or ethanol. It is estimated that 10% to 20% of adults in the United States use benzodiazepines on a regular basis [96]. The early signs of withdrawal from benzodiazepines are the same as those of ethanol withdrawal. Differences include delayed time of onset, depending on the

duration of action of the agent involved, and the presence or absence of active metabolites. When delayed tachycardia, hypertension, and irritability develop in a hospitalized patient, prior benzodiazepine abuse should be suspected.

Pathophysiology

Signs and symptoms of benzodiazepine withdrawal occur when tolerant patients experience a decline in brain benzodiazepine levels. Individuals who have not developed tolerance do not experience symptoms of withdrawal. Patients who have taken therapeutic amounts of these drugs over an extended period may experience withdrawal (therapeutic dose withdrawal) [97,98], although more commonly it occurs in those who have been regularly taking higher than recommended antianxiety doses. A high daily dose and long duration of benzodiazepine use correlate with a greater risk of developing a moderate-to-severe withdrawal syndrome [96,99]. Although withdrawal usually occurs after abrupt discontinuation of these medications, it may occur to a lesser extent during drug tapering [95]. Iatrogenic benzodiazepine withdrawal has also been described in patients following discontinuation of midazolam-induced sedation in the ICU [100].

Although the mechanisms for benzodiazepine tolerance and withdrawal are not fully understood, it appears that changes in $GABA_A$ receptor subunits, similar to those that occur with chronic ethanol use, may be responsible [101]. Ultimately, a decrease in the availability of exogenous benzodiazepine results in unopposed nervous system stimulation and an increase in agitation and anxiety.

Variability in the time course and severity of withdrawal among the various benzodiazepines can be explained by their differing pharmacokinetics [102]. Drug half-life and the presence of active metabolites correlate with the onset, frequency, and severity of withdrawal symptoms. The onset of withdrawal from shorter-acting agents without active metabolites, such as lorazepam or alprazolam, may be precipitous, with marked symptoms as early as 24 hours after cessation of the drug [103]. Signs of withdrawal from longer-acting agents, such as diazepam, which have a long elimination half-life in addition to active metabolites, may be delayed for 8 days or longer. Withdrawal symptoms from long-acting benzodiazepines may persist for months [104,105]. Concurrent use of other cross-tolerant sedative–hypnotic substances, such as ethanol, barbiturates, chloral hydrate, glutethimide, ethchlorvynol, or meprobamate, along with benzodiazepines increases the probability of developing withdrawal on abrupt discontinuation of these substances.

Administration of the competitive benzodiazepine antagonist flumazenil can result in iatrogenic benzodiazepine withdrawal. Flumazenil is used to reverse sedation in the settings of benzodiazepine overdose, IV conscious sedation, and general anesthesia [106] and was suggested as an adjunct in the weaning of patients from mechanical ventilation [107]. However, flumazenil has not been proved effective in the treatment of benzodiazepine-induced respiratory depression [106]. A history of benzodiazepine use and dependence may not be available when unconscious patients are admitted to the ICU, and benzodiazepine withdrawal with seizures and death has been reported after the use of flumazenil [108–110]. Hence, flumazenil should be used with caution (see Chapter 143).

Clinical Manifestations

Benzodiazepine withdrawal is characterized by CNS excitation and autonomic hyperactivity. Mild early manifestations of withdrawal include psychological symptoms such as anxiety, apprehension, irritability, mood swings, dysphoria, and insomnia. Somatic complaints commonly include nausea, palpitations, tremor, diaphoresis, and muscle twitching.

More severe signs of withdrawal include vomiting, cramps, tachycardia, postural hypotension, and hyperthermia. Significant neuromuscular hyperactivity may be manifested as fasciculations, myoclonic jerks, and seizures [111]. Agitated delirium accompanied by hallucinations and paranoid delusions, and catatonia, have been described [112,113].

In patients taking clonazepam, withdrawal symptoms may develop 3 to 4 days after cessation of therapy. Clonazepam withdrawal may be precipitated or accentuated, or both, by concomitant neuroleptic therapy [114,115].

Diagnostic Evaluation

Benzodiazepine withdrawal may be difficult to distinguish from an underlying anxiety disorder [112]. The time course of the symptoms helps distinguish these two diagnoses. Withdrawal symptoms often worsen rapidly in the early period, followed by gradual improvement and resolution. Unmasked anxiety disorders tend not to deteriorate significantly and persist with time. Perceptual disturbances, not generally associated with underlying anxiety disorders, are commonly found during early withdrawal and may also help distinguish withdrawal from the return of anxiety [104]. These disturbances include paresthesia, tinnitus, visual abnormalities, vertigo, metallic taste, depersonalization, and derealization [98].

Management

Treatment strategies for benzodiazepine withdrawal are similar to those used for ethanol withdrawal. Reinstitution of the drug at a dose that relieves withdrawal symptoms followed by slow withdrawal during 2 to 4 weeks minimizes symptoms and affects the desired decrease in CNS tolerance. Alternatively, a similar cross-tolerant agent can be used. A long-acting benzodiazepine such as diazepam or chlordiazepoxide is preferred. Short-acting agents are disadvantageous because maintenance of therapeutic serum drug levels requires frequent drug administration. In patients with moderate-to-severe symptoms (e.g., seizures, delirium), small IV boluses, such as 5 mg of diazepam, should be given until adequate sedation is achieved. Patients experiencing milder symptoms can be treated by the oral route. Barbiturates such as pentobarbital and phenobarbital can also be used in the treatment of benzodiazepine withdrawal [116,117].

Beta-blockers and clonidine have also been used in the treatment of benzodiazepine withdrawal [118]. Propranolol (10 to 40 mg every 6 hours) may help ameliorate tremor, muscle twitching, tachycardia, and hypertension. However, it has little effect on anxiety, agitation, and dysphoria [96]. Clonidine use has also been advocated, although its efficacy in modulating the intensity, severity, and duration of withdrawal has been questioned [119]. As with ethanol withdrawal, it is important to realize that treating peripheral manifestations of withdrawal may obscure early signs of impending delirium and impedes the assessment of adequate sedation. Phenothiazines and butyrophenones exhibit no cross-tolerance to the benzodiazepines and do not have a role in the treatment of benzodiazepine withdrawal, for the same reasons seen in ethanol withdrawal [120].

Limited data are available on the treatment of flumazenil-induced benzodiazepine withdrawal. Because flumazenil has a relatively short half-life (approximately 1 hour), supportive care should be sufficient in the treatment of mild withdrawal symptoms. The precipitation of seizure activity may require treatment with a benzodiazepine or barbiturate. Due to flumazenil receptor blockade, higher doses of GABAergic agonists may be required.

γ-HYDROXYBUTYRATE WITHDRAWAL

Withdrawal from the commonly abused street drugs GHB or its congeners γ-butyrolactone and 1,4-butanediol (see Chapter 143) may be dramatic and potentially life threatening [121,122]. The pathophysiology is similar to that for benzodiazepine withdrawal. Heavy users of these chemicals report using multiple daily doses (as frequent as every 1 to 3 hours) around the clock [123]. GHB acts as an agonist at GHB and $GABA_B$ receptors. Withdrawal symptoms may include agitation, mental status changes, hypertension, and tachycardia. Other findings are tremulousness, diaphoresis, tachypnea, rigidity, irritability, paranoia, insomnia, and auditory and visual hallucinations [124,125]. High-frequency users appear to be at greatest risk for developing withdrawal delirium after abrupt discontinuation of these agents. Onset of symptoms may begin as early as 1 to 6 hours after the last dose [126]. Severe withdrawal symptoms may persist from 5 to 15 days onward and require prolonged ICU care. Many of these patients require physical restraints and heavy sedation [126]. The use of IV benzodiazepine and other cross-tolerant agents is recommended in the management of these patients. As use and abuse of GHB and its precursors becomes more common, more cases of withdrawal are being reported, including cases in which patients are refractory to large doses of benzodiazepines. Successful treatment of this subset of patients with pentobarbital [127,128] and baclofen [129] has been reported. Barbiturates such as pentobarbital may be helpful because unlike benzodiazepines, they are capable of opening $GABA_A$ chloride channels independently of GABA's presence. Pentobarbital dosages used in case series were 1 to 2 mg per kg IV every 30 to 60 minutes, titrated to improvement in vital signs and altered sensorium. Baclofen's usefulness may stem from the fact that like GHB, it is an agonist at $GABA_B$ receptors, whereas benzodiazepines act only on the $GABA_A$ receptor. One case report describes dosing of 10 mg orally three times daily successfully prevented seizures which occurred every time GHB was withdrawn from a dependent patient.

BACLOFEN WITHDRAWAL

Baclofen is a $GABA_B$ receptor agonist used to treat spasticity resulting from multiple sclerosis or CNS injury. It can be taken orally or delivered by an intrathecal pump, which allows higher CNS levels without the side effects associated with large oral doses. An abrupt discontinuation or decrease in baclofen dose may result in a withdrawal syndrome [130]. The pathophysiology is similar to that for benzodiazepine withdrawal. There are many scenarios in which an intrathecal drug delivery system may fail, including errors in programming the pump or filling the reservoir, development of kinks or occlusions in the tubing, and battery failure.

Onset of withdrawal symptoms may occur within a few hours to a few days after a decrease in baclofen dose. Mild-to-moderate withdrawal symptoms may include increased spasticity, tachycardia, hypertension, fever, neuromuscular rigidity, hyperreflexia, psychosis, and delirium. Severe withdrawal, particularly from intrathecal baclofen, may result in coma, seizures, rhabdomyolysis, hyperthermia, disseminated intravascular coagulation, circulatory failure, delirium, and coma [131–134]. Occasionally, patients may develop a reversible cardiomyopathy. In the most severe cases, multiorgan failure and death may occur [120,121]. The delirium observed with baclofen withdrawal may resemble the altered mental status caused by baclofen intoxication, and baclofen intoxication should always be considered along with withdrawal in the differential diagnosis of delirium in a patient on baclofen. The severe withdrawal syndrome may also mimic other conditions such as infection, serotonin syndrome, and neuroleptic malignant syndrome. In cases such as these, the diagnosis may be easy to miss, and evaluation for pump failure should always be considered. Pump integrity and function may be assessed by plain films, dye studies, nuclear medicine flow studies, port aspirations, or if necessary, operative exploration. Cautiously administering a bolus of baclofen by the pump, by way of lumbar puncture, or by a lumbar drain, and assessing for improvement in 30 to 60 minutes may help confirm the diagnosis. Oral baclofen may also be used, though large doses may be needed and clinical improvement may be delayed by several hours [134].

In addition to supportive care, the most important step in management of baclofen withdrawal is the replacement of the baclofen. Patients who were receiving oral therapy may have the drug administered by nasogastric tube if they are unable to take it by mouth secondary to their withdrawal symptoms. Patients withdrawing from intrathecal baclofen may require high doses of oral baclofen, or may not respond to oral replacement therapy [135]. Replacement oral baclofen doses for intrathecal baclofen withdrawal often range between 10 and 30 mg orally, every 4 to 8 hours [134]. In patients not responding to oral replacement, the reason for pump failure should be identified and remedied, with the previous intrathecal baclofen dose reinstituted [136]. Bolus dosing of baclofen by the pump, by way of lumbar puncture, or by a lumbar drain may be required to initially reverse severe manifestations. If there is any delay in administering baclofen intrathecally in these patients, other sedative medications such as benzodiazepines, barbiturates, or propofol should be provided intravenously. As with oral baclofen dosing and with benzodiazepine treatment of severe ethanol withdrawal, large doses of these agents may be necessary to control severe symptoms, with attention to airway support if the patient is not already intubated. Cyproheptadine (4 to 8 mg orally every 6 to 8 hours) has been suggested as a useful adjunctive therapy in patients with intrathecal baclofen withdrawal who are well enough to take oral medications. More study is needed before this can be definitively recommended. [137].

OPIOID WITHDRAWAL

Opioid withdrawal occurs when a tolerant individual experiences a decline in CNS levels of a chronically used opioid. Unlike withdrawal from sedative–hypnotic agents [138], the manifestations of opioid withdrawal are not usually life-threatening. Recognition of the problem facilitates optimum management of the critically ill patient.

Pathophysiology

Opioid receptors in the locus ceruleus bind exogenous opioids, such as heroin, methadone, or codeine, as well as endogenous opioid-like substances known as *endorphins* and *enkephalins*. Stimulation of opioid receptors reduces the firing rate of locus ceruleus noradrenergic neurons, resulting in the inhibition of catecholamine release [139,140]. The stimulation of inhibitory adrenergic receptors, also found in the locus ceruleus, causes a similar reduction in sympathetic outflow. Chronic opioid use may produce an increase or upregulation of these adrenergic receptors. Subsequent withdrawal of opioids results in increased sympathetic discharge and noradrenergic hyperactivity.

The time course of the withdrawal syndrome depends on pharmacokinetic parameters of the individual opioids [139]. Withdrawal symptoms usually appear about the time of the next expected dose [141]. Withdrawal from heroin, which has

a short half-life, begins 4 to 8 hours after the last dose, whereas withdrawal from methadone, with a long half-life, is delayed until 36 to 72 hours after the last dose. Withdrawal symptoms are more intense if the opioid has a shorter half-life, whereas symptoms are less dramatic but often more prolonged if the abused opioid has a long half-life. Typically, heroin withdrawal peaks at 36 to 72 hours, with symptoms subsiding by 7 to 10 days. Methadone withdrawal may not peak until the sixth day of abstinence and may persist for weeks.

Because prolonged opioid use may be required to facilitate ventilator management in intensive care patients, iatrogenic opioid withdrawal may complicate ventilator weaning [142,143]. Methadone administered by nasogastric tube or subcutaneously has been successfully used to treat these withdrawal symptoms. The use of methadone may shorten the phase of ventilator weaning in these patients.

Clinical Manifestations

Early signs of opioid withdrawal include mydriasis, lacrimation, rhinorrhea, diaphoresis, yawning, piloerection, anxiety, and restlessness [144]. With time, these symptoms may worsen and be accompanied by mild elevation in pulse, blood pressure, and respiratory rate. Myalgias, vomiting, diarrhea, anorexia, abdominal pain, and dehydration accompany more severe withdrawal. Although these patients may become extremely restless, fever and central agitation such as seizures (except in cases of neonatal withdrawal) and mental status alteration are not part of opioid withdrawal. An intense craving for the drug accompanies withdrawal. Recognition of these signs and symptoms in the ICU patient obviates the need for extensive evaluation of the gastrointestinal symptoms and puts clinically puzzling pain complaints in perspective. Appropriate therapy alleviates the patient's discomfort and facilitates management of more pressing ICU problems. After the resolution of most of the objective signs of withdrawal, subjective symptoms, especially dysphoria, may persist for weeks [140].

Opioid withdrawal may occur suddenly in the opioid-dependent patient given naloxone [145]. This iatrogenic withdrawal often occurs after naloxone is given to a patient who is lethargic or comatose and has unrecognized opioid dependency. Naloxone-induced withdrawal may also occur in dependent patients after use of naloxone to reverse the effects of an opioid used during procedural sedation. Vomiting and subsequent aspiration in the unconscious patient are the major complications arising from this problem. This abstinence syndrome is of brief duration due to the short half-life of naloxone, lasting 20 to 60 minutes, and treatment with opioids to reverse the unwarranted effects of naloxone is not indicated. Naloxone, if required, should not be withheld in the dependent patient. A starting dose of 0.04 to 0.10 mg should be used, titrated until the desired effect is achieved or mild signs of withdrawal occur. Coma or hypoventilation that persists after the onset of withdrawal signs is not reversed by administration of additional naloxone.

Naltrexone, an orally active opioid antagonist, induces withdrawal symptoms for up to 48 hours. Nalmefene, another opioid antagonist, may also cause prolonged withdrawal symptoms in the opioid-tolerant patient. A less commonly recognized cause of opioid withdrawal is the use of agonist-antagonist in the opioid-dependent person. Drugs with agonist-antagonist activity include pentazocine (Talwin), nalbuphine (Nubain), and butorphanol (Stadol).

Management

Treatment of opioid withdrawal is a two-tier approach, using cross-tolerant opioid replacement or sympatholytic therapy (e.g., clonidine), or both. The benzodiazepines are not cross-tolerant with opioids. Their role is limited to the management of significant anxiety associated with opioid withdrawal.

Substitution of long-acting methadone for heroin has played a prominent role in the management of opioid addiction [138]. First used in the 1960s for the treatment of heroin addiction [146], methadone was chosen for its chemical similarity to heroin, oral availability, and long half-life (24 to 36 hours). Although the use of methadone for the outpatient treatment of opioid dependence is tightly regulated, physicians do not need special licensing to prescribe methadone to hospitalized patients.

Methadone may be useful in treating the uncomfortable symptoms in patients who depend on any opioid. The dose should be judiciously titrated to relieve symptoms but avoid oversedation. A safe initial dose is 20 mg orally or 10 mg IM. The IM route guarantees absorption in the vomiting patient [144]. Relief of symptoms usually occurs within 30 to 60 minutes when the drug is given parenterally and longer when it is given orally. A second 10 mg IM dose can be given if significant relief is not achieved 1 hour after the first IM dose. Administering 10 to 20 mg by IM route blocks most manifestations of physiologic withdrawal, although some patients may require 20 to 40 mg daily or divided twice per day to avoid psychological withdrawal. In general, dosing to prevent withdrawal symptoms requires considerably less drug than dosing for methadone maintenance. Although withdrawal from opioids should not be attempted during an acute medical illness, once they are medically stabilized, heroin-dependent patients can be tapered with methadone over 1 week. Methadone-dependent patients require 4 weeks or more of gradually decreasing dosages. Notable drugs that interact with methadone, lowering its plasma concentration and potentially precipitating opioid withdrawal, include rifampin and phenytoin [147,148].

For those patients enrolled in methadone maintenance programs, considerably larger doses of methadone are often employed. Some of these patients, particularly early in treatment, may continue to abuse heroin. Higher methadone doses, as much as 150 mg a day or more, have been recommended as a means to reduce concurrent heroin use and retain patients in treatment programs [149,150]. Some community clinics use doses as high as 200 to over 300 mg per day in select patients.

The treatment of pain in patients receiving methadone may require the use of additional opioid analgesia, such as morphine, codeine, or oxycodone. In patients on methadone maintenance, the established maintenance dose may not provide adequate analgesia because of tolerance to the analgesic effects of methadone. Successful pain relief requires the continuation of the methadone maintenance dose supplemented by additional analgesics [151].

Every attempt should be made to minimize significant withdrawal manifestations in the opioid-dependent pregnant patient. Withdrawal in these patients may adversely affect the developing fetus, causing fetal distress and even intrauterine death [152]. Oral methadone maintenance is more compatible with maternal and fetal well-being than continued heroin abuse [153,154] and would likely also decrease the risk of intrauterine acquisition of acquired immunodeficiency syndrome. Cautious treatment of these patients with sufficient methadone to avoid withdrawal may avert these additional complications. After delivery, the neonate must be hospitalized and withdrawn from the drug. In selected pregnancies, lowering the maternal methadone dosage may lead to decreased incidence and severity of neonatal withdrawal [155].

While methadone has been extensively used for decades to help opiate addicted patients circumvent the health problems associated with illicit intravenous drug abuse, there are valid concerns about its safety as well. Methadone is known to cause dose-related respiratory depression and sleep apnea,

which varies greatly based on an individual patient's underlying tolerance. The risk of this increases when methadone is combined with other depressant drugs [156]. Other concerns have increasingly come to light in recent years. Disproportionate numbers of patients on methadone were found to have suffered sudden cardiac death, often without underlying structural heart disease [156]. Though the majority of methadone associated sudden deaths are likely due to respiratory depression, it was also discovered that methadone is a potent potassium channel blocker, especially at higher doses. This prolongs cardiac repolarization (lengthening the QTc interval and predisposing to Torsades de Pointe) [156]. While it is unknown how clinically significant this finding may be, some experts suggest that QTc intervals be checked prior to initiating methadone therapy and be followed during chronic therapy to watch for lengthening of the QTc [156–158].

In recent years, buprenorphine, a partial mu-opioid agonist and K-opioid antagonist, has been increasingly advocated as an alternative to methadone for both maintenance and short-term management of opioid withdrawal [159]. Buprenorphine can be given orally, sublingually, intramuscularly, or intravenously [160,161]. Because of its partial agonist activity, it causes less CNS and respiratory depression and has a ceiling effect, so is less likely to be dangerous in overdose than methadone (though respiratory depression may still occasionally be seen, especially at higher doses, and deaths have been reported). This characteristic also renders it able to block the euphoric effects of heroin and morphine. It produces only a mild withdrawal syndrome when treatment is ceased, but care should be taken when initiating therapy in opioid dependent patients as it may precipitate withdrawal [161]. Of interest, a recent case of deliberate buprenorphine overdose resulted not in respiratory depression but severe opioid withdrawal lasting 4 days [162]. Compared to methadone, opioid withdrawal symptoms may resolve more quickly with buprenorphine but the latter is no more effective when used in the maintenance treatment of heroin dependence [163,164]. Buprenorphine does not seem to have the same propensity to prolong the QT interval as methadone [158]. Buprenorphine has a long half-life (□40 hours), so an additional benefit is that it may be administered every other day or even three times a week as maintenance therapy for opioid addicted patients. Special training and licensing are required for physicians who wish to prescribe buprenorphine or methadone (when used as treatment for opioid dependence) on an outpatient basis.

Sublingual buprenorphine tablets and solution are available as monotherapies as well as in combination with naloxone in a 4:1 (buprenorphine: naloxone) ratio (Suboxone). The naloxone is poorly absorbed sublingually and therefore does not interfere with buprenorphine's effects when taken as directed. Naloxone is added to the buprenorphine to block buprenorphine's euphorigenic effects if an attempt is made to divert the drug for illicit intravenous use (crushing and dissolving tablets etc.).

Sublingual dosing of buprenorphine for opioid dependence maintenance therapy starts with an introductory dose of 2 to 8 mg, based on the patient's degree of neuroadaptation to opioids. Dosing may be to be advanced to 4 to 16 mg on the second day. Over time the dose may be individualized to a range of 4 to 24 mg daily, every other day, or three times a week (though currently this dosing regimen is not recommended) [165]. When initiating buprenorphine therapy, physicians must be alert to the possibility of precipitated withdrawal, and patients should always be prepared for this. Because buprenorphine binds more tightly to the mu-opioid receptor than does heroin or methadone, it knocks any residual drug off the receptor and blocks its agonist effects since buprenorphine itself is only a partial agonist). To minimize this risk, the first dose of buprenorphine should be given at least 6 hours after the last heroin use (ideally once if the patient is already experiencing mild withdrawal symptoms). If the patient is on methadone, the first dose of buprenorphine should be given as long as possible after the last methadone dose (at least 24 hours, longer if the baseline methadone dose is higher) [165]. Precipitated withdrawal symptoms usually start 1 to 4 hours after the buprenorphine dose and last about 12 hours. These symptoms are worst during the first day, but patients transitioning to buprenorphine from methadone may experience mild discomfort and dysphoria for up to 1 to 2 weeks, depending on how much methadone they were using previously. Symptomatic treatment with medication such as clonidine may be employed during this period as needed.

When transitioning from methadone maintenance to buprenorphine, it is recommended that the patient be stabilized on as small a methadone dose as possible (preferably < 30 mg daily) prior to initiating transfer. This minimizes risk of withdrawal and improves success. It is not recommended that patients on 60 mg or more of methadone daily be transitioned. While starting on too low a buprenorphine dose may be insufficient to manage withdrawal, too high a dose increases the risk of precipitated withdrawal. An average starting dose for patients on 20 to 40 mg methadone daily is 4 mg of buprenorphine, with reassessments later in the day or the next day to titrate dose [165]. In addition to maintenance therapy, various tapering opioid detoxification regimens using buprenorphine exist, with starting doses ranging from 1 to 8 mg daily. Therapy may be tapered over 5 to 14 days [161].

Clonidine, a central α_2-adrenergic agonist that binds to the α_2-receptors in the locus ceruleus, is also used to treat opioid withdrawal [166,167]. Stimulation of central α_2-receptors results in feedback inhibition of the norepinephrine activity, decreasing the firing rate of the noradrenergic neurons. These noradrenergic neurons also possess opioid receptors whose stimulation produces a similar reduction in sympathetic activity through the same intracellular messenger system [141]. Clonidine used without the addition of a replacement opioid has been found to be as effective as methadone in treating medically ill hospitalized patients in opioid withdrawal [168]. Clonidine may be administered in doses of 0.1 to 0.2 mg every 4 to 6 hours. Treatment is often continued for 5 to 10 days and then slowly tapered by 0.2 mg per day. Clonidine transdermal patches provide steady-state clonidine levels and may also be useful [151]. Tachyphylaxis to the effects of clonidine may develop by 10 to 14 days [139]. The most concerning side effect of clonidine is hypotension, especially with the first dose. This requires close monitoring. In one study, patients administered buprenorphine–naloxone were more likely to complete a short-term detoxification program and report fewer withdrawal and craving symptoms than those treated with clonidine [169]. The long-term success of this approach is unclear.

Combination therapy with clonidine and naltrexone has also been used for rapid opioid detoxification. Proponents of this approach emphasize the shortened period of withdrawal associated with the addition of naltrexone [170]. Continuing naltrexone as deterrent therapy after opioid withdrawal (akin to the use of disulfiram with alcoholics) has also been advocated, but this approach has a high attrition rate [171]. Delirium has been reported during rapid opioid detoxification of methadone maintenance patients [172].

Administering high doses of opioid antagonists to addicted individuals while under anesthesia has been suggested as a method of achieving detoxification from opiates within 24 to 48 hours. This method, known as ultrarapid detoxification, has been associated with pulmonary and renal failure as well as other complications, including death [173]. Additionally, long-term follow-up has demonstrated relapse of drug abuse in many of these patients [174]. This approach is not recommended.

CHAPTER 146 ■ EPISTAXIS

AVINASH V. MANTRAVADI, CHAD A. ZENDER AND LOUIS G. PORTUGAL

Epistaxis is a common occurrence in the general population and most frequently is minor and self-limiting. In the intensive care setting, however, epistaxis may further destabilize an already unstable patient and may be life-threatening. Appropriate management of epistaxis requires careful evaluation and management of the patient's hemodynamic status and prompt control of the source of bleeding.

BLOOD SUPPLY OF THE NOSE

The internal and external carotid arteries, with frequent free anastomoses within the nasal mucosa, provide a rich blood supply to the nose, and venous drainage parallels the arterial supply.

The internal carotid artery (ICA) supplies the nasal mucosa through the ethmoid branches of the ophthalmic artery. The ophthalmic artery, the first branch off of the ICA, enters the orbit through the optic canal and divides into anterior and posterior ethmoidal branches. Both anterior and posterior ethmoidal arteries exit the orbit through the medial orbital wall at the level of the frontoethmoid suture line, an important landmark in the operative management of epistaxis originating from these vessels. These arteries then pass medially through the roof of the ethmoid sinuses and enter the anterior cranial fossa, from which they descend through the cribriform plate to enter the nose. The anterior ethmoidal artery, the larger of the two, supplies the anterior nasal septum and lateral nasal wall. The posterior ethmoidal artery supplies the region of the superior turbinate and corresponding portion of the septum.

The external carotid artery (ECA) supplies the nose through two of its terminal branches, the facial artery and the internal maxillary artery. The facial artery, a major branch of the external carotid system, providing blood supply to most of the lower face and lips, supplies the superior labial artery, which enters the nose lateral to the anterior nasal spine and supplies the anterior nasal septum (Figs. 146.1 and 146.2).

The maxillary segment of the internal maxillary artery (IMA) is the primary contributor to the nasal blood supply, crossing the infratemporal fossa to the pterygopalatine fossa. At this point, it divides into multiple terminal branches that supply the nasal cavity primarily by the sphenopalatine artery (SPA). The SPA enters the nasal cavity through the sphenopalatine foramen at the lateral nasal wall posterior to the horizontal portion of the middle turbinate, and divides into multiples branches that supply the posterior septum, lateral nasal wall, and sinuses (Fig. 146.3).

On the anterior nasal septum lies *Kiesselbach's plexus* or *Little's area*, an abundant plexus of vessels consisting of the most prominent anastomoses between the external and internal carotid artery systems. It is at this region that anterior epistaxis most frequently originates, reported in up to 90% of cases [1,2]. Posterior epistaxis, on the other hand, most frequently occurs near the sphenopalatine foramen from branches of the SPA, frequently a result of prior surgery or trauma.

CAUSES OF EPISTAXIS

Risk factors and causes of epistaxis may be divided into local and systemic etiologies (Table 146.1).In the intensive care unit (ICU) setting, epistaxis usually results from a combination of these etiologies; however, direct nasal trauma still plays a central role in its development. Trauma may result from digital manipulation by the patient or nasal fractures with subsequent mucosal disruption; however, in the ICU, nasal trauma is often iatrogenic from nasal oxygen, continuous positive airway pressure (CPAP), or particularly from nasal tube placement (nasogastric feeding tubes, nasal endotracheal tubes, etc.). Nasal cannulas in particular cause bleeding as a result of mucosal abrasions or mucosal drying from non-humidified high flow oxygen. A humidified face mask or face tent is preferred in particularly high-risk patients (history of epistaxis, long-term anticoagulation). Simply moving a nasal tube to the contralateral side may minimize or prevent progression of traumatic epistaxis resulting from tube placement.

Other causes of mucosal dryness include overuse of nasal decongestants or cocaine. Alterations in nasal airflow with subsequent drying may result from congenital or acquired anatomic abnormalities such as septal spurs and deviations, as well as septal perforations (which can themselves be caused by the potent vasoconstrictive effects of drugs such as cocaine). Epistaxis occurs more frequently during the winter months, presumably because of the lower humidity in ambient air. Because factors such as mucosal dryness and trauma most frequently affect the anterior nose, most epistaxis is anterior in nature.

Systemic factors and preexisting conditions place ICU patients at particularly high risk for epistaxis. Studies show that up to 45% of patients admitted for epistaxis have a comorbid condition that could cause or exacerbate bleeding [3]. Literature has identified patients older than 50 years as being particularly predisposed to severe epistaxis refractory to local measures of control, likely due to the effects of endothelial degeneration, atherosclerotic changes, and other systemic conditions. These include hypertension, atherosclerotic vascular disease, coagulopathies, and conditions requiring antiplatelet or anticoagulative medications (aspirin, clopidogrel, heparin, warfarin) such as deep vein thrombosis (DVT), pulmonary embolus (PE), cardiac arrhythmias, coronary artery disease (CAD), and vascular stent placement. Medications such as these all affect coagulation and may subsequently result in recurrent or refractory episodes of nasal bleeding. However, the conditions for which these agents are used present a particular challenge, as stoppage of these medications can be life-threatening.

Coagulopathies such as von Willebrand disease and hemophilia must be considered in patients with recurrent or refractory disease. Failure to identify these conditions may result in a delay in administration of medical therapies such as factor VIII or desmopressin acetate that can aid in reversing the underlying disease process.

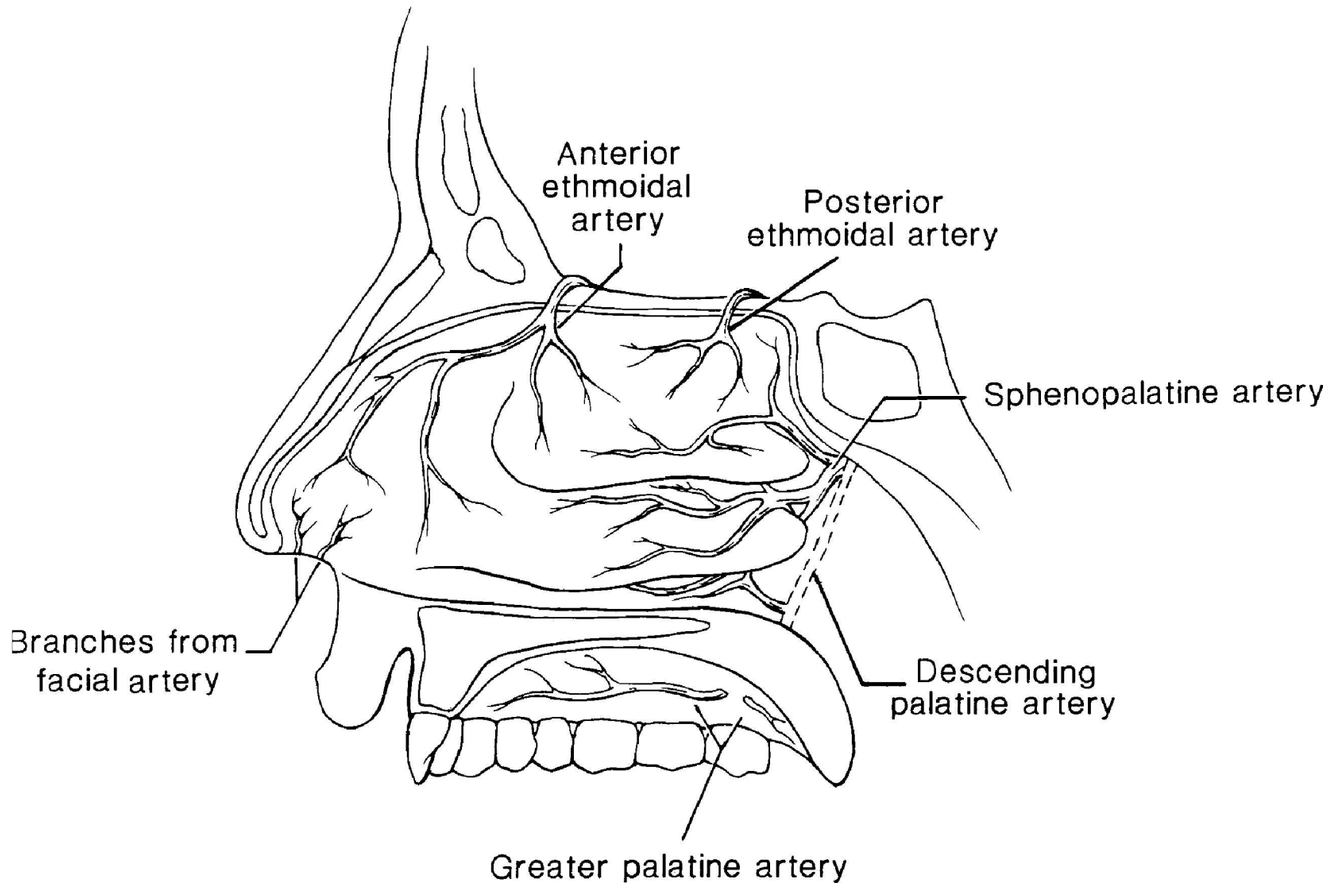

FIGURE 146.1. Blood supply of the lateral nasal wall.

In the ICU setting, it is most often a combination of a number of the above factors that results in epistaxis. Identifying and addressing the various contributing factors is of central importance when managing epistaxis in the ICU.

MANAGEMENT

Initial evaluation of the ICU patient with epistaxis should first and always be guided by the rules of *A*irway, *B*reathing, and *C*irculation, with a quick determination of the severity of the bleed. In case of a severe bleed in an unstable patient, the airway should be secured (by intubation) and two large bore intravenous (IV) lines should be placed if not already established. If the patient already has a tracheostomy tube in place, the cuff should be inflated to prevent passage of blood products and protect the airway. Frequent suctioning of the pharynx can assist in reducing aspiration. Once the airway is secured and hemodynamic status addressed, efforts can be focused on the control of bleeding. Typically, most patients are hemodynamically stable and are able to protect their airway, allowing for a more thorough examination.

In patients who are hemodynamically stable, a short and focused history, including information regarding nasal trauma, duration, and amount of blood loss is invaluable. After the severity has been assessed, one can discern laterality, history of coagulation and hemodynamic disorders, and iatrogenic factors that may be contributing. In the ICU setting, patients are frequently unable to provide a history such that nursing, family members, and other ancillary staff are needed to provide crucial information. It is also necessary to determine if a bleed is originating anteriorly in the nasal vault or more posteriorly (e.g., copious amounts of expectorated blood, hematemesis), which is typically more severe and is not easily stopped with local pressure or topical cauterization. One must exercise caution when suctioning the nasopharynx to avoid dislodgment of clot into the hypopharynx and larynx, which may result in airway compromise.

Vital signs should be assessed and hypertension controlled to reduce the bleeding. The nasal examination may then be undertaken, best accomplished with good lighting, a nasal speculum, and suction. If a discrete source of bleeding is easily visualized, then local coagulation with silver nitrate applicators may suffice. However, diffuse bleeding is often noted, and a vasoconstrictive agent such as oxymetazoline or phenylephrine may be sprayed to decrease bleeding and improve visualization.

The first step in attempted control of epistaxis should consist of a topical vasoconstrictive agent (oxymetazoline or phenylephrine) sprayed liberally on the side of bleeding (if localized) or bilaterally, followed by uninterrupted external digital pressure for 15 to 20 minutes. Pressure should be applied with a tight pinch, compressing the nasal alae against the nasal septum in such a manner as to prevent passage of nasal airflow. During this time, the oropharynx should be examined to evaluate for

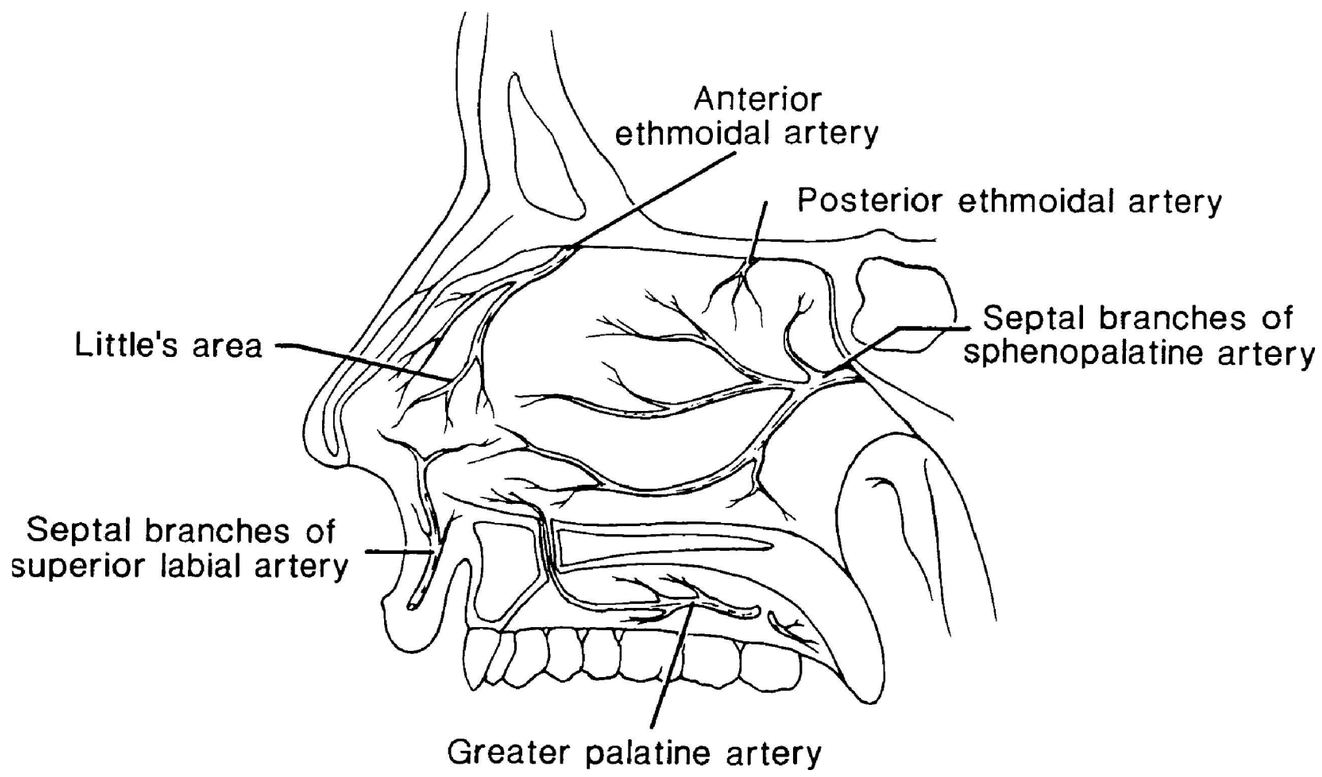

FIGURE 146.2. Blood supply of the nasal septum.

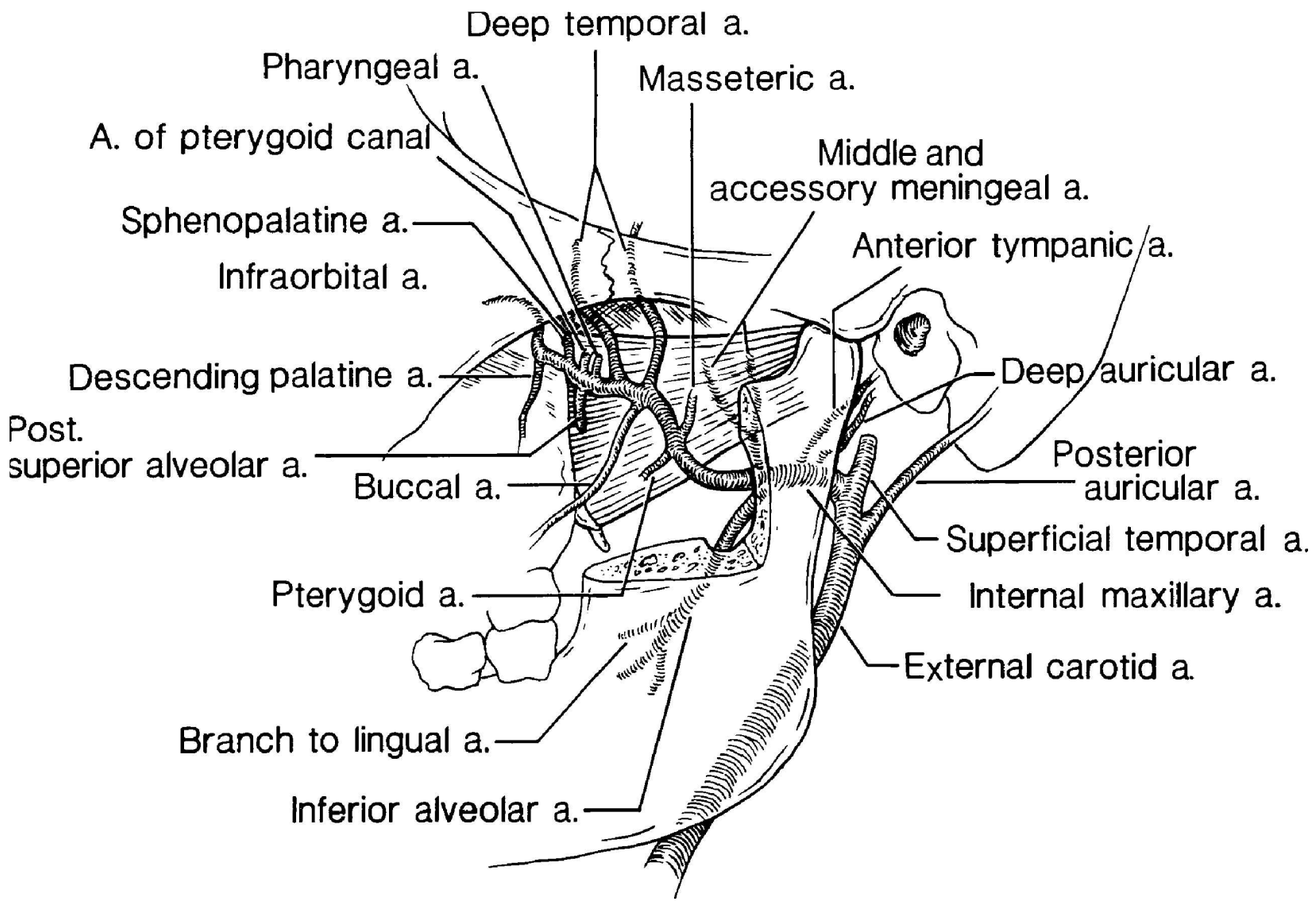

FIGURE 146.3. Course and branches of the internal maxillary artery.

continued bleeding, which may raise suspicion for a posterior source. One should be aware that only minimal anterior bleeding may occur with significant posterior epistaxis.

Because the majority of bleeding is anterior on the septum, a topical vasoconstrictive agent and external pressure will frequently achieve hemostasis and is sometimes all that is necessary. Krempl et al. found that up to 65% of cases of epistaxis were controlled with a topical vasoconstrictor and pressure alone [4]. If these measures are successful, measures should be taken to decrease mucosal drying and subsequent recurrence, including placement of a humidified face tent, topical vasoconstrictive agent twice daily for a maximum of 5 days (to prevent complications such as rebound nasal congestion and septal perforation), frequent topical saline sprays, application of lubricating ointment (e.g., neomycin/polymyxin) to the nasal septum twice daily, and control of hypertension.

Laboratory tests should be considered in patients with significant or recurrent epistaxis. A complete blood cell count, coagulation studies, and a bleeding time should be performed. In patients with severe bleeding or those who are severely anemic, one should consider a crossmatch with the initial blood draw due to the time necessary to prepare blood products. Liver function tests may help elucidate the cause and identify patients with coagulopathies as a result of impaired hepatic function.

TABLE 146.1

ETIOLOGIES OF EPISTAXIS

Local factors	Systemic factors
Anatomic Septal deviation, Septal spur Septal perforation	Hypertension[a]
Trauma[a] Digital/nose-picking Nasal/facial fractures Nasal tube placement (nasogastric, nasotracheal, etc.)	Coagulopathy[a] Hepatic dysfunction Disorders of platelet function/aggregation (e.g., von Willebrand disease) Hematologic malignancy Hemophilia
Mucosal dryness[a] Cold weather Nasal cannula use CPAP Chronic intranasal corticosteroid use Nasal decongestant overuse Cocaine abuse	Medication effect[a] ASA Clopidogrel Warfarin Heparin
Sinonasal infection/ inflammation	Vascular disorders Wegener's granulomatosis Churg-Strauss syndrome Hereditary hemorrhagic telangiectasia
Nasal polyposis	Drug abuse (e.g., cocaine)
Intranasal mass Arteriovenous malformation Malignancy	Alcohol abuse
Foreign body	Renal failure
Recent nasal/facial surgery	Malnutrition

[a]In ICU patients, epistaxis most commonly results from a combination of these factors.

Cautery

The majority of nosebleeds arise from Kiesselbach's plexus on the anterior nasal septum, and cauterization may be performed either with silver nitrate applicators or electrocautery to the bleeding site if unresponsive to topical vasoconstrictors and pressure. In stable patients with mild to moderate bleeding, a nasal endoscope (0-degree telescope with light source) can aid in visualizing bleeding sites and focus cauterization more precisely on the source, but a nasal speculum remains a viable alternative. In the awake patient, topical anesthesia should be used (such as 4% lidocaine or tetracaine) that may be mixed with the topical vasoconstrictor being applied, to decrease pain and improve examination conditions. Silver nitrate, when in contact with water in blood, precipitates and is reduced to neutral silver metal, which releases reactive oxygen species to coagulate tissue. Silver nitrate use is useful for minor bleeds, but may be inadequate with more severe bleeds as heavy blood flow washes away the silver nitrate before it can act.

Overly aggressive cauterization or bilateral cautery should be avoided to prevent ulceration, which may subsequently cause re-bleeding or result in a septal perforation in the long term. Injudicious cautery may also lead to synechia (scar) formation between the septum and the turbinate/lateral nasal wall,

which can later impair the patient's breathing and result in abnormal airflow.

An additional tool in initial control in patients with evidence of significant posterior bleeding includes transpalatal vasoconstriction of the sphenopalatine artery, utilizing a 25-gauge needle bent at 2.5 cm and injecting 1 to 2 mL of 1% lidocaine with epinephrine (1:100,000) in the descending palatine foramen, located just medial to the upper second molar. This procedure may slow bleeding enough to allow for improved examination [5].

Nasal Packing

Nasal packing, which is typically described as anterior or posterior, should be considered as the next step in management after failure of local and medical measures such as external pressure and cautery. Packing can also be used in cases where the source of bleeding is not evident on physical examination, or when the bleeding is severe and must be temporized until further definitive management can be performed.

Anterior Nasal Packing

Anterior nasal packing is generally performed for epistaxis originating from the anterior nasal cavity to tamponade the vessel at the source, as well as to provide coverage of the bleeding site, allowing the primary stages of healing to occur in the absence of further local trauma and desiccation that can result in re-bleeding. As most epistaxis occurs anteriorly, this form of packing is usually sufficient. Many different types of packs are now available, utilizing a variety of both absorbable and nonabsorbable materials. The choice of anterior packing material is based on clinician preference and comfort level, as well as product availability in the hospital.

Common absorbable materials used for anterior packing include gelatin foam (e.g., GelFoam®-Pfizer, Inc, New York, NY) and oxidized cellulose (e.g., Surgicel®-Ethicon, Inc, Somerville, NJ), which encourage platelet aggregation and protect bleeding sites from further trauma and desiccation. Other materials include microfibrillar collagen (e.g., Avitene©-Davol Inc, Cranston, RI) and thrombin-gelatin combinations (Floseal®-Baxter International, Deerfield, IL) that can be instilled in the nasal cavity as a slurry. The advantages of these products include their ease of use, decreased patient pain, elimination of the need for pack removal, and improved conformity to the irregular contours of the nasal cavity. However, these products may not be effective in control of brisk arterial bleeding as they apply only low pressure to the nasal mucosa, and they are significantly more expensive than traditional packs.

Traditional nasal packing has involved the use of 0.5-in by 72.0 petroleum jelly strip gauze, layered with a bayonet forceps from inferior to superior along the length of the nasal cavity (Fig. 146.4). Over the years, the use of nonabsorbable sponges composed of hydroxylated polyvinyl acetate that expands when wet (e.g., Merocel® Medtronic Inc, Mystic, CT) has gained popularity due to their ease of use and applicability by hand without the need for additional instruments. The sponge is coated in antibiotic ointment prior to placement primarily for lubrication to ease application and decrease further septal trauma, but there is no published evidence to support a decrease in infectious complications [5,6]. Using a bayonet forceps or by hand, the sponge is then placed in the nasal cavity on the side of bleeding, sliding along the nasal septum to avoid the turbinates and ensure tamponade of the septal bleeding source. The packing should slide easily and should not require a high degree of force to decrease further mucosal trauma. Once in place, the sponge is copiously impregnated with a vasoconstrictive agent or sterile saline. Subsequent swelling of the sponge provides high pressure against the site of bleeding resulting in hemostasis. At this point, the oropharynx should be inspected to evaluate for continued bleeding posteriorly. Persistent anterior bleeding around the pack may necessitate repositioning or augmenting the pack. Anterior nasal packing has been shown in randomized, controlled trials to successfully control bleeding in up to 80% of cases [7,8]. The use of the Merocel® has published success rates up to 92% [9].

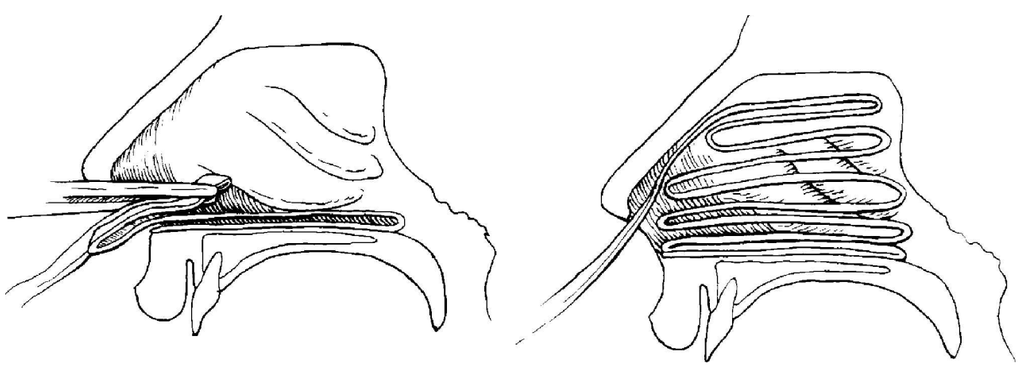

FIGURE 146.4. Correct placement of an anterior nasal pack.

Posterior Packing

After anterior packing is applied, continued postnasal bleeding should necessitate placement of a posterior pack. Posterior epistaxis is seen more frequently in elderly patients and patients with a history of prior sinus surgery or craniofacial trauma, systemic disorders, and prior nosebleeds [10]. The incidence of posterior epistaxis is, therefore, greater in ICU patients. Because of the often severe nature of the bleeding and relative inaccessibility of the source, conservative measures with pressure and cauterization as well as anterior packing have a limited role in the control of posterior epistaxis. The sphenopalatine artery is a large-caliber vessel, and the blood loss from an episode of posterior epistaxis is often significant, such that consideration should be given to blood transfusion as indicated. Posterior packing is also used as a temporizing measure to slow bleeding in anticipation of surgical management.

The classic posterior nasal packing consists of rolled gauze or tonsil packs secured in the posterior choanae by inserting the pack through the oral cavity and then into the nasopharynx by sutures through the nose (Fig. 146.5). Although very effective, this is difficult to perform, time consuming, and painful for the patient, and it is rarely performed today.

A more commonly used method of posterior nasal packing utilizes a Foley catheter (12 or 14 French) with a 30-mL balloon, readily available in the ICU setting. The nose is first cleared of any previously placed packs, debris, or clots, and topical anesthesia with a vasoconstrictor is applied. With the balloon deflated, the Foley catheter is inserted through the involved nares into the nasopharynx. One may examine the posterior oropharynx to confirm that the tip of the catheter has been placed entirely through the nasal cavity. The catheter is inflated with 10 to 20 mL saline and then pulled anteriorly to wedge the balloon snugly into the posterior nasal cavity and choanae (Fig. 146.6). The oropharynx is again examined to ensure that the soft palate is not displaced or engaged by the balloon, as this may lead to palatal necrosis. While the catheter is held under tension, anterior nasal packing is placed as above. The Foley catheter is then secured against the anterior nasal packing (extending out of the involved nares) using an umbilical cord clamp to maintain pressure and prevent posterior migration of the balloon into the pharynx. The clamp should be rotated periodically to reduce the occurrence of alar and columellar necrosis (additional padding may be placed), and the area must be checked frequently for this complication.

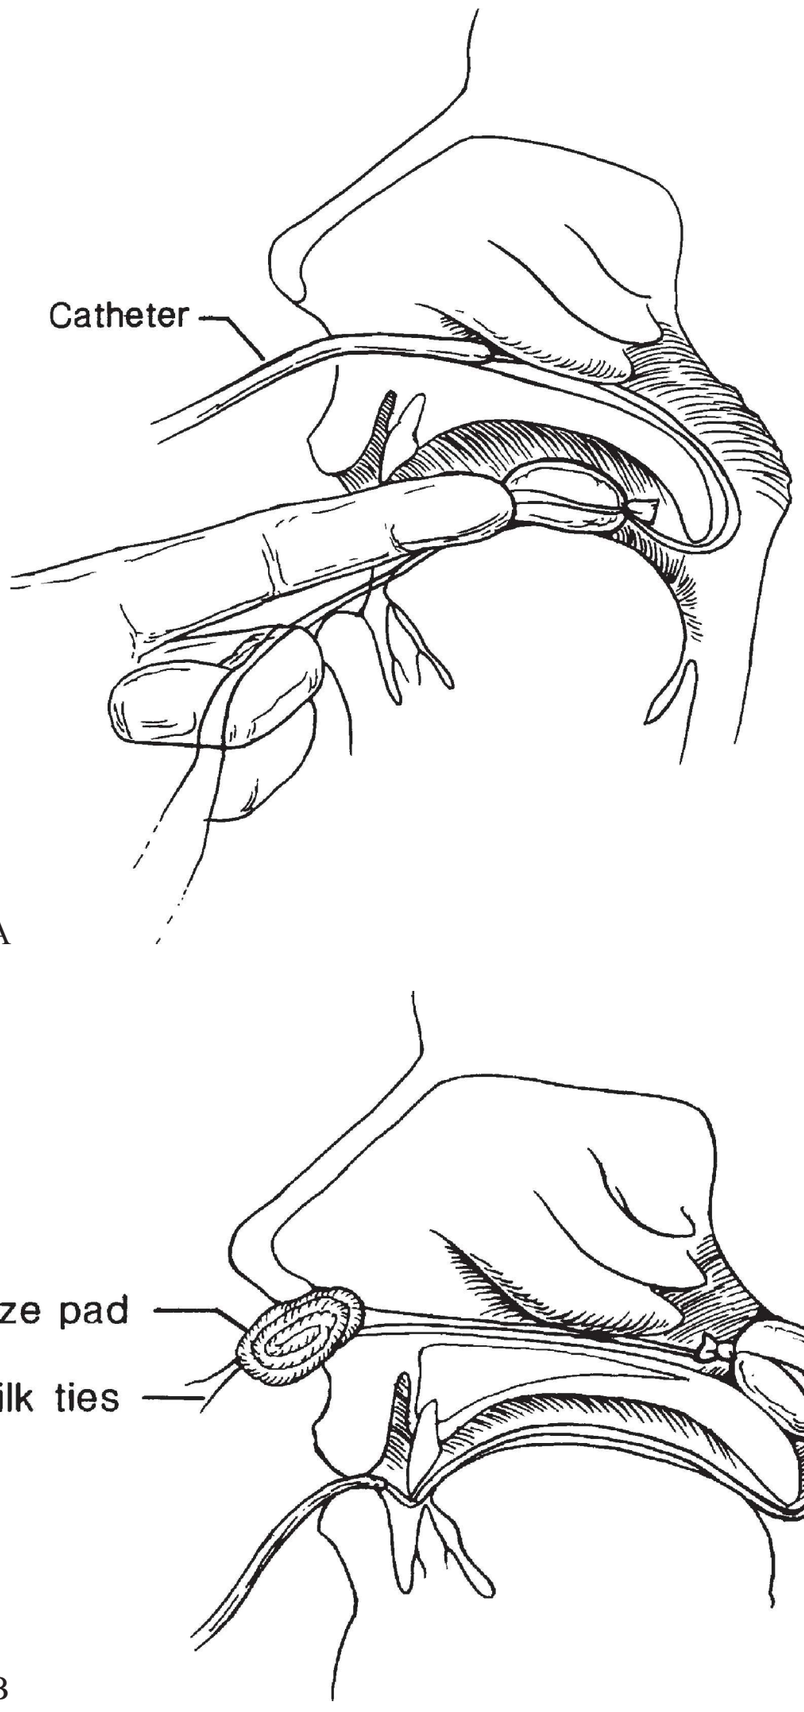

FIGURE 146.5. A,B: Insertion of a nasopharyngeal (posterior) pack (traditional method).

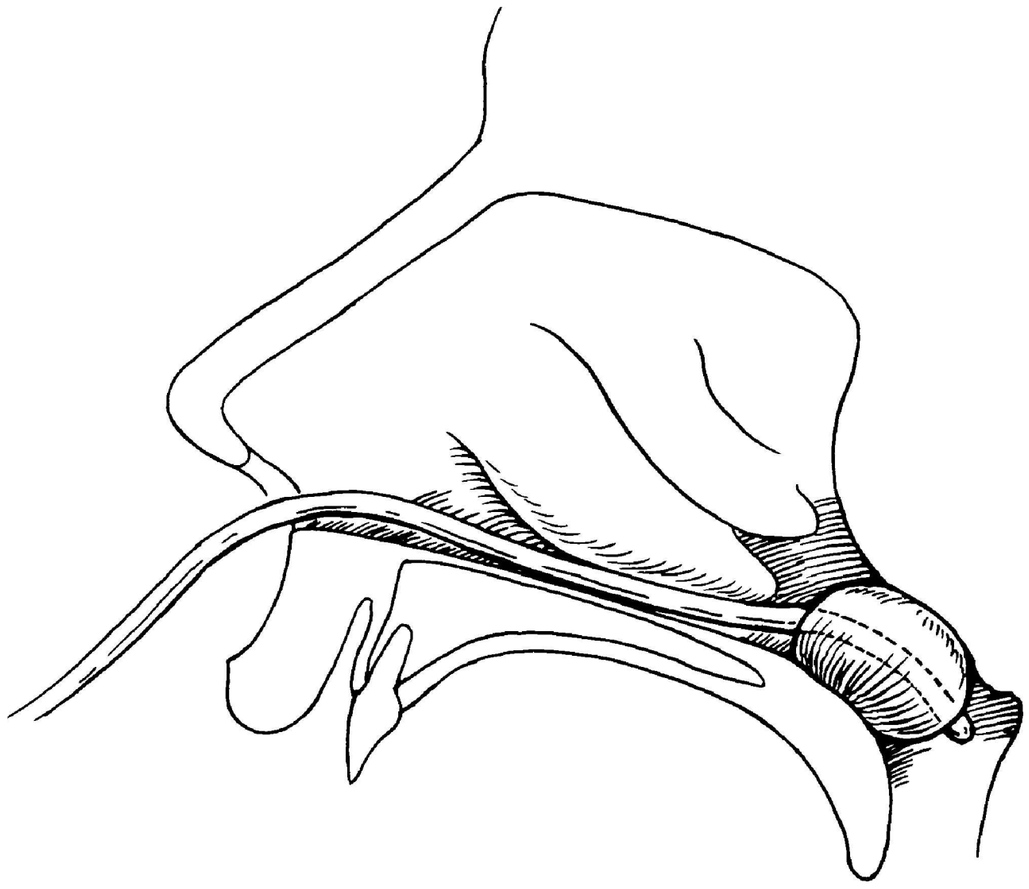

FIGURE 146.6. Foley catheter with balloon inflated.

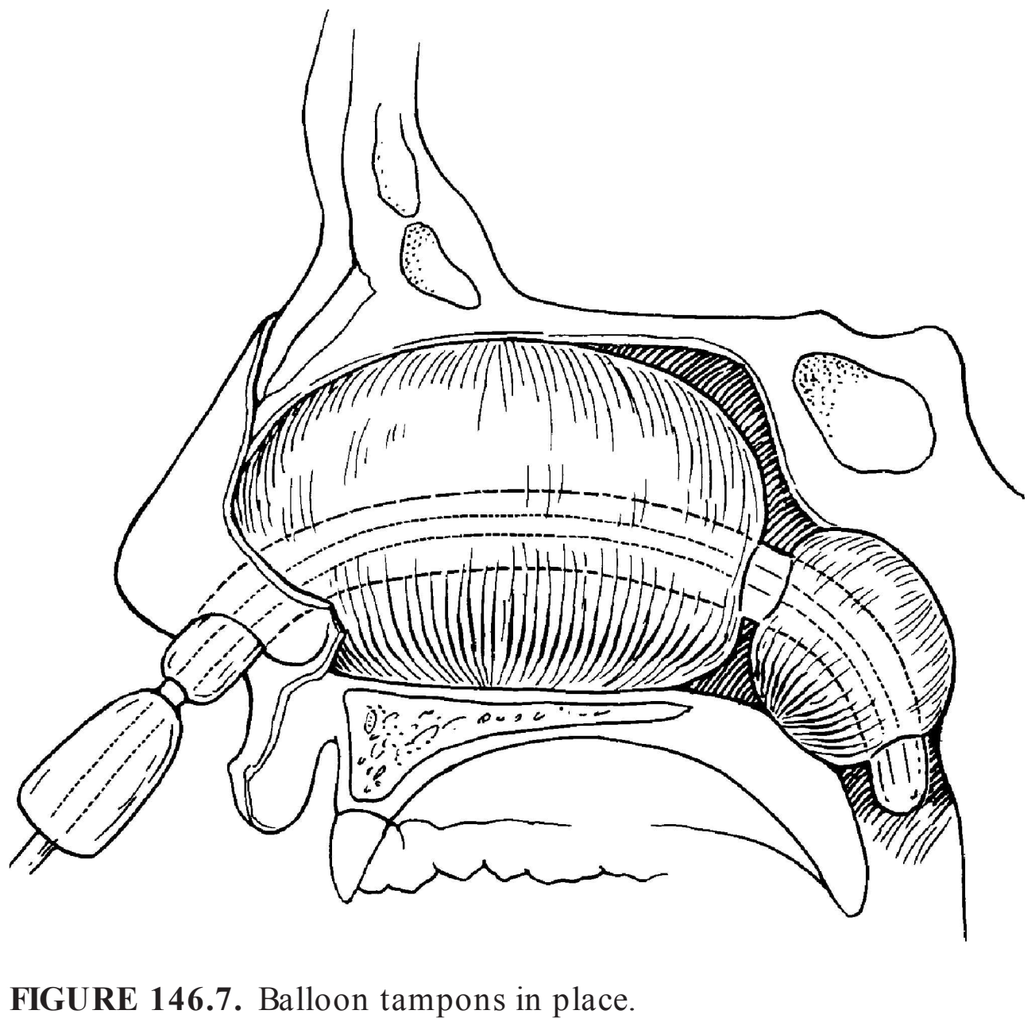

FIGURE 146.7. Balloon tampons in place.

Additional options for posterior nasal packing include balloon tampons designed for this purpose (Fig. 146.7). These devices consist of a catheter with two balloons: one that inflates in the choanae and a second that inflates in the nasal cavity. Although easy to insert, the balloons do not conform to the contour of the nasal cavity and consequently may fail. If bleeding persists, a classic posterior pack should be placed.

Complications associated with the posterior nasal pack may be serious, and all of these patients should remain hospitalized and monitored. Pulmonary compliance may be impaired through a postulated "nasopulmonary reflex" ("diving reflex"), of questionable clinical significance, which may result in apnea, hypoxia, and dysrhythmias [11,12]. All patients with posterior packs are hospitalized and monitored, and unstable or unhealthy patients should be admitted to the ICU. Eating is impaired by a posterior pack, and strong consideration should be given to keeping the patient NPO. The airway may become compromised, and intubation or rarely tracheostomy may be necessary. In addition, the procedure is often painful due to pressure on the posterior septum and choanae, and alar necrosis may result from pressure anteriorly. Posterior nasal packing alone has been shown to have a success rate of up to 70% for control of bleeding, a modest figure considering the aforementioned risks and potential complications [13,14]. As a result, additional measures have gained support in the treatment of posterior epistaxis, as later described.

MANAGEMENT AFTER PACKING

Once the patient's condition has been stabilized and bleeding controlled, attention should be redirected to the patient's general state. If the bleeding was significant, the blood cell count should be checked and the patient transfused as needed with ample additional units available. Coagulopathies and hypertension should be addressed and reversed, and other factors that may aggravate bleeding should be corrected. Adequate pain control should be provided.

In general, packing is left in place for 3 to 5 days to permit the patient's condition to stabilize and adequate primary healing of the source of bleeding. The decision of when to remove packing in an ICU patient is also influenced by the patient's comorbidities, which should be aggressively

controlled/minimized. Antibiotics with adequate *S. Aureus* coverage (e.g., cephalexin, clindamycin if penicillin allergy) should be used while nasal packing is in place to decrease the bacterial load that accumulates on the packing and prevent a life-threatening toxic shock syndrome. If antibiotic-impregnated gauze packing is used, the incidence of clinically significant secondary infections is quite low, and antibiotics may not be needed in immunocompetent, stable patients [12]. It is also important to minimize the amount of time that packing is used in immunocompromised individuals because of their increased susceptibility for infections.

If a posterior nasal pack is used, utilizing a balloon in the choanae, it should be slowly deflated prior to removal. If bleeding recurs, the balloon can be reinflated and left in place longer. If repeated attempts at removing nasal packing are unsuccessful, arterial ligation or embolization must be considered. Endoscopic-guided cauterization may be effective in controlling persistent localized bleeding [15].

ARTERIAL LIGATION

If nasal packing fails to achieve control of bleeding, or if the patient has had multiple episodes of epistaxis, arterial ligation may be warranted. In an extreme situation in which a patient is having life-threatening epistaxis, ligation of the external carotid artery decreases the nasal blood flow and can be life saving but does not result in long-term control of bleeding [16]. If the bleeding is localized to the anterior/superior nasal cavity, consideration should be given to ligation of the ethmoidal arteries. Most often, the bleeding is diffuse, and the ethmoidal arteries are ligated together with the sphenopalatine artery.

Angiographic arterial embolization of the ethmoidal arteries is not advised due to the risk of blindness and stroke, and they must therefore be ligated surgically, which drastically reduces these risks [17]. The ethmoidal arteries are approached through the external ethmoidectomy ("Lynch") incision made halfway between the medial canthus and the nasal dorsum. The vessels are identified along the frontoethmoid suture line as they leave the orbit and enter the ethmoid sinus. Once identified, the arteries are ligated with clips or suture [18]. The relationship of these vessels to the lacrimal crest and optic nerve is critical because the posterior ethmoidal artery lies just a few millimeters from the optic nerve, and severe iatrogenic complications can result if the anatomy is not respected.

Ligation of the sphenopalatine artery in the treatment of posterior epistaxis may be performed using an open or endoscopic approach. However, endoscopic techniques are being performed with greater frequency due to its equal efficacy and decreased morbidity when compared to the open Caldwell-Luc procedure. It has even been shown to have a role in treating patients with severe epistaxis and coagulopathies [19]. Transnasal endoscopic sphenopalatine artery ligation (TESPAL) is performed under general or local anesthesia using a nasal endoscope to identify the sphenopalatine artery and its branches at the sphenopalatine foramen. Endonasally, an incision is made with a sickle knife just anterior to the crista ethmoidalis under the middle turbinate, and a mucoperiosteal flap is raised. As the crista ethmoidalis is encountered, the vessels are identified leaving the sphenopalatine foramen posteriorly, and vascular clips and/or cautery are applied under direct vision. Complications include palatal numbness, sinusitis, decreased lacrimation, and septal perforation; however, control rates are reported up to 87% to 100% [20,21].

The traditional open approach involves clipping the internal maxillary artery (prior to the SPA) in the pterygopalatine foramen through the maxillary antrum. A Caldwell-Luc approach is undertaken (intraoral sublabial incision for access to the anterior face of the maxillary sinus), and the anterior wall of the maxillary sinus is partially removed. The posterior wall of the sinus is then breached and the pterygopalatine fossa entered. The internal maxillary artery and its branches are identified and locking clips placed. The vessels themselves are not transected. Complications of this procedure include facial and buccal numbness and discomfort (from potential infraorbital nerve transection), sinusitis, oroantral fistula, and chronic pain. Failures can occur in up to 40% of cases due to difficulty in identifying the internal maxillary artery, incomplete vessel ligation, formation of anastomoses distal to the ligation (e.g., in the descending palatine artery), and persistent hypertension [14].

After the arteries are ligated, any nasal packing is removed and the nasal cavity is examined for persistent bleeding. If bleeding is present, endoscopic cauterization should be attempted, as well as further medical evaluation for an uncorrected coagulopathy.

ARTERIAL EMBOLIZATION

Selective angiography with embolization of source vessels has compared well in the literature with other invasive techniques for management of refractory epistaxis, with success rates reported from 80% to 90% [20,22]. It may be performed prior to or after surgical management in the event of failure, and presents a treatment option for patients who are very poor operative candidates. However, the procedure is dependent on the availability of an experienced interventional neuroradiologist. As noted earlier, embolization cannot be performed for epistaxis in the superior nasal cavity in the region supplied by the ethmoidal arteries, as these vessels arise from the ICA and ligation could have devastating consequences including blindness or stroke. The internal maxillary artery, however, arises from the ECA, and embolization is a viable option. The procedure is performed using a single femoral puncture, usually under local anesthesia. After diagnostic carotid angiography is performed, the catheter is advanced into the IMA, and embolization is performed with Gelfoam®, coils, or polyvinyl alcohol particles. Often the vessels are embolized bilaterally to decrease the likelihood of development of collateral circulation and re-bleeding, reported in 10% to 20% of cases. Complications are similar to those for any cerebral angiography and include stroke (reported in up to 4% of cases), blindness, temporofacial pain, and renal abnormalities due to contrast loads.

SURGERY, EMBOLIZATION, OR PACKING?

Data remains controversial regarding which is the superior treatment modality for epistaxis: arterial ligation or embolization, both of which are employed when local cautery or nasal packing has failed. Patients with bleeding from the ethmoidal artery region (anterior epistaxis) are better served by surgery due to the risks associated with embolization of the internal carotid artery system. However, bleeding from the SPA/IMA region (posterior epistaxis) may be treated by either or both modalities.

Although both approaches have been shown to control bleeding in up to 85% of patients [23–25], multiple case series reports have found surgical arterial ligation to be equal to or better than embolization in terms of success rate [20,22]. Patients not stable enough to tolerate general anesthesia may benefit from embolization, which does not require general anesthetic but does expose the patient to the risks of angiography. Skilled personnel are required for either technique. Goddard and Reiter showed that there were no differences in length of

TABLE 146.2

SUMMARY OF EVIDENCE-BASED TREATMENT RECOMMENDATIONS IN THE MANAGEMENT OF EPISTAXIS

Intervention	Year	Study	No. of patients	Findings	Reference
A. Medical/nonsurgical management					
Hold warfarin (if applicable)	1997	Prospective	20	No decrease in bleeding or effect on hospital stay	Srinivasan, et al. [41]
Oral ice pack placement	1991	Prospective	16	Decreased nasal mucosal blood flow	Porter, et al. [42]
Intranasal topical antiseptic	1999	RCT	22	Topical is equal to silver nitrate cautery in control	Murthy, et al. [43]
Intranasal topical lubricant + steroid	1999	Prospective	100	Resolution of symptoms in 89% of chronic bleeds	London, et al. [44]
Oxymetazoline as initial therapy	1995	Retrospective	60	Effective as sole therapy in 65% of patients	Krempl, et al. [4]
Oxymetazoline for posterior epistaxis	1999	Retrospective	36	All cases resolved with initial or repeat doses only	Doo, et al. [45]
Iodoform gauze pack versus Merocel	1995	RCT	50	No significant difference in controlling epistaxis, Merocel more comfortable and easier to insert	Corbridge, et al. [46]
Merocel as initial therapy	1996	Retrospective	83	Effective in controlling epistaxis in 91.5% alone	Pringle, et al. [9]
B. Surgical management					
Endoscopic electrocautery for posterior epistaxis	2005	Prospective	43	Effective localization of source and control	Thornton, et al. [47]
TESPAL for control of refractory bleed	2003	Retrospective	127	98% control rate with no further therapy	Kumar, et al. [20]
TESPAL versus packing for recurrent epistaxis	2006	RCT	19	TESPAL superior for control, comfort, hospital stay and cost	Moshaver, et al. [28]
TESPAL +/− ant. ethmoid ligation for refractory bleeding	2000	Retrospective	287	TESPAL +/− ant. Ethmoid ligation equally effective as conventional measures, but improved cost and shorter stay	Srinivasan, et al. [17]
Embolization for refractory epistaxis	2008	Retrospective	70	Effective for control but increased cost	Christensen, et al. [48]

stay, transfusions, complications, or deaths between packing, embolization, and surgery, but the study did show a significant decrease in hospital charges in the packing group as compared to the embolization and surgery groups. However, Klotz et al. showed that early intervention with invasive measures results in a shorter hospital course, improved control of bleeding, decreased discomfort as associated with packing, and ultimately *less* cost [26,27]. In a randomized, prospective trial, Moshaver et al. further added support to early surgical intervention, demonstrating that health care costs were decreased by more than 50% and earlier hospital discharge was facilitated when posterior epistaxis was treated with temporizing packing followed by early TESPAL [28].

In the ICU setting in a patient population with multiple comorbidities, it is often the overall stability of the patient, ability to tolerate general anesthesia (for surgical intervention), or ability to tolerate angiography (e.g., no history of severe atherosclerosis, ability to lay flat, adequate renal functio) that dictates the most appropriate course of care for a patient with severe epistaxis. An in-depth knowledge of the treatment modalities available is critical to the clinician responsible for the direction of therapy (Table 146.2).

CHAPTER 147 ■ ESOPHAGEAL PERFORATION AND ACUTE MEDIASTINITIS

JASON W. SMITH, CHRISTOPHER H. WIGFIELD AND ROBERT B. LOVE

ESOPHAGEAL PERFORATION

Introduction

Esophageal perforation is both a highly lethal disease and primarily a surgical problem, and has remained such since nearly 4,000 BC as documented in the Edwin Smith Papyrus. Boerhaave then recorded his classical description of spontaneous rupture of the esophagus in 1724 [1]. Recently, there has been a shift in the etiology of esophageal perforation such that iatrogenic injury from instrumentation is the most common cause of esophageal perforation accounting for 40% of cases, while trauma represents 20%, spontaneous rupture (Boerhaave's) 15%, and tumor, foreign bodies, and operative injury collectively represent the remaining 25% of cases, leaving the two

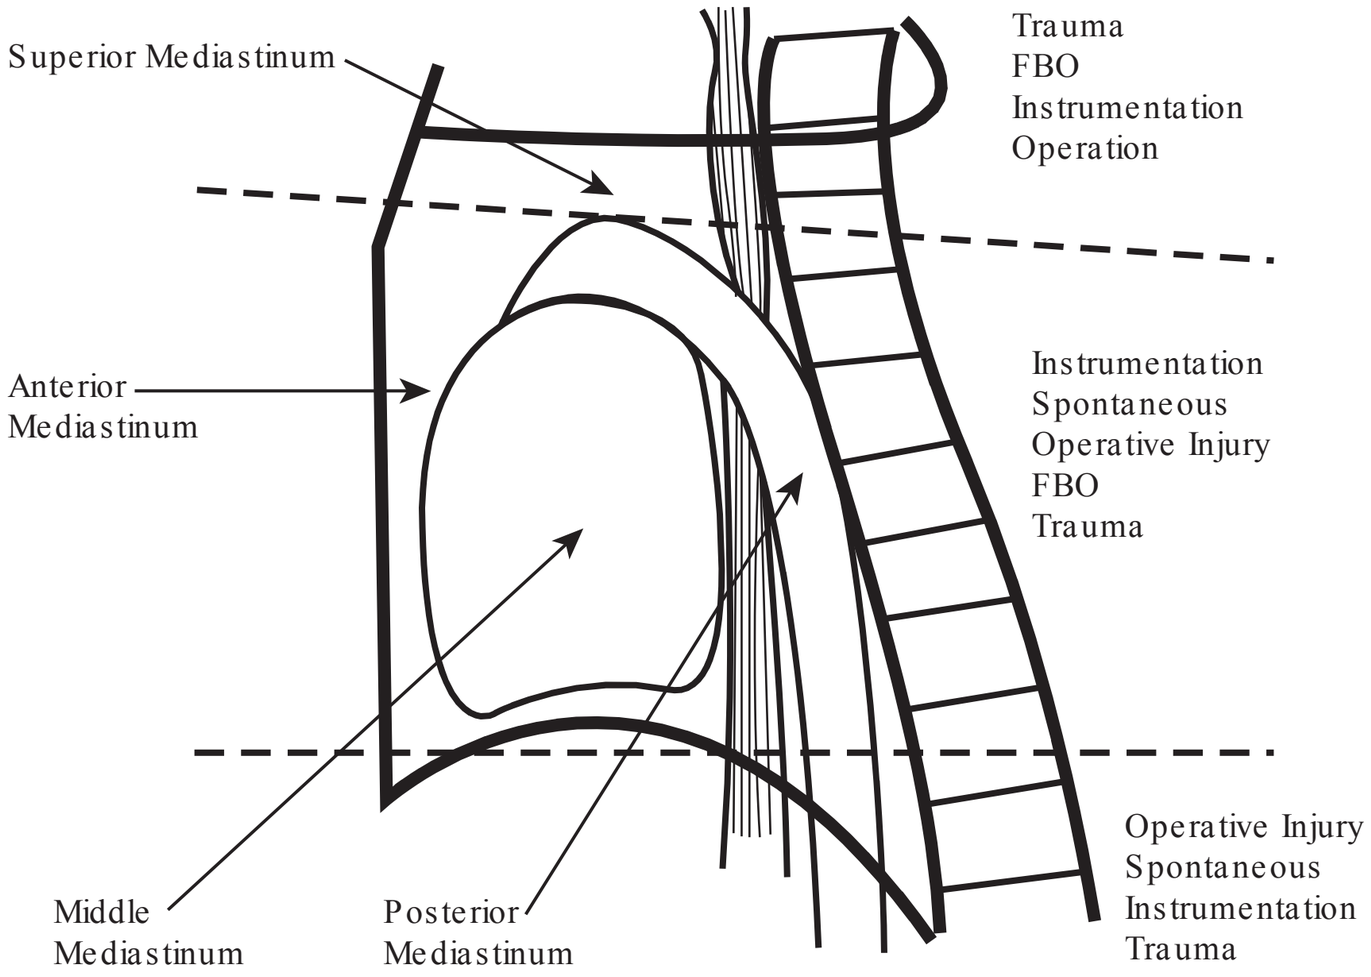

FIGURE 147.1. Zones of the mediastinum: these are identified on the left-hand side of the diagram. The superior mediastinum contains the thymic remnants, brachiocephalic veins, superior vena cava, aortic arch, trachea, phrenic nerve, vagus nerve, and the left recurrent laryngeal nerve. The anterior mediastinum contains primarily adipose and lymphatic tissue. The middle mediastinum is composed of the heart, pericardium, pulmonary trunk, aortic root, phrenic nerve, and tracheal bifurcation. The posterior mediastinum holds the descending thoracic aorta, azygos vein, esophagus, sympathetic chains, splanchnic nerves, and the thoracic duct. The right side of the diagram depicts each region of the esophagus, cervical, thoracic, and abdominal, and the injuries that occur there in decreasing order.

most common causes in the modern era as endoscopy related injury and anastomotic leakage [2]. The mortality associated with perforation of the esophagus remains high despite the most modern surgical and medical care, and ranges from 10% for early diagnosis to 75% for cases with late presentation.

Esophageal Anatomy

The esophagus is a muscular tube that extends from the pharynx to the stomach and is between 23 and 27 cm in length. It has three anatomic narrowings at the upper esophageal sphincter, at the level of the aortic arch and crossing of the left mainstem bronchus, and at the lower esophageal sphincter. The wall of the esophagus is comprised of the outer longitudinal muscle and the thicker inner layer of circular muscle. The innermost layer is the epithelial mucosa of the esophagus. The blood supply to the esophagus in the cervical region is primarily derived from the inferior thyroid artery. The thoracic esophagus receives its primary blood supply from the bronchial arteries and also receives branches directly from the descending thoracic aorta. The left gastric artery and the inferior phrenic arteries supply the abdominal portion of the esophagus. These arteries form a rich submucosal network of anastomoses that permit extensive mobilization and resection without fear of devascularization. The innervation of the esophagus is primarily from the vagus. Injury to the recurrent laryngeal branch of the vagus is well known for resulting in vocal cord paralysis, but less well known is the fact that significant functional impairment also occurs in the cricopharyngeal constrictor and motility of the cervical esophagus, contributing to the risk of aspiration after such an injury.

Pathophysiology

The most common locations for perforation of the esophagus to occur are at the narrowest portions of the organ but they can and do occur at any point. The absolute narrowest area in most people is at the cricopharyngeus muscle at the level of C5–C6, which corresponds to the upper esophageal sphincter (UES). This represents the portion of the esophagus most often injured during endoscopy and the risk is increased with hyperextension of the neck and in patients with bone spurs on the anterior surface of the vertebral bodies secondary to the presence of minimal tissue in the posterior cervical compartment between the posterior wall of the esophagus and the spine. The incidence of perforation during flexible endoscopy is about 0.03%; this is markedly improved over the era of routine rigid endoscopy which carried a much higher incidence of injury in the 0.11% range. Other iatrogenic causes of injury at the UES is transesophageal echocardiography performed during cardiac surgery and has a slightly higher incidence at 0.18% and other manipulations of the hypopharynx as in endotracheal intubation or nasogastric tube placement (Fig. 147.1).

The next narrow portion is at the level of the aortic arch and left mainstem bronchus and this is a common site for foreign body obstruction and ultimate perforation. Fish and chicken bones are the most common offenders in adults, while children tend to have a much wider variety of culprit objects such as safety pins, parts of toys, plastic elements. In the elderly, oral hardware such as dentures account for the majority of ingested items.

The gastroesophageal junction (GEJ) is the third region of narrowing and is most often perforated iatrogenically during dilations of the distal esophagus for achalasia or distal esophageal strictures. Perforation also results from biopsies in this area during evaluations for metaplasia. The GEJ is the most severely injured area of the esophagus in patients with accidental or intentional ingestion of chemical substances. The relaxation of the LES in response to injury along with intense pylorospasm results in continued reflux of caustic substances into the distal esophagus. This prolongs contact with the mucosa resulting in more severe injuries. Alkaline substances tend to create a more severe injury to the esophagus due to the liquefactive necrosis and the slow transit time, while acids tend to move more quickly through the esophagus and create a coagulative necrosis limiting the depth of injury.

Spontaneous perforation of the esophagus (Boerhaave's) is most commonly discovered in the distal left posterior lateral aspect about 2 to 3 cm from the GEJ. This area has a less developed muscular layer to accommodate the exit of neurovascular structures and tapering of the muscle as to spread out onto the stomach wall, allowing the increased pressure during retching to result in rupture into the left chest. The cervical esophagus is much more vulnerable to external trauma than

TABLE 147.1

CAUSES OF ESOPHAGEAL PERFORATION

Spontaneous (Boerhaave's syndrome)
Iatrogenic
Endoscopy (esp. with sclerotherapy or biopsy)
Dilation with bougie or balloon
Naso/orogastric tubes
Endotracheal intubation
Operative injury
Trauma
Caustic ingestion
Infections (tuberculosis, herpes simplex, CMV)
Malignancy
Zollinger–Ellison syndrome

Note: The percentages of each etiologies will vary depending on the location of the perforation and time period studied.
CMV, cytomegalovirus.

the thoracic esophagus and up to 6% of penetrating injuries to the neck may have a concomitant esophageal perforation, whereas only 0.7% of penetrating thoracic injuries result in an injury to the esophagus. Blunt traumatic injury to the esophagus is extremely rare and is almost always located in the cervical esophagus (Table 147.1).

Presentation

Delay in diagnosing an injury to the esophagus is the most important determinant of mortality in this disease and thus a high index of suspicion should be maintained whenever injury to the esophagus is a possibility in a differential diagnosis. Perforation of the esophagus leads to contamination of the surrounding tissues in the neck, mediastinum, or abdomen and localized sepsis due to the degree of aerobic and anaerobic bacterial contamination. Chief complaints are therefore related to the effects of local tissue inflammation and the systemic inflammatory response. The most common presenting symptom in patients with esophageal perforation is pain followed by other common signs including fever, dyspnea, and subcutaneous emphysema, which may extend into the head and neck. Auscultation of the heart tones may reveal a crunching sound that is related to air in the mediastinum and is a classic sign of esophageal perforation. Pain resulting from esophageal perforation is dependent on the location. A cervical perforation tends to cause less pain and more vague symptoms of neck stiffness, headache, and backache. Symptoms with more distal perforation in the thoracic esophagus tend to be substernal and can lateralize to the side of perforation with proximal esophageal perforations tending to be on the right side and more distal perforations on the left side. This must be differentiated from acute coronary syndromes and should be considered in patients with severe chest pain after an acute myocardial infarction has been eliminated as the etiology.

Presenting signs of perforation may be subtle and nonspecific in the early phase with tachycardia being the most well recognized, and persistent tachycardia in a patient who has undergone an endoscopic evaluation or a surgical procedure involving the esophagus should warrant an evaluation for rupture. As the course progresses, these patients rapidly develop systemic sepsis with hypotension and tachycardia, tachypnea and worsening respiratory distress, renal failure, and mental status alterations. Failure to recognize septic shock and intervene early in this patient population may lead to death within 12 to 24 hours.

Diagnostic Evaluation

A chest radiograph is often one of the first tests obtained in patients with pain in the chest or neck. The presence of a pleural effusion, pneumothorax, or pneumomediastinum, in the setting of a suspicious history, is highly suggestive of an esophageal perforation. A contrast esophagram, however, is the gold standard for diagnosis of perforation. It has a high sensitivity and specificity and is relatively easy to obtain in any facility. Following an initial evaluation with water-soluble contrast, a barium contrast study should be done to rule out a leak. The false negative rate for esophageal perforation utilizing water-soluble contrast is 20% to 25%, even when digital subtraction imaging techniques are used [3,4]. Therefore, a negative study with water-soluble contrast does not complete the evaluation [5]. Concern over the inflammatory reaction associated with barium extravasation in the setting of bacterial contamination is warranted if an intra-abdominal perforation is suspected and the patient is presenting with peritonitis [6]. Such a response has not been demonstrated in the mediastinum and barium should be used to increase the sensitivity of the imaging [7]. Patients who cannot perform a swallowing test or are in extremis are most often imaged with computed tomography with oral contrast administered by nasogastric tube, which must be positioned in the proximal esophagus to provide diagnostic value. The key finding on a computed tomography (CT) scan for diagnosing a perforation is an extraluminal collection of gas or subcutaneous emphysema. Periesophageal fluid collections with air-fluid interfaces, esophageal wall thickening effacement of fat planes, extravasation of oral contrast and pleural effusions are other radiographic findings consistent with a perforation. Computed tomography is also useful in the evaluation for abscess or empyema formation with a long-standing leak [8–11] (Fig. 147.2).

The role of esophagoscopy in the diagnosis of esophageal perforation has been established in the setting of traumatic injuries with a high sensitivity for detecting injury [12–14]. In non-traumatic settings, the sensitivity has not been established and the use of endoscopy remains as an adjunct to imaging modalities. This may be related to the difficulty in locating sites of perforation in the esophageal mucosa when there are no attendant signs of trauma [15].

Treatment

There is a paucity of reliable data regarding the treatment of esophageal perforation. This is partly a result of the fact that patients present with a wide variety of symptoms, differing severity of injury and are treated by several different specialties. Several principles in the management of esophageal perforation are paramount: control of ongoing soilage by closure of the leak, management of sepsis with adequate drainage and support of the patient with fluids, nutrition, and appropriate antibiotics.

After goal-directed resuscitation and initiation of broad-spectrum antibiotic therapy, the treatment of choice for most patients with perforations of the esophagus remains surgical. For early perforations less than 24 hours in hemodynamically stable patients, consideration may be given to direct primary repair of the injury. This is generally possible in cases where there is a small injury with little soilage or devitalized tissue in a surgically accessible location and early detection has been achieved. Access to the cervical esophagus is generally obtained through an anterior neck incision along the anterior border of the left sternocleidomastoid muscle. The carotid sheath and its contents are retracted laterally and the thyroid and trachea retracted medially to expose the esophagus. In the mediastinum,

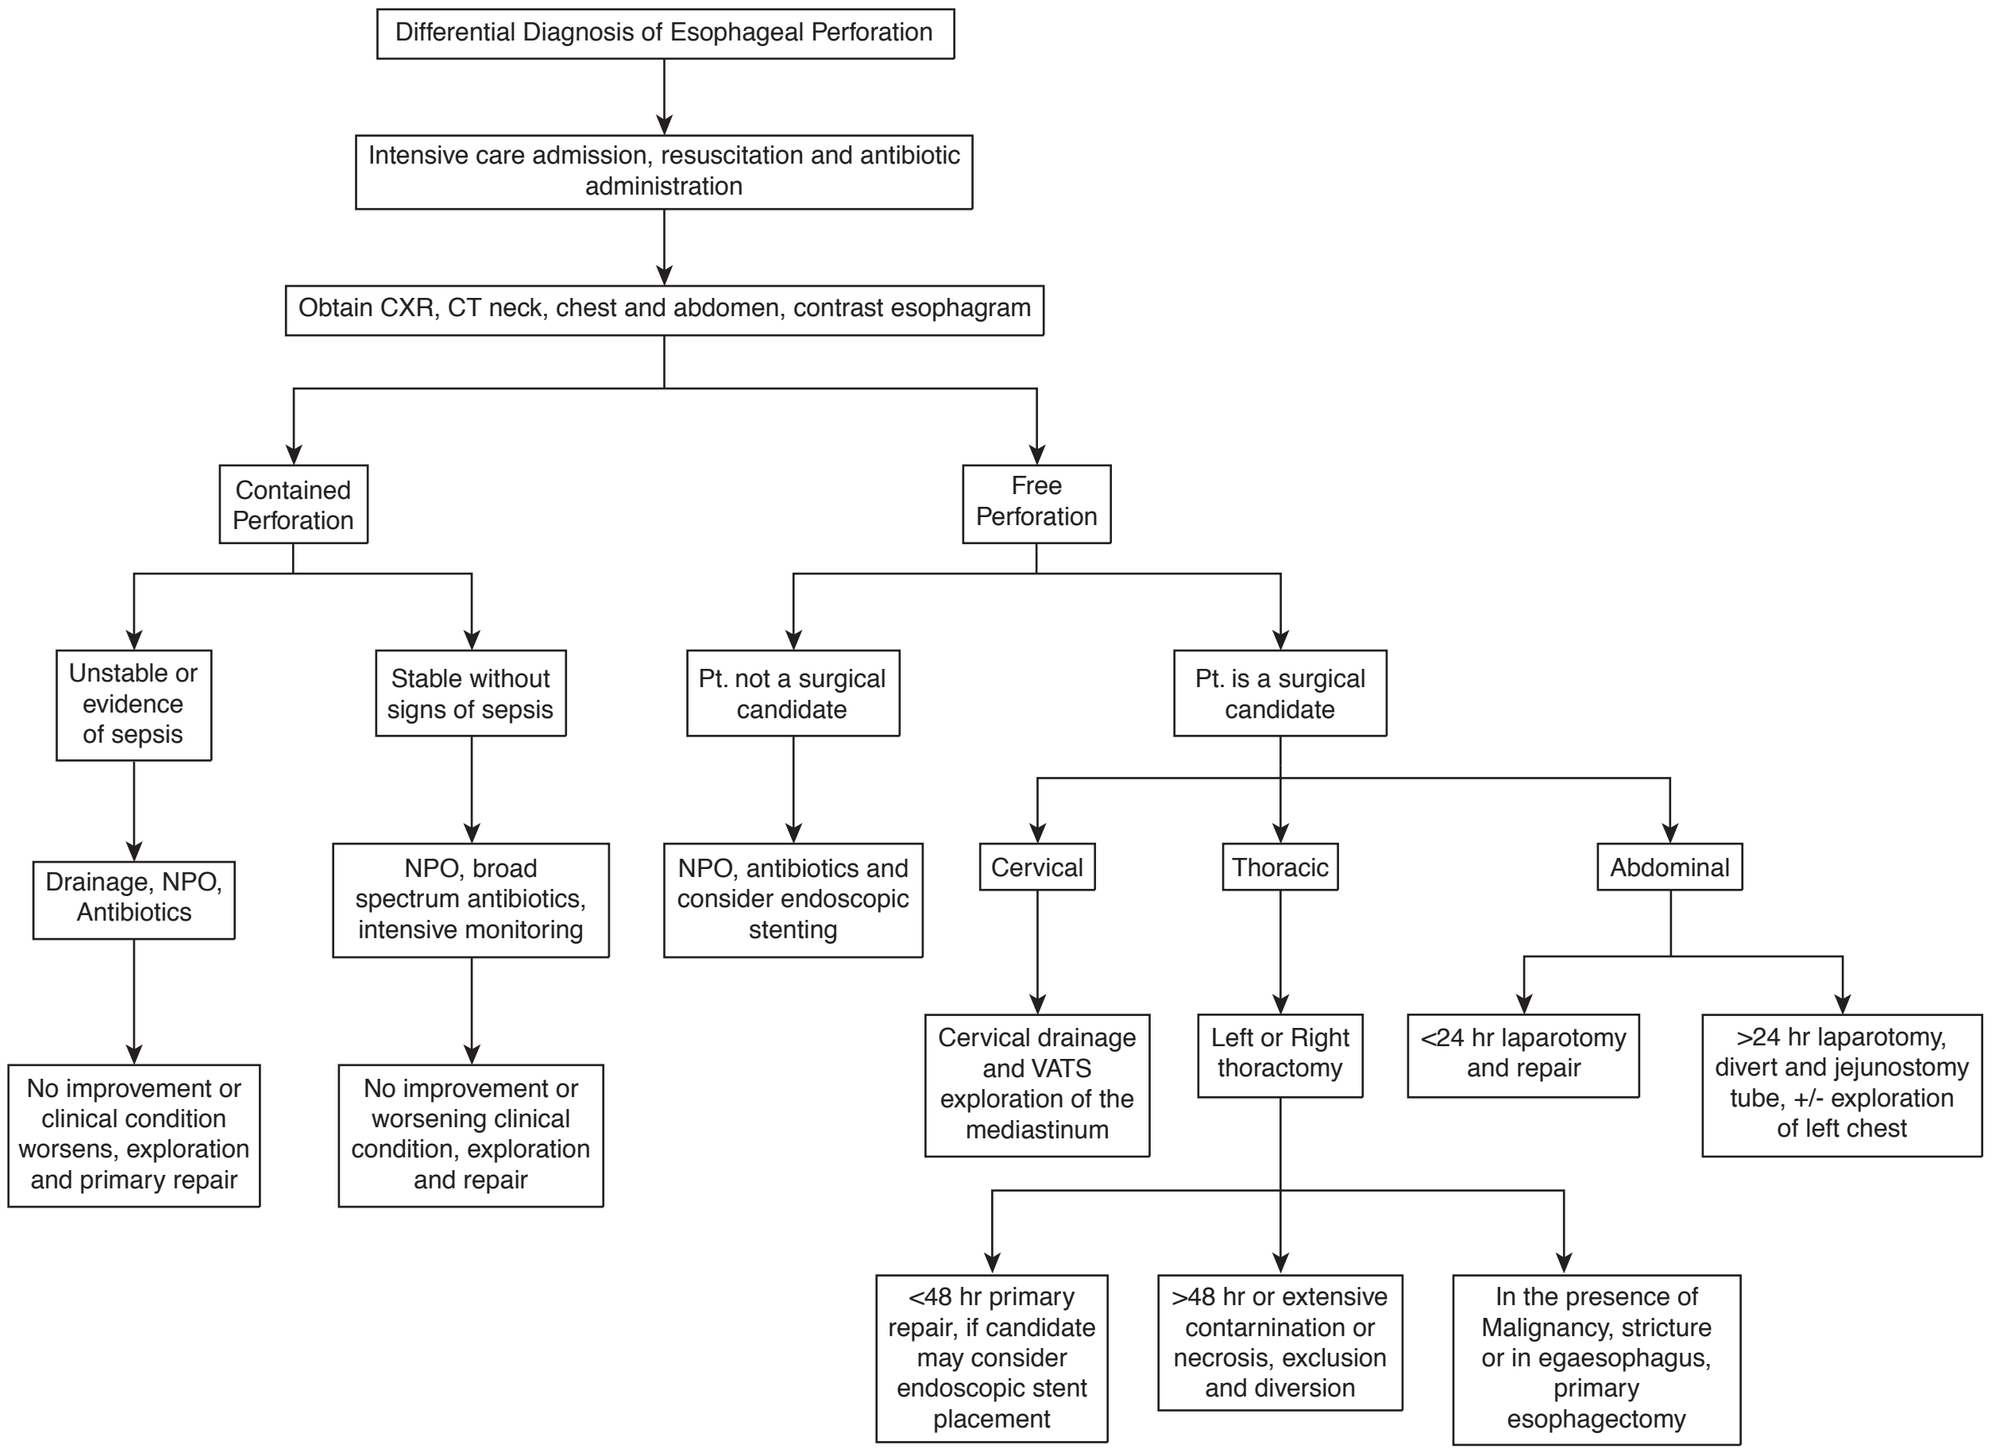

FIGURE 147.2. Algorithm for the diagnosis and management of a perforation of the esophagus. Early diagnosis followed by resuscitation and surgical consultation are the keys to decreasing the mortality from this highly lethal condition.

a right posterolateral thoracotomy is used to access lesions in the middle third of the esophagus and a left posterolateral thoracotomy provides exposure for the distal third of the thoracic esophagus. Upper midline laparotomy or left thoracotomy may be used to access the gastroesophageal junction. If amenable to repair, the esophagus is usually closed with a single layer of interrupted full thickness sutures and the anastomosis is reinforced with a well-vascularized local tissue flap from the latissimus dorsi muscle, pericardium, or omentum.

In cases where the diagnosis has been delayed for more than 24 hours, there is extensive tissue injury, or intense local sepsis, primary repair is ill-advised. In this situation, it is prudent to perform a resection of the esophagus or proximal diversion with a cervical esophagostomy and exclusion of the injured esophagus with creation of enteral feeding access. After the resolution of sepsis and once the patient is nutritionally repleted, reestablishment of intestinal continuity can be achieved with a gastric pull-up or intestinal interposition techniques. If there is a coexisting underlying esophageal pathology such as megaesophagus, achalasia, esophageal stricture, or carcinoma, esophagectomy with or without reconstruction is the operation of choice. In patients who cannot tolerate a definitive repair, surgical management should be limited to placement of an esophageal T-tube for drainage and creation of a controlled esophageal fistula.

Patients who have a small contained perforation, stable vital signs and no ongoing sepsis may be candidates for nonoperative management. This includes radiographic demonstration that ongoing soilage is absent and drainage of intrathoracic fluid collections is amenable to interventional radiology or by the placement of thoracostomy tubes. These patients should also be placed on a substantial course of culture directed antibiotic therapy, and be started on parenteral nutrition with complete rest of the upper gastrointestinal tract.

Given the high mortality associated with surgical repair of esophageal perforations, it is not surprising that innovation continues in this complex disease process. The development of even more advanced endoscopic therapeutic modalities has provided some new options in the management of these patients, including endoscopic closure and stenting. There are several small series which have been published recently that suggest that endoscopic stenting of spontaneous or iatrogenic esophageal perforations can be effective as initial or definitive therapy [16]. There is experimental evidence demonstrating the efficacy of endoluminal closure devices for management of esophageal perforation. There appears to be a faster rate of healing and return to normal function with the use of clipping devices over endoluminal suturing techniques [17]. Clinical evidence is limited to case reports and series, but does appear feasible. Although there is a clear selection bias favoring patients with less severe disease and more favorable prognosis, it is appealing to consider a therapy with a much less invasive approach and potentially less severe dysregulation of systemic inflammation. The other major endoluminal therapy in use is the esophageal stent. Endoscopically placed occlusive stents have been used to close perforations and quickly restore

intestinal continuity with good effect. A recent series reported that 23 patients were treated with endoluminal stents and they had no resultant mortality and only 10% went on to require surgical intervention [16]. This may represent a new paradigm in the management of this disease process that will have a less profound effect on the counter regulatory cytokine response and immune function.

Follow-up

In addition to the operative mortality, there is a high risk of anastomotic complications after repair of esophageal perforations approaching 40% to 50%. This includes stricture and disruption of the esophageal anastomosis [18]. In the immediate postoperative period, these patients should remain in the intensive care setting or in a specialized surgical unit where early signs of anastomotic complications can be identified and addressed in a timely fashion. Thoracostomy tubes are generally left in place until the first feeding to identify an early anastomotic dehiscence. Once the patient is discharged from the hospital, the most important chronic problem is stricture of the anastomosis and complaints of dysphagia should prompt a contrast imaging study of the esophagus.

MEDIASTINITIS

Introduction

Since the time of Boerhaave, physicians have recognized mediastinitis as a highly lethal disease for which treatments have only been developed in the very recent past [1]. The incidence of mediastinitis after coronary artery bypass grafting (CABG) ranges from 0.5% to 1.25% and carries an in-hospital mortality up to 14% compared to 1.1% in CABG patients who do not develop sternal wound infections [19,20]. Mediastinitis is also associated with a significant increase in long-term mortality after coronary artery bypass grafting with patients survival at 1 year dropping from 95% to 78% [19]. We now recognize a number of causes of mediastinitis in addition to the original description of spontaneous esophageal rupture. These include the acute causes of mediastinitis, iatrogenic perforation of the esophagus, post-sternotomy, head and neck infections, pulmonary infection, abdominal infections, chest wall osteomyelitis, or direct posttraumatic. Chronic causes of mediastinitis include granulomatous diseases, fibrotic diseases, autoimmune diseases, and drug reactions [21].

The mediastinum is divided into the superior and inferior regions, and the inferior mediastinum includes the anterior, middle, and posterior compartments [22]. The superior mediastinum is bounded by the pleura laterally, the thoracic inlet superiorly and inferiorly by a line extending from the sternal angle to the intervertebral disc between the fourth and fifth thoracic vertebral bodies. Structures contained in the superior mediastinum include the thymic remnants, brachiocephalic vein, superior vena cava, aortic arch and the branch vessels, the trachea and the phrenic, vagus and recurrent laryngeal nerves. The anterior mediastinum is defined by the posterior surface of the sternum and the anterior pericardium, the inferior margin of the superior mediastinum and the diaphragm. The anterior mediastinum is devoid of major anatomical structures and is primarily occupied by adipose, connective, and lymphatic tissue. The middle mediastinum consists of the heart and pericardium, the pulmonary trunk, phrenic nerves, and the distal trachea including the bifurcation into the right and left mainstem bronchi. The posterior mediastinum extends from the posterior surface of the pericardium to the spinal column. The major contents of this compartment are the descending aorta, azygos vein, esophagus, sympathetic chains, splanchnic nerves, thoracic duct, and lymphatics.

Acute Mediastinitis

The most common cause of acute mediastinitis is post sternotomy. The Centers for Disease Control and Prevention define mediastinitis as a deep sternal incisional surgical site infection [23]. The incidence of mediastinitis after sternotomy ranges from 0.4% to 5.0% in the literature with most series reporting 1% to 2%, and an associated mortality of 10% to 20% [19,24]. Risk factors associated with the development of a deep sternal wound infection can be divided into preoperative, intraoperative, and postoperative risks. Preoperative factors are male gender, presence of hypertension, chronic obstructive pulmonary disease, diabetes, obesity, large breast size, history of smoking, and older than 70 years [20,25–31]. Intraoperative variables include an extended cardiopulmonary bypass pump time, the use of autotransfused shed mediastinal blood, and harvest of both internal mammary arteries [32–34]. Postoperative risk factors include reexploration for bleeding, prolonged intubation, and tracheostomy [35–37]. Recognition of the importance of these predictors allows the intensivist to maintain a high index of suspicion in the immediate postoperative period for the development of this devastating complication (Table 147.2).

The next most common cause of acute mediastinitis is descending cervical infection generally from odontologic procedures or disease, tonsillitis, or pharyngitis. Infections of the head and neck region can reach the mediastinum by three primary pathways from the cervical fascial planes. The pretracheal, perivascular, and retropharyngeal spaces have all been implicated as routes for spread of descending infections to gain access through the thoracic inlet into the mediastinum [38]. Based on the report by Pearse in 1938, the retropharyngeal space was once thought to be the culprit in the majority (70%) of descending cervical infections, however, a small recent study suggests that the perivascular space may be more important and that the carotid sheath may need to be opened and drained in a majority of cases [39,40].

Presentation

Acute mediastinitis usually presents within the first 7 to 10 days after surgery with fever, leukocytosis, chest pain, dysphagia, or respiratory distress [41]. Other presenting symptoms

TABLE 147.2

RISK FACTORS FOR POSTOPERATIVE MEDIASTINITIS

Diabetes
COPD
Harvest of bilateral internal thoracic arteries
Tobacco use
Prolonged ventilation
Obesity
Advanced age
Renal failure
Prolonged bypass pump time
Extensive use of electrocautery
Bleeding requiring reexploration

COPD, chronic obstructive pulmonary disease.

include drainage or erythema in the sternal wound, presence of a sternal click or dehiscence of the sternum, and subcutaneous emphysema.

When the source of infection is the neck, the primary symptoms are neck and/or throat pain in the early phases followed by edema, dysphagia, and odynophagia which is generally easily recognized. Although fever and leukocytosis are relatively nonspecific findings, in the presence of chest pain in the postoperative period it should raise the suspicion for diagnosis. One must be alert to the possibility of acute airway obstruction in the case of descending infection secondary to airway edema or epiglottitis [42].

Diagnosis

The initial evaluation, especially in cases with respiratory compromise, usually includes a chest radiograph, which is often nondiagnostic, but may show alterations in the normal tissue planes with edema, fluid, or air [42]. Chest x-ray may demonstrate diffuse mediastinal widening or air-fluid interfaces in the mediastinum in advanced cases. With esophageal perforation pneumothorax, pneumomediastinum and pleural effusion are common findings.

Computed tomography imaging of the chest with both oral and intravenous contrast is generally the next study evaluating pathologic processes in the thorax and has the most utility in identifying major infections in the mediastinum. CT allows the easy evaluation of both the neck and the abdomen to assess the relationship of any fluid collections in the chest to other potential sources of infection. It also allows precise localization of the fluid collection and possible intervention in selected cases. CT is also an important element in the preoperative planning of surgical drainage procedures and should not be omitted in the work up of this highly lethal disease. In cases where esophageal perforation is suspected, a contrast esophagram with Gastrografin is indicated as discussed in the previous section.

The diagnosis of mediastinitis is defined by the Centers for Disease Control as an infection in a patient who has one of the following conditions: (i) organisms cultured from mediastinal tissue or fluid, obtained during a surgical operation or needle aspiration; (ii) evidence of mediastinitis seen during a surgical operation or histologic examination; (iii) a patient with fever, chest pain, or sternal instability with no cause and at least one of the following: (a) purulent discharge from mediastinal area, (b) organisms cultured from blood or discharge from mediastinal area, or (c) mediastinal widening on chest x-ray [43].

Treatment

The treatment of mediastinitis is directed toward the primary pathological process, but initial measures include the administration of broad-spectrum antibiotic therapy, fluid resuscitation, and surgical drainage for control of the source. Mediastinitis tends to be a polymicrobial infection, however, antimicrobial therapy can be directed toward likely organisms depending on the etiology of the infection. Cultures from patients with descending cervical mediastinitis secondary to an odontologic or oropharyngeal process are likely to grow Gram-negative aerobes and anaerobes, including anaerobic *Streptococcus* and *Bacteroides* species. Deep sternal wound infections in postoperative mediastinitis most often grow *Staphylococcus aureus*, aerobic *Streptococcus*, *Pseudomonas aeruginosa*, and *Enterococcus* spp. When the origin of the septic focus is within the chest wall, periosteum of the ribs, or pleural space, the infected tissues may harbor tuberculosis or fungi.

Patients with mediastinitis will often present late in the course of the disease due to the nonspecific and misleading nature of the early symptoms. Because of this they often have clinical signs of sepsis with significant third space fluid losses and vasodilatory shock. Volume resuscitation should be started early with emphasis on goal-directed resuscitation to restore hemodynamic parameters. Most of these patients will ultimately require surgical intervention and adequate cardiac preload is essential for successful anesthesia induction. Once volume expansion is adequate, consideration can be given to the addition of vasoactive agents to increase the systolic blood pressure if vasodilation is an element of the patient's presentation.

Surgical drainage is the standard definitive therapy in all forms of mediastinitis. Descending cervical infections will require the primary oral process to be addressed in addition to incision and drainage of the neck through either a vertical incision along the anterior border of the sternocleidomastoid muscle, and thoracotomy or thoracoscopy for mediastinal drainage and placement of thoracostomy tubes for continued chest drainage. Incisions in the neck should be allowed to heal by the secondary intention to prevent ongoing sources of infection. Occasionally, infections limited to the superior mediastinum may be adequately addressed by the cervical incision, however, these patients must be carefully selected to avoid leaving the patient with ongoing septic foci as nearly 50% of patients treated by the cervical approach alone go on to require thoracotomy for unrecognized mediastinal disease [44].

Poststernotomy mediastinitis requires an aggressive approach to reduce the morbidity and mortality associated with this complication. Exploration of the mediastinum by reopening the median sternotomy incision is the standard approach. All necrotic tissue and bone are widely debrided, and tissue is mobilized as a flap to fill the dead space left by the debridement. Reclosure of the sternum by direct rewiring has been reported to carry a mortality up to 45%, which is unacceptably high [45]. Tissue flaps may be created with various rotational techniques or omental harvest, but the most common is medialization of bilateral pectoralis major muscles as local flaps. Using omentum has the disadvantage of requiring a laparotomy and opening of an additional body cavity, but has the distinct advantage of being simple and performed quickly in the unstable patient. Vacuum closure of the mediastinum is gaining acceptance as an alternative to immediate flap closure. Reports indicate that mortality is comparable when used as definitive therapy or as a bridge to a delayed myocutaneous flap closure [46].

Chronic Mediastinitis

Granulomatous infections like histoplasmosis, syphilis, tuberculosis, and coccidiomycosis as well as noninfectious processes like sarcoidosis cause a subacute prolonged mediastinal inflammation called chronic mediastinitis. The primary pathologic process is one of diffuse fibrosis of the mediastinum. This may also result from prolonged acute mediastinitis. Risk factors for development of chronic mediastinitis include the presence of autoimmune diseases such as lupus erythematosus, rheumatoid arthritis, and Raynaud's phenomenon, or the presence of mediastinal foreign bodies. Symptoms are generally low grade and well tolerated in the early stages and include cough, dyspnea, wheezing, chest pain, or dysphagia. Compression or obstruction of major vascular structures such as the superior vena cava (SVC) may lead to SVC syndrome. Radiographic studies may demonstrate widening of the mediastinum resulting from diffuse fibrosis or calcifications of involved lymph nodes and granulomas. Contrast CT of the chest is particularly helpful in the evaluation of vascular compression but will also clarify the extent of the mediastinal involvement in the fibrotic process and evaluate the lung parenchyma and associated thoracic viscera. There is no single accepted or effective treatment for chronic mediastinitis. Antibiotics are indicated for documented

bacterial or fungal infection, while chemotherapeutic regimens have had limited success in modulating the ongoing inflammatory process, and surgical therapy is generally limited to tissue biopsy for diagnosis. For vascular compression, endovascular stenting may have an increasing role in palliation of SVC syndrome.

Esophageal perforation and mediastinitis represent relatively rare disease processes that often present as acute life threatening illnesses. As such they are not particularly amenable to well designed randomized controlled trials in the evaluation of different therapeutic options. A review of the literature does not demonstrate any class I data related to therapies for the treatment of these diseases and such data is not likely to be forthcoming. Further advances are likely to continue to come from retrospective analysis of innovative approaches to these complex problems.

CHAPTER 148 ■ MANAGEMENT OF THE POSTOPERATIVE CARDIAC SURGICAL PATIENT

SAJID SHAHUL, CATHY DUDICK AND ALAN LISBON

The management of the postoperative cardiac surgical patient is a dynamic process that requires modern intensive care unit (ICU) technology and sharp clinical skills. Early detection of acute complications has a significant impact on morbidity and mortality. The postoperative care of cardiac surgical patients is best handled using a systematic approach [1,2].

MONITORING

The restoration and maintenance of physiologic homeostasis without further injury to the heart and other organs represent the most important goal in the care of the postoperative cardiac surgical patient and requires proper patient monitoring. An arterial cannula, usually in the radial artery, permits easy access to blood for various laboratory tests (see Chapter 3) and provides the ability to measure systemic blood pressure continuously, mean arterial pressure (MAP) being the value of most interest. The MAP is the least dependent on site or technique of measurement and the least affected by measurement damping; it also determines tissue blood flow by autoregulation [3].

At least one lead of the surface electrocardiogram also should be displayed, with several leads being monitored for ST-segment changes. Pulse oximetry allows assessment of oxygen saturation and reduces the need for arterial blood gases.

A triple-lumen pulmonary artery catheter (PAC) inserted through an internal jugular vein permits measurement of the right atrial, pulmonary artery, and pulmonary artery occlusion (PAOP) pressures and the determination of cardiac output (CO) and mixed venous saturation. Pulmonary artery catheters with an oximeter probe at the distal end allow continuous monitoring of mixed venous oxygen saturation and cardiac index. However, based on multiple, randomized controlled clinical trials in a variety of settings, the routine use of pulmonary artery catheterization does not lead to improved clinical outcomes [4–9]. Although the PAC-Man trial, an open randomized trial involving 65 UK ICUs and over 1,000 patients, demonstrated no clear benefit or harm in using a PAC [4], the use of a PAC carries attendant risks such as infection, pulmonary artery rupture, and arrhythmia.

Transesophageal echocardiography is now used both as a monitoring and a diagnostic tool, both in the operating room and the ICU. It allows real-time evaluation of intracardiac blood flow, anatomy, and function. It may be superior to invasive monitoring [10], particularly in the setting of valvular disease or respiratory disease when pressure-based readings may not accurately reflect volume status. In both cardiac and noncardiac patient populations, several studies demonstrated that TEE provided unexpected information that significantly altered the therapeutic plan, even in patients with an indwelling PAC [10]. The therapeutic management decisions gleaned from TEE ranges from 10% to 69%, with the majority of studies demonstrating the 60% to 65% range. The diagnostic yield of TEE approaches 78% [11].

INITIAL ASSESSMENT

A brief but systematic physical examination of the patient is mandatory on arrival in the ICU. Inspection of the skin and extremities may reveal intraoperative injuries, infiltration or disconnection of intravenous (IV) infusions, absence of pulses, signs of drug or transfusion reactions, or evidence of hypoperfusion. Auscultation of the chest may reveal unilateral absence of breath sounds due to malposition of the endotracheal tube or pneumothorax. The abdomen should be inspected to ensure that no abdominal distention is present. Mediastinal and chest tubes should be examined for drainage.

Initial laboratory studies should include arterial blood gas, hematocrit, sodium, potassium, glucose, calcium, magnesium, prothrombin time (PT), partial thromboplastin time (PTT), and platelet count. A portable chest radiograph and a 12-lead electrocardiogram with atrial electrograms should be obtained immediately on admission to the ICU. The postoperative chest radiograph should be inspected with specific attention to the following: (a) pneumothorax and mediastinal shift; (b) position of the endotracheal tube, nasogastric tube, and intravascular catheters; (c) size and contour of the mediastinal silhouette; and (d) pleural and extrapleural fluid collections.

PHYSIOLOGIC PRINCIPLES OF CARDIAC FUNCTION

Cardiac function is determined by intrinsic myocardial properties as well as by ambient loading conditions. The inotropic state (contractility) of the myocardium during systole is a determinant of systolic stroke volume (SV). Systolic function is also determined by ambient hemodynamic conditions (heart rate [HR], preload, and afterload). The conceptual framework that provides maximal information about intrinsic myocardial properties, as well as the interrelationships between systolic contractility, preload, and afterload, is represented by the ventricular pressure–volume (PV) relationship (Fig. 148.1). The cardiac cycle has four phases: (a) passive ventricular filling during diastole (which, in Fig. 148.1, has been extended as a curvilinear line to describe the distensibility of the ventricle beyond the range of the illustrated cardiac cycle), (b) isovolemic systole (before aortic valve opening), (c) systolic ejection, and (d) isovolemic relaxation.

The SV for an individual cardiac cycle can be obtained by subtracting end-systolic ventricular volume from the end-diastole volume (EDV). The systolic ejection fraction can be determined from the fractional relationship between SV and EDV. This framework aids in conceptualizing and predicting the effects of changes in loading conditions and contractility on measurable hemodynamic parameters.

Left atrial pressure can be measured, or its mean can be estimated by the measurement of PAOP pressure or pulmonary diastolic pressure. These three pressures are equal only under

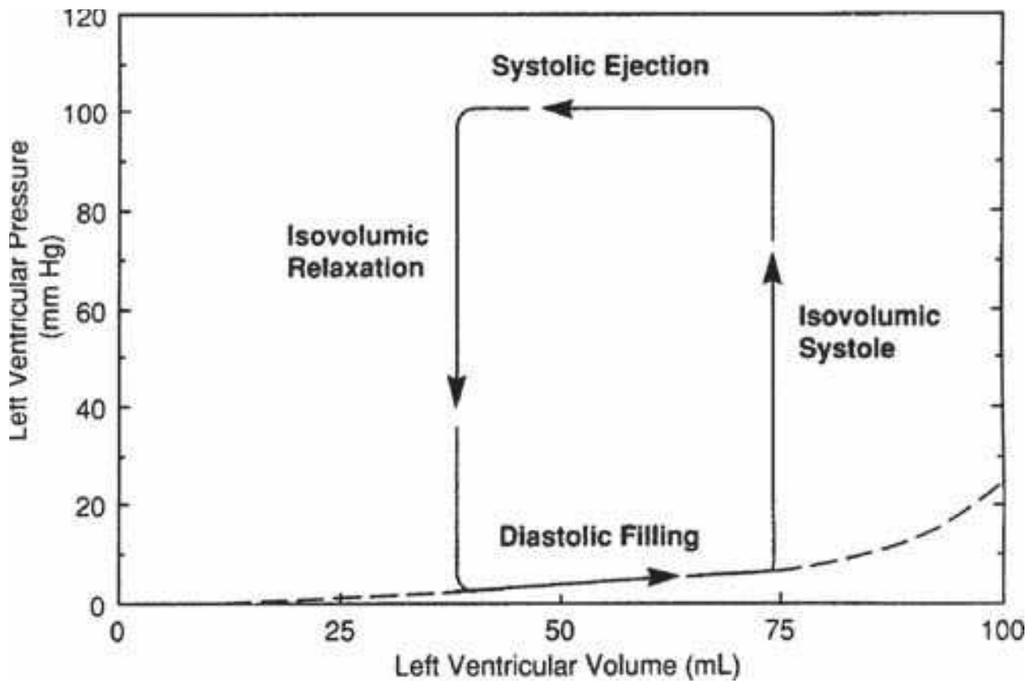

FIGURE 148.1. The left ventricular pressure-volume diagram. Phases of the cardiac cycle.

ideal circumstances. Generally, pulmonary diastolic pressure exceeds pulmonary artery occlusion pressure, which exceeds mean left atrial pressure. These differences are determined by gravitational effects related to pulmonary artery catheter position and by diastolic pressure gradients in the pulmonary vasculature.

Although the systolic SV of the left ventricle is not measured directly, it can be determined from measurements of CO and HR. If LV systolic ejection fraction (EF) has been determined, the end-diastolic volume (EDV) and end-systolic volume (ESV) of the left ventricle can be determined: EDV = SV/EF and ESV = EDV − SV.

Preload is an estimation of average end-diastolic myocardial fiber length and correlates best with ventricular EDV. As the left ventricle distends, EDV, rather than end-diastolic pressure, is a highly predictive determinant of systolic function. Mechanical interaction between the two ventricles and between each ventricle and the surrounding mediastinal and thoracic structures can also influence ventricular distensibility. LV end-diastolic pressure (rather than EDV) can be used to monitor preload only when those factors that alter ventricular distensibility are constant. When ventricular distensibility is changing (due to, for example, the loss of myocardial compliance that occurs with transient ischemia), the measurements or estimates of ventricular diastolic pressure do not accurately represent preload.

The term *afterload* usually is used to describe the forces that retard the ventricular ejection of blood. The afterload of the right and left ventricles is determined primarily by the resistive and capacitive characteristics of the pulmonary and systemic circulations. As blood is ejected from the ventricle, the actual afterload forces that oppose the shortening of myocardial fibers are distributed as stresses throughout the ventricular walls.

The Frank-Starling principle is useful in predicting the hemodynamic outcome of therapeutic interventions. This is illustrated by the curvilinear relationship between ventricular stroke work (*y*-axis) and ventricular end-diastolic pressure (*x*-axis). When preload is represented by EDV, rather than by end-diastolic pressure, this relationship becomes linear and is minimally affected by afterload and HR [12]. The slope of this relationship is a sensitive indicator of intrinsic myocardial performance and responds appropriately to inotropic interventions. The augmentation of stroke work by increases in preload is referred to as *preload recruitable stroke work* (Fig. 148.2).

Increases in CO, afterload, preload, inotropic state, and HR are all achieved with increased myocardial oxygen demand. Intraoperatively, myocardial oxygen demand is eliminated by hypothermia and chemical cardioplegia. Postoperatively, if the myocardial work is too intense or the blood supply is too small, myocardial ischemia, failure, and infarction may result. An important feature of myocardial oxygen consumption is that oxygen extraction is nearly maximal at rest, so that increases in myocardial oxygen consumption can only be achieved by increases in coronary blood flow. Increased afterload is, to a degree, self-compensatory in that increased diastolic coronary perfusion pressure tends to increase coronary blood flow. Increases in inotropic activity may also be associated with increases in myocardial blood flow and a correspondent increase in diastolic aortic pressure.

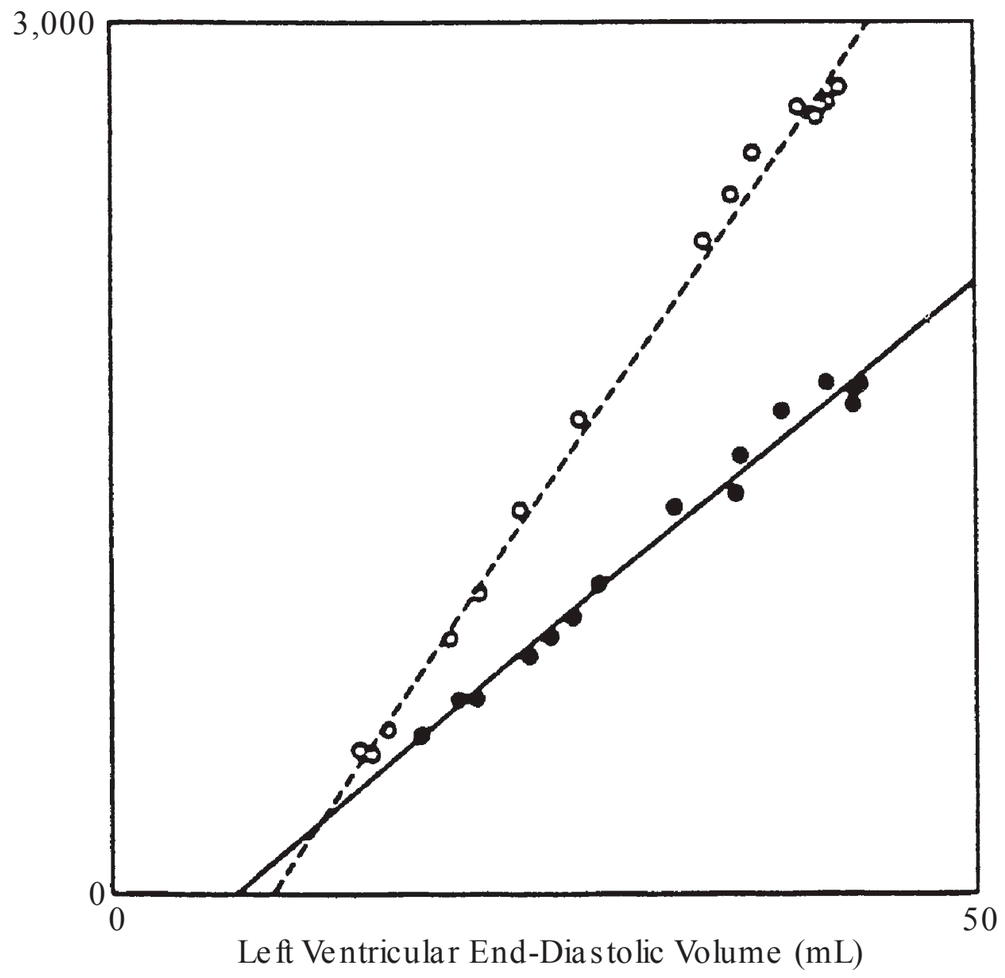

FIGURE 148.2. The preload recruitable stroke work relationship for the left ventricle. The slope of this relationship is sensitive to inotropic interventions and is increased by the infusion of calcium. [Reprinted from Glower DD, Spratt JA, Snow ND, et al: Linearity of the Frank-Starling relationship in the intact heart: the concept of preload recruitable stroke work. *Circulation* 71:994, 1985, with permission.]

Maximizing cardiac function to meet metabolic demands, therefore, involves the manipulation of volumes and pressures that affect preload and afterload and the support and enhancement of myocardial contractility. Andre and DelRossi [13] note that the postoperative myocardium is cold and stiff and generally behaves as a pressure-overloaded system. Volume may be needed despite high measured filling pressures. As the patient recovers and the myocardium warms, compliance improves and the relationship of filling pressures to ventricular volumes changes.

Initial Status

On arrival to the ICU, a systematic assessment should include preoperative history with attention to medications and cardiac function, intraoperative history, vital signs, and physical examination. Immediate goals and short-term goals need to be established. Many patients arrive hypothermic with temperatures ranging from 34°C to 36°C as a result of deliberate systemic cooling during cardiopulmonary bypass. Persistent peripheral vasoconstriction can be the result of elevated angiotensin levels [14]. Shivering during rewarming increases metabolic and circulatory demands, increases carbon dioxide production, and complicates ventilator management. Shivering can be eliminated with paralyzing agents and sedation [15,16]. The patient is generally maximally warm by 4 to 6 hours after operation.

As the patient rewarms and awakens, the goal is to support the recovering myocardium until it is independently able

to meet metabolic demands. Cardiac output is measured and normalized to cardiac index (CI) by dividing it by the patient's body surface area. Efforts to correct an initial cardiac index of less than 2 L per m^2 per minute should be made because low cardiac index is associated with an increased risk of death [17,18]. The clinical correlates of reduced cardiac index are pale and cool skin, cyanotic mottling of the skin (occurring first over the knees), decreased urine output, and deterioration of mental status or slowness in awakening from anesthesia. A low CI and decreased peripheral perfusion also cause metabolic acidosis (from lactic acid accumulation in poorly perfused tissues; see Chapter 71), which, to a mild degree, occurs even after routine operations.

Normally, the mixed venous hemoglobin saturation (SvO_2) should be 60% or higher. If it is less than 50%, a high likelihood of death exists [17,19]. The SvO_2 should be interpreted in light of the cardiac index and hemoglobin. In the worst situation, and the one that often leads to death, the SvO_2 may be adequate only because so much of the peripheral tissues are underperfused [17]. In this case, however, the cardiac index also is reduced. The value of SvO_2 is limited because it does not describe the balance of oxygen in those tissues with fixed oxygen extraction. The kidney, skin, and resting muscle can maintain viability during reduced blood flow by augmenting oxygen extraction. The heart and brain, on the other hand, extract oxygen nearly maximally at rest, and their vulnerability to ischemia is not reflected by widened oxygen extraction.

Postoperative hypertension is common and may be a consequence of several factors, such as inadequate sedation, hypoxemia, hypercarbia, activation of cardiogenic reflexes, vasoactive drug administration, and withdrawal of beta-blocking agents; however, intense vasoconstriction accounts for most of the hypertension. Failure to control the blood pressure increases the risk of aortic tear, elevates myocardial oxygen demand, leading to the possibility of decreased subendocardial perfusion and ischemia.

As a consequence of fluid administration, the patient seen in the ICU just after an operation on cardiopulmonary bypass usually weighs 2 to 5 kg more than preoperatively. Urine output is typically high in patients with good LV function. If urine output is low, intravascular volume or CO may be low. Inappropriate antidiuretic hormone excretion commonly exists as a consequence of operative trauma. The patient is frequently treated with IV nitroglycerin and other afterload-reducing and venodilating agents. These agents shift blood volume to the periphery and consequently decrease preload. These factors tend to reduce urine output.

TABLE 148.1

CAUSES OF LOW CARDIAC OUTPUT

- Inadequate preload
  - Volume deficit
  - Excessive positive end-expiratory pressure
- Increased afterload
  - Vasoconstriction from endogenous catecholamines (sympathetic stimulation)
    - Painful stimuli
    - Nonpulsatile flow during cardiopulmonary bypass
    - Hypothermia
    - Preexisting hypertension
  - Vasoconstriction from exogenous catecholamines
  - Aortic stenosis
  - Idiopathic hypertrophic subaortic stenosis
- Myocardial depression
  - Uncorrected mechanical lesions
    - Incomplete coronary revascularization
    - Valvular stenosis or insufficiency
    - Mechanical valve malfunction
  - Functional depression (lasts □24 h)
  - Coronary spasm
  - Inadequate myocardial protection intraoperatively
    - Myocardial edema
    - Myocardial ischemia
    - Myocardial necrosis-infarct
- Metabolic derangement
  - Hypocalcemia
  - Hypomagnesemia
  - Hypoxia
  - Acidosis
- Arrhythmias
- Conduction defects
- Tamponade
- Pharmacologic depression
  - Anesthetic agents
  - Quinidine
  - Procainamide
  - Lidocaine
  - Beta-blockers
  - Calcium channel blockers

Treatment of Low Cardiac Output

Low CO in the postoperative period is associated with a higher incidence of respiratory, renal, hepatic, and neurologic failure. Treatment of low CO first requires an analysis of possible causes (Table 148.1). Operative complications, such as coronary graft closure, inadequate revascularization, poor myocardial protection, valve malfunction, or paravalvular leak, can cause pump dysfunction. Graft closure or acute coronary occlusion can have immediate hemodynamic effects (a fall in CO and a rise in left-sided filling pressures). Early graft failures are usually due to technical factors, but perioperative myocardial infarction due to coronary spasm can also occur in operated or in nonoperated vessels [20]. When the diagnosis of spasm is entertained and ST-segment changes as well as wall motion abnormalities occur, aggressive management with nitroglycerin and diltiazem should be instituted [21]. If these drugs are unsuccessful in reversing the hemodynamic deterioration, cardiac catheterization or reexploration, or both, inspection of the grafts should be considered [22]. Myocardial depression can be seen in the first 24 hours as a result of the operation. Common causes of perioperative pump dysfunction include arrhythmias, tamponade, hypovolemia, myocardial infarction, systemic acidosis, electrolyte imbalance, and hypoxia.

Early graft patency is an important determinant of postoperative ventricular function and performance on stress tests. On the other hand, the occurrence of perioperative myocardial infarction without hemodynamic compromise has not been shown to be significantly related to graft patency, late survival, or cardiac performance status [23]. The treatment of perioperative infarction consists of therapy to maintain CO, including afterload reduction, especially with nitroglycerin and beta-blockade, if tolerated.

If an obvious cause of low CO is not identified, a systematic approach toward optimizing pump function should be undertaken (Table 148.2). An easy way to organize this approach is by examining preload, afterload, rate, contractility, and rhythm. Because CO is the product of SV and HR (CO = SV ∞ HR), either can be increased.

On arrival to the ICU, many patients exhibit intravascular volume depletion, despite an increase in total body water. The rewarming that is actively done during the early postoperative period causes progressive peripheral vasodilatation and relative

TABLE 148.2

TREATMENT OF LOW CARDIAC OUTPUT

Treat or exclude complications
Valve malfunction (reoperate)
Coronary graft occlusion (reoperate)
Tamponade (reoperate)
Bleeding (reoperate)
Coronary spasm (nifedipine, 10 mg sublingually)
Treat arrhythmias by optimizing heart rate
Increase rate to 90–100 beats/min
Atrial pacing if no heart block
Atrioventricular pacing if heart block
BP (systolic) ≥ 100, or BP (MAP) ≥ 85
Low LAP (< 15 mm Hg)
Give volume (packed cells) if Hct < 25%
Give Ringer's lactate or hetastarch if Hct ≥ 25%
Continue stepwise treatment with volume and dilators until cardiac index adequate (≥ 2.5); do not allow LAP to remain > 15 mm Hg or BP to remain < 100
High LAP (≥ 15 mm Hg): Begin nitroprusside[a] or nitroglycerin, 0.2–0.6 µg/kg/min and increase until desired effect obtained
BP (systolic) < 100 or BP (MAP) < 85
Low LAP (< 15 mm Hg)
Give volume (packed cells) if Hct < 25%
Give Ringer's lactate or hetastarch if Hct ≥ 25%
High LAP (≥ 15 mm Hg): if BP still low
Give epinephrine 2–5 µg/min; increase gradually to 10 µg/min maximum; dobutamine, milrinone
When BP ≥ 100, begin nitroprusside,[a] 0.2–0.6 µg/kg/min; increase until desired effect obtained

[a] See text for alternative drugs.
Note: If BP and cardiac output still low, insert intra-aortic balloon pump.
BP, blood pressure; Hct, hematocrit; LAP, left atrial pressure; MAP, mean arterial pressure.

hypovolemia. The goal MAP is 70 to 80 mm Hg [13]. Normovolemia is essential and can be accomplished with autotransfusion, normal saline, lactated Ringer's solution, albumin (25% solution), or hydroxyethyl starch (hetastarch). In the Saline versus Albumin Fluid Evaluation (SAFE) study involving almost 7,000 patients, albumin had no proven advantage over crystalloids in critically ill patients, although a larger volume of crystalloid is necessary compared to colloid [24]. Hetastarch can provide volume expansion for more than 24 hours. At doses more than 20 mL per kg, it can cause a decrease of factor VIII levels and platelets. Urticarial and anaphylactoid reactions as well as pancreatitis can occur with the use of this product [25].

In addition to ensuring adequate volume resuscitation, clinician should optimize cardiac rate and rhythm. Ventricular filling occurs during diastole and is augmented by a properly timed atrial contraction. If the heart rate is excessive to the extent that there is inadequate time for ventricular filling, cardiac output will be affected. This is particularly true of the hypertrophied or pressure overloaded ventricle and a heart rate of 90 to 100 beats per minute is optimal [13]. After cardiac surgery, atrial fibrillation, sinus bradycardia, and varying degrees of heart blockage can occur. These arrhythmias are usually transient and may be related to perioperative beta-blockade, hyperkalemic damage during the administration of cardioplegia, or unprotected ischemia of the conduction system [26]. Permanent injury to the conduction system is usually the result of surgically induced trauma.

Temporary atrial and ventricular wires are placed at the time of surgery and can be used to maintain CO. Simple atrial pacing (at a rate of 80 to 100 beats per minute) for the treatment of sinus bradycardia may effectively augment CO. Atrial pacing can aggravate a first-degree heart blockage and introduce an atrioventricular dyssynchrony. In this situation, atrioventricular sequential pacing should be attempted. The optimal atrioventricular interval is usually in the range of 100 to 175 milliseconds, depending on the HR. The advantage of atrial pacing over atrioventricular sequential pacing is the maintenance of the normal anatomic pattern of ventricular activation. Loss of the normal sequence of activation depresses ventricular function by approximately 10% to 15%.

Although a low MAP is most common, occasionally one must lower excessive afterload to improve cardiac output. Decreasing systemic vascular resistance (SVR) decreases the heart's oxygen demand. In patients with relatively normal LV function, nitroprusside reliably decreases SVR and increases CO, whereas nitroglycerin may lower CO, perhaps as a result of too great a decrease in cardiac preload (left atrial pressure).

The PV relationship of the left ventricle can be used to predict improvements in stroke volume secondary to reductions in afterload. The therapeutic results depend on the inotropic state of the ventricle. Ventricles with the poorest contractility benefit the most from afterload reduction. If the ventricle is operating on an end-systolic PV relationship with a shallow slope (depressed contractility), reducing afterload (and end-systolic pressure) results in a relatively large increase in SV (Fig. 148.3).

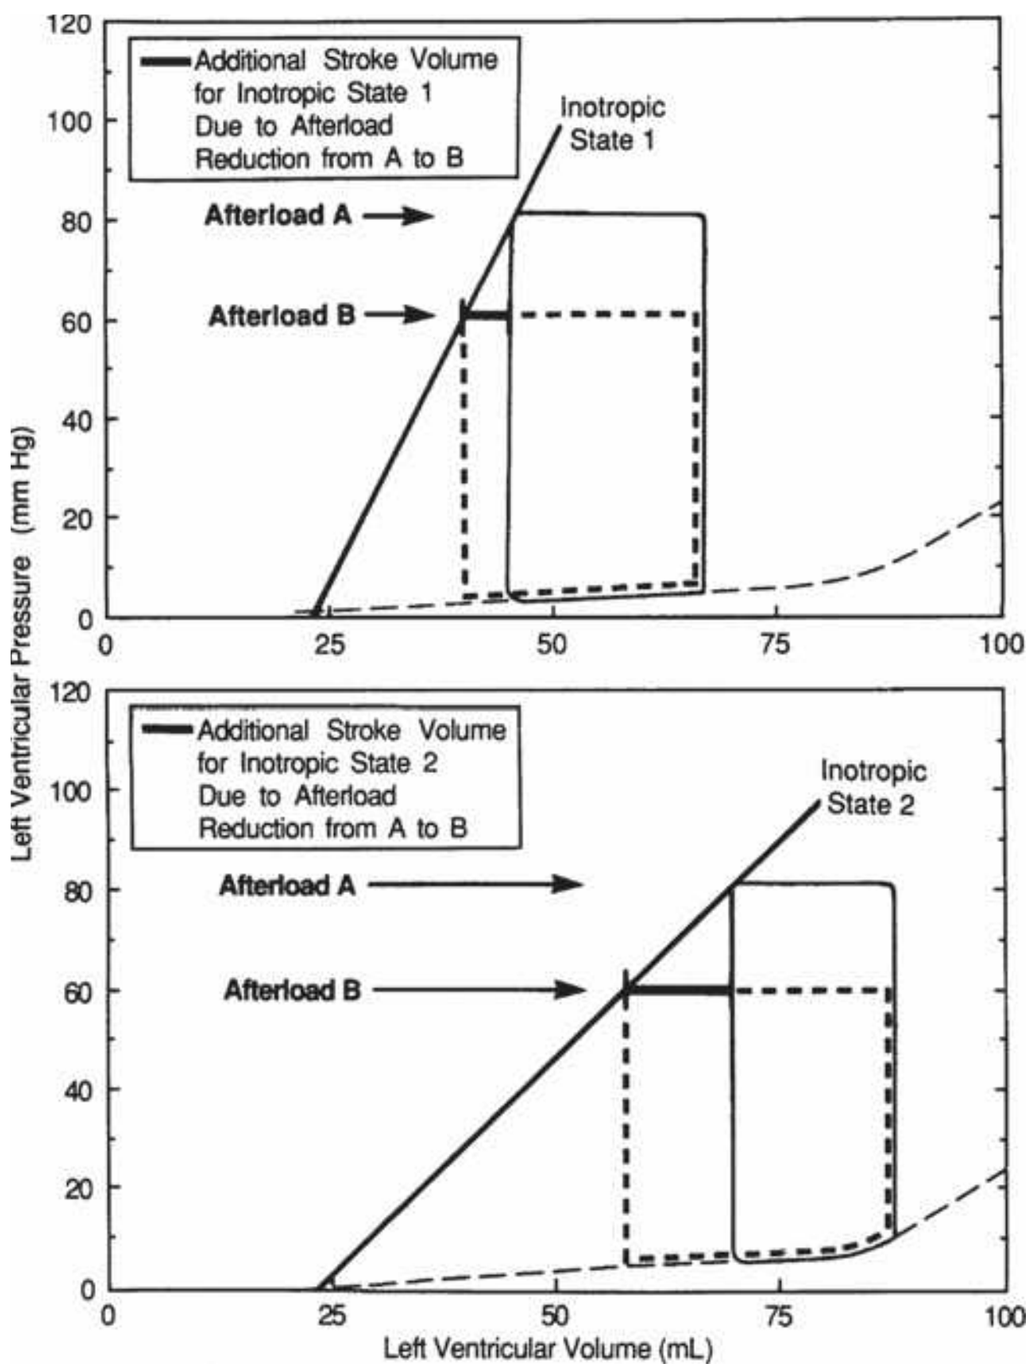

FIGURE 148.3. The improvement in stroke-volume that can be achieved with a reduction in afterload (and consequently, a reduction in end-systolic pressure) depends on the inotropic state of the myocardium. There is more to be gained by afterload reduction in a ventricle with depressed inotropic state (a smaller slope of the end-systolic pressure-volume relationship).

TABLE 148.3

VASODILATORS USED IN POSTOPERATIVE CARDIAC SURGERY PATIENTS

Drug	Dosage range[a]	Activity						
		Arterial	Venous	Onset	Duration	Mechanism	Comments	Toxicity
Nitroprusside (Nipride)	0.2–5.0 µg/kg/min	+3	+2	Immediate	Immediate	Direct vasodilator	May increase myocardial ischemia	Cyanide and thiocyanate
Nitroglycerin	0.3–5.0 µg/kg/min	+1	+4	Immediate	30 min	Direct vasodilator	Improves myocardial ischemia	—
Clevidipine	2–6 mg/h	+3	−	Immediate	Immediate	Direct vasodilator	Low incidence of side effects in comparison to other vasodilators	
Hydralazine	5–10 mg IV	+4	0	15–30 min	2–6 h	Direct vasodilator	Reflex increases cardiac output and heart rate; may cause angina in ischemic heart	None short term
Enalaprilat	10–20 mg IM 0.625–1.25 mg IV	+4	0	20–80 min 15 min	4–6 h	Angiotensin-converting enzyme inhibition	Use cautiously with renal impairment	May cause hyperkalemia; rare angioedema

[a]Initiate treatment at low end of dosage range.

Afterload reduction is also beneficial when residual mitral regurgitation and aortic insufficiency are present.

The postoperative patient with a low CO and an adequate blood pressure may benefit from afterload reduction using incremental doses of nitroprusside. Cardiac index and SV rise as filling pressures and blood pressure fall. Nitroprusside must be used with caution because of its potential for causing cyanide or thiocyanate poisoning, or both. Nitroprusside infusions generally should not exceed 8 µg per kg per minute (Table 148.3). In the presence of ischemia or an acute myocardial infarction, nitroglycerin increases regional myocardial flow and decreases ischemic ST segments toward normal, whereas nitroprusside may have an opposite and deleterious effect [27,28]. Improvement in cardiac function with inotropic agents is generally at the expense of increased myocardial oxygen demand. Inotropic agents, therefore, should be used only when manipulation of HR, rhythm, preload, and afterload are ineffective. When LV depression and low output persist, inotropic therapy must be used. A number of drugs and drug regimens can be used, including dopamine, dobutamine, epinephrine, norepinephrine, and amrinone or milrinone (Table 148.4).

Dopamine usually causes a small increase in HR, although in some patients severe tachycardia can be seen. Dopamine increases cardiac index by stimulating β-adrenergic receptors. At doses less than 3 µg per kg per minute, dopamine causes renal, splanchnic, coronary, and cerebral arterial vasodilatation by the activation of dopaminergic receptors. When dopamine is infused at a rate below 7.5 µg per kg per minute, it causes little change in SVR; above this rate, systemic vasoconstriction, due to stimulation of α-adrenergic receptors, increases. The usual dose range for dopamine is 1 to 20 µg per kg per minute.

Dobutamine is a synthetic catecholamine with minimal α-adrenergic activity but pronounced β_1- and β_2-adrenergic activity. It increases CO by increasing ventricular contractility and rate as well as causing peripheral vascular dilatation. For patients with a low CO and marked peripheral vasoconstriction, dobutamine is preferable to dopamine when the latter is used alone. Nevertheless, because dobutamine is a vasodilator, use of this drug in the presence of hypotension may lead to further hypotension. The usual doses for dobutamine are 5 to 20 µg per kg per minute.

Epinephrine is an α-, β_1-, and β_2-receptor agonist. It increases myocardial contractility and rate. It also increases ventricular irritability. Peripherally, its β-mediated effects (vasodilation) predominate at low doses, whereas α-mediated effects (vasoconstriction) predominate at high doses. The usual epinephrine dose is 1 to 10 µg per minute (0.015 to 0.15 µg per kg per minute).

Norepinephrine has α- and β-adrenergic activity. It increases systemic and pulmonary blood pressure myocardial contractility and CO. Internal mammary grafts remain innervated and are responsive to vasoactive drugs; saphenous vein grafts are not. Norepinephrine has been shown to decrease flow in internal mammary grafts less than phenylephrine in the early postoperative period [29]. The usual dosage is 4 to 10 µg per minute (0.06 to 0.150 µg per kg per minute).

Milrinone is an "inodilator," producing a positive inotropic independent of adrenergic stimulation and causing a reduction in systemic and pulmonary vascular resistance. Milrinone is a phosphodiesterase inhibitor that increases intracellular concentrations of cyclic adenosine monophosphate. Milrinone is a bipyridine derivative that is 20 times more potent than amrinone [30,31]. They are usually used as a second-line medication when a low CO persists despite catecholamines. Concomitant use of catecholamines usually offsets any associated vasodilation. The usual dosage of milrinone is a loading dose of 50 µg per kg over 10 minutes, followed by an infusion of 0.375 to 0.75 µg per kg per minute. Administration of milrinone over a period of 10 minutes prevents the vasodilation that is observed with rapid loading [32–34].

Arginine vasopressin may be helpful if hypotension persists despite adequate cardiac output, despite use of vasoactive

TABLE 148.4

INOTROPIC AGENTS USED IN POSTOPERATIVE CARDIAC SURGERY PATIENTS

Drug	Dose range	Activity					
		Alpha	Beta	Onset	Offset (min)	Heart rate[a]	Comments
Dopamine	1–3 µg/kg/min	Plus renal and mesenteric vasodilatation, dopaminergic	Same as alpha	Immediate	Few	Increase of 20%–30% non-dose related (rate: idiopathic increase to 50%–70%)	Minimal PVR at dose < 10 µg/kg/min; renal blood flow at low dose[b]
	1–10 µg/kg/min	+2	+2				
	> 10 µg/kg/min		+2				
Dobutamine	1–10 µg/kg/min	0	+4	Immediate	2–3	25%–30%	Very similar to isoproterenol; tachyphylaxis[b]
Epinephrine	1–2 µg/min	0	+2	Immediate	2–3	+1	Predominant effect varies with dose, marked vasoconstriction at high doses
	2–10 µg/min	+2	+2				
	> 10 µg/min	+2	0				
Norepinephrine	2–16 µg/min	+4	+2	Immediate	2–3	0	Pronounced vasoconstriction increases myocardial work; valuable in vasodilated patient or in use with vasodilator; may reduce renal perfusion, especially at higher doses[b]
Amrinone	10–30 µg/kg/min[c]			2–10 min	60–90	0	Increases output and decreases SVR; no tachyphylaxis; may cause thrombocytopenia
Milrinone	0.375–0.75 µg/kg/min[d]			5 min	2–4 h	+10%	Increases output; decreases SVR, PVR; may increase ventricular ectopic activity
Calcium chloride ($CaCl_2$)	100–200 mg	Restores ionized Ca^{2+} and acts synergistically with inotropic catecholamines	Same as alpha	Immediate	15	0	
Vasopressin	0.1–0.4 U/min			Immediate	Few	0	Works by V1 and V2 receptors to offset vasoplegia

[a]Depends on balance of direct cardiac effect versus reflex effects.
[b]May all decrease endocardial ratio (diastolic pressure time index/systolic pressure time index).
[c]Initiate amrinone with 0.75-mg/kg bolus over 5 min; repeat up to 2 times if necessary. Next, titrate infusion to increase cardiac index 25% to 40%.
[d]Initiate with 50-µg/kg bolus over 5 min.
PVR, pulmonary vascular resistance; SVR, systemic vascular resistance.

substances like epinephrine; "vasoplegia" or autonomic failure may be present. Vasopressin levels are low in normotensive patients after cardiac surgery and disproportionately low in patients with "vasodilatory shock." Acting on vascular V1 and renal V2 receptors, in doses ranging from 0.1 to 0.4 U per min, vasopressin can be effective in improving vascular tone. Care in its use must be taken in patients with marginal cardiac output as vasopressin may further compromise splanchnic blood flow [13].

Myocardial depression can occur as a result of excess citrate administration, as seen during massive blood transfusions. Administration of calcium chloride (100 to 200 mg IV) can augment contractility.

Occasionally, CO remains inadequate even after preload, afterload, and contractility are optimized. Additional energy can be added to the system by mechanical support. The most common method to achieve this is by the insertion of an intra-aortic balloon pump (IABP), through a femoral artery. By raising

aortic diastolic pressure, the IABP increases diastolic pressure time index (DPTI). Because the IABP decreases afterload, it allows better ventricular emptying, which decreases LV diastolic pressure, thus further increasing DPTI. Coronary blood flow and CO increase. Proper balloon pump function requires synchronization with the cardiac cycle using the electrocardiogram or intra-arterial pressure tracing. The IABP is inflated with helium (40 mL) at the onset of diastole and deflated at the onset of systole. Weaning is usually accomplished by gradually reducing the proportion of augmented beats from 1:1 to 1:3 or by reducing balloon volume.

The insertion of the IABP is done preoperatively typically for unstable angina, LV failure, or cardiogenic shock. The balloon is inserted intraoperative mainly because of an inability to wean from bypass. The IABP has a high complication rate; these complications include aortic dissection, arterial perforation, femoral artery occlusion or thrombosis with leg ischemia, arterial emboli, and wound infection [35]. Although extremely rare, spinal cord ischemia resulting in paraplegia has been reported [36]. Blood seen in the lumen of the IABP signals rupture of the balloon and requires immediate removal.

Rarely, patients require even more mechanical assistance than can be provided with the IABP. In these cases, an option is the use of an LV-assist device [37,38]. This device pumps blood around the injured left ventricle, something that the IABP cannot do.

Hypotension

Causes of hypotension (MAP less than 70) include those for low CO (see Table 148.1). Therapeutic interventions for hypotension must prevent a catastrophic outcome. Untreated hypotension results in coronary hypoperfusion, arrhythmias, ventricular dysfunction, and death. Other possible causes of decreased afterload include pharmacologic vasodilatation or sepsis. Immediate treatment consists of norepinephrine (approximately 4 to 10 µg per minute) and volume repletion.

Evaluation of hypotension should include measurements of cardiac index, HR, and right and left atrial filling pressures. Hypovolemia presents with low filling pressures and low CO. LV depression presents with high left atrial and, sometimes, right atrial pressures and a very low CO. Bradycardia, especially in the presence of a poorly compliant postoperative ventricle, causes hypotension because the ventricle is unable to compensate by augmenting SV. Treatment of hypotension begins with optimization of rate (Table 148.5). If the rate is too slow, atrial (or, in the presence of complete heart block, atrioventricular) pacing should be used to bring the rate up to 90 to 100, depending on the response. Arrhythmias should be treated promptly (see "Arrhythmias" section of this chapter and Chapters 41–43). Intravascular volume should be optimized. Ventricular filling pressures in the early postoperative patient routinely need to be higher than normal to maximize SV, because the ventricle is stiff and dysfunctional after cardiopulmonary bypass.

TABLE 148.5

MANAGEMENT OF BRADYCARDIA

Diagnosis	Treatment
Sinus or nodal	Atrial pacing at 80–100 beats/min
AV block	AV sequential pacing at 80–100 beats/min (? digoxin toxic)
Atrial fibrillation	Ventricular pacing

AV, atrioventricular.

Echocardiography provides for a real time measure of the filling status of the ventricles. It avoids the pitfalls of a Swan as it can measure volume and does not use pressures as a surrogate for volume. Also right and left sided outputs can be calculated. It provides for a very reliable and quick way to evaluate and treat hypotension.

Tamponade

Cardiac tamponade results from the accumulation of fluid or clotted blood within the mediastinum, creating a restriction for diastolic filling of both ventricles. The findings associated with tamponade in the immediate postoperative period include: (a) elevation and equalization of the central venous pressure, pulmonary diastolic pressure, left atrial pressure (pulmonary artery capillary wedge pressure), and right ventricular diastolic pressure (central venous pressure); (b) low urine output; (c) excessive chest tube drainage; (d) mediastinal widening on chest radiograph; and (e) low CO and hypotension. Echocardiographic findings of tamponade include RV diastolic collapse, right atrial systolic collapse, IVC plethora, and respirophasic changes in transmitral filling.

The treatment for cardiac tamponade is early reoperation. The patient may temporarily respond to some simple supportive measures such as reducing airway pressure, infusing intravascular volume expanders, and providing inotropic support. Myocardial dysfunction and myocardial edema reduce the amount of space occupied by fluid and clot required to cause tamponade physiology [39].

Although cardiac tamponade usually presents within the first 24 hours postoperatively, it can present as a subacute syndrome as late as several weeks following surgery. The symptoms are often nonspecific and can include malaise, low-grade fever, diaphoresis, dyspnea, chest pain, and anorexia. Transesophageal or transthoracic echocardiography may demonstrate retained clot and blood or wall abnormalities characteristic of tamponade (diastolic collapse of the right atrium and right ventricle). On occasion, right-sided heart catheterization may be necessary to establish the diagnosis (equalization and elevation of filling pressures).

Hypertension

Postoperative hypertension frequently occurs after coronary artery bypass grafting in patients with good LV function, or after corrective surgery for aortic stenosis or idiopathic hypertrophic subaortic stenosis. Postoperative hypertension is a common problem in patients with a history of hypertension. Other causes of hypertension may also involve hypoxemia, hypercarbia, shivering, or anxiety. Hypertension is deleterious because it increases myocardial work and it increases wall tension that may result in rupture of aortic suture lines. The treatment of choice for systolic blood pressures higher than 150 mm Hg is nitroprusside. Beta-blockers can be added for additional blood pressure reduction.

In some patients with a hyperdynamic left ventricle (normal SV and increased peripheral resistance), sodium nitroprusside treatment may be ineffective. In this group, nitroprusside reduces peripheral vascular resistance, which causes reflex sympathetic stimulation. This unmasks the underlying hyperdynamic heart, and SV, pulse pressure, and HR increase [40,41].

Beta-blockers are also effective in controlling hypertension in the cardiac surgical patient; esmolol can be given as a 500 µg per kg loading dose and an infusion of 50 to 300 µg per kg per minute [41]. Enalaprilat, 0.625 to 1.25 mg IV, can also be effective. Diuretics are valuable for managing patients with difficult-to-control hypertension. If the hypertension existed

preoperatively, long-term antihypertensive agents should be restarted.

Arrhythmias

Arrhythmias primarily affect CO and blood pressure. At Beth Israel Deaconess Medical Center in Boston, most cardiac surgical patients undergo placement of temporary epicardial pacing wires—two ventricular and two atrial electrodes. The wires are used diagnostically or therapeutically in approximately 80% of patients.

Atrial wires facilitate the diagnosis or conversion of supraventricular tachycardia, especially atrial flutter. By pacing at a rate faster than the intrinsic atrial rate, the atrium becomes entrained. The critical entrainment rate is evidenced by lead II P waves changing from negative to positive. When the critical entrainment rate has been reached for the critical duration (usually 10 to 20 seconds), the atrial pacer may be slowed and then stopped; the atrial rhythm follows the slowing and then converts to sinus rhythm mechanism. The atrial electrical activity can be recorded on a unipolar precordial (V) lead while standard limb leads are in place; the atrial wires can be attached to the right and left arm leads (with standard leg leads in place) and the electrical signals recorded on a bipolar lead (I) or unipolar leads (II or III). Homogeneous atrial flutter with an atrial rate of 240 to 340 breaks more easily than a more rapid atrial flutter [37,38].

The primary use of the pacing wires postoperatively is to increase a slow HR (see Table 148.5). For sinus bradycardia, atrial pacing should be used. For a junctional slow rhythm, atrial pacing should be tried, but if any atrioventricular block exists, sequential atrial and ventricular pacing are necessary. For complete heart block, sequential atrial and ventricular pacing should be used. Postoperatively, CO is higher with atrial than with ventricular pacing. In patients with LV hypertrophy, the difference may be as great as 40% [42], because these patients have a greater need for atrial systole to fill the poorly compliant, hypertrophied ventricle.

TREATMENT OF SPECIFIC ARRHYTHMIAS

Ventricular arrhythmias can be caused by myocardial ischemia, hypokalemia, hypomagnesemia, hypoxia, acidosis, sympathetic stimulation, or irritation related to malpositioned intracardiac catheters. Initial treatment should be directed at eliminating any of the triggering factors. Atrial pacing at a more rapid rate may exceed the rate of firing of an ectopic ventricular focus and then suppress its emergence. In the early postoperative period, ventricular ectopy often occurs when the serum potassium concentration is in the low normal range. Keeping the potassium concentration between 4.5 and 5.0 mEq per L and the magnesium more than 2 mEq per L tends to suppress ectopic beats [43,44]. It is not necessary to treat isolated premature ventricular contractions (PVCs) because they are most likely benign. However, if PVCs are more than six per minute, multifocal, or present in salvos of three or more consecutive beats, treatment is then necessary. The easiest therapy for PVCs is atrial pacing at a rate faster than the patient's baseline. Amiodarone bolus IV, followed by an IV infusion usually suppresses them. Among the risks of treatment are the proarrhythmic effects of most available agents [45].

Ventricular tachycardia (VT) can occur at a relatively slow rate and depress blood pressure minimally, or it can occur at a rapid rate, leading to severe LV depression. In either case, VT can degenerate into ventricular fibrillation. When VT markedly depresses blood pressure, direct current cardioversion should be performed immediately. Cardioversion should be performed using a synchronized (with the QRS) mode with 200 J, escalating if necessary to 400 J. In hemodynamically stable patients, lidocaine or amiodarone sometimes terminates VT and obviates the need for cardioversion (see Chapter 6).

TABLE 148.6

MANAGEMENT OF VENTRICULAR ARRHYTHMIAS

Diagnosis	Treatment
Premature ventricular contractions	Atrial pacing to suppress automatic focus; Amiodarone bolus, plus drip; keep K^+ 4.5–5.0; eliminate acidosis; $Mg^{2+} > 2$
Ventricular tachycardia	If BP adequate: Amiodarone bolus plus lidocaine drip; keep K^+ 4.5–5.0; eliminate acidosis ischemia; if tachycardia persists, electrical cardioversion $Mg^{2+} > 2$ If BP low: immediate electrical cardioversion, followed by lidocaine; maintain K^+ 4.5–5.0; amiodarone, 150 mg IV over 10 min
Ventricular fibrillation	Immediate defibrillation

BP, blood pressure.

Ventricular fibrillation is fatal if not treated immediately. This arrhythmia mandates immediate electrical defibrillation (asynchronous mode) using the same energy levels mentioned above (see Chapter 6). An overall approach to ventricular arrhythmias in the postoperative cardiac surgery patient is found in Table 148.6. Amiodarone by IV administration may be useful in the treatment and prophylaxis of ventricular fibrillation or tachycardia.

Supraventricular tachycardias occur commonly during the first few postoperative days. They develop in 11% to 40% of patients after coronary bypass grafting and more than 50% of patients after valvular surgery [46]. Premature atrial contractions may progress to either atrial flutter or atrial fibrillation. These arrhythmias occur in 25% to 33% of postoperative cardiac surgical patients and may be due to unprotected atrial ischemia, atrial stretch, administration of hyperkalemic cardioplegic solutions, or pericarditis secondary to surgery [47]. Prophylactic treatment of all post–heart surgery patients with beta-blockers reduces the incidence of atrial fibrillation [48–50]. Patients who were taking beta-blocking agents preoperatively benefit more from beta-blocker prophylaxis than do those who were not taking beta-blockers before operation. Most recently, the Prophylactic Oral Amiodarone for the Prevention of Arrhythmias That Begin Early After Revascularization, Valve Replacement, or Repair (PAPABEAR) data demonstrated that oral amiodarone prophylaxis of atrial tachyarrhythmias after cardiac surgery is effective [51].

Atrial fibrillation is the most common arrhythmia affecting patients in the postoperative period and is more common in the elderly and those undergoing valvular surgery. Other supraventricular tachycardias can also affect the patient during the first 24 to 36 hours after surgery. When junctional tachycardia occurs, the rapid rate causes inadequate ventricular diastolic filling. In addition, the lack of a normal atrioventricular delay causes mitral and tricuspid regurgitation, because the ventricles contract before the mitral and tricuspid valves have closed. For atrial fibrillation, the class I recommendation of the American College of Cardiology practice guidelines is to administer AV

nodal blocking agents [52], such as diltiazem or a beta-blocker. Use of beta-blockers must be done with care particularly in the immediate postoperative period when myocardial function is still compromised. Despite the current recommendation, the mainstay of treatment is conversion to and maintenance of sinus rhythm with amiodarone (150 mg IV over 10 minutes followed by an infusion of 1 mg per minute for 6 hours and then 0.5 mg per minute for 6 hours) (13 IV ibutilide, a class III potassium channel blocker, can also acutely convert atrial fibrillation or flutter after cardiac surgery) [49].

Atrial flutter often can be treated effectively with atrial overdrive pacing, using the atrial epicardial electrodes (usually at rates of 350 to 400 beats per minute). Atrial fibrillation ordinarily cannot be treated using overdrive pacing. Indeed, atrial fibrillation can be induced when these techniques fail to convert atrial flutter to sinus rhythm. The ventricular response to atrial fibrillation, however, is sometimes slower and better tolerated than that of the ventricular response to atrial flutter. Pharmacologic therapy for atrial flutter has two goals: (a) blockade of the atrioventricular node to decrease ventricular response and (b) conversion to sinus rhythm. IV diltiazem (10 to 20 mg, followed by 5 to 15 mg per hour) or esmolol (500 µg per kg loading dose and an infusion of 50 to 300 µg per kg per minute) slows the rate by increasing the degree of atrioventricular block. Esmolol may be more effective in restoring sinus rhythm [53]. Beta-blockers and calcium channel blockers should not be used concomitantly. Procainamide (see Chapter 42) may convert the rhythm to sinus mechanism. If pharmacologic therapy fails to convert atrial flutter, electrical cardioversion can be used [54]. An overall approach to supraventricular and ventricular arrhythmias as well as common drug therapy for rate control in the postoperative cardiac surgery patient is found in Table 148.7.

Respiratory System

Respiratory dysfunction can complicate the postoperative course in approximately 8% of cardiac patients. Cardiac surgery reduces functional residual capacity, causes atelectasis [55], increases shunting, and decreases arterial oxygenation. The alveolar–arterial oxygen tension gradient typically widens on the day of and the day after surgery, but then the gradient usually narrows. A positive end-expiratory pressure (PEEP) of 5 cm H_2O helps to restore functional residual capacity toward normal [56].

Most cardiac surgical patients arrive in the cardiac surgical ICU requiring mechanical ventilation (see Chapter 58). The initial ventilator settings are typically as follows: rate, 8 to 10 breaths per minute; fractional inspired oxygen (FIO_2) concentration, 1.0; tidal volume, 6 ml per kg predicted body weight. Lung protective ventilation is recommended in patients with established acute lung injury [57]. After the first set of arterial blood gas measurements returns, the FIO_2 is decreased to maintain the oxygen pressure at 80 to 100 mm Hg; minute volume is regulated to keep carbon dioxide pressure at approximately 40 mm Hg. Oxygen consumption and carbon dioxide increase as the patient warms. PEEP is added as needed to keep FIO_2 below 0.5. High levels of PEEP may be necessary when there is a large intrapulmonary shunt.

Patients should be extubated in the first 6 hours post routine cardiac surgery, unless specific hemodynamic concerns apply. Sato and colleagues have demonstrated extubation within is feasible (9.5%) with low complications in on pump CABG'S. Extubation within the first few hours postoperatively can be done in most patients with good LV function without significant valvular disease and uneventful weaning from cardiopulmonary bypass. If hemodynamic instability is present, controlled ventilation allows better control of arterial pH and carbon dioxide pressure as well as more vigorous fluid administration without as much worry about adverse pulmonary effects. In the presence of excessive mediastinal bleeding, continued mechanical ventilation permits a smoother return to the operating room if re-exploration is necessary (see the section Bleeding).

A complete discussion of management of mechanical ventilation (e.g., initiation and discontinuation) can be found in Chapters 58, 59, and 60. Contraindications to weaning from mechanical ventilation include unstable hemodynamics, excessive bleeding, severe acid–base abnormalities, unstable arrhythmias, and patients who are still warming. In patients who are doing well from cardiac and respiratory standpoints, the presence of an IABP is not a contraindication to weaning and extubation.

Some patients arriving in the cardiac surgical ICU may have undergone minimally invasive procedures such as single-vessel bypass grafting through a small anterior thoracotomy [59]. These patients typically have been extubated in the operating room. They may have more pain than patients who have undergone a standard median sternotomy and have a need for careful balance of pain relief against respiratory depression. They may also have areas of myocardium that have not been revascularized.

Rarely, the postoperative course is complicated by fulminant, noncardiogenic pulmonary edema. Left atrial pressures are low, and the protein content of the edema fluid is high—70% to 96% that of plasma [60]. Some patients may present with "postpump syndrome." In its most severe form, these individuals have a coagulopathy, pulmonary dysfunction with hypoxia, renal and cerebral insufficiency, and a diffuse inflammatory response that is characterized by increased capillary permeability and leakage of fluid into the interstitial space with diffuse edema, fever, and leukocytosis. The cause of these derangements may be activation of complement (C3 and C5) during cardiopulmonary bypass [61,62]. Various drugs have been implicated, including protamine and plasma protein fractions [62].

The phrenic nerve may be injured at the time of surgery by surgical manipulation and by cooling [63]. In a patient with good pulmonary function preoperatively, the postoperative course is not affected. However, in the patient with marginal

TABLE 148.7

MANAGEMENT OF SUPRAVENTRICULAR ARRHYTHMIAS

Diagnosis	Treatment
Premature atrial contractions	Atrial pacing at faster rate
Atrial flutter	If markedly BP or ischemia: DC cardioversion, followed by Amiodarone If BP adequate and no ischemia: Amiodarone overdrive pacing; if heart rate > 120 beats/min; diltiazem or esmolol to slow
Atrial fibrillation	If markedly ↓ BP or ischemia: DC cardioversion, followed by Amiodarone If BP adequate and no ischemia Amiodarone; if heart rate > 120 beats/min, diltiazem or esmolol

↓, low; BP, blood pressure; DC, direct current.

reserves, prolonged ventilatory support may be necessary. Poor diaphragmatic function must be suspected if there is paradoxic breathing when weaning, elevated diaphragm on chest radiograph, or decreased vital capacity. The diagnosis can usually be made with fluoroscopy.

Renal System

Renal function is, in many respects, a reflection of cardiac function. The risk factors commonly seen in acute renal failure include: (a) preoperative renal failure, (b) diabetes mellitus, (c) postoperative hypotension, (d) old age, and (e) prolonged operation. With adequate CO, most post-cardiac surgical patients have a high urine output, usually more than 50 mL per hour.

Many patients exhibit a marked diuresis in the immediate postoperative period with urine outputs of 200 to 500 mL per hour. The cause of this diuresis is multifactorial. Hypothermia diminishes flow to the outer renal cortex, decreases the free water clearance, and increases the filtration fraction [64]. Atrial distention may promote the release of atrial natriuretic factor and inhibit the release of vasopressin. A marked diuresis is generally not seen in those patients who have acute reductions in chronically elevated left atrial pressures [65].

Salt and water, accumulated during the intraoperative and early postoperative periods, are excreted over the first several days postoperatively. In patients who have good LV function, the diuresis usually begins on the second postoperative day.

Renal failure following heart surgery occurs in approximately 7% of post-cardiac patients. It carries a high mortality rate—27% to 47% [66,67]. Factors that increase the risk of perioperative renal failure include exposure to contrast media, perioperative use of aminoglycosides, nonsteroidal anti-inflammatory agents, or angiotensin-converting enzyme inhibitors.

Bleeding

Bleeding is a common problem after cardiac surgery and can be surgical or nonsurgical in nature. Persistent surgical bleeding may require reoperation. Nonsurgical bleeding can be multifactorial. Common causes include residual heparin activity, abnormal clotting factors, uncontrolled fibrinolysis, and thrombocytopenia. A careful history provides the best clue to intrinsic bleeding problems. Patients taking aspirin or antiinflammatory drugs usually have some degree of platelet dysfunction. Screening tests include PT, PTT, platelet count, and bleeding time. Specific abnormalities require further evaluation and correction before elective heart surgery is performed (see Chapters 108 to 109).

Intraoperative factors can predispose to bleeding. Inadequate heparin administration results in excessive consumption of clotting factors. Inadequate neutralization of heparin with protamine leaves residual heparin activity. Improved titration of heparin and protamine can be achieved by assaying heparin activity either indirectly with an activated clotting time or directly with a heparin analyzer [68,72]. Prolonged cardiopulmonary bypass causes platelet dysfunction and depletion and dilution of clotting factors. Disseminated intravascular coagulation occurs rarely, whereas a substantial body of evidence suggests that some primary fibrinolysis occurs routinely during cardiopulmonary bypass (see Chapter 108). We routinely use Tranexamic acid—intraoperatively at our institution.

A standard battery of screening tests enables an assessment of postoperative clotting mechanisms. For abnormal bleeding workup, we routinely obtain a PT, PTT, platelet count, and thrombin time (TT). When the TT is prolonged, a reptilase time distinguishes between excess heparin and fibrinolysis or consumption. A systematic analysis of clotting disorders may be based on the information given in Table 148.8. Platelets may

TABLE 148.8

EXCESSIVE BLEEDING FROM CLOTTING ABNORMALITIES IN THE POSTOPERATIVE CARDIAC SURGERY PATIENT

Cause	Tests							
	PT	PTT	TT	Platelet count	RT	FIB	FSP	Treatment
Heparin excess	N			N	N	N	N	Protamine sulfate titrated with activated clotting time or heparin assay
Excessive primary fibrinolysis		N–Sl		N		N		EACA, 4–8 g IV over 10 min followed by 1 g/h infusion for 5–8 h (until clotting factors N); FFP to regulate clotting factors
Compensated[a]	N							
Uncompensated[a]			N					
Excessive consumption[b]								Treat cause: FFP, cryoprecipitate, platelets
Thrombocytopenia or platelet dysfunction[c]	N	N	N		N	N	N	Platelets
Undefined[d]	Sl		Sl	N	N	N	N	FFP, cryoprecipitate, ? EACA

[a] *Compensated* refers to a minor fibrinolysis under which the body can keep up with the deficiencies; *uncompensated* refers to a rapid process under which the body cannot keep up with the fibrinolysis.
[b] Rare excessive consumption (also known as *disseminated intravascular coagulation*) always has associated secondary fibrinolysis.
[c] Platelets may be reduced in function as well as number.
[d] This group, probably of mixed etiology, occurs frequently.
EACA, epsilon-aminocaproic acid; FFP, fresh-frozen plasma; FIB, fibrinogen; FSP, fibrin-split products; N, normal; PT, prothrombin time; PTT, partial thromboplastin time; RT, reptilase time; Sl, slightly; TT, thrombin time.

be deficient in function as well as in number; cardiopulmonary bypass causes both defects [69].

Treatment is based on the diagnosis, although the diagnosis may not be straightforward because the pathogenesis of abnormal clotting may be mixed. Residual heparin effect is a common problem. Although heparin is fully reversed after the operation, heparin rebound can occur as heparin that was stored in body fat elutes into the blood. Heparin rebound is the most common cause of prolonged PTT and TT [70–72]. A normal reptilase time establishes this diagnosis, and additional protamine treats it.

Excessive primary fibrinolysis and excessive consumption may be indistinguishable by the tests listed, although the latter condition is usually characterized by a lower platelet count. Treatment of disseminated intravascular coagulation should be aimed at its cause. Treatment of primary fibrinolysis consists of repleting clotting factors and infusing an antifibrinolytic agent, epsilon–aminocaproic acid. Cryoprecipitate is the cold insoluble protein fraction of plasma that is rich in factor V, factor VIII, von Willebrand factor, and fibrinogen. It is more concentrated than fresh-frozen plasma, but, because it is a pooled product, it carries a higher risk of transfusion-related infection.

When platelet dysfunction is suspected, either on the basis of preoperative aspirin intake or prolonged cardiopulmonary bypass, platelets should be transfused. Platelet transfusion should be considered in any patient with a platelet count of 100,000 per mm^3 who continues to bleed despite aggressive procoagulant therapy [71,72].

In some centers, PEEP is used to help control bleeding after cardiac surgery. Some studies have shown a marked diminution of bleeding with levels of PEEP from 10 to 20 cm H_2O [73,74]; others have not [75].

The definition of *excessive bleeding* varies with each patient. As a general guideline, however, bleeding is excessive when drainage from chest tubes is more than 400 mL per hour for the first hour, 300 mL per hour for the first 2 hours, 200 mL per hour for the first 3 consecutive hours, or 100 mL per hour over the first 6 hours. A sudden increase in bleeding suggests an arterial source and mandates re-exploration. Bleeding that is sufficient to cause marked hypotension or tamponade also requires re-exploration. Massive bleeding necessitates emergency re-exploration, regardless of any clotting abnormalities [76,77].

When bleeding is so rapid that cardiac arrest is imminent, the patient should *not* be brought back to the operating room to control bleeding. Instead, the sternotomy should be reopened immediately in the ICU and digital pressure must be applied on the obvious site of bleeding. Transfusions are administered to increase blood volume and blood pressure. Then the patient is transferred to the operating room for definitive control of the bleeding [76,77].

The use of autotransfusion has reduced requirements for transfusing homologous blood. Blood for autotransfusion can be collected in a removable chamber that is part of the standard chest drainage system and is reinfused by gravity drainage, much like a homologous transfusion. It has been demonstrated that autotransfused blood is extensively defibrinated [77].

Fever and Antibiotics

Temperature fluctuations are expected after cardiac surgery. Systemic warming before the termination of cardiopulmonary bypass brings the core temperature to 37°C, but cooling subsequently occurs as heat transfers to the cool extremities. Patients routinely have temperatures in the 34°C to 36°C range when they arrive in the ICU. Warming, shivering, and vasodilatation occur during the first several hours. Temperatures in the 38°C to 39°C range should be expected at this time and require no further evaluation. However, fever during subsequent days is abnormal and requires the usual investigation (see Chapter 76).

Prophylactic antibiotics are widely recommended because of the seriousness of infections of the mediastinum, sternum, cardiac suture lines, and prosthetic valves. Although staphylococcal infections are the greatest concern, antibiotics with broad-spectrum coverage are generally used in preference to specific antistaphylococcal antibiotics [78,79]. Antibiotics should be stopped within 2 days; administration for a longer period offers no advantage [80].

One third of all hospital-acquired bacteremias and most candidemias are associated with vascular catheters [80]. Positive cultures are yielded in 1.5% of vascular catheters, and pulmonary artery catheters have the highest rate of colonization (2.1%) [81]. Catheter-related sepsis is most commonly due to coagulase-negative staphylococci and cannot be treated successfully with antibiotics unless the catheter is removed. A 7- to 10-day course of systemic antibiotics is then usually sufficient, although 4 to 6 weeks is necessary for cases of septic venous thrombosis.

Mediastinal infections are seen in approximately 1% of postoperative cardiac surgical patients. Risk factors include long operation, reoperation, low CO, and prolonged mechanical ventilation [82].

Psychological and Neurologic Dysfunction

Severe neurologic dysfunction occurs in 0.5% to 2.0% of coronary artery bypass graft operations. The incidence is higher in open chamber operations (4% to 10%). More commonly, subtle changes occur, such as cognitive dysfunction and ophthalmologic abnormalities. Central and peripheral nervous system dysfunction occur postoperatively. These events may be caused by emboli of air, clot, or other particulate matter [83].

Peripheral neuropathies can occur in the lower extremities and involve the femoral and peroneal nerves. Both neuropathies are preventable. Injuries of the brachial plexus can occur during sternal retraction secondary to compression or penetration of bone fragments [84,85]. Postoperative psychological dysfunction occurs in 40% to 60% of patients. Three types have been described: (a) an organic syndrome, which corresponds to the central metabolic neurologic dysfunction described above, (b) a postcardiotomy delirium, occurring after a lucid interval, and (c) a postcardiotomy depressive syndrome. Multiple risk factors for the latter two syndromes have been identified, including increased use of anticholinergic drugs, elevated preoperative blood urea nitrogen or decreased body weight, decreased body temperature while on cardiopulmonary bypass, and increased magnitude of overall preoperative sickness. Patients undergoing valve operations are affected more commonly than are patients undergoing coronary revascularization. The incidence seems to be higher in the elderly. Postulated pathogenic mechanisms include cerebral microemboli, cerebral red cell sludging, and sensory deprivation [85–88].

Treatment of the depressed patient begins with frequent reassurance and antidepressant therapy. In patients with postcardiotomy delirium, helpful measures include family support, general reassurance, and adequate sleep. Removing the patient from the ICU is desirable. Administration of small doses of IV haloperidol (1 to 2 mg or more) is very helpful in postcardiotomy delirium.

Gastrointestinal Complications

Gastrointestinal complications occur in approximately 1% of patients undergoing cardiac surgery. Patients with low CO and multiple organ failure are more prone to developing gastric and

duodenal bleeding (see Chapters 91, 92). Other gastrointestinal complications include cholecystitis, pancreatitis, intestinal obstruction, or ischemia. These complications can occur anytime from 2 days to 4 weeks after operation. A nasogastric tube is placed in the operating room and used routinely to prevent postoperative gastric distention. In most cases, the tube can be removed on the first postoperative day after endotracheal extubation.

Bowel ischemia and bowel infarction can be caused by embolism or low mesenteric flow. Emboli can originate from the heart, from an atherosclerotic aorta, or from suture lines communicating with the systemic circulation. Atrial fibrillation predisposes to the formation of atrial thrombi and embolization. Low CO, α-adrenergic pressors, and digoxin all increase the risk of low mesenteric flow (see Chapter 151). When bowel ischemia or infarction is suspected, laparotomy should be performed urgently.

To prevent upper gastrointestinal ulceration and bleeding, the gastric pH should be maintained above 4.0. Histamine-2–blockers or proton pump inhibitors and antacids may be required. Sucralfate is an effective prophylactic agent, and because it does not reduce acidity, it may decrease colonization of the upper gastrointestinal tract with Gram-negative organisms [89]. The early institution of enteral feedings may also reduce the incidence of gastrointestinal bleeding and complications. During low CO states, intestinal absorption is not totally suppressed, only delayed [90].

Pancreatitis is a potentially lethal complication of cardiac surgery. Its occurrence is probably related to decreased splanchnic blood flow, and therefore it tends to occur in patients who have associated cardiac complications. In approximately one third of cardiac surgical patients, there is a significant rise in the level of serum amylase (> 300 IU per L) by the second postoperative day [91]. However, clinically overt pancreatitis occurs in only approximately 2% of patients. Nonpancreatic hyperamylasemia is associated with increased mortality. The cause is unknown [92].

Endocrine Complications

Hyperglycemia is the most common endocrine abnormality requiring postoperative management and occurs frequently whether or not there was preexisting diabetes. Van de Berge et al. [93] published data from a mixed medical/surgical patient population of which a majority had undergone cardiac surgery demonstrating a significant reduction in morbidity and mortality for those who had tight glycemic control (at or below 110 mg per dL). However, in a recent study published by the NICE sugar study investigators, it was found that intensive glucose control increased mortality among adults in the ICU: a blood glucose target of 180 mg or less per deciliter resulted in lower mortality than did a target of 81 to 108 mg per deciliter [94]. During cardiac operations, insulin requirements under hypothermia are low but increase dramatically during rewarming. Insulin requirements usually decrease by the third postoperative day as the stress of surgery diminishes. However, intensive management of diabetes may be necessary when the patient resumes an oral diet. It is not uncommon for non–insulin-dependent diabetics to require insulin at the time of discharge.

Thyroid dysfunction can occur in seriously ill patients who were euthyroid preoperatively. The perioperative determination of thyroid function is difficult because of abnormalities in thyroxine binding and the fact that thyroid-stimulating hormone responds sluggishly to decreased triiodothyronine and thyroxine levels in critically ill patients. Advances in the care of the postoperative cardiac surgery patient, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 148.9.

TABLE 148.9

SUMMARY OF ADVANCES IN MANAGEMENT OF POSTOPERATIVE CARDIAC PATIENT

- Albumin has no proven advantage over crystalloids for resuscitation in critically ill patients [24].
- Prophylactic use of beta-blockers reduces the incidence of atrial fibrillation [42,49,50].
- The rapid shallow breathing index (RSBI) predicts success in weaning from mechanical ventilation [95].
- Hyperamylasemia occurs in one third of cardiac surgical patients but only 2% develop overt pancreatitis [91].
- Tight glycemic control increases morbidity and mortality [94].
- The routine use of pulmonary artery catheterization does not lead to improved clinical outcomes [5–9].

CHAPTER 149 ■ NONCARDIAC SURGERY IN THE CARDIAC PATIENT

STEVEN B. EDELSTEIN AND SCOTT W. BYRAM

Much has been written regarding the management of the patient with significant coronary artery disease presenting for noncardiac surgery. As the patient population in the United States continues to age, the issues surrounding risk assessment, perioperative optimization of drug regimens, and evidence-based improvement in overall outcome will persist. This chapter will focus on the issues of risk assessment and the current state of perioperative medical management for the cardiac patient presenting for intermediate- to high-risk surgical procedures.

PATHOPHYSIOLOGY OF PERIOPERATIVE CARDIAC COMPLICATIONS

It is well known that nonfatal perioperative myocardial infarction (MI) is an independent risk factor for subsequent MI and cardiac death within 6 months [1]. It has also been reported that those patients who have cardiac arrest after noncardiac surgery have a significantly elevated hospital mortality rate that has been reported as high as 65% [2].

Much research has been performed to elucidate the etiology of cardiac complications. A recent review of the subject matter by Grayburn and Hillis [3] identified some of the major issues and pathophysiologic changes that surround perioperative cardiac complications. It has become clear that plaque rupture occurs in about half of all perioperative myocardial infarctions [4]. Autopsy series also indicate that acute coronary thrombosis contributes to approximately one third of perioperative ischemic morbidity [5]. In fact, a study that involved patients who underwent coronary angiography prior to vascular surgery revealed that the majority of nonfatal myocardial infarctions occurred in arteries without high-grade stenosis [6].

The remainder of ischemic events appears to be the result of an imbalance between myocardial oxygen supply and consumption in the presence of existing coronary artery disease. It is well known that myocardial supply/demand can be adversely affected by anemia, hypotension leading to tachycardia, hypertension (resulting from postoperative pain or withdrawal of anesthesia), or shifts in intravascular volume. Also, alterations in the inflammatory and coagulation cascades can ultimately play a role in the development of myocardial ischemic events [3,7,8].

Obviously, the causes of perioperative myocardial infarction/ischemia are complex and not clearly elucidated. Devereaux et al. [9] have developed a summary of potential triggers for perioperative elevation in troponin levels, arterial thrombosis, and fatal myocardial infarction. It is also important to note that the majority of perioperative myocardial infarctions occur 1 to 4 days following noncardiac surgery [10] (Fig. 149.1).

DIAGNOSIS OF PERIOPERATIVE MYOCARDIAL INFARCTION IN NONCARDIAC SURGERY

A problem exists when discussing the issues of myocardial infarction and noncardiac surgery. Currently there is no consensus on diagnostic criteria as to what constitutes a perioperative MI in patients undergoing noncardiac surgery. Devereaux et al. [11], to overcome this issue, formulated a proposed diagnostic criterion for perioperative MI. The criteria were adapted from a consensus document of the European Society of Cardiology/American College of Cardiology (ESC/ACC) [12]. These criteria have been summarized in Table 149.1. The criteria rely on biochemical markers such as cardiac troponin, creatine kinase MB (CK-MB), and other objective measures such as

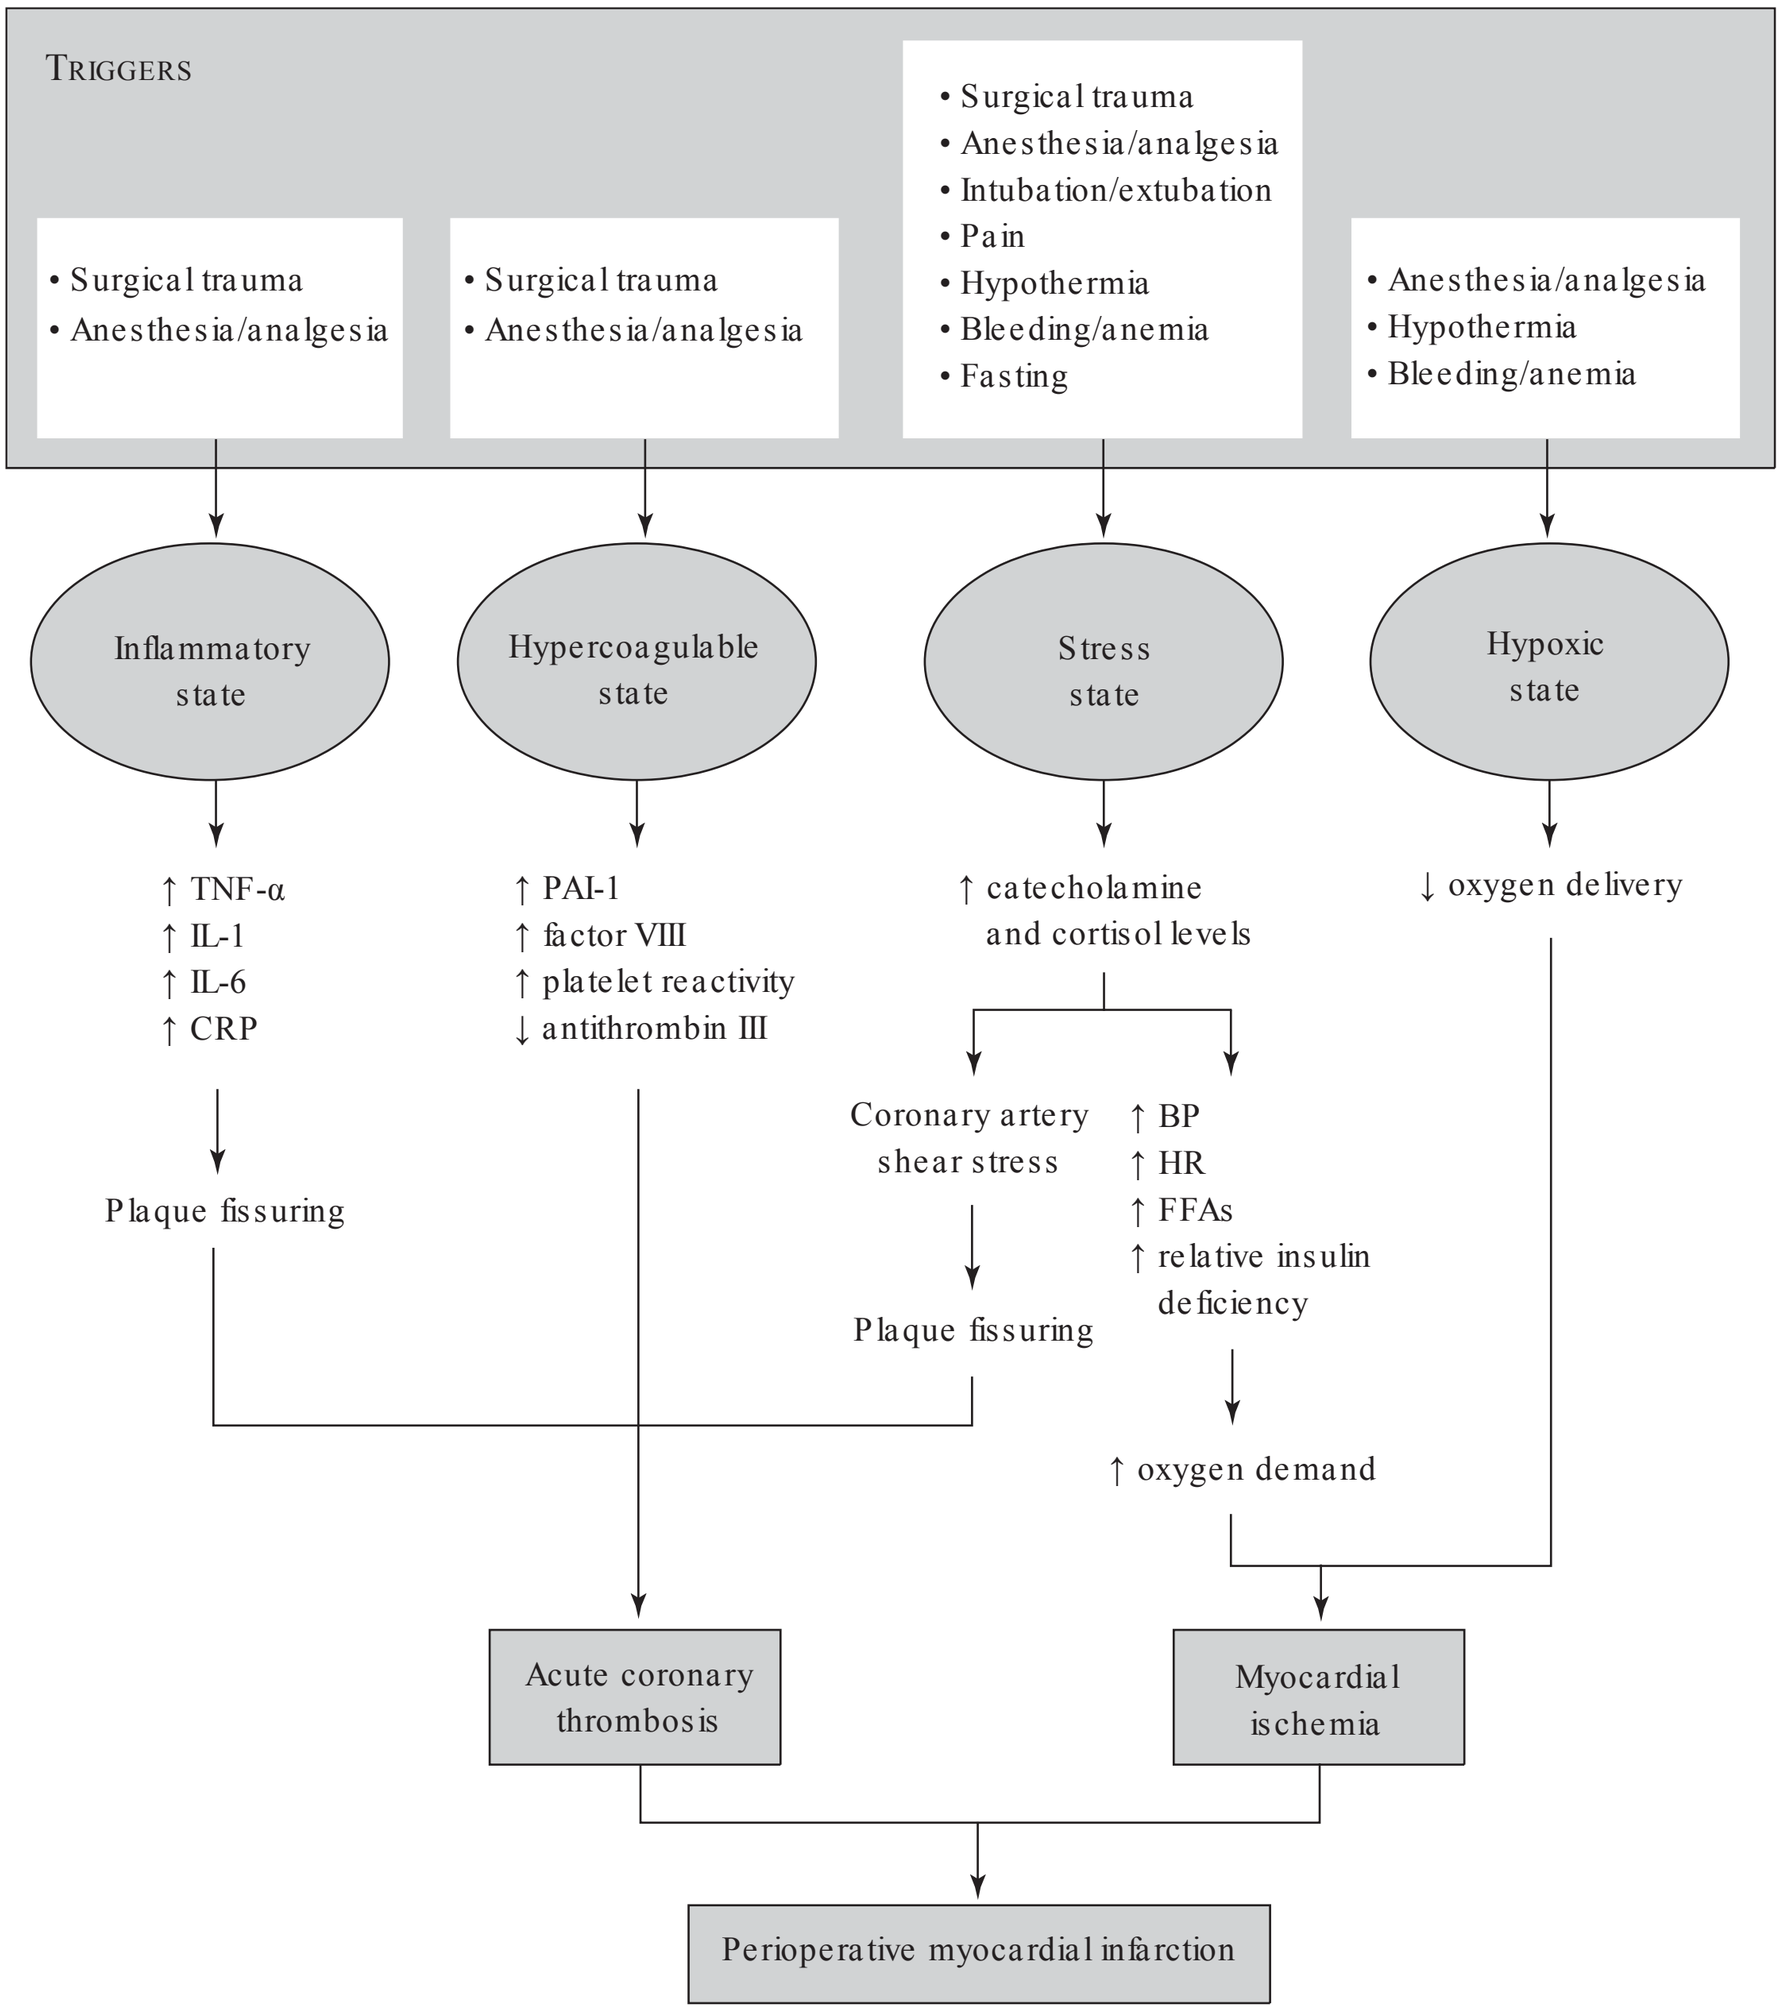

FIGURE 149.1. Potential triggers of states associated with perioperative elevations in troponin levels, arterial thrombosis, and fatal myocardial infarction. BP, blood pressure; CRP, C-reactive protein; FFAs, free fatty acids; HR, heart rate; IL, interleukin; PAI-1, plasminogen activator inhibiter-1; TFN-α, tumor necrosis factor-α. electrocardiogram (ECG) changes and echocardiographic evidence of ischemia.

HISTORY OF RISK ASSESSMENT

For many years, the goal has been to identify a risk assessment tool that would help to identify patients at risk for perioperative cardiac complications. Once identification of this patient subset has been made, interventions could then be performed to reduce the incidence of perioperative myocardial ischemia and infarction [13].

Dripps Index of the American Society of Anesthesiologists

Since the 1960s, the desire to find the optimal tool of risk assessment has been present. The American Society of Anesthesiologists (ASA) developed the Dripps Index as a way not only to identify risk among patient groups, but also to provide a common framework and communication device that could easily be distributed among differing medical specialties [14]. In 1970, Vacanti et al. [15] used the index to predict cardiac death within 48 hours of surgery. Within the five physical status

TABLE 149.1

PROPOSED DIAGNOSTIC CRITERIA FOR PERIOPERATIVE MYOCARDIAL INFARCTION IN PATIENTS UNDERGOING NONCARDIAC SURGERY

The diagnosis of perioperative MI requires any one of the following criterion:

Criterion 1: A typical rise in the troponin level or a typical fall of an elevated troponin level detected at its peak after surgery in a patient without documented alternative explanation for an elevated troponin level (e.g., pulmonary embolism); or a rapid rise and fall of CK-MB only if troponin measurement is unavailable.[a]

This criterion requires that one of the following criteria must also exist:

- Ischemic signs of symptoms (e.g., chest, arm, or jaw discomfort, shortness of breath, pulmonary edema)
- Development of pathological Q waves on ECG
- ECG changes indicative of ischemia
- Coronary artery intervention
- New or presumed new cardiac wall motion abnormality on ECG, or new or presumed new fixed defect on radionuclide imaging

Criterion 2: Pathological findings of an acute or healing MI

Criterion 3: Development of new pathological Q waves on an ECG if troponin levels were not obtained or were obtained at times that could have missed the clinical event

[a]Because CK-MB is both less sensitive and less specific in the perioperative setting compared with other settings and compared with troponin levels, it should be used for diagnostic purposes only when troponin levels are not obtainable.
CK-MB, creatine kinase; MB, isoenzyme; ECG, electrocardiogram; MI, myocardial infarction.
From Devereaux PJ, Goldman L, Yusef S, et al: Surveillance and prevention of major perioperative ischemic cardiac events in patients undergoing noncardiac surgery: a review. *CMAJ* 173(7):779–788, with permission. © 2000 CMA Media Inc.

grades identified, perioperative mortality rates range from 0% for ASA status 1 to 9.4% for ASA status 5. However, some of the major drawbacks to the utilization of the ASA score are that it was developed prior to multivariate clinical prediction rules, has limited utility, is very subjective, and is not uniformly reproducible [16].

Goldman Risk Assessment Tool

One of the original cardiac risk assessment tools developed in the 1970s by Goldman was an elaborate attempt to identify those patients at undue risk [17]. Risk assessment was based on several clinical variables. Goldman identified nine independent variables associated with perioperative cardiac events. These are included in Table 149.2, and consist of variables ranging from advanced age to the presence of significant valvular heart disease.

Each variable was assigned specific points and the patients were divided into risk class depending on the number of points generated. The highest classification—class IV (more than 26 points) was associated with a 78% incidence of major cardiac complications in the perioperative period. However, the drawback to use of the tool was the cumbersome nature, making the utilization of the Goldman risk assessment tool somewhat impractical.

TABLE 149.2

GOLDMAN'S NINE INDEPENDENT VARIABLES ASSOCIATED WITH PERIOPERATIVE CARDIAC EVENTS

Age over 70 years
Myocardial infarction in the preceding 6 months
Preoperative third heart sound or jugular venous distention
Significant valvular aortic stenosis
Emergency surgery
Intraperitoneal, intrathoracic, or aortic operation
More than 5 premature ventricular beats per minute documented at any time before operation
Rhythm other than sinus or the presence of atrial premature contractions on preoperative electrocardiogram
One or more markers of poor general medical condition

From Goldman L, Caldera DL, Nussbaum SR, et al: Multifactorial index of cardiac risk in noncardiac surgical procedures. *N Engl J Med* 297:845–850, 1977.

Detsky Modification of the Goldman Risk Assessment Tool

In 1986 Detsky attempted to modify the Goldman risk assessment tool by the addition of angina severity and a history of recent pulmonary edema [18]. Broad categories included the variables of coronary artery disease, Canadian Cardiovascular Society Angina Classification, alveolar pulmonary edema, suspected critical aortic stenosis, arrhythmias, poor general medical status, emergency surgery, and age 70 or older. However, just as with Goldman, this risk assessment tool was viewed to be exceedingly cumbersome. It appears that both indices may not have sufficient discriminate power to identify significant coronary artery disease in patients at the lower end of the spectrum of clinical risk [19] and both indices have been refuted or supported by an equal number of studies [20].

Adding to the controversy has been a prospective cohort study that compared the varying risk indices for patients undergoing noncardiac surgery. Gilbert et al. [16] compared 2,035 patients referred for consultation prior to noncardiac surgery and four risk indices: the Dripps Index of the ASA, the original cardiac risk index described by Goldman, the modified Detsky (which had been modified in 1997 by the American College of Physicians by stratifying patients into three risk groups) [21], and the Canadian Cardiovascular Society (CCS) Index for angina level [22]. The most striking finding of the study was that existing cardiac risk prediction methods had a generally poor degree of accuracy.

Eagle Criteria

Eagle et al. [23], while assessing the validity of dipyridamole-thallium stress testing in vascular patients, developed another set of risk criteria for patients undergoing major vascular surgery. The group found five clinical predictors of postoperative cardiac events. These included: presence of Q waves on resting ECG, history of angina, history of ventricular ectopy requiring treatment, diabetes mellitus requiring medical treatment, and age above 70 years. Also on logistic regression, the group noted two independent dipyridamole thallium test predictors of ischemic events that included thallium redistribution and ischemic ECG changes during or after pharmacologic stressing.

Lee Revised Cardiac Risk Index Stratification System

In an attempt to simply the Goldman index, Lee et al. [24] developed the Revised Cardiac Risk Index (RCRI) Stratification System. The RCRI for the first time identified six independent risk predictors associated with cardiac morbidity and noncardiac surgery. These included: high-risk surgery (examples included intraperitoneal, intrathoracic, or suprainguinal vascular reconstruction), a history of ischemic heart disease (excluding previous revascularization), a history of congestive heart failure (CHF), a history of cerebrovascular disease, preoperative treatment with insulin, and a preoperative serum creatinine level more than 2.0 mg per dL (greater than 177 µmol per L).

Cardiac events were determined to be myocardial infarction, cardiac arrest, pulmonary edema, or complete heart block. Four classifications were noted in which risk factors ranged from 0 to 3 or more and correlated to event rate:

- Class I (0 risk factors)—event rate 0.4% (95% confidence interval)
- Class II (1 risk factor)—rate 0.9%
- Class III (2 risk factors)—rate 6.6%
- Class IV (3 or more risk factors)—rate 11.0%

The RCRI has been the most widely accepted risk index, and Romero and de Virgilio [20] have proposed utilizing the RCRI to identify patients who should be treated with strategies to reduce oxygen consumption rather than undergo additional noninvasive testing. They based their recommendations on comments elicited by Bodenheimer [25], who felt that improved outcomes were more likely a result from controlling postoperative myocardial oxygen demand than additional risk stratification.

Miscellaneous Risk Assessment Tools

Other attempts at risk stratification and adjustment are mentioned in the literature. In 2004, Atherly et al. [26] compared the National Surgical Quality Improvement Program (NSQIP), the DxCG, and the Charlson Comorbidity Index. The NSQIP [27] is based on a medical record abstraction of 45 preoperative and 17 intraoperative factors. Factors are multiplied by weights drawn from a model developed using 41,360 patients from the Veteran Affairs Health Care System. Some of the major components of the NSQIP specific to mortality include: ASA class, ventilator dependence, emergency case, age, abnormal albumin, ascites, complexity score, and contaminated wound [28]. In addition to those mentioned earlier, functional status, a history of chronic obstructive pulmonary disease, anemia (hematocrit 38% or less), and elevated white blood cell counts (11,000 or more) are important predictors of morbidity. The ultimate risk score represents the probability of individual patient mortality.

The DxCG uses *International Classification of Disease* (ICD-9) codes, sex, and age to assign a continuous risk score, and the Charlson Comorbidity Index (CCI) was developed to predict empirically the probability of 1-year mortality. The CCI contains 19 categories of comorbidities drawn from the ICD-9 codes. Each of the categories has a weight, which indicates an increase in the risk for 1-year mortality and scores range from 0 to 6.

Atherly et al. [26] found substantial disagreement in the risk assessment calculated by the three methodologies. A weak association was noted between the CCI and DxCG, but neither correlated well with the NSQIP. Overall, the NSQIP was felt to be the best predictor of surgical mortality.

AMERICAN COLLEGE OF CARDIOLOGY/AMERICAN HEART ASSOCIATION TASK FORCE: PRACTICE GUIDELINES ON PERIOPERATIVE CARDIOVASCULAR EVALUATION FOR NONCARDIAC SURGERY

Practice guidelines serve the purpose of putting forth recommendations based on critically evaluated studies with special emphasis on blinded, randomized, placebo-controlled trial studies. The American College of Cardiology/American Heart Association (ACC/AHA) Practice Guidelines on Perioperative Cardiovascular Evaluation for Noncardiac Surgery [29], most recently revised in 2007 (30), begins with the opening statement that the overriding theme of the guidelines was that preoperative intervention was rarely necessary simply to lower the risk of surgery unless such intervention was indicated irrespective of the preoperative context. The desire of the guideline was also to integrate the clinical determinants of risk, the risk of the surgical procedure, and the role of testing into a cohesive format. In addition, the goal of the preoperative consultation was to provide short- and long-term assessment of cardiac risk and avoid unnecessary testing.

Clinical Predictors

One of the major changes in the 2007 revision of the ACC/AHA guidelines is the manner in which risk is assessed. In the 2002 version of the guidelines, risk factors were divided into three groups: major, intermediate, and minor clinical predictors [29]. With the new revision, the minor clinical predictors were removed from the algorithm because, although they may signify risk for coronary disease, they have not been shown to independently increase risk for perioperative cardiac complication [30].

Also changed in 2007, the *major clinical predictors* have been renamed *active cardiac conditions* (Table 149.3). Because of the increasing use of the Revised Cardiac Risk Index created by Lee et al. [24], the committee chose to replace the *intermediate clinical predictors* with five of six risk factors identified by Lee's group. These five risk factors are: history of ischemic heart disease, compensated heart failure, history of cerebrovascular disease, diabetes mellitus, and renal insufficiency. The sixth risk factor identified by Lee et al., type of surgery, is addressed elsewhere in the new guidelines.

Functional Capacity

The guidelines also focused significantly on the concept of functional capacity. Functional capacity is best expressed in metabolic equivalent (MET) levels that correlate with specific activities. Basic energy expenditure for activities of daily living (e.g., eating, walking) are around 1 to 4 METs, while strenuous exercise is often more than 10 METs [31]. It has been shown in prior studies that patients unable to obtain a 4-MET demand do poorly in the perioperative period [32] as well as in the long term [33].

Risk of Surgical Procedure

Different surgical procedures are clearly associated with varying amounts of hemodynamic stress. For example, application and release of an aortic cross clamp during abdominal aortic aneurysm repair induces far more physiologic insult than

TABLE 149.3

ACTIVE CARDIAC CONDITIONS FOR WHICH THE PATIENT SHOULD UNDERGO EVALUATION AND TREATMENT BEFORE NONCARDIAC SURGERY (CLASS I, LEVEL OF EVIDENCE: B)

Condition	Examples
Unstable coronary syndromes	Unstable or severe angina[a] (CCS class III or IV[b]) Recent MI[c]
Decompensated HF (NYHA functional class IV; worsening or new-onset HF)	
Significant arrhythmias	High-grade atrioventricular block Mobitz II atrioventricular block Third-degree atrioventricular heart block Symptomatic ventricular arrhythmias Supraventricular arrhythmias (including atrial fibrillation) with uncontrolled ventricular rate (HR > 100 beats per minute at rest) Symptomatic bradycardia Newly recognized ventricular tachycardia
Severe valvular disease	Severe aortic stenosis (mean pressure gradient > 40 mm Hg, aortic valve area < 1.0 cm^2, or symptomatic) Symptomatic mitral stenosis (progressive dyspnea on exertion, exertional presyncope, or HF)

[a]According to Campeau.[9]
[b]May include "stable" angina in patients who are unusually sedentary.
[c]The American College of Cardiology National Database Library defines recent MI as more than 7 days but less than or equal to 1 month (within 30 days).
CCS indicates Canadian Cardiovascular Society; HF, heart failure; HR, heart rate; MI, myocardial infarction; NYHA, New York Heart Association.

cataract surgery does. Furthermore, recent evidence suggests that major vascular surgery (excluding carotid endarterectomy) may be associated with more than 5% risk for perioperative cardiac death or nonfatal myocardial infarction [30]. With this in mind, the most recent revision of the ACC/AHA guidelines classifies vascular surgery separately as the highest risk group [30] (Table 149.4). Procedures associated with a 1% to 5% cardiac risk, such as orthopedic and intraperitoneal surgeries, are classified as intermediate risk. Most ambulatory surgeries are associated with less than 1% cardiac risk and are classified as low risk.

TABLE 149.4

CARDIAC RISK STRATIFICATION FOR NONCARDIAC SURGERY[a]

Risk stratification	Procedure examples
Vascular (reported cardiac risk often > 5%)	Aortic and other major vascular surgery Peripheral vascular surgery
Intermediate (reported cardiac risk generally 1%–5%)	Intraperitoneal and intrathoracic surgery Carotid endarterectomy Head and neck surgery Orthopedic surgery Prostate surgery
Low[b] (reported cardiac risk generally < 1%)	Endoscopic procedures Superficial procedure Cataract surgery Breast surgery Ambulatory surgery

[a]Combined incidence of cardiac death and nonfatal myocardial infarction.
[b]These procedures do not generally require further preoperative cardiac testing.
Reprinted from Fleisher et al: ACC/AHA 2007 Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery: Executive Summary. *J Am Coll Cardiol* 50(17):1717, 2007, with permission from Elsevier.

American College of Cardiology/American Heart Association Five Step Algorithm

In the 2007 revision, the authors generated a five-step algorithm for preoperative risk assessment (Fig. 149.2). This was a definite improvement from the somewhat confusing 3-part, 8-step algorithm published in 2002. The simplified recommendations were necessary considering the abysmal (as low as 21%) implementation of the 2002 guidelines [34]. These new guidelines reflect the authors' sentiment in their opening statement that cardiac intervention is not indicated unless it would be performed regardless of a preoperative context. In addition, the algorithm offers recommendations for noninvasive testing and treatment with beta-blockers for selected patients.

Despite these improvements, many authors are still critical of the algorithm. Brett argues that the guidelines are still too ambiguous, referring to the final point of the decision tree: "consider testing if it will change management" [35]. He also makes a point that sometimes noninvasive testing helps patients weigh the risks and benefits of truly elective surgery. In any case, the new algorithm will likely decrease the number of noninvasive test ordered, thus reducing cost and delay in performing elective procedures.

Preoperative Screening ECG

Not long ago it was commonplace to see electrocardiograms in the chart for most surgical patients as part of a preoperative workup. Because these extensive workups were often fruitless, and some testing caused more harm than good, the ASA assembled a task force to develop a practice advisory for

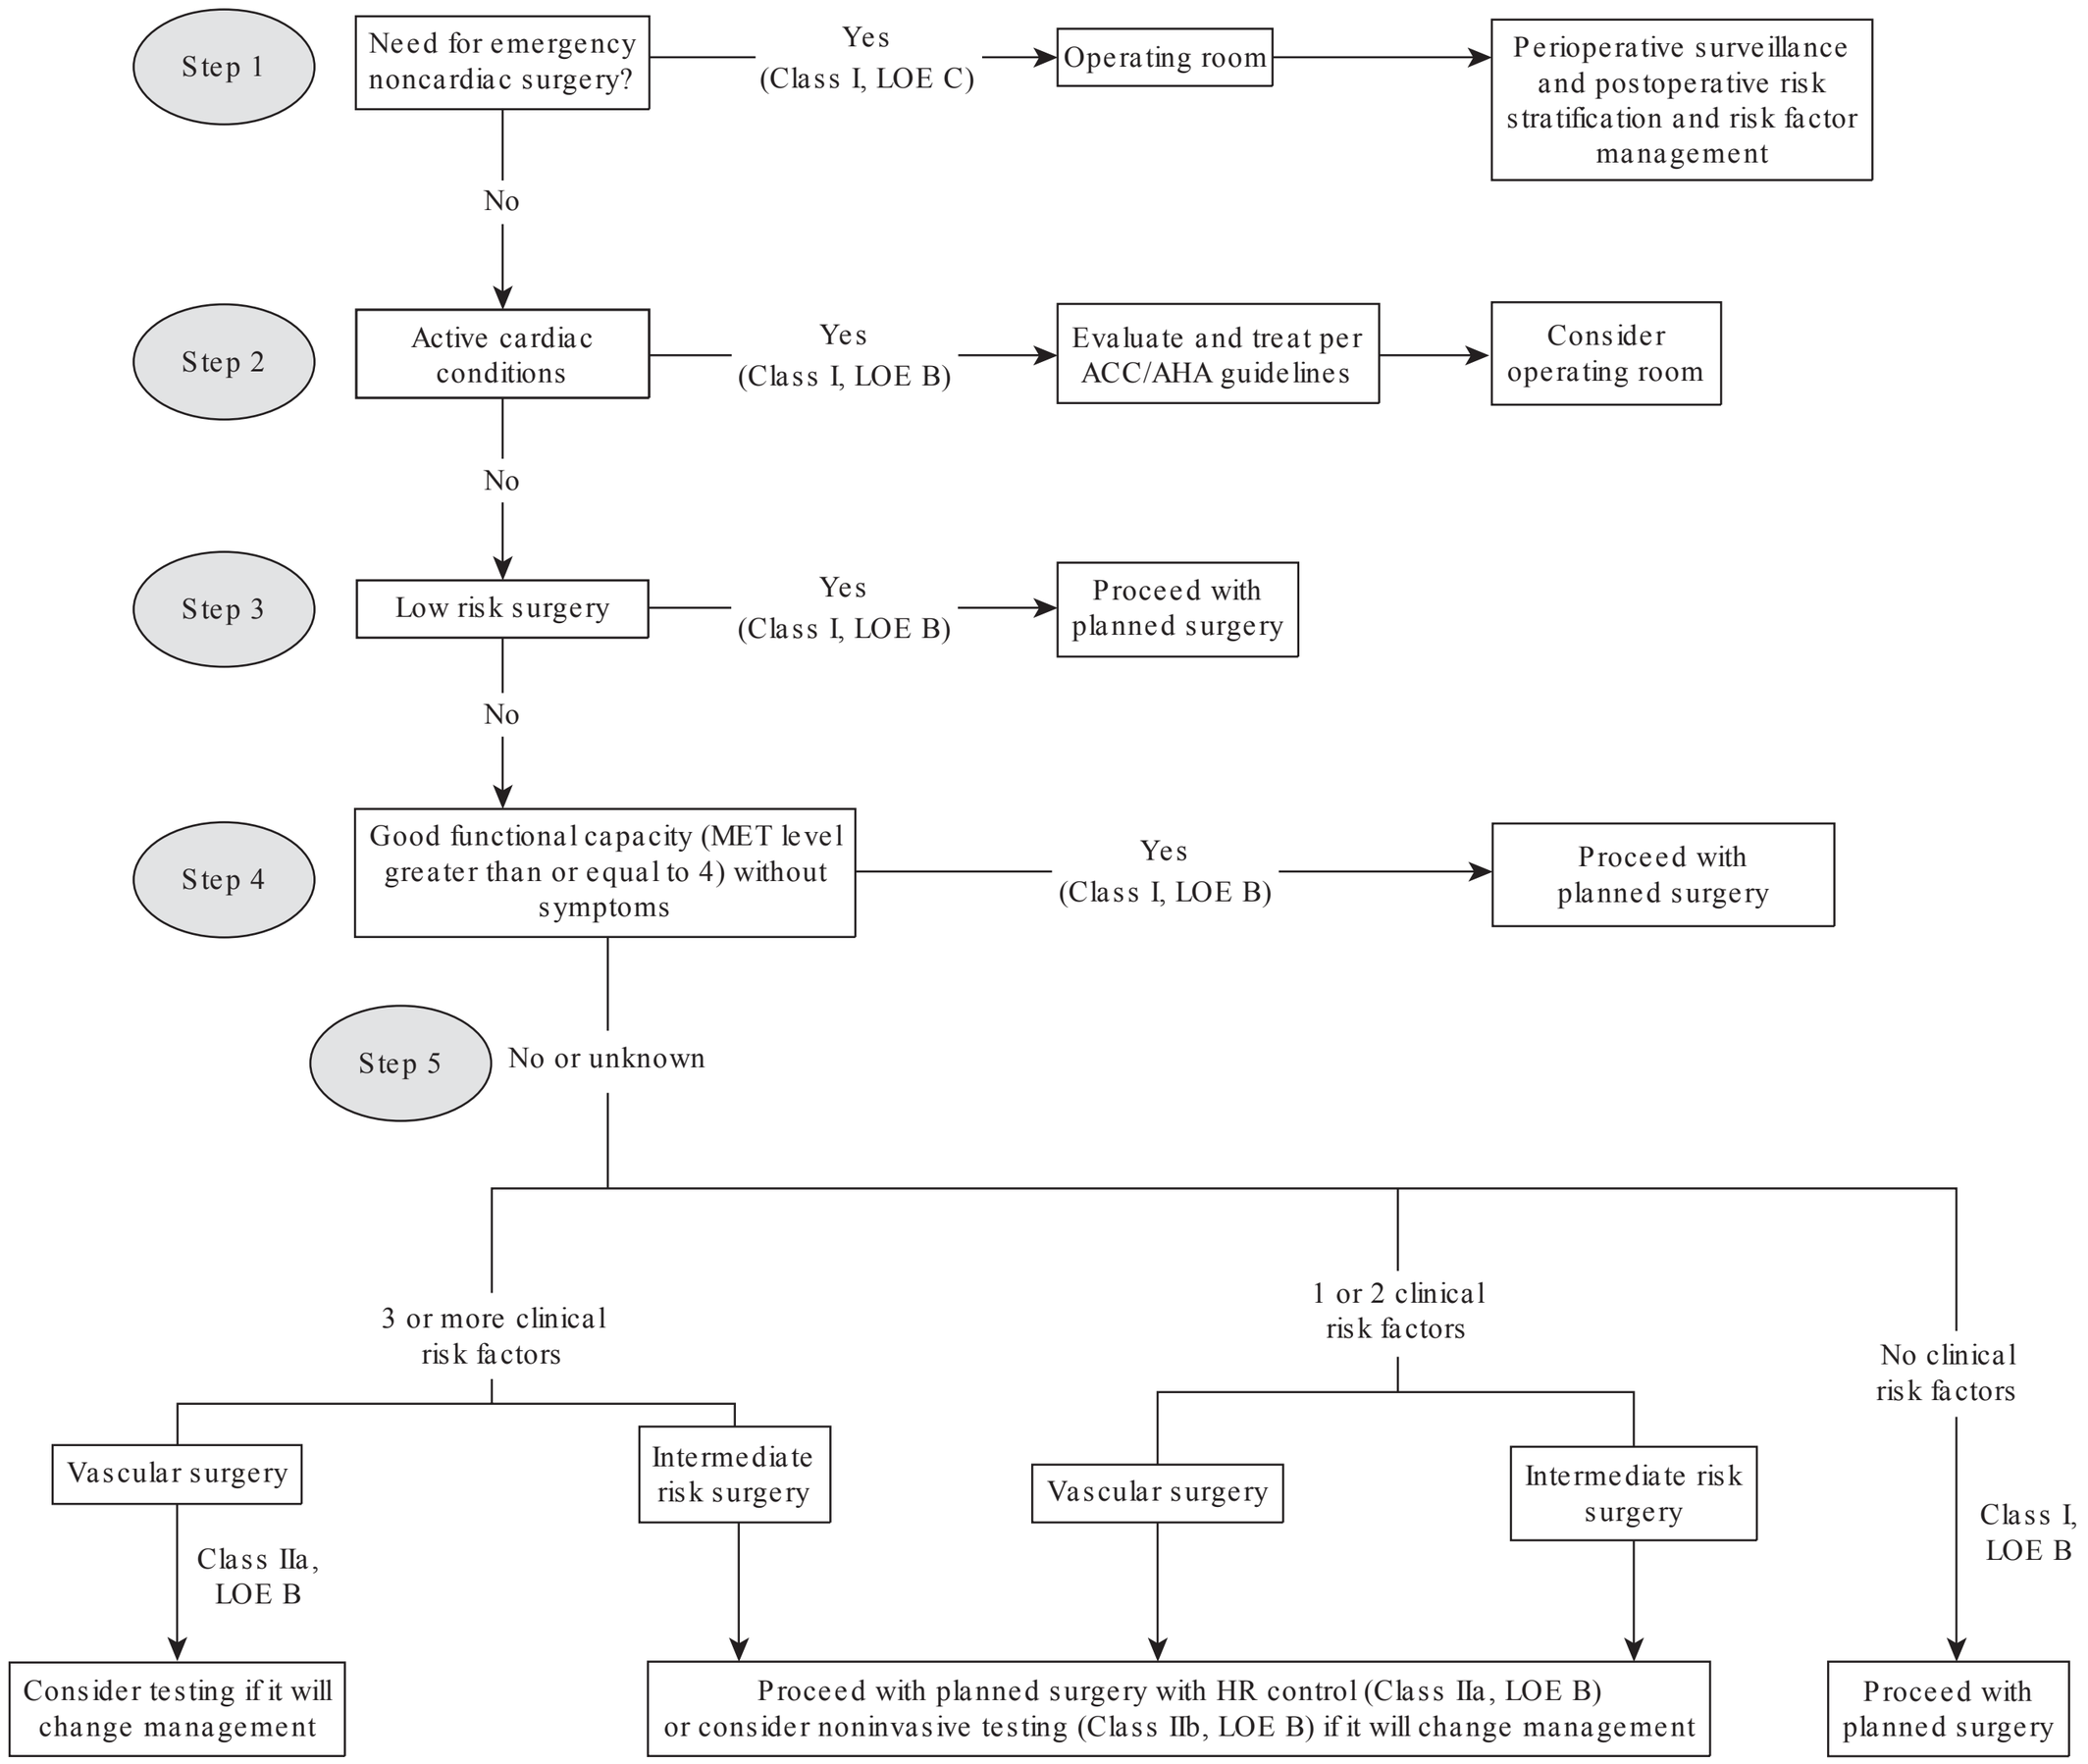

FIGURE 149.2. Cardiac evaluation and care algorithm for noncardiac surgery based on active conditions, known cardiovascular disease, or cardiac risk factors for patients 50 years of age or older. (Reprinted from Fleisher et al: ACC/AHA 2007 Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery: Executive Summary. *J Am Coll Cardiol* 50(17):1716, 2007, with permission from Elsevier.)

preanesthetic evaluation [36]. The task force cited that few screening ECG findings resulted in changes in clinical management. They also stated that based on evidence, age alone may not be an indication for ECG. Proponents of screening ECGs argue that these studies may identify patients with coronary disease not recognized by clinical history. Moreover, these newly identified patients could then be further tested or medically managed with beta-blockade. However, this argument may be flawed for several reasons. First of all, a positive ECG in an asymptomatic patient would not alter further testing if the practitioner uses the ACC/AHA algorithm [30]. Second, according to van Klei et al., ECG abnormalities, including left and right bundle branch blocks, were no more predictive of postoperative MI than history alone [37]. Finally, starting beta-blocker therapy is probably not indicated in otherwise asymptomatic patients [30]. Fleisher, however, does make one argument that may be valid for obtaining preoperative ECG [38]. Without a preoperative ECG, the first occasion that the ECG may be seen as abnormal is when the patient is in the operating room prior to induction. Under these circumstances, it may be beneficial to compare the new findings with an old ECG to identify the acuity of the changes and determine whether or not to proceed. Currently, however, the ACC/AHA states that preoperative screening ECGs are indicated only for vascular surgeries and for certain patient populations having intermediate-risk surgery (Table 149.5) [30].

PREOPERATIVE NONINVASIVE CARDIAC TESTING

As mentioned earlier, part of the ACC/AHA guidelines [29] was to help direct the clinician as to which patients should undergo preoperative testing. The guidelines, however, did not elucidate which noninvasive testing regimen should be undertaken. Exactly which method of evaluation is chosen is again another source of controversy. Testing the low-risk patient undergoing low-risk surgery is ultimately an exercise in futility and an overall waste of time and resources. High-risk patients undergoing high-risk surgery will most likely benefit from invasive testing [39]. The question arises as to what to do with the patient

TABLE 149.5

INDICATIONS FOR PREOPERATIVE RESTING ECG

Benefit >>> Risk (class I)
1. Patients with at least one clinical risk factor (coronary heart disease, history of CVA, renal insufficiency, diabetes mellitus) who are undergoing vascular surgery
2. Patients with known coronary heart disease, peripheral arterial disease, or cerebrovascular disease who are undergoing intermediate-risk surgery

Benefit >> Risk (class IIa)
1. Patients with no clinical risk factors who are undergoing vascular surgery

Benefit ≥ Risk (class IIb)
1. Patients with at least one clinical risk factor who are undergoing intermediate-risk surgery

Risk > Benefit (class III)
1. Asymptomatic patients undergoing low-risk surgery

Reprinted from Fleisher et al: ACC/AHA 2007 Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery: Executive Summary. *JAm Coll Cardiol* 50(17):1711, 2007, with permission from Elsevier.

with intermediate clinical predictors and needs intermediate- to high-risk surgery [40].

The purpose of noninvasive testing is to accrue information that adds to that already provided by whichever cardiac risk index was implemented. Ideally, it will not lead to harmful delays but rather to proven therapy to reduce risk [3].

There are some generally accepted principles regarding what exactly is an effective screening test [36]. These principles should be kept in mind when assessing any test:

1. Accuracy of test: The test must be able to detect the target condition earlier than without screening and with sufficient accuracy to avoid producing large numbers of false–positive and false–negative results.
2. Effectiveness of early detection: Screening for and testing persons who have early disease should improve the likelihood of favorable health outcomes (e.g., reduced disease-specific morbidity and mortality) compared to treating patients when they present with signs and symptoms of the disease.

Exercise Stress Testing

Exercise stress testing is a well-established mechanism of assessment that allows the identification or absence of myocardial ischemia while the patient is undergoing physical exertion. The purpose of the examination is to elevate the myocardial oxygen consumption to a rate in which demand outweighs supply, leading to ischemic changes on ECG. The inherent drawback of this method of assessment is that it relies on patient participation. At times, due to deconditioning or medical issues, such as claudication, the patient cannot reach target heart rate and thus ischemic episodes may be missed.

Unfortunately in meta-analysis, the mean sensitivity of exercise ECG testing for the prediction of multivessel coronary artery disease has been reported to be 81% (range 40% to 100%) with a mean specificity of 66% (range 17% to 100%) [41]. The meta-analysis also reconfirmed that the sensitivity of the examination was adversely affected in patients who could not reach maximal heart rate, especially vascular surgery patients in which approximately 50% could not reach the target rate.

In addition to the failure to reach target heart rate, other limitations of exercise testing exist. These include ECG changes on resting ECG, the presence of left bundle branch block, failure in determining the extent of myocardial ischemia, and lack of information regarding left ventricular function [42].

Myocardial Perfusion Imaging

To overcome some of the inherent problems of exercise stress testing, pharmacologic stress myocardial perfusion imaging was developed [43]. This examination consists of the administration of a vasodilating agent such as adenosine or dipyridamole to induce vasodilation that would parallel the effect of exercise on coronary anatomy. In addition, a radionuclide is administered, such as thallium-201. Images are obtained over time and positive examinations are those in which areas of initial filling defects resolve, or undergo redistribution of thallium, during the rest phase.

Several complications and contraindications exist with the use of adenosine and dipyridamole. Since they are potent vasodilators, these agents are obviously contraindicated in those patients with preexisting hypotension and ongoing symptoms of unstable angina. Other relative contraindications to administration of adenosine include high-degree atrioventricular block, bronchospastic disease, and atrial arrhythmia disorders such as sick sinus syndrome.

Eagle et al. found that patients with one or two risk factors for coronary artery disease, and redistribution on dipyridamole thallium had a 29% cardiac event rate versus a 3.2% rate in patients without redistribution. The sensitivity of the examination, however, appears to be in detecting the presence or absence or coronary artery disease, not ischemia [23].

In addition it has been reported that the accuracy and positive likelihood ratio for dipyridamole thallium stress testing is low and that the examination does not provide independent prognostic value beyond clinical risk stratification [44]. Other prospective blinded studies confirmed a lack of association between reversible defects on dipyridamole thallium and adverse cardiac events in patients undergoing elective vascular surgery (of note, these studies excluded low-risk patients undergoing vascular surgery) [45,46].

In the study by de Virgilio et al. [46], the adverse cardiac event rate was 13.8% for patients with a reversible defect on thallium testing versus 9.8% for those who did not have a reversible defect ($p = 0.70$). The adverse event rate in patients with two or more reversible defects was 12.5% versus 11.1% in patients with fewer than two reversible defects. Sensitivity with two or more defects was 11%, with a specificity of 90%. The overall positive and negative predictive values were 12.5% and 89%, respectively. The authors concluded that since there was no demonstrable correlation between dipyridamole thallium and perioperative adverse cardiac events, one could not recommend the test as a screening tool prior to vascular surgery.

Another imaging study is dipyridamole technetium-99m sestamibi testing. Technetium-99m sestamibi is a radiotracer that differs from thallium-201 and ultimately allows for acquisition of higher resolution tomographic cardiac images. Stratmann et al. [47] studied 229 patients scheduled for vascular surgery who underwent sestamibi testing. Of those enrolled, 197 underwent surgery within 3 months of the initial examination with an overall cardiac event rate of 5%. The perioperative cardiac event rate between those with normal, abnormal, or reversible sestamibi images was not clinically significant; however, abnormal and reversible sestamibi images were independent multivariable predictors of increased risk of late cardiac events.

Dobutamine Stress Echocardiography

Dobutamine stress echocardiography (DSE) was developed as a tool for assessing the presence of coronary artery disease and

was reported by Berthe et al. [48] in 1986. Essentially the examination is composed of the administration of a pharmacologic inotropic agent (e.g., dobutamine), which is designed to increase heart rate and myocardial contractility, thus increasing myocardial oxygen consumption. In the presence of coronary artery disease, demand will overcome supply and myocardial dysfunction will be present. Myocardial dysfunction will be evident by echocardiography, manifested by areas of hypokinesis, akinesis, or dyskinesis. The development of new wall motion abnormalities following dobutamine administration is considered an indication of significant coronary artery disease [49].

When dobutamine stress echocardiography and dipyridamole-thallium testing were compared in the same patient population, they appeared to have comparable specificity and sensitivity [50]. A subsequence meta-analysis study revealed a 9% incidence of perioperative myocardial infarction in patients with reversible ischemia or regional wall abnormalities in one or more areas [51].

The Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography (DECREASE) Study Group performed a large retrospective study with results released in 2001. The study noted that the adverse event rate was 10.6% in patients with three or more cardiac risk factors and five or more segments of new wall motion abnormalities (NWMAs) versus a 2% adverse event rate in patients without NWMAs. It is also interesting to note that the study reported perioperative death and myocardial infarction rates of 6.5%, 10%, and 16% in patients with respective scores on a modified Revised Cardiac Index of 3, 4, and 5 who were treated with beta-blockade but also had ischemia on DSE [52]. A drawback to the utilization of echocardiography was that the study showed that DSE did not add incremental value in low- or medium-risk patients (score of 0 to 2 on Revised Cardiac Risk Index) [3].

Although the results of this retrospective study were encouraging, there are other studies that tend to question the validity of DSE for preoperative evaluation. It appears that echocardiography has limited prognostic value as a routine test. Rohde et al. [53] reported that an abnormal echocardiogram with any degree of systolic dysfunction, moderate to severe left ventricle hypertrophy, moderate to severe mitral regurgitation, or aortic gradient of 20 mm Hg or higher provided a sensitivity of 80%, specificity of 52%, positive predictive value of 12%, and negative predictive value of 97%. However, severe left ventricular (LV) dysfunction compared to mild–moderate LV dysfunction did not have a strong association with cardiogenic pulmonary edema and MI. Thus, given the heterogeneity of findings, it appears that echocardiography adds little to risk models.

Another retrospective study in 2002 by Morgan et al. [54] examined the utility of dobutamine stress echocardiography in 85 preoperative patients in accordance with the ACC/AHA guidelines. The DSE was positive in 4 patients (4.7%), negative in 74 (87.1%), and nondiagnostic in 7 (8.2%). The DSE obtained in 48 patients with a history of diabetes mellitus (DM), mild angina, or "minor clinical predictors" produced only negative results. Of the four positive patients, three underwent angiography and one underwent coronary artery bypass grafting (CABG) prior to surgery. No patient had any perioperative morbidity related to myocardial ischemia. Morgan et al. [54] went further to recommend that DSE is recommended in patients with:

1. Intermediate clinical predictors (one or more) [prior MI, compensated CHF, DM with mild angina] with poor functional capacity less than 4 METs
2. Intermediate clinical predictors (one or more) with moderate to excellent functional capacity greater than 4 METs and high surgical risk and unable to perform exercise stress test

Grayburn and Hillis [3] went on to state more strongly that the test had limited value given that the likelihood ratio of a positive test report was low and thus had a low positive predictive value. The authors strongly felt that patients with positive test results are often subjected to further evaluation that may cause an unnecessary delay in noncardiac surgery.

A recent study by Kertai et al. [55] used a meta-analytic approach adjusting for reported variability in test performance between the individual studies. The results revealed that there was clinical utility for the use of dobutamine stress echo in perioperative risk assessment. Overall sensitivity and specificity of the test were found to be high, 85% and 70%, respectively. The conclusion by the authors was that the predictive value of a positive DSE for the composite endpoint of cardiac death and myocardial infarction was significantly increased. However, much work is still in progress regarding the overall utility of DSE and cardiac risk assessment.

So is DSE better than nuclear scintigraphy (thallium imaging)? Beattie et al. [56] addressed this question with a recent meta-analysis. The authors felt that the meta-analysis contained the statistical power to demonstrate that DSE had better negative predictive characteristics than thallium imaging (TI). Although a moderate to large perfusion defect by either DSE or TI predicted postoperative MI and death, they concluded that DSE was superior to TI in predicting postoperative cardiac events.

What about the patient with a negative examination? The meta-analysis [56] also revealed that a negative DSE reduced the probability of MI or death. It was evident that there were fewer false negative DSE results. And what about the patient with moderate or multiple defects? Moderate or multiple defects on DSE were noted to be at least as accurate as the demonstration of a large perfusion defect on TI. However, the group's final conclusion was that a negative test did not reliably confirm less risk of a perioperative cardiac event, although a positive DSE was two times more predictive than a positive TI.

Invasive Cardiac Evaluation

Once a decision has been made regarding preoperative invasive cardiac evaluation, either based on clinical history or noninvasive testing, several questions remain. Namely, what is to be done with the information obtained? Is a surgical or percutaneous intervention warranted? Will it make a difference?

There are clearly some indications in which invasive testing are warranted. These include recent myocardial infarction with residual angina, angina unresponsive to medical therapy, unstable angina, and proposed intermediate-risk or high-risk noncardiac surgery after equivocal noninvasive test results [39].

Essentially, the original ACC/AHA guidelines [29] did not recommend coronary angiography as risk stratification in patients undergoing noncardiac surgery; however, they did recommend angiography if indications for angiography independent of planned surgery were present [40]. However, confusion persists regarding the role of preoperative angiography and subsequent preoperative intervention to reduce risk of noncardiac surgery.

Role of Coronary Artery Bypass Grafting Prior to Noncardiac Surgery

In the 1980s, an initial study by Hertzer et al. [57] revealed that the cumulative cardiac mortality rate at 10 years was markedly increased for patients with suspected but uncorrected coronary artery disease as compared with those patients without evidence of coronary artery disease or those patients who had

undergone myocardial revascularization. This ultimately led to the belief that aggressive coronary revascularizations prior to vascular operations were warranted.

A series of studies by Gagnon et al. [58] and Allen et al. [59] also recommended prophylactic CABG or angioplasty prior to noncardiac surgery. Nielsen et al. [60] found in the early 1990s that patients who had a CABG operation appeared to have a low rate of perioperative cardiac complications. This observation was further enhanced by Eagle et al. [61] who used the Coronary Artery Surgery Study (CASS) registry. After reviewing the data, the group found that patients who underwent major vascular, abdominal, thoracic, or head/neck surgery after previous CABG had fewer perioperative deaths and myocardial infarctions than patients receiving medical therapy.

Ultimately, these observational studies became the basis for the ACC/AHA guideline recommendations that invasive testing for risk stratification was not indicated in patients who had a CABG surgery within 5 years and were currently without symptoms [29]. Grayburn and Hillis [3] have strongly voiced opposition to the utilization of CABG in the *asymptomatic* patient. They felt that the morbidity and mortality associated with the CABG procedure, which includes nonfatal MI, death, stroke, and cognitive dysfunction, outweighed any benefit.

The group also held the valid viewpoint that recovery from CABG would cause a significant delay in obtaining the noncardiac surgery. In fact, as indicated by Mason et al. [62], coronary angiography appears to carry a 0.3% risk of mortality, while CABG has been reported to have an operative risk of 3% overall and approximately 5% in the patient with peripheral vascular disease.

One of the stronger studies in support of avoiding coronary artery revascularization before noncardiac surgery was published from the CARP (Coronary Artery Revascularization Prophylaxis) trial [63]. This was a multicenter trial that randomly assigned patients who were at increased risk and had clinically significant coronary artery disease to either undergo revascularization or no revascularization before elective major vascular surgery. The major end point of the study was long-term mortality. A group of 510 patients out of 5,859 were deemed eligible, with 258 assigned to preoperative revascularization (CABG or percutaneous angioplasty) and 240 assigned to medical management.

The study revealed that at 2.7 years, mortality in the revascularization group was 22% and in the nonrevascularization group 23%. Positive postoperative myocardial infarction (as documented by elevated troponin levels) was 12% in revascularization group and 14% in nonrevascularization group. One problem with the study was that it lacked the power to detect a beneficial effect on the intervention in the short term; however, the group felt that there appeared to be no reduction in the number of postoperative myocardial infarctions, deaths, or days in the hospital. Another criticism of the study has been that the selection of patients was based on intermediate or minor clinical predictors and as such may have selected a lower risk patient population. The study also did not account for patients with left main disease, aortic stenosis, or severe left ventricular dysfunction [64].

A recent review of the role of preoperative coronary revascularization was performed by Kertai [65]. Within the review, Kertai noted that though CABG provided more complete revascularization as compared to percutaneous coronary intervention, the CARP trial and subsequent studies with subgroup analyses found that coronary revascularization preoperatively did not improve perioperative and long-term mortality rates.

The Role of Preoperative Coronary Angioplasty

As evident from the previous section there appears to be little support for prophylactic CABG in the asymptomatic patient presenting for noncardiac surgery. However, what about the patient who has received a percutaneous coronary intervention (PCI)? Does preoperative PCI reduce the operative risk of the patient undergoing noncardiac surgery?

Several studies have addressed this question. In a retrospective cohort study by Posner et al. [66], adverse outcomes after noncardiac surgery among patients with a prior PCI, patients with nonrevascularized coronary artery disease (CAD), and normal controls were compared. They ultimately compared the risk for developing adverse cardiac outcomes within 30 days (notably death, myocardial infarction, angina, CHF, malignant dysrhythmias, cardiogenic shock, coronary artery bypass graft after angioplasty). The results of the study revealed that patients who underwent PCI had twice the risk of adverse cardiac outcome as normal controls and half the risk of adverse outcomes as patients with CAD. Compared to the group with uncorrected CAD, the PCI group exhibited no difference in myocardial infarction rates or death.

Timing between the PCI and noncardiac surgery was also important in this study. It was revealed that patients who had a PCI more than 90 days from the noncardiac surgery seemed to have a lower risk of poor outcome as compared to the nonrevascularized patients with CAD. But of note, the study revealed that those who underwent recent PCI had a threefold increase in risk compared to normal controls.

Posner et al. felt that the most surprising result of the study was the similarity of outcome between patients with recent PCI and uncorrected CAD. The group also felt that this helped to substantiate earlier work by Lauperta et al. [67] and Seeger et al. [68] who found similar noncardiac surgery outcomes between patients who underwent prophylactic revascularization and patients without intervention.

Adding to the controversy is a retrospective study performed by Landesberg et al. [69] who reviewed patients who underwent coronary revascularization prior to noncardiac surgery based on the results of a preoperative positive stress thallium examination. His group concluded that long-term survival after major vascular surgery was significantly improved in patients undergoing coronary revascularization. However, Godet et al. [70] were highly critical of this provocative study, deeming it importantly flawed on several points:

1. The study lacked adequate power.
2. Propensity score analysis, which balances all the observed covariants associated with exposure to PCI [71], did not take into account important variables occurring during or after the procedure that may be associated with poor outcomes.
3. The goodness of fit of the propensity score was significant, indicating inappropriate fit of the model.

Godet et al. ultimately performed their own study that analyzed a cohort of 1,152 patients after abdominal aortic aneurysm repair, in which 78 underwent PCI. The study revealed five variables that independently predicted severe postoperative coronary events: age over 75 years, blood transfusion, repeated surgery, preoperative hemodialysis, and previous cardiac failure. The study also revealed five variables that independently predicted postoperative death: age over 75 years, repeated surgery, previously abnormal ST segment/T waves, previous hypertension, and previous cardiac failure. In their conclusions, the group stated that in the PCI group, the observed percentages of patients with a severe postoperative coronary event (9%) were not significantly different from the expected percentages (8.2% and 6.9%, respectively). Of note, when all patients were pooled together, the odds ratios of PCI were not significant and the propensity score analysis provided a similar conclusion.

In the Bypass Angioplasty Revascularization Investigation (BARI) trial, a prospective, randomized trial was designed to

compare PCI to CABG on risks of subsequent noncardiac surgery [72]. The results ultimately indicated that the rates of myocardial infarction and death between the two groups PCI and CABG after noncardiac surgery were similar, thus failing to favor one intervention versus another.

In 2007 the COURAGE trial research group reported the results of a multicenter, randomized trial of 2287 patients with multivessel coronary artery disease. The study noted that PCI compared with optimal medical therapy did not reduce the risk of death, myocardial infarction, or other major cardiovascular events during an average observation period of 4.6 years [73]. Though this study was not directed to the patient undergoing noncardiac surgery, it makes the point that interventions in medically optimized, cardiac stable patients may have little value in reducing overall morbidity and mortality.

Obviously, the question regarding the value of PCI or coronary bypass grafting prior to major vascular surgery has not been definitively answered. Complicating the situation is the observation that both the risk of surgery and PCI are substantially higher in patients with peripheral artery disease. This, as noted by Saw et al. [74], may be due to systemic atherosclerotic burden that ultimately leads to increased cardiovascular and cerebrovascular complications.

Considerations for the Patient with Recent Percutaneous Coronary Intervention

An important clinical situation to consider is what to do with the patient who has undergone recent PCI. It is conceivable that during the noninvasive preoperative screening of the intermediate- to high-risk patient, a clinically significant coronary artery lesion is noted. The decision to correct the lesion is usually undertaken by the invasive cardiologist, sometimes during a diagnostic angiography [75]. Balloon angioplasty has given way to more definite treatments such as the placement of bare metal or drug-eluting coronary artery stents. Exactly when and which intervention was made has tremendous implication if these patients present for noncardiac surgery.

Complications from stent placement usually arise from the nature of the thrombogenicity of the stent at the blood-tissue interface leading to thrombosis or embolization. There appear to be multifactorial causes for these events, namely, the type of stent, its length, the size of the final lumen diameter, and the presence of persistent dissection at the time of implantation. Cutlip et al. [76] have reported a 50% incidence of acute myocardial infarction that carries an overall 20% mortality rate in the patient who has had thrombosis with recent stent placement. These concerns have also caused many to recommend caution when dealing with patients and recent PCI [77].

The 2002 ACC/AHA recommendations regarding the patient who has a coronary artery stent suggested at least 2 weeks and ideally 4 to 6 weeks between stent implantation and noncardiac surgery [29]. This would include a full 4 weeks of dual antiplatelet therapy (aspirin and a thienopyridine, such as clopidogrel or ticlopidine) during stent reendothelialization and 2 weeks for restoration of normal platelet function.

Interestingly, the recommendations by the 2002 ACC/AHA committee arose not from randomized controlled trials, but from two retrospective studies [29]. Kaluza et al. [78] noticed that 40 patients who underwent noncardiac surgery within 2 weeks of implantation had a high incidence of severe, catastrophic complications. Of the patients evaluated, 18% had myocardial infarctions, 20% died, and 28% had major bleeding. In a larger series, Wilson et al. [79] noted that 4% of patients undergoing noncardiac surgery within 6 weeks of stent placement suffered a myocardial infarction in which 2.9% of this group ultimately died. They noted that there were no complications seen in patients who were 7 weeks after implantation.

A retrospective study reviewing the risks of noncardiac surgery after coronary stenting was performed by Reddy and Vaitkus [80]. In their small patient population, they noted that of the patients who had major adverse cardiovascular events (MI, stent thrombosis, major bleeding, or death), 38% had undergone noncardiac surgery within 14 days of stent placement and 62% had undergone noncardiac surgery 15 to 42 days after implantation. No patient developed major adverse cardiovascular events after 42 days, leading the authors to suggest that a patient should be considered high-risk if surgery was performed up to 6 weeks following stent placement.

Drug-Eluting Cardiac Stents

It is also important to note that the 2002 ACC/AHA guidelines [29] were only for bare metal stents and not for drug-eluting coronary stents or patients who are under brachytherapy. The presence of paclitaxel or sirolimus may delay endothelialization of the coronary stent and may necessitate a longer period of antiplatelet therapy [81]. A case report by Auer et al. [82] discusses a patient who had the simultaneous placement of a bare metal stent in the right coronary artery and two paclitaxel-eluting stents in the left circumflex 12 weeks prior to noncardiac surgery. Interestingly, 2 hours after surgery the patient had an acute myocardial infarction and catheterization revealed patency of only the RCA-bare metal stent.

In an editorial, Berger et al. [83] recommended that if a patient was scheduled to have noncardiac surgery within 2 months of PCI and the surgery/surgeon did not permit continuation of aspirin and clopidogrel throughout the perioperative period, then bare-metal stents should be used. Mendoza et al. [84] recommended at least a 3-month delay from time of implantation of a drug-eluting stent and noncardiac surgery. This recommendation was based on observations and extrapolation of case reports.

However, a new set of recommendations has been issued regarding the discontinuation of antiplatelet therapy in patients with coronary artery stents. The American Heart Association Scientific Statement by the AHA/ACC/ACS/ADA in February 2007 stated that elective surgical procedures in patients receiving drug-eluting stents should be delayed for at least 12 months. During that time, the patient should receive an entire course of dual antiplatelet therapy composed of aspirin and thienopyridines. However, if surgery cannot be delayed, then the consensus of the group was to recommend the implantation of bare metal stents or balloon angioplasty or continuation of aspirin throughout the perioperative period [85]. This recommendation was also incorporated into the 2007 ACC/AHA guidelines [30]. A summary of the recommendations regarding percutaneous coronary interventions is noted in Figure 149.3.

Heart Failure and Noncardiac Surgery

Definition

As mentioned earlier, one of the high-risk clinical predictors for a postoperative complication is the history of heart failure (HF). The question arises as to how to approach the patient with a history of HF and how best to manage these patients as they present for noncardiac surgery. In 2003, the Framingham Heart Study estimated that there are approximately 550,000 new cases of HF each year with a prevalence of 5 million patients [86].

Heart failure patients presenting for noncardiac surgery are known to have a twofold higher mortality and readmission rate than those patients with CAD alone or no disease. This has been noted to be the case across all types of surgeries. In

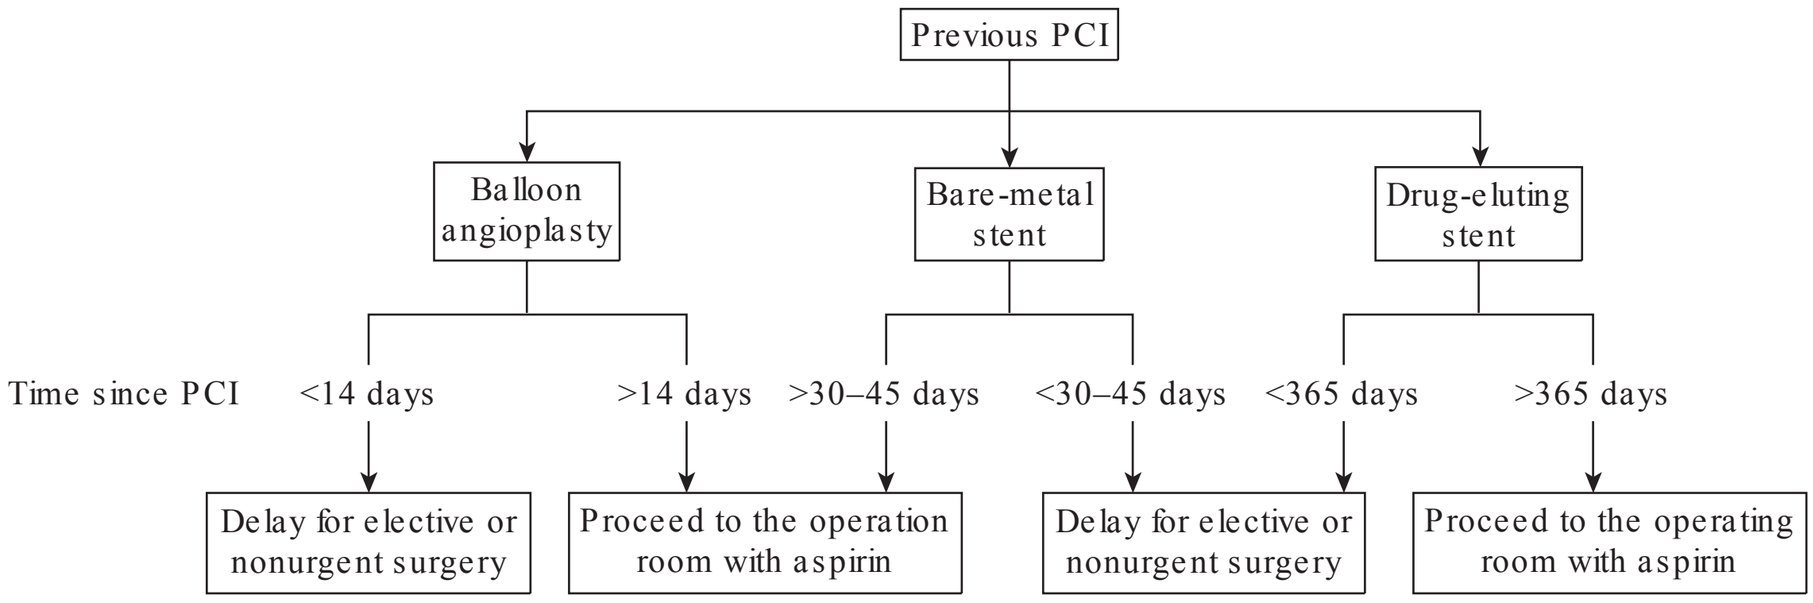

FIGURE 149.3. Proposed approach to the management of patients with previous percutaneous coronary intervention who require noncardiac surgery, based on expert opinion. (Reprinted from Fleisher et al: ACC/AHA 2007 Guidelines on Perioperative Cardiovascular Evaluation and Care for Noncardiac Surgery: Executive Summary. *J Am Coll Cardiol* 50(17):1720, 2007, with permission from Elsevier.)

fact, there is a two- to fourfold increase in mortality for HF patients compared with all others [87]. In evaluating outcomes of Medicare HF patients undergoing noncardiac surgery, Hernandez et al. [88] used a multivariable logistic regression model to assess mortality and readmission rates in the presence of preexisting HF. The group noted that the risk-adjusted operative mortality (defined as death before discharge or within 30 days of surgery) was 11.7% in the HF group versus 6.2% in the control group and 6.6% in the group with isolated CAD. The risk-adjusted 30-day readmission rate in the HF group was as high as 20% and with control, it was approximately 11%. The patients with CAD without the presence of HF had a readmission rate of 14.2%.

Defining exactly which signs and symptoms constitute CHF can be somewhat controversial. However, the ACC/AHA have developed a definition of heart failure that includes various stages, each with their own specific treatment regimen (Table 149.6). It is also important to remember that patients with left ventricular dysfunction may present with a variety of syndromes, notably, a syndrome of decreased exercise tolerance, a syndrome of fluid retention, or those who have no symptoms and incidentally discovered left ventricular dysfunction [89].

TABLE 149.6

ACC/AHA STAGES OF EVOLUTION HEART FAILURE

Stage A: High risk for heart failure, but without structural heart disease or symptoms of heart failure (e.g., hypertension, coronary artery disease, diabetes mellitus, utilizing cardiotoxins, or family history of cardiomyopathy)
Stage B: Structural heart disease but without symptoms of heart failure (e.g., patients with previous MI, LV systolic dysfunction, asymptomatic valvular disease)
Stage C: Structural heart disease with prior or current symptoms of heart failure (e.g., patients with known structural heart disease, shortness of breath and fatigue, reduced exercise tolerance)
Stage D: Refractory heart failure requiring specialized interventions (e.g., patients who have marked symptoms at rest despite maximal medical therapy)

LV, left ventricular; MI, myocardial infarction.

Evaluation of the Patient with Heart Failure

The Lee Revised Cardiac Risk Index does not take into account changes in the patient's clinical status over time. Hernandez et al. [90] gives the following example of a common clinical conundrum. For example, if a patient has decompensated HF on the day of surgery, the surgery is subsequently cancelled for the patient to clinically improve. We can assume that improvement has been made over time and the patient presents again for noncardiac surgery. The patient's calculated risk remains the same, which may or may not reflect reality. This situation is similar to the patient who has a recent acute coronary syndrome who returns for surgery after being delayed for months to undergo coronary revascularization.

Are there specific noninvasive tests that have particular value when assessing the patient with CHF presenting for noncardiac surgery? Numerous studies have shown value in diagnostic and prognostic markers of HF such as natriuretic peptides. With commercial assays of B-type natriuretic peptide and N-terminal pro-B-type natriuretic peptide being more widespread, it may be possible to improve both the preoperative classification of HF and diagnosis of HF as a postoperative complication by incorporating markers in routine assessment [90–92].

Echocardiography has been found to have a limited prognostic value as a routine test in the presence of heart failure. Rohde et al. [53] addressed this issue regarding the value of transthoracic echocardiography as a tool for risk stratification and found that an abnormal echocardiogram with any degree of systolic dysfunction, moderate to severe left ventricle hypertrophy, moderate to severe mitral regurgitation, or aortic gradient of 20 mm Hg or higher provided a sensitivity of 80%, specificity of 52%, a positive predictive value of 12%, and negative predictive value of 97%. However, severe LV dysfunction compared to mild to moderate LV dysfunction did not have a strong association with cardiogenic pulmonary edema and MI. Because of the heterogeneity of findings, the authors concluded that transthoracic echocardiography added little to risk models.

Right Heart Catheterizations in the Heart Failure Patient

The utilization of right heart catheterization (RHC) in patients having noncardiac surgery has also been evaluated. Obviously, intraoperative hemodynamic changes are associated with increased perioperative complication rates [10]. However, in a

TABLE 149.7

TESTS AND STRATEGIES FOR MANAGING PATIENTS WITH HEART FAILURE IN THE PERIOPERATIVE SETTING

Perioperative beta-blockade: Patients with HF should normally be taking beta-blockers for long-term benefits. If not, try to start beta-blocker therapy early enough to ensure it is well tolerated before surgery.
Stress testing: It should be done in high-risk patients with ≥3 points on the Revised Cardiac Risk Index or in patients considered at intermediate risk who are unable to receive perioperative beta-blockers of if testing would be done as normal clinical care for long-term goals.
Degree of HF compensation: Currently requires clinical judgment. No objective testing strategies have been evaluated in the perioperative setting.
Echocardiography: Routine use of echocardiography does not add information for risk stratification or potential changes in management. It should be reserved for evaluation of clinical changes as done for routine management of HF.
Right heart catheterization and monitoring: Current evidence does not support its routine use. If needed, measurement of central venous pressure is adequate for perioperative management of volume status.

HF, heart failure.

recent randomized controlled trial of elderly patients undergoing major noncardiac surgery, Sandham et al. [93] showed no benefit for the utilization of perioperative RHC. Within the study, 2,000 patients over the age of 60 with ASA classifications of III and IV were randomized to RHC-directed care versus usual care. Results revealed no improvement in the perioperative course of the RHC-directed therapy over those receiving standard care. There was a slightly higher incidence of pulmonary embolism in the catheter group that was not explained. A reported limitation of this study was that the patients with a NYHA class III or IV HF comprised only 13% of study population. Thus, it is clearly unknown whether RHC is of value in this subpopulation. The study also noted that there was a higher use of inotropes (48.9% vs. 32.8%) in the RHC-directed group, which the authors felt may be the reason for the overall lack of benefit of the invasive monitors.

The appropriate management for this patient population includes risk assessment by the previously mentioned tools. This goes along with constant surveillance and reevaluation of clinical scenarios as they arise. Hernandez et al. [90] suggested a template for tests and strategies for the management of patients with heart failure in the perioperative period (Table 149.7). Again, tailoring to each specific patient is warranted.

Pharmacologic Interventions to Reduce Risk During Noncardiac Surgery

It is obvious that many patients with coronary artery disease will continue to present for noncardiac surgery. Interventions such as coronary stent placement and CABG appear to be of value only if the patient is symptomatic prior to coming for surgery. As such, there is a strong interest in developing pharmacologic regimens that may help reduce the incidence of major cardiac events.

Role of α_2-Agonists and Myocardial Ischemia Prevention

The purported mechanism of action for α_2-agonists in the prevention of myocardial ischemia is a reduction in sympathetic outflow and ultimately myocardial oxygen consumption. The α_2-agonists are known to reduce postganglionic norepinephrine availability and spinal efferent sympathetic output. In the European Mivazerol trial, a double-blind, randomized placebo controlled study was performed at 61 European centers utilizing intravenous mivazerol, an α_2-agonist [94]. Patients either had documented coronary artery disease or were at high-risk for the disease. The drug was administered for 72 hours from induction of anesthesia into the postoperative period. There was a mix of perceived high-risk or intermediate-risk surgeries including vascular surgery or nonvascular thoracic, abdominal, and orthopedic procedures. The conclusions of the study revealed no alterations in the rates of myocardial infarction or cardiac death in patients with known disease.

Two further studies seemed to substantiate the protective properties of α_2-agonists, specifically clonidine. Maekawa et al. [95], in a meta-analysis of the literature, noted that in subgroup analysis, clonidine reduced the incidence of myocardial ischemia in patients undergoing cardiac or noncardiac surgery. Rates of bradycardia were similar in the clonidine and the placebo groups. Wallace et al. [96] performed a prospective, double-blind, clinical trial with patients with documented coronary artery disease or who were at-risk for coronary artery disease. Oral clonidine plus patch therapy was used, and patch therapy was maintained for 4 days. There was a noted decrease in the incidence of perioperative myocardial ischemia with clonidine, intraoperatively and postoperatively. Also of interest, there was a marked reduction in the incidence of postoperative mortality for up to 2 years.

In a quantitative systematic review, six trials utilizing α_2-agonists were reviewed [97]. The group noted that α_2-agonists decreased the incidence of myocardial ischemia during surgery (19.4% vs. 32.8%) compared with placebo. Of note, there was not a significant decrease in myocardial infarction rates (6.1% vs. 7.3%) compared with placebo. Also of significance, the α_2-agonist decreased the risk of cardiac death from 2.3% to 1.1% as compared to placebo.

Statin Therapy

Statins have recently gained favor as medications used to possibly alter perioperative myocardial ischemia. These low-density lipoprotein lowering agents are well known to attenuate coronary artery plaque inflammation. Statins also contain pleiotropic properties that possibly affect plaque stability by the inhibition of anti-thrombogenic, antiproliferative, and leukocyte anti-adhesive properties [98] (Table 149.8).

Early work has shown a decrease in risk of a major coronary event in the presence of statin therapy [99]. In a relatively recent case–control study, Poldermans et al. [104,105] have shown that the utilization of statin therapy has been associated with a fourfold reduced risk in perioperative mortality. This result was seen consistently within subgroups according to the type of surgery, cardiac risk factors, and cardioprotective medication use including aspirin and beta-blockers. These results were also later substantiated in a randomized trial by Durazzo et al. [106], which also noted a reduction in perioperative myocardial infarction rates.

TABLE 149.8

PROPOSED MECHANISM OF STATINS IN THE PRESENCE OF CORONARY ARTERY DISEASE

Inhibition of neovascularization [99–101]
Inflammatory modulation [99–101]
↑ Atherosclerotic plaque stabilization by decreasing the size of the lipid core [101]
↓ Endothelial basement membrane degradation [101]
↓ Smooth muscle apoptosis by decreasing macrophage infiltration [100,102]
↓ The release of matrix metalloproteinases [100,102]
↓ Interferon-Γ release and leukocyte adhesion [100–102]
↓ Complement mediated injury by decreasing C-reactive protein [100–103]
↑ Decay-accelerating factor [100]
↑ The expression of the vasodilator eNOS and ↓ the vasoconstrictor endothelin-1 [100,101]
↓ Thrombogenic response to plaque rupture by inhibiting platelet activation (by increasing eNOS and decreasing thromboxane A2 production) [100,102]

eNOS, endothelial nitric oxide synthetase.
Adapted from Biccard BM, Sear JW, Foex P: Statin therapy: a potential useful perioperative intervention in patients with cardiovascular disease. *Anaesthesia* 60:1106–1114, 2005.

In a review of the literature by Biccard et al. [107], it was evident that a majority of studies have shown statins to be beneficial in the surgical patient, especially in regard to all-cause mortality, cardiovascular mortality, and myocardial infarction. The group ultimately recommended that statins be administered preoperatively in high-risk patient populations, but recognized the fact that larger studies would need to be performed to verify this position.

Assuming patients present for noncardiac surgery while on statin drugs, is it acceptable to discontinue therapy? Lindenauer et al. [108] noted that temporarily discontinuing statin therapy for approximately 24 hours appears to be safe. However, Heeschen et al. [109] noted that in high-risk patients, if the drug is discontinued for more than 3 days, these patients appear to be at increased risk for a major cardiac complication. It would appear to be prudent to reinstitute the utilization of lipid-lowering agents as soon as feasibly possible.

Beta-Blocker Therapy

The utilization of beta-blocker therapy to reduce perioperative morbidity and mortality in the cardiac patient undergoing noncardiac surgery has gained much favor. The initial study by Mangano et al. [7] noted that with the use of atenolol, the postoperative mortality rate was reduced from 14% to 3% during the first year and 21% to 10% the second year after noncardiac surgery. This study was ultimately substantiated by Poldermans et al. [110] in a retrospective study, which confirmed the benefit of beta-blockade, bisoprolol, in intermediate-risk patients.

However, the study revealed that beta-blockers failed to lower the cardiac event rate in patients who were at very high risk (three or more clinical risk factors and five or more new wall motion abnormalities on echocardiography).

Another study supportive of the use of beta-blocker therapy was that of the previously cited DECREASE (Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography Study Group) study [52]. The DECREASE supported the merits of beta-blocker therapy and was a controlled trial study in which 112 patients were randomized to standard care or bisoprolol. The results revealed that 3.4% of the bisoprolol group compared with 34% of the standard group experienced the study's primary end point of either death from cardiac causes or nonfatal myocardial infarction.

Stevens et al. [97], on systemic review, revealed that the utilization of beta-blockers in the noncardiac surgical patient resulted in a reduction of ischemic episodes during surgery (7.6% vs. 20.2%) as compared with placebo. Beta-blockers also appeared to decrease ischemic episodes after surgery and reduced the risk of myocardial infarction and cardiac death. Important to note was that only two trials were performed with high-risk groups.

However, recently, the effectiveness of beta-blocker therapy in the perioperative period has come under question [111,112]. In a large systematic review and meta-analysis of randomized controlled trials, Devereaux et al. [113] came to some interesting conclusions. Perioperative outcomes for the study included total mortality, cardiovascular mortality, nonfatal MI, nonfatal cardiac arrest, nonfatal stroke, congestive heart failure, hypotension needing treatment, bradycardia needing treatment, and bronchospasm within 30 days of surgery.

In 22 trials that were reviewed, approximately 2,437 patients were randomized. The utilization of perioperative beta-blockers did not show any statistically significant beneficial effects on any of the individual outcomes, only nominally statistically significant beneficial relative risk for the composite outcome of cardiovascular mortality, nonfatal MI, and nonfatal cardiac arrest. There was also a relative risk in regard to bradycardia requiring treatment and only a nominally significant risk for hypotension needing treatment.

Some of the problems identified in this systematic review were that only a moderate number of events occurred in the perioperative beta-blocker trials. In addition, the meta-analyses revealed a large treatment effect, which is inconsistent with the beta-blocker trials in myocardial infarction and congestive heart failure [114,115]. More importantly, the authors felt that the nominally statistically significant beneficial result of decreased major perioperative cardiovascular events with beta-blocker treatment showed moderate heterogeneity that ultimately weakened the reliability of this finding.

In 2006, the Metoprolol after Vascular Surgery (MaVS) was associated with a reduction in cardiovascular events, but also, treated patients were found to have lower postoperative heart rates and more intraoperative hypotension. Overall, there was not a substantial difference in cardiac events when compared to placebo on 6-month follow-up [116]. The incidence of hypotension and bradycardia was also substantiated in the DIPOM (diabetic postoperative mortality and morbidity) trial [117]. The trial failed to show a reduction in cardiac events in diabetic patients without coronary artery disease undergoing vascular surgery but noted significant hypotension and bradycardia.

Data from the recently concluded POISE (Perioperative Ischemic Evaluation) trial has also added to the controversy [118]. The result of this large, randomized controlled trial in which perioperative metoprolol was utilized, revealed fewer nonfatal myocardial infarction rates and fewer nonfatal cardiac arrests in the treatment group. However, it was also noted that more deaths were in the metoprolol treated group, though they were noncardiac in nature. In addition, more patients in the metoprolol group developed ischemic stroke (41 vs. 19) compared with placebo and for every 1200 patients treated, metoprolol appeared to prevent 15 myocardial infarctions at a cost of eight excess deaths and five disabling strokes.

On a recent analysis of noncardiac surgical randomized trials by Beattie et al. [119], it was recognized that effective control of heart rate is important for achieving improved cardiac outcomes. The cardioprotective effects of heart rate control appear to be evident, but beta-blockers do not appear to reliably

TABLE 149.9

CLINICAL RECOMMENDATIONS FOR IMPLEMENTING BETA-BLOCKERS IN THE PERIOPERATIVE SETTING

Recommendations	Description and rationale
Monitor perioperative heart rate and blood pressure	Serially assess hemodynamic measures at pre-specified intervals. Withhold or administer beta-blocker according to preset thresholds/criteria. Such an approach may help detection of issues such as hypovolemia, infection, sepsis.
Implement a "run-in" phase for perioperative beta-blockade	Initiate therapy at least 7 days before operative intervention. Allows for both acute (hemodynamic) and delayed (anti-inflammatory) effects of beta-blockers. Promotes early recognition of adverse effects (e.g., bradycardia, hypotension, bronchospasm).
Adjust dose to achieve target heart rate of 60 beats per minute, avoiding hypotension	Heart rate control remains the major mechanism of beta-blocker benefit. Helps identify and prevent perioperative bradycardia and intraoperative hypotension. Can require variable doses of drug and thus allows for individualization of therapy.
Recognize that beta-blockers differ considerably	Short vs. long-acting agents, varying clinical effects based on receptor agonism. IV vs. PO route of administration important as IV route can rapidly precipitate side effects. Tailor therapy to maintain same agent/dose (s) as in the preoperative setting.
Continue beta-blockers if already on therapy	Sudden withdrawal of beta-blockers known to cause upregulated beta-receptor state. Class I ACC/AHA recommendation, especially if an original indication already exists. Strive to maintain same agent as the preoperative setting.

Reprinted from Chopra V, Plasiance B, Cavsooglu E, et al: Perioperative beta-blockers for major noncardiac surgery: Primum Non Nocere. *Am J Med* 122(3):228, 2009, with permission from Elsevier.

decrease heart rate in all patients and may be associated with more significant side effects. As such, other medications may be necessary to achieve the goal of heart rate control.

So what to recommend? A recent review by Chopra et al. [120] recognized that though there was a benefit from perioperative beta-blockers, the widespread implementation of perioperative beta-blockade to lower risk groups was probably unwarranted. The group strongly recommended caution when using beta-blockers in patients with low to moderate cardiovascular risk profiles (Table 149.9).

Anesthetic Management and Cardiac Outcome

Currently little is known about the long-term effects of anesthetic management on the cardiac patient presenting for noncardiac surgery. What is known is that there are some well-known predictors of perioperative morbidity and mortality: presence of clinical comorbidities, nature of surgical procedure, and clinical management [121]. Overall, Arbous et al. [122] and Sigurdsson and McAteer [123] have reported that the risk of anesthesia in the immediate perioperative period is remarkably small with a frequency of death attributed to anesthesia to be less than 1 in 200,000 anesthetics. To date there has been no study that has shown a definitive difference regarding the choice of anesthetic technique (e.g., regional vs. general anesthesia) and perioperative outcome.

Monk et al. [124] tried to address the issue of long-term outcomes and anesthesia. The group performed a prospective observational study in which 1,065 patients underwent general anesthesia for major noncardiac surgery. There were no protocols that regulated the type of anesthetic agents used, except for the utilization of Bispectral Index (Aspect Medical Systems, Inc., Norwood, MA) monitoring and electroencephalogram electrode montage. The study revealed that the following preoperative clinical indicators were significant univariate predictors of 1-year mortality: Charlson Comorbidity Score 3 or higher, ASA status III or IV, age 65 or older, history of hypertension, history of coronary artery disease, history of hepatic disease, and history of myocardial infarction. Perioperative factors that were significant predictors of 1-year mortality included: long surgical procedure, intracavitary surgery, longer duration of intraoperative systolic hypotension, and increased cumulative deep hypnotic time (BIS less than 45). Interestingly enough, protective factors that were deemed to be important were advanced education level, larger values of BMI (body mass index), increased preoperative diastolic blood pressure, and high performance on the preoperative Mini-Mental Status Examination.

The results of this study have not been universally accepted, with several criticisms regarding design and data interpretation. Especially difficult to accept were the results surrounding anesthetic depth, cumulative deep hypnotic time, and interpretation of BIS data [125]. Ultimately, studies that are better designed to address these concerns will need to be performed to validate the position of Monk et al.

There is, however, some evidence to support use of inhaled volatile anesthetics over total intravenous anesthesia. Recent studies have suggested a cardioprotective effect of volatile anesthetics. In fact, in the most recent revision of the ACC/AHA guidelines, the authors acknowledge the benefit of volatile anesthetic use in patients at risk for myocardial ischemia [30]. The mechanisms for the cardioprotection are not completely known, but are likely to involve a preconditioning effect, a post-conditioning effect, and an anti-apoptotic effect [126]. These recommendations may help the practitioner decide how to provide anesthesia if general anesthesia is planned; however, they do not aid with the decision between general and regional anesthesia.

SUMMARY

The care of the cardiac patient presenting for noncardiac disease will continue to be challenging. Risk assessment and risk modification continue to evolve, and currently no examination

TABLE 149.10

SUMMARY OF ADVANCES FOR REDUCING PERIOPERATIVE CARDIAC MORBIDITY AND MORTALITY FOR NONCARDIAC PROCEDURES

- Perioperative beta-blockers reduce incidence of cardiac events, however, are associated with complications of perioperative hypotension and bradycardia and possibly stroke [7,110–119].
- Identification of at risk patients continues to evolve [24,29,30].
- Dobutamine stress echocardiography is preferred to noninvasive screening test for identifying patients at risk for postoperative cardiac events [56].
- Routine use of pulmonary artery catheters in high-risk surgical patients is controversial but may be of value [93].
- Myocardial ischemia is reduced with α_2-agonists and statins [94,96,105–108].
- Anesthetic agents may play a cardioprotective role in high risk populations [30,126]

or biochemical marker appears to meet all the criteria necessary. Each of the noninvasive tests previously mentioned have their supporters and detractors, but all have the same goal, that is, to identify the patient at risk who would benefit from further medical optimization prior to undergoing the stress of surgery.

The role for preoperative coronary artery bypass and coronary angioplasty continues to appear to be limited; however, definitive trials are yet to be performed. The utilization of pharmacologic agents such as beta-blockers and statins continue to show great promise but questions also continue to arise, especially when focusing on the risk versus benefits of these therapies. Results of the large, multicenter trials such as the POISE trial have refocused attention to the need of balancing the risk of instituting therapy without regard to the possible detrimental side effects of such medications.

Advances in noncardiac surgery in the cardiac patient, based on randomized, controlled trials or meta-analyses of such trials, are summarized in Table 149.10.

CHAPTER 150 ■ DIAGNOSIS AND MANAGEMENT OF INTRA-ABDOMINAL SEPSIS

DENNIS I. SONNIER, SHRAWAN G. GAITONDE, PATRICK D. SOLAN AND THOMAS L. HUSTED

INTRODUCTION

The intensive care unit is home to a diversity of patients suffering from intra-abdominal sepsis. Patients may be undergoing treatment for a cardiac or pulmonary condition and may develop an intra-abdominal process as an additional insult, or abdominal distention or peritonitis may arise in a patient recently transported from the operating room after an abdominal procedure, and some patients may be new admissions to the hospital with the signs and symptoms of an intra-abdominal infection.

Several principles are crucial to the management of these patients, such as aggressive resuscitation and monitoring, early administration of antibiotics, and careful consideration of an expanded list of differential diagnoses. Also required are thorough assessments of the patient's ability to tolerate various interventions, the importance of gaining source control, and the need for multidisciplinary teams made of intensivists, surgeons, interventional radiologists, and gastroenterologists among others. With the ubiquitous presence of drug resistant organisms, it is imperative to prescribe antimicrobial medications with the mind-set of antibiotic stewardship.

New paradigms are developing in the management of these diseases, such as molecular targets of therapy, delivery of advanced care at the bedside, damage control strategies, and minimally invasive techniques alone or in combination with a definitive surgical procedure.

PATHOPHYSIOLOGY OF THE LOCAL AND SYSTEMIC RESPONSE TO INTRA-ABDOMINAL INFECTIONS

Patients with intra-abdominal infections can be viewed as a unique subset of sepsis syndrome patients. The defense mechanisms of the peritoneal cavity help explain the specific pattern of response seen. Well-defined systems are available for rapid mechanical clearance of foreign particulates and solutes from the intraperitoneal space. Diaphragmatic lymphatic channels provide a means for the entry of peritoneal fluid (and any bacteria or proinflammatory mediators) through the thoracic duct into the venous circulation. Lymphatic capillaries are distributed in the subperitoneal connective tissue of the diaphragm. Mesothelial cells are organized into two discrete populations: cuboidal cells and flattened cells. Gaps (stomas) between neighboring cells are abundant in the peritoneal mesothelium and found only among cuboidal cells [1,2]. The average area of a stoma is approximately 102 μm. Peritonitis increases the diameter of these stomas [3]. Inspiration decreases intrathoracic pressure relative to intra-abdominal pressure, creating a pressure gradient favoring fluid movement across the diaphragm and out of the abdomen. Entry of proinflammatory substances into the lymphatic channels and subsequently the vascular space would be expected to produce many of the hemodynamic and respiratory signs of severe sepsis. Positive-pressure ventilation likely attenuates this process but has not been well studied as a therapeutic maneuver [4].

Other peritoneal defense mechanisms include resident peritoneal macrophages and large recruitable pools of circulating neutrophils and monocytes. These cell types participate in bacterial isolation and abscess formation. Ingestion of microorganisms by these cells may result in secretion of a variety of proinflammatory mediators, including chemokines, cytokines, lipid derivatives, oxidants, and lysosomal enzymes. Manipulation of the number and function of these resident and recruited cells is now possible through the use of colony-stimulating factors, but has not been examined in clinical trials. Similarly, manipulation of the expression of proinflammatory mediators from these inflammatory cells has been postulated to modulate the sepsis response, but clinical trials have been disappointing to date.

The release of proinflammatory products of peritoneal origin into mesenteric, lymphatic, and vascular channels, and this contribution to the systemic septic response has not been fully addressed. Liver dysfunction is common during the course of intra-abdominal infection and occasionally progresses to fatal hepatic failure [5,6]. Considerable evidence supports the notion that various macrophage products, including interleukins-1 and -6 and tumor necrosis factor-α, substantially alter hepatocyte function [7]. In addition to conversion of hepatic synthetic function to acute-phase reactants, serum chemistries reveal evidence of ductal epithelial cytotoxicity, including elevated alkaline phosphatase levels and elevated bilirubin levels. The large number of fixed tissue phagocytes (Kupffer cells) in the liver that are capable of responding to endotoxin absorbed from systemic or mesenteric blood vessels represents a potentially important source of chemokines, cytokines, and other hepatocyte regulatory substances, although portal endotoxemia has not been detected in humans [8,9].

The bacteriology of mixed flora infections, encompassing aerobic, anaerobic, and facultative Gram-negative organisms, explains at least part of the local histopathology of intra-abdominal infection. Facultative and aerobic Gram-negative organisms express and release endotoxin and endotoxin-associated proteins spontaneously, and such shedding is likely intensified by administration of antibiotics [10]. Aside from the potential for inducing the release of cytokines and other inflammatory mediators, these substances induce local thrombosis through a variety of endothelial and macrophage-mediated processes. Synergistic interactions between certain anaerobes, most notably *Bacteroides fragilis*, and endotoxin-bearing Gram-negative organisms suppress local host defense mechanisms and facilitate the establishment of infection [11–13]. *B. fragilis* produces a capsular polysaccharide that interferes with complement activation and inhibits leukocyte function [14]. These phenomena are thought to restrict the delivery of phagocytes to the site of infection, permitting a more rapid rate of bacterial growth than would otherwise be seen.

CLINICAL ASPECTS OF CARE FOR PATIENTS WITH INTRA-ABDOMINAL INFECTIONS

Initial Therapeutic Goals

For the critically ill patient with an intra-abdominal infection, perforation, or ischemic process, timely resuscitation is crucial to their survival. Resuscitative efforts should begin when the patient enters the hospital, rather than waiting for admission to the ICU. During a thorough diagnostic workup with a history and physical, laboratory values and imaging, findings such as severe peritonitis, portal venous gas, or free intraperitoneal air may be discovered that necessitate immediate intervention. In these cases, the need for intervention supersedes the need for ICU admission. Without source control, peritoneal soiling will continue, and the patient's condition will continue to deteriorate. The patient should be prepared for the operating room. Due to the global vasodilatory effects of anesthesia, the patient should receive rapid volume loading. Resuscitative efforts can continue intraoperatively, led by a combined effort of the surgeon and anesthesiologist.

In patients not requiring immediate operative intervention, resuscitation should begin rapidly. Supplemental oxygen should be provided, with a secure airway by endotracheal intubation, if indicated. Lung-protective ventilatory strategy should also be employed to prevent volutrauma, with tidal volumes of approximately 6 ml per kg of ideal body weight [15]. Adequate venous and arterial access should be gained to infuse fluids and blood products as well as provide invasive hemodynamic monitoring and easy blood sampling. Pulmonary artery catheters should be carefully considered, but have proven to be of marginal assistance when the patient is unresponsive to fluid resuscitation [16].

Appropriate resuscitative goals must be established and pursued for each patient, starting by using crystalloid solution to achieve a central venous pressure of 8 to 12 mm Hg. Vasopressors, namely, norepinephrine, should be used to achieve a mean arterial pressure of 65 mm Hg, with supplemental low dose vasopressin use, if necessary. Transfusion of packed red cells should be considered in patients with active bleeding or with hemoglobin less than 7 g per dL, to augment oxygen delivery. In addition to the standard hemodynamic parameters, oxygen delivery parameters such as continuous mixed venous oxygen saturation (SvO2) or mixed central venous oxygen saturation (ScvO2) may be followed. ScvO2 of more than 70% is desirable, with transfusion or pressor therapy to achieve this endpoint. Arterial lactate clearance is another useful parameter. A lactate clearance of at least 10%, measured at 2-hour intervals, has been recently demonstrated to be equal to ScvO2 as an indicator of response to resuscitation. More traditional endpoints should also be considered, such as adequate urine

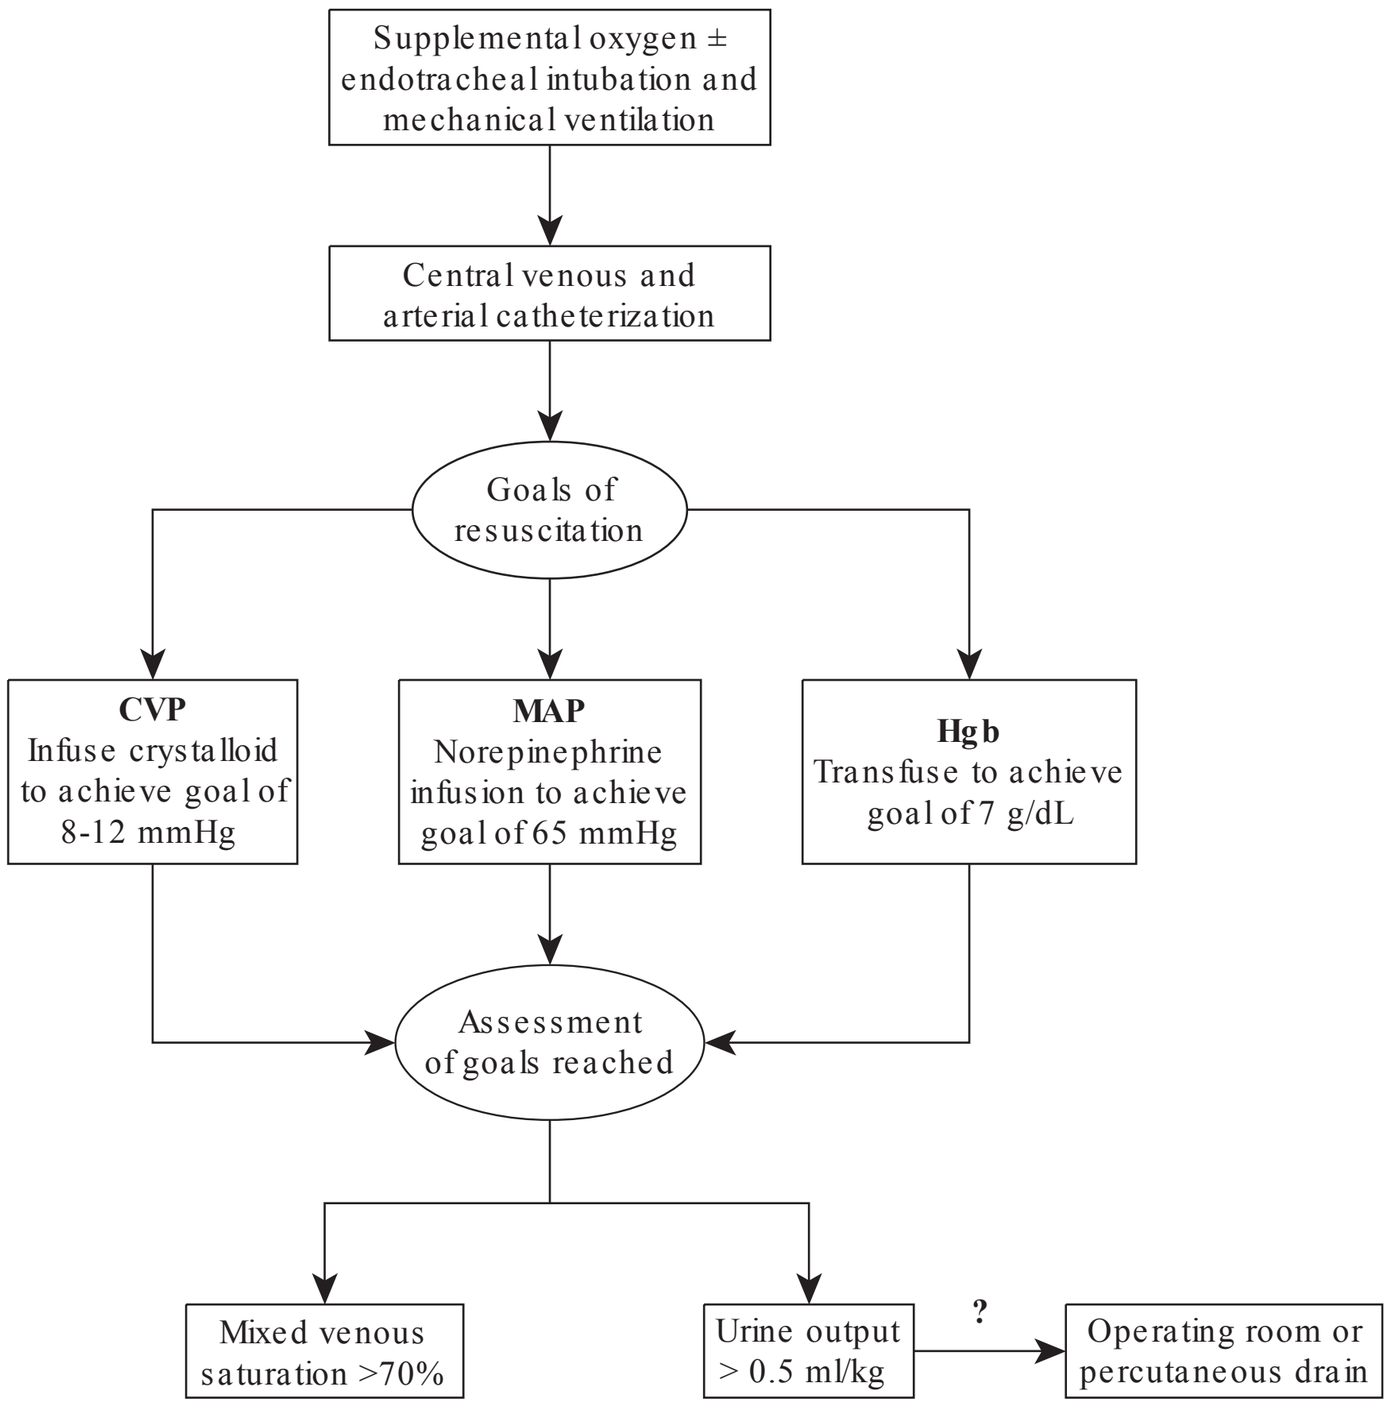

FIGURE 150.1. Algorithm for resuscitation of patients with suspected intra-abdominal infections. Crystalloid or packed red blood cells are infused to achieve goals of resuscitation, while end points are assessed by means of urine output and mixed venous saturation from a superior vena caval sample. Patient responsiveness to resuscitation will dictate whether operative or radiographic intervention is warranted. CVP, central venous pressure; MAP, mean arterial pressure; Hgb, serum hemoglobin level.

output and serial physical exam, specifically extremity warmth and level of consciousness. Newer measures such as tissue oxygen saturation measured by near infrared spectroscopy are being studied and may be beneficial as additional noninvasive means of guiding resuscitative efforts [16–22].

Blood cultures should be obtained upon admission, ideally before administration of intravenous antibiotics. Antibiotic therapy should be started immediately. Broad-spectrum antibiotics against Gram-positive, Gram-negative, and anaerobic bacterial organisms should be chosen. Antifungal coverage should be considered, especially if there is an upper gastrointestinal source, in those on long-term antibiotics or in an immunosuppressed patient [17,23].

Sepsis may be complicated by coagulopathy and DIC. For the patient about to undergo an operation, coagulopathy should be reversed with FFP and/or cryoprecipitate, and platelets should be transfused if counts are less than 50,000 per mm^3. Thromboelastography (TEG) is being increasingly used in ICUs and may prove beneficial for patients with intra-abdominal sepsis [24–26] (see Fig. 150.1).

Surgical Management of Diffuse Peritonitis

First of the surgical concerns during management of any intra-abdominal infection is achieving source control. The infectious or inflammatory process should be removed. All compartments of the abdomen should be explored, including the subphrenic, subhepatic, pelvic, and interloop spaces. All abscesses are drained, all inflamed or perforated bowel is resected, and the abdomen is irrigated with copious amounts of warm saline. The mantra "drainage, debridement, diversion then drugs" expresses the surgeon's opinion about the importance of gaining source control.

After source control is achieved, the surgeon turns their attention to intra-abdominal reconstruction. Primary anastomosis is nearly always performed after resection of small bowel segments. Large intestinal reconstruction is not as straight forward. The majority of data regarding restoring intestinal continuity in the setting of diffuse peritonitis is taken from the treatment of diverticulitis. A two-stage procedure is the default operative mode in sick patients. After resection of all inflamed bowel, this involves creation of an end colostomy proximally and leaving a rectal stump distally, with the intention of restoration of intestinal continuity at a future date. The goal of a two-stage procedure is to avoid anastomotic dehiscence. This procedure is associated with its own morbidities, including stoma complications, abscess formation, and leakage. Primary anastomosis, with on-table colonic washout is increasingly used in perforated diverticulitis, with the goal of avoiding morbidity of stoma complications and need for future laparotomy. Mortality and complications have been shown to be similar to two-stage procedure, with similar operative times. These studies involve heavy selection bias, thus primary anastomosis is still not universally accepted as an alternative to two-stage procedure. The most important factors for the surgeon to consider are the amount of peritoneal soilage and the hemodynamic status of the patient. Patients with perioperative shock, especially those on vasopressors, should not undergo primary anastomosis of small or large bowel [27–30].

In the patient with diffuse peritonitis, after a stoma or anastomosis is created, a drain is usually placed. Closed suction drains (Jackson-Pratt or Blake type) are preferred to open drains (Penrose type). Drain tips are positioned near the inflamed organ, in paracolic gutters or another dependent

portion of the abdomen and exit through the skin and fascia, away from the laparotomy incision. These drains allowed continued efflux of contaminated material from the abdomen. Change in character or quantity of the effluent should raise suspicions of leak or need for further debridement. Absence of drainage, though, may be a sign of a nonfunctioning drain rather than a sign of lack of continued pathology. Drain removal is a variable and stepwise process. Patients often keep drains until enteral diet is tolerated. Occasionally, patients are discharged with drains in place.

A critically ill patient who is likely not to eat in the near future should have a feeding tube placed. Various feeding tubes are used, including nasogastric, gastric, jejunostomy, or g-j tubes, allowing for gastric decompression and jejunal feeding simultaneously.

Though the open abdomen has long been a part of postoperative management of patients, the term "damage control surgery" has only recently been coined. Damage control was first used in the management of traumatic injuries, but is applicable in the setting of inflammatory, infectious, and vascular pathology in the abdomen of a patient in extremis. This process is now the subject of extensive study as a deliberate process in management. The intensivist's role in this strategy is paramount [31].

Damage control surgery (DCS) is defined as an abbreviated laparotomy, consisting of gaining control of bleeding and contamination in a patient on the verge of physiologic collapse. DCS is designed to help solve the problem of the lethal triad of acidosis, coagulopathy, and hypothermia. This triad continues to develop intraoperatively and can lead to patient death despite a technically correct operation [31,32].

Selecting the proper patient for this strategy is based on criteria involving disease process and physiologic status. The decision is made early in the preoperative or intraoperative phase of care by the surgeon, with constant communication with the anesthesiologist. These criteria have been defined by multiple authors. The disease based criteria consist of an inaccessible injury, multiple severe injuries, severe contamination, need for a time consuming procedure, need for a second look to reevaluate the intra-abdominal contents or inability to close abdominal fascia. The physiologic criteria include hypothermia ($< 35^{\circ}$C), metabolic acidosis (< 7.30), nonmechanical bleeding, and poor response to resuscitation [33].

Three general phases of damage control are described. In the initial phase, the abbreviated laparotomy involves a thorough exploration and control of bleeding, and then contamination. No reconstruction efforts are made at this time. The abdomen is closed with towel clamps, a running nylon skin suture, or a layered vacuum assisted closure.

Second is the resuscitative phase. This involves establishing clean IV access and removing femoral lines if possible. A ventilation strategy should have the goal of oxygenation and ventilation while avoiding volutrauma from excess tidal volumes and careful use of Positive End-Expiratory Pressure (PEEP) to avoid diminishing venous return. Fluid and product resuscitation should be used to correct acidosis, restore normal tissue perfusion, and optimize oxygen delivery. This should all be done in a warm ICU room with warm IV fluids to correct hypothermia. Twelve to 48 hours should be allowed for the completion of resuscitation [31–34].

Third is the definitive operation, when packs are removed, the abdomen is reexplored, reconstruction is undertaken, and the abdomen is irrigated [31–34]. Abdominal closure is also part of the definitive operation. Frequently a tension free closure of fascia is not possible. In this case, surgeons often elect for replacing the suction assisted closure in conjunction with a progressive closure strategy. Several strategies exist but all involve changing abdominal dressings every 2 to 3 days and progressively cinching the dressing with re-approximation of the fascia. The goals of these strategies are to provide negative pressure to the wound and continuous evenly distributed fascial traction. Some choose a planned ventral hernia, in which only the skin is closed. This requires reoperation in several months, but avoids placement of a foreign body. Other surgeons perform a fascial closure with absorbable mesh, allow granulation to occur, and then place a skin graft [35–42].

Occasionally, while the patient is undergoing resuscitation, an unplanned operation is necessary. Problems arise such as bleeding, abdominal compartment syndrome, or continued septic shock. Abdominal compartment syndrome is a life threatening condition that develops during resuscitation due to accumulation of fluids and intra-abdominal swelling or due to continued bleeding. Compartment syndrome may present as decreased pulmonary compliance on the ventilator resulting in peak inspiratory pressures more than 40 cm H_2O, as cardiovascular collapse due to decreased venous return or as elevated bladder pressures more than 20 mm Hg with decreasing urine output [31–34].

The intensivist should also be aware of common postoperative problems, namely abscess and fistula formation. If fevers, ileus, or wound drainage arise during this phase, CT scan of the abdomen and pelvis are performed at approximately postoperative day 7. If any suspicious fluid collections are found, they can then be drained percutaneously.

Diagnostic Imaging for Suspected Intra-abdominal Infections

A critically ill patient with a suspected intra-abdominal process and a clinical exam consistent with peritonitis should be taken to the operating room for exploration and treatment. Without such findings on exam, diagnostic imaging is the next important step in the management of these patients.

Routinely, plain abdominal X-rays are obtained. They are easily acquired, have minimal radiation exposure, and can be done at the bedside. The acute abdominal series routinely consists of upright chest, upright abdominal, and supine abdominal films. Plain films have shown the most utility in the diagnosis of the perforated viscous and acute intestinal obstruction. For proper detection of free air, 5 to 10 minutes in the upright position are necessary before performing the study, to allow air to move to a visible location under the diaphragms. If the patient is unable to maintain an upright position, left lateral decubitus position is the next best. Plain films may demonstrate an obstructive process, showing distended bowel loops, step ladder air–fluid levels, and a paucity of distal bowel gas. Frequently however, critically ill patients are unable to sit upright or in a decubitus position for any amount of time. In addition, plain films lack the diagnostic accuracy to discover most intra-abdominal infections, and another mode is needed [43–45].

Computed tomography (CT) is the gold standard for the diagnosis of intra-abdominal processes, their locations and complications, with superior sensitivity and specificity for a range of life threatening diseases including, but not limited to, mesenteric ischemia, hernia, pancreatitis, diverticular abscess, and aneurysmal disease. Helical CT technology has improved both the quality and ease of administration of CT scans. Despite its diagnostic superiority, CT is not without its problems, especially in the ICU setting. Many critically ill patients are unable to be transferred to the radiology suite. Some morbidly obese patients are unable to fit into conventional scanners. CT scans obtained for suspected intra-abdominal infection should be performed with intravenous, oral, and sometimes rectal contrast. Failure to use contrast can significantly decrease

diagnostic accuracy. Many ICU patients are unable to receive contrast, due to renal insufficiency or inability to tolerate orally administered contrast. Decisions about the use of contrast should be made with careful consideration weighing the input from surgeons and radiologists alike [43–45].

Ultrasound (US) is the workhorse of the ICU. In addition to its use as a tool in obtaining central and arterial access, echocardiography, bladder scans, focused abdominal sonogram for trauma (FAST), thoracentesis, and the detection of DVTs, ultrasound is a portable technology with applications in diagnosis and treatment of many intra-abdominal processes at the bedside in the ICU. US is the diagnostic procedure of choice in the setting of right upper quadrant diseases such as acalculous cholecystitis and hepatic lesions, as well as in pelvic diseases including ovarian torsion, PID, and ectopic pregnancy. US is also used at the bedside by the interventional radiologist to percutaneously drain abdominal fluid collections. In addition, US techniques are expanding to include natural orifice translumenal endoscopic surgery (NOTES) procedures for endoscopic ultrasound (EUS) guided drainage of collections in the chest, abdomen, and pelvis. Limitations of ultrasound include poor imaging with increased body wall thickness and bowel gas interference [44–49].

In the era of increasing use of minimally invasive technologies, bedside laparoscopy in the ICU is increasingly common and safe. Bedside laparoscopy can be performed by an abdominal drain tract or new port site. In addition, new devices are being developed that can be used without general anesthesia or pneumoperitoneum. The utility of bedside laparoscopy lies in its ability to diagnose various conditions such as mesenteric ischemia and cholecystitis or for use in trauma, while avoiding the morbidity of an exploratory laparotomy in a critically ill patient [50–53].

MANAGEMENT OF SPECIFIC INTRA-ABDOMINAL INFECTIONS

Management of Abscesses

Once intra-abdominal infection is recognized, and resuscitation and antibiotics have been started, a decision must be made regarding the most appropriate avenue for gaining source control. Percutaneous abscess drainage (PAD) has replaced the need for emergent operative intervention in the management of many intra-abdominal processes [20]. In some patients who become asymptomatic after drainage, PAD provides definitive therapy. In those with ultimately fatal diseases, palliation is provided, and the morbidity of subsequent surgical drainage may be avoided. In other situations, it allows for initial source control and medical stabilization so that an elective one stage operation can be performed. PAD and operative intervention are best viewed as complementary rather than competitive techniques.

Inflammation may manifest as a phlegmon, seen as a viable inflamed mass around the affected tissue, a liquefied abscess, necrotic tissue, or a combination. Liquefied abscesses are drainable, whereas phlegmon and necrotic tissue are not. Decisions regarding which mode of intervention to use are largely based on CT findings and require experience, clinical judgment, and careful consideration of underlying and coexistent disease processes. Close cooperation between the surgeon, interventional radiologist, and other physicians involved in the patient's care is mandatory.

The basic requirements for catheter drainage include a safe route of percutaneous access and a fluid collection of drainable viscosity. Specific indications for PAD have expanded significantly and now include many conditions that were previously thought undrainable, such as multiple or multiloculated abscesses, abscesses with enteric communication, infected hematomas, and deep pelvic abscesses [54,55]. In fact, for abdominal collections that require drainage, PAD is considered the standard, unless a hard indication for an operation exists [54,55]. Advances in endoluminal ultrasound techniques have facilitated advanced drainage procedures. Those abscesses in contact with the rectum or vagina can be treated with catheter drainage through these organs. These ultrasound-guided transrectal and transvaginal drainage procedures are effective and well tolerated [47,56,57].

It is generally possible to distinguish drainable fluid from phlegmon or necrotic tissue using a combination of imaging and fine-needle aspiration. Not all fluid collections require drainage, but intervention is required for those that are infected and for sterile collections that cause symptoms due to mass effect.

It is important to consider the possibility of underlying neoplastic disease in the setting of enteric perforation, especially in elderly patients. Significant soft tissue thickening of the bowel wall, especially if localized and non-circumferential, should raise the possibility of an underlying tumor, as should the demonstration of potential metastatic disease such as adenopathy or liver lesions. A "target" appearance, with circumferential low-attenuation submucosal thickening sandwiched between the enhancing mucosa and submucosa, is believed to be specific for inflammatory disease. To exclude the possibility of neoplasia fully, follow-up imaging is needed to document resolution, or confirmatory tests such as barium contrast studies or endoscopy can be performed.

Technical Aspects of Drainage Procedures for Intra-abdominal Abscesses

Excellent imaging is a key element for successful PAD. Imaging permits precise localization and characterization of disease, appropriate access route planning, and immediate assessment of technical success. Imaging is also needed for adequate follow-up to identify problems and gauge outcome. It is important that the drainage route not cross a sterile fluid collection or other infected space because of the risk of cross-contamination. Crossing the pleural space for thoracic and upper abdominal drainage carries the risk of empyema formation. Thus, collections in the upper abdomen often require an angled subcostal or low intercostal approach [58]. It is acceptable to cross the peritoneal space to drain an extraperitoneal abscess. Placement of a catheter through the small bowel or colon should always be avoided. Transgastric drainage of lesser sac pseudocysts has been advocated by some authors and appears to be safe, although this approach remains controversial [55]. Lesser sac collections also can be approached transhepatically through the left lobe of the liver [59], although traversing solid organs should be avoided whenever possible. Obviously, it is important to be aware of, and avoid, major vascular structures.

In most cases, drainage is performed following fine-needle (18- to 22-gauge) aspiration with the aspirate being used to document infection and gauge the viscosity of the fluid. In some situations, single-step aspiration of the fluid may suffice, without the need for tube placement. Examples include clearly aseptic collections, small abscesses (2 to 3 cm) into which tube placement would be difficult and relatively nonviscous collections that can be completely evacuated. However, for most collections, a drain should be placed to ensure complete evacuation and to minimize the chance of recurrence. If the patient is not already receiving antimicrobial therapy, this should be

instituted before the drainage procedure to minimize the infectious complications of contaminating sterile tissue, although continued antibiotic coverage will be dictated by the contents of the fluid collection.

A multitude of catheters are available for percutaneous insertion. The choice of catheter size is determined primarily by the viscosity of the fluid to be drained. In the majority of cases, 8 to 12 French drains are sufficient [60,61]. Larger drains may be needed for collections that contain debris or more viscous fluid. Drains of larger caliber can be placed at a later time, if needed, by exchange over a guidewire. Although most abscesses can be drained with a single catheter, there should be no hesitation in placing as many drains as are needed to evacuate the abscesses effectively.

After catheter placement, the cavity should be evacuated as completely as possible and irrigated with saline until the fluid is clear. Initial manipulation of the catheter(s) and irrigation should be done as gently as possible to minimize the induction of transient bacteremia and subsequent potential hemodynamic instability. For cavities that are completely evacuated at the initial drainage and for which there are no abnormal communications to viscera, simple gravity drainage generally suffices. For larger or more viscous collections and those with ongoing output due to fistulous connections, suction drainage with sump catheters is more effective [59,61,62]. Thoracic drains should always be placed to water-seal suction to avoid the complication of simple or tension pneumothorax.

Proper catheter management following the initial placement is a critical determinant of success and requires the interventional radiologist to become an active member of the management team [63]. Drains should be checked regularly (at least daily) to monitor the volume and nature of the output, ensure adequate function and clinical response, and quickly recognize and correct any catheter-related problems. Periodic irrigation of the drains is recommended, once or several times per day, with sterile saline [64]. This can be performed by either physicians or trained nurses. Fibrinolytic agents may be useful for evacuation of fibrinous or hemorrhagic collections. Repeat imaging studies and catheter injections are frequently used to document progress and identify problems. Occasionally, it is necessary to add, replace, or reposition drain catheters.

Catheters should be removed when criteria for abscess resolution are met. Clinical criteria of success include resolution of symptoms and indicators of infection. Catheter-related criteria include a decrease in daily drainage to less than 10 mL and a change in the character of the drainage from purulent to serous. Radiographic criteria include abscess resolution and closure of any fistulous communications. If catheters are maintained until these criteria are satisfied, the likelihood of recurrence of the abscess is minimized. For sterile fluid collections, the drain should be removed as soon as possible, generally within 24 to 48 hours, to minimize the risk of superinfection [64].

In evaluating the causes of PAD failure, a number of factors are consistently identified, namely a fluid collection too viscous for drainage and the presence of phlegmon or necrotic debris. Technical modifications such as increasing the drain size and irrigation can salvage some of these drainage procedures. Recognition of phlegmon or necrotic tissue on follow-up imaging studies may lead to cessation of attempts at PAD. Multiloculated collections and multiple abscesses are another cause of failure that can be minimized by using an adequate number of catheters along with mechanical disruption of adhesions with a guidewire. Fistulous communications, either unrecognized or persistent, are yet another potential cause of failure, as is drainage of a necrotic tumor mistaken by imaging to represent an abscess.

Recognition of a significant soft tissue component, maintenance of a high index of suspicion, and the use of percutaneous biopsies can minimize the risk of failing to appreciate the presence of tumor. Suspicious fluid also can be sent for cytologic assessment. The success rate for PAD tends to be lower in immunocompromised patients (53%) patients, as compared to immunocompetent patients (73%) [65].

Appendicitis

Inflammation and infection of the vermiform appendix is the most common intra-abdominal infection requiring surgical intervention [66]. Though the highest incidence is during the first two decades of life, acute appendicitis affects all age groups.

Appendicitis results from obstruction of the appendiceal lumen due to fecalith, lymphadenopathy, foreign body or mass, which initially results in increased luminal pressure, stasis of luminal contents, and soft tissue edema. An intense inflammatory reaction ensues, causing neutrophil infiltration. Venous outflow obstruction develops followed by arterial inflow insufficiency, ultimately resulting in gangrene and perforation.

Classic appendicitis presents with migratory abdominal pain. Initially dull and poorly localized in the periumbilical region, the pain changes to a sharper quality located in the right lower quadrant over McBurney's point. Anorexia is present early and a mild fever is often present. Nausea and vomiting may also be seen, but if they appear early, before development of pain, suspicion should arise for gastroenteritis. Exam reveals focal peritonitis, often evidenced by rebound tenderness, though a cadre of different signs may be elicited [66]. Leukocytosis, if present at all, is mild. Clinical signs of perforation include intense pain, prolonged symptoms, high fever, significant leukocytosis, tachycardia, and severe tenderness [67].

If the diagnosis cannot be made confidently or if perforation is suspected, contrast enhanced CT scan of the abdomen and pelvis may be ordered and has a 95% positive predictive value for acute appendicitis. CT scan may demonstrate appendiceal dilation and wall thickening, periappendiceal fat stranding, appendicolith, phlegmon, abscess, gross perforation, or free fluid [44,68]. Ultrasound is slightly less reliable for diagnosis and demonstration of complications, but is most useful in evaluating for alternate diagnoses, especially gynecologic disorders [68]. Care should be taken to distinguish periappendiceal changes with those around the terminal ileum that may represent inflammatory bowel disease.

Management is started by early administration of intravenous antibiotics covering against Gram-negative bacteria and anaerobes [69]. In acute non-perforated appendicitis, operative intervention should proceed as quickly as possible. Laparoscopic appendectomy is now the procedure of choice, though in thin males open appendectomy is acceptable. Laparoscopic approach provides superb visualization and allows evaluation of other pelvic and abdominal organs [66]. If perforation is found at laparoscopy, the appendix is resected, irrigation is performed, and antibiotics are continued for an extended course of 7 days.

Periappendiceal masses found on imaging may be a phlegmon or an abscess, representing a contained perforation. If feasible, percutaneous drainage of discrete abscesses is standard. If adequate drainage is achieved, management without appendectomy in the acute setting is safe and effective. Less than 10% of patients will fail this approach and require emergent appendectomy [70].

Current controversy exists concerning the need for interval appendectomy (IA) after initial nonsurgical management. Standard for many years was to perform an IA after a resolution phase of 6 to 8 weeks. IA is often a technically difficult operation due to adhesions and distorted anatomy, and many surgeons will elect not to perform IA. This strategy may be most appropriate, as risk of recurrence of appendicitis or

related complication is low, only 5% to 9% in current studies [69–72]. Accurate predictors of recurrence are needed. Also of concern is the risk of malignancy. Appendiceal neoplasm is present in 1.7% of surgical specimens [73,74]. In 1.2% of patients managed nonoperatively, a malignancy was discovered at follow up [70]. Careful consideration of the patient's physiologic status and risk factors must be made.

Diverticulitis

Diverticulitis is an inflammation of colonic diverticula, while these are actually pseudodiverticula – small herniations of colonic mucosa and submucosa through the muscularis [75]. Diverticula develop from a combination of increased intracolonic pressure and mural weakness at the site of blood vessel penetration into the colon [76,77]. The diverticula become occluded with fecal matter. Local ischemia and bacterial overgrowth result in microperforation and the start of the inflammatory cascade [29].

Diverticulitis presents as a constellation of signs and symptoms, most commonly a triad of fever, lower abdominal pain, and leukocytosis. It is typically a disease of older patients, and very rare in patients younger than 40 [78]. Patients also report constipation, recent hematochezia, nausea, vomiting, and dysuria. Pneumaturia and fecaluria are rare, but indicate colovesicular fistula [79]. Diverticulitis is primarily a clinical diagnosis, but contrast enhanced CT is usually performed to assess the location and severity of disease. CT shows colonic wall thickening and fat stranding around an area with diverticula [80]. Masses, fistulas, abscesses, and perforation may also be visualized.

Management is based upon severity of symptoms, number of recurrences, and presence of any complications of diverticulitis. For those with minor symptoms, oral antibiotics can be given, with a gentle resumption of a regular diet. Complicated disease is defined as having a pericolic or pelvic abscess, fistula, stricture, obstruction, hemorrhage, perforation, or diffuse peritonitis [29,81]. For those with complicated diverticulitis, with more severe symptoms or with signs of systemic inflammation, hospital admission, bowel rest, and parenteral antibiotics are mandated after immediate fluid resuscitation [79]. Length of therapy is variable, but usually is continued until leukocytosis is improved, the patient is afebrile, and has decreased abdominal tenderness [29,75,79].

Emergent surgical intervention may be required. Any patient with diffuse peritonitis, obstruction, severe perforation, or not responding to antibiotics alone mandates an immediate surgical exploration and washout with any necessary interventions for repair of colonic perforation [75,81]. Abscesses as a result of complicated diverticulitis are treated similarly as all other intra-abdominal abscesses. In the abscess of generalized peritonitis and hemodynamic instability, well-circumscribed abscesses should be drained percutaneously [75,82,83]. After hospital discharge, patients should undergo colonoscopy, especially in cases of right-sided diverticulitis and those cases with perforation. It is imperative to rule out a potential malignancy. Typically, a 6-week cooling off period is allowed before endoscopy.

Elective surgical intervention is indicated in several circumstances. Those patients with numerous recurrences are at risk for multiple hospital admissions, future complicated disease, and associated colostomy. Elective resection may spare them this morbidity. Complicated disease is much more likely on first presentation, however, and better predictors are needed to determine who will have a recurrence of complicated disease [81]. Any patient having an attack complicated by abscess, stricture, fistula, or contained perforation should undergo elective resection. Patients in whom an underlying colon cancer cannot be successfully ruled out should also undergo interval elective resection [84].

Operative intervention in the elective setting is usually a resection of the affected colon, with colorectal anastomosis. Technique in emergent operations can range from resection of the grossly inflamed tissue and end colostomy (Hartmann's procedure) to resection and primary anastomosis. Both approaches have been shown to be safe, and the decision depends on extent of inflammation and soilage [27,28,30]. The resection of all areas containing diverticula is not necessary, as often they can be scattered about the entirety of the colon [80].

Acute Pancreatitis

Pancreatitis continues to be a difficult disease to treat, despite numerous attempts to clarify and standardize treatment algorithms [85]. The leading causes of acute pancreatitis in North America are biliary disease and alcohol use [86]. The diagnosis of acute pancreatitis is often not difficult – the combination of acute abdominal pain, elevated serum pancreatic enzymes, and nausea and vomiting strongly suggest the diagnosis. The controversy arises in the treatment of complicated acute pancreatitis.

Complicated acute pancreatitis is a disease often encountered in the modern ICU. Patients with pancreatitis often require massive fluid resuscitation and are at increased risk for organ failure [86]. Initial consideration should be given to adequate resuscitation, preserving organ function, providing enteral nutrition, and possibly antibiotics. Although controversy exists for each therapy, the consensus is to resuscitate patients with crystalloid to preserve organ function. Urine output remains the most reliable parameter. Enteral nutrition should be established through gastric feeds to preserve gut immune function and attempt to reverse the catabolic state [86]. Antibiotics directed to Gram-negative and anaerobic flora are reserved for patients with proven infection or prophylactic treatment for those with worsening clinical condition and developing organ failure [87].

Acute pancreatitis is frequently plagued by one of four possible complications – pancreatic pseudocyst, pancreatic abscess, pancreatic necrosis, and infected pancreatic necrosis. Pancreatic pseudocyst is rarely a cause of intra-abdominal sepsis and the natural history of pseudocyst is usually self-limited. If a pseudocyst becomes infected it is classified and treated as an abscess. Percutaneous drainage of infected fluid collections is the treatment of choice and should be undertaken expeditiously once the collections are discovered [88]. Pancreatic necrosis is diagnosed by contrast-enhanced CT scan. Absence of enhancement of the organ strongly suggests necrosis. Necrosis can be missed if CT scan is performed too soon after admission [89]. Treatment strategy is determined by whether the necrosis is sterile or infected. Patients with pancreatic necrosis exhibiting neither organ failure nor hemodynamic instability likely have sterile necrosis. Conversely, patients with worsening clinical conditions despite maximum therapy likely have infected necrosis. Any doubt may be answered by percutaneous image-guided biopsy for culture. The distinction is important since markedly different treatments are employed.

Pancreatic necrosis which remains sterile does not require any additional antimicrobial therapy. Should clinical deterioration occur, it is best to initiate treatment for infected pancreatic necrosis. The treatment for infected pancreatic necrosis is as drastic as it is controversial. Antibiotic therapy should be initiated immediately; a carbapenem such as imipenem/cilastin is recommended [87]. Prophylactic antibiotic coverage for sterile pancreatic necrosis has been proposed to prevent infection, but meta-analysis has not shown this to be true. Sterile pancreatic necrosis should not receive antimicrobial therapy [87].

In addition to antimicrobial therapy for infected pancreatic necrosis, surgical intervention should be considered. The timing and approach of surgical intervention is often debated. Consensus is that if clinically possible, delayed debridement is optimal, resulting in decreased mortality. Pancreatic necrosectomy in the acute stages of necrotizing pancreatitis may become necessary in the clinically worsening patient, but mortality remains exceedingly high [88]. Interest has developed in a minimally invasive approach to pancreatic debridement, using a combination of retroperitoneal nephroscopic debridement, percutaneous drainage, and endoscopic drainage and debridement. These approaches will require further study and have not reached the standard of care in North America [90,91].

Biliary Tract Infections

Acute Acalculous Cholecystitis

Acute cholecystitis in the intensive care setting is a different disease than the stone related disease found in ambulatory patients. Acute acalculous cholecystitis (AAC) is seen in patients suffering from diverse disease processes such as cardiac ischemia, burns, hemorrhage, pneumonia, or severe volume depletion. These patients may be undergoing such treatments as vasopressor support, transfusion, prolonged ventilatory support, high levels of PEEP, prolonged NPO status, and TPN. All of these conditions and treatments are risk factors for development of AAC [92–94]. Acalculous cholecystitis is the gallbladder's reaction to severe systemic illness, rather than a local process as occurs in gallstone related disease.

Decreased digestive stimulation causes stasis, gallbladder distention, and increased intraluminal pressure with associated bile infiltration into the mucosal and muscular layers. There is lymphatic distention and tissue edema [95]. Transfusion of packed red blood cells leads to changes in bile composition and increased sludge [92]. Gut hypoperfusion results in microvascular occlusion and leukocyte recruitment [95–99]. Thus gallbladder empyema, gangrene, and perforation may occur.

Critically ill patients are often obtunded or sedated and are unable to exhibit right upper quadrant tenderness. Hepatic transaminase and alkaline phosphatase levels are often normal and not helpful for diagnosis. A new leukocytosis or fever in a patient with appropriate risk factors should prompt radiographic evaluation, as a delay in diagnosis substantially increases mortality [100,101].

As in all cases of suspected right upper quadrant disease, ultrasound is the initial test of choice. Findings on ultrasound consistent with AAC are pericholecystic fluid, gallbladder distention or elongation, wall thickening, mucosal sloughing, and especially intramural gas [102,103]. Concern exists about the poor accuracy of US in the setting of acalculous disease as there are no standards for the normal gallbladder appearance in critical illness and diagnosis may be missed [104,105]. Since US is quick, portable, and repeatable, accuracy improves upon repeating the exam or using US in conjunction with cholescintigraphy [103,106]. CT scan is most useful in its ability to evaluate the entire abdomen, therefore it is ordered when AAC is not foremost of differential diagnoses. CT is still able to detect AAC in many cases, with findings similar to ultrasound [103,107–109]. Cholescintigraphy, a type of HIDA scan, visualizes injected intravenous radionucleotide buildup in the gallbladder. With intravenous morphine to augment the biliary secretion of the radionucleotide and CCK to visualize gallbladder emptying, superior diagnostic accuracy is achieved [103,105,106]. The large drawbacks of cholescintigraphy is that it is a time consuming test performed in the radiology suite and thus may not be appropriate for critically ill patients.

Antibiotics against Gram-negative rods should begin immediately after the diagnosis is made [69]. Definitive therapy for AAC is cholecystectomy, but treatment strategy is guided by the physiologic status of the patient. ICU patients already suffering complications from their primary, non-gallbladder illness are often unable to tolerate anesthesia and operative intervention. In this setting, percutaneous cholecystostomy under US or CT guidance is safe and effective. With a low failure rate, it can provide adequate source control [110–112]. Open cholecystostomy was performed in the past, but is obsolete in settings where image guided percutaneous drainage is available. When the patient physiologically improves, definitive therapy may be administered by laparoscopic cholecystectomy, on an elective rather than emergent basis [101,103,113]. Only in extremely ill or elderly patients, may cholecystectomy be avoided and cholecystostomy be considered definitive therapy [114].

Ascending Cholangitis

Since Charcot described the elements of "hepatic fever" in 1877, ascending cholangitis (AC) has been consistently defined as having two main features: common bile duct (CBD) obstruction and bactibilia [115]. Today, many of the critically ill patients presenting with AC have recently undergone manipulation of the biliary tract or stent placement. In patients without recent instrumentation, choledocholithiasis, benign or malignant stricture, adenopathy, and postoperative anastomotic stricture are important causes of cholangitis [116–118].

Partial obstruction of the hepatobiliary tract results in higher levels of bactibilia, but any acute obstruction will result in increased intraductal pressures. The increased pressure distends the ducts and increases wall permeability. Translocation of bacteria and toxins occurs and causes systemic toxicity, bacteremia, and hepatic abscesses [118].

The diagnosis of ascending cholangitis is clinical. Charcot described a triad of fever with rigors, right upper quadrant abdominal pain, and jaundice. Reynold's pentad also includes hypotension and altered mental status [119]. These clinical findings are still commonly seen in AC today; however, the classic triad and pentad are only seen in late disease. Patients presenting earlier often have right upper quadrant pain, fever without chills, and hyperbilirubinemia. Elevated transaminases and alkaline phosphatase may also be present due to biliary obstruction and hepatic injury and should not be confused with acute viral hepatitis [115,116].

In the patient with ascending cholangitis, imaging serves several functions—especially confirming diagnosis. Cross-sectional imaging is important for defining the level of obstruction. Etiology and treatment of a proximal CBD obstruction would be quite different than that of a periampullary obstruction. Imaging will also serve to elucidate associated pathology such as hepatic metastasis or abscess. As in all patients with right upper quadrant pain, the initial study of choice is ultrasound [120]. Both ultrasound and CT can accurately detect a dilated CBD and extrahepatic biliary obstruction, but neither can determine the cause and exact level of obstruction, compared to direct cholangiography [121,122]. MRCP is comparable to direct cholangiography in its ability to determine cause and level of obstruction and is noninvasive. Unfortunately, MRCP has a minimal role in the management of acute AC, since these patients will need an invasive procedure for treatment [115,122].

Once a diagnosis of cholangitis is made, prompt initiation of antibiotics and drainage of the biliary tree is required. ICU admission is needed in moderate and severe cases, and aggressive supportive care should ensue. Antibiotic profile should be selected to cover enteric organisms, including *E. coli, Klebsiella, Pseudomonas, and Enterococcus* [115,116]. The preferred method for complete visualization and decompression of

the biliary tree is endoscopic retrograde cholangiopancreatography (ERCP). Bile samples should be sent for culture. If the patient is unstable or all stones are unable to be cleared, a nasobiliary drain should be placed. Nasobiliary drains allow for subsequent imaging and sampling. In a stable patient, after successful removal of all stones, an internally draining stent should be placed [115,123,124]. If malignancy is suspected, brushings and cytology should be performed. If a gallstone is lodged at the ampulla or multiple impacted stones are present, papillotomy is required. Percutaneous transhepatic cholangiography (PTC) may be performed if ERCP provides inadequate decompression, if obstruction is proximal, or if the patient is too unstable to tolerate sedation needed for ERCP. If all interventions should fail, the final and definitive solution may be operative drainage of the bile ducts. After cholangitis resolves, patients will require a definitive operation. Laparoscopic cholecystectomy should be performed for gallstone related disease. Advanced imaging or laboratory studies may be needed for workup and planning for resection of malignant disease [115–118, 125].

Colonic Disease

Clostridium difficile **Pseudomembranous Colitis**

Initially named because of the difficulty in cultivating the bacterium [126], *Clostridium difficile* infection is an increasingly common and severe problem in modern intensive care units. With abundant use of broad-spectrum antibiotics and frequent colonization, *C. diff* associated diarrhea or pseudomembranous colitis is the most common nosocomial infectious diarrhea in adults [127–131].

C. Diff colitis is an opportunistic infection. During antimicrobial therapy for various infections, intestinal flora is destroyed, leaving ample resources for *C. difficile* to multiply. *C. difficile* is a Gram-positive, anaerobic, spore-forming bacillus. This microbe produces two exotoxins, toxin A and toxin B, which are responsible for causing diarrhea, colitis, and systemic illness. Recently, a hypervirulent strain has emerged, BI/NAP1/027, which produces "binary toxin" and increased levels of toxins A and B. This strain has been associated with increased disease severity and recurrence [132–134].

C. difficile infection can manifest in several forms. The most common *C. diff* presentation is colitis with diarrhea, though as many as 20% to 37% [135–137] of patients may have such severe colonic dysmotility that diarrhea is absent. Severe enteritis has been described, and though it is rare, it is capable of producing profound illness [138]. Patients presenting with signs and symptoms of systemic illness are labeled as having severe or fulminant colitis, carrying a mortality rate of 35% [139].

Multiple modalities may be implemented in the diagnosis of fulminant pseudomembranous colitis. In the critically ill patient, the presence of diarrhea is often the first clue. The presence of abdominal distention or peritonitis on physical exam, as well as profound leukocytosis and bandemia are all significant in *C. diff* infection. The gold standard for diagnosis of *C. diff* infection is the notoriously slow cytotoxin assay, which takes 1 to 3 days to result. Most commonly, hospitals use an ELISA to detect the presence of toxin A or B, but these assays have been criticized as having a high false negative rate [135]. Many institutions have established the practice of repeating the test at the next episode of diarrhea to improve diagnostic accuracy. New assays are being tested, which are both rapid and highly accurate [140].

Presence of pseudomembranes, disseminated yellow punctuate mural plaques on endoscopy, can assure the diagnosis. Flexible sigmoidoscopy is commonly performed, but studies have shown poor accuracy in the setting of disease limited to the ascending colon. Colonoscopy of the entire colon may be performed, but would require bowel prep and carries greater risk of colonic perforation in a patient already suffering from severe illness [135,137,141].

In patients with a clinical picture consistent with fulminant colitis, computed tomography (CT) has been found to be the most sensitive measure of colonic inflammation [137]. CT scan may show perforation, colonic thickening, colonic distention, pericolonic inflammation, or free abdominal fluid. CT can localize disease as right or left side predominant or can confirm presence of pancolitis. Though the predictive nature of CT scan is debated, diagnosis made by CT scan, as compared to endoscopy or toxin assay, has been shown to predict survival in patients undergoing colectomy for pseudomembranous colitis [135,141,142].

The mainstay of *C. diff* colitis treatment is medical. When feasible, patients with moderate disease should be discontinued from other antimicrobial therapy. Narcotics, loperamide, Lomotil, or other antimotility agents should also be discontinued, as they promote retention of toxins. Patients should receive general supportive therapy.

Moderate disease is treated with oral metronidazole, with oral vancomycin reserved for recurrent disease. Other antibiotic usage, as well as the duration of therapy is frequently debated. Ten days of therapy after cessation of other antibiotics is considered sufficient [143].

For initial recurrent disease, another round of metronidazole is given, followed by oral vancomycin therapy for a second recurrence. For patients with inability to tolerate oral medications, a nasogastric tube should be used to deliver the medications or vancomycin may be given rectally. Intravenous metronidazole may be added in this scenario, but independently is not as effective as oral therapy [144]. Adjunctive medical therapies may be considered for recurrent disease. Probiotics are frequently used to repopulate gut flora. *Saccharomyces boulardii* is thought to have anti-inflammatory effects on the colon [145]. In small, randomized controlled trials, probiotics have shown a favorable effect. Probiotic cocktails have been shown to both prevent and decrease recurrence of *C. diff* infections [146].

Cutting-edge therapies target the toxin-mediated mechanism of *C. diff* colitis. IVIG administration [147] and treatment with monoclonal antibodies [133] are currently being used in clinical trials. *C. difficile* infections progress to fulminant disease in 3% to 8% of patients [132]. Fulminant or complicated disease is defined variably throughout the literature. Definitions generally include such parameters as need for ICU admission, need for surgery, and presence of shock, respiratory failure, or renal failure.

Physicians and researchers have struggled to find adequate predictors of disease severity. Many recent studies have sought to elucidate exactly which factors predict a patient's risk of mortality. Profound leukocytosis is often seen in *C. diff* infections and several studies show increase in mortality associated with a WBC count more than 20,000 per μL. High band percentage or leukopenia were also associated with poor survival. Patient age more than 70 years, ASA score of 4 or 5, low diastolic blood pressures are all factors frequently associated with poor survival in fulminant disease [50,128,132,139]. Length of stay preceding diagnosis of *C. diff* colitis was associated with decreased survival, both in surgically and medically treated groups [50].

Development of fulminant colitis is a surgical concern, and colectomy can be curative in many patients. The true difficulty for the clinician is discovering a window in which patients with fulminant disease will benefit from colectomy, without exposing excess numbers of patients to the morbidity of surgery. Overall, the mortality associated with colectomy in the setting of fulminant *C. diff* colitis is between 35% and 57%. Several studies call for early surgical management

and even a surgical opinion in all cases of severe disease [128,132,135,136,141,148,149].

Need for preoperative vasopressors was associated with increase in perioperative mortality from 14% to 65% [135]. Similarly, in another study, patients requiring preoperative vasopressors or intubation had an increase in mortality from 16% to 84% [141]. Preoperative presence of acute respiratory failure and acute renal failure have been identified as independent predictors of mortality after colectomy [149]. However, patients having a recent surgical procedure had improved mortality after colectomy (77%), compared to those that did not have a recent procedure (23%) [141].

Though several operative approaches have been described for fulminant pseudomembranous colitis, the operation of choice is total colectomy with end ileostomy. In series where left hemicolectomy was performed, mortality increased from 11% to 14% after total colectomy to 100% after left hemicolectomy [136,150]. The exception to this finding is in right-side only disease, identified on endoscopy. Patients undergoing right hemicolectomy had no decrease in survivals [135]. These data highlight the need for early diagnosis of *C. difficile* infection and early surgical intervention, before the development of organ failure.

Toxic Megacolon

Toxic megacolon (TM) has been recognized as a clinical entity for over 60 years, and is defined as an inflammation of the colon causing progressive dilation in the presence of systemic toxicity [151]. Initially described in patients with complicated ulcerative colitis (UC) or Crohn's disease, it is seen more recently as a complication of many various conditions of the colon. Due to improved management techniques of inflammatory bowel disease (IBD) and increased awareness of associated complications, the incidence of TM has decreased in these conditions. TM is still frequently diagnosed as the initial presentation of previously unknown UC [152–154]. TM caused by *C. diff* colitis is on the rise in modern hospitals due to the increasing severity and incidence of *C. diff* infections. Associated with immunosuppression due to AIDS, CMV colitis is also increasingly common. Salmonella, *E. coli* 0157, Shigella, Campylobacter, amoeba, and other infectious diarrheal illnesses have each been recognized as a cause of TM. TM has also developed after various chemotherapy treatments, bowel ischemia, and treatment with antimotility drugs [155–163]. During a workup for possible TM, it is also important to consider intestinal pseudo-obstruction and actual bowel obstruction, though these patients do not exhibit the systemic illness of TM patients.

On gross pathologic specimens, IBD related TM shows dilation, mural thinning, and deep ulcerations while microscopic examination shows myocyte degeneration, abundant granulation tissue with intact Auerbach and Meissner's plexuses. *C. diff* related disease shows the yellow plaques consistent with that disease. CMV related disease shows inclusion bodies on microscopic specimens [151]. The etiology of toxic megacolon lies in the induction of nitric oxide (NO) in the inflamed colonic tissue. NO has been shown to decrease smooth muscle activity. NO synthase was upregulated in surgical specimens of TM as well as in animal models, which also demonstrated colonic dilation and decreased contractile activity [164,165].

Diagnosis of toxic megacolon first involves key elements in the patient's history. Especially important are a personal or family history of inflammatory bowel disease, symptoms of extraintestinal manifestations of IBD, timing of symptoms of diarrhea, abdominal pain and blood per rectum, recent antibiotic use or hospitalization, HIV status and sexual history, recent travel, recent meals as well as any recent starting or stopping of any medications. Next, determining the level of systemic illness is important. Classic criteria require three of the following: fever > 38°C, HR > 120 per minute, leukocytosis > 10,500 per μL, anemia. In addition, one of the following is needed: dehydration, altered consciousness, electrolyte disturbances, or hypotension. The severity of each of these criteria is not specifically defined [154]. These criteria pre-date modern definitions of SIRS/sepsis, which could be used alternatively. Coupled with these above criteria, radiographic evidence of colonic dilation is required.

Classically plain films have been used to diagnose and follow progression of colonic dilation. Typically, a colon dilated to 6 cm was worrisome of an impending perforation, although large variability is seen. Plain films are also able to demonstrate colonic perforation. Recently, CT scan has been found to be superior to plain films. CT scans of TM patients demonstrate dilation in the right and transverse more than left colon. Diameter of 6 to 10 cm with abnormal haustral patterns is the typical finding. Frequently target or accordion signs are visible. Also, significant ascites and pleural effusions are present. CT does not demonstrate superiority in diagnosing the underlying etiology of the TM, but CT is able to detect complications of the disease that were missed on plain films. These findings include small perforations, abscesses, ascending phlebitis, and septic emboli [151,166]. CT scans should be performed upon diagnosis if possible, but are unnecessary in the severely ill patient.

Management of TM involves aggressive medical treatment from the moment of diagnosis and early surgical consultation. Patients should receive supportive ICU therapies and monitoring. Nasogastric tubes should be placed for decompression. Broad-spectrum antibiotics should be started. Treatment of the specific etiology of the TM should begin promptly. Steroids have been given for patients with diagnosis of toxic megacolon due to Crohn's disease or ulcerative colitis, but extreme caution should be used to ensure that an infectious cause is not present and avoid steroids in such cases. Salicylates should also be avoided in the setting of TM [151,159]. An adjunct to medical therapy is postural therapy. Benefit has been shown to patient rolling or a knee-elbow posture. This is presumed to reduce distention by allowing colonic gas to move distally and be more easily expelled [167,168].

Surgical consultation should be obtained as soon as the diagnosis of toxic megacolon is established. Though medical therapy has been shown to be effective in some cases, many patients will not respond and will need a timely, life saving colectomy. Certain indications for an operation include signs of peritonitis, free air, uncontrollable rectal bleeding, and failure of medical therapy. There is no specific size for colon diameter that necessitates colectomy, rather the overall clinical picture should determine therapy. Controversy exists as to the timing of surgery and the definition of medical failure. Medical failure should be viewed as continued clinical deterioration or progressive colonic dilation. Some patients exhibit marked improvement with medical therapy. Others exhibit prompt deterioration and should be taken to the operating room. Often patients show variable degrees of toxicity and questionable response to therapy (i.e., improvement in heart rate but continue to have fever). These patients may undergo a short trial of medical therapy, lasting 24 to 36 hours, with close examination by critical care and surgical teams. Any sign of complication or worsening condition should be managed operatively [152,153,156,169].

Several procedures are proposed for operative management of toxic megacolon. Overall operative mortality for TM is in the range of 7% to 30%, depending on the timing and type of procedure performed. The procedure of choice in modern surgical care is the subtotal colectomy with end ileostomy, leaving a rectal stump or creating a sigmoid mucous fistula. This procedure removes the diseased colon and leaves adequate tissue for future resection or reconstruction. It can be performed safely and quickly [151–153,156,169].

Postoperative Peritonitis

Postoperative peritonitis (PP) is primarily a consequence of anastomotic leakage (66%), intra-abdominal abscess (13%), or perforated viscous (7%) [170]. Local tissue ischemia, infected hematoma, and bile leakage are also common causes of PP and all have an iatrogenic component [171].

PP is a highly lethal condition, with a mortality rate of 30% [172], in part because it is often diagnosed late, due to ascribing clinical deterioration to other possible primary processes, or the reluctance to admit the possibility of a suture-line dehiscence. Malnourished patients, those with resistant organisms, those with multiple organ failures, and the elderly are all at risk for PP [173].

This diagnosis should be considered in any patient with signs of sepsis who has undergone a recent abdominal procedure, particularly those that included a gastrointestinal anastomosis or diffuse soilage. Laparotomy itself introduces free air into the abdominal cavity, thus pneumoperitoneum is a nonspecific finding in patients during the first few days after operation. Diffuse tenderness may not be uniformly present, as it can be masked by incisional pain. Intra-abdominal fluid is to be expected in the recent postoperative period. However, if US or CT reveals large amounts of fluid or persistent peritoneal fluid, image-guided aspiration should be considered for diagnostic purposes. A Gram's stain that reveals white cells, bacteria, or enteric contents is an indication for immediate laparotomy.

Surgical treatment should include either re-anastomosis in small bowel leaks or end-colostomy in colonic leaks, depending upon the degree of fecal contamination and the patient's condition. Postoperative abscesses should be percutaneously drained with image guidance. Patients suffering from PP who have been hospitalized for several days may be infected with resistant organisms. Cultures should be followed closely and therapy extended if the patient is without clinical improvement [174]. The postoperative patient deserves the highest degree of suspicion for anastomotic leak upon any suggestion that an intra-abdominal process has developed.

Enteric Fistula

Gastrointestinal fistulas are among the most dreaded and difficult to manage complications treated by surgeons and intensivists. A fistula is defined as an abnormal communication between two epithelialized surfaces. Enterocutaneous fistulas (ECFs), connections between bowel and skin, are associated with mortality rates of up to 21% [175] and long, expensive hospital stays. Patients suffering from ECFs are also frequently plagued with such problems as severe fluid and electrolyte imbalances, malnutrition, anemia, sepsis, and difficult wound care issues.

More recently, open-air fistulas, or enteroatmospheric fistulas (EAF) are increasingly common, as a consequence of damage control surgery and the open abdomen. EAFs involve spillage of intestinal contents into an open laparotomy wound, rather than to the skin. This combination of a large open wound and continuing peritonitis leads to a profoundly catabolic state. This is a dire situation, with mortality approaching 65%, considerable patient suffering, and huge demands on resources and clinicians to provide adequate nursing and wound care [175,176].

Enteric fistulas have numerous antecedent causes, including trauma, foreign body, infection, inflammatory bowel disease, radiation treatment, vascular insufficiency, anastomotic leak, inadvertent enterotomy, and other iatrogenic injury. Fistulas are classified as high output (>500 mL per day), moderate output (200 to 500 mL per day), or low output (<200 mL per day). It is also important to classify a fistula according to its site of origin (e.g., gastrocutaneous, colocutaneous). EAFs are classified as superficial or deep, depending on if they drain outward onto the exposed bowel or inward into the peritoneal cavity [175,176].

ECFs typically present as occult sepsis in a postoperative patient, who has a continued postoperative ileus, a distended abdomen, late postoperative fevers, or increasing leukocytosis. Often there are signs of a wound infection followed by the appearance of intestinal contents through the wound. Diagnosis of fistula is a clinical one, made at the bedside, though laboratory and imaging studies are useful in fistula characterization and management. Fistulogram, that is, contrast injected into the fistula or drain under fluoroscopy, is the prime means of characterizing the fistula, providing information about its location and most importantly can show presence or absence of obstruction distal to the fistula, which precludes spontaneous closure in all instances. CT scan is most useful in elucidating intra-abdominal abscess or other pathology and allows for percutaneous drainage [175,177]. Studying the fistula is the clinician's lowest priority among management goals. Stabilization of the patient, protection of the skin, and ramping nutrition up to goal should all be accomplished first.

Management of patients with fistula disease demands aggressive supportive care. Volume replacement and maintenance is paramount, as patients may lose several liters of fluid daily from intestinal contents measured by drains and bags, as well as large amounts of insensate losses from open wounds and increased respiratory rates. Fluid losses should be measured and replaced. Hypokalemia can be a lethal problem commonly seen with high output fistulas, and should be meticulously managed. Patients should be placed on strict NPO status, gastric secretions should be minimized with a proton pump inhibitor and initially a nasogastric tube should be inserted to prevent distal transit of gastric secretions. Octreotide is often used to decrease fistula output by inhibiting pancreatic and intestinal secretions and decreasing intestinal motility [175,176,178].

Wound management is crucial to timely healing of ECFs and requires a thoughtful and imaginative approach by a team including senior surgeons and wound care/stoma specialists. Goals of wound management include protection of surrounding skin, measuring the effluent, and avoiding desiccation of the exposed bowel. Careful efforts should be made to avoid worsening of the fistula or creation of a new fistula in the surrounding area. Skin should be kept clean and dry. Skin protection can be accomplished with duoderm and ostomy glue placed around the wound edges. Effluent can be collected in a standard ostomy pouch or by intubating the fistula opening with a sump or "whistle-tip" catheter on low suction [175,177]. Recent reports show that with painstaking wound care, 37% to 46% of ECFs may close spontaneously [179,180].

Wound management in patients with open-air fistulas is considerably more complex, due to exposed intra-abdominal contents. Approximately 12 to 14 days postoperatively, dense adhesions form between exposed bowel loops, and they become fused. If a deep EAF is present, and the opening is unable to be drained with sumps, free soiling of the peritoneal cavity will continue. Negative pressure wound therapies are now being employed with some success in this situation, as they allow for continuous drainage. Caution should be used to protect exposed bowel from direct suction with plastic sheeting [176,180]. Superficial EAFs can be functionally converted into an ECF by placing a skin graft onto the granulation tissue of the fused, exposed bowel. Once the skin graft heals, an ostomy pouch may be placed over the fistula [175,176]. Patients with EAF may have a difficult, open wound for months.

Prolonged intestinal failure is the hallmark of severe fistula disease and aggressive nutritional support is a chief principle in the management of ECFs. Ongoing inflammatory processes result in increased nutritional need and inefficient use of supplied nutrients. Draining intestinal secretions result in major protein

losses. Patients with high output fistulas have substantially increased nutritional requirements, often more than double their baseline calculated calorie and protein requirements. Additionally, patients will require much higher doses of vitamins and trace elements [175]. Patients with fistula disease may also benefit from immunonutrition supplementation. Glutamine supplementation is thought to normalize intestinal immunology and cytokine profiles as well as reversing intestinal villus atrophy. Other nutrients such as arginine and fish oil are associated with improved outcomes in critically ill patients [181–183].

Patients with low output fistulas should be able to receive the majority of their nutrition enterally, by a low residue, easily absorbable formula. High output fistulas can also be managed with enteral nutrition. Using a feeding tube in the proximal jejunum, sufficient absorption should occur if at least 4 feet of normal intestine exists between the ligament of Treitz and the fistula. If insufficient length is present here, then enteral feeding may be provided with the tip of the feeding tube distal to the fistula. Another alternative for enteral feeding is fistuloclysis, feeding directly into the fistula itself. When enteral nutrition is provided, it is best given in elemental or semi-elemental formulations, which facilitate absorption. Enteral nutrition is believed by many to have equal efficacy in fistula closure to parenteral nutrition, is able to prevent intestinal mucosal atrophy and reduce incidence of other nosocomial infections [175,184–188]. Full enteral nutritional support is not always possible, due to distal obstruction, sepsis, hypotension, or poor absorptive capacity, and additional support is needed.

The widespread use of parenteral nutrition (TPN) has improved fistula management dramatically, allowing patients' nutritional needs to be met when it is not possible to do so enterally. TPN is thought to reduce overall patient mortality and result in increased rates of fistula closure. Parenteral nutrition also allows for custom replacement of micronutrients and trace elements. Unfortunately, TPN carries risks of central venous catheter insertion, increased expense, catheter related sepsis, thrombosis, and TPN associated cholestasis, and liver dysfunction [175,185–188].

Surgical mantra dictates that if ECFs do not heal spontaneously by 6 weeks, then they will ultimately require operative management. Timing of surgical repair is crucial, since early in the postoperative process, patients develop dense adhesions intra-abdominally that prevent access into the abdomen. Most surgeons describe a waiting period of several months before attempting surgical repair. This delay is to allow time for maturation of these adhesions, for resolution of any infectious processes, and for optimization of nutrition.

CONCLUSION

Intensive care unit patients can have primary intra-abdominal infections leading to sepsis or the abdomen may be a source of secondary sepsis in the previously physiologically compromised patient. Regardless of the circumstances, intra-abdominal sepsis requires a stepwise approach that includes prompt and judicious resuscitation, adequate source control, and broad-spectrum antibiotic coverage. Equally important as fluid and medical therapy is an overall design to preserve and restore gastrointestinal function and continuity. A multidisciplinary team approach to essential to succeed in the intensive care unit caring for patients with intra-abdominal infections.

CHAPTER 151 ■ MESENTERIC ISCHEMIA

TAKKI MOMIN AND JOHN RICOTTA

Mesenteric ischemia is a rare, life-threatening condition characterized by compromise of the splanchnic circulation resulting in bowel ischemia. Recognition of this disorder has been increasing, and it is estimated to occur in 1 of every 1,000 hospital admissions [1]. It is often encountered in association with other critical illnesses and has a wide spectrum of clinical presentation, making the diagnosis difficult to establish. In mild cases, asymptomatic reversible mucosal ischemia may ensue, whereas frank bowel necrosis and perforation may follow prolonged malperfusion. The classic finding of pain out of proportion to physical examination is often present, but some patients may have only vague abdominal complaints [2]. Frank bowel necrosis with peritonitis portends a poor prognosis with a mortality rate that can reach 90% [3]. Associated cellular injury often induces a systemic inflammatory response that triggers a cascade of events leading to multiorgan failure and death, even after successful intestinal resection. Effective treatment of this disease requires prompt diagnosis, rapid restoration of circulation, surgical resection of nonviable bowel, and supportive care [4].

ANATOMY OF THE MESENTERIC CIRCULATION

The small bowel and colon are principally supplied by the celiac artery (CA), superior mesenteric artery (SMA), and inferior mesenteric artery (IMA). These arteries communicate through an extensive network of collateral blood vessels that can preserve arterial perfusion to the splanchnic organs when one or more of the main arteries occludes or becomes stenotic due to atherosclerotic disease. The gastroduodenal artery and pancreaticoduodenal arcades provide an important source of collateral flow between the CA and SMA. The SMA and IMA communicate through several collateral vessels including the marginal artery of Drummond and the meandering artery also known as the arc of Riolan. The hypogastric artery can provide collateral flow to the IMA through the hemorrhoidal and sacral arteries in the pelvis [5,6] (Fig. 151.1).

ETIOLOGY

Mesenteric ischemia can occur acutely, resulting in rapid development of bowel ischemia, or chronically, producing postprandial pain, fear of eating, and weight loss. Acute ischemia may result from acute arterial occlusion due to thrombosis or embolism, acute occlusion of intestinal venous outflow, or ischemia from impaired flow without fixed obstruction in the setting of sepsis and shock. Chronic ischemia is usually the result of progressive atherosclerotic narrowing of multiple mesenteric arteries.

Acute Mesenteric Insufficiency

Arterial insufficiency accounts for approximately 95% of cases of acute mesenteric insufficiency (AMI) and may be embolic (50%), thrombotic (25%), or nonocclusive (20%). The remaining 5% of cases of AMI are due to mesenteric venous thrombosis [7]. The most common source of arterial emboli is the heart. Patients will typically have a history of atrial fibrillation, myocardial infarction, left ventricular aneurysm, or a prosthetic heart valve [8]. The SMA is the most frequent site of embolization because of the preferential flow pattern established at the origin of the artery where it takes an oblique angle [9]. More than half of the emboli will lodge at or near the branch point of the middle colic artery, a point of anatomic narrowing in the SMA. When this occurs, flow through the proximal jejunal branches continues, producing a distinct pattern of bowel ischemia with preservation of proximal jejunum [10].

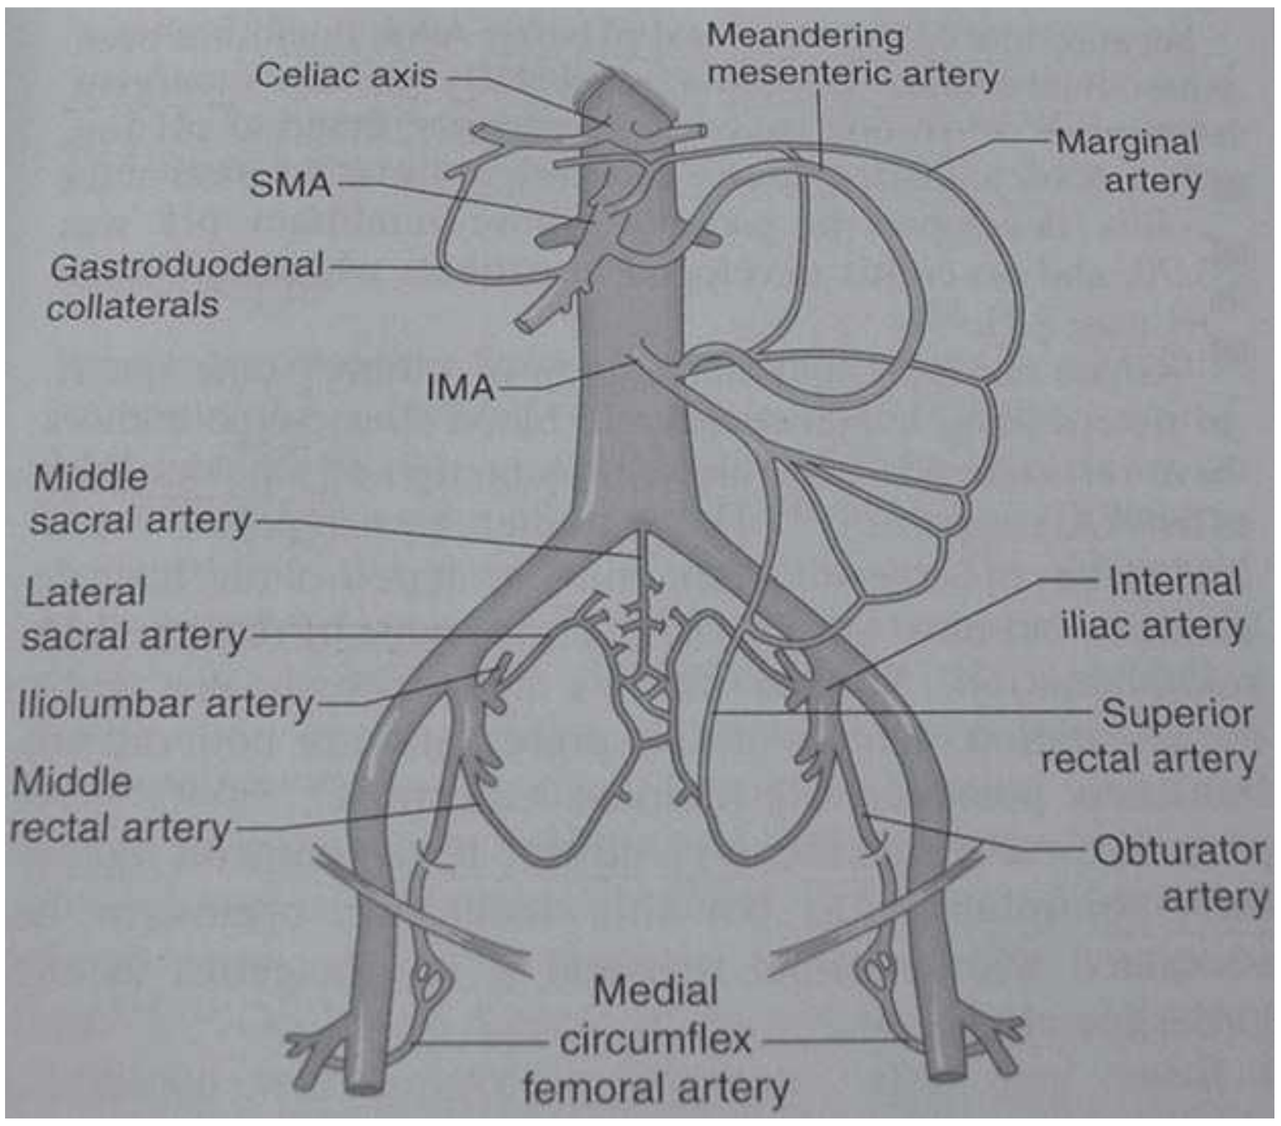

FIGURE 151.1. Schematic of splanchnic circulation. Rutherford Vascular Surgery. Abdominal and Iliac Aneurysms, 1431–1436, Copyright Elsevier (2005).

Acute thrombosis is usually superimposed on chronic coexisting atherosclerotic occlusive disease. The thrombus develops within the proximal SMA or CA in close proximity to the origin of the vessel where it is affected by atherosclerotic disease. In patients with asymptomatic, compensated mesenteric occlusive disease, acute ischemia develops from abrupt thrombosis of a diseased but patent artery (usually the SMA) as a consequence of plaque disruption or flow disturbance beyond a high-grade orificial stenosis [11].

In nonocclusive mesenteric ischemia, the reduction in blood flow usually occurs from low cardiac output or splanchnic vasoconstriction. This is often seen in the intensive care setting, associated with a number of underlying medical conditions such as congestive heart failure, cardiogenic shock, renal disease, hypovolemia, and sepsis [10,12,13]. In addition, vasoactive agents like digitalis and α-adrenergic agonists can induce mesenteric ischemia by splanchnic arteriolar vasoconstriction [13]. Intestinal hypoperfusion can also result from the release of inflammatory mediators associated with severe systemic illness such as pancreatitis, sepsis, trauma, and burns [14,15]. Abdominal compartment syndrome should also be considered as a potential cause of mesenteric ischemia. Excessive intra-abdominal pressure, measured as a bladder pressure more than 25 mm Hg, leads to direct compression of the inferior vena cava and portal vein as well as decreased flow in the inferior vena cava and superior vena cava [16].

Acute mesenteric ischemia may also result from extrinsic mechanical compression of either the arterial or the venous supply to the bowel when local blood supply becomes compromised by a strangulated hernia or intussusception [17]. Sacrifice of a major visceral branch or surgical interruption of the collateral circulatory pathways in the setting of prior visceral artery occlusion may, on rare occasions, result in acute mesenteric ischemia [18]. A well recognized example is ischemia to the sigmoid colon following ligation of the inferior mesenteric artery during aortic resection, or left colectomy, in a patient who has an asymptomatic SMA occlusion and relies on the IMA for visceral perfusion. Aortic dissection may occasionally cause mesenteric ischemia by creating a static or dynamic obstruction at the origin of one or more of the visceral vessels [19]. In this circumstance, perfusion to the mesenteric arteries may be established by either a fenestration procedure or surgical revascularization [19,20].

Mesenteric venous thrombosis (MVT) is an infrequent cause of bowel ischemia. Over 80% of patients diagnosed with MVT are associated with an underlying identifiable coagulation disorder that predisposes them to venous thrombosis. These include both inherited hypercoagulable disorders such as protein C or S deficiency, antithrombin III deficiency, factor V Leiden mutation, and methylenetetrahydrofolate reductase mutations and acquired hypercoagulable states such as malignancy, oral contraceptive use, polycythemia vera, thrombocytosis, trauma, or critical illness [21–23]. The presentation of patients with MVT varies depending on the extent and location of thrombus. Patients typically present with anorexia and nonspecific, vague abdominal pain that may be acute, but is more commonly insidious. Peritonitis is rarely seen and restricted to patients with frank bowel necrosis. The triad of thrombus within the SMV, thickened small bowel wall, and free fluid in the peritoneal cavity as identified on CT maybe an early indication of bowel infarction and the subsequent need for laparotomy [24].

Chronic Mesenteric Insufficiency

Chronic mesenteric ischemia (CMI) results from atherosclerotic disease of the mesenteric arteries and usually requires stenosis or occlusion of two or more mesenteric vessels. Stenosis or occlusion of a single mesenteric vessel will rarely result in abdominal pain; when it does, the SMA is usually the vessel involved. Progression to occlusion most often occurs gradually and allows development of robust collaterals in the splanchnic circulation to compensate for inflow disease. The basal circulation to the intestine is sufficient to maintain adequate blood flow at rest, but when metabolic demands increase, such as in the postprandial state, the higher resistance collateral circulation is inadequate to meet the increased oxygen requirements and symptoms of vascular insufficiency develop. The classic presentation includes a preexistent history of postprandial abdominal pain that results in food avoidance and significant

weight loss. Abdominal pain without weight loss is unusual for mesenteric ischemia and suggests an alternate diagnosis [25].

PATHOPHYSIOLOGY

Mesenteric ischemia occurs when there is inadequate delivery of oxygenated blood to satisfy the metabolic demands of the intestines. The presence of an extensive collateral network in the splanchnic circulation maintains intestinal viability even with as much as a 75% reduction in normal blood flow [25,26]. Under normal conditions, the splanchnic circulation maintains regional blood flow to compensate for systemic changes in hemodynamics through autoregulatory mechanisms. This is achieved by altering the vasomotor tone of the arteriolar resistance vessels. Under circumstances of decreased perfusion pressure, the precapillary arterioles reflexively vasodilate to enhance regional blood flow by lowering mesenteric vascular resistance. A combination of local, humoral, and neural factors mediate the vasomotor tone of these resistance vessels in response to various pathologic conditions [25–27].

In the setting of acute mesenteric thrombosis or embolus, reflexive vasodilation initially occurs and transiently enhances blood flow through existing collateral circulatory pathways. As intestinal ischemia progresses, paradoxical vasoconstriction results and local blood flow is critically reduced to a point where secondary arteriolar thrombosis ensues [28].

Intestinal ischemia from mesenteric venous thrombosis results from venous outflow obstruction leading to venous hypertension resulting in reduction of capillary and arteriolar flow. The thrombosis initially begins in the small veins out in the periphery and extends proximally toward the superior mesenteric vein. Vasospasm of the mesenteric arterioles is also believed to play a major role in ischemia associated with venous thrombosis [28–33].

Early histologic evidence of intestinal ischemia can be observed after only 5 to 10 minutes of arterial occlusion [34–38]. When the ischemic insult is not severe and perfusion can be rapidly restored, these changes are reversible. If ischemic cellular injury persists, tissue infarction will occur, starting from the mucosal surface of the intestine where blood supply is most tenuous. With prolonged ischemia, the bowel wall becomes edematous from increased vascular permeability. Hemorrhage of the mucosal and submucosal layers follows. As infarction extends transmurally, the integrity of the intestinal wall is destroyed and risk of perforation increases. During advanced stages of ischemia, the intestine loses its protective barrier function, resulting in passage of inflammatory cells and translocation of enteric organisms into the portal circulation. Locally produced mediators are released into the circulation along with bacterial endotoxin, triggering an intense systemic inflammatory response. The resulting sepsis and physiologic stress imposed by systemic inflammatory response often leads to multiorgan dysfunction and possibly death [15,39].

CLINICAL PRESENTATION

Mesenteric ischemia can manifest itself in a variety of ways depending on etiology and degree of intestinal ischemia. The signs and symptoms may be subtle, nonspecific, and insidious, especially in chronic and subacute forms of mesenteric ischemia. When ischemia develops acutely, the most common predominant symptom is sudden onset of severe abdominal pain that is often out of proportion to physical findings. However, pain is absent in 25% of individuals with acute nonocclusive ischemia [39]. Symptoms may be nonspecific, including nausea, vomiting, diarrhea, and abdominal distension. Gastrointestinal symptoms may not always dominate the clinical presentation. Acute mental status changes have been reported in 30% of elderly patients with intestinal ischemia [40].

DIAGNOSTIC EVALUATION

Leukocyte count, serum lactic acid level, and arterial blood gas are the most common tests routinely ordered to screen patients for mesenteric ischemia. In patients with acute intestinal ischemia, 75% will have a leukocytosis greater than 15,000 cells per mm^3 and 50% will present with a metabolic acidosis [41]. Unfortunately, abnormalities in these studies accompany other abdominal pathologies, making them nonspecific [42–47].

Plain radiographs lack specificity, and in some cases, abdominal films may even appear normal in the presence of bowel infarction [48]. Some common radiographic features observed in intestinal ischemia include presence of bowel wall thickening, intramural gas (pneumatosis), bowel distention, and mesenteric or portal venous air [49,50]. None of these findings, however, are sensitive or specific to intestinal ischemia. Pneumatosis, when present, is often a sign of advanced ischemia with bowel infarction, although it may also be associated with other acute abdominal conditions such as peptic ulcer and inflammatory bowel disease [51]. The most practical purpose of obtaining plain films in the workup of mesenteric ischemia is often to exclude other causes of acute abdominal pain, most notably gastrointestinal perforations.

Computed tomography (CT) has emerged as one of the most accurate and expeditious methods of diagnosing abdominal pathologies (Fig. 151.2). It is often the first and most common imaging modality employed in the initial evaluation of abdominal pain. Computed tomography is more sensitive than plain films in detecting abnormalities associated with intestinal ischemia such as bowel edema, pneumatosis, and portal venous gas [52]. With intravenous contrast enhancement, CT scanning can assess the mesenteric arterial and venous circulation, permitting detection of both arterial occlusion and venous thrombosis [53,54]. CT angiography (CTA) is the best imaging technique for diagnosis of mesenteric venous occlusion (Fig. 151.3). CTA, however, is not useful in the diagnosis of nonocclusive mesenteric ischemia, and the absence of findings on CT imaging does not exclude the diagnosis of mesenteric ischemia. In recent years, the use of magnetic resonance imaging (MRI) in the detection of intestinal ischemia has been investigated [55–57]. Limited availability, longer scanning time, and higher expense limits the utility of MRI, and it has not been widely accepted in the routine workup of a patient with abdominal pain suspected of having acute mesenteric ischemia [58].

Angiography is used when CTA is inconclusive and when an endovascular intervention is contemplated. Arteriography not only permits endoluminal intervention in select cases of arterial or venous thrombosis, but also allows for selective arterial administration of vasodilating agents like papaverine to counteract vasospasm in patients with nonocclusive mesenteric ischemia [59]. Both lateral and anterior–posterior projections of the mesenteric arteries should be obtained to allow optimal imaging of the proximal and distal SMA and celiac artery [60]. Although effective in identifying arterial pathology, arteriography cannot assess the extent of bowel ischemia or infarction.

Nonocclusive mesenteric ischemia produces a characteristic irregular pruning pattern on arteriography related to segmental vasoconstriction of the arterial branches [60,61] (Fig. 151.4). Acute arterial embolus often demonstrates an abrupt luminal cutoff sign with a meniscus where the clot lodges [62]. In the SMA, the embolus frequently lodges at or just distal to the origin of the middle colic artery and is best visualized on arteriography in the lateral projection. Thrombosis of the mesenteric artery typically occurs at the origin of the vessel where there is underlying arteriosclerotic occlusive disease precipitating the

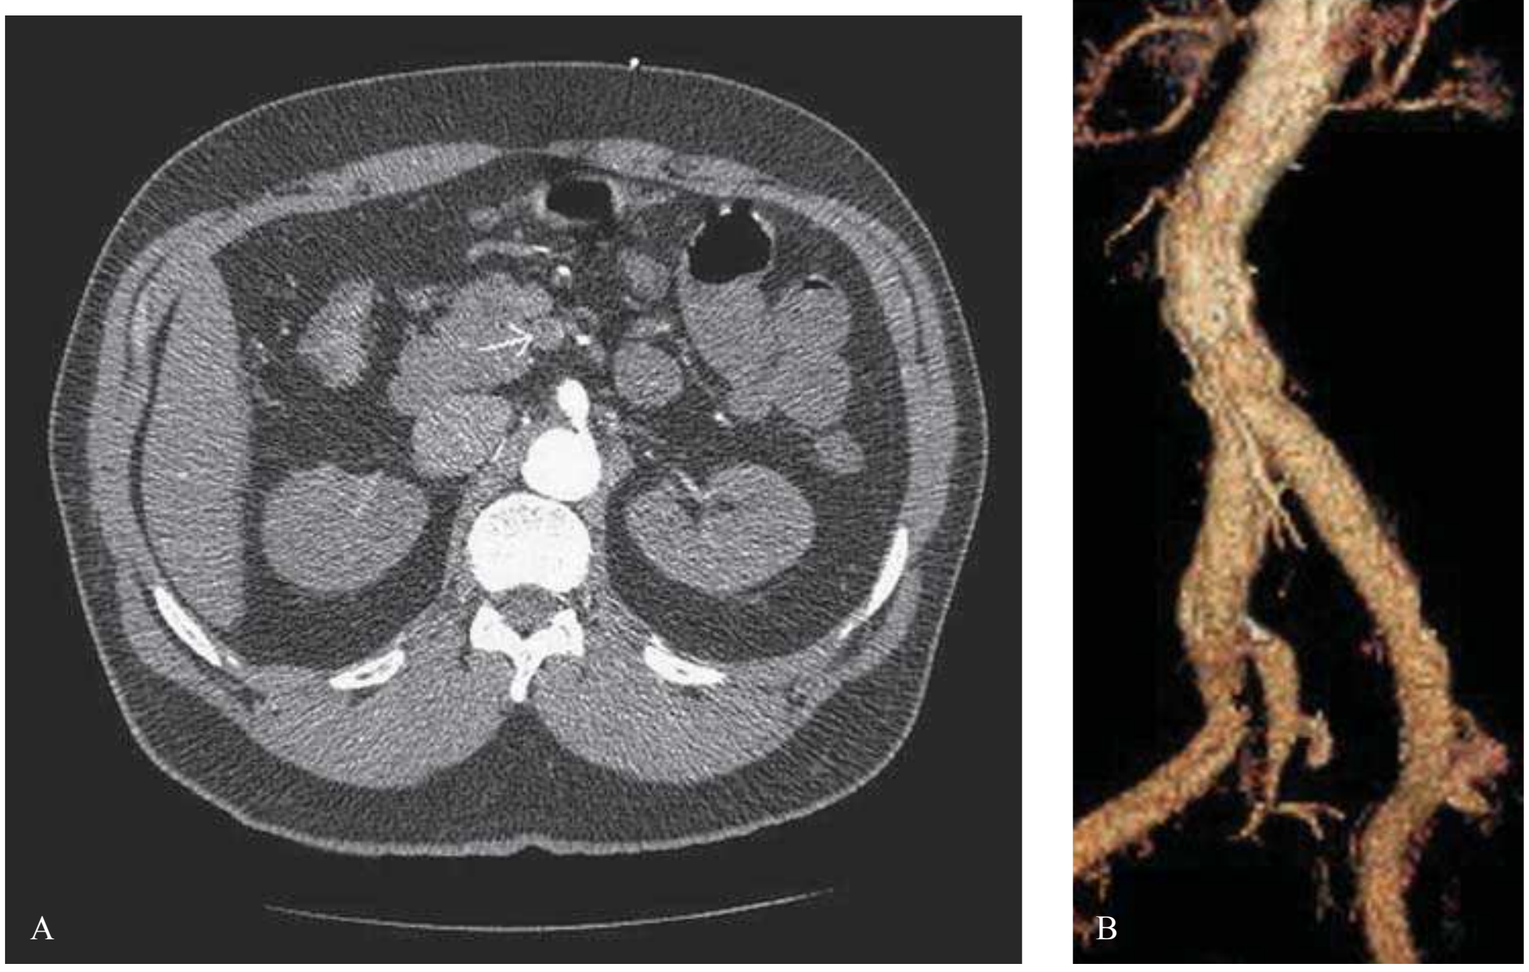

FIGURE 151.2. CTA of patient with mesenteric occlusion axial **(A)**, 3D reconstruction **(B)**.

thrombotic process [60]. There are exceptions to these observations but differentiating embolic from thrombotic disease on arteriography has important clinical implications in planning therapeutic interventions [41,63,64].

Duplex ultrasonography of the mesenteric vessels can be an accurate and cost-effective method of assessing the proximal celiac and superior mesenteric arteries. Ultrasonography can identify the presence of occlusive disease and quantify the degree of stenosis based on velocity criteria [65,66] (Table 151.1). Ultrasound is commonly employed as an initial screening study in the vascular evaluation of symptomatic patients suspected of having chronic mesenteric arterial disease. In addition, ultrasonography can identify nonspecific abnormalities including bowel wall edema, absent peristalsis, and even hepatic portal venous gas [67,68]. Duplex ultrasonography, however, has limited application in the diagnosis of acute mesenteric ischemia due to limitations in its ability to visualize beyond the proximal mesenteric circulation and to insonate through distended bowel.

In the intensive care setting, endoscopy may provide diagnostic alternative in the critically ill patient avoiding the danger of patient transport [69,70]. Endoscopic findings in ischemic colitis can be quite varied. Friable edematous mucosa or patchy areas of mucosal ischemia requires repeat endoscopy and supportive care, while frank intestinal necrosis mandates immediate surgical intervention. Endoscopy is unable to accurately

FIGURE 151.3. Beaded appearance of celiac artery **(A)**, superior mesenteric artery **(B)**, and inferior mesenteric artery **(C)** in a patient with nonocclusive mesenteric ischemia.

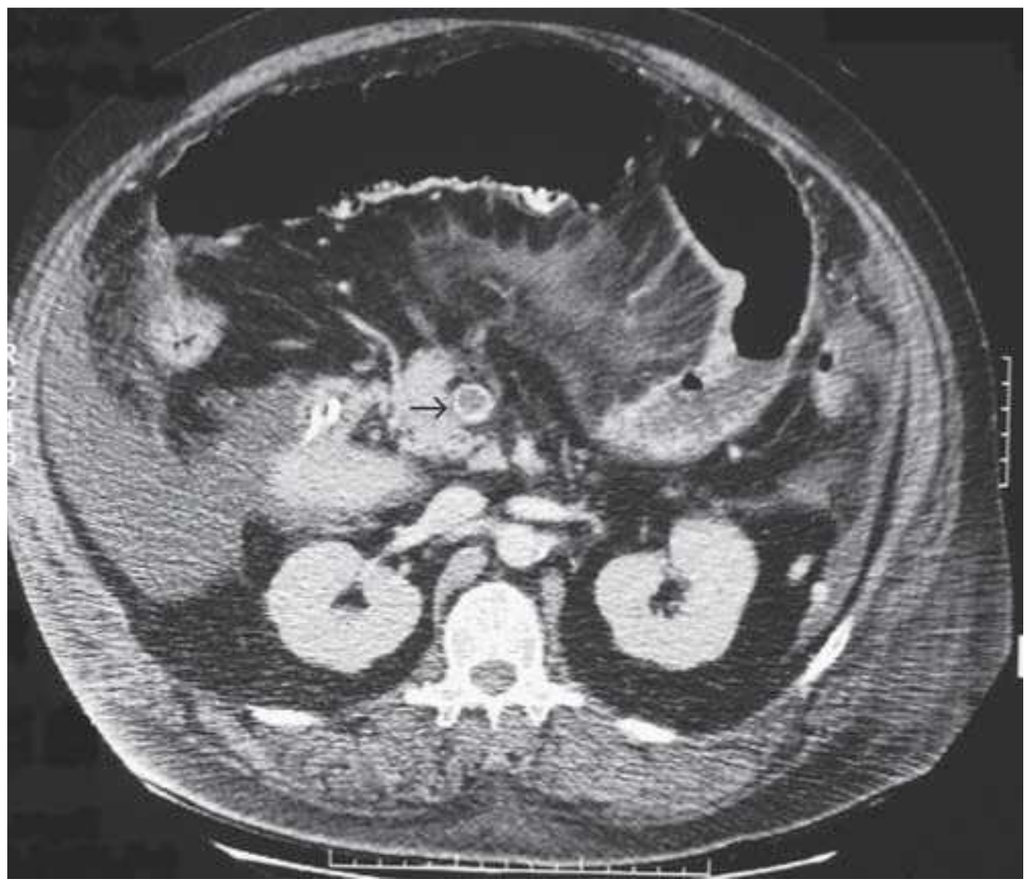

FIGURE 151.4. CT scan showing SMV thrombosis.

assess the depth of ischemic involvement beyond the mucosal surface [71–76], and most of the intestine supplied by the SMA is not readily accessible by conventional endoscopy.

TREATMENT

The treatment of mesenteric ischemia is largely determined by its specific etiology, the duration of ischemic insult, and the extent of infarcted bowel. It is critical to make the diagnosis accurately and expeditiously, initiate treatment to minimize ischemic injury, and preserve intestinal length to avoid the sequelae of short gut syndrome [77,78]. The initial management of patients with mesenteric ischemia involves resuscitation to optimize perfusion and physiologically prepare the patient for possible surgery. Broad-spectrum antibiotics should be initiated for potential infection along with systemic anticoagulation to minimize propagation of the thrombotic process [79]. If symptoms are mild, patients may be considered for immediate arteriography to elucidate the cause of ischemia with consideration of simultaneous catheter-based therapeutic intervention [79,80]. Patients presenting with peritonitis or bowel infarction require immediate laparotomy in lieu of time-consuming diagnostic evaluation that can risk further ischemic injury. The surgical management entails resection of grossly necrotic or nonviable intestine along with embolectomy or arterial revascularization to restore perfusion.

SMA embolus requires surgical extraction of the obstructing clot with assessment of distal perfusion to affected bowel. The arterial vasoconstriction that occurs distal to the embolus can be treated by direct intra-arterial administration of papaverine [81]. Pharmacologic thrombolysis using endovascular techniques has been reported for treating select patients with early mesenteric ischemia without bowel infarction [81–86]. In most cases of acute mesenteric thrombosis, however, severe atherosclerotic occlusive disease is present in the proximal vessel and open revascularization with a bypass is recommended over a percutaneous approach [87,88].

Patients with nonocclusive mesenteric ischemia are initially treated medically to optimize perfusion. The underlying systemic illness is aggressively treated while avoiding any aggravating agents like vasopressors. The diagnosis of nonocclusive ischemia is best made angiographically, which also allows for catheter-based intervention with intra-arterial infusion of papaverine to reverse vasospasm [81]. Patients who have nonocclusive mesenteric disease may still require surgical intervention if the ischemia results in bowel infarction.

Treatment of mesenteric venous thrombosis is focused on systemic anticoagulation with bowel rest. The underlying specific condition or coagulation disorder responsible for causing the thrombotic event should be identified, and the patient should be vigorously resuscitated since considerable third space loss can occur. Surgical thrombectomy of the venous circulation is rarely effective and should be reserved for cases of acute thrombosis without establishment of effective collaterals for venous drainage [89–92]. Patients require systemic anticoagulation in the postoperative period and many may need lifelong therapy due to a hypercoagulable state. Intestinal infarction may be present in the acute form, but the mortality rate and length of involved bowel is less than in acute arterial disease [93]. Preexisting liver disease and previous abdominal surgery, most commonly splenectomy, are two strongly associated risk factors for patients who develop mesenteric venous thrombosis [93].

Patients with chronic mesenteric ischemia have classically been treated with surgical revascularization through either an aortomesenteric bypass or transaortic endarterectomy. More than 90% of the patients will have occlusions in both the SMA and CA [94]. An arteriogram is necessary to determine the location of inflow occlusion and to assess the status of the distal mesenteric circulation for operative planning. Considerable controversy exists regarding the method of revascularization, the number of vessels to revascularize, and the best suited conduit [94]. The two commonly employed methods of revascularization include antegrade supraceliac aortomesenteric bypass and retrograde infrarenal aortomesenteric bypass. In general, antegrade bypass is preferred as the flow is more hemodynamically optimal and the supraceliac aorta is more likely to be disease free. Antegrade bypass, however, involves some degree of renal and visceral ischemia, in addition to increased afterload on the heart. In patients with renal insufficiency or significant underlying cardiac disease, a retrograde bypass, from the aorta or the iliac vessels, may be preferred. However, the rate of symptomatic recurrence is not definitely related to either the method of revascularization or the number of vessels revascularized [12,94]. The goal of multiple visceral revascularization therefore must be balanced against the operative risks entailed in a more extensive procedure.

The endovascular approach for patients with chronic mesenteric ischemia is emerging as a first line treatment option [95–99]. The objective in management of patients with chronic mesenteric ischemia is to relieve symptoms, prevent bowel infarction, and enable weight gain. Total mesenteric arterial occlusions are considered a relative contraindication to endovascular therapy due to fear of distal embolization. Comparisons of open versus endoluminal treatment for mesenteric arterial insufficiency suggest lower periprocedural complications associated with endoluminal techniques, but a higher incidence of late failure [96–99].

In patients with bowel ischemia, determining bowel viability can be the most challenging aspect of the operation. Accurate

TABLE 151.1

DUPLEX CRITERIA FOR MESENTERIC ARTERIAL STENOSIS

Vessel	Peak systolic velocity	Stenosis (%)
Superior mesenteric artery	≥275 cm/sec	70–100
Celiac artery	≥200 cm/sec	70–100

differentiation between viable and nonviable bowel determines the limits of resection and maximizes the residual absorptive reserve of the digestive tract. Determination of bowel viability involves visual and Doppler inspection and if needed a fluorescein-assisted tissue perfusion scan [100]. When bowel viability is indeterminate at initial exploration, a "second-look" procedure to reassess intestinal viability within 24 to 48 hours is used to avoid extensive resection at the first operation [100]. During the initial exploration, grossly nonviable bowel is resected and the intestinal tract is left in discontinuity. The abdomen is closed with drapes or a plastic bag, and the patient is transferred to the critical care unit for aggressive resuscitation and optimization. A second operation is performed in 18 to 24 hours after the patient's condition has been rendered optimal, or earlier in cases of deterioration.

The high mortality rate traditionally associated with intestinal ischemia has decreased in recent years with advancements in surgical revascularization and postoperative critical care. Contemporary studies on survival rates in patients with acute mesenteric ischemia have identified several factors associated with higher mortality: advanced age, inadequate intestinal resection, and presence of nonocclusive mesenteric disease [12]. An aggressive approach to diagnosis and treatment, employing liberal use of arteriography and minimally invasive techniques combined with traditional surgical intervention increases survival [95]. Open surgical revascularization is associated with lower rates of symptom recurrence compared to percutaneous treatment [96]. The most common cause of postoperative death is multiorgan failure followed by cardiovascular complications. Even with successful treatment, long-term survival for patients with acute mesenteric ischemia is generally poor with the majority of deaths related to coronary artery disease, short bowel syndrome, or recurrent mesenteric ischemia [12].

CHAPTER 152 ■ COMPARTMENT SYNDROME OF THE ABDOMINAL CAVITY

AJAI K. MALHOTRA AND RAO R. IVATURY

ABDOMINAL COMPARTMENT SYNDROME

Introduction

The association of elevated intra-abdominal pressure (IAP) and organ system dysfunction was described as early as the mid-nineteenth century [1]. However, the acceptance of this association as a distinct nosologic entity—abdominal compartment syndrome (ACS)—happened only in the late twentieth century. Even now, more than 20 years after the phrase was coined by Kron et al. [2], there is disagreement as to whether ACS is a distinct clinicopathologic entity in which the organ system dysfunction is causally related to the elevation in IAP or whether the elevated IAP is merely an epi-phenomenon observed in some critically ill patients, especially those receiving large volume crystalloid resuscitation [3]. The reasons for this are many and include (1) the variability of normal IAP [4], (2) lack of agreement as to the best method of measuring IAP [5], (3) lack of agreement about the level of IAP that is well tolerated and any elevation beyond which leads to pathologic consequences in the form of organ system dysfunction (Fig. 152.1) [6], (4) lack of agreement as to when intervention is necessary—in the prodromal phase to prevent development of organ system dysfunction or only after there is evidence of organ system dysfunction [7], and (5) the ideal intervention. These reasons not withstanding, the sheer volume of literature published about all aspects of this condition over the last two decades has reduced the army of skeptics to a corporal's guard. The current chapter focuses on the current understanding of ACS and attempts to provide a practical approach to the diagnosis, and management of this potentially devastating condition.

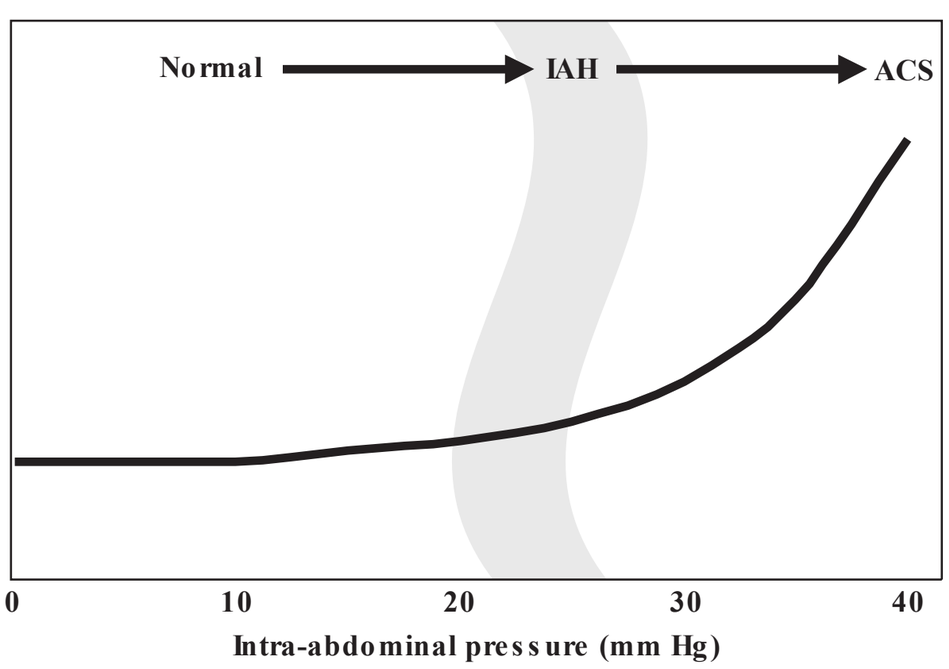

FIGURE 152.1. The continuum of normal intra-abdominal pressure to intra-abdominal hypertension (IAH). As the level of IAH increases organ dysfunction appears and the condition is called abdominal compartment syndrome. Note that the boundaries of normal IAP/IAH and IAH/ACS are wavy (grey zone). These boundaries are different in different individuals and also under different physiological state in the same individual.

The abdominal cavity is a space defined partly by rigid and inflexible structures—pelvis, spine, and coastal arches—and partly by more flexible structures—the musculoaponeurotic abdominal wall and the diaphragm. The total volume that can be accommodated within the confines of the abdomen is limited by these anatomical boundaries. Whenever there is a discrepancy between the available space, defined by the anatomical limits of the abdominal cavity, and the sum total volume of intra-abdominal structures—fluids and intra-abdominal organs—the pressure within the abdominal cavity tends to rise. This situation may arise from any condition that leads to increase in the total volume of structures—accumulation of fluid or swelling of organs—or decreased space—vigorous muscle contraction, loss of domain, etc. Initially the discrepancy is well tolerated by stretching of the flexible boundaries. However, as the limits of this accommodation are reached, even small increments in the intra-abdominal volume lead to large increases in IAP [6]. The elevated IAP affects organ system function in multiple ways. In the initial stages there is a purely mechanical effect best observed in the respiratory system, with embarrassment of ventilation due to elevation of the diaphragm, and in the kidneys where there is a fall in the glomerular filtration pressure affecting renal function. As the IAP continues to rise, there is decreased venous return to the heart affecting cardiac function and resulting in decreased cardiac output (CO). This reduction in CO has profound effects on every cell within the body as it globally decreases tissue perfusion. Finally, there is evidence that the elevated IAP in and of itself acts as a potent pro-inflammatory stimulus augmenting the systemic inflammation already set in motion by (1) the primary process that initiated the elevation of IAP and (2) tissue hypoperfusion caused by the diminished CO.

Definitions

As already mentioned earlier, there are no uniformly accepted definitions of the terms used in the context of ACS. Often, ACS and elevated IAP are used interchangeably, and the units of pressure measurement vary between mm Hg and cm H_2O. At the first World Congress on Abdominal Compartment Syndrome held at Noosa, Australia, in December 2004, attempts were made to develop consensus definitions of these terms and also to standardize the units and methodology used for measuring IAP. The definitions that follow are those that were developed at that conference and are used throughout the chapter. The units used are mm Hg unless otherwise specified. The method used to measure IAP, unless otherwise specified, is by the well-described technique of measuring bladder pressure, where the level of the pubic symphysis is considered 0 mm Hg [8].

Normal IAP: IAP varies between subatmospheric to a mean of 6.5 mm Hg [4]. It is affected by body habitus (chronically elevated in morbid obesity) [4], phase of respiration (higher during inspiration), and body position (elevated in the erect position) [5].

Consensus definition: IAP to be considered normal should be measured in the supine position, at end expiration and should have a value < 10 mm Hg [7].

Elevated IAP—intra-abdominal hypertension (IAH): Brief elevations of IAP are fairly common and seen during sneezing, coughing etc and are of little clinical significance. Even in critically ill patients, brief elevations maybe observed during changes in body positions etc and are likewise clinically unimportant [4]. For IAP to be considered elevated, in a clinically significant fashion the elevation has to be sustained. The value at which IAP is considered elevated is a matter of debate; however, since alterations in physiology maybe observed even at relatively mild elevations to about 12 mm Hg, this value is the one supported by consensus.

Consensus definition: IAH should be defined as peak measured IAP of ≥ 12 mm Hg on two measurements 1 to 6 hours apart [7].

ACS: The point at which IAH develops into ACS remains controversial. Although it is generally agreed that ACS is the association of IAH, causing one or more organ system dysfunction, how the organ system dysfunction should be identified is not as well defined. When very sensitive and often invasive measures of organ system dysfunction are used, even minor elevations of IAP have been shown to affect function (Fig. 152.2) [9]. Also organ system function maybe affected at a certain IAP in one individual whereas the same level of IAP may not significantly alter organ system function in another individual [4]. Second, the level of IAH that is well tolerated can be different under differing physiologic states even in the same individual. For example, the threshold at which IAH leads to organ system dysfunction is significantly lowered posthemorrhagic shock as compared with baseline conditions [10]. Last, there is evidence that primary ACS (caused by an intra-abdominal pathology—see later) is less well tolerated than secondary ACS [11] (caused by resuscitation in the absence of significant intra-abdominal pathology—see below).

Consensus definition: ACS should be diagnosed in the presence of (1) peak IAP of ≥ 20 mm Hg on two measurements 1 to 6 hours apart and (2) one or more organ system failure that was not previously present as defined by sequential organ failure assessment (SOFA) score of ≥ 3 (or an equivalent scoring system) [7].

Types of ACS: Initially ACS was described after intra-abdominal catastrophe—traumatic or inflammatory—and termed primary ACS [2]. More recently, it has been recognized that ACS can also develop in the absence of abdominal injury/pathology. This is usually observed in patients requiring massive volume resuscitation for any form of shock, usually traumatic or septic. It is believed that this form of ACS, termed secondary ACS, is due to leakage of fluid from within the capillaries resulting in massive edema of the intra-abdominal organs causing increased volume [11,12]. At times, the two conditions may coexist as in a patient with an intra-abdominal injury/pathology who during the recovery phase develops pneumonia and sepsis resulting in leaky capillaries. Recurrent ACS may be observed following therapy for either primary or secondary ACS, and this has been called tertiary ACS [13]. Finally, a very early hyperacute form of secondary ACS has been recognized that develops while repair of extra-abdominal injuries is being carried out simultaneous with massive volume resuscitation required for the hemorrhagic shock produced by the extra-abdominal injury [11]. Previously, hyperacute ACS was used to describe physiologic, transient, clinically insignificant elevations of IAP observed during sneezing, coughing, etc [14].

Consensus definitions

Primary ACS: Primary ACS is defined as ACS developing in a person where the proximate cause of the ACS is intra-abdominal/pelvic pathology that usually requires abdominal surgery and/or angio-radiologic intervention. The pathology may be traumatic, and/or inflammatory in nature [7].

Secondary ACS: Secondary ACS is defined as ACS developing due to increased volume of intra-abdominal contents from accumulation of fluid and/or visceral swelling, and where the proximate cause of the increase in volume is not any intra-abdominal/pelvic pathology requiring abdominal surgery and/or angio-radiologic therapy. Secondary ACS is usually observed during massive volume resuscitation for major nonabdomino/pelvic injuries, burns, severe acute pancreatitis, septic shock from a nonabdomino/pelvic infective source, etc [7].

Tertiary ACS: Tertiary ACS solely refers to ACS that develops or persists despite previous attempts to prevent or treat primary or secondary ACS [7].

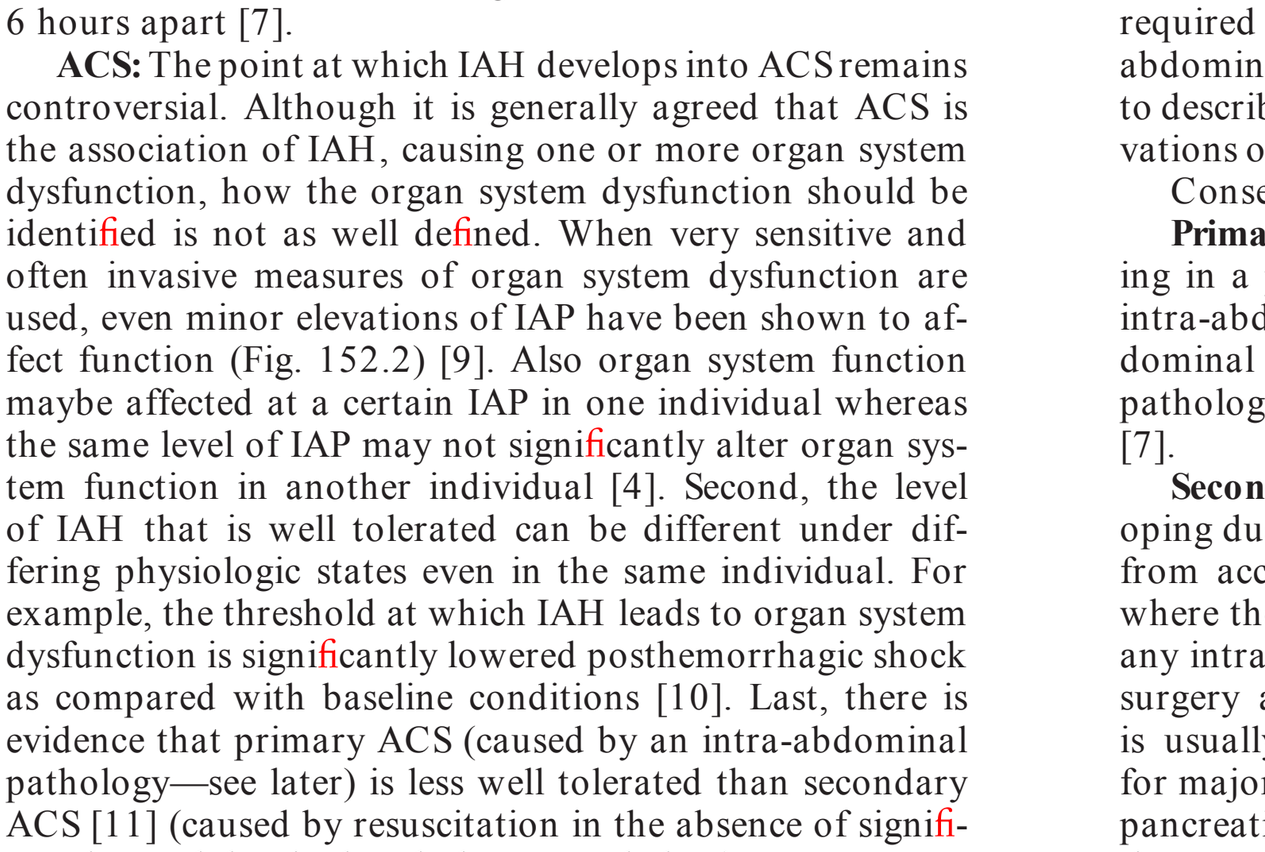

FIGURE 152.2. Effect of increasing intra-abdominal pressure on cardiac output (CO), hepatic artery flow (HA), superior mesenteric artery flow (SMA), and gastrointestinal mucosal flow (mucosa). Note that the splanchnic and mucosal flows start to decrease even at fairly low levels of intra-abdominal hypertension and even when global CO has not been affected.

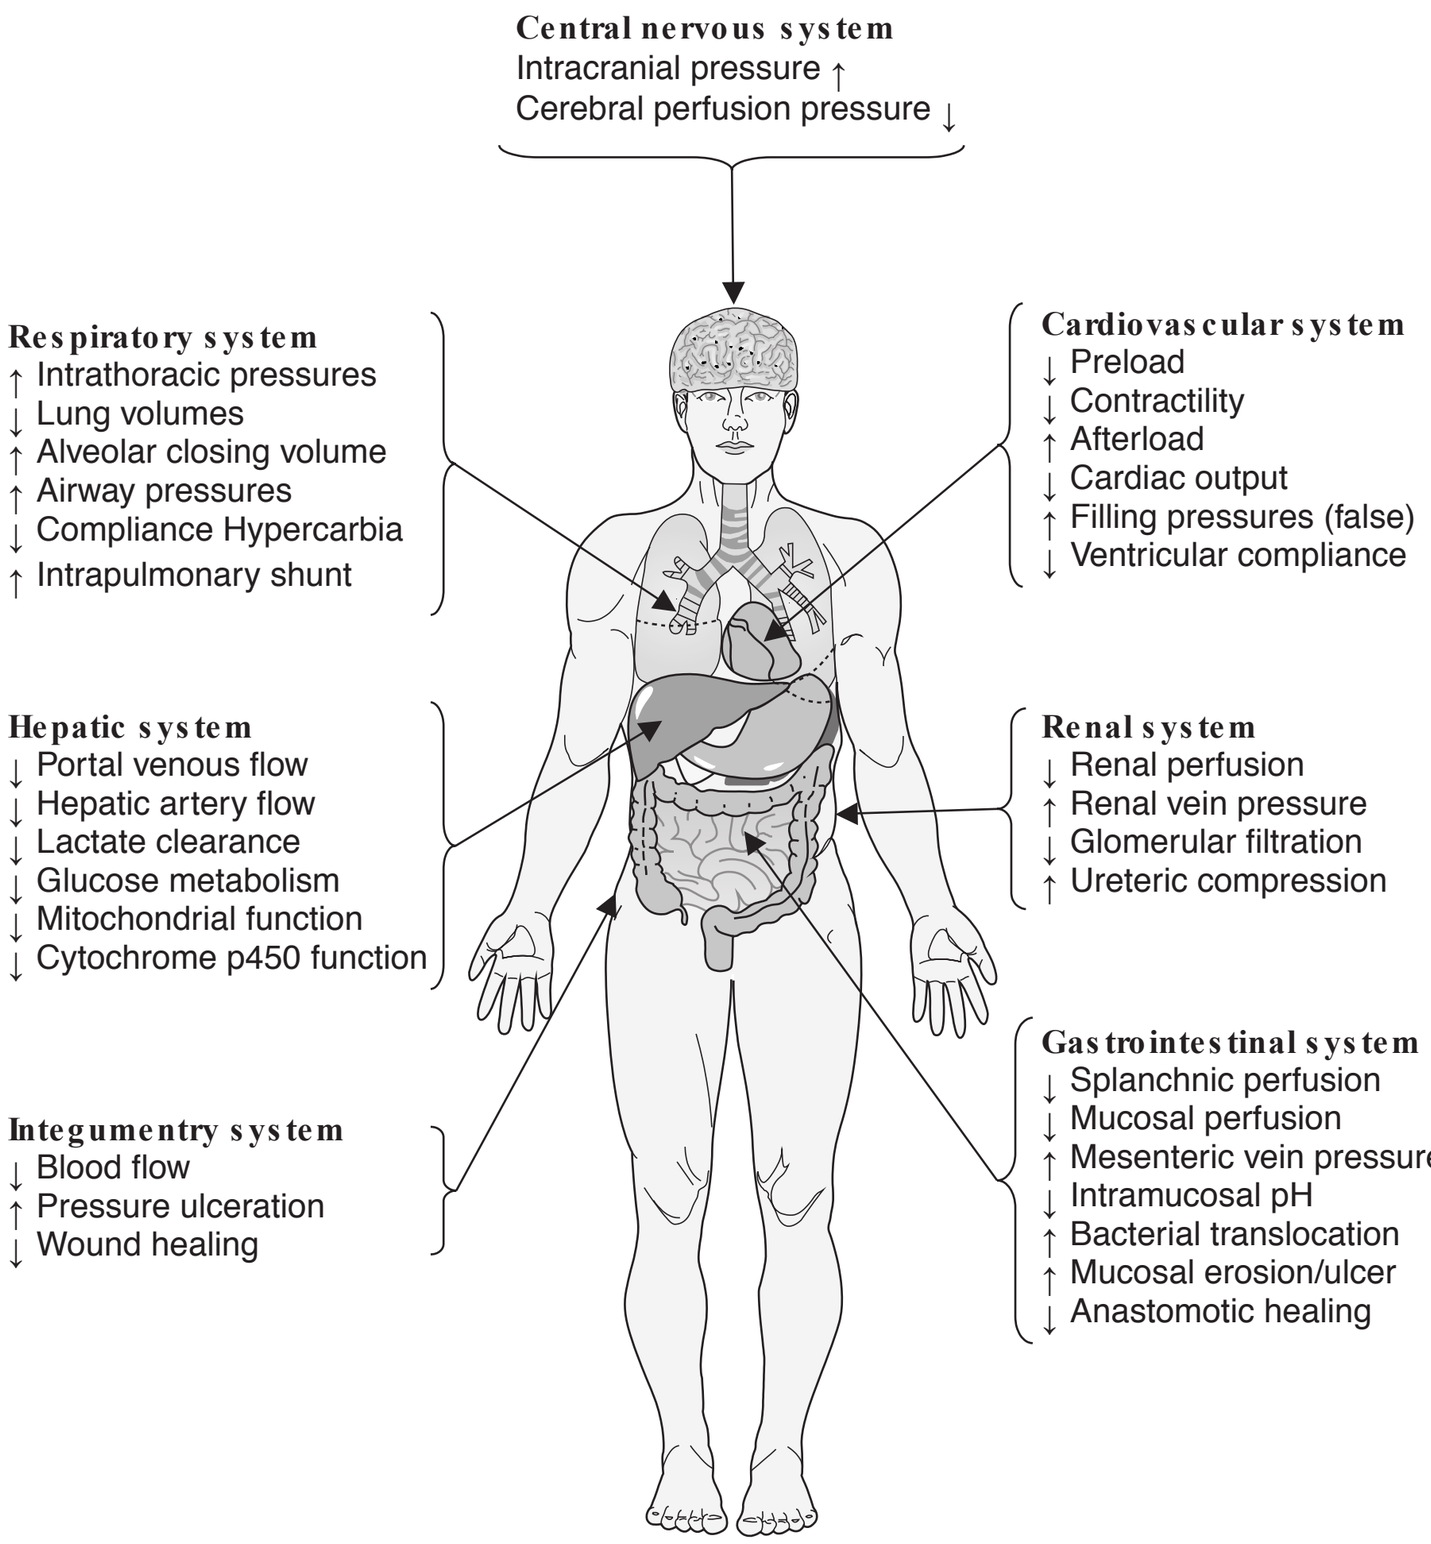

FIGURE 152.3. Effect of abdominal compartment syndrome on various body systems.

Hyperacute ACS: The term should be reserved for a very early form of secondary ACS that develops while surgical and/or angio-radiologic control of an injury is being carried out simultaneous with massive volume resuscitation for the shock caused by the same injury [11].

Impact of ACS on the Body

ACS has profound and far reaching effects on every major organ system of the body (Fig. 152.3). As mentioned earlier, these effects are related to (i) the mechanical pressure caused by IAH, (ii) the reduced perfusion to the tissues caused by diminished CO, and (iii) ACS amplifying the systemic inflammatory response already in motion due to the primary pathology, its treatment and tissue hypoperfusion.

Cardiovascular Effects

ACS affects each of the three determinants of cardiac function—preload, contractility, and afterload. IAH leads to compression of the inferior vena cava decreasing venous return from the lower half of the body [15]. In addition, elevated IAP raises the diaphragm leading to increased intrathoracic pressure, further impeding venous return to the heart [16]. Paradoxically, the central venous and the pulmonary capillary wedge pressures actually rise leading to a dissociation between the commonly used measures of cardiac filling and true cardiac end diastolic volumes. This increase in the filling pressure is merely the transmission of increased intrathoracic pressure to the measured intravascular pressure and not a true reflection of intravascular volume and cardiac filling [17]. Other techniques that directly measure cardiac end diastolic volumes tend to give a more accurate picture of cardiac filling [18]. The decreased venous return and cardiac filling negatively impact cardiac contractility. In addition, ACS directly leads to a decrease in ventricular compliance further affecting cardiac filling and contractility [15]. The effects of elevated intrathoracic pressures are more prominent on the right ventricle. Normally the right ventricle acts more as a conduit than as a pump. The elevated intrathoracic pressures however lead to an increase in pulmonary vascular resistance due to direct compression of the lung parenchyma leading to an increase in right-sided afterload. To overcome this increased right-sided afterload, the right ventricle has to play a more active role if left ventricular filling is to be maintained [19]. Last, ACS leads to an increase in systemic vascular resistance—left-sided afterload—that initially may cause the mean arterial pressure to rise; however, as the CO continues to fall, the net result is a lowering of systemic blood pressure, further compromising perfusion [20]. The diminution in CO can be partially ameliorated by volume loading [15,16,20]. However, for a sustained improvement in systemic perfusion, the ACS needs to be treated usually by abdominal decompression.

Respiratory Effects

The direct mechanical effect of elevated IAP results in the diaphragm moving cephalad into the chest [21]. This results in a reduction in minute ventilation leading to hypercarbia and

respiratory acidosis. The compressive effect also leads to an increase in pulmonary closing volume and decrease in functional residual capacity and lung compliance [16]. The effect of these later changes is a mismatch between ventilation and perfusion and increased right to left shunting causing hypoxia. Clinically the earliest observed change is an increase in peak airway pressure, or if the patient is on a pressure limited ventilatory mode, a decrease in tidal volume [16]. If the ACS is not treated at this stage, the full effects on the respiratory system are observed with hypoxia, hypercarbia, and respiratory acidosis [16]. The hypoxia caused by the respiratory system effects adds to the tissue hypoxia produced by the diminished tissue perfusion due to the cardiovascular effects of ACS.

Renal Effects

ACS causes direct compression of the renal parenchyma causing elevation of renal venous pressure and increased renal vascular resistance [22–24]. In addition, the reduction in CO leads to diminished perfusion to the kidneys [20]. The end result is a reduction in urine production and, if left untreated, overt renal failure. Decreased urine output is often the first sign of developing ACS. Increasing CO only partially compensates for the reduction in glomerular filtration pressure, and insertion of ureteric stents offers no benefit [25].

Splanchnic and Hepatic Effects

While difficult to observe clinically, animal studies have demonstrated profound reductions in mesenteric and hepatic blood flow occurring with ACS. The reduction in flow is disproportionate, that is, it is observed whenever IAH is present even in the absence of significant hypotension and decrease in CO (Fig. 152.2) [26]. Within the bowel, the mucosa seems to be the most sensitive to these reductions. Initially, the reduced flow leads to increasing mucosal hypoxia and acidosis [27]. In later stages frank mucosal ulceration maybe observed. The net effect of these changes is loss of the selective absorptive function of the mucosa causing increased bacterial translocation and production of oxygen free radicals [28]. The exact consequences of bacterial translocation into the mesenteric venous and lymphatic systems are not clear. Some continue to believe that bacterial translocation may be responsible for driving the systemic inflammatory response [29]. Besides increased translocation, there is evidence that ACS, by decreasing mesenteric perfusion, may negatively impact healing of intestinal anastomosis [30].

Central Nervous System Effects

Elevated IAP leads to elevations in central venous pressures that are directly transmitted to the venous outflow from the cranial cavity leading to increased intracranial pressure (ICP) and reduction in cerebral perfusion pressure (CPP) [31]. Although these effects may be well tolerated by the uninjured brain, there is concern that ACS may contribute to secondary brain injury by its effect on CPP. Although not uniformly accepted as a therapy, there are some reports of head injured patients with elevated ICP, unresponsive to other measures for reduction of ICP, being treated by abdominal decompression [32,33].

Effects on the Integument

The effects of reduction in CO are particularly prominent in the integumentary blood flow. Profound reductions in flow to the abdominal wall have been observed. The reduction in integumentary flow may lead to problems with wound healing and higher risk of decubitus ulcers.

ACS, Systemic Inflammation, and Multiple Organ Dysfunction Syndrome

The large majority of patients that develop ACS are in a state of systemic inflammation and due to this are at a high risk for developing multiple organ dysfunction syndrome (MODS). The systemic inflammatory state in these patients is caused by (1) the primary pathology and its treatment causing ACS and (2) the tissue hypoperfusion and hypoxia caused by the cardiovascular and respiratory effects of ACS. Studies have clearly demonstrated an association of ACS and MODS [34]. What is less clear is whether MODS is caused or contributed to by ACS or whether the primary condition and its treatment that led to the development of ACS, independently caused MODS also. In animal models, ACS is associated with a disproportionate reduction in mesenteric flow, even when the mean pressure and CO are maintained [26]. In a human study of patients requiring high-volume resuscitation it was shown that patients resuscitated to a supraphysiologic oxygen delivery of 600 mL per minute per m^2 by volume loading required significantly larger volume as compared with a matched group resuscitated to only 500 mL per minute per m^2. As expected, the supraphysiologic group with the higher volume resuscitation had a higher incidence of ACS. The unexpected finding however was that the supraphysiologic group that developed ACS also had a higher incidence of gut ischemia, as measured by gastric mucosal pH, and worse outcomes [35]. The authors opined that the mesenteric ischemia, present despite higher systemic oxygen delivery in the supraphysiologic group, was caused by the ACS and was responsible for the worse outcomes. A large animal (swine) study examined the cytokine response to ACS alone, shock alone, or sequential shock resuscitation and ACS. It demonstrated that when ACS follows shock and resuscitation the cytokine response and neutrophil-mediated end organ injury are amplified as compared to either of the states occurring alone [36]. Another small animal study examined the effect of ACS at different time periods following shock and resuscitation. That study demonstrated that ACS was associated with worse outcomes in terms of end organ damage, and mortality when it occurred at the time when the neutrophils were maximally primed by the preceding shock and resuscitation [37]. Putting all of these studies together the hypothesis gaining acceptance is that the ACS acts as a second inflammatory stimulus—second hit in a two hit model—precipitating MODS in patients already primed by the primary condition that led to the development of ACS [38]. If this hypothesis is accepted, then the mechanism by which ACS acts as a second inflammatory stimulus needs further study. Some believe that increased bacterial translocation is the mechanism by which ACS acts as a second inflammatory stimulus leading to MODS. Some [28,39,40], though not all [41], animal studies of ACS have demonstrated increased bacterial translocation from the gut.

TECHNIQUE OF MEASURING IAP

A number of techniques have been used to measure IAP. Some are more invasive than others. IAP can be measured directly by accessing the peritoneal cavity. This method has been used during laparoscopic procedures, but is impractical due to the invasiveness and risk of infection outside of the operating room. Other techniques depend upon indirectly measuring IAP by measuring the pressure within the lumen of a hollow structure to which the IAP is directly transmitted—urinary bladder, stomach, rectum, or inferior vena cava. Of all the techniques, the most commonly used one is measuring pressure within the urinary bladder via a bladder catheter. The technique is simple and noninvasive since virtually all patients that may or do develop ACS have an indwelling bladder catheter. The setup

consists of a three-way stop cock connected to (1) the aspiration port of the urine collection bag tube via pressure tubing and an 18-gauge needle, (2) a 50-mL syringe with sterile saline, and (3) pressure transducer tubing. The actual technique consists of emptying the bladder, clamping the tube of the collection bag distal to the aspiration port, and instilling 50 mL of sterile saline into the bladder. After instillation of the saline, the clamp should be briefly loosened to empty the tubing toward the patient's side of air, and reapplied without loosing the saline. After emptying the air, the pressure within the bladder is measured and recorded. The level of the pubic symphysis is considered 0 mm Hg [8]. Studies have shown excellent correlation between the true IAP and the bladder pressure measured by this technique. Like all techniques however, the accuracy of the measured pressure depends on how meticulously it is performed. The greatest source of error comes from incomplete emptying of the air. Air in the system anywhere from the transducer through the three-way connection into the pressure tubing, urine collection bag tubing, and the bladder catheter can dampen the pressure and give an erroneously low reading. Also in patients with very small bladders or those having bladder spasms the pressure recording maybe falsely high. If the above sources of error are kept in mind and care taken to avoid them, bladder pressure measurement is an excellent technique of monitoring patients for ACS, and is by far the commonest one used for this purpose.

MONITORING FOR AND INCIDENCE AND PREVALENCE OF ACS IN THE ICU

Patients at risk of developing ACS may broadly be classified into five categories: (1) patients with severe systemic sepsis from any source, especially those where the source is within the abdomen; (2) patients undergoing massive fluid resuscitation for shock usually septic or traumatic, especially where the source of hemorrhage is within the abdomen; (3) patients undergoing abdominal damage control surgery; (4) patients with an intra-abdominal catastrophe, for example, severe pancreatitis, bowel necrosis, etc; and (5) patients undergoing large-volume resuscitation for major burn injuries. All such patients should be monitored for the development of ACS usually by intermittent bladder pressure measurements. It should be borne in mind that even patients that are being managed with the open abdomen technique for the prevention or treatment of ACS can develop recurrent ACS—tertiary ACS—and should be monitored for it. In addition, any critically ill patient with acute cardiorespiratory deterioration should be evaluated for the development of ACS.

The exact prevalence of ACS in the ICU population is difficult to determine since (1) it is different in differing patient populations, so if the ICU manages trauma, surgical and burn patients the incidence and prevalence will be higher as opposed to a medical ICU, with the mixed ICU falling somewhere in between and (2) differing definitions of IAP, IAH and ACS used by different investigators. In a prospective multicenter study examining the prevalence of IAH and ACS, where IAH was defined as IAP > 12 mm Hg, and ACS was defined as IAP > 20 mm Hg with at least one organ system failure, 59% of patients had IAH and 8% had ACS. As expected, the prevalence was higher in surgical, trauma and burn patients as compared to medical patients. Also in burn patients the development of ACS was correlated to the size of the burn [42]. Another multicenter study with similar definitions of IAH and ACS was conducted in fourteen ICUs. That study enrolled 250 consecutive patients and followed them to discharge, death, or for 28 days and recorded the cumulative incidence of IAH and ACS. The cumulative incidence for the period of study was 32% for IAH and 4% for ACS, although only one patient required decompression. In this later study however, medical patients that tend to have a lower incidence of ACS accounted for 46% of the study population. The same study also examined the risk factors for the development of IAH and also it's effect on outcomes. It concluded that the development of IAH was an independent predictor of mortality, and the independent predictors of IAH on day one were liver dysfunction, abdominal surgery, fluid resuscitation with > 3,500 mL over the preceding 24 hours, and ileus [43].

TREATMENT THRESHOLD

Although all agree that if a patient has severely elevated IAP with multiple organ system dysfunction, the patient should be treated for ACS. What is less clear is whether to treat patients much earlier in the process where the IAP is only moderately elevated and there is borderline dysfunction of only one organ system, or even earlier when the IAP is barely above 12 mm Hg. Since in the large majority of patients the treatment entails surgery and leaving the abdomen open, there are potential risks to the therapy. On the other hand there is evidence to suggest that earlier the treatment is initiated better is the final outcome [11,12,44]. In balance, all patients at risk of developing ACS should be monitored by frequent bladder pressure measurements. Patients that develop organ system dysfunction that, in the judgment of the treating physician, can be causally related to IAH should have therapy initiated. If the patient has increasing IAP but does not have any organ system dysfunction then the monitoring should continue with close observation for the development of organ system dysfunction, so that therapy can be initiated at the earliest sign of dysfunction. Finally almost all patients with IAP > 20 mm Hg and rising, even without evidence of organ system dysfunction, should have therapy for impending ACS.

TREATMENT OF ACS

Therapy for ACS or impending ACS is aimed at reducing IAP. In the large majority of patients, this entails surgical decompression by performance of a laparotomy, and leaving the abdomen open till the visceral swelling and/or the fluid accumulation within the abdomen is diminished to a point that the IAP will not rise to pathological levels on abdominal closure. As this is fairly radical therapy with significant morbidity less invasive medical therapy has been attempted.

Medical (Minimally Invasive) Management

Medical management of ACS has limited application at best. It is possible that with more study, medical management may become the modality of choice for the patients in the prodromal phase where there is impending organ system dysfunction. Medical therapy consists of one or more of (1) neuromuscular blockade; (2) needle/tube drainage of intra-abdominal fluid; and (3) continuous external negative pressure therapy by special custom made devices.

Neuromuscular blockade is attractive in theory but no studies have been performed to evaluate it as sole therapy for ACS. It is often used in situations where abdominal closure was desirable and hence was performed but due to many factors, the closure was "tight." Two case reports are available where neuromuscular blockade was used for the treatment of acute ACS. One report however cautioned that surgical decompression may still be necessary after treatment with neuromuscular-blocking agents [45,46]. Aside from these case reports no

studies are available that have adequately tested this form of therapy for acute ACS.

A small proportion of patients develop ACS not due to swelling of the viscera, rather due to accumulation of large volume of fluid and/or blood within the abdominal cavity. This is more often observed in patients with secondary ACS especially when caused by volume resuscitation for major burns. Such patients can be treated by placing a needle or small catheter within the peritoneal cavity. Case reports of successful management are present in the burn literature [47].

Continuous external negative pressure therapy is performed using custom made devices that surround the abdomen and create a negative pressure outside of the abdominal wall. Such devices have been used successfully in morbidly obese patients with chronic ACS [48,49]. There application in patients with acute ACS has not been reported, but in animal studies of acute ACS, they have shown potential [50].

Surgical Therapy

Surgical therapy in the form of decompressive laparotomy with the abdomen left open is the most often used treatment modality for impending or actual ACS. There is a large body of literature to support that such therapy, when performed early, rapidly reduces IAH and reverses organ system dysfunction. However, it should be pointed out that there have been no randomized trials to prove the benefits. The available evidence in favor of its use is class-II at best and is based on expert opinion and case control studies.

Surgical decompression of the abdomen for the treatment of ACS is performed by a generous midline laparotomy. After the laparotomy, the abdomen is left in the open state—fascia is not reapproximated. There are a number of methods available for managing the open abdomen. The method of management should be such that it can be performed rapidly, prevent heat loss from the internal viscera, protect the swollen viscera, and allow relatively free egress of the large amount of fluid that may accumulate within the cavity with continued resuscitation. In addition, the method should not damage the fascia and skin so that formal closure can be achieved later. In the authors' current practice, a large plastic sheet is laid over the bowel, and tucked deep in the paracolic gutters laterally, over the stomach/spleen and liver superiorly, and deep in the pelvis inferiorly. This sheet not only protects the internal viscera, and prevents heat loss, it also prevents adhesion formation between the bowel surface, and the abdominal wall, allowing for formal fascial closure at a later date. Small perforations are made in this sheet to allow fluid egress. Moistened gauze bandage is placed on top of this plastic sheet, and drains—Jackson Pratt or large (20 Fr) red rubber with multiple holes—are placed within the bandage. A Steridrape large enough to cover the bandage and adhere to the surrounding skin is placed over the bandage. The drains are connected, through collecting buckets, to wall suction at about 100 mm Hg. This system is easy to manage for the nursing staff, and allows for the fluid to be measured.

There are multiple problems associated with the open abdomen. In the absence of normal biological coverage, the body loses heat, the exposed viscera can desiccate, fistula can form from the mechanical trauma of dressing changes, and the large open wound is a major metabolic drain to the body. In addition to these short-term problems, in the longer term, in the absence of a complete fascio-muscular envelope, it is difficult to perform many physical actions for gainful employment. Because of these factors, how the open abdominal wound is managed has both long- and short-term consequences. There is no single method that will be suitable for all patients, and some tailoring to the need of the individual patient will be necessary to optimize functional outcome, and minimize complications.

Patients, in whom recovery progresses rapidly with brisk diuresis, and resolution of bowel edema, it may be possible to achieve fascial closure within 5 to 7 days. In many instances, however, this does not happen, or the patient develops some septic complication and the bowel becomes swollen again. After about a week in the open situation two factors prevent fascial closure. First, the fascial edges retract laterally, and second, adhesions form between the external surface of the bowel, and the abdominal wall. A plastic sheet interposed between the bowel surface and abdominal wall serves to prevent adhesion formation, and the VAC apparatus (KCI USA, Texas) can help medial mobilization of the retracted fascial edge. Using these techniques fascial reapproximation has been achieved up to 3 weeks after decompressive surgery [51].

Patients in whom, despite all measures, fascial closure is not possible, skin flaps can be mobilized, and closed over the bowel. In situations where skin flaps cannot be mobilized, the bowel surface can be allowed to granulate over, and then covered with split thickness skin graft. While waiting for adequate granulation tissue to form, extreme care is necessary, with minimum dressing changes performed very delicately so that mechanical trauma to the bowel surface is minimized, and fistula formation is prevented. After skin coverage is achieved, either by medial mobilization of skin flaps or by split thickness skin grafts over the granulated bowel, patients are left with a large ventral hernia that will require repair at a later date. The repair is usually carried out 6 to 9 months later to allow the inflammatory reaction to subside, and adhesions to become less vascular. A good way to check if a patient with split thickness skin graft is ready to have it taken off and hernia repaired is to try and pinch the skin off the bowel. In the initial stages, the skin graft is tightly adherent to the bowel wall, not allowing the skin to be pinched up. With the passage of time, and resolution of the inflammatory adhesions, the skin can be pinched off the bowel. Multiple techniques are used to repair the ventral hernia and reconstruct the abdominal wall. An innovative approach involves separating the various layers of the abdominal wall and instead of the patient having an incomplete multilayered abdominal wall the patient ends up with a single layered, but complete, fascio-muscular abdominal wall [52]. This approach allows native tissue to be used and avoids the need of prosthetic meshes, with their attendant complications. Good long-term functional results have been reported with this technique [53]. Alternatively, permanent prosthetic mesh may be used to bridge the gap in fascia, or a combination of techniques can be used. Preoperative use of tissue expanders to facilitate tension-free repair of these large ventral hernias has also been reported [54].

PREVENTION OF ACS

The best method of preventing the development of ACS is prompt recognition by frequent bladder pressure measurements and early action to prevent rising IAP turning into frank ACS with organ system dysfunction. In some surgical patients however, it may be possible to recognize that the patient has a high likelihood of developing ACS postoperatively. In such patients, surgeons are leaning toward preventing the development of ACS by leaving the abdomen in the open state. An interesting study was performed on patients with ruptured abdominal aortic aneurysms, in whom outcomes of patients with early placement of mesh (avoiding tight fascial reapproximation and possible ACS) were compared with outcomes from similar patients in whom tight closure was performed only later to be replaced by mesh due to the development of ACS. The incidence of multiorgan system failure was significantly lower in the patients where a tight closure and possible ACS were avoided [44]. In patients undergoing laparotomy and who fall

into the high-risk category for the development of ACS, strong consideration should be given to leave the abdomen open and prevent ACS.

The other major group of patients that is likely to develop ACS are those receiving large volume crystalloid resuscitation. Although early and rapid volume resuscitation is in many situations the only therapy that will rapidly reverse hypoperfusion, it is an independent risk factor for the development of ACS. Careful and frequent reevaluations should be performed on all patients receiving large volume resuscitation so that as soon as the need for the large volume diminishes, the infusion is turned down to minimize the chances of developing ACS [55].

OUTCOMES FOLLOWING ACS THERAPY

Patients requiring therapy for, or prevention from, ACS tend to be critically ill and have high morbidity and mortality. However, the development of ACS tends to increase mortality [34]. The reported mortality of patients requiring abdominal decompression for ACS is 29% to 62% [56]. In addition, patients with open abdomens pose significant management challenges if the morbidity of the treatment—open abdomen—is to be kept low. The most significant source of morbidity is the development of enterocutaneous fistula with rates reported as high as 18% [57]. To avoid this, dressing changes should be kept to a minimum and the exposed bowel should not be allowed to desiccate by placing nonadherent dressings over it. Besides this, the open abdomen is a significant metabolic drain to the body. This large open wound, coupled with the inflammation from the condition leading to the development of ACS, can rapidly lead to a state of severe malnutrition. Patients should be given adequate nutritional support, enteral if possible, and parenteral if not. By using evidence-based practices and continuously evolving clinical practice as knowledge becomes available, certain ICUs have shown a remarkable improvement in outcomes. Cheatham et al. in a recent study demonstrated that although the patient population remained the same, survival to hospital discharge improved from 50% to 72% and same admission primary fascial closure improved from 59% to 81% [58].

Despite improvements, the short-term in-hospital mortality and morbidity of patients managed with the open-abdomen technique for ACS remains high. However, patients that survive to discharge do surprisingly well. A prospective study examining the physical and mental states and employability of patients that had undergone management of ACS by the open-abdomen technique, demonstrated that within 18 months of abdomen closure, these indices were equivalent to a comparable cohort that did not have the open abdomen [59].

THE FUTURE

Despite the large body of literature about ACS, there are a significant number of intensivists and a small number of surgeons who continue to discount the existence of this disease entity. It is important to continue to educate these clinicians for the benefit of their patients. Further research needs to be carried out to define exactly which patients are likely to develop ACS so that prophylactic measures can be performed and ACS prevented. In addition, there needs to be a better understanding of the threshold at which therapy is the most beneficial so that only the patients that are likely to benefit from the therapy are subjected to the risks of the therapy. Finally, research in other modalities of resuscitation that can reduce the large volumes necessary will help in preventing ACS. A better understanding of the systemic inflammatory response with the attendant capillary leak may allow therapies to be developed that can attenuate the "runaway" systemic inflammation or at least reduce the capillary leak thereby reducing the chance of developing ACS.

CONCLUSION

Raised IAP leads to IAH that can cause organ system dysfunction and this combination of IAH and organ system dysfunction is termed ACS. There remain many areas of confusion in terms of terminology, diagnosis, appropriate treatment threshold, and the best treatment. The recent World Congress on ACS has helped clarify some of these issues. Any patient with organ system dysfunction or impending dysfunction in association with IAH should have prompt therapy. Although there are some medical therapies that show some promise, the best therapy to rapidly decrease IAP and reverse the organ system dysfunction remains surgical decompressive laparotomy and leaving the abdomen open. The open abdomen can be associated with significant morbidity hence extreme care is necessary in the management of such patients. As soon as the patient's condition improves attempts to close the abdomen or at least provide biological coverage should be initiated. In patients who are left with a large hernia, delayed repair with component separation or prosthetic mesh offers excellent long-term functional results.

CHAPTER 153 ■ NECROTIZING SOFT TISSUE INFECTIONS

RICHARD L. GAMELLI AND JOSEPH A. POSLUSZNY JR

Necrotizing soft tissue infections (NSTIs) include a spectrum of diseases ranging from necrotizing fasciitis to gas gangrene and Fournier's gangrene. These infections occur within the soft tissue compartment from the dermis to the fascia and deep to the muscle layer, are associated with necrotizing changes, progress rapidly and can occur at any location in the body. Although many terms have been used to describe these infections, NSTI encompasses all necrotizing infections of the soft tissue compartment as they share common clinical, pathophysiologic, microbial, treatment, and outcome characteristics [1].

Most of the clinical information for NSTIs stems from large retrospective reviews [2–6]. Few prospective studies have

been performed given the high morbidity and mortality associated with these infections. However, these retrospective reviews have been surprisingly similar, each confirming previous data on risk factors, inciting events, microbiology, diagnosis, prognosis, and management while providing unique findings about their populations, NSTI, and its management.

EPIDEMIOLOGY AND RISK FACTORS

Surveillance of NSTIs in the United States no longer occurs, but the incidence can be estimated from epidemiologic studies [7]. Using a statewide database, Mulla et al. estimated an incidence of NSTI of 1.3/100,000 people with a total of 216 patients in Florida treated for NSTI in 2001 [8]. Demonstrating the frequent occurrence of cellulitis and rare incidence of NSTI, using an insurance claims database in Utah, Ellis Simonsen et al. estimated an incidence rate of cellulitis of 24.6/1,000 person years with an incidence rate for NSTI of only 0.04/1,000 person years [9]. NSTI is found in all age groups but most commonly in adults [10].

NSTIs occur in a wide range of patients who almost always possess preexisting conditions. More than 80% to 90% of patients with NSTIs possess comorbidities [2,3,11], whereas 62% may have three or more preexisting conditions [11]. Diabetes is the most frequent preexisting condition. In two large retrospective reviews, diabetes was present in 56% and 70% of the patients, respectively [2,4]. Other common preexisting conditions include obesity, hypertension, cirrhosis/chronic liver failure, peripheral vascular disease, HIV, and immunosuppressive therapy [2,3,12,13]. Behaviors like intravenous drug abuse (IVDA) and alcoholism leading to chronic liver disease also increase the risk of developing a NSTI [2,6,11,14]. Preexisting disease is not only a risk factor for NSTI but also for mortality [15]. When totaling comorbidities, patients who died had an average of 1.5 comorbidities versus 1.0 for survivors [3]. Preexisting conditions that correlated with mortality include cardiac disease, pulmonary disease, carcinoma, malnutrition, and IVDA [4].

Although preexisting conditions may increase the risk of developing a NSTI and mortality from NSTI, time to surgical debridement is the main risk factor for mortality. Since 1985, we have known that both prompt and radical surgical debridement of all devitalized tissue improves mortality [16]. Since then, many studies have supported early and aggressive surgical therapy for NSTI. Bilton et al. showed that delay in therapy increased mortality (38% mortality) when compared with early and aggressive surgical debridement (4% mortality) [12]. McHenry et al. found an average time to debridement of 25 hours in survivors but 90 hours for nonsurvivors [5]. Elliott et al. showed an average time to debridement of 1.2 days for survivors and 3.1 days for nonsurvivors [4]. On multivariate analysis, Wong et al. found that a delay in surgery of more than 24 hours was the only variable to correlate with increased mortality [2].

Although the incidence of NSTI is relatively low, the mortality is high at approximately 25% [17,18]. Early and radical surgical debridement is the key to successful treatment.

INCITING EVENTS

Many patients report an insect bite, blister, abscess, or the feeling of a pulled muscle several days prior to presenting with a NSTI. Although some (15% to 52%) cases of NSTI are idiopathic in origin, the remainder have an identifiable source [3,5,11,15]. Abscesses, foot ulcers, traumatic wounds, burns, surgical wounds, IVDA, decubitus ulcers, perforated viscus, and strangulated hernia were all identified as inciting events by Elliott et al. [4]. Endorf et al. also reported liposuction, an infected arteriovenous graft, invasive rectal cancer, a percutaneous gastrostomy tube site, and an enterocutaneous fistula as suspected causes of NSTI [3]. Anaya et al. found inciting events to include subcutaneous/IV injection, trauma, postoperative wound infection, boils, chronic wounds/ulcers, bites, and perirectal abscesses [11].

PATHOPHYSIOLOGY

Regardless of the inciting event, the pathophysiology of NSTIs is quite similar. NSTIs are a specific disease process in which entry of organisms through a compromised skin barrier results in a soft tissue infection that rapidly spreads along the superficial fascia of the subcutaneous tissue but initially spares the overlying skin and underlying muscle [19]. The rapidly spreading infection causes thrombosis of penetrating vessels, which in turn causes necrosis of overlying tissues supplied by those vessels. Histologic examination reveals necrosis of the superficial fascia, thrombosis and suppuration of veins traversing the fascia and microorganisms proliferating in the destroyed fascia [2]. Systemic spread of infection causes overwhelming sepsis or toxic shock syndrome if associated with streptococcal exotoxin of group A streptococcus (GAS) [20,21]. When muscle is involved early, the pathogen is commonly a clostridial species [22].

MICROBIOLOGY

The microbial causes of NSTIs can be polymicrobial or monomicrobial. The majority of NSTIs (53% to 85%) are polymicrobial [2,4,5]. Organisms in polymicrobial NSTIs include anaerobes and aerobes, Gram-positive and Gram-negatives and rarely fungi (< 5%) [3,4,5]. In Elliott et al., the organisms recovered from NSTIs included streptococci, staphylococci, enterococci, *E. coli, Proteus, Klebsiella, Enterobacter, Pseudomonas, Acinetobacter, Eikenella, Citrobacter,* peptostreptococci, *Bacteroides*, clostridia, and fungal species [23]. In a similar analysis, Wong et al. identified streptococcal species, staphylococcal species, enterococci, *Escherichia coli*, *Acinetobacter*, *Pseudomonas,* and *Klebsiella* as the most common isolates with *Bacteroides* being the most frequent anaerobe [2]. In Elliott et al., four or more organisms grew from the initial wound culture almost 50% of the time [4].

Monomicrobial NSTI occurs in approximately 15% to 29% of cases and over 50% of these monomicrobial NSTI are attributable to GAS [2,4,5]. Occasionally, monomicrobial NSTIs are caused by clostridia species [22], methicillin-resistant *Staphylococcus aureus* (MRSA) [24–28], and even group B streptococcus [20]. Tissue cultures have been found to not yield any organisms in 9% to 18% of debrided tissue samples [2,3]. In cases in which no organism is cultured and GAS is suspected, polymerase chain reaction can be used to amplify the streptococcal pyrogenic exotoxin B gene in tissue samples [29]. Although this may not be necessary for immediate management, it may aid in subsequent antibiotic therapy, prophylaxis of other close personal contacts, and for epidemiologic studies.

Attempts have been made to classify NSTIs based on microbial characteristics and to correlate the infectious organism to an inciting event, risk factor, or anatomic location [2,30,31]. Given the lack of uniformity and consistency in this classification system and the need to still treat all NSTIs initially

TABLE 153.1

MICROBIAL CLASSIFICATION OF NECROTIZING SOFT TISSUE INFECTIONS

Type I	Polymicrobial
Type II	Group A Streptococcus ± additional organisms
Type III	Unique and emerging pathogens (CA-MRSA, *Acinetobacter*, *Clostridia*, *Vibrio*)

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*.

with prompt diagnosis, early surgical debridement, broad-spectrum antimicrobials, adequate nutrition and critical care support, labeling an NSTI based on the type of organism present should be used only to guide later antimicrobial choice and for research purposes. Therefore, we supply a slightly modified table listing the historical classification of Type I (polymicrobial) and II (GAS ± additional organisms) NSTIs with an additional classification of Type III (community-acquired MRSA, *Acinetobacter*, *Clostridial*, and *Vibrio* species) to include emerging or unique pathogens which require consideration when NSTI is suspected (Table 153.1) [30,31]. These unique NSTI pathogens are discussed in more detail later. Although some classifications consider Type I to be polymicrobial and Type II to be monomicrobial, given the virulent nature and incidence of GAS, these infections remain as their own group.

DIAGNOSIS

The diagnosis of NSTI is not difficult when obvious signs of tissue necrosis are present. However, this is rare. Wong et al. found that only 14.6% of their patients eventually diagnosed with NSTI had the diagnosis of NSTI or a suspicion of NSTI on admission [2]. Most often, patients were diagnosed with cellulitis or an abscess. Hard clinical signs of NSTI (bullae, skin necrosis, crepitance, gas on radiograph) are present on admission for only 44% of patients with NSTI [14]. The difficulty with diagnosing NSTI is determining when NSTI is present before these obvious signs present as delay is detrimental to patient outcome. If distinguishing nonnecrotizing infection from NSTIs is not possible, then close monitoring of physical examination changes is required to avoid further progression of the disease process. Therefore, the majority of this section focuses the physical examination features common to NSTI and measures that can be employed to earlier diagnose NSTI and thus, prompt more expeditious treatment.

Physical Exam

Signs shared by both nonnecrotizing and necrotizing soft tissue infections include pain, erythema, induration, and swelling. The hard signs of NSTI which may help to differentiate it from nonnecrotizing infection include crepitus, blistering, and skin necrosis, all of which occur at later stages of the disease process. In Elliott et al., on admission, crepitus was present in 36% of patients, skin necrosis in 31% and blistering in 23% [4]. Similarly, Faucher et al. found an open wound in 39%, crepitus in 32%, and vesicles in 23% of patients on admission. However, symptoms common to nonnecrotizing and necrotizing soft tissue infections (pain 89%, edema 84% and erythema 74%) were predominant on admission [11]. If a patient presents with tenderness, erythema and warmth, the development of bullae may be the first sign leading to a higher suspicion of NSTI [2]. NSTI has also been described as having poorly defined and indistinct margins of tissue involvement, tenderness beyond the area of cutaneous involvement and pain out of proportion to physical findings [2,4]. In an attempt to earlier differentiate benign soft tissue infections from NSTI, Wang et al. developed a staging system for the progression of NSTI using only cutaneous manifestations. Stage 1 included tenderness to palpation beyond the apparent area of skin involvement, erythema, swelling, and calor. Stage 2 included blister or bullae formation and later, Stage 3 included crepitus, skin anesthesia, and skin necrosis with dusky coloration. By Day 4 of hospitalization, 68% of their patients with NSTI displayed Stage 3 cutaneous manifestations whereas only 5% did at time of admission. Although this system helps to describe the cutaneous manifestations of NSTI, absence of these cutaneous manifestations does not exclude NSTI [32]. Waiting for the presence of Stage 3 cutaneous manifestations may be detrimental to the patient.

Imaging

Plain radiography, ultrasound, CT and MRI have all been studied as adjuncts to physical exam in cases of suspected NSTI. Classically, air or gas between the muscle and soft tissue layer is diagnostic of NSTI and very often, clostridial NSTI. However, gas is found on x-ray in only a small percentage (16–19%) of cases [2,14]. The soft tissue changes seen with both complex cellulitis and NSTI are indistinguishable on plain radiograph. Therefore, plain radiography is only valuable in the rare cases in which air is present between the tissues. Ultrasound may benefit these patients in that it is quick, noninvasive and can be performed at the bedside. However, there are few studies on ultrasound use to distinguish NSTI from cellulitis [33,34]. Yen et al. showed that ultrasound had 88% sensitivity and 93% specificity for NSTI in a limb using diffuse thickening of the subcutaneous tissue accompanied by a layer of fluid accumulation more than 4 mm in depth along the deep fascial layer when compared with the contralateral limb [33]. Ultrasound is limited by the need for operator experience, the interpretation of the images, and its use in body areas aside from limbs. CT can be used as an adjunct to an equivocal physical exam. Similar to the findings on plain radiograph, gas in the subcutaneous tissues is characteristic of NSTI on CT. Since gas is not seen in all cases of NSTI, other features include thickened, asymmetrical fascia, fluid and gas collections along the deep fascial sheaths, and extension of edema into the intermuscular septa and muscles [35,36]. MRI has also been studied in the differentiation between NSTI and simple/complex cellulitis using fascial inflammatory changes as the indicator of NSTI [37,38]. MRI was found to have a sensitivity of 100% and specificity of 86% in a small cohort [37]. However, whether NSTI could have been diagnosed prior to MRI or if the delay needed for MRI altered patient outcome were not identified. If an imaging modality is deemed necessary to confirm NSTI due to equivocal physical examination findings, it may be prudent to start with the least invasive plain radiograph to look for gas and then progress to CT if necessary. Ultrasound can be used in centers if the technician and radiologist are comfortable with the exam and its interpretation. Operative debridement should not be delayed in cases in which NSTI can be confirmed on physical exam.

Laboratory

Laboratory values may aid physical examination in differentiating nonnecrotizing from necrotizing soft tissue infections.

Wall et al. used admission white blood cell count greater than 15.4×10^9 per L and serum sodium less than 135 mmol per L to help differentiate necrotizing infections from simple cellulitis [39]. Their model had a sensitivity of 90% and specificity of 76%. Positive predictive value was only 26%, but negative predictive value was 99%. This model was particularly effective in the absence of hard signs of NSTI. Wong et al. proposed another scoring system entitled the Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) [40]. This model consists of point values assigned for C-reactive protein (above or below 150 mg per L), white cell count per mm^3 (less than 15, 15 to 25, or more than 25), hemoglobin (more than 13.5, 11 to 13.5, or less than 11), sodium (more or less than 135 mmol per L), creatinine (more or less than 141 µmol per L), and glucose (more or less than 10 mmol per L). With a possible total score of 13, they conclude that anyone with a score of 6 or greater should be carefully evaluated for NSTI, and a score of 8 or greater is highly predictive of NSTI (positive predictive value 93%). Careful physical examination and clinical suspicion should trump any score based on laboratory values, but these may be useful adjuncts in questionable cases.

Combined Diagnostic Modalities

Although adjunctive diagnostic modalities may help differentiate necrotizing from nonnecrotizing soft tissue infections, studies on their effectiveness are singular; little is known about the effectiveness of these modalities when combined [13]. In an attempt to combine physical exam and laboratory findings, Chan et al. prospectively studied the diagnosis and management decisions of surgery residents when presented patients with suspicion of NSTI using first only physical examination findings and then a combination of physical examination and serum WBC and Na values. Only 43% of patients had hard signs of NSTI on presentation. 90% of NSTI patients met one of these laboratory criteria (WBC count of > 15,400 and Na level of < 135) whereas 81% met both. Prior to knowing the laboratory values, residents felt that only 43% of patients had an NSTI. After reviewing these laboratory values and correlating their physical exam findings, suspicion of NSTI increased to 86%. Combining physical exam and radiographic data, Elliot et al. found crepitus, blistering or radiographic evidence of soft tissue gas in 85.3% of NSTI patients on admission [4]. Unfortunately, 20% of their NSTI patients did not have any of these three findings, leaving a large percentage of patients needing additional methods for diagnosing NSTI. As diagnosis of NSTI remains clinical, prospective trials incorporating multiple modalities for diagnosing NSTI will be essential to providing clinicians with a more reliable means of early diagnosis.

Others

Frozen-section biopsies have been effective in the diagnosis of NSTI. Again, the delay in waiting for pathologic review, the morbidity and high rate of negative tissue biopsies, and other logistical problems make frozen section somewhat unwieldy in the practical setting. Others have proposed a "finger test" consisting of a small incision under local anesthesia with digital probing. Lack of bleeding or presence of dishwater pus prompts exploration in the operating room [41]. Wang and Hung used tissue oxygen-saturation monitoring to diagnose NSTI [42]. In their series, a tissue oxygen saturation of less than 70% had a sensitivity of 100% and specificity of 97%. However, they excluded patients with peripheral vascular disease, venous stasis, shock, and hypoxia, while these subgroups may make up a significant portion of patients with NSTI.

Definitive Diagnosis

Histologic examination of involved tissue provides a definitive diagnosis but is not practical as infection may significantly progress during the time required for pathologic review. There are no consensus criteria for determining whether an infection is necrotizing in nature, but several common signs and symptoms are seen. Intraoperative findings of a NSTI include graying necrotic fascia, lack of resistance of muscular fascia to blunt dissection, lack of bleeding during dissection and the presence of foul-smelling dishwater pus [32].

SURGICAL MANAGEMENT

The mainstay of therapy for NSTI is surgery. Early surgical intervention has been shown to improve outcomes in patients with these infections [2,4,12,14,16]. The primary principle in operative debridement of NSTIs is expeditious removal of all necrotic or infected skin and subcutaneous tissue. Confirmatory findings include necrosis of the superficial fascia, thrombosis of superficial vessels, and foul-smelling discharge. There may be little or no resistance to blunt dissection along normally adherent superficial fascial planes [41]. Complete debridement of all necrotic tissue to areas of healthy, bleeding tissue is essential to allow delivery of antibiotics to the area as delivery cannot occur through the thrombosed vessels. Fluid and tissue cultures should be sent for immediate Gram's stain and aerobic and anaerobic culture and sensitivities. Deep fascia and muscle should be inspected; if muscle is involved, this may signal a clostridial infection. Dire circumstances necessitate amputation and can occur in 18% to 27% of cases [2,4,5]. Peripheral vascular disease and/or diabetes may predispose to amputation [2,5]. Colostomies may be necessary to temporarily control fecal flow in patients with large perineal defects [4] although it can be delayed if the infectious process is suspected to spread along the anterior abdominal wall.

Despite the obvious need for swift radical excision, incisions may be planned along geometric lines with an eye on eventual wound closure. Clearly viable skin should be preserved if possible to aid in future definitive wound coverage. Once hemostasis has been achieved, the wounds should be packed open, and a dilute Betadine solution in saline can be used for the initial dressing. Repeat debridements may be necessary, but it is preferable to attempt complete debridement at the initial setting to prevent further spread of infection. Large retrospective reviews have reported 2.7 to 3.8 debridements per patient [2–6]. Frequent wound examination is prudent, and any signs of ongoing spread of infection, including failure to respond to resuscitation, should prompt a return trip to the operating room for a second look. Bedside intervention may be necessary in the unstable patient and can be accomplished with sharp debridement and portable electrocautery.

Although prompt surgical management is key to decreasing morbidity and mortality, patients in septic shock on admission are an interesting challenge. The question is whether it is better to treat these patients with supportive care, antibiotics, and pressors and wait until hemodynamic stabilization for debridement or to continue resuscitation and supportive care while debriding the necrotic tissue. Boyer et al. showed that waiting > 14 hours for surgical treatment in patients with NSTI and septic shock significantly decreased survival [43].

Clearly, early surgical debridement of necrotic tissue is beneficial to patient outcomes. Easily identifying patients with an NSTI early in their course remains a clinical challenge, but relies on experienced physical exam and if needed, additional diagnostic modalities.

ANTIBIOTICS AND PHARMACOTHERAPY

Prompt empiric broad-spectrum antibiotic therapy is an important adjunct to operative debridement. Antibiotic choice should cover Gram-positive, Gram-negative, and anaerobic organisms. The most common antibiotic regimens consist of Gram-positive coverage with penicillin or an extended-spectrum penicillin derivative (or vancomycin in penicillin-allergic patients), Gram-negative coverage with aminoglycosides, cephalosporins or carbapenems, and anaerobic coverage with clindamycin or metronidazole [4]. The use of vancomycin, linezolid, daptomycin, or quinupristin/dalfopristin should be considered until MRSA has been ruled out [31,44]. Clindamycin has had particular success in the pediatric population [45] and may be of most benefit in blocking exotoxin and M protein production, leading to decreased tissue inflammation and sepsis [44,46]. The duration of antibiotic use has not been prospectively studied. Antibiotics should continue until at least all surgical debridement has taken place.

The use of intravenous immunoglobulin and activated protein C has been explored, but their usefulness remains undefined. Intravenous polyspecific immunoglobulin G has been used in combination with antibiotics in patients with accompanying toxic shock syndrome from invasive GAS infection [47]. Recombinant activated protein C/drotrecogin alpha has been used in critically ill patients with severe sepsis [48]. One case report identifies a potential benefit in the use of drotrecogin alpha in a patient with NSTI [44]. However, the use of drotrecogin alpha should be used with caution given the high risk of bleeding associated with its use combined with the typical need for repeated operative debridement and grafting.

Starting with broad-spectrum antibiotic coverage for Gram-positive, Gram-negative, and anaerobes with the addition of coverage for community-acquired (CA)-MRSA is essential. Once the pathogen(s) has been isolated, narrowing the antibiotic coverage is appropriate.

WOUND MANAGEMENT

After surgical debridement of NSTIs, patients may have extremely large soft tissue defects. Definitive wound coverage may require multiple modalities. Repetitive dressing changes should be used in the initial days following debridement until the wound is clean and there are no signs of recurrent or ongoing infection. Many surgeons advise saline wet-to-dry or wet-to-wet dressing changes. The use of 5% mafenide acetate solution applied to postgraft NSTI wounds has been shown to increase the success of first-time wound closure [49]. Additional topical antimicrobials that can be used include bacitracin, polymyxin, vancomycin, nystatin, and Betadine based on the culture and sensitivities of the pathogen [3].

A vacuum-assisted closure (VAC) device (Kinetic Concepts, Inc., San Antonio, TX) can be employed to reduce chronic edema, increase local blood flow, enhance the formation of granulation tissue, and promote contraction of the wound edges [50,51]. The VAC has also been useful in secondary wound infection after debridement of large areas of NSTI [52]. A small study by Huang et al. showed that a VAC may reduce wound size and decrease overall nursing care time, but was more expensive per day than conventional wet-to-dry dressings [53]. Any surrounding erythema, excessive pain or fevers should prompt removal of the VAC and examination of the wound. Regardless of the methods used, after the appearance of adequate granulation tissue, further surgical closure of the wound may be contemplated. In these often obese patients, redundant skin and subcutaneous tissue may allow for primary closure of the wounds, particularly in those involving the groin and perineal areas. Wounds not amenable to primary closure require coverage with split-thickness skin grafts and have been found to be necessary in 36% to 46% of patients [3,14].

The use of hyperbaric oxygen (HBO) has been advocated as a postsurgery adjunct in the treatment of NSTI as a means of decreasing morbidity, mortality and time to wound closure. However, a consensus on the benefit from HBO has not been established [4,54–56]. A recent retrospective review of hyperbaric oxygen therapy for NSTI showed a small, but not statistically significant decrease in mortality with HBO therapy [57]. A survival benefit may exist for the use of HBO in clostridial myonecrosis [4,56].

Following surgical debridement, operative wounds should be managed with frequent dressing changes with topical antimicrobial solutions until the area is free of infection and necrotic tissue. The use of a VAC device or HBO therapy may be employed based on a center's familiarity with these techniques.

NUTRITIONAL SUPPORT

These often critically ill patients will inevitably need nutritional supplementation to meet their increased metabolic state. Graves et al. found that 94% of their patients with necrotizing fasciitis needed either total enteral or parenteral nutrition for a mean of 24 days [58]. They used indirect calorimetry to determine individual energy requirements in this population, and found that these patients required caloric intake at 124% of their basal energy expenditure, or roughly 25 kcal per kg per actual weight per day. However, there were wide variations in energy requirements between patients, and they recommend routine indirect calorimetry to better provide appropriate nutritional supplementation.

Concomitant with ensuring adequate nutrition in patients recovering from an NSTI is proper glycemic control. Although no studies connecting poorer outcomes and hyperglycemia exist for patients with NSTIs, the depth of literature promoting the benefits of glycemic control in critical care can reasonably be extrapolated to the NSTI patient. Reduced morbidity and mortality in surgical ICU patients with tight glycemic control was first demonstrated in 2001 with the van den Berghe study [59]. Since then, control of blood glucose levels with algorithm or computer program assistance has become the standard of care in all ICUs [17]. Although preventing hyperglycemia is a priority so to is preventing hypoglycemia from overaggressive insulin use. Recently, the NICE-SUGAR study has demonstrated the side effects of hypoglycemic events with intensive insulin therapy; the safest and most beneficial glucose range has not yet been established [18]. Regardless, prevention of hyper- and hypoglycemia should improve patient outcomes. With the high prevalence of diabetes in patients with NSTI, glycemic control is an even more challenging task in this patient population.

OUTCOMES

Mortality

Mortality rates for NSTI range from 6% to 76% [5]. A recent review summarizing 67 outcome studies on NSTI since 1980 shows an average mortality of 23.5% [60], while another recent review reports a similar mortality rate of 25% [61]. As mentioned earlier, the greatest risk factor for mortality is time to surgical debridement [4,5,12,16,62]. In a more recent

examination of time to surgical debridement influencing outcome, Gunter et al. was able to reduce time from presentation to OR to 8.6 hours and thus decrease overall mortality to 9% by using an emergency general surgery service [63].

Various parameters have been used to predict mortality. In Yilmazlar et al., an APACHE II score of <13 was associated with a mortality of 21% while an APACHE II score of ≥ 14 was associated with an 86% mortality [57]. APACHE II scores of >20 have been associated with 100% mortality [57], and a 14.2-fold increased risk of death [62]. A LRINEC score of ≥ 6 was associated with increased amputation and mortality rates [64]. Bacteremia on admission has been associated with a 5.2-fold increased risk for death [19]. Preexisting conditions associated with higher mortality rates include IVDA, chronic renal insufficiency, and heart disease [62]. As expected, nonsurvivors have more body surface area involvement (13 vs. 6%), are obtunded (62%), have elevated serum lactate and creatinine on admission [4] and are older (age >60) [19].

Function, Disposition, and Cost

Given the high mortality rates associated with NSTI, the majority of studies focus on mortality outcomes. However, knowledge of functional outcome, hospital length of stay, and cost are important for the health care provider, patient, and families in terms of predicting physical, social, and economic support after recovery from the acute illness. Commonly, patients who survive an NSTI are left with a permanent physical disability. Retrospective reviews have shown that 15% to 28% [2,4,5,14,62] of patients with an NSTI will have an extremity amputated. Pham et al. retrospectively reviewed survivors of NSTI and found that, as expected, extremity involvement was associated with more functional limitations [65]. More long-term studies are necessary to assess the physical disability and therapy needs for these patients once their acute illness has resolved to properly maximize outcomes.

Almost half of all patients requiring radical surgical debridement will require further hospitalization or transfer to an inpatient rehabilitation facility after resolution of acute treatment [3]. Endorf et al. found the average length of hospital stay was 32 days for survivors and the overall ICU length of stay was 21 days [3]. Other studies report the average duration of hospitalization ranging from 29 to 41 days for all survivors [2,11].

Given the number of surgical interventions, length of hospital stay and use of critical care services, the cost of treating a patient with NSTI is quite high. Faucher et al. estimated a cost of $5,202 per patient day in 1999 for an average total of $153,803 per survivor [11]. Mulla et al. found that the median total patient charges for NSTI in 2001 were $54,533 [8]. With escalating health care costs both in and out of the hospital, an updated analysis of the long-term cost of NSTIs is necessary.

EMERGING PATHOGENS

Pathogens with unique antimicrobial resistance patterns and that specifically affect certain patient populations have recently been identified as causes of NSTIs. These pathogens should be considered when a patient is not improving despite adequate debridement and administration of broad-spectrum antibiotics.

MRSA

MRSA has been classified as either hospital-acquired (HA) or CA. Of NSTIs caused by MRSA, the majority of cases are CA [14,25–28]. The emergence of CA-MRSA may lie in its increased virulence and potential for necrosis. CA-MRSA manifests its virulence via Panton-Valentine leukocidin, a cytotoxin against leukocytes. These CA-MRSA infections are similar in presentation to other bacterial causes of NSTI. Unique inciting events or preexisting conditions leading to CA-MRSA susceptibility have not been identified. In a retrospective review, Lee et al. found MRSA in 39% of their NSTIs with at least 80% of these being CA-MRSA [27] Interestingly, 86% to 93% of CA-MRSA NSTI are monomicrobial [27,28]. Also, their antibiotic susceptibility profiles differ based on region. In Lee et al., from Houston, TX, they found that their MRSA were 100% susceptible to vancomycin or rifampin, 93% to trimethoprim-sulfamethoxazole, and 62% to clindamycin [27]. However, Miller et al. in Los Angeles, CA found their MRSA from NSTIs to be 100% susceptible to vancomycin, rifampin, clindamycin, gentamicin, and trimethoprim-sulfamethoxazole, 71% to tetracycline, 36% to levofloxacin, and 14% to erythromycin [28].

Acinetobacter

Acinetobacter baumannii as the cause for NSTI is rare but presents a clinical challenge in that it is resistant to most antibiotics, possesses unique virulence factors that may increase the speed at which necrosis occurs and is difficult to diagnosis given its pleomorphic appearance on Gram stain. *Acinetobacter* NSTIs are common in United States soldiers with wartime wounds sustained in Iraq and/or Afghanistan [66–68]. Antibiotic choice with an *Acinetobacter* infection may be the most challenging decision. In several case series and reports, *A. baumannii* strains were found to be sensitive to only amikacin, tobramycin, ampicillin/sulbactam [69], carbapenems [68], and possibly colistin [66,67] or were found to be resistant to all tested antibiotics [66,67,69]. Colistin should be used with caution due to its nephrotoxicity.

Clostridia

Clostridial myonecrosis, also known as "gas gangrene," is an aggressive infection of skeletal muscle. It is often associated with skeletal muscle trauma or recent surgery, but may be found with IVDA [70] and malignancy [22]. The most common organism seen is *Clostridium perfringens*, although it may be caused by *Clostridium novyi, Clostridium septicum, Clostridium histolyticum, Clostridium sordelli*, or *Clostridium fallax*. These organisms produce more than 12 toxins that may rapidly

TABLE 153.2

SUMMARY OF ADVANCES IN REDUCING MORBIDITY AND MORTALITY FROM NSTIs

- Early surgical debridement and management reduces morbidity and mortality [2,4,5,12,16].
- Laboratory values and imaging may help in the diagnosis of NSTIs when physical examination is equivocal [33–40].
- Empiric broad-spectrum antibiotics are critical adjunctive therapy [4,44–46].
- Prolonged nutritional support is needed for increased metabolic needs [58].
- CA-MRSA and *Acinetobacter* are new pathogens in NSTIs [14,25–28,57,64–66].

CA-MRSA, community-acquired methicillin-resistant *Staphylococcus aureus*; NSTIs, necrotizing soft tissue infections.

cause systemic shock. Symptoms may be similar to NSTI but gas in skeletal muscle or involved muscle at surgery can signal a clostridial infection. Antibiotic coverage is also similar, with penicillin, clindamycin, and metronidazole being the most common combination. Surgical exploration of superficial and deep muscle compartments is mandatory, and severe limb infection may require amputation [7]. Trunk involvement is associated with a worse outcome than limb infection (63% vs. 12% mortality) [71].

SUMMARY

NSTIs, albeit somewhat rare, can be rapidly lethal. The mainstays of management are prompt diagnosis, aggressive use of empiric antibiotics, and, most importantly, early radical debridement of affected tissue.

Advances in diagnosing and treating NSTIs are summarized in Table 153.2.

CHAPTER 154 ■ ACUTE LIMB ISCHEMIA: ETIOLOGY, DIAGNOSIS, AND TREATMENT STRATEGIES

PEGGE M. HALANDRAS AND ROSS MILNER

INTRODUCTION

Acute limb ischemia (ALI) occurs in the setting of inadequate blood flow and therefore, oxygen delivery to an extremity. This state of hypoperfusion leads to systemic acid–base abnormalities and electrolyte disturbances that ultimately affect cardiopulmonary and renal function in patients managed in the intensive care unit (ICU). Revascularization of an ischemic limb leads to an additional host of metabolic problems as toxic byproducts that build up in the ischemic tissue bed and inflammatory mediators are released. ALI is a vascular emergency with 30-day mortality rates of 15% and amputation rates of 10% to 30% reported in the literature [1]. This chapter outlines common etiologies, diagnosis, and treatment strategies to manage acute lower extremity ischemia in patients that are often critically ill.

ETIOLOGY

The most common etiologies of ALI can be separated into two categories consisting of either embolism or thrombosis. Embolic events result from the detachment of thrombus or atherosclerotic plaques from proximal sources and often result in extreme peripheral ischemia as emboli may become lodged in a previously normal artery without significant collateral vasculature. Cardiac sources of emboli constitute 80% to 90% of peripheral emboli [2]. Myocardial infarction and cardiac arrhythmias such as atrial fibrillation lead to stasis and dilation of the left atrium and ventricle resulting in the formation of a cardiac thromboembolic source [3,4]. The presence of valvular heart disease and prosthetic heart valves are additional sources of cardiac emboli. Noncardiac sources of emboli include arterial aneurysms, ulcerated atherosclerotic plaque, and paradoxic emboli from venous thrombi. Additional noncardiac sources of emboli may occur with recent vascular interventions such as aortic surgery, percutaneous interventions with the passage of wires and catheters or balloon pump placement. The contribution of noncerebral emboli to the development of acute limb ischemia is illustrated by the observance that two-thirds of emboli travel to the lower extremity vasculature. One-half of these emboli obstruct iliofemoral arteries and the remaining half obstructs the popliteal and tibial vessels [5].

Thrombotic occlusions may occur in either native arteries or bypass grafts. Thrombosis of a native artery occurs with progression of an atherosclerotic lesion or rupture of an unstable plaque. Thrombotic occlusions occur most frequently at the site of arterial bifurcations or at areas of anatomic compression such as the superficial femoral artery at the level of the adductor canal [6]. Arterial trauma from fractures, dislocations, blunt injury, bullet wounds, or catheter access may result in pseudoaneurysms, intimal flaps, or dissections and may progress to acute thrombosis of a native artery. Femoral or popliteal aneurysms may also be responsible for ALI by either embolism of thrombus from the aneurysm or thrombosis of the aneurysm itself and occlusion of distal perfusion in the setting of inadequate collateral formation. More commonly,

thrombosis in situ occurs with occlusion of bypass grafts. Occlusion of a bypass graft in the immediate postoperative period is typically secondary to a technical defect. Occlusions of bypass grafts at later time periods may be due to intimal hyperplasia, progression of distal disease, low flow states experienced by critically ill patients, or acquired hypercoagulable states. In general, ALI secondary to thrombosis in situ or bypass graft occlusion may manifest as an acute-on-chronic process with less profound ischemia due to collateral formation not seen with acute embolic events. Therefore, management may not require immediate surgical revascularization and it is possible to proceed with initial nonoperative management including preoperative imaging such as angiography and thrombolytic therapy.

Other etiologies of ALI include aortic dissection creating malperfusion, intense vasospasm resulting from drugs such as cocaine, ergots or vasopressors, and hypercoagulable disorders. Alterations in coagulability have been attributed to both venous and arterial thromboembolism. Increases in coagulation activity in the arterial system in the ICU population have been observed in multitrauma victims, septic patients, and in the setting of heparin-induced thrombocytopenia (HIT) and disseminated intravascular coagulation (DIC) [7,8]. Likewise, inherited coagulation disorders are associated with arterial occlusions. Circulating antiphospholipids (lupus anticoagulant and anticardiolipin antibodies), gene mutations (prothrombin, factor V Leiden, methylene tetrahydrofolate reductase), alterations in activity levels of protein C and S, deficiencies of antithrombin III, and protein C&S have all been shown to contribute to the pathogenesis of arterial thrombosis [9].

EVALUATION

A careful history and physical examination is important in determining the etiology, establishing the extent of ischemia, and determining appropriate treatment of patients with acute lower extremity ischemia. Frequently, patients in the ICU are unable to provide valuable history regarding possible comorbidities that may contribute to the acute onset of their ischemia, coexistence of chronic arterial ischemia, and information concerning the onset of symptoms. Therefore, a careful review of the patient's medical history including a history of atrial fibrillation, coagulation disorders, recent percutaneous interventions, imaging demonstrating mural thrombus or aneurysmal disease, history of claudication or rest pain, and past lower extremity revascularization procedures should be performed. Risk factors including coronary artery disease, hypertension, diabetes mellitus, hyperlipidemia and history of tobacco use should also be assessed.

A thorough physical examination is necessary to determine the duration and extent of ischemia that will ultimately determine the most suitable algorithm for treatment. Both lower extremities should be evaluated for signs of chronic disease including sparse hair growth, elevation pallor, dependent rubor, dystrophic nail growth, or chronic ulcers. Identifying the 6 "Ps" of acute ischemia including paresthesia, pain, pallor, pulselessness, poikilothermia, and paralysis is a useful tool to help establish the diagnosis and duration of acute ischemia. Initially, patients may experience pain in an ischemic limb that may progress to sensory deficit and eventually to paralysis. In addition, the level of pallor, coolness, or mottling may assist in determining the level of arterial injury of obstruction. Frequently, ischemic findings are most severe one joint distal to the level of obstruction.

A pulse exam may provide important clues about the underlying pathology but may also be misleading secondary to the subjectivity of this physical examination finding. Findings such as a "water-hammer" pulse indicating pulsation against an occlusion may be present following embolism or early thrombosis. A palpable thrill, audible bruit, or hematoma may indicate pseudoaneurysm or arteriovenous fistula in the setting of noniatrogenic or iatrogenic trauma seen with percutaneous interventions. If used correctly, continuous wave Doppler is a crucial tool in the bedside evaluation of the ischemic limb. A normal triphasic signal consists of forward systolic, reverse systolic and forward diastolic flow. A monophasic signal is characterized as a signal without pulsatile variability and signifies a proximal obstruction. Ankle–brachial indices (ABI) may also be obtained at the bedside and consist of calculating a ratio of ankle-to-brachial pressure. Abnormal results (< 0.9) must be interpreted with caution as medial calcification of vessels frequently observed in diabetics yield an ABI > 1. This occurs as calcifications prevent vessels from being compressed by a pneumatic cuff. ABIs may also be decreased at baseline in those patients with chronic lower extremity ischemia. Therefore, in a situation of suspected acute ischemia, ABIs should be compared between limbs and to ABIs obtained before the event if this value was recorded.

Further diagnostic testing may be required for operative planning but institution limitations and the urgency of revascularization should be considered when obtaining additional tests. Arterial duplex ultrasound is valuable for determining occlusive lesions, bypass graft occlusions, and the presence of distal and proximal arterial disease. This noninvasive test is operator dependent but has been shown to correlate with contrast angiography findings [10]. Digital subtraction angiography is considered the gold standard for diagnostic imaging in the acute setting. This testing modality provides anatomical detail concerning the offending lesion, presence of chronic atherosclerotic disease, and the status of distal arterial targets. Findings will assist in planning operative intervention including thrombectomy, bypass, or further percutaneous intervention. In addition to its diagnostic advantages, angiography may also be used as a therapeutic modality with the institution of catheter directed therapies. Adverse effects of contrast angiography include nephrotoxicity from contrast administration, embolization, and access site complications including dissection, pseudoaneurysm, arteriovenous fistula, and bleeding. Further imaging with CT or MRI may be necessary if aortic dissection or aortoiliac occlusion is suspected. Otherwise, these tests are time consuming and may not supply information regarding distal arterial runoff that cannot be obtained by angiography in the patient requiring urgent revascularization.

TREATMENT

Planning revascularization of the acutely ischemic limb requires consideration of the patient's overall medical condition, likely etiology and the viability of the ischemic limb. If the patient is not medically stable to proceed to the operating room or angiography suite, revascularization may be postponed in the interest of preserving "life over limb." In addition, revascularization of an ischemic limb with permanent ischemic nerve or muscle damage may result in a nonfunctional limb and primary amputation may be the most effective treatment strategy. Predicting the urgency of revascularization required to salvage an acutely ischemic limb is a difficult task and treatment paradigms have evolved with the advent of catheter directed thrombolytic therapy. The goal of the revised Rutherford Criteria proposed by The Society for Vascular Surgery and International Society for Cardiovascular Surgery (SVS/ISCVS) is to stratify levels of severity of ALI (Table 154.1). Category I limbs are considered viable with no sensory or muscle deficits. This category includes limbs that are not immediately threatened and may be managed either without an intervention or after a thorough evaluation. Class II limbs have been stratified into two subcategories. Class IIa limbs are marginally threatened

TABLE 154.1

CLINICAL CATEGORIES OF ACUTE LIMB ISCHEMIA

Category	Description/prognosis	Sensory loss	Muscle weakness	Doppler signal (arterial)	Doppler signal (venous)
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	Minimal (toes) or None	None	Inaudible	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, moderate	Inaudible	Audible
III. Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound paralysis (rigor)	Inaudible	Inaudible

Modified from reporting criteria recommended by the Society for Vascular Surgery and the International Society for Cardiovascular Surgery [11], Vascular Surgery, and the NORTH American Chapter.

with minimal sensory loss. This category of ischemic limbs can be salvaged with appropriate revascularization directed by further studies such as angiography. Class IIb limbs are immediately threatened with more profound sensory loss and mild-to-moderate muscle weakness. Salvage of Class IIb limbs should be managed with emergent revascularization efforts [11].

The main treatment modalities of acute limb ischemia include anticoagulation, open surgical management, percutaneous intervention, and primary amputation. A combination of both open surgery and percutaneous management are often required. Once the decision to proceed to either the operating room or angiography suite has been made, the patient should be systemically heparinized if no contraindications to anticoagulation exist. Full intravenous anticoagulation with heparin prevents further propagation of thrombus and recurrent emboli until definitive management is instituted [5]. Heparin bolus should routinely be 100 to 150 U per kg and a drip of 60 to 80 U per kg per hour should be started to achieve an activated partial clotting of greater than two times control.

Surgical Revascularization

Open surgical treatment includes Fogarty balloon thromboembolectomy, endarterectomy with patch angioplasty, and surgical bypass. If the diagnosis of an embolus to the femoral bifurcation is suspected, patients may be expediently managed by the passage of thromboembolectomy catheters via a groin incision in a retrograde and antegrade fashion. Femoral artery exposure may suffice but exposure of the below-knee trifurcation vessels may also be needed for adequate tibial–peroneal thrombectomy. Preoperative testing such as angiography or other imaging studies may be bypassed to avoid prolonged ischemic time. Focal femoral artery occlusions have become more common with frequent percutaneous interventions and the subsequent use of arterial closure devices. This complication can also be effectively managed by open surgical techniques such as foreign body removal, thromboembolectomy, endarterectomy with patch angioplasty, or interposition bypass. If after thrombectomy, an occluded outflow signal is detected or there is an absent pedal signal, an intraoperative arteriogram should be performed to identify native arterial lesions or residual thrombus. If the arteriogram reveals adequate inflow and distal target, and an appropriate conduit is available, surgical bypass may be the most appropriate option for revascularization. Long segment occlusions and thrombosed popliteal aneurysms with patent distal targets are indications for proceeding with surgical bypass.

Thrombolysis

Catheter-directed thrombolytic therapy has emerged as an alternative to open surgical treatment for ALI. Patients with Rutherford category I and IIa ischemia or with a high likelihood of thrombosis (in situ or bypass graft in the setting of inadequate conduit) are candidates for thrombolysis. Therapy includes performing an arteriogram to identify an acute occlusion and percutaneously crossing the lesion with a guidewire. Thrombus is then infused with thrombolytic agents through an infusion catheter. Infusion catheters typically allow for saturation of the entire thrombus with a lytic agent through a multi-sideport design or infusion guidewire. The effectiveness of thrombolytic therapy is typically monitored by reimaging with angiography at 6- to 12-hour intervals after initiation. Patients should also undergo serial neurologic, vascular and laboratory examinations. CBCs and fibrinogen levels should be followed to identify hemorrhagic trends and because fibrinogen levels less than 100 mg per dL have been associated with systemic fibrinolysis and an increased risk of bleeding, including intracranial hemorrhage [12]. Restoration of flow within a thrombosed artery or bypass graft will assist with unmasking the causative lesion and assist in planning future interventions to maintain patency. Percutaneous interventions may include angioplasty or stenting of native or anastomotic stenoses and open surgical interventions may include a new surgical bypass or surgical bypass revision.

Common thrombolytic agents used include streptokinase (produced by cultures of β-hemolytic streptococci), urokinase (extracted from human urine), and recombinant tissue-type plasminogen activator (rt-PA). Currently, there is no consensus regarding the superiority of one agent in terms of efficacy and safety. One open trial comparing intra-arterial streptokinase with intra-arterial and intravenous rt-PA confirmed 100% angiographic success with intra-arterial rt-PA as compared with intra-arterial streptokinase (80%) and intravenous rt-PA (45%). Thirty-day limb salvage rates were 80%, 60%, and 45%, respectively [13]. In contrast, a randomized trial comparing rt-PA to urokinase (UK) confirmed a faster 24-hour lysis rate with rt-PA but similar 30-day clinical success rates [14]. A secondary end point of the randomized Surgery versus Thrombolysis for Ischemia of the Lower

Extremity (STILE) study compared patency rates and safety between rt-PA and UK. No difference in efficacy or bleeding complications was reported between the two treatment groups [12]. In contrast, a randomized study treating thrombotic infrainguinal arterial occlusions with either UK or rt-PA showed slightly improved lysis in the rt-PA group with an increase in the rate of local hematomas [15]. A newer alternative is the concurrent use of abciximab, the platelet glycoprotein IIb–IIIa antagonist, with UK. A randomized trial in which patients received UK plus abciximab versus UK plus placebo showed a trend toward amputation-free survival at 90-days in the combination group as compared to the placebo group. Thrombolysis occurred at a faster rate but a higher risk of nonfatal major bleeding was seen in the combination group [16].

Several multicenter randomized control trials have compared open surgical revascularization with catheter directed thrombolysis. The Thrombolysis or Peripheral Arterial Surgery (TOPAS) study randomized patients with acute arterial obstruction (less than or equal to 14 days) to catheter-directed intra-arterial thrombolysis with UK or bypass surgery. Patients had both embolic and thrombotic etiologies including occluded bypass grafts. There were no significant differences between the two groups with regards to amputation-free survival at 6 months and mortality rates at discharge, 6 months and a year after randomization. At 6 months, the thrombolysis group underwent fewer open surgical procedures without a significant increased risk of amputation or death when compared to the surgical group [17]. The STILE trial randomized patients with nonembolic native artery or bypass occlusions (bypass within the past 6 months) to either treatment group. Composite outcomes of death, major amputation, and ongoing or recurrent ischemia were higher in the thrombolysis versus surgery group (61.7% vs. 36.1%). A secondary stratification of patients with regards to duration of ischemia confirmed that in patients with acute ischemia of < 14 days, amputation-free survival at 6 months and shorter hospital stays were improved in those patients treated with thrombolysis [12]. In summary, the findings in these trials are difficult to generalize as different etiologies (embolism, thrombosis, and occluded bypass grafts), different durations of pretreatment ischemia and different thrombolytic agents were analyzed. Therefore, a working party reached a consensus proposal on the use of thrombolysis in the management of lower-limb arterial occlusion [18]. Recommendations included the following:

1. Thrombolysis followed by correction of the causative lesion in patients with native artery occlusions with ischemia < 14 days is recommended. Immediate surgical revascularization should be a priority if thrombolysis will lead to an unacceptable delay in reperfusion.
2. Primary amputation is indicated in patients with irreversible ischemia.
3. Occluded bypass grafts may be managed by thrombectomy and surgical revision, catheter-directed thrombolysis, or insertion of a new graft. The age and type of bypass, duration, and degree of ischemia and availability of venous conduit should be considered when deciding on a treatment strategy.

Advances in percutaneous treatment of ALI include the adjuncts of mechanical thrombectomy and aspiration thrombectomy. These treatment modalities may be used alone in patients with contraindications to thrombolytic therapy, to debulk occlusive thrombus and thereby reduce the time needed for effective thrombolysis, or to remove residual thrombus following thrombolysis. Mechanical thrombectomy is performed with two FDA-approved devices in the infrainguinal arterial system. AngioJet relies on the Venturi effect in which saline is directed at high pressure in a retrograde fashion within the inflow lumen of the thrombectomy catheter. This creates a negative pressure zone at the tip of the catheter and results in thrombus fragmentation and aspiration. A pulse-spray of thrombolytic agent within the thrombus followed by mechanical thrombectomy, termed pharmacomechanical thrombolysis, is an additional treatment strategy employed with the AngioJet system. The Trellis Thrombectomy System is an additional mechanical thrombectomy device. This device allows isolation of a treatment segment by proximal and distal occlusion balloons. A dispersion catheter infuses thrombolytic agent within the treatment zone and an oscillating dispersion wire exposes the thrombus to the agent and fragments the thrombus. The fragmented thrombus is then aspirated via a port distal to the proximal balloon. Finally, mechanical thrombectomy may also be achieved with the use of percutaneous aspiration thrombectomy catheters. This technique involves a large-bore catheter connected to a syringe to aspirate thrombus.

TABLE 154.2

ABSOLUTE AND RELATIVE CONTRAINDICATIONS TO TREATMENT WITH THROMBOLYTIC THERAPY

Contraindications to thrombolytic therapy

Absolute
1. Established cerebrovascular event (including TIAs within last 2 months)
2. Active bleeding diathesis
3. Recent gastrointestinal bleeding (< 10 days)
4. Neurosurgery (intracranial, spinal) within last 3 months
5. Intracranial trauma within last 3 months

Relative major
1. Cardiopulmonary resuscitation with last 10 days
2. Major nonvascular surgery or trauma within last 10 days
3. Uncontrolled hypertension: > 180 mm Hg systolic or > 110 mm Hg diastolic
4. Puncture of noncompressible vessel
5. Intracranial tumor
6. Recent eye surgery

Relative minor
1. Hepatic failure, particularly those with coagulopathy
2. Bacterial endocarditis
3. Pregnancy
4. Diabetic hemorrhagic retinopathy

Modified from Working Party on Thrombolysis in the Management of Limb Ischemia: Thrombolysis in the management of lower limb peripheral arterial occlusion—consensus document. *J Vasc Interv Radiol* 7:S337–S349, 2003.

Contraindications to management of ALI with thrombolysis include category IIb ischemic limbs requiring immediate revascularization or category III ischemic limbs best treated with primary amputation. Contraindications to the use of thrombolytic agents are patients with a hemorrhagic disorder or an anatomic lesion with the potential to cause hemorrhage [18]. Table 154.2 lists both absolute and relative contraindications to thrombolytic therapy. Intracranial hemorrhage is one of the most devastating complications of thrombolytic therapy and may be fatal in some instances.

Finally, revascularization of an acutely ischemic limb may create significant tissue edema. The ischemia-reperfusion theory of cellular injury proposes that reperfusion of ischemic muscle results in multiple events causing cellular swelling and the formation of excessive interstitial fluid. This creates an environment in which extravascular pressure exceeds capillary pressure within a confined muscle compartment. Consequently, nutrient blood flow is restricted and will ultimately result in tissue infarction [19]. Therefore, four-compartment fasciotomy to prevent compartmental hypertension and further morbidity

may be necessary. The decision to perform a fasciotomy is frequently clinically based but may also be objectively guided by the measurement of compartment pressures.

CONCLUSION

In summary, ALI is associated with significant morbidity and mortality. ALI has multiple etiologies with the most common being embolism and thrombosis. Effective management demands that a clinician critically evaluate a patient to determine the patient's overall medical condition, contributing comorbidities and degree of ischemia. Careful physical examination will reveal clues regarding an acute embolic event in the setting of healthy lower extremity vasculature versus acute ischemia in the setting of chronic lower extremity ischemia. Open thromboembolectomy may offer the most expedient and effective revascularization of an acute embolic ischemic event. In contrast, catheter-directed thrombolytic therapy provides a mechanism for clearance of thrombus from distal runoff and unmasking of lesions responsible for an ischemic event. Correction of responsible lesions may proceed with percutaneous or open management. In general, revascularization with thrombolysis requires a longer time to revascularization and patients that have a contraindication to thrombolytic therapy may be excluded. Therefore, the management of ALI is most successful with a logical protocol that allows for the institution of multiple treatment modalities.

CHAPTER 155 ■ PRESSURE SORES: PREVENTION AND TREATMENT

VICTOR G. CIMINO, WELLINGTON J. DAVIS III AND SAMIR R. SHAH

PATHOPHYSIOLOGY

Pressure sores develop secondary to unrelieved pressure exerted on soft tissue overlying bony prominences. The National Pressure Ulcer Advisory Panel defines pressure ulcers as localized areas of tissue necrosis that develop when soft tissue is compressed between a bony prominence and an external surface for a prolonged period of time [1]. Clinicians frequently use the terms *decubitus ulcer* and *pressure sore* interchangeably. The word *decubitus* has its origin from the Latin word decumbre, which means to lie down [2]. The term decubitus ulcer therefore only applies to ulcers that occur in a lying position; it fails to describe ulcers that may occur in seated or other positions. Pressure sore is the preferred term because it describes all ulcers that result from pressure over weight-bearing areas regardless of position.

Landis [3] in 1930 suggested that constant pressure greater than the normal arterial capillary pressure, 32 mm Hg, can impair local perfusion. This is the most important determinant

in the development of pressure sores. The distribution of pressure in healthy patients in supine, prone, and various sitting positions has been extensively documented by various authors [4,5]. It is well accepted that the sacrum, buttocks, heels, and occiput are subject to the highest pressures in the supine position, with a range of 40 to 60 mm Hg. In the sitting position, pressures in excess of 75 mm Hg have been recorded over the ischial tuberosities [6]. The majority of pressure sores occur below the umbilicus, two-thirds in the hip and buttock region, and one-fourth to one-third in the lower extremities.

Studies of pressure tolerance in various tissue types by Husain [7] have demonstrated that muscle has a lower pressure tolerance when compared with skin and subcutaneous tissue. Le et al. [8] demonstrated that pressure applied to the soft tissue over bony prominences can cause infarction of muscle and subcutaneous tissue without skin necrosis. This explains the "tip of the iceberg" phenomenon not infrequently seen in clinical pressure sores. One of the most important studies regarding pressure tolerance was performed by Kosiak [9]. He demonstrated irreversible changes in dog muscle and skin when subjected to a pressure of 70 mm Hg applied continuously for 2 hours. More importantly, he showed that no changes occurred if pressure was relieved every 5 minutes. These findings illustrate the mechanism of pressure sore formation as well as reveal the major key to prevention.

There are multiple additional factors that contribute to the formation of pressure sores outside the local effects of unrelieved pressure. As suggested by the multifactorial hypothesis of Enis and Sarmiento [10], the intrinsic factors of malnutrition, advanced age, hypotension, impaired mobility, impaired sensation, and sepsis predispose critically ill patients to the development of pressure sores. Skin contamination with stool, excess moisture, and shear forces are extrinsic factors that further increase the risk of pressure sore formation.

EPIDEMIOLOGY

In the early twentieth century, pressure sores were most commonly observed in young patients with chronic diseases such as tuberculosis, osteomyelitis, and chronic renal disease. This changed in the mid-1940s with improved early and late mortality rates after spinal cord injury. Spinal cord injury patients became the largest high-risk group for the development of pressure sores. Today, the elderly citizens have become the fastest growing segment in the American population. Residents in nursing homes and chronic care facilities are now recognized as the largest high-risk group for the development of pressure sores.

In an acute care hospital, the prevalence of pressure sores ranges from 3% to 11% of all admissions. It increases to 28% when subpopulations of high-risk patients are studied. The average cost of treating an established pressure ulcer ranges from $4,000 to $40,000. This does not include medicolegal liability costs, which are an increasing concern and focus.

Patients in the intensive care unit (ICU) often have multiple risk factors for the development of pressure sores: restricted mobility, impaired sensation and/or mental status, impaired perfusion, fecal and urinary incontinence, poor nutrition, advanced age, shear forces, and friction. In addition, ICU patients have various other physiologic impairments. A study by Eachempati et al. [11] has revealed emergent admission, age, days in bed, and days without nutrition as independent predictors of pressure sore formation. Even more recently, Feuchtinger et al. [12] have found in the cardiac surgery population temperature manipulation, vasoactive agents, hypotensive periods, anemia, operating room time, steroids, and low albumin levels to be significant risk factors for the development of pressure sores. Diabetes mellitus and high acute physiology and chronic health evaluation (APACHE II) scores also identify high-risk patients [13]. Spinal cord injury patients continue to be a challenging subgroup. Improved awareness of the risk factors as well as knowledge of the options for prevention and treatment of pressure sores will improve patient care and allow for more efficient use of healthcare resources. Once pressure sores develop. There are few patients who will be candidates for definitive surgical closure because of their concurrent medical disabilities. The pressure sore then becomes a costly chronic medical problem. In any debilitated patient population, pressure sores are extremely difficult to heal.

RISK, EVALUATION, AND PREVENTION

Prevention of pressure sores in the ICU begins with education of the entire hospital staff. Identification of patients at high risk is the initial step. All patients should be routinely screened on admission for risk factors that may predispose them to the development of pressure sores. The basic tenets of prevention include pressure reduction over bony prominences, alternation of weight-bearing surfaces, good skin hygiene, and the maintenance or restoration of adequate nutrition. At this time, there is no universally accepted screening tool for quantifying risk for pressure sore development, but the risk factors are well known. Considering the cost of managing an established pressure sore, it is likely that excess prevention is less costly than nonaction. The Braden scale is one of the most widely used risk assessment tools. It has six subscales: sensory perception, skin moisture, activity, mobility, friction and shear, and nutritional status. Regardless of the screening tool, the most important factor is starting preventive measures as soon as patients at risk are identified [14]. Inattention to previously noted risk factors or early signs of skin breakdown can result in a clinically significant pressure sore in less time than the standard 8-hour nursing shift.

Dispersion of pressure is a vital component of preventive measures and management. Before the 1960s, frequent patient body positioning for avoidance of skin maceration was the mainstay of pressure sore prevention. This is still considered the basic tenet in preventive measure. Patients confined to bed should be turned every 2 hours. Alternating 30-degree oblique supine positions are best [15]. The 90-degree lateral position should be avoided. More importantly, patients in a sitting position should have their weight shifted several times every hour [6].

In the 1960s, pressure-reduction technology using the principle of dispersion became available to improve local blood flow and minimize tissue ischemia. These devices are based on the concept of suspension or buoyancy [16]. The greater the body surface area supported by the surface, the greater the distribution of the patient's weight against the mattress and the lower the effective contact pressure on the skin. The available devices achieve buoyancy through the use of water, air, gel, foam, or circulating ceramic beads. The cost of these various systems ranges from $35 to $140 per day of use.

It has been well demonstrated in the literature that transcutaneous oxygen tension can be maintained in an acceptable range in the supine position with the use of air-fluidized and low-air–loss beds in comparison to standard hospital mattresses [17]. Only with the use of air-fluidized systems is this maintained in the lateral decubitus position. Inman et al. [18] studied 100 consecutive patients who were at risk for pressure ulcer development and randomly assigned half to receive care on a standard ICU bed and half to a low-air–loss surface.

The patient groups were comparable, and all other treatment measures were standardized. The low-air–loss patient group developed fewer and less severe pressure ulcers than those who were treated on the standard surface. Taking into account the cost of the low-air–loss surface and the treatment of an established pressure sore, low-air–loss therapy is not only effective in preventing pressure sores from occurring, but it is also cost-effective. The low-air–loss mattress is a highly valuable preventive measure for the critically ill patient while not interfering with the patient's care.

Good skin care is another important adjunctive component of pressure sore prevention. This involves keeping the bed free of particulate matter and solid objects that may cause abrasions or lacerations. Daily skin assessments should be a part of routine nursing care to screen for the development of pressure sores, especially heel ulcers. Daily application of creams and lotions to the feet is inexpensive and can be vital to heel ulcer prevention. Control of both urinary and fecal incontinence and diarrhea are also important. As discussed previously, excess moisture may increase the possibility of pressure sore formation. Bacterial contamination can delay wound healing and extend the zone of tissue necrosis. Enterostomal therapists or wound care nurses can be invaluable resources in the management of these wounds. Colostomies are occasionally necessary to obtain control of the fecal stream with complex sacral or perineal wounds and open pelvic fractures. This decision should be made in conjunction with plastic and general surgical consultation.

Heel ulcers are a clinical problem that warrants special attention. A national pressure ulcer prevalence study by Meehan [19] identified the heel as the second most common site for the development of pressure ulcers. With the introduction of pressure-reduction surfaces, the incidence of sacral ulcers decreased, but there was a concomitant increase in heel ulcers. A study by Blaszczyk et al. [20] developed a useful heel pressure ulcer risk assessment tool to identify patients at risk for the development of heel ulcers.

The patient specific variables include; age over 70 years, diabetes mellitus, mental status changes (agitation, confusion, stupor, unresponsiveness), and immobility of the lower extremity. These specific risk factors are added up and the activity level is then assessed; this determines the risk factor level. Ambulatory patients should get universal heel precautions only. Patients who walk with assistance with one or no risk factors receive universal precautions only, two risk factors yield preventive precautions, and three or more risk factors yield strict precautions. Nonambulatory patients without any risk factors receive universal precautions, one risk factor yields preventive precautions, and patients with two or more risk factors receive strict precautions [20].

Universal heel precautions include daily assessment of feet, daily skin care (creams or lotions), turning every 2 hours, standard hospital pressure-reduction mattress, mobilization out of bed three times a day, and active range of motion. Preventive heel precautions additionally include assessment of feet two times a day, friction reduction (creams or lotions twice daily, socks or support hose, transparent films, or hydrocolloid to heels every week), and pressure reduction (pillow support keeping heels off bed, heel roll or heel cushion, passive range of motion exercises). Strict heel precautions additionally include foot assessment three times a day, creams or lotions three times a day, and heel protection (heel lift, heel cushion). This protocol resulted in a decrease of heel pressure ulcers in the medical ICU patient population [20].

Prior to surgical intervention for heel ulcers, including debridement, patients should be evaluated for vascular insufficiency by obtaining an ankle–brachial pressure index. If this is abnormal, a formal vascular surgery consultation should be obtained.

An effort should be made to remove trauma patients from spine boards and also remove rigid cervical collars as quickly as possible. Patients who require a cervical collar for an extended period should be assessed so that the collar fits properly. Blaylock [21] reported a successful routine for care that significantly reduced pressure ulceration from cervical collars. In patients with an unstable cervical spine, an oscillating support surface may reduce the risk of developing pressure sores. These low-air-loss mattresses also oscillate continuously from side-to-side up to 62 degrees to redistribute pressure on the skin. Selection of this surface should be made after consultation with a spine surgeon.

Nutritional assessment and support are obvious integral components in the care of every critically ill patient. It is well known that malnutrition impairs wound healing. A serum albumin less than 2.5 g per dL has been correlated with the development of pressure sores. It is important that a patient's nutritional status is optimized prior to any reconstructive surgical intervention needed to close a chronic pressure sore. Weekly monitoring of the visceral protein prealbumin can be used to assess the adequacy of the patient's nutritional status and response to dietary supplementation. A more detailed discussion of nutritional assessment and management is beyond the scope of this chapter.

Other patient specific issues to consider are anemia of chronic disease, spasticity in spinal cord injury patients, and long-standing contractures.

WOUND CLASSIFICATION AND MANAGEMENT

According to the National Pressure Ulcer Advisory Panel, wounds are generally classified as follows [1]:

Grade I: Nonblanchable erythema of the skin with the lesion being limited to the epidermis and dermis. Heralds skin ulceration. (Persistent skin erythema.)

Grade II: Any partial-thickness skin loss. Full-thickness ulceration of the skin extending through to the subcutaneous adipose tissue at any level above muscle fascia. (Ranges from abrasion, blister to shallow crater clinically.)

Grade III: Ulceration extending down through the subcutaneous tissue to the underlying muscle. Muscle fascia exposed but not violated.

Grade IV: Ulceration extending through muscle to bone or involving any joint space or supporting structures (such as tendon).

There are two other classification systems, Shea and Yarkony-Kirk, with parameters similar to those of the National Pressure Ulcer Advisory Panel classification. None of these classifications takes into account presence of infection, amount of necrotic tissue, or size of the ulcer.

Wound management is based on awareness of the acute, chronic, local, and systemic factors that resulted in wound formation. The premorbid status, with particular attention to nutritional history and ambulatory status, is critical to management.

The principles of pressure sore management are the following:

- Prevention
  - Education of staff
  - Identification of high-risk patients
  - Precautions
- Early identification of skin impairment
- Debridement
- Treatment of infection
- Local wound care

- Pressure dispersion
- Optimization of global medical status
- Definitive wound closure

Pressure sores are best evaluated by history and physical. Clinical findings can guide the initial management of most pressure sores without costly additional studies. Initial management should focus on the identification of active infection. This is suspected when wound edge cellulitis, purulent discharge, and/or foul odor are present [6]. The gold standard for a diagnosis of osteomyelitis is bone biopsy. More recently, though, magnetic resonance imaging has become a useful noninvasive tool that is very sensitive for the diagnosis of osteomyelitis. The overall clinical condition of the patient should determine the aggressiveness of workup and surgical intervention. Most often, the diagnosis can be made by physical examination, and other studies rarely provide more information. Debridement is probably best limited to infected and obviously necrotic tissue until nutritional status has been optimized.

Most grade I and II pressure sores respond well to debridement, control of infection, and pressure dispersion if the patient is stable medically. Nonetheless, these sores require careful attention despite their initial, relatively innocuous appearance. As discussed previously, the skin is more resistant to pressure than the underlying muscle and subcutaneous fat; this may result in necrotic tissue beneath intact skin. Not infrequently, what may initially appear to be a grade I or II ulcer may actually be a grade III or IV lesion before the eventual loss of the overlying skin.

Ideally, wound debridement will consist of the removal of all necrotic tissue and evacuation of pus and any infected material. This can be performed by sharp debridement or with enzymatic agents with the additional assistance of frequent dressing changes. Extent and aggressiveness of debridement at the authors' institution is often tempered by the clinical status of the wound (infected or noninfected, wet vs. dry necrotic tissue) and the clinical status of the patient (severity of anemia, hemodynamic stability, severity of malnutrition, presence of sepsis). Decisions about wound management are made on a case-by-case basis in conjunction with the ICU and infectious disease teams.

Debridements can commonly be performed at the patient's bedside with appropriate lighting and instruments. Most patients require little or no anesthetic for the debridement of frankly necrotic material. Wound cultures will provide data regarding bacterial colonization. Colonization of pressure sores is polymicrobial. *Bacteroides, Pseudomonas, Proteus, Staphylococcus,* and *Streptococcus* species as well as other enteric flora are the most commonly cultured organisms.

Fortunately, invasive sepsis from a pressure sore is rare. Anecdotally, most cases of sepsis are secondary to abscess formation under an unroofed dry eschar. Sepsis more commonly results from a urinary tract infection or pneumonia. In cases in which the source of sepsis is unclear, computed tomography scanning of the soft tissue or surgical exploration of pressure sores may be mandated. When sepsis is attributed to a pressure sore, the mortality rate is high [22]. Parenteral antibiotics are administered only in the presence of sepsis or if wound closure is planned.

Currently, it is recognized that most topically applied antimicrobial agents and detergents have a toxic effect on human fibroblasts and keratinocytes [15,21–29]. Detergents are used for cleansing the skin surrounding the ulcer. Topical antibiotics such as dilute Dakin's solution or neomycin irrigant help control bacterial colonization in highly contaminated wounds with minimal adverse effect on fibroblasts and keratinocytes [30].

A moist environment with minimal bacterial contamination is desirable for the optimization of reepithelialization. Wet-to-moist dressings with normal saline are recommended as the initial treatment of most grade III and IV pressure ulcers. If the wound is limited to the skin or superficial subcutaneous tissue, an occlusive hydrocolloid dressing may be used as an alternative to wet gauze dressings if the wound has been adequately debrided [31]. Xakellis and Chrischilles [32] performed a prospective randomized study comparing hydrocolloid versus saline gauze dressings in the treatment of pressure ulcers in the long-term care setting. Hydrocolloid treatment required one-eighth the nursing time required by saline gauze treatment. There was no statistically significant difference in the healing time between the study groups; however, the cost was 3.3 times greater in the hydrocolloid group. The value of reducing the time nurses spend on dressing changes may translate into improved overall care of the patient. If an occlusive dressing is applied, fecal contamination under the dressing must be prevented.

Grade III and IV ulcers are treated, in principle, the same as grade I and II ulcers. In the case of exposed or devitalized bone, debridement of all necrotic tissue is necessary. Plain films, bone scans, and erythrocyte sedimentation rates are very nonspecific and generally provide little useful information to support the diagnosis of osteomyelitis. One must rely on clinical suspicion, magnetic resonance imaging, or bone biopsy to confirm the diagnosis. Again, the treatment is focused on adequate debridement, local wound care, pressure dispersion, and nutritional support. Prolonged parenteral antibiotics for bone exposure alone are not recommended unless a definitive debridement and wound closure are contemplated. Some patients may require multiple serial debridements until the wound is controlled.

At the authors' institution, the management of eschars is primarily dictated by the clinical status of the eschar. If the eschar is dry, firm, immobile, and shows no evidence of infection, the eschar is often dressed with silver sulfadiazine twice a day to lower bacterial counts and serially reevaluated until it begins to soften and slough. The necrotic tissue is then debrided at that time. This is done to allow time for healing and allow nonviable tissue to clearly demarcate itself, thereby minimizing the amount of healthy tissue that will be excised at the time of debridement. Eschars that are soft, soupy, mobile, or have evidence of infection are debrided early. On rare occasion, a computed tomography scan may assist in making the decision to observe what may appear to a stable ulcer, when there is a concern of underlying infection that is not apparent on physical examination.

After initial sharp wound debridement, subsequent debridement may be facilitated with the use of topical enzymes. Collagenase ointment facilitates eschar separation and is most applicable in chronic conditions. It works well at removing fibrinous exudate overlying healthy tissue in the base of grade III and IV pressure sores. Enzymatic debridement is particularly useful in patients with intact sensation, in whom surgical debridement at the wound margins may be painful. Collagenase is generally applied once a day with a topical antibiotic powder. Once all eschar is separated and fibrinous exudate removed, the collagenase ointment should be discontinued. Calcium alginate products minimize bacterial contamination and are highly absorbent. They may be useful in treating wounds with a high exudative component after adequate debridement. Enzymatic debridement is a good adjuvant therapy in pressure sores but should not be considered a substitute for sharp debridement. Clinical judgment and experience should dictate its use and application.

An increasingly utilized option in the management of Stage III/IV pressure ulcers is the use of negative pressure wound therapy (NPWT) known as the vacuum-assisted closure (V.A.C.®). This device applies subatmospheric pressure to the wound bed through a secured foam dressing [33]. The V.A.C.® is thought to improve the status of chronic "unsalvageable" wounds in

four ways: decreased time for granulation tissue and wound contracture, reduced bacterial colonization, decreased edema, and minimized dressing changes [33,34].

Several studies have focused on the use of the V.A.C.® for pressure sores. Isago et al. treated 10 patients with Stage IV pressure ulcers for 5 weeks. They demonstrated that after V.A.C.® therapy the wound area and depth was reduced by an average of 55% and 61% respectively [35]. Other studies have compared the V.A.C.® with saline, hydrocolloid, or alginate dressings. Overall, patients with V.A.C.® treatment had evidence of more healthy tissue growth [34,36]. Healthpoint system (HP) products offer enzymatic ointments (Accuzyme, Iodosorb, and Panafil) to manage pressure sores. In an article by Ford et al., the NPWT group versus the HP had a decreased number of polymorphonuclear cells and lymphocytes per high-powered field. This translates to increased rates of wound healing and reduced inflammatory changes [37].

Negative pressure therapy has maximum benefits with large wounds with high exudates, tunneling, or undermining [33]. Prior to use, wounds must be adequately prepared. The end points of treatment with wound V.A.C.® therapy depend on whether a patient is a surgical candidate. In such an instance, the V.A.C.® may be used as an adjunct modality until nutritional status is optimized, appropriate antibiotics are instituted, and comorbidities are stabilized. This may allow progression to the point that wound closure is achieved or a lesser surgical procedure may be performed [33].

Once the wound is determined that it will re-epithelialize, V.A.C.® may be discontinued. Nonetheless, it is imperative to assess the wound frequently and document volume changes. If there is no progress or worsens after 2 to 4 weeks of therapy, then it is reasonable to reassess the appropriateness of VAC therapy [33]. Also, it is paramount that patients adhere to strict off loading regimen, maintain an adequate seal, and tolerate dressing changes all of which may be problems in the ICU setting.

Pressure ulcers are a costly healthcare problem and it is estimated that over 1.6 million wounds develop each year, with a cost of $2.2 to $3.6 billion [33]. There is literature to support early initiation of NPWT which may be associated with reduced length of stay at long-term care facilities leading to overall reduced healthcare costs [38]. Philbeck et al. surmised that there would be approximately $9,000 in savings for pressure sores with NPWT versus saline-soaked gauze over a period of 97 days [39].

Nonetheless, there is a paucity of prospective randomized studies evaluating the cost-effectiveness of the wound V.A.C.® with pressure sores. In the future, we need data that will ascertain the role of NPWT in reducing costs. In addition, we need to determine the role of NPWT as an adjunctive therapy in advanced pressure ulcers management.

Newer technologies such as topical growth factors and cultured skin material are evolving, but their current use is still experimental. When the roles of these treatments are defined, they will not substitute conventional measures of wound care. With appropriate treatment, Conway and Griffith [40] found that 30% to 80% of pressure sores healed without surgical intervention during 3 to 6 months.

OPERATIVE TREATMENT

Patients are considered candidates for surgical closure of pressure sores if they have failed the previously described treatment and are otherwise in reasonably good health. The majority of ICU patients with pressure sores do not meet the general criteria for definitive wound closure during their ICU stay. Chronic malnutrition, poor neurologic status, and noncompliance with postoperative protocol are a few of the relative contraindications to definitive wound closure. The wounds of most ICU patients that do require closure will not be closed for weeks to months after the patients' initial ICU admission. At the time of closure, it is critical that the patient's medical condition is stable and has been restored as close as possible to the premorbid state. The wound must also be well controlled. The lack of enthusiasm of surgeons for primary flap closure is related to the high recurrence rate. Evans and Dufresne [41] reviewed their experience with the surgical therapy of pressure sores and found that 82% recurred at the same site in paraplegic patients. Overall, there was a 91% recurrence rate in the same group. The average time to pressure sore recurrence was 18.2 months and pressure sore recurrence was unaffected by the type of closure that was performed. The authors concluded that the physician and the patient must be willing to accept the inevitability of recurrence at the same or other location. Surgical flap closure is reserved for patients in whom healing has plateaued after maximizing all factors. They must also demonstrate the personal and social support necessary to participate in a comprehensive wound care program.

Prior to surgery, nutritional status is optimized. Bowel preparation is based on the surgeon's preference and is individualized according to the wound and the patient. All nonviable tissue is debrided and bony prominences are reduced. This is frequently a staged procedure to minimize hematoma formation and acute blood loss. The goals of wound closure are to eliminate dead space and to provide wound approximation with minimal tension while the patient is positioned in a normal resting posture. The most common reasons for early failure of flap closure are inadequate debridement, hematoma formation, wound tension, and postoperative positioning. Other reasons for failure are uncontrolled spasm, unaddressed limb contracture, infection, and noncompliance with postoperative protocols.

A myriad of options are available for the flap closure of pressure sores. At the authors' institution, rotation advancement flaps based on the gluteal muscles are preferred for sacral ulcer closure due to the ability to safely readvance the flap if a recurrence should occur. Posterior thigh flaps are preferred for the closure of ischial ulcers, and the traditional tensor fascia lata flap is generally used for trochanteric ulcer closure. Patients with trochanteric ulcers should be evaluated for hip joint stability because they may require a Girdlestone arthroplasty if hip dislocation is contributing to pressure sore formation.

Surgery is usually not necessary for definitive wound closure in ICU patients who were previously ambulating and who in the long term will maintain the ability to ambulate. Even grade III and IV ulcers usually heal with local wound care, good nutritional support, and alleviation of the pressure in ambulators. In the rare instance of a refractory sacral pressure ulcer in an ambulatory patient, use of the gluteus muscle should be tempered to minimize the significant disability caused by the sacrifice of this muscle.

POSTOPERATIVE MANAGEMENT

The critical principles of postoperative management are avoidance of compression of the vascular pedicle, minimization of tension on wound edges, obliteration of dead space, adequate drainage, minimization of shear forces, and pressure dispersion. Air-fluid beds are generally used a minimum of 3 weeks postoperatively. This helps to reduce the likelihood of secondary pressure sores. At the authors' institution, air-fluidized beds are used postoperatively in all patients who undergo flap

TABLE 155.1

SUMMARY OF ADVANCES FOR REDUCING RISK OF PRESSURE SORES

- Early identification of patients at risk using standardized risk assessment tools reduces the incidence of skin breakdown [14,38].
- Pressure-reducing bedding maintains transcutaneous oxygen tension [16,17].
- Hydrocolloid dressing reduces nursing time but increases cost compared with saline dressings for pressure sores [30].
- Negative-pressure wound therapy promotes angiogenesis, new tissue growth, and reduced bacterial growth [31–34].

closure of pressure sores. Jackson-Pratt drains are left in place for a minimum of 2 weeks to facilitate the evacuation of any fluid collections and to obliterate dead space underlying the flap. Parenteral antibiotics are continued for an additional 4 to 6 weeks for all patients diagnosed with osteomyelitis. Bone cultures are sent routinely in all cases in which reduction of bony prominences is performed. Attention to urinary and fecal diversion should be maintained. Recently, at the authors' institution, the V.A.C.® has proved a useful tool postoperatively for edema control, wound drainage, and the obliteration of dead space with good success in place of or as an adjunct to Jackson-Pratt drains. It has been used in selected cases immediately after wound closure and on a few occasions after reexploration for hematoma evacuation.

After flap closure, patients are instructed to remain off the flap surface for a minimum of 5 weeks postoperatively. At 5 weeks, a progressive program of gradual return of weight-bearing tolerance on the operative site is started. The greatest challenge is a life-long commitment to self-care that minimizes the risks of the development of pressure sores in patients with long-standing risk factors.

Advances in reducing risks in pressure sores, based on randomized, controlled trials or meta-analyses of such trials as well as prospective studies, are summarized in Table 155.1.

CHAPTER 156 ■ MANAGEMENT OF THE OBSTETRICAL PATIENT IN THE INTENSIVE CARE SETTING

JOHN G. GIANOPOULOS AND JONATHAN F. CRITCHLOW

Pregnancy is a common occurrence in everyday life. Yet, many women suffer significant risk and even death from the normal physiologic phenomenon of pregnancy. The United States enjoys one of the lowest maternal mortality levels in the world. However, for every 100,000 live births 10 to 12 women die secondary to medical or obstetric complications of pregnancy. It is not uncommon for the intensive care team to care for pregnant patients with critical conditions. Improvements in obstetric, anesthetic, and intensive care have led to the decline in maternal mortality and the shifting of responsible causes [1,2]. Today there are fewer pregnant patients with septic causes for their critical illness and more patients with hypertension and concurrent medical illness admitted to the intensive care setting [3].

The approach to the pregnant patient in the intensive care setting requires a thorough knowledge of the normal maternal adaptations to pregnancy, the potential fetal effects of any diagnostic or therapeutic modalities needed, and the potential for obstetric complication of any procedures. This chapter reviews the maternal anatomic and physiologic adaptations to pregnancy, considerations of potential harm from diagnostic studies, selected therapeutic interventions, and specific pregnancy disease states that may complicate the care of the critically ill pregnant patient such as preeclampsia, eclampsia, obstetric hemorrhage, and trauma. Specifics related to the diagnosis and treatment of respiratory failure in pregnancy is discussed elsewhere in the text (see Chapter 51).

MATERNAL PHYSIOLOGIC ADAPTATION TO PREGNANCY

Cardiovascular System

The cardiovascular system undergoes significant alteration under the influence of the altered hormonal milieu of pregnancy. Cardiac output begins to rise in the first trimester and continues a steady rise peaking at 30% to 50% of preexisting levels by 32 weeks' gestation [4]. The rise in cardiac output is produced by increases in both heart rate and stroke volume which are in response to an increase in endogenous circulating catecholamines, which affect both an inotropic and a chronotropic response [5,6]. Peripheral vascular resistance is reduced secondary to a direct effect of progesterone relaxing the smooth muscle intima of the precapillary resistance vessels, resulting in vasodilatation [6]. The arterial–venous shunt of the placenta also contributes to decreased vascular resistance. In the third trimester, the enlarged uterus may compress the vena cava (particularly in the supine position) leading to decreased venous return to the heart and a decrease in cardiac output. The third-trimester pregnant patient is best positioned so that the uterus is displaced to the left, allowing adequate venal caval flow and venous return to avoid hypotension. There is a slight drop in mean arterial pressure in normal pregnancy beginning during the second trimester secondary to the reduction in peripheral resistance. Blood volume increases in pregnancy, peaking at 50% above prepregnancy levels. The maximal increase in blood volume occurs at about 32 weeks' gestation [7,8]. This increased blood volume leads to normalization of mean arterial pressures by term.

The pulmonic and systemic circulations undergo similar alterations. There is vasodilatation with an increased volume to capacitance. However, in the pulmonic circulation the volume and capacitance changes almost equal each other. Therefore, there is virtually no change in mean pulmonic pressures [9,10]. When the pulmonic circulation is evaluated by central catheterization, no changes in pulmonary artery pressures or wedge pressures can be attributed to pregnancy [9,11]. The increased pulmonic volume with increased capacitance renders the pregnant patient susceptible to fluid overload and pulmonary edema. Pulmonary edema will occur much more readily in pregnancy secondary to these specific maternal adaptations.

Respiratory Adaptations

Progesterone affects the hypothalamic apneustic center. Carbon dioxide sensitivity is reduced to 30 mm Hg. This results in an increased respiratory rate and an increased tidal volume. The pregnant patient is in a chronic state of respiratory alkalosis. The kidneys compensate by excreting bicarbonate to maintain normal acid–base equilibrium [12]. The normal blood gas of pregnancy is a compensated respiratory alkalosis. The normal pH is 7.44 and the bicarbonate decreases 4 mEq per L [12]. Vital capacity and maximum voluntary ventilation are not altered. The functional residual capacity is reduced as the diaphragm is elevated. The reduced bicarbonate level renders the pregnant patient much more susceptible to the development of metabolic acidosis in response to a variety of conditions [12,13].

Hematologic Adaptations

Plasma volume in pregnancy increases by 50% for prepregnancy levels. The red cell mass will increase in pregnancy by 30% over prepregnancy levels. This leads to a dilutional effect, decreasing hemoglobin concentrations (lower normal: 10.5 to 11 g per dL) and hematocrit levels (30% to 35%). This phenomenon has been termed the *physiologic anemia* of pregnancy [8,14].

Increased catecholamine and steroid levels in pregnancy cause a demargination of mature leukocytes from the

endothelium. This leads to a physiologic leukocytosis of pregnancy, with the white blood cell count increasing by 5,000 to 10,000 cells per mL [8,14].

Estrogen stimulates the hepatocyte endoplasmic reticulum, leading to an increased protein production. There is also increased synthesis of several clotting factors (VII, VIII, IX, and X) throughout pregnancy. Fibrinogen increases by 20%, with an average level during gestation of 400 mg. These increases render the pregnant woman hypercoagulable [15]. Critically ill pregnant patients rendered immobile require some form of prophylaxis to prevent venous thromboembolic events as they are at higher risk secondary to the hypercoagulability of pregnancy.

Renal Adaptations

Renal plasma blood flow and glomerular filtration rate increase by approximately 30% to 50% from prepregnant levels resulting in an increased creatinine, urea, and uric acid clearance, with a decrease in serum creatinine (normal: 0.5 to 0.9 mg per dL), blood urea nitrogen (normal: 10 to 15 mg per dL), and uric acid (normal: 2.5 to 3.5 mEq per L) levels [15–17]. When drugs with renal clearance are used in pregnancy, their dose needs to be adjusted to account for increased renal clearance. Progesterone relaxes the renal collecting system. The muscularis of the bladder is relaxed and urinary stasis occurs. The angle of the urethra to the vagina is altered, making urinary tract infections common in pregnancy. If bladder catheterization is required for more than 12 hours, antibiotic prophylaxis is needed to prevent urinary tract infection (Table 156.1).

TABLE 156.1

PHYSIOLOGIC MATERNAL ADAPTATION TO PREGNANCY

System	Alternations
Cardiovascular	Cardiac output, HR × SV = CO Increased 20%–30% Both heart rate and stroke volume increased
Peripheral vascular resistance	Decreased as resistance vessels with vasodilatation
Blood flow	Increased to Uterus Skin Kidney Breast
Pulmonic circulation	Blood volume increases equal capacitance increase No change in pulmonary artery pressures
Pulmonary system	Tidal volume increased Respiratory rate increased Functional residual capacity reduced Compensated respiratory alkalosis
Renal system	Renal artery perfusion increased Glomerular filtration rate increased Creatinine clearance increased BUN, serum creatinine, serum uric acid decreased Renal clearance of drugs increased Bladder muscularis relaxation Urinary stasis infection risk Dilated renal pelvises and ureters
Gastrointestinal system	Decreased gastric motility Aspiration risk with anesthesia Decreased colonic motility Constipation complaints
Hematologic system	Plasma volume increases 40%–50% Red cell mass increases 20%–30% "Physiologic anemia" Leukocytosis Increased liver-produced clotting factors Increased fibrinogen Hypercoagulable state

BUN, blood urea nitrogen; CO, cardiac output; HR, heart rate; SV, stroke volume.

DIAGNOSTIC RADIATION EXPOSURE

Diagnostic radiographic procedures are essential in the management of the critically ill patient. These procedures may be undertaken with care in the pregnant patient. Adverse fetal effects are reported with ionizing radiation exposure to the fetus in excess of 10 cGy [18–20]. Microcephaly, intrauterine growth restriction, and poor fetal development have all been reported [18–20]. Direct radiation exposure to the pelvis of 10 cGy or greater in the first trimester may result in intrauterine fetal death. Direct fetal exposure of 5 cGy or less has not been shown to increase fetal malformation. However, a very small risk of increased childhood malignancy has been reported. Direct doses of 1 cGy or less have not been shown to produce any significant fetal effect [18–20]. Single-shot examinations such as chest radiographs, abdominal images, or imaging of long bones expose the fetus to very little risk. Fluoroscopic examinations are to be avoided in pregnancy because of the significant amount of radiation exposure [19,20].

Computed tomography (CT) of the head and thorax produces little direct radiation to the pelvis (0.05 to 0.1 cGy) and may be undertaken with relative safety [21]. Abdominal and pelvic CT scanning delivers 3 to 10 cGy to the pelvis and should be avoided in the first trimester. In the second and third trimester, abdominal and pelvic CT examinations may be done with caution [21,22]. If a significant alteration in management is to be undertaken as a result of the information obtained from the procedure, the potential fetal risk should be considered. Magnetic resonance scanning has not been extensively studied in pregnancy. However, this technology is considered extremely safe in pregnancy and may be an alternative to CT scanning in the first trimester [23,24]. Magnetic resonance imaging examinations are used as an adjunct to ultrasound in the second and third trimesters to aid in the diagnosis of certain fetal anomalies. Contrast agents should be avoided in the first trimester [23,24].

Radionuclide procedures may be done in pregnancy. The overall radiation dose to fetus with most procedures is low. Most of the contrast agents used in these examinations are renally cleared. It is important to place an indwelling bladder catheter to reduce total radiation dose to the fetus because retained urine in the maternal bladder could expose the fetus to larger radiation doses than the initial pass through the placental circulation [19,25–27].

TABLE 156.2

RADIATION DOSE AND FETAL EFFECT

Radiation dose to fetus (cGy)	Theoretical or actual fetal effect
0–5	No reported malformation; potential for oncogenesis and increased cancer risk
5–10	Potential for oncogenesis; potential for IUGR
10–20	Microcephaly, IUGR, 2.4% mental retardation
20–50	Microcephaly, IUGR, fetal death, mental retardation
50–100	Microcephaly, IUGR, 18% mental retardation, fetal death

IUGR, intrauterine growth retardation.

If excessive radiation doses to the pelvis are inadvertently administered, it is important to calculate the fetal isodose radiation exposure. If an excess of 10 cGy has been delivered to the fetus, there may be significant fetal effect. Table 156.2 outlines potential fetal effects of radiation exposure.

MEDICATIONS AND PREGNANCY

Analgesic Agents

Opiate narcotic agents administered for short periods of time have been shown to be safe in pregnancy. Morphine and meperidine administered intravenously, intramuscularly, or in patient-controlled pumps, have demonstrated no adverse fetal effects. Chronic opiate use in pregnancy has been associated with intrauterine growth restriction. Intrauterine fetal addiction with withdrawal may occur [28–30]. Intrauterine fetal withdrawal has been associated with intrauterine fetal demise. Oral opiates may be used with similar cautions.

Codeine-containing compounds should be avoided in the first trimester because they have a small teratogenic potential [30]. These compounds may be used in the second and third trimesters for short intervals with little fetal risk. Nonsteroidal anti-inflammatory agents may decrease fetal renal blood flow, leading to oligohydramnios. They also will lead to the in utero closure of the ductus arteriosus, producing fetal pulmonary hypertension after 32 weeks' gestation. Short courses of indomethacin may be used with caution prior to 32 weeks' gestation. Benzodiazepines may be used; they have not been shown to exert an adverse fetal effect. High doses near the time of delivery may lead to neonatal depression [30,31].

Antibiotics

Penicillin, penicillin derivatives, as well as cephalosporins have no known adverse fetal effect. Erythromycin, clindamycin, and vancomycin are considered safe in pregnancy. There is some concern regarding renal toxicity with vancomycin. Aminoglycosides have been implicated with fetal ototoxicity [30]. However, only streptomycin and kanamycin have been implicated. Gentamicin has not been reported to have significant ototoxicity. Gentamicin may be used in life-threatening infections while carefully monitoring levels. Sulfonamides complete with bilirubin-binding sites and may lead to neonatal kernicterus if administered in the third trimester. Tetracycline is teratogenic, leading to brown teeth and abnormal long bone development [30,32,33] (Table 156.3).

TABLE 156.3

ANTIBIOTICS IN PREGNANCY

Penicillin/cephalosporin
- No adverse effect in nonallergic patient

Aminoglycosides
- Renal toxicity and ototoxicity
- Use in life-threatening infections

Tetracycline
- Contraindicated
- Staining of teeth
- Bone demineralization

Sulfa drugs
- Avoid first trimester
- Third trimester use with bilirubin displacement
- Kernicterus

Chloramphenicol
- Grey baby syndrome

Fluoroquinolones
- Fetal effect—avoid use

Anticoagulants

Unfractionated heparin, because of its molecular size and ionic negative charge, has been shown not to cross the placental membrane [34]. Therefore, it is the anticoagulant of choice in all trimesters of pregnancy and may be used with relative fetal safety. Fractionated heparins also have been shown not to cross the placental membrane. They may be used throughout pregnancy as well. If fractionated heparins are used in pregnancy, it is advised to change to unfractionated heparin late in the third trimester. If surgical intervention is needed, unfractionated heparin may be reversed with protamine sulfate and the activated partial thromboplastic time is a more reliable monitor for anticoagulant effect than the activated factor Xa assessment needed to assess the activity of fractionated heparins [35,36]. Warfarin and its derivatives are contraindicated in the first trimester as these agents are teratogenic, producing midline defects such as clefts, cardiac septal defect, and limb bud abnormalities. In all trimesters, warfarin crosses the placenta and may lead to spontaneous fetal bleeding [37–39]. In some select cardiac patients (particularly those with mechanical valves), warfarin may be used in the second and early third trimesters. Fetal intracranial bleeding has been observed with warfarin use in the late third trimester.

Antihypertensives

Pregnant patients will require acute antihypertensive intervention when the systolic blood pressure exceeds 160 mm Hg or the diastolic blood pressure exceeds 110 mm Hg. Preservation of the fetal circulation must be kept in mind when treating these conditions. For the acute management of hypertensive crisis in pregnancy, hydralazine has been recommended [40,41]. A test

dose of 5 mg intravenous (IV) is given, followed by 10-mg doses. However, recent data show labetalol may be a superior antihypertensive in acute situations, as it does not increase the maternal pulse rate. A 10-mg test dose is given IV, followed by a 20-mg dose at 10 minutes if no response is observed. If still no response in blood pressure is observed, the dose may be increased to 40 mg in 10 minutes and followed by 80 mg in 10 minutes. The 80 mg dose may be repeated one time. The total dose should not exceed 220 mg. Labetalol may also be administered as a continuous IV drip at 2 to 4 mg per minute [42,43]. Nifedipine may be used in less acute conditions with caution due to paradoxical hypotension. Hydrating the patient with IV fluids will reduce the incidence of a decrease in blood pressure

Sodium nitroprusside should be avoided if possible. This agent is converted in the fetus to sodium thiocyanate, which cannot be metabolized because the fetus lacks the necessary hepatic cytochrome. In extreme situations when other agents have not been effective, it may be used with caution [44–46]. Angiotensin-converting enzyme inhibitors and angiotensin receptor blocker agents are contraindicated in pregnancy. They have been associated with fetal anomalies and intrauterine fetal death secondary to fetal cardiovascular collapse [30].

Vasoconstrictor and Inotropic Agents

Profound hypotension unresponsive to postural change and fluid resuscitation may require vasoconstrictor therapy. Phenylephrine has been shown to be safe in treating hypotension secondary to spinal or epidural anesthesia. Its excessive alpha activity makes it less effective in treating critically ill patients. Dopamine and isoproterenol alter uterine blood flow less than phenylephrine. In situations in which vasoconstrictor therapy is needed in a critically ill patient, dopamine is recommended. At low doses, 2 to 4 µg per minute, uterine blood flow is increased [46,47].

SPECIFIC PREGNANCY DISORDERS

Hypertensive Disorders of Pregnancy

Hypertension complicates 8% to 10% of all pregnancies, yet despite modern medical management it continues to be a leading cause of maternal mortality. Hypertension during pregnancy is classified as preexisting chronic hypertension, preeclampsia/eclampsia, chronic hypertension with superimposed preeclampsia, and gestational hypertension [42].

Preeclampsia is defined as proteinuric hypertension after the 20th week of gestation. Hypertension is defined as a sustained blood pressure of 140 mm Hg systolic and/or 90 mm Hg diastolic. Proteinuria must exceed 300 mg in 24 hours. A dipped urine sample of 1+ repeated in 6 hours or a single 3+ or 4+ dip also will meet the criteria to make the diagnosis. Preeclampsia may lead to significant maternal end organ damage, secondary to vasospasm [42,48]. The organ dysfunction leads to with renal failure, liver compromise, intravascular coagulopathy, thrombocytopenia, pulmonary edema, hemolysis, and cardiac failure. Preeclampsia is classified as mild or severe. Severe preeclampsia occurs when any of the following criteria are met: blood pressure 160/110 mm Hg, thrombocytopenia, elevated liver enzymes, oliguria, proteinuria in excess of 5 g in 24 hours, hyperreflexia, scotomata, epigastric pain, renal failure, pulmonary edema, disseminated intravascular coagulopathy, and fetal compromise. Mild preeclampsia is preeclampsia without any criteria met to classify as severe. Eclampsia is defined as preeclampsia with the onset of maternal seizure in a patient without previous seizure disorder.

The specific etiology of pre-eclampsia remains a medical enigma. However, much is known regarding the underlying pathophysiology of this disease. Arteriolar vasospasm with intravascular volume depletion is the primary pathologic alteration leading to preeclampsia. Precipitating pathologic factors include failure of prostacyclin-mediated vasodilatation in the vascular system, endothelial damage leading to the release of endothelins, thromboxane, and vasoactive proteins [49–51]. Placental vascular growth factor inhibitory proteins have been implicated in the etiology.

These intravascular changes lead to the loss of catecholamine insensitivity of normal pregnancy and angiotensin hypersensitivity. The increase in peripheral vascular resistance leads to hypertension, diminished blood flows to vital organs, and microangiopathy. Albumin concentrations decrease in the blood secondary to proteinuria which contributes to a decrease in plasma oncotic pressure. This, along with endothelial damage, leads to generalized edema, ascites, and in severe cases, pulmonary edema. Renal blood flow is decreased and fibrin deposition occurs in the glomeruli. Renal endothelial cells swell and the filtration function of the kidney is impaired, allowing large protein molecules to enter the collecting tubules [52]. Hyperreflexia is common. The mechanism responsible for central nervous system dysfunction is not totally understood. Hypertensive encephalopathy, cerebral vasospasm, and cerebral edema contribute to the pathologic milieu, which may lead to an area of localized cerebral irritability leading to an epileptic focus resulting in seizure activity.

A syndrome of hemolysis, elevated liver enzymes, and low platelets is sometimes seen in patients suffering from preeclampsia and is termed the HELLP syndrome [53]. This constellation of end organ abnormalities may be seen in 2% to 12% of patients with preeclampsia. As many as 30% to 50% of these patients may not manifest hypertension or proteinuria. This syndrome is a severe form of preeclampsia and is life threatening. The exact pathogenesis is not known; however, vasospasm, endothelial damage, and microangiopathic hemolysis all contribute. Platelet consumption and fibrin deposition in the liver lead to areas of necrosis. Rarely, subcapsular hematoma may occur. The diagnosis is made by the observation of hemolysis on peripheral blood smear, elevations in lactate dehydrogenase, alanine aminotransferase, and thrombocytopenia (platelet count less than 100,000 per mm^3) [53]. Occasionally, in very preterm gestations, one may treat this condition conservatively with IV steroids (dexamethasone, 10 mg IV every 6 hours). However, a randomized trial assessing this therapy failed to show any improvement in most cases. There was a minimal effect in the most severe cases however. This therapy may be used with very preterm infants [54,55]. In most cases, especially in the mid-to-late third trimester, delivery is warranted [42].

Management

The definitive treatment of preeclampsia is delivery. At term, patients should be stabilized and delivery effected. A preterm pregnancy may be treated conservatively if no signs of severe preeclampsia are observed [42,48]. In select cases of severe preeclampsia, remote from term patients may be followed in a tertiary care setting conservatively. The agents of choice for the treatment of hypertension are hydralazine or labetalol. Labetalol acts on both alpha- and beta-receptors without increasing the heart rate [54]. Patients remote from term should be given steroids to enhance fetal pulmonary maturity (betamethasone, 12 mg intramuscularly [IM] every 24 hours for two doses or dexamethasone, 6 mg IM every 12 hours for four doses). Tests of fetal well-being with ultrasound and fetal monitoring

(nonstress test) should be performed. In severe cases (particularly with oliguria or pulmonary edema), invasive maternal hemodynamic monitoring may be beneficial. Diuretics should not be used unless pulmonary edema is present, as intravascular volume is already depleted. At the time of labor or in severe cases, IV magnesium sulfate is the analeptic of choice. It has been shown to be superior to other agents in randomized trials at preventing eclamptic seizures [56–59]. A loading dose of 2 to 4 g is given IV slowly during 15 to 20 minutes. This is then followed by a maintenance dose of 1 to 2 g per hour. Magnesium levels may become toxic, leading to respiratory or cardiac arrest [56,57]. These patients require intensive monitoring of their respiratory function, cardiovascular function, and neurologic status. As magnesium is renally cleared, adequate urine output must be maintained. If patients manifest oliguria, a decrease or discontinuation of magnesium is indicated. Magnesium toxicity may be reversed with the administration of IV calcium (10 mL of a 10% solution of calcium gluconate given slowly IV over 10 minutes).

Eclamptic seizures are treated with IV magnesium. In cases unresponsive to magnesium, benzodiazepines may be used, such as diazepam (5 to 10 mg IV). When the seizure activity persists, the next agent of choice is phenytoin (10 to 20 mg per kg IV during 20 minutes). If the seizure still continues, IV amobarbital in 50-mg increments to a total dose of 200 mg is administered. In severe refractory cases, muscle paralysis with general anesthesia and ventilatory support is needed [57,59,60].

Patients with severe disease during weeks 24 to 28 of pregnancy are treated conservatively with aggressive maternal support and steroids for fetal lung development. An attempt should be made to achieve a gestational age of 28 weeks, if the maternal and fetal condition remains stable. From 28 to 34 weeks, steroids are given and delivery should be undertaken within 48 hours, if the maternal and fetal conditions remain stable. When severe pre-eclampsia presents after 34 weeks of gestation, delivery should occur after maternal stabilization [59]. The route of delivery should be determined by obstetric factors and vaginal delivery may be undertaken.

Rarely, patients may rupture a subcapsular liver hematoma. This manifests with severe right upper quadrant and shoulder pain. If shock ensues, immediate operation is needed. In more stable patients, the diagnosis may be confirmed with ultrasound or CT scan.

Obstetric Hemorrhage

Despite medical interventions, obstetric hemorrhage remains a significant cause of maternal morbidity, mortality, and fetal loss. Physiologic changes in the uterine blood flow increase uterine artery blood flow to 500 to 600 mL per minute at term. Patients in the third trimester with placental disruptions such as placenta previa or abruption may suffer rapid and significant blood loss, leading to hemodynamic compromise. Hemorrhage in the third trimester of pregnancy is an acute medical emergency.

There is a normal physiologic blood loss at the time of delivery. In an average vaginal delivery, the patient may lose 300 to 500 mL, and this increases to 1,000 to 1,500 mL with cesarean section [14]. When significant hemorrhage occurs, prompt medical or surgical intervention is needed.

Antepartum Hemorrhage

First and second trimester conditions such as spontaneous abortion and ectopic pregnancy may lead to significant blood loss. Patients treated for spontaneous abortion or ruptured ectopic gestation need continuous hemodynamic monitoring and aggressive fluid and blood product replacement to avoid hemodynamic compromise and hypovolumic shock. Third trimester bleeding is most often placental in nature, such as abnormal placental location, placenta previa or premature placental separation from the uterine wall (abruption placenta).

Placenta Previa

The placenta is located over the cervical os in 1 in 150 to 200 pregnancies. These patients usually present with painless vaginal bleeding and may have multiple sporadic episodes of bleeding. The diagnosis is made ultrasonically with observation of the placenta covering all or part of the cervical os [60,61]. The bleeding episodes are usually self-limiting, although sometimes the bleeding will not remit and immediate cesarean section is warranted. Once the diagnosis is made, these patients are treated with conservative management. Bed rest, blood replacement, and close surveillance of maternal and fetal well-being are the mainstays of therapy [61]. In stable cases remote from term, patients with good family support at home, may be treated as outpatients. Most cases near term require hospitalization and close monitoring. If stable, patients are assessed for fetal lung maturity with an amniocentesis at 35 to 36 weeks and cesarean section is preformed if fetal lung maturity is documented [61]. Rarely, the placenta may invade the myometrium (accreta abutting the myometrium, increta invading partially into the myometrium, and percreta invading through the myometrium). These conditions often will require hysterectomy at the time of cesarean operation. These procedures incur significant blood loss and these patients need close postoperative monitoring for hemodynamic status [61].

Abruption Placenta

Placental abruption, the premature separation of the placenta from the uterine wall, complicates up to 1% of all pregnancies. This condition may lead to severe vaginal bleeding or may be concealed within the uterus. These patients have a significant risk of coagulopathy, and coagulation studies are indicated. The therapy consists of maternal stabilization with fluid and blood product replacement, if necessary, and fetal monitoring since fetal mortality rates may be as high as 25% to 40%. Fetal loss is more likely if fetal maternal hemorrhage has occurred, and assessment of fetal blood in the maternal circulation with Kleihauer–Betke testing is indicated. If coagulopathy ensues (as is seen in 15% to 30% of these cases), resuscitation with blood-replacement products such as fresh-frozen plasma or cryoprecipitate is necessary [62]. At term, delivery is indicated. With preterm presentation, if the abruption is not severe and maternal and fetal status are stable, an attempt at conservative management with intensive surveillance may be undertaken. In these cases, steroids are given to enhance fetal lung maturity. At the time of delivery, bleeding may be vigorous and operative interventions such as uterine artery ligation, hypogastric artery ligation, radiographic directed embolization, or hysterectomy may be necessary [62].

Postpartum Hemorrhage

Significant hemorrhage postpartum occurs in 2% to 5% of deliveries. The most common cause is uterine atony in the immediate postpartum period. Retained placental fragments, lacerations of the cervix and vagina, and unrecognized coagulopathies are other potential causes [63]. Blood loss of more than 500 mL at vaginal delivery or 1,000 mL at cesarean section is classified as postpartum hemorrhage [16]. Delayed hemorrhage, 3 to 7 days postpartum, most often is due to retained

placental fragments or unrecognized congenital coagulopathies [63].

The immediate management consists of an investigation for the cause. Careful examination of the cervix and vagina to assess for unrecognized lacerations is warranted. Assessment of the contractile status of the uterus is also performed. In cases of atony, uterine oxytocic agents are administered. Oxytocin solutions are given IV (20 to 40 units added to 1 liter IV solutions and administered at 200 to 300 mL per hour) [63–65]. Vigorous external uterine massage is also used. In most cases, this is all that is necessary to resolve the problem. If atony persists, ergot-containing agents such as Methergine, 0.2 mg IM, may be used. These compounds are contraindicated in patients with hypertension as significant elevations in blood pressure may occur and rarely may lead to intracerebral hemorrhage. Prostaglandin agents of the F2 alpha class (Hemabate, 250 µg) may be given intramuscularly [65,66]. These agents may cause significant bronchospasm and are contraindicated in patients with asthma. Assessment for coagulopathy is warranted in unresponsive cases [66,67].

If medical management is unsuccessful, surgical intervention is needed. An intrauterine examination under anesthesia for retained products and dilatation and uterine curettage may be performed. If still unresponsive, angiographic uterine artery embolization or surgical intervention with uterine artery or hypogastric artery ligation is needed. In cases of unresponsive atony, uterine-constricting suture of the B Lynch type may be employed. If all measures have failed to resolve the bleeding, hysterectomy may be employed as a last resort [68,69].

Amniotic Fluid Embolism

Amniotic fluid embolism presents as a sudden and acute cardiovascular and respiratory collapse at or around the time of delivery. In the past, this condition had an 80% to 100% maternal mortality. Most cases follow vaginal births, but cases have been associated with abruption, ruptured uterus, and second and early third trimester abortions. Today, with rapid identification and maternal cardiovascular and respiratory support, the mortality rate has been reduced to 50% [70,71]. Amniotic fluid contains many vasoactive and fibrinolytic compounds that, if extravasated into the vascular space, may cause an immediate cardiovascular collapse, with respiratory failure. Immediate and aggressive intervention is necessary to save the mother's life. Intubation and mechanical ventilation with positive end-expiratory pressure is employed. Inotropic and vasoconstrictor agents are needed for cardiac and vascular support. Invasive right-sided cardiac monitoring is also indicated. Blood from the pulmonary artery should be assessed for fetal squamous cells. If found, the diagnosis is confirmed, although the absence of these cells does not preclude the diagnosis [72]. These patients will often experience a rapid and fulminant disseminated intravascular coagulation, requiring resuscitation with fresh-frozen plasma and cryoprecipitate. These patients require intensive monitoring and support (see Chapter 51). If the patient survives the initial insult, most will survive [72–74].

Hemolytic Uremic Syndrome/Thrombotic Thrombocytopenic Purpura

Hemolytic uremic syndrome/thrombotic thrombocytopenic purpura rarely occurs in pregnancy. It is often confused with preeclampsia. Renal failure, thrombocytopenia, and hemolysis are observed in the hemolytic uremic syndrome. If neurologic symptoms are observed, thrombotic thrombocytopenic purpura is diagnosed. This rare condition carries a high maternal mortality if not recognized and rapidly treated. It occurs late in the third trimester or in the immediate postpartum period [75]. Thrombotic occlusion of the microvasculature with platelets leads to hemolysis, producing the findings of this syndrome [75,76,77]. Plasma exchange should be initiated immediately, as it is the most effective treatment for this condition. In some patients as an adjunct to plasma exchange, high-dose IV steroids have sometimes been used with some positive effect on outcome. Patients will usually recover if aggressive therapy and support through their renal failure phase is undertaken early in the course of the disease [77–79].

Burn Injuries

Pregnancy does not alter the acute management of the patient suffering from burn injuries. Aggressive fluid replacement therapy, antibiotics, and oxygen therapy are the mainstays of treatment. The fetal outcome is related to the severity of the maternal burn injury and the development of any maternal complications [80]. If maternal burn injury exceeds 50%, the fetal mortality approaches 100%. In the third trimester, if maternal burn injury is greater than 50%, delivery is indicated. If the maternal burn is 30% or less, fetal survival approaches 80% [80]. Fetal death usually occurs in the first week flowing the burn injury. If the fetus is remote from term, steroids for fetal lung maturity are indicated. If preterm labor ensues and the maternal burn injury is less than 30%, uterine-relaxant tocolytic agents are indicated. Septic complications of burn wound and frank maternal sepsis may lead to labor or fetal amnionitis. Broad-spectrum antibiotics, tetanus toxoid, and immunoglobulin therapy are not contraindicated in pregnancy. Prompt and aggressive therapy for the maternal burn injury produces the best pregnancy outcomes [81].

Trauma Complicating Pregnancy

Trauma is the most common cause of death in pregnancy not related to obstetric factors. Six percent to 7% of pregnant patients will suffer a traumatic injury during their pregnancy. However, less than 1% will require hospitalization [82].

The physiologic alterations of pregnancy, particularly the increased blood volume, make the pregnant trauma patient less likely to immediately manifest signs of shock, although uterine blood flow may be compromised early and fetal compromise is common. The abdominal position of the uterus in the third trimester makes this organ more susceptible to both blunt and penetrating trauma. As the uterus grows, the bladder is pulled superior and rendered more susceptible to traumatic injury in pregnancy.

Motor vehicle accidents with either deceleration forces or blunt trauma are the most common mechanisms occurring during pregnancy. They account for 60% of injuries in pregnancy. The pregnancy outcome is directly related to the severity of the maternal injuries. The most common cause of fetal death is maternal death [83,84].

Following blunt injury secondary to a motor vehicle accident, placental abruption is the most common complication associated with the pregnancy. Abruptions occur in 2% to 4% of patients with these injuries. Ultrasound to detect abruptions is not sensitive, having only 20% to 30% sensitivity [84–86]. Fetal contraction monitoring is a sensitive measure for the diagnosis of abruptions. Contraction monitoring has a high negative predictive value. Most abruptions will occur in the first 4 to 8 hours postinjury. No consensus exists as to the length of the post-trauma monitoring interval, but at least 4 hours is recommended [87,88]. Rarely, a delayed abruption up to 48 hours postinjury may occur. There is no sensitive test to predict

delayed abruption. However, if fetal maternal hemorrhage is observed, the incidence is higher. All patients should be screened with a Kleihauer–Betke assay to assess for fetal–maternal bleeding [89]. If positive, a longer period of observation is warranted. As small amounts of fetal blood may enter the maternal circulation, all patients require blood typing and assessment of Rh status. All Rh-negative patients should receive prophylaxis with Rh immunoglobulin, 300 µg, to prevent isoimmunization. The mother and fetus require continuous monitoring. The usual markers of severity of maternal illness—blood pressure, heart rate, hematocrit, and arterial partial pressure of carbon dioxide—are not predictive of fetal outcome. All maternal injuries need to be treated as they normally would be, regardless of the pregnancy. Pneumatic antishock devices should be avoided in the pregnant patient, as uterine blood flow is dramatically decreased by these devices. Imaging studies with ultrasound are the first line for assessment. In the second and third trimesters, CT scans of the abdomen and pelvis may be undertaken but they expose the fetus to 5 to 7 cGy of radiation. If peritoneal lavage is necessary, it may be performed with care taken to avoid the uterus during catheter insertion; either an open technique or using ultrasonic guidance are preferable. In severe cases, cesarean section may improve maternal outcome, by removing the placental arteriovenous shunt [90].

Penetrating Trauma

Penetrating injuries to pregnant patients most commonly are gunshot wounds or knife wounds. Pregnant patients have a better prognosis after penetrating abdominal trauma as the large muscular uterus protects maternal vital organs. Maternal visceral injuries complicate 19% of penetrating abdominal trauma with a 3.9% maternal mortality rate [91]. The anterior and central location of the uterus subjects the fetus to significant risk with penetrating wounds. The fetus is injured in 66% of these cases, with a high 40% to 70% fetal mortality rate [92]. The management of these injuries remains controversial. Many experts advocate surgical exploration. Conservative management with imagining and observation also may be considered. Lower abdominal penetrating injuries have a less likely chance of producing maternal organ injury, but carry a significant risk of fetal injury. The best management is to individualize assessment with aggressive surgical intervention when fetal or maternal indicators warrant. A coordinated effort between the trauma surgeon and obstetrician will provide the best outcome for both mother and fetus [91–93].

Advances in management of critically ill pregnant patients, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 156.4.

TABLE 156.4

SUMMARY OF ADVANCES IN MANAGEMENT OF THE CRITICALLY ILL PREGNANT PATIENT AS IDENTIFIED IN RANDOMIZED CONTROL TRIAL DATA

- Magnetic resonance imaging is used in the second and third trimesters to aid with fetal diagnosis [25,26].
- Magnesium sulfate is preferred treatment for preeclamptic seizures at the time of labor [57,59].
- Coagulopathy associated with abruption placenta should be managed with replacement blood products [64].
- Dexamethasone to treat HELLP syndrome only has minimal affect in the most severe cases [55].

ARTHUR L. TRASK · STEPHEN L. BARNES

CHAPTER 157 ■ SHOCK: AN OVERVIEW

MICHAEL L. CHEATHAM, ERNEST F.J. BLOCK, HOWARD G. SMITH,
MATTHEW W. LUBE AND JOHN T. PROMES

Shock is one of the most complex conditions encountered in the critically ill patient. The term "shock" encompasses a broad range of pathologic processes that may require diametrically opposed methods of treatment. The underlying cause may be quite evident, as in traumatic hemorrhage, or occult, as in severe sepsis due to infection. Delayed shock resuscitation is associated with significant morbidity and mortality. Therapy must commonly be initiated before all clinical information and diagnostic studies are available. As a result, the intensivist must possess a solid understanding of the common shock states, their clinical presentation, and the necessary therapeutic interventions. Although mortality remains high, increasing application of early goal-directed resuscitation to achieve defined physiologic endpoints has significantly improved patient outcome from shock [1–3].

Over the centuries, shock has been defined in various ways. In 1534, Ambrose Pare wrote that shock was caused by "toxins in the blood" and recommended phlebotomy as the treatment, a practice that persisted until the early 1800s. By that time, shock-associated hypotension was well recognized as was the detrimental impact of bloodletting on systemic perfusion [4]. Although subsequent early definitions of shock lack scientific terminology, they compensate for this in their simplicity. John Collins Warren described shock as "a momentary pause in the act of death," whereas Samuel David Gross defined shock as "a rude unhinging of the machinery of life" [5]. In the 1930s, Alfred Blalock published his classic series of investigations into shock confirming that hypotension was due to loss of blood and plasma into the tissues (so called "third-space losses" due to increased capillary permeability) [6]. Blalock found that the hypotension and high mortality of shock were reversible through the infusion of crystalloid solutions to replace lost intravascular and interstitial fluid, and that simple reinfusion of lost blood was not sufficient. Shock was thus identified as a systemic disorder caused by increased vascular permeability, interstitial edema, and intravascular volume depletion with the classic signs of hypotension, decreased urinary output, and multiple organ failure.

The importance of regional end-organ perfusion, rather than simply systemic blood flow alone, is the singular concept for recognizing and improving patient outcome from shock. Perfusion may be decreased either systemically (as in hemorrhagic or cardiogenic shock) or only regionally (as in septic shock) with global perfusion being normal or even elevated. Regardless of cause or severity, all forms of shock have the commonality of perfusion inadequate to meet metabolic demands at the cellular level. Decreased organ perfusion leads to tissue hypoxia, anaerobic metabolism, activation of the inflammatory cascade, and eventually organ dysfunction. The ultimate consequences of shock depend on the degree and duration of hypoperfusion, the number of organs affected, and the presence of prior organ dysfunction. The challenges to the intensivist are identifying the hypoperfused state, diagnosing its cause, and rapidly restoring cellular perfusion.

PHYSIOLOGY

Significant progress has been made in elucidating the cellular basis for shock. Although low blood pressure and other vital sign derangements were previously thought to be sufficient to cause shock, they are now recognized as being signs of a complex physiologic cascade of events. The delivery and consumption of oxygen at the mitochondrial level, as well as the adequate removal of cellular waste products, is of paramount importance to survival. Cellular hypoxia leads to local vasoconstriction, thrombosis, anaerobic glycolysis, release of superoxide radicals, accumulation of pyruvate and lactate, and intracellular acidosis. The severity of a patient's acidemia, demonstrated by elevated base deficit or lactate levels, correlates with the lethality of shock [7].

In patients who experience such an anaerobic insult, injured tissues and damaged cells release a variety of intracellular mediators which initiate the proinflammatory cascade. Cytokines are small polypeptides and glycoproteins produced by a variety of immunologic cells that are responsible for many of the sequelae seen during shock. Tumor necrosis factor alpha (TNF-α) is one of the earliest cytokines released and is a product of monocytes, macrophages, and T-cells. TNF-α levels rise after a variety of cellular insults and cause hypotension, procoagulant activity, muscle breakdown, catabolism and cachexia. TNF-α levels have been seen to correlate with mortality in animal models of hemorrhagic shock [8]. Produced by macrophages and endothelial cells, interleukin-1 (IL-1) has similar effects, producing fever and anorexia. Activated T-cells produce interleukin-2 which augments cell mediated immunity. Interleukin-6, together with IL-1, mediates the acute phase response to injury and may have a role in the development of acute lung injury. Interleukin-8 is chemotactic for neutrophils and interleukin-12 has a role in cell-mediated immunity by promoting the differentiation of T-helper 1 cells. A variety of "anti-inflammatory" cytokines such as growth hormone interleukin-4, interleukin-10, interleukin-13, soluble TNF receptors (sTNFR), and IL-1 receptor antagonists (IL-1ra) are simultaneously released in an attempt to counterbalance the proinflammatory cascade.

These proinflammatory and counter-regulatory substances may lead to processes that may not be in the best interest of the patient in shock. The body's (mal)adaptive response to the primary injury or inciting event may cause secondary injury to previously unaffected cells and organs leading to impaired perfusion, cellular death, and organ dysfunction. This systemic inflammatory response syndrome, if left unabated, may result in the multiple organ dysfunction syndrome, a common cause of shock-related morbidity and mortality.

IL-1 also activates the patient's hypothalamopituitary axis (HPA) as well as the neuroendocrine response to critical illness. HPA activation releases adrenocorticotrophic hormone (ACTH) that acts on the adrenal gland to stimulate

glucocorticoid (cortisol) production. Appropriate adrenocortical response to shock is essential for patient survival. Relative adrenal insufficiency during critical illness is a commonly underappreciated reason for a patient's failure to respond to resuscitative interventions [9]. Vasopressin (antidiuretic hormone [ADH]) is cosecreted from the posterior pituitary and potentiates the effect of ACTH. In addition to its primary osmoregulatory role in resorption of water from the nephron's collecting duct, ADH is also a potent vasoconstrictor, improving systemic perfusion, and promoting gluconeogenesis and glycolysis to provide much needed metabolic substrates.

The neuroendocrine response to shock involves many counter-regulatory substances. Epinephrine and norepinephrine are produced from the adrenal medulla and synapses of the sympathetic nervous system respectively. β-Adrenergic stimulation results in increased heart rate and contractility, and α-adrenergic stimulation increases systemic vascular resistance and blood pressure through peripheral vasoconstriction. Blood is thus shunted from less essential organs preserving flow to the heart and brain. Sympathetic stimulation also causes venoconstriction accelerating venous return to the central circulation. Through their metabolic effects, catecholamine secretion contributes to stress induced hyperglycemia, a common problem during critical illness. The renin angiotensin system is activated resulting in the release of angiotensin-II (AT-II), another potent vasoconstrictor and stimulus for aldosterone secretion. Aldosterone promotes salt and water conservation at the level of the distal renal tubule in an attempt to preserve intravascular volume. It also regulates acid-base and potassium homeostasis. Glucagon is produced by the pancreatic alpha islet cells and, unlike insulin, has a catabolic role. Release of many of these substances also leads to decreased levels of circulating insulin. The resultant catabolic state characterized by insulin resistance, hyperglycemia, lipolysis, free fatty acid formation, ketogenesis, erosion of lean body mass and negative nitrogen balance may last for weeks to months.

CLASSIFICATION

Shubin and Weil's classic paper distinguished the various forms of shock with respect to cardiovascular parameters [10]. Four categories of inadequate systemic perfusion were described: (a) hypovolemic, (b) obstructive, (c) cardiogenic, and (d) distributive. Although new etiologies of shock (e.g., adrenal insufficiency of critical illness) have recently received significant attention, they are easily placed into one of these physiologic descriptions.

Hypovolemic Shock

Hypovolemic shock is the most common form of shock. Almost all forms include some component of hypovolemia as a result of decreased intravascular volume or "preload." The sympathetic response to reduced preload is arterial vasoconstriction, diverting blood from the splanchnic viscera, skin, and skeletal muscle. Physical findings include cold clammy skin, tachypnea, tachycardia, and low urinary output, all a result of either hypovolemia or compensatory mechanisms.

Hypovolemic shock is stratified into four classes based on the degree of circulating volume loss (Table 157.1). It is important to recognize that significant blood volume may be lost in the absence of any clinical signs. Compensatory mechanisms allow systemic blood pressure to be maintained and a well-compensated patient may display tachycardia as the only objective clinical abnormality, even with a blood volume loss of up to 30%. Hypovolemic shock may be further subclassified as either hemorrhagic or nonhemorrhagic. Hemorrhagic shock may be visibly apparent (external blood loss from traumatic injury) or occult (chronic gastrointestinal hemorrhage). Emphasis on hemorrhage control rather than simply volume replacement is an essential difference in the management of hemorrhagic shock [11,12]. Nonhemorrhagic hypovolemic shock is seen in a number of pathologic states and may be caused by absolute loss of total body fluid volume and/or migration of acellular fluid from the intravascular to the interstitial compartment (third spacing). Third spacing of fluid occurs predictably in severe illnesses such as pancreatitis, small bowel obstruction, and burns. Volume depletion may also occur as a consequence of uncompensated gastrointestinal, urinary, or evaporative losses. It is imperative that the intensivists focus on resuscitation of the patient's intravascular volume as opposed to total body volume. Failure to do so will uniformly result in under-resuscitation and poor patient outcome.

Obstructive Shock

Obstructive forms of shock are those in which the underlying pathology is a mechanical obstruction to normal cardiac output (CO) with a resulting diminution in systemic perfusion. Cardiac tamponade is an example of obstructive shock. A small amount of fluid (usually less than 200 mL) within a noncompliant pericardium may produce significant myocardial compression [13]. Clinical signs of tamponade include jugular venous distention and a central venous pressure (CVP) waveform

TABLE 157.1

CLASSIFICATION OF SHOCK[a]

	Class I	Class II	Class III	Class IV
Blood loss (mL)	Up to 750	750–1,500	1,500–2,000	≥2,000
Blood loss (% blood volume)	Up to 15	15–30	30–40	≥40
Pulse rate	<100	>100	>120	≥140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal/increased	Decreased	Decreased	Decreased
Capillary refill	Normal	Decreased	Decreased	Decreased
Respiratory rate	14–20	20–30	30–40	>35
Urinary output (mL/h)	30 or more	20–30	5–15	Negligible
Central nervous system	Slightly anxious	Anxious	Anxious, confused	Confused, lethargic
Fluid replacement	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

[a]Estimates based on a 70-kg male.
Modified from Committee on Trauma of the American College of Surgeons: *Advanced Trauma Life Support for Doctors*. Chicago, American College of Surgeons, 2008, p 61.

demonstrating a rapid "x" descent and a blunted "y" descent due to inability of the heart to fill during diastole. Pulsus paradoxus, an exaggerated fluctuation in arterial pressure caused by changes in intrathoracic pressure during respiration, may be present. Formal echocardiography is helpful in making the diagnosis although recent advances in the use of bedside ultrasonography by noncardiologists have demonstrated excellent sensitivity and rapid performance of the examination [14].

Pulmonary venous thromboembolism is another example of obstructive shock and may present as profound circulatory collapse. CO is restricted either by mechanical obstruction of the pulmonary arterial tree or by pulmonary hypertension induced by release of secondary mediators. Additional findings include elevated CVP and pulmonary hypertension, but normal pulmonary artery occlusion pressure (PAOP). Through similar mechanisms, venous air embolism can completely obstruct pulmonary arterial blood flow, with ensuing cardiac arrest. Central hemodynamics mimic those of pulmonary embolism. Although numerous causes exist, of greatest concern are the placement and removal of central venous catheters and surgical procedures in which the operative site is more than 5 cm above the right atrium [15]. Venous air embolism is diagnosed by auscultation of the classic "mill wheel" heart murmur. Immediate placement of the patient in a head-down, left lateral decubitus position is advocated, as are attempts to aspirate air from the right ventricle through a central venous catheter.

Finally, tension pneumothorax may cause shock through obstruction of venous return. Elevated intrapleural pressure collapses intrathoracic veins resulting in inadequate venous filling. Tension pneumothorax should be diagnosed by physical examination and not by radiography. Needle decompression often restores venous filling sufficiently until a thoracostomy tube can be placed.

Cardiogenic Shock

In cardiogenic shock, the underlying defect is primary ventricular pump failure, the most common cause of coronary artery disease related mortality. The foundations of ventricular failure include (a) myocardial infarction with loss of myocardium, (b) reduced contractility (cardiomyopathy), (c) ventricular outflow obstruction (aortic stenosis or dissection), (d) ventricular filling anomalies (atrial myxoma, mitral stenosis), (e) acute valvular failure (aortic or mitral regurgitation), (f) cardiac dysrhythmias, and (g) ventriculoseptal defects. Most often, cardiogenic shock is a direct or indirect consequence of acute myocardial infarction.

Cardiogenic shock due to left ventricular infarction suggests that more than 40% of the left ventricle is involved [16]. On physical examination, signs of peripheral vasoconstriction are evident and oliguria is common. The typical hemodynamic profile includes systemic hypotension with decreased CO and elevated PAOP. Physical examination findings of pulmonary and peripheral edema as well as hepatomegaly may suggest volume overload, but are commonly due to third spacing of fluid due to shock with relative intravascular volume depletion being present. In such situations, hemodynamic monitoring using echocardiography or a volumetric pulmonary artery catheter may provide additional diagnostic information clarifying the patient's true volume status.

Right ventricular dysfunction as a consequence of inferior wall myocardial infarction carries a better prognosis than left-sided failure. Diagnosis may be suggested by elevated right ventricular diastolic pressure with decreased pulmonary artery pressure [17]. Hypotension caused by right-sided heart failure must be distinguished from left-sided failure because of the significant differences in their management. Shock from right-sided failure is corrected by volume resuscitation to maintain right ventricular preload while left-sided failure is treated by volume restriction to reduce myocardial work. If inotropes are indicated, agents that do not increase pulmonary vascular resistance should be chosen [18].

Dysrhythmias are another source of cardiogenic shock. In addition to malignant dysrhythmias, such as ventricular fibrillation, atrial dysrhythmias such as atrial fibrillation or flutter as well as supraventricular tachycardia are common in the critically ill and may result in shortened diastolic filling time with a profound decrease in CO.

Distributive Shock

The classic hemodynamic profile of septic shock (high CO and systemic hypotension) has prompted some clinicians to institute antimicrobial therapy and search for an infectious source in any patient who exhibits these cardiac parameters. Such hyperdynamic patterns, however, are seen in non-infectious conditions as well including anaphylaxis, spinal cord injury, and severe liver dysfunction. The term distributive shock, rather than septic shock, is therefore used to account for these dissimilar diseases with a common hemodynamic picture.

The management of septic shock remains a major challenge to the intensivist [1–3]. A milieu of inflammatory cytokines, bacterial factors, and complement and coagulation activation combine to induce the complex hemodynamic pattern characteristic of septic shock. In most forms of shock, illness leads to a low CO state with elevated systemic vascular resistance (SVR) and reduced mixed venous oxygen saturation (SvO_2). Early septic shock, however, is manifested by normal-to-low cardiac filling pressures, increased CO, decreased SVR, and increased SvO_2 [19]. Despite elevated systemic blood flow and oxygen delivery (DO_2), abnormalities exist in tissue oxygen extraction at the cellular level, perhaps through disruption of normal mitochondrial metabolic pathways [20,21]. Sepsis-induced myocardial depression may be demonstrated through decreased ejection fraction, right ventricular dysfunction, and left ventricular dilation. In the later stages of septic shock, cardiac function deteriorates with the patient's hemodynamic status mimicking that of cardiogenic shock with decreased CO and increased SVR [22].

Anaphylaxis represents another form of distributive shock in which histamine-mediated vasodilatation occurs. The most common causes are medications, insect envenomations, blood products, radiographic contrast media, and food allergies [23]. Reactions severe enough to result in shock occur shortly after exposure to the offending agent. Physical findings include a dermatologic reaction (erythema, urticaria) and obstructive respiratory processes. Occasionally, the reaction is severe enough to produce shock through myocardial depression.

Neurogenic shock, another form of distributive shock, occurs as a result of upper thoracic spinal cord injury with hypotension, bradycardia, and warm, dry skin due to loss of sympathetic vascular tone. Although euvolemic, patients demonstrate relative hypovolemia due to vasodilatation of the intravascular space. If hypotension does not respond to volume resuscitation, it may be treated with vasopressors and any bradycardia may be corrected with atropine. In the trauma patient, hemorrhage should always be excluded before attributing shock to a neurogenic source [24].

Over the last decade, endocrine insufficiency as a result of critical illness has been recognized as an underappreciated cause of distributive shock. This relative adrenal insufficiency may worsen the impact of the various shock states as the patient is unable to respond appropriately to the stress of their critical illness [25,26]. Corticosteroid supplementation in such

patients can significantly improve systemic perfusion as well as reduce the patient's requirement for vasopressor support.

PHYSIOLOGIC MONITORING

Vital sign derangements are typically the first indication that a shock state is present. Normalization of such parameters signifies that the patient is appropriately responding to resuscitative therapy. Physiologic monitoring is thus essential to both the diagnosis and management of shock. Such monitoring typically begins with the use of routine vital signs, but may progress to the application of invasive monitoring techniques.

Vital Signs

The diagnosis of shock was originally based on abnormalities in a patient's vital signs. Until the late 1960s, the presence of tachycardia and hypotension was considered synonymous with shock. Over time, it became apparent that normalization of heart rate, blood pressure, temperature, and urinary output was not necessarily sufficient to reverse a patient's shock state. Critically ill patients continued to have a high incidence of multiple organ failure and mortality despite seemingly adequate resuscitation based on restoration of vital signs to "normal." Shock is therefore defined by the adequacy of end-organ perfusion rather than derangements in vital signs alone. Nevertheless, these physiologic parameters remain the foundation for the initial recognition that shock is present.

Heart Rate

Alterations in heart rate are common during shock. Tachycardia is most common and is usually a direct effect of intravascular volume loss in where heart rate increases to maintain adequate CO and DO_2 to tissues. These increases may become pathologic if inadequate diastolic filling time results in decreased stroke volume. Tachycardia can be used to predict the presence of intravascular volume depletion and its resolution to suggest volume resuscitation adequacy [27]. Decreased heart rate, in response to a volume challenge, can be a simple and useful test for diagnosing hypovolemia.

Bradycardia is usually representative of severe physiologic derangement and impending cardiovascular collapse. Its presence in a critically ill patient demands immediate attention. Patients receiving beta-blocker therapy or with high spinal cord injuries or pacemakers may not be able to increase their heart rate and compensate for their shock. Patients with an inappropriately low heart rate and inadequate CO will benefit from increasing heart rate by withholding beta-blocker therapy, use of chronotropic medications, or reprogramming their pacemakers to a higher rate.

Blood Pressure

Hypertension is an uncommon finding in shock. Patients are typically hypotensive due to the presence of hypovolemia, decreased cardiac contractility, or systemic vasodilatation. Normotension should be restored as quickly as possible to improve tissue perfusion and oxygen delivery at the cellular level. Blood pressure may be measured either noninvasively or invasively. Both techniques are subject to certain mechanical and physiologic measurement errors, or "dynamic response artifacts," that can result in inappropriate therapy if unrecognized by the clinician [28]. Because of these intrinsic monitoring errors, systolic blood pressure (SBP) and diastolic blood pressure (DBP) measurements may vary widely from one measurement technique to another. The mean arterial pressure (MAP), however, will remain fairly consistent regardless of the measurement method and any artifact present. As a result, MAP should be used to titrate resuscitative therapies rather than SBP or DBP. MAP is calculated as

$$MAP = [SBP + 2(DBP)]/3$$

Temperature

Patient temperature, although not indicative of either the presence or absence of shock, may help define the cause and can have significant prognostic value [29,30]. The presence of hypothermia (core body temperature less than 96.8°F or 36.0°C) suggests severe physiologic derangement and has a significant impact on patient survival [31]. Hypothermia places the patient at risk for cardiac dysrhythmias, acute renal failure, and refractory coagulopathy [32]. Although hypothermia reduces metabolic activity of the body, rewarming significantly increases global metabolic demands and oxygen consumption ($\dot{V}O_2$). Such demands may exceed the patient's capacity to deliver oxygen to the cells, resulting in an oxygen transport imbalance. Care must be taken to ensure adequate DO_2 and tissue perfusion during rewarming. Because of its significant morbidity and mortality, nontherapeutic hypothermia should be avoided or rapidly corrected in most critically ill patients [29,30].

Urine Output

Inadequate renal blood flow results in decreased urinary output. Oliguria is one of the earliest signs of inadequate perfusion at the tissue level. Worsening renal function is an important indicator of the presence of shock. Decreases in urine output as a result of hypovolemia are seen before changes in heart rate or blood pressure (Table 157.1). Improvements in urine volume in response to fluid loading can guide shock resuscitation as long as confounding factors are not present (e.g., diabetes insipidus, diabetic ketoacidosis, and diuretic therapy).

Pulse Oximetry

Technologic advances in the 1970s and 1980s led to the widespread introduction of pulse oximetry as the "fifth" vital sign [33]. Pulse oximetry is now routinely used in the critically ill as a noninvasive method of continuously monitoring arterial oxygen saturation. This addition to the traditional four vital signs serves two purposes. First, it provides an early warning of hypoxemia, allowing corrective interventions to be made. Second, it can be used as an endpoint in the resuscitation of patients and in the assessment of oxygen transport balance.

Hemodynamic Monitoring

In 1970, Swan and Ganz introduced the flow-directed pulmonary artery catheter, allowing clinicians to measure pulmonary artery pressures at the bedside [34]. In 1972, addition of a temperature thermistor provided the ability to calculate CO. These advancements provided clinicians with the ability to assess a variety of new hemodynamic parameters evaluating patient preload, contractility, and afterload. In the 1980s, continuous mixed venous oximetry was added as the importance of DO_2, $\dot{V}O_2$, and oxygen transport balance in the diagnosis and management of the shock states became clear. By the early 1990s, catheters capable of calculating right ventricular volumes became available, further improving preload assessment. Current pulmonary artery catheters continuously assess hemodynamic and oxygen transport variables providing the clinician with minute-by-minute assessments of cardiopulmonary function by which to guide resuscitation. Although pulmonary artery catheterization is performed with much less frequency than in years past, it remains an important

monitoring technology for the most critically ill patients with shock and has recently been demonstrated to improve patient outcome when used in a goal-directed fashion [35,36]. A variety of other hemodynamic monitoring techniques have been developed including arterial pressure wave contour analysis, esophageal Doppler, and transesophageal echocardiography among others. Regardless of the method by which hemodynamic data is obtained, a thorough understanding of the available hemodynamic and oxygenation variables is essential if resuscitative therapy is to improve patient outcome from shock (Tables 157.2 and 157.3) [37].

Pressure and Pressure-Derived Variables

Pressure variables form the foundation for physiologic monitoring in shock assessment. It is important to recognize, however, that the absolute value of any single pressure variable is not as important as the trend, calculated variables, and perfusion pressures that may be identified using this pressure.

TABLE 157.2

HEMODYNAMIC VARIABLES

Variable (abbreviation)	Unit	Normal range
Measured variables		
Systolic blood pressure (SBP)	mm Hg	90–140
Diastolic blood pressure (DBP)	mm Hg	50–90
Systolic pulmonary artery pressure (PAS)	mm Hg	15–30
Diastolic pulmonary artery pressure (PAD)	mm Hg	4–12
Pulmonary artery occlusion pressure (PAOP)	mm Hg	2–15
Central venous pressure (CVP)	mm Hg	0–8
Heart rate (HR)	beats/min	Varies by patient
Cardiac output (CO)	L/min	Varies by patient
Stroke volume (SV)	mL/beat	Varies by patient
Right ventricular ejection fraction (RVEF)	Fraction	0.40–0.60
Calculated variables		
Mean arterial pressure (MAP)	mm Hg	70–105
Mean pulmonary artery pressure (MPAP)	mm Hg	9–16
Cardiac index (CI)	$L/min/m^2$	2.8–4.2
Stroke volume index (SVI)	$mL/min/m^2$	30–65
Systemic vascular resistance index (SVRI)	Dyne/sec/cm^5	1,600–24,00
Pulmonary vascular resistance index (PVRI)	Dyne/sec/cm^5	250–340
Left ventricular stroke work index (LVSWI)	g × m/m^2	43–62
Right ventricular stroke work index (RVSWI)	g × m/m^2	7–12
Coronary perfusion pressure (coronary PP)	mm Hg	> 50
Cerebral perfusion pressure (cerebral PP)	mm Hg	50–70
Abdominal perfusion pressure (APP)	mm Hg	> 60
Right ventricular end-diastolic volume index (RVEDVI)	mL/m^2	80–120
Global end-diastolic volume index (GEDVI)	mL/m^2	600–800
Stroke volume variation (SVV)	%	< 10
Pulse pressure variation (PPV)	%	< 10
Body surface area (BSA)	m^2	Varies by patient

TABLE 157.3

OXYGENATION VARIABLES

Variable (abbreviation)	Unit	Normal range
Measured variables		
Arterial oxygen tension (PaO_2)	mm Hg	70–100
Arterial carbon dioxide tension ($PaCO_2$)	mm Hg	35–50
Arterial oxygen saturation (SaO_2 or SpO_2)	Fraction	0.92–0.98
Mixed venous oxygen saturation (SvO_2)	Fraction	0.65–0.75
Mixed central venous oxygen saturation ($ScvO_2$)	Fraction	0.70–0.80
Mixed venous oxygen tension (PvO_2)	mm Hg	35–40
Hemoglobin (Hgb)	g/dL	13–17
Calculated variables		
Oxygen delivery index (DO_2I)	$mL/min/m^2$	500–650
Oxygen consumption index ($\dot{V}O_2I$)	$mL/min/m^2$	110–150
Arterial oxygen content (CaO_2)	mL O_2/dL blood	16–22
Venous oxygen content (CvO_2)	mL O_2/dL blood	12–17
Arterial–venous oxygen content difference ($Ca–vO_2$)	mL O_2/dL blood	3.5–5.5
Oxygen utilization coefficient (OUC)	Fraction	0.25–0.35

Mean Arterial and Mean Pulmonary Arterial Pressure. MAP has been discussed previously. Mean pulmonary arterial pressure (MPAP) is the equivalent pressure for the pulmonary circuit (Fig. 157.1) and is calculated using pulmonary arterial systolic (PAS) and diastolic (PAD) pressure:

$$MPAP = [PAS + 2(PAD)]/3$$

Mean pressures should be used to guide decision making and resuscitative therapy whenever possible as they are less

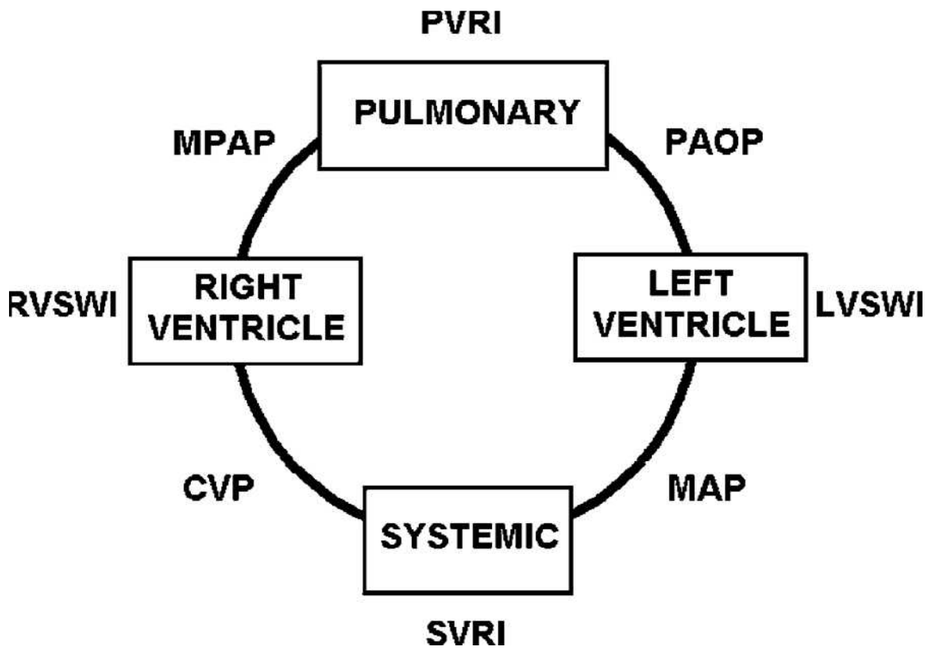

FIGURE 157.1. Hemodynamic calculations. PAOP, pulmonary artery occlusion pressure; CVP, central venous pressure; MAP, mean arterial pressure; MPAP, mean pulmonary artery pressure; SVRI, systemic vascular resistance index; PVRI, pulmonary vascular resistance index; LVSWI, left ventricular stroke work index; RVSWI, right ventricular stroke work index.

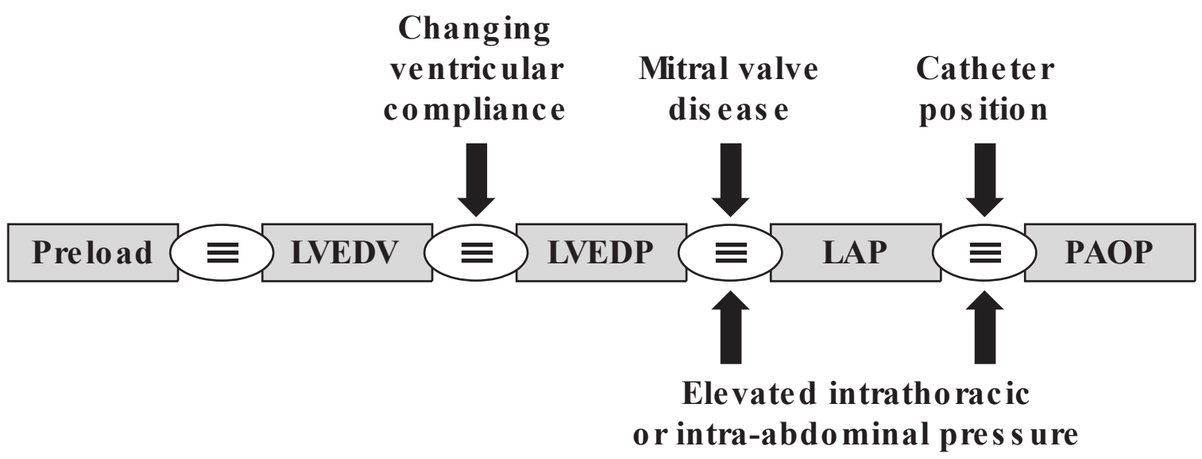

FIGURE 157.2. The "PAOP assumption": Why intracardiac filling pressures do not accurately estimate preload status? LVEDV, left ventricular end-diastolic volume; LVEDP, left ventricular end-diastolic pressure; LAP, left atrial pressure; PAOP, pulmonary artery occlusion pressure. [Adapted from Cheatham ML: Right ventricular end-diastolic measurements in the resuscitation of trauma victims. *Int J Crit Care* 7:165–176, 2000, with permission.]

subject to monitoring artifacts. They are also essential components to calculate vascular resistance and cardiac work.

Pulmonary Artery Occlusion and Central Venous Pressure. Fluid administration is an essential element in the initial resuscitation of almost all forms of shock. Intracardiac-filling pressure measurements such as PAOP or "wedge" and CVP are commonly used to estimate intravascular volume or "preload." Preload, by the Frank–Starling Law, is defined in terms of myocardial fibril length at end-diastole. Because this is clinically immeasurable, several assumptions are made to use PAOP to clinically assess the preload status of the left ventricle (Fig. 157.2). These assumptions are frequently invalid in critically ill patients due to changing ventricular compliance caused by a variety of factors. As a result, PAOP measurements should be carefully considered as estimates of intravascular volume status in the patient with shock [38–40]. In fact, reliance on PAOP measurements for preload assessment in critically ill patients may lead to inappropriate interventions in more than 50% of patients [41]. The trend rather than the absolute value of such measurements in response to therapeutic interventions is of greater value. The optimal PAOP is that value which, through careful evaluation of the patient's hemodynamic status, is determined to optimize systemic perfusion (CO) and cellular oxygenation (DO_2, $\dot{V}O_2$). For similar reasons, absolute CVP measurements do not accurately portray left ventricular volume status or ventricular function [38–41]. As with PAOP, the trend of CVP measurements in response to therapeutic measures may be of value.

Perfusion Variables

The importance of adequate end-organ perfusion in correcting the shock state cannot be overemphasized. The following perfusion variables are easily calculated and represent important resuscitation endpoints in the critically ill.

Coronary Perfusion Pressure. Maintaining adequate coronary perfusion pressure (PP) should be a primary goal in the resuscitation of any patient in shock. Patients with preexisting coronary artery disease may have marginal myocardial blood flow, which is only worsened by inadequate systemic perfusion during shock. Coronary PP is calculated as the pressure change across the coronary artery during maximal blood flow:

$$\text{coronary perfusion} = \text{pressure change across the coronary artery}$$
$$\text{coronary PP} = \text{DBP} - \text{PAOP}$$

The goal should be to maintain coronary PP greater than 50 mm Hg. Failure to maintain this level of perfusion increases the risk for myocardial ischemia and infarction. Note that DBP and not SBP is the critical determinant of coronary perfusion as maximal myocardial blood flow occurs during diastole. PAOP estimates myocardial wall tension and resistance to perfusion by approximating end-diastolic pressure in the left ventricle.

Cerebral Perfusion Pressure. Monitoring cerebral perfusion pressure is important in the head-injured patient with increased intracranial pressure (ICP) [42]. Because the brain is enclosed within the skull with little room for expansion, increases in ICP and development of cerebral edema can have significant and detrimental effects on cerebral blood flow and oxygenation. Monitoring of ICP is an important component of the hemodynamic monitoring of patients with brain injury and shock. Cerebral PP is calculated as the pressure change across the brain:

$$\text{cerebral perfusion} = \text{pressure change across the brain}$$
$$\text{cerebral PP} = \text{MAP} - \text{ICP (or CVP, whichever is higher)}$$

The goal should be to maintain a cerebral PP of 50 to 70 mm Hg [42]. This may be accomplished by either increasing MAP (using a vasopressor such as norepinephrine) or decreasing intracerebral volume (through the use of mannitol or hypertonic fluids), thereby decreasing ICP. Maintenance of a cerebral PP > 70 mm Hg does not appear to provide a survival benefit and may lead to potentially detrimental over-resuscitation.

Abdominal Perfusion Pressure. Analogous to coronary and cerebral PP, abdominal perfusion pressure (APP) has been identified as a valuable parameter in the resuscitation of patients with elevated intra-abdominal pressure (IAP), a condition present in over half of all ICU patients [43,44]. IAP is most commonly determined as intravesicular or "bladder" pressure by transducing the patient's indwelling urinary catheter [45,46]. APP is calculated as the pressure change across the abdominal organs:

$$\text{abdominal perfusion} = \text{pressure change across the abdominal organs}$$
$$\text{APP} = \text{MAP} - \text{IAP}$$

Failure to maintain APP ≥ 60 mm Hg has been found to discriminate between survivors and nonsurvivors [43]. Maintenance of adequate APP through a balance of judicious fluid resuscitation and application of vasoactive medications has been demonstrated to reduce the incidence of acute renal failure [47].

Blood Flow and Flow-Derived Variables

Critically ill patients with shock and systemic malperfusion frequently benefit from calculation of blood flow-related variables such as CO and stroke volume (SV). Flow-related variables are used with pressure variables to calculate vascular resistance and estimate the work performed by the left and right ventricles. Such advanced hemodynamic monitoring should be implemented whenever a patient fails to respond to resuscitation as expected.

Interpatient variability makes it difficult to assign a normal range to flow-derived variables. What might be an adequate CO for a 50-kg woman is inadequate for a 150-kg man. To normalize these measurements and allow comparison from patient to patient, flow-derived variables are indexed to body surface area (BSA), obtained from a nomogram. Indexed variables, such as cardiac index (CI) and stroke volume index (SVI), are more meaningful because normal ranges aid in interpretation.

All flow-derived hemodynamics should be indexed to facilitate comparison with accepted normal ranges.

Cardiac Index and Stroke Volume Index. CI is the total blood flow from the heart (in liters per minute) divided by BSA. SVI is the volume of blood ejected from the heart per beat, divided by BSA:

$$CI = \text{cardiac output/BSA}$$
$$SVI = CI/\text{heart rate}$$

Most shock states have a decreased CI as a result of intravascular volume depletion, poor underlying cardiac pump function, increased vascular resistance, or a combination of these factors. To maintain CI, tachycardia is the usual response to inadequate preload and a low SVI. Appropriate therapy is to restore intravascular volume and increase SVI, thus improving CI. An increased CI may be seen in early septic shock, but may also be seen with other nonshock hyperdynamic states, such as cirrhosis, pregnancy, and high-performance athletes.

Systemic Vascular Resistance Index/Pulmonary Vascular Resistance Index. According to Ohm's law, the resistance of an electrical circuit is equal to the voltage difference across the circuit divided by the current. A simplified view of the circulatory system can be likened to an electrical circuit in which the resistance across the systemic or pulmonary vascular beds is calculated using Ohm's law (Fig. 157.1):

$$\text{Resistance} = \text{voltage difference/current}$$
$$\text{Vascular resistance} = \text{pressure change/total blood flow}$$
$$SVRI = \frac{\text{change in pressure across the systemic circuit (mm Hg)}}{\text{total blood flow (L/min/m}^2\text{)}}$$
$$SVRI \text{ (in dynes/sec/cm}^5\text{)} = (MAP - CVP)(79.9)/CI$$
$$PVRI = \frac{\text{change in pressure across the pulmonary circuit (mm Hg)}}{\text{total blood flow (L/min/m}^2\text{)}}$$
$$PVRI \text{ (in dynes/sec/cm}^5\text{)} = (MPAP - PAOP)(79.9)/CI$$

The constant, 79.9, is used to convert mm Hg · L per minute to the more physiologic units of dynes per seconds per · cm^5.

Increased SVRI is commonly seen in obstructive, hypovolemic, late septic, and cardiogenic shock. Systemic resistance may also rise in nonshock states such as pheochromocytoma (secondary to increased endogenous catecholamine output). Decreased SVRI is common in distributive shock states (neurogenic, early septic, endocrine shock). Vasodilators such as sodium nitroprusside, nitroglycerin, and other antihypertensives reduce SVRI.

Increased PVRI is indicative of pulmonary hypertension and may be classified as being either primary or secondary. Primary pulmonary hypertension is an intrinsic lung disease developing over many years and typically refractory to treatment. Secondary pulmonary hypertension may develop as a result of acute respiratory distress syndrome, application of positive end-expiratory pressure (PEEP), or development of mitral or aortic stenosis. Treatment of pulmonary hypertension begins with institution of increased inspired oxygen fractions due to oxygen's effect as a potent pulmonary vasodilator. Nitroglycerin and morphine sulfate also are helpful in the acute treatment of pulmonary hypertension. Decreased PVRI occurs in the setting of various shock states. Treatment is rarely instituted to specifically increase PVRI alone.

Perfusion pressure and vascular resistance determine total blood flow to an organ, but absolute values of these determining factors do not define the shock state. For example, a high vascular resistance is commonly compensatory for reduced systemic perfusion pressure. The same numeric value of high resistance may contribute to organ dysfunction when it is so high that perfusion pressure cannot overcome it. When organ blood flow is maldistributed, as in septic shock or abdominal compartment syndrome, multiple organ dysfunction may occur despite normal systemic perfusion pressures. It is also important to recognize that vascular resistance numbers are calculated and are inversely proportional to CI. Therefore, therapy should usually be directed at enhancing CI in addition to reducing vascular resistance as simply reducing vascular resistance may reduce perfusion pressure.

Ventricular Stroke Work Indices. The ventricular stroke work indices describe how much work the ventricles perform and can identify patients with poor cardiac function. They may also be useful to construct ventricular function curves to assess a patient's response to therapy. As with vascular resistance, the work performed by the heart can also be calculated using the laws of physics. Work is calculated as the force generated multiplied by the distance over which the work is performed. Clinically, the force generated (per area) by each side of the heart is the change in pressure it creates across the ventricle. The distance (per area) is the volume of blood ejected with each beat (SVI) normalized for patient size. Therefore,

$$\text{Ventricular stroke work index} = \text{change in pressure} \times \text{change in volume}$$
$$\text{Left ventricular stroke work index (LVSWI)} = (MAP - PAOP)(SVI)(0.0136)\ (g \cdot m/m^2)$$
$$\text{Right ventricular stroke work index (RVSWI)} = (MPAP - CVP)(SVI)(0.0136)\ (g \cdot m/m^2)$$

The constant (0.0136) converts mm Hg · L/beat · m^2 to g · m/m^2.

Increased LVSWI/RVSWI is relatively uncommon, but may be encountered in patients with ventricular hypertrophy, pulmonary hypertension, or in athletes. Decreased LVSWI/RVSWI is much more common and may be seen in various shock states; heart failure; aortic or mitral stenosis; myocardial depression, ischemia, or infarction; or advanced age. When evaluating decreased ventricular stroke work, it is important to keep in mind that the decreased function may be due to decreased intravascular volume (decreased SVI), changes in vascular resistance (increased MAP or MPAP), or decreased contractility. If preload and afterload remain constant, decreases in stroke work indicate decreases in ventricular contractility.

Volumetric Variables

The clinical accuracy of pressure-based monitoring techniques is limited by a variety of factors including proper catheter positioning, pressure transducer calibration, and pressure waveform interpretation. By the Frank–Starling principle, ventricular preload is defined as myocardial muscle fiber length at end-diastole with the appropriate clinical correlate being end-diastolic volume. As ventricular chamber volume cannot be directly measured, intracardiac filling pressures such as PAOP and CVP have been used as estimates of end-diastolic volume under the erroneous assumption that ventricular compliance remains constant. Ventricular compliance, however, is *constantly* changing in the critically ill, resulting in a variable relationship between pressure and volume. Further, PAOP and CVP must be measured relative to an arbitrary reference point (typically the perceived position of the right atrium) and are subject to the impact of increased intrathoracic and intra-abdominal pressure (as may occur with acute lung injury, PEEP, intra-abdominal hypertension, abdominal compartment syndrome, etc.) (Fig. 157.2). Although attempts may be made to calculate transmural PAOP and CVP values, these estimates are inexact and the level of precision necessary to measure CVP accurately at the bedside is rarely performed [48]. As a result, changes in PAOP and CVP as commonly measured do not directly reflect changes in intravascular volume in the critically ill and may lead

to inappropriate clinical interventions and under-resuscitation [41].

In the 1990s, a new generation of monitoring technologies were introduced that provide volumetric as opposed to pressure-based estimates of hemodynamic function. These included continuous CO, right ventricular ejection fraction (RVEF), and right ventricular end-diastolic volume index (RVEDVI), via a modified pulmonary artery catheter, or global ejection fraction (GEF), global end-diastolic volume index (GEDVI), intrathoracic blood volume index (ITBVI), and extravascular lung water (EVLW) via an arterial catheter using the arterial pulse contour analysis technique. Continuous volumetric monitoring provides a minute-by-minute assessment of patient response to therapeutic interventions, potentially allowing more rapid and effective resuscitation compared to traditional pressure-based monitoring techniques [27,49–52]. Both RVEDVI and GEDVI have been demonstrated to be superior to PAOP and CVP as predictors of preload recruitable increases in CI during shock resuscitation [27,40,41,49–52]. Further, several studies have demonstrated either significantly improved organ perfusion and function or increased patient survival when volumetric resuscitation endpoints are employed [27,49,50]. More recently, arterial pulse contour analysis has been used to measure stroke volume variation (SVV), the variation in beat-to-beat stroke volume during a single respiratory cycle, as well as pulse pressure variation (PPV), the beat-to-beat difference between SBP and DBP. Both of these parameters have been suggested to be valuable predictors of hypovolemia and fluid responsiveness [53]. These advanced hemodynamic monitoring techniques are appropriate for patients with shock who fail to respond appropriately to initial attempts at resuscitation using conventional endpoints.

Oxygen Transport Variables

With recognition of the importance of oxygen delivery (DO_2) and oxygen consumption ($\dot{V}O_2$) in the treatment of the various shock states, monitoring of a patient's oxygen transport balance has become commonplace (Table 157.3). The foremost question in critical care is whether oxygen transport to the tissues is sufficient to meet the demand for oxygen at the cellular level.

Oxygen transport represents the balance between supply and demand. When supply exceeds demand, the cellular oxygen requirements of the body are being met, and normal metabolic processes proceed uninhibited. When oxygen supply equals demand, vital functions may progress normally, but with little physiologic reserve, such that a relatively minor insult can upset the oxygen transport balance. In such a situation, organs that possess a high baseline oxygen extraction, such as the heart, are at significant risk for ischemia. When shock-induced systemic or regional malperfusion exists, oxygen demand exceeds supply, and the available cellular oxygen is inadequate to support normal physiology. Energy must therefore be produced via anaerobic metabolism with production of lactic acid as a by-product. As lactic acid cannot be reutilized in the absence of oxygen, it accumulates leading to metabolic acidosis, cellular injury, and cellular death. Left unchecked, this imbalance in oxygen transport will result in the development of multisystem organ failure and patient death. The role of the intensivist is to recognize oxygen supply imbalances at the cellular level, initiate therapeutic interventions to increase oxygen delivery, prevent further organ dysfunction, ensure adequate physiologic oxygen reserve to cope with acute increases in oxygen demand, and improve patient outcome from shock.

Knowledge of the oxygen transport equations is essential to understanding the pathophysiology and appropriate treatment for the various shock states. Any assessment of oxygen transport begins with the calculation of DO_2 and $\dot{V}O_2$. To accomplish this, the oxygen content of the blood at various points in the systemic and pulmonary circulation must be identified (Fig. 157.3). Central to these calculations are the recognition that (1) oxygen may be either "bound" or "unbound" to erythrocytes, (2) each gram of hemoglobin (Hgb) can carry up to 1.34 mL of oxygen, (3) the solubility of oxygen in blood is 0.0031 mL per dL, and (4) the amount of oxygen carried by Hgb depends upon its saturation.

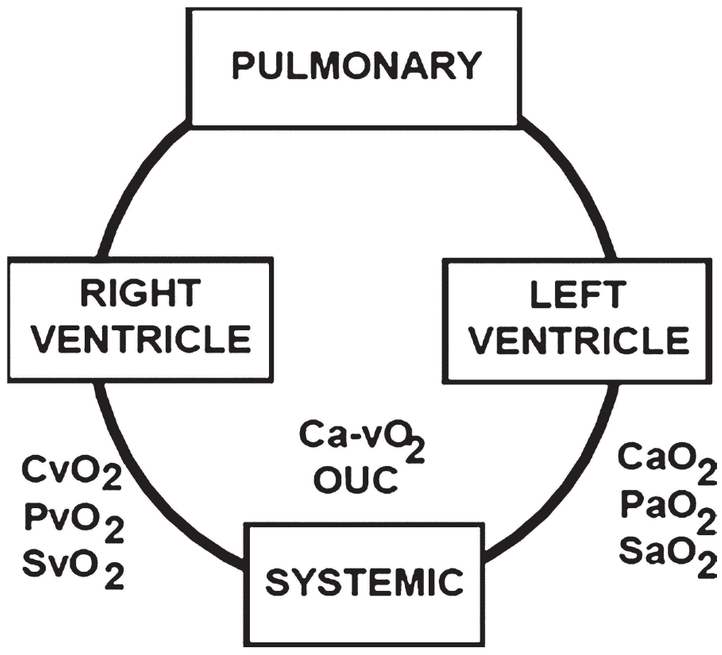

FIGURE 157.3. Oxygenation calculations. CaO_2, arterial oxygen content; PaO_2, arterial oxygen tension; SaO_2, arterial oxygen saturation; CvO_2, venous oxygen content; PvO_2, venous oxygen tension; SvO_2, mixed venous oxygen saturation; $Ca–vO_2$, arterial–venous oxygen content difference; OUC, oxygen-utilization coefficient.

The oxygen content of arterial blood as it leaves the heart may be calculated as:

$$\begin{aligned} CaO_2 &= \text{oxygen bound to arterial Hgb} + \text{oxygen dissolved in arterial blood} \\ &= (1.34 \times \text{Hgb} \times SaO_2) + (PaO_2 \times 0.0031) \end{aligned}$$

In a similar fashion, the oxygen content of venous blood as it returns to the heart may be calculated as:

$$\begin{aligned} CvO_2 &= \text{oxygen bound to venous Hgb} + \text{oxygen dissolved in venous blood} \\ &= (1.34 \times \text{Hgb} \times SvO_2) + (PvO_2 \times 0.0031) \end{aligned}$$

The partial pressure of oxygen in venous blood (PvO_2) is typically 35 to 40 Torr. As a result, for most purposes, the contribution of dissolved oxygen in venous blood is so small as to be clinically insignificant and is often disregarded. The arterial–venous oxygen content difference ($Ca–vO_2$) therefore represents the amount of oxygen extracted by the tissues and organs of the body. It is frequently elevated in shock, due to the increased oxygen demands of injured tissue, and represents an important resuscitation endpoint. The $Ca–vO_2$ is calculated as:

$$\begin{aligned} Ca–vO_2 &= \text{arterial–venous oxygen content difference} \\ &= CaO_2 - CvO_2 \end{aligned}$$

$Ca–vO_2$ is an important indicator of the relative balance between CI and $\dot{V}O_2$. A $Ca–vO_2$ in excess of 5.5 mL per dL of oxygen suggests that CI is inadequate to meet cellular oxygen demands and that anaerobic metabolism and lactic acidosis may result. Maneuvers to improve CI and DO_2 should be performed to meet the patient's cellular oxygen demand and reduce $Ca–vO_2$ to a normal range.

The volume of oxygen delivered from the left ventricle (DO_2) and the amount of oxygen consumed by the organs ($\dot{V}O_2$) provide the clinician with vital information by which to assess the patient's overall oxygen transport balance. DO_2 is determined by two factors: the volume of oxygen in blood

(CaO_2) and the blood flow delivered (CI). Values indexed to BSA allow comparison across patients of differing body habitus, so that

DO_2I = oxygen delivery index
= volume of oxygen pumped from the left ventricle per minute per m^2
= (CaO_2) (CI) (10 dL/L)

$\dot{V}O_2$ is calculated similarly, using $Ca–vO_2$ to account for the oxygen consumed by the body:

$\dot{V}O_2I$ = oxygen consumption index
= volume of oxygen consumed by the body per min per m^2
= volume of oxygen delivered − volume of oxygen returned per minute per m^2
= ($Ca–vO_2$) (CI) (10 dL/L)

One of the most important determinants of tissue DO_2I is Hgb concentration. The optimal Hgb concentration during shock resuscitation remains a topic of significant debate. Although previous clinical trials concluded that a Hgb concentration of 7 g per dL is sufficient and that transfusion to higher levels provides no survival benefit, it must be remembered that hemodynamically unstable patients, including hemorrhagic shock victims, were excluded from the study [54]. Further, patients with recent acute myocardial infarction or unstable angina were felt to require a higher Hgb concentration to ensure adequate DO_2I. More recent studies in hemorrhagic shock patients, however, have demonstrated significantly improved survival among patients resuscitated to a Hgb > 11 g per dL [55]. Recent evidence-based medicine guidelines have advocated higher Hgb levels in patients with myocardial ischemia, severe hypoxemia, acute hemorrhage, cyanotic heart disease, lactic acidosis, or closed head injury [2]. Although a subject of continued controversy, the optimal Hgb concentration can appropriately be considered the level that restores a patient's oxygen transport balance while minimizing the potentially detrimental infectious and immunosuppressive effects of allogeneic blood.

Shock Resuscitation Adequacy

Resuscitation of the critically ill patient who has developed one of the shock states is an ongoing process. It requires constant assessment of the patient's response to resuscitative therapy. In the patient whose shock state and oxygen transport balance fail to improve, the administered therapies must be reconsidered and adjusted as necessary to achieve the desired outcome. To guide this dynamic resuscitation, "resuscitation adequacy" endpoints may be employed.

Mixed Venous Oximetry

Continuously measured SvO_2 correlates well with calculated oxygen extraction ratios and represents a valuable endpoint for assessing the adequacy of shock resuscitation [56]. The four factors affecting SvO_2 are (1) SaO_2, (2) Hgb concentration, (3) CO, and (4) $\dot{V}O_2$. Increases in any of the three variables affecting DO_2 (SaO_2, Hgb concentration, and CO) result in an increase in SvO_2, whereas uncompensated increases in $\dot{V}O_2$ result in a decrease in SvO_2. The SvO_2 measured in the proximal pulmonary artery is a global flow-weighted average of the effluent blood from all perfused vascular beds. SvO_2 does not reflect the oxygenation of nonperfused tissues; thus, a normal SvO_2 does not mean that all organs are adequately oxygenated. In the absence of a pulmonary artery catheter, the mixed central venous oxygen saturation ($ScvO_2$) may be measured either intermittently using a venous blood gas drawn from a central venous catheter whose tip is located in the superior vena cava or continuously via a special oximetric central venous catheter [1]. It should be recognized that SvO_2 and $ScvO_2$ are not equivalent measurements with normal $ScvO_2$ values being 0.05 to 0.1 higher than SvO_2.

A low SvO_2 (less than 0.65) virtually always indicates an unfavorable disturbance in the normal balance between DO_2 and $\dot{V}O_2$. Normal or high values of SvO_2 are more difficult to interpret. A normal SvO_2 in a patient with otherwise normal hemodynamics generally indicates a stable condition with a satisfactory oxygen transport balance. A high SvO_2 (greater than 0.75) is difficult to interpret and implies a either a maldistribution of peripheral blood flow, providing some vascular beds with DO_2 in excess of consumption, or the presence of "shunting" in which oxygenated blood is returned to the heart without releasing its bound oxygen. This state of vaso-deregulation is often associated with high-flow states such as cirrhosis, sepsis, pregnancy, and inflammation.

Arterial Lactate

As discussed previously, shock is hypoperfusion resulting in inadequate DO_2 to meet tissue oxygen demand at the cellular level. The resulting oxygen debt forces cells to switch to anaerobic metabolism to make adenosine triphosphate by the inefficient method of glycolysis. The by-products of glycolysis are hydrogen ion, pyruvate, and lactate. If aerobic metabolism is restored through resuscitation and improved tissue DO_2, the excess hydrogen ion is buffered, and both pyruvate and lactate are metabolized to yield adenosine triphosphate. Under continued anaerobic conditions, however, hydrogen ion and lactate accumulate within the cell, resulting in acidosis, injury, and cellular death. Serum lactate levels therefore provide the clinician with an excellent laboratory marker of the presence of anaerobic metabolism as well as resuscitation adequacy.

Elevated serum lactate levels indicate that the patient has sustained a period of inadequate perfusion and oxygenation within the past 6 to 12 hours with the severity of lactic acidosis directly correlating with the severity of the shock insult. If such levels are rising, anaerobic metabolism remains ongoing and the magnitude of resuscitative therapy should be increased. A decreasing lactate level suggests that resuscitation has been adequate and anaerobic metabolism has resolved. Although serum lactate levels identify the presence of anaerobic metabolism, they are not specific in identifying the location of abnormal regional perfusion. Further, profound hypoperfusion can exist despite normal lactate levels when there is inadequate blood flow to ischemic tissues. Some septic patients have increased lactate levels in the absence of hypoperfusion as a result of increased aerobic glycolysis. In this situation, the elevated lactate continues to be significant despite resuscitation and is an indicator of a potentially severe pathologic process. Patients with significant hepatic dysfunction do not clear lactate normally, and will therefore manifest higher lactate levels in the absence of anaerobic metabolism [57].

Elevated lactate concentrations predict an increased mortality rate. The magnitude and duration of the elevation correlate with mortality and reversal of hyperlactatemia suggests a better prognosis. Mortality rates of 24% to 86% are seen if lactate has not normalized by 48 hours [57–61].

Base Deficit

The presence of an elevated base deficit correlates directly with the presence and severity of shock [61–63]. It predicts fluid resuscitation requirements and is a rapidly obtainable monitor of resuscitation adequacy [62]. Further, base deficit normalizes rapidly with restoration of aerobic metabolism, making it a useful physiologic marker by which to guide resuscitation. Base deficit must be interpreted with caution in the patient who has

received exogenous sodium bicarbonate as it will no longer be useful as a predictor of resuscitation adequacy.

Rutherford et al. identified that patients younger than 55 years of age without a head injury who demonstrate a base deficit of −15 mmol per L have a 25% mortality rate [63]. Patients with a head injury or patients older than 55 years without a head injury have a 25% mortality at a base deficit of −8 mmol per L. These authors suggested that base deficit could be used to identify patients in severe shock who might benefit from having operative procedures terminated early (so-called "damage control laparotomy").

Treatment Principles

Patient morbidity and mortality after development of one of the shock syndromes correlates directly with the duration and severity of malperfusion. The intensivist must therefore rapidly diagnose the presence and cause of shock, restore systemic and regional perfusion to prevent ongoing cellular injury, and prevent the development of end-organ failure. The intensivist must command a strong understanding of the various therapeutic options for each of the shock states. Using the hemodynamic variables and calculations previously described, shock resuscitation should focus on assessment of preload, contractility, afterload, and oxygen transport balance with the intent to optimize the patient's end-organ perfusion and cellular oxygenation. In addition, the etiology for the shock state should be investigated to treat and/or correct the underlying cause. This may be simple, as in needle decompression for a tension pneumothorax, or may be complex, as in the treatment of sepsis.

Preload

In almost all shock states, a component of diminished preload, either relative or absolute, exists. Therefore, the initial therapeutic intervention for almost all patients in shock should be a crystalloid bolus of 20 mL per kg with subsequent resuscitation guided by signs of improved organ perfusion: reduction in tachycardia, restoration of normotension, maintenance of adequate urinary output, return of normal mentation, improvement in systemic oxygenation, and/or correction of abnormalities in serum lactate or base deficit. In patients with preexisting cardiopulmonary disease or those who do not respond to resuscitation as expected, invasive hemodynamic monitoring may be of value in achieving these goals.

Over-resuscitation with intravenous fluids should be avoided and can cause acute lung injury, intra-abdominal hypertension, and abdominal compartment syndrome. Although some authors have suggested the use of colloid-based resuscitation to avoid such complications, large-scale clinical trials and meta-analyses have failed to demonstrate a survival advantage to such an approach [64,65]. A subset analysis of the SAFE trial demonstrated an increased mortality in head injured patients who received colloid-based resuscitation [66]. A balanced resuscitation using a combination of crystalloid and colloid reduces the required resuscitation volume and appears to be associated with decreased organ dysfunction and failure [65].

In patients with hemorrhagic shock, blood product transfusions should be considered early in the volume resuscitation phase as increasing evidence from the battlefield has demonstrated improved survival with early, aggressive blood, plasma, and platelet transfusions to restore adequate hemoglobin concentration and normal coagulation [55]. Current evidence suggests that a 1:1:1 ratio of packed red blood cells/plasma/platelets reduces the morbidity and mortality of hemorrhagic shock [67,68].

Contractility

Resuscitative therapy should optimize the patient's heart rate. Although tachycardia may partially compensate for low perfusion, further increases in heart rate may only decrease diastolic filling of the heart and reduce CO. Treatment of pain and anxiety as well as control of supraventricular tachyarrhythmias in the volume-resuscitated patient can improve CO. In bradycardia from neurogenic shock, atropine-induced blockage of parasympathetic stimulation may help ameliorate the hypoperfusion by raising heart rate and CO. Patients taking beta-blockers who have inappropriately low heart rates may benefit from administration of both calcium and glucagon. Those with pacemakers who are unable to raise their own heart rates in response to shock will frequently benefit from resetting their pacemakers to a more physiologically appropriate higher rate.

Contractility agents should be considered only after adequate attempts to improve preload have been made. Dopamine, a naturally occurring catecholamine that is the immediate precursor of norepinephrine, is a widely used agent with a variable dose response. Classically, low rate (0 to 3 µg per kg per minute) or so-called "renal dose" dopamine was advocated to increase glomerular filtration rate, renal blood flow, and urinary output. The clinical benefit of such therapy, however, has been disproven and dopamine's use in this fashion has largely been abandoned [69]. In moderate doses (5 to 10 µg per kg per minute), cardiac contractility and heart rate are increased through stimulation of cardiac beta-receptors. High-dose dopamine therapy (10 µg per kg per minute and higher) results in stimulation of α-adrenergic receptors, elevating systemic blood pressure. Although a valuable tool in improving cardiac performance, dopamine should be used with caution in patients with coronary artery stenosis because of the potential risk of tachycardia and increased myocardial oxygen demand.

Dobutamine is a synthetic catecholamine that also acts on β_1-receptors, but, unlike dopamine, does not directly release norepinephrine. Dobutamine has both chronotropic and systemic vasodilatory effects, reducing afterload and increasing CO in the weakened heart. However, it should be used with caution in hypovolemic, vasodilated states, as it may decrease blood pressure and increase heart rate, leading to reduced systemic perfusion [70].

Norepinephrine is a naturally occurring catecholamine with both α- and β-adrenergic activity. As a potent vasoconstrictor, there is some reluctance to use this agent because of its possible effects on mesenteric and renal blood flow. However, in the setting of an appropriately volume-repleted patient who remains hypotensive, norepinephrine has been shown to be effective and safe and may have beneficial effects on renal function [71]. It should be considered the vasopressor of choice of all but the cardiogenic shock states [2].

Amrinone is a noncatecholamine intravenous inotrope that, like dobutamine, has vasodilatory effects. Its mechanism of action is as a phosphodiesterase-III inhibitor, raising intracellular cyclic adenosine monophosphate levels. In patients with shock due to congestive heart failure, amrinone increases stroke volume without an effect on heart rate. In some patients with hypovolemic shock, its vasodilatory properties preclude its use because of dramatic hypotension.

Afterload

If preload is optimized and hemodynamic goals have still not been met, afterload should be assessed and corrected as needed. The persistently hypotensive patient should not be considered a candidate for afterload reduction. In patients with hypertension or even normotension, however, afterload reduction may allow for improved CO and, hence, improved resuscitation especially in patients with decreased contractility.

Sodium nitroprusside is a commonly used agent with the advantages of rapid onset and short duration, making it ideal

for titration in the hemodynamically labile patient. Nitroprusside acts as both a venous and arterial vasodilator, in essentially equal amounts. However, it should be used with caution in patients with coronary artery disease when concerns of coronary steal and myocardial ischemia exist. Alternatively, intravenous nitroglycerin may be used. Although primarily affecting venous capacitance, nitroglycerin also decreases arterial resistance and may improve CO. Angiotensin-converting enzyme–inhibiting agents may also be of significant value in reducing afterload in the normovolemic patient with poor cardiac function.

Afterload may also be reduced mechanically, using a percutaneously placed intra-aortic balloon counterpulsation pump (IABP). IABP is most commonly used in myocardial infarction and in the immediate postoperative period following coronary artery bypass. IABP provides mechanical afterload reduction and improves coronary artery perfusion. IABP demonstrates survival benefit primarily in myocardial infarction patients who have reversible pathology and has been used successfully in high-risk patients undergoing noncardiac surgery [72].

Although afterload reduction may be beneficial in improving cardiac performance, the patient with aortic stenosis leading to shock may be harmed by use of these agents. In this disease, left ventricular wall tension remains high, and afterload reduction only serves to reduce coronary perfusion by reducing coronary perfusion pressure.

In septic and neurogenic shock, it will often be necessary to counteract the vasodilatory effects of the underlying disease process. Recent studies suggest that norepinephrine should be used as the first-line agent and vasopressin in low doses (0.01 to 0.04 U per minute) should be added when patients fail to respond to norepinephrine. Vasopressin should be used with caution in patients with poor cardiac function [2]. Studies in Europe with terlipressin, a synthetic vasopressin analogue with theoretical advantages over arginine vasopressin, are ongoing [73].

Oxygen Transport

The goal of shock resuscitation is to improve tissue oxygenation so that oxygen delivery meets the demand of cells to function aerobically. Beginning in 1977, Shoemaker et al. suggested in a series of clinical trials that resuscitation to achieve "supranormal" CI (> 4.5 L per minute per m^2), DO_2I (> 600 mL per minute per m^2), and $\dot{V}O_2I$ (> 170 mL per minute per m^2) levels was associated with improved high-risk patient survival following operative procedures [74,75]. Subsequent trials, however, identified that it is a patient's ability to spontaneously reach such supranormal levels of oxygen transport that is predictive of survival and not the applied intervention itself [74–79]. In fact, Balogh et al. have demonstrated that supranormal resuscitation is associated with a higher incidence of over-resuscitation, intestinal malperfusion, abdominal compartment syndrome, multiple system organ failure, and death [80]. They concluded that traumatic shock patients should be resuscitated to achieve a DO_2I of 500 mL per minute per m^2 during the first 24 hours of resuscitation and that maintaining such a level beyond 24 hours is rarely beneficial unless evidence of ongoing shock is present. The potential benefits of adequate sedation and analgesia as a method to reduce oxygen demand must always be considered in any patient who presents with shock.

SYSTEMATIC APPROACH TO THE TREATMENT OF SHOCK

Perhaps most noteworthy in the recent literature on the treatment of shock are multiple studies demonstrating that a proactive, systematic, evidence-based approach to shock resuscitation improves patient outcome (Table 157.4) [1–3]. The Surviving Sepsis Campaign is a multimodality approach to timely resuscitation of the septic patient encompassing diagnosis, source control, fluid resuscitation, vasoactive medications, appropriate antimicrobial therapy, correction of oxygen transport inequalities, low-dose steroid administration for relative adrenal insufficiency, selective use of recombinant human activated protein C, targeted blood product administration, mechanical ventilation strategies geared at reducing barotrauma, sedation, and neuromuscular blocking protocols that include daily interruption, glycemic control, deep venous thrombosis prophylaxis, and stress ulcer prophylaxis [2,3]. This comprehensive approach to the critically ill patient has also been applied with marked success outside the ICU setting using the "rapid response team" concept to treat nonseptic shock patients as well [81]. Many of these same tenets of shock resuscitation are also applicable to the other shock states that may be encountered.

Shock resuscitation continues to evolve as new research identifies the pathophysiology of the various shock states. Numerous treatments for shock are currently being evaluated

TABLE 157.4

SUMMARY OF ADVANCES IN MANAGING SHOCK BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

- Patients with hypotension or evidence of anaerobic metabolism should receive immediate early goal-directed resuscitation to restore systemic perfusion and oxygenation within six hours [1,2]
- Fluid resuscitation using either 0.9% normal saline or 4% albumin may be considered equivalent with similar outcomes in 28-day mortality [64].
- Patients in shock should be resuscitated to maintain a mean arterial pressure ≥ 65 mm Hg [2,3]
- Centrally administered norepinephrine or dopamine should be considered the vasopressors of choice for noncardiogenic shock resuscitation [2]
- Dobutamine is the inotropic agent of choice for cardiogenic shock [2]
- Low-dose dopamine infusions should not be used for renal protection [69]
- Resuscitation to achieve supranormal levels of oxygen delivery or consumption do not improve patient outcome [78,80]
- Recombinant human activated Protein C should not be administered to septic patients with an APACHE-II < 25 [2]
- Corticosteroids should not be used to treat septic shock unless the patient demonstrates evidence of symptomatic adrenal insufficiency [2]
- Transfuse packed red blood cells when hemoglobin decreases to < 7.0 gm/dL. A higher hemoglobin level is appropriate in patients with myocardial ischemia, severe hypoxemia, acute hemorrhage, cyanotic heart disease, lactic acidosis, or closed head injury [2,54].
- A 1:1:1 red blood cell/plasma/platelet transfusion strategy should be utilized in patients with massive hemorrhagic shock (≥ 4 units of packed red blood cells over 1 h or ≥ 10 units over 24 h [more than one total blood volume]) [67].
- Hypothermia should be rapidly corrected in any patient with shock [30].
- Patients resuscitated to elevated levels of preload have significantly improved visceral perfusion than those resuscitated to normal preload with additional inotropes. Elevated preload levels do not affect pulmonary function [49].

including nitric oxide therapy, levosimendan, intravenous immunoglobulin, continuous hemodiafiltration, factor VIIa, and statin therapy among others [82–86]. Time will determine whether these therapies provide a survival benefit to the patient with shock.

SUMMARY

Shock is a common and highly lethal condition that is commonly encountered in the critically ill patient. Its cause is varied and complex. It may present in a spectrum from subclinical laboratory abnormalities to complete cardiovascular collapse. A high degree of clinical suspicion and thorough evaluation are essential to both making the diagnosis and initiating timely resuscitative therapy. Inadequate tissue perfusion that is unresponsive to initial treatment should lead to early, goal-directed therapy. Correction of abnormalities in ventricular preload, contractility, afterload, and oxygen transport are the first steps to breaking the cycle of cellular injury and microcirculatory failure. Correction of the precipitating, underlying condition is essential for patient survival. Early treatment to predefined physiologic endpoints reduces the potentially devastating complication of end-organ dysfunction and failure.

CHAPTER 158 ■ RESUSCITATION FROM SHOCK FOLLOWING INJURY

DONALD H. JENKINS, JOHN B. HOLCOMB, PHILLIP A. LETOURNEAU, DUSTIN L. SMOOT AND STEPHEN L. BARNES

After the initial evaluation and operative management of the surgical/trauma patient, many patients require further resuscitation, support, and care in an intensive care unit (ICU) setting. This chapter provides a brief outline of considerations, priorities, treatment algorithms, and the newest innovations that may assist any intensivist tasked with managing such critically ill surgical patients.

STATEMENT OF THE PROBLEM

Surgical patients die from shock abruptly through lack of oxygen delivery to the heart and brain, or subacutely through development of multiple organ dysfunction from late recognition of shock or inadequate resuscitation. Unlike the typical nonsurgical critically ill patient, exsanguination is often the cause of death in the surgical/trauma patient, second only to central nervous system injuries as the cause of death of trauma victims in the United States [1–3]. The control of hemorrhage has been identified as a priority in modern trauma patient care, second in importance only to adequate ventilation [4]. Advanced Trauma Life Support teaches a schema that incorporates the vital signs, skin color, capillary refill, and mentation to alert the physician to how severely injured the patient may be and help to quantify how much blood the patient may have lost [4]. By the time the blood pressure falls, the patient has lost 30% to 40% of his or her blood volume, or approximately 2,000 mL. This situation demands rapid action, but action should not wait until this point has been reached.

One classification system defines four types of shock: *Hypovolemic* (such as dehydration, diarrhea, and hemorrhage, the most common form of shock following major trauma), *distributive* (such as septic shock, the most common form of shock in the late phase of recovery—5 days or more—after major surgery/trauma), *cardiogenic* (such as from massive myocardial infarction or arrhythmia), and *obstructive* (such as from tension pneumothorax, pulmonary embolus, or pericardial tamponade). By far, hemorrhagic shock is the most common form following major surgery/trauma and the major focus of this chapter (although the astute physician should always keep tension pneumothorax in the differential diagnosis). Therefore, in most instances, the ICU physician faced with a surgical patient in shock should direct initial efforts toward correction of hypovolemia.

Without obvious external bleeding, vital signs and evidence of organ hypoperfusion are assessed to evaluate the patient for significant or ongoing hemorrhage. A falling hematocrit may be a sign, but as hemorrhage causes loss of cells and fluid in equal proportion, an isolated normal hematocrit should not be reassuring to the clinician. With very rapid hemorrhage, a patient can die with a normal hematocrit. A fall in central venous oxygen saturation when the cardiac output remains the same may be one of the earliest signs of hemorrhage in the ICU setting as the body begins to extract more oxygen from the remaining blood.

PHYSIOLOGY OF EFFECTS OF HEMORRHAGE

The physiologic responses to hemorrhage can be broken into three categories: Hemostasis, oxygen delivery, and immunology.

Hemostasis

If bleeding does not stop, then no intervention can prevent death. It is this concept that has led to some of the most heated debates in the resuscitation literature: "Does resuscitation promote tissue perfusion and cellular metabolism, thus increasing survival, or does the increase in blood pressure destroy clot, promote rebleeding, and decrease survival?" [5]. The astute physician recognizes that both concepts are true. Cellular metabolism must be ensured, without overwhelming the clotting mechanism.

After injury, the body attempts to stop hemorrhage by clotting at the site of vascular injury. This is accomplished by the interaction of circulating clotting factors, platelets, and tissue factors from the injured cells. These factors work primarily to form a "plug" initiated by the physical presence of the platelets and augmented by the cross-linking of fibrin to form a more permanent seal. The tissue injury factors released may also lead to constriction of the local blood vessels to decrease the blood flow to the leaking area concurrently with platelet plug formation and is mediated both locally by tissue factors as well as centrally. Finally, when the blood loss leads to a fall in the blood pressure, the clotting efforts are aided by a smaller vessel diameter, decreased wall tension, and lower pressure head.

Oxygen Delivery

In 1872, Gross called shock a "rude unhinging of the machinery of life." Although this definition is accurate, it is not precise. It is at the level of cellular oxygen delivery and utilization that the understanding of shock is defined. Without oxygen, the cells may survive briefly using anaerobic metabolism. Many of the physiologic defense mechanisms work to augment this delivery and depend on oxygen-carrying capacity, cardiac output, and oxygen delivery to and utilization by the cell.

The oxygen-carrying capacity of blood depends on the amount of circulating hemoglobin, which diminishes continually during hemorrhage. Although erythropoietin stimulates the production of new red blood cells (RBCs) and eventually restores hemoglobin over weeks, this response does not acutely restore oxygen-carrying capacity [6]. As hemorrhage proceeds, the body becomes incapable of supporting metabolic need. The primary defense, however, is the extra capacity inherent in the human system: only approximately 25% to 30% of the transported oxygen is normally used, leaving central venous or mixed venous oxygen saturations in the range of 70%. When fully stressed, extraction improves as anaerobic metabolism leads to lactic acidosis, which shifts the oxygen dissociation curve to favor release of oxygen at the tissue level. This allows much more oxygen to be removed from the hemoglobin, and much lower central venous oxygen saturations.

Cardiac output is the product of heart rate and stroke volume. There is reserve built into the heart rate, in that most people use only approximately two-thirds of their maximal heart rate. Pain, fear, and a variety of baroreceptors release catecholamines and other factors in response to hemorrhage. These lead to an increased heart rate, and thus increased cardiac output and oxygen delivery. With a few exceptions, in the elderly or those with heart disease, this response is maximally achieved by the body, in an unaided fashion.

The stroke volume can be increased by increased contractility through the direct effects of many of the same substances that increase heart rate. In hemorrhage, however, the primary component of cardiac output is the volume of blood coming into the heart (preload). During hemorrhage, the preload falls. As the blood pressure falls, oncotic forces predominate and fluid begins to shift into the vascular space. This "borrowing" of fluid from the interstitial, and ultimately from the intracellular, space is gradual, with a gradual restoration of the blood pressure—often not to normal—which allows time for the clotting mechanisms to stop the bleeding and stabilize the clot.

Other factors that restore the preload include the prevention of further fluid loss via the kidney. A lower blood pressure leads to less filtration and less fluid removed in urine. In addition, antidiuretic hormone and the renin–angiotensin systems act to augment this response. Catecholamines and large proteins circulate as part of the defense signaling systems. These augment the oncotic pull. The glucose that increases with the release of corticosteroids also acts to pull fluid into the vascular space. Finally, the body is willing to shunt blood away from most areas of the body to support cardiac preload and the brain. This shunting is very evident in the pale clammy skin of hemorrhagic shock. Initially it is less evident in the relative ischemia that occurs in every other organ of the body.

Oxygen delivery (DO_2) to the tissues includes the variables of cardiac output, arterial oxygen content (CaO_2, the total amount of oxygen in the blood), which includes the amount of hemoglobin that is present. During hemorrhage, these components are altered, and oxygen delivery may be decreased. Cardiac output can be indexed to body surface area and expressed as cardiac index, which when multiplied by CaO_2 yields an oxygen delivery index (DO_{2I}). Normal DO_{2I} is roughly 450 mL per minute per m^2 and it may increase by as much as 30% in response to injury. The primary goal of shock resuscitation is the early establishment of "adequate" oxygen delivery (DO_2) to vital organs; however, adequate is subject to ongoing debate.

The complications of a "successful" resuscitation that should be watched for are related to ischemia and reperfusion injury. These may manifest as multiple organ dysfunction syndrome or individual organ dysfunction. Hepatic dysfunction

may present as jaundice and coagulopathy. Pulmonary dysfunction and acute respiratory distress syndrome may be seen as renal failure, with rising blood urea nitrogen and creatinine. Compromise of intestinal mucosa may lead to sepsis, bleeding, or perforation.

Immunology

Hemorrhagic shock alone, without tissue injury, was once thought to have minimal consequences [7]. Hemorrhagic shock alone has been shown to result in a multitude of responses, however, especially in the immune system. The immune system is intended to protect the body from infectious invaders and remove aberrant cells to prevent cancer. During shock, cells produce messengers or mediators that signal for the help of this system [8]. During reperfusion, these mediators are released widely into the systemic circulation.

Currently, a focus in hemorrhagic shock research is the effect of resuscitation on the immune and coagulation system. Extensive research in the last decade has shown that hemorrhagic shock from trauma activates both the inflammatory and coagulation system, resulting in profound perturbations in both. This is often manifested by a spectrum of clinical problems starting from acute lung injury, progressing to acute respiratory distress syndrome, systemic inflammatory response syndrome, hypo- or hypercoagulation, bleeding or diffuse thrombosis, and even multiple organ dysfunction syndrome [9]. One of the major areas of study involves the activated immune response that results in enhanced activation and increased adhesion of leukocytes. During this activated stage, neutrophils can release harmful reactive oxygen species, which are thought to play a major role in loss of capillary integrity. This leads to edema and the sequestration of fluid in the tissues outside the vascular space.

Although it has been clear that the immune response occurs in response to shock and reperfusion, it now seems that some of the resuscitation fluids used to treat the shock may trigger this altered immune and coagulation response. The immunologic response to various resuscitation fluids is now an area of intense research [10,11].

HEMORRHAGIC SHOCK MANAGEMENT

The first goal in hemorrhagic shock, following assessment of the ABCs (airway, breathing, and circulation), is to stop ongoing bleeding. In the surgical/trauma patient reaching the ICU, this has generally been accomplished in the emergency department (ED), interventional suite, and/or operating room. During the ICU phase, resuscitation is continued, and can last 24 to 48 hours. The goal of resuscitation is to restore normal perfusion to all body organ systems, using the components of oxygen delivery: hemoglobin, cardiac output, and oxygenation. In hemorrhagic shock, this primarily involves hemorrhage control, reversal of coagulopathy, and then administration of sufficient volumes of blood products and crystalloid fluid volume to restore normal aerobic metabolism.

Confirmation of a hypoperfusion state (shock) is obtained through simple examination and a single blood test. Shock is diagnosed by the effect of hypoperfusion on the body's organ systems: low blood pressure, tachycardia, oliguria, tachypnea, decreased mental status or agitation, skin cyanosis, pallor, decreased pulse character, or mottling. Equivocal cases can be confirmed by obtaining an arterial blood gas and looking for a base deficit exceeding 6 or a serum lactate assay (more than 2 mmol per L). Hypoperfusion implies inadequate delivery of oxygen to the body's cells. Oxygen delivery is a function of cardiac performance, arterial hemoglobin content, and arterial oxygen saturation. All attempts to correct shock involve optimizing these three variables. Hypotension is not synonymous with shock, which can be present in a normotensive patient. Conversely, not all hypotensive patients are in shock. Hypotension, like many other physical findings, is but one sign helpful in the overall clinical picture of shock diagnosis. As detailed below, reestablishment of normal heart rate, blood pressure and urine output does not equate to resolution of shock; resolution of tissue hypoperfusion as manifested by lactate clearance does.

Resuscitation of the patient in shock should be approached in two phases, based on the end points of the resuscitative effort. In the first phase, the patient should be resuscitated to a systolic blood pressure of 80 to 100 mm Hg or mean arterial pressure of 55 to 65 mm Hg, a urine output of 0.5 mL per kg per hour, and an arterial oxygen saturation of 93% or higher. These end points are pursued to prevent imminent death from hypoperfusion to the heart and brain, and should be achieved optimally within 1 hour.

In the second phase, resuscitation is continued with fluid, as well as inotropic and vasopressor agents, as needed, to the goal of eliminating the base deficit of metabolic acidosis, or, if available, restoring the serum lactate or base deficit to a normal level. This end point is important in reversing systemic anaerobic metabolism, which, if unrelieved, leads inexorably to multiple organ failure (MOF). This goal should be accomplished within 12 to 24 hours.

Lessons Learned from War

The modern-day trauma system owes a large debt to combat casualty care. Techniques from system development to operating room procedures have their roots in battlefield medicine. Resuscitation as well, is no stranger to advancement during wartime. To understand the advancements made and differences that exist with modern combat resuscitation strategies it is important to understand the history of combat resuscitation.

A modern ATLS resuscitation strategy of 2 L of crystalloid owes its roots to strategies developed during the Vietnam War. Based on research by Shires [12,13], Dillon [14], and others, the need for volume resuscitation was brought to the forefront to replace an interstitial volume debt secondary to intravascular movement in hemorrhagic shock. High volume crystalloid resuscitation strategies were used to replace volume loss encountered by the bleeding soldier in ratios of 3:1 to as high as 8:1. The physiology was sound, but disappointingly when outcomes were examined, clinical efficacy in the way of improved survival was not seen over previous war efforts with Killed in Action rates of 16% for the US Civil War, 19.6% for World War I, 19.8% for World War II, and 20.2% for the Vietnam War [15]. In fact, the adopted strategy of IV fluid administration would spawn its own set of complications, most notably the emergence of Da Nang lung known more widely now as acute respiratory distress syndrome. Initially felt to be the result of the volume of resuscitation, eventually its mechanisms linked to immunologic effects would come to be understood by Ashbaugh et al. in their case series of 12 patients (seven with trauma) published in the Lancet in 1967 [16].

High-volume crystalloid resuscitation strategies were further supported by Shoemakers early prospective study of 67 patients with greater than 2,000 mL of blood loss. Supranormal endpoints of resuscitation, defined as a cardiac index >4.52 L per minute per m^2, oxygen delivery ≥ 670 mL per minute per m^2, and oxygen consumption ≥ 166 mL per minute per m^2 were assessed against "standard" therapy. Survival was nearly double in the supranormal group as well as statistically significant decreases in length of ICU stay, mean number of organ

failures, and days of ventilation [17]. Despite these promising results, several other groups failed to achieve similar findings. More importantly with an ever increasing understanding of the immunology of intravenous fluids and resulting proinflammatory properties the complications of high-volume crystalloid resuscitation for combat casualties came into question.

If aggressive crystalloid resuscitation was not the answer, then what would the optimal resuscitation strategy be? A report by the Institute of Medicine in 1999 as well as two consensus conferences held by Office of Naval Research, the US Army Medical Research and Material Command and the Uniformed Services University of Health Sciences in 2001 and 2002 tried to answer the question.

The IOM report was the first to recognize the several inadequacies of the then standard fluid therapy. First noted was the paucity of good Level I and II data to support the then standard of care. Second, the immunologic activity of common intravenous fluids used and deleterious effects of high-volume resuscitation was better defined as it related to complications [17]. This report would mark a significant paradigm shift. Initial recommendations were to remove the racemic mixture of D and L Lactated Ringers (still clinically available) in favor of L-isomer only. Replacement of lactate with ketones was advocated. Finally, the report supported the initial battlefield use of low volume hypertonic saline (HTS) resuscitation [18]. A 250-mL bolus of HTS was chosen based on research showing decreased neutrophil activation as well as increased oncotic properties as well as the battlefield logistics of less fluid to carry for frontline medics.

The 2001 consensus conference took it one step further by defining what the endpoints of resuscitation would be on the battlefield [19]. Triggers for fluid resuscitation would be systolic blood pressure less than 80 mm Hg or absence of palpable radial pulse, decreasing blood pressure, or altered mental status with no confounding brain injury [19]. This protocol allowed for "permissive hypotension" during resuscitation until definitive hemorrhage control. The goal was not to return blood pressure to normal, but rather to target clinical goals of mentation and palpable pulse. These protocols were developed with several civilian trauma studies in mind.

The first by Bickel and Mattox done at the Ben Taub in which 598 adult patients sustaining penetrating torso trauma with a systolic blood pressure less than 90 were assigned to either standard fluid therapy with Lactated Ringers or IV cannulation with no fluid infusion. Although controversies with study design and protocol surround the results, a significant survival benefit 70% versus 62% was seen for the delayed resuscitation arm [20].

Second were several studies that suggested early aggressive fluid resuscitation before hemorrhage control may have a deleterious effect. As early as 1964, Shaftan et al. published data showing the effects of aggressive volume correction slowed spontaneous control of arterial bleeding [21]. This was followed by military research data done in swine by Bickell et al. Adult swine had their infrarenal aorta cannulated with a stainless steel wire. The wire was pulled creating a 5-mm aortotomy and free intraperitoneal hemorrhage. Eight pigs received 80 mL per kg of Lactated Ringers where the control group received nothing. Hemorrhage was significantly higher in the intravenous fluid group (2,142 ± 178 mL vs. 783 ± 85 mL, $p < 0.05$) as well as mortality (8 of 8 vs. 0 of 8, $p < 0.05$) [22]. This ultimately culminated in a complete 180-degree shift from the high volume crystalloid resuscitation seen in the Vietnam War.

If awake, alert, and having a palpable pulse, a soldier sustaining a penetrating wound should have an IV placed, but no fluids would be infused. PO fluids would be encouraged and evacuation undertaken to the next level of care. If resuscitation had to be undertaken, again recognizing a low-volume strategy the recommendation of the panel was for 500 mL hetastarch (Hespan or Hextend) as FDA approval for HTS was lacking. The hetastarch bolus could be repeated at which point a reassessment was done and if no response the possibility of futility was entertained [23].

Expanding on this the 2002 consensus conference held in conjunction with the Canadian Defense and Civil Institute for Environmental Medicine reexamined prehospital requirements for fluid therapy. The "hypotensive" strategy was again approved, but the recommendation for initial battlefield fluid was changed to hypertonic saline dextran (HTS-D) based on then current research showing a favorable volume expansion profile of the dextran with the inflammatory inhibition of the HTS component [24,25].

Current strategies in the Iraq and Afghanistan wars are very similar. First and foremost, the problem had to be defined with the unique set of circumstances that are present in live fire situations. The first point of care would be the battlefield medic. It was recognized that logistical problems exist in bringing care to the wounded at the point of injury. Hemorrhage control still remains the first priority in resuscitating the injured patient, for if quick, effective hemostasis cannot be achieved fluid therapy has no hope of working in austere environments where definitive therapy may be hours away [23]. This has led to the reintroduction of vascular tourniquets, the use of Battlefield hemostatic dressings, and newer therapies such as Factor VII to arrest hemorrhage so that resuscitation efforts can be effective, a discussion of which is beyond the scope of this chapter.

As recognized in the previous consensus conferences, if medics are to be mobile and effective on the battlefield they need the ability to carry their supplies with them [18,19,23,24]. This makes low-volume intravascular expansion much more attractive. For this reason, colloid solutions, specifically Hespan or Hextend, continue to be the fluid of choice for military applications [23]. HTS-D has fallen out of favor due to more current civilian prehospital data that has shown an increase in mortality in trauma patients during interim analysis of the recent ROC trial [26].

With the choice of fluids now made (Hespan or Hextend), the next decision point is how to get those fluids into an injured soldier. Trauma providers know the key tenet of ATLS "two large-bore IVs in the antecubital fossa." This principle becomes increasingly difficult in combat conditions. To this end, the US military takes a different approach. If awake, alert and having a palpable radial pulse, a wounded soldier with a palpable radial pulse have a single 18-gauge peripheral IV placed (chosen for ease of cannulation versus a larger bore IV) and PO fluids encouraged [23]. If IV access cannot be obtained or conditions will not allow access, a sternal intraosseous device is placed. Sternum was chosen as the reproducible target as extremity injuries prevail in current warfare and the trunk remains relatively protected with modern armor. The sternal IO can be placed with reproducible landmarks quickly and in low- or no-light conditions making it extremely beneficial in modern combat [23].

Resuscitation then continues as appropriate with evacuation to the next level of care. It is at this level that the paradigm has shifted dramatically. The emphasis now is on damage control. This pertains not only to the way in which the operations are done (quick procedures leaving abdominal wounds open, temporary packing for hemorrhage control, and temporary vascular shunts) but also to the way in which resuscitation is continued. The use of early blood and coagulation component therapy as well as fresh whole blood (FWB) is emphasized. Again logistics dictate limited storage capabilities in far forward treatment centers. This continues to promote a walking blood bank using fellow combat troops as donors, a luxury not afforded by the civilian trauma provider.

Clinically, FWB has been demonstrated to reverse dilutional coagulopathy, with evidence that a single unit of FWB has a

hemostatic effect similar to 10 units of platelets [27–34]. In a retrospective study of the results of the FWB procedures for one U.S. Combat Support Hospital in 2004, 87 patients received 545 units. In that experience the FWB drive was called for only after the patient had received a massive transfusion, yet the transfusion of FWB resulted in significant improvements in both hemoglobin concentration and coagulation parameters [32].

The nature of military medical logistics frequently limits the availability of FFP, platelets, and cryoprecipitate for transfusion in theaters, giving the battlefield physician few options in the treatment of traumatic coagulopathy. However, the use of FWB in massively transfused patients may circumvent the problem of dilutional coagulopathy. Consider the usual mixture of one packed RBC unit (335 mL) with a hematocrit of 55%, one unit of platelet concentrate (50 mL) with 5.5×10^{10} platelets, and one unit of FFP (275 mL) with 80% coagulation factor activity. This combination results in 660 mL of fluid with a hematocrit of 29%, 88,000 platelets per μL, and 65% coagulation factor activity. By definition, transfusion of these standard components will only serve to further dilute critical factors in a bleeding casualty. In contrast, FWB is replete with functional platelets as well as fully functional clotting factors. A 500-mL unit of FWB has a hematocrit of 38% to 50%, 150,000 to 400,000 platelets per μL, and 100% activity of clotting factors diluted only by the 70 mL of anticoagulant [35]. In addition, the viability and flow characteristics of fresh RBC are better than their stored counterparts that have undergone metabolic depletion and membrane loss.

Initial retrospective studies by Holcomb found higher 24-hour (96% vs. 88%, $p = 0.018$) and 30-day (95% vs. 82%, $p = 0.020$) survival in a group of combat casualties when FWB was used [36]. The immunology and pathophysiology of improved clinical outcomes continues to be an active area of research. Also reported from military and civilian evidence is that higher ratio FFP to PRBC improves outcomes [37–39]. The exact ratio is still part of ongoing research, with some evidence suggesting that there may be a survival bias in those patients receiving higher ratios. Despite these controversies, the early and aggressive use of blood and coagulation factors forms the cornerstone of damage control resuscitation.

DAMAGE CONTROL RESUSCITATION

The concept of damage control resuscitation or hemostatic resuscitation has rapidly evolved on the modern battlefield. This concept is philosophically derived from the widely practiced damage control surgery approach to severely injured patients. Understanding the epidemiology of combat casualties is paramount to devising a logical resuscitation strategy. Most deaths (80%) in combat operations are not preventable [40,41]. Of the remaining 20% of potentially preventable deaths in combat casualties, two-thirds are from hemorrhage. Furthermore, the killed in action rate is lower than at any time in history, while the died of wounds rate has increased, largely due to improved body armor, rapid evacuation, improved extremity hemorrhage control, and medic training [40]. With the recent widespread use of tourniquets and hemostatic dressings for compressible hemorrhage control, the current unmet need is for rapid, effective interventions for noncompressible hemorrhage from the neck, axilla, thorax, abdomen, groin, and pelvis.

Fortunately, most casualties receive at most one to four units of packed RBCs after injury and are not at high risk of presenting or developing a coagulopathy and subsequently dying [42]. Only 5% to 10% of all combat casualties require massive transfusion (10 or more units of packed RBCs) and this group constitutes those at risk for hemorrhagic death [43]. These same patients are those who will benefit from early use of recombinant activated factor VII (rFVIIa), as described in the Clinical Practice Guideline (Table 158.1).

The 5% to 10% of all combat casualties that require massive transfusion fall into two broad categories. Group 1 patients are the wounded who are clearly in profound shock, arrive moribund, and are resuscitated with heroic efforts. These casualties do not pose a diagnostic dilemma; rather, they require immediate hemorrhage control and very rapid resuscitation with the optimal ratio of all available products. Surgically, the only question is what cavity to enter first, as they usually have multiple significant injuries. Frequently, these casualties have severely injured extremities, requiring life-saving tourniquets and delayed completion amputations after successful truncal hemorrhage control. These casualties, if surviving the initial 10 to 15 minutes resuscitation in the ED, require the full massive transfusion protocol and surgical intervention described in the following sections.

Group 2 patients are more difficult to recognize. They are typically the young soldier with incredible physiologic reserve who arrive "talking and looking good," who are actually in shock, have had significant blood loss, and soon progress to cardiovascular collapse. This classic presentation occurs once a week at a busy combat hospital. The challenge is rapidly separating these critical casualties from those who are really hemodynamically stable. These casualties require rapid and accurate diagnosis of their hemorrhagic injury. This group needs immediate hemorrhage control, as fast as group 1; however, they are much more difficult to initially diagnose. Traditional reliance on mental status, blood pressure and pulse rate is notoriously inaccurate for individual risk stratification [44–47].

Fortunately, there are five risk factors that are easily identified very early in the hospital course of severely injured casualties, each of which independently predicts the need for massive transfusion and/or increased risk of death. These simple variables are now available within 2 to 5 minutes after presentation in every ED and each of these variables is independently associated with massive transfusion or death after trauma; any one of them should prompt activation of the massive transfusion protocol (discussed later).

First, an initial international normalized ratio (INR) of 1.5 or more reliably predicts those military casualties who will require massive transfusion [48–50] Patients who have a significant injury present with a coagulopathy as a marker of severe injury. Severity of injury and mortality is linearly associated with the degree of the initial coagulopathy [35,47–50]. Second, a base deficit of 6 or more is strongly associated with the need for massive transfusion and mortality in both civilian and military trauma. Patients have an elevated base deficit before their blood pressure drops to classic "hypotension" levels [51–53]. Third, a temperature of 96°F or less is associated with an increase in mortality. Trauma patients who are hypothermic are in shock, not perfusing their mitochondria, and are not generating heat fast enough to keep up with their ongoing heat loss [52–54]

Fourth, a hemoglobin of 11 mg per dL or less on presentation to the ED is associated with massive transfusion and a mortality rate of 39% [43]. Otherwise, young healthy soldiers who present with a low hemoglobin have only one reason for their anemia, namely, acute blood loss [43,55]. Lastly, a systolic blood pressure of 90 mm Hg or less is indicative casualties who have lost more than 40% of their blood volume (2,000 mL in an adult), are experiencing impending cardiovascular collapse, and have a significantly increased mortality [56,57].

The current resuscitation protocol for combat casualties not only has an affect on current military outcomes (initial reports show Case Fatality Rates dropping from a historic 20% to close to 10%), but has provided exciting tools for civilian trauma providers [40,58].

TABLE 158.1

U.S. CENTRAL COMMAND CLINICAL PRACTICE GUIDELINE FOR USE OF RECOMBINANT FACTOR VIIA (RFVIIA) AND THAWED PLASMA

1. Background: The most critically injured casualties present hypothermic (T ≤ 96°F) acidemic (BD ≤ 6), with a coagulopathy (INR ≥ 1.5), hypotensive (SBP ≤ 90 mm Hg) or with a Hgb ≤ 11). Interventions aimed at reversing the coagulopathy starting as soon after arrival as possible may improve survival.
2. Recombinant factor VIIa is FDA-approved for use during critical bleeding or surgery in hemophilic patients with inhibitors to factor VIII or IX. rFVIIa has been shown to be safe and decreases transfusion requirements in humans with life-threatening hemorrhage, including patients with hypothermia (30°C–33°C, pH > 7.1). In a total of seven prospective randomized surgical trials, the drug causes no increase in any complication.
3. Plasma used in a 1:1 ratio with PRBCs has been shown to improve survival in combat casualties.
4. In the combat surgical setting, rFVIIa and plasma should be used in patients who are
   (a) Hypotensive from blood loss (SBP ≤ 90 mm Hg)
   (b) Have a base deficit ≥ 6
   (c) Hypothermic (*T* ≤ 96°F)
   (d) Coagulopathic (clinically or an INR ≥ 1.5)
   (e) Have a Hgb ≤ 11
   (f) Have weak or absent radial pulse character
   (g) Have more than one major amputation
   (h) Have major truncal injury with a positive FAST examination
   (i) Abnormal mental status from trauma or CT scan with intracranial injury
   (j) Have > 1,000 mL immediately out of a chest tube or > 200 mL/h
   (k) Anticipated and actual transfusion of > four units of PRBCs
   (l) Require damage control maneuvers
   (m) Require fresh whole blood
5. Guidelines for administration
   (a) Protocol for use
      (i) Infuse rFVIIa at dose of three vials (2.4 mg) or 90–120 μg/kg IV push.
      (ii) If coagulopathic bleeding continues 20 min after infusion
         (1) Administer two additional units fresh whole blood or four units FFP, 10 packs of cryoprecipitate and 6 packs of platelets
         (2) Redose rFVIa 90–120 μg/kg rFVIIa IV push.
   (b) Administration limits
      (i) Four doses (typically 12 vials) within a 6-h period.
      (ii) If bleeding persists after four doses, there should be attention to conservation of resources. Consult the senior surgeon before administering more rFVIIa.

BD, base deficit; CT, computed tomography; FAST, focused abdominal sonogram for trauma; FDA, Food and Drug Administration; Hgb, hemoglobin; INR, international normalized ratio; PRBC, packed red blood cell; SBP, systolic blood pressure; T, temperature.

Emphasis on early hemorrhage control and damage control resuscitation through aggressive replacement of blood component and coagulation factors still needs further study, but remains one of the positive hallmarks of modern combat medicine. From the point of injury on the battlefield to the arrival at definitive care facilities the current combat casualty enters into a well thought out system of multiphasic resuscitation with specific goals to be achieved at each level; early hemorrhage control, limited intravascular replacement until definitive control is available, and the early use of blood and coagulation factors in a damage control resuscitative strategy.

Civilian Experience

Damage control resuscitation defines a new philosophy of acute traumatic resuscitation. Its tenants define a number of important maneuvers during the resuscitation. First is permissive relative hypotension, with a goal systolic blood pressure slightly below normal. Next is prevention and treatment of hypothermia, acidosis, and hypocalcemia, while avoiding hemodilution with crystalloid fluids. Early surgical control of bleeding is also tantamount to damage control resuscitation. Lastly, hemostatic resuscitation with blood products in high ratios of fresh frozen plasma (FFP) and platelets to packed red blood cells, with appropriate use of adjuvants like factor VIIa, and fibrinogen containing compounds, is considered fundamental to this approach to the hemorrhaging patient [59].

There has been ongoing controversy in the surgical literature concerning the optimal use of resuscitative fluids. Questions of type, amount, and timing dominate the ongoing discussion. In addition, some authors maintain that the differences between civilian and military mechanisms of injury limit the applicability of military data to the civilian practice patterns. There is some belief that combat-related injuries result in a distinct patient population, and that lessons learned there may not be translatable to the civilian population [60,61]. However, multiple civilian studies in Europe and in the United States demonstrate similar results to wartime casualties and the benefits to aggressively resuscitating these patients with plasma and platelets versus excessive crystalloid. The evidence in these studies is all retrospective, and is subject to survivor bias and multiple other confounding variables. Unfortunately, no prospective randomized trials have been conducted examining any resuscitation strategy, including damage control resuscitation.

The early coagulopathy of trauma, identified by as early as 1969 by Simmons and Borowiecki, and highlighted separately by Brohi and MacLeod is a common and dangerous condition that many patients manifest upon admission to the emergency department [50]. Brohi defines coagulopathy as prothrombin time (PT) over 18 seconds, activated partial thromboplastin time (aPTT) over 60 seconds, or thrombin time over 15 seconds. This London study found a significant coagulopathy in 24.4% of patients admitted to their ED. This coagulopathic cohort had a much greater mortality (46% vs. 10.9%, $p < 0.001$) compared with those with normal coagulation studies. Contradicting previous suspicions about the contribution of fluids to coagulopathy, Brohi found that the early coagulopathy of trauma was not linked to amount of IV fluids (crystalloid and colloid) administered [49].

Adding to this observation, Gonzalez et al. demonstrated that patients that arrived to the emergency department in a coagulopathic state (INR = 1.8 ± 0.2) and received primarily PRBCs and crystalloid fluids were persistently coagulopathic on admission to the ICU (INR = 1.6 ± 0.1). Ninety-one patients were identified who received > 10 units of PRBCs in the first 24 hours of admission. According to the massive transfusion protocol at that time, FFP was not transfused until the patients received six units of PRBCs. Once admitted to the ICU, patients received a ratio of FFP/PRBC 1:1. Using univariate logistic regression analysis, the authors concluded that risk of mortality was increased with higher initial ICU INR. This study highlighted the potential importance of earlier administration of FFP and its possible benefits in the form of improved patient survival [34].

Recent civilian studies have demonstrated benefits in survival with high FFP to PRBC ratios, as well as platelets to PRBCs. A study by Holcomb et al.included 466 massively transfused (≥ 10 units PRBCs in 24 hours). This retrospective multicenter study demonstrated that patients who received a high ratio of FFP to PRBCs (≥ 1:2) had increased survival (59.6%) compared with those who received a low ratio (< 1:2) of FFP to PRBCs (40.4%, $p = < 0.01$). This effect was also seen in patients who received a high ratio (≥ 1:2) of platelets to PRBCs. Those patients had 59.9% survival compared with those in the low (< 1:2) platelet to PRBCs group, who demonstrated only 40.1% survival at 30 days ($p = < 0.01$) [37]. Another paper with the same cohort of patients highlighted the importance of early (within 6 hours) administration of high FFP ratios. This study showed that a transfusion ratio of ≥ 1:1 FFP/PRBCs in the first 6 hours of admission decreased mortality at 6 hours (2% vs. 15.2% and 37.3% for ratios ≥ 1:1, 1:4 to 1:1, and < 1:4, $p = < 0.001$) and in hospital mortality (25% vs. 41.1% and 54.9% for the same groups, $p = < 0.04$). Patients receiving high platelet/PRBC ratios also had improved survival [62].

Another large single-center retrospective study examined 383 patients that received greater than 10 units of PRBCs in the first 24 hours of admission. This group, from Los Angeles, demonstrated survival benefit with higher ratios of FFP to PRBCs. Patients that received ≤ 1:3 FFP to RBC had 25% mortality, whereas those that received > 1:3 had 49% mortality. Further analysis demonstrated that the mean FFP/PRBC ratio for survivors was 1:2.1. Nonsurvivors received 1:3.7 FFP/PRBC ($p < 0.001$). They concluded that higher FFP/PRBC ratios improve survival, but unlike the Holcomb study, no benefit was shown when ratios were more aggressive than 1:3 [63].

Two recent studies from New Orleans also examine FFP/PRBC ratios and survival. Both are retrospective single center-studies. The first study reports that 135 patients, suffering 72% penetrating injuries, received > 10 units of PRBCs during the first 24 hours of treatment. All of these patients received surgical intervention. In this population they report a dramatic improvement in survival for patients that received > 1:2 FFP to PRBC compared with those who received 1:4, 26% versus 87.5% ($p = 0.0001$) [37]. The second study also examines patients who underwent emergency surgery for trauma and received > 10 units of PRBCs. The population of 135 patients were coagulopathic, as defined by INR > 1.2, PT > 16 seconds, and partial thromboplastin time > 50 seconds. A statistically significant improvement in survival was demonstrated in patients receiving 1:1 ratio of FFP to PRBCs compared with those who received 1:4, 28% compared with 51% ($p = 0.03$). This study also demonstrated an improvement in ICU days (10 vs. 23, $p = < 0.01$) in the 1:1 group versus 1:4 [64].

Other studies have demonstrated improved survival with aggressive use of FFP associated with massive transfusion protocols. One study, from Nashville, is a retrospective study with a historical control before implementation of a massive transfusion protocol that specified a ratio of 2:3 FFP to PRBC and 1:5 platelets to PRBCs. The study included 264 total patients, with 125 in the protocol group and 141 in the historical group. The authors demonstrated an improvement in survival from 37.6% to 56.8% ($p = 0.001$) after implementation of the protocol. The transfusion protocol cohort also protected against MOF in univariate and logistic regression analysis. The authors attribute the protection from multiorgan failure to the overall decrease in number of blood product units that patients received as a result of enrollment into the transfusion protocol [65].

Two recent European studies also demonstrate benefits to early plasma transfusion both in trauma patients and in other surgical patients. Maegele et al.demonstrate survival benefit for trauma patients at < 6 hours, 24 hours, and 30 days in groups that received high (1:1 and < 0.9) ratios of FFP/PRBC. This study included a multicenter retrospective review of 713 patients who received > 10 units PRBCs in 24 hours. Patients who received > 1:1 FFP to PRBCs had 6-hour mortality equal to 24.6%, 24-hour mortality at 32.6%, and 30-day morality at 45.5%. The mortality rates for 1:1 ratio were 9.6%, 16.7%, and 35.1% at the same time points ($p < 0.005$ for all values). However, these increases in survival came with the cost of increase septic-related complications. The incidence of multiorgan failure in the 1:1 FFP/PRBC group was the greatest at 67% [66].

A group of investigators in Denmark have assessed the principles of damage control resuscitation outside of trauma. A review of 832 surgical patients, including abdominal surgery, cardiovascular, orthopedic surgery, and trauma patients, demonstrated improved survival for patients receiving a ratio of FFP/PRBC equal to 1:1.3 compared with those who received 1:1.6. Mortality at 30 days was 20.4% for the high ratio group compared with 31.5% ($p = 0.0002$). Higher FFP/PRBC ratios did increase ICU days and hospital stay [67]. This study suggests that aggressive use of plasma may be indicated in all bleeding patients, regardless of traumatic etiology.

One recent multicenter study from the Glue grant project demonstrates a lower risk of mortality with a high FFP/PRBC ratio, but also highlights risks associated with transfusion. This study, by Sperry et al., included 415 patients and did not show a crude improvement in mortality, but did reveal a significant difference in 24-hour mortality (high FFP/PRBC 3.9% vs. low FFP/PRBC 12.8%, $p = 0.012$). Their high ratio group received ≥ 1:1.5 FFP to PRBCs. On Cox regression analysis, the group demonstrated a 52% reduced risk in mortality if patients received the higher FFP/PRBC ratio ($p = 0.002$). Although there was no increase in multiorgan failure or infection, the high FFP/PRBC group did have an increased (2×) risk of acute respiratory distress syndrome ($p = 0.004$) [68].

Watson et al. demonstrate an association between plasma and MOF in an examination of 1,175 patients in a prospective multicenter study. Using Cox proportional hazard regression, the researchers found a 2.1% increased risk of MOF with every unit of FFP transfused. The risk of ARDS increased 2.5% with

each unit of FFP. However, the group also reported that each unit of FFP decreased the risk of mortality by 2.9% [69].

Other civilian studies that do not find a survival benefit to high FFP/PRBC ratios. Kashuk et al., report a single-center retrospective study that examined 133 patients who received > 10 units of PRBCs in the first 6 hours. This study presented data that patients receiving FFP/PRBC ratios of 1:2 to 1:3 had the lowest predicted probability of mortality. However, the study did note improvement in coagulopathy with higher ratios of FFP/PRBC. However, because of small study size, this was not statistically significant. Also, of important note, the number of patients receiving FFP/PRBC at a 1:1 ratio was only 11 [61]. Another paper, from Baltimore, also fails to demonstrate a survival benefit from high (1:1) FFP/PRBC ratios. However, their massive transfusion subgroup was underpowered, at 81 patients, to demonstrate a survival benefit [60]. A previous study from the same group also highlighted the increased risk of infection and mortality associated with transfusion of PRBCs and FFP [70].

In summary, much like the recent military experience, the preponderance of civilian experience suggest that early and increased use of FFP and platelets in trauma resuscitation results in an overall reduction in early and late mortality. By decreasing early hemorrhagic death, there may be an association with increased risk of infection, ARDS, and multiorgan failure, but patients will survive to suffer these events.

RESUSCITATIVE FLUIDS

In hemorrhagic shock, the choice of intravenous fluid has been long debated and is beyond the scope of this chapter. Historically, a crystalloid solution such as normal saline or lactated Ringer's solution was used in the initial resuscitation. Recent evidence suggests that a more aggressive use of blood and blood products, a so-called damage control resuscitation encompassing "hemostatic resuscitation" may be more beneficial (see Damage Control Resuscitation section). Traditional regimens call for using crystalloids while awaiting blood products from the blood bank, with a rate of infusion of 500 mL to 1,000 mL bolus during 15 to 20 minutes and repeated as necessary. Certainly by the time 2 L of crystalloid have been used for resuscitation, blood product replacement should be given at similar rates of infusion. All fluids should be infused via a warming device to alleviate or prevent hypothermia. Unfortunately, this approach may worsen the coagulopathy present in the most severely injured trauma patients.

Our current recommendations are to minimize the amount of crystalloid a patient receives. Physicians in the ED have little control over what fluids a patient may receive before arrival to the hospital. Blood is the fluid of choice to resuscitate the surgical patient from hemorrhage. Although hemorrhage as the cause of shock had been debated for many years, the treatment of hemorrhage by returning blood to the body seemed logical. The first successful animal transfusion was by Richard Lower in 1665. In 1667, he transfused the blood of a lamb into a human to treat melancholy [71]. Because of transfusion reactions, blood transfusions were infrequently used before the 1900s. During this period, however, the use of autotransfusion emerged. The first American use of autotransfusion was in 1916 after a splenectomy. World War I saw the widespread use of blood banks. Brown, in 1931, was the first to autotransfuse the blood obtained from a hemothorax [72]. World War II demonstrated that truly massive use of blood across multiple theaters of war was possible. With the advent of cardiac surgery in the 1950s, autotransfusion became more common [73]. Its usefulness for the trauma victim was firmly established in the late 1960s and the early 1970s [74–78]. Complications from autotransfusion such as thrombocytopenia, disseminated intravascular coagulopathy (DIC), hypofibrinogenemia, infection, and air embolism have been well documented [78]. Improvement of delivery systems with filters and air monitors, as well as a limit to the amount of blood autotransfused, has kept these problems to a minimum. Because autotransfusion has restrictions on its use, autotransfusion alone will never be adequate for resuscitation, but the value of its use should not be overlooked.

Whole blood contains all of the factors lost by the bleeding patient; this includes plasma proteins, clotting factors, platelets, and white blood cells, as well as erythrocytes. Although FWB is a superb resuscitation fluid, it has a short storage life [36]. Infectious disease testing and blood banking inventory management issues have made FWB largely unavailable in civilian trauma centers. However, whole blood is used in many centers and clinical studies on whole blood are planned for civilian trauma patients. Prospective data collected in these studies may present an impetus for change in blood banking and provide access to this resuscitative fluid.

Usually, oxygen-carrying capacity is gained by giving RBCs. These should be typed and cross-matched to the patient to avoid transfusion reactions. In severe hemorrhage, time may not be available for cross-matching, so type-specific or even O-negative blood should be administered. PRBCs can be stored for 42 days according to current FDA standards. However, detrimental effects of stored PRBCs can be related to their age. Hyperkalemia is a well-known problem with red cell storage. Potassium is lost into the PRBC supernatant at a rate of 1 mEq a day [79]. Cardiac events have been attributed to PRBCs stored for less than a week [80]. Also multiple studies have documented increased infection risk, multiorgan failure and decreased survival associated with older RBCs [81–85]. Despite safeguards, clerical errors lead to mismatched blood administrations, with a rate of fatal major ABO blood group reactions of between 1 in 500,000 and 1 in 2 million. Currently, the risk of infection from a transfused unit is 1 in 30,000 to 1 in 150,000 for hepatitis C, and 1 in 200,000 to 1 in 2,000,000 for human immunodeficiency virus [86].

Thawed plasma is FFP that is stored for up to 5 days at 1°C to 6°C. This storage timeline is based on similar red blood cell storage guidelines and preservation of factors V and VIII, however clinical data is lacking [59,87]. It is unknown what the biologic effect is of storing thousands of proteins at 4°C for 5 days and then administrating them to patients who are in shock. As more centers are using earlier and increased amounts of plasma, thawed plasma is now routinely available at many trauma centers, and increasingly stored in emergency departments. Type AB plasma, the universal donor for plasma, is chosen initially before cross-matched product is available. Having thawed plasma available in the ED allows for identification of severely injured patients requiring massive transfusion and initiation of a protocol driven high ratio of FFP to PRBCs. Primary risks associated with plasma are transfusion-related lung injury (TRALI), infection, and multiorgan failure [69,70]. As described earlier, the risk of infection and MOF was increased 2.1% with each unit of plasma [69]. However, these observations have been made in the context of higher survival in patients that received high ratios of FFP, suggesting that those patients survived with the potential cost of developing sepsis and multiorgan failure.

Platelets are transfused in two different formulations. Pooled whole blood-derived platelets are generally transfused in six unit increments from five to six different blood donors. Apheresis platelet units are derived from a single donor and are transfused in volumes approximately equal to five to six units of pooled whole blood-derived platelets. Both types of platelets are stored at room temperature for up to 5 days. Bacterial contamination from skin flora remains the greatest risk of platelet transfusion. However, apheresis platelet units have been shown

to have lower risk of infection in the United States. This risk is derived from a decreased number of venipunctures of donors. European studies have failed to demonstrate a similar benefit [88].

Cryoprecipitate is a product of FFP that contains factor VIII, von Willebrand factor, fibrinogen, fibronectin, factor XIII, and platelet microparticles. Cryoprecipitate is made after centrifuging thawed plasma and removing the supernatant. It has a shelf life of one year when frozen at −20°C [89]. The American Association of Blood Banks mandates a minimum of 150 mg of fibrinogen per unit. Cryoprecipitate is customarily transfused in 10 unit bags, although this is highly variable. As a result of this practice, patients generally receive 2.5 g of cryoprecipitate per transfusion. Its indications for use and benefits derived from it are controversial. Two studies from the military demonstrate improved survival in patients who received relatively high doses of cryoprecipitate [90,91]. Fibrinogen concentrate, a product licensed for use in many European countries, has also been investigated. Fries et al., in Austria, have demonstrated that blood loss is decreased after administration of fibrinogen in coagulopathic swine with a liver injury [92]. Ex vivo experiments also demonstrated improved clot characteristics after administration of fibrinogen concentrate [93,94]. However, the data for this product are limited and this is a potential area of clinical investigation.

HTS is any sodium chloride solution that is more concentrated than normal saline. Solutions of 3.0%, 5%, and 7.5% are commercially available. However, 7.5% HS is not approved for use in the United States. High concentrations of sodium chloride in the vascular system favor the flux of water from the interstitial space and from the cells to augment the blood volume. This results in a rapid restoration of intravascular volume. Infusions of small amounts of these solutions lead to hemodynamic responses equivalent to much larger volumes of crystalloid solutions. This is advantageous because of the rapidity of the response. In some military and wilderness environments, the smaller and much lighter volume of fluid is a significant advantage logistically. Recent work suggests that these fluids decrease the activation of neutrophils, so they may offer an advantage in preventing multiple organ dysfunction syndrome [95]. The proponents of these fluids believe that the smaller volumes lead to less tissue edema and associated potential complications. Once fluid is drawn into the vascular space, the sodium chloride is diluted, so it then equilibrates across the fluid spaces of the body. As this happens, the effect of the HTS is gradually lost. Increases in mean arterial pressure are short-lived, with hemodynamic effects lasting only 15 to 75 minutes [96]. The largest potential danger with hypertonic solutions is hypernatremia. This may be accentuated in the previously dehydrated patient without additional extravascular fluid to donate to the vascular system. Although some rapid and transient hypernatremia seems to be tolerated, caution in administration and careful monitoring of sodium levels are important in the safe use of these solutions [97].

Vasopressor agents can be useful for achieving a minimal acceptable blood pressure, but typically only after adequate resuscitation. Phenylephrine, dopamine, norepinephrine, and vasopressin are the preferred agents, starting in the lower dose range. If blood pressure and intravascular volume status are acceptable but there is evidence of ongoing hypoperfusion (elevated lactate or base deficit), an inotropic agent such as dobutamine or dopamine can be used. Recent work suggests that adrenal insufficiency is much more common than previously thought, especially in conjunction with etomidate use, and responds well to 2 to 3 days of steroids and vasopressin [98].

In general, the intensivist should approach cardiovascular support in the surgical and trauma patient using the four parameters of hemodynamic performance: (a) preload (best index: pulmonary artery occlusion pressure, "wedge"), (b) afterload (best index: calculated systemic vascular resistance = (mean arterial pressure − central venous pressure [CVP])/cardiac output × 80), (c) cardiac contractility (best index: stroke volume = cardiac output/heart rate), and (d) heart rate. All but heart rate traditionally require invasive monitoring with a pulmonary artery catheter for accurate measurement.

For intravascular volume depletion, hypovolemia, and cardiovascular instability due to sepsis, this manipulation of variables should proceed in the order listed, assuring adequate preload (wedge of 15 to 18 mm Hg) by volume repletion before adjusting other variables (such as adding inotropes for diminished cardiac output). There is, however, a certain cohort of surgical patients who are "nonresponders" to ongoing volume resuscitation. These patients do not vasodilate with initial volume loading. Additional volume loading in the setting of persistent high systemic vascular resistance sets the stage for a problematic tissue edema entity called secondary abdominal compartment syndrome (ACS) wherein intra-abdominal pressure reaches deleterious levels due to "third-spacing" of resuscitation fluid in the abdomen. This occurs in patients without intra-abdominal injuries who require massive resuscitation for injuries in which hemorrhage control is difficult or delayed (e.g., pelvic fractures, mangled extremities). These are the patients who receive 10 to 20 L of crystalloid. In contrast, primary ACS occurs in patients with abdominal injury and the ACS is directly attributed to hemorrhage and tissue response within the abdomen to the primary trauma. Formation of secondary ACS in this group of nonresponders led Balogh and colleagues [99] to decrease DO_2 goal from 600 or more to 500 mL per minute per m^2. The cardiac index and SvO_2 response to this ICU resuscitation protocol and clearance of metabolic acidosis were similar to historic matched controls. The DO_2 600 or more cohort received significantly more crystalloid, had greater incidence of intra-abdominal pressure more than 20 mm Hg (42% vs. 20%; $p < 0.05$), ACS (16% vs. 8%), MOF (22% vs. 9%), and death (27% vs. 11%). The use of plasma has also been linked to avoiding ACS. Cotton et al. demonstrate a significant decrease (from 9.9% to 0%, $p < 0.001$) in the incidence of ACS after implementation of a massive transfusion protocol [65].

MANAGEMENT OF COAGULOPATHY

Ideally decisions regarding management of coagulopathy in trauma, the operating room, or the ICU ideally should be based on laboratory data. Unfortunately, this ideal situation is rarely achieved. Although point-of-care coagulation testing is commercially available via devices designed for home use monitoring of INR, most EDs and ICUs do not have this capability, and they have not been validated in critically injured patients. Patients who have received large amounts of crystalloids, colloids, and/or packed RBCs or other blood components should have a coagulation panel performed that includes PT, activated partial thromboplastin time, INR, and platelet count. When suspicion of consumption and/or dilutional coagulopathy exists, a more complete coagulopathy panel should be performed to include fibrinogen, d-dimer, and fibrin split products. The bleeding patient with thrombocytopenia, hypofibrinogenemia, elevated fibrin split products, and d-dimer should be considered to have a dilutional coagulopathy. We have recently added thromboelastography (TEG) to our coagulation panel.

A recent study by Hess et al. describes the relationship of abnormal coagulation studies and mortality. This paper highlights the connection between injury severity score and coagulopathy, with a linear correlation between the two values. The authors find that an abnormal INR increases the risk of death

from 4.2% to 26.4%. Abnormal aPTT increases the risk from 4.0% to 43.2%. These laboratory values are therefore cheap and reliable indicators of mortality risk, and suggest that early and aggressive treatment of coagulopathy may impact survival [100].

TEG, a simple test developed in 1948 and used primarily in cardiac and transplant surgery, provides a rapid and comprehensive analysis of coagulation status and can likely be used in place of a DIC panel [101–104]. Use of the thrombelastography test is occurring more frequently in trauma patients. In swine TEG has been shown to be a more sensitive test than PT and aPTT, and may be a better test than traditional laboratory tests [105]. TEG has been shown to be better in certain circumstances as it allows testing of blood in its in vivo state temperature rather than warming it up in the laboratory. Watts et al. [106] showed enzyme slowing and decreased platelet function each individually contribute to hypothermic coagulopathy in trauma patients, particularly at body temperatures $< 34^{\circ}C$, whereas such changes were not evident on standard coagulation testing. TEG will likely become more widely used as clinicians become more aware of its usefulness and limitations.

Because prolonged hypotension is a known predisposing factor for the development of coagulopathy after trauma, aggressive resuscitation is the most critical factor in prevention of coagulopathy in the injured patient [107]. Platelets and coagulation factors are consumed with ongoing bleeding. In addition, intravascular volume replacement with crystalloid, colloid, or packed RBCs results in dilution of coagulation factors and platelets, with dilutional thrombocytopenia being the most frequent coagulopathy in trauma patients [108,109]. DCR concepts describe replacing lost intravascular volume with plasma and platelet proteins and minimizing ongoing dilution with excessive crystalloids. Various formulas exist regarding whether to begin with platelets, cryoprecipitate, or FFP when correcting dilutional coagulopathies and regarding when to begin this replacement (e.g., after *n* units of packed RBCs).

Recent studies have investigated the role of activated protein C in traumatic coagulopathy. Brohi et al. describe indirect evidence for consumption of activated protein C as a result of hypoperfusion [110]. Another study by Brohi correlates d-dimer levels, as a corollary of fibrinolysis, with degree of shock and hypoperfusion. This relationship between shock and the anticoagulant and fibrinolytic pathways suggests the need to decrease the severity and duration of shock as a method to manage coagulopathy [111].

If laboratory data are available, they can be used to guide therapy. However in most rapidly bleeding patient's laboratory data returns far too slowly to make intelligent decisions for optimal care. It is this reason that ratio driven transfusion is likely optimal while the patient is bleeding. Once bleeding is controlled, transfusion therapy can convert to laboratory driven parameters. Platelet counts can be obtained to assess need for platelet transfusion (see later discussion), PT/activated partial thromboplastin time to assess need for FFP (if PT or activated partial thromboplastin time are greater than 1.5 times normal), and fibrinogen levels to assess need for FFP (below normal fibrinogen level) and/or cryoprecipitate (fibrinogen levels less than 100 mg per dL). A panel of the aforementioned tests plus fibrin split products and d-dimer demonstrate whether dilutional coagulopathy or fibrinolysis is present. [112]. Conversely, if TEG is available (especially rapid TEG), it likely can be used to drive optimal use of blood products, although these guidelines have not been prospectively validated [113].

Acute hemolytic transfusion reactions, although rare, remain a cause of coagulopathy (from compatibility mismatch). The physician must consider this as a possible inciting cause for DIC, especially when no other cause is apparent. The physician must also be familiar with other less common coagulopathies in the trauma patient (and treatment) such as primary fibrinolysis (epsilon–aminocaproic acid), uremia (desmopressin/1-deamino-8-d-arginine vasopressin), and primary liver disease (FFP and vitamin K). With wider spread of the use of TEG early in trauma resuscitation, the incidence of fibrinolysis is likely to increase.

Platelet counts of less than 20,000 per μL should always be corrected in any bleeding trauma patient being resuscitated, whether or not a life-threatening injury has been identified. If the patient has a known history of aspirin use within the preceding 7 days, ibuprofen or other nonsteroidal anti-inflammatory drug use within the last 2 to 3 days, or an unknown history, it may be necessary to transfuse platelets despite a platelet count greater than 50,000 per μL, particularly in those patients with head injury or those being managed nonoperatively for significant liver or other solid organ injury. Platelet counts of less than 100,000 per μL are a relative indication for platelet transfusion in the head-injured patient with evidence of intracranial hemorrhage, whether as a single-system injury or as part of multisystem injuries. Each unit of platelets transfused can be expected to raise the platelet count by at least 5,000. It is possible that we have been overly restrictive in the use of platelet transfusions, as recent data suggests that increased and early use improves survival, and that keeping platelet counts > 100,000 are associated with improved outcomes [66,89].

Recombinant factor VIIa (rFVIIa) has emerged as an adjuvant to plasma and platelets in the military and has also been extensively studied in civilian trauma centers. However, there exists controversy on timing, appropriate doses, and indications for the use of recombinant factor VIIa [114]. One Level I study on rFVIIa has been published. The primary endpoint for this randomized double-blind clinical trial was blood product use. In blunt trauma patients, a decreased need for RBC transfusion was seen in patients who received rFVIIa (14% vs. 33% required > 20 units of PRBCs, $p = 0.02$). In penetrating trauma, a similar trend was demonstrated, but it did not decrease statistical significance. There were no differences in thrombotic complications between groups and mortality differences were not seen [115]. One military study did demonstrate a survival benefit in patients who received rFVIIa compared to those that did not (14% vs. 35%, $p = 0.01$). Other retrospective studies have demonstrated decreased transfusion requirements with rFVIIa use and no increase in thromboembolic events when matched to controls [116]. Timing of administration has also been studied. The dose of rFVIIa seems to be most effective when given early in a massive transfusion protocol [117]. The use of rFVIIa remains controversial and may be considered as an adjuvant to massive transfusion, based on individual physician preference, although no improvement in survival has been seen.

The early use of plasma and platelets has been demonstrated to improve coagulopathy, although it is unclear why this happens. It seems simplistic to think a minimally improved INR could account for changes in survival or be based on replacing a small percentage of lost coagulation factors. Dente et al.demonstrated an improvement in PT and INR (15.1 ± 0.26 and 1.31 ± 0.29 compared with 17.5 ± 1.1 and 1.72 ± 0.17, $p = 0.04$) with their massive transfusion protocol compared with a historical control group. These benefits were demonstrated on admission to the ICU [118]. Subjectively, using the concepts of DCR has decreased the incidence of coagulopathic bleeding, allowing easier control of surgical bleeding [119]. By identifying patients with coagulopathy secondary to injury, early implementation of an evidenced-based massive transfusion protocol should decrease coagulopathy and improve the possibility of survival. Our recommendation marries the use of a massive transfusion protocol to the tenants of damage control resuscitation. This approach to the severely injured trauma patient will improve survival, but also may present more risk to infection and multi-organ failure. Patients will, however, suffer those complications with the benefit of survival. Critics

of this approach have wisely and appropriately noted the pitfalls of retrospective studies and the potential for survivorship bias. To address these concerns, prospective observational trials are ongoing and randomized control trials are being planned.

PRACTICING DAMAGE CONTROL RESUSCITATION

Damage control resuscitation consists of two components: Hypotensive resuscitation and hemostatic resuscitation [120,121]. Hypotensive resuscitation is a military concept that dates from World Wars I and II, and was resurrected in the early 1990s in Houston. The key is to maximize the resuscitation benefit to the mitochondria while at the same time minimizing rebleeding by not "popping the clot," a strategy that is supported by a significant body of scientific data. This not only preserves the resuscitation fluid within the vascular system but is also logistically sound by preventing needless waste of blood and fluids [20,46,122–127].

Hemostatic resuscitation is a concept centered on the surgical judgment inherent in damage control surgery, namely, "staying out of trouble rather than getting out of trouble" [120,121,128]. By focusing on restoring normal physiology, rather than normal anatomy, this surgical approach has decreased mortality in severely injured trauma patients and has become standard surgical teaching. From a resuscitation viewpoint, the damage control philosophy can be extended to resuscitation, focusing on restoring normal coagulation and minimizing crystalloid and even initial packed RBC resuscitation in the severely injured casualty. Both traditional resuscitation products further dilute the already deficient coagulation factors and can increase MOF [129–139]. The aggressive hemostatic resuscitation techniques described herein should be performed in parallel with equally aggressive and definitive control of bleeding.

PROCESS OF DAMAGE CONTROL RESUSCITATION

The first element of damage control resuscitation is the rapid diagnosis and surgical control of named vessels and gauze packing (standard damage control surgery) in the operating room. Damage control surgery has improved outcomes in severely injured trauma patients [125,128].

Thawed plasma is used as a primary resuscitative fluid, and is started in the ED. This product is shelf-stable for 5 days and thus is available on casualty arrival. This approach not only addresses the metabolic abnormality of shock, but also reverses the coagulopathy present on arrival in the ED. Storing plasma for 5 days does not significantly impair the labile factors (V and VIII), and allows this product to be immediately available for transfusion [140]. The Office of the U.S. Army Surgeon General Blood Bank consultant has recommended use of thawed plasma in theaters and the only two Level 1 trauma centers in the Department of Defense have this product available for their trauma patients [47,120,121].

The packed RBC to plasma ratio of 1:1, early transfusion of platelets, and cryoprecipitate are indicated [141,142]. Coagulopathy is not only present on presentation to the ED but is exacerbated by the "bloody vicious cycle" of hemorrhage leading to crystalloid resuscitation, then hemodilution and hypothermia, followed by further hemorrhage, and so on [48,49,52]. Furthermore, transfusion of large amounts of preserved RBCs contributes to a dilutional coagulopathy, which is primarily the result of thrombocytopenia and poor platelet function [129–131]. In addition, compared to fresh blood cells, stored platelets demonstrate decreased thrombotic function, primarily due to a decrease in expression of high-affinity thrombin receptors during platelet storage [143].

End Points of Resuscitation

The search has been to find this "holy grail" of resuscitation: a better end point of adequate resuscitation than heart rate, blood pressure, or urine output. Cardiac output, venous return, low perfusion, and acidosis were all observed in Cannon's original shock experiments [122,144]. Urine output is often used as a surrogate marker of adequate resuscitation of an end organ, but has several drawbacks as a lone marker of adequacy of resuscitation. Resuscitation to normal levels of oxygen delivery and oxygen consumption were seen as possible goals of resuscitation, but even using these parameters, a significant number of patients proceeded to organ failure and death.

Lactate that accumulates with a lack of tissue oxygenation correlates with base deficit in hemorrhagic shock. Correction of an elevated serum lactate or base deficit is viewed as a better, if not the best, end point for resuscitation of hemorrhagic shock [145]. One criticism of using the base deficit is that its recovery lags behind resuscitation, it is complicated by excess chloride, and its continued pursuit of a normal value leads to overresuscitation. Serum lactate elevation has also been criticized as being too broad a test, and it does not portray what goes on at the cellular level.

Therefore, other techniques that include subcutaneous or intraluminal oxygen tension probes and gastric or luminal wall pH probes have all been described to show end-organ resuscitation [146–148]. Most recently, the use of near-infrared spectroscopy has shown promise in identifying patients in shock, but it remains to be seen if these indices can be used to judge adequacy of resuscitation from shock [149,150]. They all have their benefits, but they are variously invasive and expensive in relation to serum base deficit and lactate. At this time, their impracticality precludes their generalized use [151].

CONCLUSIONS

The thoughtful intensivist balances all needs of the patient when using blood products, fluids, and drugs in the resuscitation of patients in shock. Volume replacement is given for lost volume. Oxygen-carrying capacity replaces lost RBCs, and coagulopathy is reversed with hemostatic replenishment. Judicious use of steroids, pressors, and metabolic control are

TABLE 158.2

SUMMARY OF ADVANCES IN MANAGING RESUSCITATION BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

- A restrictive transfusion strategy is at least as effective and possibly superior to a liberal transfusion strategy in critically ill patients, with the possible exception of acute myocardial infarction and unstable angina patients [5].
- Factor VIIa decreased transfusions with *trends* toward decreased mortality and critical complications [115].
- Gastric mucosal pH may be an important marker of resuscitation and may provide an early warning for systemic complications in the postresuscitative period [148].
- Etomidate use results in temporary and reversible adrenal insufficiency, responsive to vasopressin and steroids [98].

the order of the day. The effect of each treatment is carefully monitored for its impact on the patient in a stepwise fashion, all the while monitoring indicators of tissue perfusion. Interventions are crisply applied and then removed on the basis of critically and serially evaluated data.

Research must continue to focus on rapid surgical control of hemorrhage and the use of hemostatic adjuncts. Research should also consider the immunologic and coagulation response of the body when creating a better fluid for initial resuscitation, such as an oxygen-carrying product, and the identification of accurate measurements of adequate resuscitation. The overarching metabolic milieu, including adrenal function, glucose control, and response to vasoactive medications, must also be carefully studied for best practices and best combination therapies, including dose–response effects. Finally, identifying the best marker or, better yet, combination of markers to prove adequacy of resuscitation deserve thorough study. The risks and benefits of given therapies must be thoughtfully balanced, given the needs of the patient in a particular situation.

Advances in managing resuscitation, based on randomized controlled trials or meta-analyses of such trials, are summarized in Table 158.2.

ACKNOWLEDGMENTS

The authors would like to acknowledge the outstanding contributions to this chapter by Dr. David G. Burris, Dr. Christoph R. Kaufmann, Dr. David Elliot, and all the brave men and women of the 10th Combat Support Hospital and the 332nd Expeditionary Medical Group, Iraq.

CHAPTER 159 ■ THE MANAGEMENT OF SEPSIS

PAUL E. MARIK

Sepsis is among the most common reasons for admission to medical ICUs throughout the world. Over the last two decades, the incidence of sepsis in the United States has trebled and is now the 10th leading cause of death [1,2]. Advances in medical technologies, the increasing use of immunosuppressive agents, and the aging of the population have contributed to the exponential increase in the incidence of sepsis. In the United States alone, approximately 750,000 cases of sepsis occur each year, at least 225,000 of which are fatal [1,2]. Septic patients are generally hospitalized for extended periods, rarely leaving the ICU before 2 to 3 weeks. Despite the use of antimicrobial agents and advanced life support, the case fatality rate for patients with sepsis has remained between 20% and 30% over the last two decades [1,2]. This chapter provides an overview of this vast topic with particular emphasis on the management of severe sepsis and septic shock.

DEFINITIONS

Sepsis originally meant "putrefaction," a decomposition of organic matter by bacteria and fungi. Since then, a wide variety

of definitions have been applied to sepsis, including sepsis syndrome, severe sepsis, septicemia, and septic shock [3]. In 1991, the American College of Chest Physicians/Society of Critical Care Medicine developed a new set of terms and definitions to define "sepsis" in a more precise manner [4]. The definitions take into account the findings that sepsis may result from a multitude of infectious agents and microbial mediators and may not be associated with actual bloodstream infection. Although the use of these criteria has been criticized and a "newer" diagnostic schema has been suggested (PIRO, which stands for predisposition, insult infection, response, organ dysfunction), these criteria still provide a useful framework to approach patients with infectious diseases [5]. The term "systemic inflammatory response syndrome" (SIRS) was coined to describe the common systemic response to a wide variety of insults. It is characterized by two or more of the following clinical manifestations: (a) a body temperature of $>38^{\circ}C$ or $<36^{\circ}C$; (b) a heart rate greater than 90 beats per minute; (c) tachypnea, as manifested by a respiratory rate of greater than 20 breaths per minute; (d) an alteration of the WBC count of greater than 12,000 cells per mm^3, less than 4,000 cells per mm^3 or the presence of greater than 10% immature neutrophils. When the SIRS is the result of a confirmed infectious process, it is termed "sepsis." Severe sepsis is defined as sepsis plus either organ dysfunction or evidence of hypoperfusion or hypotension. Septic shock is best defined as systolic pressure less than 90 mm Hg (or a fall in systolic pressure of >40 mm Hg) or a mean arterial pressure less than 65 mm Hg after a crystalloid fluid challenge of 30 mL per kg body weight (approximately 2,000 mL) in patients with sepsis and in the absence of other causes for hypotension [6]. In a patient previously known to have a low baseline blood pressure, septic shock is defined as a 30% or greater drop in the mean arterial pressure.

Three stages in the hierarchy of the host's response to infection was therefore recognized, namely, sepsis, severe sepsis and septic shock, with sepsis having the best prognosis and septic shock the worst. Data from recently published trials support this postulate, with the mortality from sepsis ranging from 10% to 15%, severe sepsis from 17% to 20% and septic shock from 43 to 54% [6]. The distinction between severe sepsis and septic shock is critically important as it stratifies patients into groups with a low and high risk of dying respectively. It also suggests that a more aggressive treatment strategy may be indicated in patients with septic shock (see Fig. 159.1).

In patients with shock, the serum lactate has long been recognized to be a marker of disease severity and to be useful for disease stratification [7,8]. Septic patients with a lactate above 4 mmol per L are at an increased risk of death and warrant a more aggressive approach to resuscitation [9–11]. In addition the rate of lactate clearance has been demonstrated to be a good prognostic marker [12].

SITES OF INFECTION AND BACTERIOLOGY

The microbiology and primary sources of infection have undergone a remarkable transition over the past 30 years. The predominant pathogens responsible for sepsis in the 1960s and 1970s were Gram-negative bacilli; however, over the last few decades there has been a progressive increase in the incidence of sepsis caused by Gram-positive and opportunistic fungal pathogens [1]. Data from the large sepsis trials published during the last decade indicate that Gram-positive and Gram-negative pathogens are responsible for about 25% of infections each, with a further 15% due to mixed Gram-positive, Gram-negative organisms, with fungal pathogens accounting for between 5% and 10% of cases. This evolution in the spectrum of pathogens has been associated with an increase in the incidence of multiresistant organisms. Although the abdomen was the major source of infection from 1970 to 1990, in the last two decades pulmonary infections have emerged as the most frequent site of infection.

PATHOGENESIS OF SEPSIS

The pathogenesis of sepsis is exceeding complex and involves an interaction between multiple microbial and hosts factors. Indeed, after exposure to both Gram-negative and Gram-positive bacteria, macrophages upregulate the expression of over 1,000 genes (and proteins) and downregulate an excess of 300 genes, the net result depending on the complex interrelated interaction of these factors [13]. With advances in molecular biology many of the mysteries of sepsis are being unraveled; however, we have only just embarked on our journey along the "sepsis superhighway." The reader is referred to many excellent reviews on this topic [14–19]. Essentially as noted by William Osler in 1921 "*except on a few occasions the patient appears to die from the body's response to infection rather than from it*" [20]. Sepsis can be viewed as an excessively exuberant proinflammatory response with increased production of proinflammatory mediators with activation of leukocytes, mononuclear cells, and the coagulation cascade. The end result is widespread microvascular and cellular injury. The cellular injury results in alteration of cellular and subcellular membranes and receptors, activation of intracellular enzymes, increased apoptosis, mitochondrial dysfunction, and sepsis-related immunosuppression. The excessive proinflammatory responses together with activation of the coagulation cascade are believed to be fundamental events resulting in a systemic microvascular injury. The systemic microvascular injury is a defining characteristic of sepsis and is believed to play a major pathophysiologic role in the progressive organ dysfunction of sepsis.

ORGAN SYSTEM INVOLVEMENT IN SEPSIS

The Hemodynamic Derangements of Sepsis

Sepsis is characterized by a complex combination of cardiovascular derangements, including vasodilation, hypovolemia, myocardial depression, and altered microvascular flow. In volume resuscitated patients with septic shock, systemic vascular resistance is usually low, contractility and biventricular ejection fractions are reduced while ventricular dimensions and heart rate are increased. Despite these changes, volume resuscitated patients typically have a hyperdynamic circulation with a high cardiac output. However, recent data suggest that up to 60% of patients with septic shock may have a hypodynamic circulation with a deceased ejection fraction ($<45\%$) and global left ventricular (LV) hypokinesia [21]. Furthermore, increasing evidence suggests that patients with sepsis develop structural injury to the contractile apparatus of the heart that may contribute to the myocardial dysfunction in sepsis. This is evident by elevated levels of troponin and B-type natriuretic peptide in patients with sepsis [22–24]. Estimates of LV ejection fraction correlate negatively with increased levels of cardiac troponin in patients with septic shock. These data suggest that all patients with sepsis should undergo serial echocardiography to characterize the hemodynamic pattern, as this impacts on the approach to the use of vasopressor and inotropic agents [21]. In addition, cardiac troponin should be measured to assess the degree of myocardial injury.

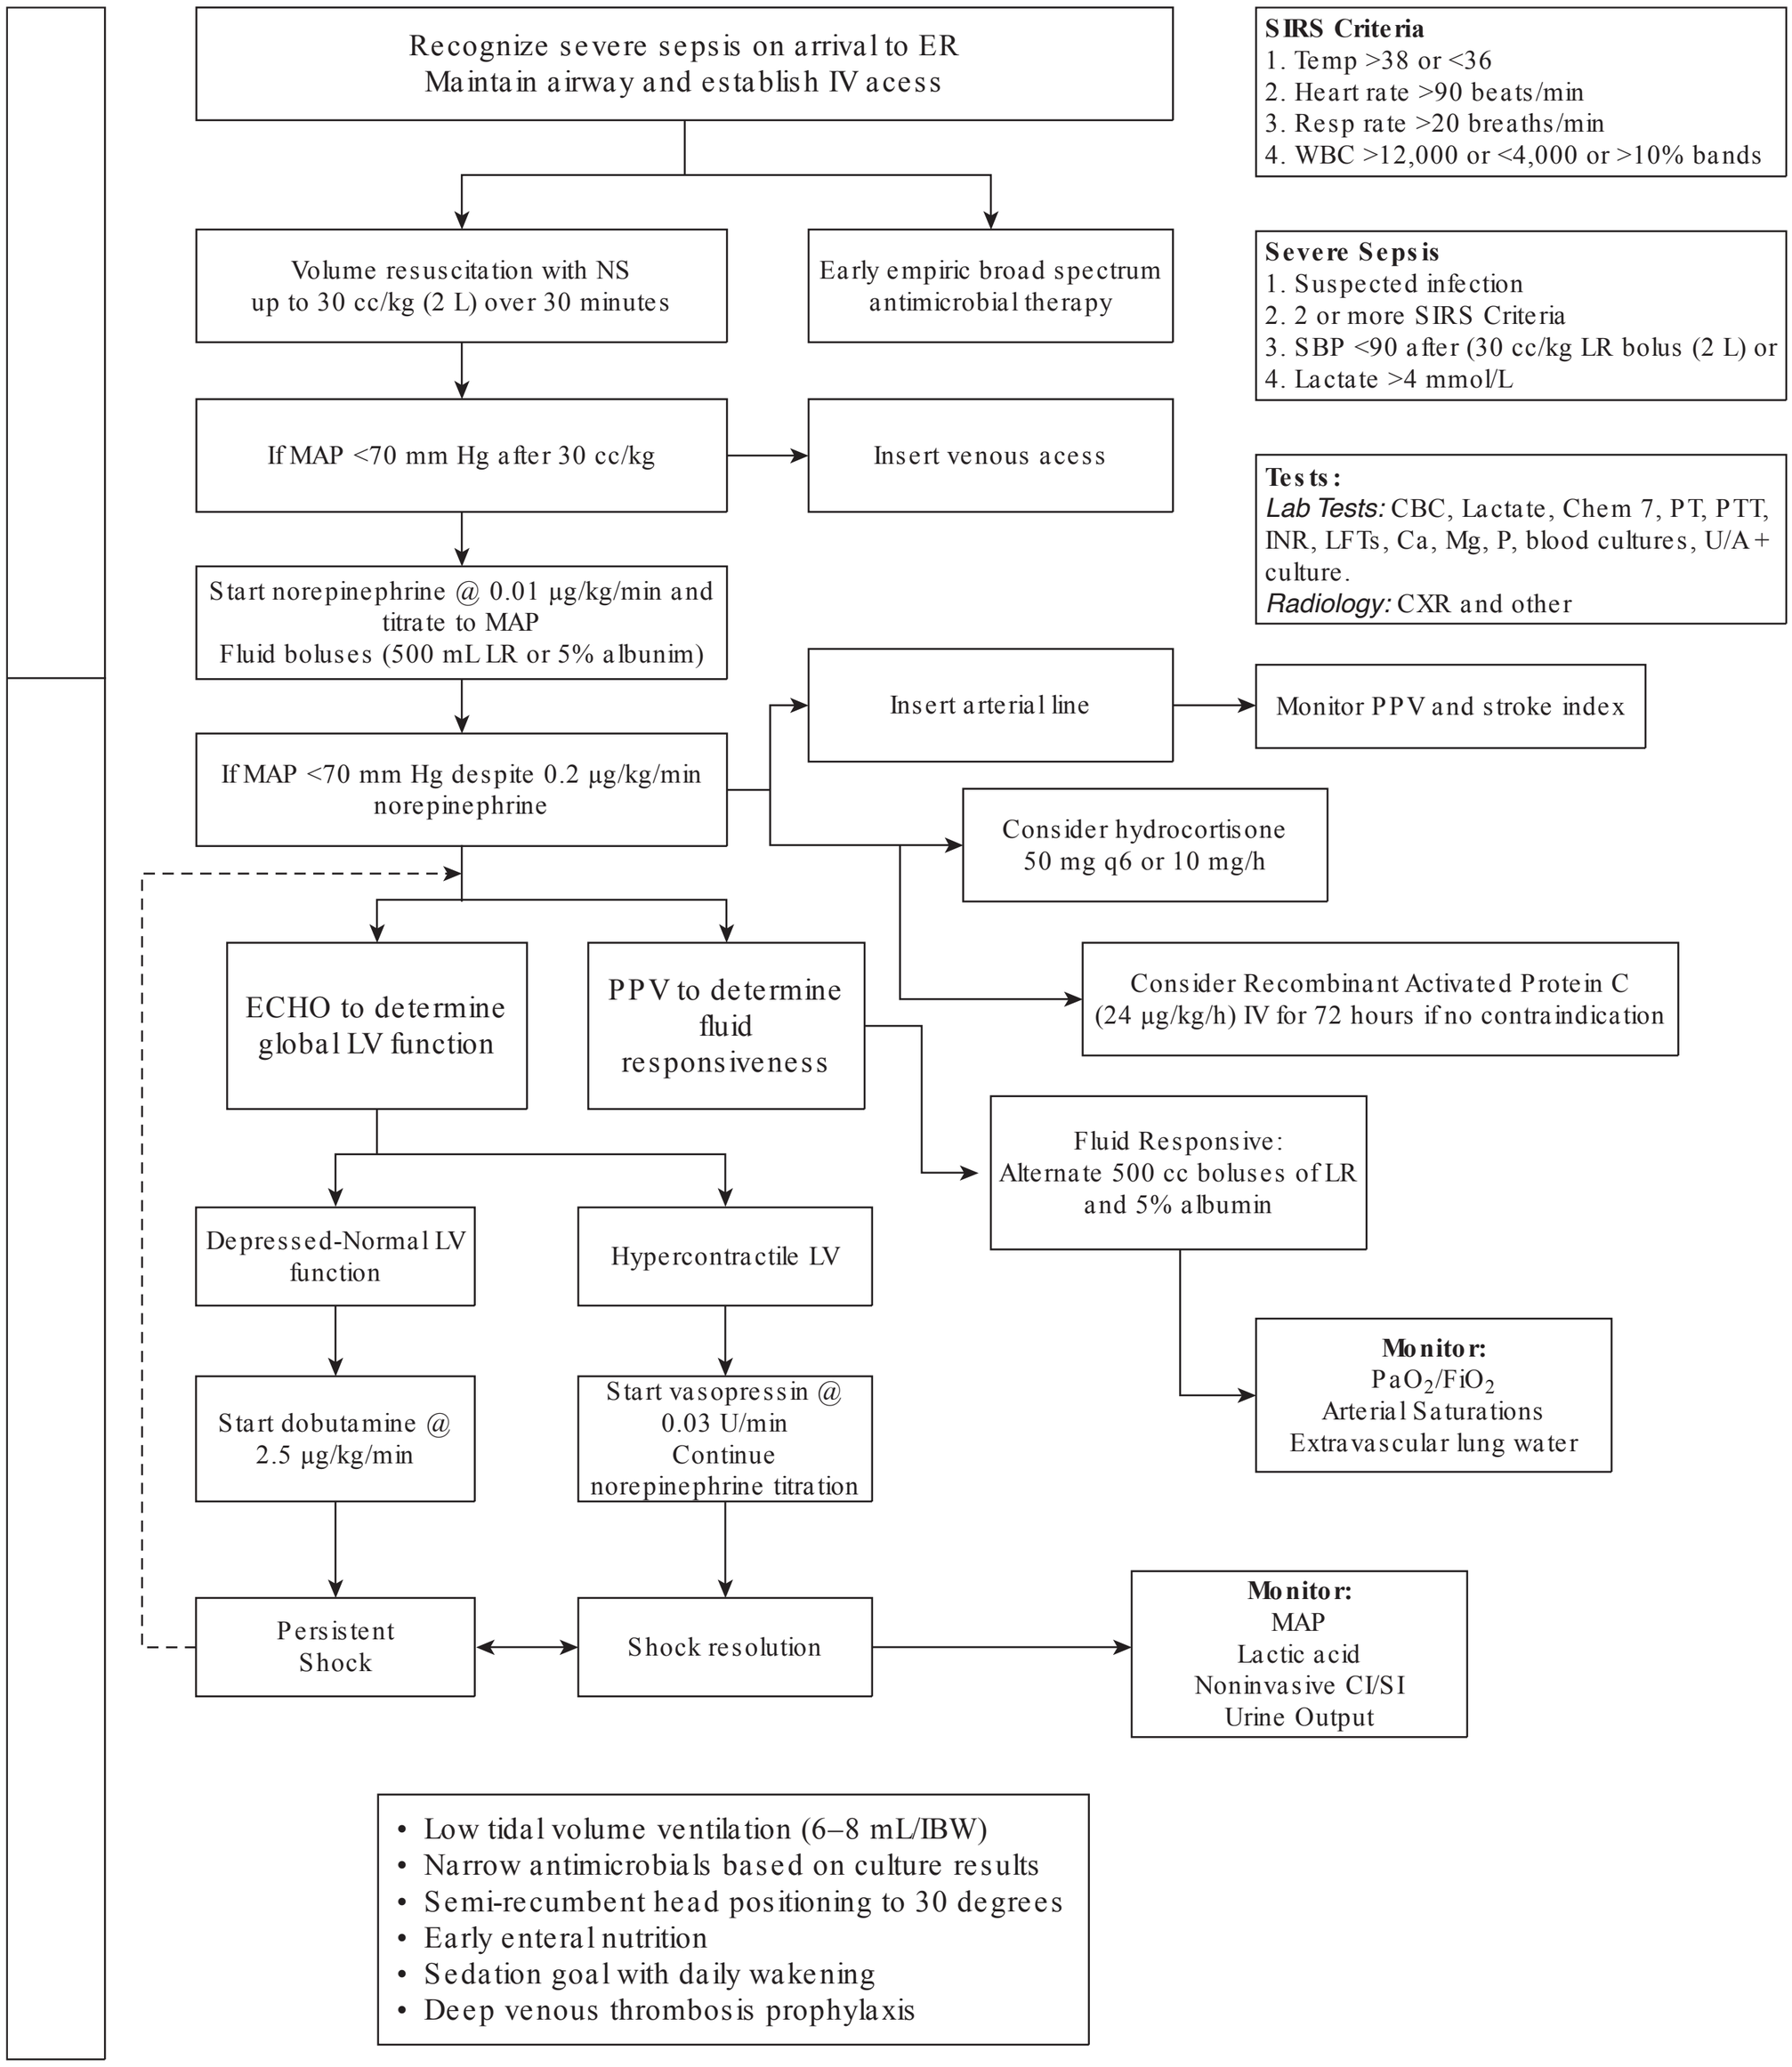

FIGURE 159.1. Suggested approach to the management of patients with severe sepsis and septic shock. CBC, complete blood cell count; CI, cardiac index; CXR, chest x-ray; ER, emergency room; IBW, ideal body weight; ICU, intensive care unit; IV, intravenous; LFTs, liver function tests; LR, lactated Ringer's solution; LV, left ventricle; MAP, mean arterial pressure; NS, normal saline; PPV, pulse pressure variation; PT, prothrombin time; SBP, systolic blood pressure; SI, stroke index; SIRS, systemic inflammatory response syndrome; PTT, partial thromboplastin time; WBC, white blood cell.

Coagulation Activation

Activation of the coagulation cascade with the generation of fibrin is a pathologic and physiologic hallmark of sepsis that occurs in both the intravascular and extravascular compartments [25]. Intravascular coagulation is characterized by diffuse microvascular thrombosis that contributes to widespread ischemic organ damage. Activation of coagulation during sepsis is primarily driven by the tissue factor pathway. Fibrin formation in sepsis likely results from both increased fibrin generation and impaired fibrin degradation. Inhibition of fibrinolysis

is primarily due to increases in plasminogen activator inhibitor-1 (PAI-1). Downregulation of the anticoagulant Protein C pathway also plays an important role in the modulation of coagulation and inflammation in sepsis. Because activation of the coagulation cascade almost all septic patients are thrombocytopenic (or have a falling platelet count), and indeed a normal platelet count makes the diagnosis of sepsis unlikely. An elevated D-dimer, thrombin–antithrombin complexes and a prolonged prothrombin time are found in the majority of patients with severe sepsis while antithrombin, protein C, and protein S levels are significantly decreased. Replacement of coagulation factors with fresh frozen plasma ([FFP] and cryoprecipitate if the fibrinogen is less than 100 mg per dL) is only indicated in patients with clinical evidence of bleeding. Although it had previously been assumed that such therapy "fuels the fire of DIC," there is no evidence that the infusion of plasma products stimulates the ongoing activation of coagulation [26].

Pulmonary

Sepsis is by far the most common cause of the acute respiratory distress syndrome (ARDS) [27–29]. The mortality rate for patients with sepsis complicated by ARDS has been reported to be as high as 60%. The pathophysiology and management of patients with ARDS has been extensively reviewed in the literature.

Renal

Acute renal failure is a serious complication in patients with sepsis. Despite improvements in the support of these patients, the mortality rate remains consistently above 50%. It is, therefore, essential that all patients with sepsis be aggressively resuscitated in an attempt to prevent this complication. The pathogenetic mechanisms leading to ARF in patients with sepsis are unclear ;however, mediator-induced cytotoxicity, alterations in renal perfusion and apoptosis have been suggested [30,31].

Gastrointestinal

The most important gastrointestinal complications occurring in patients with sepsis include gastric stress ulceration, a diffuse splanchnic mucosal injury with increased intestinal permeability and intrahepatic cholestasis.

Nervous and Musculoskeletal

Septic encephalopathy is an acute, reversible, generalized disturbance in cerebral function [32,33]. Septic encephalopathy is essentially a diagnosis by exclusion as many factors such as sedative drugs, encephalitis, liver or renal failure, hypoperfusion, fever, adrenal insufficiency, cerebral vascular accidents, and drug fever either alone or in combination may result in disturbed cerebral function. Electroencephalography is useful in confirming the diagnosis of septic encephalopathy and allows assessment of the severity of the encephalopathy. Treatment is essentially supportive.

Critical illness polyneuropathy (CIP), as initially described by Bolton et al. in 1984, is a sensorimotor polyneuropathy that is often a complication of sepsis and multiorgan failure, occurring in 70% of such patients [34–36]. Postmortem examination of peripheral nerve specimens from patients with CIP has shown primary degeneration of motor and sensory nerves that supply the limbs and respiratory system. Although this denervation is more widespread and severe in the distal muscle groups, the phrenic nerve, diaphragm, and intercostals muscles are also involved. Classically, CIP is associated with a symmetric predominantly distal paresis, with legs involved worse than arms, along with impaired sensory testing in the feet and hyporeflexia. CIP is difficult to diagnose clinically and is often suspected when critically ill patients are otherwise improving yet continue to have difficulty in weaning from mechanical ventilation.

In addition to neuropathy, weakness in critically ill septic patients may stem from disturbances in the structure or function of muscle per se. According to biopsy and neurophysiologic studies, myopathies occur much more frequently during critical illness than was previously recognized. Myopathic changes have been demonstrated by electromyographic examination and biopsy in many septic ICU patients. The changes are often mild and usually accompany CIP. In other patients however, myopathy is the predominant finding. This myopathy has been called critical illness myopathy.

Sepsis and Multisystem Organ Dysfunction

The ultimate cause of death in patients with sepsis is multiple organ failure. Typically, patients will first develop a single organ failure and then, if the disease remains unchecked, will progressively develop failure/dysfunction of other organ systems. There is a close relationship between the severity of organ dysfunction on admission to an ICU and the probability of survival. The pathogenesis of organ dysfunction is multifactorial and incompletely understood. Tissue hypoperfusion and hypoxia are dominant factors. Multisystem organ dysfunction has an extraordinarily high mortality and, for many patients, the support of this syndrome does not improve survival but rather prolongs the dying process.

CLINICAL FEATURES AND DIAGNOSIS OF SEPSIS

Sepsis is a systemic process with a variety of clinical manifestations. The initial symptoms of sepsis are nonspecific and include malaise, tachycardia, tachypnea, fever, and sometimes hypothermia. Although most patients with sepsis have an elevated white cell count, some patients present with a low white cell count, which in general, is a poor prognostic sign. A band count in excess of 10% has been reported to have a high specificity (92%) but low sensitivity for the diagnosis of sepsis (43%) [37]. Other clinical manifestations include altered mental status, hypotension, respiratory alkalosis, metabolic acidosis, hypoxemia with acute lung injury, thrombocytopenia, consumptive coagulopathy, proteinuria, acute tubular necrosis, intrahepatic cholestasis, elevated transaminases, hyperglycemia, and hypoglycemia. Patients may present with clinical features of a localized site of infection, such as cough, tachypnea and sputum production due to pneumonia; flank pain and dysuria with urinary tract infection and abdominal pain with intra-abdominal infection.

The manifestations of sepsis can sometimes be quite subtle, particularly in the very young, the elderly, and those patients with chronic debilitating or immunosuppressing conditions. These patients may present with normothermia or hypothermia. The failure to generate a temperature greater than 99.6°F (37.5°C) in the first 24 hours of clinical illness, has been associated with an increased mortality rate. An altered mental state or an otherwise unexplained respiratory alkalosis may be the presenting feature of sepsis.

The signs and symptoms of systemic inflammation are not useful in distinguishing infectious from noninfectious causes of SIRS. Furthermore, a bacterial pathogen is not isolated in

all patients with sepsis. Consequently, a number of biomarkers have been evaluated as more specific indicators of infection, including procalcitonin (PCT) and triggering receptor expressed on myeloid cells (TREM-1). PCT, a propeptide of calcitonin, is normally produced in the C-cells of the thyroid. In healthy individuals, PCT levels are very low (< 0.1 ng per mL). In patients with sepsis, however, PCT levels increase dramatically, sometimes to more than several hundred nanograms per milliliter. The exact site of PCT production during sepsis is uncertain; however, mononuclear leukocytes and the liver seem to be the major sources of PCT. TREM-1 is a monocyte receptor that is upregulated by bacterial and fungal pathogens [38]. The ligand for TREM-1 is unknown. A soluble form of TREM-1 (sTREM-1) is released from activated phagocytes and can be found in body fluids. The use of these biomarkers has not gained widespread acceptance presumable due to the cost of the tests and the uncertain diagnostic accuracy.

Blood cultures are considered to provide the clinical gold standard for the diagnosis of bacterial infections. However, blood cultures are only positive in between 20% and 30% of patients with sepsis; moreover, it takes 2 to 3 days before the results become available. Molecular methods based on polymerase chain reaction (PCR) technology have been developed for infection diagnosis and pathogen identification. These methods offer a new approach based on detection and recognition of pathogen DNA in the blood, or indeed other clinical samples, with the potential to obtain results in a much shorter time frame (hours) than is possible with conventional culture. PCR based pathogen detection depends on the ability of the reaction to selectively amplify specific regions of DNA, allowing even minute amounts of pathogen DNA in clinical samples to be detected and analyzed. This technique holds great promise and may revolutionize our approach to the diagnosis of bacterial, fungal, and viral infections.

MANAGEMENT OF SEPSIS

The management of patients with severe sepsis and septic shock is complex requiring multiple concurrent interventions with close monitoring and frequent re-evaluations. These patients are best managed in intensive care units by physicians experienced in the management of critically ill septic patients. The reader is referred to the "*Surviving Sepsis Campaign guidelines for the management of severe sepsis and septic shock*"; these guidelines were developed by a number of international critical care organizations and should serve as the framework for the management of patients with sepsis [10].

The current strategy for the management of patients with sepsis is largely based on treating or eliminating the source of infection, timely and appropriate usage of antimicrobial agents, hemodynamic optimization, and other physiologic organ supportive measures (see Table 159.1). Attempts at downregulating the proinflammatory response with novel agents directed at specific proinflammatory mediators has uniformly met with failure. However, both activated protein C (APC) and glucocorticoids (low dose) are immunomodulators that have been demonstrated to improve the outcome of patients at high risk of death.

TABLE 159.1

SUGGESTED FLUID RESUSCITATION ALGORITHM FOR HEMODYNAMIC INSTABILITY OF SEVERE SEPSIS AND SEPTIC SHOCK

1 L Normal Saline 15–20 minutes
1 L 30 minutes
Start Norepinephrine if MAP ≤ 70 mm Hg
1 L 500 cc 5% albumin over 30–40 minutes
1 L Ringers 30–40 minutes
1 L 500 cc 5% albumin over 30–40 minutes
Ringers lactate 200 cc/h
Bolus 500 cc 5% albumin or Ringers Lactate

It has become increasingly apparent that in many patients there is a long delay in both the recognition of sepsis and the initiation of appropriate therapy. This has been demonstrated to translate into an increased incidence of progressive organ failure and a higher mortality. Kumar et al. investigated the relationship between the duration of hypotension prior to antimicrobial administration in 2600 patients with sepsis induced hypotension [39]. They reported that the risk of dying increased progressively with time to receipt of the first dose of antibiotic. Furthermore, there was a 5% to 15% decrease in survival with every hour delay over the first 6 hours. In the ENHANCE study, the mortality was 33% if drotrecogin alpha-activated (APC) was given within the first 24 hours of admission as compared to 52% if it was given on day 3 of hospitalization [40].

Levy et al. retrospectively analyzed the Sequential Organ Failure Assessment scores during the first 48 hours in 1,036 severely septic patients [41]. From baseline to day 1, the direction of change in cardiovascular, renal, respiratory, hematologic, and hepatic functions independently predicted 28-day mortality. The implications of this study is that if organ dysfunction is not improving during the first day of severe sepsis, the mortality risk is significantly increased, underscoring the importance of early recognition and therapeutic intervention to prevent sequential organ dysfunction [42]. Similarly, Rivers et al. demonstrated that early (within 6 hours) clearance of lactate is associated with improved outcome in severe sepsis and septic shock [12].

The concept that early aggressive treatment (within the first 6 hours of admission to hospital) of patients with severe sepsis and sepsis shock reduces sequential organ failure and improves survival has been demonstrated in the "landmark" study by Rivers et al. [43]. In this study, *early aggressive therapy* that optimized cardiac preload, afterload, and contractility in patients with severe sepsis and septic shock improved survival. The patients in the early-therapy group received, on average, approximately 1,500 mL more in total fluids in the first 6 hours of treatment than did the standard-therapy group and had a significantly higher mean arterial pressure (mean [± SD], 95 ± 19 vs. 81 ± 18 mm Hg; $p < 0.001$). Mortality was 30.5% in the group receiving early goal-directed treatment, as compared with 46.5% in the control group ($p = 0.009$). This strategy for managing patients with severe sepsis and septic shock has been called "early goal-directed therapy (EGDT)."

While the concept of early, as opposed to delayed, volume resuscitation and the timely initiation of appropriate antibiotics in patients suffering from severe sepsis and septic shock is a scientifically sound concept, the author believes that the major pillars on which EGDT is based (central venous pressure [CVP] > 8 mm Hg, $ScvO_2$ > 70% and blood transfusion) may be flawed (see later) [44]. A more evidence-based approach is provided in Figure 159.1.

Identification and Eradication of the Source of Infection

One of the most challenging features of the sepsis syndrome is that of identifying and eradicating, as early as possible, the source of infection. The majority of patients presenting with severe sepsis usually have a pulmonary, genitourinary, primary blood stream, intra-abdominal, or intravenous catheter as a source of infection. Recent studies have demonstrated that in approximately 75% of patients with presumed sepsis, an

etiological agent can be isolated, these being equally divided amongst Gram-positive and Gram-negative organisms. It has been known for centuries that, unless the source of the infection is controlled, the patient cannot be cured of his or her infective process and that death will eventually ensue. Surgical control or percutaneous drainage of the infective process is therefore essential in most patients with severe intra-abdominal infections; recovery will not occur without them. Infected central venous catheters must be removed from patients with catheter related sepsis [45].

Antimicrobial Agents

Antimicrobial therapy remains the cornerstone of treatment in patients with sepsis. Empiric intravenous antibiotic therapy should be started within the first hour of recognition of severe sepsis, after appropriate cultures have been obtained. The choice of antibiotics is largely determined by the source or focus of infection, the patient's immunologic status, whether the infection is nosocomial or community acquired as well as knowledge of the local microbiology and sensitivity pattern. Initial empirical anti-infective therapy should include one or more drugs that have activity against the likely pathogens (bacterial or fungal) and that penetrate into the presumed source of sepsis. Because the identity of the infecting pathogen(s) and its sensitivity pattern(s) are unknown at the time of initiation of antibiotics, patients with severe sepsis and septic shock the initial regimen should include two or more antibiotics or an extended spectrum β-lactam antibiotic. A number of studies have demonstrated that appropriate initial antimicrobial therapy, defined as the use of at least one antibiotic active in vitro against the causative bacteria reduced mortality when compared with patients receiving inappropriate therapy [45,46]. Once a pathogen is isolated, monotherapy is adequate for most infections; this strategy of initiating broad-spectrum cover with two or more antibiotics and then narrowing the spectrum to a single agent when a pathogen is identified is known as "antimicrobial de-escalation." The indications for continuation of double-antimicrobial therapy include enterococcal infections and severe intra-abdominal infections. The role of double-antimicrobial therapy with a β-lactam antibiotic and aminoglycoside in patients with suspected or proven *Pseudomonas aeruginosa* infections is unclear; however, double coverage is prudent in immunocompromised patients [47,48]. In patients with culture-negative sepsis, continuation of the initial empiric combination is warranted. Additional antibiotics or a change in antibiotics may be required in patients with culture-negative sepsis who do not appear to be responding to the initial empiric regimen.

Although monotherapy is considered standard for community-acquired pneumonia, a survival benefit of a combination β-lactam and macrolide has been suggested. Waterer et al. found that patients with bacteremic pneumococcal disease who receive at least two effective antibiotic agents within the first 24 hours after presentation to hospital had a significantly lower mortality than patients who received only one effective antibiotic agent [49]. The most common combination was a third-generation cephalosporin with a macrolide or quinolone. Using a large hospital database, Brown et al. demonstrated a lower mortality, shorter length of stay and lower hospital charges for patients with community-acquired pneumonia treated with dual therapy using macrolides as the second agent [50].

To rapidly achieve adequate blood and tissue concentrations, antibiotics should be given intravenously, at least initially. Dosing regimens should take into account whether the antibiotic "kills" by time-dependent kinetics (e.g., β-lactam antibiotics, vancomycin) or concentration-dependent kinetics (e.g., aminoglycoside) [51,52]. The clinical effectiveness of β-lactam antibiotics and vancomycin is optimal when the concentration of the antimicrobial agent in the serum exceeds the minimum inhibitory concentration of the infecting organism for at least 40% of the dosing interval. In addition, antibiotic dosing should also take into account the patient's hepatic and renal function.

Chastre et al. performed a study in which patients with ventilator associated pneumonia were randomized to receive either 8 or 15 days of antibiotics [53]. Those treated for 8 days had neither excess mortality nor more recurrent infections, although those with nonfermenting Gram-negative bacilli did have a higher pulmonary infection recurrence rate. Antibiotics should therefore be continued until clinical improvement is noted and ordinarily should not be continued for more than 10 days (14 days for *P. aeruginosa* and Acinetobacter species), except in cases of osteomyelitis and endocarditis.

Hemodynamic Support

Fluid Resuscitation: Initial Versus Late

In the first hours of severe sepsis, venodilatation, transudation of fluid from the vascular space into the tissues, reduced oral intake and increased insensible loss combine to produce hypovolemia. Along with ventricular dysfunction, and arteriolar dilation volume depletion contributes to impaired global perfusion and organ function. Treating hypovolemia is the most important component of the early management of severe sepsis. However, once the patient has received an adequate fluid challenge (3 to 5 L) further fluid challenges may not increase cardiac output and global perfusion. Additional fluid may increase interstitial edema and further comprise the microvascular dysfunction that characterizes severe sepsis. The current paradigm of fluid management in patients with sepsis is one of adequate initial fluid resuscitation followed by conservative late fluid management. Conservative late fluid management is defined as even-to-negative fluid balance measured on at least two consecutive days during the first 7 day after septic shock onset. In a retrospective cohort study, Murphy et al. demonstrated that an approach that combines both adequate initial fluid resuscitation followed by conservative late fluid management was associated with improved survival [54]. Additional studies have demonstrated that those patients who have a smaller cumulative fluid balance have improved clinical outcomes [55–57].

Although the type of fluid used in the resuscitation of patients with sepsis has not been definitively shown to affect outcome, subgroup analysis of the SAFE study suggested a trend towards a more favorable outcome in patients who received albumin [58]. This finding is supported by experimental studies [59] and patients with malaria (similar pathophysiology to Gram-negative sepsis) [60]. Albumin has a number of properties that may be advantageous in patients with sepsis including the maintenance of the endothelial glycocalyx and endothelial function as well as having antioxidant and anti-inflammatory properties that may translate into less "third" space fluid loss. Hydroxyethyl starch solutions were previously recommended in patients with sepsis; however, these synthetic colloids have recently been demonstrated to be associated with an increased risk of renal failure (and death) and should therefore be avoided in patients with sepsis [61]. Despite differences in composition, normal saline (NS) and Lactated Ringer's solution (LR) are frequently considered equivalent and lumped under the term "balanced salt solution." However, both experimental and clinical data have demonstrated that these fluids are not equivalent. Studies have demonstrated the development of a hyperchloremic metabolic acidosis in human volunteers and patients

resuscitated with normal saline [62–65]. Although the clinical implications of this finding are unclear, the additional loss (renal) of HCO_3 in the setting of reduced buffering capacity only adds to the acid–base burden characteristic of hypoperfused states [63]. Furthermore, resuscitation with normal saline may produce a "dilutional acidosis." Many erroneously believe that LR may worsen or cause a "lactic acidosis." This is impossible as lactate (the base) has already donated H+ ions; indeed, LR is converted to glucose (mainly in the liver). This reaction consumes hydrogen ions, thereby generating HCO_3 [66]. Although, the lactate concentration (base) may increase with LR, this increase is associated with an increase in HCO_3 and an increase in pH (even with liver disease). This observation was elegantly demonstrated by Phillips et al. in a swine hemorrhagic shock model; the results demonstrated a significantly higher pH (7.41 vs. 7.17) in animals resuscitated with LR as compared to normal saline [67]. In addition to its effects on acid–base balance, solutions high in chloride have been shown both experimentally and clinically to reduce the glomerular filtration rate (GFR) (due to tubuloglomerular feedback) [68]. The effects of normal saline on acid–base balance and renal function may be dose related. These data suggest that in patients with sepsis (except those with hyperkalemia), LR may be preferable to normal saline. There is however, no outcome data to support this recommendation. Furthermore, it should be noted LR solution is a racemic mixture containing both the L- and D-isomer of lactate. Small animal hemorrhagic shock models have suggested that the D-isomer is proinflammatory and increases apoptotic cell death [69–71]. The clinical implications of these findings are unclear.

On the synthesis of these data, we recommend initial resuscitation with NS (30 mL per kg). Normal saline is preferred until renal function tests and potassium are known. Patients who respond poorly to this initial bolus (± 2 L) may best be fluid resuscitated with alternating boluses (500 mL) of albumin and LR until the hemodynamic goals are achieved (see "The Endpoints of Resuscitation" section and Fig. 159.1). The goal of this approach is to maintain normal acid–base balance, achieve adequate intravascular volume, and yet limit the total amount of fluid given.

Vasopressors, Inotropes, and Cardiac Function

The optimal time to initiate vasopressor agents has not been rigorously studied. Many patients with severe sepsis will respond to a 2-L fluid challenge and require little additional hemodynamic support. Others will remain hypotensive despite 10 L of fluid (fluid does not increase vascular tone!). The goal of fluid resuscitation is the rapid early restoration of intravascular volume followed by a conservative fluid strategy. We have therefore recommended that a vasopressor agent (norepinephrine) be started once the patient has received 2 L of crystalloid [6,72]. At this point, the norepinephrine (starting at 0.01 µg per kg per minute) should be titrated upwards while fluid resuscitation continues (albumin and LR). Ongoing fluid resuscitation should be guided by mean arterial pressure, pulse pressure variation, urine output, oxygenation as well as cardiac output (determined noninvasively), and extravascular lung water measurement [73,74]. Bedside echocardiography is very useful to determine LV size and function. The CVP neither intravascular volume nor does it predict fluid responsiveness and therefore has no place in the resuscitation of patients with sepsis [75].

Although there are little data to suggest that one vasopressor results in better outcomes than another (norepinephrine, epinephrine, vasopressin) [76–78], we favor norepinephrine as the first-line agent followed by dobutamine or epinephrine in patients with poor LV function and vasopressin (fixed dose of 0.03 U per minute) in patients with "preserved" LV function and a low systemic vascular resistance (see Fig. 159.1). In patients with sepsis, norepinephrine increases blood pressure, as well as cardiac output, renal, splanchnic, cerebral blood flow, and microvascular blood flow while minimally increasing heart rate [79,80]. Norepinephrine would therefore appear to be the ideal fist-line agent for the management of septic shock; additional agents should be considered in patients who remain hypotensive or display evidence of inadequate tissue or organ perfusion despite doses of norepinephrine up to 0.2 µg per kg per minute. The second/third-line agents should be chosen based on the patient's hemodynamic profile as determined by ECHO and noninvasive assessment of cardiac output.

Dopamine has a number of theoretical disadvantages in patients with sepsis. It tends to increase heart rate that increases myocardial oxygen demand and is associated with splanchnic mucosal ischemia. In addition, dopamine inhibits T and B lymphocytes and decreases secretion of prolactin, growth hormone, and TSH. The SOAP study suggested that septic patients who received dopamine had an increased mortality when compared with other vasopressors [81]. This drug should therefore be avoided in patients with sepsis. Similarly phenylephrine is not recommended, as in experimental models it decreases cardiac output as well as renal and splanchnic blood flow [82]. Furthermore, these agents have not been rigorously tested in randomized controlled studies.

The Endpoints of Resuscitation

The optimal "hemodynamic" endpoint of resuscitation in patients with sepsis is unknown. Similarly, the target mean arterial pressure (MAP) is controversial. Traditional teaching suggests that we should achieve a MAP above 60 mm Hg. However, this pressure is below the autoregulatory range of a number of organs, particularly in elderly patients with atherosclerotic disease. The *Surviving Sepsis Campaign* Guidelines suggest targeting a MAP above 65 mm Hg [10]. In a dose escalation study, Jhanji et al. incrementally increased the dose of norepinephrine to achieve a MAP of 60, then 70, then 80, and lastly 90 mm Hg [80]. In this study, global oxygen delivery, cutaneous microvascular flow, and tissue oxygenation increased with each sequential increase in MAP. However, LeDoux et al. demonstrated that increasing the MAP from 65 to 85 mm Hg with norepinephrine did not significantly affect systemic oxygen metabolism, skin microcirculatory blood flow, urine output, or splanchnic perfusion [83]. Dubin demonstrated that increasing mean arterial pressure from 65 to 75 and 85 mm Hg did not improve microcirculatory blood flow [84]. Similarly, Bourgoin et al. demonstrated that increasing MAP from 65 to 85 mm Hg with norepinephrine neither affected metabolic variables nor improved renal function [85]. However, Derudre et al. demonstrated that in patients with septic shock when the MAP was increased from 65 to 75 mm Hg, urinary output increased significantly while the renal resistive index significantly decreased [86]. These data suggest that although the endpoint of resuscitation should be individualized, a MAP of 65 to 70 mm Hg may be a reasonable initial target.

Central venous oxygen saturation ($ScvO_2$) is used as the endpoint of resuscitation in the EGDT algorithm [43]. This is problematic for a number of reasons. Septic patients usually have a normal or increased $ScvO_2$ due to reduced oxygen extraction [87,88]. A normal $ScvO_2$ therefore does not exclude tissue hypoxia [89]. A low $ScvO_2$ is an important sign of inadequate oxygen delivery to meet systemic oxygen demands. However, it provides no information for the reason for this inadequacy, nor does it provide guidance as to the optimal therapeutic approach. It is noteworthy that in the Rivers study the mean $ScvO_2$ was 49% with 65% of patients having a $ScvO_2$ less than 70%. To our knowledge, no other sepsis study has reproduced this finding, with the mean $ScvO_2$ (on presentation)

in most sepsis studies being approximately 70% [89–91]. This suggests that other factors may have been in play to account for the low $ScvO_2$ in the Rivers study [92,93]. These factors include the delayed presentation to hospital (possibly due to socioeconomic factors), greater number of patients with comorbid medical conditions and a high incidence of alcohol use [93]. Thus the combination of significant comorbidities (including heart disease) and a more delayed arrival of patients to the Emergency Department in the River's study may have led to a low cardiac output state, and in turn, to the very low $ScvO_2$ values.

ADJUNCTIVE THERAPIES

While antibiotics, fluid resuscitation, vasopressors/inotropic agents and source control form the basic elements of the management of severe sepsis/septic shock, a number of adjunctive agents have been demonstrated to improve outcome or hold promise in improving the outcome of patients with sepsis. These agents should be considered in patients with severe sepsis/septic shock. The benefit of these agents is, however, time dependent and should be started as soon as possible and always within the first 24 hours of ICU admission

Corticosteroids

While the role of hydrocortisone in patients with septic shock is controversial, hydrocortisone should be considered in patients who require in excess of 0.2 µg per kg per minute of norepinephrine [94,95]. Adrenal function testing is not required in these patients. Evolving data suggest that increased levels of inflammatory mediators persist long after clinical resolution of sepsis [96,97]. Furthermore, abruptly stopping steroids results in a rebound phenomenon with worsening lung inflammation and hypotension These data suggest that the duration of therapy should be guided by the length of the immune dysregulation and should then be followed by a slow taper. Furthermore, the risk/benefit ratio of treatment with glucocorticoids is tightly linked to the dosage used. Although high doses of glucocorticoids blunt all arms of the immune system, stress-doses (200 to 300 mg hydrocortisone Eq per day) inhibit systemic inflammation; yet, maintain innate and Th1 immune responsiveness and prevent an overwhelming compensatory anti-inflammatory response [98,99]. Similarly, although myopathy is common in patients treated with high-dose corticosteroids, this complication is uncommon with stress-doses of corticosteroids. On the basis of these data, we suggest treatment with hydrocortisone in a dose of 50 mg every 6 hourly or a 100 mg bolus followed by an infusion at 10 mg per hour for 10 to 14 days followed by a slow taper.

Activated Protein C

The PROWESS study demonstrated a significant reduction in mortality in patients with severe sepsis and septic shock who were treated with activated protein C (APC) within 24 hours of hospital admission [100]. APC should be considered in patients with septic shock and those with sepsis and at least one organ failure, who are at a high risk of death, particularly patients with severe community-acquired pneumonia [101]. The use of APC in patients with sepsis has, however, become a very controversial and charged issue. This is largely driven by the high rate of serious bleeding that has been reported in retrospective cohort studies [102]. APC should be avoided in patients at high risk of bleeding, including patients with a platelet count of $< 30{,}000$ per mL^3. Although APC increases the partial thromboplastin time (PTT) in vitro, the PROWESS study demonstrated an increased risk of bleeding when the PTT increased above 75 seconds. On the basis of these data, we monitor the PTT in patients on APC and hold the infusion (for a few hours) and transfuse FFP when the PTT exceeds 80 seconds (anecdotal experience only). Disseminated intravascular coagulation (DIC) is not a contraindication to APC; indeed in PROWESS the risk reduction was greater in patients with overt DIC than those without DIC (RR of 0.6 vs. 0.85) [103].

Patients with purpura fulminans and multiorgan failure due to meningococcal infection have significantly higher plasma PAI-1 levels as well as lower protein C levels than patients with meningococcal infection, but without purpura or organ failure [104]. In view of the low protein C levels in purpura fulminans, numerous case reports as well as open label studies have been published suggesting a benefit of treatment with APC [104–106]. Many of these patients concomitantly received FFP, fibrinogen, and platelets. APC has also been used for the treatment of purpura fulminans associated with Streptococcal and Staphylococcal infections [107].

Enteral Nutrition Supplemented with Omega-3 Fatty Acids

Three randomized controlled trials have demonstrated that in patients with sepsis and ARDS an enteral nutritional formula high in omega-3 fatty acids was associated with an increase in ventilator-free days, a shorter ICU stay, and a lower morality than patients fed a diet with a low omega-3 to omega-6 fatty acid ratio [108]. On the basis of these data, an enteral nutritional formula high in omega-3 fatty acids should be initiated within 24 hours of admission to the ICU. Patients are best fed gastrically via an oral or nasogastric tube. The use of vasopressors agents is not a contraindication to the use of enteral nutrition; indeed, enteral nutrition reduces the risk of gastric stress ulceration and bowel ischemia [109,110].

Polyclonal Immunoglobulins

Two meta-analyses have demonstrated that polyclonal immunoglobulins particularly those preparations enriched with IgA and IgM (IgGAM) reduce the mortality in patients with septic shock [111,112]. It is not clear which patient subgroups would benefit from this therapy; clearly asplenic patients should receive IgGAM as well as those patients at high risk of death.

ADJUNCTIVE THERAPIES OF POSSIBLE BENEFIT

Statins

HMG-CoA reductase inhibitors (statins) are a group of drugs with anti-inflammatory, immunomodulating, antioxidant, antiproliferative, antiapoptotic, antithrombotic, and endothelial stabilizing effects. Statins increase expression of endothelial nitric oxide (eNOS) while downregulating inducible nitric oxide (iNOS) [113]. Furthermore, statins interfere with leucocyte–endothelial interactions by decreasing expression of adhesion molecules and have antithrombotic effects. Experimental

sepsis studies have demonstrated improved outcome with the use of statins and clinical studies have demonstrated that patients taking statins have a better outcome when they become septic [113–115]. We recommend the use of high-dose statins (e.g., atorvastatin/simvastatin 80 mg daily) in patients with severe sepsis; statins should however be avoided in patients taking azole antifungal as well as calcineurin inhibitors. The clinician should monitor for rhabdomyolysis.

Selenium

Sepsis is associated with an increase in reactive oxygen species and low endogenous antioxidative capacity. The selenium dependent glutathione-peroxidases (GPx) as well as thioredoxin reductases are important compounds responsible for the maintenance of the redox system in all cells including the immune-competent cells. The activity of these enzymes is mainly regulated by the availability of selenium. The selenium in intensive care (SIC) study demonstrated that high-dose intravenous selenium improved the outcome of patients with severe SIRS, sepsis, and septic shock [116]. Selenium supplementation should be considered in patients with severe sepsis and septic shock. Although the optimal dose and route remain to be established, we recommend a dose of 400 to 600 µg PO daily.

Zinc

Zinc is required for normal function of both the innate and acquired immune systems. Zinc deficiency results in marked abnormalities of immune function with zinc supplementation restoring natural killer cell activity, lymphocyte production, mitogen responses, wound healing, and resistance to infection. Stress, trauma, and sepsis have been associated with very low serum zinc levels [117,118]. In an experimental sepsis model, mortality was significantly increased with zinc deficiency, while zinc supplementation normalized the inflammatory response, diminished tissue damage and reduced mortality [119]. The benefit of zinc supplementation in patients with sepsis has yet to be determined.

CONCLUSION

The last two decades has seen a remarkable growth in our understanding of sepsis and the complex interconnection of multiple biological pathways involved in the septic process. This increased knowledge has opened the door to new therapeutic approaches to sepsis, and it is likely that these new approaches will lead to a reduction in the morbidity and mortality of patients with sepsis.

CHAPTER 160 ■ MULTIPLE ORGAN DYSFUNCTION SYNDROME

ANDREW C. BERNARD AND TIMOTHY A. PRITTS

Care of the critically ill has advanced substantially in the past 50 years to the point that patients who previously succumbed to illness or injury may now survive their initial insult. Unfortunately, this places them at risk for multiple organ dysfunction syndrome (MODS), with subsequent failure of organ systems and increased mortality [1]. A thorough understanding of the pathophysiology and treatment of MODS is necessary to attempt to mitigate associated secondary morbidity and mortality.

MODS can be defined as "the inability of one or more organs to support its activities spontaneously without intervention" [2]. Initial recognition of MODS came from combat casualty care during World War II as resuscitation strategies advanced sufficiently to allow casualties to survive the initial hemorrhagic shock insult, but rendered them vulnerable to subsequent acute renal failure [3]. Improved intensive care and resuscitation strategies subsequently led to the recognition of pulmonary failure in the form of ARDS during the Vietnam conflict [4]. Basic science and clinical research has increased our insight into the role of cellular hypoxia in the development of organ dysfunction and failure. Although advances in support for failing organs, including continuous dialysis and advanced ventilator care, have potentially increased survival, MODS remains a common cause of death in the intensive care unit.

DIAGNOSTIC CRITERIA AND SCORING SYSTEMS

MODS severity determines mortality [5]. Organ failure severity scoring was initially described by Knaus in 1985 [6]. Modern scoring systems consider grade and severity and are intended to serve as predictors of outcome. Among the most commonly used scoring systems are the multiple organ dysfunction score (MODS), sequential organ failure assessment (SOFA) and logistic organ dysfunction score (LODS) [7–9]. All include clinical and laboratory data for six organs: respiratory, cardiovascular, hematologic, hepatic, renal, and central nervous system (Table 160.1) [10]. The Denver Multiple Organ Failure (MOF) score is a simpler 4-point scale that has similar or superior specificity [11]. A "cellular injury score" based on measures of cellular dysfunction has also been described [12]. No single scoring system has been proven superior but all predict outcome more accurately than health care resource utilization [11,13]. The acute physiology and chronic health evaluation (APACHE), originally described by Knaus in 1985, is a scoring system that considers patient factors unrelated to the acute illness as well as acute illness severity [14]. APACHE considers many variables and is therefore not as easily calculable at

TABLE 160.1

CRITERIA USED IN COMMON ORGAN DYSFUNCTION SCORING SYSTEMS

Organ	Variable	Denver MOF [11]	SOFA [8]	LODS [9]	MODS [7]
Respiratory	PaO_2/FIO_2	Yes	Yes	Yes	Yes
	MV		Yes		
Hematology	Platelets		Yes	Yes	Yes
	WBC			Yes	
Hepatic	Bilirubin	Yes	Yes	Yes	Yes
	Prothrombin time			Yes	
Cardiovascular	MAP		Yes		
	SBP			Yes	
	Heart rate			Yes	
	PAR [(HR□CVP)/MAP]				Yes
	Dopamine		Yes		
	Dobutamine		Yes		
	Epinephrine		Yes		
	Norepinephrine		Yes		
	Any inotrope	Yes			
CNS	GCS		Yes	Yes	Yes
Renal	Creatinine	Yes	Yes	Yes	Yes
	BUN			Yes	
	Urine output		Yes	Yes	

Denver MOF, Denver multiple organ failure score; SOFA, sequential organ failure assessment; LODS, logistic organ dysfunction score; MODS, multiple organ dysfunction score; PaO_2, blood partial pressure of oxygen; FIO_2, fraction of inspired gas which is oxygen; MV, mechanical ventilation requirement; WBC, elevated white blood count; PAR, pressure adjusted heart rate; HR, heart rate; CVP, central venous pressure; MAP, mean arterial pressure; SBP, systolic blood pressure; CNS, central nervous system; GCS, Glasgow Coma Scale score; BUN, blood urea nitrogen.
Modified from Mizock BA: The multiple organ dysfunction syndrome. *Dis Mon* 55(8):476–526, 2009.

the bedside as MODS, SOFA, LODS, or Denver, but it reliably predicts both outcome and resource utilization, has been refined to its current version, APACHE IV, and may be useful for benchmarking ICU performance [15].

EPIDEMIOLOGY

Incidence of MODS varies based on primary diagnosis and the scoring system used to determine organ dysfunction. Seventy-one percent of ICU patients have some organ dysfunction [16] and about half have MODS [17], depending on the criteria used. For example, in one adult trauma ICU 47% had MODS, defined by SOFA ≤3 in two or more systems [18]. Septic patients are more likely to have organ dysfunction and more organ failures than nonseptic patients and mortality is higher if sepsis is present (31% vs. 21%) [16].

ETIOLOGY

MODS is most often the result of shock, sepsis, and trauma but there are many causes (Table 160.2) [19]. Forty-one percent of those patients with organ dysfunction have sepsis [16]. Sepsis most commonly originates in the lung (68%) and abdomen (22%) but there are many causes of sepsis-induced MODS [16].

MECHANISMS OF MULTIORGAN DYSFUNCTION SYNDROME

The systemic inflammatory response syndrome (SIRS) is frequently viewed as a predecessor to MODS and these syndromes represent a continuum of dysfunction. Components of the SIRS response are seen in virtually all patients following operation or injury. This response is usually self-regulating and rarely progresses to MODS. MODS may be viewed as a result of an ongoing and dysregulated SIRS response with progressive organ system derangement.

Despite extensive efforts, the pathophysiology of MODS is not fully understood and remains an area of intensive investigation [20]. Several mechanisms for the onset and propagation of MODS have been proposed, including an initial insult leading immediately to organ failure, a "two hit" model, where an initial stimulus primes the immune system to respond to a subsequent insult with an exuberant reaction, and the concept that a continuous ongoing insult contributes to MODS [20]. In clinical practice, each of these scenarios may result in MODS.

A common theme in the onset and propagation of MODS is the presence of a disordered immune response. It is likely that ongoing tissue hypoxia leads to activation of the acute inflammatory response and to dysregulation of the immune system [21]. Although the inflammatory response is an important component of normal recovery from injury and illness, organ failure appears to result from a loss of the balance between the pro- and anti-inflammatory cascades [22]. The proinflammatory response to a stimulus predominates initially, with increased release of proinflammatory mediators, increased capillary permeability, macrophage and neutrophil activation with tissue invasion and damage, disordered apoptosis, and microvascular thrombosis [23]. This initial response is normally tempered by the anti-inflammatory response, but this relationship may become dysfunctional. Together, these processes lead to early onset of MODS. If the organism survives the initial insult and onset of MODS, a period of immunosuppression follows. During this period, the patient becomes highly susceptible to nosocomial infection, with a normally survivable event such as pneumonia representing a life-threatening "second hit" [24].

TABLE 160.2

RISK FACTORS FOR MODS

- Infection
  - Peritonitis and intra-abdominal infection
  - Pneumonia
  - Necrotizing soft tissue infections
  - Tropical infections (e.g., falciparum malaria, typhoid fever, dengue fever)
- Inflammation
  - Pancreatitis
- Ischemia
  - Ruptured aortic aneurysm
  - Hemorrhagic shock
  - Mesenteric ischemia
- Immune reactions
  - Autoimmune disease
  - Reactive hemophagocytic syndrome
  - Antiphospholipid antibody syndrome
  - Transplant rejection
  - Graft versus host disease
- Iatrogenic causes
  - Delayed or missed injury
  - Blood transfusion
  - Injurious mechanical ventilation
  - Treatment associated increased intra-abdominal pressure
- Intoxication
  - Drug reactions (anticonvulsants, carboplatin, antiretrovirals, colchicines, propofol, amiodarone, monoclonal antibodies)
  - Arsenic
  - Drug intoxication (ecstasy, cocaine, salicylates, acetaminophen)
- Endocrine
  - Adrenal crisis
  - Pheochromocytoma
  - Thyroid storm
  - Myxedema coma

Reproduced from Mizock BA: The multiple organ dysfunction syndrome. *Dis Mon* 55(8):476–526, 2009.

Extensive research continues to examine the potential role of the intestine in the onset and propagation of SIRS and MODS. From this work, it is hypothesized that acute injury damages the intestinal mucosa, leading to increased cytokine production from the intestinal epithelium and lamina propria with resultant systemic inflammatory response, and organ injury [25,26]. Under these circumstances, the intestinal barrier fails, leading to organ dysfunction. More recent studies have begun to examine the gut as a source of mediators that directly lead to organ damage [27]. These studies suggest that substances in the gut-derived mesenteric lymph directly lead to pulmonary dysfunction during shock states [28]. Full characterization of these mediators remains elusive.

CURRENT MANAGEMENT STRATEGIES

Course of MODS

Outcome in MODS partly depends upon host factors including genetics. Some patients are genetically predisposed to enhanced immune reactivity [29]. In most patients, MODS progression follows a typical sequence first described by Don Fry in 1980, beginning with lung failure, followed by the liver, gastric mucosa, and kidney [30]. Lung dysfunction was recently reaffirmed as the initial manifestation of MODS in the majority of patients [31]. Although a typical sequence of organ dysfunction usually occurs, the timing and rate of progression vary. MODS follows a bimodal onset with early and late MODS characterized by different patient characteristics and mechanisms of death [32]. An important distinction must also be made with early organ dysfunction during resuscitation, which is often reversible, and not necessarily the same as early MODS [33].

Respiratory organ dysfunction is the most common early manifestation of MODS but is often not associated with death [34]. Renal, central nervous and hematologic system impairments characterize MODS progression and are more strongly associated with mortality. Treatment of MODS therefore is focused on early recognition of those at risk, removing the source, and preventing MODS progression [35]. Clinicians should move briskly to optimize cardiorespiratory function, remove catabolic foci, and provide nutrition while using antimicrobials selectively and avoiding transfusion. Key advances in the treatment of patients with severe critical illness and MODS based on randomized controlled trials are summarized in Table 160.3.

TABLE 160.3

ADVANCES IN MANAGEMENT OF MULTIPLE ORGAN DYSFUNCTION SYNDROME BASED ON RANDOMIZED CONTROLLED CLINICAL TRIALS

Advance	Reference	Remarks
Early goal-directed therapy using venous oxygen saturation as a target.	[35]	Included as one of the Surviving Sepsis Guidelines.
Digestive tract or oropharynx decontamination with antimicrobials reduces 28-day mortality in ICU patients	[40]	Not widely practiced in the United States, as it conflicts with principles of antimicrobial stewardship
Lung protective ventilation strategies are associated with reduced mortality and increased ventilator-free days	[43]	Lung protective strategies are commonly utilized in ICU settings
Aggressive enteral nutrition is associated with improved immune function and less mortality in burned children	[49]	Landmark study suggested that protein repletion is essential in critically ill patients
Adjuvant treatment of patients with severe sepsis and septic shock with selenium is associated with decreased mortality	[53]	Mechanism of effect is unknown

Resuscitation

The Surviving Sepsis Guidelines summarize current best practice regarding resuscitation as of 2008 [36]. One major strategy to reduce MODS is to ensure optimal initial resuscitation. Resuscitation should target adequate oxygen delivery evidenced by oxygen saturation in mixed venous blood (SvO_2-saturation in mixed venous blood obtained from a pulmonary artery catheter or $ScvO_2$-saturation in central venous blood obtained from a central venous catheter in superior vena cava). Rivers et al. showed that by using oxygen delivery as a target for resuscitation with fluid, blood, and inotropes, lactic acidemia was less severe and outcomes were improved [37]. Inadequate initial resuscitation contributes to MODS [38]. For a comprehensive discussion of this topic, see Chapter 159.

Preventing MODS Progression

Source control is critical to prevent perpetuation of the inflammatory response [36]. Antimicrobials should be used as above, with tailored therapy and de-escalation [13]. On the basis of the possible role of the gut and enteric bacteria as a "motor" for MODS, several groups have proposed cleansing the bowel of bacteria to disrupt this relationship, but studies have yielded conflicting results and this practice remains controversial [27–29,39]. Although a recent European study supports parenteral and topical oropharyngeal antibiotics in reducing mortality, this is not widely accepted in the United States because it seemingly goes against the principle of antimicrobial stewardship [40]. Transfusion is a risk factor for MODS, suggesting that a conservative approach to blood transfusion is appropriate [41].

Mechanical ventilation contributes to distant organ dysfunction in acute lung injury (ALI) and acute respiratory distress syndrome (ARDS) [42]. In the ARDSNet trial, the "lung protective strategy" of plateau ≤ 30 cm H_2O and tidal volumes ≤ 6 mL per kg body weight was associated with a reduction in all cause mortality of 9% compared with conventional ventilation with plateau pressures ≤ 50 cm H_2O and tidal volumes ≤ 12 mL per kg body weight [43]. A European study affirmed that use of a ventilation strategy with volumes greater than ARDSNet (>7.4 mL tidal volume per kg body weight) increased mortality [44]. For a comprehensive discussion of this topic, see Chapters 47 and 58.

Although Van den Berghe initially reported reduced mortality with intensive insulin therapy and the mortality reduction was in septic MODS [45], unacceptably high rates of hypoglycemia have since been reported [46] without a mortality benefit.

Steroid therapy in patients with sepsis and MODS may be used for select indications. For a comprehensive discussion of this topic, see Chapter 159.

Nutrition

There are data to suggest that early initiation of enteral nutrition improves outcome in patients with severe trauma, surgery, sepsis, and MODS. MODS is attenuated in patients receiving enteral nutrition within 24 hours as opposed to initiation later [47,48]. Recent retrospective data support early enteral feeding to reduce ICU and hospital mortality [49]. Both the American and European Societies of Parenteral and Enteral Nutrition (ASPEN and ESPEN) recommend enteral nutrition in ventilated patients if hemodynamics are adequate and gastrointestinal function is present and the gut works [50,51]. Arginine has been shown to be beneficial in surgical and trauma patients but cannot be recommended in septic medical patients because of immunoinflammatory characteristics [50]. However, omega fatty acids do appear beneficial in shortening length of stay, ventilator days, and mortality in septic patients. Serum selenium is depleted in trauma and surgical patients and some evidence suggests that selenium depletion contributes to MODS. Selenium repletion reduced MODS in a multi-institutional prospective randomized trial [52]. For a comprehensive discussion of this topic, see Chapters 159 and 192.

Recombinant human activated protein C was initially shown to reduce mortality in septic patients though its benefit has been questioned in recent studies [13]. rhAPC remains indicated in adults with high risk of death [36]. For a comprehensive discussion of this topic, see Chapter 159.

Continuous renal replacement therapy has been associated with reduction of MODS severity, theoretically due to modulation of elevated pro- and anti-inflammatory cytokines [53], but no large studies currently support its use for this purpose. Other novel therapies include pharmacologic manipulation of the microcirculation or augmentation of mitochondrial oxidative metabolism to enhance oxygen delivery [13].

PROGNOSIS AND ICU LENGTH OF STAY

Up to 20% of patients admitted to intensive care units develop aspects of MODS, with significantly increased morbidity and mortality [54]. MODS severity is decreasing but ICU mortality remains stable, perhaps because overall acuity is increasing [35,55]. In an epidemiologic study of sepsis in 2001, Angus determined that dysfunction of one, two, or three organ systems conveys 1%, 4.7%, and 20.7% mortality, respectively [19]. Four-organ dysfunction was associated with 65% to 74% mortality [16,19]. A more recent study examining the outcomes of critically ill patients reported ICU mortality of 10% for failure of three systems or less, increasing to 25% and 50% for four- and five-organ system failure, respectively. Mortality of seven-system failure was 100% [56]. In addition to mortality, MODS also affects long-term functional outcome [18].

MODS is the most common reason for prolonged stays in the intensive care unit, exceeding single organ system failure and simply the need for ventilatory support [54]. The onset of MODS is associated with a markedly increased length of ICU stay and risk of mortality [17]. Determining prognosis for individual patients with MODS remains challenging. Severity of organ dysfunction at the time of ICU admission or during the ICU stay correlates well with mortality, with the highest scores suggestive of a nonsurvivable situation, but does not allow accurate bedside prediction of an individual patient's outcome [7]. The strongest independent risk factors for death appear to be CNS failure (RR = 16.06) and cardiovascular failure (RR = 11.83) [56].

CONCLUSIONS

MODS is largely a result of medical progress and modern ICU care. A common denominator in the pathogenesis of MODS appears to be cellular hypoperfusion, leading to an imbalanced immune response, with resultant organ damage and failure. Treatment of patients at risk for MODS is supportive, ensuring adequate resuscitation, nutrition, source control, and support of individual organ systems as they fail. Despite modern critical care, MODS remains a common cause of death in critically ill patients.

CHAPTER 161 ■ TRAUMA SYSTEMS

CHRISTOPH R. KAUFMANN AND KEVIN DWYER

INTRODUCTION

The number of people who die from injuries worldwide is tremendous, numbering in the millions annually. Trauma also constitutes a public health crisis in the United States and is responsible for 150,000 lives lost annually. Trauma is the fifth leading cause of death in the United States by 2006 statistics published by the Center for Disease Control (CDC). It is the leading cause of death in the young, ages 1 to 44. Trauma is responsible for more years of productive life lost than cancer and heart disease combined. On average 36 life years (productive years) are lost per one trauma death compared with 12 life years lost for a heart disease death and 16 life years for cancer. For every death from trauma, there are three individuals who suffer permanent disability and 75 who suffer temporary disability. The cost of injuries in terms of lost wages, direct and indirect medical expenses, and property damage is over $400 billion [1,2].

BACKGROUND

Trauma is a time-sensitive disease, perhaps more so than any other. Indeed, half of all injury deaths occur before any intervention. Patients who are bleeding have only minutes to live unless the hemorrhage can be controlled. This control often involves operative intervention. This time-sensitive nature is best described by the "Golden Hour" concept. Severely injured trauma patients have a "golden hour" during which they should be transported to a trauma center and their injuries addressed.

Baron Dominique Jean Larrey, Napoleon's surgeon-in-chief, created the concept of the flying ambulance or "ambulance volantes." The important concept was that soldiers injured on the battlefield should be treated in the field and evacuated for surgical treatment as soon as possible. To achieve this goal, Larrey instituted the use of a horse-drawn cart on the battlefield—the flying ambulance.

Trauma systems today are focused on the rapid transport of injured patients to the appropriate level of care. This should be a verified trauma center rather than simply the closest hospital with an emergency department. The goal of trauma systems is quite simple: get the right patient to the right facility at the right time. Delay in care may result in early effects such as hemorrhagic shock or late effects such as sepsis from open fractures.

DEFINITIONS

Typically, trauma patients are individuals suffering from penetrating, blunt, or thermal trauma. Clearly combinations of mechanisms may occur, as well as special circumstances such as blast injury. Trauma patients should be triaged to the most appropriate facility for care. Triage should be based both on severity of injuries identified as well as on risk of severe injury. This is because the total sum of injuries is not known until the patient has been fully evaluated at the appropriate trauma center. Just because a patient is hemodynamically normal at a given point in time does not imply that he or she will remain that way.

Trauma centers are hospitals that have been designated by the state or other designating authority as qualified to care for injured patients. There are usually a limited number of trauma centers in a certain geographic area so that each receives an adequate volume of patients required to maintain clinical expertise. Most frequently, trauma centers are designated as Level I through Level IV (some states have also designated Level V trauma centers). Level I trauma centers provide the highest level of care, plus have research and teaching responsibilities. Level II trauma centers are intended to also provide for the full spectrum of trauma care, but do not have the research and teaching requirements. Level III facilities do not provide the full spectrum of trauma care; they usually do not provide neurosurgical services. Level IV trauma centers provide trauma care commensurate with their existing resources.

HISTORY

In 1966, the National Academy of Sciences and the National Research Council published "Accidental Death and Disability: The Neglected Disease of Modern Society," which highlighted trauma as a major public health problem and made specific recommendations to reduce accidental death and disability. This led to national and state legislation including the Highway Safety Act and the National Traffic and Motor Vehicle Safety Act that was the first effort to regulate traffic safety and reduce automobile related death and injuries. The Emergency Medical Systems (EMS) program was also established. Later, in 1973, the EMS Systems Act identified trauma systems as one of 15 essential components of an EMS system and appropriated federal funds [3].

VERIFICATION AND DESIGNATION

The trauma system encompasses the complete care of the injured patient from the point of injury prehospital to the completion of the rehabilitative process. Important activities of that system include injury prevention, education, research, and financial viability. For this, there needs to be a lead agency established by each state that has the authority to create and execute policy for the injured patients, as well as designate the trauma centers to manage the injured patients. In order to receive a designation, a hospital or medical center has to demonstrate the standards of care established by the designating authority to achieve the level of trauma center, I, II, III, or IV desired. The trauma center is then evaluated and verified by either an internal team or an external reviewer, such as the American

College of Surgeons (ACS), as meeting the necessary criteria to be a trauma center in the system. This verification is then recommended to the lead agency of the state for designation of a trauma center. The lead agency regulates the quality of trauma systems components and establishes trauma triage guidelines.

The American College of Surgeons Committee on Trauma wrote the "Optimal Hospital Resources for Care of the Seriously Injured" in 1976 and there is presently the fifth edition called the Resources for Optimal Care of the Injured Patient 2006. The ACS established this document and his since added greatly to it as a resource for quality of care and standards of both trauma centers and trauma systems. The ACS verification process consists of hospital site reviews to determine quality of care and appropriateness of the trauma PI process. This verification process can then be accepted by the state as the designating authority to either designate or maintain designation of the trauma center. The ACS-COT also reviews statewide trauma systems to make recommendations to the system as a whole [4–8].

QUALITY OF CARE

Early studies, such as those done in Orange County and San Diego County, California, refined the preventable mortality concept. These studies were able to clearly identify a group of trauma patients that died from inadequate care—preventable mortalities. This concept provided a tool that could be used to examine quality of trauma care in any region or system. Teaching local and state legislators about the shortcomings of existing systems of care resulted in improved funding for trauma system components in many of the areas examined. Publication of these studies provided a necessary stimulus to many parts of the United States to begin to improve trauma care and develop trauma care systems.

As it became appreciated that data was important for determining quality of care, trends, and preventable mortality, trauma registries became a required part of trauma center work. Aggregations of these hospital-based trauma registries then developed as a result of State-sponsored trauma registries and research-oriented databases (such as the Major Trauma Outcome Study). Being able to examine populations of trauma patients led to developing mathematical formulas calculating the probability of survival of an individual trauma patient and comparing quality of care at trauma centers based on patient survival.

In 1990, the U.S. federal government passed Federal Law 101–590, Title XII of Public Health Service Act, which provided for grants to states to develop statewide trauma care systems. One of the products developed during the time the program was active (1992 to 1995) was the Model Trauma Care System Plan. The MTCSP was written to be a guide for states to implement a trauma system. The grant funds were modest (approximately $5 million per year), but resulted in states developing legislation, designating trauma centers, and establishing state trauma offices and procedures. Unfortunately, this Health Resources and Services Administration program underwent rescission of program funds in 1995 and was closed. In 1998, the program was again appropriated for several years, as before. During this time, a new State trauma system template was developed based on the public health model. Benchmarks, indicators, and scores were included in this federal document to permit states to score their own progress in developing an inclusive statewide trauma system.

The ACS-COT also helped develop the prototype Advanced Trauma Life Support Course in Nebraska in 1978 [9]. The course was then adopted and managed by the College as one of the most successful educational programs for doctors worldwide. ATLS lays the groundwork for the initial assessment and resuscitation of the injured patient. Every physician and medical student and perhaps all healthcare workers are familiar with the principles of the ATLS approach to trauma patients. These are the primary survey with the concept of ABCDE, and the secondary survey. In the primary survey, A is for airway, B is for breathing, C is for circulation, D is for disability, and E is for exposure. The secondary survey is a head-to-toe physical exam as well as pertinent history. The concept of the primary survey is to identify life-threatening problems and begin treatment within 15 to 30 seconds. The remainder of the ATLS teaches diagnostic and life-saving interventions as well as emphasizing the need to transfer a seriously injured patient to a trauma center. ATLS has been introduced in over 50 countries worldwide.

The ACS-COT also has developed a trauma system consultation process that can be applied to states, multistate jurisdictions, and even single-county systems.

As one examines the challenges and successes of trauma systems over the past 25 years, it remains clear that all phases of care are equally important to the successful outcome desired. In the context of critical care, let us examine each phase of care.

A. Identification/recognition of incident: Should the system fail to identify that an injury has occurred, the patient may succumb before medical care can be started. This happens not infrequently in rural and remote parts of our country. Even if the patient is found and transported to an appropriate trauma center, the delay in care may result in sepsis from open fractures not cared for in a timely manner or organ failure from delay in resuscitation. Some locations in our nation are so remote that even when the injured patient is recognized immediately, it can take more than 24 hours for him or her to arrive in a definitive care facility. The risk for poor outcomes is the same in either case.
B. EMS care and transport: The prehospital care systems are extremely variable across the United States. These systems range from volunteer to fire-based to government-employed professionals to contracted professionals. Again, the timely and vigorous resuscitation required by trauma patients can tax even the most experienced crew. Indeed, what quality EMS providers do is provide intensive care in the prehospital setting. Inadequate or delayed resuscitation can have profound immediate and late effects, similar to those already mentioned. The single greatest cause of mortality among trauma patients is head injury. If the patient is not rapidly and adequately resuscitated, the brain may never recover from even minor insult. The most severe brain insults may be rapidly fatal, even near the most capable institutions. Some brain injury patients appear to be awake at first but then drop their GCS score dramatically. The most classic of these is the epidural hematoma—the "talk and die" injury. As the epidural hematoma increases in size, herniation will occur unless the intracranial blood is rapidly evacuated. This entity is a good test of system performance; the patient must quickly get to a trauma center where a neurosurgeon is rapidly available. If this is the case, this is a readily survivable injury. Otherwise, it will result in death or permanent disability. Head-injured patients are among the most demanding in intensive care medicine. Early surgical intervention is much preferred over long-term care.
C. Emergency Department (ED) care: Many clinicians feel that the battle is won or lost by the time the patient arrives in the trauma center ED. This is not correct. Again, inadequate or delayed resuscitation may contribute to a poor outcome. This may happen many ways: too slow a resuscitation may result in prolonged hypotension with potential for organ damage—the brain being particularly susceptible. Too slow

to the operating room for care of open fractures may result in infection and sepsis.

Conversely, overaggressive resuscitation in the face of some injuries such as brain injury or pulmonary contusion may also cause problems. In these cases, too much resuscitation fluid may result in unnecessary tissue edema. This will cause increased intracranial pressure and poor perfusion in the closed space of the skull. With the lungs, the leaky capillaries associated with pulmonary contusion will cause the contusion to blossom more than necessary, with potential for more difficulty in ventilating the patient and weaning him or her from the ventilator.

D. Operating room (OR) care: Prior to intensive care unit (ICU) admission, many trauma patients will have required operative intervention. Inadequate correction of coagulopathy during the operation may contribute to later difficulties in ICU care. More hemorrhage into the tissues may cause pressure problems in fascial compartments, ongoing hemorrhage in the abdomen or chest causing abdominal compartment syndrome or thoracic compartment syndrome. All these compartment syndromes can also be caused by inadequate fluid resuscitation. Tissue hypoxemia and injury with later swelling and edema can result in any of these compartment syndromes. A modern massive transfusion protocol is a must for each trauma center today.
E. ICU care: Each of the issues mentioned above may also occur in the ICU setting. Just because the patient is now in the ICU does not mean that preventable problems will not arise. The burden remains for each care provider involved in the care of an individual trauma patient to make sure that care is provided in a thoughtful, timely, and expert manner. Under- or over-resuscitation can still occur. Delay in identification of injuries, such as bowel injuries may result in sepsis. Inattention to the need to decompress the stomach of a trauma patient with a gastric tube may lead to aspiration and pneumonia. Inattention to a small "CT" pneumothorax may lead to a complete or even a tension pneumothorax, particularly in the face of positive pressure ventilation. Patients can die of a tension pneumothorax even in an ICU setting. Intravenous catheters placed in the field under less-than-ideal circumstances may be contaminated and lead to sepsis if not replaced in a timely manner. Other chapters in this section give detail for the care of shock, resuscitation, management of sepsis, multiple organ dysfunction syndrome, traumatic brain injury, spinal cord injury, thoracic and cardiac trauma, abdominal trauma, burn management, and orthopedic injuries.
F. Ward care after leaving the ICU—these critical care trauma patients will need close follow up on the trauma center wards. Often sepsis may occur on the floor and MOD syndrome as well. The physicians following these patients must be capable of early recognition of these problems and institute immediate therapy when such problems are recognized.
G. Rehabilitation: Though many think the rehabilitative process begins after leaving the hospital, it should begin on the first full hospital day. Patients need to be mobilized early, and physical and occupational therapy consults should be on the admission orders. All patients with even minor head injuries need cognitive testing and evaluation by speech therapists. Any patients with head or spinal cord injuries or with a cluster of serious injuries need a physical medicine and rehabilitation physician involved with their care early in their hospitalization. The discharge plan needs to be formulated early and the resources of the patient and families need to be understood so the maximum benefit of rehabilitation and recovery can be realized. Trauma patients may also have been injured while using drugs or alcohol. Some trauma patients may have suicidal or depressive motives related to their injuries. All seriously injured patients may suffer from posttraumatic stress. It is the obligation of the trauma service to address these issues and have social services, counselors, and psychiatric services as part of the team so that the patient has the opportunity for the best possible outcome.
H. Performance Improvement, Research, Education, and Injury Prevention: An essential mission of any trauma service is quality assurance of care and performance improvement (PI). Opportunities for improvement in patient care from specific events or trends in complications must be recognized, discussed, and acted upon to promote the quality of care of trauma patients and the function of the trauma team. It is essential that all trauma centers have a current, thorough trauma registry to record all the clinical information from every trauma patient. As part of the trauma system, this information needs to be shared with the state trauma registry and the National Trauma Data Bank at the ACS. The information obtained from the trauma center registry feeds an effective PI program. The information from the trauma registry as well as those registries of the state and the NTDB also promote research and injury prevention. It is essential for the trauma center to be involved in injury prevention. The knowledge of which injuries are prevalent in that region will direct the focus of the injury prevention program. Research activity is encouraged at all trauma centers but is essential for a level one center. Finally, ongoing educational programs of all care givers involved with trauma care, including prehospital and rehabilitative services as an essential duty of a trauma center, and the trauma system.
I. Special Considerations in Trauma Systems

DISASTER MANAGEMENT

Most disasters are major incidents such as plane crashes, explosions in chemical factories, natural disasters such as hurricanes, or results of war and terrorist activities such as the events of 9/11/2001. An effective trauma system should be primed to manage these disasters. To successfully manage a disaster with many victims, there needs to be preplanning and organization of resources. There needs to be training done within the trauma system, stockpiling of supplies, an effective communication and triage system, and a clear understanding of the resources of each hospital and trauma center in the area. Without a trauma system, the wrong facilities would end up with the wrong patients (i.e., a seriously injured patient to a small hospital). The trauma system needs to predefine the triage of patients of a disaster according to severity of injury and volume of patients. This planning needs to have the trauma centers and trauma medical directors involved as they are the experts in the management of trauma patients. The most important principle is triage of the most seriously injured to the higher level of care in the fastest amount of time, and to avoid overtriage of minor injuries to the major trauma center. Triage guidelines should include re-triage to the trauma facilities. In a wider scope, there needs to be disaster planning between neighboring trauma systems in the event the trauma centers in a system are also damaged or unable to manage the load of injured patients [10,11].

RURAL TRAUMA

The establishment of a trauma system is of even greater necessity in a rural environment to improve the outcomes of the injured patients. In 9 of the 10 categories of injury for both urban and rural hospitals, the mortality rate is higher in the rural facility, and it is double for motor vehicle crashes.

Most of the problems with rural trauma relate to the time to definitive care at a trauma center. There is increased discovery time, time for the prehospital personnel to get to the patient, transportation over great distances and hard terrain, and transfer to the highest level of medical center. To decrease the mortality and morbidity of these patients, the trauma system needs to be firmly established and designate and train lower level trauma centers in areas of sparse population, provide consistent training of the volunteer prehospital personnel, and establish effective communication and transport systems between the prehospital and level III and IV trauma centers as well as to the regional Level II or I trauma center [12].

The American College of Surgeons sponsors specific courses for training in both rural trauma and disaster management, the Rural Trauma Team Development Course (RTTDC), and the Disaster Management and Emergency Preparedness course (DMEP).

In summary, trauma systems provide for early recognition, prehospital care, resuscitation and operative care critical care management, long-term care, and rehabilitation. Performance improvement remains an essential trauma system function.

CHAPTER 162 ■ TRAUMATIC BRAIN INJURY

TODD W. TRASK AND ARTHUR L. TRASK

When Dr. Rosner first published his recommendations that were to change the management of traumatic brain injury (TBI), he recommended using cerebral perfusion pressure (CPP = mean arterial pressure [MAP]—intracranial pressure [ICP]) as a better way to manage severe TBI patients than just using the level of ICP [1,2]. This was the beginning of the changes in TBI management. Dr. Marion and Spiegel have published the article "Changes in the Management of Severe TBI: 1991–1997" [3]. Recommendations to change severe TBI management, based on evidence, developed by The Brain Trauma Foundation, in combination with the Trauma committee of the American Association of Neurological Surgeons (AANS), the Congress of Neurological Surgeons (CNS), and AANS/CNS Joint Section on Neurotrauma & Critical Care have been updated several times with the latest version in 2007 [4]. Neurosurgeons were surveyed by the Brain Trauma Foundation in 1991 and 1997 to determine if they were changing their management of severe TBI patients. The use of steroids was significantly reduced from 1991 to 1997 and hyperventilation was also discontinued. In 2004, we published our results of an evidence-based medicine protocol [5]. Our results showed a decrease in hospital intensive care stay by 1.8 days ($p = 0.021$). The Glasgow Outcome Scores (GOS) of good or moderate from 1991 to 1995 were 43.3%. For the period 1997 to 2000, our patients' GOS of good or moderate were 61.5% ($p = < 0.001$). The overall mortality rate decreased from 17.8% for the early group compared to 13.8% for the later group [6–8].

We recommend that the intensive (ICU) care of severe TBI patients be driven by institutional protocols developed by key participants, that is, ICU care providers, using current recommendations for managing these patients [4]. Each hospital has different approaches to critical care and the reason we suggest assembling this key group of individuals is to assure that the plan for care fits into the way things are done in each hospital.

Above all, we recommend an evidence-based approach to the care of these critically ill patients. New evidence will be presented each year and adopting what has high credibility to that protocol makes good sense. We recommend keeping a TBI patient database to know with certainty how your results compare with other trauma centers in the USA and the world. By having a TBI database, you might also consider doing a prospective study using different techniques for similar TBI problems or management [9–13].

IDENTIFICATION

Identification of severe traumatic brain injury requires two criteria to be met. First, the Glasgow Coma Score (GCS) must

be 8 or less. The GCS was first described in 1974 by Graham Teasdale and Bryan J. Jennett, professors of neurosurgery at the University of Glasgow, Scotland. In 1981, they approached F.A. Davis, the author of a textbook *Management of Head Injuries* who included the scoring system for identification of different levels of TBI.

The next criteria for a severe TBI is an abnormal brain computed tomography (CT) with findings such as contusion, hematoma, diffuse axonal injury (DAI), compressed basal cistern, subarachnoid hemorrhage (SAH), and/or other clear signs of brain injury. When only an abnormal GCS is present, it is possible to be due to something other than TBI. When an injured patient arrives in an emergency department (ED), these two assessments are done to identify a severe TBI patient. When these criteria are met, the patient should be moved to a Neurotrauma ICU, a part of the recognized Trauma Center, as soon as possible, provided other types of operative treatment are not more urgently needed. Placement of an intracranial pressure monitor should be considered in the multiple-injured TBI patient, simultaneously with the non-neurosurgical operative procedures.

MONITORS

We recommend intracranial pressure (ICP) monitors for assessing the moment-to-moment status of your patient. Generally, a ventriculostomy type monitor is superior to an intraparenchymal (Bolt) monitor. The ventriculostomy can accurately determine the intracranial pressure but also allows the neurophysicians to drain cerebrospinal fluid (CSF). The latest recommendation for ICP monitors is to have an electronic continuous record with instantaneous alerts for significant increases to allow immediate interventions per protocol. Many devices are available for measuring brain oxygen levels as well as oxygen from the jugular bulb. The value of these measurements is yet to be determined by the BTF and AANS [14–19].

An understanding of the Monro-Kellie doctrine is essential. In 1783, Alexander Monro deduced that the cranium was a "rigid box" filled with a "nearly incompressible brain" and that its total volume tends to remain constant. The doctrine states that any increase in the volume of the cranial contents (e.g., brain, blood, or cerebrospinal fluid), will elevate intracranial pressure. Furthermore, if one of these three elements increases in volume, it must occur at the expense of the volume of the other two elements. In 1824, George Kellie confirmed many of Monro's early observations. If as a result of trauma a hematoma forms on the outside of the brain (epidural hematoma), under the dura (subdural hematoma), or within the brain itself, the space occupied by the hematoma must result in a commensurate decrease of the intracranial blood or CSF volume. Once these compensatory mechanisms are exhausted, intracranial pressure will rise rapidly, and brain herniation may occur. Cerebral edema can mimic an expanding mass lesion, with similar pathophysiology, and potential for the irreversible damage associated with uncal and/or tonsillar herniation (see graph in Fig. 162.1).

In general, the reaction to an intracranial mass or cerebral edema is to reduce the amount of venous blood and CSF within the skull. The body's response to the injury is to keep the pressure inside the skull as close to normal as possible by reducing those volumes that can be reduced. When a sudden increase of ICP occurs and the patient has a ventriculostomy, the neurointensivist may drain additional CSF from this closed box. This in turn helps to keep the ICP under control while other measures are taken to reduce the ICP in a more lasting fashion. We will discuss more about this under patient management.

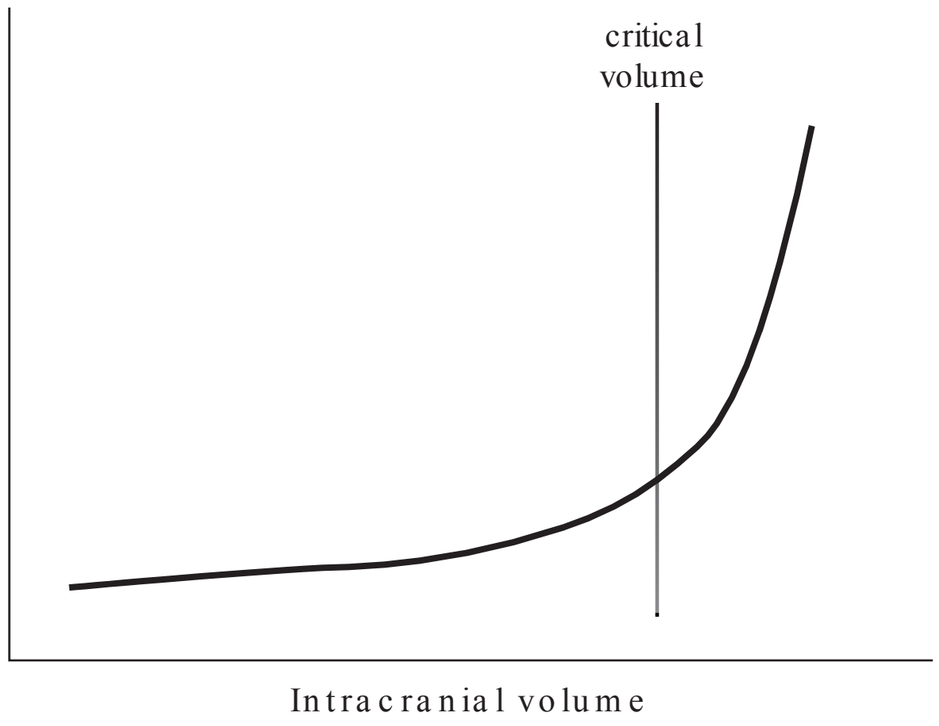

FIGURE 162.1. As the Monro-Kellie doctrine indicates, the skull is a closed box. When intracranial volume increases to the *critical volume* due to traumatic brain injury, that is, subdural hematoma (SDH), epidural hematoma (EDH), or massive cerebral edema, note the dramatic vertical increase in intracranial pressure. If this occurs and the volume is not reduced, brain herniation will occur.

The next consideration for the severe TBI patient is determining what other injuries the patient might have. A qualified trauma surgeon must be involved to assist the neurointensivist with the fluid/blood product management. For example, a patient with a class III anterior posterior pelvic fracture will lose huge amounts of blood even if managed by a trauma orthopedist with pelvic circumference reduction. This is an indication for a pulmonary artery catheter (PAC) (or one of the newer devices for monitoring pressures and cardiac output) to monitor the resuscitation as closely as possible. The goal is maintaining the patient's systolic pressure at or above 90 torr. In the book, *Management and Prognosis of Severe Traumatic Brain Injury*, a joint project of the Brain Trauma Foundation and American Association of Neurological Surgeons, class two evidence states that allowing the systolic BP to drop below 90 torr will likely produce secondary brain injury. The BTF class two evidence criteria are clinical studies in which the data was collected prospectively or retrospective analyses that were based on clearly reliable data. Types of studies so classified include: observational studies, cohort studies, prevalence studies, and case control studies. Class two evidence shows that post injury hypotension has dramatic impact on the brain injury outcome. We recommend using the PAC data to assist in fluid/blood product management to maintain a PCWP between 10 to 15 mm Hg and a CI of 2.6 L per minute per m^2. Invasive hemodynamic monitoring may also help avoid fluid overload and possibly associated increases in cerebral edema. A new monitoring device is now being evaluated for these multiply-injured patients. The use of The InSpectra^{TM} StO_2 Tissue Oxygenation Monitor will provide continuous, real-time information for perfusion status monitoring and a new hemodynamic parameter (StO_2) to assist clinicians in the early detection of inadequate tissue perfusion (hypoperfusion). This device would noninvasively monitor hemodynamic status and tissue oxygenation, both of which are critical for severe TBI patients [19].

The oxygen saturation level and the PCO_2 level are also extremely important for the ICU management of these patients. The Brain Trauma Foundation has gone to great lengths to provide training to prehospital providers so that they recognize the importance of keeping the O_2 saturation more than 90%. This same standard must be maintained in the ICU as well. Patients with severe TBI should have endotracheal intubation as early as possible after the traumatic event. Once the patient arrives in

the Trauma Bay, the ventilator must be set to assure adequate oxygenation and also to maintain the PCO_2 level around 38 to 40 mm Hg. Most intensivists/respiratory care physicians recommend keeping the head of the bed elevated to 30°. In addition to aiding respiratory function, elevation also provides some slight assistance in maintaining the ICP in the desired range.

Major trauma accompanied with significant blood loss often will result in coagulopathy. The American College of Surgeons Committee on Trauma in their Advanced Trauma Life Support Course™ classifies shock into four classes. Primarily, class III (1,500 to 2,000 mL blood loss) and class IV (> 2,000 mL blood loss) are frequently associated with coagulopathy. In addition, we also know that certain severe TBI cases may present or develop coagulation abnormalities. Using a device called a Thromboelastogram™ (TEG) will assess the coagulation status of these patients and offers a rapid technique for identification of coagulation problems. A TEG is also useful for identifying hypercoagulability, and the associated risk of venous thromboembolism [20–26]. Electroencephalography (EEG) monitoring and Ultrasound monitors are being used more frequently today and are very useful for those patients being treated with pharmacological coma.

It is necessary to observe closely for impending Diabetes Insipidus (DI) by frequent serum Na determinations, urine output > 200 cc per hour and urine specific gravity < 1.005. This is considered Central DI and is due to a lack or an inadequate amount of ADH (vasopressin). Treatment is with subcutaneous vasopressin (ADH) or intravenous deamino-8-d-arginine (DDAVP).

Cerebral microdialysis is possible with a ventriculostomy in place. During periods of metabolic stress with TBI, many neurointensivists are using this technique to measure changes in lactate, excitatory amino acids, glycerol, glucose, and pyruvate as well as other metabolic compounds during periods of metabolic stress of TBI. The future of patient management may be augmented by these studies, but at present no recommendations are evidence based.

PATIENT MANAGEMENT

Avoiding seizures is a key management endeavor. This activity may exacerbate metabolic derangements already present, and result in secondary injury. Loading severe TBI patients with phenytoin is recommended provided adequate hemodynamic stability exists. The loading dose we recommend is 18 mg per kg at a rate of 25 mg per minute. The maintenance dose is 100 mg every 8 hours IV. Maintenance dosing for 7 days is indicated. Class II evidence shows that prophylactic anticonvulsants have no benefit after 7 days, provided there have been no seizures. We recommend obtaining a free phenytoin level 72 hours after the loading dose [27–29].

The syndrome of inappropriate antidiuretic hormone (SIADH) may occur. This usually appears late in the course of TBI and appears as hyponatremia since the hormone causes water retention diluting the plasma electrolytes. If early in the care for mild hyponatremia, water restriction is usually sufficient but, the CPP should not be allowed to drop as a result of the restriction. This syndrome needs to be distinguished from the cerebral salt wasting syndrome which is thought to be caused by a brain-secreted natriuretic peptide. The difference can usually be elicited by measuring urine sodium levels that are inappropriately elevated in cerebral salt-wasting syndrome. Treatment for this syndrome is salt and volume replacement. For an in-depth discussion of this subject, readers are referred to Chapter 72.

Attempting to keep the brain activity at a minimum is another management activity. Fast acting drugs are suggested during the first 48 hours after injury to allow the neurospecialists to reexamine the patient frequently to determine deterioration or improvements in coma scoring. Use of propofol and fentanyl for this period is suggested. When the status of the patient has been well established, we suggest switching to longer acting (less expensive) medications. We recommend using lorazepam and morphine to keep the Richmond Agitation Sedation Scale (RASS) score @ −2 to −3 (see Fig. 162.2). The RASS has been shown to be a useful adjunct in the management of the severe TBI patient [30].

Another adjunct in the management is temperature control. While a study has been suggested using hypothermia (to 32°C) for patients aged less than 45 years, normovolemia and with a GCS > 4, the multicenter trial did not confirm this hypothesis and was terminated [31]. Nonetheless, it is essential to avoid temperature elevations. Anticipating temperature elevations and monitoring closely will allow the management team to use cooling techniques and/or medications such as acetaminophen to keep the temperature ≤ 38°C.

Gastric mucosal protection is necessary to prevent stress ulcers. We suggest prophylaxis using a histamine receptor antagonist, a proton pump inhibitor. Once a feeding program is started the problem of stress ulcers decreases.

The nursing staff must play an important role in the management of these critical ill patients. They should repeat the motor score and eye score to detect improvement or deterioration. They must assume responsibility for frequent checks of urine output, temperature, ICP, CPP, Hb, electrolytes, and graphing trends for the neurointensivist to review during reexaminations.

When the nurse documents an elevated ICP of ≥ 20 for more than 10 minutes, (these are suggested criteria and each hospital will need to decide what early criteria they will use) we suggest immediate drainage of CSF by the ventriculostomy. Next optimize temperature control, increase sedation, and paralyze patient. The next step is again a decision each hospital should make. Hyperosmolar therapy with mannitol or hypertonic saline should be considered. Nicole Forster in her publication suggests that mannitol is the first choice for pharmacological ICP reduction [31]. Cruz, Battison, Valadka, Shackford, Ware, and White all believe some form of hypertonic saline should be used to reduce the ICP [32–38]. There are considerable differences of opinion on this topic. At this time, each facility should review these articles and the ICU team must decide on what hyperosmolar therapy to use. Repeat imaging should always be considered in the event of unexpected ICP changes.

If the ICP rises to ≥ 25 for 30 minutes the neurology team should discuss the use of pentobarbital coma or consider performing an early decompressive craniectomy as recent literature suggests a role for this procedure in some patients [39–42]. The best results are observed when the craniectomy is performed early and before significant deterioration has occurred.

Hopefully, with all of the above strategies, patients will gradually improve showing better motor scores and improved CT scan. The criteria for discontinuing the major TBI protocol should be (a) when the patient is requiring less sedation with the RASS being −2 to −3, (b) the paralytics have been discontinued, (c) temperature control is no longer a problem, (d) recent CT scan shows stability and/or improvement, and (e) the ICP has been ≤ 20 for at least 24 hours and the neurosurgeon has discontinued the ventriculostomy.

During this critical period, nutritional support should be initiated. Assessment of the metabolic needs of these patients is crucial and nutritional support plays a major role in recovery. A consultation with a physiatrist, who in collaboration with the neurointensivist team, will suggest the physical therapy, occupational therapy, and speech therapy. These therapies will be started to aid in the long-term recovery of these patients.

Score	Term	Description
+4	Combative	Overly combative, violent, immediate danger to staff
+3	Very agitated	Pulls or removes tube(s) or catheter(s), aggressive
+2	Agitated	Frequent nonpurposeful movement, fights ventilator
+1	Restless	Anxious but movements not aggressive, vigorous
0	Alert & calm	
−1	Drowsy	Not fully alert, but has sustained awakening (eye opening/eye contact) to voice (≥10 sec)
−2	Light sedation	Briefly awakens with eye contact to voice (<10 sec)
−3	Moderate sedation	Movement or eye opening to voice (but no eye contact)
−4	Deep sedation	No response to voice, but movement or eye opening to physical stimulation
−5	Unarousable	No response to voice or physical stimulation

Procedure for RASS Assessment

1. Observe patient
   a. Patient is alert, restless, or agitated. (score 0 to +4)
2. If not alert, state patient's name and say to open eyes and look at speaker
   b. Patient awakens with sustained eye opening and eye contact. (score −1)
   c. Patient awakens with eye opening and eye contact, but not eye contact. (score −2)
   d. Patient has any movement in response to voice but no eye contact. (score −3)
3. When no response to verbal stimulation, physically stimulate patient by shaking shoulder and/or rubbing sternum.
   e. Patient has any movement to physical stimulation (score −4)
   f. Patient has no response to any stimulation (score −5)

FIGURE 162.2. The Richmond Agitation Sedation Scale (RASS). [Adapted from Sessler CN, Gosnell MS, Grap MJ, et al. The Richmond Agitation-Sedation Scale: validity and reliability in adult intensive care unit patients. *Am J Respir Crit Care Med* 166:1338–1344, 2002.]

FUTURE POTENTIAL TREATMENT OPTIONS

a. A multicenter trial: Citicoline Brain Injury Treatment Trial (COBRIT). This is a phase 3 double-blind, randomized, prospective clinical trial to determine if treating head injured patients (severe, moderate, and complicated mild) with citicoline will improve recovery. Citicoline, also known as cytidine diphosphate-choline (CDP-choline) is a psychostimulant/nootropic. It is an intermediate stage in the generation of phosphatidylcholine from choline and increases dopamine receptor densities. The patients are randomized to citicoline or placebo. The reason for this compound being tested is that several meta-analyses indicate a benefit of this compound in stroke and dementia. Eight sites are participating.
b. Spreading Depressions (formerly COSBID) is in the study preparation phase. Cortical Spreading Depression (CSD) is a wave of mass neuronal firing, neuronal, and glial depolarization. It propagates through gray matter at a rate of between 1 and 5 mm per minute and depletes energy stores and may activate cell death cascades. Spreading Depressions (SD) are seizure like waves that actively propagate a breakdown of ion homeostasis and may alter blood flow through injured, but potentially salvageable brain tissue. The objective of this study will be to determine if SD actually causes secondary brain injury after TBI. If the answer is yes, then a method to block the SD waves will be developed. The results of this study are eagerly awaited.
c. Another study, labeled SOLVAY, is designed to study SLV334 in a phase 2a randomized, placebo-controlled, double-blind pharmacokinetic and safety study. If shown to be safe, a phase 3 trial of this drug which has a new mechanism—endothelin antagonism, matrix metalloprotease inhibition, and "anti-apoptotic effect"—will be developed with multiple centers.
d. A phase 3 prospective randomized multicenter clinical trial is underway with an expectation of about 1,400 patients over a 5-year period. Titled the *B*rain *O*xygen and *O*utcome in *S*evere *T*raumatic Brain Injury (BOOST) Study, it is designed to compare the standard management of ICP/CPP versus brain oxygen-based therapy to determine which category of patients will have the best long-term outcome.

Much progress in treating TBI has occurred. Careful management of the CPP, ICP, cardiac output, tissue oxygenation, PCO_2, temperature, and the other body parameters that support brain metabolism and recovery is indicated. Much opportunity for improving the management of TBI patients still exists when given by well-trained critical care teams resulting in more updates on management sequelae in this ever-encouraging field of emergency trauma care.

CHAPTER 163 ■ SPINAL CORD TRAUMA

HOWARD B. LEVENE, MICHAEL Y. WANG AND BARTH A. GREEN

INTRODUCTION

"The Spine" is often thought of a single unit, as is "the liver" or "the intestines," but the concept is somewhat misleading. "The Spine" is really a structure with two parts. The first part, the bony spine, serves dually to support the body and to protect the vulnerable neurological structures inside. The second of the two parts of the spine, the neurological spine, is more than just a "coaxial cable" connecting the brain to the remainder of the body. The neurological spine, the spinal cord, is a complex extension of the central nervous system, capable of learning and adapting. When the bony protection fails, the spinal cord (and possibly the cervical-medullary brainstem or the cauda equina) is traumatized with multiple systemic consequences. These consequences may result in a catastrophic injury. To better develop treatments for spinal cord injury, the pathophysiology of the injury continues to be thoroughly studied [1–8]. In this chapter, traumatic forces are emphasized, but the reader should keep in mind that vascular, infectious, or toxic/metabolic/ischemic damage to the spinal cord may present in a patient with a similar profile of deficits and clinical challenges.

Injury to the spine can be thought of in two phases. The first phase called "Primary Injury" is the moment when excessive kinetic energy is transmitted to the spinal cord in the moment of trauma. The "Secondary Injury" follows immediately after that as the damage from the primary injury creates biologic sequelae. Secondary injury in spinal cord injury (SCI) is believed

to involve the release of neurotoxic chemicals, creation of free radicals, recruitment/activation of macrophages, disruption of the blood-spinal cord barrier, generation of lipid peroxidation, presence of oxidative cell stress, and other events [9]. Even without a complete understanding of all of the variety of events in spinal cord injury, it is believed that secondary injury can be modulated with appropriate therapeutic interventions. These include, but are not limited to, decompressive surgery [10,11] steroids [12–17], hypothermia [18–23], immunomodulation [24–26], nutrition [27,28], and other therapies.

Given the tremendous socioeconomic and psychosocial impact of spinal cord injury, there have been several human clinical trials [12,15,29–32] to date in an effort to limit the secondary injury, but there is no one therapeutic strategy that is clearly effective in affecting outcome.

Surgical management of spinal cord injury is also still under debate, especially in terms of the timing and utility of the surgical intervention [11,33,34]. Fortunately, there are treatments available for the spinal cord injured patients such as physical therapy, outpatient therapy, and adaptive therapies [35–40].

The future of treatment for spinal cord injured patients will likely involve a combination of techniques, such as applying neurotrophic factors, nerve grafting, cellular injection, hypothermia, tissue engineering, neuromodulation, and other innovative approaches. This chapter addresses the many problems unique to the management of a spinal cord-injured patient. The specific surgical treatments for each pathologic entity are beyond the scope of this chapter.

HISTORY

The Edward Smith Papyrus [41–43] represents one of the earliest records of spinal cord injury. Dating back approximately to 2500 B.C.E., there is a case report by Imhotep, a physician and architect to the Pharoh Zoser III. In this Papyrus, he describes 48 trauma cases, 6 of which involve vertebral column injury. In the most famous case, Imhotep describes a case of "crushed vertebra" where "incontinence, paralysis, and loss of sensation" follow. In his medical opinion, treatment was not to be pursued. The Greek Physician Galen, some 3000 years later, conducted animal experiments noting the difference in effects between longitudinal and horizontal cord transactions [41]. Only 500 years after Galen, the laminectomy was introduced by Paulus. In 1543, Vesalius then introduced remarkably detailed anatomical drawings of human anatomy. In the early twentieth century, despite significant scientific and engineering advancements, the opinion of Imhotep still reigned true and traumatic SCI was felt to be a terminal condition.

The recognition that spinal cord injury should not be viewed as a terminal condition owes much to the insights of Sir Ludwig Guttmann (UK) and Sir George Bedbrook (Australia). In the aftermath of World War II, these two physicians were at the forefront of refusing to accept the inevitable prognosis for SCI [44,45]. They pioneered the idea that the sequelae of SCI do not need to be fatal and that an intensive regiment of physical therapy and care may be life-saving and life-improving.

EPIDEMIOLOGY

There are more than 200,000 people in the United States living with a chronic SCI. Each year, approximately 11,000 Americans are afflicted with this condition [46]. More than half of the people who sustain SCIs are 15 to 29 years old (CDC data: http://www.cdc.gov/ncipc/factsheets/scifacts.htm). Approximately 80% of the injured are male [46]. There is a growing trend of seeing SCI among middle-aged and elderly patients due to improved lifestyle habits and improved survivability of injuries. Data collected from North America, Europe, and Australia confirm similar results [47]. The cervical spine is the most commonly injured site, with the remaining injury sites divided between thoracic, thoracolumbar, and lumbosacral levels [48].

The mechanism of injury can be blunt (e.g., motor vehicle accident, fall, assault) or penetrating (e.g., gunshot wound, knife, and other sharp object). Approximately 50% of the injuries derive from a motor vehicle accident, with the remainder primarily from falls (23%), violence (14%), and sports (9%) [46].

NEUROLOGIC INJURY

As a trauma patient is assessed through the initial "ABCDE" of Advanced Trauma Life Support, the physician must perform a neurologic examination. The neurologic examination is of paramount importance localizing the probable site of injury as well as to assess the severity of injury to the spinal cord. Once the SCI is identified, the physician can classify the injury by mechanism (e.g., penetrating vs. blunt), level (cervical, thoracic, lumbar), and degree of neurological impairment (often through the American Spinal Injury Association [ASIA] scale).

To assess the degree of neurologic injury, particular attention is paid to the motor, sensory, reflex, and rectal examinations. Based on the degree of functional impairment, the ASIA has proposed an easily used scoring system (Table 163.1). The neurologic injury is categorized using this score and by noting lowest normal segmental level. (When referring to the "level" of injury, it is important to note that the level is the corresponding "neurological level" or dermatological level and not the "bony level." For example, consider a patient shot in the spine. A neurosurgeon evaluates the patient and states that the patient has a complete neurological injury at the "L4" level. This means that the lowest spinal level with completely normal function is at the L4 neurons of the spinal cord. The bony disruption, however, may be at approximately T12, which corresponds to the locations of neurons that innervate L5 and below.)

In this classification scheme, the severity of injury is denoted by Grade, followed by letters A-E. The letters serve as shorthand to classify the severity of injury as it relates to sensory and motor function. Grade A (complete) denotes a complete injury with no sensory or motor function preserved in sacral segments S4–5. Grade B (incomplete) denotes sensory, but not motor function preserved below the neurologic level and extends through sacral segments S4–5. Grade C (incomplete) denotes motor function preserved below the neurologic level with muscle strength graded below antigravity strength. Grade D (incomplete) denotes motor function preserved below neurologic level with muscle strength graded more than or equal to antigravity strength, but not normal. Grade E denotes a normal

TABLE 163.1

AMERICAN SPINAL INJURY ASSOCIATION GRADING SCALE FOR SPINAL CORD INJURY

Clinical grade	Neurologic examination
A	No motor or sensory function preserved
B	Sensory but no motor function preserved
C	Nonuseful motor function preserved (less than antigravity strength)
D	Motor function preserved but weak
E	Normal motor and sensory function

sensory and motor exam [49,50]. The grades have a prognostic feature. Complete recovery of function after a Grade A injury is unlikely. However, improvement of one or two grades is seen in more than 10% of patients. Some recovery is most likely to occur in Grade D injuries [51].

SCI may be also classified as complete or incomplete. In complete SCI, there is no preservation of motor function and/or sensation for three spinal segments below the level of injury. Complete injuries above T6 are usually associated with spinal shock. Spinal shock is characterized by: hypotension from interruption of sympathetics, bradycardia from unopposed vagal (parasympathetic) output, hypothermia, and transient loss of all neurologic function resulting in a flaccid paralysis and areflexia. Incomplete SCI may be further subclassified into specific neurological symptoms based on the anatomy of the injury.

SPECIFIC NEUROLOGIC SYNDROMES

Specific neurologic syndromes have been described for particular incomplete spinal cord injuries [52,53]. These syndromes include the anterior cord syndrome, the central cord syndrome, the posterior cord syndrome, Brown-Sequard (hemisection cord syndrome), conus medullaris syndrome, cauda equina syndrome, and cord concussion syndrome.

The **anterior cord syndrome** is characterized by complete paralysis and hypoalgesia (to pain and temperature) from damage to anterior and anterolateral column function below the level of injury, with preservation of proprioception (vibration and position sense) and light touch from posterior column function. This syndrome occurs most commonly after trauma focused at the anterior spinal cord as well as ischemia in the territory supplied by the anterior spinal artery, which supplies the corticospinal and spinothalamic tracts in the anterior 2/3 of the spinal cord. It is classified as an ASIA B injury.

The **central cord syndrome** is characterized by motor dysfunction more pronounced in the distal upper extremities than in the lower extremities ("man in a barrel"), accompanied by varying degrees of sensory loss and bladder dysfunction. The injury occurs characteristically after a hyperextension injury in elderly patients with acquired cervical stenosis from spondylosis or in athletes with congenital cervical stenosis. The injury can be seen in the absence of any clear radiographic disruption of the bones or ligaments. Most patients recover the ability to walk, with partial restoration of upper-extremity strength. It is associated with severe allodynia of the hands. (Allodynia is pain from stimuli that are not normally painful.)

The **posterior cord syndrome** is an uncommon presentation in which position sense, vibration sense, and crude touch are impaired due to injury to the dorsal columns or injury directed to the posterior of the spinal cord.

The **Brown-Sequard syndrome,** or **hemisection cord syndrome,** presents with ipsilateral paresis and loss of proprioception, touch, and vibration below the level of the lesion and the contralateral loss of pain and temperature sensation. This can be the result of penetrating injuries or asymmetrical lateral closed injuries resulting in a spinal cord hemisection, and is usually not seen in the pure form. Asymmetrical, lateral closed injuries are often confused with an ipsilateral brachial plexus injury.

The **conus medullaris syndrome** occurs with injuries at the thoracolumbar junction. This syndrome has components of both spinal cord and nerve root injury due to the dense population of nerve roots emerging from the caudal end of the spinal cord. Symmetric lower-extremity motor impairment and anesthesia with bowel, bladder, and sexual dysfunction are typically seen. There is typically a symmetric "saddle" area loss of sensory function. Spinal cord function recovery from this syndrome is less likely than recovery from nerve root injury. In cases of the **cauda equina syndrome,** partial recovery is possible with decompression [54]. Cauda equina injuries occur at spinal levels below the termination of the cord, typically at L1 or below.

Cord concussions present with transient neurologic symptoms followed by rapid resolution. These injuries are seen most commonly in athletes with low velocity hyperflexion or extension injuries of the cervical spine. Complete recovery is the rule; however, patients should be evaluated meticulously for severe stenosis or occult spinal instability and intraspinal hematomas. This is in contrast to "stingers or burners" that involve cervical nerve roots only. The issue of "return to play" [55–60] is especially important in the field of athletics. Currently, there is no agreed upon measure to predict which athletes are most at risk of further injury. However, "functional" stenosis [61] and anatomic measurements [56] may both play a role.

PATHOPHYSIOLOGY

The injury to the spinal column and spinal cord involves the transfer of energy sufficient to disrupt the cell membranes and mechanical attachments of the ligaments, muscles, and joints. This results from movement and stressing of the spine beyond its biomechanical/physiological limits in hyperflexion/hyperextension, rotation, compression, or a combination thereof. Injury may result in retropulsion of materials (e.g., bone, cartilage, blood, foreign body) into the spinal canal. Disruption of the vertebral column may also damage the spinal cord within the canal (e.g., dislocation injuries) by reducing the spinal column diameter and compressing the spinal cord. The spinal cord may also be injured by direct laceration or transaction of the cord (e.g., bullet or knife injury). Direct crush, stretch, and shear injury to neurons within the spinal cord leads to immediate cell death.

Secondary injury occurs as the body responds to the damage from the primary injury. There are many mechanisms that initiate secondary injury. These include systemic hypoxia (e.g., hypotension from neurogenic shock or hypovolemic shock, hypoperfusion, etc), local vascular insufficiency (local hypoxia) from trauma, direct penetrating trauma, and spinal compression.

The secondary injury involves biochemical changes and the release of neurotoxic substances. Toxic substances, such as glutamate and free radicals contribute to cell damage and death. These biochemical changes lead to excitotoxicity, neurotransmitter accumulation, arachidonic acid release, free radical production, eicosanoid production, and lipid peroxidation. There are electrolytic shifts such as increased intracellular calcium, increased extracellular potassium, and increased intracellular sodium. The disruption in electrolytes is compounded with the loss of energy metabolism, as the neurons are unable to produce adenosine triphosphate (ATP). Within minutes to hours, oxidative stress leads to cell necrosis. Apoptosis follows further depletion of cells. Over the following days to months, demyelination occurs with the loss of oligodendrocytes. Glial scar formation and axonal degeneration/retraction follow [9]. The damage of the cord may be visualized as edema.

Because spinal cord-injured patients frequently also suffer polytrauma, they are susceptible to derangements of homeostasis. Cardiovascular and pulmonary compromise may affect perfusion and oxygen delivery to the spinal cord, exacerbating the damage. Recent work in animal models of SCI suggests that SCI itself may further disrupt homeostasis. There is evidence from animal models of SCI for a systemic inflammatory response capable of disrupting the cardiopulmonary and renal system [62]. Vasoactive substances released by injured cells

and endothelin released from damaged capillaries may also disrupt the spinal cord microcirculation. Ischemia may thus cause neurologic deficits to extend rostrally beyond the initially injured area [63,64].

Because cell death due to secondary injury is an ongoing process, it is believed that early pharmacologic intervention and maintenance of adequate tissue perfusion can salvage these neurons. Given that only 5% to 10% of the descending pathways are necessary for retention of some neurological function [4], even a modest preservation of axons during an injury could have a profound impact on the life of a person with spinal cord injury.

ACUTE MANAGEMENT

Care of the spinal injury patient begins in the field with Emergency Medical Services personnel. The "ABCDE" (**A**irway, **B**reathing, **C**irculation, **D**isability, **E**xposure) of Advanced Trauma Life Support are followed. Attention to maintaining a patent airway and the management of shock take precedence. The patient is immobilized with a rigid cervical collar and backboard for transportation to a trauma center. Intubation and helmet removal should be attempted only with strict attention to maintaining neck alignment. This is particularly important in unresponsive patients, as 3% to 5% of comatose patients have a coexisting cervical spine injury. Additionally, there may be a second site spinal injury, which occurs in 15% of SCI patients.

In the trauma center, the priority remains the maintenance of tissue oxygenation and perfusion, with particular attention to maintaining an adequate mean arterial blood pressure. In this regard, the spinal injury patient presents particular challenges. Immobilization of the cervical spine during intubation is essential and is best accomplished with fiberoptic or awake nasotracheal maneuvers. Mechanical respiratory efforts may be minimal when the injury level is C5 or higher. In these patients, muscular expansion of the rib cage is absent and diaphragmatic breathing may be weakened. Thus, intubation with in-line stabilization using two physicians may be the only option to quickly establish airway control and ventilation. Caution should be exercised in suctioning the oropharynx, as this may stimulate autonomic reflex arcs, causing profound bradycardia and even cardiac arrest. The emergent cricothyroidotomy for airway access must also be considered.

Cervical and high thoracic injuries may result in spinal shock, which can severely complicate the management of a patient already in hypovolemic shock. The clinical picture is hypotension with an associated bradycardia and often hypothermia. Treatment is with mild fluid resuscitation and continuous intravenous inotropic infusions possessing alpha-adrenergic properties to increase the heart rate, cardiac output, and vasomotor tone. Dopamine, because of its mixed alpha-and beta-adrenergic effects, is a useful medication to treat spinal shock. Acutely symptomatic bradycardia should be treated with intravenous atropine. Monitoring with pulmonary atrial catheters (e.g., Swan-Ganz catheters) can help determine the adequacy of perfusion and cardiac output.

Associated extraspinal injuries are common and must also be ruled out. This would be assessed in the "D" and "E" sections of the assessment. Because spinal column injuries are typically the result of severe traumatic mechanisms, the incidence of associated cranial, thoracic, abdominal, and orthopedic injuries is high. Priority must be given to the most life-threatening injuries. If the patient is stable and cooperative, an exam to determine the level of injury (e.g., the ASIA scale) is performed.

The diagnosis of a spinal column injury is based on the clinical examination and radiologic investigations. In an awake, non-intoxicated patient, the absence of pain along the spinal axis is useful to rule out injury. In these patients, a low-velocity injury may require no x-rays, and a high-velocity injury requires only limited plain x-rays. It is essential that radiographic evidence of spinal column injury be correlated with the clinical examination, as 15% of patients have injuries at multiple spinal segments. X-ray, computed tomography, and magnetic resonance imaging investigations are needed in patients who are not able to fully cooperate with the neurologic examination.

Radiographs are useful not only for the detection of but also for the classification of injuries. The fracture types, as well as the degree of cord compression, are particularly important aspects of the injury that determine the management strategy. For the cervical spine, plain lateral x-rays must include the C7-T1 junction, as 31% of injuries occur between C6 and T1. In large, bulky patients, downward traction on the shoulders, a swimmer's view, or a computed tomography scan of the cervical spine may be needed to properly visualize the cervicothoracic junction. Lateral x-rays allow evaluation of vertebral alignment (> 3 mm subluxation suggests instability), canal diameter (normal is > 12 mm), angulation of the intervertebral space (normal is < 11°), width of the interspinous gap, and the atlantodental interval (the distance between the anterior margin of the dens and the closest point on the anterior arch of C1, which should be 3 mm in adults). Soft tissue swelling in the prevertebral space is an indirect indicator of cervical spine injury (maximum prevertebral space in adults at C1 is 10 mm, C2–4 is 5 to 7 mm, and C5–7 is 22 mm).

In the thoracic and lumbar spine, anterior compression fractures and fracture dislocations are usually clearly visible on lateral x-rays. Splaying of the interspinous ligaments is indicative of disruption of the posterior tension band, comprised of the spinous processes and the interspinous ligament. Burst fractures may be difficult to detect on a lateral x-ray but are evident from an abnormally increased intrapedicular space when compared to adjacent levels. Computed tomography is particularly useful in burst fractures for assessing the degree of canal compromise by retropulsed bone fragments from the vertebral body.

If the patient is otherwise systemically stable, cervical traction using a halo frame or Gardner-Wells tongs may be used to restore alignment of the cervical spine and to reduce neural compression. Traction must be initiated with caution, however, as neurologic deterioration can occur from overdistraction or movement of acutely herniated disk material [65]. Before traction is initiated, a full set of x-rays and a magnetic resonance imaging scan help to reduce the likelihood of worsening deficits. In the subaxial spine, it is prudent to begin with 10 lbs and to add weight until reduction is achieved or a total of 5 lbs per cervical level has been used. Serial lateral x-rays or fluoroscopic images should be taken and repeat physical exams performed after each addition of weight to ensure that the neck and spine have not been overdistracted. Of note, not all spine surgeons advocate the routine use of MRI in all cervical spine injuries [66]. Care should be also taken to avoid traction when possible in patients with ankylosing spondylitis because further fracture and·distraction of the vertebral column is likely.

Early intervention to prevent delayed sequelae should also be initiated at this point. This would include use of good respiratory therapy (e.g., incentive spirometry), GI prophylaxis (e.g., H-blockers), and pulmonary embolism prophylaxis (e.g., heparin derivatives, supportive stockings, and sequential compression devices).

ANATOMY

The human vertebral column consists of 7 cervical, 12 thoracic, 5 lumbar, and 1 fused sacrococcygeal vertebrae. A plum line

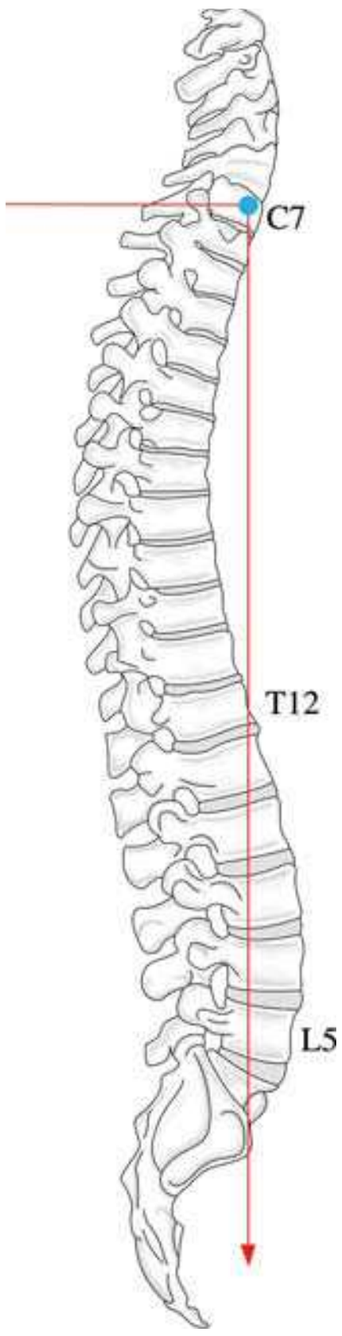

FIGURE 163.1. Sagittal balance image.

dropped from the C7 vertebra, tracing an imaginary line of gravity, runs anterior to the vertebral column in the thoracic and somewhat posterior in the lumbar regions. The line should normally fall near the sacral promontory. This is known as "sagittal balance" (Fig. 163.1).

The cervical canal is wider at the Cl and C2 levels, below which the canal diameter slowly tapers caudally. The lumbar canal is slightly wider than the thoracic canal. The greatest degree of flexion and extension occurs at the atlanto-occipital junction, and the greatest rotatory capability occurs at the atlantoaxial joint. Cervical vertebrae have transverse foramina that transmit the vertebral artery, which usually enters between C6 and C7.

The rib cage and costovertebral ligaments afford an additional element of stability compared with either the cervical or the thoracolumbar junction. Therefore, more force is required to produce a fracture in the mid thoracic spine region than the cervical or lumbar region. By the same token, less mobility is afforded in the thoracic spine [67]. The facet joint plane in the thoracic region is more sagittal than the cervical spine, but more coronal than the typical lumbar spine. The combination of these factors protects against rotational injury and allows somewhat more axial rotation.

The vascular supply of the spinal cord comprises the single anterior spinal artery, the paired posterior spinal arteries, and the segmental radicular arteries. The anterior spinal artery supplies the anterior two thirds of the cord, and the posterior spinal arteries supply the posterior third of the cord. In the cervical cord, the main vascular supplies come from the spinal arteries, but in the thoracic and lumbar regions, the segmental radicular arteries are the major contributors of blood supply. In the upper thoracic cord, the vascular supply may be sparse, especially between the fourth and eighth vertebrae, creating the watershed zone [68], which may be prone to hypotensive and hypoxic insults. The artery of Adamkiewicz (artery of lumbar enlargement) usually arises from T8 to T12 on the left side, most commonly arising from T10 to T12 on the left.

At the thoracolumbar junction and distally, the vertebral bodies allow a greater degree of motion. The lack of rib cage support, the increased room for flexion-extension, and the change in disc size and shape may all contribute to the relatively greater mobility of the lumbar spine. However, the additional degree of mobility at the thoracolumbar junction, especially from Tll to L2, makes this region more susceptible to injury than other adjacent portions of the spine. Because the middle and upper thoracic regions are relatively fixed, the thoracolumbar junction acts as a zone of mechanical stress concentration. The conus medullaris usually resides between the Tll and the Ll-2 disc space, and could be compromised by injuries at this level.

BIOMECHANICS OF INJURY AND STABILITY

Because the neural and musculoskeletal components of the human spine are intimately associated, any discussion regarding blunt traumatic spinal cord injury requires an understanding of the vertebral column. Concepts of stability in the vertebral column are complex. This reflects the intricate nature of the arrangements of joints in the spinal column. Each vertebra has multiple sites of articulation and interaction with the neighboring vertebra (intervertebral disks, facet joints, connecting ligaments). To maintain the stability of this naturally flexible structure, the body must incorporate a complex array of muscles and ligaments.

The vertebral column serves to transmit loads, to permit motion, and to protect the spinal cord. Instability of the spinal column may then be defined as its failure to perform any of these functions under physiologic levels of mechanical loading. This failure may occur acutely or in a progressive, delayed manner. In cases of traumatic spinal cord injury, the vertebral column acutely fails to shield the neural elements from external forces as a result of being stressed beyond its mechanical tolerances.

Various classification schemes have been devised to predict if the spine is unstable. The most common of these is the

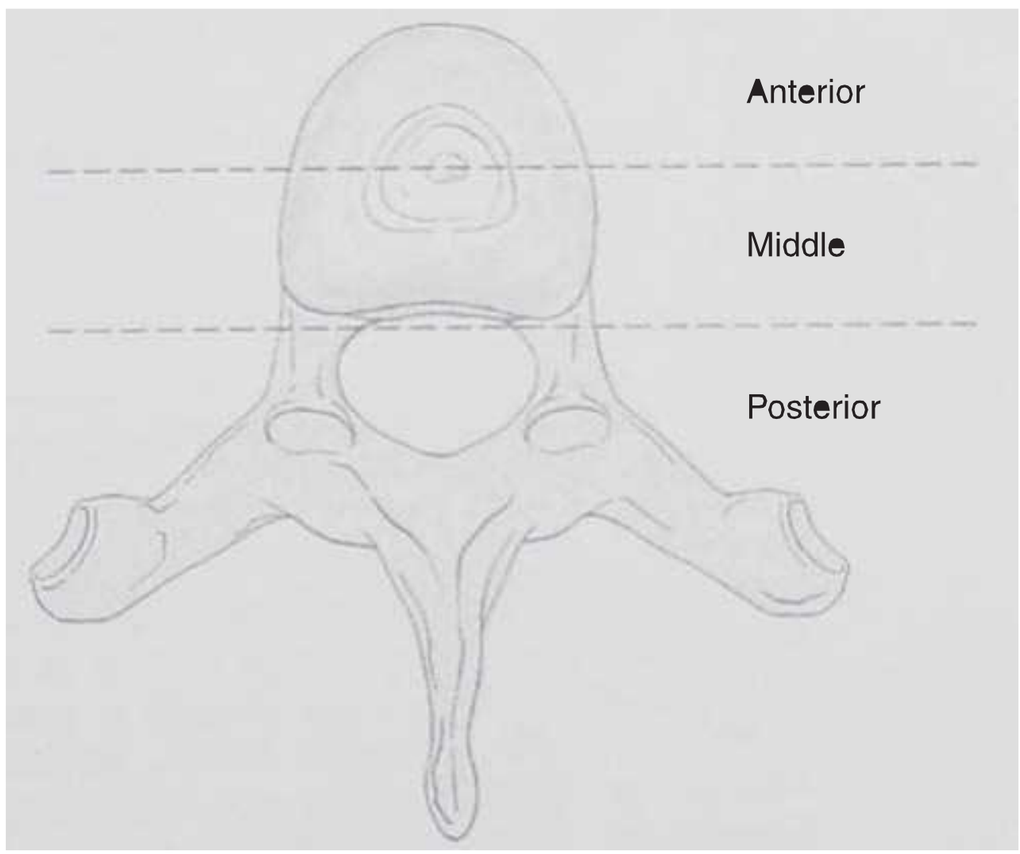

FIGURE 163.2. Denis three-column injury model.

three-column theory introduced by Denis [69,70] (Fig. 163.2). Although these concepts were originally based on studies of thoracolumbar fractures, these principles have been applied successfully to other regions of the spine. This classification system divides the spine into anterior, middle, and posterior columns. The anterior column consists of the anterior half of the vertebral body, the anterior half of the intervertebral disk, and the anterior longitudinal ligament. The middle column consists of the posterior half of the vertebral body, the posterior half of the intervertebral disk, and the posterior longitudinal ligament. The posterior column consists of the posterior arch, the facet joint complex, the interspinous ligament, the supraspinous ligament, and the ligamentum flavum. The diagnosis of instability is made if two or more of the columns are compromised.

External forces placed on the spine include axial compression, distraction, flexion, extension, and translation. Axial compression in the cervical spine results in disruptions of the ring of Cl and burst fractures of the remaining vertebrae. Axial compression in the thoracolumbar spine results in burst fractures. When compressive forces are applied anterior to the spinal column and result in a component of flexion, anterior compression fractures result. Severe flexion is the most common injury mechanism in the cervical spine. This can cause odontoid fractures, teardrop fractures of the vertebral bodies, dislocations of the vertebral bodies, and jumped facets. In the thoracolumbar spine, severe flexion results in compression of the anterior vertebral body. If the fulcrum of force is anterior to the vertebral column, as occurs when a seat-belted passenger is involved in a motor vehicle accident, a flexion-distraction injury of the thoracolumbar junction may result. If the injury passes through the disk space or through the vertebral body, a "chance fracture" may occur (Fig. 163.3).

White and Panjabi [67] recommended a systematic approach to stability, and devised a checklist to determine it. In an adult cervical spine, horizontal subluxation more than 3 mm or an angulation more than 11 degrees is considered unstable [71]. Fractures or alignment patterns that suggest substantial disruption of the bony/ligamentous structures on radiographs suggest injury. Other more complex systems to measure spine stability have also been developed [72].

FIGURE 163.3. Radiographic image of chance fracture.

Instability of the spinal column requires maintenance of spinal precautions and bracing. In many instances, surgical realignment, fixation, and fusion will be necessary. Of note, missile injuries do not usually destabilize the spine.

TREATMENT

Initial (Field)

As the ABCDEs of trauma assessment are completed, the surgeon must reach certain goals. Maintaining an airway while stabilizing the spine is paramount. Blood pressure should be maintained to assure perfusion. Suggested levels are SBP >120 mm Hg and MAP >90 mm Hg. All unconscious patients (e.g., major blunt trauma victims) must be assumed to have an SCI until proven otherwise. A rigid backboard and cervical collar should be used to stabilize the spine.

Surgical

Radiologically proven compression of the spinal cord and nerve roots mandates surgical intervention for decompression and stabilization in the incomplete patient (e.g., ASIA B, C, or D).

Neural compression typically results from acute displacement of bone fragments, disruption of ligaments, and disk herniation. Delayed spinal cord compression may also develop from an expanding hematoma within the spinal canal or an inadequately immobilized spine where a prolapsed disk or bone could dynamically compress the cord. Late deterioration of motor or sensory function would prompt a clinician to search for a cause such as post-traumatic syringomyelia and/or progressive deformity. Overall, loss of neurologic function when compared to admission occurs in approximately 3% of patients [51].

Surgery for patients with complete loss of neurologic function remains controversial. Early surgical stabilization within the days after injury has more recently become popular because of the increasing safety of general anesthesia. Early stabilization allows for safe mobilization of the patient, physical and occupational therapy, and improved pulmonary toilet. Surgery for patients who have suffered severe injuries to vital organs may have to have their surgeries delayed. In these cases, maintenance of spinal precautions with a cervical collar and strict "log rolling" for nursing care should prevent deterioration.

The question of whether emergent surgery to the spinal cord improves the neurologic outcome remains controversial [11,33,34,65,73–76]. To directly answer this question, the STASCIS trial (Surgical Treatment of Acute Spinal Cord Injury Study) has been initiated. In this ongoing study, patients with cervical SCI, ASIA scores A, B, C, D, are identified and enrolled in this multicenter study. Patients were stratified into "early" (<24 hours) or "delayed" (>24 hours) groups based on time to decompression. (Decompression occurred by either cervical traction or surgery). At a 1-year follow up, 25% of patients in the early decompression group had a 2 or more grade improvement in ASIA score as compared to the delayed group, with 0% ($p = 0.009$). These results suggest that early decompression (within 24 hours of injury) is the most favorable course of action to treat traumatic SCI [77]. However, there are criticisms of the study. The study has a significant selection bias as the groups are noncontrolled. However, experimental models in animals do suggest that earlier decompression maximizes recovery [78].

Reviews of patients from the National Inpatient Sample allow comparisons between conservative treatment and laminectomy and/or fusion for patients with SCI. When compared to nonsurgical SCI patients, patients with surgery had

longer lengths of hospital stay (14 days vs. 9 days), but had lower mortality rates (3% vs. 7%) [10]. Other reviews of the literature provide somewhat contradictory conclusions regarding lengths of stay and neurological improvement [74].

PHARMACOLOGIC THERAPY FOR SPINAL CORD INJURY

Animal models of spinal cord injury have offered the hope that damage caused by secondary injury can be mitigated by early pharmacologic intervention. Three large, randomized, multicenter clinical trials have investigated the use of high dose methylprednisolone for spinal cord injury [13,79]. The standard dose is 30 mg per kg intravenous (IV) methylprednisolone over 1 hour, then 5.4 mg per kg per hour over the next 24 hours.

There has been a great deal of controversy surrounding the quality of the NASCIS trials, leading some authors to conclude that any possible benefits from high-dose methylprednisolone are outweighed by the increased incidence of steroid-related complications [15,16,80,81]. The authors of this chapter no longer use steroids for the treatment of acute spinal cord injury.

Trials of novel pharmacologic interventions for spinal cord injury are currently underway in both clinical and animal models. The therapies include using pharmaceuticals such as riluzole [1,30,82], minocycline [1,30,33,83], polyethylene glycol [1,30,84], erythropoietin [1,30], hypertonic saline [24,85–89], and Cethrin® [1,33]. Injections of autologous macrophages [90–93] and the application of hypothermia [18,19,20,22,23,94,95] are also being investigated. None of these therapies have been shown to be completely safe or effective for the treatment of acute spinal cord injury as of the date of this publication, although several are under clinical trial investigations.

MEDICAL MANAGEMENT OF SPINAL CORD-INJURED PATIENTS

The SCI patient presents unique challenges for the medical team providing both acute and chronic care. As with many other patients, those SCI patients with multiple comorbidities and advanced age are more likely to have poorer outcomes [10]. Several medical problems are frequently associated with a vertebral fracture or spinal cord injury. Some are related to the systemic effect of spinal cord injury, and the others are related to paralysis and prolonged immobilization. The concepts of kinetic therapy and the Roto-Rest treatment table (or similar devices) is endorsed by these authors as a means of minimizing the high morbidity associated with the effects of paralysis and immobility in all of the body systems following acute spinal cord injury.

Cardiovascular

Hypotension and bradycardia from spinal shock may be present. Management with titrated dopamine to support BP and atropine to increase heart rate are recommended. The patient may demonstrate autonomic hyperreflexia or dysreflexia, which is periodic autonomic instability triggered by stimuli such as bladder filling or catheterization when the injury occurs at or above the T6 level. The patients often describe exaggerated autonomic responses, including headache, flushing, diaphoresis, and paroxysmal hypertension. The effects of autonomic hyperreflexia may be life threatening if associated with hypertension. The treatment is to remove offending stimuli, such as by bladder decompression or bowel disimpaction. If a patient is in crisis, sublingual Procardia may be used to help avert a hemorrhagic stroke while one searches for the aggravating factors.

Pulmonary

The risk of pulmonary complications clearly increases with higher-level injuries due to the loss of phrenic nerve innervations (C3–5). For patients with injuries at C1–4, tracheostomy and prolonged mechanical ventilation are probably required. In patients with lower-level injuries, however, all attempts should be made to avoid a tracheostomy. For high cervical injury, one could consider a diaphragmatic pacemaker [96–98]. All injuries above T5 will have significant loss of inspiratory/expiratory force and volume given intercostals denervation.

Respiratory diseases account for 28% of deaths and are the leading cause of mortality in the first year after spinal cord injury [99]. Spinal injury patients are at high risk for pulmonary infection for a number of reasons. Prolonged poor pulmonary toilet, an inability to clear upper airway secretions, poor respiratory capacity, nosocomial exposure, weakened immune responses, and any accompanying chest trauma all increase the risk of pneumonia. The judicious use of aggressive suctioning, pulmonary toilet (e.g., incentive spirometry), chest physiotherapy, bronchodilators, positive-pressure ventilation, and bronchoscopic airway clearance helps prevent infection. Severe atelectasis can also cause respiratory distress in the absence of infection. The authors of this chapter advocate kinetic therapy (the Roto-Rest treatment table) to minimize the risks of pulmonary complications. The placement of an abdominal binder can minimize paradoxical respiratory effort and increase respiration.

Upper Gastrointestinal and Nutrition

All patients should have a nasogastric tube placed to suction drainage in the emergency room, as immobilization predisposes the patient to aspiration. Post-traumatic ileus is also common in this patient population. An indwelling gastric or duodenal tube also allows for early feeding as soon as any ileus has resolved. This supplementation is critical after trauma, as the energy demand of the patients is roughly 150% of their basal requirement. Special attention must also be directed at meeting the patient's increased protein requirements. Proper nutritional support prevents catabolism, supplements wound healing, and maximizes immune protection [27,100]. Parenteral appropriate until the ileus resolves, but tube feeding should begin as early as possible. Even small feeds through a nasogastric tube ("trophic feeding") may reduce the risk of sepsis through enterocyte nutrition.

Gastric ulcers are common in spinal cord injury patients, and this risk is increased with the use of high-dose methylprednisolone. Gastrointestinal hemorrhage is less common and occurs in 3% of patients [101]. H_2-blockers, proton-pump inhibitors, and sucralfate appear to be similarly effective in reducing the risk of gastrointestinal hemorrhage. GI protection is also especially important in patients receiving high-dose steroids. Pancreatitis and acalculous cholecystitis can also occur, especially if parenteral nutrition is used for prolonged periods of time. These disorders can be diagnosed by elevated amylase and bilirubin levels, respectively. Early recognition of these disorders depends on a high level of clinical vigilance. Since the SCI patient may have lost sensation of the abdomen, cardinal signs of acute abdomen e.g., rebound) may not be present.

Lower Gastrointestinal and Genitourinary

Immediately after a complete spinal cord injury the bladder is acontractile. Indwelling catheterization allows bladder drainage and measurements of fluid balance. Intermittent catheterization every 4 to 6 hours should commence as soon as possible to reduce the risk of urinary tract infections. These infections are common and should be treated aggressively to prevent urosepsis. The presence of urea-splitting organisms also increases the incidence of renal stone formation [101]. In addition, clinicians should be aware of autonomic dysreflexia, where an out of proportion sympathetic response may be elicited from a distended bladder or distended bowel. The person with SCI (often a T2 or higher injury) who presents to the emergency department with tachycardia, hypertension, severe headache, and so on, needs to be properly diagnosed rapidly. Often a simple treatment (bladder catheterization, bowel disimpaction) may be what is primarily required [102]. Other causes include decubitus ulcers, undiagnosed fistulae, or other infectious lesions. Sublingual Procardia may provide quick relief of hypertension. This relief can be life sparing.

After severe spinal injury, rectal tone is most often flaccid in lower motor neuron injuries. Constipation can easily occur unless manual evacuation is carried out on a regular basis. The liberal use of rectal suppositories stimulates bowel emptying, and regular doses of stool softener should also be used. New surgical procedures to restore manual bladder control are available [40,103]. Devices to aid in defecation are also being investigated and developed [38].

Clinicians should be aware of the systemic effects that SCI has on the reproductive system, especially in men [104–106] and should be prepared to counsel the patient on his options.

Infectious Disease/Fever

The "5 W's" of fever workup are relevant for the SCI patient: Wind (atelectasis), Water (urinary infection), Wound (wound infection), Walk (DVTs), and Weird (drug reactions.) Routine lab analysis should be part of the initial workup for fever. These include erythrocyte sedimentation rate (ESR) and C-reactive protein as infection markers. One should also order tests such as urine analysis and culture for UTI, duplex ultrasound for DVTs, blood cultures for sepsis, skin inspection for breakdown or infection, liver function tests (LFTs) including total and direct bilirubin, amylase, and lipase for hepatitis, acalculous cholecystitis, or pancreatitis. Again, it is important to note that SCI patients may be unable to alert physicians to common signs (e.g., leg pain, abdominal pain) due to their injuries.

Cutaneous and Musculoskeletal

Pressure ulcers are common after spinal cord injury and occur in up to 25% to 30% of patients (101). Transport on hard backboards, prolonged immobilization, loss of cutaneous sensation, and reduced skin perfusion all predispose to skin breakdown. The sacrum, heels, ischium, and occiput are most commonly involved.

Prevention of pressure ulcers begins in the emergency room. Patients should be removed from the backboard and any hard surfaces as soon as possible, as pressure necrosis of the skin can occur in less than 1 hour on these surfaces. In the acute care setting, the patient should be turned in a "log roll" fashion every 2 hours until the spine is proven to be stable or until the spine is stabilized surgically. Alternatively, an electrically driven kinetic bed such as the Roto-Rest (Kinetic Concepts, San Antonio, TX) or other pressure relieving beds or mattress overlays can be used [107].

Stage I lesions can be managed with aggressive mobilization and adhesive barrier dressings. Once the dermis has been compromised, however, daily sterile dressing may be needed for wound debridement. Deeper lesions may require debridement and skin grafting in the operating room. Proper management of even mild lesions prevents devastating late sequelae such as sepsis from infected ulcers. The development of the "VAC" aided healing of severe decubitus ulcers provides gentle suction which debrides and reduces the size of the ulcer. Relief of the pressure source and debridement and cleaning of the wound is essential. The patient must be given a high protein diet to facilitate decubitus ulcer healing. In the subacute and chronic setting, muscle denervation leads to atrophy, spasticity, and contracture formation. Passive range of motion exercises and splinting forestall the formation of contractures. Etidronate sodium and increasing mobility may reduce heterotopic ossifications [108]. Proper nutritional support is essential.

Thromboembolism

The combination of trauma, paralysis, and immobility places paralyzed patients at high risk of developing deep venous thrombosis and pulmonary embolism. The incidence of lower-extremity venous thrombosis varies widely in literature reports depending on the test used (fibrinogen scanning, clinical, impedance plethysmography, venography). Rates ranging from 12% to 81% have been reported. The highest reported frequency of PE was approximately 5% [109]. PE is responsible for 10% of all deaths after SCI [99]. The risk of PE peaks at 2 to 3 weeks after injury.

These authors advocate the use of the Roto-Rest kinetic treatment table (or similar devices) for all acute spinal cord injury to combat pulmonary emboli. Routine use of pneumatic compression devices and subcutaneous heparin (or similar drugs) can reduce the risk of thromboembolism [110–112]. For example, 5,000 units of subcutaneous heparin can be administered twice daily within the first 2 days of injury. The prophylactic use of a vena cava filter is advocated by some, but controversy exists [113,114]. For patients who are not able to utilize to pneumatic compression devices and prophylactic heparin, vena cava (temporary or permanent) filters are a recommended option [115–118].

Psychosocial

All acute spinal cord injury patients experience psychological sequelae to their catastrophic injury. Most often, family and friends experience similar effects including denial, depression, anger, and finally coping. The coping phase is when the person decides to deal with the realities of their disability, although not to accept that their paralysis is "forever." A team of caring physicians and other health professionals including rehabilitation psychologists is essential for a number of psychosocial actions. Antidepressants can also be helpful in certain cases.

The spinal cord injured community has unique needs. This community is not a homogenous group, as different levels of injury will leave the person with SCI with different amounts of residual function. As such, the immediate needs of the person with SCI are also not uniform. When asked what problems if addressed would lead to the greatest increase in quality of life, the people with high cervical injuries (quadriplegics) identified restoration of hand and arm use as the most important. People with lower injuries (paraplegics) identified bladder, bowel, autonomic dystrophy, and sexual function as the most important issues to address [35]. Listening to the needs of this

community will help researchers develop practical improvements to help the SCI community.

SPINAL CORD INJURY IN CHILDREN

By adolescence the spine is well developed and the patterns of injury resemble those of adults. Perhaps because of the increased mobility of the developing spine, pediatric spinal cord injuries are rare [119]. Because of the greater proportional mass of the head, however, children are more susceptible to atlanto-occipital injuries. The hypermobility of the pediatric spine also accounts for cases of spinal cord injury without radiographic abnormality (SCIWORA). This represents 15% to 20% of all pediatric spinal cord injuries [120,121].

The principles in managing pediatric spinal cord injuries are similar to that of adults. Because children cannot cooperate fully with the physical examination, it is important to recognize subtle physical and radiologic signs. As such, an increased reliance must often be placed on radiographic studies. Many of the standard measurements used to evaluate cervical x-rays need to be adjusted for the pediatric spine.

In young children, the increased relative size of the head compared to body results in neck flexion when placed on a rigid backboard. This malalignment can accentuate deformity in cervical spine and should be avoided. Equipment tailored

TABLE 163.2

COMPLETED PROSPECTIVE RANDOMIZED CONTROLLED SCI CLINICAL TRIALS[a]

Trial name	Year	No. of patients	Study design	SCI type, treatment window (h)	Treatment arms	Conclusions
NASCIS I	1984	330	Phase III RCT	I, 48	MPSS 100 mg × 10 d MPSS 1000 mg × 10 d	No difference
NASCIS II	1990	487	Phase III RCT	C/I, 12	MPSS (24 h) Naloxone Placebo	Negative primary analysis; secondary analysis showed improved recovery if treated w/MPSS win 8 h of injury; naloxone negative
Maryland GM-1	1991	34	Phase II RCT—pilot study	I, 72	GM-1 Placebo	Improved neurological recovery w/GM-1 in this small pilot study
Otani et al.	1994	158	Nonblinded RCT	?, 8	MPSS (NASCIS II 24 h) Placebo	Significantly more steroid-treated patients had some sensory improvement, no motor differences
TRH	1995	20	Phase II RCT—pilot study	C/I, 2	TRH Placebo	Suggestion of improved neurological recovery w/TRH in this small pilot study
NASCIS III	1997	499	Phase III RCT	I, 12	MPSS (24 h) MPSS (48 h) MPSS bolus then TM	Improved neurological recovery w/ MPSS if administered early (w/in 3 h after SCI); TM not superior to MPSS
Nimodipine	1998	100	Phase III RCT	C/I, 6	Pimodipine MPSS (24 h) Nimodipine + MPSS (24 h) Placebo	No difference; study likely underpowered to detect a difference
Gacyclidine	1999	280	Phase II RCT	C/I, 2	Gacyclidine (0.005 mg/kg) Gacyclidine (0.01 mg/kg) Gacyclidine (0.02 mg/kg) Placebo	Negative study; trend to improved motor recovry w/imcomplete cervical injuries
Pointillart et al.	2000	106	Blinded RCT	?, 8	MPSS (NASCIS II 24 h) Nimodipine MPSS & nimodipine Placebo	No neurological differences between groups; trend to increased infections in groups receiving MPSS
Sygen (GM-1)	2001	797	Phase III RCT	I, 72	MPSS & low-dose GM-1 MPSS & high-dose GM-1 MPSS & placebo	Negative primary outcomes; trend to improved secondary outcomes

[a]Further trials are not planned for any of the agents presented in this table, to the knowledge of the authors.
C, complete; I, incomplete; RCT, randomized controlled clinical trial; TM, tirilizad mesylate; ?, unpublished or unclear data.

for pediatric spine immobilization should be used whenever possible. Unlike adults, the majority of these injuries can be treated nonsurgically with bracing [122].

FUTURE ADVANCES

Approximately 100 years ago at the beginning of the 20th century, Dr. Alfred Reginald Allen induced a spinal cord injury in an animal model for the purpose of understanding SCI [123]. His advancements were not alone, as the 20th century was remarkable for incredible advances in science, medicine, engineering, and technology. Many of these advances have helped to make the opening years of the 21st century, 2001 to 2010, the "decade of the spine."

In the realm of Basic Science research, there have been great advances in understanding the pathophysiology of SCI [1,5,6,82]. Understanding of the mechanisms of inflammation, cell migration, immunology, and cell death allow for basic scientists to identify pathways that can be directly targeted in future clinical investigations. Understanding biochemical environment of the region of the SCI allows scientists to better engineer biological repair strategies. For example, understanding the inhibitory properties of the glial scar after an injury may allow scientists to target and overcome these obstacles [9].

The surgical realm continues to advance, with improvements in spine fusion techniques and hardware. Clinical studies, like STASCIS [33,77,76] also allow the clinician to best judge the optimal time to initiate treatment. New and innovative devices are coming to market to stabilize and repair the bony, ligamentous, and disk injuries that often accompany SCI [124–131].

Additional studies into autologous (e.g., macrophage, oligodendrocyte, Schwann) and stem cell transplantation, tissue engineering, and hypothermia are being actively pursued to further develop methods to preserve function or to restore function to the person living with an SCI [1,9,19,33,41,45,93,132–138]. Hypothermia research suggests that cooling patients with SCI may protect neural tissue from secondary injury by increasing tissue tolerance to reduced blood flow and oxygenation. Efficacy and safety studies of moderate hypothermia (32°C to 34°C) are currently under investigation [19].

New medical therapies are being tested. Minocycline is being tested in a Canadian trial [83,139,140] as a treatment to reduce oligodendrocyte and microglial apoptosis. Riluzole, a sodium channel inhibitor, is also in multicenter trials [1,104,139]. Rho inhibitors are also being investigated. This includes Nogo, a critical inhibitor of neural regeneration by inhibition of guanosine triphosphatase (GTPase). Local injection of anti-Rho antibodies is in a phase II study [141].

Oscillating field stimulation to promote axonal regrowth along the cranial/caudal plane (as opposed to random orientation) is being studied as well [142,143].

There have been studies to bypass the injured CNS and to tap directly into the brain, allowing a person with SCI to control simple machines [144–150]. These are adaptive strategies such as Functional Electrical Stimulation (FES), Robotics and Brain Machine Interfaces.

The hope of neural restoration remains the focus of intense basic science research. Whether through stem cell transplantation, molecular manipulation, or modulation of the local cytokine milieu, the aim is to restore function to cells that have already been damaged or destroyed. Because reinnervation of the spinal cord is the best way to fully restore neurologic function, research in this area remains the primary goal at the Miami Project to Cure Paralysis.

Despite all of the exciting advances forthcoming in the field of spinal cord injury, prevention of injury remains a top priority. Programs such as the Think First initiative in Florida have already dramatically reduced the incidence of diving-related cervical spine injuries. Physicians, who are most acutely aware of the devastating consequence of spinal cord injury, must assume a key role in educating the public on how to avoid these catastrophic injuries.

SUMMARY OF RECOMMENDATIONS BASED UPON RANDOMIZED CONTROLLED CLINICAL TRIALS

A recent review of completed clinical trials has been published by Dr. Fehling's group. Completed trials are reproduced as Table 163.2, and ongoing clinical trials are reproduced as Table 163.3 [139].

Unfortunately, there is no consensus on the single best treatment available for a spinal cord injury. At present, there are multiple options available for treatments that include hypothermia, reduction by traction, and surgical decompression. Fortunately, there are ongoing clinical trials to aid clinicians in future decision making and with evidence-based medicine. One such example comes from our department at the University of Miami. Allan Levi and colleagues have been investigating hypothermia in treating Spinal Cord Injury in clinical settings [94,95].

CHAPTER 164 ■ THORACIC AND CARDIAC TRAUMA

SCOTT B. JOHNSON AND JOHN G. MYERS

INTRODUCTION

Thoracic trauma is responsible for 20% to 25% of the estimated 150,000 trauma related deaths per year in the United States and is the leading cause of death in the first four decades of life. Two thirds of thoracic-related deaths occur in the prehospital setting, usually due to significant cardiac, great vessel, or tracheobronchial injuries. In a study of over 1,300 patients presenting to a level I trauma center with thoracic trauma, Kulshrestha and colleagues reported an overall mortality rate of 9.4%, with 56% of these occurring within the initial 24 hours. While the two strongest determinants of increased mortality were a low GCS and increased age, penetrating injury, liver or spleen injury, long bone fracture, and more than five rib fractures also adversely affected mortality [1]. In a study of trauma-related hospital deaths at an urban level I trauma center, Demetriades and colleagues found a penetrating mechanism, age more than 60, and chest AIS > 3 to be significant variables associated with patients who had no vital signs on admission [2].

Overall, motor vehicle collisions account for 70% to 80% of all thoracic injuries. The incidence of penetrating injuries varies widely but is usually more prevalent in urban centers. The majority of thoracic injuries can be treated with careful observation or tube thoracostomy. It is historically reported that 12% to 15% of patients with thoracic injury will require thoracotomy. In a Western Trauma Association multicenter review, only 1% of all trauma patients required nonresuscitative thoracotomy [3]. With the improvements in prehospital care and transport, more of the severely injured patients who would have previously died at the scene are making it to the hospital alive. Success in the management of these injuries rests in having a high index of suspicion for the life-threatening thoracic injuries, prompt recognition and treatment of associated injuries, and aggressive management of coexisting pulmonary dysfunction.

INDICATIONS FOR URGENT SURGICAL INTERVENTION

Bleeding

Hemothorax is second only to rib fractures as the most common associated finding in thoracic trauma, being present in approximately 25% of patients with thoracic trauma. Bleeding can arise from the chest wall, lung parenchyma, major thoracic vessels, heart, or diaphragm. A small or moderate-size hemothorax that stops bleeding immediately after placement of a tube thoracostomy can usually be managed conservatively. However, if the patient continues to bleed at a rate of more than 200 cc per hour, exploration is indicated. The accumulation of more than 1,500 cc of blood within a pleural space is considered a massive hemothorax and is an indication for exploration. If the patient becomes hemodynamically unstable at anytime and an intrathoracic source is suspected, emergent thoracotomy should be performed irrespective of chest tube drainage. A chest radiograph should always be obtained after placing a tube thoracostomy to ensure proper position of the tube and complete drainage of the pleural space. Video-assisted thoracoscopic surgery (VATS) can be considered in the stable patient with retained hemothorax or in a stable patient who continues to bleed at a slow but steady rate; however, the surgeon should not hesitate to convert to open thoracotomy if visualization is inadequate or drainage and evacuation of the pleural space is incomplete.

Cardiovascular Collapse

The indications for resuscitative emergency department thoracotomy (EDT) continue to be debated. Our indications, which are considered to be fairly liberal, include (1) loss of vitals

in the Emergency Department for both blunt and penetrating trauma and (2) loss of vitals en route, with less than 10 minutes of prehospital CPR, with some sign of life upon arrival, or a suspected intrathoracic etiology. Penetrating thoracic injuries, specifically stab wounds, have the highest rate of survival. Data for blunt trauma are much less encouraging but should not be used as a deterrent, as there are several functional survivors in most reported series. A retrospective study of 959 patients undergoing resuscitative thoracotomy concluded that EDT in blunt trauma with more than 5 minutes or penetrating trauma with more than 15 minutes of prehospital CPR is futile care [4]. When performed, resuscitative thoracotomy should be performed early. Discovered tamponade should be released; massive pulmonary bleeding should be quickly controlled with staplers, clamping, or manual compression; and cardiac wounds should be controlled. With no intrathoracic source, the aorta should be clamped and internal cardiac massage continued.

Massive Air Leak

Findings on initial presentation of significant subcutaneous emphysema, a subsequent large or persistent air leak, or persistent pneumothorax should alert the clinician to the presence of a major tracheobronchial injury. This injury is potentially lethal but relatively rare, found in only 2% to 5% of patients with thoracic trauma. Significant tracheobronchial injuries may result in a massive air leak, leading to hypoventilation. Maneuvers to stabilize the patient should include decreasing airway pressures. Contralateral mainstem intubation can also be attempted. Major tracheobronchial injuries generally should be repaired as early as the patient's condition allows.

Tamponade

Cardiac tamponade results when fluid or air collects within an intact pericardial sac, resulting in compression of the right heart with subsequent obstruction of venous return and cardiovascular collapse. Potential findings upon presentation include tachycardia and hypotension, cervical cyanosis, jugular venous distension, muffled heart sounds, and pulsus paradoxus. The diagnosis is confirmed with echocardiography, pericardial window, or at the time of emergent thoracotomy. Treatment requires prompt resuscitation and decompression of the pericardium, followed by repair of the bleeding source.

DIAGNOSTICS

Diagnostic imaging plays a key role in the management of patients after chest trauma and has considerable impact on therapeutic decision-making. The information generated by diagnostic imaging procedures not only serves to tailor therapy to the individual needs of the patient, but also helps to determine overall prognosis and outcome. Radiologic imaging plays an important role in the workup of any patient with suspected chest trauma. The chest radiograph is the initial imaging study of choice to be obtained in patients with suspected chest injury. Chest Computed Tomography (CT), however, is being used with increasing frequency in the evaluation of patients with chest trauma. CT can be useful in assessing suspected traumatic aortic, pulmonary, airway, skeletal, and diaphragmatic injuries. Magnetic resonance imaging (MRI) on the other hand has a limited role in the initial evaluation of any patient with suspected chest trauma. To undergo an MRI, the patient must be stable, and many trauma patients cannot be scanned because of bulky, mechanical supportive equipment. However, in selected patients who are hemodynamically stable, MRI may be particularly useful for the evaluation of spine and diaphragm injuries. Other imaging modalities available to the clinician include echocardiography, angiography, and VATS, which can be both diagnostic and therapeutic when appropriately indicated.

Plain Chest Radiograph

The frontal chest radiograph is the most appropriate initial radiographic study to obtain for the evaluation of patients with suspected chest injury. This study is particularly useful in helping to rule out major injury. Ideally, the radiograph should be obtained with the patient in the upright position because of mediastinal widening that is typically seen in the supine position. Chest radiography has a 98% negative predictive value and is therefore quite useful when normal. However, abnormal findings may be subtle and quite nonspecific. Radiographic findings that may indicate mediastinal injury, such as major aortic disruption, include abnormal contour or indistinctness of the aortic knob, apical pleural cap, rightward deviation of the nasogastric tube, thickening of the right paratracheal stripe, downward displacement of the left mainstem bronchus, rightward deviation of the trachea, and, not uncommonly, nonspecific mediastinal widening. Most life-threatening injuries can be screened by the plain chest radiograph and a careful physical exam. Blunt thoracic injuries detected by CT alone infrequently require immediate therapy. If immediate therapy is needed, findings will usually be visible on plain radiographs or obvious on clinical exam. Although a plain upright chest radiograph remains one of the basic imaging studies routinely performed on initial screening, it may be over-utilized. A recent study suggests that in the presence of a normal physical exam in the hemodynamically stable patient, obtaining a routine chest radiograph is actually unnecessary, since it rarely, if ever, changes clinical care [5].

Chest Computed Tomography

CT is highly sensitive in detecting thoracic injuries after blunt chest trauma and is superior to routine CXR in visualizing lung contusions, pneumothorax, and hemothorax, and it can often alter initial therapeutic management in a significant number of patients with suspected chest trauma. It has also been shown to detect unexpected injuries and abnormalities, resulting in altered management in a substantial number of patients when applied appropriately [6]. It can be particularly useful in screening for major intrathoracic aortic injury. In one study, contrast-enhanced CT scanning was 100% sensitive in detecting major thoracic aortic injury based on clinical follow-up and was 99.7% specific, with 89% positive and 100% negative predictive values for an overall diagnostic accuracy of 99.7% [7]. An unequivocally normal mediastinum at CT, with no hematoma and a regular aorta surrounded by a normal fat pad, has essentially a 100% negative predictive value for aortic injury [7–10]. It has also been shown that CT scanning detects 11% of thoracic aortic injuries that are not detected by routine, plain chest radiography alone [11].

CT scanning can also be useful in detecting hemopericardium and/or hemothorax from any cause, injury to the brachiocephalic vessels, pneumothorax, rib fractures, pulmonary parenchymal contusion, and sternal fractures. It can also be useful in detecting pneumomediastinum caused by pulmonary interstitial emphysema, bronchial or tracheal rupture (commonly associated with pneumothorax), esophageal rupture, or iatrogenic injury from over-ventilation or traumatic intubation. In addition, CT scanning can detect injuries otherwise missed by routine plain radiograph. In one study comparing CT

scanning with plain radiography, CT scanning detected serious injuries in 65% of those patients not found to have injury on plain film. These injuries included (in decreasing order of frequency) lung contusions, pneumothoraces, hemothoraces, diaphragmatic ruptures, and myocardial ruptures [12]. Even in those patients without suspected chest trauma, CT scanning of the abdomen, which commonly includes the lower portion of the thorax, often yields important information regarding possible intrathoracic injury. In one study, hematoma surrounding the intrathoracic aorta near the level of the diaphragmatic crura seen on intra-abdominal CT scanning was found to be a relatively insensitive but highly specific sign for thoracic aortic injury after blunt trauma. Therefore, the presence of this sign seen on abdominal CT imaging should prompt more specific imaging of the thoracic aorta to evaluate potential thoracic aortic injury [13]. CT scanning has also been shown to be useful to help define the extent of pulmonary contusion and identify those patients at high risk for acute pulmonary failure in those patients with PaO_2/FIO_2 lower than 300. 3-D CT scanning has also been shown to be useful in diagnosing and determining the severity of sternal fractures [14]. With the advent of high resolution CT scanners that can reconstruct axial, coronal, and sagittal images, even penetrating diaphragmatic injuries, which are difficult to image preoperatively, can be diagnosed with a relatively high sensitivity and specificity [15]. Despite its usefulness however, thoracic CT scanning is not necessarily routinely indicated for all patients with chest wall trauma. In addition, although there has been a dramatic increase in the utilization of CT scanning in the last decade, its usefulness in detecting clinically relevant injury has recently come into question, especially in those patients with a normal screening plain chest radiograph [16].

Ultrasound

Transesophageal echocardiography (TEE) is rapidly gaining acceptance as an important diagnostic tool available to the trauma surgeon and is showing particular promise in diagnosing traumatic intrathoracic aortic injuries. Although somewhat invasive, its portability makes it a diagnostic procedure of choice in looking at the heart and great vessels in multiply injured trauma patients. In one particular study of 58 patients with thoracic trauma, TEE demonstrated its usefulness in diagnosing thoracic aortic injury and permitted the identification of small lesions not detectable by CT scanning or angiography [17]. TEE has shown to be an important diagnostic tool for examining the thoracic aorta and is valuable in identifying aortic injury in high-risk trauma patients who are too unstable to undergo transport to the aortography suite. Nienaber et al. prospectively compared TEE with aortogram in evaluation of nontraumatic aortic dissection and found the technique to be a safe and highly sensitive method of diagnosing lesions of the descending aorta, with accuracy approaching 100% [18]. When an aortic injury is present, typical findings on the TEE can include aortic wall hematomas, intimal flaps, or disruptions. Several groups have shown TEE to be accurate in identifying aortic pathology after trauma, with its diagnostic efficacy mainly limited by the experience of the person performing the exam [19–21]. In addition, it has been shown to be useful in diagnosing blunt cardiac rupture, when other diagnostic modalities have failed, as well as in diagnosing severe valvular regurgitation intraoperatively following foreign body removal [22,23].

Numerous studies report that transthoracic echocardiography (TTE) is emerging as an effective noninvasive screening examination for pericardial effusion in the trauma setting. Although subxiphoid pericardial window is currently considered the gold standard to confirm the diagnosis of pericardial tamponade, conventional 2-dimensional TTE has been shown to reveal as little as 50 mL of blood within the pericardium and can show cardiac pseudoaneurysms and the location of foreign bodies [24–27]. Lopez et al. [28] showed that TTE can detect and distinguish hemopericardium from other effusions of lower echogenicity. In prospective studies of patients sustaining penetrating precordial injuries, TTE demonstrated sensitivities of 56% to 90%, with specificities of 93% to 97%. Its overall accuracy was 90% to 96% [29,30]. Because TTE is an examination that can be performed at the bedside, it can be performed rapidly and may decrease the time to diagnosis versus pericardial window (15.5 minutes vs. 42.4 minutes in one study by Meyer et. al.) [30]. It has also been shown that earlier therapeutic intervention facilitated by TTE may be associated with improved survival [31]. In addition, TTE has been shown to be able to identify cardiac sources for hemodynamic instability in the operating room unrelated to tamponade, such as the relatively rare case of atrioventricular valve rupture, which would otherwise be difficult to diagnose, therefore allowing for expeditious repair using cardiopulmonary support [32]. Thus, both TTE and TEE are emerging as useful screening modalities that can be used to evaluate both penetrating and blunt cardiac injuries.

Angiography

Thoracic aortography historically has been the gold standard for diagnosing thoracic aortic injury and for defining the extent of the injury and involvement of branch disease, if present. Aortography usually requires approximately 40 mL of a nonionic iodinated contrast material injected at a rate of 18 to 20 mL per sec. At least two views are obtained—one in the anteroposterior plane and another usually at a 45 degree left anterior oblique projection. If these do not accurately visualize the areas of concern, then additional views may be necessary, either from a lateral or a right anterior oblique projection. Diagnosis of aortic injury angiographically is usually made by finding one or more of the following: an irregular or discontinued contour of the aortic lumen, an intimal flap, an aortic dissection, and/or a luminal outpouching (i.e., pseudoaneurysm). Thoracic aortography can detect blunt traumatic aortic injuries with 96% sensitivity and 98% specificity. False negative examinations are usually related to incomplete or inadequate injections or projections. To be an adequate study, the aortic root as well as the distal descending thoracic aorta should be visualized since these locations are involved, respectively, with 8% and 2% of all blunt thoracic aortic injuries. False positives usually relate to a prominent ductus diverticulum or from an ulcerated atheromatous plaque. A ductus diverticulum can be seen in up to 9% of thoracic aortograms and is related to a remnant of the enlarged mouth of the ductus arteriosus. It appears as a localized bulge of the anterior wall of the aorta and can be differentiated from a pseudoaneurysm due to its usually smooth, regular, symmetrical borders; intimal disruption is typically absent. In addition, the aortic lumen adjacent to the diverticulum is not narrowed, and there is absence of retention of contrast upon the washout phase of the angiogram, which is often typical of pseudoaneurysms. Ulcerated atheromas usually are small, isolated outpouchings of the aortic wall with a collar button appearance. They are typically located in the mid-descending aorta rather that at the aortic isthmus. It is not uncommon for them to occur in individuals that demonstrate widespread atherosclerotic disease and should, therefore, be suspected on angiograms obtained in clinically relevant individuals. Angiography is invasive and can have associated complications. The complications associated with arteriography include allergic reactions, renal failure, local puncture site problems, stroke, and even death. Radiographic contrast media cause severe anaphylactic reactions in less than 2% of cases. A prior history of allergic reaction to intravascular contrast material increases the risk for a subsequent reaction, even after premedication with histamine

blockers and steroids. Patients with preexisting comorbidities, such as renal disease, diabetes mellitus, congestive heart failure, or who are elderly (over 70 years of age) have the highest risk for acute renal dysfunction following contrast administration. The reported incidence of contrast-induced nephropathy varies from less than 1% in the general patient population to as high as 92% among patients with comorbidities that predispose to renal insults, such as diabetes and renal insufficiency [33].

Arteriography requires arterial puncture with cannulation, usually percutaneously. Possible entry sites include not only the femoral artery (most common) but also the axillary and brachial arteries. Possible puncture site complications include hematoma, pseudoaneurysm, arteriovenous fistula, hemorrhage, arterial thrombosis, and femoral neuralgia. Fortunately, clinically significant local arterial complications occur in only 0.1% to 5% of cases. The risk of complications is also related to the indication for arteriography. Fortunately, the lowest risk for complications occur in trauma patients and the complication rates quoted in older studies may not accurately reflect current risk.

Video-Assisted Thoracoscopic Surgery

The role of thoracoscopy in trauma has been explored by a number of investigators in the literature. Prior to the modern video era, Jones et al. described management of 36 patients with thoracoscopy under local anesthesia as a diagnostic tool to define intrathoracic injuries and to visualize ongoing hemorrhage [34] Four patients in their series were spared abdominal exploration when the diaphragm was found devoid of injury. More recently, Ochsner et al. [35] and Mealy et al. [36] have demonstrated the usefulness of VATS as a diagnostic tool in the assessment of diaphragmatic integrity in cases of penetrating and blunt thoracic injuries respectively. VATS has become an acceptable surgical modality in the diagnostic evaluation of suspected diaphragmatic injury and has been shown to have therapeutic benefit when evacuation of clotted hemothoraces is able to be performed in stable patients with penetrating chest injures [37]. Main indications for VATS include diagnosis and treatment of diaphragmatic injuries, diagnosis of persistent hemorrhage, management of retained thoracic collections, assessment of cardiac and mediastinal structures, diagnosis of bronchopleural fistulas, and diagnosis and treatment of persistent posttraumatic pneumothorax. VATS has been shown to be a useful alternative to an open thoracotomy in selected patients. Because lung deflation with single-lung ventilation is a critical component of the technique, VATS is relatively contraindicated in patients unable to tolerate this. Caution should be used in patients with suspected obliteration to their pleural cavity secondary to previous infection ("pleurisy") or surgery. VATS should have no role in the management of unstable patients or in those patients unable to tolerate formal thoracotomy for any reason. Whether VATS should be considered as the initial approach in evaluation of all stable chest trauma patients when an intrathoracic injury is suspected is still debated, and appropriate patient selection remains important.

SPECIFIC INJURIES

Chest Wall

Rib Fractures

Rib fractures are a common injury and are often associated with other injuries. Rib fractures themselves usually cause only minor problems; however, they may be a marker of more severe injury, and it may be the underlying pulmonary contusion that often accompanies the rib fracture that may be more clinically relevant. A study by Flagel et al. showed that 13% of those patients in the National Trauma Data Bank who had one or more rib fractures (n = 64,750) developed complications including pneumonia, acute respiratory distress syndrome, pulmonary embolus, pneumothorax, aspiration pneumonia, empyema, and the need for mechanical ventilation. They also showed that increasing number of rib fractures correlated directly with increasing pulmonary morbidity and mortality. The overall mortality rate for patients with rib fractures was 10%. The mortality rate increased ($p < 0.02$) with each additional rib fracture, independent of patient age. This ranged from 5.8% for a single rib fracture to 10% in the case of 5 fractured ribs. The mortality rate increased dramatically for the groups with 6, 7, and 8 or more fractured ribs to 11.4%, 15.0%, and 34.4%, respectively [38]. Interestingly, in their study epidural analgesia was associated with a reduction in mortality for all patients sustaining rib fractures, particularly those with more than four fractures. Since this was not a prospective randomized study, it is difficult to tell if there was a correlation between patients that received epidural catheters having an overall lower injury severity score. However, in one prospective randomized trial by Bulger et al., trauma patients with rib fractures were randomized to either receive epidural anesthesia or intravenous opioids for pain relief, and it was shown that those patients with epidural anesthesia had a lower incidence of nosocomial pneumonia and shorter duration of mechanical ventilation [39]. The number of patients that could receive epidural anesthesia was limited, however, due to strict inclusion criteria. The age of the patient sustaining rib fractures should be taken into account, as well as the location of the fractures. It has been shown that rib fractures occurring in the very young should alert the clinician to possible nonaccidental trauma (NAT). In one study by Barsness et al., rib fractures in children under 3 years of age had a positive predictive value of NAT of 95%, and rib fracture was the only skeletal manifestation of NAT in 29% of the children [40]. With regards to the elderly, it has been shown that there is a linear relationship between age and complications, including mortality. It has been shown that elderly patients with rib fractures have up to twice the mortality of younger patients with similar injuries [41]. In addition, this increase in mortality may begin to be seen in patients as early as 45 years of age when more than four ribs are involved [42]. The location of the rib fracture(s) is also important, as it has been shown that left-sided rib fractures are associated with splenic injuries, and right-sided rib fractures are associated with liver injuries. While isolated rib fractures have an associated incidence of vascular injury of only 3%, first rib fractures in association with multiple rib fractures have a 24% incidence of associated vascular injury. A first rib fracture along with findings of a widened mediastinum, upper extremity pulse deficit, brachial plexus injury, and/or expanding hematoma should prompt work-up for a possible subclavian arterial injury.

Flail Chest

Flail chest occurs when multiple adjacent ribs are broken in two locations, thereby allowing that portion of the chest wall to move independently with respiration. The strict definition of flail chest is the fracture of at least four consecutive ribs in two or more places; however, the functional definition is an incompetent segment of chest wall large enough to impair the patient's respiration. Major mortality and morbidity of flail chest can be attributed to the usual underlying associated pulmonary contusion and the hypoventilation/hypoxia that results from the paradoxical movement of the chest wall. This is a mechanical problem in which negative pressure generated during inspiration within the thorax is dissipated by movement of the flail segment inward. This movement equalizes the intrathoracic

pressure, which would normally be accomplished by the movement of air into the lungs. In addition, the underlying pulmonary contusion usually leads to a ventilation perfusion mismatch, contributing to the hypoxia; the pain associated with multiple rib fractures can lead to splinting and contribute to hypoventilation. As a result, both oxygenation as well as ventilation is compromised. Usually a large number of ribs have to be involved to be clinically significant. Fortunately, this occurs relatively rarely with rib fractures. Flagel et al. showed an overall incidence of flail chest of 3.95% in patients with 6 rib fractures; 4.84% in those with 7 rib fractures; and 6.42% in those with 8 or more rib fractures [38].

The basic treatment for flail chest injury has not changed appreciably over the last several decades. Ventilatory support in the form of mechanical, positive pressure ventilation remains the gold standard against which all other forms of treatment are measured. Avery et al. coined this type of treatment "internal pneumatic stabilization" in 1956 [43]. Positive pressure ventilation, which effectively forces the flail segment to rise and fall normally with inspirations, effectively allows stabilization of the flail segment with respect to the remainder of the chest wall. Surgical stabilization of the chest wall has been shown to be of some benefit with regard to shorter length of ventilator dependency, lower rates of pneumonia, and shorter intensive care unit stays, although this form of therapy is not yet widely practiced [44]. Pain control continues to be an important adjunct in any treatment regimen.

Sternal Fracture

Sternal fractures have been shown to decrease the stability of the thorax in cadavers [45]. They usually occur as a deceleration force during traffic accidents together with blunt force trauma from foreign objects, such as steering wheels, although they have been reported as a complication of CPR, which interestingly was found in 14% of medical autopsy cases that had received chest compressions prior to death [46]. Traffic accidents are the cause of sternal fractures in almost 90% of cases, with approximately 25% of fractures graded as moderately to severely displaced. Approximately 30% of patients will have associated injuries, with craniocerebral trauma and rib fractures being the most commonly associated injuries [47]. Displaced fractures are more likely to have associated thoracic and cardiac injuries and are more likely to require surgical fixation.

However, the majority of patients can be safely observed and even discharged home as long as the following criteria are met: (1) the injury is not one of high-velocity impact, (2) the fracture is not severely displaced, (3) there are no clinically significant associated injuries, and (4) complex analgesic requirements are not required. Most serious complications and deaths that occur in patients with sternal fractures are not due to the fracture itself but rather are related to the associated injuries, such as flail chest, head injury, or pulmonary or cardiac contusion. Although approximately 22% of patients will exhibit electrocardiographic changes, elevated creatine kinase MB isoenzymes, or echocardiographic abnormalities, only approximately 6% of patients will exhibit a clinically significant myocardial contusion. In addition to myocardial contusion, other complications of sternal fracture such as mediastinal abscess, mediastinitis, and acute tamponade have all been reported. Indications for operative sternal fixation are certainly not absolute and should be judged individually. Generally accepted criteria include severe pain, sternal instability causing respiratory compromise, and severe displacement. Only a small percentage of patients (2% in one series) actually require sternal fixation [48]. A lack of consensus among surgeons on how to treat these injuries, in addition to a lack of randomized trials concerning their optimal approach, continues to prevail.

Scapular Fracture

Scapular fractures are relatively rare and were once presumed to be an indicator of severe underlying trauma and subsequent higher mortality. They occur in only approximately 1% to 4% of blunt trauma patients who present to a level I trauma center and are associated with a higher incidence of thoracic injury compared to those patients who sustain blunt trauma without a scapular fracture. However, more recent studies have indicated that although patients with scapular fractures tend to have more severe chest injuries and a higher overall injury severity score, their length of intensive care unit stay, length of hospital stay, and overall mortality is not necessarily increased [49,50]. Treatment is usually conservative and, most of the time, necessarily aimed at the associated injuries that are commonly present.

Scapulothoracic Dissociation

Scapulothoracic dissociation is an infrequent injury with a potentially devastating outcome. Scapulothoracic dissociation results from massive traction injury to the anterolateral shoulder girdle with disruption of the scapulothoracic articulation. Identification of this injury requires a degree of clinical suspicion, based upon the injury mechanism and physical findings. Assessment of the degree of trauma to the musculoskeletal, neurologic, and vascular structures should be made. Based upon clinical findings, a rational diagnostic approach can be navigated and appropriate surgical intervention planned. Scapulothoracic dissociation frequently is associated with acromioclavicular separation, a displaced clavicular fracture, subclavian or axillary vascular disruption, and a sternoclavicular disruption. Clinically, patients usually present with a laterally displaced scapula, a flail extremity, an absent brachial pulse, and massive swelling of the shoulder. Vascular injury occurs in 88% of patients and severe neurologic injuries occur in 94% of patients. Many of these patients have a poor outcome and present with a flail, flaccid extremity that usually results in early amputation and have an overall mortality of 10%. One of the most devastating aspects of scapulothoracic dissociation is the brachial plexus injuries that occur, which are typically proximal, involving the roots and cords—brachial plexus avulsions are not unusual. Attempts at repair of complete brachial plexus injuries with grafts or nerve transfers have generally been unsuccessful [51]. Treatment includes arterial and venous ligation to stop exsanguination if present, orthopedic stabilization and consideration for above elbow amputation electively, if brachial plexus avulsion is present, to allow for a more useful extremity. Overall prognosis for limb recovery is poor.

Traumatic Asphyxia

Traumatic asphyxia occurs as a result of a sudden or severe compression injury of the thorax or upper abdomen. It is most often associated with blunt trauma secondary to a crush injury. Entrapment of children under automatic garage doors is a prime example, as reported by Kriel et al. [52]. The true incidence of traumatic asphyxia is unknown, but it is considered to be a relatively rare event. The diagnosis is usually made based on the mechanism of injury and physical examination. Associated injuries are common and therefore should be investigated. The usual physical findings consist of facial edema, cyanosis, and petechial hemorrhages of the upper torso, neck, and face. The petechiae usually occur within the conjunctiva and oral mucosa and become most prominent a few hours after the initial injury. Neurologic findings are not rare and are thought to be secondary to anoxic injury, as well as possible cerebral edema and hemorrhage. The exact pathophysiology is thought to be due to a crushing injury applied to the mediastinum, which causes the heart to force blood out of the right

atrium retrograde into the valveless innominate and jugular venous system. In addition, a sudden reflexive inspiration is thought to occur against a closed glottis, which may elevate the intrathoracic pressures to high levels. This results in a sudden and rapid increase in the pressure of the small veins of the face and neck, resulting in the typical petechial hemorrhages that are observed.

Treatment is generally supportive. Specific therapy for traumatic asphyxia is based on physiologic techniques to decrease intracranial pressure, including elevation of the head of the bed and oxygen therapy. The need to treat possible associated injuries may take priority. Commonly associated injuries include rib fractures, pulmonary contusions, extremity fractures, pneumothorax, hemothorax, flail chest, and blunt pelvic and intra-abdominal injuries (i.e., splenic and/or liver lacerations). The prognosis of patients with traumatic asphyxia is generally good, as long as the patient did not sustain prolonged apnea or hypoxia. The majority of fatalities are usually from associated injuries and their complications. When death does occur, it usually occurs in patients who have sustained a prolonged compression, causing massive irreversible neurologic insult from the resultant apnea and hypoxia.

Pleural Space

Pneumothorax

This section will only focus on pneumothoraces associated with trauma. For further general discussion of pneumothorax in the critically ill, readers are referred to Chapter 57. For in depth discussion of imaging studies on the topic of pneumothorax, readers are referred to Chapters 57 and 63. A traumatic pneumothorax occurs from either blunt or penetrating trauma, with resultant direct injury to the pleural barrier. Rib fractures may or may not be present. Mechanical ventilation can also be considered a traumatic cause of pneumothorax and has an overall associated incidence of 5%. This incidence increases dramatically in patients with underlying lung diseases, such as COPD and acute respiratory distress syndrome (ARDS). Iatrogenic causes of pneumothorax are also prevalent within the hospital setting. Central-line insertions are associated with a 3% to 6% incidence of pneumothorax.

All types of pneumothorax may progress to tension pneumothorax, which occurs in 1% to 3% of spontaneous pneumothoraces and can occur at any stage of treatment. As tension pneumothorax is a rapidly progressive condition, early identification is essential and immediate decompression should be performed when suspected on clinical grounds.

Tension pneumothorax is a clinical diagnosis, and treatment should never be delayed to obtain a confirmatory radiograph. Open pneumothorax is caused when a penetrating chest injury opens the pleural space to the atmosphere. Open pneumothorax may also occur with massive blunt trauma that literally rips open the chest. This leads to a collapsed lung and a "sucking" chest wound. Open pneumothorax is an injury commonly seen on the battlefield. In civilian life, impalement by objects is a common cause. In injuries where the chest wall wound diameter approaches two thirds of the diameter of the trachea, air will preferentially enter the pleural space through the wound during respiration, thereby inhibiting normal ventilation through the upper airway, leading to profound hypoventilation and subsequent hypoxia. Changes in venous return can occur similar to that seen in a tension pneumothorax, which in turn can lead to hemodynamic instability. The presence of a "sucking" chest wound makes the diagnosis obvious. External wound size may not correlate with the degree of compromise, as it is the size of the atmospheric-pleural connection that is most correlative.

Treatment includes appropriate resuscitative maneuvers, including securing the airway, adequate ventilation, and locating the wound and placing a sterile occlusive dressing over it to allow negative pressure ventilation to resume. If this does not suffice, intubation and positive pressure mechanical ventilation may be necessary. A standard method of coverage involves placing a nonporous dressing over the wound and taping it on three sides, allowing it to act as a one-way valve, allowing air to escape during expiration but occlusive during negative pressure inspiration. A chest tube is routinely sterilely inserted at a separate site away from the site of injury to treat any possible tension pneumothorax that may arise. The wound should be cared for locally and associated injuries should be sought and treated appropriately.

Hemothorax

After rib fractures, hemothorax is the second most common complication of chest trauma. It can be caused by bleeding from anywhere in the chest cavity, including the chest wall, lung parenchyma, major thoracic vessels, heart, or diaphragm. It presents in approximately 25% of patients with chest trauma. Patients with hemothorax typically have decreased breath sounds and dullness to percussion over the affected side with associated dyspnea and tachypnea. Depending on the amount of blood loss, they may be in hemodynamic shock. The major cause of significant hemothorax is usually due to a laceration to the lung or bleeding from an injured intercostal vessel or internal mammary artery. Radiographic films may not reveal a fluid collection of less than 300 mL. Small hemothoraces usually seal themselves within a few days. Accumulation of more than 1,500 mL of blood within a pleural space is considered massive, is more commonly seen on the left side, and is usually due to aortic rupture (blunt trauma) or pulmonary hilar or major vessel injury (penetrating trauma). Massive hemothorax can lead to hemodynamic instability including hypotension and circulatory collapse. Neck veins may be flat or distended, depending on whether or not blood loss or increased intrathoracic pressure predominates. A mediastinal shift with tracheal deviation is typically away from the side of blood accumulation.

Treatment of acute hemothorax includes supplemental oxygen therapy and, in most cases, the insertion of a large bore (i.e., 36 French) tube thoracostomy anterior to the midaxillary line at the fifth or sixth intercostal space. A moderate-size hemothorax (500 to 1,500 mL) that stops bleeding immediately after a tube thoracostomy can usually be managed conservatively with a closed drainage system. Bleeding from pulmonary parenchymal injuries that do not involve the hilum usually will stop on their own because of the low pulmonary pressures and high concentrations of tissue thromboplastin within the lung [53]. If, however, the patient continues to bleed at a rate of 100 to 200 mL per hour, then exploration is indicated. Likewise, if the patient bleeds out more than 1,500 mL initially through the chest tube, exploration is indicated. If the patient is hemodynamically unstable at any time, and intrathoracic bleeding is suspected as the cause, emergent thoracotomy should be done regardless of chest tube output. A chest radiograph should always be obtained after placing a tube thoracostomy to check position of the tube and to make sure that the pleural space is adequately drained. If a large amount of retained blood and clot remains within the pleural space despite tube thoracostomy, exploration with open evacuation should be considered. VATS is an option in the stable patient with retained hemothorax or in a stable patient that continues to bleed at a slow but steady rate; however, the surgeon should not hesitate to convert to open thoracotomy if visualization is inadequate or drainage and evacuation of the pleural space is incomplete. If the retained hemothorax is not massive, nonoperative therapy

can be considered as these may lyse with time. Alternatively, it has been shown that a retained hemothorax can be successfully treated with instillation of thrombolytics into the pleural space. This has been deemed safe even in patients who have sustained multiple trauma [54].

Lung

Contusion

Pulmonary contusion is a common injury found in patients sustaining blunt chest trauma, with an approximate incidence of 30% to 75%. Mortality is between 10% and 25%. Hemorrhage and interstitial edema result from injury to the lung. This can lead to alveolar collapse and the typical parenchymal consolidation seen on radiograph. Injury to the parenchyma from blunt force trauma is thought to be caused by a combination of events that include alveolar stretching, parenchymal tearing, and concussive forces. Lung injury in the absence of identifiable rib fractures typically exhibits diffuse injury; whereas rib fractures and flail chest are associated with more localized injury. The extravasation of blood into the alveolar space causes subsequent consolidation which can then lead to an intrapulmonary shunt. A flail chest may be associated with pulmonary contusion in approximately three fourths of the time, which more than doubles the morbidity and mortality. Hypoxemia, although nonspecific, is the most common clinical finding associated with pulmonary contusion and should raise the suspicion of its diagnosis. Typical chest radiographic findings in the appropriate clinical setting remain the mainstay of diagnosis. Typical findings usually demonstrate a focal or diffuse consolidative process that does not typically follow anatomical segments or lobes. Rib fractures are the most common bony injuries seen and should raise suspicion for the diagnosis of pulmonary contusion, even if other clinical signs are absent at the time. Pulmonary contusion may not become radiographically apparent for up to 48 hours postinjury, with an average delay of 6 hours. On the other hand, CT scanning of the chest has been shown to be able to demonstrate the presence of pulmonary contusion almost immediately postinjury [55–58]. In addition, it can help estimate the total volume of injured lung present. This can be helpful in predicting the need for eventual ventilatory support. It has been shown that when pulmonary contusion involves 28% or more of the total lung volume, essentially all patients eventually require mechanical ventilation; whereas when 18% or less of the lung volume is involved, the need for mechanical ventilatory support is unlikely [59]. Treatment of pulmonary contusion is generally supportive. Close respiratory monitoring and frequent clinical examination is important, as approximately half of all respiratory failures secondary to pulmonary contusion occur usually within the first few hours postinjury. Once diagnosed and coexistent injuries are treated, and the need for emergent surgery is ruled out or performed as required, the patient should be transferred to a monitored bed. Good pulmonary toilet should be employed and may be achieved through several mechanisms, including nasotracheal suction, chest physiotherapy, and postural drainage. This helps to minimize atelectasis and expel bronchial secretions. If patients are still unable to clear their secretions adequately, bronchoscopy can be helpful. Adequate analgesia is also important in maintaining good pulmonary toilet. This can be achieved through nerve blocks, systemic opioids, or epidural anesthesia. Mechanical ventilation can minimize edema and increase functional residual capacity, which in turn can decrease shunting and reduce hypoxemia. Positioning patients with the injured lung in the nondependent position may also improve oxygenation, especially in those patients refractory to other measures. Fluid administration should be done judiciously, as hypervolemia may worsen fluid extravasation into the alveolar spaces and worsen parenchymal consolidation, especially since capillary permeability is already compromised. However, under-resuscitation should also be avoided, as this may lead to thickened secretions, possibly worsening cardiac output and shunt fraction. Obviously, fluid administration in these patients can be a difficult balancing act, and good clinical judgment is important. Positive end expiratory pressure (PEEP) should be maintained at the minimum value necessary to ensure adequate oxygenation, since excessive PEEP may actually worsen gas exchange and can actually extend the area of injury. Atelectasis can lead to infectious pneumonia, which typically begins to contribute more to the hypoxia after the initial couple of days postinjury. Pulmonary infections may develop in up to 50% of patients with pulmonary contusion. Furosemide, in addition to its diuretic affect, can be useful in the treatment of patients with pulmonary contusion. Acute respiratory distress syndrome (ARDS) can complicate pulmonary contusion in 5% to 20% of cases, and respiratory dysfunction is a common sequela that can be found in a majority of patients in the long term. Dyspnea may affect as many as 90% of patients during the first 6 months postinjury. In addition, functional reserve capacity has been found to be diminished as late as 4 years after injury, with the majority of patients demonstrating subtle changes on CT [60].

Tracheobronchial Injury/Lung Laceration

Tracheobronchial injury can be a challenge to diagnose, manage, and definitively treat. The true incidence of tracheobronchial injury is difficult to establish, as a large proportion (30% to 80%) of these patients will die before reaching the hospital. It is estimated on the basis of autopsy reports that 2.5% to 3.2% of patients who die as a result of trauma may have associated tracheobronchial injury [61,62]. More than 80% of tracheobronchial injury due to blunt trauma is located within 2.5 cm of the carina. Resuscitation of a patient with tracheobronchial injury can be difficult, since obtaining adequate ventilation may require novel approaches to secure the airway. Patients with tracheal or bronchial injuries make this initial assessment particularly challenging. The majority of patients with tracheobronchial injury seen in the emergency department have some degree of respiratory difficulty, and these patients may require emergent measures to secure and control the airway. Orotracheal intubation is the most common method used. Patients with cervical injuries and open neck wounds can be intubated through the open wound to secure the airway if necessary. The initial physical findings in patients with tracheobronchial injury can be subtle. However, several abnormalities can alert the physician to the diagnosis. Tachypnea and subcutaneous emphysema are common. Pneumothorax may or may not be seen on a plain radiograph. The liberal use of bronchoscopy is mandatory in identifying tracheobronchial injuries and constitutes the gold standard in diagnosis. Findings that can typically be seen on bronchoscopy include obstruction of the airway with blood and inability to visualize the more distal lobar bronchi because of collapsed proximal bronchi. Visualization of a bronchial tear is confirmatory. Associated injuries are common and are usually related to the mechanism and location of the tracheobronchial injury. The most commonly associated injury related to penetrating tracheobronchial injury is esophageal perforation. Most repairs of cervical tracheal injuries are approached through a collar incision. In patients with injuries high in the mediastinal trachea or with suspected great-vessel injury, a median sternotomy may be necessary. When the injury is associated with a unilateral pneumothorax or a bronchial injury is diagnosed preoperatively, an ipsilateral posterolateral thoracotomy is the incision of choice. For injuries to the mediastinal trachea, an approach by a right posterolateral

thoracotomy (usually high through the fourth intercostal space) is reasonable. Since the initial report by Shaw and colleagues, primary repair of the injured tracheobronchial tree has been encouraged [61,63–67]. Most patients can undergo primary repair of their tracheobronchial injury using tailored surgical techniques specific to the injury. When a major bronchus is disrupted, lobectomy is the preferred method of treatment, with closure of the bronchial stump debrided back to healthy tissue. With injuries to the mainstem bronchi, primary repair is preferred over pneumonectomy whenever possible, due to the higher mortality associated with pneumonectomy, especially in the trauma setting. Injury to the trachea can be either primarily repaired or converted to a tracheostomy if necessary for airway control. Nonoperative management of tracheobronchial injury has been reported to be successful in selected cases. Those patients that seem most appropriate for this approach are those with membranous injuries. Patients that have cartilaginous injuries are more likely to require operative repair. Tracheobronchial injury encompasses a heterogeneous group of injuries that requires skillful airway management, careful diagnostic evaluation, and operative repairs that are often creative and necessarily unique to the given injury.

Heart

Cardiac Contusion/Blunt Cardiac Rupture

Most blunt cardiac injuries are not serious. However, moderately severe cardiac injuries may cause arrhythmias or result in low-output cardiac failure. The clinical significance of myocardial contusion following blunt thoracic trauma is still largely unknown. In one study by Lindstaedt et al., approximately 20% of patients who were admitted to a surgical intensive care unit because of their injuries met the criteria for diagnosis of myocardial contusion [68]. Their criteria include exclusion of pathologic findings on ECG known to be present prior to injury; echocardiographic evidence of akinetic wall motion abnormalities; combination of regional wall motion abnormality, significant isoenzyme elevation (CK-MB > 7%), and ECG abnormality; regional wall motion abnormality in the baseline echocardiogram and in the control echocardiogram at follow-up; or confirmation of myocardial contusion at autopsy or intraoperatively. Even though the prevalence of the injury was significant in their population, the overall prognosis was excellent, and the authors recommend that specific diagnostic and therapeutic measures should be limited to cases where cardiac complications develop. The combination of a normal ECG and normal serum troponin levels, drawn at the time of presentation and 8 hours later, essentially rule out significant myocardial contusion and is sufficient, in the absence of other reasons for hospitalization, to discharge such patients safely home. However, patients with an abnormal ECG and elevated troponin should be monitored for at least 24 hours. Cardiac contusion may lead to cardiogenic shock resistant to inotropic support. The use of intra-aortic balloon counterpulsation as a mechanical means of augmenting cardiac function following cardiac contusion has been reported with success even in elderly patients [69]. Severe injuries to the heart can result in cardiac rupture. Atrial and/or ventricular rupture can occur, leading to profound hemodynamic compromise. Rapid recognition of such injuries is necessary for successful treatment. Associated injuries are common and include closed head injury, pulmonary contusion and/or laceration, multiple rib fractures, liver and spleen injury, and traumatic aortic injury; these account for approximately 25% of fatalities seen in patients with blunt cardiac injury. The usual clinical presentation of cardiac rupture is cardiac tamponade secondary to hemopericardium, although less than 15% of these patients actually manifest physiological evidence of tamponade. Associated pericardial tears may allow for decompression of intrapericardial hemorrhage through the pleural space, preventing the development of cardiac tamponade but leading to hemothorax. Pericardial rupture is rare, but can occur in isolation or with associated injuries such as blunt cardiac or diaphragmatic rupture, which has a high mortality. Hypotension is usually present, and the diagnosis of cardiac rupture should be considered in any patient who has hypotension in the absence of overt blood loss. The chest radiograph may not show evidence of cardiac injury, even in the face of tamponade and hemodynamic compromise, since a rapid accumulation of blood into the pericardial space can occur without significantly altering the cardiac silhouette. Echocardiography can be useful in diagnosing pericardial tamponade. Diagnosis of blunt cardiac rupture should be strongly suspected when hemopericardium is seen by ultrasound in the setting of blunt trauma. The diagnostic dependability of pericardiocentesis is limited in the assessment of traumatic hemopericardium and potential cardiac rupture because of significant false negative and false positive results. Performing a pericardial window in the operating room, however, can be both diagnostic and therapeutic, and it can confirm hemopericardium and allow for rapid decompression and median sternotomy. Nevertheless, the diagnosis of blunt cardiac rupture requires a fair degree of clinical suspicion, particularly in the setting of hypotension that does not respond to adequate volume resuscitation. Perchinsky et al. reviewed a consecutive series of 27 patients seen between 1984 and 1993 with blunt cardiac rupture. Overall survival rate was 41%. Of note was that three out of nine (33%) patients presenting to the emergency department with no identifiable blood pressure or viable electrical heart rhythm survived resuscitation, surgery, and initial hospital care. No patient survived rupture of two or more cardiac chambers in their series, however [70]. Although cardiac exploration should be performed with cardiopulmonary bypass support nearby, repair of cardiac rupture does not necessarily require its use.

Cardiac Valvular Injuries

Blunt cardiac injury may result in valvular insufficiency. The right ventricle is immediately behind the sternum, which makes it particularly vulnerable to injury. Acute severe elevation of right intraventricular pressures has been shown to result in injury of the tricuspid valvular apparatus [71]. The most common injury is chordal rupture, followed by rupture of the anterior papillary muscle and leaflet tears. Posttraumatic aortic valve regurgitation has also been reported and affects all ages and is often found in association with sternal or multiple rib fractures [72]. Traumatic mitral valve insufficiency has been shown to present with either complete papillary muscle avulsion from its ventricular attachment or with chordal tears and/or leaflet damage. Those with papillary muscle avulsion typically present with severe regurgitation. Those patients with less severe injuries to the mitral valve, such as chordal tears and/or leaflet damage, usually present with less severe symptoms and may even be asymptomatic. Not only can blunt cardiac injury cause acute valvular incompetence, but it can also predispose patients to delayed valvular dysfunction. In a study performed by Ismailov et al. looking at hospital patient discharges, patients who sustained blunt cardiac injury had an associated 12-fold increased risk for developing tricuspid valve insufficiency and a 3.4-fold increased risk of developing aortic valvular insufficiency later in life, which appeared to be independent of age, race, sex, and injury severity score [73]. There was no correlation found with increased risk for mitral valve insufficiency, however. Traumatic valve insufficiency, depending on severity and valve involved, may necessitate surgical treatment.

Penetrating Cardiac Injury

The clinical presentation of penetrating cardiac injury ranges from one of hemodynamic stability to complete cardiopulmonary arrest. Beck's Triad represents the classical presentation of the patient arriving in the emergency department in pericardial tamponade and includes venous hypertension, arterial hypotension, and muffled heart sounds. Kussmaul's sign, jugular venous distention seen with expiration, is another classic sign attributed to pericardial tamponade. The physiology of pericardial tamponade is related to the relative inelastic and noncompliant pericardium. Sudden acute loss of intracardiac blood volume into the pericardial sac leads to an acute pressure rise and compression of the thin-walled right ventricle and atria. This decreases the heart's ability to fill, resulting in decreased left ventricular filling and ejection fraction, thus decreasing cardiac output. Subxiphoid pericardial window remains the gold standard for the diagnosis of cardiac injury. It can also be therapeutic and can be done under local anesthesia in the operating room to allow release of tamponade prior to the induction of general anesthesia. If blood is found, then the surgeon can proceed immediately to median sternotomy and cardiorrhaphy. In relatively stable patients who do not require emergency room thoracotomy, median sternotomy is the incision of choice to repair penetrating cardiac wounds [74,75]. TTE has clearly emerged as the technique of choice for the diagnosis of penetrating cardiac injuries. Jimenez et al. showed that TTE had 90% accuracy, 97% specificity, and 90% sensitivity in detecting penetrating cardiac injuries [29]. The usefulness of echocardiography may be in its ability to identify obvious hemopericardium, thereby allowing the trauma surgeon to proceed directly to median sternotomy and thus eliminating the need for a subxiphoid pericardial window in many cases. Indications to perform EDT include loss of vital signs with suspected pericardial tamponade, especially in the case of suspected penetrating trauma to the heart. An anterolateral thoracotomy is typically performed in between chest compressions and should be extended through all of the subcutaneous tissues, as well as the anterior chest wall muscles, until the intercostal space is identified. Typically, the patient's vital signs quickly return to acceptable levels. Internal defibrillation may be necessary, as the heart is often found to be in ventricular fibrillation. Epinephrine and similar drugs should specifically be avoided, as release of the tamponade is usually more than sufficient to allow the patient's vital signs to return. Epinephrine can increase chronotropy, inotropy, and intraventricular pressures, which can potentially extend ventricular injuries and make repair difficult and unnecessarily challenging. If sinus rhythm cannot be restored despite all attempts, the prognosis is grave and the outcome is invariably poor. Once vital signs are reestablished, attention can then be given to repairing the cardiac injury. Definitive cardiac repair does not necessarily have to be done immediately, however, and in some cases may be ill-advised when performing an emergency room thoracotomy, since it is the tamponade and not the blood loss per se that causes hemodynamic collapse. Once the tamponade is released, digital pressure can be directly applied to the cardiac wound which is often all that is needed once vital signs are restored to maintain relative hemostasis until definitive repair can be done in an operating room. In the authors' opinion, the use of adjunct measures, such as balloon tamponade with a Foley catheter, can be fraught with creating more injuries or extending existing myocardial lacerations and should be avoided if possible. Vascular clamps can be placed on bleeding right atrial wounds but usually are not necessary and may cause more harm than not, extending small injuries into larger ones. In addition, cross-clamping of the thoracic aorta is generally not necessary and ill-advised with isolated penetrating cardiac wounds. If necessary, it can be temporarily occluded digitally against the bodies of the thoracic vertebrae until adequate resuscitation has taken place. An attempt should be made to trace the trajectory of the wounding agent, as missiles often enter into one thorax and then enter the contralateral hemithorax. Once the tamponade has been released, and the patient has regained a rhythm and a blood pressure and the bleeding sites are identified and digitally controlled, the experienced surgeon can then attempt closure of the cardiac wound in an appropriate equipped operating room. Total inflow occlusion of the heart can be done if the blood loss is substantial through the wound and proper placement of sutures difficult in the face of on-going blood loss without the aid of cardiopulmonary bypass. This maneuver is performed by placing caval tapes around both the superior and inferior vena cavae within the pericardium, which, when tethered, results in immediate emptying of the heart. The tolerance of the injured heart to this maneuver is limited, however, and should be used only for short periods if found to be necessary. This procedure can result in cardiopulmonary arrest and ventricular fibrillation, and appropriate plans should be made prior to caval occlusion should this happen. Atrial injuries can be repaired with running 2-0 Prolene. Ventricular wounds may be repaired while digitally occluding the laceration while placing a horizontal mattress stitch with a pledget surrounding the wound, usually with 2-0 Prolene. Repairing cardiac injuries resulting from gunshot wounds can be more challenging when compared with stab wounds, since they tend to have associated blast defects, which can make repair difficult. The repair of ventricular wounds adjacent to or involving coronary arteries can be challenging. If the coronary artery is injured itself but is quite distal (e.g., distal 1/3 of the left anterior descending artery), simple ligation can be done without serious consequences. However, if the injury is more proximal than this, ligation of the injury with distal bypass using a segment of saphenous vein or mammary artery is recommended. This can be done on or off cardiopulmonary bypass but usually requires the expertise of an experienced cardiac surgeon to perform. If the injury does not involve the coronary artery but is in close proximity, suturing of the injury may require placement of a horizontal U-stitch underneath the bed of the coronary artery, thereby closing the injury without compromising coronary blood flow. Patients who have sustained injury to their coronary artery that has already sustained irreversible myocardial damage may require intra-aortic balloon counterpulsation as part of their resuscitation.

Esophagus

Iatrogenic injuries to the esophagus are the most common, particularly those of iatrogenic esophageal perforation. Traumatic injury and Boerhaave's syndrome account for most of the rest.

Flexible endoscopy is associated with an extremely low risk of perforation. However, when flexible endoscopy is paired with a therapeutic intervention, such as dilatation or stent placement, the risk of perforation dramatically increases. As a result, most patients with iatrogenic perforation occur in patients undergoing therapeutic maneuvers in response to treating an underlying esophageal problem. Almost any form of esophageal instrumentation can cause perforation. Examples include nasogastric tube placement and performance of TEE. Common sites for perforation of the esophagus occur at areas of narrowing, such as in the pyriform fossa, at the aortic arch, near the carina, or at the lower esophageal junction. Perforation of an existing diverticulum can also occur, but this occurs rarely and is usually associated with blind passage of an endoscope when no antecedent barium swallow was obtained. The esophagus may also perforate at the site of a malignant stricture during forceful dilation or, more commonly, in the area of the esophagus just proximal to the stricture. Pneumatic dilatation

for achalasia carries an increased risk compared with routine esophageal dilatation, since this requires an uncontrolled tear of the lower esophageal sphincter to affect a myotomy. The risk of perforation with pneumatic balloon dilatation of the lower esophageal sphincter for achalasia ranges from 2% to 6%. Risk of perforation when performing esophageal dilation increases when dealing with long strictures or ones with poor blood supply, such as with radiation-induced strictures. Caustic strictures are usually transmural associated with extensive esophageal wall fibrosis and usually require repeated dilations, thereby multiplying the risk of perforation over time. Stent placement for the palliation of esophageal cancer is associated with a perforation rate of 7% to 15%. The incidence of perforation following sclerotherapy for esophageal varices is approximately 1% to 3% and typically occurs several days after the procedure, presumably due to tissue necrosis.

Patients who present with esophageal perforation usually complain of pain. Findings may include fever and subcutaneous or mediastinal air. Crepitus in the neck is relatively common following perforations of the cervical esophagus and can be detected on physical exam in approximately 60% of patients. Pleural effusions are present in more than 50% of patients with perforations of their thoracic esophagus. Radiologic studies are important in diagnosing patients with esophageal perforation. A plain chest radiograph may show subcutaneous emphysema, pneumomediastinum, pleural effusion, mediastinal air–fluid levels, or pneumothorax. Radiographic abnormalities can be found in as many as 90% of patients on plain film. Contrast studies are performed to confirm the diagnosis of perforation and to define the exact site. Water-soluble contrast agents such as Gastrografin have been the preferred agents of choice, at least initially. However, Gastrografin can cause severe pneumonitis if aspirated into the lungs, and its use may not demonstrate small leaks. Because of this, it is the authors' preference to use thin barium, because it is more inert and is better at detecting smaller leaks. CT scanning can be particularly helpful in showing mediastinal findings when the perforation has already sealed.

The optimal management of esophageal perforation is patient-specific and should take into account the clinical setting. This includes consideration of the patient's underlying disease process, the degree of sepsis, if any, the location of the perforation, and whether or not the perforation is contained. A nonoperative approach may be considered in patients with minimal symptoms and physical findings who do not appear septic and have a small, contained leak. Nonoperative management should include the use of broad-spectrum intravenous antibiotics and nothing to eat or drink by mouth (NPO). A nasogastric tube should be specifically avoided. There is no clear consensus as to generally how long a patient with a contained leak should be left NPO or how long intravenous antibiotics should be continued. However, clear liquids can usually be safely started within a few days and the diet advanced cautiously, especially when no further extravasation is seen on repeat contrast study.

Surgery should be performed if the patient appears septic, the leak freely communicates with either the peritoneal or thoracic cavities, or there is an associated mediastinal abscess. Primary repair can be done regardless of the timing of the injury, as long as the tissues appear healthy at the time of surgery. Drainage alone can be done for cervical perforations, especially if the perforation cannot be found at the time of operation, which is not infrequent. Primary repair with drainage is the preferred method when possible; however, if the esophageal tissues do not appear viable to hold sutures, then esophagectomy with proximal diversion may be necessary. It is important when primarily repairing the esophagus that the mucosal edges are defined, as the injury seen in the muscle layer is often only the "tip of the iceberg," and closure of the entire mucosal defect is necessary if adequate healing is to occur. As a general rule, esophageal reconstruction should not be done at the time of esophageal resection if the patient is septic, as it can usually be done at a later date once the patient heals and is beyond the acute event. In these cases, it is better to create an end cervical esophagostomy and oversew the gastric stump with the placement of enteral feeding catheters. If a cancer is perforated during instrumentation, then resection over primary repair is the preferred surgery of choice. Obviously, if the patient has widespread metastatic disease, then good clinical judgment needs to be used in deciding whether an operation should be done at all. Management of a perforation following achalasia dilatation should consist of primary closure of the perforation in addition to performing a surgical myotomy 180 degrees away from the site of perforation. An antireflux procedure consisting of a partial wrap to cover the area of repair can also be done to buttress the repair. This type of surgery is most commonly approached through the chest.

Spontaneous perforation of the esophagus usually can be related to forceful vomiting and retching. Boerhaave's syndrome has been reported following a variety of activities including straining, weightlifting, coughing, and emesis. The clinical features of Boerhaave's syndrome are similar to that of iatrogenic perforation, in that pain is the most common presenting symptom. Many patients with Boerhaave's syndrome do not have the classic antecedent history of forceful vomiting. The vast majority of these patients develop perforations in the distal esophagus on the left side, and the workup and treatment of patients with Boerhaave's syndrome is similar to those with iatrogenic perforations. Operation is usually indicated.

A Mallory-Weiss tear is a mucosal laceration, usually near the gastroesophageal junction, caused by forceful vomiting, and a hiatal hernia is found in more than 75% of patients. Most tears occur within 2 cm of the gastroesophageal junction on the lesser curvature of the stomach. Majority of the patients present with gastrointestinal bleeding. The classic presentation in up to 80% of patients is that of forceful emesis followed by hematemesis. Massive bleeding occurs in 10% of patients. Upper endoscopy usually confirms the diagnosis. The management of Mallory-Weiss tears is generally supportive, since the bleeding is usually self-limited. Occasionally gastric embolization may be necessary; surgical over-sewing of the tear is rarely necessary.

Esophageal injuries due to penetrating trauma are rare, with most series averaging only a handful [76–78]. They result most commonly from transmediastinal gunshot wounds. Asensio et al. reported their experience consisting of 43 penetrating esophageal injuries managed over a period of 6 years. Overall, 28 of their 32 survivors (88%) were managed by primary repair alone [79]. The overall mortality for their series was 26%. The authors also reported that these mortality figures were consistent with others reported in the literature, which have remained high and relatively stable approximately for the last 20 years, thus attesting to the critical nature of these injuries. Only Symbas et al. (48 cases) and Defore et al. (77 cases) have reported larger experiences but over much longer spans of time–15 and 22 years, respectively [76,77]. Penetrating esophageal injuries are not easily detected and require a high index of suspicion. Delay in diagnosis is associated with higher mortality. However, mortality can exceed 20% even for patients who are promptly diagnosed. Esophagoduodenoscopy (EGD) is a sensitive and safe diagnostic test for the detection of esophageal injury. A study by Flowers et al. showed that EGD had a sensitivity of 100%, a specificity of 96%, and an accuracy of 97% in detecting penetrating esophageal injuries [80]. There was no morbidity related to the examination, and, most importantly, no esophageal injuries were missed. The authors commented that the most significant potential weakness of flexible EGD for esophageal trauma is that it actually may

be too sensitive. EGD is most helpful in excluding esophageal injury in patients who require a surgical procedure for another injury. When found, prompt primary repair is the treatment of choice.

Caustic Injuries of the Esophagus

Caustic injuries of the esophagus can be very challenging to manage. They are most frequently due to suicide attempts in adults and accidental ingestion in children. The degree of injury to the esophagus is directly proportional to the amount of caustic substance ingested. Lye causes transmural liquefaction necrosis of the esophagus and therefore is most injurious. Diagnosis is usually from history, although patients attempting suicide may present with no history at all or, even worse, an inaccurate one. Examination of the buccal mucosa, mouth, tongue, and gums can often show chemical burns and suggest the diagnosis. Endoscopy should be performed to document the proximal extent of the injury only; there is no need to pass the endoscope further, since it may actually be harmful and potentially lead to perforation. Passage of an NGT is controversial, although it may actually help to "stent" the esophagus open and be associated with lower rates of stricture formation. Arterial blood gases should be obtained with particular attention paid to the base deficit, as this can be a marker for severity of injury. Signs and symptoms of perforation and sepsis should be carefully monitored. The patient should be made NPO, and broad spectrum intravenous antibiotics should be given. Steroids are controversial but have been associated with lower rates of stricture formation in some series [81,82]. Intravenous fluids should be given and consideration given to performing esophagectomy, if signs of perforation and mediastinal sepsis are present. Intra-abdominal perforations can also occur, as well as injury to surrounding structures (e.g., spleen, colon). If esophageal resection becomes clinically indicated due to sepsis, immediate reconstruction is ill-advised. Esophagectomy can be performed either transhiatally or transthoracically, with creation of an end cervical esophagostomy. Intra-abdominal feeding tubes should be placed for enteral access. Delayed reconstruction can then be performed electively once the sepsis clears and the patient heals, usually several months later. Late stricture formation is common and can be difficult to manage. In addition, the pharyngeal phase of swallowing can be affected, leading to debilitating problems with speech and swallowing. It is not uncommon to require serial dilations or even late esophagectomy if stricture formation develops. It typically involves long segments of the esophagus and is panmural in depth, often making dilation impossible or at best marginally effective. Overall prognosis is variable depending on the degree of injury.

Thoracic Aortic Injury

Traumatic disruption of the thoracic aorta immediately leads to death in majority of the patients. These horizontal acceleration/deceleration injuries usually result from a disruption of the integrity of the aortic wall just distal to the ligamentum arteriosum. Patients fortunate enough to survive initial injury usually do so because the aortic adventitial tissues are able to tamponade the tear, thereby preventing fatal intrathoracic exsanguination. The risk of rupture is dependent on multiple factors, including the ability of the adventitial tissues to contain the leak, the patient's systemic blood pressure, and the size of the contained pseudoaneurysm.

The entire surgical treatment section is confusing and needs to be rewritten. It jumps back and forth to operate and then not operate. It can be summarized and your opinion then given.

While emergent operative repair of thoracic aortic tears had become the standard of care, after 1997 there has been emerging evidence that not all thoracic aortic tears should be treated equally. In addition, associated injuries such as pulmonary contusions, intracranial hemorrhage, and/or intra-abdominal hemorrhage (which are common in these patients) may take precedence over the aortic injury. In these cases, the aortic injury can be acutely managed medically and definitive treatment delayed, so long as certain criteria are met. With careful medical management (strict blood pressure control, minimization of dP/dT), it has been shown that many thoracic aortic injuries can undergo delayed repair, perhaps resulting in superior outcomes when compared with those patients undergoing emergent repair [83,84]. A recent prospective, observational study sponsored by the American Association for the Surgery of Trauma (AAST) looked at the subgroup of patients that underwent immediate repair versus those that underwent delayed repair [85]. Those patients that underwent delayed repair of stable thoracic aortic injury actually had improved survival regardless of the presence of major associated injuries, although their length of ICU stay was longer. It should be noted that patients with no major associated injuries who underwent delayed repair had a significantly higher complication rate when compared to those patients undergoing immediate repair. Although there has not been a randomized, controlled trial of early versus delayed repair, these results probably reflect selection bias. However, selection bias, which reflects the "art" of clinical treatment planning, should not be underscored when making decisions regarding these often multiply injured patients. In addition, successful nonoperative therapy of descending thoracic aortic injury has been reported [86]. Justification for nonoperative therapy includes favorable anatomy of the injury (contained, small injury, hemodynamic stability) as well as the presence of coexisting injuries, which would render the operative risk prohibitively high. These include patients with spinal cord injury that might make lateral decubitus positioning dangerous; patients with pulmonary contusions that may make single lung ventilation difficult; and patients with closed head injury, solid abdominal organ injury, or major fractures in which systemic heparinization would be ill-advised. One accepted method of operative repair is the "clamp-and-sew" technique, in which the proximal and distal aorta are simply clamped, thereby isolating the injury so that either primary repair or interposition grafting can be performed. Operative mortality is generally reported to be 10% to 20% in most series, with major morbidity including renal failure and paraplegia, which appears to increase with prolonged (i.e., >30 minutes) clamp times [87]. Another accepted method of operative repair utilizes bypass of the injured segment during repair, either with partial left heart bypass or with proximal to distal aortic shunt placement (i.e., Gott shunt). Partial left heart bypass (with cannulae in the left atrium and distal aorta) allows controlled off-loading of the left heart in addition to maintaining distal aortic perfusion, especially to the kidneys, that may decrease (but not negate) the incidence of paraplegia, especially when prolonged clamp times are anticipated. Since there has not been a randomized controlled trial comparing the two techniques, and there is no conclusive evidence that one technique is superior over the other in terms of outcome, both methods are acceptable, and their performance is usually based on surgeon preference. The need for operative repair, however, which was once considered the gold standard, is now coming into question. There have been many reports showing that endovascular stent grafting of selected patients may actually be superior to that of "mandatory" operative repair. A prospective, multicenter study sponsored by the AAST was recently published that clearly shows the early efficacy and safety of endovascular stent grafting in selected patients with traumatic thoracic aortic injuries [88]. The patients who underwent stent grafting

had a significantly lower mortality (adjusted odds ratio: 8.42; 95% CI: [2.76 to 25.69]; adjusted p value < 0.001) and fewer blood transfusions (adjusted mean difference: 4.98; 95% CI [0.14 to 9.82]; adjusted p value < 0.046) compared to those patients that underwent operative repair. In addition, among the patients with major extrathoracic injuries, a significantly higher mortality and pneumonia rate were found in the operative group (adjusted p values 0.04 and 0.03, respectively). The major drawback seen in patients undergoing stent grafting were device-related complications, which developed in 20% of the patients. Their conclusion was that stent grafting of thoracic aortic injuries is now more commonly chosen by surgeons as the preferred method of repair and is associated with significantly lower mortality but that there is a considerable risk of serious device-related complications.

CARDIOPULMONARY CRITICAL CARE

Overview

It is not uncommon for severely injured patients to require cardiac and/or pulmonary support. This may be independent of whether or not they have sustained direct thoracic trauma. Pharmacologic drug therapy may be required to sustain adequate cardiac output and maintain necessary end-organ perfusion. In severe cases, cardiac failure may require mechanical support in the form of intra-aortic balloon pump counterpulsation. Respiratory support may be provided simply with supplemental oxygen administration; however, intubation and mechanical ventilation may be required. Unique ventilatory strategies such as high frequency oscillatory ventilation are sometimes required. In extreme cases, extracorporeal membrane oxygenation (ECMO) can be used and is potentially life-saving in a certain subset of selected patients. Due to both the severity of injury as well as the need for ventilatory support, it is not unusual for these patients to develop acute lung injury as well as ventilator-associated pneumonia.

Pharmacologic Drug Therapy

Pharmacologic agents are usually used early in the treatment of cardiogenic shock. For an in depth discussion of this topic, readers are referred to Chapter 58–60. Perfusion of vital organs is dependent on adequate oxygen and nutrient delivery to the tissues. This delivery is dependent on an adequate blood pressure (perfusion pressure), cardiac output, and intravascular volume including hemoglobin. If cardiac output and perfusion is maintained and yet there is not adequate oxygen-carrying capacity (i.e., hemoglobin), oxygen delivery to the tissues will be limited. There continues to be controversy and debate regarding what is considered to be an adequate hemoglobin level. However, many centers now use a hemoglobin level of < 7 g per dL as a transfusion trigger for patients without evidence of ischemic cardiac disease, signs and symptoms of impaired tissue perfusion, shock, or ongoing blood loss [89].

In addition, intravascular volume status, especially in chronically ill patients, is sometimes confusing. In fact, only half of ICU patients with hemodynamic instability will actually respond to fluid loading with a significant increase in their cardiac output [90]. This is because it is sometimes difficult to assess clinically exactly where the patient's heart is working on the Frank-Starling curve. If it is on the initial rise of the curve, the stroke volume is highly and directly dependent on the preload, and administering fluid will result in an increase in stroke volume. In contrast, however, if the heart is working on the top, more flat (and possibly even declining) portion of the Frank-Starling curve, fluid administration will not increase stroke volume and may actually worsen heart failure and pulmonary edema and, therefore, oxygen delivery to the tissues. Passive leg raise, which auto-transfuses volume to the patient, may be a reliable and simple predictor of responsiveness to volume administration. Measurements of cardiac output and responsiveness to fluid challenges can be obtained through the use of traditional, invasive pulmonary arterial catheter monitoring or, more recently, through less invasive means, such as esophageal Doppler monitoring, pulse contour analysis, indicator dilution, thoracic bioimpedance, and partial nonrebreathing systems.

Intra-Aortic Balloon Pump

When pharmacologic treatment is inadequate and cardiogenic shock becomes refractory due to pump failure, mechanical devices may be indicated. One such device is the intra-aortic balloon pump (IABP). For an in depth discussion of this topic, readers are referred to Chapter 45.

Metabolic support of the critically ill patient is important. For an in depth discussion of this topic, readers are referred to Chapter 190.

Mechanical Ventilation

For a complete discussion of mechanical ventilatory support, readers are referred to Chapter xx.

EXTRACORPOREAL MEMBRANE OXYGENATION

In patients who fail standard ventilatory strategies, rescue modalities such as ECMO may be a life-saving alternative. ECMO provides oxygenation of blood outside of the body (hence its extracorporeal nature) by membrane oxygenators similar to those used in cardiopulmonary bypass circuits. It requires placement of catheters within the vascular tree that allows deoxygenated blood to be drained and delivered to the membrane oxygenators; it then allows oxygenated blood to be delivered back to the patient. A certain degree of heparinization is usually required to prevent clotting of both the bypass circuits as well as the oxygenators. Typically, a catheter is strategically placed to drain the venous system to maximize the increase in O_2 content that can be achieved, which provides inflow into the oxygenators, which then oxygenate the blood and sweep off the excess carbon dioxide. The blood is then transfused back into the arterial system (venoarterial ECMO) or venous system (venovenous ECMO) depending on the setup. Given the low pressure characteristics of the venous system as well as its overall easier accessibility, venovenous ECMO is becoming increasingly more common. In addition, with the advent of newer catheters, a single catheter can now be used for both inflow and outflow which can be placed into the jugular vein and positioned such that deoxygenated blood drains from the superior and inferior vena cava (outflow) to the oxygenator, which is then returned directly to the right atrium (inflow). There is generally some mixing of the oxygenated and deoxygenated blood, but this type of system obviates the needs to access the arterial system and is still quite effective at oxygenating blood.

Several recent articles have suggested the usefulness of ECMO in the surgical intensive care unit, but its exact role is yet to be determined [91–93].

Respiratory Complications

As a result of either primary lung contusion or from the treatment necessary to treat generalized traumatic injury (e.g., massive transfusions, mechanical ventilation, etc.), the lungs are susceptible to acute injury. Complications which can develop include transfusion related lung injury (TRALI), ventilator associated pneumonia (VAP), or ARDS. For an in depth discussion of these three complications, readers are referred to Chapters 47, 68, and 114.

SUMMARY

In summary, most thoracic trauma can be managed without surgery or, at most, with minimally invasive interventions. Multiply injured patients with thoracic injuries need to be comprehensively evaluated and their injuries prioritized and as a result, their successful care often requires a multidisciplinary approach. The treatment of thoracic injuries is evolving and requires a working knowledge of a number of both diagnostic and therapeutic modalities. As with almost all other traumatic injuries, the key to optimal treatment and outcome is dependent upon having a high index of suspicion for the injury and to identify it early. The ability to competently manage all aspects of a critically injured patient is also important in effecting a successful overall outcome.

CHAPTER 165 ■ CRITICAL CARE OF THE PATIENT WITH ABDOMINAL TRAUMA

JUSTIN L. REGNER AND JOHN B. CONE

In many ways the care of the abdominal trauma patient in the intensive care unit (ICU) is similar to that of other patients with abdominal pathology and as such should be familiar to the intensivists. This chapter will focus on those common aspects of abdominal trauma care that are sufficiently rare in the nontrauma patients that many intensivists may have little experience in recognizing or managing them.

One possible origin of the word abdomen is the Latin *abdere*, meaning to conceal. Few areas of the human body are as difficult to assess following injury or to monitor subsequently as is the abdomen. Much of the morbidity and mortality due to abdominal injury results from delay in recognizing conditions that are easily corrected once identified. Improvements in resuscitation and modern high-speed imaging have done much to

improve the initial management of abdominal trauma. However, after the patient reaches the ICU, the ability to follow changes occurring within the abdomen deteriorates substantially.

ICU ADMISSION

In previous years, trauma patients arriving in the ICU were assumed to have had their injuries identified and repaired prior to arrival, and therefore the ICU was for monitoring and support. Today the ICU plays a larger role in the care of trauma patients. Many patients with abdominal injuries are managed nonoperatively. Many operated patients have their surgery performed in stages with interposed additional resuscitation in the ICU. The management of the abdominal injuries is now known to have an impact on the function of remote organs such as the lung and the brain, thus there must be close cooperation and shared knowledge between the trauma surgeon and the intensivist.

Trauma surgeons have traditionally divided injured patients into those injured by penetrating mechanisms such as gunshot wounds or stab wounds and those injured by blunt mechanisms such as car crashes and falls. Clearly, some patients manifest components of both types of injury but this classification has been a useful way to divide and compare trauma patients for years. Despite this long tradition and its advantages, for our purposes, it may be more useful to think of abdominal trauma patients coming into the ICU as those who have been operated upon and those who have not.

Operative trauma patients will have had a laparotomy and their injuries should have been defined. There will be a tendency for the intensivist to consider them identical to the elective general surgical patient who has undergone a comparable operation. While there are certainly areas of commonality, there are critical differences that must be considered. The elective general surgical patient will not, in all probability, have had a period of shock preoperatively and intraoperatively. The general surgical patient will usually have only a single acute problem unlike the trauma patient who may have sustained multiple organ system injuries including more than one in the abdomen. These differences often lead to management problems and complications that would not be expected in the general surgical patient and to more frequent complications such as infections.

Many blunt injury patients and some penetrating injury patients are now managed with the intention of not operating on them. This approach has grown out of the recognition that many trauma laparotomies are nontherapeutic as opposed to negative. For example, a laparotomy for hemoperitoneum that identifies a small liver laceration and a minor tear in the mesentery is certainly not a negative laparotomy but if both injuries have stopped bleeding spontaneously, it is difficult to argue that the surgery was therapeutic. Nontherapeutic laparotomies are not without consequences. They are painful, they expose the patient to early risks of wound infection, pneumonia, DVT, and so on, and the late risks of incisional hernia and bowel obstruction [1,2]. These risks are statistically small but significant. However, avoiding them by attempting to manage injured patients nonoperatively is only sensible if it can be done without a significant increase in the incidence of missed injures that do need intervention.

NONOPERATIVE MANAGEMENT

Nonoperative management of intra-abdominal injury is so widely practiced that trauma surgeons often feel they have to attempt nonoperative management or justify why they want to operate on a splenic or liver laceration. Nonoperative management of abdominal organ injury is appropriate only for hemodynamically stable patients whose injuries are identified by imaging. Hemodynamic stability is a nonspecific state but generally implies a systolic blood pressure more than 90 mm Hg without the rapid infusion of fluid, blood products, or the use of pressors. Significant tachycardia or metabolic acidosis if present would also preclude a state of hemodynamic stability. Other factors beyond hemodynamic stability also deserve consideration before a decision to attempt nonoperative management is made. Are there multiple injuries that may increase the risk of failure? Are there medical conditions such as portal hypertension or the use of anticoagulants? Patients with severe head injuries or ischemic heart disease are often considered a high operative risk but a failure of nonoperative management also poses a high risk mortality. Other factors also play a role. Older patients are less likely to undergo successful nonoperative management [3,4].

As imaging has improved, trauma surgeons have been given a more precise determination of the anatomic location and severity of the injury prior to deciding whether or not to operate. This information has allowed the construction of a number of models intended to predict the success of nonoperative management [5]. CT based injury grading systems do show a positive correlation with clinical outcomes but like most scoring systems work better for analyzing populations than for predicting the outcome of individual patients [6,7].

One of the most useful CT findings is the presence of extravasated vascular contrast. This contrast blush usually represents either active bleeding or a pseudoaneurysm of a parenchymal artery. Such patients have a higher probability of failing nonoperative management. Angiographic embolization of the injured vessel may help to restore them to the nonoperative pathway [8].

Spleen

The current practice of managing splenic injury without surgery grew out of a desire to protect children from postsplenectomy sepsis. It was discovered that most children's injured spleens stop bleeding without surgery. This practice was gradually extended into the adult population where the results are not as good but still approach 80% among stable patients. Multiple studies have been conducted in an attempt to more accurately predict which patients will succeed and which will fail attempts at nonoperative management. They have focused on combinations of patient factors such as age and vital signs and CT factors such as contrast blush and depth of laceration [3,4,6]. Failure of nonoperative management not only delays effective therapy and consumes resources, but patients who fail attempted nonoperative management have greater morbidity and mortality [8]. Advanced age, portal hypertension, and coagulopathy increase the probability of the failure of nonoperative management.

The nonoperative management of a ruptured spleen must be a joint effort between the surgical team and the ICU team. The parameters that will default the patient to the operative pathway should be agreed upon in advance between those who will be monitoring and supporting and those who will operate. In general, any indication of hemodynamic instability should lead to immediate surgery and splenectomy. If the patient experiences a steadily falling hemoglobin level but never manifests any change in vital signs, there should be prior agreement regarding the number of units of packed red blood cells (PRBCs) to be transfused prior to resorting to surgery. The absolute number will vary with the estimated operative risk, other factors predicting success or failure, and the patient's preference but should rarely exceed four units of PRBCs for an isolated splenic injury.

Splenic embolization may be an option in some facilities for those patients whose CT demonstrates a contrast blush within the spleen. If embolization is to be utilized, it should

be performed by a team that is readily available and has demonstrated success with the procedure.

Patients admitted to the ICU for nonoperative management of an isolated splenic injury should receive their planned immunizations including pneumococcal, meningococcal, and Hemophilus influenza vaccine since there is evidence that these vaccines are more effective with the spleen *in situ* [9].

When the splenic injury is successfully managed nonoperatively, there are still potential complications. Delayed bleeding of a lacerated spleen is a well-recognized complication of splenic injury. Many programs will follow elaborate algorithms specifying when patients may increase physical activity and participate in activities such as physical therapy since such activity is perceived to play a role in delayed rupture. However, there is no convincing evidence that, short of avoiding a blow to the flank, one regimen is superior to another. Pain associated with either capsular distention or infracted splenic tissue may eventually necessitate splenectomy, particularly if the spleen is embolized. The other major complication is an infection involving the injured splenic parenchyma or the perisplenic hematoma resulting in either splenic or subphrenic abscess [10]. Unexplained fever, leukocytosis, pleural effusion, or hiccoughs should necessitate an abdominal CT scan looking for evidence of infection. Most such infections can be effectively treated with antibiotics and percutaneous drainage but failure to respond promptly should result in exploration, evacuation of the infected hematoma, and splenectomy.

Liver

The other commonly injured organ in blunt abdominal trauma is the liver. The injured liver differs from the injured spleen in two significant ways. First, removal of the injured organ is not a treatment option. Second, the liver secretes bile directly into the GI tract so that liver injuries have a more complex range of complications including bile leak, hemobilia, obstructive jaundice, and so on. While the surgical options differ from the spleen, the decision to operate should be based on similar considerations. The first criterion for successful nonoperative management is hemodynamic stability. A patient who does not meet this condition should be taken to the OR, explored, and if necessary, packed, since the organ cannot be totally removed. Experienced trauma or hepatic surgeons will more often be able to perform a definitive procedure initially but the lack of such surgeons should rarely lead to an attempt to manage an unstable patient nonoperatively. Perihepatic packing followed by either angiography with embolization, reexploration when more experienced personnel are available, or transfer to a more capable facility are all preferable to attempting to manage an unstable patient nonoperatively. Conversely, surgical exploration in the face of hemodynamic stability by an inexperienced team is a recipe for disaster and should be avoided.

Patients with solitary liver injuries admitted to the ICU for nonoperative management should first be evaluated for hemodynamic stability and if stable should next be evaluated to determine whether they are likely to benefit from angiography and embolization. Patients with contrast extravasation or severe lacerations extending deep into the hepatic parenchyma are candidates for angiography with embolization. Liver injuries in the face of cirrhosis, portal hypertension, or coagulopathy are much more likely to fail nonoperative management than comparable injuries lacking these comorbidities.

Complications of nonoperative management are primarily the result of bleeding, infection, bile leak, hepatic necrosis, and jaundice. Delayed bleeding from a liver laceration may occur but sudden unrelenting hemorrhage from the liver necessitating emergency surgery is rare beyond 24 hours postinjury. Steadily falling hemoglobin levels in an otherwise stable patient are an indication for either repeat CT scanning to verify that the bleeding is coming from the liver or angiography in an attempt to identify a vessel suitable for embolization.

Bile leaks from the injured liver may result in either contained collections known as bilomas or more diffuse biliary ascites. Bilomas may cause compression of adjacent structures producing jaundice or gastric outlet obstruction in the subhepatic location but the more common problem resulting from bile leak is secondary infection. Small bile leaks occur commonly after liver injury but most are of no clinical significance. Elevated liver function tests after liver injury are an indication for hepatobiliary imaging, or hepatobiliary iminodiacetic acid (HIDA) scan to evaluate for a bile leak. Signs and symptoms of infection are usually better evaluated with a CT scan. Patients in whom a fluid collection is identified should undergo percutaneous drainage if they show evidence of infection. If the drained fluid shows a bilirubin level significantly above that of serum, the patient should then undergo HIDA scanning. Most such bile leaks will seal with adequate drainage of the fluid collection. If bilious drainage persists, they should be evaluated for endoscopic retrograde cholangiopancreatogram (ERCP) with stent placement.

High fevers, often exceeding 39°C, may be seen in patients with liver injury typically beginning 48 to 72 hours postinjury. These fevers have been blamed on atelectatic lung immediately above the diaphragm or on areas of hepatic necrosis. Solid evidence to firmly establish the cause of such fevers is not available. Patients who sustain severe liver injuries but remain hemodynamically stable may nonetheless harbor significant areas of devitalized liver. In the vast majority, this necrotic liver does not require resection. However, if the necrotic liver becomes infected or if the patient deteriorates, resectional debridement of the necrotic material may be necessary.

Hemobilia is a rare complication of hepatic injury. The classic triad of gastrointestinal hemorrhage, jaundice, and right upper quadrant pain should suggest the diagnosis. It may present anytime from the first few days postinjury to months later. Diagnosis is often difficult and delayed. The bleeding is usually intermittent so that diagnostic endoscopy may demonstrate no source for the bleeding. Any patient with a history of hepatic trauma, either immediate or more remote, who has evidence of unexplained gastrointestinal hemorrhage, should undergo diagnostic angiography coupled with therapeutic embolization if a hepatic pseudoaneurysm is identified [11].

Kidney

Renal injury is most often the result of blunt trauma and frequently occurs in conjunction with other injuries. Right renal injury most frequently occurs in conjunction with hepatic injury and left renal injury in conjunction with splenic injury. Renal injury is almost always associated with hematuria but the severity of the hematuria and the degree of the renal injury are often discordant. Gross hematuria may appear dramatic but most renal bleeding diminishes spontaneously within a few hours of injury. Even impressive perinephric hematomas on CT often have little impact on management decisions [12,13].

The kidney has two possible responses to injury that may require monitoring and or intervention, contrast extravasation from bleeding or a urine leak. Rarely will the hemodynamically stable patient continue to bleed from a lacerated kidney. In such cases, the management is similar to the other solid organs with appropriate imaging to confirm the source of bleeding followed either by embolization or surgical exploration. Usually, extravasation of urine from an injured kidney will resolve spontaneously [12,13]. Extravasated contrast that is confined within Gerota's fascia does not mandate immediate intervention since it will frequently resolve spontaneously or respond to minimally invasive methods. Leakage of urine as demonstrated by delayed contrast extravasation outside of Gerota's

fascia may still resolve but is more likely to benefit from percutaneous drainage of the renal collecting structures. Persistent urine leakage often indicates ureteral obstruction from either urinoma or retroperitoneal hematoma and may benefit from ureteral stenting.

Renal vascular injury is most often recognized on CT with intravenous contrast as an area of renal parenchyma that does not enhance. This injury may involve a single segment of the kidney or the entire kidney. Although gross hematuria may occur, it is typically of very short duration and may be absent altogether. Microscopic hematuria is virtually always present. The arterial injury may be either complete disruption or thrombosis. However, even with complete disruption, significant hemorrhage into the retroperitoneum is rare. Revascularization is rarely of benefit since in most cases, the time required for diagnosis, surgical exposure, and repair is beyond the warm ischemia tolerance of the kidney. Segmental infarction or even infarction of one entire kidney is usually well tolerated if the other kidney is healthy. Sequelae such as pain, abscess, bleeding, or hypertension are rare. Compression of the kidney by either hematoma or urinoma with subsequent renovascular hypertension (Page kidney) is extremely rare.

Pancreas

Blunt pancreatic injury is typically the result of high energy impact to the epigastrium. Because the pancreas is well protected by the costal margin and is located deep in the retroperitoneum, isolated pancreatic injury is rare. Physical findings are usually minimal and laboratory and imaging studies are often nondiagnostic. As a result of the difficulty in early diagnosis, isolated pancreatic injuries are rarely the cause of ICU admission. However, patients with injuries to liver, spleen, or kidney may show some abnormality associated with the pancreas during the course of their nonoperative management. Elevations in serum amylase or nonspecific findings on CT scan will not usually change the plan to manage the patient nonoperatively. However, it is important to insure that the duodenum is not injured. Duodenal perforation and pancreatic injury are often difficult to differentiate.

Serum amylase values are commonly relied upon to evaluate the pancreas following injury but the sensitivity and specificity of serum amylase leaves much to be desired in the early postinjury period. Serum amylase values determined within 3 hours of injury appear to be particularly unreliable [14]. A normal serum amylase value later in the patient's course appears reliable in excluding a significant pancreatic injury. An elevated serum amylase value is much less specific, particularly in the setting of head injury [15]. Certainly, an elevated amylase should raise the level of suspicion sufficiently to pursue further evaluation of the pancreas. CT findings may also be less than diagnostic. Suggestive CT findings include visualization of a fracture of the pancreas, intrapancreatic hematoma, fluid in the lesser sac, retroperitoneal hematoma or fluid, and so on. As with the serum amylase value, CT scans obtained very early postinjury may be falsely negative [16]. These findings should not be interpreted as suggesting that a delayed work up is the preferred method but rather these results emphasize the importance of repeating both the amylase and if necessary the CT scan in cases where suspicion of pancreatic injury remains.

The critical determinant of whether pancreatic injuries can be managed nonoperatively is the integrity of the pancreatic duct. If pancreatic ductal disruption is present, distal resection or internal drainage produces much less morbidity than simple drainage or noninvasive management [17]. If no definitive reason for surgical exploration exists but there is reason to suspect or diagnose a pancreatic injury, it is imperative to evaluate the ductal integrity. If there is any suggestion of instability or peritoneal signs, this should be performed at the time of abdominal exploration. Otherwise, the patient may be a candidate for magnetic resonance cholangiopancreatography (MRCP) or even the more invasive ERCP. Delay in diagnosing and providing definitive therapy for a ductal injury may have devastating consequences.

Pelvic Fracture

Pelvic fractures represent the exception to the rule that nonoperative management is only suitable for hemodynamically stable patients. Surgical exploration of the pelvic hematoma is usually not an effective way to control the hemorrhage from a pelvic fracture. Thus, once other sources of bleeding have been excluded, even hemodynamically unstable patients may be managed in the ICU.

Although the focus of pelvic fracture management in the ICU is on dealing with the blood loss into the pelvis, it is important not to lose sight of the abdominal distention, and limitation of diaphragmatic excursion that can occur. Patients with significant bleeding into the pelvis should be monitored very carefully for respiratory compromise. This is particularly true during any transport out of the ICU to sites such as radiology. If there is any doubt of the patient's ability to maintain adequate spontaneous ventilation, the airway should be secured electively and the patient placed on positive pressure ventilation.

A great deal of force is required to fracture the pelvis. Therefore, it is not surprising that associated injuries are common. Abdominal injuries and lower extremity fractures are both common in patients with pelvic fractures. These associated injuries often make it difficult to ascertain the site of bleeding. It is essential to evaluate the CT scan for the presence of intraperitoneal blood and solid organ injury as well as the size of the pelvic hematoma and the type of pelvic fracture. Lower extremities should be examined and x-rayed if any question exists of fracture. The type and location of pelvic fracture can provide valuable information regarding the likelihood of bleeding. Fractures or ligamentous disruptions of the posterior pelvis are more likely to be associated with severe hemorrhage than anterior fractures, acetabular fractures, or fractures of the iliac wing [18]. So called vertical shear fractures of the pelvis are particularly likely to be associated with arterial bleeding from the superior gluteal artery or other branches of the internal iliac system [19].

It is imperative to carefully examine the perineum for lacerations that may suggest an open pelvic fracture. This includes a careful rectal examination and a vaginal examination for females. If there is any indication of blood in the rectum or vagina, an endoscopic or speculum examination is required. An adequate examination is likely to be extremely painful with the pelvic fracture and often fractured lower extremities that make positioning very difficult. The examination should not be compromised even if it requires airway control and deep sedation. It may also require the assistance of the orthopedist to minimize fracture movement during the examination. The consequences of missing an open pelvic fracture may be disastrous.

Imaging of the abdomen and pelvis can provide a tremendous amount of information to assist the physician in deciding whether the ongoing blood loss is coming from the pelvic fracture or the abdominal viscera. However, the old adage, "Death begins in radiology" remains true today. Patients with pelvic fractures are at risk for both massive hemorrhage and the respiratory compromise often associated with a massively distended abdomen. They should be accompanied by personnel capable of dealing with these problems whenever they leave the ICU.

If there is a significant increase in the free blood within the peritoneal cavity on repeat focused assessment with sonography for trauma (FAST) examination or repeat CT scan, it may be impossible to be certain whether the bleeding is coming from a decompressed pelvic hematoma or from an abdominal site. In

such cases, the patient should be explored. If the only source of the blood loss is found to be the pelvis, the hematoma should be left intact, the abdomen closed, and the patient's pelvic fracture managed in the appropriate manner based on the fracture and hematoma. If the pelvic hematoma is significantly disrupted the only option is packing of the pelvis to achieve tamponade of the bleeding. If the patient has not already been studied angiographically, this should also be completed urgently.

Once the bleeding has been determined to be arising from the pelvic fracture, the first priority as with any other trauma patient, is the maintenance of intravascular volume, hemoglobin concentration, and the correction of coagulation abnormalities. The blood bank should be notified to keep adequate quantities of PRBCs, plasma, and platelets available. The fracture should be stabilized since continued movement of fracture fragments leads to further bleeding. This may be accomplished by one or more of several techniques depending on the fracture and the pelvic geometry [20]. Close consultation between the orthopedic trauma service, the general surgical trauma service, and the ICU is vital. If the pelvic volume is enlarged by the expanding hematoma, every effort should be made to reduce the volume toward normal thus compressing the hematoma. This may be accomplished by external fixation devices or some form of pelvic binder [21]. If stabilization of the fracture and compression do not promptly control the hemorrhage, the patient should undergo angiography of the pelvis with the plan to embolize any bleeding vessels arising from the internal iliac system and stent any injury to the common or external iliac systems. Severe vertical shear pelvic fractures even when managed appropriately may frequently require up to 20 units of PRBCs and the accompanying plasma and platelets. If all the other options have been exhausted or are unavailable, consideration may be give to retroperitoneal exploration for the purpose of packing or ligation of the internal iliac vessels [22].

The complications of pelvic fracture are primarily the result of massive blood loss and transfusion and of increased intra-abdominal pressure from the hematoma leading to respiratory compromise, renal failure, and acidosis that will be discussed in more detail under the abdominal compartment syndrome.

Other

Nonoperative management of abdominal injuries is usually confined to the so-called solid organs. There are two exceptions to this generalization. Intramural hematoma of the duodenum and extraperitoneal rupture of the urinary bladder are commonly and effectively managed nonoperatively.

Blunt duodenal injuries are primarily the result of a direct blow to the epigastrium such as from the steering wheel or seat belt in a motor vehicle crash. In the American Association for the Surgery of Trauma (AAST) grading system, duodenal hematomas are either Grade I or II injuries depending on the length of the duodenum involved [23]. This injury is commonly thought of as an injury of childhood, particularly from child abuse, but it does occur in adults as well. Symptoms, when present, will be those of gastric outlet obstruction. Diagnosis is made from a CT scan with oral contrast or an upper GI study. The patient should be carefully evaluated for any evidence of a concomitant pancreatic injury. Such patients are best managed conservatively if there are no associated injuries. Gastric decompression and nutrition support should be employed and the patient reevaluated radiographically at weekly intervals. The obstruction usually resolves in 2 to 3 weeks. If it has not resolved in this time period, surgical exploration for possible stricture repair should be considered.

Approximately 80% of bladder injuries occur in the setting of pelvic fracture although only about 5% of pelvic fractures are associated with bladder injuries [24]. Bladder injuries are most often extraperitoneal and result from perforation of the bladder by bone fragments from fractures of the parasymphyseal pelvis. This may occur even though the final position of the bone fragments as demonstrated on radiographs does not appear near the bladder. Radiographs taken in the hospital do not reflect the location of the bone fragments at the point of maximal displacement during the crash. Bladder injury is also suggested by the inability to void or the incomplete return of catheter irrigation into the bladder. Any pelvic fracture associated with gross hematuria requires imaging of the bladder. Diagnosis requires retrograde contrast injection into the bladder with images taken in both the AP and lateral views and postvoiding. CT scan with IV contrast can give a high quality image of the bladder if the Foley catheter is clamped early enough to produce distention of the bladder or extravasation. Extraperitoneal rupture is demonstrated by the leakage of contrast with the contrast confined to the area around the base of the bladder. Extraperitoneal injuries typically resolve with simple catheterization in 7 to 10 days. Prior to removal of the catheter, a repeat cystogram should be obtained to confirm closure. Persistent extravasation often requires surgical repair of the bladder.

PENETRATING INJURY

The majority of the patients admitted to the ICU for nonoperative management will have sustained blunt trauma but in some institutions selected cases of penetrating trauma may be admitted to the ICU for close monitoring. As with blunt trauma, the fundamental requirement for nonoperative management is hemodynamic stability and the absence of peritonitis. Any change toward hemodynamic instability or the development of peritoneal signs should mandate exploration.

Stab wounds are much more likely to be monitored nonoperatively than gunshot wounds. This is because knife wounds not only have a lower incidence of actually penetrating the posterior abdominal fascia but even if penetration occurs, they have a lower risk of producing an injury that requires repair. In addition to frequent serial abdominal examination and serial laboratory studies, any of the several techniques may be employed in an effort to determine the need for subsequent surgical exploration. These may include local wound exploration looking for evidence of posterior fascial penetration, diagnostic peritoneal lavage, FAST examination, or CT scan [25]. These modalities will most commonly have been employed in the emergency department but the intensivist should be familiar with the results and the possibility that they may need to be repeated while the patient is in the ICU.

Gunshot wounds are rarely managed nonoperatively if they enter the peritoneal cavity because of the much higher probability of visceral, particularly hollow viscus, injury. However, the advent of high-resolution CT imaging is now allowing the nonoperative management of highly selected abdominal gunshot wounds. These cases are primarily patients in whom the entire tract of the missile appears to be visible within the liver [26] and who are considered high-risk operative candidates either because of multiple previous abdominal operations or serious medical comorbidities. Such patients should be monitored in a manner similar to blunt trauma patients with the added concern that hollow viscus injury is still a concern.

MISSED INJURIES

No matter how careful the initial evaluation of the trauma patient, almost all series report a 10% to 20% incidence of missed injuries that are discovered in a delayed fashion [27]. Most of these are minor fractures discovered as the patient begins to increase activity and reports pain. The consequences of these delays in diagnosis are generally minor. However, a delay in

the diagnosis of a hollow viscus injury may have serious repercussions. Avoiding delays in diagnosis requires the cooperation of the entire trauma team including emergency physicians, surgeons, intensivists, and radiologists. The initial examination should be complete and take into account mechanism of injury, bruises and abrasions, patient complaints, and laboratory and radiographic studies. In spite of such a thorough evaluation, additional information will often become available over the first 24 to 48 hours. Bruises, abrasions, seat belt marks, and so on will often be more apparent the next day. Laboratory and even imaging studies are less sensitive when the patient arrives at the trauma center within an hour or two of injury. Although not a formal component of the Advanced Trauma Life Support (ATLS) course, these facts have led many trauma centers to institute a formal tertiary survey at 24 of injury after admission [28]. During the tertiary survey, the patient should be carefully reexamined looking for new evidence of traumatic injury, such as seat belt abrasions that were not apparent initially. The abdomen should be reevaluated for evidence of peritoneal irritation. Radiographs should be reexamined and compared with the formal radiology interpretation. Such tertiary surveys are even more important when the patient is initially unstable and examiners may be distracted by urgency of the situation. Although there is no evidence to suggest the routine use of repeat imaging, a repeat FAST or even CT scan should be obtained if there is any question of change in the initial evaluation. Some injuries such as pancreatic or duodenal injury may be more apparent on a CT scan performed at 24 hours postinjury than on the initial scan. Even the sensitivity of procedures such as peritoneal lavage increases with time.

Bowel

The major concern with missed abdominal injury is the possibility of a missed bowel perforation. A patient who has a bowel perforation with significant spillage will manifest signs of peritoneal irritation quickly if the examination is not compromised by head injury, intoxication, or distracting injuries. Small perforations with minimal spillage may show little in the way of physical findings for several hours. Such injuries are often missed on preoperative imaging and can be easily missed at the time of surgical exploration. Both the patient arriving in the ICU with negative abdominal imaging studies and the patient admitted following abdominal exploration must be reevaluated for bowel injury if they show signs of intra-abdominal infection, unexplained sepsis, prolonged ileus, glucose intolerance, and so on.

With typical 20–20 hindsight it is the knee-jerk reaction to ask how an injury could have been missed at the time of surgical exploration but unfortunately it is easy to be misled at the time of exploration. Urgency of hemorrhage control may lead to oversight. An apparently straight missile tract may not have been so straight. Bowel may have been in a different configuration at the time of penetration. Areas that did not appear injured such as the retroperitoneum may not have been explored. Areas of bowel injury that did not appear transmural may have been deeper than was realized. It is incumbent upon the operating surgeon to explore the abdomen thoroughly but in spite of this, injuries will at times be missed. Neither the operating surgeon nor the intensivist caring for the patient in the ICU should dismiss the possibility if the patient is not recovering as anticipated.

Patients admitted to the ICU for planned nonoperative management are at particular risk. The sensitivity and specificity of CT scanning leave much to be desired for hollow viscus injury [29]. Spillage of oral contrast into the peritoneal cavity is a relatively infrequent finding, even with significant bowel injury. The segmental ileus resulting from the injury tends to obstruct the flow of contrast proximal to the site of injury. Free air may be demonstrated but its absence certainly cannot exclude bowel injury. An area of localized thickening of the bowel wall is suggestive of injury, while a diffuse thickening is more compatible with either excess fluid administration or poor perfusion. The CT finding that causes the most confusion is free fluid in the peritoneal cavity without evidence of a solid organ injury to account for the bleeding. Some consider this sufficient evidence for exploration, while others disagree [30].

Injuries of the mesentery are usually detected on CT due to the associated hemoperitoneum and mesenteric hematoma. It is much more difficult on CT to recognize which mesenteric rents will be associated with intestinal ischemia and delayed perforation. Any mesenteric injury that is not explored surgically must be monitored carefully in the postinjury period to allow the recognition of ischemic bowel prior to perforation. The development of a rising WBC, glucose intolerance, persistent ileus, or signs of peritoneal irritation should prompt investigation if not exploration.

Even bowel injuries that are transmural may show little in the way of physical findings for several days. The localized area of ileus associated with the injury, the diffuse ileus from injury, edema, and narcotic administration may limit the degree of spillage. This same process will often prevent the spillage of CT contrast delaying the diagnosis initially. The physician caring for such patients should remember that an ileus is not a diagnosis but a sign. If it persists, it is important for the intensivist to search for the cause. This may require repeat imaging.

Pancreas

Injuries to the pancreas are easy to miss. CT scans and serum amylase determinations performed in the first 3 hours after injury may be normal [14,16]. The accuracy of both tests increases with time. With isolated pancreatic injury, a missed injury is most likely to result in the leakage of pancreatic secretions but since the enzymes are not activated this is usually well tolerated. Most often the fluid is confined to the lesser sac and unless it becomes infected will resolve spontaneously assuming it does not arise from a major ductal injury. If a major duct is injured the fluid may eventually organize into a pseudocyst requiring internal drainage. Less frequent is the development of pancreatic ascites.

Renal Collecting System

Injuries to the renal collecting system including the renal pelvis, ureters, and bladder may present as a rising blood urea nitrogen (BUN) without obvious explanation, as new onset ascites without evidence of portal hypertension, as drainage of serosanguineous fluid from the incision, or as a mass in the flank or pelvis. In the presence of urinary tract infection, this may lead to the serious complication of an infected pelvic hematoma. The diagnosis is usually not difficult as long as a urine leak is considered. CT with intravenous contrast will usually establish the diagnosis. Any unexplained fluid collection in the abdomen that is aspirated should be analyzed for creatinine and compared to a simultaneous serum level. Most injuries that are diagnosed late can be managed with decompression or stenting although complete transection of a ureter will require reimplantation.

Solid Organs

The probability of missing a solid organ injury if the patient has received a CT scan with intravenous contrast is low. Such scans identify approximately 98% of solid organ injuries. However, if the patient does not receive such a scan on the basis of what

is perceived to be a normal physical examination with or without a FAST examination, such errors are then more likely. As already discussed, there are many reasons for an erroneous physical examination. Blood in the peritoneal cavity does not always produce peritoneal irritation immediately. There may be associated intoxication, head injury, or distracting injuries. FAST examinations are intended to assess the quantity of free fluid in the abdomen, not the integrity of the organs. Many liver, spleen, or kidney lacerations produce little or no free fluid on initial examination. Patients admitted to the ICU without abdominal CT scanning or if no contrast was employed should be monitored with both vital signs and serial laboratory studies at a frequency appropriate for their overall condition. Any unexplained deterioration in either should prompt an immediate FAST examination if the patient is unstable and both a FAST and a CT if the patient is sufficiently stable to transport to radiology.

ABDOMINAL COMPARTMENT SYNDROME

The abdominal compartment syndrome (ACS) is a well-recognized complication of abdominal trauma but despite widespread familiarity among intensivists, the diagnosis is often delayed or missed all together. There are reports in the medical literature dating back to the 1800s describing the deleterious results of intra-abdominal hypertension but the clinical diagnosis was imprecise, unreliable, and infrequently made. With the report by Kron et al. [31] in the 1980s describing the indirect measurement of intra-abdominal pressure by the bladder, the bedside diagnosis became more precise and easily quantifiable. The pathophysiology and treatment became well defined. Abdominal compartment syndrome assumed even greater importance with the widespread use of damage control surgical techniques. A complete review of abdominal compartment syndrome is presented in Chapter 156, including current definitions, pathophysiology, systemic consequences, measuring techniques, and management. We discuss it briefly here as it relates specifically to abdominal trauma.

Pathophysiology

The fundamental physiology of ACS does not differ from any other compartment syndrome, whether in the leg, the cranium, or elsewhere. It may occur as a result of bleeding, edema, or packing within the abdomen; referred to as primary compartment syndrome, or as a result of ischemia-reperfusion and capillary leak associated with other disease processes such as major burns or systemic sepsis. This is referred to as secondary compartment syndrome. Pressure within the relatively rigid abdominal compartment increases until the perfusion pressure is inadequate to meet the oxygen and nutrient needs of the tissues within the compartment.

$$APP = MAP - IAP \quad (1)$$

where APP, abdominal perfusion pressure; MAP, mean arterial pressure; IAP, intra-abdominal pressure.

However, unlike the more rigid bony cranium, the abdominal compartment is only semirigid. As IAP increases, the abdomen distends and a portion of the pressure is transmitted to the surrounding structures. To have a reproducible diagnosis we must standardize the measurement technique. While the most direct technique involves the insertion of a fluid filled catheter directly into the peritoneal cavity, this is often not practical in injured patients. The accepted clinical technique is an indirect measurement by the bladder although IAP can also be measured through the stomach or the inferior vena cava (IVC).

TABLE 165.1

GRADING SCALE FOR INTRA-ABDOMINAL HYPERTENSION [32]

Grade	IAP (mm Hg)	Recommendations
I	10–15	Monitor, maintain intravascular volume
II	16–25	Sedation, muscle relaxants, increase cardiac output, often with volume expansion
III	26–35	Decompression
IV	> 35	Decompression and reexploration, especially if organ dysfunction is present

Intra-abdominal hypertension is usually defined as an IAP > 12 mm Hg or an APP < 60 mm Hg.

When IAP rises to a critical level it not only compromises blood flow to intra-abdominal organs, it also produces deleterious effects on the respiratory, cardiovascular, and central nervous systems. Various grading scales of intra-abdominal hypertension have been proposed such as the one shown in Table 165.1.

Abdominal compartment syndrome (ACS) may be defined as an abdominal pressure more than 25 mm Hg, APP less than 50 mm Hg, or with one or more organs showing signs of dysfunction at IAP > 20 mmHg [31a,b].

Clinical Manifestations

Increases in IAP impact virtually every system in the body. Often the first measurable findings involve the respiratory system where increased IAP is often the cause of increased $PaCO_2$ due to altered distribution of ventilation. This is usually followed by increased airway pressure and decreased pulmonary compliance, both static and dynamic [32,33]. These changes are often not correctly attributed to increased IAP because there are a multitude of other possible explanations such as pulmonary edema, acute lung injury, and so on.

Increased IAP increases renal vein pressure with elevations in plasma rennin and aldosterone as well as decreased renal blood flow, glomerular filtration, and urine output [34]. The fall in urine output may briefly be offset by volume expansion but as the pressure in the abdomen rises, this ceases to be effective and BUN and creatinine increase.

The increase in IAP results in an elevated CVP and pulmonary capillary wedge pressure as the volume is shifted into the thoracic cavity. In spite of this, actual venous return and cardiac output decrease and systemic and pulmonary vascular resistance increase. This compromise in venous return is transmitted to the CNS with resulting increase in intracranial pressure and decrease in cerebral perfusion pressure.

Management of Intra-abdominal Hypertension

In patients judged to be at high risk for the development of ACS, the risk may be reduced by leaving the abdomen open at the time of surgery. Similarly, a patient who is very difficult to close due to edematous bowel or pelvic hematoma may be better managed as an open abdomen from the beginning (Fig. 165.1). Anytime there is a suspicion of ACS, the initial diagnostic step should be the measurement of IAP, usually by the bladder. If IAP is elevated to harmful levels the only

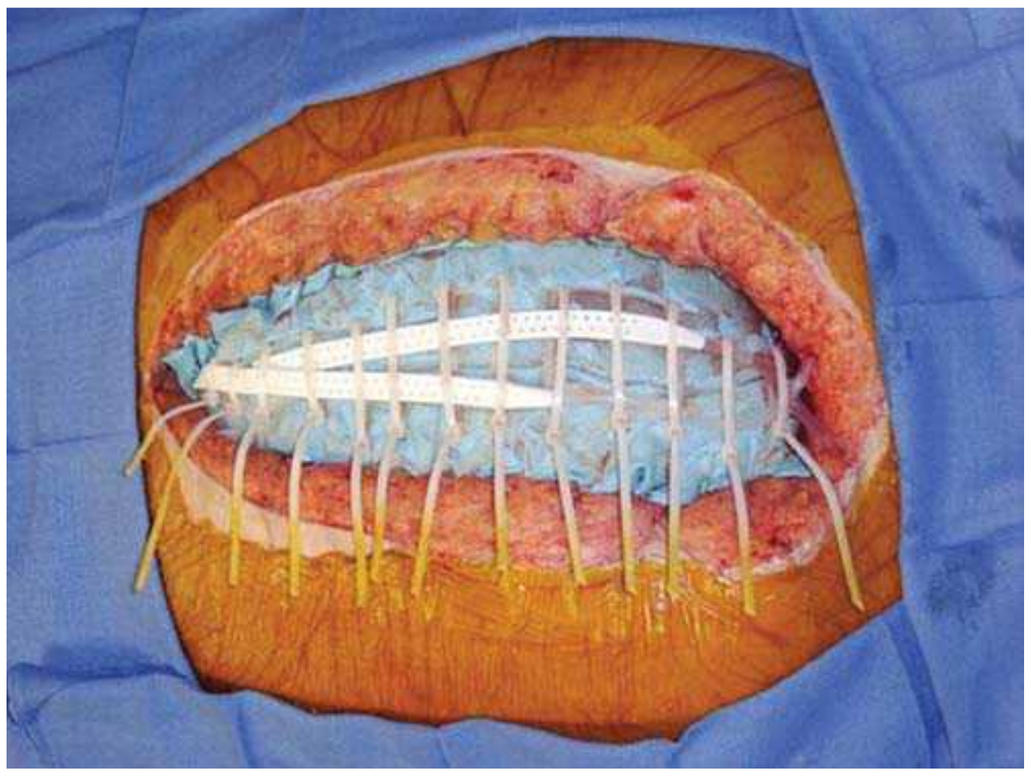

FIGURE 165.2. Homemade vacuum pack dressing for temporary closure of a damage control abdomen.

therapeutic choices are to either remove a portion of the contents or to enlarge the compartment. The next step is a determination of what is causing the increased pressure if this is not already known. Bedside ultrasound will allow the determination of whether there is a large quantity of free fluid in the abdomen. If so, either simple paracentesis or the insertion of a drain may resolve the problem. Large quantities of fluid within distended bowel loops may be reduced with a nasogastric tube. IAP may also be reduced in some patients with the use of improved analgesia and/or pharmacologic muscle relaxation. While these few special cases should not be overlooked, most cases of ACS will require surgical decompression and some form of temporary abdominal closure.

Open Abdomen

Patients whose abdomen is opened to prevent or treat ACS will require some alternative method of closure to prevent evisceration, to reduce fluid and heat loss, and to minimize loss of domain of the abdominal viscera. One of the easiest forms of closure that allows expansion of the abdominal cavity is the towel clip closure. This technique is based on the rapid closure of the skin only with multiple surgical towel clips [35]. The success of this technique depends on the elasticity of the skin to allow expansion of the visceral compartment. While it is simple and fast, towel clip closure has largely been abandoned in recent years as it has been recognized that a significant number of patients developed a recurrent compartment syndrome as the elastic limits of the skin were reached and exceeded. The gap in the *linea alba* has also been bridged with absorbable mesh or simple gauze packing [36]. Other popular techniques have been based on the silo idea similar to that used for newborns with gastroschisis [35]. Several materials have been utilized for the silo from 3 liter bags of fluid to adhesive drapes to sterile silastic sheets.

Currently the most popular management of the open abdomen is some form of vacuum pack dressing [37] (Fig. 165.2). The fundamental principal is the application of a nonadherent barrier over the bowel followed by some form of negative pressure connection and then a closed, sealed covering over the abdomen. The benefits of such a negative pressure dressing include the more rapid removal of fluid from the peritoneal cavity and the collapse of any free space in the abdomen. The negative pressure should also assist with the more rapid mobilization of edema from the bowel and abdominal walls and possibly minimize the contracture of the abdominal wall muscles. A number of homemade devices have been described and a commercial system is now also available.

When the bleeding has been controlled, the edema is resolving, and the packing has been removed, the next priority is abdominal closure. The longer the abdomen remains open, the greater will be the difficulty in achieving closure. Efforts to reduce the volume of the abdominal contents will include dieresis, removal of packing, and removal of fluid collections or hematoma. Actual re-approximation of the midline fascia may be facilitated by frequent "reefing" of the closure in a manner analogous to that employed in neonates with a silo, by the use of pharmacologic muscle relaxants or by more complex surgical techniques such as component separation [38]. In some patients, the bowel may heal into a solid mass prior to achieving closure. In these cases, a planned ventral hernia is the best option available with skin closure accomplished by either elevating skin flaps directly over bowel or by performing a split thickness skin graft directly onto bowel.

Prolonged exposure of the bowel by any of these techniques results in a substantial risk of enterocutaneous fistula formation. Fistula formation into such large open wounds almost never allows spontaneous fistula closure and greatly complicates the wound management as well as fluid and nutritional management. The primary goal of this phase of open abdominal management is to achieve some form of wound closure before fistula formation occurs.

DAMAGE CONTROL SURGERY

Historically trauma surgeons were taught that all bleeding must be stopped, all sources of contamination repaired or exteriorized, and other injuries definitively repaired prior to closing the abdomen regardless of the duration of the operation. However, with a better understanding and improved recognition of the metabolic failure that accompanies the so-called "bloody vicious cycle" of hypothermia, acidosis, and coagulopathy, current practice calls for a more abbreviated surgical technique referred to as damage control surgery [39]. These techniques should be employed only in the small percentage of patients with life threatening injuries complicated by profound shock. Damage control surgery as generally practiced consists of three phases:

I. Limited operative intervention to control hemorrhage, usually by ligation, shunting, or packing and to control contamination usually by ligation or stapling.

Little or no repair or reconstruction is performed at this stage. Closure is rapid and temporary.

II. Resuscitation to include aggressive correction of volume and hemoglobin deficits, replacement of coagulation factors, correction of acidosis, and restoration of body temperature usually carried out in the ICU.

III. Planned return to the operating room to complete definitive repairs, remove packs, and look for additional injuries. Definitive closure may be accomplished at this time or delayed for a later time. This phase should take place only when the deficits described above have been corrected.

Inability to correct the deficits described above may reflect continued bleeding. It is not difficult to overlook a surgical bleeding site when it is obscured by diffuse nonsurgical bleeding. Despite this fact, making the decision to return to the OR before correction of the deficits is a difficult one. Various criteria have been described for emergent return to the OR [40] but in practice the decision is often based on progress or the lack thereof. If the temperature, the pH, the coagulation studies, and the vital signs are getting better, it is usually worth persisting with the resuscitation efforts. If over a predefined time period of 2 to 3 hours of maximal effort most of these parameters are not improving, it is worth the risk of transporting the patient back to the OR for another look. Another indication for cutting short the resuscitation period is the development of an abdominal compartment syndrome that is limiting ventilation or cardiac output.

Acidosis

Hypovolemic shock in the severely injured patient produces a metabolic derangement that will not have disappeared with the restoration of normal vital signs. One manifestation of this metabolic failure is a persistent lactic acidosis. A variety of endpoints for resuscitation have been proposed including CVP, wedge pressure, oxygen delivery, oxygen consumption, and right ventricular volume but none have been shown to be more reliable than resolution of the lactic acidosis. Although crystalloid undoubtedly has a place in this resuscitation, recent data suggests that more of the resuscitation should be based on PRBCs, fresh frozen or thawed plasma, and platelets [41]. The traditional ratio has been one unit of plasma for each four units of PRBCs but current information suggests that a ratio closer to 1:1 may be advantageous. Spontaneous resolution of the acidosis with resuscitation suggests that the oxygen debt incurred during the shock phase is being repaid and serves as a marker of adequate resuscitation. However, during severe acidosis the patient is at increased risk for cardiac arrhythmias and becomes unresponsive to catecholamines either endogenous or exogenous. Coagulopathy is made worse by severe acidosis. Thus, it may be appropriate to use alkalinizing agents such as sodium bicarbonate or THAM (trishydroxymethylaminomethane) to raise the pH to approximately 7.2 [42]. Although the use of such agents is widely practiced, their use is largely based on *in vitro* data and theory. There is no clinical proof that they are beneficial. Evidence of supranormal oxygen delivery or consumption during resuscitation have been proposed as appropriate goals of resuscitation but current evidence suggests that they should be considered as predictors of improved outcome rather than therapeutic goals [43].

Hypothermia

If a patient's last body temperature prior to leaving the OR was less than 35°C, the risk of death is more than 40× greater than for patients with final body temperature more than 35°C. [44]. Hypothermia in the abdominal trauma patient is a multifactorial problem. Many patients arrive hypothermic due to exposure and shock prior to presentation to the trauma center. This problem is often compounded by further exposure to cold environments in the ED or the OR, the infusion of cold fluids, and the open body cavity. Inadequate oxygen delivery leads to inadequate oxygen consumption and a failure of heat production. This may be worsened by vasodilation from either intoxicants or anesthetic agents and loss of shivering ability from muscle relaxants. It is critical to prevent the development of hypothermia since it is very difficult to correct once present.

However, despite efforts in the ED and the OR, many damage control patients will be delivered to the ICU already hypothermic. In this circumstance, aggressive efforts must be employed including warming all fluids, raising the room temperature to uncomfortable levels, covering all body regions including the head, and the use of warming systems such as the Bair Hugger®. Lavage of the NG tube or chest tube with warm saline solution may also be utilized. In severe cases of hypothermia, it may be appropriate to utilize continuous arteriovenous rewarming as described by Gentilello et al. [45]. The inability to correct hypothermia if these measures have been employed usually indicates a failure of adequate resuscitation and that oxygen consumption is still inadequate.

Coagulopathy

The coagulation abnormalities associated with severe trauma include dilution of clotting factors and platelets from crystalloid infusion, consumption of clotting factors, hypothermia, and the anticoagulant effects of fibrin degradation products. In addition, there is the increasing use of anticoagulants and antiplatelet agents in patients with underlying comorbidities. Current data suggests that the coagulopathy of trauma and shock can be minimized by the use of blood component therapy with ratios closer to those of whole blood [41].

Upon arrival in the ICU from the initial phase of damage control surgery, blood should immediately be sent to the laboratory for clotting studies including prothrombin time, activated partial thromboplastin time, platelet count, and fibrinogen level. Hypothermia and acidosis impair the coagulation process and should be the initial focus of ICU care since factor replacement will have limited benefit in a patient who is hypothermic and acidotic.

Patients with prolonged clotting times should have aggressive replacement of clotting factors with fresh frozen or thawed plasma, while those with low levels of fibrinogen should also receive cryoprecipitate. Platelets should be replaced to achieve levels of more than 100,000 per μL.

Patients with nonsurgical bleeding who are judged to have adequate factor replacement and who are not extremely acidotic or hypothermic should be considered for the administration of recombinant Factor VIIa (rFVIIa). Although not formally approved for use in trauma patients, rFVIIa has shown benefit in two clinical trials of bleeding from trauma patients and while expensive, does appear to be safe in the injured patient [46].

SUMMARY

There are a host of similarities between the abdominal trauma patient and the general abdominal surgery patient and it has been assumed for the purposes of this chapter that the intensivist is familiar with managing these general surgical patients. This chapter has attempted to focus on the areas of abdominal trauma infrequently seen in general surgery or nonsurgical

patients. The elective abdominal surgery patient will usually have a single defined problem and will generally begin in a hemodynamically stable state. The abdominal trauma patient has an unknown number of injuries on presentation and the physiologic disruption resulting from the injury and the period of shock may compromise the ability to locate or repair all of them prior to arrival in the ICU. The trauma surgeon and the trauma intensivist must work in close cooperation since diagnosis, resuscitation, and treatment are a continuum beginning in the ED and extending seamlessly into the OR and the ICU. There should be no rigidly defined rules regarding who identifies the injuries or resuscitates the patient. Nowhere is the concept of the trauma team more important than in the ICU management of abdominal trauma patients.

CHAPTER 166 ■ BURN MANAGEMENT

PHILIP FIDLER

DEFINITION AND GENERAL CONSIDERATIONS

A burn is a tissue injury resulting from excessive exposure to thermal, chemical, electrical, or radioactive agents [1]. The transfer of thermal energy over time is proportional to tissue damage.

In the United States, 60,000 to 80,000 people are hospitalized annually for burn care, but only 1,500 to 2,000 people sustain more than 40% total body surface area (TBSA) burns [2]. The elderly population is growing and contributes significantly to the increase in burn related hospitalizations. Among elderly victims, two thirds are flame burned, half have impaired judgment, and three fourths have a concomitant medical condition [2,3]. This population, typically debilitated by limited mobility, is particularly susceptible to large scald injuries, which can be devastating despite their clean appearance [4].

While all human tissue can be burned, the skin is most susceptible and is composed of essentially two distinct layers; the superficial epidermis, which is attached by a basement membrane to the foundation layer—dermis. The epidermis is of ectodermal origin and is invaluable for its vapor barrier, pigment, and immunological functions. While biologically very active, at approximately seven cell layers of keratinocytes, it has little mechanical integrity—the role of the dermis. Fortunately, the epidermis for practical purposes is "immortal" and when mechanically disrupted, will recover anew, without scar. In contrast, the dermis is derived from mesenchymal cells and provides the mechanical integrity to the skin, our "leather" so to speak, and has no native regenerative qualities. Dermis, when injured, repairs by way of scarring. Therefore, the essence of acute burn wound care is to sustain dermal viability.

The term burn will mean "burned skin of partial or full thickness depth." It is essential to discern between partial thickness and full thickness injuries of the dermis (commonly called second and third degree burns), as the latter requires operative interventions [2,3]. Pale, leathery, and insensate skin are features of full thickness injury, while blistering, weeping, pink and painful burns characterize partial thickness injury. Currently, no technology supersedes clinical experience in making this distinction, however, laser Doppler imaging has been validated in some centers [5]. Furthermore, the injury is dynamic and partial thickness injuries can worsen ("convert") to full thickness injuries for a variety of reasons.

When the burn injury coincides with blunt trauma, an evaluation for internal hemorrhage, closed head trauma, and long bone fractures is mandatory; the burned skin becomes a secondary concern [6]. Victim extrication from a closed space fire, such as in a bedroom, should make one expect an inhalational injury (see "Inhalation Injury"). The TBSA involved as partial and full thickness skin injury, age, comorbidities, and inhalational injury contributes to the morbidity and mortality of burn victims. Burns involving over 20% TBSA and those with inhalational injury of any burn size are at risk for burn shock (see "Burn Shock" section).

By the 1980s, a paradigm shift toward "early" (within 5 days) operative excision occurred because of the realization that the presence of burned tissue drives "burn shock" [6,7]. During the first half of the twentieth century burn wounds were treated with topical antibiotics and allowed to suppurate from the viable margin; subsequently, bacterial infections causing burn wound sepsis were commonplace [3,7]. The diminution of burn wound sepsis and advances in critical care borrowed from all disciplines have contributed to a remarkable LD50 for 90% TBSA burned in young people and 40% TBSA burned in the elderly [3,8] (Pruitt diagram; Fig. 166.1). Three clinical data points: age more than 60 years, TBSA burned more than 40%, and inhalational injury confer mortality rates over 90% when all three are present and 33% when two factors are present [8]. A rule of thumb with larger burns is a day in the ICU for each percentage of TBSA burned. Mortality usually occurs from multisystem organ failure secondary to sepsis. The substantial reduction in mortality at major burn centers has prompted research focus on improvement in quality of life [7]. Early transfer of patients to regional burn centers as per the guidelines of the American Burn Association has been shown to confer best outcomes [2,9].

BURN SHOCK

Burn shock is a form of vasodilatory shock, akin to "systemic inflammatory response," and creates an astounding volume requirement for the burned patient. It occurs most commonly with burns of at least 20% TBSA and is essentially universal in larger surface area burns. Increased vascular permeability and decreased capillary oncotic pressure combine to create severe edema, even in non-burned tissues. Kinins, serotonin, histamine, prostaglandins, and oxygen radicals are some of the vasoactive mediators released in response to burn injury and stimulate vascular permeability. Albumin is functionally lost into the interstitium thereby increasing extravascular oncotic pressure compounding the edema [3,10]. Unresuscitated patients perish from hypovolemic shock, historically likened to the demise from cholera; this association contributed to the understanding of the profound dehydration following burn injury [11].

While the resuscitation in burn shock may be conceptualized as optimizing the viability of the partial thickness (second degree) component of the burn injury, treatment is focused on intravascular volume repletion. Central shunting of blood compensates for the anhydremia, yet deprives the injured tissue of perfusion. Under perfusion deprives the partial thickness injury of essential nutrient delivery and gas exchange resulting in conversion of partial thickness injury to full thickness injury—which requires operative repair. Excessive resuscitation compounds tissue edema resulting in the same demise. It seems evolutionary biology has not accounted for intravenous fluid resuscitation, hence the response is maladaptive [12].

The patient's TBSA burn and weight dictates their fluid requirements for the first 24 hours. A number of methods to calculate the TBSA burned exist. The "rule of nines" and the Lund-Browder scales are useful for contiguous injury, while the palmer surface of the patient's hand, representing 1% TBSA, is used as a guide in noncontiguous injuries [3] (Fig. 166.2).

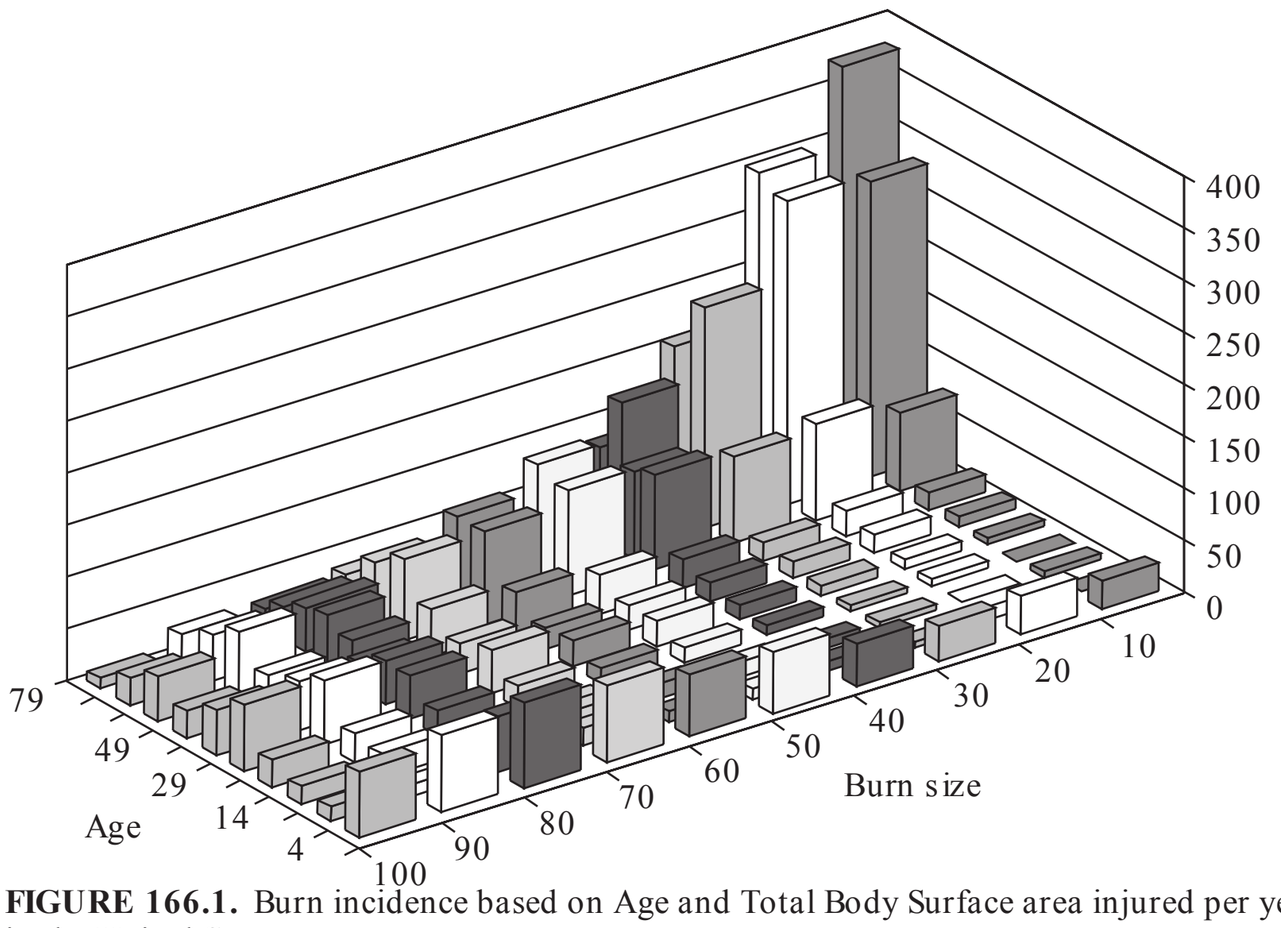

FIGURE 166.1. Burn incidence based on Age and Total Body Surface area injured per year in the United States.

Fluid "requirement" should be thought of as that volume needed to optimize organ function; debate continues over appropriate endpoints of resuscitation—most clinicians accept $^1/_2$ cc per kg per hour of urine output. If the urine output is more than 1 mL per kg per hour, then the rate of infusion should be decreased, this typically occurs by the third post burn day with the return of vascular integrity (See Fig. 166.4 Parkand formula). Thereafter, it is sufficient to limit the infusion and allow the concurrent insensible losses to correct volume overload—judicious diuresis with a loop diuretic may be employed. The timing and use of pressors requires clinical judgment in the face of hypotension despite adequate intravascular volume repletion. In patients with persistent oliguria, preexisting renal failure, or congestive heart failure, a pulmonary artery catheter is advised. While oliguria bodes poorly, excessive urine output should not be admired. If urine output is exceeding expectations, it is good practice to check the urine electrolytes, particularly for glycosuria and treat hyperglycemia accordingly [13]. Tight glucose control between 80 to 120 mg per dL with insulin is advocated [13].

The biological basis of burn wound conversion has not been fully elucidated. It is known that necrosis occurring from direct cellular damage and ischemia is not the only pathway. With cell death in evidence, the presence of apoptotic populations has been identified [14]. Macrophage inducible nitric oxide synthase may be an inciting factor in such apoptosis and its inhibition seems to limit apoptosis in animal models [14,15].

Central venous access is generally necessary because extremity edema makes peripheral access tenuous and is ideally, but not essentially, placed through non-burned tissue.

A number of resuscitative regimens have been advocated, none proven superior to date. Most are iterations of an isotonic solution in the first 12 hours of shock [3,11,15,16].

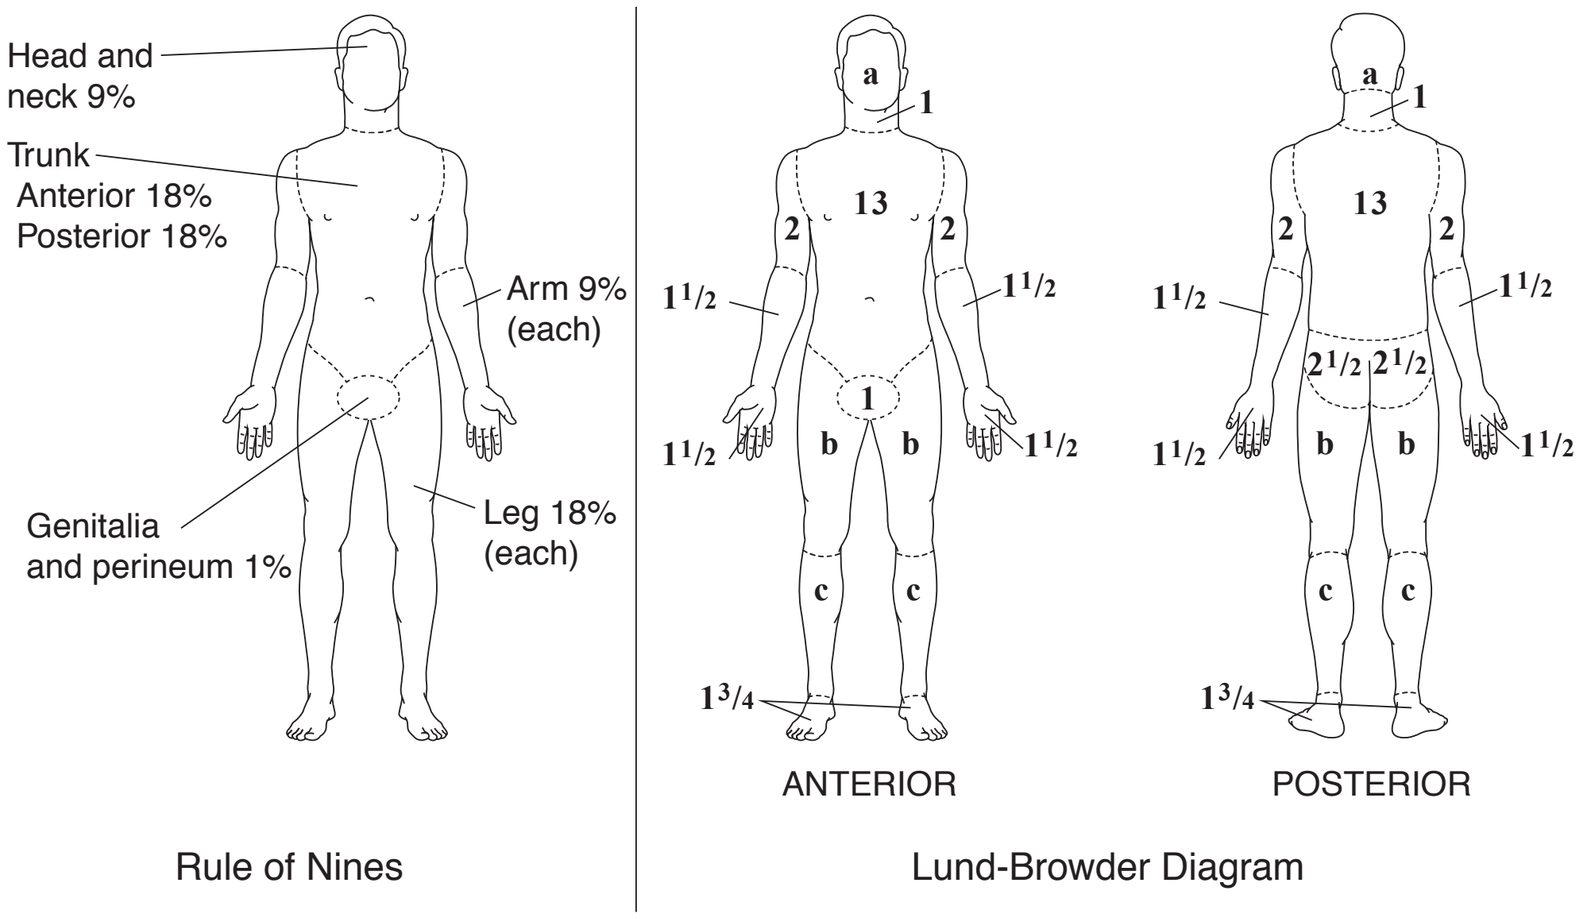

FIGURE 166.2. The Rule of Nines has been the primary method used to identify the percent of body surface burn. The Lund-Browder Diagram is a newer way of estimating the percent of body burn.

The use of colloid seems ill advisable in the first 12 hours after injury, as it seems to aggravate water loss into the pulmonary interstitium and potentiates pulmonary edema [3,15,16]. The commonest colloids are albumin, the most popular, and fresh frozen plasma (FFP). Proponents of albumin value its high oncotic pressure and maintenance of intravascular volume. Those against, argue that albumin is lost into the interstitium worsening edema there, possibly aggravating pulmonary edema. Again, the evidence suggests this risk is most pronounced within the first 12 hours post injury. Albumin is generally not used in patients with serum concentrations above 2.5 mg per dL. While FFP has less oncotic potential than albumin it may have a favorable immunomodulatory benefit, resulting in a truncation of the capillary leak associated with burn shock [3]. Both groups state that the use of colloid reduces the total volume of resuscitation and consequently protects against the detriments of excessive water administration. No level I evidence exists for the resuscitative fluid of choice [10]. A prospective, multicenter trial is needed to answer this question [10].

The pathophysiological similarities between septic shock, systemic inflammatory response, and burn shock may have a common pathway that could be interrupted to improve outcomes [17]. Beta blockade, antihistamines, FFP, generous narcosis, nonsteroidal anti-inflammatory agents, glucocorticosteroids and recently, drotrecogin alfa are amongst the many approaches investigated to mitigate this cellular "hysteria" [2,17]. None of these approaches have proven superiority in multicenter prospective trials to date.

The GI tract is an underutilized resuscitative venue and enteral hydration seems to have been forgotten with the advent of improved intravenous therapy [18]. Enteral nutrition and resuscitation may begin on the day of injury with the caution that patients in shock, requiring vasopressors, can develop bowel ischemia and enteral feeds may increase the metabolic needs of the gut, contributing to bowel ischemia and necrosis. Patient's not tolerating enteral feeds or those with abdominal hypertension (see "Abdominal Compartment Syndrome" section) should be given TPN; this is uncommonly necessary.

Adrenal insufficiency should be suspected when volume repleted hypotension persists despite pressors and is further suggested by concurrent hyponatremia and hyperkalemia. While the characterization of adrenal insufficiency is more expansive in the septic shock literature, numerous case reports and some prospective data support its presence in thermally injured patients. A high mortality exists when disturbances in the hypothalamic-pituitary-adrenal axis are found early in a patient's burn shock course [19,20]. One need not await the results of a corticotropin stimulation test in the face of circulatory collapse and glucocorticoid supplementation should be initiated. In questionable cases, a corticotropin stimulation test is confirmatory and not skewed by Decadron, which enhances vascular tone but has no mineral corticoid activity unlike hydrocortisone. A single blood cortisol of less than 15 μg/dL, in a stressed patient, is suggestive of insufficiency, and it is probably wise to supplement. Glucocorticoids are known to unfavorably affect skin engraftment, and this risk must be weighed against the patients' circulatory failure. Vitamin A supplementation seems to limit the unfavorable wound healing delays and atrophy seen with glucocorticosteroid therapy [20,21].

INHALATION INJURY

Burn victims have two unique pulmonary disorders: restrictive respiratory failure secondary to burn eschar involving the anterior torso and inhalational injury. Torso eschar needs to be divided (see "Escharotomy" section).

An inhalational injury occurs when toxic combustants have been inhaled, and cause a severe inflammatory response in the bronchial pulmonary tree and systemically [22,23]. Extrication from a smoke filled room and findings of singed facial structures, carbonaceous sputum, and respiratory distress corroborate the diagnosis but are not exclusionary. Approximately 30% of adult burn admissions have inhalational injury, which increases mortality rate for like burn size [8,9]. Concurrent inhalational injury intensifies burn shock and may require up to 50% more fluid for adequate resuscitation [3,24,25]. This component of the inhalational injury cascade seems driven mainly by the sensory neuronal pathway, as it can be truncated by capsaicin blockade in an experimental ovine model. Histamine, cyclooxygenase, and atropine blockade do not decrease the response [23,26,27]. Neutrophils invade alveolar spaces via the pulmonary vasculature and likely contribute to O_2 radical production and injury [27,28].

Airway management is paramount. One needs to be particularly observant for signs of upper airway obstruction, secondary to edema, which often develops hours after initial injury. Stridorous patients should be intubated urgently; preferably with an 8 fr endotracheal tube to allow for bronchoscopy and toilet. Immediate threats to life are, in particular, carbon monoxide (CO) poisoning and cyanide (CN^-) toxicity. Generally the lethal level is >60% COHgb and 100% mask O_2 should bring the half-life of COHgb to normal within an hour's time [29]. CN^- poisoning causes cytochrome oxidase inhibition and loss of hypoxic pulmonary vasoconstriction increasing dead space. CN^- is lethal in levels over 1 μg per mL, while 0.02 μg per mL occurs in healthy nonsmokers [25,29]. It would seem rare to have an increased CN^- level without corresponding increase in COHgb; thus, it is fair to say that a normal COHgb, for practical purposes, rules out CN^- toxicity [22,29].

Inhalational injury may best be thought of as a syndrome with a number of sequelae, including endobronchial and interstitial edema, alveolar damage, mucociliary dysfunction, endobronchial slough with cast formation, functional pulmonary shunting, and decreased compliance. Increased bronchial blood flow causes increased interstitial edema [23]. In time, the bronchial epithelium sloughs and combines with exudates and fibrin to form aggregates ("plugs") that support bacterial growth. The tenacious plugs create subsequent mechanical airway obstructions. While there is a dearth of prospective data, aerosolized heparin in conjunction with *N*-Acetyl-cysteine, is advocated in some centers to prevent cast formation and seems particularly helpful in the pediatric population where the narrower airways are at greater risk for obstruction [30]. Burn victims are susceptible to pneumonia because of their immunocompromised state, their immobility, and inability to clear secretions.

Ongoing study of the mechanisms of this form of shock and pharmacological interventions are being intensely investigated. Currently, no objective scale of severity for inhalational injury exists. Bronchoscopy is most useful to characterize the presence or absence of tracheobronchial inflammation and provide toilet.

Prophylactic antibiotics are not recommended. Pneumonia and tracheobronchitis should be treated by culture directed therapy, utilizing Gram's stain, culture of sputum, or bronchoscopy specimens, and local biograms [30,31]. Goals to minimize incidence revolve around proper toilet, limiting aspiration, utilizing lung protective ventilator management, and frequent surveillance [3,30,31]. Patients' overall condition and pulmonary performance by way of usual weaning parameters dictate extubation time. The risk of upper airway obstruction prior to extubation should be assessed by deflating the balloon and audible appreciation of air leak, "no air leak, no extubation." Laryngoscopy may reveal glottic swelling. Glucocorticoid steroids may be considered for the treatment of upper airway edema in lieu of an early extubation but are not

indicated for the pulmonary component of inhalational injury and not recommended when a large surface area burn is present. Healing time for patients with lower respiratory injury is longer [23]. The timing of tracheostomy has not been standardized but is probably beneficial in patients expected to be intubated beyond 3 weeks particularly for the benefits of oral hygiene, positioning, and earlier weaning.

SURGICAL CONSIDERATIONS FOR THE ICU

The decision to operate or manage partial thickness injuries expectantly is complex and depends on the location of injuries, patient condition, and survivability (see introduction).

Escharotomy

Full thickness burned skin (eschar) is a restrictive entity; its noncompliance, especially when circumferential, in the face of growing interstitial pressure deprives limb perfusion. This mandates operative release termed escharotomy, which is often limb saving. It may be performed at the bedside, ideally but not essentially, with electrocautery. Incisions are made through the eschar to relieve the underlying pressure. When eschar is involved around the chest wall, incisions are made along the bilateral anterior axillary lines craniocaudally and intercepted transversely joining these incisions at the approximate level of the second rib and xiphoid (Fig. 166.3). This maneuver releases the chest wall, enhancing tidal volume and decreasing airway pressure. If involving the neck region, incisions are made to allow jugular venous drainage. Rarely, lateral canthotomies, which are incisions through the lateral orbital skin and tendon of the canthus, are needed to release ocular pressure in the instance of retrobulbar edema. Although vigilance is the rule, the areas in question are typically apparent within the first 12 hours of injury.

Burn Wound Sepsis

Burn victims develop multiple defects in their immune system that predispose them to an increased risk of infection. Primary treatment is surgical excision and tissue coverage with autograft, skin substitute, or topical antibiotics, alone or in combination. This immunocompromised state combined with loss of the skin barrier can lead to severe infections. Topical antimicrobials (e.g., silver sulfadiazine or mafenide acetate), as well as local wound care, help decrease the amount of burn wound infections [2,6,7]. However, they cannot eradicate burn wound sepsis. Mafenide acetate penetrates eschar and is most effective against Gram negative organisms. It is known to cause metabolic acidosis as a carbonic anhydrase inhibitor and may select for fungal overgrowth.

The signs of burn wound sepsis are diffuse, typically a greenish grey discoloration of the burn, purulent fluid from the wound, and eschar separation along with cellulitis in the surrounding unburned skin. If not treated at the earliest possible time, systemic sepsis will develop. Diagnosis can be confirmed by biopsy of the wound but should not preclude total and urgent excision. Systemic antibiotics are started if infection is suspected and altered or stopped once burn biopsies for quantitative bacterial counts and blood culture results are obtained and negative for infection.

FIGURE 166.3. Burn patient with full thickness constricting torso burns. Escharotomy incisions are in progress to permit ventilation. A transverse abdominal or chevron subcostal incision (not shown) would complete the release.

Abdominal Compartment Syndrome

By transducing a transurethral catheter, the urinary bladder pressure is obtained as an indirect measure of intra-abdominal pressure. A measurement more than 20 cm H_2O is loosely defined as abdominal hypertension, which may develop into organ dysfunction, namely renal failure, respiratory embarrassment, and bowel ischemia and denotes abdominal compartment syndrome. Extrinsic renal vein compression leads to progressive oliguria, and respiratory failure is secondary to restrictive airway dynamics. The definitive treatment is celiotomy, although lesser interventions such as peritoneal drainage and or continuous venovenous hemodialysis (CVVHD) are under investigation [32,33].

Cardiovascular Response

Unresuscitated burn victims die of hypovolemic shock. An untreated victim would show progressively decreasing preload and cardiac output. Unfortunately, during the initial 12 to 36 hour postinjury period, even "adequate" volume repletion will not maintain cardiac output. Decreased cardiac contractility and diastolic dysfunction prevail. Animal data suggests a pro inflammatory mediated mechanism *vis-a-vis* the CD-14 and Toll-like–receptor 4 complexes–as seen with endotoxic shock; it is corroborated by echocardiographic abnormalities in burn victims [34,35]. This decrease in contractility is more pronounced in those with inhalational injury and is, in part, nitric oxide mediated [36]. This temporary, seemingly maladaptive cardiac dysfunction passes with time and is followed by a hyperdynamic cardiac performance, which is maintained, often for weeks, post burn [34].

Naturally, the elderly, particularly those with pre-injury cardiac compromise, are more susceptible to congestive heart failure. The quest to rule out an acute myocardial ischemic event will often reveal elevations in cardiac enzymes, both CPK and Troponin-I. Heart muscle is obviously compromised in burn shock, and serum levels of cardiac enzymes are often found within the range attributed to myocardial infarction in the "acute chest pain" setting [35,37]. This quandary is common—what to do about it? Surprisingly, the actual occurrence of a coronary artery thrombosis has rarely been reported. Cardiac stress or "Troponin leak" is seen in many shock states. Emergent cardiac catheterization based on these enzyme elevations

may be more harmful than helpful in that traveling long distances throughout a hospital with a critically ill burn victim has substantial inherent risks [38]. A 12-lead EKG should be obtained, and if regional ischemic pattern is present or is suggestive of coronary artery thrombosis or spasm, then a cardiac catheterization is prudent [35]. The lab value of Troponin-I or CPK-MB alone in the course of early burn shock should not dictate emergent catheterization.

Metabolic and Nutritional Considerations

The insensible fluid and protein losses from burn wounds are extraordinary. We know that protein catabolism, compounded by losses through the wound bed and the interstitium, results in severe hypoproteinemia. The hypermetabolic response that occurs, after a thermal injury is more than that observed after any form of trauma or sepsis [3,8]. The magnitude of the response parallels the severity of the burn to a maximum at a burn size of 60%. An increase in temperature of 2°F to 3°F occurs with this response. Patients are kept in a warm environment to help decrease the total energy expenditure [39]. The loss of vasomotor tone autoregulation, possibly in an effort to provide maximal nutrient delivery and gas exchange to the wounded tissues, results in significant evaporative heat loss. Hypothermia from weeping wounds and dwindling energy supplies from the catabolic, muscle wasting condition of burn shock is easily avoided with external warming. Burn centers often keep patients' rooms 90°F to 100°F in the hopes of shunting caloric needs away from thermostasis toward needed wounded repair [40].

Early surgical excision of the burn wound is the most effective means to this end; it truncates the shock state. Clearly, the presence of burned tissue drives the inflammation in the early post injury period, not to be confused with supervening bacterial sepsis, which often occurs days later or in neglected burn wounds.

Muscle wasting, a seemingly unavoidable complication of the hypermetabolism associated with burn wounds, can be ameliorated through anabolic enhancement [41,42]. The two most common approaches are recombinant Human Growth Hormone (HGH) and Oxandrolone. HGH is associated with hyperglycemia, often requiring insulin support and has largely been supplanted by Oxandrolone, which must be given enterally at 10 mg b.i.d., and so the effect is limited in the face of ileus [42,43]. A major thermal injury is characterized by increased muscle proteolysis, lipolysis, and gluconeogenesis. Burn wounds use glucose in greatly increased quantities. Hyperglycemia is common in burn catabolism and may exacerbate muscle wasting. Nonetheless, the known benefits of glucose control from other disease entities in the critically ill are likely to be beneficial in burn victims, and insulin supplementation is recommended [44]. Severe loss of nitrogen, which also occurs, needs to be replaced to combat the muscle wasting and to enhance the immune system. This replacement is absolutely necessary to fight infection and for wound healing. Burn patients need two to three times the basal energy expenditure. Significant burn injuries require 2 g per kg protein. Glucose should contribute 50% to 60% of the calories and the calorie-to-nitrogen ratio should approach 100:1 [43]. All attempts should be made to feed the patient enterally, as enteral feeding decreases the risk of infection. Nutrition may be started on the day of injury.

Infection and Immunity

Patients with significant burns are at high risk for infection, and this is often the precipitating cause of late deaths. The pulmonary tree and the wound beds themselves are the commonest sites and foci for fatal infection. Burn wounds, particularly devitalized full thickness eschar, provide fertile ground for bacterial growth. Early wound infections, within the first 10 days, are typically Gram positive organisms. Later, Pseudomonas is a common and potentially lethal organism, and even later, fungal infections may occur and portend an ominous sign [45]. When surgical excision is not an option, topical antibiotics are the mainstay. Other sites of infection include central lines and Foley catheters. A strong belief exists that the intestine may be a source of unexplained bacteremia by bacterial translocation. This risk may be decreased by enteral feedings. Immunoenhancing regimens are an area of intense study [43,46]. The integrity of the atrophied GI tract is compromised, leading to translocation of bacteria, toxins, or both, putting the burn victim at risk. Evidence demonstrating the presence of bacteria and endotoxin in the lymphatic system makes a plausible case for concern.

ELECTRICAL INJURY

Electrical injuries are divided into high voltage (more than 1,000 volts) or low-voltage injuries (less than 1,000 volts). Low-voltage injuries present as thermal burns, with injuries to the tissue from the outside in. High-voltage injuries may present with little injury to the skin, but significant injuries to the muscle, vasculature, and the bone underneath [47]. Very high voltage injuries occur with obvious disruption of the soft tissue common in electrical line workers. Electrical injuries vary with the source voltage, contact time, and current pathway [2,47,48].

Immediate threats to life are dysrhythmias and spinal cord injury, from either direct nerve injury or tetany resulting in spinal column fracture and cord injury [49,50]. The latter can cause mechanical respiratory failure and paralysis [47,48]. The cutaneous lesions may be subtle and efforts should be made to find entrance and exit lesions, as these will direct the practitioner to focus on the intervening tissues. Compartment syndromes from myonecrosis are common, particularly in the upper extremities, and compartment releases by fasciotomy should be pursued. Often nonviable muscle needs resection. Fluid resuscitation must be initiated quickly; frequently, these patients require a higher volume of fluid due to the underlying tissue injury. Myonecrosis will lead to myoglobinuria, which can lead to renal failure. Serum levels of creatinine phosphokinase into the tens of thousands are often present, and the risk of renal failure is reduced by maintaining a high urine output of 100 mL per hour. Mannitol may be added once resuscitation is well underway. Alkalinizing the urine is advocated by some with the theoretical benefit of preventing heme pigment sedimentation; however, at present, it is by no means mandatory. Pyrophosphate scanning can be used to find occult myonecrosis [51]. One may find serial daily monitoring of the CPK helpful to assess the extent of muscle damage and recovery. Persistent elevations are suggestive of skeletal muscle necrosis and surgical debridement is likely to be beneficial [47].

CHEMICAL INJURY

Acids, "burn" by coagulation necrosis, creating an eschar that limits deeper penetration, whereas alkali, "burn" by liquefaction necrosis in the subcutaneous fat, creating vascular thrombosis and subsequent dermal ischemia. Hydrofluoric acid (HF) burns carry the unique concern of calcium and magnesium chelation and risk cardiac arrest secondary to severe hypocalcemia; intra-arterial infusion of calcium gluconate has been met with some success and may limit digital ischemia and

intravenous calcium repletion is necessary. A calcium gluconate slurry may be massaged into the exposed area to potentiate systemic absorption of HF.

PSYCHIATRIC AND ANALGESIC CONSIDERATIONS

Theoretically, those with altered thought processes or coping skills are accident prone. Suicide attempts by self-immolation account for as many as 5% of seriously burned adults. The concurrence of a serious psychiatric comorbid condition is alarmingly high in burn victims and is estimated between 30% and 70% [3].

Burns are commonly known to be one of the most painful medical conditions. No single analgesia regimen can possibly characterize the needs of all burn victims, and suffice to say, the uninitiated practitioner may find the dosing of narcotics multiples of what is commonly used post surgery. Generally, narcotics and benzodiazepines are given as continuous drips; it is common to have moderately burned patients on morphine drips of 10 to 20 mg per hour and benzodiazepines coinciding at 1 to 4 mg per hour. Overtime, the large doses require large volumes of distribution and tolerance lead to even higher dosing. Unlike other critically ill patients, it is not prudent to eliminate these medications for frequent "full" neurological assessment. The physiological benefit of "successful" doses of these medications goes far beyond simple mercy, but portends toward decreased catabolism, cardiovascular stress, and reduced risk of posttraumatic stress disorder [4]. Once the patient's burn wounds have been managed adequately, and wound closure and burn shock are resolving, a stepwise weaning of these agents is done to permit ventilator weaning and to avoid sequelae of withdrawal.

Parkland Formula: Total Fluids for 24 hours
Ringers Lactate = 4 cc × kg × % BSA
Example: A 70-kg man with a 50% TBSA burn would thus have a total deficit of 14 L (4 cc × 70 kg × 50% BSA = 14,000) in 24 h. Half the 24-h deficit should be repleted in the first 8 h, due to the high risk of hypovolemic shock early in the course. In this example that is 7 L within the first 8 h would mean a rate of 875 cc/h for the first 8 h. It is important to note that this recommendation starts at the time of injury, and often, patients are brought in hours after injury, often necessitating an increase or decrease in the rate to insure that this amount is given within the first 8 h. The rate would subsequently be decreased to **438 cc/h** for the next 16 h. The formulas are used to determine how much fluid should be given to the burn victim in the first 24 hours. Both formulas are being used today. The Brooke formula is the military formula and our service personnel will be resuscitated using this formula. Many of the other burn centers use the Parkland formula which was developed at the Parkland Trauma Center in Dallas, Texas.

FIGURE 166.4. Modified Brooke Formula:
Total Fluids for 24 hours
Ringers Lactate = 1.5 mL × kg × % BSA
Plasma = 0.5 mL × kg × % BSA
D5W = 2,000 mL

CHAPTER 167 ■ ORTHOPEDIC INJURY

GREGORY J. DELLA ROCCA AND SEAN E. NORK

EPIDEMIOLOGY

Blunt and penetrating trauma kills more than 100,000 people in the United States each year, is the leading cause of death in Americans younger than 45 years of age, and results in staggering losses of health in surviving trauma patients, with associated losses of economic productivity [1]. Trauma evacuation systems have improved dramatically over the past few decades, and patients are much more likely to survive injuries that would have resulted in early mortality only 30 to 40 years ago. Many polytraumatized patients sustain orthopedic injuries, such as extremity fractures, pelvic fractures, or dislocations. These need to be recognized and addressed appropriately to minimize consequent morbidity and mortality. A dedicated orthopedic trauma service, specifically constructed to manage patients with complex fractures and dislocations in the setting of other systemic injuries, may be associated with improved outcomes for trauma patients. The orthopedic traumatologist is not only trained in the surgical management of the individual orthopedic injuries, but is also comfortable with functioning as a member of a multidisciplinary team that, of necessity, also includes emergency physicians, abdominal and chest surgeons, neurosurgeons, urologists, and plastic surgeons, to name a few.

Musculoskeletal injuries in trauma patients come in many varieties. Articular (joint) fractures represent complex injuries requiring prolonged reconstruction; although they routinely occur in polytraumatized patients, their management is beyond the scope of this discussion. Long bone (femur, tibia, humerus, forearm) fractures can have direct impact upon a patient's early mortality and late morbidity. Pelvic fractures are associated with early mortality, and their recognition and acute management is vital as part of the life-saving efforts of the trauma team. Open fractures are associated with the development of sepsis if not properly addressed. Compartment syndrome, a sequela of severe extremity trauma, is a soft-tissue condition that can result in early morbidity, associated with the impact of myonecrosis on renal function, as well as late disability, associated with fibrosis of one or more muscles important for activities of daily living. Venous thromboembolic (VTE) disease is a danger for all trauma patients, and the risk of VTE has been shown to be increased significantly in patients with pelvic and hip fractures. Finally, lesser fractures can have dramatic implications on future function for trauma patients; it has been shown that failure to identify and/or address complex injuries of the foot, for example, is associated with poor long-term outcomes in patients who survive major trauma [2,3].

In this chapter, we will introduce challenges and knowledge associated with multiple problems that affect trauma patients: open fractures, pelvic fractures, long bone fractures, knee dislocations, compartment syndrome, deep venous thrombosis, and neurological injury. It is our goal to discuss orthopedic treatment considerations for all of these trauma sequelae such that they can be integrated into the management of the patient who is the victim of multiple trauma.

OPEN FRACTURES

Open fractures, or fractures with associated skin wounds allowing communication of the external environment with the fractured bone surfaces, are present in a high percentage of polytraumatized patients. Frequently, the open fracture wound contains gross contamination, including dirt or vegetable matter, clothing, or glass. These wounds historically are at high risk of infection without adequate and early treatment of the open wound. Management protocols for open fractures are different from those for closed fractures, and considerations regarding timing of definitive stabilization of both types of fractures may differ. The basic treatment protocol for open fractures includes

antibiotic administration, wound debridement, wound irrigation, fracture stabilization, and wound closure or coverage.

The Gustilo-Anderson classification scheme is the most widely utilized classification for open fractures. It was initially published in 1976 [4]. Type I open fractures are fractures with a clean wound measuring less than 1 cm in length. Type II open fractures are fractures with a laceration measuring more than 1 cm in length and without extensive soft tissue damage. Type III open fractures are fractures with extensive soft tissue damage or an open segmental fracture (a two-level fracture of the same long bone). "Special categories" were created for open fractures associated with vascular injuries, farm injuries, and high-velocity gunshot wounds. Type III fractures, therefore, represented a highly heterogeneous group of severe open fractures; a modification of the classification scheme for type III open fractures, published in 1981, was therefore developed [5]. Type IIIA open fractures have extensive soft tissue damage but adequate soft tissue coverage, or are the result of high-energy trauma irrespective of laceration size. Type IIIB open fractures entail extensive soft tissue loss, periosteal stripping, bone exposure, and massive contamination. No mention of requirement for muscle flap fracture coverage is made by the authors (despite the fact that many of these wounds indeed do require flap coverage); this is a bastardization of the classification that has been propagated over the years [6], although it was suggested by Gustilo himself in a subsequent letter to the editors of the *Journal of Bone and Joint Surgery* [7]. Type IIIC open fractures are those associated with a vascular injury that (importantly) requires repair; those open fractures associated with arterial injuries that are not repaired do not fall into this type. An important point must be made about this classification scheme: it is best utilized during operative debridement of the open fracture. The presence of a small open wound in the skin may belie the extensive soft tissue injury underneath, leading to a misclassification of the open fracture. However, this may be of relative unimportance, as the reliability of this classification scheme has been questioned [8–10].

Antibiotic administration has been shown to be highly effective in decreasing infection rates after open fractures [11]. Short courses of first generation cephalosporins (typically, cefazolin), initiated as soon as possible after injury, appear to be beneficial in limiting infections after open fracture [12]. Aminoglycosides and penicillins are often utilized in the treatment of type III open fractures and highly contaminated open fractures [13], respectively. Older studies have demonstrated that administration of broad-spectrum antibiotics lead to decreased infection rates [14]. However, the scientific evidence for this practice is limited [12]. Administration of aminoglycosides for the treatment of open fractures must be accomplished judiciously to minimize risk of oto- and nephrotoxicity. Quinolone antibiotics, effective against gram-negative bacteria, have been shown to be effective at reducing infection rates for type I and type II open fractures [15], but they may have an adverse effect on fracture healing; this effect has been shown in animal studies [16,17]. Duration of antibiotic administration is a matter of debate. Older recommendations included 72 hours of antibiotic treatment for types I and II open fractures and 120 hours for type III open fractures [18]. However, Dellinger et al. published in 1988 that a single day of antibiotics is as effective as 5-day regimens for preventing infection after open fracture, in a prospective randomized trial [19].

Surgical debridement of open fracture wounds in a complete and expeditious manner is likely the most important factor in successful management. Sharp debridement should be meticulous and methodical. All foreign material is removed. Bone ends should be delivered into the wound, and complete exploration of the injury zone is necessary. Often, long longitudinal extensions of the traumatic wound are necessary for adequate exploration. All tissue which is completely devitalized, including bone fragments devoid of soft tissue attachments, should be removed [20,21]. Judgments related to the removal of large articular (i.e., joint surface) fragments may be required to balance the risk of severe disability with loss of said fragments *versus* risk of infection with their retention. Devitalized extra-articular fragments can be cleaned and used as a reduction aid intraoperatively if fixation is proceeding immediately, or they may be stored and utilized later if fixation is delayed; these fragments are ultimately discarded [22]. In general, therefore, it is better not to discard bone fragments from open fractures until the patient has arrived in the operating room for definitive management of the open fracture by the orthopedic surgeon.

Wound irrigation generally follows sharp debridement. Little data exists on the type of irrigant, the amount of irrigant, and the method of irrigation that is the best. Irrigation solutions generally are based upon normal saline (0.9% NaCl). Additives historically have included bacitracin, cefazolin, neomycin, soaps, bleach, Betadine, and other antiseptics (such as benzalkonium chloride). Some of these, such as antiseptics, have been shown to be detrimental to wound viability [23]. Antibiotics appear to offer no benefit over normal saline alone [24]. A prospective, randomized study revealed that a nonsterile soap solution demonstrated decreased wound complications and equal efficacy at reducing infection after open fracture as compared to a sterile saline solution containing bacitracin [25]. A recent survey of nearly 1,000 orthopedic surgeons revealed a high preference for saline irrigant [26]. High *versus* low-pressure lavage for open fracture wounds has also been a source of debate. Although high-pressure lavage has been thought historically to be better for removal of surface bacteria and inorganic material from soft tissues, it is damaging to both soft tissues and bone, and there is some evidence that it can *increase* bacterial penetration of bone in an animal model [27]. The same survey of 984 orthopedic surgeons who revealed a preference for saline irrigant also revealed a preference for low-pressure lavage for open fracture wounds [26]. No consensus exists on the volume of irrigant. Protocols vary between institutions and even within institutions, based upon surgeon preference. Up to 9 liters of irrigant are utilized in some centers, but there is no scientific evidence upon which a recommendation can be based. Ultimately, it is the opinion of most surgeons that wound debridement is the most critical aspect of treating open fracture wounds, and that the irrigation component of this treatment is of relatively less importance.

Methods of fixation for open fractures are variable. Historically, acute open reduction and internal fixation of open fractures was contraindicated, without good scientific evidence. However, the Harborview group in Seattle demonstrated that acute open reduction and internal fixation of open ankle fractures is a safe and effective method of treatment [28]. External fixation is relatively rapid and fixation points can be kept out of the zone of injury. Mobilization of fracture ends can be accomplished at the time of future debridement, if necessary, and staged open reduction and internal fixation with external fixator removal is safe and effective [29–31]. Plate or nail fixation at the time of irrigation and debridement is also safe and effective [28,32], but limits the surgeon's ability to re-displace bone ends for wound exploration if repeat debridement is indicated.

Early wound closure or coverage is preferred, as this appears to limit the infection of open fracture wounds [33]. Acute primary closure of open fracture wounds after debridement and fixation, if possible, has been shown to be a safe method of treatment [34]. Early coverage of open fracture wounds that

are unable to be closed primarily has also been shown to be safe and effective [35]. Adjuncts to wound closure, especially in the setting of skin tension, include "pie-crusting" of skin about the wound(s) [36] or performing open wound management with a vessel loop closure technique to re-approximate wound edges [37] and/or use of negative pressure wound dressings [38,39]. Also, if doubts about the safety of closure at the time of initial debridement and fixation persist, then open wound management and repeat debridement are appropriate until closure or coverage is considered safe. This may be a consideration for significantly contaminated wounds at the time of presentation, or open fracture wounds in polytraumatized patients [33]. Negative pressure wound dressings can be utilized successfully for open fracture wounds as a bridge to delayed closure with successful reduction of infection rates in some series [40], or as a bridge to delayed free tissue transfer with reduction of infection rates as compared to traditional dressings [41], perhaps allowing for a possible reduction in need for free tissue transfer [42]. However, this may be a limited process, and earlier wound closure or flap coverage may reduce infection rates over late wound closure or coverage, despite utilization of the negative pressure dressing [43].

An ongoing source of debate in the management of open fractures relates to the timing of debridement. A standard benchmark that has been propagated internationally is that open fractures should undergo urgent irrigation and debridement procedures within 6 hours. However, this benchmark has recently been questioned, as it appears to have little scientific evidence supporting it. In a seminal article on treatment of open fractures, Patzakis and Wilkins demonstrated no relationship between time from injury to surgical debridement of open fractures and subsequent development of infection [14]. A recent prospective, observational study of open fracture patients across eight trauma centers in the United States also failed to show a correlation between time to surgical debridement and the risk of infection of open fracture wounds [44]. Although urgency of treatment for open fractures associated with massive contamination, vascular injury, and/or limb crush is evident, routine emergent management does not appear to be required for open fractures, and after-hours surgery done in a hurried fashion by under-experienced practitioners and teams may result in an increased rate of minor complications [45]. However, it is generally accepted by orthopedic surgeons internationally that open fracture treatment does not represent an elective practice [46].

The polytraumatized patient who sustains high-energy open fractures of the extremities occasionally is a candidate for amputation. Properly indicated, a well-executed amputation can be a life-saving procedure which has the potential to shorten rehabilitation times associated with prolonged reconstruction of the mangled extremity. The debate often centers on whether a limb might be amenable to salvage *versus* amputation at the time of the trauma patient's arrival to the hospital. Errors in judgment regarding this problem have the potential to affect a patient's outcome significantly, both physiologically and psychologically. It should be noted that short-term and intermediate-term outcomes reveal similar levels of disability between limb salvage patients and amputees after major lower extremity trauma [47,48], perhaps indicating that one practice is not routinely better than another. Multiple assessment tools have been developed to assist surgeons with making decisions regarding limb salvage *versus* amputation, including the Mangled Extremity Severity Score (MESS) [49,50] (Table 167.1). However, many of these tools are mediocre at best with regard to their predictive value, as demonstrated by the Lower Extremity Assessment Project (LEAP) [51,52]. A historically held indication for acute amputation in the setting of a mangled extremity, the lack of plantar foot sensation, has been refuted

TABLE 167.1

MANGLED EXTREMITY SEVERITY SCORE (MESS)

Type	Characteristics	Injuries	Points
Skeletal/soft tissue group			
1	Low energy	Stab wound, simple closed fracture, small-caliber GSW	1
2	Medium energy	Open or multilevel fractures, dislocations, moderate crush injury	2
3	High energy	Shotgun blast, high-velocity GSW	3
4	Massive crush	Logging, railroad, oil rig accidents	4
Shock group			
1	Normotensive	BP stable in field and OR	0
2	Transiently hypotensive	BP unstable in field, responsive to IV fluids	1
3	Prolonged hypotension	Systolic BP < 90 in field and unresponsive to IV fluids	2
Ischemia group			
1	None	Pulsatile limb, no sign of ischemia	0[a]
2	Mild	Diminished pulses, no sign of ischemia	1[a]
3	Moderate	No pulse via U/S, sluggish CR, paresthesia, diminished motor	2[a]
4	Advanced	Pulseless, cool, paralyzed, numb limb without CR	3[a]
Age group			
1	< 30 years		0
2	30–50 years		1
3	> 50 years		2

[a]Points × 2 if ischemic time > 6 hours.
Note: MESS equals sum of scores for each of the group types; minimum score is 1, maximum score is 14.
BP, blood pressure; CR, capillary refill; GSW, gunshot wound; IV, intravenous; OR, operating room.
Adapted from Helfet DL, Howey T, Sanders R, et al: Limb salvage versus amputation: preliminary results of the Mangled Extremity Severity Score. *Clin Orthop* 256:80–86, 1990.

by the LEAP study team; many patients presenting with absent plantar foot sensation recovered it completely over time, indicating that the most tibial nerve injuries are neurapraxias (as opposed to complete disruptions) [53]. Ultimately, each injured patient must be carefully scrutinized, and no particular physical examination finding or trauma scale has been shown to be absolutely predictive of the success or failure of attempts at limb salvage. Therefore, thoughtful interpretation of trauma scores is imperative prior to making the choice between salvage and amputation for the mangled extremity in the traumatized patient.

PELVIC FRACTURES

Evaluation

The pelvic ring, functionally, is a rigid ring, despite the fact that it comprises three bones—two hipbones and the sacrum—with three articulations—two sacroiliac joints and the pubic symphysis. It is designed to distribute the weight of the torso, arms, and head onto the legs for normal bipedal ambulation. The pelvis contains the acetabulae, which represent the articulations with the lower extremities, and the lumbosacral junction, representing the articulation with the spine. The sacroiliac joints and pubic symphysis are thought to have minimal motion, and are connected by stout ligaments. In some cases, incompetence of these joints can lead to laxity and chronic pain, which may occur after trauma, complicated vaginal birth in females, or in an idiopathic manner [54,55]. Further ligamentous connection between the posterior and anterior pelvis is provided by the sacrospinous and sacrotuberous ligaments. The transverse processes of the fifth lumbar vertebra are attached to the posterior iliac crests by the iliolumbar ligaments.

Disruption of the pelvic ring in young patients requires a high-energy mechanism, such as a motor vehicle crash or fall from a significant height. As the pelvis functionally is a rigid ring, the discovery of a single break in that ring should prompt careful scrutiny for at least one other break. For example, pubic ramus fractures, in the anterior aspect of the pelvic ring, may be obvious on plain radiographs, but associated sacral fractures may not be readily apparent on plain radiographs due to the overlying bowel gas, radio-opaque contrast agents in the bowel or bladder, or bony anatomy. They may be visible on CT scanning. A high index of suspicion must be maintained. It should also be emphasized that acetabular fractures of a transverse nature (not isolated wall or column fractures) often represent a component of a pelvic ring disruption, and suspicion that such disruption has occurred should be maintained when these acetabular fracture types are present.

Multiple classification schemes exist that describe various aspects of pelvic ring injuries. The Young and Burgess classification is perhaps the most commonly utilized descriptive scheme for pelvic ring injuries, in which they are classified as anteroposterior compression (APC) injuries, lateral compression (LC) injuries, vertical shear (VS) injuries, and "complex patterns" [56]. The Young and Burgess classification can be helpful for identification of other problems that can be associated with the pelvic ring injury, such as increased incidence of head trauma with LC injuries and of abdominal and chest trauma with APC injuries [57], and it can be somewhat predictive of transfusion requirements in trauma patients [58]. Other commonly utilized classification schemes include the Tile classification [59] and the AO/Orthopedic Trauma Association classification [60]. No pelvic fracture classification scheme, however, possesses all seven of the following requisites for universally applicable schemes: ease of use, prognostic value (outcomes), descriptive value (describe the injury), therapeutic value (direct treatment), research value (allows direct comparison between groups), intra-observer reliability, and inter-observer reliability.

Orthopedic examination of the pelvic fracture patient is similar to the orthopedic examination of all polytraumatized patients, covering the entire musculoskeletal system in a methodical manner. Focused examination of the pelvis includes observation of limb deformity; abnormal limb rotation or shortening in the setting of pelvis injury may be secondary either to pelvic deformity or to hip dislocation (with or without associated acetabular fracture), or to extra-pelvic lower extremity fracture. Skin about the pelvis, including about the perineum, must be carefully examined for lacerations that can be associated with open pelvic fractures. Open wounds may be present within folds of skin, and a thorough examination is necessary. Lacerations may lurk within the fold of skin inferior to the scrotum in males, and examination of this area cannot be neglected. Extensive ecchymoses should be noted; these may be indicative of degloving injuries. Digital rectal examination is also required to detect occult open fractures into the rectum, and (chaperoned) vaginal examination is also required in women to detect open fractures violating the vaginal vault. Speculum examination is not generally performed in the trauma bay. Blood emanating from the anus or vagina can be an indicator of open pelvic fracture. Urethral disruptions can also occur with pelvic fracture, and blood at the urethral meatus can be indicative of such an injury. Manual palpation of the pelvis and gentle compression of the iliac crests may detect abnormal motion or crepitus associated with an unstable disruption of the pelvic ring, although this manipulation lacks sensitivity and specificity [61]. Pelvic manipulations must be undertaken judiciously; unstable pelvic ring disruptions can cause life-threatening hemorrhage, which can be exacerbated by repeated examinations. Repeated examinations also can induce severe patient discomfort. A neurovascular examination of both legs, as well as examination of anal sphincter tone and of the bulbocavernosus reflex, is routine.

Standard radiography of the pelvis begins with the anteroposterior view. The inlet radiograph, with the beam tilted approximately 40° caudad, can detect anteroposterior translation of the hemipelvis and rotational hemipelvic deformities. The outlet radiographs, with the beam tilted approximately 40° cephalad, can detect "vertical" translation (more often, a flexion deformity) of the hemipelvis and is useful for visualizing sacral fractures. Judet radiographs, with the patient or x-ray beam tilted approximately 45° to either side, are reserved for patients with acetabular fractures detected on anteroposterior radiographs. Computed tomography (CT) has become routine for polytraumatized patients, and provides extensive information regarding the bony anatomy of a pelvic fracture and/or dislocation. In the setting of pelvic and acetabular fractures, CT scanning is also invaluable for planning of the surgical reconstruction. The CT scan is of limited utility, however, for acetabular fractures if the hip remains dislocated during the scan. Therefore, it is desirable to reduce fracture-dislocations of the hip (acetabulum) prior to CT scanning of the pelvis for adequate delineation of fracture anatomy and for preoperative planning.

Acute Management

Pelvic fracture patients often have multiple associated injuries, all of which may contribute to the overall physiological condition of the patient. Early mortality of patients with pelvic fractures may be related to patient age and occurs as a result of catastrophic hemorrhage, head injury, or multiple organ system

failure [62,63]. As the pelvic fracture may contribute directly to morbidity and mortality, early stabilization is preferred. This stabilization may be performed at the scene of the injury by emergency medical personnel, by the application of a circumferential sheet, pelvic binder, or other compressive garment. Sheets are readily available, inexpensive, and easy to apply [64]. The personnel applying the sheet should do their best to avoid wrinkling the sheet, which may cause skin compromise [65]. Overcompression of the pelvic ring is avoided, as the exact nature of the pelvic injury is unknown; overcompression of certain types of unstable fracture patterns may lead to laceration of the bladder, rectum, vagina, or other intrapelvic structures. Although circumferential pelvic wraps may assist with patient transport and comfort and can successfully reduce some types of pelvic ring disruptions [66], a recent study failed to demonstrate decreases in mortality, transfusion requirements, or the need for pelvic angiography by their use [67].

Upon arrival at the trauma center, all circumferential clothing (including pelvic wraps/binders) is removed to allow for examination of the lower abdomen and pelvis. Binders or wraps can easily be re-applied after examination. Large-bore intravenous access is necessary for fluid resuscitation. Keeping patients warm avoids coagulopathy. Although pelvic fractures may be associated with catastrophic hemorrhage, ongoing hemodynamic instability can arise from a number of causes unrelated to the specific pelvic injury. A full assessment of the patient is required. "Open book" (i.e., anteroposterior compression) injuries of the pelvis can be treated with reapplication of a circumferential wrap. Grossly unstable pelvic injuries can be treated provisionally with the application of skeletal traction, on the same side(s) of the pelvic injury(ies), through either the distal femur or the proximal tibia as the side of pelvic instability. Skeletal traction is also used routinely in the provisional stabilization of acetabular fractures prior to definitive treatment in the operating room; traction can minimize contact of the femoral head with rough acetabular fracture edges.

Pelvic external fixation can be utilized in a resuscitative fashion. External fixator application is difficult, but possible, in the trauma bay. An experienced orthopedic surgeon should perform external fixation of the pelvis, if indicated, to avoid inaccurate pin placement and associated cutout of pins from the iliac crests or injury to the intrapelvic or gluteal structures [68]. Factors that increase difficulty for the application of anteriorly based external fixators can be the rotational deformity and/or instability of one or both hemipelves. Anteriorly based pelvic external fixators are not good at controlling completely unstable posterior pelvic ring disruptions, and reduction of the anterior pelvic ring may be associated with further displacement of the posterior pelvic ring in some circumstances [69]. The antishock "C-clamp" has also been utilized successfully for emergent stabilization of the unstable pelvic ring disruptions [70]. It was designed to be placed posteriorly, with the clamp engaging the posterolateral ilia and exerting compression. The connecting frame can be rotated out of the way to allow for access to the abdomen or perineum. Dangers of application of the C-clamp, especially by inexperienced practitioners, can include fracture and/or penetration of one or both ilia or aberrant placement of one or both ends of the clamp through the greater sciatic notch(es) [71]. The C-clamp has also been applied successfully to the anterior pelvic ring as a resuscitative aid [72].

Patients with pelvic ring disruptions may demonstrate hemodynamic instability that is refractory to volume resuscitation. An ongoing search for sources of blood loss is vital. A recent publication demonstrated that, at a single trauma center, 21% of patients with pelvic fractures and hemodynamic instability (systolic blood pressure < 90 mm Hg) refractory to a 2 L bolus of saline ultimately expired, and 75% of those patients expired as a result of exsanguination [73]. Unstable pelvic fractures are more highly associated with pelvic hemorrhage than are stable pelvic fractures. Therefore, investigation of other potential sources of hemorrhage is vital, especially in the hemodynamically unstable trauma patient with a stable pelvic fracture pattern [74]. Patients with unstable anteroposterior compression injuries have been demonstrated to require massive transfusions, followed by those patients with vertical shear or complex mechanism pelvic ring disruptions, and lastly by those with lateral compression injuries [58,75]. However, fracture pattern may not always be indicative of transfusion requirements or the need for angiographic arterial embolization [76].

The hemodynamically unstable patient with a pelvic ring disruption may have significant fracture-associated hemorrhage. Pelvic fracture-associated bleeding comes from three sources: fracture surfaces, lacerated or ruptured veins, or lacerated or ruptured arteries. Fracture surfaces may not be a source of ongoing massive blood loss, and therefore may contribute negligibly to hemodynamic instability [77]. Distinguishing between major sources of pelvic hemorrhage—arterial or venous—represents a challenging but important task, and prior studies have examined multiple factors that may be associated with successful angiographic embolization, used for arterial hemorrhage, including patient age, trauma scores, shock on arrival to the trauma center, and fracture pattern [78]. Venous hemorrhage after pelvic fracture can be adequately treated with pelvic stabilization, either by circumferential pelvic wrap or by external fixation, while arterial hemorrhage can be addressed with angiographic embolization [79]. Transient response to initial resuscitation, lack of response to provisional pelvic stabilization, and presence of a contrast blush on pelvic CT scanning are all thought to be indicative of arterial hemorrhage that may be amenable to angiographic embolization [80,81].

Pelvic packing has been used for control of severe hemorrhage in hemodynamically unstable patients. It has been proposed that packing may be a more reliable method of treating severe pelvic fracture-associated hemorrhage than angiographic embolization with regard to controlling continued hemorrhage and limiting patient death due to exsanguination [82]. Angiography may also be delayed, and emergency stabilization of the fracture along with or without pelvic packing may be more reliable at controlling severe fracture-associated hemorrhage [83]. Another recent series documented a 30-day survival rate for pelvic fracture patients treated with extraperitoneal pelvic packing of 72%, and subsequent angiography was successful in detecting arterial hemorrhage in 80% of the patients after packing. Immediate increases in systolic blood pressure after packing were also noted [84]. Importantly, both angiography and pelvic packing must be used in a judicious fashion; this will help minimize complications related to both (such as gluteal necrosis).

Genitourinary injuries occur in a small subset of patients with pelvic fracture. This frequency has been shown to approximate 4.6% in a recent study of the U.S.A. National Trauma Data Bank [85]. Another recent study estimated a genitourinary injury rate of 6.8% in pelvic fractures; importantly, 23% of these injuries were missed at the time of initial evaluation [86]. Bladder injuries can also be seen in conjunction with acetabular fractures [87]. Urological injuries most commonly take the form of urethral disruption, extraperitoneal bladder rupture, or intraperitoneal bladder rupture. Diagnosis is often by retrograde cystourethrogram, with careful attention to post-drainage images to detect bladder ruptures not detectable when the bladder is filled with contrast [88]. Urethral disruption appears to occur distal to the urogenital diaphragm, contrary to classical teaching [89]. Primary realignment, when possible, is accomplished endoscopically followed by threading

of the urinary catheter by the Seldinger technique [90]. This repair may be accomplished at the time of pelvic fracture repair, using a team approach [91]. Routine use of suprapubic catheters in the management of urethral disruptions is discouraged, as it may increase the rate of infection, especially in the setting of open reduction and internal fixation of anterior pelvic ring injuries [92]. Bladder injuries are more commonly extraperitoneal. Nearly all present with gross hematuria. Intraperitoneal bladder ruptures are generally treated with surgical exploration, to delineate the extent of injury fully, and with Foley (preferred if open reduction and internal fixation of the pelvic ring fractures will be accomplished) or suprapubic catheters. Extraperitoneal ruptures may be managed with Foley catheters; the bulk of these require no formal repair [93]. However, if open reduction and internal fixation of the pelvic fracture is planned, then primary repair of the extraperitoneal rupture is also accomplished at the same time, with a low infection rate [91]. Use of suprapubic catheters is not required if large-bore Foley catheters are employed after repair of bladder ruptures.

Open pelvic fractures represent a subset of severe injuries with a historically high mortality rate. A recent systematic review calculated the total mortality rate in open pelvic fracture patients across multiple published series prior to 1991 as 30%, and since 1991 as 18%, with the decrease likely owing to aggressive management of the pelvic fracture, selective diversion of the fecal stream, and advances in critical care medicine [94]. These open fractures may be occult, localized within the rectum or vagina. Visual as well as digital exploration is mandatory in these patients. Examination of bowel contents for gross or occult blood is also necessary. Diversion of the fecal stream may be indicated in patients with extensive or posterior wounds associated with their pelvic fractures, but routine use of fecal diversion does not appear to reduce infection rates in patients with open pelvic fractures [95]. Selective fecal diversion, however, does appear beneficial in open pelvic fracture patients with perineal wounds [96].

LONG BONE FRACTURES

Femoral Shaft Fractures

Femoral shaft fractures often occur in conjunction with other injuries after high-velocity blunt or penetrating trauma. Fracture of the femur is associated with significant morbidity in the polytraumatized patient; significant hemorrhage can occur, even in the absence of open wounds. Bilateral femoral shaft fractures are associated with higher mortality rates than are seen in patients with unilateral femoral shaft fractures [97]. Open femoral shaft fractures are unusual and require significant energy to create the situation where the fracture fragment(s) travel(s) through the robust soft tissue envelope of the thigh. Thorough evaluation of any femur fracture patient for associated injuries is necessary.

Initial management of femoral shaft fractures often entails placement of traction devices in the field. These devices are meant to be portable, and they rest against the ischial tuberosity, against which they provide traction through the ankle or the foot. Splinting of femoral shaft fractures is marginally effective at best, as it requires a splint to include the trunk for effective immobilization. The portable traction devices should be removed as quickly as possible to prevent sciatic nerve pressure injury or skin ulceration. Skin or, more commonly, skeletal traction is routinely applied in the emergency department, as a temporizing measure prior to transport to the operating room and to allow for continued evaluation of the patient for other injuries. This traction provides patient comfort, provides immobilization for the fracture, and limits fracture shortening. It can also function as a temporary treatment modality in the setting of operating room unavailability. Evaluation of the patient prior to transport to the operating room should include an investigation of the ipsilateral femoral neck with thorough radiographic imaging. A high percentage of femoral neck fractures are missed in the setting of ipsilateral femoral shaft fractures, and CT scans do not appear to be 100% sensitive for their diagnosis [98].

Operative management is the mainstay of therapy for fractures of the femoral shaft. In the United States, definitive treatment of the femoral shaft fracture patient in skeletal traction is of historical interest only. A distinct advantage of femur fracture stabilization includes the ability to mobilize the patient, thereby avoiding complications associated with prolonged bed rest in critically injured patients, such as pneumonia, pressure ulcers, and deep vein thrombosis. The gold standard for treatment of closed fractures of the femoral shaft is reamed, statically locked, antegrade (from the hip region) medullary nailing. This method of treatment has been demonstrated to be highly effective in numerous studies [99–101], and it can allow for early unprotected weight bearing [102]. Open fractures of the femoral shaft are also effectively treated with medullary nailing, after appropriate irrigation and debridement [10]. Entry portal—piriformis fossa *versus* trochanteric—seems to make little difference in healing rates [101]. Early dynamic locking can be associated with shortening of the fracture, and is generally not utilized in trauma [103]. Retrograde nailing (entry point through the knee) is also effective [104]. Reaming prior to nailing appears to improve healing rates of femoral shaft fractures [105,106], although this may come at the expense of increased pulmonary injury in the setting of chest-injured patients [107].

Other methods of fixation for femoral shaft fractures include open reduction and internal fixation with a plate-and-screw construct and external fixation. Plate fixation is often, but not always, reserved for extremely proximal or extremely distal femoral shaft fractures and for fractures in which intramedullary fixation is contraindicated (e.g., the presence of device, such as a total hip arthroplasty stem, within the femoral canal). Plate fixation has been employed successfully in polytraumatized patients with femoral shaft fractures [108]. External fixation can also be used in the acute setting to stabilize femoral shaft fractures in a minimally invasive and rapid fashion. Although femoral shaft fractures can heal with definitive external fixation, this method of treatment is rarely utilized. Conversion of external fixation to medullary nail fixation for femoral shaft fractures has been demonstrated to be effective and safe [29–31].

Early femoral shaft stabilization is associated with improved outcomes in polytraumatized patients [109]. The method of stabilization is unimportant for these early outcomes; medullary nailing, plate and screw fixation, or external fixation all provide similar benefit. Controversy remains regarding the optimal method of early femur fracture stabilization in the polytraumatized patient, including chest- and head-injured patients. The Hannover group has published extensively regarding the second-hit phenomenon of femoral nailing in polytraumatized patients, and has made recommendations that pulmonary- and head-injured patients perhaps undergo acute "damage-control orthopedic surgery" with external fixation of a femoral shaft fracture, followed by staged conversion from external fixation to medullary nailing when the patient's condition has improved and resuscitation has been completed [107,110–112]. However, some recent studies have demonstrated that reduced rates of acute respiratory distress syndrome (ARDS) can be achieved with acute nailing of femoral shaft fractures, instead of with damage control orthopedics, in polytraumatized patients [113–115]. Adequate resuscitation

has been shown to be important prior to nailing [114]. Also, the utilization of reaming has been shown not to create increased rates of ARDS in polytraumatized patients undergoing medullary nailing of femur fractures, as compared to patients undergoing nailing without reaming [114].

Tibial Shaft Fractures

Fractures of the tibial shaft are very common in polytraumatized individuals and after high-velocity trauma. Tibial fractures have a higher likelihood of being open [116,117], perhaps secondary to the thin soft tissue envelope surrounding the human tibia. This soft tissue envelope may also play a role in the increased likelihood of infection and nonunion for tibial fractures treated operatively; infected nonunion is more common after tibial fracture than after any other fracture of a long bone [118]. Compartment syndrome is also common after high-energy fractures of the tibia, even when the fractures are open [10].

Principles of treatment of tibial shaft fractures are similar to those of femoral shaft fractures; to provide comfort, restore length, alignment, and rotation, and allow for early mobilization. Tibial fractures are commonly treated with medullary nailing techniques, unless there are fracture extensions into the knee and/or ankle joint. Nailing of tibia fractures can provide sufficient stability to allow for full weight bearing after surgery [119]. Plating of tibia fractures is more often done for those fractures with involvement of the articular surfaces of the tibia, and normally weight bearing is restricted in those patients until some evidence of radiographic healing is present. External fixation is most often utilized in a temporary fashion, especially with large open wounds requiring repeat debridement, in complex fractures involving the tibial plateau or tibial plafond, or in patients with significant physiological instability. Conversion of external fixation to nailing is safe, when the patient's condition permits [30,31].

Tibia fractures in patients sustaining multisystem trauma can be stabilized in a delayed fashion, after the physiological condition of the patient has improved. Unlike femoral shaft fractures, tibia fractures can be effectively treated temporarily with long-leg splints. This allows for patients to be gotten out of bed and to sit up in bed or a chair, with improvements in pulmonary function. However, splinted tibia fractures must be carefully monitored for skin breakdown from the splinting material, compartment syndrome, and impending skin compromise from unstable fracture ends.

Humeral Shaft Fractures

Fractures of the humeral shaft are a source of morbidity in polytraumatized patients. They have implications for early rehabilitation as well as for future function. Injuries associated with humeral shaft fractures that have profound consequences on outcomes include brachial artery injuries and nerve injuries; the radial nerve is particularly susceptible to concomitant injury with humeral shaft fracture. Management of humeral shaft fractures and their sequelae are based upon the overall condition of the patient and on the personality of the injury.

Humeral shaft fractures, when they occur in isolation, are particularly amenable to closed management. Splinting, casting, and fracture bracing have all been noted to be highly successful in achieving union of humerus fractures [120,121], and long-term outcomes (at a minimum of 1 year) are thought to be as good as those after surgical repair [122]. Critically, these results were obtained in isolated humeral shaft fractures. Considerations for the management of humerus fractures in polytraumatized patients, however, likely are different.

Polytraumatized patients often require the use of both arms for effective mobilization and rehabilitation. They often are subjected to prolonged bed rest, and may be incapable of the frequent fracture brace adjustment that is advocated by Sarmiento and colleagues [120]. As fracture braces are not generally utilized in the acute phase after fracture (delay of 1 to 3 weeks prior to application is common), early splints can be cumbersome for patients and caregivers, can be unwieldy, and are not generally removable for the purposes of skin monitoring and vascular access. Obtunded patients also cannot complain about pressure points beneath a non-removable splint, and they do not routinely change position in an effort to alleviate pressure points. Skin necrosis can be a danger in this setting. For all of these reasons, management of humeral shaft fractures in polytraumatized patients is normally operative.

Humerus fractures can be treated either with open reduction and internal fixation, utilizing a plate-and-screw construct, or with medullary nailing. Advocates of plate-and-screw fixation cite the ability of humeral shaft fracture patients to utilize their arms for assistance with ambulation (i.e., weight-bearing on crutches or a walker) after fixation [123]. Advocates of medullary nailing for humeral shaft fractures have demonstrated good outcomes [124], although no literature exists that provides evidence regarding immediate weight bearing after nailing of humerus fractures. Some literature exists that appears to favor plating *versus* nailing for humeral shaft fractures, as shoulder impingement and reoperation risk appear to be lower with plating [125–127], although a definitive answer regarding optimal surgical treatment of humeral shaft fractures is not available. In the setting of radial nerve palsy, present between 8% and 11% of the time [128,129], nerve exploration can also occur at the time of surgery. However, radial nerve palsy is not an indication for operative exploration of the nerve [130]; the bulk of radial nerve palsies appear to be neurapraxias, and a recent study reported that 89% recover normal distal neurological function after closed humeral shaft fracture management [131]. Even secondary radial nerve palsies (those occurring later, such as after fracture manipulation) appear to have a high rate of complete recovery despite nonoperative management [129].

Forearm Fractures

Forearm fractures, while not often a contributing factor to mortality in the polytraumatized patient, are a source of long-term morbidity if not properly addressed. The forearm functions as a mobile unit which is dependent upon the anatomy of the radius and the ulna. The radius and ulna are "parallel" but curved bones, and this anatomy is vital for the maintenance of proper forearm rotation (pronation and supination). The maximal radial bow has been shown, in anatomical studies, to be approximately 16 mm and located near the junction between the middle and distal one thirds of the forearm length [132]. Encroachment of either bone or of foreign material into this region may have adverse consequences on forearm rotation, and may create limitations of pronation, supination, or both.

Fracture of one bone of the adult forearm often leads to injury associated with the other bone, whether it is fracture or dislocation of the other bone, with dislocation of the other bone; dislocation, when it occurs, is either at the elbow (radius) or wrist (ulna). The anatomical connections between the radius and ulna include the proximal and distal radioulnar joints and the interosseous ligaments; deformation of one bone, due to fracture, that is not "compensated" by fracture of the other bone will cause the other bone to be drawn in the direction of the deformation, causing dislocation. Typical patterns include displaced proximal ulnar shaft fractures associated with dislocations of the radial head from the capitellum

(the "Monteggia" fracture–dislocation) and displaced distal radial shaft fractures associated with dislocations of the ulnar head from the distal radioulnar joint (the "Galeazzi" fracture–dislocation).

Careful scrutiny of the elbow, forearm, and wrist is vital for the detection of these injuries, which may be overlooked in the setting of multiple trauma. Failure to recognize these injuries acutely can result in increased difficulty with surgical reconstruction (if accomplished late) or significant disability (if reconstruction is never accomplished). Forearm fractures tend to shorten, due to the powerful investing musculature of the forearm, and surgical repair is often more straightforward when it can be undertaken within a few days of injury. Perfect anatomical reconstruction is associated with the best outcomes. Early motion is encouraged to minimize the likelihood of excessive bone formation within the injured tissues between the radius and ulna, which can lead to encroachment of the two bones and restriction of forearm rotation. The repaired forearm is often protected and weight bearing is restricted for a number of weeks. However, "platform" walkers or crutches may be utilized for assistance with ambulation in many cases; the weight of assisted ambulation is borne through the elbow (as opposed to the wrist and forearm) with these devices.

Although forearm fractures may not be a direct cause of early mortality in most patients who succumb to the sequelae of severe trauma, it can be a contributing factor. Forearm fractures can result in lacerations of the ulnar and/or radial arteries, which can contribute to blood loss. Forearm compartment syndrome can also develop in the patient with severe forearm fractures; unrecognized compartment syndrome can result in myonecrosis with resultant myoglobinuria and potential contribution to renal insufficiency (see below), let alone future disability. Open fractures of the forearm should not be thought to decompress the compartments of the forearm adequately; a heightened index of suspicion of compartment syndrome should be maintained in all patients with high-energy fractures of the forearm, whether they are closed or open fractures.

COMPARTMENT SYNDROME

Muscle groups are divided into compartments by layers of fascia, which are noncompliant. Injury to a particular muscular compartment can induce edema and/or hemorrhage within the compartment, leading to increased intracompartmental pressures due to the noncompliant nature of the surrounding fascia. Increased intracompartmental pressure can lead to venous congestion and resultant muscle ischemia within the involved compartment(s). This scenario is termed "compartment syndrome." As nerves traverse the muscular compartments, they are also susceptible to compartment pressure-related compromise.

The absolute intracompartmental pressure at which a compartment syndrome exists continues to be a matter of debate. Some authors have previously advocated threshold intracompartmental pressures, such as absolute values of 30 mm Hg or 40 mm Hg, as diagnostic of compartment syndrome. However, a differential between intracompartmental pressure and diastolic blood pressure is thought to be a more reliable indicator of evolving compartment syndrome. The pressure differential (referred to as ΔP or "delta-P") thought to be diagnostic of compartment syndrome is commonly accepted to be 30 mm Hg or less [133]. The improved reliability of ΔP measurements, as opposed to absolute measurements of intracompartmental pressures alone, was recently illustrated in a series of 101 tibial fracture patients. In this series, 41 patients had continuous leg intramuscular compartment pressures more than 30 mm Hg for over 6 hours in the setting of a satisfactory ΔP (defined as $\geq$30 mm Hg). No difference in outcome regarding return to function and muscle strength was noted, as compared to a control group of 60 patients without elevated intramuscular pressures [134].

The number of muscle compartments is variable based upon location in the body. The brachium has two muscular compartments (anterior and posterior), the forearm has three muscular compartments (dorsal, volar, and mobile wad), the thigh has three muscular compartments (anterior, posterior, and adductor), and the leg has four muscular compartments (anterior, lateral, superficial posterior, and deep posterior). The exact number of muscular compartments in the hand and the foot are a matter of debate. Hand compartments include the interosseous compartments as well as the thenar and hypothenar compartments, and foot compartments include the interosseous compartments as well as the abductor and adductor compartments. The gluteal muscles are also contained within fascial compartments, and gluteal compartment syndromes have been documented in obtunded trauma patients as well as intoxicated patients (and others with an altered level of consciousness), with the gluteal muscles in a dependent position, who do not change their position for an extended period of time [135].

Compartment syndrome is a problem that can arise in polytraumatized patients who have sustained high-energy injuries. Younger patients may be more susceptible [136]. Typical injuries associated with development of compartment syndrome include fractures, dislocations, crush injuries, and prolonged episodes of limb ischemia. The syndrome can also develop after reperfusion of a dysvascular limb that occurs after a revascularization procedure or simply after a manipulative reduction of a fracture that reduces kinking and occlusion of vessels. Isolated soft-tissue injury (without fracture) was the second most common cause of compartment syndrome in a large series of patients reviewed over an eight-year period [137]. Another study examined a cohort of 38 patients without fracture who developed compartment syndrome at a single trauma unit in Great Britain. Frank muscle necrosis was noted in 20% of patients without fracture, as compared to 8% of patients with fracture, indicating that a high index of suspicion for compartment syndrome in trauma patients must be maintained, even in patients without fractures [138]. Penetrating injuries, such as gunshot and stab wounds, can lacerate arteries within a single compartment or multiple compartments, leading to hemorrhage under pressure into a confined environment and creating a compartment syndrome. The presence of a penetrating injury or open fracture (which results in fascial disruption) should not create a false sense that compartment syndrome will not develop; compartment syndromes have been documented to occur in the setting of penetrating injury or open fracture [139].

Compartment syndrome can also develop after stabilization of a fracture, such as after nailing a tibia fracture, once the compartment has been returned to its pre-injury length and its available volume is thereby diminished. This "finger-trap" phenomenon was initially described in the literature by Matsen and Clawson [140]. More recent mathematical and experimental analyses indicate that the available volume within a given muscular compartment varies inversely with acute changes in the length of the limb [141]. Tibial traction or fracture reduction in the setting of tibial shaft fractures raises compartment pressures [142]. A fracture situation in which excessive shortening is corrected, or vigorous traction is required to maintain reduction, should perhaps prompt increased vigilance for the development of compartment syndrome. This risk must be balanced, however, during staged management of severe fractures, as the consequence of initial inadequate limb-length restoration may be increased difficulty of the definitive reconstructive procedure at the time of formal open reduction and internal fixation. Also, a recent report revealed that in tibial plateau fractures, application of an external fixator device which spans

the knee and fracture may lead to transient elevations of intracompartmental pressure, but does not appear to cause a compartment syndrome [143].

Missed compartment syndromes can lead to significant morbidity. Frank muscle necrosis is a normal sequela of compartment syndrome, and associated joint contractures have been extensively described in the literature. Elevated levels of serum creatine phosphokinase (CPK) or the appearance of myoglobinuria (which can be misinterpreted as hematuria) are associated with muscle necrosis, and have been utilized in the past as diagnostic tools for evolving compartment syndromes [144,145]. Delayed treatment of compartment syndrome is fraught with complications [146]. Infection rates are dramatically increased when fasciotomy for compartment syndrome is delayed [147]. Fasciotomy revision, performed in a delayed fashion for inadequate index fasciotomy (and failure to relieve compartment syndrome), has been associated with increased rates of mortality and major amputation [148]. Often, it is not possible to determine the exact time of onset for a compartment syndrome. Therefore, the recommendation is that fasciotomy be undertaken as expeditiously as possible after diagnosis of compartment syndrome, and that a high index of suspicion for the development of compartment syndrome should be maintained in patients with high-energy trauma or trauma patients who are obtunded.

Compartment syndromes should be diagnosed during the evolution phase. A high clinical suspicion should be maintained in any patient who has sustained a high-energy injury. Pain out of proportion to the injury should alert the examiner to the possibility of impending compartment syndrome. Orthopedic injuries are very painful by their nature, and patients often have differing pain tolerances (sometimes affected by chronic narcotic use/abuse), so the examiner should be sensitive to *changes* in pain level as reported by the injured patient. Traditionally, the "five P's" have been utilized in the awake, responsive patient for examination of the leg and ruling out compartment syndrome: pain with palpation of the compartment, pallor, paresthesia, pain with passive stretch, and pulselessness are commonly quoted as signs of compartment syndrome. Pulselessness should not be included in this list, as it requires excessive pressures to occlude arteries–in excess of systolic pressure–and should this scenario arise, it would likely be associated with complete myonecrosis within compartments involved. Excessive pain with passive stretch of muscles within each compartment should alert the examiner to evolving compartment syndrome. Awareness of the patient's injuries and their direct contribution to pain with the motion of a joint (e.g., intra-articular fracture) should be considered. All compartments in a traumatized extremity should be examined. Muscle compartments tend to be very firm in the setting of evolving compartment syndrome.

Direct monitoring of intracompartmental pressure is possible utilizing the wick catheter technique, an arterial pressure line setup, or a variety of commercially available devices. These methods provide direct measurements of intracompartmental pressures in mm Hg. It should be emphasized, however, that compartment syndrome is primarily a diagnosis based upon physical examination. Physical examination findings consistent with evolving compartment syndrome should prompt surgical intervention, even in the setting of compartment pressure measurements that indicate normal ΔP, as the consequences of missed compartment syndrome include frank myonecrosis and irreversible neurological injury. Complete reliance upon direct intracompartmental measurements may result in undertreatment or overtreatment of compartment syndrome. Intracompartmental pressure measurements have been shown to be highest within 5 cm of fracture, and measurements taken outside of this zone may be spuriously low and lead to undertreatment [149]. Also, there is a documented decrease in diastolic blood pressure after induction of general anesthesia; intracompartmental pressure measurements obtained in a patient under anesthetic must be interpreted cautiously as the ΔP value may be spuriously low and lead to overtreatment [150]. Diagnosis of compartment syndrome is variably difficult, even at large trauma centers [151], and high indices of suspicion need to be maintained to prevent undertreatment (and overtreatment) of compartment syndromes.

Obtunded patients should be monitored serially. The examiner should note compartment firmness and proceed appropriately. Significant degrees of subcutaneous edema can mask tense compartments. Compartment pressure monitoring with commercially available devices or with an arterial pressure line setup may be utilized for diagnosis in the obtunded patient, especially if the patient exhibits no response to painful stimuli and if physical examination of compartment tightness is impeded by extensive surrounding edema (e.g., with anasarca).

Open fractures do not necessarily decompress compartments through which the fracture fragments or projectiles have penetrated. An approximately 9% rate of compartment syndrome has been reported with open fractures of the tibial shaft [139]. The degree of soft tissue injury appeared to be directly proportional to the incidence of compartment syndrome in this population. Therefore, compartment syndrome should be suspected in all patients with appropriate symptomatology, and the presence of open wounds does not negate the possibility that compartment syndrome may be evolving.

Techniques of fasciotomy have been described extensively. Adequate decompression of all compartments in the affected portion of the extremity is the goal. During fasciotomy, nonviable muscle is debrided. Following fasciotomy, closure of the fascia is not indicated (this would re-create the compartment syndrome). Skin closure should be undertaken cautiously. Use of vessel loops to assist with skin reapproximation has been described [152]. Negative-pressure wound therapy devices may also be beneficial in promoting growth of granulation tissue on a fasciotomy bed, in anticipation of skin grafting, or in maintaining smaller wound dimensions, in anticipation of delayed primary closure [153,154]. Most fasciotomy patients will require return to the operating room for further irrigation and debridement procedures, followed by delayed primary skin closure or skin grafting.

The greatest risk of fasciotomy in patients with evolving compartment syndrome is incomplete fasciotomy technique. It is imperative to verify that all compartments in the affected extremity have been released, regardless of surgical approach utilized. Anatomy may be distorted due to fracture deformity, excessive hematoma, or soft tissue avulsion, and it occasionally can be difficult to discern fascial planes. Also, visualization can be impaired by "minimally invasive" or "cosmetic" incisions, and therefore it is inappropriate to perform fasciotomy in the urgent to emergent situation on a traumatized extremity through anything but full-length incisions. Small incisions for fasciotomy are described and often are used for the treatment of exertional compartment syndrome, but their utility in trauma is questionable at best. Visual verification of complete release of all four compartments should be made prior to the initiation of wound closure and departure from the operating room.

Fasciotomy can be associated with both acute and long-term morbidity. Multiple neurovascular structures can be injured during fasciotomy. Risk can be minimized by careful and meticulous dissection technique, maintaining nerves and vessels within a cutaneous flap (if possible), and assuring that neither is directly exposed to the environment (dressing) at the conclusion of the case. At least one case of profound hemorrhage after erosion of an artery beneath a negative-pressure wound therapy device has been reported [155]. Analysis of long-term outcomes related to fasciotomy is difficult in the

trauma setting due to the concomitant injuries that have invariably occurred and which can have an effect upon function. Nevertheless, a retrospective analysis of 40 patients undergoing leg fasciotomy for a variety of reasons has been published [156]. Complications of leg fasciotomy were common, and included neurological injury in 15%, hemorrhage in 35%, and infection in 25%. Only 45% of legs healed with a good functional result, and 27.5% had a severely disabled leg at the time of final healing. Five of the patients (12.5%) ultimately required ipsilateral leg amputation, and six patients (15%) expired. Another report indicated frequent patient complaints related to fasciotomy wounds, including decreased sensation, tethering of tendons, and recurrent ulceration [157]. Other known side effects of compartment release include pruritus, reflex sympathetic dystrophy, temperature sensitivity, venous stasis, and chronic edema. Despite these concerns, the morbidity and potential mortality of an untreated compartment syndrome is likely to be much higher. Also, a number of published reports, reviewed by Bong et al. [158], indicate that outcomes of fasciotomy for chronic exertional compartment syndrome (in the absence of trauma) are reliably good. These reports, however, require cautious interpretation for their application to trauma, as they did not include patients who required fasciotomy for trauma-related compartment syndrome.

OTHER SEQUELAE OF ORTHOPEDIC TRAUMA

Deep Venous Thrombosis

Polytraumatized patients with lower extremity or pelvic fractures often are subjected to prolonged periods of immobilization or reduced mobility. They are at risk for development of deep venous thrombosis (DVT) and subsequent pulmonary thromboembolism (PE). Management of the orthopedic trauma patient must take into account the increased propensity for these patients to develop venous thromboembolic disease.

There has been much debate in the literature about appropriate methods of DVT prophylaxis in orthopedic trauma patients. The Eastern Association for the Surgery of Trauma (EAST) states that the greatest risk factors in trauma patients for development of venous thromboembolism (VTE) are spinal fractures and spinal cord injury. They also state that insufficient evidence exists regarding risk of VTE in trauma patients as it relates directly to long bone fracture or pelvic fracture [159]. Trauma patients with pelvic and acetabular fractures are thought to have an increased risk of VTE [160]. However, there is little evidence in the literature, apart from observational studies, regarding the best method of DVT prophylaxis for pelvic and acetabular fracture patients [161].

Prophylaxis of trauma patients, especially those with pelvic and acetabular fractures, is important to reduce the risk of DVT. Trauma patients have been shown to have lower rates of DVT when both chemical and mechanical means of prophylaxis are utilized [162]. Mechanical DVT prophylaxis can consist of foot pumps or pneumatic compression devices. Continuous passive motion for the knee in the injured extremity has also been shown to be helpful [163]. Chemical DVT prophylaxis often consists of low-molecular-weight heparin (LMWH) in hospital inpatients; warfarin is not commonly used acutely in the trauma patient (although it may be utilized for longer-term DVT prophylaxis when indicated). In patients thought to be at higher risk of VTE and who are awaiting surgical intervention for fracture repair, chemical prophylaxis does not need to be halted in anticipation of surgery [164]. Despite adequate prophylaxis, however, patients are still at risk for development of DVT [165].

Patients with pelvic, acetabular, and proximal femoral (hip) fractures are at risk of development of VTE [160]. Fractures below the hip are associated with lower risk of DVT; 8% of patients with below-the-hip fractures were demonstrated in one study to develop DVT [166]. Fractures below the knee (i.e., tibia, ankle, foot) do not seem to elevate the risk of VTE significantly; low rates of DVT have been found in patients with ankle fractures treated with cast immobilization [167], and a recent study demonstrated that DVT prophylaxis was of limited to no benefit in patients with fractures below the knee [168].

Routine screening for the presence of DVT in trauma patients is not commonly done. Methods of detecting DVT include compression Doppler ultrasound and venography. In patients with pelvic and acetabular fracture, known to be at a higher risk for DVT than other patients with lower extremity fractures, venography has not been shown to be an effective screening tool [169]. In general, routine screening for DVT is ineffective in trauma patients with pelvic and acetabular fractures, as demonstrated in a recent review of 973 patients [170].

Peripheral Nerve Injury

The bulk of peripheral nerve injuries that occur as a consequence of trauma are neurapraxias, which often will recover with time. Typical neurological injuries include radial nerve palsies in association with humeral shaft fractures, sciatic nerve palsies (peroneal branch, in particular) in association with pelvic and acetabular fractures, and brachial plexopathies in association with scapulothoracic dissociation.

Radial nerve palsies occur after approximately 12% of humeral shaft fractures [129]. An early description of radial nerve palsy in association with humeral shaft fracture was published by Holstein and Lewis, and describes the association with a spiral fracture of the humeral shaft located at the junction between the middle and distal one thirds of the diaphysis [171]. However, some more recent research has called the relationship between this particular humerus fracture pattern and radial nerve palsy into question [129]. The radial nerve supplies motor innervation to the extensors of the hand and wrist; patients with radial nerve motor palsies will lack the ability to extend the wrist or hyperextend the interphalangeal joint of the thumb, which is mediated by the extensor pollicis longus. The extensor digitorum communis (EDC), also supplied by the radial nerve, extends the metacarpophalangeal joints of the hand, but patients may recruit other muscles or perform other functions (such as wrist flexion) that will serve to extend the digits, even though the EDC is not functional. The interphalangeal joints of the fingers (index, long, ring, small) are extended by the intrinsic muscles of the hand, which are innervated by the median and ulnar nerves, and therefore are not affected by radial nerve palsy. Radial nerve-mediated sensation includes the dorsal surfaces of the forearm and hand; the most specific location for radial nerve sensation is the dorsum of the first web space on the hand.

Most radial nerve palsies are thought to be traction injuries (neurapraxias), as opposed to complete disruptions (neurotmesis) or impalings on bone edges [172]. Rarely, the radial nerve may become entrapped within the humeral fracture site, creating neurological deficits [129]. In the setting of high-velocity penetrating injury (gunshot wounds), a radial nerve palsy may be secondary to blast effect of the projectile (as opposed to nerve transaction). Radial nerve palsy at presentation in a patient with a humeral shaft fracture is not considered an indication for surgery, either for nerve exploration or humeral shaft fracture fixation. In the past, humeral shaft fracture

patients presenting with intact radial nerve function which then is lost after manipulation of the fracture (e.g., for reduction) was considered an indication for operative nerve exploration; it has been shown, however, that the bulk of these "iatrogenic" radial nerve palsies resolve on their own, with no residual deficit, and that fracture fixation or nerve exploration is not indicated in these patients either [129]. Humeral shaft fracture fixation should be undertaken in patients who would benefit (or who specifically request fixation), after thorough risk and benefit discussions with the patients and/or their families, and should not be prompted by the presence of a radial nerve deficit. Electromyography and nerve conduction studies are not helpful in the acute setting, and have low sensitivity and specificity regarding the etiology of radial nerve palsy immediately after injury. Ultrasonic examination, however, can be beneficial to detect nerve laceration or entrapment, when utilized by experienced practitioners [173].

Although radial nerve palsies are most often transient, their recovery can take many weeks to months. During this time, flexion contractures of the wrist and digits can occur. Splinting and occupational therapy, with daily manual stretching exercises, are beneficial to minimize this problem. Electromyography and nerve conduction studies may be performed between 6 and 12 weeks following the onset of the radial nerve palsy if there has been absolutely no recovery of function after the injury [172]. Functional recovery is slow; rapid recovery should not be expected. A good rule of thumb is that nerve recovery progresses at approximately 1 mm per day [174]. Therefore, an injury to the radial nerve at the midshaft of the humerus should be expected to result in dorsal hand sensory deficits for many weeks.

Sciatic nerve palsies can occur in conjunction with pelvic or acetabular fractures. Acetabular fractures with posterior dislocation of the hip have an association with the development of sciatic nerve palsy [175]. Pelvic or acetabular fractures, with extensions of fracture lines into the sciatic buttress at the greater sciatic notch, can result in direct laceration of the sciatic nerve; this pattern of fracture can also result in catastrophic hemorrhage due to laceration of the superior and/or inferior gluteal arteries. Pelvic ring disruptions, with wide displacement of the hemipelvis, can also cause sciatic nerve palsies or lumbosacral plexopathies [176], perhaps due either to avulsion of nerve roots or to neurapraxia [177,178]. Nerve roots may be lacerated in association with sacral fractures [179]. The peroneal division of the sciatic nerve is more commonly affected than the tibial division [180]; it has been postulated that this has to do with more points at which the peroneal nerves are tethered down the lower extremity than the tibial nerves.

The bulk of sciatic nerve palsies are also neurapraxias [177]. Prognosis of these, however, is poorer than that for radial nerve palsy, perhaps secondary to the long distance across which recovery must occur (the nerve bud must travel from the pelvis to at least the superior leg, where innervation of the peroneal muscles and ankle and toe dorsiflexors occurs) [180]. Electromyography and nerve conduction studies are useful for characterizing the injury, and many patients with mild injuries regain good function [181].

Scapulothoracic dissociation, likened to a closed forequarter amputation [182], occurs when the shoulder girdle and upper extremity are pulled away from the midline [183]. Prompt recognition of this injury complex is vital. Significant degrees of scapulothoracic dissociation can result in the rupture of subclavian or axillary vessels [182,184]. The injury complex can have devastating effects upon the neurological function of the upper extremity, due to the stretch of nerves or brachial plexus, or due to the avulsion of nerve roots from the cervical spine [182]. Degree of neurological injury and prognosis for recovery correlates with the location of vascular injury; more proximal vascular injury correlates with more severe neurological compromise and poorer prognosis [185]. Evidence of expanding hematoma within the axilla of a patient with such an injury should prompt emergent vascular surgical consultation. Careful attention to the vascular status of the distal upper extremity must be paid to any patient with a distracted clavicular fracture, a significantly-displaced scapular fracture, or a clear increase in distance on anteroposterior chest radiograph between the thoracic spine and the medial border of the scapula, known as the scapular index [186]. Computed tomography is of questionable benefit for initial diagnosis, as the axis of the beam may not be perfectly perpendicular to the axial skeleton, and therefore determination of scapular index may be unreliable. Recovery of brachial plexus function after scapulothoracic dissociation is unreliable at best, especially after nerve root avulsion [184,185,187].

DAVID A. DRACHMAN · DAVID PAYDARFAR

CHAPTER 168 ■ AN APPROACH TO NEUROLOGIC PROBLEMS IN THE INTENSIVE CARE UNIT

DAVID A. DRACHMAN

Neurologic problems present in the intensive care unit (ICU) in two modes: (a) primary neurologic problems, usually under the care of a neurologist or neurosurgeon, and (b) secondary neurologic complications, occurring in patients with other medical or surgical disorders. Only a handful of common clinical situations bring neurologists and patients together in the ICU, although they may be caused by myriad disease states [1]. These situations include:

1. Depressed state of consciousness; coma
2. Altered mental function
3. Required support of respirations or other vital functions
4. Monitoring of increased intracranial pressure (ICP), respirations, state of consciousness
5. Determination of brain death
6. Prevention of further damage to the central nervous system
7. Management of seizures or status epilepticus
8. Evaluation of a neurologic disease that occurs in the course of a severe medical disease
9. Management of a severe medical disease that develops in the course of a neurologic illness

Patients with primary neurologic problems most commonly have conditions with an identified cause, such as stroke, seizures, Guillain-Barré syndrome, head trauma, or myasthenia gravis. Such patients are admitted to the ICU for close observation and management of vital functions, such as respiration, control of ICP, or arrest of seizure activity. These patients represent the minority of neurologic problems seen in the ICU. Far more frequently the neurologist is called on to evaluate the neurologic complications of medical disease: impairment of consciousness in a patient who has undergone cardiopulmonary resuscitation, development of delirium in an elderly individual with a serious infection, or occurrence of focal neurologic deficits in a patient with a ponderous medical record that reveals long-standing diabetes, renal failure, hypertension, and pulmonary disease.

The questions posed to the neurologic consultant are often imperfectly framed. Background observations regarding the origin, onset, and course of the neurologic abnormality may be unavoidably sparse and the history unavailable. The classic neurologic methodology, which involves a comprehensive history and meticulous examination, is rarely possible in patients encumbered with endotracheal tubes, cardiac monitors, and indwelling arterial and venous lines. For these reasons, neurologists must adopt special strategies to function effectively in the ICU, focusing sharply on the specific question with which they are dealing.

INDICATIONS FOR NEUROLOGIC CONSULTATION IN THE INTENSIVE CARE UNIT

Depressed State of Consciousness

The patient with the most common of ICU neurologic problems—a depressed state of consciousness, ranging from lethargy to coma—raises a host of questions. Does the patient have a focal brainstem lesion or diffuse cerebral involvement? Is there an anatomic lesion or a metabolic disorder? Have vital brainstem functions been impaired? Is ICP increased?

The most common primary neurologic causes of depressed consciousness include head trauma, intracranial hemorrhage, post cardiac arrest anoxia-ischemia, and less commonly, inapparent seizures. The secondary conditions seen most often are metabolic, such as anoxia, drug intoxication, or diabetic acidosis. Sometimes the diagnosis is evident, as in head trauma; other times determination of the cause of depressed consciousness may present a diagnostic challenge, demanding a race against the clock to avoid irreversible changes. In every case, it is crucial to establish whether depressed consciousness is due to intrinsic brainstem damage, increased ICP, toxins, widespread anoxia or ischemia, or some other less common cause. It is particularly important to sort out rapidly the component(s) that may be treatable.

Examination of the patient with depressed consciousness exemplifies some of the difficulties of neurologic care in the ICU. Details of this examination are described elsewhere [2]. Like the standard neurologic examination, however, it includes evaluation of mental status, cranial nerve functions, motor functions and coordination, reflexes, sensation, and vascular integrity. The observations made must be used to answer the questions posed above, supplemented by appropriate laboratory studies when possible.

A detailed evaluation of memory and cognitive function is rarely possible in patients who are lethargic, and never possible in those who are stuporous or comatose. Instead, the physician must estimate the patient's responsiveness. Can the patient say any words or respond to commands? Does the patient open his or her eyes? Does the patient groan in response to a painful stimulus or attempt to remove it in a purposeful way? What is the status of the vital functions? Is the respiratory pattern disturbed? The Glasgow Coma Scale score is a simple, but useful, way to document the patient's sensorium [3].

Cranial nerve evaluations include determination of vision, done by observing how the patient follows a large object or a light, gazes toward right and left visual fields, or blinks to a visual threat. Pupillary size, equality, and responsiveness to light

are assessed. Corneal reflexes, cough, and vibrissal (nasal) reflexes are evaluated. "Doll's eyes" (vestibulo-ocular) responses are determined by rotation of the head from side to side; if they are absent, ice water caloric testing can be carried out. Facial movements are assessed in response to painful supraorbital stimuli; the gag reflex is tested in the usual fashion.

Motor function is evaluated as completely as possible. All limbs are observed for spontaneous movement and symmetry as well as tremor or other adventitious movements. If no spontaneous movements take place, a pinch or other noxious stimulus can be used to observe purposeful defensive movements. Decerebrate (i.e., four-limb extensor) and decorticate (i.e., upper limbs flexor, lower limbs extensor) rigidity are observed. Tone is assessed passively for spasticity or rigidity. Deep tendon reflexes are checked in the usual way, working around restraints and intravenous tubing. Grasp, suck, snout, and plantar reflexes are evaluated.

Pain is often the only sensory modality that can be tested. The physician must determine whether withdrawal from pinch or pinprick is appropriately defensive or (in the lower extremities) merely part of an exaggerated extensor–plantar response with triple flexion (flexion at hip, knee, and great toe), which may be mistaken for purposeful withdrawal. Finally, the vascular status is evaluated by listening for bruits over the carotid and subclavian arteries, the vertebral arteries, and the orbits.

Such an examination reveals the patient's state of consciousness, the integrity of brainstem reflexes, and the presence or absence of lateralizing or focal neurologic deficits. The value of the systematic (if limited) neurologic examination cannot be overestimated. For example, in a comatose patient, the finding of decerebrate rigidity that points to significant damage at the level of the pons may be more valuable than many laboratory studies, and unilateral weakness of limbs with ipsilateral hyperreflexia indicates a focal brain disorder rather than a diffuse metabolic problem.

Neurodiagnostic studies are often critical in the analysis of comatose patients in the ICU, but the patient's immobility and dependence on life support systems present special difficulties. A neuroradiology suite that is distant from the ICU presents additional obstacles. It is frequently difficult to obtain a magnetic resonance imaging scan, computed tomographic scan, or arteriogram on a patient who is dependent on a respirator. Paradoxically, in patients with the most urgent problems, it is often least convenient to obtain the maximum amount of neurodiagnostic information. The decision that a patient is too sick to have the crucial study performed is often incorrect. In such desperate cases, risks must be taken to obtain life-saving information.

Management of the patient with depressed consciousness depends largely on the cause. Techniques for eliminating toxins, reducing ICP, and maintaining vital functions must be applied, depending on the diagnostic context (see Chapter 169).

Altered Mental Function

In patients who remain relatively alert, other organic disorders may affect mental function, producing an often perplexing variety of clinical patterns. These include confusion, delirium, aphasia, and isolated memory impairment. The first question for the physician is whether the patient's abnormal mental function represents a recent change that is part of the present illness, or instead is part of a long-standing problem. It is also critical to note whether the change developed abruptly (e.g., after surgery or cardiac arrest) or if there is no known precipitating event; and whether it is improving, worsening, or stable.

Confusion and delirium are commonly reversible and generally result from metabolic and toxic disorders (see Chapters 169 and 197). Persistent aphasia and isolated memory impairment suggest focal damage to the brain, and an anatomic lesion should be sought. Dementia—cognitive and memory impairment—cannot be accurately evaluated in patients who have a depressed state of consciousness or the other mental changes indicated above. When dementia occurs *de novo* in a patient with a clear sensorium, it may indicate either reversible conditions (e.g., drug-induced, depression-related) or irreversible damage (e.g., diffuse anoxia or ischemia; see Chapter 169).

Any recent change of mental status in a patient in the ICU requires *prompt* investigation. Whether it signals worsening of the underlying medical disorder or direct involvement of the brain, the change should be assessed by an experienced neurologist as early in its evolution as possible, before it is complicated by the passage of time, advance of disease, and effects of additional treatments.

Support of Respiration and Other Vital Functions

Respiratory support is needed for neurologic patients in two circumstances: loss of brainstem reflex control of respiration and impairment of effective transmission of reflex impulses to functioning respiratory muscles. Ischemia, anoxia, compression, hemorrhage, and toxic depression may alter brainstem control of respirations, producing characteristic respiratory patterns that depend on the site of damage [2], such as central neurogenic hyperventilation, Cheyne-Stokes or periodic breathing, or apnea. The intensivist and neurologist should be familiar with the use of positive end-expiratory pressure and other ventilatory regimens, operation and interpreting read-out of the hospital's respirators, and the endotracheal intubation equipment. Further, the neurologist must understand the neurologic significance of different respiratory patterns, which are as much a part of the ICU neurologic examination as is reflex testing.

Effective transmission of respiratory impulses may be impaired at the cervical spinal cord, anterior horn cells, peripheral nerves, neuromuscular junctions, or muscles of respiration. Cervical traumatic injuries, amyotrophic lateral sclerosis, Guillain-Barré syndrome, myasthenia gravis, and muscular dystrophy may interfere with breathing at the respective levels noted. Some of these conditions are transitory (e.g., Guillain-Barré syndrome) or treatable (e.g., myasthenia gravis), with complete recovery depending largely on the success of maintaining respiration. Even in incurable conditions (e.g., amyotrophic lateral sclerosis), sustaining respiration during periods of decompensation, such as respiratory infections, can prolong life significantly.

Monitoring of Intracranial Pressure and State of Consciousness

In a number of neurologic disorders, extremely close observation is needed to avoid the development of dangerous, often irreversible, further damage to the brain. The most common disorder requiring such monitoring is head trauma. The lethargic patient must be carefully observed for evidence of increasing ICP due to cerebral edema, intracranial (subdural, epidural, intracerebral) hemorrhage, or both [4].

The need for prompt recognition and early treatment of significantly increased ICP cannot be overemphasized. Once uncal or tonsillar herniation with brainstem compression and development of Duret hemorrhages has occurred, the consequences of this secondary effect of brain injury may far outweigh the initial damage. (The methods for monitoring ICP with pressure-detecting catheters or bolts and assessing

consciousness and brainstem functions with the Glasgow Coma Scale are described in Chapters 28 and 169.)

Determination of Brain Death

With the recognition that death of the brain and brainstem is equivalent to death of the patient, even though the heart continues to beat and respirations are sustained by artificial ventilation, the need to ascertain brain death has become more critical [5]. Early identification of brain death has three important justifications: (a) the use of viable donor organs for transplantation, (b) the termination of the hopeless vigil of a distraught family, and (c) the freeing of ICU beds for patients who may be helped. When one or more of these conditions prevails, it is important to determine the occurrence of brain death promptly. When none of the conditions is present, there is no urgency in declaring the patient brain dead.

It should be emphasized that brain death is specifically a determination that the brain and the brainstem are already dead—not a prediction that useful recovery is unlikely. It is also true that the longer one waits in even marginally uncertain cases, the clearer the evidence of brain death becomes. (The criteria for brain death are discussed extensively in Chapters 169 and 185.) The "CADRE" mnemonic may be useful in recalling the established criteria for brain death, in the absence of sedative drugs: *C*oma; *A*pnea; *D*ilated, fixed pupils; *R*eflex (brainstem) absence; and *E*lectroencephalographic silence.

Prevention of Further Damage to the Central Nervous System

A variety of neurologic disorders have the potential to cause further damage to the central nervous system. Acute strokes, or stroke in evolution, for example, may be arrested by thrombolytic treatment [6], endovascular clot removal or angioplasty, and stenting. These modalities may limit or even reverse the underlying ischemic process; and neuroprotective agents may, in the foreseeable future, prevent further damage. Coma following cardiac arrest should be promptly treated with hypothermia to preserve neurological function [7]. Spinal cord compression by metastatic tumor urgently requires surgical decompression followed by radiation therapy to avoid irreversible complete cord transection [8]. Among the infectious diseases of the nervous system, bacterial meningitis and certain treatable encephalitides (e.g., herpes simplex) require the immediate institution of antibiotic or antiviral therapy; spinal epidural abscess requires prompt surgical decompression as well. Although much of neurologic practice involves disorders for which progress is measured in months or years, cerebral anoxia, ischemia, hemorrhage, increased ICP, spinal cord compression, infectious diseases, and other acute disorders require prompt institution of treatment to avoid extension of the initial process. It is useful to remember that, as a largely post-mitotic structure, the brain has limited capability of regeneration, and its ability to survive without a continuing supply of nutrients is measured in minutes. Only in the ICU, with its facilities for careful monitoring and adjustment of therapy, can many of these treatments be successfully carried out.

Management of Status Epilepticus

Unlike simple, brief seizures, status epilepticus threatens lasting deficits or death if not controlled (see Chapter 172). Any patient whose sequential seizures cannot be arrested promptly with routine management (e.g., intravenous benzodiazepines, phenytoin) must be observed in the ICU, where therapy ranging up to general anesthesia with artificial ventilation may be required.

Evaluation of Neurologic Disease Accompanying Severe Medical Disease

Neurologic signs or symptoms develop in many patients admitted to the ICU for myocardial infarction, subacute bacterial endocarditis, cardiac arrhythmia, pneumonia, acute respiratory distress syndrome, septic shock, renal disease, hepatic failure, and other similar disorders while they are under treatment for the primary medical problem. Numerous questions are raised: Is the neurologic finding a consequence of the underlying disease, or is it coincidental? Does it demand further investigation at once, or can it wait? Should therapy be changed, or should new therapy be started? These issues demand the attention of the neurologist.

Management of Severe Medical Disease Accompanying Neurologic Illness

In patients with severe medical disease accompanying neurologic illness, unrelated medical illness most often develops in the setting of a chronic neurologic disorder. The demented patient may experience a myocardial infarct, or septicemia may develop in the patient with multiple sclerosis. Indirect relationships should be sought. Does the demented patient have multiple cerebral emboli from underlying cardiac disease? Is the patient with multiple sclerosis septicemic from a bladder infection due to impaired urinary control? Early recognition of a change in the seriousness of the neurologic patient's condition is often difficult, but it may be critical to a successful outcome.

PROGNOSTIC AND ETHICAL CONSIDERATIONS

When severe damage involves the brain, either as a separate neurologic condition or as a secondary consequence of other medical disease, the physician who requested neurologic consultation and the family often need guidance regarding the probable outcome. There are three critical questions: Will the patient survive? Has irreversible brain damage occurred? What is the likely degree of residual disability?

There are few simple rules that can be applied infallibly to determine the prognosis in, for example, comatose patients, especially early in the course. The most important consideration is often whether irreversible damage has affected crucial areas of the brain, rather than the depth of impairment of consciousness. The patient with glutethimide poisoning, for example, may show no evidence of any neurologic function yet can recover fully if vital functions are maintained. In contrast, the comatose patient with head trauma resulting in pontine hemorrhage and decerebrate rigidity may have a far worse prognosis. The probability of neurologic recovery generally declines with advancing age, size and location of the lesion, and duration of deficit. A number of studies have provided statistical guidelines that are of value in gauging the probability of recovery [9,10]. Guidelines for the evaluation of prognosis following cardiac arrest and resuscitation are particularly well documented, and the absence of pupillary and corneal reflexes or motor response to pain, the occurrence of myoclonic status epilepticus, absence of somatosensory evoked potentials (N20), and elevated neuron-specific enolase are particularly useful in early determination of poor prognosis (9).

Early in the course of coma, the physician should not be hasty in abandoning hope and vigorous medical efforts to maintain survival and to limit neurologic damage. Late in the course, or as poor prognostic signs accumulate, it is important to recognize the outer limits of possible recovery and to assess the value of continuing life support accordingly. The patient's wishes, expressed in a living will or durable power of attorney for health care and as interpreted by close, responsible family members ("substituted judgment"), should combine with the physician's prognostic judgment to help determine a medical course of action. Although management in the ICU usually entails the unstinting use of every available means of life support and treatment, there must eventually be a transition either to recovery or to a permanent state of dependence, and the nature and extent of continued treatment should be adjusted accordingly. The technical means of maintaining survival almost indefinitely by the use of extraordinary measures is now available. It is important for the physician and the patient's family to consider whether, in the case of a patient with irreversible and severe neurologic damage, they are extending life or prolonging the process of dying [11].

It is clear that neurologic problems abound in the ICU. A successful approach to these disorders requires the physician to recognize the nature of the clinical situation prompting neurologic consultation or admission to the ICU. An analysis of which of the nine types of neurologic clinical situations is being encountered often guides the physician initially in diagnosis and management. The following chapters discuss some of the more common neurologic problems encountered in the ICU, with specific attention to management in the ICU and a broader view of the neurologic conditions in general.

CHAPTER 169 ■ EVALUATING THE PATIENT WITH ALTERED CONSCIOUSNESS IN THE INTENSIVE CARE UNIT

RAPHAEL A. CARANDANG, LAWRENCE J. HAYWARD AND DAVID A. DRACHMAN

The spectrum of disease that leads to acute impairment of consciousness is broad; the disorders are varied and potentially life threatening and may be treatable if recognized early. The clinician evaluating the patient with an altered level of consciousness must do so in a systematic and efficient fashion. The approach consists of (a) rapidly determining the type of mental status change, (b) administering life support measures where urgently needed, (c) obtaining a detailed history and physical examination directed at determining more precisely the cause of the nervous system disorder, (d) selecting appropriate and informative diagnostic and laboratory studies, and (e) initiating more definitive treatment based on this assessment.

As a practical matter, *consciousness* refers to a state of awareness of self and environment that depends on intact arousal and content [1,2]. Arousal is the level of attentive wakefulness and readiness to respond to relevant sensory information. Alerting stimuli activate the ascending reticular activating system (ARAS), which extends from the superior pons to the thalamus and projects to multiple cortical areas. Diminished arousal implies dysfunction of either the ARAS or both cerebral hemispheres; lesions of the brainstem sparing the ARAS (e.g., of the medulla) or of only one hemisphere do not affect wakefulness. This chapter defines altered states of consciousness and presents a systematic approach to bedside evaluation and prognostication of the comatose patient.

ALTERED STATES OF CONSCIOUSNESS

Neurologists are frequently consulted for evaluation of patients who appear unconscious, confused, or awake and alert but noncommunicative.

Patient Who Appears Unconscious

Patients who appear unconscious lie mostly motionless, usually with the eyes closed and seemingly unaware of their environment. The causes of this condition include normal sleep, depressed consciousness, psychogenic coma, locked-in state, vegetative states, minimally conscious state, and brain death.

Sleep

The normal unconsciousness of sleep is characterized by prompt reversibility on threshold sensory stimulation, and maintenance of wakefulness following arousal. The degree of stimulation required depends on the stage of sleep (stage IV non–rapid eye movement sleep is the deepest) and the sensory stimulation used.

Depressed Consciousness

Consciousness is deemed depressed when suprathreshold sensory stimulation is required for arousal and wakefulness cannot be maintained unless the stimulation is continuous [1,2]. Responsible specific lesions involve the ARAS or both cerebral hemispheres; the former by brainstem damage, or compression due to masses situated in other compartments, and the latter by multifocal insults or unilateral lesions with associated major mass effect. In addition, a wide array of metabolic derangements, toxins, or diffuse injuries may depress consciousness by affecting the ARAS, the cerebral hemispheres, or both. The spectrum of depressed states—lethargy, hypersomnolence, obtundation, stupor, and coma—is defined by the level of consciousness observed on examination. The etiologies are diverse (Table 169.1), with the degree of depression dependent on the nature of the insult, its duration, and the location and extent of the brain injury.

The first signs of brain dysfunction may be mild and barely noticeable. The patient may be described initially as confused or drowsy before progressing to *lethargy* or *hypersomnolence* and eventually to a more depressed state. Hypersomnolent patients maintain arousal only with vigorous and continuous sensory stimulation; while awake, however, they may be oriented and make appropriate responses. The most common cause of hypersomnolence in the hospital is sleep deprivation, mostly iatrogenic, especially in the around-the-clock care setting of the intensive care unit (ICU). Patients with discrete diencephalic or midbrain tegmentum lesions may also present with hypersomnolence [3,4]. Because these lesions affect the ARAS and spare the cerebral hemispheres, cognitive content is usually preserved. Rostral extension of a midline lesion may involve thalamic structures (especially the dorsomedial nuclei) and cause difficulties with the ability to store new memories. Other mesencephalic structures may be affected and cause abnormalities of pupillary function, internuclear ophthalmoplegia, and third nerve dysfunction.

Obtunded patients usually can be aroused by light stimuli but are mentally dulled and unable to maintain wakefulness. *Stuporous* patients can be aroused only with vigorous noxious stimulation. While awake, neither obtunded nor stuporous patients demonstrate a normal content of consciousness, but both may display purposeful movements, attempting to ward off painful stimuli or to remove catheters, endotracheal tubes, or intravenous lines.

Patients in *coma* are unresponsive to suprathreshold sensory stimulation, including noxious stimulation that is strong enough to arouse a deeply sleeping patient but not strong enough to cause physical injury. Although the patient usually lies motionless, movements such as stereotyped, inappropriate postures (decerebration and decortication) and spinal cord reflexes (triple flexion and Babinski responses) may occur. Whatever the etiology, the duration of coma is typically no longer than 2 to 4 weeks, after which one of the three conditions supervenes: arousal to full or partial recovery, a vegetative state, or death.

Most of the literature on prognosis of comatose patients comes from nontraumatic coma, largely anoxic–ischemic brain injury. A landmark paper by Levy, Plum, and associates from 1981 established the neurological examination – particularly brainstem reflexes including pupillary, corneal, and oculocephalic reflexes – as important predictors of poor outcome in nontraumatic coma [5]. Multiple studies followed which confirmed the importance of motor responses in addition to brainstem examination, and some diagnostic tests were established as useful in predicting outcomes; these are well summarized in the American Academy of Neurology Practice Parameter by Wijdicks et al., published in 2006 [6]. Given the life-or-death responsibility of the physician providing a prognosis, only clinical indicators or diagnostic tests that are highly specific with a near zero false–positive rate are utilized. A poor outcome is predicted by the absence of pupillary and corneal reflexes, absent or extensor motor responses, absent responses to caloric testing of the oculovestibular reflex at day 3 post-arrest, and the presence of myoclonic status epilepticus on day 1 post-arrest. The absence of N20 responses on somatosensory evoked potential (SSEP) testing, and the finding of serum neuron-specific enolase levels more than 33 µg per L on days 1 to 3 post-arrest also indicate a poor prognosis (Fig. 169.1). Prognostication must include consideration of the etiology of the disease process, the clinical examination findings, and radiological evidence of damage to the upper pons, midbrain, diencephalon, and other vital structures for arousal.

TABLE 169.1

DIFFERENTIAL DIAGNOSIS OF DEPRESSED CONSCIOUSNESS

I. Depressed consciousness with lateralizing signs of brain disease: brain tumor, cerebral hemorrhage, cerebral thrombosis, cerebral embolism, contusion, subdural or epidural hemorrhage, brain abscess, hypertensive encephalopathy
II. Depressed consciousness with signs of meningeal irritation: meningitis, subarachnoid hemorrhage, leptomeningeal carcinoma, or lymphoma
III. Depressed consciousness without lateralizing or meningeal signs: alcohol, barbiturate, or opiate intoxication: carbon monoxide poisoning, neuroleptic malignant syndrome, anoxia, hyponatremia, hypoglycemia, diabetic coma, uremia, hepatic coma, hypercapnia, nonconvulsive status epilepticus, infectious encephalitis, acute hydrocephalus, concussion, diffuse axonal injury, hypothermia

Adapted from Adams RD, Victor M: *Principles of Neurology*. 4th ed. New York, McGraw-Hill, 1989.

Psychogenic Coma

Patients in psychogenic coma appear comatose but have clinical and laboratory evidence of wakefulness [1]. Psychogenic unresponsiveness may be suggested by active resistance or rapid closure of the eyelids, pupillary constriction to visual threat, fast phase of nystagmus (i.e., a saccade) on oculovestibular or optokinetic testing, and avoidance of self-injury (e.g., by averting an arm dropped toward the patient's face) or annoying stimulation such as a nasal tickle (moving head away from stimulus). Caloric testing with ice water irrigation of the ear will elicit a

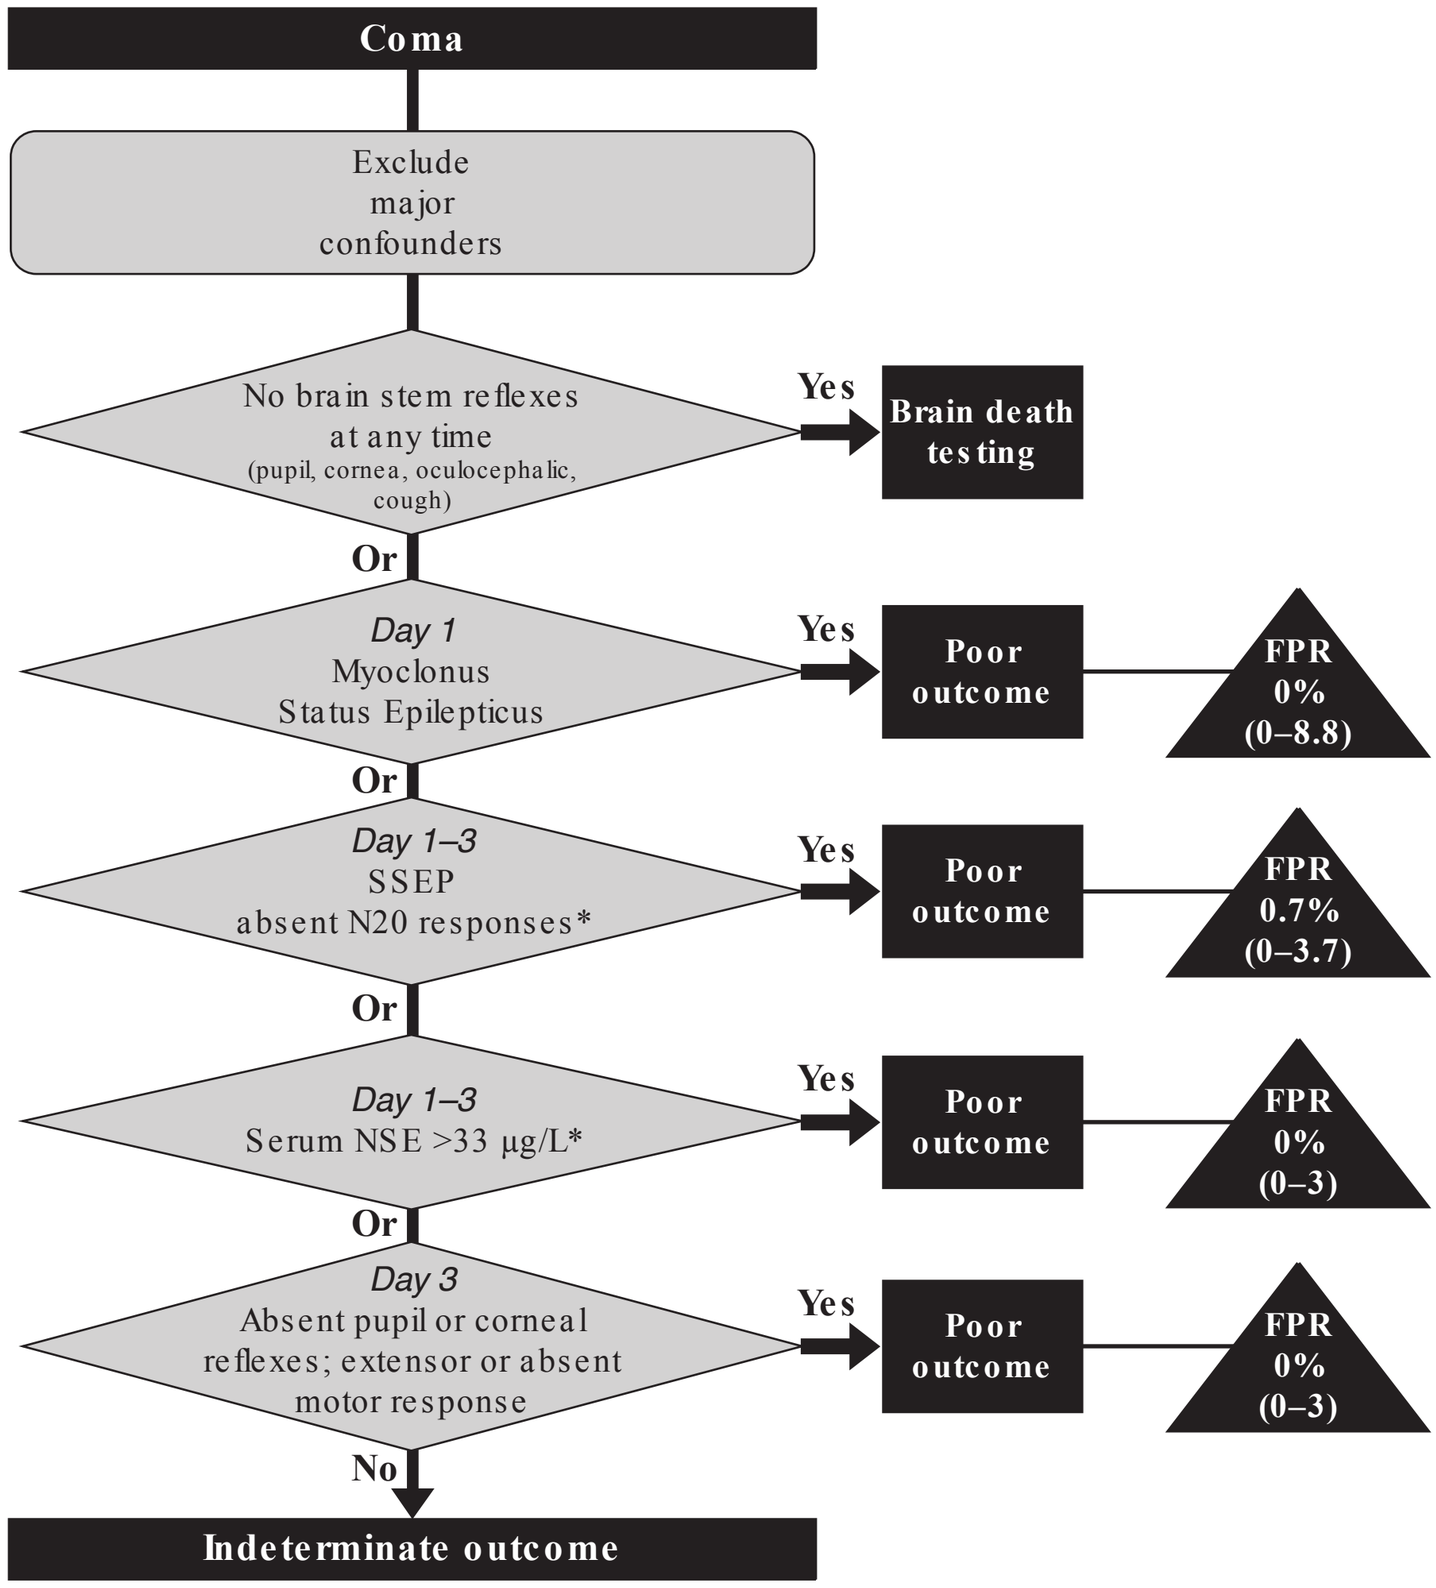

FIGURE 169.1. Algorithm for predicting outcome in comatose patients after cardiopulmonary arrest. FPR, false positive rate; NSE, neuron-specific enolase; SSEP, somatosensory evoked potential. [From Wijdicks EFM: The diagnosis of brain death. *N Engl J Med* 344:1215, 2001.]

normal nystagmoid response with the fast or corrective component directed away from the irrigated ear and possibly some nausea and vomiting. Deep tendon reflex examination is often normal but can be voluntarily suppressed. EEG alpha waves that attenuate with eye opening are inconsistent with coma or sleep. Most diagnostic tests will be unrevealing. Psychiatric conditions that may be associated with psychogenic coma are conversion reactions secondary to hysterical personality, severe depression, or acute situational reaction, catatonic schizophrenia, dissociative or fugue states, severe psychotic depression, and malingering.

Locked-in State

The locked-in state is a nearly total paralysis without loss of consciousness [7,8]. Because the most common cause of this state is destruction of the base of the pons, the patient is completely paralyzed except for muscles subserved by midbrain structures (i.e., vertical eye movements and blinking). Consciousness is preserved because the ARAS is located in the tegmentum of the pons, dorsal to the damaged area. The most frequent cause is cerebrovascular such as cerebral infarction from a basilar thromboembolism or pontine hemorrhage from uncontrolled hypertension; less frequent etiologies of the syndrome are acute polyneuropathy (Guillain-Barré syndrome), acute poliomyelitis, toxins that block transmission at the neuromuscular junction, and myasthenia gravis. It is important to note that locked-in patients are capable of hearing, seeing, and feeling external stimuli and pain. Adequate analgesia and anxiolysis should be provided despite the absence of external signs of pain and anxiety. A 5- to 10-year survival has been reported in as high as 80% of patients in some series and a surprising 58% of patients surveyed reported satisfaction with life despite their disability in a small case series [8].

Brain Death

The term *brain death* refers to a determination of physical death by brain-based, rather than cardiopulmonary-based, criteria [9]. Brain death is the irreversible destruction of the brain, with the resulting total absence of all cortical and brainstem function, although spinal cord reflexes may remain [10,11]. It is not to be confused with severe but incomplete brain damage with a poor prognosis or with a vegetative state, conditions in which some function of vital brain centers still remains. In brain death, support of other organs is futile for the patient, whereas when there is some residual brain or brainstem function, or a vegetative state, decisions regarding ongoing life support clearly depend on the wishes of the patient or his or her proxy.

In brain death, pupils are mid-position and round (not oval), and apnea persists even when arterial carbon dioxide tension (PCO_2) is raised to levels that should stimulate respiration. Table 169.2 summarizes the guidelines used in the United States. Brain death may be simulated by drug intoxications and cannot be evaluated when toxic drugs are present; depending on preserved renal and hepatic function most such toxic

TABLE 169.2

CRITERIA FOR BRAIN DEATH

Prerequisites
1. Clinical or neuroimaging evidence of an acute CNS catastrophe compatible with the clinical diagnosis of brain death
2. Exclusion of complicating medical conditions that may confound clinical assessment (no severe electrolyte, acid–base, or endocrine disturbance)
3. No drug intoxication or poisoning
4. Core temperature = 32°C (90°F)

1. Cerebral functions are absent.
   Coma, and absence of motor responses including decerebrate posturing, although spinal reflexes may be seen
2. Brainstem functions are absent.
   Absence of pupillary responses to light; pupils at mid-position and dilated
   Absent corneal reflexes, caloric reflexes, gag reflex, cough in response to tracheal suctioning, sucking and rooting reflexes
   Absence of respiratory drive at $PaCO_2$ 60 mm Hg, or 20 mm Hg above normal base-line values
   Interval between two separate examinations varies depending on the age of the patient if pediatric, but for adults is usually at least 6 hours
3. Ancillary Diagnostic tests:
   EEG showing electrocerebral silence
   Technetium Tc 99m hexametazime nuclear scan showing absence of activity in brain
   Cerebral angiography showing absence of blood flow in cerebral vessels
   Transcranial Doppler showing lack of diastolic or reverberating flow and small systolic peaks in early systole

Revised table from AAN Practice Guidelines. A Report of the Quality Standards Subcommittee of the American Academy of Neurology 1994; and Wijdicks EFM: The diagnosis of brain death. *N Engl J Med* 344:1215, 2001.

effects do not persist longer than 36 hours. Hypothermia also precludes a diagnosis of brain death, and the patient must be brought to normal temperature prior to declaring death. Brain death is a clinical diagnosis, but ancillary tests such as an EEG and blood flow studies (transcranial Doppler, technetium-99 m scan, or conventional cerebral angiography) may be useful where the clinical examination is compromised by sedating medications. Unresponsiveness that can mimic brain death may occur with extensive brainstem destruction, for example, after basilar artery thrombosis. Despite absent brainstem reflexes, continued cortical activity on the EEG and persistent cerebral blood flow would demonstrate that the patient is not brain dead.

The American Academy of Neurology has published practice parameters for the determination of brain death. The criteria take into account etiology, performance of two separate clinical examinations 6 hours apart, and include the method of apnea testing with preoxygenation and oxygen [11]. Since criteria for brain death vary from state to state, and procedures to determine brain death differ among institutions, it is important to be familiar with the guidelines in your institution [12]. The occurrence of brain death provides the opportunity for organ donation, and most institutions have a protocol that includes informing organ bank organizations to facilitate this.

Patient Who Appears Confused

Confusion is a general term used for patients who do not think with customary speed, clarity, or coherence. The causes of this condition include an acute confusional state, dementia, inapparent seizures, and receptive aphasia.

Acute Confusional State

When the cerebral hemispheres are insulted by toxic, metabolic, anoxic, structural, or infectious processes, the patient may appear acutely confused [13,14]. Poor arousal and an abnormal content of consciousness may contribute to the clinical presentation, and the etiologies are legion (Table 169.3). Patients with clouded consciousness are easily distracted or startled by environmental stimuli. Their processing of information is slow and effortful, arousal fluctuates from drowsiness to hyperexcitability, and poor attention span impairs recall and recent memory. If sensorial clouding becomes more advanced, sensory input is increasingly misinterpreted, daytime drowsiness alternates with nocturnal agitation, disorientation for place and time becomes apparent, and repeated prompting is required for a response to even the simplest commands.

Delirious patients typically manifest acutely fluctuating confusion, with psychomotor overactivity, agitation, autonomic instability, and often visual hallucinations. Clinical observations frequently suggest that the disturbance of cognition or perception is directly related to a potentially reversible general medical condition rather than to an evolving dementia. Hyperexcitability may alternate with periods of drowsiness or relative lucidity. Signs of autonomic overactivity include pupillary dilatation, diaphoresis, tachycardia, and hypertension. Patients with delirium may not sleep, sometimes for periods of several days; the success of treatment can be judged by the development of normal sleep. Delirium tremens, the most serious consequence of ethanol withdrawal, is perhaps the best-known example of this state. Because the routine Mini-Mental State Examination often cannot be administered to unstable, intubated patients, alternative screening tools have been developed for early detection and monitoring of delirium in the ICU [15,16]. Validated tools such as the Confusion Assessment Method, or CAM-ICU scale, have the advantage of being simple and easy to administer, highly reliable and applicable in patients who are intubated. Systematic screening may help detect early delirium and allow prompt, cost-effective treatment. Delirium has been linked to prolonged ICU stay and ventilator days, and is associated with postdischarge cognitive dysfunction and worse 6-month mortality outcomes [16,17]. The use of interventions that reduce delirium in the ICU include reduction and intermittent use of sedatives, or spontaneous awakening trials, as well as sedation with alpha adrenergic medications such as dexmedetomidine [18,19].

In beclouded dementia, confusion is superimposed on an underlying subacute or chronic cognitive disorder. The preexisting cerebral dysfunction may be mental retardation, dementia, or the deficits from a vascular, neoplastic, or demyelinative process. In some cases, the underlying disorder is not diagnosed until the confusion appears during an intercurrent illness (e.g., sepsis or infection, congestive heart failure, surgical procedures, anemia, drug overdose, or intolerance).

Dementia

Patients with dementia have subacute or chronic intellectual dysfunction unaccompanied by a reduction in arousal [20]. The patient exhibits a decline in multiple cognitive functions, including memory, language, spatial orientation, personality, abstract thinking, and insight. The ability to carry out testing requires relative preservation of attention and language

TABLE 169.3

CLASSIFICATION OF ACUTE CONFUSIONAL STATES

ACS not associated with focal or lateralizing neurologic signs and normal CSF
- Metabolic disorders
  - Hepatic encephalopathy
  - Uremia
  - Hypercapnia
  - Hypoglycemia
  - Diabetic ketotic coma
  - Porphyria
  - Hypercalcemia
- Infectious disorders
  - Septicemia[a]
  - Pneumonia[a]
  - Typhoid fever[a]
  - Rheumatic fever[a]
- Drug intoxication
  - Opiates
  - Barbiturates
  - Tricyclic antidepressants
  - Other sedatives
  - Amphetamines[a]
  - Anticholinergic medications[a]
- Abstinence states (i.e., withdrawal states)
  - Alcohol (delirium tremens)[a]
  - Barbiturates[a]
  - Benzodiazepines[a]
- States that reduce cerebral blood flow or oxygen content
  - Hypoxic encephalopathy
  - Congestive heart failure
  - Cardiac arrhythmias
- Situational psychoses (diagnoses)
  - Postoperative psychosis[a]
  - Posttraumatic psychosis[a]
  - Puerperal psychosis[a]
  - Intensive care unit psychosis[a]

ACS associated with focal or lateralizing neurologic signs and/or abnormal CSF
- Cerebrovascular disease or space-occupying lesions (especially of the right parietal, inferofrontal, and temporal lobes)
  - Ischemic infarct[a]
  - Neoplasm[a]
  - Abscess[a]
  - Hemorrhage (intraparenchymal, subdural, epidural)[a]
  - Granuloma
- Infectious disorders
  - Meningitis[a]
  - Encephalitis[a]
- Subarachnoid hemorrhage[a]
- Cerebral contusion and laceration[a]

ACS sometimes associated with focal or lateralizing neurologic signs
- Postconvulsive delirium[a]
- Acute hydrocephalus
- Nonconvulsive status epilepticus
- Nonketotic diabetic coma

[a]These disorders may be associated with signs of psychomotor overactivity or delirium.
ACS, acute confusional state; CSF, cerebrospinal fluid.

comprehension. The causes of dementia include degenerative processes (Alzheimer's disease, Pick's disease, Huntington's disease), metabolic and nutritional disorders (hypothyroidism, pellagra, vitamin B_{12} deficiency), infectious diseases (subacute spongiform encephalopathy, acquired immunodeficiency syndrome dementia, neurosyphilis, chronic meningitis, progressive multifocal leukoencephalopathy), cerebrovascular disorders (multi-infarct dementia, anoxia-ischemia), hydrocephalus with normal or increased intracranial pressure, and toxins.

Inapparent Seizures

Patients with nonconvulsive status epilepticus may appear disoriented, episodically unresponsive, or alternately lucid and confused; the EEG shows continuous or frequent epileptiform discharges [21,22]. Careful observation may alert the clinician to seizure phenomena, such as episodic staring, eye deviation or nystagmoid jerks, facial or hand clonic activity, and automatisms. The syndrome may be the result of a generalized (absence) status or a complex partial status. Complex partial status is the more common form seen in the ICU and may not be preceded by a history of complex partial seizures. The origin of the abnormal focal discharge may be from the temporal, frontal, or occipital lobes, and the EEG pattern during the ictus is variable. Inapparent seizures may occur in as many as 19% of all patients in the ICU, and 56% of patients who are comatose at the time of the monitoring. The yield of EEG monitoring is increased by continuous monitoring for 24 hours [23]. Nonconvulsive status epilepticus should be considered, and is the cause of otherwise unexplained coma in as many as 8% of patients [24]. A benzodiazepine, such as diazepam or lorazepam, may eliminate the discharge and improve the patient's confusion.

Receptive Aphasia

Patients with receptive aphasia often appear confused because they have a disorder of language comprehension [14]. The patient is awake and alert but unable to comprehend written or verbal commands despite voluminous (fluent) spontaneous speech. Paraphasias may be present (especially when the patient is asked to name objects) and consist of either inappropriately substituted words or nonsensical jargon. The responsible lesions are located in the dominant temporoparietal cortex and are often associated with subtle focal neurologic signs, including mild pronator drift of the right hand, right homonymous hemianopsia or superior quadrantanopsia, and right-sided sensory loss; gross hemiparesis is usually not found, as the frontal motor cortex is not affected.

Patient Who Appears Awake and Alert but Noncommunicative

Although sensory stimulation may arouse these patients, they seem unable or unwilling to speak. The causes of this condition include mutism, akinetic mutism, and the persistent vegetative state.

Mutism

Mutism is a manifestation of many clinical conditions, including aphonia, anarthria, oral-lingual apraxia, and aphasia. Only in aphasia, however, is written expression also impaired (i.e., agraphia).

Aphonia due to paralysis of the vocal cords and anarthria due to paralysis of the articulatory muscles are usually evident clinically in patients who are unable to make sounds but who mouth words appropriately. Oral-lingual (facial) apraxia is a disorder of learned mouth movements (e.g., speaking,

blowing kisses, sucking through a straw, protruding the tongue to command) seen with isolated and discrete lesions involving the facial area of the dominant motor cortex [14,25].

Patients with expressive aphasia are unable to communicate normally by verbal or written language [1,13,14]. Nonfluent (Broca's) aphasia with diminished "telegraphic" output is usually intensely frustrating to the patient; occasionally, singing his or her words, rather than merely saying them, improves speech. Lesion location differs depending on whether comprehension is also affected or whether comprehension and repetition of words are relatively preserved or lost. At the least, the dominant frontal cortex is involved, and some degree of right hemiparesis is usually present.

Akinetic Mutism

Patients with akinetic mutism appear alert and exhibit sleep–wake cycles, but they show little evidence of cognitive function and do not meaningfully interact with the environment [1,14]. Brainstem function is intact, and patients may open their eyes to verbal stimuli or track moving objects. They have a paucity of movement even to noxious stimulation, despite little evidence of corticospinal or corticobulbar damage. Akinetic mutism is associated with large bilateral lesions of the basomedial frontal lobes, small lesions of the paramedian reticular formation in the posterior diencephalon and midbrain, and subacute communicating hydrocephalus.

Persistent Vegetative State

Patients in a persistent vegetative state are also akinetic and mute but lack outward manifestations of any significant brain activity other than reflex responses [1,14]. These may include decerebrate or decorticate posturing, deep tendon reflexes, Babinski or triple flexion reflexes, yawning, and so on. The term is usually reserved for the patient who has recovered only to this extent from coma due to a severe anoxic, metabolic, or traumatic brain injury, and has been in this condition for over a month. Neuropathologic findings in anoxic encephalopathy may include cortical pseudolaminar necrosis, cerebellar Purkinje cell loss, and necrosis of hippocampal cortex but relative sparing of brainstem structures [26]. Persistent vegetative state is considered permanent if the patient has been in this state for 3 months after nontraumatic or anoxic brain injury, and more than 12 months after traumatic brain injury [27].

Minimally Conscious State

These are patients who, similar to those in the vegetative state, have severely impaired consciousness, also manifest the posturing, reflexes, and diurnal cycles, but in addition show evidence of self and environmental awareness. They may follow simple commands, give gestural yes or no responses, verbalize intelligibly, and do other purposeful behaviors and visual tracking [1,13,14]. This is considered to be a transitional phase of recovery from coma after PVS, and patients with traumatic brain injury who are in a minimally conscious state have significantly better outcomes at 1 year than PVS patients. Many publicized reports of late recoveries from vegetative states were actually patients in MCS.

BEDSIDE EVALUATION OF THE COMATOSE PATIENT

Coma in the ICU is a medical emergency. The goal of each evaluation is to identify and treat promptly (if applicable) the cause of the comatose state; even if no definitive treatment is available, general medical and neurologic support is necessary. A neurologic consultation should be obtained early; the practice of obtaining imaging studies before a careful and systematic examination is often counterproductive when it delays focused evaluation and treatment. The proper approach requires (a) immediate administration of life-support measures, (b) completion of a general physical examination, (c) performance and interpretation of the neurologic examination, (d) selection of ancillary tests, and (e) institution of definitive treatment, based on the above observations.

Initial Measures

As in all emergencies, vital signs, respiration, and circulation are first stabilized and monitored; the comatose patient often requires an endotracheal tube for respiratory support and airway protection. A large-bore intravenous line is started, and the blood is drawn for a complete blood cell count, glucose, electrolytes (including Ca^{2+}), blood urea nitrogen, creatinine, liver transaminases, and a toxicology screen. Arterial blood is obtained for determination of oxygen tension, PCO_2, and pH. If there is any doubt about the etiology of coma, 100 mg thiamine, 50 g glucose, and 0.4 mg naloxone are administered intravenously.

General Physical Examination

In addition to the usual complete examination, several points warrant special attention [1,2,13]. Severe hypothermia (rectal temperature less than or equal to 32°C or 89.6°F) may cause coma (as in elderly patients exposed to the cold) or provide clues to other etiologies (e.g., overwhelming sepsis, drug or alcohol intoxication, hypothyroidism, hypoglycemia, Wernicke's encephalopathy) [28]. Severe hyperthermia may result from intracranial causes, including infection and anterior hypothalamic or pontine destruction. Meningeal signs (e.g., nuchal rigidity) may be absent in deeply comatose patients, even in the presence of overwhelming bacterial meningitis. This sign should never be sought if cervical spine fracture or dislocation is suspected.

The skin should be thoroughly inspected for signs of trauma. Basilar skull fractures may be signaled by blood behind the ear (Battle's sign), cerebrospinal fluid rhinorrhea, or otorrhea. Orbital fractures may cause bleeding into periorbital tissues ("raccoon eyes").

The breath odor may suggest metabolic derangement or intoxication. The spoiled fruit odor of diabetic coma, the uriniferous odor of uremia, and the musty fetor of hepatic encephalopathy sometimes can be recognized. Although the odor of alcohol is usually noted, its presence does not rule out superimposed structural causes of coma (e.g., subdural hematoma), and its absence does not rule out intoxication with odorless spirits (e.g., vodka).

Respiratory patterns in comatose patients are distinctive [1,13,14]. Bilateral hemispheric or diencephalic disturbances as well as systemic disorders may lead to periodic breathing in which increasing and then decreasing breaths (crescendo–decrescendo) alternate with apnea (Cheyne-Stokes respirations). Lesions of the midbrain-pontine tegmentum may give rise to tachypnea and a respiratory alkalosis unresponsive to oxygen (central neurogenic hyperventilation), but this is much less common than hyperpnea due to low oxygen tension, metabolic acidosis, or a primary respiratory alkalosis (e.g., salicylate poisoning). Lesions of the inferior pons may be associated with 2- to 3-second pauses following full inspiration (apneustic breathing). Compressive or intrinsic lesions of the medulla may cause chaotic breathing of varying rate and depth (Biot's breathing). Complete brainstem destruction results in apnea that is unresponsive to elevated PCO_2.

Neurologic Examination

The goal of the neurologic examination in the comatose patient is to determine the location of the lesion (ARAS or bilateral cerebral hemispheres) and its etiology (structural, causing destruction or compression of brain substance; toxic, metabolic, anoxic, or traumatic, affecting the nervous system in a diffuse or multifocal manner; subarachnoid blood or infection; or nonconvulsive status epilepticus). A critical part of this determination is the medical history, and heroic efforts to locate family members, witnesses, and medication lists are almost always rewarded. For example, truly sudden coma in a healthy person suggests drug intoxication, intracranial hemorrhage, meningoencephalitis, or an unwitnessed seizure.

Often an intubated patient with altered mental status will be on pharmacological sedation or anxiolysis for management of respiration, or safety in agitated or combative patients. Neurological examination should be performed after discontinuing any sedating medication that may alter the patient's responsiveness and significantly alter the examination findings.

Neurologic assessment must include a description of the level of consciousness, examination of the pupils, direct ophthalmoscopy, observation of spontaneous and induced ocular movements, elicitation of the corneal reflex, and tests of motor system function (including spontaneous and induced limb movements and asymmetries of tone), deep tendon reflexes, pathologic reflexes, and response to sensory stimulation—often pain. The importance of repeat examinations to document the temporal course of the patient's condition cannot be overemphasized.

Level of Consciousness

The level of consciousness is determined first by observing the patient undisturbed for several minutes. Any spontaneous (e.g., yawning, sneezing) or responsive (e.g., to ventilator noise) movements or postures are noted. A battery of graduated sensory stimuli is applied (whispered names, shouted names, loud noise, visual threat, noxious stimulation by supraorbital compression, vibrissal (nasal) stimulation, sternal rub, nail bed compression, or medial thigh pinch) and the response recorded (e.g., opens eyes, squeezes eyes shut, blinks symmetrically to visual threat, nods, turns head, groans, grimaces, purposefully withdraws, displays stereotyped posturing). Such careful documentation allows serial assessments of subtle changes over time by multiple examiners.

Serial documentation and accurate and reliable communication of findings can be facilitated by the use of standardized scales such as the Glasgow coma scale. While originally intended for use in traumatic brain injury, the Glasgow coma scale has become widely used and has been found to be predictive of outcomes, particularly in traumatic brain injury (Table 169.4). Because of its limitations, a more comprehensive coma scale called the Full Outline of Unresponsiveness, or FOUR score, incorporates brainstem reflexes and respiration [1,13,14,29]. These grading scales are helpful to standardize assessment, improve communication and serial monitoring, but are limited and cannot be substituted for a detailed bedside neurological examination.

Pupils

The pupils are examined for size, equality, and reactivity to light. Normal pupils confirm the integrity of a circuit involving the retina, optic nerve, midbrain, third cranial nerve, and pupillary constrictors. A strong flashlight and magnifying glass, or an ophthalmoscope, are usually necessary, and darkening the room is helpful.

TABLE 169.4

COMA GRADING SCALES

Glasgow Coma Scale

Eye response
- 4 = eyes open spontaneously
- 3 = eye opening to verbal command
- 2 = eye opening to pain
- 1 = no eye opening

Motor response
- 6 = obeys commands
- 5 = localizing pain
- 4 = withdrawal from pain
- 3 = flexion response
- 2 = extension response
- 1 = no motor response

Verbal response
- 5 = oriented
- 4 = confused
- 3 = inappropriate words
- 2 = incomprehensible words
- 1 = no verbal response

FOUR score

Eye response
- 4 = eyelids open or opened, tracking, or blinking to command
- 3 = eyelids open but not tracking
- 2 = eyelids closed but open to loud voice
- 1 = eyelids closed but open to pain
- 0 = eyelids remained closed with pain

Motor response
- 4 = thumbs up, fist or peace sign
- 3 = localizing to pain
- 2 = flexion response to pain
- 1 = extension response to pain
- 0 = no response to pain or generalized myoclonus

Brainstem reflexes
- 4 = pupils and corneals intact
- 3 = one pupil wide and fixed
- 2 = pupil or corneal absent
- 1 = pupil and corneal absent
- 0 = absent pupil, corneal and cough reflex

Respiration
- 4 = not intubated, regular breathing pattern
- 3 = not intubated, Cheyne-Stokes breathing
- 2 = not intubated, irregular breathing
- 1 = breathes above ventilator rate
- 0 = breathes at ventilator rate or apnea

Symmetrically small, light-reactive pupils (miosis) are normally seen in elderly and sleeping patients. Opiates, organophosphates, pilocarpine, phenothiazines, and barbiturates produce small pupils that may appear to be unreactive to light, whereas a large lesion of the pons (i.e., hemorrhage) characteristically produces tiny pinpoint pupils. Symmetrically large pupils (mydriasis) that do not react to light suggest midbrain damage, but they may also be seen following resuscitation when atropine has been used (in this case, the pupils do not constrict to 1% pilocarpine) [30], in cases of anoxia, following pressor doses of dopamine [31], and often in amphetamine or cocaine intoxication. Bilaterally fixed and midposition pupils indicate absent midbrain function, although severe hypothermia [28], hypotension, or intoxication with succinylcholine [32] or glutethimide [33] must be ruled out.

Pupillary asymmetry (anisocoria) suggests neurologic dysfunction if it is of recent onset, the inequality is more than

1 mm, and the degree of anisocoria changes with ambient lighting [34]. When the larger pupil is sluggishly reactive or fixed to light (but the contralateral consensual response is spared), uncal herniation due to an ipsilateral hemispheric mass compressing the third cranial nerve against the petroclinoid ligament must be considered. Unilateral pupillary dilatation may also indicate a mass in the cavernous sinus, aneurysm of the posterior communicating artery, focal seizure, or topical atropine-like drugs (e.g., used for ophthalmoscopic examination). On the other hand, with Horner's syndrome the affected pupil is smaller. In this condition, the pupillary asymmetry is increased in darkness and the smaller pupil is associated with partial ptosis of the upper eyelid, straightening of the lower eyelid, and facial anhidrosis. It may be caused by damage to descending sympathetic fibers anywhere from the hypothalamus to the upper thoracic cord, or to ascending sympathetic fibers in the cervical sympathetic chain, the superior cervical ganglion, the carotid artery, or the cavernous sinus.

Direct Ophthalmoscopy

Direct ophthalmoscopy may be limited by miosis or cataracts, but the pupils should never be pharmacologically dilated without clear documentation (with a large sign taped to the patient's bed), or if the patient's condition is uncertain or unstable. Obscuration of the disk margins, absent venous pulsations, and flame-shaped hemorrhages suggest early papilledema from an intracranial mass or systemic hypertension [35]. Subhyaloid and vitreous hemorrhages may be observed in the patient with subarachnoid hemorrhage or suddenly increased intracranial pressure.

Ocular Movements

Assessment of ocular movements begins by observing for tonic deviation of the eyes at rest [1]. The eyes may deviate toward the side of a lesion in the motor cortex (a gaze preference—away from the hemiparetic limbs) but usually can be induced to cross the midline. The eyes deviate away from the side of a pontine lesion (toward the hemiparetic limbs) and cannot be moved across the midline (a gaze paralysis). A seizure focus in the frontal (area 8) or supplementary motor (area 6) cortex can drive the eyes or cause nystagmoid jerks contralaterally (toward the side of the convulsing limbs) [36]. Tonic upward eye deviation may be seen after anoxia [37], and tonic downward deviation may be seen in thalamic hemorrhage, midbrain compression, and hepatic encephalopathy.

Spontaneous eye movements may have a localizing value. Roving eye movements (slow and random, usually conjugate and horizontal) and periodic alternating ("Ping-Pong") gaze (cyclic, conjugate excursions to the extremes of lateral gaze every 2 to 3 seconds) [38] are found in patients with intact brainstem function. Ocular bobbing consists of a rapid conjugate downward jerk followed by a slow upward drift (rate and rhythm are variable) and suggests a lesion in the posterior fossa, especially if horizontal eye movements are impaired [39]. The reverse movement, ocular dipping (slow downward, fast upward) can be seen after anoxia and in status epilepticus [40]. Conjugate spasmodic eye movements, rotating the eyes upward for minutes or longer (oculogyric crisis), in some patients may be an untoward effect of neuroleptic medications.

If spontaneous eye movements are absent or restricted to a particular direction, reflex movements should be tested by oculocephalic ("doll's eyes") and oculovestibular (caloric) stimulation [1,17,18,41]. Full eye movements induced by these maneuvers confirm the integrity of the brainstem tegmentum from the medullary-pontine junction to the midbrain. Oculocephalic testing is never done in patients with suspected cervical spine fracture or dislocation. The maneuver is performed by holding the patient's eyelids open and briskly rotating the head from one side to the other (for horizontal eye movements) and from flexion to extension (for vertical eye movements). In comatose patients with an intact brainstem, the eyes deviate to the side opposite the direction of head movement. If the oculocephalic response is not obtained or the movements are limited or asymmetric, the oculovestibular reflex should be tested. This is never done until the tympanic membrane is examined and seen to be intact. The patient's head is elevated to 30 degrees above horizontal, and up to 120 mL ice water is instilled slowly in the external auditory meatus with a large syringe and attached Teflon catheter. Each ear is tested separately for horizontal eye movements, with a 5-minute interval between right and left ears. In awake patients (or those in psychogenic coma), nystagmus with the fast phase away from the irrigated ear is induced. In comatose patients with an intact brainstem, a tonic conjugate eye deviation toward the irrigated ear is seen; a defective response implies brainstem damage. Vertical eye movements can be induced by irrigating both ears simultaneously with cold water (eyes deviate downward) and with warm (44°C) water (eyes deviate upward). Absent or deranged responses can be caused, in addition to various brainstem lesions, by previous vestibular (labyrinthine end-organ) lesions, vestibulosuppressant drugs (e.g., benzodiazepines, antihistamines, anticholinergics), hepatic encephalopathy, and neuromuscular blockers (e.g., succinylcholine). An ophthalmoplegia after intravenous phenytoin is well known [42].

Corneal Reflex

The corneal reflex is obtained by lightly touching the limbus of the cornea with a fine material (wisp of cotton, rolled corner of tissue paper, or a squirt of saline). Both eyes should blink to unilateral stimulation, confirming the integrity of a circuit involving the fifth cranial nerve, trigeminal sensory and facial motor nuclei in the pons, and both seventh cranial nerves. A blunted corneal response is commonly seen in chronic contact lens wearers. An absent blink on the stimulated side with an intact contralateral (consensual) response indicates ipsilateral motor damage.

Motor System

The examination of the motor system identifies whether limb movements are appropriate and purposeful or inappropriate and stereotyped. Left–right asymmetries or worsening of the motor response over time must be carefully noted. Appropriate movements include spontaneous turning in bed, drawing up the sheets, crossing the legs modestly, or rapid withdrawal (especially abduction) from noxious stimulation. Inappropriate movements include spontaneous or induced flexion–internal rotation of the arms with extension of the legs (decorticate posturing) or extension-adduction of all limbs (decerebrate posturing); whether flexor or extensor postures are induced depends partly on the position of the limbs [43]. These responses may occur occasionally in toxic-metabolic coma [44,45] but are more common with anatomic brainstem lesions. Facial grimaces or groans despite absent motor responses suggest that sensory pathways are grossly intact. Flexion of the leg at the hip, knee, and ankle (triple flexion response) is a spinally mediated exaggerated Babinski reflex that may persist in brain death.

Other spontaneous movements of the limbs and trunk have been observed in brain dead patients and are all forms of spinal reflexes, including myokymia, trunk flexion and the Lazarus sign, wherein the patient actually extends and pronates his or her arms forward and then crosses them over the chest [1,17,18,46]. These signs are easily misinterpreted by family members as well as medical practitioners who are not versed in the neurological examination.

INTERPRETATION OF THE NEUROLOGIC EXAMINATION

In general, focal neurologic signs suggest a structural cause of coma. Nevertheless, focal weakness is not unknown in hypoglycemia, hyperglycemia, hyponatremia, hyperkalemia, and rarely hepatic and uremic encephalopathies [47,48]; and continuous focal motor seizures (epilepsia partialis continua) may be a presenting sign of the hyperglycemic nonketotic hyperosmolar state [49]. Focal signs due to preexisting deficits may deceive even the ablest clinician. For example, if generalized seizures from a new metabolic imbalance develop in a patient with an old hemiplegia due to a cerebral infarction, apparently focal convulsions of the nonplegic limbs might falsely suggest a structural lesion of the intact cerebral hemisphere contralateral to the previously infarcted one. Other false localizing signs include sixth nerve palsies (due to transmitted increased intracranial pressure), visual field cuts (due to compression of the posterior cerebral artery), and hemiparesis ipsilateral to a third nerve palsy (due to compression of the contralateral cerebral peduncle against the tentorium [Kernohan's notch]).

Conversely, a nonfocal examination does not invariably indicate toxic-metabolic coma. Symmetric neurologic dysfunction may be caused by meningoencephalitis, subarachnoid hemorrhage, bilateral subdural hematomas, or thrombosis of the superior sagittal sinus. Multifocal seizures, myoclonus, asterixis, or fluctuation of the examination suggests a toxic or metabolic etiology, although periodic increases in intracranial pressure (plateau waves) and nonconvulsive seizures may lead to a waxing and waning mental status.

A preserved pupillary light reflex even in deep coma with absent oculovestibular and motor responses suggests a toxic or metabolic etiology. It is important to note that the pupils may be unreactive to light in severe hypothermia, deep barbiturate coma (the patient is usually apneic and hypotensive if the pupils are fixed), and glutethimide overdose. In addition, an expanding posterior fossa mass (e.g., cerebellar hemorrhage) may present with early signs of pontine compression and small, light-reactive pupils [50].

A useful rule is that toxic-metabolic coma usually has incomplete but symmetric dysfunction of neural systems affecting many levels of the neuraxis simultaneously while retaining the integrity of other functions at the same levels. Structural coma is characterized by regionally restricted anatomic defects [1,13,14]. For example, toxic-metabolic coma might present with intact pupillary reactivity and corneal reflexes but an absence of horizontal (pontine) and vertical (midbrain) reflex eye movements to oculovestibular testing. Such a presentation would be inconsistent with coma from a structural cause.

ANCILLARY TESTS

A computed tomographic (CT) scan without contrast infusion can reliably demonstrate intracranial bleeding such as intraparenchymal, epidural or subdural hematoma, or intraventricular hemorrhage. CT scans reveal hydrocephalus and may show anoxic–ischemic brain injury, with loss of grey–white differentiation, border-zone infarction from hypoperfusion, and diffuse cerebral edema (Fig. 169.2). Other coma-inducing lesions shown by CT scan include massive middle cerebral infarction, uncal herniation, and midline shift from large mass lesions with cerebral edema. Contrast enhancement may be required for suspected infectious or neoplastic masses. The CT scan does not reliably rule out inflammation, infection, subarachnoid blood, or early ischemia. CT angiography can be helpful in showing large vessel occlusion or dissection but has limited sensitivity and specificity. A CT scan can be considered the initial brain imaging study in patients with coma if lesions that require emergent surgical intervention, such as acute cerebellar hemorrhage, are considered [1,13,14].

Magnetic resonance imaging or MRI is clearly superior to CT scan in resolution, and special sequences are highly sensitive to acute ischemia and encephalitis. MRI is superior for anatomical detail and can produce excellent images of the posterior fossa, brainstem, and craniocervical junction. Diffusion weighted MRI studies, and particularly whole brain median apparent diffusion coefficient (ADC) imaging, is useful in assessing prognosis following anoxic/ischemic coma [51,52]. While it is not always logistically possible to perform MRI imaging on patients in the ICU, whenever possible it provides important information.

The cerebrospinal fluid must be examined if meningoencephalitis is suspected or if subarachnoid blood is not visualized on the CT scan. Occasionally, a sterile cerebrospinal fluid

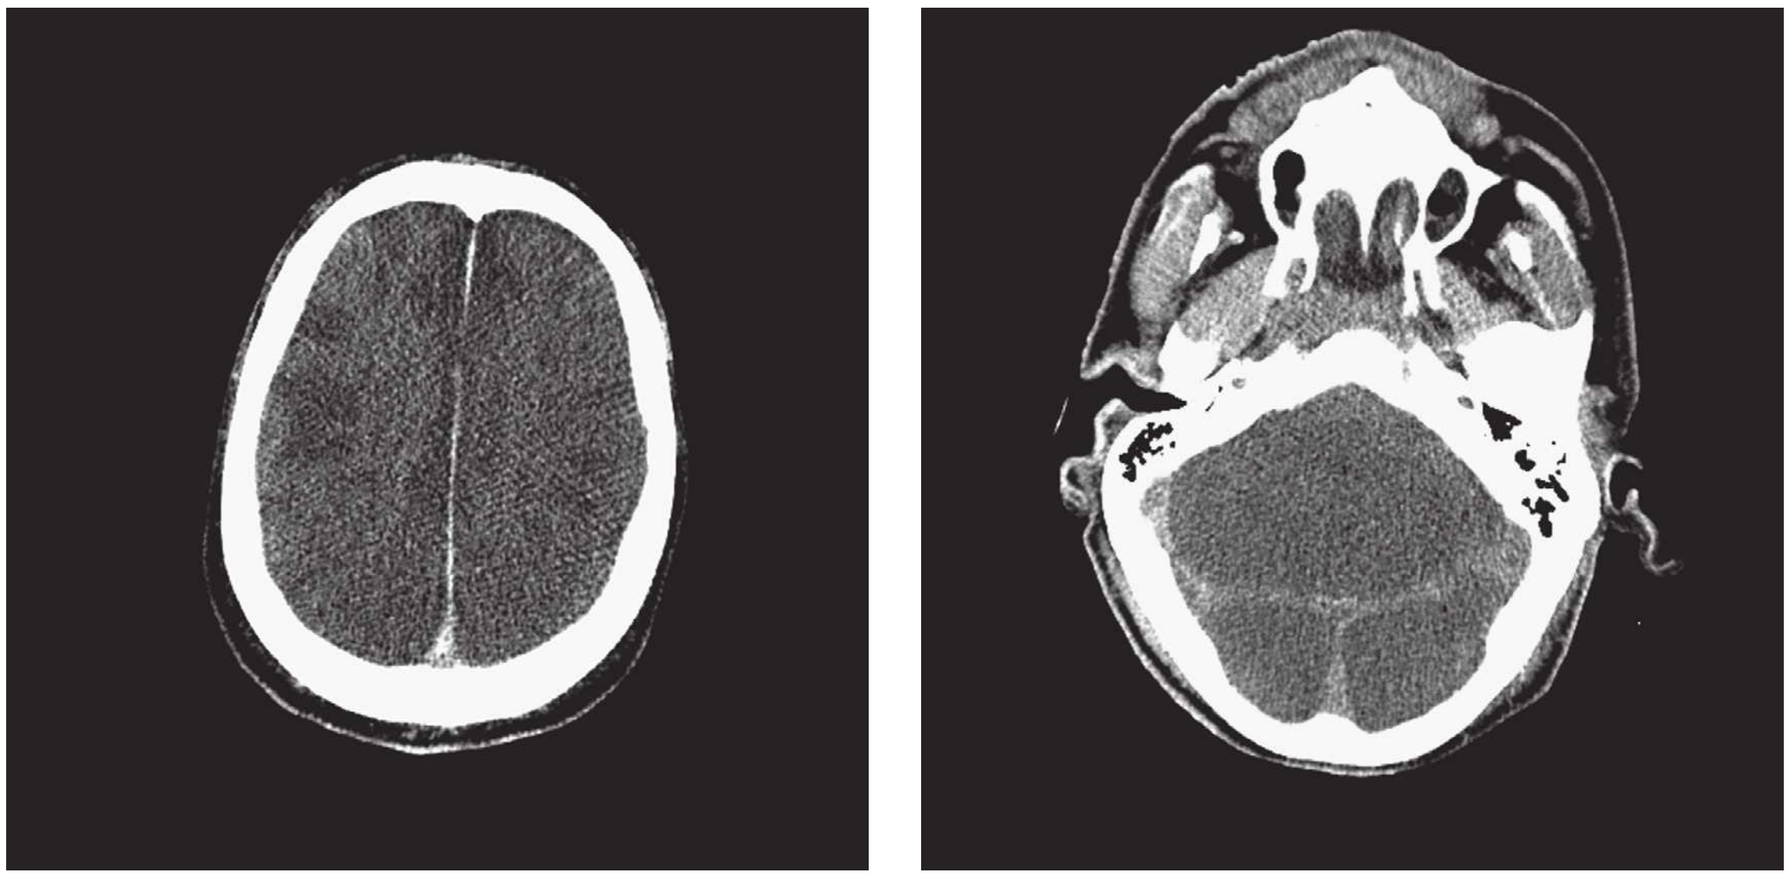

FIGURE 169.2. Noncontrast CT scan of patient with anoxic brain injury. Diffuse cerebral edema with loss of grey–white differentiation, obliteration of basal cisterns, multiple areas of hypodensity suggestive of anoxic–ischemic injury, and venous stasis with hyperdensity of the venous sinuses. This patient was brain dead clinically and by apnea testing.

pleocytosis follows status epilepticus [53]. The cerebrospinal fluid sent for protein 14–3-3 may also be useful for the diagnosis of Creutzfeldt-Jakob disease (CJD). Cytology and vascular endothelial growth factor (VEGF) levels can confirm the diagnosis of carcinomatous meningitis; and antibodies can be evaluated in paraneoplastic syndromes such as limbic encephalitis.

EEG provides a physiologic marker of brain function and may be helpful in nonconvulsive status epilepticus and psychogenic coma, and for documenting (but not primarily establishing) brain death by the presence of electrocerebral silence. In unresponsive patients, somatosensory or brainstem auditory evoked potentials may be very useful in evaluating the integrity of spinal, brainstem, or cortical pathways and, compared to EEG, are much less susceptible to drug effects and hypothermia. SSEPs are useful in prognostication of recovery from anoxic/ischemic coma during the first few days after cardiac arrest.

INITIATION OF EMERGENCY TREATMENT

Definitive treatment of altered consciousness depends on the underlying pathophysiologic process, but urgent therapeutic interventions may be required in life-threatening conditions or to prevent further central nervous system insult. Meticulous nursing care (fluid replacement, oxygenation and prevention of aspiration, nutrition, corneal protection, and conscientious skin, bowel, and bladder care) is essential. *Unnecessary sedation should be avoided*—it obscures evaluation of the patient's state of consciousness and makes assessment of any changes in the sensorium or cognition inaccessible to testing.

Recent and ongoing clinical trials are continuing to validate acute therapies that may protect the brain after insults such as cardiac arrest, traumatic brain injury, and stroke. For example, the induction of mild hypothermia (33°C for 12 to 24 hours) in comatose survivors of cardiac arrest improved the neurologic outcome in two randomized clinical trials [54,55]. Based on these studies, the American Heart Association and the International Liaison Committee on Resuscitation advised therapeutic mild hypothermia for unconscious victims of cardiac arrest [56]. Hypothermia appeared ineffective as an acute treatment for traumatic brain injury in one large randomized controlled trial [57] but may have been related to the delay in achieving goal temperature, duration of cooling, as well as other factors. A recent systematic review of 12 Randomized Controlled Trials that pooled 1,069 patients concluded that clinical mortality and outcome benefit may be derived from cooling patients with traumatic brain injury to a temperature of 32°C to 33°C for 48 hours and slowly rewarming them 24 hours after discontinuation of therapy [58]. A multicenter randomized clinical trial of early induced hypothermia for severe traumatic brain injury for 48 hours failed to show benefit but was terminated prematurely and was confounded by intracranial hypertension during rewarming [59]. There is a suggestion that hypothermia may benefit patients with acute stroke or refractory elevated intracranial pressure, but larger clinical trials are needed. Although prolonged or moderate hypothermia (28°C to 32°C) can be associated with complications of cardiac arrhythmia, coagulopathy, or infection, brief mild hypothermia appears relatively safe and effective [60,61]. If patients sustaining a neurologic insult are hypothermic upon admission to the ICU, it may be prudent to avoid aggressively warming them to normothermic levels. The benefit from mild hypothermia likely involves more complex biochemical mechanisms distinct from a simple reduction of oxygenation requirements. The deleterious effects of fever in brain injury are well documented in the laboratory and clinical outcome studies in a variety of diseases [62]. No large studies have prospectively addressed the effects of induced normothermia on outcomes. Comparison of endovascular and standard normothermia protocols to achieve a temperature of 36.5°C found no increase of adverse events, but was underpowered to show any benefit on neurologic outcome [63]. Further study in a larger sample of patients is warranted, and the development of protocols to control fever or induce normothermia is expected to benefit these patients.

CONCLUSION

Altered consciousness is common in patients in the ICU. A systematic and efficient approach is required to determine the location of the responsible lesion(s) or the cause(s) of impaired consciousness, both to allow institution of definitive therapies and to assess the prognosis accurately.

CHAPTER 170 ■ METABOLIC ENCEPHALOPATHY

PAULA D. RAVIN

Metabolic encephalopathy is a general term used to describe any process that affects global cortical function by altering the biochemical function of the brain. It is the most common cause of altered mental status in the intensive care unit (ICU) setting, either medical or surgical, and is also one of the most treatable. Early recognition of metabolic encephalopathy, therefore, is critical to the management of the ICU patient. The patients who are most at risk for development of a metabolic encephalopathy are those with single or multiple organ failure, the elderly (> 60 years of age), those receiving multiple drugs with central nervous system (CNS) toxicity, and those with severe nutritional deficiencies such as cancer patients and alcoholics. Other risk factors include infection, temperature dysregulation (hypothermia or fever), chronic degenerative neurologic or psychiatric diseases such as dementia or schizophrenia, and endocrine disorders. Metabolic encephalopathy is always suspected when there is an altered cognitive status in the absence of focal neurologic signs or an obvious anatomic lesion such as an acute cerebrovascular accident or head injury. A patient may progress over days from intermittent agitation into depressed consciousness or quickly into coma without any antecedent signs (e.g., with hypoglycemia). In mild cases, it is easily mistaken for fatigue or psychogenic depression, whereas more severe cases may develop into coma and are life-threatening.

The altered mental status observed can start as mild confusion with intermittent disorientation to person, time, or place and difficulty attending to questions or tasks at hand. Delirium is a further change toward heightened arousal alternating with somnolence, often worse at night and fluctuating throughout the day. Finally, progression to lethargy, a state of sleepiness in which the person is difficult to arouse by vigorous stimulation, can lead into stupor or coma as impaired consciousness ensues.

TABLE 170.1

PATIENT PROFILE IN METABOLIC ENCEPHALOPATHY

Gradual onset over hours
Progressive if untreated
Waxing and waning level of consciousness
Patient treated with multiple CNS-acting drugs
Patient with organ failure, postoperative state, electrolyte disturbance, endocrine disease
No evidence of brain tumor or stroke on neurologic examination—usually nonfocal (except hypoglycemia)
Sometimes heralded by seizures—focal or generalized
Increased spontaneous motor activity—restlessness, asterixis, myoclonus, tremors, rigidity, and so forth
Abnormal blood chemistries, blood gases, anemia
Usually normal CNS imaging studies
Generalized electroencephalographic abnormalities—slowing, triphasic waves
Gradual recovery once treatment is initiated

CNS, central nervous system.

This sequence of events is often punctuated by focal or generalized tonic-clonic seizures and postictal somnolence as part of the overall clinical picture (Table 170.1).

Disorders that can be confused with metabolic encephalopathy include brain tumors, encephalitis, meningitis, closed head trauma, and brainstem cerebrovascular events. Brain tumors are usually recognizable because they produce focal neurologic deficits such as hemiplegia or hemianopsia, as do traumatic lesions of the brain and cortical strokes. Hypoglycemia can also present focally and is discussed further in the section on Hypoglycemic Encephalopathy. Brainstem stroke due to thrombosis of the basilar artery can be deceptive because there may be a gradual progression of signs and symptoms over several hours rather than a sudden presentation. Table 170.2 outlines some of the cardinal differences between brainstem stroke and metabolic encephalopathy.

EVALUATION

Clinical Examination

Initial observation of the patient's level of arousal, posture in bed, breathing pattern, vital signs, and behavioral fluctuations is highly suggestive of a metabolic disturbance in many cases. Waxing and waning levels of activity are the hallmark of metabolic encephalopathy and may occur over hours to days.

TABLE 170.3

EVALUATION FOR METABOLIC ENCEPHALOPATHY

Neurologic examination
Mental status
Pupillary responses
Oculomotor responses
Respiratory pattern
Motor activity, strength
Deep tendon reflexes, plantar responses
Initial laboratory tests
Blood sugar, electrolytes, lactate dehydrogenase, serum glutamic oxaloacetic transaminase, serum glutamic pyruvic transaminase, ammonia, blood urea nitrogen, creatinine, white blood cell count/differential, hemoglobin, hematocrit, blood gases
Electroencephalography
Neuroimaging
Head computed tomography or magnetic resonance imaging
± Lumbar puncture, toxicity screens, serum and urine osmolality, psychiatric examination

Often signs of sympathetic overactivity (tachycardia, elevated blood pressure, tremulousness) and abnormal sleep patterns or "sun-downing" are present.

Mild *behavioral changes* are the earliest manifestations, such as lack of attentiveness to surroundings or a paucity of spontaneous speech, which may give the patient an apathetic or withdrawn appearance. The Mini-Mental State Examination easily reveals mild confusion and can be used to grade the patient's level of cognitive performance sequentially [1]. When there is impaired consciousness, however, this test is unreliable.

The *cranial nerve examination* is focused on pupillary responses, oculomotor function, and respiratory patterns (Table 170.3). As a rule, pupils are small, symmetric, and responsive to light in metabolic causes of obtundation or coma. Noteworthy exceptions to this are anticholinergic poisoning (e.g., atropine, scopolamine), which produces dilated sluggish pupils, and glutethimide (Doriden) poisoning, which results in mid- to large-sized sluggish or fixed pupils [2]. Ocular movements are usually unaffected initially, with eyes in midline position or slightly deviated outward and upward at rest (Bell's phenomenon). Doll's eye maneuvers produce conjugate deviation of the eyes opposite to the direction of head rotation. As the level of brainstem suppression progresses to coma, these responses may disappear completely, especially with an overdose of sedative drugs. In the face of hyperpnea and decerebrate

TABLE 170.2

SIGNS AND SYMPTOMS OF BRAINSTEM CEREBROVASCULAR ACCIDENT (CVA) AND METABOLIC ENCEPHALOPATHY

	Brainstem CVA	Metabolic encephalopathy
Patient profile	Known vascular disease	Organ failure
	Hypercoagulable state	Subacute onset(> 8 h) except in hypoglycemia
	Acute onset (< 8 h), usually > 50 y	Any age, often > 60 y
Motor involvement	Hemiplegic or paraplegic	Moving all limbs except for hypoglycemia
Sensory involvement	Unilateral facial sensory change, or hemianesthesia	No sensory symptoms
Mental status	Obtunded or agitated	Waxing and waning
Pupils	May have Horner's; may have fixed, dilated pupil	Small, normoactive
Eye movements	Disconjugate, skew deviation, cr N. III, IV, VI paresis	Conjugate, midline
Respirations	Apneustic, central hyperpnea, ataxic	Normal, hyperpneic + brief apnea

rigidity, the preservation of doll's eyes is a useful sign pointing to a metabolic, rather than anatomic, cause of coma.

Changes in the respiratory pattern are the next most important findings for the diagnosis of metabolic encephalopathy, also providing a clue as to its etiology. In the mildly confused patient, breathing may be normal, but lethargic or mildly obtunded patients tend to hyperventilate, with brief spells of apnea. This is due to transient lowering of the partial pressure of carbon dioxide (PCO_2) below 15 mm Hg without the appropriate CNS drive to breathe more rapidly at a lower tidal volume. After 12 to 30 seconds of apnea, the cycle of hyperventilation appears again, resulting in a pattern of "periodic respirations" [3]. Hypoventilation is usually seen with depressant drug overdoses, chronic pulmonary failure, and metabolic alkalosis of any cause. Cheyne-Stokes respiration, a rhythmic cycle of waxing and waning hyperpnea/apnea, is another pattern that is occasionally seen in metabolic encephalopathy caused by uremia or hypoxia, but more commonly this indicates bilateral structural lesions of the cortex. Other neurogenic respiratory patterns, such as constant or "central" neurogenic hyperventilation, cluster breathing, and ataxic breathing, are signs of brainstem dysfunction due to structural damage or suppression by barbiturates. These changes are seen only when the patient is stuporous or comatose.

Abnormal motor activity is characteristic of many metabolic encephalopathies and is quite varied in appearance; tremors, myoclonus, asterixis, rigidity, and choreoathetosis may be seen. Tremors are rhythmic, involuntary oscillatory movements seen in all limbs and often exaggerated during voluntary movement. Tremors occur most often in early hypoglycemic encephalopathy, thyrotoxicosis, acute uremia, chronic dialysis encephalopathy, hypercapnia, and drug intoxication, especially with sympathomimetic agents.

Myoclonus is multifocal, appearing as brief shock-like contractions of large muscle groups. Synchronous myoclonic jerks in all limbs can be seen in any patient who is slipping in and out of a drowsy sleep—also known as *sleep-onset myoclonus*. This is often seen in patients who are receiving large doses of narcotics. Multifocal myoclonus, in contrast, is seen in hypoxic–ischemic encephalopathy, chronic hepatic failure of all types, uremia, pulmonary failure, and intoxication with methaqualone and psychedelic agents [4].

Asterixis is a flapping movement produced by unsustained muscle contraction against gravity. Rhythmic extension and flexion of the outstretched limb is present, which disappears at rest. The most common setting for this is in hepatic encephalopathy of any cause, frequently with flapping of the hands, feet, jaw, and tongue. Subacute uremia and pulmonary failure produce asterixis accompanied by myoclonus, which presents a picture of almost constant muscular jerking movements.

Rigidity or generalized muscle spasms are states of constant muscle contraction that are seen when the degree of metabolic encephalopathy is more severe and leads to stupor or coma. This can be the result of end-stage hepatic failure, hypoglycemia (< 25 mg glucose per dL) lasting more than a few minutes, acute renal failure, hyperthermia, and hypothermia below 92°F rectally. Rigidity with dystonic posturing is a clue to amphetamine or phenothiazine poisoning. Choreoathetosis, on the other hand, occurs in chronic hepatic failure, subacute bacterial endocarditis, post-hypoxic insult, Reye's syndrome, chronic dialysis, chronic hypoglycemia, and chronic hyperparathyroidism, appearing as a nonpatterned sequence of twisting or dance-like limb movements.

The *reflex examination* often reveals diffuse hyperreflexia, symmetric except in limbs that were previously affected by a structural lesion. Plantar responses, also known as the Babinski reflex, are typically extensor in both feet and can be elicited easily. In contrast, the sensory examination is usually not affected, but is unreliable if the patient is agitated or obtunded. Response to pinprick, painful pinch/pressure, or a cold stimulus on the limbs is the most useful in demonstrating a grossly intact sensory arc.

Abnormal autonomic responses in metabolic encephalopathy may demand intervention and can cause significant morbidity and mortality. Hypotension, unresponsive to volume expansion, points to intoxication with barbiturates or opiates, myxedema, or Addisonian crisis. In this setting, occult sepsis must always be ruled out before treating for specific metabolic derangements. Fever and leukocytosis may be absent in very debilitated patients. Examination of urine, blood cell counts and coagulation factors, blood and sputum cultures, chest x-ray, and a lumbar puncture are essential to rule out infection. If there remains any doubt about the cause of hypotension, empiric antibiotics, naloxone hydrochloride (Narcan) for possible opiate overdose, intravenous (IV) glucose (1 ampoule), and pressor agents should be added to other supportive measures acutely while the cause is being investigated.

Seizures are another significant symptom of metabolic encephalopathy, especially in uremia, hypoglycemia, pancreatic failure, and various types of metabolic acidosis (e.g., ethylene glycol, salicylates, and so forth). They occur most often at the onset of the metabolic disturbance, for example, as the blood urea nitrogen (BUN) is climbing acutely, and as a preterminal expression of severe neuronal injury in a comatose patient. Management of the seizures is typically ineffective until the underlying cause is corrected. In renal failure, however, one third to half of the standard loading doses of phenytoin or phenobarbital may be all that is needed to control seizures. The interictal electroencephalogram (EEG) serves as a guideline to the need for continued treatment once the encephalopathy has cleared or has become chronic and stable. A persistent focus of epileptiform activity warrants further investigation and anticonvulsant therapy.

The *laboratory investigation* of patients with delirium or coma is crucial in defining the cause of a metabolic encephalopathy. Blood tests for glucose, electrolytes, and blood gases should be drawn immediately along with a panel of hepatic function tests [ratio of serum alanine aminotransferase to serum aspartate aminotransferase, lactate dehydrogenase, ammonium ion (NH_4^+)], BUN, and creatinine. Serum and urine osmolality, cerebrospinal fluid (CSF) analysis, serum magnesium and phosphate levels, and specific hormone levels may be needed to define the cause of encephalopathy further. Careful review of all medications taken before and during hospitalization may direct attention to toxicology screens of blood and urine. The general toxicology screen should be sensitive to opiates, benzodiazepines, caffeine and salicylates, theophylline, barbiturates, and alcohol. Additional drug levels should be ordered if their use is known or suspected (e.g., digoxin, cocaine, phenytoin, and so forth). If there has been a sudden change in mental status, a bolus of 25 g glucose should be administered intravenously without hesitation to avoid prolonged hypoglycemia.

In general, the EEG in metabolic encephalopathy is abnormal; background slowing is the most common pattern found (< 9 Hz) [5]. Other patterns can also be useful in identifying or corroborating the cause of the encephalopathy. Slow activity that is prominent frontally, with deep triphasic waves (in the 2- to 4-Hz range), is characteristic of hepatic encephalopathy but can be seen in renal failure too [6]. This has also been reported in levetiracetam toxicity [7], hyperammonemic states due to gastroplasty [8] and ureterosigmoidostomy [9], and rare metabolic disorders such as ornithine transcarbamylase deficiency [10]. Spreading of the slow activity toward the occipital leads is a sign of deepening coma in this setting. Bursts of high-voltage activity amidst normal background frequencies are also a sign of diffuse metabolic disturbance. More importantly, the EEG in a patient with an acute encephalopathy of unknown cause may reveal subclinical (electrical) status epilepticus,

warranting urgent and aggressive anticonvulsant treatment. This is particularly common in the case of alcoholics and diabetics, who are at risk for multiple CNS insults.

Neuroimaging [computed tomography (CT) or magnetic resonance imaging (MRI)] scans are often crucial in situations in which there is rapid deterioration of mental status without focal signs or an obvious metabolic cause such as hypoglycemia. Most mass lesions, such as subdural hematomas or brain tumors, are evidenced clinically by a rostrocaudal progression of neurologic signs. The initial picture may be nonfocal with obtundation, but this is followed sequentially by flexor or extensor posturing on one or both sides and then the loss of pupillary or caloric responses. Later, medullary respiratory patterns or bradycardia appear. A noncontrast head CT or MRI is definitive in many cases but does not always distinguish a brainstem stroke. Early consultation by a neurologist is crucial, especially when the cause of impaired consciousness is not clearly due to a metabolic disorder. Transient changes in vascular permeability associated with Wernicke's encephalopathy can manifest as vasogenic edema in the brainstem periaqueductal and fourth ventricular areas along with contrast enhancement of the mammillary bodies [11].

Lumbar puncture is also indicated when there is a rapid onset of encephalopathy, especially with a fever, headache, or meningismus. Occult subarachnoid hemorrhage, infection, or elevated intracranial pressure may be found in the absence of funduscopic changes or clear-cut clinical history. Ideally, the lumbar puncture should be performed atraumatically with a small (22-gauge) spinal needle and a simultaneous sample of serum obtained to compare glucose and protein levels in the blood and CSF.

ETIOLOGY

Hepatic Failure

The clinical onset of *hepatic encephalopathy* may be subtle, with a blunting of affect and lethargy, or dramatic in 10% to 20%, with mania or an agitated delirium [12]. It is easy to recognize hepatic encephalopathy in an individual with the obvious stigmata of chronic liver disease, such as ascites, varices, or jaundice. In those without apparent liver disease, the mental changes may only appear after an additional metabolic demand on the liver. Such stressors are a high-protein meal, gastrointestinal bleeding with increased blood absorption from the gut, or hepatically metabolized drugs [13]. Sedatives and acetazolamide are particularly offensive in this situation.

Asterixis is the next most common clinical sign, appearing in all limbs, the jaw, and the tongue. As the patient progresses into a coma, it may be replaced by muscle spasticity and decorticate or decerebrate posturing to stimulation. The Babinski responses are present (extensor plantar reflexes), and gaze-evoked ocular movements are variable at this stage; pupillary responses are always preserved. Oculocephalic and vestibulo-ocular (caloric) responses remain until the patient is moribund. Hyperventilation is another consistent sign of hepatic encephalopathy and results in respiratory alkalosis. The ocular, pupillary, and respiratory patterns above help to distinguish severe hepatic encephalopathy from space-occupying lesions of the cortex and brainstem.

The pathophysiology of hepatic coma is not certain, but it is thought to be caused by portacaval shunting of neurotoxic substances. These putative toxins include excess ammonia, large molecules normally excluded by the blood–brain barrier [14], increased water, and the "false" neurotransmitter octopamine [15]. Hypoglycemia, as a result of decreased glycogen stores in the liver, may complicate the CNS picture.

The serum transaminases are usually elevated two- to threefold, and serum ammonia is at least in the high normal range once the patient is lethargic—with a linear correlation thereafter between higher laboratory values and lower cognitive state. The CSF remains normal until the serum bilirubin exceeds approximately 5 mg per dL, which tints the fluid yellow. The EEG characteristically shows progressive slowing from the frontal to the occipital leads as coma deepens. Triphasic waves are seen in most cases but are not pathognomonic.

Therapy for hepatic encephalopathy is directed toward decreasing the amount of toxic substances that are being shunted to the brain. Neomycin and lactulose help to sterilize and flush the gut. A protein-restricted diet and the exclusion of hepatically cleared drugs decrease the metabolic load, and IV glucose effectively maintains the serum glucose level. Neurologic recovery then depends on the capacity of the liver to regenerate at least 25% of its full function. With prolonged or repeated bouts of hepatic coma, there may be persistent, irreversible signs of basal ganglia dysfunction evidenced by chorea, postural tremors, or a parkinsonian picture (acquired hepatocerebral degeneration) [16].

Reye's Syndrome

Reye's syndrome is a unique and quite morbid form of acute hepatic encephalopathy seen in children, usually between ages 1 and 10 years. It occurs in the clinical setting of an acute viral infection, for example, chickenpox or influenza A or B, plus aspirin therapy [17]. Approximately 4 to 7 days after the viral symptoms start, the child becomes irritable, with vomiting and sometimes with headache or blurred vision. An agitated delirium, combativeness, and progressive obtundation rapidly ensue over hours, followed by hyperventilation, pupillary dilatation, and generalized seizures. Later in the course decerebrate rigidity, Babinski responses, and papilledema may develop as well.

The pathology of Reye's syndrome includes infiltration of the liver and other visceral organs with small fat droplets and diffuse cerebral edema. In cases that are complicated by severe hypoglycemia and seizures, anoxic damage with laminar necrosis of the cerebral cortex is also found. The cause of these changes is presumed to be mitochondrial poisoning, but the pathogenic agent has not yet been identified. Acetylsalicylic acid has consistently been implicated in this cellular damage. This has led to the standard practice of prescribing acetaminophen instead of aspirin for viral symptoms in children, thereby reducing the incidence of Reye's syndrome [18].

The differential diagnosis relies on measurement of liver function and a high index of suspicion in the appropriate setting. The serum transaminases rise three- to fivefold in the first 48 hours, and the serum ammonia is dramatically increased, sometimes into the 200 μmol per L range. Hypoglycemia is also an early sign, aggravating the lactic acidosis and respiratory alkalosis that are seen later in the course.

Treatment for Reye's syndrome is directed toward diminishing the cerebral edema, controlling seizures, and providing adequate electrolytes and glucose for support while the liver is effectively shut down with respect to oxidative metabolism. This is best achieved in an ICU with a standard protocol for Reye's disease using intracranial pressure monitoring and mannitol or glycerol for reduction of intracranial pressure [19].

The prognosis in recent years has improved markedly; mortality and morbidity are now 10% to 20%, as opposed to 40% to 50% two decades ago. Factors that contribute to a poor outcome are age less than 1 year, serum ammonia levels more than five times normal at their peak, and a prothrombin time more than 20 seconds. Other negative prognostic indicators are renal failure and a very rapid progression of liver failure

in the first 48 hours. Early intervention is the key to a good outcome neurologically and systemically.

Renal Failure

Uremic encephalopathy may develop acutely, be superimposed on chronic renal insufficiency, or occur as a consequence of chronic dialysis. It is often a complication of systemic diseases that independently affect the kidneys and the CNS such as collagen-vascular disease, malignant hypertension, drug overdoses, diabetes, or bacterial sepsis. The clinical picture is initially variable and does not correlate directly with measures of renal failure such as BUN and creatinine.

The first sign of encephalopathy in uremia is delirium or a decrease in level of consciousness; hyperventilation and increased motor activity follow as the patient becomes obtunded. Also, there is a high frequency of generalized convulsions at the outset and a metabolic acidosis with low serum bicarbonate. The motor component is prominent in many patients with multifocal myoclonus, hypertonus or asterixis, and tremors, together producing a picture of "twitch-convulsif"—as if the patient had fasciculations [20]. Oculomotor function and pupillary responses are normal, but deep tendon reflexes may be asymmetric, and focal weakness often occurs, with shifting hemiparesis during a single period of encephalopathy. The variability of focal motor signs helps to rule out a structural lesion but does not obviate the need to look for multifocal seizures in a patient with overt twitching and depressed consciousness.

Studies of the effect of uremia on neuronal function have not been able to demonstrate a direct correlation between the cognitive state and levels of BUN or with any other biochemical or electrolyte markers. The EEG, although becoming slower with higher levels of BUN, also does not correlate with mental status changes, especially in chronic uremia [21]. Hence, the pathophysiology of uremic encephalopathy is not known.

The major diagnostic differential to consider is between a hypertensive crisis and uremic encephalopathy, because malignant hypertension often leads rapidly to renal failure and neurologic signs. Evidence of papilledema, retinal vasospasm, and cortical blindness or aphasia, with a diastolic blood pressure of more than 120 mm Hg, argues strongly for a hypertensive crisis. In contrast, a sudden rise of BUN alone is most consistent with uremic encephalopathy.

Two variants of this disorder are seen in patients on peritoneal dialysis or hemodialysis. The *acute dialysis dysequilibrium syndrome* is seen in children more often than in adults undergoing hemodialysis with large exchanges of dialysate. A sudden shift of solutes out of the vascular compartment produces a hyperosmolar state in the brain and subsequent water resorption intracerebrally. This results in water intoxication, with florid encephalopathy within 30 to 60 minutes. Slower dialysis obviates the problem in general [22].

Dialysis dementia is insidious by comparison and is evidenced by post-dialysis lethargy, asterixis, myoclonus, dysphasia, and progressive loss of cognitive abilities over years. This disorder has been linked to increased amounts of aluminum in the dialysate augmented by aluminum-containing antacids in the diet [23]. Although the brains of patients with this disorder do not contain excess aluminum compared to those of other dialysis patients, elimination of aluminum from these sources helps reverse the symptoms in the early stages. This syndrome is now relatively rare.

Pulmonary Failure

A combination of *hypoxemia* and *hypercarbia* can produce typical changes of a metabolic encephalopathy in patients with underlying pulmonary failure. Individuals with chronic obstructive pulmonary disease, for example, tolerate a PCO_2 of 50 to 60 mm Hg without mental status changes. However, a sudden increase of PCO_2 of up to 65 to 70 mm Hg due to hypoventilation, or impaired oxygen exchange, can lead to lethargy, headaches, and a rise in intracranial pressure. Associated signs are papilledema or retinal vein congestion, extensor Babinski signs, asterixis, myoclonus, and, often, generalized tremors. Seizures are rarely seen, and pupillary and oculomotor functions are preserved unless there is a concomitant hypoxic–ischemic insult [24].

This course of events may be precipitated by systemic infection with fatigue of ventilatory muscles, paralysis of these muscles by neuromuscular disease or Guillain-Barré syndrome, and sedative drugs with their depressant effect on the medullary respiratory center. In the well-compensated hypercarbic individual, oxygen therapy may be counterproductive by decreasing respiratory drive from the medulla. Rapid correction of hypercarbia by artificial ventilation, on the other hand, exacerbates the compensatory chronic metabolic alkalosis that these patients have, possibly resulting in a further depression of mental status plus seizures [25].

The critical factor in the development of pulmonary encephalopathy is a rapid increase in serum PCO_2. This may be complicated by the presence of sedatives, hypoxemia, cardiac failure, and renal hypoperfusion. Treatment is directed toward slow correction of hypercarbia while maintaining an adequate PO_2 and good cerebral blood flow. Prognosis for full neurologic recovery is good if the patient is not subjected to cerebral ischemia as well.
