Vital sign assessments are most accurate if the newborn is at rest, so measure pulse and respirations first if the baby is quiet. To soothe a crying baby, try placing a pacifier or your moistened gloved finger in the baby's mouth, and then complete your assessment while the baby suckles.

Neck

A short neck, creased with skin folds, is characteristic of the normal newborn. Because muscle tone is not well developed, the neck cannot support the full weight of the head, which rotates freely. The head lags considerably when the newborn is pulled up from a supine to a sitting position, but the prone newborn is able to raise the head slightly. The neck is palpated for masses and presence of lymph nodes and is inspected for webbing. Adequate range of motion and neck muscle function is determined by fully extending the head in all directions. Injury to the sternocleidomastoid muscle (congenital torticollis) must be considered in the presence of neck rigidity.

The clavicles are evaluated for evidence of fractures, which occasionally occur during difficult births or in newborns with broad shoulders. The normal clavicle is straight. If fractured, a lump and a grating sensation (crepitus) during movements may be palpated along the course of the side of the break. The Moro reflex (see pages 809 and 810) is also elicited to evaluate bilateral equal movement of the arms. If the clavicle is fractured, this response will be demonstrated only on the unaffected side.

Chest

The thorax is cylindric and symmetric at birth, and the ribs are flexible. The general appearance of the chest should be assessed. A protrusion at the lower end of the sternum, called the xiphoid cartilage, is frequently seen. It is under the skin and will become less apparent after several weeks as the infant accumulates adipose tissue.

Figure 30-33 ■ Breast hypertrophy.

Source: Reprinted from Korones, S. B. (1986), "High-risk newborn infants", 3rd edition. St. Louis: Mosby-Year-Book Medical Publishers, Inc.

Engorged breasts occur frequently in both male and female newborns. This condition, which appears by the third day, is a result of maternal hormonal influences and may last up to 2 weeks (Figure 30-33 ■). A whitish secretion from the nipples may also be noted. The infant's breast should not be massaged or squeezed because this practice may cause a breast abscess. Extra nipples or supernumerary nipples are occasionally noted below and medial to the true nipples. These harmless pink or brown (in darker skinned newborns) spots vary in size and do not contain glandular tissue. Accessory nipples can be differentiated from a pigmented nevus (mole) by placing the fingertips alongside the accessory nipple and pulling the adjacent tissue laterally. The accessory nipple will appear dimpled.

Cry

The newborn's cry should be strong, lusty, and of medium pitch. A high-pitched, shrill cry is abnormal and may indicate neurologic disorders or hypoglycemia. Periods of crying vary in length after consoling measures are used. A baby's cries are an important method of communication and alert caregivers to changes in the baby's condition and needs (see chapter 29 ∞).

Respiration

Normal breathing for a term newborn is 30 to 60 respirations per minute and predominantly diaphragmatic, with associated rising and falling of the abdomen during inspiration and expiration. Any signs of respiratory distress, nasal flaring, intercostal or xiphoid retractions, expiratory grunting or sighing,

seesaw respirations, or tachypnea (sustained or greater than 60 respirations per minute) should be noted. Hyperexpansion (chest appears high) or hypoexpansion (chest appears low) of the anteroposterior diameter of the chest should also be noted. Both the anterior and posterior chest are auscultated. Some breath sounds are heard best when the newborn is crying, but it is difficult to localize and identify breath sounds in the newborn. Upper airway noises and bowel sounds can be heard over the chest wall, making auscultation difficult. Because sounds may be transmitted from the unaffected lung to the affected lung, the absence of breath sounds may not be diagnosed. Air entry may be noisy in the first couple of hours until lung fluid resolves, especially in cesarean births. Brief periods of apnea (episodic breathing) may occur, but no color or heart rate changes occur in healthy, term newborns. Sepsis should be suspected in full-term infants experiencing apneic episodes.

Heart

Heart rates can be as rapid as 180 beats per minute (beats/min) in newborns and fluctuate a great deal, especially if the baby moves or is startled. Normal range is 110 to 160 beats/min. Auscultation provides the nurse with valuable assessment data. The heart is examined for rate and rhythm, position of the apical impulse, and heart sound intensity. Dysrhythmias should be evaluated by a physician.

The pulse rate is variable and is influenced by physical activity, crying, state of wakefulness, and body temperature. Auscultation is performed over the entire heart region (precordium), below the left axilla, and below the scapula. *Apical pulse rates are obtained by auscultation for a full minute,* preferably when the newborn is asleep.

The placement of the heart in the chest should be determined when the newborn is in a quiet state. The heart is relatively large at birth and is located high in the chest, with its apex somewhere between the fourth and fifth intercostal space.

A shift of heart tones in the mediastinal area to either side may indicate pneumothorax, dextrocardia (heart placement on the right side of the chest), or a diaphragmatic hernia. The experienced nurse can diagnose these and many other problems early with a stethoscope. Normally, the heartbeat has a "toc tic" sound. A slur or slushing sound (usually after the first sound) may indicate a murmur. Although 90% of all murmurs are transient and are considered normal, they should be monitored closely by a physician. Many murmurs are secondary to closing of patent ductus arteriosus or patent foramen ovale, which should close 1 to 2 days after birth. Occasionally, aortic or pulmonary stenosis, or small ventricular septal defect murmurs are heard. See chapter 33 for a discussion of congenital heart defects.

Peripheral pulses (brachial, femoral, pedal) are also evaluated to detect any lags or unusual characteristics. Brachial pulses are palpated bilaterally for equality and compared with the femoral pulses. Femoral pulses are palpated by applying gentle pressure with the middle finger over the femoral canal (Figure 30-34 ■). Decreased or absent femoral pulses may indicate coarctation of the aorta or hypovolemia and require additional investigation. A wide difference in blood pressure between the upper and lower extremities also indicates coarctation.

A

B

Figure 30-34 ■ A. Bilaterally palpate the femoral arteries for rate and intensity of the pulses. Press fingertip gently at the groin as shown. B. Compare the femoral pulses to the brachial pulses by palpating the pulses simultaneously for comparison of rate and intensity.

Source: Photographer, Elena Dorfman.

The measurement of blood pressure (BP) is best accomplished by using a noninvasive blood pressure device (Figure 30-35 ■). If a blood pressure cuff is used, the newborn's extremities must be immobilized during the assessment, and the cuff should cover two thirds of the upper arm or upper leg. Movement, crying, and inappropriate cuff size can give inaccurate measurements of the blood pressure.

Blood pressure *may not be measured routinely* on healthy newborns but is an essential measurement in newborns who are having distress, are premature, or are suspected of having a cardiac

CLINICAL TIP

If possible, obtain blood pressure (BP) measurement during quiet sleep or sleep state. Place cuff on arm or leg and give infant time to quiet. Obtain average of 2 to 3 measurements when making clinical decisions. Follow mean BP to monitor changes, as it is less likely to be erroneous. Noninvasive BP may overestimate BP in very low-birth-weight infants.

Figure 30-35 ■ Blood pressure measurement using the Dinemapp and Doppler devices. The cuff can be applied to either the newborn's upper arm or the thigh.

Source: Courtesy of Vanessa Howell, RNC, BSN.

anomaly, renal disease, or clinical signs of hypotension (Tappero & Honeyfield, 2009). Infants who have birth asphyxia and are on ventilators have significantly lower systolic and diastolic blood pressures than healthy infants. If a cardiac anomaly is suspected, blood pressure is palpated in all four extremities. At birth, systolic values usually range from 70 to 50 mm Hg and diastolic values from 45 to 30 mm Hg. By the 10th day of life, blood pressure may rise to 90/50 mm Hg. Table 30-4 summarizes newborn vital signs.

Abdomen

The nurse can learn a great deal about the newborn's abdomen without disturbing the infant. The abdomen should be cylindrical, protrude slightly, and move with respiration. A certain amount of laxness of the abdominal muscles is normal. A scaphoid (hollow-shaped) appearance suggests the absence of abdominal contents, seen in diaphragmatic hernia. No cyanosis should be present, and few if any blood vessels should be apparent to the eye. There should be no gross distention or bulging. The more distended the abdomen, the tighter the skin becomes, and engorged vessels appear. Distention is the first sign of many of the gastrointestinal abnormalities.

TABLE 30-4 Newborn Vital Signs

Pulse

- 110–160 beats/min
- During deep sleep as low as 70 beats/min; if crying, up to 180 beats/min (Tappero & Honeyfield, 2009)
- Apical pulse counted for 1 full minute

Respirations

- 30–60 respirations/minute
- Predominantly diaphragmatic but synchronous with abdominal movements
- Respirations are counted for 1 full minute

Blood Pressure

- 70–50/45–30 mm Hg at birth
- 90/60 mm Hg at day 10

Temperature

- Normal range: 36.5°C–37.5°C (97.7°F–99.4°F)
- Axillary: 36.5°C–37.2°C (97.7°F–99°F)
- Skin: 36°C–36.5°C (96.8°F–97.7°F)
- Rectal: 36.6°C–37.2°C (97.8°F–99°F)

Before palpation of the abdomen, the nurse should auscultate the presence or absence of bowel sounds in all four quadrants. Bowel sounds should be present by 1 hour after birth. Palpation can cause a transient decrease in bowel sound intensity.

Abdominal palpation should be carried out systematically. The nurse palpates each of the four abdominal quadrants, moving in a clockwise direction, checking for softness, tenderness, and the presence of masses. The nurse should place one hand under the back for support during palpation. When palpating the abdomen, the nurse may feel for the liver. The newborn's liver is large in proportion to the rest of the body and can usually be felt between 1 and 2 cm below the right costal margin. Depending on institutional protocol, palpation of the kidney may be performed by the staff nurse. Kidneys are more difficult to feel but can be more easily examined within 4 to 6 hours after birth, before the intestines become distended with air and feedings are initiated. The lower pole of the kidney is usually found 1 to 2 cm above the umbilicus. The spleen tip may be palpated in the lateral aspect of the left upper quadrant in the normal newborn (Gardner & Hernandez, 2011).

Umbilical Cord

Initially, the umbilical cord is white and gelatinous in appearance, with the two umbilical arteries and one umbilical vein readily apparent. Because a single umbilical artery is frequently associated with congenital anomalies, the vessels should be counted as part of the newborn assessment. The cord begins drying within 1 or 2 hours after birth and is shriveled and blackened by the second or third day. Within 7 to 10 days it sloughs off, although a granulated area may remain for a few days longer. (Care of the umbilical cord is discussed in chapter 31 ∞).

Cord bleeding is abnormal and may result because the cord was inadvertently pulled or because the cord clamp was loosened. Foul-smelling drainage is also abnormal and is generally caused by infection, which requires immediate treatment to prevent septicemia. If the newborn has a patent urachus (abnormal connection between the umbilicus and bladder), moistness or draining urine may be apparent at the base of the cord. Another umbilical cord anomaly that can occur is umbilical cord hernia and associated patent omphalomesenteric duct (Figure 30-36 ■). Umbilical hernias are more common in infants of African descent than in Caucasian infants, and seen in low birth weight males (Tappero & Honeyfield, 2009). The umbilical hernias usually close spontaneously by 2 years of age.

Serous or serosanguineous drainage that continues after the cord falls off may indicate a granuloma. It appears as a small, red button deep in the umbilicus (Tappero & Honeyfield, 2009).

DEVELOPING CULTURAL COMPETENCE

Native Americans and Umbilical Cord Care

In the Woodland Indian tribe, upon birth, the umbilical cord is tied and a small piece is saved. This section of the umbilical cord is sewn into a deerskin diamond-shaped pocket. The pocket is hung over the infant's crib to provide protection for the infant.

Figure 30-36 ■ Umbilical hernia.

Genitals

Female Infants

The nurse examines the labia majora, labia minora, and clitoris, noting the size of each as appropriate for gestational age. A vaginal tag or hymenal tag is often evident and will usually disappear in a few weeks. During the first week of life, the female newborn may have a vaginal discharge composed of thick whitish mucus. This discharge, which can become tinged with blood, is referred to as **pseudomenstruation** and is caused by the withdrawal of maternal hormones. *Smegma,* a white cheeselike substance, is often present between the labia. Removing it may traumatize tender tissue.

Male Infants

The penis is inspected to determine whether the urinary orifice is correctly positioned. *Hypospadias* occurs when the urinary meatus is located on the ventral surface of the penis; *epispadias* occurs when the meatus is located on the dorsal surface of the glans. Hypospadias occurs most commonly among people of Western European descent. *Phimosis* is a condition occurring in newborn males in which the opening of the foreskin (prepuce) is small, and the foreskin cannot be pulled back over the glans at all. This condition may interfere with urination, so the adequacy of the urinary stream should be evaluated.

The scrotum is inspected for size and symmetry. Scrotal color variations are especially prominent in African American, Indian, and Hispanic newborns (Creehan, 2008). The scrotum should be palpated to verify the presence of both testes and to rule out *cryptorchidism* (failure of testes to descend). The testes are palpated separately between the thumb and forefinger, with the thumb and forefinger of the other hand placed together over the inguinal canal. Scrotal edema and discoloration are common in breech births. *Hydrocele* (a collection of fluid surrounding the testes in the scrotum) is common in newborns and should be identified. It usually resolves without intervention. The presence of a discolored or dusky scrotum and solid testis should raise the suspicion of testicular torsion, which should be reported immediately.

Anus

The anal area is inspected to verify that it is patent and has no fissure. Imperforate anus and rectal atresia may be ruled out by observation. A digital examination, if necessary, is done by a physician or nurse practitioner. The passage of the first meconium stool is also noted. Atresia of the gastrointestinal tract or meconium ileus with resultant obstruction must be considered if the newborn does not pass meconium in the first 24 hours of life.

Extremities

Extremities are examined for gross deformities, extra digits or webbing, clubfoot, and range of motion. Normal newborn extremities appear short, are generally flexible, and move symmetrically.

Arms and Hands

Nails extend beyond the fingertips in term newborns. Fingers and toes should be counted. *Polydactyly* is the presence of extra digits on either the hands or the feet. *Syndactyly* refers to fusion (webbing) of fingers or toes. Hands should be inspected for normal palmar creases. A single palmar crease is frequently present in children with Down syndrome.

Brachial palsy, a partial or complete paralysis of portions of the arm, results from trauma to the brachial plexus during a difficult birth. It occurs most commonly when strong traction is exerted on the head of the newborn in an attempt to deliver a shoulder lodged behind the symphysis pubis in the presence of shoulder dystocia. Brachial palsy may also occur during a breech birth if an arm becomes trapped over the head and traction is exerted.

The portion of the arm affected is determined by the nerves damaged. **Erb-Duchenne paralysis (Erb's palsy)** involves damage to the upper arm (fifth and sixth cervical nerves) and is

Figure 30-37 ■ Right Erb's palsy resulting from injury to the fifth and sixth cervical roots of brachial plexus.

Source: Photo reprinted from Potter, E. L., & Craig, J. M. Pathology of the fetus and infant *(3rd ed.). Copyright © 1975, with permission from Elsevier.*

the most common type. Injury to the eighth cervical and first thoracic nerve roots and the lower portion of the plexus produces the relatively rare *lower arm injury.* The *whole arm type* results from damage to the entire plexus.

With Erb-Duchenne paralysis, the newborn's arm lies limply at the side (Figure 30-37 ■). The elbow is held in extension, with the forearm pronated. The newborn is unable to elevate the arm, and therefore the Moro reflex cannot be elicited on the affected side. When a lower arm injury occurs, paralysis of the hand and wrist results; complete paralysis of the limb occurs with the whole arm type.

The nurse carefully instructs the parents in the correct method of performing passive range-of-motion exercises (to prevent muscle contractures and restore function) and arranges supervised practice sessions for the parents and referral to physical therapy follow-up within 2 weeks of discharge. In more severe cases, splinting of the arm is indicated until the edema decreases. The arm is held in a position of abduction and external rotation with the elbow flexed 90 degrees, often called the "Statue of Liberty" position. Prognosis is related to the degree of nerve damage resulting from trauma and hemorrhage within the nerve sheath. Complete recovery occurs within a few months with minimal trauma. Moderate trauma may result in some partial paralysis. Recovery is unlikely with severe trauma, and muscle wasting may develop.

Legs and Feet

The legs of the newborn should be of equal length, with symmetric skin folds. However, they may assume a "fetal posture" secondary to position in utero, and it may take several days for the legs to relax into normal position.

To evaluate for hip dislocation or hip instability, the Barlow and Ortolani maneuvers are performed (Figure 30-38 ■). The nurse (or, more commonly, the physician or nurse practitioner) examiner performs the **Barlow maneuver** to rule out the possibility of developmental dysplasic hip, also called congenital hip dysplasia (hip dislocatability). The examiner grasps and adducts the infant's thigh and applies gentle downward pressure. Dislocation is felt as the femoral head slips out of the acetabulum. The femoral head is then returned to the acetabulum using the Ortolani maneuver, confirming the diagnosis of an unstable or dislocatable hip.

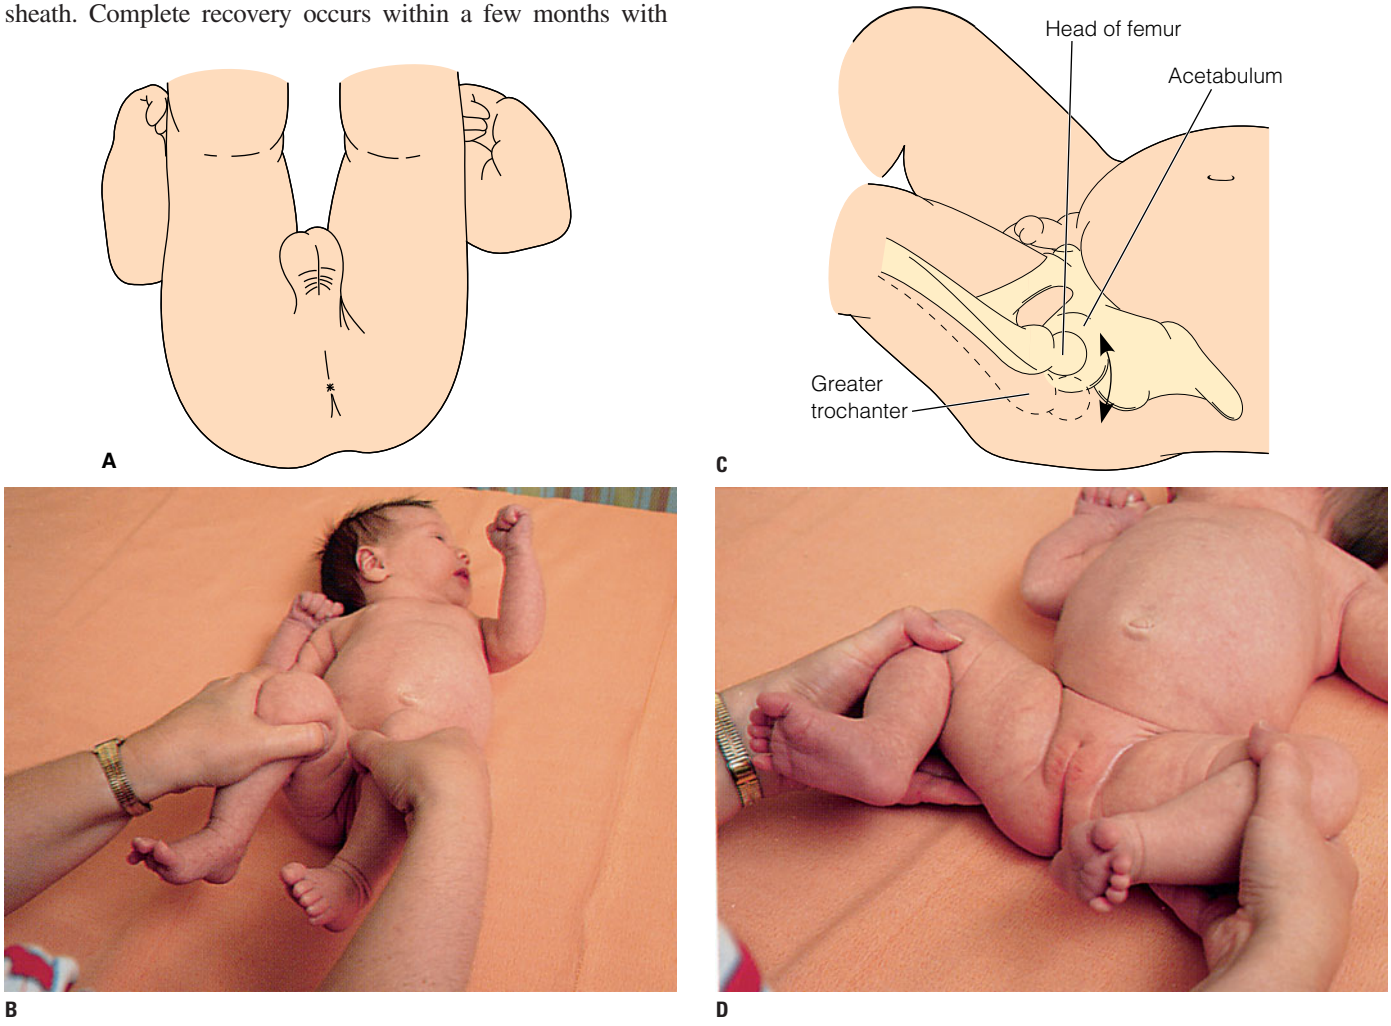

Figure 30-38 ■ A. The asymmetry of gluteal and thigh fat folds seen in infant with left developmental dysplasia of the hip. B. Barlow (dislocation) maneuver. Baby's thigh is grasped and adducted (placed together) with gentle downward pressure. C. Dislocation is palpable as femoral head slips out of acetabulum. D. Ortolani's maneuver puts downward pressure on the hip and then inward rotation. If the hip is dislocated, this maneuver will force the femoral head back into the acetabular rim with a noticeable "clunk."

Ortolani's maneuver should be performed with the newborn relaxed and quiet on a firm surface. With the hips and knees flexed at a 90-degree angle, the examiner grasps the infant's thigh with the middle finger over the greater trochanter and lifts the thigh to bring the femoral head from its posterior position toward the acetabulum. With gentle abduction of the thigh, the femoral head is returned to the acetabulum and the examiner feels a sense of reduction or a "clunk." This reduction is palpable and may be heard.

The feet are then examined for evidence of a talipes deformity (clubfoot). Intrauterine position frequently causes the feet to appear to turn inward (Figure 30-39 ■); this is termed a *"positional" clubfoot.* If the feet can easily be returned to midline by manipulation, no treatment is indicated. Range-of-motion exercises can be taught to the family. Further investigation is indicated when the foot will not turn to the midline position or align readily. This is considered the most severe type of "true clubfoot," or talipes equinovarus.

CLINICAL TIP

Always examine more closely any infant who is reluctant to move an extremity. Fractures are often asymptomatic in the newborn; paralytic injuries are characterized by immobility of an extremity.

Application: Newborn Assessment

Back

With the baby prone, the nurse examines the back. The spine should appear straight and flat because the lumbar and sacral curves do not develop until the infant begins to sit. The base of the spine is examined for a dermal sinus. The nevus pilosus ("hairy nevus") is occasionally found at the base of the spine in newborns. It is significant because it is frequently associated with spina bifida. A pilonidal dimple should be examined to ascertain that there is no connection to the spinal canal.

Assessment of Neurologic Status

The nurse should begin the neurologic examination with a period of observation, noting the general physical characteristics and behavior of the newborn. Important behaviors to assess are the *state of alertness, resting posture, cry,* and *quality of muscle tone* and *motor activity.*

The usual position of the newborn is partially flexed extremities with the legs abducted to the abdomen. When awake, the newborn may exhibit purposeless, uncoordinated bilateral movements of the extremities. If these movements are absent, minimal, or obviously asymmetric, neurologic dysfunction should be suspected. Eye movements are observable during the first few days of life. An alert newborn is able to fixate on faces and brightly colored objects. Shining a bright light in the newborn's eyes elicits the blinking response.

Videos: Newborn Reflexes

The nurse evaluates muscle tone by moving various parts of the newborn's body while the newborn's head remains in a neutral position. The newborn is somewhat hypertonic; that is, the newborn resists the examiner's attempts to extend the elbow and knee joints. Muscle tone should be symmetric. Diminished muscle tone and flaccidity require further evaluation.

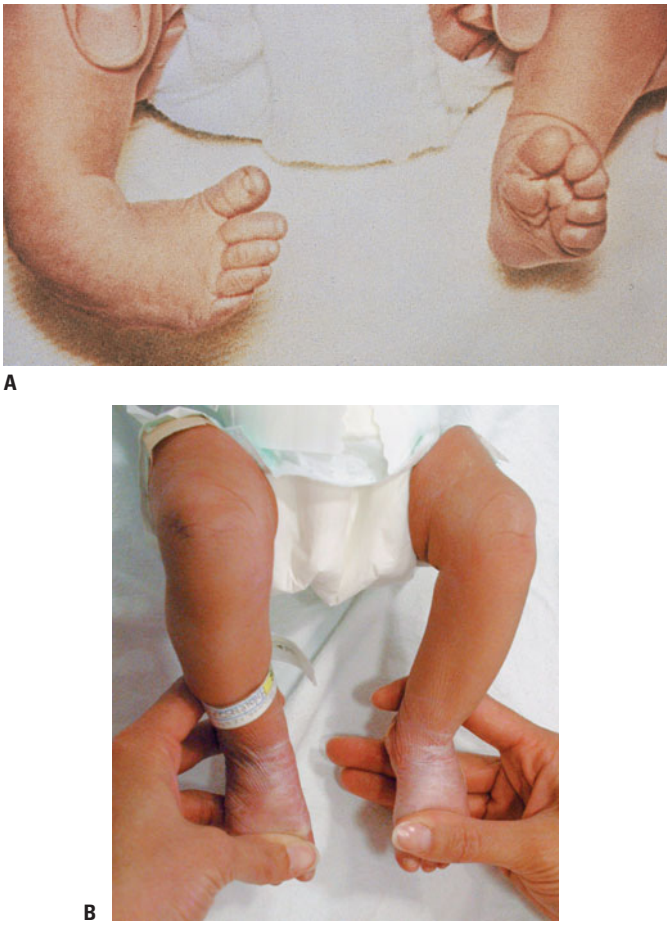

Figure 30-39 ■ A. Unilateral talipes equinovarus (clubfoot). B. To determine the presence of clubfoot, the nurse moves the foot to the midline. Resistance indicates true clubfoot.

Source: Courtesy of Mead Johnson Nutritionals, Evansville, IN.

Tremors or jitteriness (tremorlike movements) in the full-term newborn must be evaluated to differentiate the tremors from convulsions. Tremors may be related to hypoglycemia, hypocalcemia, or substance withdrawal. Environmental stimuli may initiate tremors. Jitteriness may be distinguished from tonic-clonic seizure activity because it usually can be stopped by the infant's sucking on the extremity or by the nurse holding or flexing the involved extremity. A fine jumping of the muscle is likely to be a central nervous system (CNS) disorder and requires further evaluation. Neonatal seizures may consist of no more than chewing or swallowing movements, deviations of the eyes, rigidity, or flaccidity because of central nervous system immaturity. In contrast to tremors, seizures are not usually initiated by stimuli and cannot be stopped by holding.

Specific deep tendon reflexes can be elicited in the newborn but have limited value unless they are obviously asymmetric. The knee jerk is brisk; a normal ankle clonus may involve three or four beats. Plantar flexion is present.

The immature central nervous system of the newborn is characterized by a variety of reflexes. Because the newborn's movements are uncoordinated, methods of communication are limited, and control of body functions is restricted, the reflexes serve a variety of purposes. Some are protective (blink, gag,

Figure 30-40 ■ Tonic neck reflex.
Source: George Dodson/Pearson Education.

sneeze); some aid in feeding (rooting, sucking) and may not be very active if the infant has eaten recently; and some stimulate human interaction (grasping).

The most common reflexes found in the normal newborn are the following:

- The **tonic neck reflex** (fencer position) is elicited when the newborn is supine and the head is turned to one side. In response, the extremities on the same side straighten, whereas on the opposite side they flex (Figure 30-40 ■). This reflex may not be seen during the early newborn period, but once it appears, it persists until about the third month.
- The **grasping reflex** is elicited by stimulating the newborn's palm with a finger or object. The newborn will grasp and hold the object or finger firmly enough to be lifted momentarily from the crib (Figure 30-41 ■).
- The **Moro reflex** is elicited when the newborn is startled by a loud noise or is lifted slightly above the crib and then suddenly lowered. In response the newborn straightens arms and hands outward while the knees flex. Slowly, the arms return to the chest, as in an embrace. The fingers spread, forming a C, and the newborn may cry (Figure 30-42 ■). This reflex may persist until about 6 months of age.

Figure 30-41 ■ Palmar grasping reflex.

Figure 30-42 ■ Moro reflex.

- The **rooting reflex** is elicited when the side of the newborn's mouth or cheek is touched. In response the newborn turns toward that side and opens the lips to suck (if not fed recently) (Figure 30-43 ■).
- The **sucking reflex** is elicited when an object is placed in the newborn's mouth or anything touches the lips. Newborns suck even while sleeping; this is called nonnutritive sucking, and it can have a quieting effect on the baby.
- **Trunk incurvation (Galant reflex)** is seen when the newborn is prone. Stroking the spine causes the pelvis to turn to the stimulated side.

In addition to these reflexes, newborns can blink, yawn, cough, sneeze, and draw back from pain *(*protective reflexes*)*. They can even move a little on their own. When placed on their stomachs, they push up and try to crawl *(*prone crawl*)*. When held upright with one foot touching a flat surface, the newborn puts one foot in front of the other and "walks" *(*stepping reflex*)* (Figure 30-44 ■). This reflex is more pronounced at birth and is lost in 4 to 8 weeks. Table 30-5 summarizes the stimulus for and response of the common newborn reflexes.

The nurse uses the following steps to assess CNS integration:

1. Insert a gloved finger into the newborn's mouth to elicit a sucking reflex.

Figure 30-43 ■ Rooting reflex.
Source: George Dodson/Lightworks Studio/Pearson Education.

Figure 30-44 ■ The stepping reflex disappears between 4 and 8 weeks of age.

Assessment of an Infant

2. As soon as the newborn is sucking vigorously, assess hearing and vision responses by noting sucking changes in the presence of a light, a rattle, and a voice.
3. The newborn should respond with a brief cessation of sucking followed by continuous sucking with repeated stimulation.

This examination demonstrates auditory and visual integrity as well as complex behavioral interactions.

TABLE 30-6 Potential Birth Injuries

CLASSIFICATION	EXAMPLES*
Soft-tissue injuries	Lacerations, abrasions, bruising, fat necrosis
Skull injuries	Cephalhematoma,* fractures
Scalp laceration	Fetal scalp electrode
Scalp abscess	Fetal scalp electrode
Intracranial hemorrhage	Subdural, subarachnoid
Eye injuries	Subconjunctival* and retinal hemorrhages
Fractures	Clavicle,* facial bones, humerus, femur
Dislocations	Hips
Torticollis	Sternocleidomastoid muscle
Nerve injuries	Facial nerve,* brachial plexus,* phrenic nerve, recurrent laryngeal nerve (vocal cord paralysis), Horner syndrome
Spinal cord injuries	Spina bifida
Visceral rupture	Liver, spleen

*Most common birth injuries seen in newborns.

As healthcare providers carry out the newborn physical and neurologic assessment, they are always on the alert to recognize possible alterations and possible injuries related to the birth process that require further investigation and intervention. (See Table 30-6 for potential birth injuries.)

Newborn Physical Assessment Guide

Following is a guide for systematically assessing the newborn (pages 811–819). Normal findings, alterations, and related causes are presented in correlation with suggested nursing responses. The findings are typical for a full-term newborn.

TABLE 30-5 Common Reflexes of the Newborn

REFLEX NAME	EVOKING STIMULUS	RESPONSE
Blinking reflex	Light flash	Eyelids close.
Pupillary reflex	Light flash	Pupil constricts.
Rooting reflex	Light touch of finger on cheek close to mouth	Head rotates toward stimulation; mouth opens and attempts to suck finger. Disappears by about 4 months of age.
Sucking reflex	Finger (or nipple) inserted into mouth	Rhythmic sucking occurs.
Moro reflex	Infant lying on back: slightly raised head suddenly released; infant held horizontally, lowered quickly about 6 in., and stopped abruptly	Arms are extended, head is thrown back, fingers are spread wide; arms are then brought back to center convulsively with hands clenched; spine and lower extremities are extended. Disappears by about 6 months of age.
Startle reflex	Loud noise	Similar to Moro reflex flexion in arms; fists are clenched.
Grasping reflex	Finger placed in palm of hand	Infant's fingers close around and grasp object.
Tonic neck reflex	Head turned to one side while infant lies on back	Arm and leg are extended on the side the infant faces. Opposite arm and leg are flexed.
Abdominal reflex	Tactile stimulation or tickling	Abdominal muscles contract.
Withdrawal reflex	Slight pinprick to the sole of the infant's foot	Leg flexes.
Walking reflex	Infant supported in an upright position with feet lightly touching a flat surface	Rhythmic stepping movement. Disappears at about 4 to 8 weeks of age.
Babinski reflex response	Gentle stroking on the sole of each foot	Fanning and extension of the toes (adults respond to this stimulation with flexion of toes).
Plantar, or toe-grasping, reflex	Pressure applied with the finger against the balls of the infant's feet	A plantar flexion of all toes. Disappears by the end of the first year of life.

ASSESSMENT GUIDE Newborn Physical Assessment

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
VITAL SIGNS		
Blood pressure (BP): At birth: 70–50/45–30 mm Hg	Low BP (hypovolemia, shock)	Monitor BP in all cases of distress, prematurity, or suspected anomaly.
Day 10: 90–60/50–40 mm Hg (may be unable to measure diastolic pressure with standard sphygmomanometer)		Low BP: Refer to physician immediately so measures to improve circulation are begun.
Pulse: 110–160 beats/min (if in deep sleep, as low as 70 beats/min; if crying, up to 180 beats/min)	Weak pulse (decreased cardiac output) Bradycardia (severe asphyxia, arrhythmia) Tachycardia (over 160 beats/min at rest) (infection, central nervous system (CNS) problems, arrhythmia, stress, hypovolemia)	Assess skin perfusion by blanching (capillary refill test—normal: <3 sec). Correlate finding with BP assessments; refer to physician. Carry out neurologic and thermoregulation assessments. Check blood pressure and hematocrit (Hct).
Respirations: 30–60 breaths/min		
Synchronization of chest and abdominal movements	Tachypnea (pneumonia, respiratory distress syndrome [RDS])	Identify sleep-wake state; correlate with respiratory pattern.
Diaphragmatic and abdominal breathing	Rapid, shallow breathing (hypermagnesemia due to large doses given to mothers with preeclampsia)	Evaluate for all signs of respiratory distress; report findings to physician.
	Respirations below 30 breaths/min (maternal anesthesia or analgesia)	
Transient tachypnea	Expiratory grunting; subcostal and substernal retractions; flaring of nares (respiratory distress); apnea (cold stress, respiratory disorder)	Evaluate for cold stress. Report findings to physician or neonatal nurse practitioner.
Crying: Strong and lusty Moderate tone and pitch	High pitched, shrill (neurologic disorder, hypoglycemia)	Discuss newborn's use of cry for communication. Assess and record abnormal cries.
Cries vary in length from 3 to 7 min after consoling measures are used	Weak or absent (CNS disorder, laryngeal problem)	Reduce environmental noises.
Temperature: Axilla 36.4–37.2°C (97.5–99°F)	Elevated temperature (room too warm, too much clothing or covers, dehydration, sepsis, brain damage)	Notify physician of elevation or drop.
	Subnormal temperature (brain stem involvement, cold, sepsis)	Counsel parents on possible causes of elevated or low temperatures, appropriate home care measures, when to call physician.
Heavier newborns tend to have higher body temperatures	Swings of more than 2°F from one reading to next or subnormal temperature (infection)	Teach parents how to take an axillary temperature; assess parents' knowledge regarding use of thermometer; provide teaching as needed.
Weight: 2500–4000 g (5 lb, 8 oz–8 lb, 13 oz)	Less than 2748 g (less than 6 lb) = SGA or preterm infant Greater than 4050 g (greater than 9 lb) = large-for-gestational-age (LGA) or infants of diabetic mothers	Plot weight and gestational age on growth chart to identify high-risk infants. Ascertain body build of parents. Counsel parents regarding appropriate caloric intake.
Within first 3 to 4 days, normal weight loss of 5%–10% Large babies tend to lose more due to greater fluid loss in proportion to birth weight except infants of diabetic mothers	Loss greater than 15% (low fluid intake, loss of meconium and urine, feeding difficulties, diabetes insipidus)	Notify physician of net losses or gains. Calculate fluid intake and losses from all sources (insensible water loss, radiant warmers, phototherapy lights). Daily weights and before discharge.
Length: 48–52 cm (18–22 in.)	Less than 45 cm (congenital dwarf)	Assess for other signs of dwarfism.
Grows 10 cm (3 in.) during first 3 months	Short/long bones proximally (achondroplasia)	Determine other signs of skeletal system adequacy.
	Short/long bones distally (Ellis-van Creveld syndrome)	Plot progress at subsequent well-baby visits.
POSTURE		
Body usually flexed, hands may be tightly clenched, neck appears short because chin rests on chest	Only extension noted, inability to move from midline (trauma, hypoxia, immaturity)	Record spontaneity of motor activity and symmetry of movements.
In breech births, feet are usually dorsiflexed	Constant motion (maternal caffeine intake or drug withdrawal)	If parents express concern about newborn's movement patterns, reassure and further evaluate if appropriate.
SKIN		
Color: Color consistent with ethnic background	Pallor of face conjunctiva (anemia, hypothermia, anoxia)	Discuss with parents common skin color variations to allay fears. Skin color can vary widely within African-American infants.

*Possible causes of alterations are placed in parentheses.

†This column provides guidelines for further assessment and initial nursing interventions.

(continued)

ASSESSMENT GUIDE Newborn Physical Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
SKIN (continued)		
Newborns of European descent: pink-tinged or ruddy color over face, trunk, extremities Newborns of African or Native American descent: pale pink with yellow or red tinge Newborns of Asian descent: pink or rosy red to yellow tinge	Beefy red (hypoglycemia, immature vasomotor reflexes, polycythemia)	Document extent and time of occurrence of color change.
Common variations: acrocyanosis, circumoral cyanosis, harlequin color change, or mongolian spots	Meconium staining (nonreassuring fetal status) Jaundice (hemolytic reaction from blood incompatibility within first 24 hours, sepsis)	Obtain Hgb and hematocrit values; obtain bilirubin levels. Assess for respiratory difficulty and temperature instability. Differentiate between physiologic and pathologic jaundice.
Mottled when undressed	Cyanosis (choanal atresia, CNS damage or trauma, respiratory or cardiac problem, cold stress)	Assess degree of (central or peripheral) cyanosis and possible causes; refer to physician.
Minor bruising over buttocks in breech presentation and over eyes and forehead in facial presentations		Discuss with parents cause and course of minor bruising related to labor and birth.
Texture: Smooth, soft, flexible; may have dry, peeling hands and feet	Generalized cracked or peeling skin (small-for-gestational-age [SGA] or postterm; blood incompatibility; metabolic, kidney dysfunction) Seborrheic-dermatitis (cradle cap) Absence of vernix (postmature) Yellow vernix (bilirubin staining)	Report to physician. Instruct parents to shampoo the scalp and anterior fontanelle areas daily with mild soap or baby shampoo; rinse well; avoid use of oil.
Turgor: Elastic, returns to normal shape after pinching	Maintains tent shape (dehydration)	Assess for other signs and symptoms of dehydration.
Pigmentation: Clear; milia across bridge of nose, forehead, or chin will disappear within a few weeks		Advise parents not to pinch or prick these pimplelike areas.
Café-au-lait spots (one or two)	Six or more spots (neurologic disorder such as von Recklinghausen disease, cutaneous neurofibromatosis)	If there are six or more café-au-lait spots, refer for genetic and neurologic consult.
Mongolian blue spots common over dorsal area and buttocks in dark-skinned infants		Assure parents of normality of this pigmentation; it will fade in first year or two.
Erythema toxicum	Impetigo (group A β-hemolytic streptococcus or *Staphylococcus aureus* infection)	If impetigo occurs, instruct parents about hand washing and linen precautions during home care.
Telangiectatic nevi	Hemangiomas: Nevus flammeus (port-wine stain) Nevus vasculosus (strawberry hemangioma) Cavernous hemangiomas	Collaborate with physician. Counsel parents about birthmark's progression to allay misconceptions. Record size and shape of hemangiomas. Refer for follow-up at well-baby clinic.
Rashes	Rashes (infection)	Assess location and type of rash (macular, papular, vesicular). Obtain history of onset, prenatal history, and related signs and symptoms.
Petechiae of head or neck (breech presentation, cord around neck)	Generalized petechiae (clotting abnormalities)	Determine cause; advise parents if further health care is needed.
HEAD		
General appearance, size, movement Round, symmetric, and moves easily from left to right and up and down; soft and pliable	Asymmetric, flattened occiput on either side of the head (plagiocephaly) Head held at angle (torticollis) Unable to move head side to side (neurologic trauma)	Instruct parents to change infant's positions frequently when awake. When awake, needs to spend "tummy time." Infants should be placed supine for sleep per "Back to Sleep" guidelines (see chapters 31 ∞ and 37 ∞. Determine adequacy of all neurologic signs.
Circumference: 32–37 cm (12.5–14.5 in.); 2 cm greater than chest circumference Head one fourth of body size	Extreme differences in size may be due to microencephaly (Cornelia de Lange syndrome, cytomegalic inclusion disease [CID]), rubella, toxoplasmosis, chromosome abnormalities, hydrocephalus (meningomyelocele, achondroplasia), anencephaly (neural tube defect) Head is 3 cm or more larger than chest circumference (preterm, hydrocephalus)	Measure circumference from occiput to frontal area using metal or paper tape. Measure chest circumference using metal or paper tape and compare to head circumference. Record measurements on growth chart. Reevaluate at well-baby visits.

*Possible causes of alterations are placed in parentheses.

†This column provides guidelines for further assessment and initial nursing interventions.

ASSESSMENT GUIDE Newborn Physical Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
HEAD (continued)		
Common variations: Molding	Cephalhematoma (trauma during birth, may persist up to 3 months)	Evaluate neurologic response.
Breech and cesarean newborns' heads are round and well shaped	Caput succedaneum (long labor and birth; disappears in 1 week)	Observe for hyperbilirubinemia. Check Hct. Reassure parents regarding common manifestations due to birth process and when they should disappear.
Fontanelles: Palpation of juncture of cranial bones	Overlapping of anterior fontanelle (malnourished or preterm newborn)	Discuss normal closure times with parents and care of "soft spots" to allay misconceptions.
Anterior fontanelle; 3–4 cm long by 2–3 cm wide, diamond shaped	Premature closure of sutures (craniosynostosis)	Refer to physician. Assess fontanelles and sutures daily.
Posterior fontanelle: 1–2 cm at birth, triangle shaped	Late closure (hydrocephalus)	Observe for signs and symptoms of hydrocephalus.
Slight pulsation	Moderate to severe pulsation (vascular problems)	Refer to physician.
Moderate bulging noted with crying, stooling; pulsations with heartbeat	Bulging (increased intracranial pressure, meningitis) Sunken (dehydration)	Report to physician. Evaluate neurologic status. Evaluate hydration status.
HAIR		
Texture: Smooth with fine texture variations (*Note:* Variations depend on ethnic background.)	Coarse, brittle, dry hair (hypothyroidism) White forelock (Waardenburg syndrome)	Instruct parents regarding routine care of hair and scalp.
Distribution: Scalp hair high over eyebrows (Spanish, Mexican hairline begins midforehead and extends down back of neck)	Low forehead and posterior hairlines may indicate chromosomal disorders	Assess for other signs of chromosomal aberrations. Refer to physician.
FACE		
Symmetric movement of all facial features, normal hairline, eyebrows and eyelashes present		Assess and record symmetry of all parts, shape, regularity of features, sameness or differences in features.
Spacing of features: Eyes-ears at same level, nostrils equal size, cheeks full, and sucking pads present	Eyes wide apart—ocular hypertelorism (Apert syndrome, Cri-du-chat, Turner syndrome)	Observe for other signs and symptoms indicative of disease states or chromosomal aberrations.
Lips equal on both sides of midline	Abnormal face (Down syndrome, cretinism, gargoylism)	
Chin recedes when compared with other bones of face	Atypical small jaw—micrognathia (Pierre Robin syndrome, Treacher Collins syndrome)	Maintain airway; may do best in prone position. Initiate surgical consultation and referral.
Movement: Makes facial grimaces	Inability to suck, grimace, and close eyelids (cranial nerve injury)	Initiate neurologic assessment and consultation.
Symmetric when resting and crying	Asymmetry (paralysis of facial cranial nerve)	Assess and record symmetry of all parts, shape, regularity of features, and sameness or differences in features.
EYES		
General placement and appearance: Bright and clear; even placement; slight nystagmus (involuntary cyclic eye movements)	Gross nystagmus (damage to third, fourth, and sixth cranial nerves)	
Concomitant strabismus	Constant and fixed strabismus	Reassure parents that strabismus is considered normal up to 6 months.
Move in all directions Blue-gray or slate–blue-gray	Lack of pigmentation (albinism) Brushfield spots may indicate Down syndrome (a light or white speckling of the outer two thirds of the iris)	Discuss with parents any necessary eye precautions. Assess for other signs of Down syndrome.
Brown color at birth in dark-skinned infants		Discuss with parents that permanent eye color is usually established by 3 months of age.
Eyelids: Position: above pupils but within iris, no drooping	Elevation or retraction of upper lid (hyperthyroidism). "Sunset sign" lid retraction and downward gaze (hydrocephalus), ptosis (congenital or paralysis of oculomotor muscle)	Assess for signs of hydrocephalus and hyperthyroidism. Evaluate interference with vision in subsequent well-baby visits.
Eyes on parallel plane	Upward slant in non-Asians (Down syndrome)	Assess for other signs of Down syndrome.
Epicanthal folds in Asian and 20% of newborns of northern European descent	Epicanthal folds (Down syndrome, Cri-du-chat syndrome)	
Movement: Blink reflex in response to light stimulus. Eyes open wide in dimly lighted room	Blink absent (CNS injury)	Evaluate neurologic status Refer to physician.

*Possible causes of alterations are placed in parentheses.

†This column provides guidelines for further assessment and initial nursing interventions.

(continued)

ASSESSMENT GUIDE Newborn Physical Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
EYES (continued)		
Inspection: Edematous for first few days of life, resulting from birth; no lumps or redness	Purulent drainage (infection); infectious conjunctivitis (gonococcus, chlamydia, staphylococcus, or gram-negative organisms) Marginal blepharitis (lid edges red, crusted, scaly)	Initiate good hand washing. Refer to physician. Evaluate infant for seborrheic dermatitis; scales can be removed easily.
Cornea: Clear	Ulceration (herpes infection); large cornea or corneas of unequal size (congenital glaucoma)	Refer to ophthalmologist.
Corneal reflex present	Clouding, opacity of lens (cataract)	Assess for other manifestations of congenital herpes; institute nursing care measures.
Sclera: May appear bluish in newborn, then white; slightly brownish color frequent in newborns of African descent	True blue sclera (osteogenesis imperfecta)	Refer to physician.
Pupils: Pupils equal in size, round, and react to light by accommodation	Anisocoria—unequal pupils (CNS damage) Dilation or constriction (intracranial damage, retinoblastoma, glaucoma) Pupils nonreactive to light or accommodation (brain injury)	Refer for neurologic examination.
Slight nystagmus in newborn who has not learned to focus	Nystagmus (labyrinthine disturbance, CNS disorder)	
Pupil light reflex demonstrated at birth or by 3 weeks of age		
Conjunctiva: Chemical conjunctivitis Subconjunctival hemorrhage	Pale color (anemia)	Obtain hematocrit and hemoglobin. Reassure parents that chemical conjunctivitis will subside in 1 to 2 days and subconjunctival hemorrhage disappears in a few weeks.
Palpebral conjunctival (red but not hyperemic)	Inflammation or edema (infection, blocked tear duct)	
Vision: 20/200 Tracks moving object to midline	Cataracts (congenital infection)	Record any questions about visual acuity and initiate follow-up evaluation at first well-baby checkup. May suggest toys for parents to purchase—see chapter 34 ∞.
Fixed focus on objects at a distance of about 10–20 inches; may be difficult to evaluate in newborn		
Prefers faces, geometric designs, and black and white to colors		
Lashes and lacrimal glands: Presence of lashes (lashes may be absent in preterm newborns)	No lashes on inner two thirds of lid (Treacher Collins syndrome), bushy lashes (Hurler syndrome), long lashes (Cornelia de Lange syndrome)	
Cry commonly tearless	Excessive tearing (plugged lacrimal duct, natal narcotic withdrawal), glaucoma	Demonstrate to parents how to milk blocked tear duct. Refer to ophthalmologist if tearing is excessive before third month of life.
NOSE		
Appearance of external nasal aspects: May appear flattened as a result of birth process	Continued flat or broad bridge of nose (Down syndrome)	Arrange consultation with specialist. May be normal racial variation—Asian or African ancestry.
Small and narrow in midline, even placement in relationship to eyes and mouth	Low bridge of nose, beaklike nose (Apert syndrome, Treacher Collins syndrome) Upturned (Cornelia de Lange syndrome)	Initiate evaluation of chromosomal abnormalities.
Patent nares bilaterally (nose breathers)	Blockage of nares (mucus or secretions), choanal atresia	Inspect for obstruction of nares.
Sneezing common to clear nasal passages	Flaring nares (respiratory distress)	Maintain oral airway until surgical correction is made.
Responds to odors, may smell breast milk	No response to stimulating odors	Inspect for obstruction of nares.
MOUTH		
Function of facial, hypoglossal, glossopharyngeal, and vagus nerves: Symmetry of movement and strength	Mouth draws to one side (transient seventh cranial nerve paralysis due to pressure in utero or trauma during birth, congenital paralysis)	Initiate neurologic consultation.
	Fishlike shape (Treacher Collins syndrome)	Administer artificial tears if eye on affected side of face is unable to close.
Presence of gag, swallowing, coordinated with sucking reflexes	Suppressed or absent reflexes	Evaluate other neurologic functions of these nerves.
Adequate salivation		

*Possible causes of alterations are placed in parentheses.

†This column provides guidelines for further assessment and initial nursing interventions.

ASSESSMENT GUIDE Newborn Physical Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
MOUTH (continued)		
Palate (soft and hard): Hard palate dome shaped. Uvula midline with symmetric movement of soft palate	High-steepled palate (Treacher Collins syndrome), bifid uvula (congenital anomaly)	Assess for other congenital anomalies.
Palate intact, sucks well when stimulated	Clefts in either hard or soft palate (polygenic disorder)	Initiate a surgical consultation referral. Use special feeding devices.
Epithelial (Epstein's) pearls appear on mucosa		Assure parents that these are normal and will disappear at 2 or 3 months of age.
Esophagus patent, some drooling common in newborn	Excessive drooling or bubbling (esophageal atresia)	Test for patency of esophagus.
Tongue: Free moving in all directions, midline	Lack of movement or asymmetric movement (neurologic damage) Tongue-tied Fasiculations (fine tremors) Spinal muscular atrophy	Further assess neurologic functions. Test reflex elevation of tongue when depressed with tongue blade.
Pink color, smooth to rough texture, noncoated	Deviations from midline (cranial nerve damage)	Check for signs of weakness or deviation.
	White cheesy coating (thrush) Tongue has deep ridges	Differentiate between thrush and milk curds by wiping: if white patches don't come off easily, it is thrush. Reassure parents that tongue pattern may change from day to day.
Tongue proportional to mouth	Large tongue with short frenulum (cretinism, Down syndrome, other syndromes)	Evaluate in well-baby clinic to assess development delays. Initiate referrals.
EARS		
External ear: Without lesions, cysts, or nodules	Nodules, cysts, or sinus tracts in front of ear Adherent earlobes	Evaluate characteristics of lesions.
	Low set (genetic abnormality or syndrome)	Counsel parents to clean external ear with washcloth only; discourage use of cotton-tip applicators.
	Preauricular skin tags	Refer to physician for ligation.
Hearing: Eustachian tubes are cleared with first cry		
Absence of all risk factors	Presence of one or more risk factors	Assess history of risk factors for hearing loss.
Attends to sounds; sudden or loud noise. Elicits Moro reflex	No response to sound stimuli (deafness)	Test for Moro reflex.
NECK		
Appearance: Short, straight, creased with skin folds	Abnormally short neck (Turner syndrome) Arching or inability to flex neck (meningitis, congenital anomaly)	Report findings to physician.
Posterior neck lacks loose extra folds of skin	Webbing of neck (Turner syndrome, Down syndrome, trisomy 18)	Assess for other signs of the syndromes.
Clavicles: Straight and intact	Knot or lump on clavicle (fracture during difficult birth)	Obtain detailed labor and birth history; apply figure-eight bandage. Consider oral analgesic.
Moro reflex elicitable	Unilateral Moro reflex response on unaffected side (fracture of clavicle, brachial palsy, Erb-Duchenne paralysis)	
Symmetric shoulders	Hypoplasia	
CHEST		
Appearance and size: Circumference: 32.5 cm, 1–2 cm less than head		Measure at level of nipples after exhalation.
Wider than it is long		
Normal shape without depressed or prominent sternum	Funnel chest (congenital or associated with Marfan syndrome)	Determine adequacy of other respiratory and circulatory signs.
Lower end of sternum (xiphoid cartilage) may be protruding; less apparent after several weeks	Continued protrusion of xiphoid cartilage (Marfan syndrome, "pigeon chest")	Assess for other signs and symptoms of various syndromes.
Sternum 8 cm long	Barrel chest	

*Possible causes of alterations are placed in parentheses.

†This column provides guidelines for further assessment and initial nursing interventions.

(continued)

ASSESSMENT GUIDE Newborn Physical Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
CHEST (continued)		
Expansion and retraction: Bilateral expansion	Unequal chest expansion (pneumonia, pneumothorax, respiratory distress)	Assess respiratory effort regularity, flaring of nares, difficulty on both inspiration and expiration.
No intercostal, subcostal, or supraclavicular retractions	Retractions (respiratory distress)	
	Seesaw respirations (respiratory distress)	
Auscultation: Breath sounds are louder in infants	Decreased breath sounds (decreased respiratory activity, atelectasis, pneumothorax)	Obtain transilluminator. Record findings and consult physician.
Chest and axilla clear on crying	Increased breath sounds (resolving pneumonia or in cesarean births)	Perform assessment and report to physician any positive findings.
Bronchial breath sounds (heard where trachea and bronchi closest to chest wall, above sternum and between scapulae):		
Bronchial sounds bilaterally Air entry clear Rales may indicate normal newborn atelectasis Cough reflex absent at birth, appears in 2 or more days	Adventitious or abnormal sounds (respiratory disease or distress)	Evaluate color for pallor or cyanosis. Monitor every shift or more frequently. Report to physician.
Breasts: Flat with symmetric nipples	Lack of breast tissue (preterm or SGA)	
Breast tissue diameter 5 cm or more at term	Discharge	Evaluate for infection.
Average distance between nipples 8 cm	Breast abscesses	
Breast engorgement occurs on third day of life; liquid discharge may be expressed in term newborns	Enlargement	Reassure parents of normality of breast engorgement.
Nipples	Supernumerary nipples Dark-colored nipples	No intervention is necessary.
HEART		
Auscultation: Location: lies horizontally, with left border extending to left of midclavicle		
Regular rhythm and rate	Arrhythmia (anoxia), tachycardia, bradycardia	Refer all arrhythmia and gallop rhythms. Initiate cardiac evaluation.
Determination of point of maximal impulse (PMI) Usually lateral to midclavicular line at third or fourth intercostal space	Malpositioning (enlargement, abnormal placement, pneumothorax, dextrocardia, diaphragmatic hernia)	
Functional murmurs No thrills	Location of murmurs (possible congenital cardiac anomaly)	Evaluate murmur: location, timing, and duration; observe for accompanying cardiac pathology symptoms; ascertain family history.
Horizontal groove at diaphragm shows flaring of rib cage to mild degree	Marked rib flaring (vitamin D deficiency) Inadequacy of respiratory movement	Initiate cardiopulmonary evaluation; assess pulses and blood pressures in all four extremities for equality and quality.
ABDOMEN		
Appearance: Cylindric, with some protrusion; appears large in relation to pelvis; some laxness of abdominal muscles	Distention, shiny abdomen with engorged vessels (gastrointestinal abnormalities, infection, congenital megacolon)	Examine abdomen thoroughly for mass or organomegaly. Measure abdominal girth.
No cyanosis, few vessels seen	Scaphoid abdominal appearance (diaphragmatic hernia)	Report deviations of abdominal size.
Diastasis recti—common in infants of African descent	Increased or decreased peristalsis (duodenal stenosis, small bowel obstruction)	Assess other signs and symptoms of obstruction.
	Localized flank bulging (enlarged kidneys, ascites, absent abdominal muscles)	Refer to physician.
Umbilicus: No protrusion of umbilicus (protrusion of umbilicus common in infants of African descent)	Umbilical hernia Patent urachus (congenital malformation)	Measure umbilical hernia by palpating the opening and record; it should close by 1 year of age; if not, refer to physician.
Bluish white color		Be aware of cultural practices. Taping or belly bands do not enhance closure.
	Omphalocele (covered defect) Gastroschisis (uncovered defect)	Cover omphalocele and gastroschisis with sterile, moist dressing or plastic sterile bag.

*Possible causes of alterations are placed in parentheses.

†This column provides guidelines for further assessment and initial nursing interventions.

ASSESSMENT GUIDE Newborn Physical Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
ABDOMEN (continued)		
Cutis navel (umbilical cord projects), granulation tissue present in navel	Redness or exudate around cord (infection) Yellow discoloration (hemolytic disease, meconium staining)	Instruct parents on cord care and hygiene.
Two arteries and one vein apparent	Single umbilical artery (congenital anomalies)	Refer anomalies to physician.
Begins drying 1 to 2 hours after birth	Discharge or oozing of blood from the cord	
No bleeding		
Auscultation and percussion: Soft bowel sounds heard shortly after birth every 10–30 seconds	Bowel sounds in chest (diaphragmatic hernia) Absence of bowel sounds Hyperperistalsis (intestinal obstruction)	Collaborate with physician. Assess for other signs of dehydration or infection.
Femoral pulses: Palpable, equal, bilateral	Absent or diminished femoral pulses (coarctation of aorta)	Monitor blood pressure in upper and lower extremities.
Inguinal area: No bulges along inguinal area	Inguinal hernia	Initiate referral.
No inguinal lymph nodes felt		Continue follow-up in well-baby clinic.
Bladder: Percusses 1–4 cm above symphysis	Failure to void within 24–48 hours after birth	Determine whether baby voided at birth.
Emptied about 3 hours after birth; if not, at time of birth	Exposure of bladder mucosa (exstrophy of bladder)	Consult with clinician. Cover exstrophy with sterile moist gauze.
Urine—inoffensive, mild odor	Foul odor (infection)	Obtain urine specimen if infection is suspected.
GENITALS		
Gender clearly delineated	Ambiguous genitals	Refer for genetic consultation.
MALE		
Penis: Slender in appearance, about 2.5 cm long, 1 cm wide at birth	Micropenis (congenital anomaly) Meatal atresia	Observe and record first voiding.
Normal urinary orifice, urethral meatus at tip of penis	Hypospadias, epispadias	Collaborate with physician in presence of abnormality. Delay circumcision.
Noninflamed urethral opening	Urethritis (infection)	Palpate for enlarged inguinal lymph nodes and record painful urination.
Foreskin adheres to glans	Ulceration of meatal opening (infection, inflammation)	Evaluate whether ulcer is due to diaper rash; counsel regarding care.
Uncircumcised foreskin tight for 2 to 3 months	Phimosis—if still tight after 3 months	Instruct parents on how to care for uncircumcised penis.
Circumcised		Teach parents how to care for circumcision. Check for voiding after procedure and evaluate for excessive bleeding.
Erectile tissue present		
Scrotum: Skin loose and hanging or tight and small; extensive rugae and normal size	Large scrotum containing fluid (hydrocele) Red, shiny scrotal skin (orchitis)	Shine a light through scrotum (transilluminate) to verify diagnosis.
Normal skin color Scrotal discoloration common in breech	Minimal rugae, small scrotum	Assess for prematurity.
Testes: Descended by birth; not consistently found in scrotum	Undescended testes (cryptorchidism)	If testes cannot be felt in scrotum, gently palpate femoral, inguinal, perineal, and abdominal areas for presence.
Testes size 1.5–2 cm (0.6–0.8 in.) at birth	Enlarged testes (tumor) Small testes (Klinefelter syndrome or adrenal hyperplasia)	Refer to and collaborate with physician for further diagnostic studies.
FEMALE		
Mons: Normal skin color, area pigmented in dark-skinned infants		
Labia majora cover labia minora in term and postterm newborns; symmetric size appropriate for gestational age	Hematoma, lesions (trauma) Labia minora prominent	Evaluate for recent trauma. Assess for prematurity.
Clitoris: Normally large in newborn Edema and bruising in breech birth	Hypertrophy (hermaphroditism)	Refer for genetic workup.
Vagina: Urinary meatus and vaginal orifice visible (0.5 cm circumference)	Inflammation; erythema and discharge (urethritis) Congenital absence of vagina	Collect urine specimen for laboratory examination. Refer to physician.
Discharge; smegma under labia	Foul-smelling discharge (infection)	Collect data and further evaluate reason for discharge.
Bloody or mucoid discharge	Excessive vaginal bleeding (blood coagulation defect)	
	*Possible causes of alterations are placed in parentheses.	†This column provides guidelines for further assessment and initial nursing interventions.

(continued)

ASSESSMENT GUIDE Newborn Physical Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
BUTTOCKS AND ANUS		
Buttocks symmetric	Pilonidal dimple	Examine for possible sinus. Instruct parents about cleansing this area.
Anus patent and passage of meconium within 24–48 hours after birth	Imperforate anus, rectal atresia (congenital gastrointestinal defect)	Evaluate extent of problems. Initiate surgical consultation.
No fissures, tears, or skin tags	Fissures	Perform digital examination to ascertain patency if patency uncertain.
EXTREMITIES AND TRUNK		
Short and generally flexed; extremities move symmetrically through range of motion but lack full extension	Unilateral or absence of movement (spinal cord involvement) Fetal position continued or limp (anoxia, CNS problems, hypoglycemia)	Review birth record to assess possible cause.
All joints move spontaneously; good muscle tone, of flexor type, birth to 2 months	Spasticity when infant begins using extensors (cerebral palsy, lack of muscle tone, "floppy baby" syndrome) Hypotonia (Down syndrome)	Collaborate with physician.
Arms: Equal in length	Brachial palsy (difficult birth)	Report to clinician.
Bilateral movement	Erb-Duchenne paralysis	
Flexed when quiet	Muscle weakness, fractured clavicle Absence of limb or change of size (phocomelia, amelia)	
Hands: Normal number of fingers	Polydactyly (Ellis-van Creveld syndrome) Syndactyly—one limb (developmental anomaly) Syndactyly—both limbs (genetic component)	Report to clinician.
Normal palmar crease	Single line on palm (Down syndrome)	Refer for genetic workup.
Normal-sized hands	Short fingers and broad hand (Hurler syndrome)	Evaluate for history of distress in utero.
Nails present and extend beyond fingertips in term newborn.	Cyanosis and clubbing (cardiac anomalies) Nails long or yellow stained (postterm)	Carry out cardiac and respiratory assessments. Check pulse oximetry.
Spine: C-shaped spine	Spina bifida occulta (nevus pilosus)	Evaluate extent of neurologic damage; initiate care of spinal opening.
Flat and straight when prone	Dermal sinus	
Slight lumbar lordosis	Myelomeningocele	
Easily flexed and intact when palpated	Head lag, limp, floppy trunk (neurologic problems)	
At least half of back devoid of lanugo		
Full-term infant in ventral suspension should hold head at 45-degree angle, back straight		Elicit reflex to assess degree of involvement.
Hips: No sign of instability	Sensation of abnormal movement; jerk, or snap of hip dislocation	Physician or nurse practitioner examines all newborn infants for dislocated hip prior to discharge from birthing center.
Hips abduct to more than 60 degrees		If this is suspected, refer to orthopedist for further evaluation. Reassess at well-baby visits.
Inguinal and buttock skin creases: Symmetric inguinal and buttock creases	Asymmetry (dislocated hips)	Refer to orthopedist for evaluation. Counsel parents regarding symptoms of concern and discuss therapy.
Legs: Legs equal in length	Shortened leg (dislocated hips)	Refer to orthopedist for evaluation.
Legs shorter than arms at birth	Lack of leg movement (fractures, spinal defects)	Counsel parents regarding symptoms of concern and discuss therapy.
Feet: Foot is in straight line	Talipes equinovarus (true clubfoot)	Discuss differences between positional and true clubfoot with parents.
Positional clubfoot—based on position in utero		Teach parents passive manipulation of foot. Refer to orthopedist if not corrected by 3 months of age.
Fat pads and creases on soles of feet	Incomplete sole creases in first 24 hours of life (premature)	
Talipes planus (flat feet) normal under 3 years of age		Reassure parents that flat feet are normal in infants.

*Possible causes of alterations are placed in parentheses.

†This column provides guidelines for further assessment and initial nursing interventions.

ASSESSMENT GUIDE Newborn Physical Assessment continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
NEUROMUSCULAR		
Motor function: Symmetric movement and strength in all extremities	Limp, flaccid, or hypertonic (CNS disorders, infection, dehydration, fracture)	Appraise newborn's posture and motor functions by observing activities and motor characteristics.
May be jerky or have brief twitchings	Tremors (hypoglycemia, hypocalcemia, infection, neurologic damage)	Evaluate for electrolyte imbalance, hypoglycemia, and neurologic functioning.
Head lag not over 45 degrees	Delayed or abnormal development (preterm, neurologic involvement)	
Neck control adequate to maintain head erect briefly	Asymmetry of tone or strength (neurologic damage)	Refer for genetic evaluation.
REFLEXES		
Blink: Stimulated by flash of light; response is closure of eyelids	Lack of blink response (damage to cranial nerve, CNS injury)	Assess neurologic status.
Pupillary reflex: Stimulated by flash of light; response is constriction of pupil	Lack of reflex (damage to cranial nerve, CNS injury)	
Moro: Response to sudden movement or loud noise should be one of symmetric extension and abduction of arms with fingers extended; then return to normal relaxed flexion.	Asymmetry of body response (fractured clavicle, injury to brachial plexus)	Discuss normality of this reflex in response to loud noises or sudden movements.
Infant lying on back: slightly raised head suddenly released; infant held horizontally, lowered quickly about 6 inches, and stopped abruptly	Consistent absence (brain damage)	Absence of reflex requires neurologic evaluation.
Fingers form a C		
Present at birth; disappears by 6 months of age		
Rooting and sucking: Turns in direction of stimulus to cheek or mouth; opens mouth and begins to suck rhythmically when finger or nipple is inserted into mouth; difficult to elicit after feeding; disappears by 4 to 7 months of age	Poor sucking or easily fatigable (preterm, breastfed infants of drug-addicted mothers, possible cardiac problem) Absence of response (preterm, neurologic involvement, depressed newborns)	Evaluate strength and coordination of sucking. Observe newborn during feeding, and counsel parents about mutuality of feeding experience and newborn's responses.
Sucking is adequate for nutritional intake and meeting oral stimulation needs; disappears by 12 months		
Palmar grasp: Fingers grasp adult finger when palm is stimulated and held momentarily; lessens at 3 to 4 months of age	Asymmetry of response (neurologic problems)	Evaluate other reflexes and general neurologic functioning.
Plantar grasp: Toes curl downward when sole of foot is stimulated; lessens by 8 months	Absent (defects of lower spinal column)	Assess for other lower extremity neurologic problems.
Stepping: When held upright and one foot touching a flat surface, will step alternately; disappears at 4 to 8 weeks of age	Asymmetry of stepping (neurologic abnormality)	Evaluate muscle tone and function on each side of body.
Babinski: Fanning and extension of all toes when one side of sole is stroked from heel upward across ball of foot; disappears at about 12 months	Absence of response (low spinal cord defects)	Refer to specialist. Refer for further neurologic evaluation.
Tonic neck: Fencer position—when head is turned to one side, extremities on same side extend and on opposite side flex; this reflex may not be evident during early neonatal period; disappears at 3 to 4 months of age	Absent after 1 month of age or persistent asymmetry (cerebral lesion)	Assess neurologic functioning.
Response often more dominant in leg than in arm		
Prone crawl: While on abdomen, newborn pushes up and tries to crawl	Absence or variance of response (preterm, weak, or depressed newborns)	Evaluate motor functioning. Refer to specialist.
Trunk Incurvation (Galant): In prone position, stroking of spine causes pelvis to turn to stimulated side	Failure to rotate to stimulated side (neurologic damage)	

*Possible causes of alterations are placed in parentheses.

†This column provides guidelines for further assessment and initial nursing interventions.

CLINICAL JUDGMENT

Case Study: Maria Reyes

Maria Reyes, a 19-year-old G2 (now P2) mother, delivered a 40-week-old female newborn 24 hours ago. The newborn exam was normal. Mrs. Reyes asks about the newborn's exam. She says she has noticed that the baby cries more than her first child did and seems to require holding for longer periods of time after feeding before "quieting down." She is concerned that there is something she is doing wrong and wants to know when her newborn will start to act like her first baby.

Critical Thinking

What should you discuss with her about newborn behavior?

See www.nursing.pearsonhighered.com for possible responses.

Newborn Behavioral Assessment

Two conflicting forces influence parents' perceptions of their newborn. One is the parents' preconceptions, based on hopes and fears, of what their newborn will be like. The other is their initial reaction to their baby's temperament, behaviors, and physical appearance. Nurses can assist parents in identifying their baby's specific behaviors.

> "One of the newborn's first responses is to move into a quiet but alert state of consciousness. The baby is still; his body molds to yours; his hands touch your skin; his eyes open wide and are bright and shiny. He looks directly at you.
>
> This special alert state, this innate ability to communicate, may be the initial preparation for becoming attached to other human beings. One feels awed by the intensity and appealing power of this little bud of humanity meeting the world for the first time."
>
> THE AMAZING NEWBORN

Brazelton's Neonatal Behavioral Assessment Scale The behavioral assessment tool attempts to identify the newborn's repertoire of behavioral responses to the environment and also documents the newborn's neurologic adequacy and capabilities. (For a complete discussion of all test items and maneuvers, see Brazelton & Nugent, 1995.) It provides a way for the healthcare provider, in conjunction with the parents (primary caregivers), to identify and understand the individual newborn's states, temperament, capabilities, and individual behavior patterns. Families learn which responses, interventions, or activities best meet the special needs of their newborn, and this understanding fosters positive attachment experiences.

Because the first few days after birth are a period of behavioral disorganization, the complete assessment should be done on the third day after birth. The nurse should make every effort to elicit the best response. This may be accomplished by repeating tests at different times or by testing during situations that facilitate the best possible response, such as when parents are holding, cuddling, rocking, or singing to their baby.

The behavioral assessment of the newborn should be carried out initially in a quiet, dimly lighted room, if possible. The nurse should first determine the newborn's state of consciousness, because scoring and introduction of the test items correlate with the sleep or awake state. The newborn's state depends on physiologic variables, such as the amount of time from the last feeding, positioning, environmental temperature, and health status; presence of such external stimuli as noises and bright lights; and the sleep-wake cycle of the infant. An important characteristic of the neonatal period is the pattern of states, as well as the transitions from one state to another. The pattern of states is a predictor of the newborn's receptivity and ability to respond to stimuli in a cognitive manner. Babies learn best in a quiet, alert state and in an environment that is supportive and protective and that provides appropriate stimuli.

The nurse should also observe the newborn's sleep-wake patterns (as discussed in chapter 29 ∞) and the rapidity with which the newborn moves from one state to another, the newborn's ability to be consoled, and the newborn's ability to diminish the impact of disturbing stimuli. The following questions provide the nurse with a framework for assessment:

- Does the newborn's response style and ability to adapt to stimuli indicate a need for parental interventions that will alert the newborn to the environment so that the baby can grow socially and cognitively?
- Are parental interventions necessary to lessen the outside stimuli, as in the case of the baby who responds to sensory input with intensity?
- Can the baby control the amount of sensory input to be dealt with?

The behaviors and the sleep-wake states in which they are assessed are categorized as follows:

- ***Habituation.*** The newborn's ability to diminish or shut down innate responses to specific repeated stimuli, such as a rattle, bell, light, or pinprick to heel.
- ***Orientation to inanimate and animate visual and auditory assessment stimuli.*** How often and where the newborn attends to auditory and visual stimuli are observed. Orientation to the environment is determined by an ability to respond to cues given by others and by a natural ability to fix on and to follow a visual object horizontally and vertically. This capacity and parental appreciation of it are important for positive communication between infant and parents; the parents' visual (*en face*) and auditory (soft, continuous voice) presence stimulates their infant to orient to them. Inability or lack of response may indicate visual or auditory problems. It is important for parents to know that their newborn can turn to voices usually soon after birth or by 3 days of age and can become alert at different times with a varying degree of intensity in response to sounds.
- ***Motor activity.*** Several components are evaluated. Motor tone of the newborn is assessed in the most characteristic state of responsiveness. This summary assessment includes overall use of tone as the newborn responds to being handled—whether

Care Plan Activity: Assessment of the Uncomplicated Newborn

during spontaneous activity, prone placement, or horizontal holding—and overall assessment of body tone as the newborn reacts to all stimuli.

- ***Variations.*** Frequency of alert states, state changes, color changes (throughout all states as examination progresses), activity, and peaks of excitement are assessed.
- ***Self-quieting activity.*** Assessment is based on how often, how quickly, and how effectively newborns can use their resources to quiet and console themselves when upset or distressed. Considered in this assessment are such self-consolatory activities as putting hand to mouth, sucking on a fist or the tongue, and attuning to an object or sound (Figure 30-45 ■). The newborn's need for outside consolation must also be considered—for example, seeing a face; being rocked, held, or dressed; using a pacifier; and being swaddled.
- ***Cuddliness or social behaviors.*** This area encompasses the infant's need for and response to being held. Also considered is how often the newborn smiles. These behaviors influence the parents' self-esteem and feelings of acceptance or rejection. Cuddling also appears to be an indicator of personality. Cuddlers appear to enjoy, accept, and seek physical contact; are easier to placate; sleep more; and form earlier and more intense attachments. Noncuddlers are active, are restless, have accelerated motor development, and are intolerant of physical restraint. Smiling, even as a grimace reflex, greatly influences parent-infant feedback. Parents identify this response as positive.

Figure 30-45 ■ The newborn can bring hand to mouth as a self-soothing activity.

FOCUS YOUR STUDY

- A perinatal history, determination of gestational age, physical examination, and behavioral assessment form the basis for complete newborn assessment.
- The common physical characteristics included in the gestational age assessment are skin, lanugo, sole (plantar) creases, breast tissue and size, ear form and cartilage, and genitals.
- The neuromuscular components of gestational age scoring tools are usually posture, square window sign, popliteal angle, arm recoil, heel-to-ear extension, and scarf sign.
- By assessing the physical and neuromuscular components specified in a gestational age tool, the nurse can determine the gestational age of the newborn.
- After determining the gestational age of the baby, the nurse can assess how the newborn will make the transition to extrauterine life and can anticipate potential physiologic problems.
- The nurse identifies the newborn as small for gestational age (SGA), appropriate for gestational age (AGA), or large for gestational age (LGA), and prioritizes individual needs.
- Normal ranges for vital signs assessed in newborns are heart rate of 110 to 160 beats per minute; respiratory rate of 30 to 60 respirations per minute; axillary temperature of 36.5°C to 37.2°C (97.7°F to 99°F); skin temperature of 36°C to 36.5°C (96.8°F to 97.7°F); rectal temperature of 36.6°C to 37.2°C (97.8°F to 99°F); and blood pressure of 70/45 to 50/30 mm Hg (at birth).
- Normal newborn measurements include weight from 2500 to 4000 g (5 lb, 8 oz to 8 lb, 13 oz), with weight dependent on maternal size and age; length from 48 to 52 cm (18 to 22 in.); and head circumference from 32 to 37 cm (12.5 to 14.5 in.). Head circumference is approximately 2 cm larger than the chest circumference.

- Commonly elicited newborn reflexes are tonic neck, Moro, grasping, rooting, sucking, and blink.
- Newborn behavioral abilities include habituation, orientation to visual and auditory stimuli, motor activity, cuddliness, and self-quieting activity.
- An important role of the nurse during the physical and behavioral assessments of the newborn is to teach parents about their newborn and involve them in their baby's care. This facilitates the parents' identification of their newborn's uniqueness and allays their concerns.

CRITICAL THINKING IN ACTION

Susan Pine, a 21-year-old G2, now P1011, delivers a 39 2/7-weeks gestation female newborn. The vaginal birth is assisted with a vacuum extractor. The prenatal record is significant for an increase of maternal blood pressure to 140/90 on the day of birth. Susan is treated with magnesium sulfate during her labor and has an epidural analgesia for the pain of labor. The baby's Apgar is 8 and 9 at 1 and 5 minutes, and she has been admitted to the newborn nursery. The newborn's admission exam is normal except for a 2-cm round caput succedaneum.

Now, 8 hours later, the baby's condition is stable and she needs to be bottle-fed. You take her to her mother's room where you observe that Susan does not reach out to take her from you. She seems unsure when handling her baby. Susan asks you about the swelling on her baby's head and wonders if it will ever go away.

1. How would you explain the cause of Susan's baby's caput succedaneum?
2. Compare the difference between a cephalhematoma and caput succedaneum.
3. Explore with Susan her baby's reflexes and state of alertness.
4. Susan asks you how she will know what her baby needs. How would you respond?

See www.nursing.pearsonhighered.com for possible responses.

The Normal Newborn: Needs and Care

CHAPTER 31

In the sheltered simplicity of the first days after a baby is born, one sees again the magical closed circle, the miraculous sense of two people existing only for each other.

—Anne Morrow Lindbergh

LEARNING OUTCOMES

1. Summarize the essential areas of information to be obtained about a newborn's birth experience and immediate postnatal period.
2. Explain how the physiologic and behavioral responses of a newborn during the first 4 hours after birth (admission and transitional period) determine the newborn's nursing care.
3. Identify activities that should be included in a daily care plan for a normal newborn.
4. Discuss the common concerns of families regarding their newborns.
5. Identify opportunities to individualize parent teaching and enhance each parent's abilities and confidence while providing infant care in the birthing unit.
6. Explain how the common and specific concerns of families can be included in parent teaching during daily newborn and infant care and discharge planning.

KEY TERMS

Circumcision *834*
Newborn screening tests *843*
Parent-newborn attachment *832*

At the moment of birth, numerous physiologic adaptations begin to take place in the newborn's body. Because of these dramatic changes, newborns require close observation to determine how smoothly they are making the transition to extrauterine life. Newborns also require special care that enhances their chances of making the transition successfully.

The two broad goals of nursing care during this period are (1) to promote the physical well-being of the newborn, and (2) to support the establishment of a well-functioning family unit. The nurse meets the first goal by providing comprehensive care to newborns while in the mother-baby unit. The nurse meets the second goal by teaching family members how to care for their new baby and by supporting their efforts so that they feel confident and competent. Thus, the nurse must be knowledgeable about family adjustments that need to be made as well as the healthcare needs of the newborn. It is important that the family return home with the positive feeling that they have the support, information, and skills to care for their newborn. Equally important is the need for each member of the family to begin a unique relationship with the newborn. The cultural and social expectations of individual families and communities affect the way normal newborn care is carried out.

The previous two chapters present an informational database of the physiologic and behavioral changes occurring in the newborn and the pertinent nursing assessments that are needed. This chapter discusses nursing care management while the newborn is in the birthing unit.

Nursing Care During Admission and the First Four Hours of Life

Immediately after birth, the baby is formally admitted to the healthcare facility.

Nursing Assessment and Diagnosis

Before the birth of an infant, the nurse reviews the prenatal record of the mother for information concerning possible risk factors for the infant. These include infectious disease screening results, drug or alcohol use by the mother, gestational diabetes, and any other data determined to be of use in anticipating the needs of the newborn. In addition, the nurse reviews the birth record for prolonged rupture of membranes, instrument or vacuum delivery, use of narcotic analgesia, presence of meconium, and any other data that may impact the infant's ability to successfully transition to the extrauterine environment.

During the first hours after birth, the nurse carries out a preliminary physical examination, including an assessment of the newborn's physiologic adaptations. In many birthing units, the nurse performs and documents the initial head-to-toe physical assessment during the first hour of transition. The nurse is responsible for notifying the physician or nurse practitioner of any deviations from normal. A complete physical examination is also performed later by the physician or nurse practitioner, within the first 24 hours after birth and within 24 hours before discharge. This can be accomplished with one physical examination (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2007). (See chapter 30 ∞.)

Nursing diagnoses are based on an analysis of the assessment findings. Physiologic alterations of the newborn form the basis of many nursing diagnoses, as does the family's incorporation of them in caring for their new baby. Nursing diagnoses that may apply to the newborn include the following:

- ***Ineffective Airway Clearance*** related to presence of mucus and retained lung fluid
- ***Risk for Imbalanced Body Temperature*** related to evaporative, radiant, conductive, and convective heat losses
- ***Ineffective Peripheral Tissue Perfusion*** related to ineffective thermoregulation or poor peripheral circulation
- ***Acute Pain*** related to heel sticks for glucose or hematocrit tests, vitamin K injection, or Hepatitis B immunization

As discussed in chapter 29 ∞, the newborn's physiologic adaptation to extrauterine life occurs rapidly. All body systems are affected. Therefore, many of these nursing diagnoses and associated interventions must be identified and implemented in a very short period (Table 31-1).

Nursing Plan and Implementation

The nurse initiates newborn admission procedures and evaluates the newborn's need to remain under observation. This evaluation may take place in a special transition area or at the mother's bedside. It includes the following:

- Maternal and birth history
- Airway clearance
- Vital signs
- Body temperature
- Neurologic status
- Ability to feed
- Evidence of complications and/or illness

TABLE 31-1 Signs of Newborn Transition

Normal findings for the newborn during the first few days of life include the following:

Pulse: 110–160 beats/minute
- During sleep as low as 100 beats/minute
- If crying, up to 180 beats/minute
- Apical pulse is counted for 1 full minute because rate may fluctuate

Respirations: 30–60 respirations/minute
- Predominantly diaphragmatic but synchronous with abdominal movements
- Brief periods of apnea (less than 15 seconds) with no color or heart rate changes

Temperature:
- Axillary: 36.4°C–37.2°C (97.5°F–99°F)
- Skin: 36°C–36.5°C (96.8°F–97.7°F)

Blood pressure: 70–50/45–30 mm Hg at birth; 90/60 mm Hg at day 10

Blood glucose: greater than or equal to 40 mg%

Hematocrit: less than 65% to 70% central venous sample

If the evaluation is normal, the baby is successfully making the transition to extrauterine life and may need less frequent observations. In some settings, this may also be a time for moving the mother and baby to another care unit.

Initiation of Admission Procedures

After birth the baby is formally admitted to the healthcare facility. The admission procedures include a review of prenatal and birth information for possible risk factors, a gestational age assessment, and an assessment to ensure that the newborn's adaptation to extrauterine life is proceeding normally. This evaluation for risk factors and the status of the newborn must be done no later than 2 hours after birth (AAP & ACOG, 2007).

If the initial assessment indicates that the newborn is not at risk physiologically, the nurse performs many of the routine admission procedures in the presence of the parents and others in the birthing area. Some care measures indicated by the assessment findings may be performed by the nurse or by family members under the guidance of the nurse in an effort to educate and support the family. Other interventions might best be delayed if the newborn must be transferred to an observational nursery.

The nurse responsible for the newborn first checks and confirms the newborn's identification with the mother's identification and then obtains and records all significant information. The essential data to be recorded as part of the newborn's chart include the following:

1. ***Condition of the newborn.*** Pertinent information includes the newborn's Apgar scores at 1 and 5 minutes, resuscitative measures required in the birthing area, physical examination, vital signs, voidings, and passing of meconium. Complications to be noted include excessive mucus, delayed spontaneous respirations or responsiveness, abnormal number of cord vessels, abnormal vital signs, and obvious physical abnormalities.
2. ***Labor and birth record.*** A copy of the labor and birth record should be placed in the newborn's chart or be accessible on computer. The record contains all the significant data about the birth, for example, duration, course, and status of mother and fetus throughout labor and birth and any analgesia or anesthesia administered to the mother. Particular care is taken to note any variation or difficulties such as prolonged rupture of membranes, abnormal fetal position, meconium-stained amniotic fluid, signs of nonreassuring fetal status during labor, nuchal cord (cord around the newborn's neck at birth), precipitous birth, use of forceps or vacuum extraction assisted device, maternal analgesia and anesthesia received within 1 hour of birth, and administration of antibiotics during labor.
3. ***Antepartum history.*** Preexisting maternal conditions or any maternal problems that may have compromised the fetus in utero—such as preeclampsia, spotting, illness, recent infections, rubella status, serology results, hepatitis B screen results, exposure to group B streptococci, or a history of maternal substance abuse—are of immediate concern in newborn assessment. The chart should also include information about maternal age, estimated date of birth (EDB), previous pregnancies, and presence of any congenital anomalies. An HIV test result, if obtained, is also relevant. State statutes vary as to who may have access to this information (AAP & ACOG, 2007).
4. ***Parent-newborn interaction information.*** The nurse notes parents' interactions with their newborn and their desires regarding care, such as rooming-in, circumcision, and type of feeding. Information about other children in the home, available support systems, interactional patterns within each family unit, situations that compromise lactation (breast surgery, previous lactation failure), and any high risk circumstances (adolescent mother, domestic violence, history of child abuse) help in providing comprehensive care (AAP & ACOG, 2007).

As part of the admission procedure, the nurse weighs the newborn in both grams and pounds (Figure 31-1 ■). In the United States, parents understand weights best when stated in pounds and ounces. The nurse cleans and covers the scale each time a newborn is weighed to prevent cross-infection and heat loss from conduction.

The nurse then measures the newborn, recording the measurements in both centimeters and inches. Three routine measurements are length, circumference of the head, and circumference of the chest. In some facilities, abdominal girth may also be measured. The nurse rapidly assesses the baby's color, muscle tone, alertness, and general state. Remember that the first period of reactivity may have concluded, and the baby may be in the sleep-inactive phase, which makes the infant hard to arouse. The nurse does basic assessments for estimating gestational age and completes the physical assessment. (For more discussion of the process of newborn assessment, see chapter 30 ∞.)

In addition to obtaining vital signs, the nurse performs hematocrit and blood glucose evaluations on at-risk newborns or as clinically indicated (such as for small-for-gestational-age [SGA] or large-for-gestational-age [LGA] infants or if the newborn is jittery). These procedures may be done on admission or

Figure 31-1 ■ Weighing a newborn. The scale is balanced before each weighing, with the protective pad in place.

CLINICAL PATHWAY For Newborn Care

Category	First 4 Hours	4–12 Hours Past Birth	8–24 Hours Past Birth
Referral	Review labor/birth record Review transitional nursing record Check ID bands and security alarms if present Consult prn: orthopedics, genetics, infectious disease	Check ID bands and security alarms Transfer to mother-baby care at 4–6 hours of age if stable for at least 2 hours As parents desire, obtain circumcision permit after their discussion with physician Check ID bands and crib cards to ensure they are in the correct crib Lactation consult prn	Check ID bands and security alarm q shift ■ ***Expected Outcomes*** Mother/baby ID bands correlate at time of discharge; security alarms in place at all times; consults completed prn
Assessments	Continue assessments begun first hour after birth Vital signs: TPR, BP prn, q1h × 4 (skin temp 96.8°F–97.7°F (36°C–36.5°C), resp may be irregular but within 30–60 per min) ■ ***Newborn Assessments*** • Respiratory status with resp distress scale × 1 then prn. If resp distress, assess every 5–15 min • Cord: bluish white color, clamp in place and free of skin • Color: skin, mucous membranes, extremities, trunk pink with slight acrocyanosis of hands and feet • Wt (5 lb, 8 oz–8 lb, 13 oz) 2500–4000 g, length (18–22 in.) 46–56 cm, HC (12.5–14.5 in.) 32–37 cm, CC (32.5 cm, 1–2 cm less than head) • Extremity movement—may be jerky or brief twitches • Gestational age classification—term AGA • Anomalies (cong. anomalies can interfere with normal extrauterine adaptation)	Assess newborn's progress through periods of reactivity Vital signs: TPR q8h; and prn or per agency protocol, BP prn ■ ***Newborn Assessments*** • Skin color q4h prn (circulatory system stabilizing, acrocyanosis decreased) • Auscultate lungs q4h (noisy, wet breath sounds clear and equal) • Eyes for drainage, redness, hemorrhage • Umbilical cord base for redness, drainage, foul odor, drying, damp in place • Increased mucus production (normal in 2nd period of reactivity) • Check apical pulse q4h • Temp before and after admission bath • Extremity movements q4h • Check for expected reflexes (suck, rooting, Moro, grasp, blink, yawn, sneeze, tonic neck, Babinski) • Note common normal variations • Assess suck and swallow during feeding • Note behavioral characteristics	VS q8h; normal ranges: T, 97.5°F–99°F (36.4°C–37.2°C) axillary; P, 110–160; R, 30–60; BP, 70–50/45–30 mm Hg ■ ***Continue Newborn Assessments*** • Skin color q4h prn • Signs of drying or infection in cord area • Check that clamp is in place until removed before discharge • Check circ for bleeding after procedure, then q30 min × 2, then q4h and prn • Observe for jaundice, obtain total serum bili (TSB) if infant visibly jaundiced before 24 hours of age. Obtain transcutaneous bili on all infants not previously tested before discharge ■ ***Expected Outcomes*** Vital signs medically acceptable, color pink, assessments WNL, circ site without s/s infection, cord site without s/s of infection and clamp removed; newborn behavior WNL
Teaching/ psychosocial	Admission activities performed at mother's bedside if possible, orient to nursery prn, hand washing, assess teaching needs Teach parents use of bulb syringe, signs of choking, positioning, and when to call for assistance Teach reasons for use of radiant warmer, infant hat, and warmed blankets when out of warmer Discuss/teach infant security, identification	Reinforce teaching about choking, bulb syringe use, positioning, temperature maintenance with clothing and blankets Teach infant positioning to facilitate breathing and digestion Teach new parents holding and feeding skills Teach parents soothing and calming techniques Teach parents about introducing newborn to sibling	Final discharge teaching: diapering, normal void and stool patterns, bathing, nail, and cord care, circumcision/uncircumcised penis/genital care and normal characteristics, rashes, jaundice, sleep-wake cycles, soothing activities, taking temperatures, thermometer reading Explain s/s of illness and when to call healthcare provider Infant safety: car seats, immunizations, metabolic screening ■ ***Expected Outcomes*** Mother/family verbalize comprehension of teaching; demonstrate care capabilities
Nursing care management and reports	Place under radiant warmer Place hat on newborn (decreases convection heat loss) Suction nares/mouth with bulb syringe prn Keep bulb syringe with infant Attach security sensor Obtain lab tests: blood glucose, as needed Obtain blood type, Rh, Coombs on cord blood, HSV culture if parental hx Notify physician's office of infant's birth and any change in status Maintain standard precautions	Wean from radiant warmer (T 98.6°F [37°C] axillary) Glucose testing prn; BP prn Suction nares prn (esp during 2nd period of reactivity) Oxygen saturation prn Bathe infant if temp greater than 97.7°F (36.5°C) axillary Position on back Obtain peripheral Hct per protocol Cord care per protocol Fold diaper below cord (for plastic diapers, turn plastic layer away from skin)	Check for hearing test results Weigh before discharge Cord assessment every shift DC cord clamp before discharge[1] Perform newborn metabolic screening blood tests before discharge Circumcision if indicated; circumcision care: change diaper prn, noting ability to void; follow policy for circumcision clamp or Plastibell care ■ ***Expected Outcomes*** Newborn maintains temp, lab test WNL, cord dry without s/s infection and clamp removed, screening tests accomplished, circ site without s/s infection or bleeding

1. In the case of very early discharge, the cord may still be moist enough that the decision may be made to leave it in place until the follow-up visit with the physician.

Category	First 4 Hours	4–12 Hours Past Birth	8–24 Hours Past Birth
Activity and comfort	Place under radiant warmer or wrap in pre-warmed blankets until stable Soothe baby as needed with voice, touch, cuddling, nesting in warmer	Leave in warmer until stable, then swaddle Position on back after each feeding	Place in open crib Swaddle to allow movement of extremities in blanket, including hands to face ■ ***Expected Outcomes*** Infant maintains temp WNL in open crib; infant attempts self-calming
Nutrition	Assist newborn to breastfeed as soon as mother/baby condition allows Supplement breast only when medically indicated or per agency policy Initiate formula-feeding within first hour Gavage feed if necessary to prevent hypoglycemia	Breastfeed on demand, at least q3–4h Teach positions, observe/assist with feeding, breast/nipple care, establishing milk supply, breaking suction, feeding cues, latching-on techniques, nutritive suck, burping Formula-feed on demand, at least q3–4h Determine readiness to feed and feeding tolerance	Continue breastfeeding or formula-feeding pattern Assess feeding tolerance q4h Discuss normal feeding requirements, signs of hunger and satiation, handling feeding problems, and when to seek help ■ ***Expected Outcomes*** Mother verbalizes knowledge of feeding information; breastfeeds on demand without supplement; bottle: tolerates formula feeding, nipples without problems
Elimination	Note first void and stool if not noted at birth	Note all voids, amount and color of stools q4h	Evaluate all voids and stool color q8h ■ ***Expected Outcomes*** Voids qs; stools qs without difficulty; stool character WNL, diaper area without s/s of skin breakdown or rashes
Medication	Prophylactic ophthalmic ointment both eyes after baby makes eye contact with parents within 1 hr after birth Administer AquaMEPHYTON IM, dosage according to infant weight per MD/NP order	Hepatitis B injection as ordered by physician after consent signed by parents	Hepatitis B vaccine within 2 hr of birth or before discharge ■ ***Expected Outcomes*** Baby has received ophthalmic ointment and vitamin K injection; baby has received first Hep B vaccine if ordered and parental permission received
Discharge planning/ home care	Hepatitis B consent signed Hearing screen consent signed Plan discharge call with parent or guardian in 24 hr to 2 days Assess parents' discharge plans, needs, and support systems	Review/reinforce teaching with mother and significant other Review home preparedness Present birth certificate instructions	Initial newborn screening tests (hearing, blood tests, genetic/metabolic screen) before discharge Bath and feeding classes, videos, or written information given Give written copy of discharge instructions Newborn photographs Set up appointment for follow-up PKU test Have car seat available before discharge. All discharge referrals made, follow-up appt. scheduled ■ ***Expected Outcomes*** Infant discharged home with family; mother verbalizes follow-up appt. time/date
Family involvement	Facilitate early investigation of baby's physical characteristics (maintain temp during unwrapping), hold infant *en face* Dim lights to help infant keep eyes open	Assess parents' knowledge of newborn behaviors, such as alertness, suck and rooting, attention to human voice, response to calming techniques Facilitate parent interaction with infant by performing care in presence of parents and encouraging parents to participate in care	Assess mother-baby bonding/interaction Incorporate father and siblings in care Enhance parent-infant interaction by sharing characteristics and behavioral assessment Support positive parenting behaviors Identify community referral needs and refer to community agencies ■ ***Expected Outcome*** Demonstrates caring and family incorporation of infant
Date			

Abbreviations: AGA, average for gestational age; Appt, appointment; CC, chest circumference; cong, congenital; esp, especially; HC, head circumference; Hct, hematocrit; Hx, history; ID, identification; PKU, phenylketonuria; qs, quantity sufficient; s/s, signs and symptoms; temp, temperature; TPR, temperature, pulse, respirations; VS, vital signs; WNL, within normal limits.

within the first 2 hours after birth (AAP & ACOG, 2007). (See Procedure 34-1 ∞: Performing a Heel Stick on a Newborn on page 961.)

CLINICAL JUDGMENT

Case Study: Baby Johannson

You overhear Mr. Johannson speaking to his mother on the phone. He is telling her about the "cute little noises" his 30-minute-old baby makes. The infant is in the room with the mother.

Critical Thinking

What is your best course of action?

See www.nursing.pearsonhighered.com for possible responses.

Maintenance of a Clear Airway and Stable Vital Signs

Free-flow oxygen should be readily available. The nurse positions the newborn on his or her back (or side, if the infant has copious secretions). If necessary, a bulb syringe or DeLee wall suction (see Procedure 24-1 ∞: Performing Nasal Pharyngeal Suctioning on page 622) is used to remove mucus from the nasal passages and oral cavity. A DeLee catheter attached to suction may be used to remove mucus from the stomach to help prevent possible aspiration. When possible, this procedure should be delayed for 10 to 15 minutes after birth, reducing the potential for severe vasovagal reflex apnea.

In the absence of any newborn distress, the nurse continues with the admission by taking the newborn's vital signs. The initial temperature is taken by the axillary method. A wider range of normal exists for axillary temperature, specifically 36.4°C to 37.2°C (97.5°F to 99°F).

Once the initial temperature is taken, the nurse monitors the core temperature either by obtaining axillary temperatures at intervals or by placing a skin sensor on the newborn for continuous reading. The usual skin sensor placement site is on the newborn's abdomen, but placement on the upper thigh or arm can give a reading closely correlated with the mean body temperature. The vital signs for a healthy term newborn should be monitored at least every 30 minutes until the newborn's condition has remained stable for 2 hours (AAP & ACOG, 2007). The newborn's respirations may be irregular yet still be normal. Brief periods of apnea, lasting only 5 to 10 seconds with no color or heart rate changes, are considered normal. The normal pulse range is 110 to 160 beats per minute (beats/min), and the normal respiratory range is 30 to 60 respirations per minute.

Maintenance of a Neutral Thermal Environment

A neutral thermal environment is essential to minimize the newborn's need for increased oxygen consumption and use of calories to maintain body heat in the optimal range of 36.4°C to 37.2°C (97.5°F to 99°F). If the newborn becomes hypothermic, the body's response can lead to metabolic acidosis, hypoxia, and shock.

The nurse can best achieve a neutral thermal environment by performing the assessment and interventions with a newborn unclothed and under a radiant warmer. The radiant warmer's thermostat is controlled by the thermal skin sensor taped to the newborn's abdomen, upper thigh, or arm (Figure 31-2 ■). The sensor indicates when the newborn's temperature exceeds or falls below the acceptable temperature range. The nurse should be aware that leaning over the newborn may block the radiant heat waves from reaching the newborn. It is common practice in some institutions to cover the newborn's head with a cap made of stockinette or other material to prevent additional heat loss, in addition to placing the newborn under a radiant warmer (Blackburn, 2007).

CLINICAL TIP

A cap can be fashioned from a piece of stockinette to help reduce heat loss from the head.

In light of early discharge practices (12 to 48 hours), healthy term infants can be safely bathed immediately after the admission assessment is completed. The baby is bathed while still under the radiant warmer and should, when possible, take place in the parents' room or with parents present. Bathing the newborn offers an excellent opportunity for teaching and welcoming parent involvement in the care of their baby. If there is any doubt regarding the infant's condition, the baby may be given a sponge bath when the newborn's temperature is normal and vital signs are stable (about 2 to 4 hours after birth), when the newborn's condition dictates, or when the parents wish to give the first bath.

The nurse rechecks the temperature after the bath and, if it is stable, dresses the newborn in a shirt, diaper, and cap; wraps the baby; and places the baby in an open crib at room temperature. If the baby's axillary temperature is below 36.5°C (97.7°F), the nurse returns the baby to the radiant warmer. The rewarming process should be gradual to prevent the possibility of hyperthermia. Once the newborn is rewarmed, the nurse implements measures to prevent further neonatal heat loss, such as keeping the newborn dry, swaddled in one or two blankets with hat on, and away from cool surfaces or instruments. The nurse also protects the newborn from drafts, open windows or doors, and air conditioners. Blankets and clothing are stored in a warm place. See "Temperature" in chapter 30 ∞ and Procedure 31-1. Newborns are often "double-wrapped" in two or more blankets for temperature maintenance.

CLINICAL TIP

Take action to help the newborn maintain a stable temperature:

- Keep the newborn's clothing and bedding dry.
- Double-wrap the newborn and put a stocking cap on him or her.
- Use the radiant warmer during procedures.
- Reduce the newborn's exposure to drafts.
- Warm objects that will be in contact with the newborn (e.g., stethoscopes).
- Encourage the mother to snuggle with the newborn under blankets or to breastfeed the newborn with hat and light cover.

Prevention of Vitamin K Deficiency Bleeding

A prophylactic injection of vitamin K_1 (AquaMEPHYTON) is given to prevent hemorrhage, which can occur because of low

PROCEDURE 31-1 Thermoregulation of the Newborn

NURSING ACTION

Preparation

- Pre-warm the incubator or radiant warmer. Make sure warm towels and/or lightweight blankets are available.
- Maintain the temperature of the birthing room at 22°C (71°F), with a relative humidity of 60% to 65%.

  Rationale: *The change from a warm, moist intrauterine environment to a cool, dry, drafty environment stresses the newborn's immature thermoregulation system.*

Equipment and Supplies

Pre-warmed towels or blankets

Infant stocking cap

Servocontrol probe

Infant T-shirt and diaper

Open crib

Figure 31-2 ■ Temperature monitoring for the newborn. A skin thermal sensor is placed on the newborn's abdomen, upper thigh, or arm and secured with porous tape or a foil-covered foam pad.

Source: Photographer, Elena Dorfman.

Procedure: Clean Gloves

1. Don gloves.

   Rationale: *Gloves are worn whenever there is the possibility of contact with body fluids—in this case, a newborn wet with amniotic fluid, vernix, and maternal blood.*

2. Place the newborn under the radiant warmer. Wipe the newborn free of blood, fluid, and excess vernix, especially from the head, using pre-warmed towels.

   Rationale: *The radiant warmer creates a heat-gaining environment. Drying is important to prevent the loss of body heat through evaporation.*

3. If the newborn is stable, wrap him or her in a pre-warmed blanket, apply a stocking cap, and carry the newborn to the mother. The mother and her support person can hold and enjoy the newborn together. Alternatively, carry the wrapped newborn to the mother, loosen the blanket, and place the infant skin to skin on the mother's chest under a warmed blanket.

   Rationale: *Use of a pre-warmed blanket reduces convection heat loss and facilitates maternal-newborn contact without compromising the newborn's thermoregulation. Skin-to-skin contact with the mother or father helps maintain the newborn's temperature.*

4. After the newborn has spent time with the parents, return him or her to the radiant warmer and apply a diaper. Leave the newborn uncovered (except for the cap and diaper) under the radiant warmer.

   Rationale: *Radiant heat warms the outer skin surface, so the skin needs to be exposed.*

5. Tape a servocontrol probe on the newborn's anterior abdominal wall, with the metal side next to the skin. Do not place it over the ribs. Secure the probe with porous tape or a foil-covered aluminum heat deflector patch. Figure 31-2 shows a newborn with a skin probe. Note that in this picture the newborn is no longer wearing a stocking cap.

6. Turn the heater to servocontrol mode so that the abdominal skin is maintained at 36.0°C to 36.5°C (96.8°F to 97.7°F).

7. Monitor the newborn's axillary and skin probe temperatures per agency protocol.

   Rationale: *The temperature indicator on the radiant warmer continually displays the newborn's probe temperature. The axillary temperature is checked to ensure that the machine is accurately recording the newborn's temperature.*

8. When the newborn's axillary temperature reaches 37°C (98.6°F), add a T-shirt, double-wrap the infant (two blankets), and place the newborn in an open crib.

9. Recheck the newborn's temperature in 1 hour and regularly thereafter according to agency policy.

   Rationale: *It is important to monitor the newborn's ability to maintain his or her own thermoregulation.*

10. If the newborn's temperature drops below 36.1°C (97°F), rewarm the infant gradually. Place the infant (unclothed except for a diaper) under the radiant warmer with a servocontrol probe on the anterior abdominal wall.

    Rationale: *Rapid heating can lead to hyperthermia, which is associated with apnea, insensible water loss, and increased metabolic rate.*

11. Recheck the newborn's temperature in 30 minutes, then hourly.

12. When the temperature reaches 37°C (98.6°F), dress the newborn, remove him or her from the radiant warmer, double-wrap, and place in an open crib. Check the temperature hourly until stable, then regularly according to agency policy.

Note: *An infant who repeatedly requires rewarming should be observed for other signs and symptoms of illness and a physician notified, because it may warrant screening for infection.*

DRUG GUIDE Vitamin K_1 Phytonadione (AquaMEPHYTON)

OVERVIEW OF NEONATAL ACTION

Phytonadione is used in prophylaxis and treatment of vitamin K deficiency bleeding (VKDB), formerly known as hemorrhagic disease of the newborn. It promotes liver formation of the clotting factors II, VII, IX, and X. At birth, the newborn does not have the bacteria in the colon that are necessary for synthesizing fat-soluble vitamin K_1. Therefore, the newborn may have decreased levels of prothrombin during the first 5 to 8 days of life, reflected by a prolongation of prothrombin time.

PREGNANCY RISK CATEGORY: C

ROUTE, DOSAGE, FREQUENCY

Intramuscular injection is given in the vastus lateralis thigh muscle. A one-time-only prophylactic dose of 0.5 to 1 mg is given intramuscularly in the birthing area or within 1 hour of birth or may be delayed until after first breastfeeding in the birthing area (Wilson et al., 2010).

If the mother received anticoagulants during pregnancy, an additional dose may be ordered by the physician and is given 6 to 8 hours after the first injection. IM concentration: 1 mg/0.5 ml (neonatal strength); can use 10 mg/ml concentration to minimize volume injected.

NEONATAL SIDE EFFECTS

Pain and edema may occur at the injection site. Allergic reactions, such as rash and urticaria, may also occur.

NURSING CONSIDERATIONS

- Protect the drug from light.
- Observe for signs of local inflammation.
- Observe for jaundice and kernicterus, especially in preterm infants.
- Give vitamin K_1 before circumcision procedure.
- Observe for bleeding (usually occurs on second or third day). Bleeding may be seen as generalized ecchymoses or bleeding from the umbilical cord, circumcision site, nose, or gastrointestinal tract. Results of serial prothrombin time (PT) and international normalized ratio (INR) should be assessed.
- Observe for jaundice and kernicterus, especially in preterm infants.

prothrombin levels in the first few days of life (see Drug Guide: Vitamin K_1 Phytonadione [AquaMEPHYTON]). The potential for hemorrhage results from the absence of gut bacterial flora, which influences the production of vitamin K in the newborn. (See chapter 34 ∞ for further discussion.) Current recommendations underscore the need for treatment in infants who are exclusively breastfed (Blackburn, 2007).

Vitamin K injection is given intramuscularly in the vastus lateralis muscle that lies along the midanterior lateral aspect of the thigh (Figure 31-3 ■). Before injecting, the nurse must clean the newborn's skin site for the injection thoroughly with a small alcohol swab. The nurse uses a 25-gauge, 5/8-inch needle for the injection. An alternative site is the rectus femoris muscle in the anterior aspect of the thigh. However, this site is near the sciatic nerve and femoral artery and should be used with caution (Figure 31-4 ■).

Figure 31-3 ■ Procedure for vitamin K injection. Cleanse area thoroughly with alcohol swab, and allow skin to dry. Bunch the tissue of the midanterior lateral aspect of the thigh (vastus lateralis muscle) and quickly insert a 25-gauge 5/8-inch needle at a 90-degree angle to the thigh. Aspirate, then slowly inject the solution to distribute the medication evenly and minimize the baby's discomfort. Remove the needle and massage the site with an alcohol swab.

Source: Photographer, Elena Dorfman.

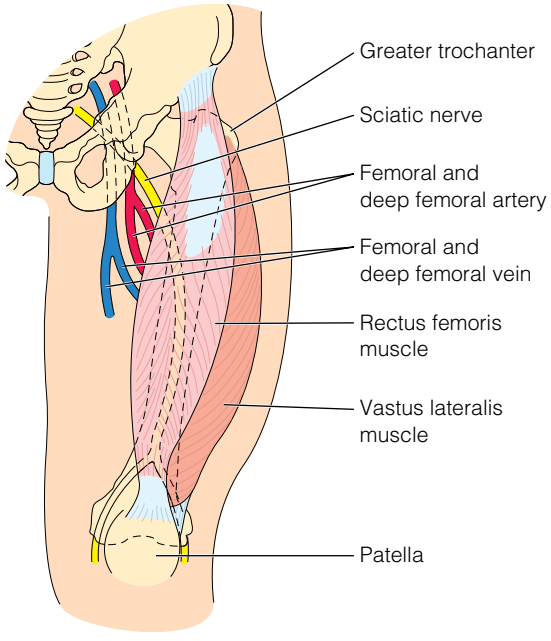

Figure 31-4 ■ Injection sites. The middle third of the vastus lateralis muscle is the preferred site for intramuscular injection in the newborn. The middle third of the rectus femoris is an alternative site, but its proximity to major vessels and the sciatic nerve necessitates caution in using this site for injection.

Prevention of Eye Infection

The nurse is also responsible for giving the legally required prophylactic eye treatment for *Neisseria gonorrhoeae,* which may have infected the newborn of an infected mother during the birth process. A variety of topical agents appear to be equally effective. Ophthalmic ointments that are used include 0.5% erythromycin (Ilotycin Ophthalmic) (see Drug Guide: Erythromycin Ophthalmic Ointment [Ilotycin Ophthalmic]), 1% tetracycline, or per agency protocol. All are also effective against chlamydia, which has a higher incidence rate than gonorrhea.

Successful eye prophylaxis requires that the medication be instilled into the lower conjunctival sac of each eye (Figure 31-5 ■).

Figure 31-5 ■ Ophthalmic ointment. Retract lower eyelid outward to instill a 1/4-inch strand of ointment from a single-dose ampule along the lower conjunctival surface.

The nurse massages the eyelid gently to distribute the ointment. Instillation may be delayed up to 1 hour after birth to allow eye contact during parent-newborn bonding.

Eye prophylaxis medication can cause chemical conjunctivitis, which gives the newborn some discomfort and may interfere with the baby's ability to focus on the parents' faces. The resulting edema, inflammation, and discharge may cause concern if the parents have not been informed that the side effects will clear in 24 to 48 hours and that this prophylactic eye treatment is necessary for the newborn's well-being.

Early Assessment of Neonatal Distress

During the first 24 hours of life, nurses are constantly alert for signs of distress. If the newborn is with the parents during this period, the nurse must take extra care to teach them how to maintain their newborn's temperature, recognize the hallmarks of newborn distress, and respond immediately to signs of respiratory problems. The parents should learn to observe the newborn for changes in skin color or activity, rapid breathing with chest retractions, nasal flaring, or facial grimacing. Their interventions should include nasal and oral suctioning with bulb syringe, positioning, and vigorous fingertip stroking of the newborn's spine to stimulate respiratory activity if necessary. The nurse must be immediately available to provide appropriate interventions should the newborn develop distress (Table 31-2).

A common cause of neonatal distress is early-onset group B streptococcal (GBS) disease. Infected mothers transmit GBS infection to their infants during labor and birth; thus it is recommended that at-risk mothers receive intrapartum antimicrobial prophylaxis (IAP) for GBS disease. All infants of mothers identified as at risk should be assessed and observed for signs and symptoms of sepsis. It is important to know the policy and procedures that your hospital follows for surveillance of at-risk infants.

DRUG GUIDE Erythromycin Ophthalmic Ointment (Ilotycin Ophthalmic)

OVERVIEW OF NEONATAL ACTION

Erythromycin (Ilotycin Ophthalmic) is used as prophylactic treatment of ophthalmia neonatorum, which is caused by the bacteria *Neisseria gonorrhoeae.* Preventive treatment of gonorrhea in the newborn is required by law. Erythromycin is also effective against ophthalmic chlamydial infections. It is either bacteriostatic or bactericidal, depending on the organisms involved and the concentration of the drug.

PREGNANCY RISK CATEGORY: B

ROUTE, DOSAGE, FREQUENCY

Ophthalmic ointment (0.5%) is instilled as a narrow ribbon or strand, 0.5 to 1 cm long, along the lower conjunctival surface of each eye, starting at the inner canthus. It is instilled only once in each eye. The ointment may be administered in the birthing area or, alternatively, later in the nursery so that eye contact between infant and parent is facilitated and the bonding process immediately after birth is not interrupted. After administration, gently close the eye and manipulate to ensure spread of ointment (Wilson et al., 2010).

NEONATAL SIDE EFFECTS

Sensitivity reaction; may interfere with ability to focus and may cause edema and inflammation. Side effects usually disappear in 24 to 48 hours.

NURSING CONSIDERATIONS

- Wash hands immediately before instillation to prevent introduction of bacteria.
- Do not irrigate the eyes after instillation. Use new tube or single-use container for ophthalmic ointment administration shortly after birth. May wipe away excess after 1 minute.
- Observe for hypersensitivity.
- Teach parents about need for eye prophylaxis. Educate them regarding side effects and signs that need to be reported to the healthcare provider.

TABLE 31-2 Signs of Neonatal Distress

- Increased respiratory rate (more than 60/minute) or difficult respirations
- Sternal, substernal, intercostal retractions
- Nasal flaring
- Grunting
- Excessive mucus
- Facial grimacing
- Cyanosis (central: skin, lips, tongue)
- Abdominal distention or mass
- Vomiting of bile-stained material
- Absence of meconium elimination within 24 hours of birth
- Absence of urine elimination within 24 hours of birth
- Jaundice of the skin within 24 hours of birth or because of hemolytic process
- Temperature instability (hypothermia or hyperthermia)
- Jitteriness or glucose less than 40 mg%

Source: Adapted from Tappero, E. P., & Honeyfield, M. E. (1996). Physical assessment of the newborn *(2nd ed.). Petaluma, CA: NICU Inc.*

Initiation of First Feeding

The timing of the first feeding varies, depending on whether the newborn is to be breastfed or formula-fed and whether there were any complications during pregnancy or birth, such as maternal diabetes or intrauterine growth restriction (IUGR).

Mothers who choose to breastfeed their newborns should be encouraged to put their baby to breast during the first period of reactivity. This practice should be encouraged because successful, long-term breastfeeding during infancy appears to be related to beginning breastfeedings in the first few hours of life. Sleep-wake states affect feeding behavior and need to be considered when evaluating the newborn's sucking ability (Tedder, 2008).

Newborn Care

Formula-fed newborns usually begin the first feedings by 5 hours of age, during the second period of reactivity, when they awaken and appear hungry. Signs indicating newborn readiness for the first feeding are licking of the lips, placing a hand in or near the mouth, mouthing the blanket, active bowel sounds, absence of abdominal distention, and a lusty cry that quiets with rooting and sucking behaviors when a stimulus is placed near the lips. Observing the earlier, more subtle cues that baby is ready to nurse provides an opportunity for the nurse to teach the parents to recognize these cues and respond before the baby is frustrated and crying.

Facilitation of Parent-Newborn Attachment

To facilitate **parent-newborn attachment**, eye-to-eye contact between parents and their newborn is extremely important during the early hours after birth, when the newborn is in the first period of reactivity. The newborn is alert during this time, the eyes are wide open, and direct eye contact is made with human faces within optimal range for visual acuity (7 to 8 inches). Eye contact is an important component of the emerging parent-baby bond (Klaus & Klaus, 1985). Consequently, the prophylactic eye medication is often delayed, but no more than 1 hour, to provide an opportunity for this period of eye contact between parents and their newborn, thus facilitating the attachment process (AAP & ACOG, 2007). Parents who cannot be with their newborns in this first period because of maternal or infant distress may need reassurance that the bonding process can proceed normally as soon as both mother and baby are stable.

Another situation that can facilitate attachment is the interactive bath. While bathing their newborn for the first time, parents attend closely to their baby's behavior. In this way the newborn becomes an active participant and parents are drawn into an interaction with their newborn. The nurse can interpret the infant's behavior, model ways to respond to the behavior, and support parental strategies for doing so (Tedder, 2008).

> "Now I believe in love at first sight!"
>
> — A New Mother Holding Her Infant for the First Time

Evaluation

When evaluating the nursing care provided during the period immediately after birth, the nurse may anticipate the following outcomes:

- The newborn baby's adaptation to extrauterine life is supported and complete.
- The baby's physiologic and psychologic integrity is supported.
- Positive interactions between parent and infant will be supported.

Nursing Management of the Newborn Following Transition

Once healthy newborns have demonstrated successful adaptation to extrauterine life, they need appropriate observations for the first 6 to 12 hours after birth and the remainder of their stay in the birthing facility.

Nursing Diagnosis

Examples of nursing diagnoses that may apply during daily care of the newborn include the following:

- ***Risk for Ineffective Breathing Pattern*** related to periodic breathing
- ***Imbalanced Nutrition: Less Than Body Requirements*** related to limited nutritional or fluid intake and increased caloric expenditure
- ***Impaired Urinary Elimination*** related to meatal edema secondary to circumcision
- ***Risk for Infection*** related to umbilical cord healing, circumcision site, immature immune system, or potential birth trauma (forceps or vacuum extraction birth)
- ***Readiness for Enhanced Knowledge*** related to lack of information about basic baby care, male circumcision, and breast- and/or formula-feeding
- ***Readiness for Enhanced Family Relationship*** related to integration of newborn into family unit or demands of newborn care and feeding
- ***Risk for Injury*** related to hyperbilirubinemia

CLINICAL JUDGMENT

Case Study: Aisha Khan

Aisha Khan gave birth to a healthy girl 2 hours ago. Now she calls you to her room. She sounds frightened and says her baby can't breathe. You find Aisha cradling her newborn in her arms. The baby is mildly cyanotic, is waving her arms, and has mucus coming from her nose and mouth.

Critical Thinking

What would you do?

See www.nursing.pearsonhighered.com for possible responses.

Nursing Plan and Implementation

Maintenance of Cardiopulmonary Function

The nurse assesses vital signs every 6 to 8 hours or more, depending on the newborn's status. The newborn should be placed on his or her back (supine) for sleeping. A bulb syringe is kept within easy reach should the baby need oral-nasal suctioning. If the newborn has respiratory difficulty, the airway is cleared. Vigorous fingertip stroking of the baby's spine will frequently stimulate respiratory activity. A cardiorespiratory monitor can be used on newborns who are not being observed at all times and are at risk for decreased respiratory or cardiac function. Indicators of risk are pallor, cyanosis, ruddy color, apnea, or other signs of instability. Changes in skin color may indicate the need for closer assessment of temperature, cardiopulmonary status, hematocrit, glucose, and bilirubin levels.

Maintenance of a Neutral Thermal Environment

The nurse makes every effort to maintain the newborn's temperature within the normal range. The nurse must make certain the newborn is dried completely after the bath, dressed, and exposed to the air as little as possible. A head covering should be used initially and continued with the small newborn, who has less subcutaneous fat to act as insulation in maintaining body heat. Ambient temperature of the room where the newborn is kept should be monitored to prevent excessive cooling. Parents may be advised to dress the newborn in one more layer of clothing than is necessary for an adult to maintain thermal comfort. The use of clothes layering allows for flexibility as the infant is moved from one area to another.

A newborn whose temperature falls below optimal levels will use calories to maintain body heat rather than for growth. Chilling also decreases the affinity of serum albumin for bilirubin, thereby increasing the likelihood of newborn jaundice. It also increases oxygen use and may cause respiratory distress. An infant who is overheated will have an increased respiratory and heart rate and may also become more active, burning up precious caloric reserves. The increase in respiratory rate also results in insensible fluid loss.

CLINICAL JUDGMENT

Case Study: John Fredericks

John Fredericks, the father of a child less than a day old, has the child lying on its back with only a diaper. When you suggest that the baby may need more covering, he responds: "He doesn't like all that stuff on. After all, he's been naked until now."

Critical Thinking

What actions and teaching are appropriate in this situation?

See www.nursing.pearsonhighered.com for possible responses.

Promotion of Adequate Hydration and Nutrition

The nurse records the newborn's caloric and fluid intake and enhances adequate hydration by maintaining a neutral thermal environment and offering early and frequent feedings. Early feedings promote gastric emptying and increase peristalsis, thereby decreasing the degree of hyperbilirubinemia by limiting the amount of time fecal material is in contact with the enzyme β-glucuronidase in the small intestine. This enzyme acts to free the bilirubin from the stool, allowing bilirubin to be reabsorbed into the vascular system. The nurse records voiding and stooling patterns. The first voiding should occur within 24 hours and passage of stool within 48 hours. When they do not occur, the nurse continues the normal observation routine while assessing for abdominal distention, bowel sounds, hydration, fluid intake, voiding pattern, and temperature stability.

The newborn should be weighed at the same time each day for accurate comparisons and must be kept warm during the weighing. A weight loss of up to 10% for term newborns is considered within normal limits during the first week of life. This weight loss is the result of limited intake, loss of excess extracellular fluid, and passage of meconium. Parents should be told about the expected weight loss, the reason for it, and the expectations for regaining the birth weight. Birth weight should be regained by 2 weeks if feedings are adequate.

Excessive handling can cause an increase in the newborn's metabolic rate and calorie use and cause fatigue. The nurse should be alert to the baby's subtle cues of fatigue, including a decrease in muscle tension and activity in the extremities and neck, as well as loss of eye contact, which may be manifested by fluttering or closing the eyelids. The nurse quickly ceases stimulation when signs of fatigue appear and demonstrates to the parents the need to be aware of newborn cues of fatigue and to wait for periods of alertness for contact and stimulation. The nurse is also responsible for assessing the woman's comfort and latching-on techniques, if breastfeeding, or bottle-feeding techniques. Newborn nutrition is addressed in depth in chapter 32 ∞.

Promotion of Skin Integrity

Newborn skin care, including bathing, is important for the health and appearance of the individual newborn and for infection control within the nursery. Ongoing skin care involves cleansing the buttock and perianal areas with fresh water and cotton, or with a mild soap and water, with diaper changes. If commercial baby wipes are used, those without alcohol should be selected. Wipes that are perfume- and latex-free are also available.

The umbilical cord is assessed for signs of bleeding or infection. Removal of the cord clamp within 24 to 48 hours of birth reduces the chance of tension injury to the area. Keeping the umbilical stump clean and dry can reduce the chance for infection (Figure 31-6 ■). Many types of routine cord care are practiced, including the use of triple-dye or an antimicrobial agent such as bacitracin or application of 70% alcohol to the cord stump. These practices are largely based on tradition rather than current research findings. The skin absorption and toxicity of triple-dye agents in newborns have not been carefully studied. No single method of umbilical cord care (topical antimicrobials [triple-dye, iodophor ointment, or hexachlorophene powder] or alcohol)

Care Plan Activity: Infant Care During Transition

Figure 31-6 ■ The umbilical cord base is carefully cleaned.
Source: George Dodson/Lightworks Studio/Pearson Education.

has been proven to be superior in preventing colonization and disease (AAP & ACOG, 2007). The use of sterile water or air drying results in umbilical cords separating more quickly than those treated with alcohol (Askin, 2008).

Folding the diaper down to prevent coverage of the cord stump can prevent contamination of the area and promote drying. The nurse is responsible for cord care per agency policy. It is also the nurse's responsibility to instruct parents in caring for the cord and observing for signs and symptoms of infection after discharge, such as foul smell, redness and greenish yellow drainage, localized heat and tenderness, or bright red bleeding or if the area remains unhealed 2 to 3 days after the cord has sloughed off.

Promotion of Safety

Safety of the newborn is paramount. It is essential that the nurse and other caregivers verify the identity of the newborn by comparing the numbers and names on the identification bracelets of mother and newborn before giving a baby to a parent (Askin, 2008). Another form of identification band attached to the ankle or umbilical cord has a built-in sensor unit that sounds an alarm if the baby is transported beyond set birthing unit boundaries. Individual birthing units should practice safety measures to prevent infant abduction and provide information to parents regarding their role in this area, as well as in general newborn safety measures (Vincent, 2009). Parental measures to prevent abduction and promote newborn safety include the following:

Security

- Checking that identification bands are in place as they care for their infant and, if missing, asking that they be replaced immediately
- Allowing only people with proper birthing unit identification to remove their baby from their room. If parents do not know the staff person, they should call the nurse for assistance.
- Reporting the presence of any suspicious people on the birthing unit

Safety

- Never leaving their newborn alone in their room. If parents walk in the halls or take a shower, they should have a family member watch the newborn or they should return the newborn to the nursery.
- Never lifting the newborn if a parent feels weak, faint, or unsteady on his or her feet. Instead, the parent should call for assistance.
- Always keeping an eye and hand on the newborn when he or she is out of the crib.
- Protecting from infection, even though newborns do possess some immunity. Parents should ask visitors to leave if they have any of the following: cold, diarrhea, discharge from sores, or contagious disease.

Prevention of Complications

Newborns are at continued risk for the complications of hemorrhage, late-onset cardiac symptoms, jaundice, and infection. Pallor may be an early sign of hemorrhage and must be reported to the physician. The newborn is placed on a cardiorespiratory monitor to permit continuous assessment. Several newborn conditions or procedures such as circumcision put the newborn at risk for bleeding. Cyanosis that is not relieved by oxygen administration requires emergency intervention, may indicate a congenital cardiac condition or shock, and requires immediate and ongoing assessment.

Infection in the nursery is best prevented by requiring that all personnel having direct contact with newborns scrub for 2 to 3 minutes from fingertips to and including elbows at the beginning of each shift. The hands must be washed with soap and rubbed vigorously for 15 seconds before and after contact with every newborn or after touching any soiled surface, such as the floor or one's hair or face. Parents are instructed to practice good hand washing and/or use of an antiseptic hand cleaner before touching the baby. They are also instructed that anyone holding the baby should wash hands as well, even after the family returns home. In some clinical settings family members are requested to wear a gown (preferably disposable) over their street clothes during contact with infants. These are good opportunities for the nurse to reinforce the efficacy of hand washing in preventing the spread of infection.

Jaundice occurs in most newborn infants. Most jaundice is benign, but because of the potential toxicity of bilirubin, newborn infants must be monitored to identify those who might develop severe hyperbilirubinemia and, in rare cases, acute bilirubin encephalopathy or kernicterus (see chapter 34 ∞ for a more detailed discussion) (AAP & ACOG, 2007). Current recommendations include obtaining a total serum bilirubin level in any infant who is visibly jaundiced in the first 24 hours of life, and obtaining either a serum or transcutaneous bilirubin level before discharge. Nomograms for evaluating risk factors based on bilirubin levels and age of infant are available (see chapter 29 ∞ for discussion).

Circumcision

Circumcision is a surgical procedure in which the prepuce, an epithelial layer covering the tip of the penis, is separated from the glans penis and excised. This permits exposure of the glans for easier cleaning.

Circumcision was originally a religious rite practiced by Jews and Muslims. The practice gained widespread cultural ac-

ceptance in the United States but is much less common in Europe. Families make the decision about circumcision for their newborn male child. Many parents choose circumcision because they want the male child to have a physical appearance similar to that of the father or the majority of other children, or they may feel that it is expected by society. Another commonly cited reason for circumcising newborn males is to prevent the need for anesthesia, hospitalization, pain, and trauma should the procedure be needed later in life (AAP & ACOG, 2007). To ensure informed consent, parents should be advised during the prenatal period about possible long-term medical effects of circumcision and noncircumcision.

CURRENT RECOMMENDATIONS The 2005 AAP policy statement reaffirmed that it does not recommend *routine* circumcision but acknowledges that medical indications for circumcision still exist (AAP & ACOG, 2007). The policy recommends that analgesia (e.g., dorsal penile nerve block [DPNB] or subcutaneous ring block) be used during circumcision to decrease procedural pain (American Academy of Pediatrics (AAP) & Canadian Paediatric Society (CPS), 2006). The DPNB and subcutaneous ring block are the most effective options. If a circumcision is to be performed it should be done using the least painful method. Recent studies show that using oral sucrose for painful procedures can be effective in managing pain for newborns and it should be used with other nonpharmacologic measures to enhance its effectiveness (AAP & CPS, 2006).

Circumcision *should not be performed* if the newborn is premature or compromised, has a known bleeding problem, or is born with a genitourinary defect, such as hypospadias or epispadias, which may necessitate the use of the foreskin in future surgical repairs.

NURSE'S ROLE A well-informed nurse can allay parents' anxiety by sharing information and allowing them to express their concerns. In order for parents to make a truly informed decision, they must be knowledgeable about the potential risks and outcomes of circumcision. Hemorrhage, infection, difficulty in voiding, separation of the edges of the circumcision, pain, and restlessness are early potential problems. Later there is the risk that the glans and urethral meatus can become irritated and inflamed from contact with ammonia from urine. Ulcerations and progressive stenosis may develop. Adhesions, progressive stenosis, entrapment of the penis, and damage to the urethra are all potential complications that could require surgical correction (AAP & ACOG, 2007).

The parents of an uncircumcised male infant require information from the nurse about good hygiene practices. They should be told that the foreskin and glans are two similar layers of cells that separate from each other. The separation process begins prenatally and is normally completed at between 3 and 5 years of age. In the process of separation, sterile sloughed cells build up between the layers. This buildup looks similar to the smegma secreted after puberty, and it is harmless. Occasionally during the daily bath, the parents can gently test for retraction. If retraction has occurred, daily gentle washing of the glans with soap and water is sufficient to maintain adequate cleanliness. The parents should teach the child to incorporate this practice into his daily self-care activities. Most uncircumcised males have no difficulty doing so.

If circumcision is desired, the procedure should be performed after the newborn is well stabilized and has received his initial physical examination by a healthcare provider. The parents may also choose to have the circumcision done after discharge. However, they need to be advised that if the baby is older than 1 month, the current practice is to hospitalize him for the procedure.

Before a circumcision, the nurse ascertains that the physician has explained the procedure, determines whether the parents have any further questions about the procedure, and verified that the circumcision permit is signed. As with any surgical procedure, the identification band of the infant should be checked to verify his identity before the procedure begins. The nurse gathers the equipment and prepares the newborn by removing the diaper and placing him on a padded circumcision board or some other type of restraint, but restraining only the legs. These restraint measures along with the application of warm blankets to the upper body increase comfort during the procedure. In Jewish circumcision ceremonies, the infant is held by the father or grandfather and given wine before the procedure.

There are a variety of devices (Gomco clamp, Plastibell, Mogen clamp) used for circumcision (Figures 31-7 ■ and 31-8 ■), and all produce minimal bleeding. Therefore the nurse should make special note of infants with a family history of bleeding disorders or with mothers who took anticoagulants, including aspirin, prenatally. During the procedure, the nurse assesses the newborn's response. One important consideration is pain experienced by the newborn. A DPNB or ring block using 1% lidocaine without epinephrine or similar anesthetic significantly minimizes the pain and the shifts in behavioral patterns, such as crying, irritability, and erratic sleep cycles associated with circumcision. Other studies of pain control measures involve the use of topical anesthetic applied 60 to 90 minutes before prepuce removal and the use of sucrose pacifiers before and during the procedure, acetaminophen, and cryoanalgesia. Studies indicate that a combination of methods is most effective in reducing pain during circumcision (AAP & CPS, 2006).

During the procedure, the nurse can provide comfort measures such as lightly stroking the baby's head, providing a pacifier, and talking to him. Following the circumcision, the infant should be held and comforted by a family member or the nurse. The nurse must be alert to any cues that these measures are overstimulating the newborn instead of comforting him. Such cues include turning away of the head, increased generalized body movement, skin color changes, hyperalertness, and hiccuping.

Ideally, the circumcision should be assessed for signs of hemorrhage and infection every 30 minutes for at least 2 hours following the procedure. It is important to observe for the first voiding after a circumcision to evaluate for urinary obstruction related to penile injury and/or edema. Petroleum and gauze are applied to the site immediately following the procedure to help prevent bleeding and can be used to protect the healing tissue afterward.

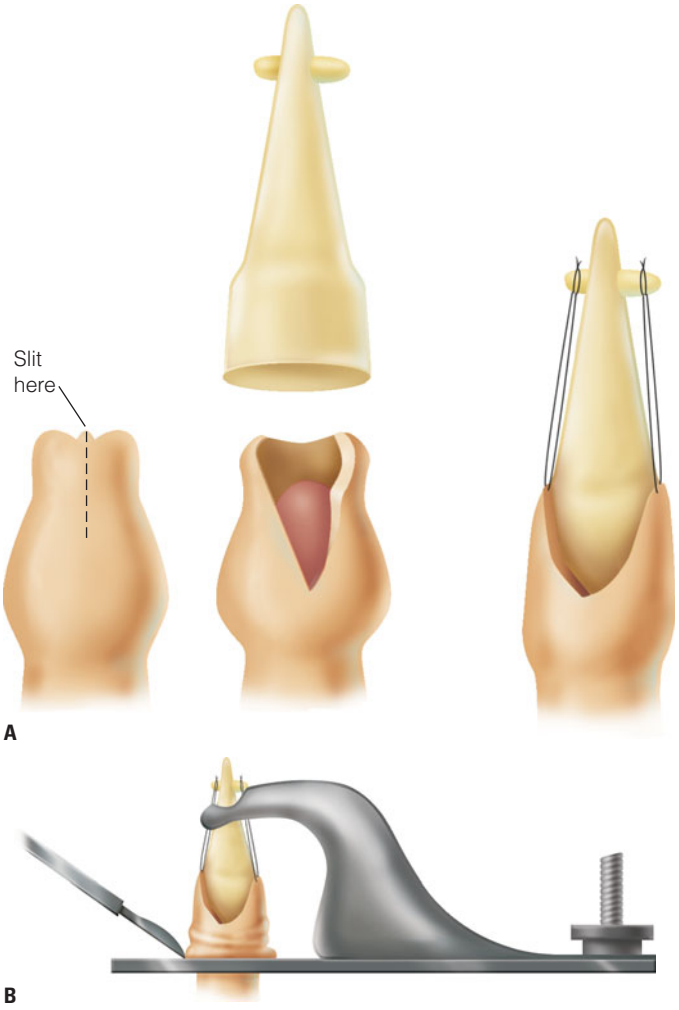

Figure 31-7 ■ Circumcision using the Yellen or Gomco clamp. A. The prepuce is drawn over the cone. B. The clamp is applied. Pressure is maintained for 3 to 4 minutes, and then excess prepuce is cut away.

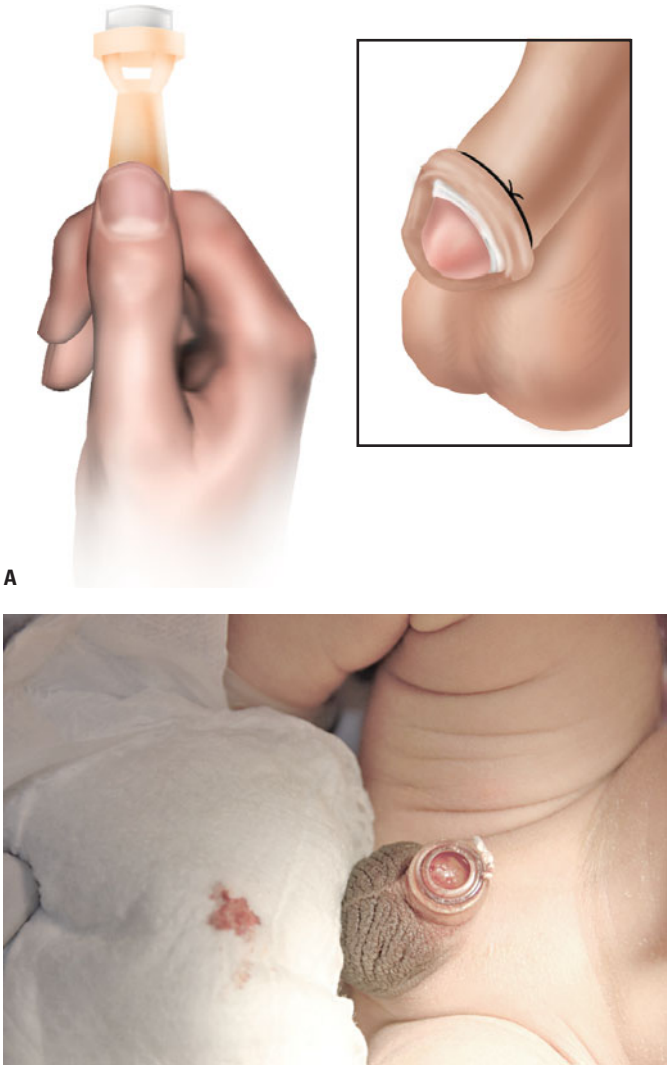

Figure 31-8 ■ Circumcision using the Plastibell. A. The bell is fitted over the glans. A suture is tied around the bell's rim, and the excess prepuce is cut away. The plastic rim remains in place for 3 to 4 days until healing occurs. The bell may be allowed to fall off; it is removed if still in place after 8 days. B. Plastibell.

Source: B. Courtesy of Jo Engle, RN, MSN, NNP-BC and Vanessa Howell, RN, MSN, NNP-BC.

The nurse must also teach family members how to assess for unusual bleeding, how to respond if it is present, and how to care for the newly circumcised penis. Parents of babies circumcised with a method other than Plastibell should receive the following information:

- Clean with warm water with each diaper change.
- Apply petroleum ointment for the next few diaper changes to help prevent further bleeding (Figure 31-9 ■).
- If bleeding does occur, apply light pressure with a sterile gauze pad to stop the bleeding within a short time. If this is not effective, contact the physician immediately, or take the baby to the healthcare provider's office.
- The glans normally has granulation tissue (a yellowish film) on it during healing. Continued application of a petroleum ointment (or ointment suggested by the healthcare provider) can help protect the granulation tissue that forms as the glans heals.
- Report to the care provider any signs or symptoms of infection, such as increasing swelling, pus drainage, and cessation of urination.
- When diapering, ensure that the diaper is not loose enough to cause rubbing with movement, or tight enough to cause pain.
- If the infant's care provider recommends oral analgesics, follow instructions for proper measuring and administration.

If the Plastibell is used, parents should receive information about normal appearance and how to observe for infection. The parents are informed that the Plastibell should fall off within 8 days. If it still remains after 8 days, they should consult with their physician. Though no ointments or creams should be used while the bell remains, use of petroleum ointment to protect granulation tissue may be useful afterward.

Enhancement of Parent-Newborn Attachment

Parent-newborn attachment is promoted by encouraging all family members to be involved with the new member of the family. Some specific interventions are examined in chapters 24 ∞ and 36 ∞ and the accompanying Patient Teaching: Enhancing At-

Figure 31-9 ■ Following circumcision, petroleum ointment may be applied to the site for the next few diaper changes.

tachment. Infant massage is a common childcare practice in many parts of the world, especially Africa and Asia, and has recently gained attention in the United States. Parents can be taught to use infant massage as a method to facilitate the bonding process and to reduce the stress and pain associated with teething, inoculations, constipation, and colic. Infant massage not only induces relaxation for the infant, but also provides a calming and "feel good" interaction for the parents, which fosters the development of warm, positive relationships.

DEVELOPING CULTURAL COMPETENCE

Infant Naming in Kenya

In Kenya, the naming of the child is an important event. Names are commonly selected to mirror important or current events. For example, an infant who is born while traveling may be given a name that means "wanderer" or "traveler." Other names may be chosen after a relative who is among the "living-dead" (deceased). It is believed that this results in a partial reincarnation of that relative, especially if the child has characteristics in common with that individual. It is also believed there is a connection between newborns and the spirit world. In some parts of the country, the name is chosen when the child is crying. Different names of the living-dead are called, and when the child stops crying when a particular name is called, that becomes the child's given name. In some areas, the name is given on the third day and is marked by a celebration with feasting and rejoicing. On the fourth day, the father of the child commonly hangs an iron necklace on the child's neck. It is at this time that the infant is considered a full human being and the connection with the spirit world is lost.

The nurse can discuss waking activities such as talking with the baby while making eye contact, holding the baby in an upright position (sitting or standing), gently bending the baby back and forth while grasping under the knees and supporting the head and back with the other hand, and gently rubbing the baby's hands and feet. Quieting activities may include swaddling the baby to increase a sense of security; using slow, calming movements; and talking softly, singing, or humming to the baby (Figure 31-10 ■).

A Letter From Your Baby

Dear Parents:

I come to you a small, immature being with my own style and personality. I am yours for only a short time; enjoy me.

1. Please take time to find out who I am, how I differ from you, and how much I can bring you joy.
2. Please feed me when I am hungry. I never knew hunger in the womb, and clocks and time mean little to me.
3. Please hold, cuddle, kiss, touch, stroke, and croon to me. I was always held closely in the womb and was never alone before.
4. Please don't be disappointed when I am not the perfect baby that you expected, nor disappointed with yourselves that you are not the perfect parents.
5. Please don't expect too much from me as your newborn baby, or too much from yourself as a parent. Give us both six weeks as a birthday present—six weeks for me to grow, develop, mature, and become more stable and predictable, and six weeks for you to rest and relax and allow your body to get back to normal.
6. Please forgive me if I cry a lot. Bear with me and in a short time, as I mature, I will spend less and less time crying and more time socializing.
7. Please watch me carefully and I can tell you the things that soothe, console, and please me. I am not a tyrant who was sent to make your life miserable, but the only way I can tell you that I am not happy is with my cry.
8. Please remember that I am resilient and can withstand the many natural mistakes you will make with me. As long as you make them with love, you cannot ruin me.
9. Please take care of yourself and eat a balanced diet, rest, and exercise so that when we are together, you have the health and strength to take care of me.
10. Please take care of your relationship with others. Relationships that are good for you, support both you and me.

Although I may have turned your life upside down, please realize that things will be back to normal before long.

Thank you,

Your Loving Child

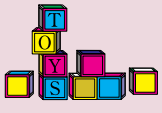

Figure 31-10 ■ A letter from your baby.

PATIENT TEACHING Enhancing Attachment

PATIENT GOALS At the completion of teaching, the parents will be able to:

1. Demonstrate appropriate nurturing behaviors such as touching, bonding, talking to, kissing, and holding their baby.
2. Discuss the normal characteristics and emotional needs of the newborn.
3. List at least three comforting techniques.

TEACHING PLAN

Content	Teaching Method
■ Present information on periods of reactivity and expected newborn responses.	Focus on open discussion.
■ Describe normal physical characteristics of the newborn (see chapter 30 ∞).	Present slides showing newborn characteristics, or in teaching an individual family, point out the normal physical characteristics of their child.
■ Explain the bonding process, its gradual development, and the reciprocal interactive nature of the process.	
■ Discuss the infant's capabilities for interaction, such as nonverbal communication abilities. The nonverbal communications include movement, gaze, touch, facial expressions, and vocalizations—including crying. Emphasize that eye contact is considered one of the cardinal factors in developing infant-parent attachment and will be integrated with touching and vocal behaviors.	Show a video on the interactive capabilities of newborns. In the mother-baby or newborn setting, this teaching is effectively done by nurses who point out the communication that babies are exhibiting throughout the day, enhancing the parents' awareness of the responses of their own infant.
■ Explain that touching, including stroking, patting, massaging, and kissing, will progress to interactive touch between the parents and their infant; discuss their need to assimilate these behaviors into their daily routine with the baby.	Provide handouts, and use a doll to demonstrate behaviors, because repeating even soothing touch, as each family member practices it, can be overstimulating to the infant, thus use of a doll to reinforce teaching can be very helpful.
■ Describe and demonstrate comforting techniques, including the use of sound, swaddling, rocking, massage, and stroking.	Demonstrate the techniques and ask for a return demonstration.
■ Describe the progression of the infant's behaviors as the infant matures, and the importance of the parents' consistent response to their infant's cues and needs.	Allow time for questions and discussion.
■ Provide information about available pamphlets, videos, classes, and support groups in the community.	

Evaluation

Evaluate the learning by providing time for discussion, questions, and return demonstrations in the birthing unit, and during the postpartal return visit or home visit. Continue to observe the parents' positive interaction with their baby during the remainder of their stay in the birthing unit.

Documentation

The nurse should document the information that was given, the type of teaching method used, indicate if the parent performed nurturing behaviors such as touching and comfort techniques, and if verbal or written directions were given. Verbalization of understanding and clarification of any information should be documented. Safety issues and instructions on newborn physical characteristics and normal progression of infant behaviors were given.

Caring for newborns in the birthing setting means that the nurse will have contact with patients from a wide variety of racial, religious, and cultural backgrounds. Though it may not be possible to be conversant with all cultures, the nurse can demonstrate cultural competence with both colleagues and patients. The nurse must be sensitive to the cultural beliefs and values of the family and be aware of cultural variations in newborn care such as the timing of naming the newborn, giving compliments about the baby, and using good luck charms. The nurse plays a vital role in fostering parent-infant attachment. It is important to be sensitive to the cultural beliefs and values of the family.

Several methods may be used to teach parents about newborn care. Daily newborn care videos or classes are a nonthreatening way to convey general information. Individual instruction is helpful to answer specific questions or to clarify an item that may have been confusing in class. Currently many birthing centers have 24-hour educational video channels or videos to be viewed in the mother's room on a variety of postpartum and newborn care issues.

DEVELOPING CULTURAL COMPETENCE

Examples of Cultural Beliefs and Practices Regarding Baby Care*

UMBILICAL CORD

- People of Latin American or Filipino cultural background may use an abdominal binder or bellyband to protect against dirt, injury, and umbilical hernia. They may also apply oils to the stump of the cord or tape metal to the umbilicus to ward off evil spirits (D'Avanzo & Geissler, 2008).
- People of northern European ancestry may expect a sterile cutting of the cord at birth. They may allow the stump to air-dry and discard the cord once it falls off.
- Some Latin American cultures cauterize the stump with a hot flame, hot coal, or the like (World Health Organization [WHO], 1999).
- In Kenya, women may express colostrum to the cord stump (WHO, 1999).
- In Ecuador, the cord is left long in girls to prevent a small uterus and problems with childbirth (WHO, 1999).

PARENT-INFANT CONTACT

- People of Asian ancestry may pick up the baby as soon as he or she cries, or they may carry the baby at all times.
- Some Native Americans, notably the Navajos, may use cradle boards so the infant can be with the family even during work (Andrews, 2008).
- The Muslim father traditionally calls praise to Allah in the newborn's right ear and cleans the infant after birth.

FEEDING

- Some women of Asian heritage may breastfeed their babies for the first 1 to 2 years of life. Many Cambodian refugees practice breastfeeding on demand without restriction, or, if formula-feeding, provide a "comfort bottle" in between feedings (Lipson & Dibble, 2008).
- People of Iranian heritage may breastfeed female babies longer than male babies.
- Some people of African ancestry may wean their babies after they begin to walk.
- Some Asians, Hispanics, Eastern Europeans, and Native Americans may delay breastfeeding because they believe colostrum is "bad" (D'Avanzo & Geissler, 2008).
- Haitian mothers may believe that "strong emotions" spoil breast milk (Lipson & Dibble, 2008).

CIRCUMCISION

- People of Muslim and Jewish ancestry practice circumcision as a religious ritual (Lipson & Dibble, 2008).
- Many natives of Africa and Australia practice circumcision as a puberty rite.
- Native Americans and people of Asian and Latin American cultures rarely perform circumcision (Lipson & Dibble, 2008).
- As of 2006, global estimates are that about 30% of males are circumcised (WHO, 2008).

HEALTH AND ILLNESS

- Some people from Latin American cultural backgrounds may believe that touching the face or head of an infant when admiring it will ward off the "evil eye." They may also neglect to cut the baby's nails to avoid nearsightedness and instead put mittens on the baby's hands to prevent scratching. They also may believe that fat babies are healthier (Andrews, 2008).
- Some people of Asian heritage may not allow anyone to touch the baby's head without asking permission.
- Some Orthodox Jews believe that saying the baby's name before the formal naming ceremony will harm the baby.
- Some Asians and Haitians delay naming their infants (D'Avanzo & Geissler, 2008).
- Some people of Vietnamese ancestry believe that cutting a baby's hair or nails will cause illness.

*Note: The information is meant only to provide examples of some of the behaviors that may be found within certain cultures. Not all members of a culture practice the behaviors described.

Evaluation

When evaluating the nursing care provided during the newborn period, the nurse may anticipate the following outcomes:

- The baby's physiologic and psychologic integrity is supported.
- The newborn feeding pattern will be satisfactorily established.
- The parents express understanding of the bonding process and display attachment behaviors.

Nursing Management in Preparation for Discharge

Although the adjustment to parenting is a normal process, going home presents a critical transition for the family. The parents become the primary caregivers for the newborn and must provide a nurturing environment in which the emotional and physical needs of the newborn can be met. Nursing interventions focus on promoting health and preventing possible problems.

Nursing Assessment and Diagnosis

When preparing for discharge, assess whether parents have realistic expectations of the newborn's behavior and the depth of their knowledge in caring for their newborn.

Nursing diagnoses that may apply to the newborn's family include the following:

- ***Readiness for Enhanced Parenting*** related to appropriate behavioral expectations for the newborn
- ***Readiness for Enhanced Family Processes*** related to integration of newborn into family unit or demands of newborn care and feeding

Planning and Implementation

HEALTH PROMOTION EDUCATION

To meet parent needs for information, the nurse who is responsible for the daily care of the mother and newborn should assume the primary responsibility for parent education. Nearly every contact with the parents presents an opportunity for sharing information that can facilitate their sense of competence in newborn care. The nurse also needs to recognize and respect the fact that there are many good ways to provide safe care. Unless their care methods are harmful to the newborn, the parents' methods of giving care should be reinforced rather than contradicted.

The information that follows is provided to increase the nurse's knowledge of newborn care and is used to meet parents' needs for information. Parents may be familiar with handling and caring for infants, or this may be their first time to interact with a newborn. If they are new parents, the sensitive nurse gently teaches them by example and provides instructions geared to their needs and previous knowledge about the various aspects of newborn care.

The nurse observes how parents interact with their infant during feeding and caregiving activities. Even during a short stay, there will be opportunities for the nurse to provide information and evaluate whether the parents are comfortable with changing diapers and wrapping, handling, and feeding their newborn (Figure 31-11 ■). Do both parents get involved in the infant's care? Is the mother depending on someone else to help her at home? Does the mother give excuses ("I am too tired," "My stitches hurt," or "I will learn later") for not wanting to be involved in her baby's care? As the family provides care, the nurse can enhance parental confidence by giving them positive feedback. If the family encounters problems, the nurse can express confidence in the family's abilities to master the new skill or information, suggest alternatives, and serve as a role model. All these considerations need to be taken into account when evaluating the educational needs of the parents. Providing mother-baby-care and home-care instruction on the night shift assists with education needs for early discharge parents.

Figure 31-11 ■ A father demonstrates competence and confidence in diapering his newborn daughter.

CLINICAL TIP

For patients who are hearing-impaired, videotapes with information in both spoken and signed formats are most helpful. Also, birthing centers should have handouts available for families who do not speak English, as well as either interpreters (not family members) or language interpreter phones.

One-to-one teaching while the nurse is in the mother's room is shown to be the most effective educational model. Both first-time and experienced postpartum mothers rate individual teaching as the most effective method of instruction. Individual instruction is helpful both to answer specific questions and to clarify something that the parents may have found confusing in the educational video. With shorter stays, most teaching unfortunately tends to focus on infant feeding and immediate physical needs of the mothers, with limited anticipatory guidance provided in other areas. (Table 31-3 shows the broad range of information important to share with new parents. These topics are discussed in more detail next.)

> "I felt something impossible for me to explain in words. Then, when they took her away, it hit me. I got scared all over again and began to feel giddy. Then it came to me . . . I was a father."
>
> — Nat King Cole

General Instructions for Newborn Care

One of the first concerns of anyone who has not had the experience of picking up a baby is how to do it correctly. The newborn is easily picked up by sliding one hand under the neck and shoulders and the other hand under the buttocks or between the legs, then gently lifting the newborn. This technique provides security and support for the head (which the baby is unable to consistently support until 3 or 4 months of age).

The nurse can be an excellent role model for families in the area of safety. Safety topics include proper positioning of the newborn on the back to sleep and correct use of the bulb syringe (discussed shortly). The baby should never be left alone anywhere but in the crib. The mother is reminded that while she and the newborn are together in the birthing unit, she should never leave the baby alone for security reasons and because newborns spit up frequently the first day or two after birth. Other newborn safety measures are discussed in detail in chapter 37 ∞.

Case Study: Newborn Care

TABLE 31-3 What Parents Need to Know About Newborn Care

Immediate Safety Measures for the Newborn

- Watch for excessive mucus: use bulb syringe to remove mucus.
- Have baby sleep on his or her back in crib or in someone's arms.

Voiding and Stool Characteristics and Patterns

- Urine is straw to amber color without foul smell. Small amounts of uric acid crystals are normal in first days of life (may be mistaken by parents as blood in diaper because of reddish "brick dust" appearance).
- At least 6 to 10 wet diapers a day after the first few days of life.
- Normal progression of stool changes: (1) meconium (thick, tarry, dark green); (2) transitional stools (thin, brown to green); (3a) breastfed infant: yellow gold, soft or mushy stools; (3b) formula-fed infant: pale yellow, formed and pasty stools.
- Only 1 to 2 stools a day for formula-fed baby.
- Six to 10 small, loose yellow stools per day or only one stool every few days after breastfeeding is well established (after about 1 month).

Cord Care

- Wash hands with clean water and soap before and after care. Keep the cord dry and exposed to air or loosely covered with clean clothes. (If cultural custom demands binding of the abdomen, a sanitary method such as the use of a clean piece of gauze can be recommended.)
- Clean cord and skin around base with a cotton swab or cotton ball. Clean 2 to 3 times a day or with each diaper change. Touching the cord, applying unclean substances to it, and applying bandages should be avoided. Do not give tub baths until cord falls off in 7 to 14 days.
- Fold diapers below umbilical cord to air-dry the cord (contact with wet or soiled diapers slows the drying process and increases the possibility of infection).
- Check cord each day for any odor, oozing of greenish yellow material, or reddened areas around the cord. Expect tenderness around the cord and darkening and shriveling of cord. Report to healthcare provider any signs of infection.
- Normal changes in cord: Cord should look dark and dry up before falling off. A small drop of blood may present when cord falls off.
- Never pull the cord or attempt to loosen it.

Care Required for Circumcision and Uncircumcised Infants

Circumcision Care

- Squeeze water over circumcision site once a day.
- Rinse area off with warm water and pat dry.
- Apply small amount of petroleum jelly (unless a Plastibell is in place) with each diaper change.
- Fasten diaper over penis snugly enough so that it does not move and rub the tender glans.
- Because the glans is sensitive, avoid placing baby on his stomach for the first day after the procedure.
- Check for any foul-smelling drainage or bleeding at least once a day.
- Let Plastibell fall off by itself (about 8 days after circumcision).
- Plastibell should not be pulled off.
- Light, sticky, yellow drainage (part of healing process) may form over head of penis.

Uncircumcised Care

- Clean uncircumcised penis with water during diaper changes and with bath.
- Do not force foreskin back over the penis; foreskin will retract normally over time (may take 3 to 5 years).

Techniques for Waking and Quieting Newborns

Techniques for Waking Baby

- Loosen clothing, change diaper.
- Hand-express milk onto baby's lips.
- Talk with baby while making eye contact.
- Hold baby in upright position (sitting or standing).
- Have baby do sit-ups (gently and rhythmically bend baby back and forth while grasping the baby under his or her knees and supporting baby's head and back with your other hand).
- Play patty-cake with baby.
- Stimulate rooting reflex (brush one cheek with hand or nipple).
- Increase skin contact (gently rub hands and feet).

Techniques for Quieting Baby

- Check for soiled diaper.
- Swaddle or bundle baby (bring arms and legs into midline, which increases sense of security).
- Hold swaddled baby upright against mid-chest, supporting bottom and back of head. Baby can hear heartbeat, feel warmth, and hear your softly spoken words or calming sounds.
- Use slow, calming movements with baby.
- Softly talk, sing, or hum to baby.

Signs of Illness and Use of Thermometer

- See Table 31-4: When Parents Should Call Their Healthcare Provider.

CLINICAL JUDGMENT

Case Study: Sarah Feldstein

You are caring for Sarah Feldstein, who had her first child, a daughter, about 4 hours ago. She appears visibly upset when changing her infant's diaper, and says she thinks something is wrong because her daughter has tissue protruding from her vagina and some bleeding in her diaper.

Critical Thinking

What would you do?

See www.nursing.pearsonhighered.com for possible responses.

Demonstrating a bath (see chapter 37 ∞), cord care, and temperature assessment is the best way for the nurse to provide information on these topics to parents. Parents should be told to call their healthcare provider if redness, foul odor, bright red bleeding, or greenish yellow drainage occurs at the cord site or if the area remains unhealed 2 to 3 days after the cord stump has sloughed off. Current evidence does not support the routine application of topical antimicrobials to the drying cord (WHO, 1999). See Table 31-3: What Parents Need to Know About Newborn Care.

The nurse demonstrates and reviews the taking of an axillary or tympanic temperature with the family and discourages the use of mercury thermometers. It is important that families understand the differences and know how to select a thermometer. The newborn's temperature needs to be taken only when signs of illness are present. Parents are advised to call their physician or pediatric nurse practitioner immediately if they observe any signs of illness.

Nasal and Oral Suctioning

Most newborns are obligatory nose breathers for the first months of life. They generally maintain air passage patency by coughing or sneezing. During the first few days of life, however,

the newborn has increased mucus, and gentle suctioning with a bulb syringe may be indicated. The nurse can demonstrate the use of the bulb syringe in the nose and mouth and have the parents do a return demonstration. The parents should repeat this demonstration before discharge so they will feel more confident and comfortable with the procedure. Care should be taken to apply only gentle suction to prevent nasal bleeding.

To suction the newborn, the bulb syringe is compressed and the tip is placed in the nostril. The nurse or parent must take care not to occlude the passageway. The bulb is permitted to reexpand slowly by releasing the compression on the bulb (Figure 31-12 ■). The bulb syringe is removed from the nostril, and drainage is then compressed out of the bulb onto a tissue. The bulb syringe may also be used in the mouth if the newborn is spitting up and unable to handle the excess secretions. The bulb is compressed, the tip of the bulb syringe is placed about 1 inch to one side of the newborn's mouth, and compression is released. This draws up the excess secretions. The procedure is repeated on the other side of the mouth. The roof of the mouth and back of the throat are avoided because suction in these areas might stimulate the gag reflex. The bulb syringe should be washed in warm, soapy water and rinsed in warm water daily and as needed after use. Rinsing with a half-strength white vinegar solution followed by clear water may help to extend the useful life of the bulb syringe by inhibiting bacterial growth. A bulb syringe should always be kept near the newborn. New parents and nurses who are inexperienced with babies may fear that the baby will choke and may be relieved if they know how to take action if such an event occurs. They should be advised to turn the newborn's head to the side or hold the newborn with his or her head down as soon as there is any indication of gagging or vomiting and to use the bulb syringe as needed.

Some infants may have transient edema of the nasal mucosa following suctioning of the airway after birth. The nurse can demonstrate the use of normal saline to loosen secretions, and instruct parents in the gentle and moderate use of the bulb syringe to avoid further irritation of the mucous membranes. If parents will be using humidifiers at home, they should be instructed to follow the manufacturer's cleaning instructions carefully so that molds, spores, and bacteria from a dirty humidifier do not enter the baby's environment.

SIDS Resources for Parents

Swaddling the Newborn

Swaddling (wrapping) helps the newborn maintain body temperature, provides a feeling of closeness and security, and may be effective in quieting a crying baby by having the newborn's hands near the mouth to allow for sucking (Iannelli, 2007). If the infant is not resting, placing its hands at its sides then swaddling reduces the amount of stimulation of hand-to-mouth movement and may allow the child to rest. When wrapping the infant, a blanket is placed on the crib (or secure surface) in the shape of a diamond. The top corner of the blanket is folded down slightly, and the newborn's body is placed with the head at the upper edge of the blanket. The right corner of the blanket is wrapped around the infant and tucked under the left side (not too tightly—newborns need a little room to move and to allow for hands to get to the mouth). The bottom corner is then pulled up to the chest, and the left corner is wrapped around the baby's right side (Figure 31-13 ■). The nurse can show this wrapping technique to a new mother so she will feel more skilled in handling her baby.

CLINICAL TIP

You'll find that left-handed people tend to hold the baby over their right shoulder, and right-handed people do the opposite. This keeps the dominant hand free. However, most health personnel wear their name tags on the left side. To avoid scratching the baby's face, wear your name tag on the same side as your dominant hand.

Sleep and Activity

The National Institute of Child Health and Human Development and the American Academy of Pediatrics recommend that healthy term infants be placed on their back to sleep. Parents are taught the importance of following "Back to Sleep Guidelines" to reduce the incidence of sudden infant death syndrome (SIDS) (American Academy of Pediatrics [AAP] Task Force on Sudden

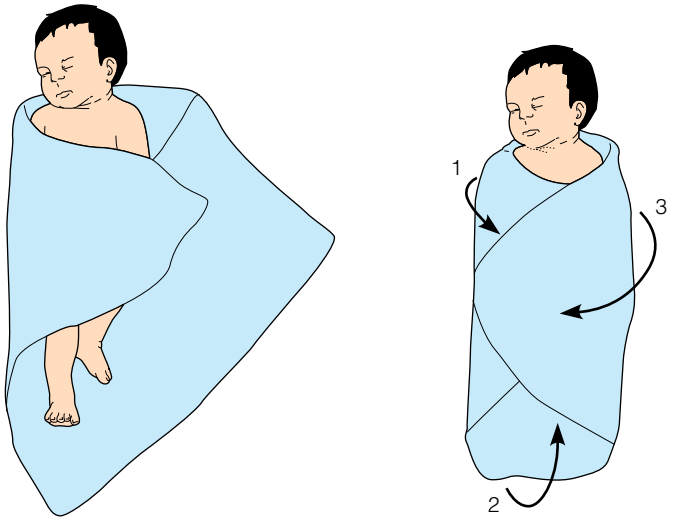

Figure 31-13 ■ Steps in wrapping a baby.

Infant Death Syndrome, 2005). Though infants may need to be placed on their sides initially because of copious or thick secretions, placing them on their backs in the newborn period serves to educate parents regarding infant positioning. Studies indicate that parents position their babies in the same positions they observe in the hospital setting, so nurses must demonstrate this behavior to reduce the risk of SIDS. If exceptions are warranted, these should be explained to families so they do not misinterpret what they observe. The placement of babies in a prone position during wakeful play sessions ("tummy time") should be encouraged as well (AAP & ACOG, 2007). Parents are also encouraged to hold their babies and not allow them to remain in infant carriers for prolonged periods of time.

Perhaps nothing is more individual to each baby than the sleep-activity cycle. It is important for the nurse to recognize the individual variations of each newborn and to assist parents as they develop sensitivity to their infant's communication signals and rhythms of activity and sleep. See chapter 30 ∞ for more detailed discussion of the sleep-activity cycle.

Car Safety Considerations

Half the children killed or injured in automobile accidents could have been protected by the use of a federally approved car seat. Newborns must go home from the birthing unit in a car seat adapted to fit newborns (Figure 31-14 ■). Babies should never be in the front seat of a car equipped with a passenger-side air bag. The safest spot in any car is the middle of the back seat. The car seat should be positioned to face the rear of the car until the baby is a year old or weighs 20 pounds (9.09 kg) (AAP, 2010). Nurses need to ensure that all parents are knowledgeable about the benefits of child safety seat use and proper installation. Nurses can encourage parents to have their infant safety seats checked by local groups trained specifically for that purpose. The Seat Check Initiative provides locations and information about child safety seats.

Figure 31-14 ■ Infant car restraint for use from birth to about 12 months of age.

Source: George Dodson/Lightworks Studio/Pearson Education.

Newborn Screening and Immunization Program

Before the newborn and mother are discharged from the birthing unit, the nurse informs the parents about **newborn screening tests** and tells them when to return to the birthing center or clinic if further tests are needed.

Several of the disorders that can be identified from a few drops of blood obtained by a heel stick are cystic fibrosis, galactosemia, congenital adrenal hyperplasia, hypothyroidism, maple syrup urine disease (MSUD), sickle cell trait, biotinidase deficiency, phenylketonuria (PKU), and hemoglobinopathies. The Expanded Newborn Screening Program allows parents to have their babies screened for more than 20 disorders. Although controversy exists over the need for such comprehensive testing, it is recommended that states test for a core panel of 29 treatable congenital conditions and an additional 25 conditions that may be detected by screening (AAP, Newborn Screening Authoring Committee, 2008).

Phenylketonuria and congenital hypothyroidism are the only tests that are performed in all 50 states and the District of Columbia. Early newborn discharge puts infants at risk for delayed or even missed diagnosis of PKU and congenital hypothyroidism because of decreased sensitivity of screening before 24 hours of age. The likelihood of detecting PKU increases as the infant grows older; the infant must be at least 24 hours old for a valid test. A second test is required in most states, usually between 1 week and 1 month of age, to minimize the chance of a positive child going undetected.

PROFESSIONALISM IN PRACTICE

Evidence-Based Routine Newborn Metabolic Disorders Screening

Best practice for routine screening of newborns for metabolic and other disorders that are initially asymptomatic has been elevated from a Level II (good evidence category) to a Level I (best evidence) based on latest evidence (Institute for Clinical Systems Improvement Guidelines, 2008).

Hearing loss is found in 1 to 3 per 1000 infants in the normal newborn population (Healthy Children, 2010). Hearing screenings before discharge are now conducted in all 50 states. The recommended initial newborn hearing screening should be accomplished before discharge from the birthing unit with appropriate follow-up if the newborn fails to pass the initial screen in all hospitals providing obstetric services (AAP & ACOG, 2007; Creehan, 2008).

According to the National Center for Hearing Assessment & Management, 95.7% of all infants obtained hearing screening in the United States. Sometimes infants fail to pass these tests for reasons other than hearing loss. Amniotic fluid in the ear canals is a frequent cause of suboptimal test results. In these cases, infants are retested in a week or two. The current goal is to screen all infants by 1 month of age, confirm hearing loss with audiologic examination by 3 months of age, and treat with comprehensive early intervention services before 6 months of

Figure 31-15 ■ Newborn hearing screen.

Application: Newborn Screening Tests

age (AAP & ACOG, 2007). Typically, screening programs use a two-stage screening approach (otoacoustic emissions [OAE] repeated twice, OAE followed by auditory brainstem response [ABR], or automated ABR repeated twice). Families need to be educated about appropriate interpretation of screening test results and appropriate steps for follow-up (Figure 31-15 ■).

Immunization programs against the hepatitis B virus during the newborn period and infancy are in place in many states, at least 20 countries, and high-incidence areas such as American Samoa. Universal vaccination of infants is recommended. See Drug Guide: Hepatitis B Vaccine (Engerix-B, Recombivax HB). Parents need to be advised as to whether their birthing center provides newborn hepatitis vaccination so that an adequate follow-up program can be set in motion (AAP & ACOG, 2007).

The nurse should teach the family all necessary caregiving methods before discharge. A checklist may be helpful to determine whether the teaching has been completed and to verify the parents' knowledge on leaving the birthing unit (Figure 31-16 ■). The nurse needs to review all areas for understanding or any outstanding questions with the mother and father, without rushing and taking time to answer all queries. Any concerns of the parents or nurse are noted.

HEALTH PROMOTION EDUCATION

The nurse discusses with parents ways to meet their newborn's needs, ensure safety, and appreciate the newborn's unique characteristics and behaviors. By assisting parents in establishing links with their community-based healthcare provider, the nurse can get the new family off to a good start. Parents also need to know the signs of illness, how to reach the pediatrician or after-hours clinic, and the importance of follow-up after

RESEARCH EVIDENCE IN PRACTICE

Universal Newborn Hearing Screening

CLINICAL QUESTION

Does universal newborn hearing screening improve early treatment of hearing deficits, enhance language acquisition, and increase childhood communication skills?

RESEARCH EVIDENCE

People who work with children who have hearing loss believe that early identification and intervention are primary factors in a child's subsequent success. Learning language through hearing and the development of speech ultimately help children achieve successful communication skills. Development and testing of automated technologies for screening hearing in newborns led to the implementation of programs for universal hearing screening in hospitals for babies in the first 3 months of life.

Three large retrospective reviews of studies involving more than 1000 babies focused on the effects of universal screening for hearing deficits within the first 3 months of life, with a goal of intervention by 6 months of age. Longitudinal studies of 700 of these children focused on language skills through early school age.

Children who were screened were referred, diagnosed, and treated significantly earlier (6.9 months) than children who were not screened but referred for hearing evaluation later in life (39.5 months). In addition, there was an inverse relationship between degree of loss and age of diagnosis, with children with more severe to profound hearing loss diagnosed very early. There was also a general increase in the identification of children with mild to moderate hearing loss. Children who had early screening had earlier interventions applied, such as hearing aids and cochlear implants.

Longitudinal follow-up indicated that those who had early versus late screening had better receptive language skills and increased communication abilities at school age.

WHAT QUESTIONS REMAIN UNANSWERED?

While improvements in receptive language were found at school age in those who had been screened and treated, expressive language and speech quality had not. What accounts for these differences? Is treatment focusing on auditory aspects of the hearing deficits rather than the acquisition of speech?

WHAT IS BEST PRACTICE?

Universal newborn hearing screening enhances the early identification and treatment of hearing loss in children. This early treatment means that children will have less difficulty acquiring language and communication skills.

CRITICAL THINKING

Usual parental reactions to an initial screen positive for hearing loss include worry, anxiety, and distress. How can the nurse mediate these expected responses?

DRUG GUIDE Hepatitis B Vaccine (Engerix-B, Recombivax HB)

OVERVIEW OF NEONATAL ACTION

Recombinant hepatitis B vaccine is used as a prophylactic treatment against all subtypes of the hepatitis B virus. It provides passive immunization for newborns of HBsAg-negative and HBsAg-positive mothers. Hepatitis B can be transmitted across the placenta, but most newborns are infected during birth.

The vaccine is produced from baker's yeast and plasmid containing the HBsAg gene.

Hepatitis B (thimerosal free) vaccine contains more than 95% HBsAg protein and is an inactivated (noninfective) product. Universal immunization is recommended.

Infants of HBsAg-positive mothers should concurrently receive 0.5 ml of hepatitis B immunoglobulin (HBIG) prophylaxis at separate injection sites (Centers for Disease Control and Prevention [CDC], 2010; Wilson, Shannon, & Shields, 2010).

PREGNANCY RISK CATEGORY: C

ROUTE, DOSAGE, FREQUENCY

The first dose of 0.5 ml (10 mcg) is given intramuscularly into the anterolateral thigh within 12 hours of birth for infants born to HBsAg-positive mothers. The second dose of vaccine is given at 1 month of age. The third dose should be administered at least 4 months after the first dose and at least 2 months after the second dose, but not before 6 months of age (CDC, 2010).

Infants born to HBsAg-negative mothers receive their first dose of vaccine at birth, the second dose at 1 to 2 months, and the third dose at 6 to 18 months (AAP & ACOG, 2007).

Infants whose mother's HBsAg status is unknown should receive the same doses of vaccine as infants born to HBsAg-positive mothers.

NEONATAL SIDE EFFECTS

The only common side effect is soreness at the injection site. Occasionally, there is erythema, swelling, warmth, and induration at the injection site; irritability; or a low-grade fever (37.7°C [99.8°F]).

NURSING CONSIDERATIONS

Delay administration during active infection; the vaccine will not prevent infection during its incubation period.

- The vaccine should be used as supplied. Do not dilute. Shake well.
- Do not inject intravenously or intradermally.
- Monitor for adverse reactions. Monitor temperature closely.
- Have epinephrine available to treat possible allergic reactions.
- Responsiveness to the vaccine is age dependent. Preterm infants weighing less than 1000 g have lower seroconversion rates. Consider delaying the first dose until the infant is term postconceptual age (PCA) or use a 4-dose schedule.

TABLE 31-4 When Parents Should Call Their Healthcare Provider

- Temperature above 38°C (100.4°F) axillary or below 36.6°C (97.8°F) axillary
- Continual rise in temperature
- More than one episode of forceful vomiting or frequent vomiting over a 6-hour period
- Refusal of two feedings in a row
- Lethargy (listlessness), difficulty in awakening baby
- Cyanosis (bluish discoloration of skin) with or without a feeding
- Absence of breathing longer than 20 seconds
- Inconsolable infant (quieting techniques are not effective) or continuous high-pitched cry
- Discharge or bleeding from umbilical cord, circumcision, or any opening (except vaginal mucus or pseudomenstruation)
- Two consecutive green watery or black stools or increased frequency of stools
- No wet diapers for 18 to 24 hours or fewer than six to eight wet diapers per day after 4 days of age
- Development of eye drainage

discharge (see Table 31-4). Parents should also check with their clinician for advice about over-the-counter medications to be kept in the medicine cabinet.

The family should have the care provider's phone number, address, and any specific instructions. Having the birthing unit or nursery phone number is also reassuring to a newborn's family. They are encouraged to call with questions. Follow-up calls lend added support by providing another opportunity for parents to have their questions answered.

Some institutions have initiated postpartum and/or newborn follow-up visits 48 hours after birth. The follow-up infant examination should be within 48 hours of discharge if the family is unable to visit their primary care physician within that time period (Creehan, 2008). The home visit focuses on normal newborn care, assessment for hyperbilirubinemia (jaundice), extreme weight loss, feeding problems, and knowledge deficits related to newborn care and feeding within the family unit.

Routine well-baby visits should be scheduled with the clinic, pediatric nurse practitioner, or physician. Regardless of the type of follow-up services available in the community, the nurse contributes to the newborn's health by stressing the importance of routine care and by helping families who have no follow-up plans to connect to local resources for care. (For detailed discussion of home care, see chapter 37 ∞.)

Evaluation

When evaluating the nursing care provided during the newborn period, the nurse may anticipate the following outcomes:

- The parents demonstrate safe techniques for caring for their newborn.
- The parents verbalize developmentally appropriate behavioral expectations of their newborn and knowledge of community-based newborn follow-up care.

FOCUS YOUR STUDY

- The overall goal of newborn nursing care is to provide comprehensive care while promoting the establishment of a well-functioning family unit.
- The period immediately following birth, during which adaptation to extrauterine life occurs, requires close monitoring to identify any deviations from normal.
- Nursing goals during the first hours after birth (admission and transitional period) are to maintain a clear airway, maintain a neutral thermal environment, prevent hemorrhage and infection, initiate oral feedings, and facilitate attachment.
- The newborn is routinely given prophylactic vitamin K to prevent possible hemorrhagic disease of the newborn.
- Prophylactic eye treatment for *Neisseria gonorrhoeae* is legally required on all newborns.
- Nursing goals in daily newborn care include maintaining cardiopulmonary function, maintaining a neutral thermal environment, promoting adequate hydration and nutrition, preventing complications, promoting safety, and enhancing attachment and family knowledge of child care.
- Essential daily care includes assessing vital signs, weight, overall color, intake, output, umbilical cord and circumcision, newborn nutrition, parent education, and attachment.
- Following a circumcision, the newborn must be observed closely for signs of bleeding, inability to void, and signs of infection.
- Signs of illness in newborns include temperature above 38°C (100.4°F) axillary or below 36.6°C (97.8°F) axillary, more than one episode of forceful vomiting, refusal of two feedings in a row, lethargy, cyanosis with or without a feeding, and absence of breathing for longer than 20 seconds.
- Newborn screening for congenital hypothyroidism and phenylketonuria may be done on all newborns in the first 1 to 3 days.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Alice Fine, age 32, G1, now P1001, spontaneously delivers a 7.25 pound baby girl over a median episiotomy. The baby's Apgars are 7 and 9 at 1 and 5 minutes. The baby is suctioned, stimulated, and given free flow oxygen at birth. As the nurse on duty, you admit baby Fine to the newborn nursery, place her under a radiant heater, and perform a newborn assessment. You obtain the vital signs of temperature 97°F, heart rate 128, respiration 55. A physical exam demonstrates no abnormalities, and you note that there were no significant problems with the pregnancy, the mother's blood type is A+, and she plans to bottle-feed. You monitor the baby until her vital signs are stable and then take her to the mother's room for her first bottle-feeding at 60 minutes old.

1. How would you explain the technique to suction the newborn with a bulb syringe?
2. How would you review measures to promote the safety of the newborn from abduction?
3. Describe the care of the newborn's cord.
4. How would you review bottle-feeding with the mother?

CHAPTER 32

Newborn Nutrition

I felt prepared for breastfeeding when my baby was born—I had taken a breastfeeding class and read several books. Breastfeeding started off well. I was a little surprised about the frequent feedings in the beginning, but we got through that just fine. The biggest surprise was that my baby developed allergy symptoms when she was 3 weeks old. It was determined that my daughter is allergic to cow's milk protein. To continue feeding her just breast milk, I had to cut out milk and foods containing milk, which severely limited what I could eat. I did that because I was determined not to let anything stop me from nursing my child for my goal of at least the first year. Fortunately, the allergy is slowly going away as she grows older. At 9 months I can now have a little cheese in my diet again.

—Allyssa, age 25

LEARNING OUTCOMES

1. Compare the nutritional value and composition of human milk and formula preparations in relation to the nutritional needs of the newborn.
2. Explain the advantages and disadvantages of breastfeeding and formula-feeding in determining the nursing care of both mother/family and newborn.
3. Formulate guidelines for helping both breastfeeding and formula-feeding mothers to feed their infants successfully in hospital and community-based settings.
4. Explain the influence of cultural values on infant feeding practices.
5. Describe the nutritional needs and normal growth patterns of infants.
6. Illustrate ways to educate parents about their infant's nutritional needs and normal growth patterns.

There is nothing so rewarding—and potentially so frustrating—as providing your newborn with nourishment. The very word runs the gamut of meaning from the mundane to the sublime:

Nourish (verb): to provide food/to sustain/to nurture/to cherish

Perhaps this is why something apparently so basic engenders such strong emotions. Feeding your newborn can involve inadequate sleep, loss of freedom, and feeling trapped by unpredictable demands that compromise your ability to get anything else done. On the other hand, it offers the chance to bond at a most basic level, the experience of unconditional love, and the reward of knowing that you are providing the basis for growth and future development.

Early nutrition has a significant impact on the present and future health and well-being of the infant because this is a period of rapid growth and brain development. In addition, infant feeding itself is an important component of newborn socialization that promotes cognitive and emotional development.

It is important that the nurse is well informed about infant nutrition and feeding methods because the parents look to the nurse for this guidance. Parents need accurate and consistent information from the nursing staff. They need to learn the skills to feed their infant successfully. Through each interaction with the parents, there is an opportunity for the nurse to support the parents and promote the family's sense of confidence.

In this chapter we will look at the nutritional needs of the full-term newborn of normal weight in the context of both breast milk and formula composition, discuss feeding methods, explore community-based nursing care, and finally look at a nutritional assessment of the newborn.

Nutritional Needs and Breast Milk/Formula Composition

The newborn's diet must supply all the nutrients required by the body to meet the rapid rate of physical and neurologic growth and development. A neonatal diet should provide adequate hydration and sufficient calories as well as protein, carbohydrates, fat, vitamins, and minerals. Exclusive breast milk and/or iron-fortified 20-calorie/ounce formula are sufficient as sole sources of nutrition to meet the dietary needs of the newborn from birth up to 6 months of age. Complementary solid foods are introduced in the second half of the first year, while the infant continues to receive human milk and/or formula until at least 12 months of age (American Academy of Pediatrics [AAP], 2005). The following several sections discuss the nutritional requirements of the newborn and how these are met by human milk and standard cow's milk–based formula.

Dietary Reference Intakes

The *dietary reference intake (DRI)* encompasses four aspects of nutrient-based reference values: (1) estimated average requirement (EAR), (2) recommended daily allowance (RDA), (3) adequate intake (AI), and (4) tolerable upper intake level (UL). The DRIs represent a framework that links nutrition and health across the lifespan.

Growth

It is physiologically appropriate for both breastfed and formula-fed infants to lose weight in the first 3 to 4 days of life. Formula-fed infants generally lose up to 3.5% of their birth weight; breastfed infants should not exceed a weight loss greater than 7% of their birth weight (Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN), 2007). Infants lose weight with the passage of meconium, with loss of extracellular fluids, and because their fluid intake is normally low in the first few days while transitioning to enteral feedings, especially among breastfed infants. This loss is normal and does not result in dehydration, as infants draw on their extracellular water reserves. Infants should begin gaining weight by day 5 of life or sooner and should be at or above birth weight by 10 to 14 days of age. Weight gain during the first 4 weeks should be about 35 gm (1 oz) per day at 1 month whereas formula-fed infants gain an average of 34.4 gm per day at 1 month. In general, infants gain about 10 g/kg/day or 5 to 7 oz/week (Riordan & Wambach, 2010).

Breastfed and formula-fed babies have different growth rates. This is understandable because the compositions of human milk and formula are different. See Table 32-1 to compare human milk and formula compositions. Most healthcare providers (as well as representatives of formula companies) consider breastfeeding to be the "gold standard" for neonatal nutrition, and the outcomes associated with its use are the norm to which other forms of nutrition should be compared (AAP, 2005; Lawrence & Lawrence, 2005).

Formula-fed infants tend to regain their birth weight earlier than breastfed infants because the formula-fed infant has a greater fluid intake early on. The breastfed infant's fluid intake depends on the mother's milk supply and breastfeeding efficiency. It is noteworthy that breastfed infants born to multiparous mothers who have previously breastfed often do not lose as much weight as infants born to primiparous mothers, because the multiparous mother's milk typically becomes more abundant sooner (Lawrence & Lawrence, 2005). If a healthy full-term infant with normal birth weight has a weight loss exceeding 7%, a feeding evaluation is indicated. If an infant has a weight loss of 10% or greater, an evaluation, an intervention, and a follow-up weight check are indicated to make certain that the infant is receiving sufficient fluid and calories and to determine if the feeding problem is resolved.

Growth rates for breastfed and formula-fed infants are somewhat different once feedings are established. Exclusively breastfed infants have the same or slightly higher weight gain than their formula-fed and mixed-fed peers in the first 3 to 4 months. *Thereafter*, formula-fed and mixed-fed infants have a greater weight gain pattern compared with breastfed infants (Riordan & Wambach, 2010). This characteristic weight gain pattern results in a leaner body build in the breastfed group by the latter half of the first year of life. Measurements of length and head circumference are the same for both groups. An infant typically grows 1 inch per month in the first 6 months, and then

TABLE 32-1 Comparison of Selected Nutrients in Milk

NUTRIENTS PER 30 ML	HUMAN MILK	SIMILAC ADVANCE	ENFAMIL LIPIL	WHOLE MILK
Calories	20	20	20	19
Protein, grams	0.31	0.41	0.42	1.1

0.5 inch for the next 6 months. Infants generally double their birth weight by 5 months, triple their birth weight by 1 year of age, and quadruple their birth weight by 2 years (Riordan & Wambach, 2010). Growth charts for tracking an infant's weight, length, and head circumference can be downloaded from the Centers for Disease Control and Prevention (CDC) Web site.

CLINICAL TIP

The following are newborn caloric and fluid needs:

- Caloric intake: 45.5 to 52.5 kcal/lb/day or 100 to 115 kcal/kg/day
- Fluid requirements: 64 to 73 ml/lb/day or 140 to 160 ml/kg/day
- Weight gain in the first few weeks: 1 oz/day (or about a half pound per week)

Fluid

Fluid requirements during the neonatal period are high (140 to 160 ml/kg/day) because of the newborn's decreased ability to concentrate urine and increased overall metabolic rate. Although the infant's total body water content is high (75% to 80%) compared with an adult's (60%), the infant has an increased surface area to mass ratio and decreased renal absorptive capacity that makes the infant more susceptible to dehydration from insufficient fluid intake or increased fluid loss due to diarrhea, vomiting, or other source of fluid loss. Parents and caretakers should be aware of the signs of dehydration. Dry or chapped lips, dry oral cavity, decreased urine output, concentrated urine, general weakness, lethargy, poor skin turgor, sunken eyes, and sunken fontanelle are some of the signs of dehydration. The infant's fluid intake should be increased above the baseline fluid needs when the infant has a fever or is

in a warm environment for an extended period of time. The increased fluid requirements should be met with additional breast milk or formula, rather than water because the increased water can cause hyponatremia and may result in seizures if water consumption is excessive.

CLINICAL TIP

A newborn with fever or an infant with persistent diarrhea or vomiting should be evaluated by a physician.

Energy

The basal metabolic rate (BMR) refers to the energy needed for thermoregulation, cardiorespiratory function, cellular activity, and growth. The healthy full-term infant's BMR is about twice that of an adult's, based on body weight (Rolfes, Pinna, & Whitney, 2006). A newborn requires 100 to 115 kcal/kg/day at 1 month and 85 to 95 kcal/kg/day from 6 to 12 months of age. When an infant does not receive sufficient calories, the infant risks losing weight, may experience tissue breakdown, and is at risk for delayed growth and development (Riordan & Wambach, 2010).

Fats

Infants receive approximately 50% of their calories from fat. Fats also help the body absorb the fat-soluble vitamins A, D, E, and K. Fats are a precursor of prostaglandins and other hormones. Essential fatty acids and their derivatives docosahexaenoic acid (DHA) and arachidonic acid (ARA) are associated with improved visual acuity and cognitive ability (Cloherty, Eichenwald, & Stark, 2008; Riordan & Wambach, 2010).

Milk Composition

Approximately 98% of the human milk fat is in the form of triglycerides, and a very small but clinically significant amount is from cholesterol. Cholesterol levels in breast milk may also stimulate the production of enzymes that lead to more efficient metabolism of cholesterol, thereby reducing its harmful long-term effects on the cardiovascular system.

Fatty acids are another key component to brain development. Omega-3 and omega-6 fatty acids are two classes of essential fatty acids found in breast milk, although the level can vary with maternal diet. Docosahexaenoic acid (DHA) and arachidonic acid (ARA) are long-chain polyunsaturated fatty acids (LCPUFAs) derived from linoleic acid and α-linolenic acid. Along with oleic acid, these LCPUFAs are needed for myelination of the spinal cord and other nerves, and impact on visual acuity and cognitive and behavioral functions.

Fat content is the most variable component in human milk, ranging from 30 to 50 grams/liter. Fat content is influenced by maternal parity, duration of pregnancy, the stage of lactation, diurnal regulation, and changes in fat content even during a single feeding. Multiparous mothers produce milk with a lower content of fatty acids. For example, the milk of a mother who delivers a preterm infant has a greater concentration of DHA and ARA than does the milk of a mother who gives birth to a full-term infant during the first few weeks postpartum. Babies born prematurely miss receiving the continuous placental transfer of DHA and ARA while developing during the third trimester. By receiving breast milk, these infants receive the increased concentrations of the preterm mother's DHA and ARA intended for the premature infant (Lawrence & Lawrence, 2005).

Phospholipids and cholesterol levels are higher in colostrum compared with mature milk, although overall fat content is higher in mature breast milk compared with colostrum (see the discussion of colostrum and mature milk in "Stages of Human Milk" on page 859). Fat content is generally higher in the evening and lower in the early morning. Within a single feeding session an infant initially receives the low-fat foremilk before receiving the higher calorie, high-fat hindmilk (see the discussion of foremilk and hindmilk in "Physiologic and Endocrine Control of Lactogenesis" on page 858). Finally, the fat content of breast milk is also affected by maternal diet and maternal fat stores. Mothers on low-fat diets have increased production of medium chain fatty acids (C6–C10), and mothers with high levels of body fat produce breast milk with a higher fat content (Lawrence & Lawrence, 2005).

The fats in the milk-based formulas are modified to parallel the fat profile of human milk by removing the butterfat from cow's milk and adding vegetable oils. There are quite a few differences in the fat sources and amounts used among the major formula brands. Since 2002 infant formulas have been supplemented with DHA and ARA. However, breast milk also contains 167 other fatty acids of uncertain function, and these are absent from formula (Cloherty et al., 2008).

Carbohydrates

Carbohydrates (sugars) serve as the other main source of energy for the infant, providing about 40% of the calories in the infant's diet. By weight, both human milk and formula contain more carbohydrates than fat.

Milk Composition

In breast milk, the primary carbohydrate is lactose. In addition to providing a cellular energy source especially for the brain in the form of glucose, lactose enhances the absorption of calcium, magnesium, and zinc (Lawrence & Lawrence, 2005).

Human milk also contains trace amounts of other carbohydrates such as glucosamines and nitrogen-containing oligosaccharides. Glucosamines are one of the building blocks for connective tissues and help strengthen and hold together ligaments and tendons. Oligosaccharides promote the growth of *Lactobacillus bifidus,* which promotes an intestinal acidic environment creating a hostile environment for bacteria to thrive (Riordan & Wambach, 2010).

In comparing carbohydrates among the standard milk-based formulas, both Enfamil and Similac provide all of their carbohydrate calories from lactose. Nestlé Good Start uses a blend of 70% lactose and 30% corn maltodextrin (a table sugar–like carbohydrate) (Sears, 2009).

Protein

Proteins are the building blocks for muscle and organ structure. They are key to just about every metabolic process in the body, including energy metabolism, cell-signaling, growth, and im-

mune function. The protein requirement for an infant is about 0.8 to 0.9 gram per deciliter (Riordan & Wambach, 2010).

Milk Composition

Milk proteins are often grouped into casein and whey proteins. Whey protein is the predominant dietary protein in human milk. During digestion this type of protein creates soft curds that are easily and quickly broken down. Because of this, breastfeeding babies digest their meals in 90 minutes and need to feed often, about 8 to 12 feedings per day. It is rare for exclusively breastfeeding babies to have constipation. Casein is the major phosphoprotein found in milk. Cow's milk contains a high amount of casein (a low ratio of whey to casein—approximately 20:80) compared with mature human milk (60:40 whey:casein). Because of its tendency to form curds, milk with high amounts of casein is less easily digested.

Cow's milk–based formulas are usually modified to get closer to the whey:casein ratio profile of mature human milk. For example, the whey:casein ratio in Enfamil is 60:40. Although Similac has a ratio of 48:52; the company claims this produces an amino acid profile in the blood that is closer to that found in the breastfeeding infant. Nestlé Good Start (hydrolyzed) and Enfamil Gentlease (partially hydrolyzed formula) reportedly targets fussy, gassy babies and reduces the incidence of spitting up and constipation according to its manufacturer (Sears, 2009). It should also be noted that the whey and casein components in breast milk are not static and change over time to meet the needs of the growing infant. In early lactation, the whey:casein ratio is 90:10. As lactation progresses, the whey:casein ratio in mature breast milk is 60:40. Finally, during late lactation, the whey:casein ratio is 50:50 (Riordan & Wambach, 2010).

Whey protein in human milk is composed of five major components: (1) alpha-lactalbumin, (2) serum albumin, (3) lactoferrin, (4) immunoglobulins, and (5) lysozyme. The latter three components are believed to be non-nutritional proteins and serve immunologic functions in the body. For instance, one of the functions of lactoferrin is to prevent infections in the gastrointestinal tract by binding to free iron and thereby limiting its availability to iron-dependent enteric pathogens. Immunoglobulins (Ig), in particular secretory IgA, is abundant in human milk. Secretory IgA (SIgA) antibodies are made in the breast by the mother in response to exposure to antigens in her environment and passed along in her milk to her infant. Hence, the infant gradually builds up antibodies to the common pathogens in the immediate environment. Lysozymes are enzymes that destroy specific pathogens and also function to enhance the growth of "friendly" intestinal bacteria, namely, lactobacilli. Other kinds of non-nutritional proteins include other enzymes, growth modulators, and hormones (Riordan & Wambach, 2010).

Vitamins, Minerals, and Trace Elements

Vitamins

Most healthy full-term infants receive sufficient vitamin intake in their diets whether receiving human milk or formula, with only a few exceptions. Infants need vitamins for the body's metabolic functions. Vitamins are grouped by how they are absorbed by the body.

Vitamins A, D, E, and K are absorbed in the presence of fat or bile and are stored in fat tissue and the liver for future use. These vitamins are known as the fat-soluble vitamins. Excessive intake of fat-soluble vitamins can result in toxicity, therefore supplementation is not generally recommended, except in the case of Vitamin D (see the following section for further discussion).

Milk Composition

Vitamins in human milk are influenced by the mother's vitamin intake, general nutritional status, and genetic differences, and vary as lactation progresses. Many healthcare providers encourage new mothers to continue their prenatal vitamins after delivery and throughout the lactation period, unless the mother generally eats a well-balanced diet (Riordan & Wambach, 2010).

Vitamin A is needed for general maintenance of healthy skin, hair, nails, gums, glands, bones, and teeth. It helps prevent infections. In developing countries where malnutrition is of great concern, human milk provides a vital source of vitamin A and helps prevent blindness (Lawrence & Lawrence, 2005).

Human milk contains little vitamin D (needed in development of strong teeth and bone mineralization), although historically this was generally sufficient to meet the needs of most infants who are also exposed to an adequate amount of sunlight. However, cases of rickets and other evidence of vitamin D deficiency due to inadequate vitamin D intake and decreased exposure to sunlight are reported in the United States and other Western countries. The American Academy of Pediatrics recommended that all infants and children should receive 400 IU of vitamin D daily, beginning within the first few days after birth. The AAP recommends that breastfed infants (including those receiving some formula supplementation) should stay on vitamin D supplementation from birth. Although not recommended prior to 1 year of age, fortified whole milk contains 400 IU of vitamin D per liter and can provide sufficient vitamin D in later childhood if intake is at least 1 liter per day (AAP Clinical Report, 2008a). Because cow's milk–based formulas are currently supplemented with at least 400 IU of vitamin D per liter, the AAP recommends that formula-fed infants should receive additional supplementation until their intake reaches 1 liter per day (generally about 3 months of age).

Vitamin E (antioxidant and free radical scavenger) is naturally present in human milk, and mothers of preterm infants produce a slightly higher level in their colostrum than mothers of term infants. This is particularly important to premature infants in the NICU who may have damage to their lungs and retina from oxygen toxicity. Iron levels impact the ability of vitamin E to stabilize cell membranes and preserve fatty acids. Iron causes destruction of vitamin E in the gastrointestinal tract, which increases the release of harmful free radicals. Thus vitamin E needs are increased. Vitamin E also serves a role in the formation of red blood cells and prevents hemolytic anemia (especially in the premature infant who may be deficient in vitamin E and whose condition is aggravated by also receiving iron supplementation).

Vitamin K is present in human milk in small quantities. After the infant begins feeding, bacteria will colonize the intestinal tract. These bacteria synthesize additional vitamin K and

form the primary source of the vitamin. Within a few days, infants generally will have produced sufficient amounts of vitamin K to prevent excessive bleeding. Vitamin K deficiency resulting in hemorrhage occurs in 0.25% to 1.7% of healthy-appearing newborns during the first week of life. In order to prevent this disorder, it has been the standard of care to give vitamin K prophylaxis after birth until the infant becomes naturally vitamin K sufficient (AAP, 2003 [reaffirmed 2009]).

The eight B vitamins and vitamin C (antioxidant) are water-soluble vitamins that pass readily from serum to breast milk. Breastfeeding mothers can ingest adequate amounts of B vitamins in their natural form from plant and animal food sources with the exception of vitamin B_{12}. Vitamin B_{12} is naturally found only in foods of animal origin. Breastfeeding mothers who follow a strict vegetarian diet or macrobiotic diet may have insufficient vitamin B_{12} in their milk unless they eat plant derived foods with vitamin B_{12} fortification (e.g., cereals) or receive vitamin B_{12} supplementation. Formula is fortified with adequate amounts of the water-soluble vitamins to meet the DRI. Unlike fat-soluble vitamins, any excess water-soluble vitamins ingested are simply excreted and the threat of toxicity is low (Lawrence & Lawrence, 2005).

See Table 32-2 for the vitamin content of human milk during the various stages of lactation (colostrum, transitional, and mature) and cow's milk.

Minerals

Minerals have diverse regulatory functions throughout the body. For example, calcium is important in the clotting mechanisms; phosphorus is a component in adenosine triphosphate (ATP), deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and phospholipids; calcium and phosphorus are necessary for bone formation; sodium is involved in fluid balance; calcium, sodium, and potassium are needed for nerve and muscle function; chlorine is involved in acid–base balance; cobalt works with vitamin B_{12} to form blood cells; copper and iron aid in extracting energy from the citric acid cycle and are also involved in blood production; iodine is needed for thyroid hormone synthesis; and magnesium, manganese, and zinc are needed to help with many enzymatic processes (Thibodeau & Patton, 2009).

MILK COMPOSITION Both human milk and infant formulas contain several major and trace minerals to satisfy the needs of the growing infant. Breast milk provides newborns with minerals in more appropriate doses than do formulas (Blackburn, 2007). The mineral content of human milk does not appear to be influenced by maternal diet. The vitamins and minerals among the formulas being compared are essentially the same, although all generally contain higher levels of minerals than human milk to compensate for their lower bioavailability.

The amount of iron transferred to the fetus during the third trimester of pregnancy is influenced by maternal iron status (Riordan & Wambach, 2010). Iron is an important mineral required by the body to make hemoglobin and is needed for neurologic function. Neurotransmitters require adequate iron levels to function properly; therefore, infants with chronic anemia are at risk for cognitive and developmental delays. Infants deficient in iron may look pale, appear sleepy or tire easily while feeding, and be tachycardic or tachypneic at rest. The infant's iron status is affected by the amount of iron accumulated in utero, the infant's diet after birth, and the general health of the infant.

The AAP recommends against the use of low-iron fortified formulas because of the increased risk for anemia associated with their use (American Academy of Pediatrics (AAP) &

TABLE 32-2 Vitamins and Other Constituents of Human Milk and Cow's Milk*

American College of Obstetricians and Gynecologists (ACOG), 2007). Low-iron formula is fortified with only 2 mg of iron per liter compared with "iron-fortified" formula, which is fortified with 12 mg of iron per liter. It should be noted that the iron concentration in human milk is 0.5 to 1 mg per liter, which is considerably lower than in iron-fortified formulas. However, the iron in human milk is much more completely absorbed—the infant receiving human milk absorbs 50% to 80% of the iron in human milk compared with less than 12% of the iron in formula. Healthy term infants with normal birth weights receiving breast milk or an iron-fortified infant formula during the first 5 to 6 months of life are unlikely to develop iron-deficiency anemia because these infants have sufficient iron stores to sustain them until they start solid feedings in the second half of the first year of life (Riordan & Wambach, 2010).

Some parents have a misconception that infants fed iron-fortified formula are likely to have constipation. Nurses have a responsibility to educate parents and help them understand that the iron added to formula is in an ionic form and does not cause constipation (Levin, Cotton, Patrick-Miller, et al., 2010). The casein in formula (which is different from the casein in human milk) creates firm, rubbery curds that are slow to metabolize and have been associated with constipation in formula-fed infants. In addition, palm olein oil is added to some formulas to provide palmitic acid in an attempt to match the natural palmitic acid profile in human milk. However, the chemical arrangements are different. Palmitic acid derived from olein oil is poorly absorbed. The unabsorbed palmitic acid in formula reacts with calcium to create insoluble soaps during digestion and contribute to constipation.

Trace Elements

Other additives to formulas not yet mentioned include nucleotides (building blocks for DNA and RNA that appear to enhance the immune system, among other things), carnitine (derived from the amino acid lysine and functioning in part to transport fatty acids to the mitochondria for oxidation), and taurine (a conditionally essential nonprotein sulfur amino acid with a number of functions, including a role in growth, and in central nervous system and auditory function development). There are many other components in human milk not yet duplicated in formula and not all components in breast milk have been identified. In general though, formula companies are always striving to improve their products to develop the best "humanized" milk possible. There is no question that formulas today are far superior to formulas in the past.

The Evolution of Formula

Finding an acceptable breast milk substitute following maternal death, infant abandonment, low milk supply, and other situations has been a challenge for centuries. Although there are no written records describing infant feedings from ancient times to the Renaissance period, there is physical evidence of societies using alternative feedings dating back to 2000 BC. Throughout Europe, spouted feeding cups and other feeding receptacles have been found in the graves of infants. Records from written works show that from 1500 to 1700, "wet nurses" (a lactating woman whose purpose of employment was to nurse another woman's infant, sometimes abandoning her own infant to gain employment) were hired at foundling homes (orphanages) and by wealthy European women, because it was customary for noblewomen to delegate all physical work, including infant care (Lawrence & Lawrence, 2005; Stevens, Patrick, & Pickler, 2009).

By the 19th century wet-nursing was falling out of favor, and "dry-nursing" was attempted. Dry-nursing is the practice of feeding an infant milk obtained from another mammal (i.e., goats, cows, mares, donkeys, etc.) (Stevens et al., 2009). Milk from cows was most commonly used because of its availability, not because it was closer in composition to human milk. This practice was used in foundling homes and was associated with very high infant mortality (Lawrence & Lawrence, 2005).

Recognizing the need for an improved breast milk substitute, a few physicians continued attempts to develop a "humanized" animal milk substitute. In the late 1830s, a report of the content of human milk and cow's milk was published. This served as the basis for developing a baby milk substitute by means of modifying milk from a cow to make it more like human milk. Around the 1860s, the first commercially available baby food and infant formula was developed in Europe and became available in the United States by the 1870s. The first formula was comprised of only malt, cow's milk, and wheat flour and required reconstitution with water (Schuman, 2003). It was severely lacking in nutrient composition and quality. Only the most desperate would consider feeding it. Between 1860 and 1920 there were additional scientific discoveries that contributed to the further advancement of the development of an artificial baby milk. These included the discovery of the germ theory and subsequent development of pasteurization of milk, the invention of the bottle and rubber nipple to replace feeding devices that required skill to use and were difficult to clean, and the invention of the "ice box" to refrigerate the baby milk (Stevens et al., 2009).

Two of the biggest commercial advances in milk science were the invention of sweetened condensed milk in the 1830s and evaporated milk in 1883. Condensed milk was made by boiling milk and permitting it to evaporate to one-fourth its original volume, and then adding 6 ounces of sugar per pint to the milk as a preservative (Schuman, 2003). The invention of sweetened condensed milk and evaporated milk meant that for the first time in history, a family did not have to have access to a cow in order to feed their infant milk (if not breastfeeding). From evaporated milk, a homemade evaporated milk formula recipe was created and made available to the public. The evaporated milk formula was a simple mixture of evaporated milk, water, and sugar or corn syrup. The evaporated milk formula gained acceptance because it was affordable, it appeared to support growth equal to that of breastfed infants, and it was widely available. When world events created a need for women to work in factories to fill in for men who went off to fight in the war, this generation of women felt compelled to help out. Bottles and formula made it a viable option for them. Following WWII, formula use was becoming widespread. It is estimated that by 1960 about 80% of bottle-fed infants were being fed with evaporated milk formula and given supplements of vitamins and iron. However, poor infant outcomes were still being observed.

In the 1960s proprietary commercial formulas had improved upon the quality of evaporated milk formulas. Parents were impressed with the advances in science and wanted to raise their children scientifically "by the book." Using formula seemed to be a progressive idea to embrace. By this time more and more women were working outside the home than ever before. "Modern women" saw formula use as more convenient than breastfeeding. Formula companies appealed to these women. In addition to a changing social climate in America, advances in agriculture created a surplus of cow's milk and offered a new marketing opportunity for global commercialization of formula (Schuman, 2003).

Artificial baby milk that was originally intended as a lifesaving product for extreme situations was now being aggressively marketed as a food for all infants. To this end formula companies began an aggressive marketing campaign. One of their marketing tactics was to provide free formula to hospitals, enabling hospitals to phase out their formula preparation rooms. Mothers viewed commercial formula as an acceptable breast milk substitute that appeared to have medical endorsement, was easy to use and affordable, and freed her to do other things such as work outside the home. By 1972, formula use peaked and breastfeeding rates in the United States plummeted (only 25% of women were breastfeeding at hospital discharge) (Schuman, 2003). Again, the public was led to believe that commercial formula was as good as, if not better than, breast milk.

Research efforts beginning in the 1970s showed that human milk was unquestionably superior to evaporated milk and proprietary infant formulas as evidenced by a significant rise in infant morbidity and mortality, especially in developing countries (Schuman, 2003). The revelation of the research findings from the 1970s up to the present has led to resurgence in breastfeeding.

Over the last 50 years or so, considerable time, effort, and money have been allocated to the development of commercial infant formulas in an attempt to better imitate the content and performance of human milk. In 1954, the executive board of the AAP established a Committee on Nutrition to set the standards for nutritional requirements and feeding practices for infants, children, and adolescents. This committee makes recommendations for nutritional requirements in infant formulas to the Food and Drug Administration (FDA). In 1980 Congress passed the Infant Formula Act, which was later amended in 1986. The safety and nutritional quality of formula are now significantly regulated. Despite this, there are several recalls of formula every year. In 1995 the National Alliance for Breastfeeding Advocacy was formed to educate the public, state and federal legislators, policymakers, and healthcare systems about such hazards and to advocate on all matters concerning breastfeeding.

Specialty Formulas

The American Academy of Pediatrics (2005) recommends breastfeeding for all infants, with rare exceptions. When breastfeeding is not an option or is not chosen, then standard cow's milk–based formula is the first choice among the formulas. However, there are situations in which standard cow's milk–based formula is not tolerated, is contraindicated, or is not acceptable to the parents. Before switching to a specialty formula, the parents should first consult with their baby's healthcare provider (Abbott Nutrition, 2009).

Milk-Based Lactose-Free Formulas

Similac Sensitive is a milk-based formula containing milk protein isolate and lactose-free. In place of lactose, the formula manufacturer substitutes a blend of corn syrup solids and sucrose. (Bear in mind that use of non-lactose products should be reserved for those rare infants with clinically proven lactose intolerance.)

Soy-Based Formulas

Soy protein–based formulas include the following products: Enfamil ProSobee with LIPIL, Similac Isomil Advance, Similac Isomil DF (marketed for infants older than 6 months who have diarrhea), and Nestlé Good Start Soy Plus. They all are iron-fortified formulas and meet the nutrient specifications as established by the FDA. They use soy harvested from soybeans and supplemented with methionine (an essential amino acid), carnitine, and taurine. Soy protein–based formulas do not contain any bovine protein (cow protein) or lactose, the formula is usually sweetened with corn syrup, corn maltodextrin, or sucrose. (The latter may cause dental decay after the teeth have erupted.) The fat content varies as well. The formula companies use vegetable oils such as soy, palm, sunflower, olein, safflower, and coconut to meet the fat requirement. Phytates present in soy formulas decrease the absorption of iron, calcium, and zinc, so greater concentrations of minerals and vitamins are added to soy formulas. Also, phytoestrogens (specifically isoflavones), which are estrogen-like compounds found in plants, are consumed in high quantity among infants being fed soy formula. So far, there is no conclusive evidence from studies that phytoestrogens cause harm to infants (AAP Clinical Report, 2008b). Further studies are warranted.

The American Academy of Pediatrics recommends against the use of soy protein–based formula for preterm infants who weigh less than 1800 grams or infants with renal failure because of the high aluminum level in soy formulas. Human milk contains 4 to 65 ng/ml of aluminum; soy protein–based formulas contain 600 to 1300 ng/ml (AAP Clinical Report, 2008b). Soy formula is also not medically indicated for infants having risk factors for allergies, or supplementation for the breastfeeding infant unless specifically indicated (AAP Clinical Report, 2008b).

Although the AAP (2008b) states that the "isolated soy protein-based formulas are safe and effective alternatives to provide appropriate nutrition for normal growth and development," for *term* infants whose nutritional needs are not being met by human milk or cow's milk–based formulas, soy protein–based formula is not intended as a first-choice formula except for infants with primary lactase deficiency or galactosemia, for term infants of formula-feeding vegan parents, and or if the infant develops secondary (transient) lactase deficiency following an acute bout with diarrhea.

Despite the few genuine indications for using soy protein–based formulas, soy formula accounts for almost 25% of the formula market in the United States (AAP Clinical Report, 2008b). The demand for its use appears to be driven by healthcare providers and parents (Vartabedian, 2007). When a newborn is fussy and gassy, many parents mistakenly believe that their infant is "lactose intolerant" because an adult family member is lactose

intolerant. On the other hand, cow protein in standard cow's milk–based formula can cause colicky symptoms in sensitive infants. Switching to soy formula will not always solve the cause of the colic symptoms, because infants who are sensitive to the protein in cow's milk–based formula may also be sensitive to the soy protein in soy protein–based formula (Greer, Sicherer, Burks, et al., 2008). Therefore, the AAP recommends using hypoallergenic formulas rather than soy formula for infants with documented cow's milk allergy (AAP Clinical Report, 2008b).

Feeding Intolerances

All too often, fussy breastfeeding or cow's milk–based formula-fed infants are switched to a lactose-free formula because of concerns about lactose intolerance. It is important to distinguish true lactose intolerance from cow's milk protein allergy or other source of feeding intolerance.

Lactose intolerance is defined as a "deficiency of the intestinal enzyme lactase that splits lactose into two smaller sugars, glucose and galactose, and allows lactose to be absorbed from the intestine" (Marks, 2008). This condition causes diarrhea, flatulence, abdominal pain, and, sometimes, abdominal bloating, abdominal distension, and nausea. There are three causes of lactose intolerance: (1) congenital lact*ase* deficiency, (2) secondary lact*ose* intolerance, and (3) developmental or acquired lact*ose* intolerance.

The most common cause of lactose intolerance is developmental or acquired. Many parents will assume that their infant has lactose intolerance because they or the child's older sibling has lactose intolerance. However, this is an age-related condition that develops after 2 to 5 years of age and is therefore not a condition affecting newborns.

Up to 15% of infants have milk protein allergy (mostly because of the beta-lactoglobulin component in cow's milk) or to some other antigen (Brill, 2008). Infants with a *cow's milk protein allergy (CMPA)* who are being fed breast milk or formula may exhibit a variety of symptoms and involves multiple body systems. Gastrointestinal symptoms include copious gas, reflux (spitting up frequently), very loose stools or diarrhea or constipation, mucous and blood (gross or occult) in the stool, may refuse to feed or want to eat small meals frequently due to discomfort and feeling bloated, and may develop failure to thrive. Infants frequently exhibit allergic respiratory symptoms, and cutaneous manifestations include skin rash. Lastly, allergies affect a baby's disposition, hence being labeled a "colicky" baby. They tend to be especially fussy in the first hour after feeding and it impacts their sleep because babies usually go to sleep after feeding. These babies may awaken early due to reflux or gas pain.

Breastfeeding babies may not be allergic to the mother's milk but rather to the cow's milk protein (an antigen) in the mother's milk. By eliminating the culprit (e.g., the bovine protein) from the mother's diet and therefore from the breast milk, the mother can continue to breastfeed, providing optimal nutrition and immune factors to her infant. However, a dietary elimination of cow's milk and milk products (and hidden sources of milk in prepared foods), is a very difficult lifestyle change to make. These mothers need a lot of support and praise for their sacrifice. They also need to know alternate food sources to receive their daily requirement for calcium and vitamin D. Encourage families to read labels and find foods fortified with calcium and vitamin D (e.g., fortified orange juice). Some mothers tolerate rice milk or goat milk on their fortified cereal, although there can be a cross-reaction or sensitivity with goat milk. The silver lining in all of this is that many infants outgrow their cow's milk allergy as early as a year of age. Some sensitive babies take longer to outgrow this problem.

Other Specialized Formulas

For infants who do not have cow's milk–based formula allergy but may have formula intolerance, the formula companies offer hydrolyzed or partially hydrolyzed formula. *(Note: "hydrolyzed" simply means the protein has been broken down into smaller components mimicking digestion.)* These include Nestlé Good Start Gentle Plus and Enfamil Gentlease. Nestlé Good Start Gentle Plus provides 100% hydrolyzed whey protein (no casein protein) for easier digestion, and the carbohydrate requirement is met with a blend of lactose and corn maltodextrin. Fats come from a combination of vegetable oils. Enfamil Gentlease provides hydrolyzed whey and casein proteins with a profile similar to mature human milk, but the lactose amount is reduced to one fifth the amount found in standard milk-based formula (Nestlé Nutrition, 2009). Lactose-free formulas raise concerns about the long-term use of lactose-free formulas when an infant's sole source of food is formula. These specialty formulas are widely available at most food stores and pharmacies that sell infant formula.

For infants with documented cow's milk–based allergies or infants with a metabolic disorder or malabsorption syndrome, the first choice formula is a hypoallergenic formula such as Nutramigen or Alimenum. Both formulas use extensively hydrolyzed casein protein supplemented with a high percentage of free amino acids such as L-cystine, L-tyrosine, and L-tryptophan with the remainder as small peptides. Both are lactose-free. Both use a combination of vegetable fats that are different from each other to meet the fat requirement.

In rare cases, some extremely sensitive infants do not tolerate Nutramigen or Alimentum, and require a "superhypoallergenic" formula. This category of formulas may be prescribed for infants who may have severe food allergies or multiple food allergies, short-bowel syndrome, or other severe GI tract disorder. Both EleCare and Neocate are used in these extreme situations. These formulas provide 100% free amino acids as their protein source, corn syrup solids for their carbohydrate source, and each has a unique fat profile. These expensive specialty formulas are available by prescription only. There are still other specialty formulas developed for infants with other medical conditions such as prematurity, heart disease, kidney disease, and specific metabolic diseases. There are commercial formulas or nutrient supplements designed for their special needs. These formulas are available by prescription only.

HEALTH PROMOTION EDUCATION: CHOICE OF FEEDING

Feeding their newborn is an exciting, satisfying, but often worrisome task for parents. Meeting this essential need of their new

child helps parents strengthen their attachment to their child and fosters their self-images as nurturers and providers, yet carries great responsibility. Whether a woman chooses to breastfeed or formula feed, she can be reassured that she can adequately meet her infant's needs. As questions about feeding arise, the nurse works with the woman to help her develop skill in her chosen method. In every interaction, it is the nurse's responsibility to support the parents and promote the family's sense of confidence.

The mother usually decides to breastfeed or formula feed by the sixth month of pregnancy and often even before conception. However, she may not make her final decision until admission to the birth center. The decision is often influenced by relatives, especially the baby's father and the maternal grandmother (AWHONN, 2007), by friends, and by social customs rather than being based on knowledge about the nutritional and psychologic needs of the mother and her newborn.

The *Healthy People 2010* National Health Promotion and Disease Prevention program states that at least 75% of all mothers will initiate breastfeeding, at least 50% will continue to breastfeed until their infants are 6 months old, and at least 25% of mothers continue to breastfeed until their infants are 12 months old. A recent survey of breastfeeding in the United States showed a slow rise to 77% of hospital-born infants receiving some breast milk but the continuation of breastfeeding until 6 months of age still falls short of the desired goal (McDowell, Wang, & Kennedy-Stephenson, 2008). In the last few years, the CDC also began tracking the rate of *exclusive breastfeeding* among infants at 3 months and 6 months of age. The *Healthy People 2010* objective for exclusive breastfeeding at 3 months is 40%; the current rate is 33%. The *Healthy People 2010* objective for exclusive breastfeeding at 6 months is 17%; the current rate is 13.6% (Centers for Disease Control and Prevention [CDC], 2009). It is the healthcare provider's responsibility to provide the parents with accurate information about the distinct advantages of breastfeeding to the mother and infant. In these times of short stays, the Baby-Friendly Hospital Initiative program promotes breastfeeding by designating hospitals as centers for breastfeeding education.

Once the parents have made an informed choice of feeding method, the nurse's primary responsibilities are to support the family's decision and to help the family achieve a positive result. No woman should be made to feel either inadequate or superior because of her choice in feeding. There are advantages and disadvantages to breastfeeding and bottle-feeding, but positive bonds in parent-child relationships can be developed with either method.

Breastfeeding

Breast Milk Production

The female breast is divided into 15 to 20 lobes, separated from one another by fat and connective tissue, and interspersed with blood vessels, lymphatic vessels, and nerves. These lobes are subdivided into lobules composed of small units called alveoli where milk is synthesized by the alveolar secretory epithelium. The lobules have a system of lactiferous ducts that eventually open onto the nipple surface. Mothers are often surprised to see milk coming out of multiple nipple pores when they express their milk. See Figure 32-1 ■ to view the anatomy of the breast.

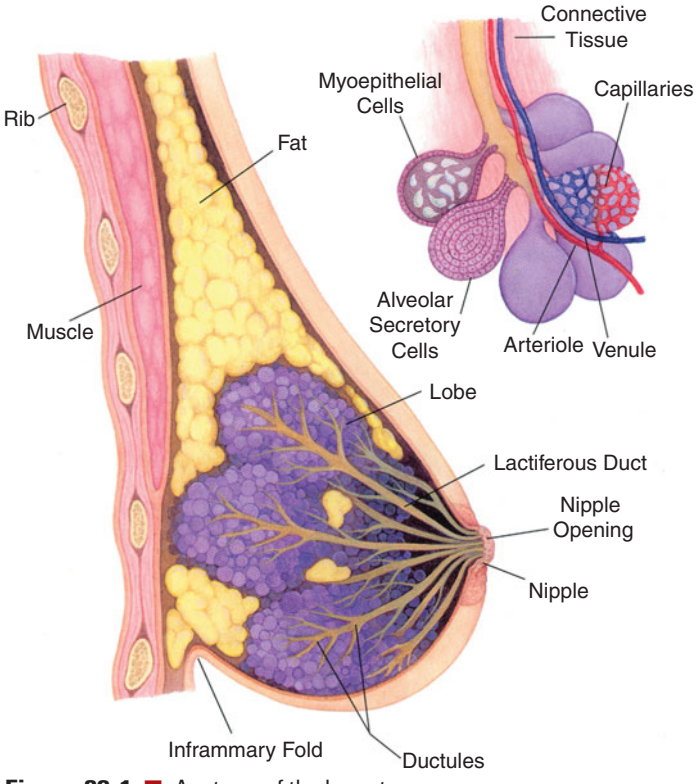

Figure 32-1 ■ Anatomy of the breast.

Physiologic and Endocrine Control of Lactogenesis

During pregnancy, increased levels of estrogen stimulate breast duct proliferation and development, and elevated progesterone levels promote the development of lobules and alveoli in preparation for lactation. Prolactin levels rise from approximately 10 ng/ml prepregnancy to 200 ng/ml at term. However, lactation is suppressed during pregnancy by elevated progesterone levels secreted by the placenta. Once the placenta is expelled at delivery, progesterone levels fall and the inhibition is removed, triggering milk production. This occurs whether the mother has breast stimulation or not. However, if by the third or fourth day breast stimulation is not occurring, prolactin levels begin to drop.

Initially, lactation is under endocrine control. The hormone **prolactin** is released from the anterior pituitary in response to breast stimulation from suckling or the use of a breast pump. Prolactin stimulates the milk-secreting cells in the alveoli to produce milk, then rapidly drops back to baseline. If more than approximately 3 hours occurs between breast stimulation, prolactin levels begin to drop below baseline. To reverse the overall decline in prolactin levels, the mother can be encouraged to breastfeed/pump more frequently (e.g., every 1.5 to 2 hours during day hours) for a few days to get baseline prolactin raised. This is especially important if the infant is not an effective feeder or if the mother is separated from her infant. Pro-

lactin receptors are established during the first 2 weeks postpartum in response to frequency of breast stimulation (Human Milk Banking Association of North America [HMBANA], 2006). Inadequate development of prolactin receptors during this time is likely to negatively impact the mother's long-term milk volume. By 2 weeks (14 days) postpartum, prolactin levels will be back to prepregnancy levels and milk production will cease if stimulation of the breasts by breastfeeding or pumping does not occur (Lawrence & Lawrence, 2005).

The milk that flows from the breast at the start of a feeding or pumping session is called **foremilk**. The foremilk is watery milk, high in lactose, high in protein, and low in fat (1% to 2%). This is milk that has trickled down from the alveoli between feedings to fill the lactiferous ducts. It is low-fat milk because the fat globules made in the alveoli stick to each other and to the walls of the alveoli and do not trickle down.

In addition to prolactin release, stretching of the nipple and compression of the areola signal the hypothalamus to trigger the posterior pituitary gland to release oxytocin. **Oxytocin** acts on the myoepithelial cells surrounding the alveoli in the breast tissue to contract, ejecting milk, including the fat globules present, into the ducts. This process is called the *milk-ejection reflex*, better known in lay terms as the **let-down reflex** response. The average initial let-down response occurs about 2 minutes after an infant begins to suckle, and there will be 4 to 10 let-down responses during a feeding session. The milk that flows during let-down is called **hindmilk**. As noted, hindmilk is rich in fat (can exceed 10%) and therefore high in calories. In a sample of expressed human milk, the average total fat concentration is about 4% and the total caloric content is about 20 calories/ounce.

By 6 months of breastfeeding, prolactin levels are only 5 to 10 ng/ml, yet milk production continues. A whey protein called feedback inhibitor of lactation (FIL) has been identified as influencing milk production through a negative feedback loop. FIL is present in breast milk and functions to decrease milk production. The more milk that remains in the breast and the longer it remains, the more milk production is decreased. On the other hand, the more often the breasts are emptied, the lower the level of FIL and the faster milk is produced. This mechanism of regulating milk at the local level is called *autocrine control*. This process is key to understanding how a mother maintains or loses her milk supply (Riordan & Wambach, 2010).

There are a number of risk factors that can delay or impair lactogenesis. Maternal factors include cesarean birth, primiparity, long duration of stage I or stage II of labor, postpartum hemorrhage, premature delivery, diabetes type 1, untreated hypothyroidism, obesity, polycystic ovary syndrome or other endocrine disturbances, retained placenta fragments, history of previous breast surgery, insufficient glandular breast tissue, and significant stress (Riordan & Wambach, 2010). Other factors that can interfere with the breast milk supply include smoking and the use of alcohol and some prescription and over-the-counter medications (e.g., antihistamines, combined birth control pills).

Stages of Human Milk

During the establishment of lactation there are three stages of human milk: colostrum, transitional milk, and mature milk.

Colostrum is the initial milk that begins to be secreted during mid-pregnancy and is immediately available to the baby at delivery. Although the volume of colostrum is small, this encourages the newborn to nurse frequently, helping to stimulate milk production. No supplementation with other fluids is necessary unless there is a medical indication. Colostrum is a thick, creamy yellowish fluid with concentrated amounts of protein, fat-soluble vitamins, and minerals, and it has lower amounts of fat and lactose compared with mature milk. It also contains antioxidants and high levels of lactoferrin and secretory immunoglobulin A (IgA). It promotes the establishment of *Lactobacillus bifidus* flora in the digestive tract, which helps to protect the infant from disease and illness. Colostrum also has a laxative effect on the infant, which helps the baby pass meconium stools, which in turn helps decrease hyperbilirubinemia.

The onset of copious milk secretion begins between 32 and 96 hours postpartum. For most women this is observed on day 3. Lay people refer to this as the milk "coming in." The milk produced during this period is called **transitional milk**. Transitional milk has qualities intermediate to colostrum and mature milk but may look indistinguishable from colostrum. It is still yellow in color like colostrum but is more copious and contains more fat, lactose, water-soluble vitamins, and calories. See Figure 32-2 ■ to view a picture of transitional milk. By day 5, most mothers are producing about 16 oz/day (Riordan & Wambach, 2010).

Mature milk is white or can be slightly blue-tinged in color. It is present by 2 weeks postpartum and continues thereafter until lactation ceases. Mature milk contains about 13% solids (carbohydrates, proteins, and fats) and 87% water. Although mature human milk appears similar to skim cow's milk and may

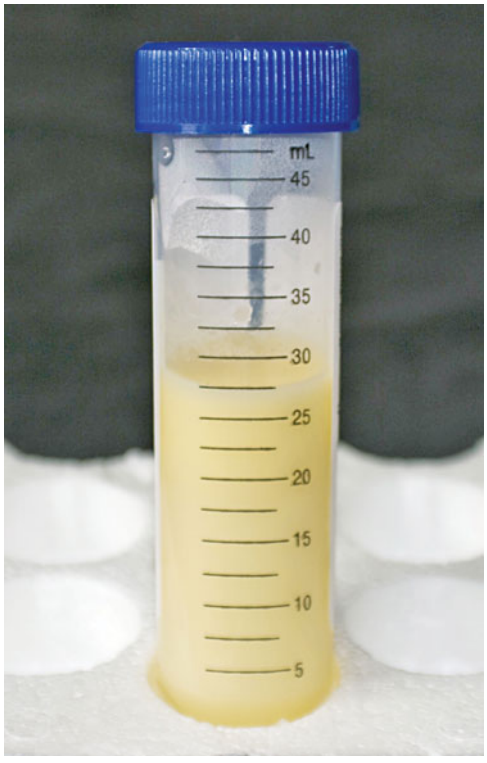

Figure 32-2 ■ Transitional human milk.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC/Pearson Education.

cause mothers to question whether their milk is "rich enough," mothers should be reassured that this is the normal appearance of mature human milk and that it provides the infant with all the necessary nutrients. Although gradual changes in composition do occur continuously over periods of weeks to accommodate the needs of the growing newborn, in general the composition of mature milk is fairly consistent, with the exception of the fat content as noted previously. Milk production continues to increase slowly over the first month. By 6 months postpartum a mother produces about 800 ml/day (Blackburn, 2007).

Advantages of Human Milk

In its breastfeeding policy statement, the AAP recommends exclusive breastfeeding as the preferred feeding for all infants, with a few exceptions, for the first 6 months and continued breastfeeding during the introduction of solids until the infant is 12 months old or older, as desired. There is compelling scientific evidence that indicates that breastfeeding provides infants with specific nutritional, immunologic, and psychosocial advantages over formula-feedings (AAP & ACOG, 2007).

Nutritional Advantages

Human milk provides optimum nutrition for the human infant because it is species specific. The macronutrients such as protein, fat, and carbohydrates (lactose) are synthesized by the mother in the alveoli of the breasts by specialized secretory cells. Micronutrient elements such as vitamins and minerals derive from the circulating maternal plasma. There are more than 200 distinct components in human milk, with more remaining to be identified (Lawrence & Lawrence, 2005).

Lactose is the primary carbohydrate in mammalian milk and plays a crucial role in the nourishment of our offspring. Human milk has a very high lactose content compared with the milk of other mammal species. After lactose is hydrolyzed into galactose and glucose, the galactose is used in the formation of cerebral galactolipids and contributes to brain and central nervous system (CNS) development. Glucose is used by many tissues, but especially by the brain, which consumes 20% of the body's energy requirements and derives this almost exclusively from glucose. In addition to providing a cellular energy source, lactose enhances the absorption of calcium, magnesium, and zinc (Lawrence & Lawrence, 2005).

Fats in breast milk give an advantage to infants who receive human milk. The mineral content in human milk (colostrum) is a little higher for the first few days after birth, and then after a slight decrease, the mineral content remains fairly constant thereafter. Maternal age, parity, and diet (even if the mother is receiving mineral supplement) has only a minimal influence on mineral content in breast milk. It is believed that the maternal body stores regulate the process. For example, if a mother's calcium intake in her diet is poor, the body will draw from its reserves (e.g., from bone) to provide a sufficient amount of calcium in her breast milk for her baby. Following weaning, through a feedback mechanism, transient bone loss normalizes (Bezerra, Mendonca, Lobato, et al., 2004).

As mentioned earlier in this chapter, the iron found in human milk, even though much lower in concentration than that of prepared formulas, is much more readily and fully absorbed facilitated by the high vitamin C and lactose levels in the breast milk and appears sufficient to meet the infant's iron needs for the first 6 months. Excess iron is not desirable because any extra iron that is not absorbed may promote the growth of pathogenic enteric bacteria as well as cause cellular oxidative injury. Lactoferrin, an iron-binding protein found only in breast milk, scavenges iron in the gut and enhances its absorption, eliminating excess iron (Lawrence & Lawrence, 2005).

There is research supporting additional health advantages for the breastfed infant. Breastfed infants have a reduced risk of developing type 1 or type 2 diabetes mellitus, lymphoma, leukemia, Hodgkin's disease, obesity, hypercholesterolemia, and asthma (AAP, 2005).

The mother benefits from breastfeeding as well. When breastfeeding is initiated right after delivery, there is decreased risk for postpartum bleeding. As breastfeeding continues in the early postpartum period, the elevated oxytocin levels stimulate rapid uterine involution.

The benefits of breastfeeding are dose related. However, both mother and baby benefit from even some breastfeeding compared to no breastfeeding at all. In a large study, the authors suggested that breastfeeding has a protective function against premenopausal breast cancer (Riordan & Wambach, 2010). In addition, breastfeeding mothers have a decreased risk of developing ovarian cancer (Lawrence & Lawrence, 2005); and may have a decreased risk of developing postmenopausal osteoporosis (AWHONN, 2007).

The breastfeeding mother also benefits from breastfeeding by burning additional calories making milk (quicker return to prepregnancy weight), thus losing more weight in the postpartum period than the mother who never breastfed. Breastfeeding frequency and total duration also influence weight loss.

Immunologic Advantages

The immunologic advantages of human milk include varying degrees of protection from respiratory tract and gastrointestinal tract infections, necrotizing enterocolitis, urinary tract infections, otitis media, bacterial meningitis, bacteremia, and allergies (AWHONN, 2007). Transplacental passage of maternal immunoglobulin gradually diminishes over the first 6 months of life until the infant can begin to produce his or her own immunoglobulins. Human milk-derived immunologic protection helps supplement this protection.

Secretory IgA, an immunoglobulin present in colostrum and mature breast milk, has antiviral, antibacterial, and antigenic-inhibiting properties, specifically across mucosal surfaces such as the intestinal tract. Secretory IgA plays a role in decreasing the permeability of the small intestine to help prevent large protein molecules from triggering an allergic response. Other constituents of colostrum and mature breast milk that act to inhibit the growth of bacteria or viruses are *Lactobacillus bifidus,* lysozymes, lactoperoxidase, lactoferrin, transferrin, and various immunoglobulins.

Some mothers wonder if there are special considerations for breastfed infants regarding immunizations. Although breastfeeding mothers pass along antibodies and other immune fac-

tors in their milk to their infant, breastfeeding is not a substitute for routine immunizations. All infants should receive vaccinations following a schedule as recommended by the Centers for Disease Control and Prevention (CDC, 2010). The current vaccination schedule can be viewed online at the CDC Web site.

Some mothers also wonder if it is safe for them to receive vaccinations while breastfeeding. Mothers should be reassured that most vaccines can safely be taken during the lactation period. According to the CDC, *General Recommendations on Immunization* (2010), "Neither inactivated nor live vaccines administered to a lactating woman affect the safety of breast-feeding for mothers or infants. Breast-feeding does not adversely affect immunization and is not a contraindication for any vaccine."

Psychosocial Benefits of Breastfeeding

The psychosocial advantages of breastfeeding include increased self-esteem, enhanced bonding, and a decrease in stress for the mother and infant.

A mother's self-esteem is increased in knowing that she has provided the perfect food for her baby and provided protection with her antibodies with her own body. For many mothers breastfeeding takes effort, understanding, and an emotional commitment to endure the demands of this lifestyle choice. The mother's sense of accomplishment in being able to satisfy her baby's needs for nourishment and comfort can be a tremendous source of personal satisfaction.

Women who breastfeed, by its nature, have close contact with their infants. Newborns are very responsive to touch, and it is vital for the infant's emotional well-being. The tactile stimulation associated with breastfeeding can communicate warmth, closeness, and comfort. The increased closeness provides both the mother and newborn with the opportunity to learn each other's behavioral cues and needs. From the release of prolactin and oxytocin while breastfeeding, mothers may feel more affectionate toward their newborns, have improved let-down response, and breastfeed more frequently and for longer periods of time (Klaus, 1998; Mohrbacher & Kendall-Tackett, 2005).

Mothers who breastfeed save money and this reduces stress for many families. There are significant cost savings for the family who chooses breastfeeding. The cost of standard formula is approximately $1,300 annually per infant for standard formulas and more for specialty formulas (AWHONN, 2007). There are also healthcare cost savings for families resulting from the decreased incidence of illness in the infant. Because breastfed babies access healthcare resources less often, the family saves money on medical visits and prescription medications and loses less time from work.

Potential societal benefits to breastfeeding include decreased spending on public assistance programs (e.g., Women Infant Children Supplemental Nutrition Program [WIC]), and environmental benefits in terms of use of natural resources and solid waste disposal. Breastfeeding is not dependent on modern technology and can provide the infant with a fresh, clean, naturally warm source of nutrition independent of transportation, supply, electricity, refrigeration, clean water, bottles, nipples, and so on. There are also substantial medical cost savings to society, estimated to be approximately $400 in excess medical costs per never-breastfed infant (AWHONN, 2007). With current breastfeeding initiation rates of approximately 66%, this amounts to an additional $544 million per year in potential healthcare costs that could be saved by breastfeeding. Table 32-3 compares several factors for parents to consider when choosing between breastfeeding and formula-feeding.

Breastfeeding

> "Another challenge I had occurred when I went back to work full-time and had to fight to keep up my milk supply. Because my baby has allergies, it was especially important for her to have only breast milk for the first 6 months. I achieved that goal, but I could not have made it without the help I got from family, friends, the staff at the lactation center, my OB, and my daughter's pediatrician. Also, my boss and coworkers have been very supportive, allowing me breaks to pump my milk 3 times a day at work. Now I know why they say "It takes a village to raise a child." In the end, there is nothing more rewarding than knowing that I'm providing the best nutrition possible and seeing my daughter smile back at me while she nurses. She is healthy and happy and that means the world to me."

Potential Disadvantages and Contraindications to Breastfeeding

Care Plan Activity: Breastfeeding Concerns

Disadvantages

The following is a list of sometimes cited potential disadvantages to breastfeeding:

1. ***Pain with breastfeeding.*** Breastfeeding is a natural process but requires a certain knowledge base that formerly was passed along from generation to generation. With the decline in the extended family structure, this source of knowledge and assistance is often missing for the new mother. Nipple tenderness is the most common source of discomfort and is usually related to improper positioning and/or not obtaining a proper attachment of the infant on the breast. Pain can also be related to engorgement or infection. Breastfeeding with proper technique should not hurt and these mothers should be encouraged to seek assistance from a knowledgeable person skilled in lactation.
2. ***Leaking milk.*** Some women will leak milk when their breasts are full and it is nearly time to breastfeed again or whenever they experience let-down, which can be triggered by hearing, seeing, or even thinking of their baby. If this causes concern to the mother, she can be instructed on how to apply gentle pressure directly over her nipple for a minute or so to stop the leaking momentarily. The mother can wear nursing pads inside her bra (with instructions to change wet pads frequently), or she might want to wear printed tops that camouflage small leaks. Mothers should be given reassurance that this problem diminishes over time.

TABLE 32-3 Comparison of Breastfeeding and Formula-Feeding

BREASTFEEDING	FORMULA (IRON-ENRICHED)-FEEDING
Infant Nutrition	
An ideal balance of nutrients, efficiently absorbed. High bioavailability of iron leaves little excess iron available for bacterial growth, cell injury.	Derived from bovine milk and/or plant sources. Lower bioavailability of nutrients requires higher concentrations in milk. Additives may cause intolerance.
Higher levels of essential fatty acids, lactose, cystine, and cholesterol, necessary for brain and nerve growth.	Still missing numerous ingredients. Formulas do not contain cholesterol. Soy and hydrolysate formulas do not contain lactose. DHA and ARA now added.
Composition varies according to gestational age and stage of lactation, meeting changing nutritional needs.	Nutritional value not varied. Nutritional adequacy depends on proper preparation/dilution.
Long-term decreased incidence of diabetes, cancer, obesity, asthma.	Contains saturated fats.
Contains unsaturated fats.	Parents or healthcare provider determine the volume consumed. Overfeeding may occur if caregiver is determined that baby empty bottle.
Infants determine the volume of milk consumed.	Frequency of feeding is determined by infant's cues. May feed less frequently as milk digestion is slower.
Frequency of feeding is determined by infant's cues. May feed more frequently as milk digestion is faster.	
Immunologic Properties	
Contains immunoglobulins, enzymes, and leukocytes that protect against pathogens. Nutrients promote growth of *Lactobacillus,* protective bacteria. Lower rates of urinary tract infections, otitis media, and other infectious diseases.	No antibodies or anti-infective properties. Formula is linked to an increased incidence of gastrointestinal and respiratory tract infections.
Anti-infective properties present in the milk permit longer storage duration.	Potential for bacterial contamination exists during preparation and storage.
Human milk is hypoallergenic, with minimal risk of protein allergy/intolerance.	Cow's milk protein intolerance relatively common.
Maternal Health	
Faster return to prepregnancy weight.	Provides complete (or supplemental) infant nutrition when human milk not available because of maternal illness, medication/drug use, lactation failure (breast surgery, endocrine disease), or if not chosen as a feeding choice.
Breastfeeding associated with lower risk of breast, ovarian cancer.	
Psychosocial Aspects	
Skin-to-skin contact enhances bonding. Maternal empowerment from satisfaction with providing optimal nourishment and antibody protection for her infant.	Both parents can participate in positive parent-infant interaction during feeding from the start.
Hormones of lactation promote maternal feelings and sense of well-being.	Father can assume feeding responsibilities.
The value system of modern society can create barriers to successful breastfeeding.	Mothers can receive more rest in the beginning because others can help assume feeding responsibilities.
Some mothers may feel ashamed or embarrassed.	
Breastfeeding after returning to work may be difficult.	
Cost	
Healthy diet for mother.	Hypoallergenic formula is more expensive than standard formula.
Savings for infant medical costs: approximately $400 average in first year of life.	Ancillary costs: bottles or bottle liners, nipples, cleaning costs.
Ancillary costs: nursing pads, nursing bras.	Refrigeration is needed if preparing more than one bottle at a time.
A breast pump may be needed.	
Refrigeration is necessary for storing expressed milk.	
Convenience	
Milk is always the perfect temperature. No preparation time is needed.	Formula must be purchased commercially. Preparation is time consuming.
The mother must be available to feed or will need to provide expressed milk to be given in her absence.	Less convenient for traveling or for night feedings.
If she misses a feeding, the mother must express milk to maintain lactation.	Mother need not be present—anyone can feed the infant.
The mother may experience discomfort in the early days of lactation.	

3. ***Embarrassment.*** Some mothers feel uncomfortable about breastfeeding because they are modest, or may feel embarrassed because our society views breasts as sexual objects, and/or an unfriendly social environment makes it difficult to breastfeed in public. This is not an easy issue to overcome. Some mothers will feel more confident after learning how to breastfeed discreetly while in public.
4. ***Stress.*** Many mothers feel a lot of stress juggling work or school and the demands of home life. Some mothers cite this reason for wanting to wean. There are multiple options to suggest for this concern. Mothers can learn about "double pumping" to save time. A double electric breast pump allows the mother to pump both breasts simultaneously, which cuts the pumping time in half. If a mother

struggles to keep up her milk supply, she can try taking an herbal supplement to give her milk supply a boost, unless contraindicated for her. (See Complementary and Alternative Therapies later in the chapter.) Finally, it is still preferable to decrease the frequency of pumping rather than quitting altogether, if that makes things more manageable for the mother. Babies who get some breast milk are still receiving more of the benefits of breast milk than babies who do not receive any breast milk.

5. ***Unequal feeding responsibilities/fathers left out.*** Some parents want feedings to be a shared responsibility. The parents should be informed that it is advisable for the father to wait to bottle feed the baby with expressed breast milk until after the milk supply and breastfeeding are established, generally when their baby is about 3 to 4 weeks old. In the meantime, encourage the father to be supportive of the breastfeeding mother, to have a lot of skin-to-skin contact with his infant, and to share the responsibilities of all other aspects of infant care (bathing, dressing, diapering, burping, rocking, etc.).
6. ***Diet restriction.*** Some mothers think that they have to give up eating certain foods when they breastfeed. This is generally not true. Most mothers can still eat all the foods they are accustomed to eating. Mothers do need to restrict alcohol intake and keep caffeine to a minimum. In the uncommon case where an infant has intolerance or allergy symptoms, as discussed earlier in the chapter, the mother should consult with a lactation consultant or the baby's healthcare provider to help her work through this complication.
7. ***Limited hormonal birth control options.*** Some mothers think that they cannot use a hormonal method of birth control while breastfeeding. Mothers should be informed that using birth control pills containing progesterone and estrogen can cause a decrease in milk volume and may affect the quality of their milk. It is preferred that the mother who wants to use a hormonal birth control method consider using the progestin-only minipill (i.e., Micronor, Nor-QD, Aygestin, or Norlutate); receive Depo-Provera, a progestin-only injection administered every 90 days; or have a progestin-only implant. Although progestin-only hormonal birth control is compatible with lactation, it should not be administered after delivery or at the time of hospital discharge. It is recommended that the mother wait 6 weeks before taking the hormonal medication to ensure a good milk supply (AAP & ACOG, 2007). Mothers can be reassured that barrier methods of birth control and natural family planning do not interfere with lactation at all and are good options to consider as well.
8. ***Vaginal dryness associated with breastfeeding.*** Some mothers experience vaginal dryness related to a low level of estrogen while lactating. Mothers can be given reassurance that this is only a temporary side effect while breastfeeding. A water-based lubricant such as K-Y jelly or Astroglide can be used during intercourse until she weans and estrogen levels increase again.
9. ***Medications and breastfeeding.*** Some mothers are concerned about the safety of breastfeeding while they are taking medications. Mothers can be reassured that most prescription and over-the-counter medications are safe for the breastfeeding infant.

   The mother should be advised to inform her healthcare provider and her infant's healthcare provider that she is breastfeeding when a drug is prescribed for her. In counseling the breastfeeding mother, the healthcare provider should weigh the benefits of the medication against the possible risk to the infant and its possible effects on the breastfeeding process. If the medication is not compatible with breastfeeding but is needed for only a short time, the mother can use a breast pump to maintain lactation and discard the milk. For additional information on medications and their compatibility with breastfeeding, see the list of resources on www.nursing.pearsonhighered.com.

Medications

It has long been recognized that medications taken by the breastfeeding mother may penetrate human milk to some degree. But having a better understanding of the kinetics of drug entry into human milk, as well as factors influencing its bioavailability to the nursing infant is important, because use of medication has been identified as a barrier to breastfeeding and a major reason women cite for discontinuing breastfeeding (Hale, 2010).

It should be noted that (1) most drugs penetrate into human milk, (2) almost all medications appear in only small amounts in human milk (usually less than 1% of the maternal dosage), and (3) very few drugs are contraindicated for breastfeeding women (AAP Committee on Drugs, 2001; Briggs, Freeman, & Yaffe, 2008; Hale, 2010).

Characteristics of a drug that influence its passage into human milk include the following:

- ***Degree of protein binding.*** Unbound drugs are more likely to enter the breast milk.
- ***Degree of ionization.*** Drugs tend to cross into breast milk in un-ionized form.
- ***Molecular weight.*** Drugs with lower molecular weight are more likely to cross into breast milk.
- ***Degree of solubility in fat and water.*** Lipid-soluble drugs pass into breast milk easily because of the high fat content in human milk.
- ***Mechanism of transport.*** Most drugs enter human milk by simple diffusion, but occasionally active transport or carrier-mediated diffusion may be involved.
- ***The pH.*** Human milk, which is acidic, attracts drugs that are weak bases.
- ***Half-life.*** Rates of absorption, metabolism, and excretion determine a drug's half-life, or how fast it leaves the body. The longer the half-life is, the greater the risk of accumulation in breast milk.

The net measurement of these effects determines the **milk/plasma ratio**, which relates the concentration of the drug in the milk to the concentration in the maternal plasma. For drugs that have equivalent dosing levels for the mother *and* equivalent safety profiles in the infant, it is preferable to use the drug with a lower milk/plasma ratio. Also, for any particular drug, it is preferable to use the lowest effective dose in the mother. Finally, the route and timing of the maternal dosing affects the

maternal plasma level and therefore also the amount of drug reaching the baby.

Five adjustments should be made when administering drugs to a nursing mother to decrease the effects on the infant (Blackburn, 2007).

1. Avoid long-acting forms of drugs. The infant may have difficulty metabolizing and excreting them, and accumulation may be a problem.
2. Consider absorption rates and peak blood levels in scheduling the administration of the drugs. Less of the drug crosses into the milk if the infant is fed before the mother is given the oral medication.
3. Use preparations that can be given at longer intervals (once versus three to four times per day).
4. When alternatives are available, select the drug that shows the least tendency to pass into breast milk.
5. Use single-symptom drugs versus multisymptom drugs (e.g., a decongestant for allergy rather than a multisymptom drug, especially because liquid forms may contain alcohol).

Potential Contraindications

There are some instances when breastfeeding is or may be contraindicated:

- If mother is HIV positive or has AIDS, she is counseled against breastfeeding except in countries where the risk of neonatal death from diarrhea and other disease (excluding AIDS) is high (AWHONN, 2007).
- Mother has active, untreated tuberculosis, has varicella, or mother is HTLV1-positive (human T-cell leukemia virus type 1).
- Mother has active herpes on her breast—the infant may still feed on the unaffected side only until the lesion has healed.
- Mother has another illness, on a case-by-case basis.
- Mother uses illicit drugs (e.g., cocaine, heroin) or is an alcoholic.
- Maternal smoking poses health risks to the mother and potential second-hand exposure risks to her baby. Research shows that smoking by breastfeeding mothers can significantly alter infants' sleep-wake cycles, causing infants to sleep less and also affects milk flavor (Mennella, Yourshaw, & Morgan, 2007). Maternal smoking can result in breast milk concentrations of nicotine of 1.5 to 3 times the maternal plasma concentration. However, babies who receive breast milk from mothers who smoke are healthier than babies who receive formula and live in a household with smokers. Mothers who smoke cigarettes can breastfeed. To minimize effects on the baby, mothers should time their smoking to immediately *after* breastfeeding and should not smoke in the same room as the infant (American Academy of Family Physicians [AAFP], 2008).
- Specific medications (e.g., radioactive isotopes, antimetabolites, chemotherapy drugs, and a few others). A mother with a diagnosis of breast cancer should not breastfeed so that she can begin treatment immediately.
- Infant has galactosemia.

Potential Problems in Breastfeeding

Because mothers are discharged from the birthing unit before breastfeeding is well established, they are frequently alone when they encounter changes in the breastfeeding process. Many women stop nursing if the situations they encounter seem to pose problems. Nurses can offer anticipatory guidance regarding common breastfeeding phenomena and provide resources for the woman's use after discharge. (See chapter 37 ∞ for a detailed discussion of self-care measures the nurse can suggest to a woman with a breastfeeding problem after discharge from the birthing unit.)

COMPLEMENTARY AND ALTERNATIVE THERAPIES

It is estimated that more than a third of Americans use herbal medicine to promote health and treat disease. Nurses working with women of childbearing years should become familiar with common herbal preparations considered for use by lactating women. *Galactogogues* are commonly used to increase a mother's milk production when her supply is decreased, to assist in reestablishing a milk supply after weaning, and to assist in initiating lactation such as when an adoptive mother desires to nurse her infant. They include fenugreek, goat's rue, milk thistle, anise, basil, blessed thistle, fennel seeds, and marshmallow, to name a few (Academy of Breastfeeding Medicine [ABM], 2004). Some of these herbs are not recommended for a nursing mother if she is also pregnant.

Most mothers taking a galactogogue notice an increase in their milk supply within 1 to 3 days. Mothers should be counseled that taking a galactogogue alone will not solve her low milk supply problem. It must be stressed to her that she must also increase the frequency of breastfeeding (or pumping with a good quality breast pump) to have the best results. Ideally, the mother should be stimulating her breasts 8 to12 times a day, especially while lactation is getting reestablished. She also needs to balance the demands in her life and try to get rest when she can and lessen her stress. (Stress has a negative impact on a mother's milk supply.) She must also continue to drink to thirst and eat a healthy diet, which includes receiving a minimum of 1800 calories per day. These behaviors will also help to increase her milk supply.

Herbal galactogogues can be consumed as a tea, or can be taken as capsules or as a tincture added to liquid to drink. The dosage of herbs in tea is not as consistent as it is for herbals in capsules or tinctures due to variable quality of the herbal leaves, differences in steeping time, and the method of tea bag storage. (Tea bags should be stored in a closed container away from light and stored in an environment with low humidity to retain their potency.)

Fenugreek is probably the most well-known herbal galactogogue among lactation consultants in the United States. To avoid potential side effects such as diarrhea in the mother, it is advisable for the mother to build up to the suggested dosing over several days. It is not uncommon for mothers to note that their urine and sweat smells like maple syrup while taking fenugreek due to the plant's fragrant seeds. Mothers should be cautioned that if the *infant's* urine smells like maple syrup, this can be a sign of an inborn error of metabolism not related to the mother's diet, and should be evaluated by their baby's healthcare provider. Mothers with diabetes, asthma, allergies to peanuts, soy, chickpeas, or garbanzo beans, or who are taking warfarin sodium (Coumadin) should consult with their health-

care provider before taking this herb (West & Marasco, 2009). Other herbs thought to increase milk supply include alfalfa, dandelion, fennel, horsetail, red raspberry, caraway, and anise. Women with lupus should read labels to avoid preparations that include alfalfa which can exacerbate their disease (West & Marasco, 2009). The following herbs may decrease milk supply, so they should be avoided until a woman is no longer breastfeeding: black walnut, sage, parsley, and yarrow.

There are also anti-galactogogues (e.g., sage, parsley, and peppermint) that may or may not be used in combination with applying cabbage leaves or ice to the breasts to decrease severe engorgement, to diminish an oversupply of milk, and to "dry up" when weaning an infant from the breast (West & Marasco, 2009). See chapter 37 ∞ for further discussion of breast engorgement.

CLINICAL TIP

To treat severe engorgement that typically occurs on day 3 and 4 postpartum, some mothers find relief applying raw chilled, green cabbage leaves topically to their breasts. The mother applies the rinsed and dried cabbage leaves after first "crunching" the "veins" in the leaves using her fist or a rolling pin. The prepared cabbage leaves are applied directly on the bare breasts (avoiding the nipple) and held in place with the mother's bra. The leaves are changed out every couple of hours when they have become wilted or when the mother awakens during the night. This remedy is discontinued as soon as the mother notices the breast swelling has decreased.

The type of herb, the dosage, and the method of administration are variable depending on the problem to resolve and personal preference. Some of these herbal products are commercially available. Women who are pregnant or nursing, or who have chronic health problems and take prescription medications, should be directed to consult with their healthcare provider before taking herbal medication. The healthcare provider will want to obtain a thorough lactation assessment so that the cause of the underlying problem can be determined, guidance and support can be offered for the management of the problem, and contraindications to any galactogogue can be considered.

CLINICAL TIP

Oil of Peppermint, an essential oil, can be added to a cold compress to be placed on the breast to provide some relief to a mother experiencing breast engorgement. Place 4 to 5 drops of peppermint oil in a basin of ice cold water. Dip a piece of clean fabric into the water so that the cloth picks up the essential oil on the surface. Wring out the fabric and place it on the breasts for about 15 to 20 minutes at a time. The breast should be washed completely before feeding. Some babies may find breathing strong fragrances emitted irritating to them. Mothers also need to avoid applying fragrances on or near their breasts because their babies might ingest them.

Timing of Newborn Feedings

The timing of newborn feedings is ideally determined by physiologic and behavioral cues rather than a set schedule. Early signs of hunger in a newborn can include any of the following behaviors: waking up, squirming, bringing hands to mouth, smacking of lips, extending the tongue repeatedly, and rooting. It is ideal to feed the baby before he or she begins to cry. When these symptoms are ignored, the infant will begin to cry (a late feeding cue). Sometimes the crying escalates and the infant becomes frantic. If his or her need for feeding is still not met, then he or she will become exhausted from crying and then fall back to sleep. Breastfed babies should feed 8 to 12 times in a 24-hour period whenever they exhibit hunger cues regardless of when they last fed. Newborns that cry can become disorganized and have difficulty latching onto the breast. The parents should be taught in this case how to calm the baby down before offering the breast. One strategy is to have either parent hold the baby vertically on his or her chest and let the baby suck on a clean finger for a minute or so. Another is to have either parent rock the baby in his or her arms or have a parent hold the infant upright on his or her chest and pat the baby's back. The baby may burp while being rocked and patted, expelling any air he or she swallowed while crying. Once the baby is calm, he or she will be ready to attempt latching on again.

Initial Feeding

If there are no complications at the birth and the mother is not overly sedated, after being dried the infant should be placed on the mother's chest. This skin-to-skin contact after birth helps the baby maintain his or her body temperature, helps with self regulation, increases maternal oxytocin levels, helps the mother to notice subtle feeding cues, and promotes bonding (Figure 32-3 ■).

Throughout the first 2 hours after birth, but especially during the first hour of life, most infants are usually alert and ready to breastfeed. This first feeding should not be forced. Some babies are content just licking the nipple or nuzzling up against the breast initially. Early breastfeeding can enhance maternal-infant bonding and facilitate release of oxytocin, which helps contract the uterus, expelling the placenta and decreasing the

Figure 32-3 ■ Mother and infant skin-to-skin.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC/Pearson Education.

risk of postpartum hemorrhage. Early feedings benefit the newborn because they help prevent hypoglycemia, promote the passage of meconium, provide the newborn with immunologic protection from colostrum, and begin to stimulate further maternal milk production, helping prevent later feeding difficulties.

If the mother plans to bottle-feed, she and her newborn can still enjoy and benefit from skin-to-skin contact initially after birth as well. Formula-feedings are not typically initiated in the birthing room. Formula-feeding newborns are offered formula as soon as they show interest/feeding cues or per agency policy. For both breastfed and formula-fed infants, early feeding stimulates peristalsis which helps the newborn to eliminate the by-products of bilirubin conjugation that have been stored up in the bowel while in utero. Early passage of the meconium stool decreases the newborn's risk of jaundice.

Assessment of the newborn's physiologic status is a primary and ongoing concern to the nurse throughout the first feeding. Extreme fatigue coupled with tachypnea, dusky in color, and diaphoretic while feeding is most likely symptomatic for respiratory and/or cardiac problems or rarely esophageal anomalies (see chapter 33 ∞). Findings associated with esophageal anomalies include maternal polyhydramnios and increased oral secretions in the infant. In cases of esophageal atresia, the feeding is taken well initially, but as the esophageal pouch fills, the infant quickly gags and regurgitates. If a fistula is present, the infant gags, chokes, regurgitates mucus, and may become cyanotic as fluid passes through the fistula into the lungs. Although the nurse is always on the alert for any complications, keep in mind that it is not unusual for healthy newborns to regurgitate a small amount of mucus, fluid, or milk shortly after feeding, or to develop hiccups. Most babies have "wet burps" at some point and so virtually all have some degree of reflux. The LES sphincter tone increases to adult pressures for most infants when the infant is 3 to 6 weeks old, though 70% of all 4-month old infants still spit up at least once a day (Vartabedian, 2007). Holding the baby upright on the parent's chest for 15 to 20 minutes after a feeding and not placing the baby in a car seat or swing (which increases abdominal pressure) for that time can help decrease the incidence of reflux. When reflux is ongoing and causes consistent feeding problems due to inflammation of the esophagus, then the reflux problem has become pathologic (called gastroesophageal reflux disease [GERD]). This problem is not evident in the early postpartum period and is managed by the baby's healthcare provider.

Establishing a Feeding Pattern

An "on-demand" feeding program facilitates each baby's own rhythm and helps a new mother establish lactation. Unrestricted feedings are best accomplished by hospitals that provide mother-baby rooming-in practices on a 24-hour basis. When the father of the baby is able to room-in with the mother and new baby, it allows both parents to participate and learn how to care for their infant; this has been shown to be important in the development of the family relationship. Having the father room-in also allows the mother with the cesarean delivery to keep her baby at the bedside too. When mothers and babies are not separated after birth, mothers and fathers are better able to respond to their baby's needs more quickly than the nursery staff may be able to, resulting in less infant crying, natural feeding intervals, and an adequate number of feedings in a 24-hour period.

Following the initial alert period (approximately the first 2 hours after birth), the newborn typically falls into a deep sleep for several hours. Mothers should be encouraged to rest during this time too. When the newborn awakens, he or she will likely want to nurse frequently, alternating between relatively short periods of light sleep and quiet wakefulness. As wakefulness and interest in nursing increase, the infant will often cluster 5 to 10 feeding episodes over 2 to 3 hours (Riordan & Wambach, 2010). Mothers may misinterpret "cluster feedings" in the first few days of life to mean that her infant is not satisfied because the mother ought to be producing more milk. The nurse should take this opportunity to reinforce the mother's perception that the infant wants additional milk, but point out that cluster feeding is a normal and necessary pattern to stimulate mother's milk production. Formula supplementation is not indicated and will actually delay milk production.

Some healthy infants are uninterested in nursing and just want to sleep for the first few days after birth. This pattern is noted in babies whose mothers have had a difficult labor, or a prolonged pushing stage during delivery, or have had medication (especially multiple dosing) for labor pain or for a cesarean birth. Late-preterm infants (infants born between 35 weeks but less than 38 weeks gestation) also tend to be very sleepy for the first few days, much more so than full-term infants. In addition, male infants who have undergone a circumcision procedure oftentimes become very sleepy after surgery. These sleepy babies are at risk of losing an excessive amount of weight, becoming dehydrated, and developing exaggerated jaundice in just a few days after birth. In addition, mothers may develop pathologic engorgement if her baby does not wake up to breastfeed frequently and effectively during this time.

To avoid these complications, parents can be taught techniques to wake their sleepy baby whenever the infant shows signs of being in the light state of sleep cycle (see chapter 29 ∞). With a little help, this baby may be gently aroused to breastfeed. One method is to remove the baby's blanket and clothing so that the infant is wearing only a diaper and T-shirt. Babies feed better when they are not bundled, and they can actually achieve a better attachment without the bulk of extra clothing and blankets in the way. If the room is too cool for the newborn to feed in just a diaper and T-shirt, have the mother apply a blanket over the top of her baby *after* the baby has attached to the breast. Another technique is to undo and check the baby's diaper. Sitting the baby in a burping position and gently "walking" fingers along the back will usually arouse the baby. Parents should also be encouraged to talk or sing to their baby while trying these techniques to further arouse their baby from sleep.

If the newborn falls asleep after the first few suckles, encourage the mother to use tactile stimulation while the newborn is still attached to the breast. The mother can also be encouraged to use breast compression or breast massage while the infant is breastfeeding to keep milk trickling into the infant's mouth until the infant stimulates the mother to release her milk. If this is not sufficient to keep the baby actively feeding, suggest that the mother remove the baby from the breast momentarily and try to burp the infant. The infant may not actually burp but the burping technique may help wake the infant.

Case Study: Patient Undecided on Formula Feeding or Breastfeeding

An infant's feeding pattern may change again when the mother's breasts become fuller. Mothers' breasts begin to look and feel noticeably heavier between the second and fourth day postpartum. When milk production has noticeably increased, the "cluster feeding" pattern ceases until the infant has his first growth spurt at about 2 weeks of age. Now an infant generally feeds every 1 1/2 to 3 hours around the clock, about 8 to 12 feedings per day. Feeding intervals are counted from the time of the start of one feeding to the start of the next feeding. During this engorgement phase of lactation some infants may struggle initially with latch-on, especially if the mother allows greater than 3 hours to lapse between feedings. If the newborn is not breastfeeding often or effectively enough to soften the breasts, then the breasts may become quite firm and the mother's nipple may become less pliable and this can lead to a shallow latch attachment and sore nipples. If this occurs, the mother can try to express some milk to soften her areola before latching her infant. When her baby breastfeeds on this fuller than usual breast, it is not uncommon for the infant to only want to feed on just the one side. This feeding pattern usually does not last long either. Within days the infant will be back to breast feeding at both breasts again.

Breastfeeding and formula-feeding infants have the same fluid requirements and receive the same amount of calories per ounce, and both feed around the clock in the beginning, but because they have different diets, their rates of digestion are different. Digestion of formula produces harder to digest casein curds that take about 3 to 4 hours to digest compared with the softer, smaller curds produced from breast milk that are digested in only 90 minutes. For this reason formula-fed newborns generally sleep longer at a stretch and awaken to feed every 3 to 4 hours, typically feeding only 6 to 8 feedings per day. To compensate for sleeping longer between feedings, formula-fed infants feed a larger volume at each feeding. It will be awhile before the baby sleeps through the night.

Regardless of whether a mother is breastfeeding or formula-feeding her infant, many parents are distressed by their infant's erratic feeding pattern. Parents need to be informed about normal infant feeding and sleeping patterns and be aware that these patterns vary among babies and change over days, weeks, and months according to the infant's growth and development. In the beginning, the "average" newborn sleeps a total of 16 hours a day. Infants wake to feed and generally fall back to sleep within an hour. By a month of age, infants are able to sleep one long stretch of sleep, maybe 4 to 5 hours at nighttime, so long as they are not given the opportunity to sleep the long stretch of sleep during the day (Jana & Shu, 2005).

Satiety behaviors are the same for formula-fed babies as for breastfed babies. These behaviors include longer pauses toward the end of the feeding, noticeable total body relaxation (the baby lies limp with hands down at his or her side and unclenched), the infant may release his mother's nipple or the bottle nipple, and many fall asleep. If a baby is satiated and content following feedings, is meeting daily output expectations, and is gaining weight as expected, then feedings are going well. On the other hand, if a breastfeeding baby awakens shortly after feeding and is exhibiting feeding cues, this baby should be offered the breast again regardless as to when he or she was last fed. The newborn may be cluster feeding or may not have fed efficiently at the previous feeding. Also, pacifier use in response to this early waking is especially inappropriate. The pacifier needlessly postpones the feeding, which is indicated based on hunger cues and can have a negative consequence for the mother's milk supply and the infant's weight. The American Academy of Pediatrics recommends waiting to introduce a pacifier in the breastfeeding newborn until breastfeeding is well established, generally when the infant is 3 to 4 weeks old. A formula-feeding infant can be offered a pacifier any time after birth and is thought to help reduce the risk for sudden infant death (AAP, 2010).

CLINICAL TIP

Parents should be instructed never to put honey or corn syrup on their infant's pacifier to encourage an infant to accept it. Honey and possibly corn syrup may be contaminated with *Clostridium botulinum*, a bacterium that causes infantile botulism. Botulism is rare, but when it occurs it causes serious illness.

Both breastfed and formula-fed infants experience growth spurts at certain times and require increased feeding volume. The breastfeeding mother may meet these increased demands by nursing more frequently to increase her milk supply. It takes up to 72 hours for the milk supply to increase adequately to meet the new demand. A slight increase in volume also meets the formula-fed infant's needs. Once the formula feeding infant appears satiated, the infant should not be forced to continue to feed in order to finish the bottle.

Some mothers may find fixed feeding schedules attractive. These mothers should be informed that feeding schedules may work for some formula-fed babies, if they allow some flexibility and increase volume as indicated; however, fixed feeding schedules do not work for breastfeeding babies and can be quite harmful. For breastfeeding babies, fixed feeding schedules do not take into account differences among breastfeeding women (breast storage capacity, as one example) and differences among infants (slow feeders, as an example). A fixed feeding schedule does not incorporate extra breast stimulation, the "cluster feedings" that are needed in order for the breastfeeding mother's milk production to accommodate growth spurts in her continuously growing infant. There are documented cases of infants diagnosed with failure to thrive, poor weight gain, dehydration, breast milk supply failure, and involuntary early weaning associated with fixed feeding schedules for the breastfeeding baby. Nourishing their newborn is a major concern of new parents. Their feelings of success or failure may influence their self-concept as they assume the role of parents. Breastfeeding mothers in particular, as primary caregivers, are especially sensitive about their ability to provide for their infants. With proper instruction, support, and encouragement from professionals, feeding becomes a source of pleasure and satisfaction to both the parents and infant.

Cultural Considerations in Infant Feeding

As healthcare professionals, we can learn about an individual patient's cultural background by engaging in discussions with them and asking questions in a sensitive and respectful way. This provides opportunity to validate healthy practices and to exert a positive influence on other matters (Callister, 2008). An occasion

for this kind of dialogue might arise during interactions with a new mother who may have misconceptions about breastfeeding. For example, if a new mother says that she heard that getting upset or angry will spoil her milk, you can point out that this belief likely stems from the correct observation that the breastfeeding infant can sense maternal tension (which also may delay let-down) and may therefore act fussy as well, appearing to behave as if he or she were getting "spoiled milk." Then reassure the mother that there is no evidence that the milk composition itself is changed. This will allow you to focus on the real issues of bonding and relaxation technique. You may also note that simply understanding what is really going on may help the mother to be more relaxed.

Breastfeeding in public is another frequently expressed concern that can create a barrier to achieving *Healthy People 2010* breastfeeding goals. Although people agree that breastfeeding is the most natural and healthy way to feed a baby, mothers feel conflicted because in America breast exposure is often viewed in a sexual context and this may lead to disapproval of attempts to breastfeed in public. As national and state efforts are being made to promote breastfeeding duration to improve the health of mothers and babies, this barrier is slowly being broken down. Public places are incorporating "mother rooms" to provide a comfortable, private area for the nursing mother. There is no state that prohibits breastfeeding in a public place, and there are now 43 states and the District of Columbia and the Virgin Islands that have created laws that specify that a woman is permitted to breastfeed in any location in which she is authorized to be (National Conference of State Legislatures, 2009). Mothers may also be taught how to breastfeed discreetly in public. This is often taught at breastfeeding classes or mother-to-mother support group meetings. See Figure 32-4 ■ to observe a mother discreetly breastfeeding. Some mothers may prefer a baby blanket or shawl to drape over their chests, which will provide more coverage. Finally, mothers who prefer not to breastfeed even discreetly in public can be encouraged to at least pump their breasts and feed the expressed milk in a bottle so they have the option of getting out of the house.

In women of African descent, higher rates of initiation of breastfeeding were associated with increased age, education, and income (McCarter-Spaulding & Gore, 2009). Social support for breastfeeding primarily came from other women, especially maternal grandmothers, but the social support was very limited and early formula and cereal supplementation is common. In many ethnic groups, self efficacy has been shown to predict breastfeeding duration and pattern (exclusive breastfeeding or breastfeeding in combination with formula feeding (McCarter-Spaulding & Gore, 2009).

Another cultural implication related to breastfeeding concerns colostrum. Among some traditional cultures around the world, it is believed that colostrum is "unclean" or even harmful to a newborn. This belief is found among some groups of Hispanics, Navajo Indians, Filipinos, and Vietnamese (D'Avanzo & Geissler, 2008). Because of this ancient belief, mothers living in regions of Central America, sub-Saharan Africa, the Middle East, and parts of Asia even today discard their colostrum or wait until 2 to 4 days to begin breastfeeding when their "true milk" arrives. While waiting for their milk to come in, mothers feed their infant a culturally specific colostrum substitute. These prelacteal feeds include cereal or gruel, animal milk, sugar water, and a variety of herbal teas (Department for International Development, 2009; Geckil, Sahin & Ege, 2009). Not only are these newborns receiving an inferior quality food that is not appropriate for their development and possibly prepared with contaminated water, they are denied vital immunity-building substances, and they

Figure 32-4 ■ Breastfeeding discreetly.

PROFESSIONALISM IN PRACTICE

Breastfeeding Promotion Legislation

It is important to be a patient advocate and be involved in legislative initiatives on the national and local level. A recently proposed piece of legislation is The Breastfeeding Promotion Act of 2009, H.R. Bill 2819/Senate Bill 1244. If enacted into law, it will protect breastfeeding in the workplace by providing five provisions. These include:

Title I: Amending the Civil Rights Act of 1964 to protect lactating women from being fired or discriminated against in the workplace.

Title II: Giving tax incentives to businesses that establish a private space in the workplace for their employees to breastfeed or express their milk. Employers can also receive tax credits for supplying breastfeeding equipment and providing lactation consultation services for their employees.

Title III: Establishing set standards for breast pumps to ensure that they are safe and effective.

Title IV: Expanding the Internal Revenue Code definition of "medical care" to include breastfeeding equipment and lactation services as tax-deductible for families.

Title V: Requiring employers with 50 or more employees to provide lactating employees break time and a private area to express their milk.

DEVELOPING CULTURAL COMPETENCE

Breastfeeding in Other Cultures

Among traditional societies around the world, weaning from the breast occurs when a child is between 2 and 4 years of age.

In Sweden both parents are entitled to share post-birth parental leave of up to 13 months paid time off. Their national social insurance system pays them 80% of their lost wages. They are also allowed an additional 90 days off without pay (International Labour Organization, 2004).

Many women in Mexico assume that not eating well and not drinking enough fluids result in low milk supply (Sacco, Caulfield, Gittelsohn, et al., 2006).

Chinese women go through a 30-day period of home confinement following delivery, during which she is also not permitted to bathe or wash her hair. This is a century's old tradition to nurture the mother back to her prenatal state and intended to keep her body warm to ward off *fong* (flatulence) and other future health ailments. A *Pui Yuet* (companion) is hired to provide total care for the mother and infant. The Pui Yuet will cook traditional confinement foods daily (provide "heating foods" and avoid "cooling foods"). Most foods must be cooked in sesame oil and old ginger. The mother drinks hot herbal tea with her meals and is not permitted to drink any water because water is thought to cause water retention (Teh, undated).

Muslim women generally breastfeed their children until their children are 2 years of age. This is encouraged in the Koran. Although Muslim women do not breastfeed in public, they will breastfeed in front of family members and relatives as long as the breast is not exposed (Ott, Al-Khadhuri, & Al-Junaibi, 2003).

Haitian mothers may believe that "strong emotions" spoil breast milk; and that thick breast milk causes skin rashes and thin milk results in diarrhea (Callister, 2008; Lipson & Dibble, 2008).

In Malaysia, the ingestion of breast milk represents a great deal more than simple nutrition for newborn infants. It is believed that the mother's milk enters the baby's blood. This is thought to cultivate a long life. Breast milk is thought to bind the mother and baby together, creating a sense of respect and closeness. While milk develops the infant's spirit and body, it also develops faith and character. It is thought that the consumption of breast milk formulates a maternal-infant bond that lasts throughout life. This bond cannot be broken by any means.

miss out on the laxative effect that colostrum provides to rid the body of bilirubin, which reduces the risk of jaundice. Nurses should be aware that some immigrant mothers may have this misconception about their colostrum. In a situation like this, in which a cultural custom is harmful or denies the infant benefit, it is the nurse's responsibility to try to educate the family about the value of colostrum.

Language is a fundamental aspect of a person's culture and can be a source of miscommunication in a healthcare system geared toward serving people who speak English. The most obvious language barrier is when a person does not speak English at all. Whenever possible, it is best to have a female, non-family member translator present to interpret for a mother. For Muslim women, it is culturally unacceptable for them to speak about intimate matters in front of their families. Therefore, it would be inappropriate to ask the new mother's husband or her children to be her interpreter. Even among those who speak English, language barriers and miscommunications still exist due in part to words having different meanings to people of different cultures. It is important to make sure that you give enough explanation to ensure that the mother clearly understands the information provided. These are but a few of the numerous cultural influences related to feeding. (See Developing Cultural Competence: Breastfeeding in Other Cultures.) When nurses are faced with an infant care practice different from the ones to which they are accustomed, nurses need to evaluate the effect of the practice. Different practices are not necessarily inferior. The nurse should intervene only if the practice is actually harmful to the mother or baby.

HEALTH PROMOTION EDUCATION: BREASTFEEDING TECHNIQUE

Breastfeeding Position and Latching On

Breastfeeding is not instinctive, it is learned. It is a natural process, but it takes "know-how." Ideally, each breastfeeding mother should have a breastfeeding evaluation to determine any knowledge deficits, acknowledge any concerns, provide instructions, and assist with breastfeeding.

Application: Breastfeeding

POSITIONING There are multiple breastfeeding positions, but only the four classic breastfeeding positions are discussed here. In addition, there are minor variations of hand placement and body position even among the four classic positions. The four positions discussed here include (1) modified cradle position, (2) cradle position, (3) football (or clutch) hold position, and (4) side-lying position (Figures 32-5 ■ through 32-8 ■). After a mother has fed using one position, encourage her to try a different position when she offers her second breast. Alternating positions facilitates drainage of the breasts and changes the pressure points on the breast. This will provide some relief to the mother with sore nipples.

CLINICAL TIP

When supporting the infant's head in preparation to breastfeed, regardless of the feeding position, it is best not to allow any fingers to be placed on the back of the baby's head. If fingers are placed on the back of the baby's head, it may inadvertently be tilted forward. Whenever the baby's chin is tucked in (chin toward chest), the angle for attachment will not be lined up correctly. This causes the infant to attach with the upper jaw first (rather than the lower jaw first, as preferred), and this will result in a shallow latch attachment and subsequent nipple trauma. Instead, encourage the mother to support her infant's head with her hand at the base of her infant's neck or upper back. This allows for the infant's head to extend slightly back so the infant leads chin first during attachment. If the infant is lined up "nose to nipple" to start with, then the infant will attach to the breast with the lower jaw first. This technique will allow for a deeper latch attachment and a pleasant breastfeeding experience.

Modified cradle position

- Have mother sit comfortably in upright position using good body alignment. Use pillows for support (may use Boppy, body pillow, or standard bed pillows). Lap pillow should help bring baby up to breast level so mother does not lean over baby.
- Place baby on mother's lap and turn baby's entire body toward mother (baby is in side-lying position). Position baby's body so that the baby's nose lines up to the nipple. Maintain baby's body in a horizontal alignment.
- To feed at left breast, mother supports baby's head with her right hand at nape of baby's neck (allow head to slightly lag back), mother's right thumb by baby's left ear, and right forefinger near baby's right ear.
- With mother's free left hand, she can offer her left breast.

Figure 32-5 ■ Modified cradle position.

Cradle position

- Have mother sit comfortably in upright position using good body alignment. Use pillows for support (may use Boppy, body pillow, or standard bed pillows). Lap pillow should help bring baby up to breast level so mother does not lean over baby.
- Place baby on mother's lap and turn baby's entire body toward mother (baby is in side-lying position). Position baby's body so that the baby's nose lines up to the nipple. Maintain baby's body in a horizontal alignment.
- If feeding from the left breast, have mother cradle baby's head near the crook of her left arm while supporting her baby's body with her left forearm.
- With mother's free right hand, she can offer her left breast.

Figure 32-6 ■ Cradle position.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

Football hold position

- Have mother sit comfortably and use pillows to raise baby's body to breast level. If using a Boppy and the Boppy is in "normal" position on mother's lap, turn it counterclockwise slightly (if feeding at left breast) to provide extended support for baby's body resting along mother's left side and near the back of mother's chair.
- If feeding at left breast, place baby on the left side of mother's body, heading baby into position feet first. Baby's bottom should rest on the pillow near mother's left elbow.
- Turn baby slightly on her side so that she faces the breast.
- Mother's left arm clutches baby's body close to mother's body. Baby's body should feel securely tucked in under mother's left arm.
- Have mother support baby's head with her left hand. With mother's free right hand, she can offer her breast. (Good position for mother with c-section).

Figure 32-7 ■ Football hold position.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

Side-lying position

- Have mother rest comfortably lying on her side (left side for this demonstration). Use pillows to support mother's head and back, and provide support for mother's hips by placing a pillow between her bent knees.
- Place baby in side-lying position next to mother's body. Baby's body should face mother's body. Baby's nose should line up to mother's nipple. Place a roll behind baby's back, if desired.
- With mother's free right hand, she can offer her left breast. After baby is securely attached, mom can rest her right hand anywhere that is comfortable for her.

Figure 32-8 ■ Side-lying position.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

LATCHING ON It is important to have the mother and baby positioned properly in order to achieve an optimal attachment. If, for example, the infant is lying flat on his or her back (supine position) to feed in the modified cradle position, cradle position, or side-lying position, the infant can obtain only a shallow latch (not attached far back onto the areola). The infant's shoulder becomes an obstacle putting distance between the infant's mouth and the mother's breast. Anything that contributes to a shallow latch is going to cause sore nipples and other complications. Nipple trauma, although relatively common, is not normal. See chapter 37 ∞ for a discussion of breastfeeding with inverted or flat nipples.

The infant needs to attach his or her lips onto the breast, or more accurately, far back onto the areola, not on the actual nipple. If the infant attaches just to the nipple, the mother will have sore nipples, and pain may inhibit the let-down reflex. To obtain a deep latch, the mother needs to be taught how to elicit the infant's rooting reflex, stimulating the infant to open his or her mouth as widely as possible (like a big yawn). Once the infant does this, the mother should quickly but gently draw her baby in toward her. During the first few days of life, the newborn typically only opens his or her mouth widely for a second or so, and then begins to close the mouth again. If the mother misses her chance to get her baby latched on, she simply needs to start over again.

Figures 32-9 ■ through 32-14 ■ demonstrate various positions and techniques used in latching on.

C-hold hand position

To be ready to draw baby's mouth onto mother's breast, as soon as the baby opens her or his mouth widely enough, the mother needs to have her hand supporting her breast in ready position. She can use various hand holds, but she needs to keep her fingers well behind the areola. One such hand position is called the "C-hold." In this hold, the thumb is placed on top of the breast near 12 o'clock position and the other four fingers are placed on the underside of the breast near the 6 o'clock position (depends on mother's hand size and length of fingers). The key point is in keeping the fingers at least 1½ inches back from the base of the nipple as the fingers support the breast. Mothers are not often aware of where they place their fingers, especially on the underside of the breast. If the fingers are too far forward (too close to the nipple), then the infant cannot grasp a large amount of areola in her or his mouth and this results in a "shallow" latch. A shallow latch is associated with nipple pain and ineffective drainage of the breast.

An alternate hand hold not shown is a "U-hold" hand position. The thumb and forefinger are near the 3 o'clock and 9 o'clock positions on the breast again with fingers at least 1½ inches back from the base of the nipple; the body of the hand rests on the lower portion of the breast. Using this hand hold, the mother's arm position is down at her side rather than sticking outward as it is when supporting the breast using the C-hold position.

Figure 32-9 ■ C-hold hand position.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

Scissor hold hand position

The scissor hold is often discouraged because mothers (especially mothers with small hands) have a difficult time keeping their fingers off the areola or at least 1½ inches back from the base of the areola. Here, the mother is able to support her breast well without letting her fingers encroach onto the areola.

The mother should be instructed to gently support the breast and not press too deeply, which can obstruct the flow of milk through the ducts.

Figure 32-10 ■ Scissor hold hand position.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

Nose to nipple

Before eliciting the rooting reflex, it is important to have the baby in good alignment. When the infant opens her or his mouth to latch on, the goal is to achieve a deep, asymmetric latch attachment. The goal is *not* to center the nipple in the baby's mouth. The rationale for this is to optimize oral-motor function. The jaw is a hinge joint. The upper jaw is immobile; the lower jaw compresses the breast. The breast is efficiently drained if more areola is drawn into the baby's mouth from the inferior aspect of the breast and a smaller amount drawn in from the superior aspect of the areola. Aligning the infant to the mother with baby's nose facing mother's nipple permits the jaw to be in a lower position. The next step is to let the infant drop his or her head back (head in "sniff position"), so that the infant leads into the breast with the chin.

Figure 32-11 ■ Nose to nipple.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

Initial attempt to elicit the rooting reflex

To trigger the rooting reflex, teach the mother to use her nipple to stroke downward in a vertical motion across the middle of baby's lower lip. Initially, the infant may respond by licking or smacking. This is a normal response to the stimulus. Encourage the mother to keep stimulating the infant's lower lip until the infant finally opens her or his mouth widely. If the infant is not responding at all, then the infant is probably too sleepy and may need help waking up. After trying wake up techniques, the infant may be ready to try breastfeeding again.

Figure 32-12 ■ Initial attempt to elicit the rooting reflex.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

Continued attempt to elicit rooting reflex

Teach the mother to be patient and wait for the infant's mouth to gape open as widely as possible. Here the infant needs to open the mouth even wider before the mother draws her baby toward the breast. The mother should be encouraged to continue stroking the infant's lip until the infant opens the mouth wider.

Figure 32-13 ■ Continued attempt to elicit the rooting reflex.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

Baby is latched-on

Once baby has latched onto the breast, the mother should check that baby is latched on properly. The infant's chin should be embedded into the mother's breast. The infant's nose should be very close but not actually touching the breast. The nose should be centered. If the mother feels a little pinch on her areola, she can slowly release the hand supporting her breast so she can have a free hand to attempt to move her baby's jaw gently downward. To do this maneuver, the mother needs to place her thumb or forefinger of her free hand (the hand that just released the breast) on baby's lower jaw (there is a horizontal groove to use as leverage—the groove on baby's chin is parallel with the baby's lips). With gentle downward pressure the mother should feel relief of any persistent tenderness. This procedure opens the jaw wider and it also helps to roll out the infant's lower lip that may have been inadvertently drawn into the baby's mouth. As the baby begins to suckle, there should be no dimpling of the infant's cheeks and no smacking or clicking noises.

Figure 32-14 ■ Baby is latched on.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

CLINICAL TIP

As you assist new mothers with breastfeeding, it is important to create a relaxed environment and approach to breastfeeding. Encourage the mother to get into a comfortable position, well supported with pillows. Remind her to bring the baby to her breast rather than leaning forward to the baby.

Breastfeeding Assessment

During the birthing unit stay, the nurse must carefully monitor the progress of the breastfeeding pair. A systematic assessment of several breastfeeding episodes provides the opportunity to teach the new mother about lactation and the breastfeeding process, provide anticipatory guidance, and evaluate the need for follow-up care after discharge. Criteria for evaluating a breastfeeding session include maternal response to infant cues, latch-on technique, positioning, signs of active feeding, let-down response, nipple condition, maternal comfort during feeding, infant's weight from previous measurement (usually from the night before), infant's report of intake and output. The literature provides various tools to guide the assessment and documentation of the breastfeeding efforts. The LATCH Scoring Table is one example (Figure 32-15 ■). Table 32-4 identifies signs of successful breastfeeding.

Breastfeeding Efficiency

Parents are often concerned because they have no visual assurance of the amount of breast milk consumed. The mother should be taught other signs of effective, active breastfeeding. The infant should have a rhythmic suckling pattern (the slight pause between jaw compressions on the breast permits the mouth to fill with milk before swallowing) with only

	0	1	2
L Latch	Too sleepy or reluctant No latch achieved	Repeated attempts Hold nipple in mouth Stimulate to suck	Grasps breast Tongue down Lips flanged Rhythmic sucking
A Audible swallowing	None	A few with stimulation	Spontaneous and intermittent > 24 hours old Spontaneous and frequent < 24 hours old
T Type of nipple	Inverted	Flat	Everted (after stimulation)
C Comfort (breast/ nipple)	Engorged Cracked, bleeding, large blisters or bruises Severe discomfort	Filling Reddened/small blisters or bruises Mild/moderate discomfort	Soft Nontender
H Hold (positioning)	Full assist (staff holds infant at breast)	Minimal assist (e.g., elevate head of bed, place pillows for support) Teach one side; mother does other Staff holds and then mother takes over	No assist from staff Mother able to position and hold infant

TABLE 32-4 Successful Breastfeeding Evaluation

A baby is probably getting enough milk if:

- The infant is nursing at least eight times in 24 hours.
- In a quiet room, the mother can hear her infant swallow while nursing, once her milk supply has become abundant.
- The mother's breasts appear to soften after breastfeeding.
- The number of wet diapers increases daily by a minimum of one additional diaper until the fifth day after birth; after day 5, the infant should have six to eight wet diapers daily.
- The infant's stools are beginning to lighten in color by the third day after birth, or have changed to yellow no later than day 5.

Note: Offering a supplemental bottle is not a reliable indicator because most newborns will take a few ounces even if they are getting enough breast milk.

brief pauses lasting seconds between spurts of active feeding. To assess if the jaw compressions are strong enough, the mother can observe or feel if there is movement at the temporomandibular joint located in front of the infant's ears. The mother should visually observe for swallowing and later, as her milk is abundant, she will hear her infant's swallows. The feeding session typically lasts for 10 to 20 minutes on the first breast; the infant may feed only a few minutes on the second breast or not at all. Discourage the mother from watching the clock to determine when the infant needs to switch breast sides but rather encourage her to watch the newborn's feeding pattern to note when active feeding ceases. When satiated, the infant will either pull away from the breast or fall asleep with the mother's nipple still in his or her mouth, though oral muscle tone will be loose. The infant will be extremely relaxed at the end of the feeding and will sleep at least an hour until the next feeding is due (unless cluster feeding). As the infant matures, the feeding intervals will lengthen. Another indicator of breastfeeding efficiency is softening of mother's breasts, although this is not a reliable indicator in the first few days postpartum while breast milk volume is low. Within a week, however, this is a good indicator of milk transfer.

The infant who feeds well will have a characteristic output. Output is a reflection of intake. See Figure 32-16 ■ for breastfeeding intake and output expectations. The infant should also have the characteristic weight loss followed by weight gain pattern discussed earlier in this chapter.

In situations where there is a question regarding milk transfer effectiveness, it can be most reliably measured by obtaining pre- and post-breastfeeding weight checks using an accurate infant scale. The difference in pre-feed and post-feed weights is the amount of milk (each gram increase reflects 1 ml) transferred to the infant and may be useful with assessing breastfeeding efficiency and maternal milk volume.

CLINICAL TIP

With a sleepy baby, unwrap the baby, and place the baby skin-to-skin with his or her mother so the mother can recognize subtle early feeding cues. Encourage the mother to offer her breasts whenever she notices her baby's eyes fluttering under his or her eyelids, or she observes her baby beginning to wriggle around and stretch, or she notices lip smacking and rooting behavior, or observes hand-to-mouth activity.

- Infants should breastfeed 8 to 12 times per day and should appear relaxed after feeding.
- Colostrum is all that a newborn needs in the first few days of life in most cases.
- It is normal for an infant to lose up to 7% of birth weight in the first few days; however, up to 10% weight loss is tolerated if the mother's breasts are full, the infant is observed to breastfeed well, and the infant is not dehydrated.
- Infants should gain 10 grams/kg/day after the mother's milk supply is abundant (about day 4 of life).
- Infants should be back to their birth weight by 2 weeks of age.
- Infant's stool should change in color, consistency, and frequency during the first few days of life. The photo images noted below depict stool color progression. Some babies progress faster to yellow milk stools, as early as day 3.

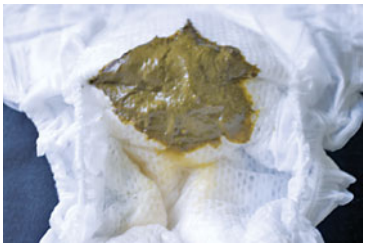
Day 1

Minimum Output

On day 1, the infant should produce at least one wet diaper and one meconium stool by 24 hours of age.

Note the pinkish-red "brick dust" appearance on the diaper. The uric acid crystals produced by the kidneys is associated with concentrated urine. A red flag is raised if their presence is continued beyond day 2 or 3 of life.

Day 2



On day 2, the infant should produce at least two wet diapers and two early transitional stools in a 24-hour period by 48 hours of age.

Day 3

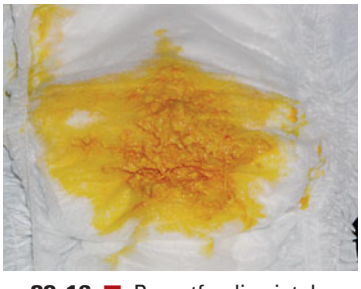
On day 3, the infant should produce at least three wet diapers and three transitional stools in a 24-hour period by 72 hours of age.

When a mother's milk supply is abundant on day 2, some babies will have transitioned to yellow milk stools as early as day 3.

Day 4

On day 4, the infant should produce at least four wet diapers and three to four yellow-green transitional stools or yellow milk stools in a 24-hour period by 96 hours of age.

Day 5



On day 5, the infant should produce at least five wet diapers and three to four yellow milk stools per day; the stools are typically explosive and have a curdy or seedy appearance.

Hereafter, breastfeeding infants will consistently produce at least six well-saturated wet diapers per day. These infants will typically continue to produce at least three to four yellow milk stools daily, but may have up to 10 stools per day until they are about a month old. Infants 4 weeks or older may suddenly decrease their stool frequency, even skipping days.

Figure 32-16 ■ Breastfeeding intake and output expectations.

Bottle-Feeding Human Milk (Expression, Pumps, Storage)

There are a number of different reasons for bottle-feeding expressed breast milk. The nurse should evaluate the indications in order to recommend the best technique for the mother and her particular need.

Hand Expression

Some mothers prefer to hand express their milk rather than use a breast pump, and many find that in the immediate postpartum period hand expression of milk may be a more effective method of removing drops of colostrum than using an electric breast pump. Nurses should teach all mothers the skill of hand expressing breast milk as it is possible the mother will find herself in a situation without a breast pump and needing to relieve herself from engorgement.

To help the mother hand express breast milk, have the mother follow steps 1 through 4 of the pumping instructions provided in Table 32-5. Then the mother can use the Marmet technique of hand expression described next. It is important that the mother take care to place her hands exactly as directed. The Marmet technique steps are as follows:

1. The mother will position her thumb at the 12 o'clock position on the top edge of the areola (about 1 to 1 1/2 inches back from the tip of her nipple) and her forefinger and middle finger pads at the 6 o'clock position on the bottom edge of the areola (about 1 to 1 1/2 inches from the tip of her nipple). If positioned correctly, an imaginary line between the thumb and fingers will cross through the nipple. See Figure 32-17 ■.
2. Next the mother will stretch her areola back toward her chest wall without lifting her fingers off her breast.
3. Now she should roll her thumb and fingers simultaneously forward. This action compresses the ducts beneath the areola and stimulates the breast to empty the breast both manually and by triggering the let-down reflex.
4. The mother should repeat the sequence multiple times to completely drain her breasts. She should try to maintain a steady rhythm, cycling 45 to 60 times/minute. It is also more effective if the mother repositions her fingers to other positions on the same breast (3 and 9 o'clock, 1 and 7 o'clock, etc.) when the milk flow slows.

The mother should take care not to traumatize her breasts or nipples. Hand expression should not be painful. Most mothers

TABLE 32-5 Pumping Instructions and Storage Guidelines

1. Once a day rinse the breasts with water while bathing or showering. Avoid applying soap directly on the nipples.
2. Wash hands well with soap and water before preparing to pump.
3. Take a few minutes to massage the breasts and relax. Do some slow, deep breathing and think about or look at a picture of your baby. Being relaxed is very important for releasing milk from the breasts. (Stress can inhibit or delay let-down because stress hormones, such as cortisol and adrenalin, can block receptors for let-down.)
4. Sit up straight or lean slightly forward. A pillow placed behind your back may facilitate the slightly tilted forward posture, as gravity aids in the flow of milk from the breasts.
5. For single-sided pumping, pump each breast for 10 to 20 minutes. Some mothers find that they empty their breasts more efficiently if they switch back and forth from one breast to the other as the milk flow diminishes, until they have stimulated each breast for 15 to 20 minutes. The entire pumping session will last 30 to 40 minutes.
6. Pump the expressed milk preferably into glass or plastic bottles. Mothers of healthy infants may also use bottle bags or liners intended for human milk collection and storage; however, note that up to 60% of secretory IgA (SIgA) is lost when milk is stored in these kinds of containers for 48 hours because of the attraction of the antibodies to the polyethylene material used in making the bottle bags/liners (Lawrence & Lawrence, 2005). Because of the loss of antibodies that can occur with bottle bags or liners, mothers of preemies and fragile infants should especially avoid using these kinds of storage containers. Do not fill milk storage containers more than 3/4 full, because milk expands during freezing.
7. Feed *freshly* expressed breast milk whenever there is a need to give a supplement, when possible. Reserve the stored milk for times when fresh milk is not available (e.g., when separated from baby). Fresh breast milk retains more nutrients than refrigerated or frozen milk, although these are still preferred over formula. Expressed human milk may be stored in the refrigerator for up to 8 days, but if intended to be frozen, this should be done within 48 hours of initial refrigeration. Avoid placing human milk in the freezer door or on the bottom of a self-defrosting freezer because the temperature fluctuates more in those areas.
8. Store expressed human milk in volumes the infant is likely to consume at a single feeding or in a volume the infant will consume in a day.
9. Human milk should never be thawed in a microwave oven or placed in a pan and warmed up on the stove. These methods may cause the milk to warm up too hot (and unevenly) and can burn an infant as well as cause heat-sensitive nutrients to be destroyed. Frozen milk can be thawed safely using one of two methods:
   - For a quick thaw, remove the container of frozen milk from the freezer, place the container in a bowl in the sink, and run warm water over it for no longer than 15 minutes. Take care not to immerse the container in water because water may leach into the container of milk possibly contaminating it and diluting it.
   - For a slow thaw overnight, take the frozen container of milk from the freezer the day before or several hours before it is needed and let it defrost in the refrigerator (not on the kitchen counter) over several hours. The time it takes to defrost depends on the volume in the container. Note that breast milk that has been sitting for awhile will normally separate. See Figure 32-18 ■ to view breast milk that has separated. To remix it, simply swirl the bottle (avoid vigorous shaking) until the milk is evenly mixed. Make certain that the fat that clings to the wall of the container has mixed into the milk. If the volume in the bottle is more than can be used in one feeding, pour only the amount needed into a clean bottle, and put the rest of the milk immediately back in the refrigerator. Place the feeding bottle in a bowl in the sink and run warm water over it for no longer than 15 minutes. The bottle should remain fairly upright and the water level in the bowl should remain below the lid of the bottle or milk container to prevent water from inadvertently entering the bottle.
10. Previously frozen thawed breast milk is good in the refrigerator for 24 hours only. It must be used in that time frame or discarded. Thawed milk should never be refrozen.
11. Check the temperature of the milk before feeding it. Babies will drink milk when the milk temperature is between room temperature and body temperature (roughly 65 to 100 degrees).
12. Any milk left over from a feeding should be discarded within an hour of starting the feeding. The reason for this is because saliva "back washes" into the bottle while nipple feeding, and the saliva contains bacteria that can multiply and potentially make a baby sick.

Figure 32-17 ■ Hand Expression.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

will need assistance in learning this technique initially. Reassure the mother that it is a skill that is learned, and with practice, she can become an expert at hand expression.

Breast Pumps

Although hand expression can be efficient, many mothers will choose to use a mechanical breast pump to express their milk. Not all breast pumps are of the same quality, even within the same category (see Table 32-6 and Figure 32-19 ■ through Figure 32-21 ■). A desirable breast pump should be able to cycle from low to high suction at a frequency similar to that of a breastfeeding infant (about 45 to 60 cycles per minute). However, differences in the quality of the pump motor or the presence or absence of controls over suction pressure mean that some pumps will generate inadequate pressure or cycle too slowly to be effective, whereas others may exert too high a suction that can cause injury. Breast flange fit and comfort are other variables to consider. Some good quality pumps have multiple flange sizes

Figure 32-18 ■ Expressed breast milk that has separated.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC/Pearson Education.

available to accommodate the various nipple sizes of mothers. Excessive rubbing of the mother's nipple in the flange tunnel can cause discomfort and result in a decreased volume expressed. The nurse should refer the mother to a lactation consultant for a flange fitting if the mother has particularly large nipples.

Storing Human Breast Milk and Formula

There are different guidelines for storage of expressed breast milk (EBM) depending on whether the infant is a healthy

full-term infant or a premature or sick infant in the hospital. The guidelines in Table 32-7 are intended as a resource for the mother of a healthy, full-term infant.

Supplementary Bottle-Feeding

Supplementary bottle-feedings with formula for the breastfeeding infant after birth are not routinely recommended. Supplementation should only be given when medically indicated (ABM, 2009). Routine supplements are not only unnecessary in the early days after birth, but bottle feeding in itself may cause the infant to develop an incorrect sucking pattern, or may cause the infant to refuse the breast altogether (Riordan & Wambach, 2010). Early supplementation with formula may contribute to a delay in early maternal milk production, may result in maternal engorgement after the mother's milk production has increased, and may possibly sensitize an at-risk infant for milk-protein allergy. These types of problems have been implicated in early breastfeeding terminations (Mercer, Teasley, Hopkinson, et al., 2010).

An infant's refusal to breastfeed after receiving bottles in the early post-delivery period may be related to a phenomenon referred to as *nipple confusion* or more accurately termed, *nipple preference*. This potential problem occurs because the techniques for breastfeeding and bottle-feeding are different. In breastfeeding, the infant has to open his or her mouth very wide in order to latch on to the breast. To transfer milk the baby has to extend the tongue forward, cupping the nipple and drawing the mother's nipple deep into the infant's mouth until the teat reaches the "comfort zone" near the junction of the infant's hard and soft palate. After the infant creates suction from the

TABLE 32-8 Factors Requiring Consideration of Supplementation

Risk factors for inadequate intake:

- Maternal/infant separation
- Maternal barriers to breastfeeding (e.g., medications, fatigue, pain, cultural)
- Congenital malformation or illness interfering with ability to breastfeed
- Delayed lactogenesis after day 3 or 4
- Primary lactation failure (usually due to breast pathology or prior breast surgery)
- Low birth weight or infant with illness/disorder requiring nutrient requirements that may exceed that available through breastfeeding

Signs of potential inadequate intake:

- Weight loss > 7% from birth weight
- Delayed bowel movements or continued meconium stools beyond day 2
- Hypoglycemia not responding to frequent breastfeeding attempts
- Hyperbilirubinemia due to breastfeeding jaundice

tongue and cheeks and seals the latch with his or her lips, then the infant rhythmically compresses the breast with his or her jaw while the tongue moves in an undulating motion to move fluid toward the infant's pharynx before swallowing, in coordination with breathing. Also, on average, it takes a couple of minutes before the breastfeeding mother's milk flow increases during let-down. With bottle-feeding, the infant keeps the tongue retracted and uses the tip of the tongue to block the flow of milk, which otherwise drips continuously by gravity even when suction is not applied. The bottle-feeding baby merely needs to create suction with his or her mouth on the bottle nipple and the fluid easily flows.

For the mother who wants her breastfeeding baby to be able to take a bottle from time to time, without risking bottle preference by her baby, it is recommended that the mother wait until her milk supply is well established, and the infant has mastered the skills of breastfeeding. Therefore, the earliest it is recommended to introduce a bottle to a breastfeeding infant is when the infant is 3 to 4 weeks old (AWHONN, 2007).

At times there are valid medical indications for supplementing a breastfeeding infant in the early postpartum period. See Table 32-8 for a list of factors requiring consideration for supplementation. When supplementation is indicated, the first choice is to use the mother's own milk (fresh, previously expressed, or frozen/thawed). If maternal milk is not available, pasteurized donor milk is the next choice, and then formula (HMBANA, 2006). Supplementation can be administered using various methods based on the particular situation, parental preference, and hospital policy. Methods of delivering the feeding supplement include: use of a supplemental nursing device at the breast, cup feeding, spoon or dropper feeding, finger-feeding, or bottle feeding (ABM, 2009).

Formula Feeding

With more attention placed on promoting and assisting breastfeeding mothers, the teaching needs of the mother who is formula-feeding may inadvertently get overlooked. Nurses may assume that families can simply follow the formula preparation instructions on the side of the formula containers. However, research shows that these parents also need teaching, counseling, and support in regard to formula preparation and bottle-feeding technique. In a systematic review of five studies from developed countries looking at how parents prepare formula, all the studies revealed "errors in reconstitution with a tendency to over-concentrate feeds, although under-concentrating also occurred" (Morin, 2005). Parents need to learn about the normal feeding pattern for a formula-feeding infant and recognize symptoms of formula intolerance. They need to know intake and output expectations, the recommended type of formula for their infant, how to prepare and store formula, what equipment they will need, the feeding technique, and safety precautions.

HEALTH PROMOTION EDUCATION: FORMULA-FEEDING GUIDELINES AND TECHNIQUE

Commercial formulas are available in three forms: powder, concentrate, and ready-to-feed. There are situations in which one formula may be better to use than another, but, in general, convenience and cost usually influence the parents' decision.

- *Powdered formula* is the least expensive type of formula. This formula can be made up one bottle at a time, or multiple bottles can be prepared, but they must be used within 24 to 48 hours depending on the manufacturers' instructions. Standard powdered formula is made by adding one level *unpacked* scoop of powdered formula to 60 ml of water (the powder is added to the water). Powdered formulas are not sterile. Preparation of any infant formula, but especially powdered formulas, requires careful handling to avoid contamination with microorganisms. Also it is a little more difficult to mix well to obtain a uniform composition throughout compared to concentrate and ready-to-feed formulas. Vigorous shaking to mix it creates foam, and babies can potentially ingest more gas. It is best to let the bottle sit for a few minutes after being shaken to allow the bubbles to dissipate.
- *Formula concentrate* is more expensive than powder but is not as expensive as ready-to-feed formula. Formula concentrate is commercially sterile. This formula requires being diluted with an equal part of water.
- *Ready-to-feed* formula is the easiest to use because it does not require any mixing; however, this convenience comes at a cost—it is the most expensive formula. It is indicated for use when adequate water is not available, when the infant has a compromised immune system and requires commercially sterile (pasteurized) formula, when an inexperienced babysitter will be feeding the infant, and at other times simply for convenience.

Whatever the type of formula chosen, the nurse should underscore the importance of proper preparation and prompt refrigeration. Parents will need to be briefed on safety precautions during formula preparation. A primary concern is proper mixing to reconstitute formula. Parents need clear instructions to avoid unintentional harm to their infant. Parents

Application: Formula Feeding

should be instructed to follow the directions on the formula package label precisely as written. They should know that adding too much water during preparation dilutes the nutrients and caloric density. This contributes to undernourishment, insufficient weight gain, and possibly water intoxication, which can cause hyponatremia and seizures if the dilution is excessive. Not adding enough water concentrates nutrients and calories and can tax an infant's immature kidneys and digestive system as well as cause dehydration (Morin, 2005). See Table 32-7 for storage guidelines for human milk and formula.

Recommended sanitary precautions and additional safety precautions include:

- Check the expiration date on the formula container.
- Ensure good hand washing before preparing formula; never dip into the can without clean hands.
- Clean bottles, nipples, rings, disks, and bottle caps.
  - Wash in a dishwasher when available (small items and heat-sensitive items on top rack secured in a basket), or
  - Boil briefly (1 to 2 minutes) in a pot of water, or
  - Clean using a microwave sterilization kit, or
  - Clean using very warm soapy water and a nipple and bottle brush
  - Inspect and replace bottle nipples as soon as they show wear—worn nipples can break apart and can become a choking hazard.
- Wash the top of the formula container before piercing the lid. Shake the liquid formulas well before pouring out desired amount.
- Shake prepared formula that has been sitting in the refrigerator before feeding.
- Allow tap water to run for 1 minute before obtaining water to use for mixing—this helps clear any lead standing in the pipes. Also, always use cold tap water because warm tap water tends to contain higher levels of lead as well.
- Use only the scoop supplied in the can of formula when formula preparation instructions call for a "scoop" of powdered formula. A scoop should not be "packed" and should be leveled off (e.g., with the back of a knife).
- Do not add anything else to the bottle, except under direction of baby's healthcare provider.
- Warm up formula in a bottle by placing the bottle in a bowl of warm tap water for no longer than 15 minutes. Do not fill the bowl with water higher than the rim of the bottle.
- Newborns can be fed formula at room temperature but most young infants will prefer it warm. Once a bottle of formula is warmed up, it must be used within an hour or discarded.
- Left over formula remaining in a bottle after feeding should be discarded within an hour of starting the feeding. Allow freshly prepared (unused) formula to sit out at room temperature for no longer than 2 hours; use an insulated pack to transport formula.
- In warm weather, transport reconstituted or formula concentrate from an open can in an insulated pack with frozen gel packs.
- Travel with water and formula separated—carry the premeasured water bottles and carry bottles with premeasured amounts of powdered formula, or carry premeasured commercially prepared formula packets, or have the can of formula available.
- Hold the infant during feedings (even later on when an older infant can hold the bottle for himself or herself) to promote bonding and prevent supine feedings.
- Do not allow the infant to bottle-feed in a supine position because this increases the risk of otitis media and dental caries in the older infant.
- Never prop a bottle—this is a choking hazard.
- Allow infants to take what they want *and* to stop when they want. Overfeeding can lead to obesity.

TABLE 32-9 Water Sources

TYPE	DESCRIPTION
Distilled Water	Minerals and most other impurities have been removed. It will not contain any fluoride. An acceptable water source for reconstituting formula.
Filtered Tap Water	Some minerals and impurities removed during filtration, including fluoride. This is an acceptable water source for reconstituting formula.
Natural Mineral Water	Comes from protected groundwater and by law cannot be treated. Naturally contains high levels of minerals and sodium and so is not suitable for infants or for reconstituting formula.
Spring Water	Comes from a single nonpolluted groundwater, but unlike natural mineral water, it can be further treated. Because there is no regulation requiring the mineral content to be printed on the bottle label, it is best to avoid this water source for reconstituting formula.
Tap Water	Water from the municipal water supply and regulated by drinking water regulations. It is treated and considered safe for use in reconstituting formula.
Well Water	Needs to be tested before use. Higher risk of nitrate poisoning. Untested water is not recommended for use in reconstituting formula.

Parents also need guidance about what kind of water to use to reconstitute formula (see Table 32-9 to review types of water sources) and should discuss with their infant's healthcare provider whether to boil the water before use. If boiling water is used, parents need to be instructed to heat the water until it reaches a rolling boil, continue to let the water boil for 1 to 2 minutes, and, most importantly, allow the water to cool before using it to reconstitute the formula. Parents should also be instructed not to let the water boil down to a low level in the pan because this can cause minerals in the water to become concentrated.

Use of distilled bottled water and filtered tap water raises concerns with regard to fluoride. The AAP recommends that no fluoride supplements should be given to an infant before 6 months of age, but does recommend supplementary fluoride for infants and children aged 6 months to 3 years of age if the water source contains less than 0.3 ppm (AAP & ACOG, 2007). Parents should be encouraged to read the labels on bottled water to see if fluoride has been added and to determine if the water source is suitable for their infant depending on his or her age.

Bottles and Nipples

Parents often have questions about the kind of bottles and nipples to purchase. Plastic, glass, or disposable bottle bags may all be used based on preference. Many newly designed bottles are marketed to lessen air intake while an infant feeds. There is not a particular bottle design that is best for all babies. A key point to emphasize to the families is feeding technique. Parents should try to avoid situations in which an infant is crying for a prolonged time. Crying results in increased ingestion of air even before the infant has started feeding. Infants who are very hungry also gulp more air. For these situations, instruct the parents to burp their infant frequently to prevent the infant from having a large emesis (Figure 32-22 ■ and Figure 32-23 ■). The parent may even want to attempt to pat the baby's back briefly before starting the feeding to calm a crying infant and possibly burp as well. Another tip to avoid excessive ingestion of air is to have the parent hold the infant cradled in his or her arms while bottle-feeding, and tilting the bottle at a 45-degree angle in order for fluid to cover the nipple. This prevents the infant from sucking in air and swallowing it. The vented bottle design eliminates the negative effects of a vacuum and channels air through an internal vent system above the milk avoiding air bubbles in the milk. See Figure 32-24 ■ to view an infant bottle feeding.

Parents will want to consider a slow-flow nipple for all newborns and for older breastfeeding babies learning to bottle-feed—over time the infant will graduate to medium-flow and high-flow nipples. Generally, nipple shape is of greater importance for breastfeeding babies receiving expressed breast milk or supplemental formula in a bottle. Breastfed babies transition best going from breast to bottle and back to breast again when using a bottle nipple that is not too firm, one that has a relatively wide base (to help maintain a wide-open latch), and one that has a medium nipple length. Nipples are generally made from either rubber or silicone. Families with a history of sensitivity to latex are advised to use the clear silicone nipples. Silicone nipples also have less of an odor, which may be an issue for some infants who are breastfed.

To know if an infant is bottle-feeding well, the nurse needs to observe a bottle-feeding session. Parents should be informed that if the infant is sucking effectively, the parents should observe bubbles rising in the fluid of standard bottles. (If a family is using vented bottles or bottles with liners that retract as fluid is removed, bubbles will not be detected.) No bubbles will be observed if the parent unintentionally places the bottle nipple under the infant's tongue, preventing their infant from sucking effectively. Some infants, especially premature infants, raise their tongue to the roof of their mouth and so it is sometimes a challenge to place the nipple on top of the tongue. Infants who persistently leak milk from the side of the mouth may be getting fluid too quickly. The nurse could suggest using a slower flowing nipple. If symptoms persist, the infant should have an oral evaluation. The infant could have a short lingual frenulum that is restricting tongue mobility (tongue-tied) and may not be able to properly cup his or her tongue under the nipple and channel fluid to the back of the throat, or the infant may have an oral-motor dysfunction and need speech therapy or occupational therapy evaluation.

Recently, there has been a growing concern regarding specific chemicals used in the manufacture of plastic baby bottles, the material used in lining formula cans, and soft plastics. Researchers at the University of Missouri reported that bisphenol-A (BPA) could leach from polycarbonate plastic used in the manufacturing of some baby bottles and may transfer BPA into the baby's milk (Vom Saal et al., 2007). Animal studies show that BPA can cause developmental, neural, and reproductive problems (National Toxicology Program Center for the Evaluation of Risks to Human Reproduction [NTP-CERHR], 2008). There is also concern about bottles made from polyvinyl chloride (PVC), which sometimes contains lead, and there is concern about soft PVC (containing phthalates which are used to soften plastic), which is another hormone-disrupting chemical used in the manufacture of bottle nipples, pacifiers, and teethers.

Although virtually everyone is exposed to these chemicals, infants who are being fed bottles of formula are at greatest risk for exposure. Many leading bottle manufacturing companies and other companies making plastics have changed their products to contain no BPA, PVC, lead, or phthalates. Parents need to be instructed to read product labels to see if the merchandise they are purchasing is free of these potentially harmful chemicals. If product labels do not explicitly state that they are free of these chemicals, then it cannot be assumed that they are BPA-free, PVC-free, lead-free, and phthalates-free.

If parents cannot afford to purchase new BPA-free bottles, then encourage them to limit heating the bottles (avoid using the dishwasher and bottle warmers) and throw out old bottles with scratches. The harmful chemicals are leached most when the plastic is heated or damaged.

Involving Fathers

Our traditional view of the family following the birth of a child places most of the attention on the mother and newborn, oftentimes leaving the father out. Nurses need to recognize this and make every effort to speak to both parents when entering the patient's room. Fathers play a vital role in the family by providing support to the mother and care for their newborn. If a mother has chosen not to breastfeed, then the father can be involved with bottle feedings from the start. However, if the mother is breastfeeding, it is important to ask the father to wait to introduce a bottle until the mother's milk supply and breastfeeding are well established, generally by 3 to 4 weeks post-delivery. The father can be encouraged to assist with breastfeeding in the meantime. He can help the mother get in position and help tweak the baby's latch if the mother complains of any discomfort. The father can also massage the mother's breasts during breastfeeding to help stimulate the sleepy baby to feed better and to relieve any engorgement. The father can help with other aspects too. He can help burp the baby, change diapers, bathe, and comfort the baby. The father can also provide skin-to-skin contact that enhances bonding, provides comfort to the newborn, and calms the baby down before offering the breast. One strategy is to have the father hold the baby vertically on his chest and let the baby suck on a clean finger for a minute or so (see Figure 32-25 ■). These are just a few ways to involve the father after the birth of the baby. These interactions promote father-mother-infant bonding and are important for paternal role development.

Figure 32-25 ■ Father and infant skin-to-skin.

Community-Based Nursing Care

Promotion of Successful Infant Feeding

To promote a supportive hospital environment for breastfeeding, the World Health Organization (WHO) and the United Nations Children's Emergency Fund (UNICEF)'s the Baby-Friendly Hospital Initiative (BFHI) recognize hospitals and birthing centers that offer optimal lactation services and comply with the 10 steps outlined in Table 32-10. Baby-friendly status is not easy to achieve. One obstacle, among many, is having to agree not to accept free or low-cost formula (WHO/UNICEF, 2009). There are approximately 91 hospitals in the United States with Baby-Friendly designation as of April 2010 (BFHI USA, 2010).

Seven of the BFHI steps focus on maternity services and newborn care in the hospital, but the third step (antenatal breastfeed-

TABLE 32-10 Baby-Friendly Requirements

Ten Steps to Successful Breastfeeding

1. Maintain a written breastfeeding policy that is routinely communicated to all healthcare staff.
2. Train all healthcare staff in skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within 1 hour of birth.
5. Show mothers how to breastfeed and maintain lactation, even if they should be separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.
7. Practice rooming in—that is, allow mothers and infants to remain together 24 hours a day.
8. Encourage unrestricted breastfeeding.
9. Give no pacifiers or artificial nipples to breastfeeding infants.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

RESEARCH EVIDENCE IN PRACTICE

Strategies to Promote Breastfeeding

CLINICAL QUESTION

What interventions are effective in the pre- and postnatal periods to promote breastfeeding as an exclusive source of nutrition for babies?

RESEARCH EVIDENCE

Breastfeeding has health advantages for both babies and their mothers. Babies that are breastfed have fewer infections and allergies, and are less likely to develop asthma, type 2 diabetes, obesity, and childhood leukemia later in life. Mothers who breastfeed are at lower risk for type 2 diabetes, breast cancer, and ovarian cancer than women who have never breastfed. Still, nearly 30% of American children have never been breastfed, and only 35% are breastfed until they are 6 months old. Strategies that can effectively encourage exclusive breastfeeding—or any breastfeeding at all—can have an impact on the health of both babies and mothers.

While a great deal of research has been conducted on strategies to promote breastfeeding, there is little in the way of definitive conclusions because the interventions tested in these studies are not standard. Promotion methods that have been tested include prenatal and postnatal interventions; efforts around the time of delivery; after birth, while breastfeeding is under way; formal education for mothers, fathers, and families; direct support of mothers during breastfeeding observation; peer support; and training of professional staff.

It is clear that interventions to promote breastfeeding can increase the rate, exclusivity, and length of breastfeeding. The characteristics of interventions that seem the most effective are those that are begun before birth and continued into the postnatal period. Programs that involve the father or parental partner are more successful in promoting exclusive breastfeeding. Peer support and education is also effective in promoting breastfeeding.

WHAT QUESTIONS REMAIN UNANSWERED?

Is there a standard approach that can be demonstrated to be effective overall in supporting exclusive breastfeeding?

WHAT IS BEST PRACTICE?

Interventions that begin during the prenatal period, involve the spouse or parental partner, and continue through the postnatal period are most effective in promoting breastfeeding. Providing these support services using a peer or trained breastfeeding coach is an effective way to encourage breastfeeding.

CRITICAL THINKING

What content would be effective in providing breastfeeding education and support? How can the nurse initiate support services in the prenatal period?

ing education) and tenth step (establishment of breastfeeding support groups), connect the mother to community-based breastfeeding promotion and support services.

Research has shown that social and community support is needed for a mother to initiate and sustain breastfeeding (WHO, 2003). Community-based support for breastfeeding mothers often focuses on breastfeeding support groups. **La Leche League International (LLLI)** is the first (not-for-profit international educational and service organization) mother-to-mother breastfeeding support group formally recognized in the United States. It also has expanded to provide educational breastfeeding conferences for professionals, and it is one of the few organizations to have a peer counselor breastfeeding training program, among other things. (See www.nursing.pearsonhighered.com for more information.) Encourage mothers to visit the International Lactation Consultant Association (ILCA) Web site to find lactation consultants in their geographic areas. Another professional organization, The Academy of Breastfeeding Medicine (ABM) provides many research-based breastfeeding protocols that are being implemented in hospitals and agencies around the country that support breastfeeding. To access the protocols, visit the ABM Web site.

Peer counseling is another type of mother-to-mother community support program targeted to low-income women, minorities, and other groups with a low incidence of breastfeeding and counselors are usually hired to work for the Supplemental Nutrition Program for Women, Infants, and Children (WIC). Peer counselors are typically economically disadvantaged mothers themselves in the community who have previously breastfed or are currently breastfeeding and desire helping other disadvantaged women breastfeed successfully. The primary role for peer counselors is providing counseling to pregnant and breastfeeding mothers on a one-to-one basis in the clinic, during home visits, and by telephone follow-up. In a recent systematic review, the use of peer counselors was shown to have a positive impact on infant feeding behavior and is an effective strategy for increasing breastfeeding rates (Chung, Raman, Trikalinos, et al., 2008).

WIC

The Supplemental Nutrition Program for Women, Infants, and Children (WIC) functions primarily to provide low-income women and children who are at risk for medical or nutritional problems with nutritious foods to supplement their diets, nutrition education and counseling, and screening and referrals to other health, welfare, and social programs. The WIC program serves 45% of all infants born in the United States. More than half of the formula used in the United States is distributed free of charge to mothers whose babies are enrolled in the WIC program (Kent, 2006). To be eligible for WIC benefits, an applicant's gross income must fall at or below 185% of the U.S. Poverty Income Guidelines. For example, a family of four must not earn more than $40,793 (gross income) per year, effective July 1, 2009 to June 30, 2010. Although WIC provides formula to eligible mothers who are not exclusively breastfeeding, the monthly allotment is not enough to meet the full nutritional

needs of a growing infant over time. Mothers need to understand that they will have to purchase additional formula out of pocket as their infant's feeding requirement increases.

Families who are eligible to be enrolled in the WIC program are usually also eligible for other need-based programs. The staff at the WIC office often makes referrals for families to these other programs where indicated. The U.S. Department of Health and Human Services, Administration for Children & Families provides 1000 government benefit and assistance programs for eligible families. Among the numerous programs available, families are likely to want information on enrollment in their state Medicaid program and information about acquiring food stamps from the Supplemental Nutrition Assistance Program (SNAP).

There are many organizations within a community at the local level that provide various kinds of support to families. At the local level hospitals, clinics, and private practice lactation consultants provide some of the following services: parenting classes, breastfeeding classes, breastfeeding consultation visits, breastfeeding support group meetings, postpartum depression support group meetings, boot camp for dads, new parent support group meetings, and infant care classes. Some home health agencies, through physician referral and self-referral, provide home visits for families to check on the newborn and mother after hospital discharge. Food banks, shelters, and churches help low income families when other community resources are not in place yet. Libraries also provide local community service to families. Besides providing books on parenting, feeding, and other related topics, libraries provide families with access to available computers for those needing Internet access.

Communities have an integral role in the promotion and support of successful infant feeding practices by providing programs that meet the emotional, informational, and instructional needs of families. It is very important that nurses discharging mothers from a hospital or birthing center provide the new mother with a list of relevant resources that are available to her in the community. Communities can make a difference in improving quality of life for infants and their families.

Nutritional Assessment

A nutritional assessment is an integral part of a thorough health appraisal and is commonly performed by the infant's primary care provider, a nurse, a lactation consultant, a registered dietitian, or a speech therapist. The nutritional assessment will include all or some of the following parameters to measure wellness:

- Nutritional intake (breast milk, type of formula, other foods)
- Anthropometric measurements (measurements of weight, length, and head circumference)
- Biochemical status (the newborn metabolic screening, iron level, etc.)
- Physical examination (vital signs, total body examination, developmental milestones)
- Sociodemographic data (parity, maternal age, impact of cultural practices on feeding)

Parents will be asked to present a feeding diary for the provider to review, or the parents will need to recall the infant's feeding pattern over the last 24 to 48 hours. The parents will also be asked to describe the infant's urine and stool output, including quantity and quality. The healthcare professional is interested in the infant's behavior pattern, especially during and immediately after feeding. If the newborn is not gaining sufficient weight, the infant's feeding history must be examined more closely. If the infant is breastfeeding, a relevant maternal history is needed to determine if the mother is having breastfeeding difficulties and to help determine the root cause of the problem. If the infant is formula-feeding, the healthcare professional will first want to investigate the family's formula-feeding practices (including formula preparation technique). While gathering these data, the healthcare professional should be sensitive to the family's cultural practices. However, if a cultural practice has harmful effects, then the provider needs to tactfully educate the family to that fact.

The provider should plot the infant's measurements for length, head circumference, and weight on a growth chart, denoting the infant's individual percentile measurement compared with the general population. Because there are variations among infants at the same age, it is important to monitor the infant's individual growth pattern over time. Ideally, the provider wants to see an infant track along the same growth curve. A drop of 20 percentile or more on the growth curve is cause for concern.

As the healthcare provider begins the infant's physical exam, the provider first obtains a subjective impression of the infant's overall appearance. The provider performs a head-to-toe physical examination, carefully noting any deviations from normal. If the infant's primary healthcare provider has any concerns about the infant's nutritional status, the provider may order relevant laboratory studies (i.e., newborn metabolic screening, iron level), may evaluate the infant for malabsorption disorders, and may refer the infant to a pediatric gastroenterologist for further evaluation.

With all the infant data available, it is now possible to determine an infant's nutritional status and potential risks.

The following example shows the effectiveness of these assessments and interventions:

Scenario: *Baby girl Smith was born at 37 weeks' gestation to an 18-year-old, G1P0 via cesarean section. The father of the baby was not present. Baby Smith is now 76 hours postpartum and she and her mother are expected to go home today. While weighing the infant for a discharge weight, the mother mentions that she does not think her daughter is getting much breast milk when she feeds because her infant keeps falling asleep at the breast during the feeding. Baby Smith weighed 3542 grams at birth and her present weight is 3173 grams. (The difference is 369 grams. 369/3542 = 0.104 × 100 = 10.4% weight loss.) An assessment of the mother's breasts reveals symmetric, soft breasts and normal-shaped nipples, with nipples intact. After contacting the infant's healthcare provider to report the significant weight loss, the nurse is now ready to formulate a plan of care.*

The nurse makes the following nursing diagnoses:

Ineffective Breastfeeding related to:

- Mother's lack of knowledge about breastfeeding
- Mother's not responding to infant's feeding cues
- Mother's inability to facilitate effective breastfeeding

As evidenced by a weight loss of 10.4% in baby.

Interrupted Breastfeeding related to:

- Insufficient knowledge regarding newborn's reflexes and breastfeeding techniques
- Lack of support by father of baby or other support persons
- Lack of maternal self-confidence
- Maternal fatigue
- Possible maternal ambivalence
- Poor infant sucking reflex
- Difficulty waking the sleepy baby

Imbalanced Nutrition: Less Than Body Requirements related to:

- Mother's increased caloric and nutrient needs status post-cesarean section
- Infant's inability to correctly latch on and transfer milk

Expected Outcomes of Care

The expected outcomes for the infant include:

- Infant will arouse to feed at least every 3 hours and will stay awake until the end of each feeding.
- The infant will correctly latch on to the breasts and effectively breastfeed 8 to 12 times per day.
- The infant will gain at least 10 g/kg/day and be back to birth weight no later than day 14 of life.
- The infant will have four wet diapers, three to four bowel movements on day 4; five wet diapers, three to four bowel movements on day 5; and six to eight wet diapers, three to four bowel movements every day thereafter during the first month of life.
- Infant's stools will transition from black to yellow by day 5 and will change in consistency from thick and sticky to loose and explosive with small curds or seedy appearance.
- Infant will not have any uric acid crystals in her diaper after day 3 or 4.
- Infant will be satiated after feeding, as evidenced by relaxed muscle tone and sleepiness.

The expected outcomes for the mother include:

- Mother will verbalize/demonstrate an understanding of breastfeeding technique, including positioning and latch on, signs of adequate feeding, self-care.
- Mother will breastfeed pain-free.
- Mother will express satisfaction with the breastfeeding experience.
- Mother will consume a nutritionally balanced diet with appropriate caloric and fluid intake to support breastfeeding.

Plan of Care and Interventions

1. Review the mother's history.
   - Maternal demographics—for example, mother's date of birth, parity, marital status, cultural feeding practices
   - Pregnancy history—for example, complications during pregnancy, gestation at delivery
   - Complications of delivery—for example, cesarean section, excessive blood loss
   - Current medical issues—for example, hypothyroidism? diabetes?
   - History of breast surgery or radiation—for example, breast reduction, radiation to treat previous breast cancer
   - Use of medications, herbs, alcohol, cigarettes
   - Psychosocial history—maternal support system, history of depression, and so on
   - History of previous breastfeeding experience
2. Maternal assessment.
   - Assess the breasts and nipples.
   - Obtain a description of lochia drainage.
3. Infant assessment.
   - Obtain the infant's weight and compare with previous weight measurements.

Note: If this were an older infant, then it would be appropriate to obtain head circumference, length, and weight measurements and track the infant's trend on the growth chart; however, because this infant is only 3 days old, daily tracking of the other growth parameters is not applicable for this situation.

   - Examine the infant, with emphasis on oral anatomy and oral-motor function, infant reflexes, overall behavior, skin color (jaundice).
   - Assess the infant for signs of dehydration.
4. Infant feeding history.
   - Diet
   - Feeding frequency and duration
   - History of supplementation
   - Review elimination pattern: Number of wet diapers, quality of urine, bowel movements, quality of stool.
5. Pre- and post-breastfeeding weight check.
   - Calculate milk transfer during breastfeeding.

Note: Post-feed weight minus pre-feed weight equals net breast milk transfer. The nurse must use a digital electronic scale accurate within 2 grams. The infant does not have to be naked but the clothing and diaper the infant is wearing cannot be changed during this next measurement.

6. Observation of breastfeeding technique.
   - Positioning and latch-on technique, infant responses, suckling pattern, satiated after feeding
7. Review feeding requirement/caloric requirement based on the infant's birth weight (3.542 kg).
   - Fluid requirement: 140 to 160 ml/kg/day
     - Should be up to full volume by day 6 or so; should then receive 496 to 567 ml/day. To convert ml to oz: take 496 ml/day, divide by 30 ml/oz, this equals 16.5 oz/day. For this scenario, the infant should receive 16.5 to 18.9 oz/day.
   - The infant should feed 8 to 12 times per day. If the infant feeds 10 times per day, then the infant should feed 496/10 = 49.6 ml/feeding.
   - On day 3, the infant will *not* be expected to feed approximately 50 ml/feeding (minimum *full* volume);

based on physiologic stomach capacity, the infant may only feed about 30 ml/feeding on day 3 of life but will be increasing volume daily as tolerated until up to full volume in the next couple of days.
- Caloric requirement 100 to 115 kcal/kg/day.
  - Should be up to full caloric requirement by about day 6; should receive 354 to 407 kcal/day. Human milk has 20 kcal/oz; standard infant formula has 20 kcal/oz. To determine how many ounces the infant will require per day, take 354 kcal/day divided by 20 kcal/oz equals 17.7 oz/day. *Note: The infant should be gradually increasing her volume of milk each day and will soon be up to full volume.*

8. Assess teaching needs and provide verbal and written instructions.
   - Review benefits of breastfeeding. *Provide frequent skin-to-skin contact.*
   - Review breastfeeding technique (positioning and latch on).
   - Watch the infant for early feeding cues. *If the infant is too sleepy to exhibit these feeding behaviors, then teach the mother to watch for signs that her infant is in a light state of sleep. When the infant is in a light state of sleep, then the mother can try "wake up techniques" to help her infant wake up at least every 3 hours to feed.*
   - Provide breast pump instructions and review collection and storage.
     - *May start pumping to increase breast stimulation. All expressed breast milk should be fed to the infant. If the mother is not able to express enough milk, then the infant should be supplemented with formula.*
     - Review the process of breastfeeding (principle of supply and demand) and practice proper breastfeeding technique. *Encourage the mother to breastfeed as often as possible and observe for signs of effective breastfeeding.*
   - Review infant intake and output, weight gain expectations. *Maintain a feeding diary to monitor the infant's intake and output; call a lactation consultant or the infant's health-care provider if the infant is not meeting expectations.*
   - Provide information on maternal nutrition and fluid requirements.
     - *Rest as much as possible and be concerned only about self-care needs (i.e., prevention of engorgement, etc.) and caring for the infant right now.*
     - *Eat healthy foods and drink plenty of fluids to quench thirst.*
     - *Plan for a follow-up weight check on infant in 1 to 2 days to assess nutritional status.*

Arrange for a follow-up lactation consultation visit in 2 days to reassess the mother and infant at that time and revise the plan of care.

FOCUS YOUR STUDY

- The American Academy of Pediatrics (AAP) recommends exclusive breastfeeding for the first 6 months and continued breastfeeding until the infant is 1 year old or older.
- During the first few days after birth, the minimum output expectations for an exclusively breastfeeding infant will be: one wet/one stool on day 1; two wets/two stools on day 2; three wets/three to four stools on day 3; four wets/three to four stools on day 4; five wets/three to four stools on day 5. Thereafter, an exclusively breastfeeding infant has a minimum of six to eight wet diapers and three to four yellow milk stools each day, generally during the first month of life.
- Infants' stools start as black and sticky at birth and transition to yellow, curdy, or seedy by day 5, or sooner.
- Formula-feeding infants lose about 3.5% of their birth weight. Breastfeeding infants lose up to 7% of their birth weight. A weight loss of more than 7% is excessive and requires an evaluation and follow-up. A weight loss exceeding 10% requires an intervention that demonstrates sufficient intake for the infant, and adequate breast stimulation for the mother, and requires a plan for follow-up within a couple of days. Infants should be back to their birth weight no later than day 14 of life.
- Growth rate over the lifespan is greatest during infancy. The healthy full-term infant gains approximately 10 g/kg/day for the first month of life. Exclusively breastfed infants have the same or slightly greater weight gain in the first 3 to 4 months of life than mixed-fed and formula-fed infants. Thereafter, formula-fed and mixed-fed infants are heavier than breastfed infants.
- Increases in body length and head circumference between breastfed and formula-fed infants is the same. An infant gains 1 inch per month in the first 6 months, and then 0.5 inch for the following 6 months.

- Generally, infants double their birth weight by 5 months, triple their birth weight by 1 year of age, and quadruple their birth weight by 2 years.
- The dietary reference intake (DRI) for calories for the newborn is 100 to 115 kcal/kg/day.
- The dietary reference intake (DRI) for fluid intake for the newborn is 140 to 160 ml/kg/day.
- Human milk has immunologic and nutritional properties that make it the optimal food for the first year of life.
- Mature human milk and standard commercially prepared formulas provide 20 kcal/oz.
- The breastfed infant's iron stores from in-utero placental transfer is usually depleted by the time the infant is 6 months old. Breastfeeding infants over 6 months of age who are eating complementary foods rich in iron, and infants consuming iron-enriched formula need no other vitamin or mineral supplements with the possible exception of vitamin D.
- There are five types of commercial infant formulas: (1) standard cow's milk–based formulas, such as Enfamil and Similac; (2) soy milk–based formulas, such as ProSobee and Isomil; (3) partially hydrolyzed formulas, such as Nestlé Good Start and Enfamil Gentlease; (4) extensively hydrolyzed hypoallergenic formulas, such as Nutramigen and Alimentum; and (5) essentially nonallergenic amino acid–based formulas, such as Neocate and EleCare.
- Neither cow's milk nor soy milk should be given to infants before 1 year of age. The use of skim milk or low-fat cow's milk is not recommended for children under 2 years old.
- Signs indicating a newborn's readiness to feed include hand-to-mouth movements, rooting, smacking, fussing, and crying (a late-feeding cue).
- By learning about cultural variations, the nurse will gain an understanding of the "context" or unstated assumptions that influence behavior, thus avoiding misunderstanding and improving the ability of the nurse to communicate with patients.
- Infants should not receive water supplements until they start solid foods, generally beginning at 6 months of age.
- Although most maternal medications are transmitted through human milk to some degree, few are actually contraindicated. The bioavailability of transmitted drugs to the infant depends on a variety of factors, including route of administration, protein binding, degree of ionization, molecular weight, timing of the dose with respect to feeding time, and absorption across the infant's intestinal tract. Mothers needing to take medications or herbs should consult with a healthcare provider knowledgeable about medications and lactation.
- Breastfeeding mothers should be taught to use proper positioning and latch-on technique. The mother should be advised to alternate feeding positions periodically to promote efficient drainage of all the ducts in the breast.
- The formula-feeding mother may need help learning about the types of formulas and how to prepare and store formula. Like the breastfeeding mother, she will benefit from understanding feeding cues and proper technique for feeding her infant.
- Nutritional assessment of the infant includes the infant's dietary history, anthropometric measurements, physical examination, and laboratory tests, if indicated.

CRITICAL THINKING IN ACTION

Patty Kline, age 28, G1, now P1, delivers a 7.3 pound baby girl by spontaneous vaginal birth over a median episiotomy. The newborn's Apgar scores are 8 and 9 at 1 and 5 minutes. The infant is suctioned in the nose and mouth and given free-flow oxygen on the mother's abdomen. Patty received an epidural during her labor and birth. Patty initiated breastfeeding within the first hour after the birth, but at that time the newborn did not latch on. The infant was held to the mother's breast, rooted, and licked the nipple. You are the nurse caring for the infant at 2 hours of age. The admission assessment is significant for asymmetric head with a 3-cm caput succedaneum. The infant's temperature is stable. You bring the infant to the mother's room to assist her with breastfeeding.

1. Describe clues that indicate the infant is ready to breastfeed with the mother.
2. How would you explain how to position the infant at the breast?
3. Explain what to observe for the infant's proper latch-on.
4. Explain the basics of milk production.
5. Explore helpful measures the mother can attempt in support of breastfeeding.

The Newborn at Risk: Conditions Present at Birth

CHAPTER 33

When I approach a child,
He inspires me in two sentiments:
Tenderness for what he is,
And respect for what he may become.

—Louis Pasteur

LEARNING OUTCOMES

1. Identify the factors present at birth that indicate an at-risk newborn.
2. Compare the underlying etiologies of the physiologic complications of small-for-gestational-age (SGA) newborns and preterm appropriate-for-gestational-age (Pr AGA) newborns and the nursing care management for each.
3. Describe the impact of maternal diabetes mellitus on the newborn.
4. Compare the characteristics and potential complications that influence nursing management of the postterm newborn and the newborn with postmaturity syndrome.
5. Discuss the physiologic characteristics of the preterm newborn that predispose each body system to various complications and are used in development of a plan of care that includes nutritional management.
6. Summarize the nursing assessments of and initial interventions for a newborn born with selected congenital anomalies.
7. Explain the special care needed by an alcohol or drug-exposed newborn.
8. Relate the consequences of maternal HIV/AIDS to the management of and issues for caregivers of infants at risk for HIV/AIDS in the neonatal period.
9. Identify physical examination findings during the early newborn period that would make the nurse suspect a congenital cardiac defect or congestive heart failure.
10. Explain the special care needed by a newborn with an inborn error of metabolism.

KEY TERMS

Fetal alcohol spectrum disorder (FASD) *921*
Fetal alcohol syndrome (FAS) *921*
Inborn errors of metabolism *931*
Infant of diabetic mother (IDM) *898*
Infant of substance-abusing mother (ISAM) *921*
Intrauterine growth restriction (IUGR) *891*
Large for gestational age (LGA) *897*
Neonatal morbidity *890*
Neonatal mortality risk *890*
Phenylketonuria (PKU) *931*
Postmaturity *900*
Postterm newborn *900*
Preterm infant *901*
Small for gestational age (SGA) *891*

The field of neonatology has expanded greatly. Many levels of nursery care have evolved in response to increasing knowledge about the newborn: special care, intensive care, and convalescent care. Along with the newborn's parents, the nurse is an important caregiver in all these settings. As a professional member of the multidisciplinary healthcare team, the nurse provides the holistic care necessary in the often high-tech perinatal environment.

In addition to the availability of excellent intensive care services, a variety of other factors influences the outcomes of at-risk infants, including the following:

- Birth weight
- Gestational age
- Type and length of newborn illness
- Environmental factors
- Maternal factors
- Maternal-infant separation

Identification of At-Risk Newborns

An at-risk newborn is one who is susceptible to illness (morbidity) or even death (mortality) because of dysmaturity, immaturity, physical disorders, or complications during or after birth. In most cases, the infant is the product of pregnancy involving one or more predictable risk factors, including the following:

- Low socioeconomic level of the mother.
- Limited access to health care or no prenatal care.
- Exposure to environmental dangers, such as toxic chemicals and illicit drugs.
- Preexisting maternal conditions, such as heart disease, diabetes, hypertension, hyperthyroidism, and renal disease.
- Maternal factors such as age or parity.
- Medical conditions related to pregnancy and their associated complications.
- Pregnancy complications such as abruptio placentae, placenta previa, oligohydramnios, preterm labor, premature rupture of membranes, preeclampsia, uterine rupture.

Various risk factors and their specific effects on the pregnancy outcome are identified in Table 15-1 ∞ on page 321. Because these factors and the perinatal risks associated with them are known, the birth of at-risk newborns can often be anticipated. The pregnancy can be closely monitored, treatment can be started as necessary, and arrangements can be made for birth to occur at a facility with appropriate resources to care for both mother and baby.

Whether or not prenatal assessment indicates that the fetus is at risk, the course of labor and birth and the infant's ability to withstand the stress of labor cannot be predicted. The nurse's use of electronic fetal heart monitoring or fetal heart auscultation by Doppler plays a significant role in detecting stress or distress in the fetus. Immediately after birth, the Apgar score is a helpful tool in identifying the at-risk newborn, but it is not the only indicator of possible long-term outcome.

The newborn classification and neonatal mortality risk chart is another useful tool in identifying newborns at risk. Before this classification tool was developed, birth weight of less than 2500 g was the sole criterion for determination of immaturity. Clinicians then recognized that newborns could weigh more than 2500 g but still be immature. Conversely, an infant weighing less than 2500 g might be functionally mature at term or beyond. Birth weight and gestational age together became the criteria used to assess neonatal maturity and mortality risk.

According to the newborn classification and neonatal mortality risk chart, gestation is divided as follows (Gardner & Hernandez, 2011):

- Preterm: less than 37 (completed) weeks
- Late preterm: 34 to 36 6/7 weeks
- Term: 38 to 41 (completed) weeks
- Postterm: greater than 42 weeks

Late preterm is an emerging classification that refers to subgroups of infants between 34 and 37 weeks' gestation; however, it is not yet used consistently for a single age range (Gardner & Hernandez, 2011). (See chapter 37 ∞ for discussion of long-term needs of late preterm infants.)

As shown in Figure 33-1 ■, large-for-gestational-age (LGA) infants are those who plot above the 90th percentile growth curve. Appropriate-for-gestational-age (AGA) infants are those between the 10th percentile and 90th percentile growth curve. Small-for-gestational-age (SGA) infants are those below the 10th percentile growth curve. A newborn is assigned to a category depending on birth weight, length, occipital-frontal circumference, and gestational age. For example, a newborn classified as Pr SGA is preterm and small for gestational age. The full-term newborn whose weight is appropriate for gestational age is classified F AGA. It is important to remember that the intrauterine growth curve charts are influenced by altitude and the ethnicity of the newborn population used to create the chart. Also the assigned newborn classification may vary according to the intrauterine growth curve chart used; therefore, the chart used should correlate with the characteristics of the patient population.

Neonatal mortality risk is the chance of death within the neonatal period, that is, within the first 28 days of life. Seventy-five percent of all neonatal deaths occur within the first week, with the highest rates occurring during the first day of life. As indicated in Figure 33-1, the neonatal mortality risk decreases as both gestational age and birth weight increase. Infants who are Pr SGA have the highest neonatal mortality risk. The previously high mortality rates for LGA infants have decreased at most perinatal centers because of improved management of diabetes in pregnancy and recognition of potential complications of LGA newborns.

Neonatal morbidity can also be anticipated based on birth weight and gestational age. In Figure 33-2 ■, the infant's birth weight is located on the vertical axis, and the gestational age in weeks is found along the horizontal axis. The area where the two meet on the graph identifies common problems. This tool assists in determining the needs of particular infants for special observation and care. For example, an infant of 2000 g at 40

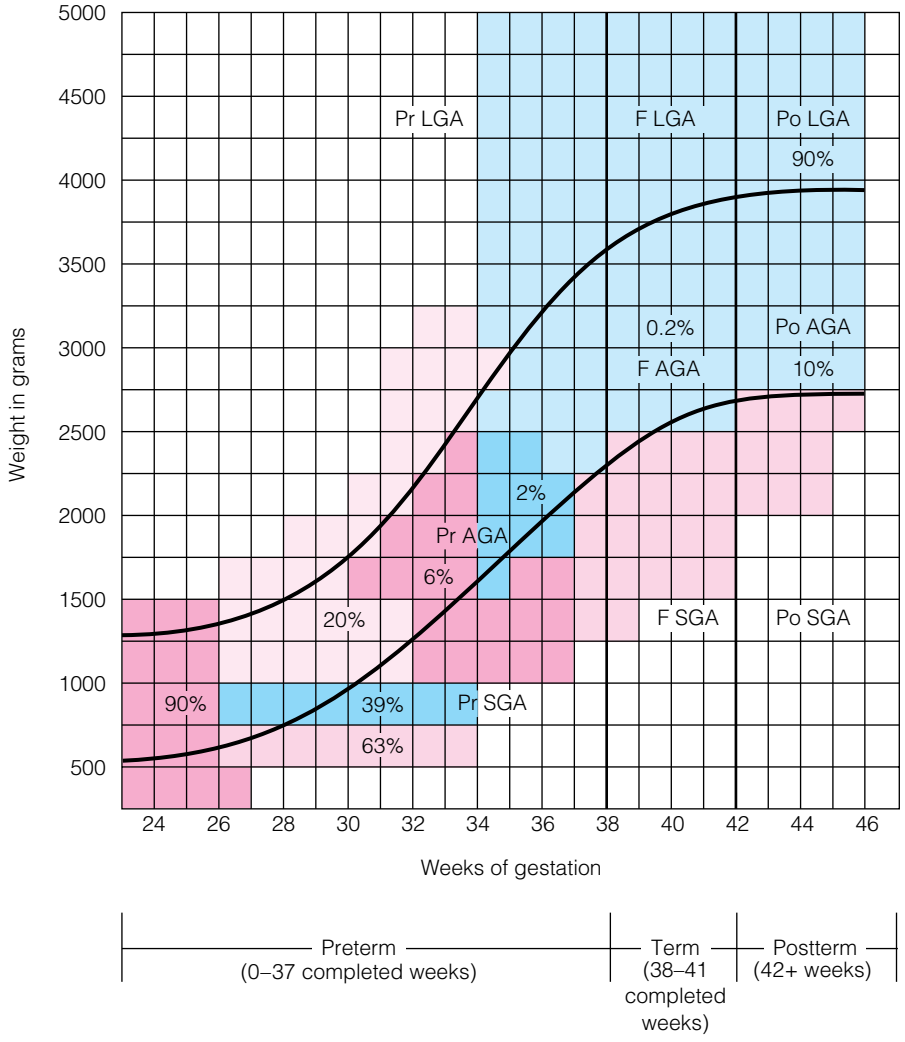

Figure 33-1 ■ Newborn classification and neonatal mortality risk chart. Infants are classified according to weight as small for gestational age (SGA), appropriate for gestational age (AGA), or large for gestational age (LGA) and by weeks of newborn as preterm (Pr), term (F), or postterm (Po). Corresponding neonatal mortality risks are indicated by the percentages in the various colored regions.

Source: Reprinted from Koops, B. L., Morgan, L. P., & Battaglia, F. C., Neonatal mortality risk in relationship to birth weight and gestational age. Journal of Pediatrics, 101*(6), 969. Copyright 1982, with permission from Elsevier.*

weeks' gestation should be carefully assessed for evidence of nonreassuring fetal status, hypoglycemia, congenital anomalies, congenital infection, and polycythemia.

Identifying the nursing care needs of the at-risk newborn depends on minute-to-minute observations of the changes in the newborn's physiologic status. Nursing care management should be directed toward the following:

- Decreasing physiologically stressful situations.
- Constantly observing for subtle signs of change in clinical condition.
- Interpreting laboratory data and coordinating interventions.
- Conserving the infant's energy for healing and growth.
- Providing for developmental stimulation and maintenance of sleep cycles.
- Assisting the family in developing attachment behaviors.
- Involving the family in planning and providing care.

Care of the Small-for-Gestational-Age/Intrauterine Growth Restricted Newborn

Currently infants are considered **small for gestational age (SGA)** when they are less than the 10th percentile for birth weight; very small for gestational age is when they are two standard deviations below the population norm or at less than the third percentile (Cunningham et al., 2010) (see Figure 33-1). When possible, the birth weight charts used to assign the SGA classification to a newborn should be based on the local population into which the newborn is born. A SGA newborn may be preterm, term, or postterm. An undergrown newborn may be also said to have **intrauterine growth restriction (IUGR)**, which describes the pregnancy circumstance of advanced gestation and limited fetal growth. This classification of abnormal growth is

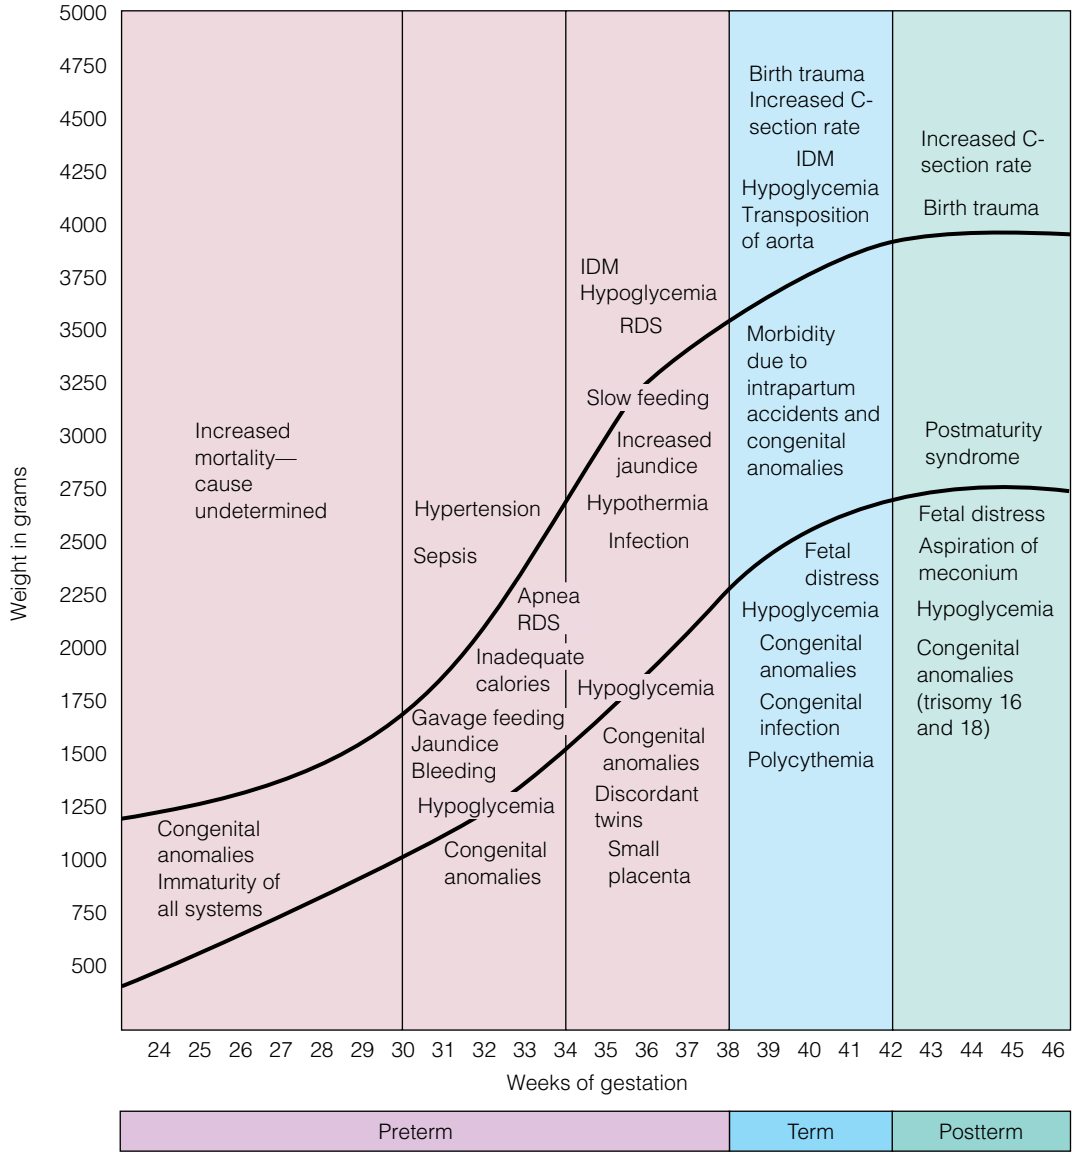

Figure 33-2 ■ Neonatal morbidity by birth weight and gestational age.

Source: Reprinted from Lubchenco, L. O., The high-risk infant, *p. 122. Copyright 1976, with permission from Elsevier.*

also enhanced by looking at growth potential by adjusting birthweight reference limits for first trimester maternal height, birth order, and fetal neonatal sex. The terms SGA and IUGR are not necessarily interchangeable.

SGA infants are commonly seen with mothers who smoke or have high blood pressure, causing these infants to have an increased incidence of perinatal asphyxia and perinatal mortality when compared with AGA infants (Resnik & Creasy, 2009). The incidence of polycythemia and hypoglycemia are also higher in this group of infants.

Factors Contributing to Intrauterine Growth Restriction

IUGR may be caused by maternal, placental, or fetal factors and may not be apparent antenatally. In the normal pregnancy, intrauterine growth is linear (follows expected growth line) from approximately 28 to 38 weeks' gestation. After 38 weeks, growth is variable, depending on the genetic growth potential of the fetus and placental function. The most common causes of growth restriction are the following:

- ***Maternal factors.*** Primiparity, grand multiparity, multiple-gestation pregnancy (twins and higher order multiples), lack of prenatal care, age extremes (under 16 or over 40), and low socioeconomic status (which can result in inadequate health care, inadequate education, inadequate living conditions, and malnutrition) affect IUGR (Resnik & Creasy, 2009). Before the third trimester, the nutritional supply to the fetus far exceeds his or her needs. Only in the third trimester are maternal malnutrition and drug abuse limiting factors in fetal growth.
- ***Maternal disease.*** Maternal heart disease, substance abuse (drugs, tobacco, alcohol), sickle cell anemia, phenylketonuria (PKU), lupus erythematosus, and asymptomatic pyelonephritis are associated with SGA. Complications asso-

ciated with preeclampsia, chronic hypertensive vascular disease, and advanced diabetes mellitus can diminish blood flow to the uterus, thereby decreasing oxygen delivery to the fetus.

- ***Environmental factors.*** High altitude, exposure to x-rays, excessive exercise, work-related exposure to toxins, hyperthermia, and maternal use of teratogenic drugs, such as nicotine, alcohol, antimetabolics, anticonvulsants, narcotics, and cocaine affect fetal growth (Resnik & Creasy, 2009).
- ***Placental factors.*** Placental conditions such as small placenta, infarcted areas, abnormal cord insertions, placenta previa, reverse end-diastolic blood flow, or thrombosis may affect circulation to the fetus, which becomes more deficient with increasing gestational age.
- ***Fetal factors.*** Congenital infections such as TORCH infections (*t*oxoplasmosis, *o*ther, *r*ubella, *c*ytomegalovirus, *h*erpes simplex virus), syphilis, congenital malformations, discordant twins (see chapter 11 ∞), sex of the fetus (females tend to be smaller), chromosomal abnormalities (trisomies 13, 18, and 21), two-vessel umbilical cord, and inborn errors of metabolism can all predispose a fetus to growth disturbances.

Identifying fetuses with IUGR is the first step in detecting common disorders associated with affected newborns. The perinatal history of maternal conditions, early dating of pregnancy by first trimester ultrasound measurements, antepartal testing (nonstress test, contraction stress test, biophysical profile—see chapter 21 ∞), Doppler velocimetry of the placenta, gestational age assessment, and the physical and neurologic assessment of the newborn are also important (Cloherty et al., 2008).

Patterns of IUGR

Intrauterine growth occurs by an increase in cell number and cell size. If insult occurs early during the critical period of organ development in the fetus, fewer new cells are formed, organs are small, and organ weight is subnormal. In contrast, growth failure that begins later in pregnancy does not affect the total number of cells, only their size. The organs are normal, but their size is diminished. There are two clinical pictures of IUGR newborns.

Symmetric (proportional) IUGR is caused by long-term maternal conditions (such as chronic hypertension, severe malnutrition, chronic intrauterine infection, substance abuse [drugs, alcohol, tobacco], and anemia) or fetal genetic abnormalities (Resnik & Creasy, 2009). Symmetric IUGR can be noted by ultrasound in the first half of the second trimester. In symmetric IUGR there is chronic, prolonged restriction of growth in size of organs, body weight, body length, and, especially, head circumference.

Asymmetric (disproportional) IUGR is associated with an acute compromise of uteroplacental blood flow. Some causes are placental infarcts, preeclampsia, and poor weight gain in pregnancy. The growth restriction may not be evident before the third trimester because although weight is decreased, length and head circumference remain appropriate for that gestational age. In these infants, head growth is usually spared. After 36 weeks' gestation, the abdominal circumference of a normal fetus becomes larger than the head circumference. In asymmetric IUGR, the head circumference remains larger than the abdominal circumference. Thus measuring only the biparietal diameter on ultrasound will not reveal asymmetric IUGR. An early indicator of asymmetric SGA is a decrease in the growth rate of the abdominal circumference, reflecting subnormal liver growth, a reduction in glycogen stores, and a scarcity of subcutaneous fat (Resnik & Creasy, 2009). Birth weight is below the 10th percentile, whereas head circumference, and/or length, may plot between the 10th and 90th percentiles. Asymmetric SGA newborns are particularly at risk for perinatal asphyxia, pulmonary hemorrhage, hypocalcemia, and hypoglycemia in the newborn period.

Despite growth restriction, physiologic maturity develops according to gestational age. Therefore, the term SGA newborn's chances for survival are better than those of the preterm AGA newborn and less predisposed to complications of prematurity such as respiratory distress syndrome and hyperbilirubinemia because of organ maturity. This newborn, however, still faces many other potential difficulties.

Common Complications of the SGA Newborn

The complications occurring most frequently in the SGA newborn include the following:

- ***Fetal hypoxia.*** The SGA infant suffers from chronically lower-than-normal oxygen levels in utero because of placental insufficiency, which leaves little reserve to withstand the demands of labor and birth. Thus intrauterine asphyxia can occur with its potential systemic problems. Cesarean birth may be necessary.
- ***Aspiration syndrome.*** In utero, hypoxia can cause the fetus to gasp during birth, resulting in aspiration of amniotic fluid into the lower airways. It can also lead to relaxation of the anal sphincter and passage of meconium. This may result in aspiration of the meconium in utero or with the first breaths after birth.
- ***Hypothermia.*** Diminished subcutaneous fat (used for survival in utero), depletion of brown fat in utero, and a large surface area decrease the IUGR newborn's ability to conserve heat. The flexed position assumed by the term SGA newborn diminishes the effect of surface area.
- ***Hypoglycemia.*** An increase in metabolic rate in response to heat loss and poor hepatic glycogen stores cause hypoglycemia. In addition, the infant is compromised by inadequate supplies of enzymes to activate gluconeogenesis (conversion of nonglucogen sources, such as fatty acids and proteins, to glucose).
- ***Polycythemia.*** The number of red blood cells is increased in the SGA newborn. This finding is considered a physiologic response to in utero chronic hypoxic stress. Polycythemia may contribute to hypoglycemia.

Newborns with significant IUGR tend to have a poor prognosis, especially when born before 37 weeks' gestation. Factors contributing to poor outcome include:

- ***Congenital malformations.*** Congenital malformations occur in 5% of SGA infants (Cloherty et al., 2008). The more severe the IUGR, the greater the chance for malformation as a result of impaired mitotic activity and cellular hypoplasia.

- ***Intrauterine infection.*** Fetuses exposed to intrauterine infections such as rubella and cytomegalovirus are profoundly affected by direct invasion of the brain and other vital organs by the offending virus, resulting in IUGR.
- ***Continued growth difficulties.*** SGA newborns tend to be shorter than newborns of the same gestational age. Asymmetric IUGR infants can be expected to catch up in weight and approach their inherited growth potential when given an optimal environment.
- ***Cognitive difficulties.*** Often SGA newborns can exhibit subsequent learning disabilities. The disabilities are characterized by hyperactivity, short attention span, and poor fine motor coordination (writing and drawing). Some hearing loss and speech defects also occur (Cunningham et al., 2010).

CLINICAL TIP

In assessing a growth-restricted infant resulting from unexplained maternal etiology (e.g., hypertension, placental insufficiency), an in utero viral infection may be the answer.

Clinical Therapy

The goal of medical therapy for SGA infants is early recognition and implementation of medical management of the potential problems.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse is responsible for assessing gestational age and identifying signs of potential complications associated with SGA infants. All body parts of the symmetric IUGR infant are in proportion, but they are below normal size for the baby's gestational age. Therefore, the head does not appear overly large or the length excessive in relation to the other body parts. These newborns are generally vigorous.

The asymmetric IUGR infant appears long, thin, and emaciated, with loss of subcutaneous fat tissue and muscle mass (Figure 33-3 ■). The baby may have loose skin folds; dry, desquamating skin; and a thin and often meconium-stained cord. The head appears relatively large (although it approaches normal size) because the chest size and abdominal girth are decreased. The baby may have a vigorous cry and appear alert and wide eyed.

Nursing diagnoses that may apply to the SGA newborn include the following:

- ***Impaired Gas Exchange*** related to aspiration of amniotic or meconium-stained fluid
- ***Hypothermia*** related to decreased subcutaneous fat
- ***Risk for Injury*** related to decreased glycogen stores and impaired gluconeogenesis
- ***Imbalanced Nutrition: Less Than Body Requirements*** related to SGA's increased metabolic rate
- ***Ineffective Peripheral Tissue Perfusion*** related to polycythemia and increased blood viscosity

Figure 33-3 ■ Thirty-one-week gestational age, 2-day-old baby girl.

- ***Risk for Impaired Parenting*** related to prolonged separation of newborn from parents secondary to illness

Nursing Plan and Implementation

Hospital-Based Nursing Care

Hypoglycemia, the most common metabolic complication of IUGR, produces such sequelae as central nervous system abnormalities and intellectual disability (mental retardation). Conditions such as asphyxia, hyperviscosity, and cold stress may also affect the baby's outcome. Paying meticulous attention to physiologic parameters is essential for immediate nursing management and reduction of long-term disorders (see the following Nursing Care Plan: For the Small-for-Gestational-Age Newborn on pages 895–897).

Community-Based Nursing Care

The long-term needs of the SGA newborn include careful follow-up evaluation of patterns of growth and possible disabilities that may later interfere with learning or motor functioning. Long-term follow-up care is especially necessary for those infants with congenital malformations, congenital infections, and obvious sequelae from physiologic problems. Parents of the IUGR newborn need support, because a positive atmosphere can enhance the baby's growth potential and the child's ultimate outcome.

Evaluation

Expected outcomes of nursing care include the following:

- The SGA newborn is free from respiratory compromise.
- The SGA newborn maintains a stable temperature.
- The SGA infant is free from hypoglycemic episodes and maintains glucose hemostasis.
- The SGA newborn gains weight and takes breast- or formula-feedings without physiologic distress or fatigue.
- The parents verbalize their concerns surrounding their baby's health problems and understand the rationale behind management of their newborn.

NURSING CARE PLAN For the Small-for-Gestational-Age Newborn

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Impaired Gas Exchange related to amniotic fluid or meconium aspiration **Goal:** The newborn's respirations will be within normal limits, no periods of apnea or evidence of worsening distress.	
■ Obtain maternal prenatal, labor, and birth records.	■ Provides information of fetal stress that may have occurred during the prenatal or intrapartal period. In addition, the birth record will provide information concerning the infant's respiratory status at birth; for example, the Apgar score.
■ Maintain airway patency through judicious suctioning.	■ Respiratory distress in small-for-gestational-age (SGA) newborns is due to in utero hypoxia and aspiration of meconium.
■ Observe for worsening signs of respiratory distress such as generalized cyanosis; worsening retractions, grunting, and nasal flaring, as evidenced by Silverman respiratory index; sustained tachypnea; apnea episodes; inequality of breath sounds; presence of rales and rhonchi, decreased oxygenation saturation (less than 86%).	
■ Monitor and maintain adequate axillary body temperature (36.4°C to 37.2°C [97.5°F to 99°F]) to avoid increased oxygen consumption.	■ Temperature elevation may cause metabolic rate and oxygen needs to increase when associated with meconium aspiration.
■ Administer oxygen or other interventions (e.g., nasal continuous positive airway pressure [CPAP], intubation) per order for relief of respiratory distress signs. (See chapter 34 ∞ for nursing care and treatment of meconium aspiration, infant resuscitation.)	■ Provides healthcare personnel with information on cardiac and pulmonary status.
■ Implement treatment plan for respiratory distress.	
■ Monitor glucose levels.	■ Respiratory distress increases consumption of glucose.
Collaborative: Obtain arterial blood gases (ABGs) and chest x-ray per physician/neonatal nurse practitioner (NNP) orders.	
■ Monitor infant's cardiac status, pulmonary status, pulse oximetry, and ABGs.	■ Oxygen demands increase with meconium aspiration. Obtaining serial ABGs and chest x-ray will provide medical personnel baseline information of infant's respiratory status, and effective medical interventions can be initiated.
EXPECTED OUTCOMES:	The newborn will maintain adequate respiratory gas exchange as evidenced by: respirations of 30–60/min with pulse oximetry and arterial blood gases within normal limits, and show no signs and symptoms of respiratory distress.
2. Nursing Diagnosis: Risk for Ineffective Thermoregulation and Cold Stress secondary to decreased subcutaneous fat **Goal:** The infant's temperature will be stable and maintained within normal limits.	
■ Provide neutral thermal environment (NTE) range for infant based on postnatal weight.	■ Neutral thermal environment charts used for preterm infant are not reliable for weight of SGA infant.
■ Place a skin probe to maintain infant's temperature at 36°C to 36.5°C.	■ A neutral thermal environment requires minimal oxygen consumption to maintain a normal core temperature.
■ Obtain axillary temperatures and compare with registered skin probe temperature. If discrepancy exists, evaluate potential cause.	■ Discrepancies between axillary and skin probe monitor temperatures may be due to mechanical causes or the burning of brown fat.
■ Adjust and monitor incubator or radiant warmer to maintain skin temperature.	
■ Minimize heat losses and prevent cold stress by: 1. Warming and humidifying oxygen without blowing over face to avoid increasing oxygen consumption 2. Keeping skin dry, especially immediately following delivery 3. Keeping incubators, radiant warmers, and cribs away from windows and cold external walls and out of drafts 4. Avoiding placing infant on cold surrounding objects such as metal treatment tables, cold x-ray plates, and scales 5. Padding cold surfaces with diapers and using radiant warmers during procedures 6. Warming blood for exchange transfusions	■ Physical principles of heat loss effects include: 1. Evaporation—loss of heat from infant by water evaporation from the skin 2. Convection—loss of heat from infant to the surrounding air 3. Conduction—loss of heat from infant to the surface in which he or she is in direct contact with 4. Radiation—loss of heat from infant to cooler, surrounding surfaces (not in direct contact)

(continued)

NURSING CARE PLAN For the Small-for-Gestational-Age Newborn continued

INTERVENTION	RATIONALE
■ Observe for signs and symptoms of cold stress: decreased temperature, lethargy, pallor (for further discussion see chapter 34 ∞)	■ Hypothermia is a potential problem for an SGA infant because: 1. SGA infant has decreased stores of brown fat available for thermogenesis, because SGA infant has used these stores in utero for survival. 2. SGA infant has poor insulation due to use of subcutaneous tissues in utero for survival.

EXPECTED OUTCOMES: The infant will not exhibit signs and symptoms of hypothermia as evidenced by axillary temperature maintenance of 36.4°C–37.2°C (97.5°F–99°F) and no signs and symptoms of respiratory distress.

3. Nursing Diagnosis: Risk for Injury related to decreased glycogen stores and impaired gluconeogenesis
Goal: Newborn will have a normal blood glucose level.

■ Monitor blood glucose levels per SGA protocol and report values less than 45 mg/dl. (The exact definition of hypoglycemia varies in the literature; it is best to follow your hospital's guidelines.)	■ Combined with depletion of glycogen stores, impaired gluconeogenesis predisposes SGA infants to profound hypoglycemia within first 2 days of life.
■ Observe, record, and report signs of hypoglycemia: cyanosis, lethargy, hypotonia, poor feeding, temperature instability, jitteriness, seizure activity, and apnea.	■ Hypoglycemia in SGA infant is indicated by whole blood sugar less than 20 mg/dl.
■ Initiate feeding schedule for SGA newborns after assessing for low blood glucose levels and signs of respiratory distress per agency protocol.	■ Frequent monitoring of heel stick glucose assists in identifying decreasing glucose levels.
■ Provide glucose intake either through early enteral feeding (before 4 hr) or by intravenous (IV) per physician/NNP order.	■ Provision of glucose through early feedings (begin before 4 hr of age) assists in maintaining glucose levels.

See further discussion of hypoglycemia in chapter 34 ∞.

EXPECTED OUTCOMES: The infant will not exhibit signs and symptoms of hypoglycemia as evidenced by a euglycemic state and blood glucose greater than 20 mg/dl.

4. Nursing Diagnosis: Altered Nutrition: Less Than Body Requirements related to increased metabolic needs in the infant
Goal: Newborn will gain weight and tolerate nipple feedings without tiring.

■ Assess suck, swallow, gag, and cough reflexes.	■ Sterile water may be used to test gag & swallow reflex because it causes fewer pulmonary complications in the presence of gastrointestinal tract abnormalities and/or aspiration of feeding. ■ Prevents feeding problems and assists in determining the best method of feeding for infant.
■ Initiate formula-feeding per protocol at 1 hour of age; move early to formula-feeding every 2–3 hr.	■ SGA newborns require more calories/kg for growth than appropriate-for-gestational-age (AGA) newborns because of increased metabolic activity and oxygen consumption secondary to increased percentage of body weight made up by visceral organs.
■ Supplement oral feedings with IV intake per orders. ■ Use concentrated formulas that supply more calories in less volume, such as 22 or 24 cal/oz.	■ Small, frequent feedings of high caloric formula are used because of limited gastric capacity and decreased gastric emptying.
■ Promote growth by providing caloric intake of 120–150 cal/kg/day in small amounts.	■ Growth is evaluated by increase in weight (about 20 g/day), length, and body measurements.
■ Observe, record, and report signs of respiratory distress or fatigue occurring during feedings.	■ Decrease in exhaustion is an important consideration in feeding SGA infant. ■ Adequate nutritional intake promotes growth and prevents such complications as metabolic catabolism and hypoglycemia.
■ Supplement gavage or nipple feedings with IV therapy per physician order until oral intake is sufficient to support growth.	■ Gavage feedings require less energy expenditure on the part of the newborn.
■ Establish a nipple feeding program that is begun slowly and progresses slowly, such as nipple feed once per day, nipple feed once per shift, and then nipple feed every other feeding.	

NURSING CARE PLAN **For the Small-for-Gestational-Age Newborn** continued

INTERVENTION	RATIONALE
■ Monitor daily weight with anticipation of small amount of weight loss when nipple feedings start.	■ Nipple feeding, an active rather than passive intake of nutrition, requires energy expenditure and burning of calories by infant.

EXPECTED OUTCOMES: The infant will maintain steady weight gain as evidenced by less than 2%/day weight loss, tolerates oral feedings, and urine output is 1–3 ml/kg/hour.

5. Nursing Diagnosis: Risk for Impaired Parenting related to lack of knowledge of infant care and prolonged separation of infant and her or his parents secondary to illness

Goal: Parents will bond with their infant and have realistic expectations about their infant. Parents are comfortable taking infant home. They are able to demonstrate normal infant care and assessments of possible complications, and know when to return for follow-up.

■ Support emotionally the psychologic well-being of family, including positive parent-infant attachment and sensory stimulation of infant.	■ Parent-infant attachment begins in first few hours or days following birth. SGA infants may experience prolonged periods of separation from their parents, which necessitates intervention to ensure parent-infant bonding.
■ Include parents in determining infant's plan of care and encourage their participation. Encourage parents to visit frequently. Provide opportunities for parents to touch, hold, talk to, and care for infant. Determine the type and amount of appropriate sensory stimulation and implement sensory stimulation program.	
■ Prepare for discharge by instructing parents in such areas as feeding techniques, formula preparation, and breastfeeding; bathing, diapering, and hygiene; temperature monitoring; administration of vitamins; care of complications and preventing exposure to infections; normal elimination patterns, normal reflexes and activity, and how to promote normal growth and development without being overprotective; returning for continued medical care; and availability of community resources if indicated.	■ Parents should receive the same postpartum teaching as any parent taking a new infant home. ■ Parents need to understand the changes to expect in color of the infant's stool and number of bowel movements plus odor from formula- or breastfeeding to avoid unnecessary concern. SGA infants usually do not require referral to community agencies such as visiting nurse associations unless there is a specific problem requiring assistance.

EXPECTED OUTCOMES: The parent will demonstrate ability to perform basic infant care tasks as evidenced by exhibiting appropriate attachment behaviors (i.e., talking and holding infant), feeding infant, and bathing infant.

Care of the Large-for-Gestational-Age Newborn

A newborn whose birth weight is at or above the 90th percentile on the intrauterine growth curve (at any week of gestation) is considered **large for gestational age (LGA)**. Some appropriate-for-gestational-age (AGA) newborns have been incorrectly categorized as LGA because of miscalculation of the date of conception due to postconceptional bleeding. Careful gestational age assessment is essential to identify the potential needs and problems of such infants.

The best known condition associated with excessive fetal growth is maternal diabetes (see White's Classification, Table 19-3 ∞ on page 423). Not all LGA newborns are infants of diabetic mothers. The cause of the majority of cases of LGA infants is unclear, but certain factors or situations have been found to correlate with their births (Cloherty et al., 2008):

- It is estimated that 3% to 10% of all pregnancies are complicated by diabetes and 90% of these women are gestational diabetics.
- Genetic predisposition is correlated proportionally to the mother's pre-pregnancy weight and to weight gain during pregnancy. Large parents tend to have large infants.
- Multiparous women have two to three times the number of LGA infants as primigravidas.
- Male infants are typically larger than female infants.
- Infants with erythroblastosis fetalis, Beckwith-Wiedemann syndrome (a genetic condition associated with macroglossia, omphalocele, and newborn hypoglycemia and hyperinsulinemia), or transposition of the great vessels are usually large.

The increase in the LGA infant's body size is characteristically proportional, although head circumference and body length are in the upper limits of intrauterine growth. The exception to this rule is the infant of the diabetic mother, whose body weight is higher but whose length and head circumference may be in the normal range. Macrosomic infants have poor motor skills and have more difficulty in regulating behavioral states. LGA infants tend to be more difficult to arouse and may have problems maintaining a quiet alert state. They may also have feeding difficulties.

Common Complications of the LGA Newborn

Complications of the LGA infant can include the following:

- ***Birth trauma due to cephalopelvic disproportion (CPD) and macrosomia.*** Often LGA newborns have a biparietal diameter greater than 10 cm (4 in.) or are associated with a maternal fundal height measurement greater than 42 cm (16 in.) without the presence of polyhydramnios. Because of their excessive size or macrosomia, there are more breech presentations and shoulder dystocia. These complications may result in asphyxia, fractured clavicles, fractured humerus, brachial plexus palsy, facial paralysis, phrenic nerve palsy, depressed skull fractures, cephalhematoma, and intracranial hemorrhage, all due to birth trauma.
- ***Increased incidence of cesarean births and oxytocin-induced births due to fetal size.*** Mothers and infants have all the risk factors associated with cesarean births.
- ***Hypoglycemia, polycythemia, and hyperviscosity.*** These disorders are most often seen in infants of diabetic mothers and infants with erythroblastosis fetalis or Beckwith-Wiedemann syndrome.

Figure 33-4 ■ Macrosomic infant of a Class B insulin-dependent diabetic mother born at 38 weeks' gestation weighing 3402 grams.

NURSING CARE MANAGEMENT

The perinatal history, in conjunction with ultrasonic measurement of fetal skull (biparietal diameter) and gestational age testing, is important in identifying an at-risk LGA newborn. Nursing care is directed toward early identification and immediate treatment of the common disorders. Essential components of the nursing assessment are monitoring vital signs, screening for hypoglycemia and polycythemia, and observing for signs and symptoms related to birth trauma. The nurse should address parental concerns about the visual signs of birth trauma and the potential for continuation of the overweight pattern. The nurse should help parents learn to arouse and console their newborn and facilitate nutritional intake and attachment behaviors. Mothers of LGA infants with bruising of the face or head may be reluctant to interact with their infants because they fear hurting their infants. The nursing care for complications associated with LGA newborns is similar to the care needed by the infant of a diabetic mother and is discussed in the next section.

Care of the Infant of a Diabetic Mother

Infants of diabetic mothers (IDMs) are considered at risk and require close observation the first few hours to the first few days of life. Mothers with severe diabetes or diabetes of long duration associated with renal, retinal, cardiac, or vascular disease may give birth to small-for-gestational-age (SGA) infants. The typical IDM, when the diabetes is poorly controlled or gestational, is large for gestational age (LGA). The infant is macrosomic, ruddy in color, and has excess adipose (fat) tissue (Figure 33-4 ■). The umbilical cord is thick and the placenta is large. There is a higher incidence of macrosomic infants born to certain ethnic groups (Native Americans, Mexican Americans, African Americans, and Pacific Islanders).

IDMs have decreased total body water, particularly in the extracellular spaces, and are therefore not edematous. Their excessive weight is due to increased weight of the visceral organs, cardiomegaly (hypertrophy), and increased body fat. The only organ not affected is the brain.

The excessive fetal growth of the IDM is caused by exposure to high levels of maternal glucose, which readily crosses the placenta. The fetus responds to these high glucose levels with increased insulin production and hyperplasia of the pancreatic beta cells. The main action of insulin is to facilitate the entry of glucose into muscle and fat cells. Once in the cells, glucose is converted to glycogen and stored. Insulin also inhibits the breakdown of fat to free fatty acids, thereby maintaining lipid synthesis; increases the uptake of amino acids; and promotes protein synthesis. Insulin is an important regulator of fetal metabolism and has a "growth hormone" effect that results in increased linear growth. IDMs may be obese as children (Cunningham et al., 2010).

Common Complications of the IDM

Although IDMs are usually large, they are immature in physiologic functions and exhibit many of the problems of the preterm (premature) infant. The complications most often seen in an IDM are as follows:

- ***Hypoglycemia.*** Hypoglycemia is defined as a blood sugar less than 45 mg/dl. Once the fetus is delivered and the maternal

Care Plan Activity: Infant of a Diabetic Mother

glucose supply is severed, the IDM continues to produce high levels of insulin, which deplete the infant's blood glucose within hours after birth. IDMs also have less ability to release glucagon and catecholamines, which normally stimulate glucagon breakdown and glucose release. The incidence of hypoglycemia in IDMs varies according to the degree of success in controlling the maternal diabetes, the maternal blood sugar level at the time of birth, the length of labor, the class of maternal diabetes, and early versus late feedings of the newborn (Moore & Catalano, 2009). Signs and symptoms of hypoglycemia, which usually present within 1 to 2 hours following delivery, include tremors, cyanosis, apnea, temperature instability, poor feeding, and hypotonia. Seizures may occur in severe cases.

CLINICAL TIP

When beginning fluids on an IDM, it is sometimes best to start at a higher concentration of dextrose to avoid hypoglycemic episodes.

- ***Hypocalcemia.*** Hypocalcemia is defined as a serum calcium of less than 7 mg/dl. Tremors are the obvious clinical sign of hypocalcemia. They may be caused by the IDM's increased incidence of prematurity and to the stresses of difficult pregnancy, labor, and birth, which predispose any infant to hypocalcemia. Diabetic women tend to have decreased serum magnesium levels at term secondary to increased urinary calcium excretion, which causes secondary hypoparathyroidism in their infants. Other factors may include vitamin D antagonism, which results from elevated cortisol levels, hypophosphatemia from tissue catabolism, and decreased serum magnesium levels.
- ***Hyperbilirubinemia.*** This condition may be seen at 48 to 72 hours after birth. It may be caused by slightly decreased extracellular fluid volume, which increases the hematocrit level. This elevation facilitates an increase in red blood cell breakdown, thereby increasing bilirubin levels. The presence of hepatic immaturity may impair bilirubin conjugation. Enclosed cranial hemorrhages resulting from a complicated vaginal birth may also contribute to hyperbilirubinemia.
- ***Birth trauma.*** Because most IDMs are macrosomic, trauma may occur during labor and vaginal birth resulting in shoulder dystocia, brachial plexus injuries, subdural hemorrhage, cephalhematoma, and asphyxia.
- ***Polycythemia.*** Fetal hyperglycemia and hyperinsulinism result in increased oxygen consumption, which can lead to fetal hypoxia (Armentrout, 2010). Hemoglobin A_{1c} binds to oxygen, decreasing the oxygen available to the fetal tissues. This tissue hypoxia stimulates increased erythropoietin production, which increases both the hematocrit level and the potential for hyperbilirubinemia. See chapter 19 ∞ for discussion of hemoglobin A_{1c}.
- ***Respiratory distress syndrome (RDS).*** This complication occurs more frequently in newborns of White's classes A through C diabetic mothers who are not well controlled (Cloherty et al., 2008). Insulin antagonizes the cortisol-induced stimulation of lecithin synthesis that is necessary for lung maturation. Thus IDMs may have lungs that are less mature than expected for their gestational age. There is also a decrease in the phospholipid phosphatidylglycerol (PG), which stabilizes surfactant. The insufficiency of PG increases the incidence of RDS. Therefore, it is important to test for fetal lung maturity, or the presence of PG, in the amniotic fluid before birth.

  Transient tachypnea of the newborn, commonly known as "wet lung" syndrome due to retained fetal lung fluid, may also occur in the IDM especially after an elective cesarean delivery. There is a delay in reabsorption of fetal lung fluid from the pulmonary lymphatic system causing a decrease in lung compliance resulting in tachypnea, grunting, and retractions, resolving in 3 to 5 days.

  RDS does not appear to be problematic for infants born to diabetic mothers in White's classes D through F; instead, the stresses of poor uterine blood supply may lead to increased production of steroids, which stimulates lung maturation. IDMs may also have a delay in closure of the ductus arteriosus and an increase in pulmonary vascular resistance (Cloherty et al., 2008; Moore & Catalano, 2009).
- ***Congenital malformations.*** These can include transposition of the great vessels, ventricular septal defect, left or right ventricular wall hypertrophy, small left colon syndrome, intestinal atresia, hydronephrosis, cystic kidneys, and sacral agenesis (caudal regression) (Cloherty et al., 2008). Early careful regulation of maternal glucose before and during pregnancy, especially during the first trimester, decreases the risk of birth defects. See chapter 19 ∞.

Clinical Therapy

Prenatal management is directed toward controlling maternal glucose levels, which minimizes the common complications of IDMs. Because the onset of hypoglycemia occurs within 1 and 2 hours following birth in IDMs (with a spontaneous rise to normal levels by 4 to 6 hours), blood glucose determinations should be performed on capillary or venous blood samples hourly during the first 4 hours after birth and at 4-hour intervals until the risk period (about 48 hours) has passed or per agency protocol.

IDMs whose serum glucose falls below 45 mg/dl should have early feedings with formula or breast milk (colostrum). If normal glucose levels cannot be maintained with oral feeding, an intravenous (IV) infusion of glucose will be necessary. An infusion of D10W at a rate of 6 to 8 mg/kg/min usually maintains normoglycemia in the IDM. If higher glucose concentrations (greater than 12.5%) are needed to maintain normal serum glucose levels, a central line will need to be placed to minimize tissue extravasation. Once the blood glucose has been stable for 24 hours, the infusion rate can be decreased as oral feedings are increased. The newborn's blood glucose levels must be carefully monitored. Repeated dextrose as a bolus infusion is contraindicated because it may lead to severe rebound hypoglycemia following an initial brief increase in glucose level. Newborns with refractory hypoglycemia will need an endocrinology workup and the administration of IV corticosteroids may be indicated.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse should not be lulled into thinking that a big baby is a mature baby. In almost every case, because of the infant's large size, the IDM will appear older than gestational age scoring indicates. The nurse must consider both the gestational age and whether the baby is appropriate-for-gestational-age (AGA) or LGA in planning and providing safe care. In caring for the IDM, the nurse assesses for signs of respiratory distress, hyperbilirubinemia, birth trauma, and congenital anomalies.

Nursing diagnoses that may apply to IDMs include the following:

- ***Imbalanced Nutrition: Less Than Body Requirements*** related to increased glucose metabolism secondary to hyperinsulinemia
- ***Impaired Gas Exchange*** related to respiratory distress secondary to delayed production of pulmonary surfactant
- ***Imbalance in Calcium Homeostasis*** related to inappropriate parathyroid response
- ***Ineffective Peripheral Tissue Perfusion*** secondary to polycythemia related to increased synthesis of erythropoietin, chronic intrauterine hypoxia, and increased metabolic rate
- ***Compromised Family Coping*** related to the illness of the baby

Nursing Plan and Implementation

Nursing care of the IDM is directed toward early detection and ongoing monitoring of hypoglycemia (by performing glucose tests) and polycythemia (by obtaining central hematocrits), respiratory distress, and hyperbilirubinemia. (These conditions are presented in chapter 34 ∞.) The nurse also assesses for signs of birth trauma and congenital anomalies.

Parent teaching is directed toward preventing macrosomia and the resulting fetal-newborn problems and instituting early and ongoing diabetic control. Parents are advised that with early identification and care, most IDMs' complications have no significant sequelae.

Evaluation

Expected outcomes of nursing care include the following:

- The IDM's respiratory and metabolic alteration problems are minimized.
- The parents understand the etiology of the baby's health problems and preventive steps they can initiate to decrease the impact of maternal diabetes on subsequent pregnancies.
- The parents verbalize their concerns surrounding their baby's health problems and understand the rationale behind management of their newborn.

Care of the Postterm Newborn

The **postterm newborn** is any newborn born after 42 weeks' gestation. Postterm or prolonged pregnancy occurs in approximately 4% to 14% of all pregnancies (Resnik & Resnik, 2009). The cause of most postterm pregnancies is not completely understood, but several factors are known to be associated with it (see chapter 27 ∞ for a discussion of maternal factors). Many pregnancies classified as prolonged are thought to be a result of inaccurate determination of the estimated date of birth (EDB). Postterm pregnancy is more common in Greek and Italian ethnic groups and the aboriginal people of Australia.

Most babies born as a result of prolonged pregnancy are of normal size and health; some keep on growing and are over 4000 g at birth, which supports the contention that the postterm fetus can remain well nourished. Potential intrapartal problems for these healthy but large fetuses include cephalopelvic disproportion (CPD) and shoulder dystocia. See chapter 27 ∞ for discussion of the necessary assessments and interventions for CPD and shoulder dystocia.

Common Complications of the Newborn with Postmaturity Syndrome

The term **postmaturity** applies only to the infant who is born after 42 completed weeks of gestation and also demonstrates characteristics of *postmaturity syndrome*. Only about 5% of postterm newborns show signs of postmaturity syndrome.

The truly postmature newborn is at high risk for morbidity and has a mortality rate two to three times higher than that of term infants. Although today the percentages are extremely low, the majority of postmature fetal deaths occur during labor, because the fetus has used up necessary body reserves.

Decreased placental function, which impairs nutrition transport and oxygenation, leaves the fetus prone to hypoglycemia and hypoxemia when the stresses of labor begin. The following are common disorders of the postmature newborn:

- Hypoglycemia from nutritional deprivation resulting in depleted glycogen stores.
- Meconium aspiration in response to in utero hypoxia. Oligohydramnios increases the danger of aspirating thick meconium. Severe meconium aspiration syndrome increases the baby's chance of developing persistent pulmonary hypertension, pneumothorax, and pneumonia.
- Polycythemia due to increased production of red blood cells (RBCs) in response to hypoxia.
- Congenital anomalies of unknown cause.
- Seizures due to hypoxic insult.
- Cold stress due to loss or poor development of subcutaneous fat.

The long-term effects of postmaturity syndrome are unclear. At present, studies do not agree on the effect of postmaturity syndrome on weight gain and IQ scores (Resnik & Resnik, 2009).

Prolonged pregnancy by itself is not responsible for the postmaturity syndrome. The characteristics of the postmature newborn are caused primarily by a combination of placental aging and subsequent insufficiency and continued exposure to amniotic fluid.

Clinical Therapy

The aim of antenatal management is to differentiate the fetus that has postmaturity syndrome from the fetus who is large, well

nourished, and active and who is tolerating the prolonged (postterm) pregnancy. Antenatal tests that can be done to evaluate fetal status and determine obstetric management are discussed in more depth in chapter 21 ∞ and chapter 27 ∞. If the amniotic fluid is meconium stained, an amnioinfusion may be done during labor. This procedure dilutes the meconium by directly infusing either normal saline or Ringer's lactate into the uterus, minimizing the risk of meconium aspiration syndrome. (For detailed discussion of clinical management and care of the newborn at risk for meconium aspiration, see chapter 34 ∞.)

Hypoglycemia is monitored by serial glucose determinations as per agency hospital protocols. The baby may be placed on glucose infusions or given early feedings if respiratory distress is not present, but these measures must be instituted with caution because of the frequency of asphyxia in the first 24 hours. Postmature newborns are often voracious eaters.

For the small-for-gestational-age (SGA) infant who is postmature, peripheral and central hematocrits are tested to determine the presence of polycythemia. Fluid resuscitation can be initiated. In extreme cases a partial exchange transfusion may be necessary to manage polycythemia and adverse sequelae such as hyperviscosity. Oxygen is provided for respiratory distress. In addition, decreased liver glycogen stores can cause temperature instability and excessive loss of body heat. See chapter 31 ∞ for thermoregulation techniques.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The newborn with postmaturity syndrome appears alert. This wide-eyed, alert appearance is not necessarily a positive sign because it may indicate chronic intrauterine hypoxia. The infant has dry, cracking, parchmentlike skin without vernix or lanugo (Figure 33-5 ■). Fingernails are long, and scalp hair is profuse. The infant's body appears long and thin. The wasting involves depletion of previously stored subcutaneous tissue, causing the skin to be loose. Fat layers are almost nonexistent.

Figure 33-5 ■ The skin of the postterm infant exhibits deep cracking and peeling.

Source: Dubowitz, L., & Dubowitz, V. (1977). The gestational age of the newborn. *Menlo Park, CA: Addison-Wesley. Reprinted by permission of V. Dubowitz, MD, Hammersmith Hospital, London, England.*

Postmature newborns frequently have meconium staining, which colors the nails, skin, and umbilical cord. The varying shades (yellow to green) of meconium staining can give some clue about whether the expulsion of meconium was a recent or a chronic problem; green coloring indicates a more recent event.

Nursing diagnoses that may apply to the postmature newborn include the following:

- ***Hypothermia*** related to decreased liver glycogen and brown fat stores
- ***Imbalanced Nutrition: Less Than Body Requirements*** related to increased use of glucose secondary to stress in utero and decreased placental perfusion
- ***Impaired Gas Exchange*** related to airway obstruction from meconium aspiration
- ***Ineffective Peripheral Tissue Perfusion*** related to polycythemic hyperviscosity

Nursing Plan and Implementation

Hospital-Based Nursing Care

Nursing interventions are primarily supportive measures. They include the following:

- Monitor cardiopulmonary status because the stresses of labor are poorly tolerated and can result in hypoxemia in utero and possible asphyxia at birth.
- Provide warmth via an external heat source to counterbalance the infant's poor response to cold stress and decreased liver glycogen and brown fat stores.
- Frequently monitor blood glucose and initiate early feeding (at 1 or 2 hours of age) or intravenous (IV) glucose per physician/neonatal nurse practitioner (NNP) order.
- Obtain a central hematocrit to determine accurately the presence of polycythemia.

The nurse encourages parents to express their feelings and fears regarding the newborn's condition and potential long-term problems. The nurse also gives careful explanations of procedures, includes the parents in developing care plans for their baby, and encourages follow-up care as needed.

Case Study: Infant with Postmaturity Syndrome

Evaluation

Expected outcomes of nursing care include the following:

- The postterm newborn establishes effective respiratory function.
- The postmature baby is free of metabolic alterations (hypoglycemia) and maintains a stable temperature.

Care of the Preterm (Premature) Newborn

A **preterm infant** is an infant born through 37 completed weeks' gestation (Gardner & Hernandez, 2011) (Figure 33-6 ■). With the help of modern technology, infants are surviving at younger gestational ages but not without significant morbidity. The incidence

Figure 33-6 ■ A 6-day-old, 28 weeks' gestational age, 960-g preterm infant.

Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.

of all preterm births in the United States is approximately 12%. In addition, 18% of African American newborns are preterm (Vargo & Trotter, 2007). The rise in multiple birthrates has markedly influenced overall rates of low-birth-weight (LBW) infants. Prematurity and LBW are common in single women and adolescents. (See chapter 20 ∞ for a discussion of preterm labor.)

The major problem of the preterm newborn is variable immaturity of all systems, the degree of which depends on the length of gestation. The preterm newborn must traverse the same complex, interconnected pathways from intrauterine to extrauterine life as the term newborn. Immaturity means the premature newborn is ill equipped to make this transition smoothly.

Alteration in Respiratory and Cardiovascular Physiology

The preterm newborn is at risk for respiratory problems because the lungs are not fully mature and not fully ready to take over the process of oxygen and carbon dioxide exchange until 37 to 38 weeks' gestation. Critical factors in the development of respiratory distress syndrome (RDS) include the following:

1. The preterm infant is unable to produce adequate amounts of surfactant. (See chapter 29 ∞ for a discussion of respiratory adaptation and development.) Inadequate surfactant lessens compliance (ability of the lungs to fill with air easily), thereby increasing the inspiratory pressure needed to expand each alveoli with air. This progressive atelectasis leads to an inability to develop a functional residual capacity (FRC) causing an ineffective exchange of oxygen and carbon dioxide. As a result, the infant becomes hypoxic, pulmonary blood flow is inefficient, and the preterm newborn's available energy is depleted.
2. The muscular coat of the pulmonary blood vessels is incompletely developed. Consequently the pulmonary arterioles do not constrict as well in response to decreased oxygen levels. This lowered pulmonary vascular resistance leads to increased left-to-right shunting through the ductus arteriosus, which increases the blood flow back into the lungs.
3. Normally the ductus arteriosus responds to increasing oxygen and prostaglandin E levels by vasoconstriction; in the preterm infant, who has higher susceptibility to hypoxia, the ductus may remain open. A patent ductus increases the blood volume to the lungs, causing pulmonary congestion, increased respiratory effort, carbon dioxide retention, and bounding femoral pulses.

The common complications of the cardiopulmonary system in preterm infants are discussed later in the chapter and in chapter 34 ∞.

Alteration in Thermoregulation

Heat loss is a major problem in preterm newborns that the nurse can do much to prevent. Two limiting factors in heat production, however, are the availability of glycogen in the liver and the amount of brown fat available for heat production. Both of these limiting factors appear in the third trimester. In the cold-stressed newborn, norepinephrine is released, which in turn stimulates the metabolism of brown fat for heat production. As a complicating factor, the hypoxic newborn cannot increase oxygen consumption in response to cold stress because of the already limited reserves and thereby becomes progressively colder. Because the muscle mass is small in preterm infants and voluntary muscular activity is diminished (they are unable to shiver), heat production is further limited.

Five physiologic and anatomic factors increase heat loss in the preterm infant:

1. The preterm baby has a high ratio of body surface to body weight. This means that the baby's ability to produce heat (based on body weight) is much less than the potential for losing heat (based on surface area). The loss of heat in a preterm infant weighing 1500 g is five times greater per unit of body weight than in an adult.
2. The preterm baby has very little subcutaneous fat, which is the human body's insulation. Without adequate insulation, heat is easily conducted from the core of the body (warmer temperature) to the surface of the body (cooler temperature). Heat is lost from the body as the blood vessels, which lie close to the skin surface in the preterm infant, transport blood from the body core to the subcutaneous tissues.
3. The preterm baby has thinner, more permeable skin than the term infant. This increased permeability contributes to a greater insensible water loss as well as heat loss.
4. The posture of the preterm baby influences heat loss. Flexion of the extremities decreases the amount of surface area exposed to the environment. Extension increases the surface area exposed to the environment and thus increases heat loss. The gestational age of the infant influences the amount of flexion, from completely hypotonic and extended at 28 weeks to strong flexion displayed by 36 weeks.
5. The preterm baby has a decreased ability to vasoconstrict superficial blood vessels and conserve heat in the body core.

In summary, gestational age is directly proportional to the ability to maintain thermoregulation; thus the more preterm the newborn, the less the infant is able to maintain heat balance.

Preventing heat loss by providing a neutral thermal environment (NTE) using a servo control skin probe is one of the most important considerations in nursing management of the preterm infant. Cold stress, with its accompanying severe complications, can be prevented (see chapter 34 ∞).

Alteration in Gastrointestinal Physiology

The basic structure of the gastrointestinal (GI) tract is formed early in gestation. Maturation of the digestive and absorptive processes is more variable, however, and occurs later in gestation. As a result of GI immaturity, the preterm newborn has the following ingestion, digestion, and absorption problems:

- A marked danger of aspiration and its associated complications due to the infant's poorly developed gag reflex, incompetent esophageal cardiac sphincter, and poor sucking and swallowing reflexes.
- Difficulty in meeting high caloric and fluid needs for growth due to small stomach capacity.
- Limited ability to convert certain essential amino acids to nonessential amino acids. Certain amino acids, such as histidine, taurine, and cysteine, are essential to the preterm infant but not to the term infant.
- Inability to handle the increased osmolarity of formula protein due to kidney immaturity. The preterm infant requires a higher concentration of whey protein than casein.
- Difficulty absorbing saturated fats due to decreased bile salts and pancreatic lipase. Severe illness of the newborn may also prevent intake of adequate nutrients.
- Difficulty with lactose digestion initially because processes may not be fully functional during the first few days of a preterm infant's life. The preterm newborn can digest and absorb most simple sugars.
- Deficiency of calcium and phosphorus may exist because two thirds of these minerals are deposited in the last trimester. Rickets and significant bone demineralization due to deficiency of calcium and phosphorus, which are deposited primarily in the last trimester, are also problems.
- Increased basal metabolic rate and increased oxygen requirements due to fatigue associated with sucking.
- Feeding intolerance and necrotizing enterocolitis (NEC) due to diminished blood flow and tissue perfusion to the intestinal tract due to a combination of contributing factors including prematurity, formula feeding, bacterial colonization, and hypoxemia/ischemic events.

Alteration in Renal Physiology

The kidneys of the preterm infant are immature in comparison with those of the full-term infant, which poses clinical problems in the management of fluid and electrolyte balance. Specific characteristics of the preterm infant include the following:

- The glomerular filtration rate (GFR) is lower because of low renal blood flow. The GFR is directly related to lower gestational age, so the more preterm the newborn, the lower the GFR, which increases steadily after 34 weeks post-conceptional age (PCA). The GFR is also decreased in the presence of diseases or conditions that decrease renal blood flow and perfusion, such as severe respiratory distress, hypotension (low blood pressure [BP]), and asphyxia. Anuria or oliguria may also be observed. A low systolic blood pressure can reflect any disease that decreases cardiac output and affect renal blood flow. Systolic blood pressure varies with gestational age and post-conceptual age. (See Table 33-1 Systolic Blood Pressure Guidelines.)

CLINICAL TIP

A gradual decline in urine output may be associated with a drop in the baby's blood pressure.

TABLE 33-1 Systolic Blood Pressure Guidelines

Day of Life #1			Post-Conceptual Age		
GESTATIONAL AGE	RANGE SYSTOLIC BP	AVERAGE SYSTOLIC BP	WEEKS	RANGE SYSTOLIC BP	AVERAGE SYSTOLIC BP
23	23–55	39	24	35–67	48
24	26–58	42	26	38–70	52
26	29–61	45	28	41–73	56
28	32–65	48	30	45–77	60

- The preterm infant's kidneys are limited in their ability to concentrate urine or to excrete excess amounts of fluid, due to a blunted response to antidiuretic hormone (ADH). This means that if excess fluid is administered, the infant is at risk for fluid retention and overhydration. If too little is administered, the infant will become dehydrated because of the inability to retain adequate fluid.
- The preterm kidneys begin excreting glucose at a lower serum glucose level than those of the term infant. Therefore, glycosuria with hyperglycemia can lead to osmotic diuresis and polyuria.
- The kidney's buffering capacity is reduced, predisposing the infant to metabolic acidosis. Bicarbonate is excreted at a lower serum level, and acid is excreted more slowly. Therefore, after periods of hypoxia or insult, the preterm infant's kidneys require a longer time to excrete the lactic acid that accumulates. Sodium bicarbonate is frequently required to treat the metabolic acidosis.
- The immaturity of the renal system affects the preterm infant's ability to excrete drugs. Because excretion time is longer, many drugs are given over longer intervals (for example, every 24 hours instead of every 12 hours). Urine output must be carefully monitored when the infant is receiving nephrotoxic drugs, such as gentamicin and vancomycin. In the event of oliguria, drugs can become toxic in the infant much more quickly than in the adult.

Alteration in Hepatic and Hematologic Physiology

Immaturity of the preterm newborn's liver predisposes the infant to several problems. After birth, the glycogen stores in the liver are rapidly used for energy. Glycogen deposits are affected by asphyxia in utero and after birth by both asphyxia and cold stress. The baby born preterm has decreased glycogen stores at birth and frequently experiences stress, which rapidly uses up these limited stores. Therefore, the preterm newborn is at high risk for hypoglycemia and its complications.

Iron is also stored in the liver, especially during the last trimester of pregnancy. Therefore, the preterm newborn is born with low iron stores. If subject to hemorrhage, rapid growth, and excess blood sampling, the preterm infant is likely to become iron depleted more quickly than the term infant. Many preterm babies require transfusions of packed cells to treat symptomatic anemia as a consequence of frequent blood sampling. As the premature infant grows and convalesces, oral iron supplementation may be started, as well as doses of erythropoietin, to enhance red blood cell (RBC) production.

Conjugation of bilirubin in the liver is impaired in the preterm infant. Thus bilirubin levels increase more rapidly and to a higher level than in the full-term infant. Early clinical assessment of jaundice associated with indirect hyperbilirubinemia is more difficult in preterm newborns because they lack subcutaneous fat. (For a further discussion of the newborn with jaundice, see "Pathophysiology of Hyperbilirubinemia" in chapter 34 ∞.)

The normal cord hemoglobin in an infant of 34 weeks' gestation is approximately 16.8 g/dl, and total blood volume ranges from 80 ml/kg to 100 ml/kg (Blackburn, 2007). Because of the small total blood volume, any blood loss is highly significant to the preterm infant. Therefore, periodic assessments of hemoglobin values are performed during the first weeks of life.

Alteration in Immunologic Physiology

Prematurity is the single most significant factor associated with the incidence of sepsis, thus placing the preterm infant at greater risk for infection and bacteria than the term infant. This increased susceptibility may be the result of an infection acquired in utero that may have precipitated preterm labor and birth. Pathogens also may be acquired during the birth process. However, all preterm infants have immature specific and nonspecific immunity.

In utero the fetus receives passive immunity against a variety of infections from maternal IgG immunoglobulins, which cross the placenta (see chapter 29 ∞). Because most of this immunity is acquired in the last trimester of pregnancy, the preterm infant has few antibodies at birth. These provide less protection and become depleted earlier than in a full-term infant. This may be a contributing factor in the higher incidence of recurrent bacterial infection during the first year of life as well as in the immediate neonatal period.

The other immunoglobulin significant for the preterm infant is secretory IgA, which does not cross the placenta but is found in breast milk in significant concentrations. Breast milk's secretory IgA provides immunity to the mucosal surfaces of the GI tract, protecting the newborn from enteric infections such as those caused by *Escherichia coli* and *Shigella.*

Another altered defense against infection in the preterm infant is the skin surface. In very small infants the skin is easily excoriated, and this factor, coupled with many invasive procedures, places the infant at great risk for nosocomial infections. It is vital to use good hand washing techniques in the care of these infants to prevent unnecessary infection.

CLINICAL TIP

The sudden onset of apnea and bradycardia, coupled with metabolic acidosis in an otherwise healthy, growing premature infant, may be suggestive of bacterial sepsis, especially if there is a central line present.

Alteration in Neurologic Physiology

The general shape of the brain is formed during the first 6 weeks of gestation. Between the second and fourth months of gestation the brain's total complement of neurons proliferate; these neurons migrate to specific sites throughout the central nervous system (CNS), and nerve impulse pathways organize. The final step in neurologic development is the covering of these nerves with myelin, which begins in the second trimester of gestation and continues into adult life (Volpe, 2008).

Because the period of most rapid brain growth and development occurs during the third trimester of pregnancy, the closer to term an infant is born, the better the neurologic prognosis. A common interruption of neurologic development in the preterm infant is caused by intraventricular hemorrhage (IVH) and in-

tracranial hemorrhage (ICH). Hydrocephalus may develop as a consequence of an IVH due to the obstruction at the cerebral aqueduct (Volpe, 2008).

Alteration in Reactivity Periods and Behavioral States

The newborn infant's response to extrauterine life is characterized by two periods of reactivity, as discussed in chapter 31 ∞. The preterm infant's periods of reactivity are delayed. In the very ill infant, these periods of reactivity may not be observed at all because the infant may be hypotonic and unreactive for several days after birth.

As the preterm newborn grows and the condition stabilizes, identifying behavioral states and traits unique to each infant becomes increasingly possible. In general, stable preterm infants do not demonstrate the same behavioral states as term infants. Preterm infants are more disorganized in their sleep-wake cycles and are unable to attend as well to the human face and objects in the environment. Neurologically, their responses (sucking, muscle tone, states of arousal) are weaker than full-term infants' responses.

By observing each infant's patterns of behavior and responses, especially the sleep-wake states, the parents and nurse can plan nursing care around the times when the infant is alert and best able to attend. The more knowledge parents have about the meaning of their infant's responses and behaviors, the better prepared they will be to meet their newborn's needs and to form a positive attachment with their child. See discussion of developmental care for the preterm newborn later in this section.

CLINICAL TIP

After observing an infant's pattern of behavior and responses, especially the sleep-wake states, use the time when the infant is alert and best able to attend to help parents learn about and provide newborn care and form a positive attachment with their child.

Management of Nutrition and Fluid Requirements

Early feedings are extremely valuable in maintaining normal metabolism and lowering the possibility of such complications as hypoglycemia, hyperbilirubinemia, hyperkalemia, and osteopenia of prematurity. However, the preterm newborn is at risk for complications that may develop because of the immaturity of the digestive system.

Nutritional Requirements

Oral (enteral) caloric intake necessary for growth in an uncompromised healthy preterm infant is 95 to 130 kcal/kg/day (Blackburn, 2007). In addition to these relatively high caloric needs, the preterm infant requires more protein than full-term infants. To meet these needs, many institutions use fortified breast milk or special preterm formulas.

Whether breast milk or formula is used, feeding regimens are established based on the infant's weight and estimated stomach capacity (Table 33-2). Initial formula-feedings are gradually increased as the infant tolerates them. It may be necessary to supplement the oral feedings with parenteral fluids to maintain adequate hydration and caloric intake until the baby is on full oral feedings. Those preterm infants who cannot tolerate any oral (enteral) feedings are given nutrition by total parenteral nutrition (TPN).

In addition to a higher calorie and higher protein formula, preterm infants should receive supplemental multivitamins, which include vitamins A, D, and E, iron, and trace minerals. A diet high in polyunsaturated fats (which preterm infants tolerate best) increases the requirement for vitamin E. Preterm infants fed iron-fortified formulas have higher red cell hemolysis and lower vitamin E concentrations and thus require additional vitamin E. Preterm formulas also need to contain medium-chain triglycerides (MCT) and additional amino acids such as cysteine, as well as calcium, phosphorus, and vitamin D supplements to increase mineralization of bones. Rickets and significant bone

TABLE 33-2 Neonatal Feeding Initiation and Advancement Practice Guidelines

BIRTH WEIGHT	FEEDING TYPE	SCHEDULE	INITIAL FEEDING RATE (ML/KG/DAY)	RATE OF ADVANCEMENT (ML/KG/DAY)	GOAL RATE (ML/KG/DAY)
750 g	EBM/PF24	q3h	10*	20	150–160
750–1000 g	EBM/PF24	q3h	10*	20	150–160
1001–1250 g	EBM/PF24	q3h	10*	20	150–160
1251–1500 g	EBM/PF24	q3h	20	20	150–160
1501–1800 g	EBM/PF24	q3h	30	30	150–160
1801–2500 g	EBM/PD22	q3h	40	40	180
>2500 g	EBM/T20	q3h	50	50	180

Note: Feeding Type key:

EBM: expressed breast milk
PD22: post-discharge formula 22 kcal/oz
PF24: premature formula 24 kcal/oz
T20: term formula 20 kcal/oz

*Continue trophic feedings of 10 ml/kg/day × 3–5 days before advancing

Source: Courtesy of NICU, Cardon Children's Hospital at Banner Desert Medical Center, Mesa, AZ, 2008.

demineralization have been documented in very-low-birth-weight infants and otherwise healthy preterm infants.

Nutritional intake is considered adequate when there is consistent weight gain of 20 to 30 g per day. Initially, no weight gain may be noted for several days, but total weight loss should not exceed 15% of the total birth weight or more than 1% to 2% per day. Some institutions add the criteria of head circumference growth and increase in body length of 1 cm (0.4 in.) per week once the newborn is stable.

Methods of Feeding

The preterm infant is fed by various methods, depending on the infant's gestational age, health and physical condition, and neurologic status. The three most common oral feeding methods are bottle, breast, and gavage.

BOTTLE-FEEDING Preterm infants who have a coordinated as well as rhythmic suck-swallow-breathing pattern are usually between 33 and 34 weeks' postconceptual age and may be fed by bottle. Oral readiness to feed is best described by the following behaviors: remaining engaged in the feeding, able to organize oral-motor functioning, to coordinate the suck-swallow-breath skill, and to maintain physiologic stability (Thomas, 2007). Those premature infants who root when their cheek is stroked and actively search for the nipple are neurodevelopmentally ready to initiate oral feeding. To avoid excessive expenditure of energy, a soft, yellow, single-hole nipple is usually used (milk flow is less rapid). The infant is fed in a semisitting position and burped gently after each half ounce or ounce. The feeding should take no longer than 15 to 20 minutes (nippling requires more energy than other methods). Preterm infants who are progressing from gavage feedings to bottle-feeding should be assessed for feeding readiness and started with one session of bottle-feeding a day. The number of times a day a bottle is offered should be increased slowly until the baby tolerates all feedings from a bottle.

The nurse assesses the infant's ability to suck. Sucking may be affected by postconceptional age, asphyxia, chronic lung disease, intraventricular hemorrhage, or other neurologic insult. Before initiating nipple feeding, the nurse observes the infant for any signs of stress, such as tachypnea (more than 60 respirations per minute), respiratory distress, or hypothermia, which may increase the risk of aspiration. During the feeding, the infant should be observed for signs of difficulty with feeding (tachypnea, a decrease in oxygen saturation levels, bradycardia, lethargy, and uncoordinated suck and swallow). Difficulty in bottle-feeding is often associated with a milk bolus that is too large for the infant's oral cavity, which can lead to aspiration. Demand feeding protocols, based on the infant's hunger cues, should be considered for a growing premature infant only when there is sufficient caloric intake to promote consistent weight gain (Kenner & Lott, 2007).

BREASTFEEDING Mothers who wish to breastfeed their preterm infants should be given the opportunity to put the infant to breast as soon as the infant has demonstrated a coordinated suck and swallow reflex, is showing consistent weight gain, and can control body temperature outside of the incubator, regardless of weight. Preterm infants tolerate breastfeeding with higher transcutaneous oxygen pressures and better maintenance of body temperature than during bottle-feeding. Besides breast milk's many benefits for the infant, it allows the mother to contribute actively to the infant's well-being (Figure 33-7 ■). Mothers should be encouraged to breastfeed if they choose to do so. It is important for the nurse to be aware of the advantages of breastfeeding as well as the possible disadvantages if breast milk is the sole source of food for the preterm infant. See chapter 32 ∞ for a detailed discussion of the advantages and disadvantages of breastfeeding and the contraindications.

Figure 33-7 ■ Mother breastfeeding her premature infant.
Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.

By initiating skin-to-skin holding of LBW infants in the early intensive care phase, mothers can significantly increase milk volume, thereby overcoming lactation problems (Turnage-Carrier, 2010).

Many mothers of preterm infants seem to find that the football hold (see Figure 32-7 ∞ on page 870) is a convenient position for breastfeeding preterm babies. Feeding time may take up to 45 minutes, and babies should be burped as they alternate breasts. Length of feeding time must be monitored so that the preterm infant does not expend too many calories.

The nurse should coordinate a flexible feeding schedule so babies can breastfeed during alert times and be allowed to set their own pace. Feedings should be on demand, but a maximum number of hours between feedings should be set. A similar regimen should be used for the baby who is progressing from gavage feeding to breastfeeding. The mother begins with one feeding at the breast and then gradually increases the number of times during the day that the baby breastfeeds. Even if the infant cannot be put to the breast, mothers can pump their breasts, and the breast milk can be given via gavage. A double-pumping system produces higher levels of prolactin than sequential pumping of the breasts (see Figure 32-20 ∞ on page 878). When breastfeeding is not possible because the infant is too small or too weak to suck at the breast,

an option for the mother may be to express her breast milk into a cup. The milk touches the infant's lips and is lapped by the protruding motions of the tongue.

GAVAGE FEEDING The tube or gavage feeding method is used with preterm infants (less than 34 weeks' gestation) who lack or have a poorly coordinated suck-swallow-breathing pattern or are ill and ventilator dependent. Gavage feeding may be used as an adjunct to nipple feeding if the infant tires easily or as an alternative if an infant is losing weight because of the energy expenditure required for nippling, which increases the chance of aspiration. See Procedure 33-1: Performing Gavage Feeding on pages 908–909. Gavage feedings are administered by either the nasogastric or orogastric route and by intermittent bolus or continuous drip method. Currently, there are no conclusive studies supporting one method over the other. In common practice, bolus feedings are usually initiated, but if intolerance occurs, then the feedings are changed to infuse on a pump over a set amount of time (i.e., over an hour) or continuously (Anderson, Wood, Keller, et al., 2011).

Early initiation of minimal enteral nutrition (MEN) via gavage is now advocated in the preterm newborn as a supplement to parenteral nutrition. MEN refers to small-volume feedings of formula or human milk (usually less than 24 ml/kg/day) which are designed to "prime" the intestinal tract, thereby stimulating many of its hormonal and enzymatic functions (American Academy of Pediatrics (AAP) & American College of Obstetricians and Gynecologists (ACOG), 2007). Benefits of early feedings (as early as 24 to 72 hours of life) include the following: no increase in the incidence of necrotizing enterocolitis; fewer days on TPN, thereby decreasing the incidence of cholestatic jaundice; increased weight gain; increased muscle maturation of the gut as well as muscle growth; increase in gut peristalsis; increased gut hormone levels, which can lead to improved feeding tolerance; lower risk of osteopenia; and a possible decrease in the total number of hospital days in the neonatal intensive care unit (NICU).

CLINICAL TIP

Persistent bilious residuals >20% of the feeding and bloody stools may be a cardinal sign of necrotizing enterocolitis (NEC) at which time an x-ray of the abdomen should be obtained.

TOTAL PARENTERAL NUTRITION (TPN) TPN is used in situations when feeding is contraindicated through the GI tract. Contraindications include GI anomalies requiring surgical intervention, NEC, intolerance of feedings, sepsis, and birth depression. TPN may also be used in adjunct with enteral feedings during the early stages of feeding advancement.

The TPN method provides complete nutrition for metabolic requirements and growth to the infant intravenously. TPN includes use of hyperalimentation and intralipids. Hyperalimentation provides vitamins, minerals, protein (in the form of amino acids), and glucose. Appropriate amino acid intake (1 to 4 g/kg/day) is necessary to avoid catabolism and maintain the newborn in a positive-nitrogen balance, and it can be initiated on the first day of life. A percutaneous central venous catheter (PCVC/PICC) is often used with the LBW infant to deliver higher concentrations of glucose (greater than D12.5) as well as to provide an energy substrate. Intralipids (1 to 3 g/kg/day) are also administered to provide essential fatty acids for normal body growth and development.

The nurse needs to monitor serum glucose levels and serum chemistries carefully during the infusion of TPN. The IV rate is monitored hourly to maintain accurate intake. The rate should not be increased to "catch up" if administration lags behind. The IV site should be observed hourly for signs of infiltration—hyperalimentation is extremely caustic and causes severe tissue destruction if it infiltrates. Intake and output are carefully monitored (hyperglycemia causing an osmotic diuresis can lead to dehydration). If hyperglycemia occurs, continuous insulin infusions may be initiated to enhance glucose uptake and utilization. Prolonged administration of TPN combined with little to no enteral intake can result in cholestatic jaundice. Monitoring liver enzymes as well as fractionated bilirubin levels is essential in long-term TPN use. The nurse needs to be aware of the potential complications associated with intralipid infusions, including increased free bilirubin concentrations, impaired pulmonary functions, and interference with platelet function. Therefore, serum triglyceride levels need to be followed. Daily lipid infusion should be spread out over a 24-hour period.

Fluid Requirements

The calculation of fluid requirements takes into account the infant's weight and postnatal age. Recommendations for fluid therapy in the preterm infant are approximately 80 to 100 ml/kg/day for day 1, 100 to 120 ml/kg/day for day 2, and 120 to 150 ml/kg/day by day 3 of life. These amounts may be increased up to 200 ml/kg/day if the infant is extremely premature, receiving phototherapy, or under a radiant warmer facilitating an increase in insensible water losses. If the infant is not hydrated properly, excessive insensible water loss can lead to hypernatremia, hyperkalemia, hypovolemia, hypotension, and oliguria. Fluid losses can be minimized through the use of heat shields and added humidification in the incubator. Daily weights, and sometimes twice-a-day weights, are the best indicator of fluid status in the preterm infant. The expected weight loss during the first 3 to 5 days of life in a preterm infant is 15% to 20% of birth weight.

Common Complications of Preterm Newborns and Their Clinical Management

The goals of medical and nursing care are to meet the growth and development needs of the preterm newborn and to anticipate and manage the complications associated with prematurity. Complications associated with prematurity that require clinical intervention are respiratory distress syndrome (RDS), patent ductus arteriosus (PDA), apnea, pulmonary interstitial emphysema (PIE), intraventricular hemorrhage, and sepsis. Long-term problems include retinopathy of prematurity, bronchopulmonary dysplasia (BPD) leading to chronic lung disease (CLD), and posthemorrhagic hydrocephalus.

PROCEDURE 33-1 Performing Gavage Feeding

NURSING ACTION

Preparation

- When choosing the catheter size, consider the size of the infant, the area of insertion (oral or nasal), and the desired rate of flow.

  Rationale: *The size of the catheter will influence the rate of flow.*
- Explain the procedure to the parents.
- Elevate the head of the bed and position the infant on the back or side to allow easy passage of the tube.
- Measure the distance from the tip of the ear to the nose to the xiphoid process, and mark the point with a small piece of paper tape (Figure 33-8 ■) to ensure enough tubing to enter the stomach.

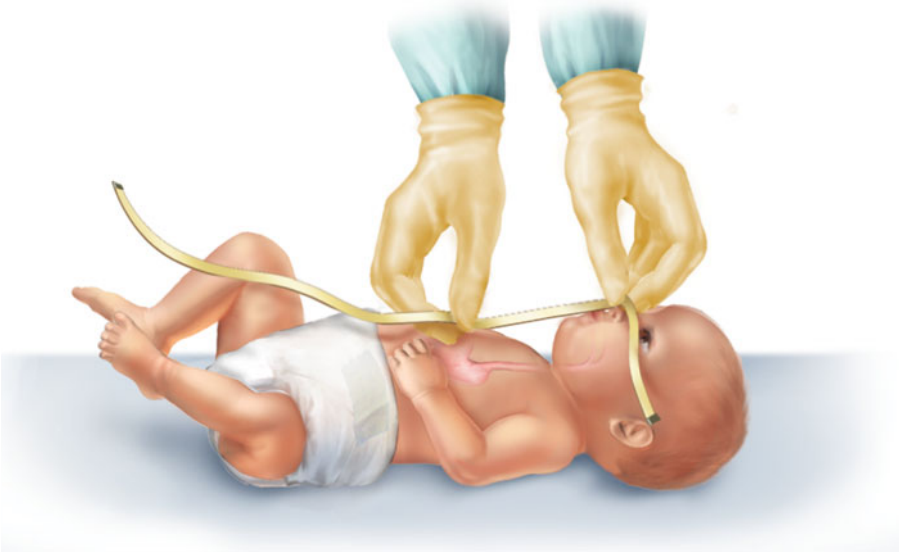

Figure 33-8 ■ Measuring gavage tube length.

Equipment and Supplies

No. 5 or no. 8 Fr. feeding tube. See the Clinical Tip below for guidelines for choosing tube size.

3- to 5-ml syringe, for aspirating stomach contents

1/4-inch paper tape, to mark the tube for insertion depth and to secure the catheter during feeding

Stethoscope, for auscultating the rush of air into the stomach when testing the tube placement

Appropriate formula

Small cup of sterile water to act as lubricant

Clean gloves

CLINICAL TIP

The very small infant (less than 1600 g) requires a 5 Fr. feeding tube; an infant greater than 1600 g may tolerate a larger tube. Long-term indwelling enteral feeding tubes may be used as an alternative to the standard "in and out" gavage tubes, and they come in sizes 5 Fr. and 8 Fr.

Orogastric insertion is preferable to nasogastric because most infants are obligatory nose breathers. If nasogastric is used, a 5 Fr. catheter should be used to minimize airway obstruction.

Procedure: Clean Gloves

Inserting and Checking Placement of Tube

1. If inserting the tube nasally, lubricate the tip in a cup of sterile water. Use water instead of an oil-based lubricant, in case the tube is inadvertently passed into a lung. Shake any excess drops to prevent aspiration.
2. If inserting the tube orally, the oral secretions are enough to lubricate the tube adequately.
3. Stabilize the infant's head with one hand and pass the tube via the mouth (or nose) into the stomach to the point previously marked. If the infant begins coughing or choking or becomes cyanotic or phonic, remove the tube immediately as the tube has probably entered the trachea.
4. If respiratory distress is not apparent, lightly tape the tube in position, draw up 0.5 to 1.0 ml of air in the syringe, and connect the syringe to the tubing. Place the stethoscope over the epigastrium and briskly inject the air (Figure 33-9 ■). You will hear a sudden rush as the air enters the stomach.
5. Aspirate the stomach contents with the syringe, and note the amount, color, and consistency to evaluate the infant's feeding tolerance. Return the residual to the stomach unless you are requested to discard it. It is usually not discarded because of the potential for electrolyte imbalance.

Administering the Feeding

1. Hold the infant for feeding, or position the infant on the right side.

   Rationale: *This position decreases the risk of aspiration in case of emesis during feeding.*
2. Separate the syringe from the tube, remove the plunger from the barrel, reconnect the barrel to the tube, and pour the formula into the syringe.
3. Elevate the syringe 6 to 8 inches over the infant's head, and allow the formula to flow by gravity at a slow, even rate. You may need to initiate the flow of formula by inserting the plunger of the syringe into the barrel just until you see formula enter the feeding tube. Do not use pressure.
4. Regulate the rate to prevent sudden stomach distention leading to vomiting and aspiration. Continue adding formula to the syringe until the infant has absorbed the desired volume.

PROCEDURE 33-1 Performing Gavage Feeding continued

NURSING ACTION

Figure 33-9 ■ Auscultation for placement of gavage tube.

Clearing and Removing the Tube

1. Clear the tubing with 2 to 3 ml of air.

   Rationale: *This ensures that the infant has received all of the formula. If the tube is going to be left in place, clearing it will decrease the risk of occlusion and bacterial growth in the tube.*

2. To remove the tube, loosen the tape, fold the tube over on itself, and quickly withdraw the tube in one smooth motion to minimize the potential for fluid aspiration as the tube passes the epiglottis. If the tube is to be left in, position it so that the infant is unable to remove it. Replace the tube per hospital policy.

Maximize the Feeding Pleasure of the Infant

1. Whenever possible, hold the infant during gavage feeding. If it is too awkward to hold the infant during feeding, be sure to take time for holding after the feeding.

   Rationale: *Feeding time is important to the infant's tactile sensory input.*

2. Offer a pacifier to the infant during the feeding.

   Rationale: *Sucking during feeding comforts and relaxes the infant, making the formula flow more easily. Infants can lose their sucking reflexes when fed by gavage for long periods.*

3. Document procedure, including untoward complications, in the baby's bedside chart or computerized electronic chart.

In-depth discussions of RDS, BPD/CLD, and sepsis, including pathophysiology, clinical management, and nursing care, are contained in chapter 34 ∞. PDA, apnea, intraventricular hemorrhage (IVH), retinopathy of prematurity, and other complications are discussed as follows.

PATENT DUCTUS ARTERIOSUS (PDA) By definition, the ductus arteriosus is the large vessel that is a conduit between the left pulmonary artery and the descending aorta. In the fetus, the ductus arteriosus shunts blood away from the fluid-filled lungs, which are nonfunctional during gestation, toward the placenta for gas exchange. The functional closure of the ductus arteriosus is related to birth weight; the incidence of a symptomatic PDA increases with a decrease in birth weight. For example, in infants 30 weeks and less, functional closure may take several days to weeks to occur.

The incidence of a PDA in an infant weighing less than 1000 g is approximately 80%. Initially, as the pulmonary vascular resistance (PVR) falls and the systemic vascular resistance (SVR) rises, a left-to-right shunt via the PDA results. Blood flows from the aorta into the pulmonary artery, thereby increasing pulmonary blood flow. This leads to left ventricular volume overload, pulmonary edema, and congestive failure. Oxygenation is compromised, and ventilator requirements will increase, leading to the possible difficulty in weaning from the ventilator and long-term pulmonary sequelae. Clinical findings include tachypnea, hyperactive precordium, bounding peripheral pulses, hypotension, widened pulse pressure, tachycardia, and hepatomegaly.

Early identification of symptomatic infants and prompt clinical intervention will minimize long-term complications. There are a multitude of medical management regimens of the PDA. Initial medical management consists of providing adequate respiratory support, restricting fluids, and using diuretics (to decrease pulmonary edema) and perhaps digoxin (to treat congestive heart failure) while waiting for spontaneous closure of the ductus to occur. The administration of prostaglandin synthetase inhibitors, such as indomethacin (Indocin), impairs synthesis of the E series prostaglandins responsible for dilatation of the ductus and can cause ductal closure. Courses of indomethacin therapy vary; the standard, short course consists of three doses of indomethacin, 0.2 mg/kg IV every 12 hours. As an alternative, a long course of indomethacin may be chosen involving dosing over approximately 7 days. A decrease in renal side effects is thought to be the advantage of the longer dosing schedule. Indomethacin is effective, but it is not without side effects and must be used cautiously. Ibuprofen lysine (Neoprofen) is another pharmacologic agent

used to close the ductus; the three-dose course consists of one dose of 10 mg/kg IV followed by two subsequent doses of 5 mg/kg IV at 24- and 48-hour intervals after the initial dose. Adverse side effects of both medications include transient renal dysfunction, oliguria, platelet dysfunction, and GI bleeding.

If medical management is unsuccessful or contraindicated, then the ductus may need to be surgically ligated. PDA will often prolong the course of illness in a preterm newborn and may lead to chronic pulmonary dysfunction.

CLINICAL TIP

A growing premature infant showing clinical signs of worsening respiratory status (i.e., increased oxygen needs, increased ventilatory settings), acidosis, and hypotension may be exhibiting signs and symptoms of a patent ductus arteriosus (PDA).

APNEA *Apnea of prematurity* refers to cessation of breathing for 20 seconds or longer or for less than 20 seconds when associated with cyanosis, pallor, and bradycardia. Apnea is the most common problem in the preterm infant < 36 weeks, presenting between day 2 and day 7 of life. The etiology of apnea is multifactorial but is thought to be primarily a result of neuronal immaturity, a factor that contributes to the preterm infant's irregular breathing patterns (central apnea). Obstructive apnea can occur in the premature infant when there is a cessation of airflow associated with blockage of the upper airway (small airway diameter, increased pharyngeal secretions, improper body alignment and positioning).

Differential diagnoses with regard to apnea include sepsis, electrolyte disturbances, hypoglycemia, lung disease (atelectasis, pneumonia, inadequate ventilation), cardiovascular changes (PDA, hypotension, congestive heart failure [CHF]), CNS disturbances (seizures, intraventricular hemorrhage, meningitis, hydrocephalus), medication use (narcotics, opioids, maternal administration of magnesium sulfate), thermoregulation problems (hypo- and hyperthermia), hematologic disturbances (anemia), and GI disturbances (NEC, distention, obstruction, feeding intolerance, gastroesophageal reflux). Gastroesophageal reflux is defined as a movement of gastric contents into the lower esophagus due to poor lower esophageal sphincter tone, activating the laryngeal chemoreflex causing apnea. Apnea of prematurity is then a diagnosis of exclusion.

Apneic onset is often insidious; cardiorespiratory monitoring allows for early recognition and intervention, thus decreasing the need for resuscitative efforts. Apnea may occur during feeding, suctioning, or stooling. However, there may be no observable activity related to apnea. All episodes of apnea are documented. The documentation includes activity at the time of apnea, length of episode (along with any bradycardia, color change, or desaturation on pulse-oximeter associated with the apneic episode), and treatment required to bring the baby out of the apneic spell. These data are useful in determining etiology and the possible course of treatment.

The nurse makes careful observations, quickly assessing the need for intervention or ascertaining that the infant is having periodic breathing. The intervention required depends on the severity of the apneic episode and the baby's response. Gentle stimulation of the infant may be sufficient. Respiratory support is provided if needed and pharmacologic intervention using caffeine citrate (a methylxanthine) is often used to treat apnea of prematurity. Conservative management of apnea associated with gastroesophageal reflux would include dietary modification by adding rice cereal to thicken feedings. Feedings may also be small and frequent to decrease gastric distention. Following feedings, the infant should be placed in a side-lying or prone position with the head of the bed elevated 30 degrees for 20 to 30 minutes to facilitate gastric emptying. Often, metoclopramide (Reglan) is begun to increase the resting tone of the esophageal sphincter, to facilitate gastric emptying, and to improve GI motility.

CLINICAL TIP

For an otherwise healthy, growing premature infant who is receiving total enteral intake and has started to experience apnea and bradycardia, one differential diagnosis to think about is reflux rather than sepsis, although sepsis may need to be ruled out.

INTRAVENTRICULAR HEMORRHAGE Intraventricular hemorrhage (IVH) is the most common type of intracranial hemorrhage in the small preterm infant, especially those weighing less than 1500 g or of less than 34 weeks' gestation. To screen for the presence and severity of intraventricular hemorrhages, a cranial ultrasound is recommended some time during the first week of life and periodically through the infant's hospitalization based upon the initial findings.

The most common site of hemorrhage is the periventricular subependymal germinal matrix in the lateral ventricles of the brain, where there is a rich blood supply and the capillary walls are thin and fragile. The matrix provides little supportive tissue for the fragile blood vessels. Before 32 weeks' gestation, an infant is much more susceptible to hemorrhage of these tiny vessels because they are vulnerable to wide fluctuations in blood pressure and to hypoxic events (such as respiratory distress, birth trauma, birth depression) that damage and rupture vessel walls.

Prenatal interventions include preventing premature birth, administering antenatal steroids, transporting the pregnant mother to a tertiary care center, and cesarean section delivery. Administration of phenobarbital and vitamin K to the mother is being studied for their preventive effect. Postnatal preventive interventions include careful resuscitation efforts, slow correction of acid–base abnormalities, prevention of large fluctuations in blood pressure, and correction of coagulation abnormalities. Potential postnatal preventive pharmacologic interventions include phenobarbital to control seizures and narcotics for sedation (Volpe, 2008).

The outcome for the infant depends on the size of the intraventricular bleed and the gestational age of the infant. The most severe hemorrhages may cause significant motor deficits, lower IQ scores, post-hemorrhagic hydrocephalus, hearing loss, and blindness. Less severe bleeds may have no observable effects. In

caring for the infant with an IVH, the nurse provides continuing support for the parents, identifying their level of understanding and facilitating interdisciplinary communication with them.

CLINICAL TIP

An extremely premature, low-birth-weight infant who presents with a sudden drop in hemoglobin along with the onset of severe metabolic acidosis, a "waxy" color, and hypotension may have experienced an intraventricular hemorrhage.

ANEMIA OF PREMATURITY The preterm infant is at risk for anemia because of the rapid rate of growth required, shorter RBC life, excessive blood sampling, decreased iron stores, and deficiency of vitamin E. The hemoglobin usually reaches its lowest level by 8 to 12 weeks and remains low for 3 to 6 months. Interventions include iron supplementation and administration of recombinant human erythropoietin (r-HuEPO). Iron supplementation ensures adequate stores for RBC production once erythropoiesis starts. The use of r-HuEPO is reported to increase neonatal erythropoiesis, thereby increasing the hematocrit and reticulocyte count. In addition, it has been shown to reduce the need for late blood transfusions (those beyond 2 to 3 weeks of age) in preterm infants (Blackburn, 2007).

Long-Term Complications

The care of the preterm infant and the family does not stop on discharge from the nursery. Follow-up care is extremely important because many developmental problems are not noted until the infant is older and begins to demonstrate motor delays or sensory disability.

Within the first year of life, LBW preterm infants face higher mortality than term infants. Causes of death include sudden infant death syndrome (SIDS)—which occurs about five times more frequently in the preterm infant—respiratory infections, and neurologic defects. Morbidity is also much higher among preterm infants, with those weighing less than 1500 g at highest risk for long-term complications.

The most common long-term problems observed in preterm infants are discussed in the following four sections.

RETINOPATHY OF PREMATURITY Extremely premature newborns are particularly susceptible to injury of the delicate capillaries of the retina causing characteristic retinal changes known as retinopathy of prematurity (ROP). It is this injury to the developing vascular system of the retina that leads to ischemia resulting in hemorrhage, scarring, and, in extreme cases, retinal detachment and impaired vision. The disease is now viewed as multifactorial in origin with hyperoxemia (increased oxygen levels) as one factor. Other risk factors include in vitro fertilization (IVH), CLD, apnea, hypoxia, sepsis, acidosis, anemia, multiple gestation, exposure to bright lights, and blood transfusions. Increased survival of very-low-birth-weight infants may be the most important factor in the increased incidence of ROP.

Judicious use of supplemental oxygen therapy in the premature infant has become the norm in NICUs across the country whereby oxygen saturations are kept $< 93\%$ in an attempt to reduce ROP. Treatment of the acute stages of ROP with laser photocoagulation and cryotherapy is an option. Because most acute cases of ROP regress spontaneously with no long-term visual impairment, the possibility of regression must be weighed against the risk of an unfavorable outcome from treatment. For infants with bilateral traction and retinal detachment, surgical vitrectomy and scleral buckling are performed. Nursing care for the visually impaired infant must concentrate on parental support and education. When the crisis of premature birth is quickly followed by the devastating news of suspected visual impairment (poor visual acuity, myopia, strabismus, amblyopia, and glaucoma) or blindness, the parents will need extensive support by all members of the interdisciplinary health team. The parents again experience overwhelming anxiety and uncertainty about their infant's future abilities. Premature infants with blindness due to ROP may be at increased risk of cognitive and emotional problems. The evidence suggests that this increased risk may be due to environmental factors rather than to inherent intellectual or neurologic factors.

CLINICAL TIP

According to the AAP & ACOG (2007), all newborns born at 32 weeks or less need to be screened for retinopathy of prematurity (ROP) at 36 weeks corrected gestational age.

NEUROLOGIC DEFECTS The most common neurologic defects include cerebral palsy, hydrocephalus, seizure disorders, lower IQ scores, and learning disabilities. However, the socioeconomic climate and family support systems have been shown to be important factors influencing the child's ultimate school performance in the absence of major neurologic defects. Families can be reminded that risk does not equal injury, injury does not equal damage, and description of damage does not allow a precise prediction about recovery or outcome.

AUDITORY DEFECTS Preterm infants have a 1% to 4% incidence of moderate to profound hearing loss and should have a formal audiologic examination before discharge and at 3 to 6 months (corrected age). One test currently used to measure hearing functions of the newborn is the evoked otoacoustic emissions (EOAE) test. Earphones are used on each ear and independently measure sounds produced in the inner ear in response to acoustic stimuli. Another test, the automated auditory brain response (AABR), measures electroencephalogram (EEG) waves in response to sound waves generated by the test. The AABR provides information about the auditory pathway to the brainstem (Figure 33-10 ■). Any infant with repeated abnormal results should be referred to speech-and-language specialists.

Infants at increased risk include those with congenital viral infections (TORCH), hyperbilirubinemia, severe perinatal asphyxia, meningitis, and birth trauma. Damage from ototoxic drugs such as gentamicin and furosemide (Lasix) is variable and related to multiple factors, including renal function, age, duration of treatment, and concomitant administration of other ototoxic agents.

When evaluating an infant's abilities and disabilities, parents must understand that the developmental progress must be evaluated based on chronologic age from the expected date of

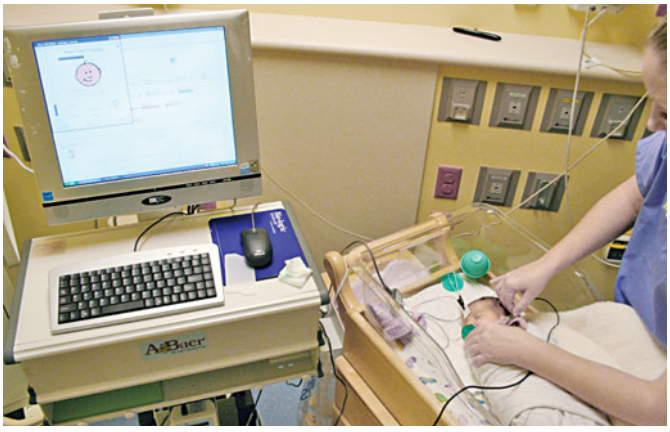

Figure 33-10 ■ Preterm infants should have a formal hearing test prior to discharge.

Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.

birth, not from the actual date of birth (corrected age). In addition, the parents need the consistent support of healthcare professionals in the long-term management of their infant. Many new and ongoing concerns arise as the high-risk infant grows and develops; the goal is to promote the highest quality of life possible.

SPEECH DEFECTS The most frequently observed speech defects involve delayed development of receptive and expressive ability that may persist into the school-age years.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse needs to assess the physical characteristics and gestational age of the preterm newborn accurately to anticipate the special needs and problems of this baby. Physical characteristics vary greatly, depending on the gestational age, but the following characteristics are frequently present:

- ***Color.*** Usually pink or ruddy but may be acrocyanotic (Cyanosis, jaundice, or pallor are abnormal and should be noted.)
- ***Skin.*** Reddened, translucent, blood vessels readily apparent, lack of subcutaneous fat
- ***Lanugo.*** Plentiful, widely distributed
- ***Head size.*** Appears large in relation to body
- ***Skull.*** Bones pliable, fontanelle smooth and flat, sutures approximated or overriding
- ***Ears.*** Minimal cartilage, pliable, folded over
- ***Nails.*** Soft, short
- ***Genitals.*** Male: nonrugated, small scrotum; testes may or may not be descended. Female: prominent clitoris and labia minora
- ***Posture.*** Flaccid, froglike position
- ***Cry.*** Weak, feeble
- ***Reflexes.*** Poor suck, swallow, and gag
- ***Activity.*** Jerky, generalized movements (Seizure activity is abnormal.)

Determining gestational age in preterm newborns requires knowledge and experience in administering gestational assessment tools. The tool used should be specific, reliable, and valid. For a discussion of gestational age assessment tools, see chapter 30 ∞.

Nursing diagnoses that may apply to the preterm newborn include:

- ***Impaired Gas Exchange*** related to immature pulmonary vasculature and inadequate surfactant production
- ***Ineffective Breathing Pattern*** related to immature central nervous system
- ***Risk for Ineffective Cardiac Tissue Perfusion*** related to hypotension secondary to PDA
- ***Ineffective Thermoregulation*** related to hypothermia secondary to decreased glycogen and brown fat stores
- ***Imbalanced Nutrition: Less Than Body Requirements*** related to weak suck and swallow reflexes and decreased ability to absorb nutrients
- ***Ineffective Peripheral Tissue Perfusion*** related to anemia of prematurity
- ***Deficient Fluid Volume*** related to high insensible water losses and inability of kidneys to concentrate urine
- ***Impaired Tisssue Integrity*** related to fragile capillary network in the germinal matrix
- ***Risk for Infection*** related to lack of passive immunity due to preterm birth
- ***Compromised Family Coping*** related to anger or guilt at having given birth to a premature baby

Nursing Plan and Implementation

Maintenance of Respiratory Function

Preterm newborns have increased danger of respiratory obstruction. Their bronchi and trachea are so narrow that mucus can obstruct the airway. The nurse must maintain patency through judicious suctioning, but only on an as-needed basis.

Positioning of the newborn can also affect respiratory function, especially in the preterm newborn. If the baby is in the supine position, the nurse should slightly elevate the infant's head to maintain the airway, being careful not to hyperextend the neck because the trachea will collapse. Also, because the newborn has weak neck muscles and cannot control head movement, the nurse should ensure that this head position is maintained by using a small roll under the shoulders. The prone position splints the chest wall and decreases the amount of respiratory effort used to move the chest wall. The prone position therefore facilitates chest expansion and improves air entry and oxygenation. Weak or absent cough or gag reflexes increase the chance of aspiration in the premature newborn. The nurse should ensure that the infant's position facilitates drainage of mucus or regurgitated formula.

The nurse monitors heart and respiratory rates with cardiorespiratory monitors as well as through physical assessments to identify alterations in the newborn's cardiopulmonary status. Signs of respiratory distress include the following:

- Cyanosis (serious sign when generalized)
- Tachypnea (sustained respiratory rate greater than 60/minute after first 4 hours of life)

- Retractions
- Expiratory grunting
- Nasal flaring
- Apneic episodes
- Presence of crackles or rhonchi on auscultation
- Diminished air entry

If respiratory distress occurs, the nurse administers oxygen per physician or nurse practitioner order to relieve hypoxemia. If hypoxemia is not treated immediately, it may result in PDA or metabolic acidosis. If oxygen is administered to the newborn, the nurse monitors the oxygen concentration with a pulse oximeter. Periodic arterial blood gas sampling to monitor oxygen concentration in the baby's blood is essential because hyperoxemia may lead to ROP.

The nurse also needs to consider respiratory function before initiation of feedings as well as during feeding. To prevent aspiration, increased energy expenditure, and increased oxygen consumption, the nurse needs to assess the infant's gag and suck reflexes before starting oral feedings.

Maintenance of Neutral Thermal Environment

Providing a neutral thermal environment minimizes the oxygen consumption required to maintain a normal core temperature; it also prevents cold stress and facilitates growth by minimizing caloric expenditure to maintain body temperature. The preterm infant's immature CNS, as well as small brown fat stores, provides poor temperature control. A small infant (less than 1200 g) can lose 80 kcal/kg/day through radiation of body heat. The nurse should implement all the usual thermoregulation measures discussed in chapter 31 ∞.

In addition, to minimize heat loss and the effects of temperature instability for preterm and LBW newborns, the nurse should do the following:

1. Allow skin-to-skin contact between mother and newborn to maintain warmth and foster security (see "Kangaroo care" discussion later in this chapter).
2. Warm and humidify oxygen to minimize evaporative heat loss and decrease oxygen consumption.
3. Place the baby in a double-walled incubator, or use a Plexiglas heat shield over small preterm infants in single-walled incubators to avoid radiative heat losses. Some institutions use radiant warmers over the baby and pipe in humidity (swamping). Do not use Plexiglas shields on radiant warmer beds because it blocks the infrared heat.
4. Avoid placing the baby on cold surfaces, such as metal treatment tables and cold x-ray plates (conductive heat loss). Pad cold surfaces with diapers and use radiant warmers during procedures; place the preterm infant on pre-warmed mattresses; and warm hands as well as the stethoscope before examining the baby to prevent heat transfer via conduction.
5. Use warmed ambient humidity. The use of humidity decreases insensible water loss but the optimal level and duration is yet to be determined (Jones, Hayes, Starbuck, et al., 2011). Humidity, however, should only be started once the infant's temperature is within normal limits.
6. Keep the skin dry (evaporative heat loss), and place a cap on the baby's head. The head makes up 25% of the total body size.
7. Keep radiant warmers, incubators, and cribs away from windows and cold external walls (radiative heat loss) and out of drafts (conductive heat loss).
8. Open incubator portholes and doors only when necessary, and use plastic sleeves on portholes to decrease convective heat loss.
9. Use a skin probe to monitor the baby's skin temperature. Correlate ambient temperatures with the skin probe in the incubator on servocontrol. The temperature should be 36°C to 37°C (96.8°F to 98.6°F). Temperature fluctuations indicate hypothermia or hyperthermia. Be careful not to place skin temperature probes over bony prominences; areas of brown fat; poorly vasoreactive areas, such as extremities; or excoriated areas.
10. Warm formula or stored breast milk before feeding.
11. Use reflector patch over the skin temperature probe when using a radiant warmer bed so that the probe does not sense the higher infrared temperature as the baby's skin temperature and therefore decrease the heater output.

Once preterm infants are medically stable, they should be clothed with a double-thickness cap, cotton shirt, and diaper. If possible, they should be swaddled in a blanket. The nurse begins the process of weaning to a crib when the premature infant is medically stable, does not require assisted ventilation, weighs approximately 1500 g, has 5 days of consistent weight gain, and is taking oral feedings, and when apnea and bradycardia episodes have stabilized. The nurse should be familiar with the individual institution's protocol for weaning to crib for preterm infants.

Maintenance of Fluid and Electrolyte Status

Hydration is maintained by providing adequate intake based on the newborn's weight, gestational age, chronologic age, and volume of sensible and insensible water losses. Adequate fluid intake should provide sufficient water to compensate for increased insensible losses and to provide the amount needed for renal excretion of metabolic products. Insensible water losses can be minimized by providing a high-ambient humidity, humidifying oxygen, using heat shields, and placing the infant in a double-walled incubator.

The nurse evaluates the baby's hydration status by assessing and recording signs of dehydration. Signs of dehydration include the following:

- Sunken fontanelles
- Loss of weight
- Poor skin turgor (skin returns to position slowly when squeezed gently)
- Dry oral mucous membranes
- Decreased urine output
- Increased urine specific gravity (greater than 1.013)
- Hypernatremia

The nurse must also identify signs of overhydration by observing the newborn for edema or excessive weight gain and by comparing urine output with fluid intake.

The preterm infant should be weighed at least once daily at the same time each day. *Weight change is the most sensitive indicator of fluid balance.* Weighing diapers is also important for accurate input and output measurement (1 ml equals 1 g). A comparison of intake and output measurements over an 8-hour or 24-hour period provides important information about renal function and fluid balance. Assessment of patterns—in particular, whether they show a net gain or loss over several days—is also essential to fluid management. Monitor blood serum levels and pH to evaluate for electrolyte imbalances.

Accurate hourly intake calculations should be maintained when administering IV fluids. Because the preterm infant is unable to excrete excess fluid, it is important that the nurse maintain the correct amount of IV fluid to prevent fluid overload. This can be accomplished by using neonatal or pediatric infusion pumps. To prevent electrolyte imbalance, overhydration, and dehydration, the nurse must take care to give the correct IV solutions and volumes and concentrations of formulas. Urine specific gravity and pH are obtained periodically. Urine osmolality provides an indication of hydration, although this factor must be correlated with other assessments (e.g., serum sodium). Hydration is considered adequate when the urine output is 1 to 3 ml/kg/hr.

Provision of Adequate Nutrition and Prevention of Fatigue During Feeding

The feeding method depends on the preterm newborn's feeding abilities and health status. Both nipple and gavage methods are initially supplemented with IV therapy until oral intake is sufficient to support growth (110 to 130 kcal/kg/day). Early, small-volume enteral feedings called *minimal enteral nutrition via gavage* have proved to be of benefit to the very-low-birth-weight infant. (See "Methods of Feeding," earlier in this chapter.) Formula or breast milk (with or without fortifiers to increase caloric content) is incorporated into the feedings slowly. This is done to avoid overtaxing the digestive capacity of the preterm newborn.

Before each feeding, the nurse measures abdominal girth and auscultates the abdomen to determine the presence and quality of bowel sounds. Such assessments permit early detection of abdominal distention and decreased peristaltic activity, which may indicate NEC or a paralytic ileus. The nurse also checks for residual formula in the stomach before each feeding. This is done when the newborn is fed by gavage method. This procedure also can be performed when the nipple-fed newborn presents with abdominal distention. The presence of residual formula may indicate intolerance to the type or amount of feeding. Carefully watch for other signs of feeding intolerance including guaiac-positive stools (occult blood in stools), lactose in stools (reducing substance in the stools), vomiting, and diarrhea.

Preterm newborns who are ill or fatigue easily with nipple feedings are usually fed by gavage. The infant is essentially passive with these methods, thus conserving energy and calories. As the baby matures, gavage feedings are replaced with nipple (breast or formula) feedings to assist in strengthening the sucking reflex and meeting oral and emotional needs. Signs that indicate readiness are a strong gag reflex, presence of nonnutritive sucking, and rooting behavior. Both LBW and preterm infants nipple-feed more effectively in a quiet state. The nurse establishes a gradual nipple-feeding program, such as one nipple feeding per day, then one nipple feeding per shift, and then a nipple feeding every other feeding. Daily weights are monitored because often there is a small weight loss when nipple feedings are started. After feedings, the baby is placed on the left side (with support to maintain this position) or on the abdomen to enhance gastric emptying and decrease the chance of aspiration if regurgitation occurs. Gastroesophageal reflux is not uncommon in preterm newborns. Long-term gavage feeding may create nipple aversion that will require developmental occupational therapy interventions.

The nurse involves the parents in feeding their preterm baby (Figure 33-11 ■). This is essential to the development of attachment between parents and infant. In addition, such involvement increases parental knowledge about the care of their infant and helps them cope with the situation.

Prevention of Infection

The nurse is responsible for minimizing the preterm newborn's exposure to pathogenic organisms. The preterm newborn is susceptible to infection because of an immature immune system and thin, permeable skin. Invasive procedures, techniques such as umbilical catheterization, peripheral venipunctures, and mechanical ventilation, and prolonged hospitalization place the infant at greater risk for infection.

Strict hand washing and the use of separate equipment for each infant help minimize exposure of the preterm newborn to infectious agents. Most nurseries have adopted the Standard Precautions recommended by the Centers for Disease Control and Prevention (CDC) of isolating every baby and the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) re-

Figure 33-11 ■ Father participating in feeding experience with his premature infant.

quirement that staff members have short-trimmed nails and no artificial nails. Staff members are required to scrub 2 to 3 minutes using antibacterial solutions, which inhibit the growth of gram-positive cocci and gram-negative rod organisms. Other nursing interventions include limiting visitors; requiring visitors to wash their hands; and maintaining strict aseptic practices when changing IV tubing and solutions (IV solutions should be changed every 24 hours or per agency protocols), administering parenteral fluids, and assisting with sterile procedures. Incubators and radiant warmers should be changed weekly. Pressure-area breakdown is prevented by changing the baby's position, and using water-bed pillows or a gel mattress. To avoid skin tears, a protective transparent covering can be applied over vulnerable joints, but use it very sparingly (Blackburn, 2007). Chemical skin preps and tape may cause skin trauma and should be avoided as much as possible.

If infection (sepsis) occurs in the preterm newborn, the nurse may be the first to identify the associated subtle clinical signs, such as lethargy and increased episodes of apnea and bradycardia. The nurse informs the clinician of the findings immediately and implements the treatment plan per clinician orders in the presence of infection. For specific nursing care required for the newborn with an infection, see chapter 34 ∞.

Promotion of Parent-Infant Attachment

Preterm newborns can be separated from their parents for prolonged periods after illness or complications that are detected in the first few hours or days following birth. The resultant interruption in parent-newborn bonding necessitates intervention to ensure successful attachment.

Nurses should take measures to promote positive parental feelings toward the newborn. Photographs of the baby are given to parents to have at home or to the mother if she is in a different hospital or too ill to come to the nursery and visit. The infant's first name is placed on the incubator as soon as it is known to help the parents feel that their infant is a unique and special person. A weekly card with the baby's footprint, weight, and length is also sent to promote attachment. The nurse provides the parents with the telephone number of the nursery or intensive care unit and names of staff members so that they have access to information about their baby at any time of the day or night. The nurse encourages visits from siblings and grandparents to foster attachment.

Early involvement in the care and decisions regarding their baby provides parents with realistic expectations for their baby. The unique personality characteristics of the infant and the parents influence bonding and contribute to the interactive process for the family. By observing each infant's patterns of behavior and responses, especially sleep-wake states, the nurse can teach parents optimal times for interacting with their infant. Parents need education to develop caregiving skills and to understand the premature infant's behavioral characteristics. Their daily participation (if possible) is encouraged, as are early and frequent visits. The nurse provides opportunities for the parents to touch, hold, talk to, and care for their baby (change diaper, take an axillary temperature). Skin-to-skin holding *(kangaroo care)* helps parents feel close to their small infants. Kangaroo care has been shown to improve sleep periods and parents' perception of their caregiving ability (DiMenna, 2006; Turnage-Carrier, 2010). See Figure 33-12 ■.

Figure 33-12 ■ Kangaroo (skin-to-skin) care facilitates a closeness and attachment between parents and their premature infant.

Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.

Figure 33-13 ■ Family bonding occurs when parents have opportunities to spend time with their infant.

Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.

The parents and nurse can plan nursing care around the times when the infant is alert and best able to attend. The more knowledge parents have about the meaning of their infant's responses, behaviors, and cues for interaction, the better prepared they will be to meet their newborn's needs and form a positive attachment with their child. Parental involvement in difficult care decisions is essential and discussed in greater detail in chapter 34 ∞.

Some parents may progress easily to touching and cuddling their infant; others will not (Figure 33-13 ■). Parents need to know that their apprehension is normal and the progression of

acquaintanceship is slow. Rooming-in or "nesting" can provide another opportunity for the stable preterm infant and family to get acquainted. This becomes most beneficial for both the infant and family before discharge, as it offers a quiet, private environment where help is readily available.

Complementary and Alternative Therapies in the NICU

As NICUs are becoming more and more "developmentally" friendly, complementary and alternative medicine (CAM) has now become an adjunct to that nurturing environment. This holistic approach in caring for the LBW infant attempts not only to mimic the intrauterine environment, but also to foster parent-infant bonding by simultaneously caring for the body, spirit, and mind.

Aromatherapy is the use of scent to alter mood or behavior to produce a calming and sedating effect. There is an enhanced bonding process between mothers and newborns associated with the natural body odor emitted from the mother (Turnage-Carrier, 2010). Aromatherapy is utilized in the NICU by placing an article of clothing belonging to the mother next to the infant to produce a soothing and consoling effect on the infant in her absence. Researchers are also investigating other aromatherapies, including peppermint as a respiratory stimulant, chamomile as a method to regulate sleep-wake cycles, Brazilian guava for its analgesic effects, and lavender sitz baths for management of diaper rash.

Skin-to-skin (kangaroo) care has become more prevalent in NICUs across the United States. Skin-to-skin care is defined as the practice of holding infants skin to skin next to their parents. The infant is usually naked, except for a diaper, and placed on his or her parent's bare chest. They are then both covered with a blanket. Benefits of skin-to-skin care as a developmental intervention include the following: improved oxygenation as evidenced by an increase in transcutaneous oxygen levels; enhanced temperature regulation; a decline in the episodes of apnea and bradycardia; increased periods of quiet sleep; stabilization of vital signs; positive interaction between parent and infant, which enhances attachment and bonding; increased growth parameters; and early discharge (Ludington, Morgan, & Abouelfettoh, 2008). Limitations to skin-to-skin care may be due to staff uneasiness when moving the infant while attached to multiple IV lines, monitor leads, and a ventilator, including high-frequency oscillatory ventilation. The restricted confines of the nursery may be another limiting factor as well as the lack of protocols or guidelines to safely maneuver, position, and hold the infant.

Music therapy as a noninvasive auditory stimulus has been shown to be advantageous for the premature infant. The music used in NICUs includes primarily lullabies and soft acoustical pieces which are pleasant, soothing, and calming. Such music has been shown to affect newborn physiologic responses, improving oxygenation, and increasing weight gain. It also has behavioral effects, leading to enhanced parental bonding and increased intervals of nonnutritive sucking periods. Language development is also enhanced if the music is live and sung by the mother or another female, which is preferential to the infant. The overall noise level in the NICU needs to be considered before including any extra auditory stimulation, including music therapy.

Infant massage and gentle human touch (GHT) have been practiced for many centuries. The types of stimulation include massage with stroking, gentle touch without stroking, and Therapeutic Touch or "hands on" containment. When infant massage therapy is applied to preterm infants, physiologic benefits such as stimulating blood and lymphatic flow, promoting weight gain, improving developmental scores, and regulating sleep patterns may be seen. Many emotional and behavioral benefits are also cited by practitioners. Classes are available to teach parents how to perform massage on their infants. Massage demonstrates compassion while increasing the parent's empathy and understanding of the baby. It helps parents learn to interpret their baby's behavioral cues such as facial expression, various crying patterns, and other body language. At the same time it helps infants learn about their various body parts and boundaries and feel how they integrate into the whole. Therapeutic Touch reduces motor activity and energy expenditure by the infant and promotes comfort. Infant massage therapy should be incorporated into the daily developmental care regimen of the stable preterm infant.

Promotion of Developmentally Supportive Care

Prolonged separation and the NICU environment necessitate individualized baby sensory stimulation programs. The nurse plays a key role in determining the appropriate type and amount of visual, tactile, and auditory stimulation.

Some preterm infants are not developmentally able to deal with more than one sensory input at a time. The assessment of preterm infant behavior (APIB) scale identifies the individual preterm newborn behaviors according to five areas of development (Als, Lester, Tronick, et al., 1982). The preterm infant's physiologic and behavioral subsystems are autonomic, motor control, state differentiation, attention maintenance and social interaction, and, finally, overall system regulation or self-regulation. Integration of these subsystems improves with increasing gestational and postconceptual age. If the premature infant's self-regulatory capacity is exceeded and the infant is not able to return to previously integrated subsystem functioning, maladaptive behaviors may result when the infant is confronted with environmental demands. The nurse observes the baby's behavioral reactions to stimulation and then bases developmental interventions on reducing detrimental environmental stimuli to the lowest possible level and providing appropriate opportunities for development (Turnage-Carrier, 2010).

Providing developmentally supportive, as well as family-centered, care has been proven to improve the outcomes of the critically ill neonate. With this in mind, specially designed NICUs with the single-room care concept are becoming more prevalent across the country to minimize lighting and noise exposure as well as to provide privacy for the parents of the convalescing neonate (Gibbins, Hoath, Coughlin, et al., 2008).

The NICU environment contains many detrimental stimuli that the nurse can help reduce. Noise levels can be lowered by replacing alarms with lights or silencing alarms quickly and keeping conversations away from the baby's bedside. Dimmer switches should be used to shield the baby's eyes from bright lights with blankets over the top portion of the incubator. Dimming the lights may encourage infants to open their eyes and be

more responsive to their parents. Nursing care should be planned to decrease the number of times the baby is disturbed. Signs (e.g., "Quiet Please") can be placed near the bedside to allow the baby some periods of uninterrupted sleep (Turnage & Carrier, 2010)). Some other suggested developmentally supportive interventions include:

- Facilitate handling by using containment measures when turning or moving the infant or doing procedures such as suctioning. Use the hands to hold the infant's arms and legs, flexed and close to the midline of the body. This helps stabilize the infant's motor and physiologic subsystems during stressful activities.
- Touch the infant gently, and avoid sudden postural changes.
- Promote self-consoling or soothing activities, such as placing blanket rolls or approved manufactured devices next to the infant's sides and against the feet, to provide "nesting." Swaddle the infant to maintain extremities in a flexed position while ensuring that the hands can reach the face. This permits the infant to do hand-to-mouth activities, which can be consoling (Figure 33-14 ■).
- Stimulate the kinesthetic advantages of the intrauterine environment by using soft or fleece-like blankets and Gel beds. Gel bed and pillow use has been reported to improve sleep and decrease motor activity as well as lead to more mature motor behavior, fewer state changes, and a decreased heart rate.
- Provide opportunities for nonnutritive sucking with a pacifier. This improves oxygen saturation; decreases body movement; improves sleep, especially after feedings; and increases weight gain.
- Provide objects for the infant to grasp (e.g., a piece of blanket, oxygen tubing, or a finger) during caregiving. Grasping may comfort the baby.

Teaching the parents to read behavioral cues will help them move at their infant's pace when providing stimulation. Parents are ideally equipped to meet the baby's need for stimulation. Stroking, rocking, cuddling, quiet singing, and talking to the baby can all be an integral part of the baby's care. Visual stimulation in the form of *en face* interaction with the caregivers and the use of mobiles is also important.

Figure 33-14 ■ A 2-day-old, 31 weeks' gestational age, IUGR infant is "nested." Hand-to-face behavior facilitates self-consoling and soothing activities.

Preparation for Home Care

Parents are often anxious when their premature infant is transferred out of the NICU or is discharged home. Parents of preterm babies should receive the same postpartum teaching as any parent taking a new infant home. In preparing for discharge, the nurse encourages the parents to spend time caring directly for their baby. This familiarizes them with their baby's behavior patterns and helps them establish realistic expectations about the infant. Some hospitals have a special room near the nursery where a mother can spend the night and "nest" with her baby before discharge.

Discharge instruction includes breastfeeding and formula-feeding techniques, formula preparation, and vitamin administration. If the mother wishes to breastfeed, the nurse teaches her to pump her breasts to keep the milk flowing and provide milk even before discharge. The nurse gives information on bathing, diapering, hygiene, and normal elimination patterns and prepares the parents to expect changes in the color of the baby's stool, number of bowel movements, and timing of elimination when the infant is switched from formula-feeding to breastfeeding. This information can prevent unnecessary concern by the parents. The nurse also discusses normal growth and development patterns, reflexes, and activity for preterm infants, especially signs and symptoms of overstimulation. In these discussions, the nurse should emphasize ways to promote bonding behaviors and deal with newborn crying. Care of the preterm infant with complications, preventing infections, recognizing signs of a sick baby, and the need for continued medical follow-up are other key issues. Family-care conferences with all the various disciplines involved in the care of the preterm infant is often helpful just prior to discharge.

Families with preterm infants usually do not need to be referred to community agencies, such as visiting nurse assistance. Referral may be necessary if the infant has severe congenital abnormalities, feeding problems, or complications with infections or respiratory problems or if the parents seem unable to cope with an at-risk baby. Parents of preterm infants can benefit from meeting with others in a similar situation to share common experiences and concerns. Nurses should refer parents to support groups sponsored by the hospital or by others in the community and make connections for parents with early education intervention centers.

Preterm and LBW infants are at greater risk of increased morbidity from vaccine-preventable diseases. Preterm infants who weigh less than 2000 g and are medically stable and thriving do show consistently high rates of seroconversion following the first dose of hepatitis B vaccine even when the first dose is given about 2 months after birth (Domonoske, 2010). The medically stable preterm infant and LBW infant should receive full doses of diphtheria, tetanus, acellular pertussis, *Haemophilus influenzae* type b (Hib), hepatitis B, inactivated poliovirus, rotavirus, and pneumococcal conjugate vaccines (PCV) at a chronologic age consistent with the schedule recommended for full-term infants (Domonoske, 2010). The influenza vaccine should be administered at 6 months of age before the beginning of and during

the influenza season. The vaccine for immunoprophylaxis against respiratory syncytial virus (RSV) is given to those high-risk infants prior to discharge from the NICU and monthly thereafter during local RSV season.

Evaluation

Expected outcomes of nursing care include the following:

- The preterm newborn is free of respiratory distress and establishes effective respiratory function.
- The preterm newborn gains weight and shows no signs of fatigue or aspiration during feedings.
- The preterm newborn demonstrates a serial head circumference growth rate of 1 cm per week.
- The preterm infant shows no signs or symptoms of bacteremia.
- The parents are able to verbalize their anger, anxieties, and guilt feelings about the birth of a preterm baby and show attachment behavior such as frequent visits and growing confidence in their participatory care activities.

Application: Congenital Defects

Care of the Newborn with Congenital Anomalies

The birth of a baby with a congenital defect places both newborn and family at risk. Many congenital anomalies can be life threatening if not corrected within hours after birth; others are very visible and cause the families emotional distress. When one congenital anomaly is found, healthcare providers should look for other ones, particularly in body systems that develop at the same time during gestation. Table 33-3 identifies some of the more common anomalies and their early management and nursing care in the newborn period.

TABLE 33-3 Congenital Anomalies: Identification and Care in Newborn Period

CONGENITAL ANOMALY	NURSING ASSESSMENTS	NURSING GOALS AND INTERVENTIONS
Congenital Hydrocephalus (progressive ventricular enlargement)	Enlarged or full fontanelles Split or widened sutures "Setting sun" eyes Head circumference greater than 90% on growth chart	Assess presence of hydrocephalus: Measure and plot occipital-frontal baseline measurements; then measure head circumference once a day. Check fontanelle for bulging and sutures for widening. Assist with head ultrasound and transillumination. Maintain skin integrity: Change position frequently. Clean skin creases after feeding or vomiting. Use sheepskin pillow under head. Postoperatively, position head off operative site. Watch for signs of infection.
Choanal Atresia (occlusion of posterior nares)	Cyanosis and retractions at rest Noisy respirations Difficulty breathing during feeding Obstruction by thick mucus	Assess patency of nares: Listen for breath sounds while holding baby's mouth closed and alternately compressing each nostril. Assist with passing feeding tube to confirm diagnosis. Maintain respiratory function: Assist with taping airway in mouth to prevent respiratory distress. Position with head elevated to improve air exchange.
Cleft Lip (unilateral or bilateral visible defect)	May involve external nares, nasal cartilage, nasal septum, and alveolar process Flattening or depression of midfacial contour 	Provide nutrition: Feed with special nipple. Burp frequently (increased tendency to swallow air and reflex vomiting). Clean cleft with sterile water (to prevent crusting on cleft before repair). Support parental coping: Assist parents with grief over loss of idealized baby. Encourage verbalization of their feelings about visible defect. Provide role model in interacting with infant: Parents internalize others' responses to their newborn. (At left) Bilateral cleft lip with cleft abnormality involving both hard and soft palates. *Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.*
Cleft Palate (fissure connecting oral and nasal cavity)	May involve uvula and soft palate May extend forward to nostril involving hard palate and maxillary alveolar ridge Difficulty in sucking Expulsion of formula through nose	Prevent aspiration/infection: Place prone or in side-lying position to facilitate drainage. Suction nasopharyngeal cavity (to prevent aspiration or airway obstruction). During newborn period feed in upright position with head and chest tilted slightly backward (to aid swallowing and discourage aspiration). Provide nutrition: Feed with special nipple that fills cleft and allows sucking. Also decreases chance of aspiration through nasal cavity. Clean mouth with water after feedings. Burp after each ounce (tend to swallow large amounts of air).

TABLE 33-3 Congenital Anomalies: Identification and Care in Newborn Period continued

CONGENITAL ANOMALY	NURSING ASSESSMENTS	NURSING GOALS AND INTERVENTIONS
Cleft Palate (continued)		Thicken formula to provide extra calories. Plot weight gain patterns to assess adequacy of diet. Provide parental support: Refer parents to community agencies and support groups. Encourage verbalization of frustrations because feeding process is long and frustrating. Praise all parental efforts. Encourage parents to seek prompt treatment for upper respiratory infection (URI) and teach them ways to decrease URI.
Tracheoesophageal Fistula (type 3) (connection between trachea and lower esophagus; upper segment ends blindly)	History of maternal polyhydramnios Excessive oral secretions Constant drooling Abdominal distention beginning soon after birth Periodic choking and cyanotic episodes Immediate regurgitation of feeding Clinical symptoms of aspiration pneumonia (tachypnea, retractions, rhonchi, decreased breath sounds, cyanotic spells) Inability to pass nasogastric tube	Maintain respiratory status and prevent aspiration. Withhold feeding until esophageal patency is determined. Quickly assess patency before putting to breast in birth area. Place low intermittent suction to control saliva and mucus (to prevent aspiration pneumonia) in pouch. Place in warmed, humidified incubator (liquefies secretions, facilitating removal). Elevate head of bed 20–40 degrees (to prevent reflux of gastric juices). Keep quiet (crying causes air to pass through fistula and to distend intestines, causing respiratory embarrassment). Maintain fluid and electrolyte balance. Give fluids to replace esophageal drainage and maintain hydration. Provide parent education: Explain staged repair—provision of gastrostomy and ligation of fistula, then repair of atresia. Keep parents informed; clarify and reinforce physician's explanations regarding malformation, surgical repair, pre- and postoperative care, and prognosis (knowledge is ego strengthening). Involve parents in care of infant and in planning for future; facilitate touch and eye contact (to dispel feelings of inadequacy, increase self-esteem and self-worth, and promote incorporation of infant into family).
		(At left) The most frequently seen type of congenital tracheoesophageal fistula with esophageal atresia.
Diaphragmatic Hernia (portion of intestines in the thoracic cavity through abnormal opening in diaphragm)	Difficulty initiating respirations Gasping respirations with nasal flaring and chest retraction Barrel chest and scaphoid abdomen Asymmetric chest expansion Breath sounds may be absent, usually on left side Heart sounds displaced to right Bowel sounds may be heard in thoracic cavity	Nurse should never ventilate with bag and mask O_2 because the stomach will inflate, further compressing the lungs. Maintain respiratory status: Immediately administer oxygen. Initiate gastric decompression. Place in high semi-Fowler's position (to use gravity to keep abdominal organs' pressure off diaphragm). Turn to affected side to allow unaffected lung expansion. Carry out interventions to alleviate respiratory and metabolic acidosis. Aspirate and irrigate tube with air or sterile water.
		(At left) Diaphragmatic hernia. Note compression of the lung by the intestine on the affected side. *Source: Courtesy of Nancy Houck, RN, BSN, NNP-BC.*

(continued)

TABLE 33-3 Congenital Anomalies: Identification and Care in Newborn Period continued

CONGENITAL ANOMALY	NURSING ASSESSMENTS	NURSING GOALS AND INTERVENTIONS
Omphalocele (herniation of abdominal contents into base of umbilical cord)	Enclosed transparent sac covering	Maintain hydration and temperature. Provide normal saline for hypovolemia. Place infant in sterile bag up to and covering defect. Initiate gastric decompression by insertion of nasogastric tube attached to low suction (to prevent distention of lower bowel and impairment of blood flow). Prevent infection and trauma to defect. Position to prevent trauma to defect. Administer broad-spectrum antibiotics.
 (At left) Newborn with omphalocele. *Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.*		
Gastroschisis (full-thickness defect in abdominal wall allowing viscera outside the body to the right of an intact umbilical cord)	No sac covering. Intestines exposed to the caustic amniotic fluid. Associated with intestinal atresia, malrotation	Maintain hydration and temperature. Prevent trauma and infection to defect. Provide normal saline for hypovolemia Place infant in sterile bag up to axilla. Initiate gastric decompression by insertion of nasogastric tube attached to low suction. Administer broad-spectrum antibiotics.
 (At left) Term newborn with gastroschisis. Note the externalized loops of bowel visible through the bag. *Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.*		
Prune Belly Syndrome (congenital absence of one or more layers of abdominal muscles)	Oligohydramnios leading to pulmonary hypoplasia common Deficiency of the abdominal wall musculature causing the abdomen to be shapeless Skin hangs loosely and is wrinkled in appearance Associated with urinary abnormalities (urethral obstruction) In males, cryptorchidism is common; rarely occurs in females	Maintain respiratory status: May need to be immediately intubated and ventilated. Prevent trauma and infection. Administer broad-spectrum antibiotics. Place a urinary catheter and monitor urinary output. Carry out interventions to alleviate respiratory and metabolic acidosis. Keep parents updated and informed about prognosis.
 (At left) Prune belly syndrome. *Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.*		

TABLE 33-3 Congenital Anomalies: Identification and Care in Newborn Period continued

CONGENITAL ANOMALY	NURSING ASSESSMENTS	NURSING GOALS AND INTERVENTIONS
Myelomeningocele (saclike cyst containing meninges, spinal cord, and nerve roots in thoracic and/or lumbar area)	Myelomeningocele directly connects to subarachnoid space so hydrocephalus often associated No response or varying response to sensation below level of defect May have constant dribbling of urine Incontinence or retention of stool Anal wink may or may not be present (At left) Newborn with lumbar myelomeningocele. *Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.*	Prevent trauma and infection. Position on abdomen or on side and restrain (to prevent pressure and trauma to sac). Meticulously clean buttocks and genitals after each voiding and defecation (to prevent contamination of sac and decrease possibility of infection). May put protective covering over sac (to prevent rupture and drying). Observe sac for oozing of fluid. Credé bladder (apply downward pressure on bladder with thumbs, moving urine toward the urethra) as ordered to prevent urinary stasis. Assess amount of sensation and movement below defect. Observe for complications. Obtain occipital-frontal circumference baseline measurements; then measure head circumference once a day (to detect hydrocephalus). Check fontanelle for fullness and bulging.
Imperforate Anus, Congenital Dislocated Hip, and Clubfoot	See discussion in "Anus and Extremities" in chapter 30 ∞.	Identify defect and initiate appropriate referral early.

Care of the Infant of a Substance-Abusing Mother

An **infant of a substance-abusing mother (ISAM)** may be alcohol or drug (licit or illicit) dependent. After birth, when an infant's connection with the maternal blood supply is severed, the baby may suffer withdrawal. In addition, the drugs the mother ingested may be teratogenic, resulting in congenital anomalies and/or developmental problems.

Alcohol Dependence

Fetal alcohol syndrome (FAS), a leading cause of preventable intellectual disability (mental retardation), includes a group of physical, behavioral, and cognitive malformations frequently found in infants exposed to alcohol in utero. It has been estimated that complete FAS occurs in up to 0.5 to 2 per 1000 live births (Pitts, 2010). FAS rates are increased among Native Americans, Alaska natives, African Americans, and women of low economic status. A new set of guidelines for diagnosis and referral of infants and children with FAS has been developed (Pitts, 2010). The term *fetal alcohol effects (FAE)* was used to describe children who had some, but not all, of the characteristics of FAS; however, it was vague. Recently the term **fetal alcohol spectrum disorder (FASD)** has been used to include all categories of prenatal alcohol exposure, including FAS. FASD, however, is an umbrella term and not meant as a clinical diagnosis. The new diagnostic categories for FAS take into consideration the various clinical manifestations of FAS, the social and family environment, and, if available, the maternal alcohol history. Five diagnostic categories are used to describe effects of alcohol exposure:

1. FAS with a confirmed history of maternal alcohol intake.
2. FAS with phenotypic features but no confirmed history of maternal alcohol intake.
3. Partial FAS with confirmed history of maternal alcohol intake, some facial abnormalities, and one of the following: central nervous system (CNS) abnormalities, growth restriction, or behavioral or cognitive disabilities.
4. *Alcohol-related birth defects (ARBD)* are usually determined only by a positive maternal drinking history. They present with one or more birth defects including malformations and dysplasias of the heart, bone, kidney, vision, or hearing systems and do not exhibit the classic facial dysmorphology of the FAS infant (Pitts, 2010).
5. *Alcohol related neurodevelopmental disorder (ARND).* These children have CNS neurodevelopmental abnormalities and complex behavior and cognitive abnormalities (Pitts, 2010). ARBD and ARND can both occur together.

Although it is known that ethanol freely crosses the placenta to the fetus, it is still not known whether the alcohol alone or the by-products of alcohol breakdown cause the damage. For an in-depth discussion of alcohol abuse in pregnancy, see chapter 19 ∞. The effects of other substances that are often combined with alcohol, such as nicotine, diazepam (Valium), marijuana, and caffeine, as well as poor diet, enhance the likelihood of FAS.

Long-Term Complications for the Infant with FAS

The long-term prognosis for the FAS newborn is less than favorable. Because of the failure-to-thrive appearance, many FAS infants are often evaluated for deficiencies in organic

and inorganic amino acids. These infants have a delay in oral feeding development but have a normal progression of oral motor function. Many FAS infants feed poorly and have persistent vomiting until 6 to 7 months of age. They have difficulty adjusting to solid foods and show little spontaneous interest in food.

CNS dysfunctions are the most common and serious problems associated with FAS. Hypertonicity and increased placidity are seen in these infants. They also have a decreased ability to habituate repetitive stimuli. Children exhibiting FAS can be severely intellectually disabled or have normal intelligence. These children show impulsivity, cognitive impairment, speech and language abnormalities, and learning disabilities indicative of CNS involvement (Pitts, 2010). As they progress through the adolescent years, they change from very thin and underweight children to those who are overweight and often obese. Short stature and microcephaly persist.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse assesses the newborn for the following characteristics:

- ***Abnormal structural development and CNS dysfunction.*** These include mental retardation, microcephaly, and hyperactivity.
- ***Growth deficiencies.*** Infants with FAS are often restricted in regard to weight, length, and head circumference being affected. These infants continue to show a persistent postnatal growth deficiency with head circumference and linear growth most affected.
- ***Classic dysmorphic facial features.*** These include short palpebral fissures, epicanthal folds, broad nasal bridge, flattened midface, short upturned or beaklike nose, micrognathia (abnormally small lower jaw), hypoplastic maxilla, thin upper lip or vermilion border, and smooth philtrum (groove on upper lip) (Kenner & Lott, 2007).
- ***Associated anomalies.*** Abnormalities affecting the heart (primarily septal and valvular defects), eyes (optic nerve hypoplasia), ears (conductive and sensorineural hearing loss), kidneys, and skeletal system (especially those involving joints, such as congenital dislocated hips) are often noted.

Alcohol-exposed newborns in the first week of life may show symptoms that include sleeplessness, excessive arousal states, inconsolable crying, abnormal reflexes, hyperactivity with little ability to maintain alertness and attentiveness to environment, jitteriness, abdominal distention, and exaggerated mouthing behaviors such as hyperactive rooting and increased nonnutritive sucking. Seizures may be common. These symptoms commonly persist throughout the first month of life but may continue longer. Alcohol dependence in the infant is physiologic, not psychologic. Signs and symptoms of withdrawal often appear within 6 to 12 hours and at least within the first 3 days of life. Seizures after the neonatal period are rare.

Nursing diagnoses that may apply to the FAS newborn include the following:

- ***Imbalanced Nutrition: Less Than Body Requirements*** related to decreased oral intake and hyperirritability
- ***Risk for Ineffective Cerebral Tissue Perfusion*** related to microcephaly secondary to maternal alcohol use
- ***Ineffective Coping*** related to dysfunctional family dynamics and substance-dependent mother

Nursing Plan and Implementation

Hospital-Based Nursing Care

Nursing care of the FAS newborn is aimed at avoiding heat loss, providing adequate nutrition, and reducing environmental stimuli. The FAS baby is most comfortable in a quiet, dimly lighted environment. Because of their feeding problems, these infants require extra time and patience during feedings. It is important to provide consistency in the staff working with the baby and parents and to keep personnel and visitors to a minimum at any one time.

The nurse should inform the alcohol-dependent mother that breastfeeding is not contraindicated but that excessive alcohol consumption may intoxicate the newborn and inhibit the let-down reflex. The nurse should monitor the newborn's vital signs closely and observe for evidence of seizure activity and respiratory distress.

Community-Based Nursing Care

Infants affected by maternal alcohol abuse are also at risk psychologically. Restlessness, sleeplessness, agitation, resistance to cuddling or holding, and frequent crying can be frustrating to parents as their efforts to relieve the distress are unrewarded. Feeding dysfunction can also result in frustrations for the caregiver and digestive upsets for the infant. Frustration may cause the parents to punish the baby or result in the unconscious desire to stay away from the infant. Either outcome may create an unstable family environment and result in the infant's failure to thrive.

The nurse should focus on providing support for the parents and reinforcing positive parenting activity. Before discharge, parents should be given opportunities to provide baby care so that they can feel confident in their interpretations of their baby's cues and their ability to meet the baby's needs. Referring the family to social services and visiting nurse or public health nurse associations is essential for the well-being of the infant. Follow-up care and teaching can strengthen the parents' skills and coping abilities and help them create a stable, healthy environment for their family. The infant with FAS should be involved in intervention programs that monitor the child's developmental progress, health, and home environment.

Evaluation

Expected outcomes of nursing care include the following:

- The FAS newborn is able to tolerate feedings and gain weight.
- The FAS infant's hyperirritability is controlled, and the baby has suffered no physical injuries.
- The parents are able to identify and meet the special needs of their newborn and accept outside assistance as needed.

Drug Dependence

Drugs of abuse by the pregnant woman can include, but are not limited to, the following singularly or in combination: tobacco, cocaine, phencyclidine (PCP), methamphetamines, inhalants, marijuana, heroin, antidepressants, and methadone. Patterns of abuse of alcohol, marijuana, and heroin in childbearing women have changed very little in the past few years. The incidence of cocaine (especially "crack") use may have stabilized but oxycodone (oxycontin) use has risen dramatically (see "Substances Commonly Abused During Pregnancy" in chapter 19 ∞ for more discussion of maternal substance abuse). Marijuana, alcohol, and nicotine are sometimes used in conjunction with cocaine.

Intrauterine drug-exposed infants are predisposed to a number of problems. Almost all narcotic drugs cross the placenta and enter the fetal circulation, so the fetus can develop problems in utero or soon after birth. The effects of polydrug use on the newborn must always be taken into consideration.

The greatest risks to the fetus of the drug-dependent mother include the following:

- ***Intrauterine asphyxia.*** Asphyxia is often a direct result of fetal withdrawal secondary to maternal withdrawal. Fetal withdrawal is accompanied by hyperactivity with increased oxygen consumption. Insufficiency of oxygen can lead to fetal asphyxia. Moreover, narcotic-addicted women tend to have a higher incidence of hypertension, abruptio placentae, and placenta previa, resulting in placental insufficiency and fetal asphyxia.
- ***Intrauterine infection.*** Sexually transmitted infections, HIV, and hepatitis are often connected with the pregnant addict's lifestyle. Such infections can involve the fetus.
- ***Alterations in birth weight.*** These may depend on the type of drug the mother uses. Women using predominantly heroin or cocaine have infants of lower birth weight who are small for gestational age (SGA). Women maintained on methadone have higher-birth-weight infants, some of whom are large for gestational age (LGA).
- ***Low Apgar scores.*** These may be related to the intrauterine asphyxia or the medication the woman received during labor. The use of a narcotic antagonist (nalorphine or naloxone) to reverse respiratory depression is contraindicated because it may precipitate acute withdrawal in the infant.

Common Complications of the Drug-Exposed Newborn

The newborn of a woman who abused drugs during her pregnancy is predisposed to the following problems:

- ***Respiratory distress.*** The heroin-addicted newborn frequently suffers respiratory stress, mainly meconium-aspiration pneumonia and transient tachypnea. Meconium aspiration is usually secondary to increased oxygen consumption and activity experienced by the fetus during intrauterine withdrawal. In addition, ingestion of heroin will elevate maternal blood pressure causing uterine vasoconstriction, which in turn reduces placental blood flow leading to fetal hypoxia, fetal distress, and meconium aspiration. Transient tachypnea may develop secondary to the inhibitory effects of narcotics on the reflex responsible for clearing the lungs. Respiratory distress syndrome (RDS), however, occurs less often in heroin-addicted newborns, even in those who are premature, because they have tissue-oxygen unloading capabilities comparable to those of a 6-week-old term infant. In addition, heroin stimulates production of glucocorticoids via the anterior pituitary gland.
- ***Jaundice.*** Newborns of methadone-addicted women may develop jaundice due to prematurity. By contrast, infants of mothers addicted to heroin or cocaine have a lower incidence of hyperbilirubinemia because these substances contribute to early maturity of the liver.
- ***Congenital anomalies and growth restriction.*** Infants of cocaine-addicted mothers exhibit congenital malformations involving bony skull defects, such as microencephaly, and symmetric intrauterine growth restriction (IUGR), cardiac defects, and genitourinary defects. Infants exposed to methamphetamines during gestation may show an increased incidence of cardiac anomalies, symmetrical growth restriction, and low birth weight (LBW) (Cunningham et al., 2010). Congenital anomalies, however, are rare.
- ***Behavioral abnormalities.*** Babies exposed to cocaine have poor state organization. They exhibit decreased interactive behaviors when tested with the Brazelton Neonatal Behavioral Assessment Scale. These infants also have difficulty moving through the various sleep and awake states and have problems attending to and actively engaging in auditory and visual stimuli.
- ***Withdrawal.*** The most significant postnatal problem of the drug-exposed newborn is narcotic withdrawal (usually from heroin or methadone). Withdrawal manifestations often begin within the first 24 to 48 hours of life. See Table 33-4 for a discussion of withdrawal symptoms.

Long-Term Effects

During the first 2 years of life, many cocaine-exposed infants demonstrate susceptibility to behavior lability and are unable to express strong feelings such as pleasure, anger, or distress, or even a strong reaction to being separated from their parents. Cocaine-exposed infants may be at higher risk for motor development problems, cognitive impairment, and feeding difficulties due to swallowing problems (Cunningham et al., 2010). Behavior state control is poorly developed in drug-exposed infants, who tend to rapidly progress from sleep to a wakeful state of crying without smooth transition from one state to the next. As a result, these infants have poor social interaction skills; cannot habituate to external stimuli; and become easily overstimulated, having difficulty sleeping.

Infants of drug-addicted mothers often demonstrate a higher incidence of gastrointestinal (GI) and respiratory illnesses. These illnesses can be related not to drug exposure but to the mothers' lack of education regarding proper infant care, feeding, and hygiene. After birth the infant born to a drug-dependent mother may also be subject to neglect or abuse, or both.

Clinical Therapy

For optimal fetal and newborn outcome, the heroin-addicted woman should receive complete prenatal care as early as possible to reduce maternal morbidity and mortality rates and to promote

TABLE 33-4 Clinical Manifestations of Newborn Withdrawal

Central Nervous System Signs
- Hyperactivity
- High-pitched cry
- Hyperirritability, difficult to console
- Increased muscle tone
- Exaggerated reflexes
- Tremors, myoclonic jerks, seizures
- Sneezing, hiccups, yawning
- Short, unquiet sleep
- Fever (accompanies the increased neuromuscular activities)

Respiratory Signs
- Tachypnea (greater than 60 breaths per minute when quiet)
- Excessive secretions

Gastrointestinal Signs
- Disorganized, vigorous suck
- Vomiting
- Drooling
- Sensitive gag reflex
- Hyperphagia
- Diarrhea
- Poor feeding (less than 15 ml on first day of life; takes longer than 30 minutes per feeding)

Vasomotor Signs
- Stuffy nose, yawning, sneezing
- Flushing
- Sweating
- Sudden, circumoral pallor

Cutaneous Signs
- Excoriated buttocks, knees, elbows
- Facial scratches
- Pressure-point abrasions

fetal stability and growth (Pitts, 2010). Methadone maintenance programs have been the standard to treat the heroin-addicted mother to combat the cravings and to prevent withdrawal. For those women dependent on narcotics, it is not recommended that they be withdrawn completely while pregnant because this induces fetal withdrawal with poor newborn outcomes.

Newborn treatment may include management of complications; serologic tests for syphilis, HIV, and hepatitis B; urine and meconium drug screen; and social service referral. Screening of meconium provides a more comprehensive and accurate indication of exposure over a longer gestational period than does screening of neonatal urine (AAP & ACOG, 2007). Pharmacologic management for opiate withdrawal may include oral morphine sulfate solution, paregoric, tincture of opium, oral methadone, phenobarbital, and diazepam (Pitts, 2010).

Optimal nutritional support to promote adequate weight gain, although a challenge, is important in light of the increase in energy expenditure that withdrawal may entail.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Early identification of the newborn needing clinical or pharmacologic interventions decreases the incidence of mortality and morbidity. The identification of substance-exposed newborns is determined primarily by clinical indicators in the prenatal period including maternal presentation, history of substance use or abuse, medical history, or toxicology results. During the newborn period, nursing assessment focuses on the following:

- Discovering the mother's last drug intake and dosage level. Women may be reluctant to disclose this information; therefore, a nonjudgmental interview technique is essential (AAP & ACOG, 2007).
- Assessing for congenital malformations and the complications related to intrauterine withdrawal, such as SGA, asphyxia, meconium aspiration, and prematurity.
- Identifying the signs and symptoms of newborn withdrawal or neonatal abstinence syndrome (see Table 33-5).

Although many of the signs and symptoms of narcotic withdrawal are similar to those seen with hypoglycemia and hypocalcemia, drug-exposed babies have glucose and calcium values within normal limits.

Neonatal abstinence syndrome (NAS) includes both physiologic and behavioral responses. A number of useful systematic scoring systems are available for assessing severity (Pitts, 2010). The severity of withdrawal can be assessed by a scoring system based on observations and measurement of the responses to neonatal abstinence such as the Finnegan scale. It evaluates the infant on potentially life-threatening signs, such as vomiting, diarrhea, weight loss, irritability, tremors, and tachypnea (Table 33-5). NAS scoring helps to guide the need for pharmacologic intervention. For example, pharmacologic treatment is recommended for Finnegan's scores greater than 8 (Pitts, 2010).

Nursing diagnoses that may apply to drug-dependent newborns include the following:

- ***Risk for CNS Injury*** related to perinatal substance abuse
- ***Impaired Breathing Pattern*** related to meconium aspiration syndrome due to fetal stress and hypoxia
- ***Imbalanced Nutrition: Less Than Body Requirements*** related to vomiting and diarrhea, uncoordinated suck and swallow reflex, hypertonia secondary to withdrawal
- ***Impaired Skin Integrity*** related to constant activity, diarrhea
- ***Impaired Parenting*** related to hyperirritable behavior of the infant and lack of knowledge of infant care
- ***Disturbed Sleep Pattern*** related to CNS excitation secondary to drug withdrawal

Nursing Plan and Implementation

Hospital-Based Nursing Care

Care of the drug-exposed newborn is based on reducing withdrawal symptoms and promoting adequate respiration, temperature, and nutrition. See the Nursing Care Plan: The Newborn

TABLE 33-5 Neonatal Abstinence Score Sheet

Neonatal Abstinence Scoring System

SYSTEM	SIGNS AND SYMPTOMS	SCORE	AM						PM						COMMENTS
Central Nervous System Disturbances	Excessive high-pitched (or other) cry	2													Daily weights
	Continuous high-pitched (or other) cry	3													
	Sleeps < 1 hour after feeding	3													
	Sleeps < 2 hours after feeding	2													
	Sleeps < 3 hours after feeding	1													
	Hyperactive Moro reflex	2													
	Markedly hyperactive Moro reflex	3													
	Mild tremors disturbed	1													
	Moderate-severe tremors disturbed	2													
	Mild tremors undisturbed	3													
	Moderate-severe tremors undisturbed	4													
	Increased muscle tone	2													
	Excoriation (specific area)	1													
	Myoclonic jerks	3													
	Generalized convulsions	5													
Metabolic/Vasomotor/ Respiratory Disturbances	Sweating	1													
	Fever < 101°F (99°F–100.8°F/37.2°C–38.2°C)	1													
	Fever > 101°F (38.4°C and higher)	2													
	Frequent yawning (> 3–4 times/interval)	1													
	Mottling	1													
	Nasal stuffiness	1													
	Sneezing (> 3–4 times/interval)	1													
	Nasal flaring	2													
	Respiratory rate > 60/min	1													
	Respiratory rate > 60/min with retractions	2													
Gastrointestinal Disturbances	Excessive sucking	1													
	Poor feeding	2													
	Regurgitation	2													
	Projectile vomiting	3													
	Loose stools	2													
	Watery stools	3

of a Substance-Abusing Mother on pages 927 to 928 for specific nursing care measures. Some general nursing care measures include the following (Pitts, 2010):

- Performing neonatal abstinence scoring per hospital protocol.
- Monitoring temperature for hyperthermia.
- Carefully monitoring pulse and respirations every 15 minutes and pulse oximetry until stable.
- Providing small, frequent feedings, especially in the presence of vomiting, regurgitation, and diarrhea.
- Properly positioning on the right side-lying or semi-Fowler's to avoid possible aspirations of vomitus or secretions.
- Administering medications as ordered, such as oral morphine, methadone, and tincture of opium. A sedative, such as phenobarbital, is usually used in combination with an opioid, as it does not control any of the GI symptoms associated with NAS (D'Apolito, 2009).
- Monitoring frequency of diarrhea and vomiting, and weighing infant every 8 hours during withdrawal.
- Swaddling with hands near mouth to minimize injury and achieve more organized behavioral state. (Offer a pacifier for nonnutritive, excessive sucking [Figure 33-15 ■]. Gentle, vertical rocking can be successful in calming an infant who is out of control.)
- Protecting face and extremities from excoriation by using mittens and soft sheets or sheepskin.
- Applying protective skin emollient to the groin area with each diaper change.
- Placing newborn in quiet, dimly lighted area of nursery.

Figure 33-15 ■ Nonnutritive sucking on a pacifier has a calming effect on newborn.

Community-Based Nursing Care

Parents need assistance to prepare for what they can expect for the first few months at home. At the time of discharge, the mother should be instructed to anticipate mild jitteriness and irritability in the newborn, which may persist from 6 days to 8 weeks, depending on the initial severity of the withdrawal (Blackburn, 2007). Infants with neonatal abstinence syndrome are at a significantly higher risk for sudden infant death syndrome (SIDS) when the mother used heroin or cocaine. The infant should sleep in a supine position and home apnea monitoring should be implemented. The nurse should demonstrate and help the mother learn feeding techniques, comforting measures, how to recognize newborn cues, and appropriate parenting responses. Parents are to be counseled regarding available resources, such as support groups, and signs and symptoms that indicate the need for further care. Ongoing evaluation is necessary because of the potential for long-term problems. Follow-up on missed appointments can bring parents back into the healthcare system, thereby improving parent and infant outcomes and promoting a positive, interactive environment after birth (AAP & ACOG, 2007).

Evaluation

Expected outcomes of nursing care include the following:

- The newborn tolerates feedings, gains weight, and has a decreased number of stools.
- The parents learn innovative ways to comfort their newborn.
- The parents are able to cope with their frustrations and begin to use outside resources as needed.

Infants of Mothers Who Are Tobacco Dependent

Despite increased knowledge about the dangers of smoking to the fetus and newborn, 15% to 20% of women continue to smoke during pregnancy (Pitts, 2010). The common consequence of tobacco use is addiction to nicotine. Most smokers report true enjoyment, associated with a sense of relaxation during stress, especially with the first cigarette of the day.

Risks of Tobacco to the Fetus and Newborn

Preconceptual cigarette smoking has been found to increase infertility. Fortunately, the reduction in fertility is reversible if the woman stops smoking. Smoking during pregnancy has been associated with spontaneous abortion, premature birth, placenta previa, and abruptio placentae. See "Tobacco" in chapter 16 ∞ for a discussion of maternal care.

The most studied compound found in cigarette smoke that can adversely affect the intrauterine environment is carbon monoxide. Carbon monoxide binds hemoglobin to form carboxyhemoglobin, which reduces the oxygen-carrying capacity of the blood. Oxygen molecules are then displaced thus lowering fetal oxygen levels and impairing tissue oxygenation. Therefore, the fetus can experience intrauterine hypoxia and ischemia. This chronic hypoxia causes the fetus to produce more red blood cells to increase available oxygen-carrying sites resulting in polycythemia/hyperviscosity, which can further impair placental blood flow. Mothers who smoke during pregnancy are more likely to have low birth weight (LBW) infants and premature infants (Pitts, 2010). These infants typically weigh 150 to 250 g less than infants of nonsmokers (Cloherty et al., 2008). The nicotine in cigarettes acts as a neuroteratogen that interferes with fetal development, specifically the developing nervous system. The greatest risks to the fetus and newborn of the mother who smokes include the following (Barron, 2008):

- *Intrauterine growth restriction and/or prematurity* secondary to cigarette metabolites crossing the placenta, displacing oxygen from hemoglobin, and impairing tissue oxygenation
- *Intrauterine distress* presenting as meconium staining and low Apgar scores
- *Neonatal neurobehavioral abnormalities* such as impaired habituation, orientation, consolability, orientation to sound
- *Hypertonia or hypotonia, tremors, increased Moro reflex*
- *Signs of nicotine toxicity* (tachycardia, irritability, poor feeding, tremors)
- *Sudden infant death syndrome (SIDS)*

Clinical Therapy

Inquiry into tobacco and smoke exposure should be a routine part of the prenatal history. Preconception and prenatal counseling about the effects of cigarette smoking on pregnancy and the fetus should occur. An estimated 5% reduction in perinatal mortality would occur if smoking during pregnancy were eliminated (AAP & ACOG, 2007).

Cotinine, a metabolite of nicotine, has been found in fetal body fluids. There is also a positive correlation between the number of cigarettes smoked per day and concentration of cotinine in maternal urine. Other factors that influence fetal and maternal serum cotinine concentrations are nicotine content of the cigarette and the time elapsed between the last cigarette smoked and the sampling. These findings indicate that cotinine may be used as a marker of maternal-fetal tobacco exposure during pregnancy (Kenner & Lott, 2007).

NURSING CARE PLAN The Newborn of a Substance-Abusing Mother

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Risk for CNS Injury related to perinatal substance abuse **Goal:** The newborn will be free of signs and symptoms of central nervous system (CNS) injury.	
■ Obtain prenatal records and question the mother about history of drug use. Include duration, type of drug or drugs used, time and amount of last dose taken before birth.	■ Noting the mother's last drug ingestion will provide the medical staff with an approximate time frame to expect the infant to exhibit withdrawal symptoms.
■ Assess newborn for signs and symptoms of withdrawal (e.g., high-pitched shrill cry, sneezing, vomiting, diarrhea, hypertonicity, restlessness, and wakefulness) using neonatal abstinence scoring tool every 3 hours.	■ The average symptoms of withdrawal occur 72 hours after birth; however, symptoms may appear as early as 6–24 hours after birth.
■ Provide a quiet, calm, darkened environment. Swaddle infant tightly and place in a side-lying or prone position.	■ Providing a quiet environment decreases stimuli, therefore reducing CNS symptoms.
■ Carefully plan tests and/or treatments to avoid excessive stimuli.	■ Planning care promotes rest and reduces external stimuli.
■ Use soothing techniques such as rocking, cuddling, soft music, and soft tones when speaking.	■ These activities promote comfort, security, and infant bonding.
■ Administer appropriate medications as ordered by physician/neonatal nurse practitioner (NNP). Monitor efficacy and side effects of these medications which may include paregoric and Phenobarbital.	■ These medications aid the infant in alleviating symptoms related to withdrawal.
EXPECTED OUTCOMES: Infant will have no signs and symptoms of CNS injury as evidenced by reduced hyperactivity, irritability, normal sleep-wake pattern, no jitteriness, and no seizure activity.	
2. Nursing Diagnosis: Risk for Ineffective Airway Clearance related to suppression of respiratory system **Goal:** Infant will be free of signs and symptoms of respiratory distress after birth.	
■ Obtain maternal prenatal, labor, and birth records.	■ Provides information about fetal stress that may have occurred during the prenatal or intrapartal period. In addition, the birth record will provide information concerning the infant's respiratory status at birth; for example, the Apgar score.
■ Assess infant's respiratory rate and effort, skin color, heart rate, presence or absence of cough reflex, and symptoms of respiratory distress.	■ Maternal narcotic consumption may depress the cough reflex and respiratory center of the newborn after birth. Symptoms such as cyanosis, tachycardia, grunting, retractions, and nasal flaring may indicate hypoxia.
■ Position infant in a side-lying or semi-Fowler's position.	■ Prevents aspiration.
■ Monitor infant for temperature elevation.	■ Temperature elevation may cause metabolic rate and oxygen needs to increase when associated with CNS stimulation.
Collaborative: Obtain arterial blood gases (ABGs) as ordered by physician.	■ Oxygen demands increase with drug withdrawal. Obtaining ABGs will provide healthcare personnel baseline information on infant's respiratory status, and effective medical interventions can be initiated.
■ Monitor infant's cardiac status and pulmonary status using electrocardiogram (ECG) and pulse oximetry.	■ Provides healthcare personnel with cardiac and pulmonary status.
EXPECTED OUTCOMES: The newborn will maintain adequate respiratory effort as evidenced by respirations of 30–60/min; no signs of retractions, grunting, or cyanosis; and arterial blood gases are within normal range.	
3. Nursing Diagnosis: Imbalanced Nutrition: Less Than Body Requirements related to vomiting and diarrhea, uncoordinated suck and swallow reflex, and hypertonia secondary to withdrawal **Goal:** The infant will gain or maintain weight.	
■ Review gestational age assessment.	
■ Assess infant's sucking and swallowing reflexes.	
■ Monitor regurgitation, vomiting, diarrhea.	■ Gastrointestinal (GI) hypermobility, irritation, and CNS stimulation can increase nutritional needs.
■ Use bulb syringe before feedings if newborn is having problems with nasal stuffiness and congestion.	■ Allows infant to breathe easier by ridding the nasal passages of excessive mucus.

(continued)

NURSING CARE PLAN **The Newborn of a Substance-Abusing Mother** continued

INTERVENTION	RATIONALE
■ Initiate appropriate feedings per physician's orders (e.g., oral, gavage, or IV feedings).	■ Oral feeding may be difficult because of CNS hyperactivity and GI hypermobility.
■ Provide small frequent feedings of a high-calorie formula.	■ Facilitates nutritional intake because small-for-gestational age (SGA) infants require 120–150 kcal/kg/day for adequate nutrition.
■ Position infant on right side after feedings.	■ Prevents regurgitation and promotes gastric emptying.
■ Monitor infant's weight and document on graph.	■ Identifies abnormalities in weight gain/loss and allows for early intervention when necessary.
■ Offer pacifier between feedings for nonnutritive sucking.	■ Nonnutritive sucking allows for sucking practice, management of infant pain, and allows self-consoling behaviors.

EXPECTED OUTCOMES: The infant will tolerate feedings, maintain weight, or gain weight as evidenced by no regurgitation or aspiration of feedings, adequate weight gain according to weight graph.

4. Nursing Diagnosis: Risk for Impaired Parenting related to lack of knowledge of infant care
Goal: The parent will demonstrate ability to independently provide infant care.

■ Assess mother's desire to learn infant care tasks as well as evaluate her present physical and emotional stability.	■ Provides knowledge of mother's ability to care for infant.
■ Instruct mother on coping strategies (e.g., exercise, listening to music, and discussing concerns openly) to manage stressful situations.	■ Gives mother the tools to handle stress, thereby decreasing the chances of exhibiting abusive behavior.
■ Assess mother's insight into her own chemical dependency.	■ Assistance in enrollment into a chemical dependency program may be necessary before mother can independently care for infant.
■ Instruct mother on signs and symptoms of withdrawal and treatment interventions.	■ Assists the mother in understanding infant's behaviors and gives her the tools to intervene without feeling anxious.
■ Offer a night of "nesting in" with infant before discharge.	■ Assists parents to care for infant by themselves, but with nursing support nearby.
■ Encourage mother and family members to perform basic infant care tasks.	■ Facilitates attachment and increases parenting competence.
■ Initiate social service consult as needed.	

EXPECTED OUTCOMES: The parent will demonstrate ability to perform basic infant care tasks as evidenced by exhibiting appropriate attachment behaviors (i.e., talking to and holding infant), feeding infant, and bathing infant.

NURSING CARE MANAGEMENT

Mothers should be counseled that eliminating or reducing smoking even late in pregnancy can improve fetal growth. The use of nicotine patches (instead of smoking) reduces the absorption of nicotine and thereby may result in increased birth weight of the fetus. See "Tobacco" in chapter 16 ∞ for further discussion of prenatal smoking cessation and other intervention programs. Newborns of mothers who are tobacco dependent may be screened with the NICU Network Neurobehavioral Scale (NNNS) to assess their neurologic, behavioral, and stress/abstinence neurobehavioral function (Kenner & Lott, 2007).

The potential for long-term respiratory problems such as asthma, as well as cognitive and receptive language delays that may persist into school age, should be evaluated.

Care of the Newborn Exposed to HIV/AIDS

In the United States, approximately 6000 pregnant women infected with the HIV virus give birth each year. Preventative strategies have reduced the risk of maternal-child transmission of HIV to approximately 1% to 2% (Havens & Mofenson, 2009). Most HIV transmissions during the perinatal and newborn periods can occur across the placenta or through breast milk or contaminated blood (Lott, 2010). The risk of vertical transmission in mothers not receiving antiretroviral (ARV) drug regimen such as oral zidovudine (ZDV) during gestation is 13% to 39% (Venkatesh, Adams, & Weisman, 2011). Pregnant women should be universally tested (with patient notification) for HIV infection as part of the routine battery of prenatal blood tests unless they decline the test (i.e., opt-out approach) as permitted by local and state regulation (Havens & Mofenson,

2009). Refusal of testing should be documented. For further discussion of maternal and fetal HIV/AIDS, see chapter 19 ∞. Some infants infected by maternal-fetal transmission suffer from severe immunodeficiency, with HIV disease progressing more rapidly during the first year of life.

Early identification of babies with or at risk for HIV/AIDS is essential during the newborn period. HIV-1 diagnostic testing for infants and children younger than 18 months differs from older children. Currently available HIV serologic tests (enzyme-linked immunosorbent assay [ELISA] and Western blot test) cannot distinguish between maternal and infant antibodies; therefore, they are inappropriate for infants up to 18 months of age. It may take up to 18 months for infected infants to form their own antibodies to HIV (Havens & Mofenson, 2009). Testing by HIV-1 nucleic acid amplification tests (NAATs) are the preferred tests. Results can be made available within 24 hours (Venkatesh et al., 2011). The first NAAT tests should be performed on the newborn before 12 hours of age (Havens & Mofenson, 2009). Umbilical cord blood should not be used for HIV testing because of the possibility of maternal blood contamination leading to false positive results. A repeat test should be performed at 1 to 2 months of age and again at 4 to 6 months of age (Havens & Mofenson, 2009). Most clinicians confirm the absence of HIV-1 infection with a negative HIV-1 antibody assay result at 12 to 18 months of age (Havens & Mofenson, 2009).

For term infants, AZT (zidovudine [ZDV]) is started prophylactically 2 mg/kg/dose PO every 6 hours beginning at 8 to 12 hours of life and continuing for 6 weeks (Havens & Mofenson, 2009; Venkatesh et al., 2011). If the infant is confirmed to be HIV positive, ZDV is changed to a multidrug antiretroviral regimen. Breastfeeding in developed countries should be avoided with an HIV-positive mother as transmission of the HIV virus to the newborn in breast milk is well documented (Havens & Mofenson, 2009).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Many newborns exposed to HIV/AIDS are premature or small for gestational age (SGA), or both, and show failure to thrive during the newborn and infant periods. They can show signs and symptoms of disease within days of birth. Signs that may be seen in the early infancy period include enlarged spleen and liver, swollen glands, recurrent respiratory infections, rhinorrhea, interstitial pneumonia (rarely seen in adults), recurrent gastrointestinal (GI) problems (diarrhea and weight loss), organic failure to thrive, urinary system infections, persistent or recurrent oral and genital candidiasis infections, and loss of developmental milestones (Venkatesh et al., 2011). There is also a high risk of acquiring *Pneumocystis carinii* pneumonia. Opportunistic diseases such as gram-negative sepsis and problems associated with prematurity are the primary causes of mortality in HIV-infected babies.

Nursing diagnoses that may apply to the infant exposed to HIV/AIDS include the following:

- ***Imbalanced Nutrition: Less Than Body Requirements*** related to formula intolerance and inadequate intake
- ***Risk for Impaired Skin Integrity*** related to chronic diarrhea
- ***Risk for Infection*** related to perinatal exposure and immunoregulation suppression secondary to HIV/AIDS
- ***Impaired Physical Mobility*** related to decreased neuromuscular development
- ***Delayed Growth and Development*** related to lack of attachment and stimulation
- ***Impaired Parenting*** related to diagnosis of HIV/AIDS and fear of future outcome

Nursing Plan and Implementation

Hospital-Based Nursing Care

Nursing care of the newborn exposed to HIV/AIDS includes all the normal care required for any newborn in a nursery. In addition, the nurse must include care for a newborn suspected of having a blood-borne infection, as with hepatitis B. Standard Precautions should be used when caring for the newborn immediately after birth until all maternal blood is removed and when obtaining blood samples via vein puncture or heel stick. (The blood of all newborns must be considered potentially infectious because the status of the infant's blood is often not known until after the infant is discharged. Most institutions recommend that their caregivers wear gloves during all diaper changes, especially in the presence of diarrhea because blood may be in the stool, and during examination of the newborn [AAP & ACOG, 2007]. There is a window of time before seroconversion occurs, during which the baby is still considered infectious.)

See Table 33-6 for some general issues for all caregivers of the newborn at risk for HIV/AIDS. In addition, the nurse provides for comfort; keeps the newborn well nourished and protected from opportunistic infections; provides good skin care to prevent skin rashes; and facilitates growth, development, and attachment.

CLINICAL JUDGMENT

Case Study: Jean Corrigan

Mrs. Jean Corrigan, a 23-year-old GIPI positive for HIV, has just given birth to a 7 lb, 1 oz baby girl. As she watches you assessing her daughter in the birthing room, she asks why you are wearing gloves and whether her daughter will have to be in isolation.

Critical Thinking

What will your response be to the new mother?

See www.nursing.pearsonhighered.com for possible responses.

Community-Based Nursing Care

Hand washing is crucial when caring for newborns at risk for AIDS; thus, parents must be taught proper hand washing technique. Nutrition is essential because failure to thrive and weight loss are common. Small, frequent feedings and food supplementation are helpful. The nurse should discuss with the parents sanitary techniques for preparing formula. The nurse should also inform parents that the baby should not be put to bed with juice or formula because of potential bacterial growth. Parents need to be alert to the signs of feeding intolerance, such

TABLE 33-6 Issues for Caregivers of Infants at Risk for HIV/AIDS

Resuscitation	For suctioning use a bulb syringe, mucus extractor, or meconium aspirator with wall suction on low setting. Use masks, goggles, and gloves.
Admission Care	To remove blood from baby's skin, give warm water-mild soap bath using gloves as soon as possible after admission.
Hand Washing	Thorough hand washing is indicated before and after caring for infant. Hands must be washed immediately if contaminated with blood or body fluids. Wash hands after removal of gloves.
Gloves	Gloves are indicated with touching blood or other high-risk fluids. Gloves should also be worn when handling newborns before and during their initial baths, cord care, eye prophylactics, and vitamin K administration.
Mask, Goggle, and Gown	Not routinely needed unless coming in contact with placenta or the blood and amniotic fluid on the skin of the newborn.
Needles and Syringes	Used needles should not be recapped or bent; they should be disposed of in a puncture-resistant plastic container belonging specifically to that baby. After the newborn is discharged the container is discarded.
Specimens	Blood and other specimens should be double bagged and/or sealed in an impervious container and labeled according to agency protocol.
Equipment and Linen	Articles contaminated with blood or body fluids should be discarded or bagged according to isolation or institution protocol.
Body Fluid Spills	Blood and body fluids should be cleaned promptly with a solution of 5.25% sodium hypochlorite (household bleach) diluted 1:10 with water. Apply for at least 30 seconds then wipe after the minimum contact time.
Education and Support	Provide education and psychologic support to family and staff. Caregivers who avoid contact with the baby at risk or who overdress in unnecessary isolation garb subtly exacerbate an already difficult family situation. Information resources include the National AIDS Hotline (1-800-342-2437) and the AIDS Clinical Trials Information Service (1-800-TRIALS-A).
Exempted Personnel	Immunologically compromised staff (pregnant women may be included in this group) and possibly infectious staff members should not care for these infants.

Issues related to human immunodeficiency transmission in schools, child care, medical settings, the home, and community. Pediatrics, 104*(2), 318–324; Mendez, H., & Jule J. E. 1990. Care of the infant born exposed to AIDS.* Obstetric and Gynecologic Clinics of North America, *17(3), 637; Krist, A. H., & Crawford-Faucher, A. (2002). Management of newborns exposed to maternal HIV infection.* American Family Physician, 65*(10), 2049–2056.*

as increasing regurgitation, abdominal distention, and loose stools. The newborn should be weighed three times a week.

The baby should have his or her own skin care items, towels, and washcloths. Most clothing and linens can be washed with other household laundry. Linen that is visibly soiled with blood or body fluids should be kept separate and washed separately in hot, sudsy water with household bleach. Prompt diaper changing and perineal care can prevent or minimize diaper rash and promote comfort. The diaper-changing area in the home should be separate from the food preparation and serving areas. Soiled diapers are to be placed in plastic bags, sealed, and disposed of daily. Diaper-changing areas should be cleaned with a 1:10 dilution of household bleach after each diaper change. Toys should be kept as clean as possible, and they should not be shared with other children. Toys should be checked for sharp edges to prevent scratches.

The nurse should instruct parents in what signs of infection to be alert for and when to call their healthcare provider. The inability to feed without pain may indicate esophageal yeast infection and may require administration of oral nystatin (Mycostatin) for oral thrush. Topical Mycostatin or Desitin ointment is used for diaper rashes. If diarrhea occurs, the baby requires frequent perineal care and fluid replacements. Antidiarrheal medications are often ineffective. Taking rectal temperatures should be avoided, as it may stimulate diarrhea. Fluids, antipyretics, and sponging with tepid water are of use in managing fever. Irritability may be the first sign of fever.

Preventive care for exposed infants includes routine immunizations, except the combined measles-mumps-rubella-varicella (MMRV). HIV-1 exposed and infected infants should receive the rotavirus vaccine at 2, 4, and 6 months of age (Havens & Mofenson, 2009).

Parents and family members need to be reassured that there are no documented cases of people contracting HIV/AIDS from routine care of infected babies. Emotional support for the family is essential because of the stress and social isolation they may face. Because of these stresses, parents may not bond with the baby or may fail to provide the baby with enough sensory and tactile stimulation. The nurse should instruct the parents to hold the baby during feedings because the infant will benefit from frequent, gentle touch. Auditory stimulation may also be provided using music or tapes of parents' voices. The nurse should offer information to families about support groups, available counseling, and information resources.

All infants born to HIV-positive mothers require regular clinical, immunologic, and virologic monitoring. At 1 month of age, the baby's physical examination should include a developmental assessment and a complete blood count, including differential blood count, CD4+ count, and platelet count. Prophylaxis for *Pneumocystis carinii* pneumonia for all infants born to HIV-infected women should be begun after completion of the ZDV prophylaxis regimen (Venkatesh et al., 2011). Pediatric HIV disease raises many healthcare issues for the family. The parents, depending on their health status, may or may not be able to care for their infant, and they must deal with many psychosocial and economic issues.

Evaluation

Expected outcomes of nursing care include the following:

- The parents are able to bond with their infant and have realistic expectations about the baby.
- Potential opportunistic infections are identified early and treated promptly.

- The parents verbalize their concerns surrounding their baby's existing and potential health problems and accept outside assistance as needed.

Care of the Newborn with Congenital Heart Defect

Congenital heart defects (CHD) occur in 3% to 8% of live births (depending on severity of the structural defects). Because accurate diagnosis and surgical treatments are now available, many deaths can be prevented (Cloherty et al., 2008). Corrective cardiac surgery is being done at earlier ages; for example, more than one half of children undergoing surgery are less than 1 year of age, and one fourth are less than 1 month old. It is crucial for the nurse to have comprehensive knowledge of congenital heart disease to detect deviations from normal and to initiate interventions.

Overview of Congenital Heart Defects

In the majority of the cases of congenital heart malformations, the cause is multifactorial with no specific trigger with the diagnosis usually made within the first week of life. Other factors that might influence development of congenital heart malformations can be classified as environmental or genetic. Infections of the pregnant woman, such as rubella, cytomegalovirus, coxsackie B, and influenza, have been implicated. Steroids, alcohol, lithium, and some anticonvulsants have been shown to cause malformations of the heart. Seasonal spraying of pesticides has also been linked to an increase in congenital heart defects. Clinicians are also beginning to see cardiac defects in infants of mothers with phenylketonuria who do not follow their diets. Infants with Down syndrome, Turner's syndrome, Holt-Oram syndrome, trisomy 13, and trisomy 18 frequently have heart lesions. Increased incidence and risk of recurrence of specific defects occur in families.

The common cardiac defects seen in the first 6 days of life are left ventricular outflow obstructions (mitral stenosis, aortic stenosis, or atresia), hypoplastic left heart, coarctation of the aorta, patent ductus arteriosus (PDA) (the most common defect), transposition of the great vessels, tetralogy of Fallot, and large ventricular septal defect or atrial septal defects.

CLINICAL TIP

When cyanosis occurs in an otherwise healthy 12- to 24-hour-old newborn displaying no respiratory distress and is unresolved with oxygen, think about a cardiac, especially a ductal-dependent, lesion.

NURSING CARE MANAGEMENT

The primary goals of the neonatal nurse are early identification of cardiac defects and initiation of referral to the physician. The three most common manifestations of a cardiac defect are cyanosis, detectable heart murmur, and signs of congestive heart failure (tachycardia, tachypnea, diaphoresis, hepatomegaly, and cardiomegaly). Table 33-7 presents the clinical manifestations and medical/surgical management of these cardiac defects.

Initial repair of heart defects in the newborn period is becoming more commonplace. The neonatal intensive care unit (NICU) staff is now more involved in both the preoperative and postoperative care of cardiac newborns. The benefits for the cardiac infant of being cared for by NICU staff include the staff's knowledge of neonatal anatomy and physiology, experience in supporting the family, and an awareness of the developmental needs of the newborn.

After the baby is stabilized, decisions are made about the special ongoing care needs. The parents need careful and complete explanations and the opportunity to take part in decision making. They also require ongoing emotional support. Families of all babies born with congenital abnormalities need genetic counseling regarding future conception. Parents need to verbalize their concern about their baby's health maintenance and to understand the rationale for follow-up care.

Care of the Newborn with Inborn Errors of Metabolism

Inborn errors of metabolism are a group of hereditary disorders that are transmitted by mutant genes. Each causes an enzyme defect that blocks a metabolic pathway and leads to an accumulation of toxic metabolites and in some cases, irreversible brain damage. Most of the disorders are transmitted by an autosomal recessive gene, requiring two heterozygous parents to produce a homozygous infant with the disorder. Heterozygous parents carrying some inborn errors of metabolism disorders can be identified by special tests, and some inborn errors of metabolism can be detected and treated in utero. Some of the inborn errors of metabolism (especially those associated with intellectual disability [mental retardation]) are now detected neonatally through newborn screening programs. With new laboratory technology and the introduction of tandem mass spectrometry (MS/MS), a spot of blood from a newborn can deduct more than 50 inborn errors of metabolism (Matthews & Robin, 2011). For a discussion of other newborn screening tests, such as cystic fibrosis (CF), see chapter 31 ∞.

Types of Inborn Errors of Metabolism

Phenylketonuria (PKU) is the most common of the group of metabolic errors known as amino acid disorders. Newborn screenings have set its incidence at about 1 in 12,000 live births in the United States; however, the incidence varies considerably among ethnic groups (Sterk, 2010). The highest incidence worldwide is noted in white populations from northern Europe and the United States. It is rarely observed in people of African, Hispanic, Chinese, or Japanese descent (Kaye & Committee on Genetics, 2006).

Phenylalanine is an essential amino acid (found in dietary protein) used by the body for growth, and in the normal individual any excess is converted to tyrosine. The newborn with PKU lacks this converting ability, which results in an accumulation of

TABLE 33-7 Cardiac Defects of the Early Newborn Period

CONGENITAL HEART DEFECT	CLINICAL FINDINGS	MEDICAL/SURGICAL MANAGEMENT
Increased Pulmonary Blood Flow		
Patent Ductus Arteriosus (PDA) ↑ in females, maternal rubella, respiratory distress syndrome (RDS), less than 1500 g preterm newborns, high-altitude births	Harsh grade 2–3 machinery murmur upper left sternal border (LSB) just beneath clavicle ↑ difference between systolic and diastolic pulse pressure Can lead to right heart failure and pulmonary congestion ↑ left atrial (LA) and left ventricular (LV) enlargement, dilated ascending aorta ↑ pulmonary vascularity	Indomethacin—0.2 mg/kg IV Q12h × 3 doses Neoprofen—10 mg/kg IV × 1 dose then 5 mg/kg IV @ 24 & 48 hrs from first dose (both prostaglandin inhibitors) Surgical ligation, occlusion coil Use of O_2 therapy and blood transfusion to improve tissue oxygenation and perfusion Fluid restriction, Digoxin, and diuretics
 The patent ductus arteriosus is a vascular connection that, during fetal life, short-circuits the pulmonary vascular bed and directs blood from the pulmonary artery to the aorta. Postnatally, blood shunts through the ductus from the aorta to the pulmonary artery. *Source: © 2010 Abbott Laboratories, used with permission.*		
Atrial Septal Defect (ASD) ↑ in females and Down syndrome	Initially frequently asymptomatic Systolic murmur second left intercostal space (LICS) With large ASD, diastolic rumbling murmur lower left sternal (LLS) border Failure to thrive, upper respiratory infection (URI), poor exercise tolerance	Surgical closure with patch or suture Umbrella occluder
Ventricular Septal Defect (VSD) ↑ in males	Initially asymptomatic until end of first month or large enough to cause pulmonary edema Loud, blowing systolic murmur between the third and fourth intercostal space (ICS) pulmonary blood flow Right ventricular hypertrophy Rapid respirations, growth failure, feeding difficulties Congestive right heart failure at 6 weeks–2 months of age	Follow medically—some spontaneously close Use of Digoxin and diuretics in congestive heart failure (CHF) Surgical closure with Dacron patch or umbrella occluder
Obstruction to Systemic Blood Flow		
Coarctation of Aorta Can be preductal or postductal	Absent or diminished femoral pulses Increased brachial pulses Late systolic murmur left intrascapular area Systolic BP in lower extremities Enlarged left ventricle Can present in CHF at 7–21 days of life	Surgical resection of narrowed portion of aorta Prostaglandin E_1 to maintain patency of PDA to ensure systemic blood flow No afterload reducer drugs
 Coarctation of the aorta is characterized by a narrowed aortic lumen. The lesion produces an obstruction to the flow of blood through the aorta, causing an increased left ventricular pressure and workload. *Source: © 2010 Abbott Laboratories, used with permission.*		

TABLE 33-7 Cardiac Defects of the Early Newborn Period continued

Hypoplastic Left Heart Syndrome	Normal at birth—cyanosis and shocklike congestive heart failure develop within a few hours to days Soft systolic murmur just left of the sternum Diminished pulses Aortic and/or mitral atresia Tiny, thick-walled left ventricle Large, dilated, hypertrophied right ventricle X-ray examination: cardiac enlargement and pulmonary venous congestion	Prostaglandin E_1 (PGE_1) until decision made Norwood procedure Fontan procedure Transplant Compassionate care
Decreased Pulmonary Blood Flow		
Tetralogy of Fallot (TET) Pulmonary stenosis Ventricular septal defect (VSD) Overriding aorta Right ventricular hypertrophy	May be cyanotic at birth or within first few months of life Harsh systolic murmur LSB Crying or feeding increases cyanosis and respiratory distress X-ray: boot-shaped appearance secondary to small pulmonary artery Right ventricular enlargement	Prevention of dehydration, intercurrent infections Alleviation of paroxysmal dyspneic attacks Palliative surgery to increase blood flow to the lungs Corrective surgery—resection of pulmonic stenosis, closure of VSD with Dacron patch
	In tetralogy of Fallot, the severity of symptoms depends on the degree of pulmonary stenosis, the size of the ventricular septal defect, and the degree to which the aorta overrides the septal defect. *Source: © 2010 Abbott Laboratories, used with permission.*	
Mixed Defects*		
Transposition of Great Vessels (TGA) (Most common cyanotic heart defect) ↑ females, infants of diabetic mothers (IDMs), LGAs	Cyanosis at birth or within 3 days Possible pulmonic stenosis murmur Right ventricular hypertrophy Polycythemia "Egg on its side" x-ray finding	Prostaglandin E to maintain patency of the PDA Initial surgery to create opening between right and left side of heart if none exists Total surgical repair—usually the arterial switch procedure—done within first few days of life
	Complete transposition of great vessels is an embryologic defect caused by a straight division of the bulbar trunk without normal spiraling. As a result, the aorta originates from the right ventricle, and the pulmonary artery from the left ventricle. An abnormal communication between the two circulations must be present to sustain life. *Source: © 2010 Abbott Laboratories, used with permission.*	

Source: Illustrations from Congenital Heart Abnormalities. *Clinical Education Aid No. 7, Ross Laboratories, Columbus, OH.*

* *Note:* Mixed defects-postnatal survival is dependent upon mixing of systemic and pulmonary blood flow.

Figure 33-16 ■ Guthrie card for newborn testing.

Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.

phenylalanine in the blood. Phenylalanine produces two abnormal metabolites, phenylpyruvic acid and phenylacetic acid, which are eliminated in the urine, producing a musty odor. Excessive accumulation of phenylalanine and its abnormal metabolites in the brain tissue leads to progressive intellectual disability. The Guthrie blood test for PKU is required for all newborns before discharge. The Guthrie test uses a drop of blood collected from a heel stick and placed on filter paper (Figure 33-16 ■). Because phenylalamine metabolites begin to build up in the PKU baby once milk feedings are initiated, the test is done at least 24 hours after the initiation of feedings containing the usual amounts of breast milk or formula. At-risk newborns should be receiving a 60% milk intake, with no more than 40% of their total intake coming from nonprotein IV fluids. The PKU testing of high-risk newborns should be deferred for at least 48 hours after hyperalimentation is initiated. It is vital that the parents understand the need for the screening procedure, and a follow-up check is necessary to confirm that the test was done.

Maple syrup urine disease (MSUD) is an inborn error of metabolism that, when untreated, is a rapidly progressing and often fatal disease caused by an enzymatic defect in the metabolism of the branched chain amino acids leucine, isoleucine, and alloisoleucine. Diagnosis of MSUD is made by analyzing blood levels of leucine, isoleucine, and alloisoleucine. Confirmation of the diagnosis depends on plasma amino acid assay.

Homocystinuria is a disorder caused by a deficiency of the enzyme cystathionine beta-synthase (CBS), which alters the pathway of the conversion of methionine to cysteine. Screening is done by a bacterial inhibition assay (BIA) to detect increased blood methionine (Kaye & Committee on Genetics, 2006). No symptoms are usually seen in the newborn period. Treatment consists of high doses of vitamin B_6.

Galactosemia is an inborn error of carbohydrate metabolism in which the body is unable to use the sugars galactose and lactose. Enzyme pathways in liver cells normally convert galactose and lactose to glucose. In galactosemia, one step in that conversion pathway is absent, either because of the lack of the enzyme galactose 1-phosphate uridyltransferase or because of the lack of the enzyme galactokinase. High levels of unusable galactose circulate in the blood, causing cataracts, brain damage, and liver damage. There appear to be ethnic differences in age of onset of symptoms and in severity of course. Caucasians have more severe symptoms and earlier onset (3 to 14 days) than people of African descent (14 to 28 days).

Another disorder frequently included in mandatory newborn blood screening tests is *congenital hypothyroidism (CH).* An inborn enzymatic defect, lack of maternal dietary iodine, or maternal ingestion of drugs that depress or destroy thyroid tissue can cause CH. An elevated thyroid-stimulating hormone (TSH) and low T_4 are commonly seen in the premature infant following birth; it may be necessary to repeat levels at 2 to 6 weeks of age. Congenital hypothyroidism occurs more often in Hispanic and Native American/Alaska native people. Infants with Down syndrome are also at increased risk of having CH (Kaye & Committee on Genetics, 2006).

The incidence of metabolic errors is relatively low, but for affected infants and their families these disorders pose a threat to survival and frequently require lifelong treatment.

Clinical Therapy

All states have universal screening of newborns for PKU, CH, and galactosemia (Matthews & Robin, 2011; Sterk, 2010). Mandatory newborn screening for other inborn errors of metabolism, including homocystinuria, MSUD, sickle cell anemia, cystic fibrosis (CF), and congenital adrenal hypoplasia, varies among states. In several states newborn screening includes an enzyme assay for galactose 1-phosphate uridyltransferase; however, this test does not detect galactosemia if it is caused by a deficiency of the enzyme galactokinase.

Identification via newborn screening and early clinical intervention for inborn errors of metabolism becomes more difficult with the advent of early discharge of newborns. If the initial specimen is obtained before 24 hours of age, then a second specimen should be obtained before 5 days of age, although few states currently require the second test (Kaye & Committee on Genetics, 2006). Early collection of specimens may yield false-positive results for certain metabolic disorders. Conversely, certain metabolic disorders may go undetected. Newborns in the NICU who require interhospital transfers and early-discharged healthy newborns are at risk for nonscreening. Newborn screen specimens are always collected before a blood transfusion.

NURSING CARE MANAGEMENT

The nurse assesses the newborn for signs of inborn errors of metabolism and carries out state-mandated newborn testing. Parents of affected newborns should be referred to support groups. The nurse should also ensure that parents are informed about centers that can provide them with information about biochemical genetics and dietary management.

Infant with PKU

The clinical picture of a PKU baby involves a normal appearing newborn, most often with blond hair, blue eyes, and fair complexion. Decreased pigmentation may be related to the

competition between phenylalanine and tyrosine for the available enzyme tyrosinase. Tyrosine is needed for the formation of melanin pigment and the hormones epinephrine and thyroxine. Without treatment, the infant fails to thrive and develops vomiting and eczematous rashes. By about 6 months of age, the infant exhibits behavior indicative of intellectual disability and other central nervous system (CNS) involvement, including seizures and abnormal electroencephalogram (EEG) patterns.

The nurse advises parents that once identified, an afflicted PKU infant can be treated by a special diet that limits ingestion of phenylalanine. Special formulas low in phenylalanine, such as Lofenalac, Minafen, and Albumaid XP, are available. Special food lists are helpful for parents of a PKU child (Blackburn, 2007). If treatment is begun before 1 month of age, CNS damage can be minimized. There is an increased risk of producing an intellectually disabled child if the mother with PKU is not on a low-phenylalanine diet during pregnancy. It is recommended that the woman reinstate her low-phenylalanine diet a few months before becoming pregnant (Blackburn, 2007).

Infant with Maple Syrup Urine Disease (MSUD)

Newborns with MSUD have feeding problems and neurologic signs (seizures, spasticity, opisthotonos) during the first week of life. A maple syrup odor of the urine is noted, and when ferric chloride is added to the urine, its color changes to gray-green. An ear swab within 6 to 12 hours after birth has a similar smell. Diagnosis is confirmed with plasma amino analysis.

Newborns with MSUD must be given a formula that is low in the branched-chain amino acids leucine, isoleucine, and valine, which is continued indefinitely. Dietary treatment before 12 days of life has been reported to result in normal intelligence.

Infant with Homocystinuria

Homocystinuria varies in its presentation, but the more common characteristics are skeletal abnormalities, dislocation of ocular lenses, intravascular thromboses, and intellectual disability. Abnormalities occur because of the toxic effects of the accumulation of methionine and the metabolite homocystine in the blood.

Infants with homocystinuria are managed on a diet that is low in methionine but supplemented with cystine and pyridoxine (vitamin B_6). Early diagnosis and careful management may prevent intellectual disability.

Infant with Galactosemia

Clinical manifestations of galactosemia include vomiting soon after ingestion of milk-based formula or breast milk, diarrhea, poor weight gain, hepatosplenomegaly, jaundice, and intellectual disability. The condition is frequently associated with anemia, sepsis, and cataracts in the newborn period (Sterk, 2010). Except for cataracts and intellectual disability, those findings are reversible when galactose is excluded from the diet. Intellectual disability can be prevented by early diagnosis and careful dietary management.

A baby with galactosemia is placed on a galactose-free diet. Galactose-free formulas include Nutramigen (a protein hydrolysate process formula), meat-based formulas, or soybean formulas. As the infant grows, parents must be educated not only to avoid giving their child milk and milk products but also to read all labels carefully and avoid any foods containing dry milk products. Even with early treatment, children may have learning disabilities, speech problems, and female ovarian failure (Kaye & Committee on Genetics, 2006).

Infant with Congenital Hypothyroidism (CH)

Approximately 5% of infants with CH, generally those who are more severely affected, have recognizable features at birth, including a large tongue, umbilical hernia, cool and mottled skin, low hairline, hypotonia, and large fontanelles (especially the posterior fontanelle in term infants) (Kaye & Committee on Genetics, 2006). Early symptoms include prolonged newborn jaundice, poor feeding, constipation, low-pitched cry, poor weight gain, inactivity, and delayed motor development. In addition, premature infants of less than 30 weeks' gestation frequently have lower T_4 and thyroid-stimulating hormone (TSH) values than those of term infants. This difference may reflect the premature infant's inability to bind thyroid hormone and a risk for hypothyroidism.

Babies with CH need frequent laboratory monitoring and adjustment of thyroid medication to accommodate their growth and development. With adequate treatment, children remain free of symptoms, but if the condition is untreated, stunted growth (slowed linear growth) and intellectual disability occur.

Evaluation

Expected outcomes of nursing care include the following:

- The risk of inborn errors of metabolism is promptly identified, and early intervention is initiated.
- The parents verbalize their concerns about their baby's nutritional status, health problems, long-term care needs, and potential outcomes.
- The parents are aware of available community health resources and use them as indicated.

FOCUS YOUR STUDY

- Early identification of potential high-risk fetuses through assessment of preconception, prenatal, and intrapartal factors facilitates strategically timed nursing observations and interventions.
- High-risk newborns, whether they are premature, small for gestational age (SGA), large for gestational age (LGA), postterm, or infants of a diabetic or substance-abusing mother, have many similar problems, although their problems are based on different physiologic processes.
- SGA newborns are associated with perinatal asphyxia and resulting meconium aspiration syndrome, hypothermia, hypoglycemia, hypocalcemia, polycythemia, congenital anomalies, and intrauterine infections. Long-term problems include continued growth and learning difficulties.
- LGA newborns are at risk for birth trauma as a result of cephalopelvic disproportion, meconium aspiration syndrome, hypoglycemia, polycythemia, and hyperviscosity.
- Infants of diabetic mothers are at risk for hypoglycemia, hypocalcemia, hyperbilirubinemia, polycythemia, and respiratory distress due to delayed maturation of their lungs.
- Postterm newborns often encounter intrapartal problems such as cephalopelvic disproportion (CPD), shoulder dystocia, and birth traumas, hypoglycemia, polycythemia, meconium aspiration, cold stress, and possible seizure activity.
- The common problems of the preterm newborn are results of the baby's immature body systems. Potential problem areas include respiratory distress syndrome (RDS), patent ductus arteriosus (PDA), hypothermia and cold stress, feeding difficulties and necrotizing enterocolitis (NEC), marked insensible water loss and loss of buffering agents through the kidneys, infection, anemia of prematurity, apnea and intraventricular hemorrhage (IVH), retinopathy of prematurity, and behavioral state disorganization. Long-term needs and problems include chronic lung disease, speech defects, sensorineural hearing loss, and neurologic sequelae.
- Newborns of alcohol-dependent mothers are at risk for alterations in physical characteristics and the long-term complications of feeding problems; central nervous system (CNS) dysfunction, including lower IQ, hyperactivity, and language abnormalities; and congenital anomalies.
- Newborns of drug-dependent mothers experience drug withdrawal as well as respiratory distress, jaundice, congenital anomalies, and behavioral abnormalities. With early recognition and intervention, the potential long-term physiologic and emotional consequences of these difficulties can be avoided or at least lessened in severity.
- Newborns of mothers with AIDS require early recognition and treatment so that the physiologic and emotional consequences may be lessened in severity and Centers for Disease Control and Prevention (CDC) guidelines implemented.
- Cardiac defects are a significant cause of morbidity and mortality in the newborn period. Early identification and nursing and medical care of newborns with cardiac defects are essential to the improved outcome of these infants. Care is directed toward lessening the workload of the heart and decreasing oxygen and energy consumption.
- Inborn errors of metabolism such as galactosemia, phenylketonuria (PKU), homocystinuria, and maple syrup urine disease (MSUD) are usually included in a newborn screening program designed to prevent intellectual disability through dietary management and medication.
- The nursing care of the newborn with special problems involves understanding normal physiology, the pathophysiology of the disease process, clinical manifestations, and supportive or corrective therapies. Only with this theoretical background can the nurse make appropriate observations concerning responses to therapy and development of complications.
- The nurse facilitates interdisciplinary communication with the parents. Parents of at-risk newborns need support from nurses and healthcare providers to understand the special needs of their baby and feel confident in their ability to care for their baby at home.

CRITICAL THINKING IN ACTION

As the nurse on duty, you are caring for baby Erin, a 38-week IDM female born by repeat cesarean birth to a 32-year-old G3 now P3 mother. Erin's Apgar scores are 7 and 9 at 1 and 5 minutes. At 2 hours of age, the baby has an elevated respiratory rate of 100 to 110, heart rate of 165 with Grade II/VI intermittent machinery murmur, and mild cyanosis. She is now receiving 30% oxygen and has a respiratory rate of 70 to 80. The baby's clinical course, chest x-ray, and lab results are all consistent with transient tachypnea of the newborn and patent ductus arteriosus. The mother calls you to ask about how her baby is doing. She tells you that her last child was born at 30 weeks and had to be hospitalized for 6 weeks. She says, "I really tried to do it right this time," and asks you if this baby will have the same respiratory problem.

1. What should you tell the mother?
2. What can you do to facilitate mother-infant attachment?
3. Discuss the emotional response of parents to the birth of an ill or at-risk infant.
4. Discuss the four psychologic tasks essential for coping with the stress of an at-risk newborn and providing a basis for the maternal-infant relationship.
5. Baby Erin is being discharged tomorrow. Review the elements of discharge and home care instructions.

CHAPTER 34

The Newborn at Risk: Birth-Related Stressors

I watched her breathe every precious breath on the respirator. I saw her covered with wires and tubes. I kept watch. She was special to me and I would tell her over and over, "Daddy is here. Daddy loves you." The three days she lived were hell—not knowing if she would make it, uncertain about what plans we should make. Somehow I thought she would live; I was hopeful. When she died, at least I was there with her. The grief was unbearable. But there was also a sense of relief. The uncertainty, the waiting, were finally over.

—Susan Borg, *When Pregnancy Fails*

LEARNING OUTCOMES

1. Explain how to identify newborns in need of resuscitation.
2. Describe the appropriate method of resuscitation of a newborn based on the prenatal/labor record and observable physiologic indicators.
3. Differentiate, based on clinical manifestations, among the various types of respiratory distress (respiratory distress syndrome, transient tachypnea of the newborn, meconium aspiration syndrome, and persistent pulmonary hypertension) in the newborn and their related nursing care.
4. Discuss the types of metabolic abnormalities (cold stress and hypoglycemia), their effects on the newborn, and their nursing implications.
5. Differentiate between physiologic and pathologic jaundice according to timing of onset (in hours), cause, possible sequelae, and specific management.
6. Explain how Rh incompatibility or ABO incompatibility can lead to the development of hyperbilirubinemia.
7. Identify the nursing responsibilities in caring for the newborn receiving phototherapy.
8. Explain the causes and nursing care of infants with anemia and polycythemia.
9. Describe the nursing assessment results that would lead the nurse to suspect newborn sepsis.
10. Discuss the nursing care of the newborn with an infection.
11. Relate the consequences of maternally transmitted infections, such as maternal syphilis, gonorrhea, herpesviridae family (HSV or CMV), and chlamydia, to the management of the infant in the neonatal period.
12. Describe interventions to facilitate parental attachment and meet the special initial and long-term needs of parents of at-risk newborns.

KEY TERMS

Acute bilirubin encephalopathy (ABE) *963*
Bronchopulmonary dysplasia (BPD) *957*
Chronic lung disease (CLD) of prematurity *957*
Cold stress *958*
Erythroblastosis fetalis *963*
Hemolytic disease of the newborn *963*
Hydrops fetalis *964*
Hyperbilirubinemia *963*
Hypoglycemia *959*
Jaundice *963*
Kernicterus *963*
Meconium aspiration syndrome (MAS) *953*
Persistent pulmonary hypertension of the newborn (PPHN) *955*
Phototherapy *966*
Physiologic anemia of infancy *973*
Polycythemia *974*
Respiratory distress syndrome (RDS) *944*
Sepsis neonatorum *975*

Marked homeostatic changes occur during the transition from fetal to newborn life. The most rapid anatomic and physiologic changes of this period occur in the cardiopulmonary system. Thus the major problems of the newborn are usually related to this system. These problems include asphyxia, respiratory distress syndrome (RDS), cold stress, jaundice, hemolytic disease, and anemia. Ideally, problems are anticipated and identified prenatally, some treatment may be initiated in the prenatal/intrapartal period, and appropriate intervention measures are begun prior to, at, or immediately after birth.

Care of the Newborn at Risk Due to Asphyxia

Perinatal asphyxia occurs in 1% to 1.5% of live births, and the incidence increases as the gestational age decreases (Cloherty, Eichenwald, & Stark, 2008). Newborn asphyxia results from circulatory, respiratory, and biochemical factors. Circulatory patterns that accompany asphyxia indicate an inability to make the transition to extrauterine circulation—in effect, a return to fetal circulatory patterns, with the majority of the blood bypassing the lungs. Failure of lung expansion and establishment of respiration rapidly produces serious biochemical changes, including hypoxemia (decreased oxygen in blood), metabolic acidosis (increased acidity of blood reflected by low pH), and hypercapnia (excess levels of carbon dioxide in the blood) (Askin, 2009; Niermeyer & Clarke, 2011).

These biochemical changes produce the following results:

- Pulmonary vasoconstriction and high pulmonary vascular resistance in relation to the lower systemic vascular resistance (following birth the pulmonary vascular resistance should be markedly lower than the systemic vascular resistance)
- Hypoperfusion of the lungs
- A large right-to-left shunt through the ductus arteriosus, bypassing the lungs and impeding oxygenation of the blood

As right atrial pressure exceeds left atrial pressure, the foramen ovale reopens, and blood flows from right to left (Askin, 2009). See chapter 29 ∞ for a review of normal newborn cardiopulmonary adaptation.

However, the most serious biochemical abnormality caused by hypoxia is a change from aerobic to anaerobic metabolism. This change results in the buildup of lactate, combining with hydrogen to form lactic acid, and subsequently developing metabolic acidosis. Lactic acidosis can develop after prolonged tissue hypoxia (oxygen starvation) as active cells rely on anaerobic metabolism.

Simultaneously, respiratory acidosis may also occur in response to a rapid increase in carbon dioxide (PCO_2) during asphyxia. In response to hypoxia and anaerobic metabolism, the amounts of free fatty acids (FFA) and glycerol in the blood increase. Glycogen stores are mobilized to provide a continuous glucose source for the brain. Hepatic and cardiac stores of glycogen may be used up rapidly during an asphyxial incident.

The newborn has several protective mechanisms against hypoxic insults:

- Relatively immature brain
- Resting metabolic rate lower than that observed in the adult
- Ability to mobilize substances within the body for anaerobic metabolism and to use the energy more efficiently
- Intact circulatory system able to redistribute lactate and hydrogen ions in tissues still being perfused

Severe prolonged hypoxia will overcome these protective mechanisms, resulting in brain damage or death of the newborn. The newborn suffering apnea requires immediate resuscitative efforts. The need for resuscitation can be anticipated if specific risk factors are present during the pregnancy or labor and birth period.

Risk Factors Predisposing to Asphyxia

The need for resuscitation may be anticipated if the mother demonstrates the antepartum and intrapartum risk factors described in Table 15-1 ∞ on page 321 and Table 23-1 ∞ on page 559. Fetal/neonatal risk factors are as follows (Gomella et al., 2009; Pappas & Walker, 2010):

- Nonreassuring fetal heart rate (FHR) pattern/sustained bradycardia
- Impairment of maternal oxygenation (maternal asthma/cardiac disease)
- Anything affecting blood flow through the placenta
- Significant intrapartum bleeding
- Difficult birth, prolonged labor
- Fetal scalp/capillary blood sample-acidosis pH less than 7.2
- Narcotic use in labor
- History of meconium in amniotic fluid
- Prematurity
- Male infant
- Small for gestational age (SGA) or macrosomia
- Infant of a diabetic mother (IDM)
- Multiple births
- Structural lung abnormality/oligohydramnios (congenital diaphragmatic hernia, lung hypoplasia)
- Congenital heart disease
- Anemia: isoimmunization, fetal-maternal hemorrhage, parvovirus

Risk factors are not always apparent prenatally. Particular attention must be paid to all at-risk pregnancies during the intrapartal period. Certain aspects of labor and birth challenge the oxygen supply to the fetus, and often the at-risk fetus has less tolerance to the stress of labor (indicated by decelerations, a fixed baseline heart rate, or lack of variability of the FHR) and birth (Ingemarsson, 2009).

Clinical Therapy

The initial goal of clinical management is to identify the fetus at risk for asphyxia so that resuscitative efforts can begin at birth.

Fetal biophysical assessment (see chapter 21 ∞) combined with monitoring of fetal pH, FHRs, and fetal oximetry, if

available, during the intrapartum period may help identify the presence of nonreassuring fetal status. If nonreassuring fetal status is present, appropriate measures can be taken to deliver the fetus immediately, before major damage occurs, and to treat the asphyxiated newborn.

The fetal biophysical profile enhances the ability to predict an abnormal perinatal outcome. In addition, fetal scalp blood sampling may indicate asphyxic insult and the degree of fetal acidosis (normal is pH >7.2 with a base deficit <6.0), when considered in relation to the stage of labor, uterine contractions, and nonreassuring FHR patterns (Cloherty et al., 2008). The stress of labor causes an intermittent decrease in exchange of gases in the placental intervillous space, which causes the fall in pH and fetal acidosis. The acidosis is primarily metabolic.

During labor, a fetal pH of 7.25 or higher is considered normal (nonacidemia). A pH value of 7.20 or less is considered an ominous sign of intrauterine asphyxia (acidemia), whereas a pH of less than 7 is considered pathologic acidemia (Cloherty et al., 2008). However, low fetal pH without associated hypoxia can be caused by maternal acidosis secondary to prolonged labor, dehydration, and maternal lactate production.

Assessment of the newborn's need for resuscitation begins at the time of birth by assessing color, heart rate, and respirations of the newborn. The nurse should note the time of the first gasp, first cry, and onset of sustained respirations in order of occurrence. The Apgar score (see chapter 24 ∞) may be helpful in describing the status of the newborn at birth and his or her subsequent adaptation to the extrauterine environment but should not be used to determine whether certain steps need to be taken during resuscitation. If indicated, resuscitation should be started before the 1-minute Apgar score is obtained. The AAP Committee on Fetus and Newborn has recommended the use of an assisted Apgar scoring system that documents the assistance the infant is receiving at the time his or her score is assigned (American Academy of Pediatrics (AAP) & American College of Obstetricians and Gynecologists (ACOG), 2007). The Apgar score at 1 minute tends to relate to intrapartal depression and umbilical cord blood pH and subsequent scores relate to adequacy of resuscitative efforts. Retrospective Apgar scores are likely to be assigned when stabilizing critically ill newborns (Pinheiro, 2009).

Resuscitative efforts are required by 10% of all newborns to begin breathing with 1% of all newborns requiring more extensive resuscitative efforts (Bry, 2008). The AAP and ACOG (2007, pg. 207) recommend identification of newborns *who do not require resuscitation* by carrying out a rapid assessment of these four characteristics:

1. Is the baby full term?
2. Is the amniotic fluid clear of meconium and evidence of infection?
3. Is the baby breathing or crying?
4. Does the baby have good muscle tone?

If the answers to these questions are "yes" then the baby does not need resuscitation and should not be separated from the mother. If the answer to *any* of the previous questions is "no," the infant should receive resuscitative assistance (Pappas & Walker, 2010). The infant should receive one or more of the following categories of action:

- Initial steps in stabilization (warmth, positioning, clearing the airway as necessary, drying, stimulating, and repositioning)
- Oxygen administration
- Positive pressure ventilation
- Chest compressions
- Administration of epinephrine, volume expansion, or both (AAP & ACOG, 2007)

In the birthing room exposure to blood or other body fluids is inevitable. Standard Precautions must be practiced by wearing caps, goggles or glasses, gloves, and impervious gowns until the cord is cut and the newborn is dried and wrapped (Cloherty et al., 2008).

Resuscitation Management

Suctioning (clearing airway) is always performed before resuscitation measures are started so that mucus, blood, or meconium is not aspirated into the lungs. Caregivers should keep the newborn in a head-down position before the first gasp to avoid aspiration of the oropharynx secretions and must suction the oropharynx and nasopharynx immediately. Clearing the nasal and oral passages of obstructive fluids, with a bulb syringe or suction catheter attached to low continuous suction, establishes a patent airway. Vigorous suctioning of the posterior pharynx should be avoided because it can produce significant reflex bradycardia and damage the oral mucosa (Pappas & Walker, 2010). Although clear mucus routinely is suctioned from the mouth in most birthing units, there is no evidence to support the value of this practice (AAP & ACOG, 2007).

After the first few breaths, the nurse places the newborn in a level position under a radiant heat source and dries the baby quickly with warm blankets to maintain abdominal skin temperature at about 36.5°C–37°C (97.7°F–98.6°F) (Angert & Adam, 2009). The stable newborn may be placed on the mother's chest or abdomen "skin to skin" as another heat source. The extremely preterm newborn (<28 weeks estimated gestational age [EGA] or <1000 grams) may be covered with a plastic wrap or placed in a plastic bag up to the neck to attempt to prevent evaporative heat loss under the radiant warmer (Gomella et al., 2009). Drying is also a good stimulus for breathing. Heat loss through evaporation is tremendous during the first few minutes of life. The temperature of a wet 1500-g baby in a cold room (16°C [62°F]) drops 1°C every 3 minutes. Hypothermia increases oxygen consumption. In an asphyxiated infant, it increases the hypoxic insult and may lead to severe acidosis and development of respiratory distress.

Breathing is established by employing the simplest form of resuscitative measures initially, with progression to more complicated methods, as required. For example:

1. Position and clear airway as necessary. Simple stimulation is provided by rubbing the back with a blanket or towel, while simultaneously drying the baby.
2. If respirations have not been initiated or are inadequate (gasping or occasional respirations), the lungs must be inflated with positive pressure. The proper sized mask is positioned securely on the face (over the nose and mouth,

Figure 34-1 ■ Demonstration of resuscitation of an infant with bag and mask. Note that the mask covers the nose and mouth and that the head is in a neutral position. The resuscitation bag is placed to the side of the baby so that chest movement can be seen.

Source: George Dodson/Lightworks Studio/Pearson Education.

avoiding the eyes) with the infant's head in a "sniffing" or neutral position (Figure 34-1 ■). Hyperextension of the infant's neck will obstruct the trachea and must be avoided. An airtight connection is made between the baby's face and the mask (thus allowing the bag to inflate). The lungs are inflated rhythmically by squeezing the bag. Oxygen can be delivered at 100% with an anesthesia bag with an attached manometer or modified self-inflating bag and adequate liter flow of 5–10 L/min (Niermeyer & Clarke, 2011). The self-inflating (Ambu or Hope) bag delivers only 40% oxygen unless it has been adapted with an attached oxygen reservoir (Cloherty et al., 2008). It may not be possible to maintain adequate inspiratory pressure, important in any newborn with surfactant deficiency, with Ambu or Hope bags. In a crisis situation, it is crucial that 100% O_2 be delivered with adequate pressure (Niermeyer & Clarke, 2011).

3. Chest movement is observed for proper ventilation. Air entry and heart rate (HR) are checked by auscultation; HR may be quickly checked by palpating the base of the umbilical cord stump and counting the pulsations for 6 seconds and then multiplying by 10. Manual resuscitation is coordinated with any voluntary efforts. During positive pressure ventilation squeeze the resuscitation bag just enough to improve HR, color, and muscle tone, at a rate of 40–60 breaths per minute. Pressure should be adequate to move the chest wall. The pressure gauge (manometer) must be in place to avoid overdistention of the newborn's lungs and other problems such as pneumothorax or abdominal distention. Increasing the pressure to 30–40 cm H_2O or greater is occasionally necessary if there is no improvement in these parameters (HR, color, muscle tone) (Gomella et al., 2009). If ventilation is adequate, the chest moves symmetrically with each inspiration, bilateral breath sounds are audible, and the lips and mucous membranes become pink. Distention of the stomach is controlled by inserting a nasogastric tube for decompression.
4. Endotracheal intubation (Figure 34-2 ■) may be needed. However, most newborns, except for very-low-birth-weight (VLBW) (less than 1500 g) infants, can be effectively resuscitated by bag-and-mask ventilation. An increasing HR and CO_2 detection are the primary methods for confirming endotracheal tube placement.

Once breathing has been established, the HR should increase to over 100 beats per minute. If the HR is absent or the HR remains less than 60 beats per minute after 30 seconds of effective positive pressure with oxygen concentration of 21% to 100% to elicit an oxygen saturation of 90%, external cardiac massage (chest compression) is begun (Rajani, Chitkara, & Halamek, 2009). Chest compressions are started immediately if there is no detectable heartbeat. The procedure for performing chest compression is as follows:

1. The infant is positioned properly on a firm surface.
2. The resuscitator stands at the foot or head of the infant and the examiner places both thumbs over the lower third of the sternum (just below an imaginary line drawn between the nipples) with the fingers wrapped around and supporting the back (Figure 34-3A ■). Alternatively, the examiner can use two fingers instead of the thumbs (Figure 34-3B ■). The two-thumb method is preferred because it may provide better coronary perfusion pressure; however, it makes access to the umbilical cord for medication administration more difficult (Gomella et al., 2009).
3. The sternum is depressed to sufficient depth to generate a palpable pulse or approximately one third of the anterior-posterior depth of the chest at a rate of 90 beats per minute (Niermeyer & Clarke, 2011). Use a 3:1 ratio of heartbeat to assisted ventilation, 90 chest compressions:30 breaths per minute (Gomella et al., 2009).

Drugs that should be available in the birthing area include those needed in the treatment of shock, cardiac arrest, and narcosis. Oxygen is the drug used most often because of its effectiveness in ventilation. After 30 seconds of ventilation and coordinated cardiac compression, the newborn's cardiopulmonary status is reassessed by palpating the umbilical cord for a pulse. If the newborn has not responded with spontaneous respirations and an HR above 60 beats per minute, resuscitative medications are necessary (Cloherty et al., 2008; Gomella et al., 2009). The most accessible route for administering medications is the umbilical vein (intravenous [IV]). When the HR remains below 60 beats per minute, despite 30 seconds of assisted ventilation followed by another 30 seconds of coordinated chest compression, epinephrine, a cardiac stimulant, is indicated. If persistant bradycardia is present, epinephrine (0.1 to 0.3 ml/kg of a 1:10,000 solution [0.1 mg/ml]) is given through the umbilical vein catheter as rapidly as possible. Endotracheal administration may be considered while IV access is being established. When epinephrine is administered by endotracheal tube, consider a higher dose (0.3 to 1 ml/kg). The

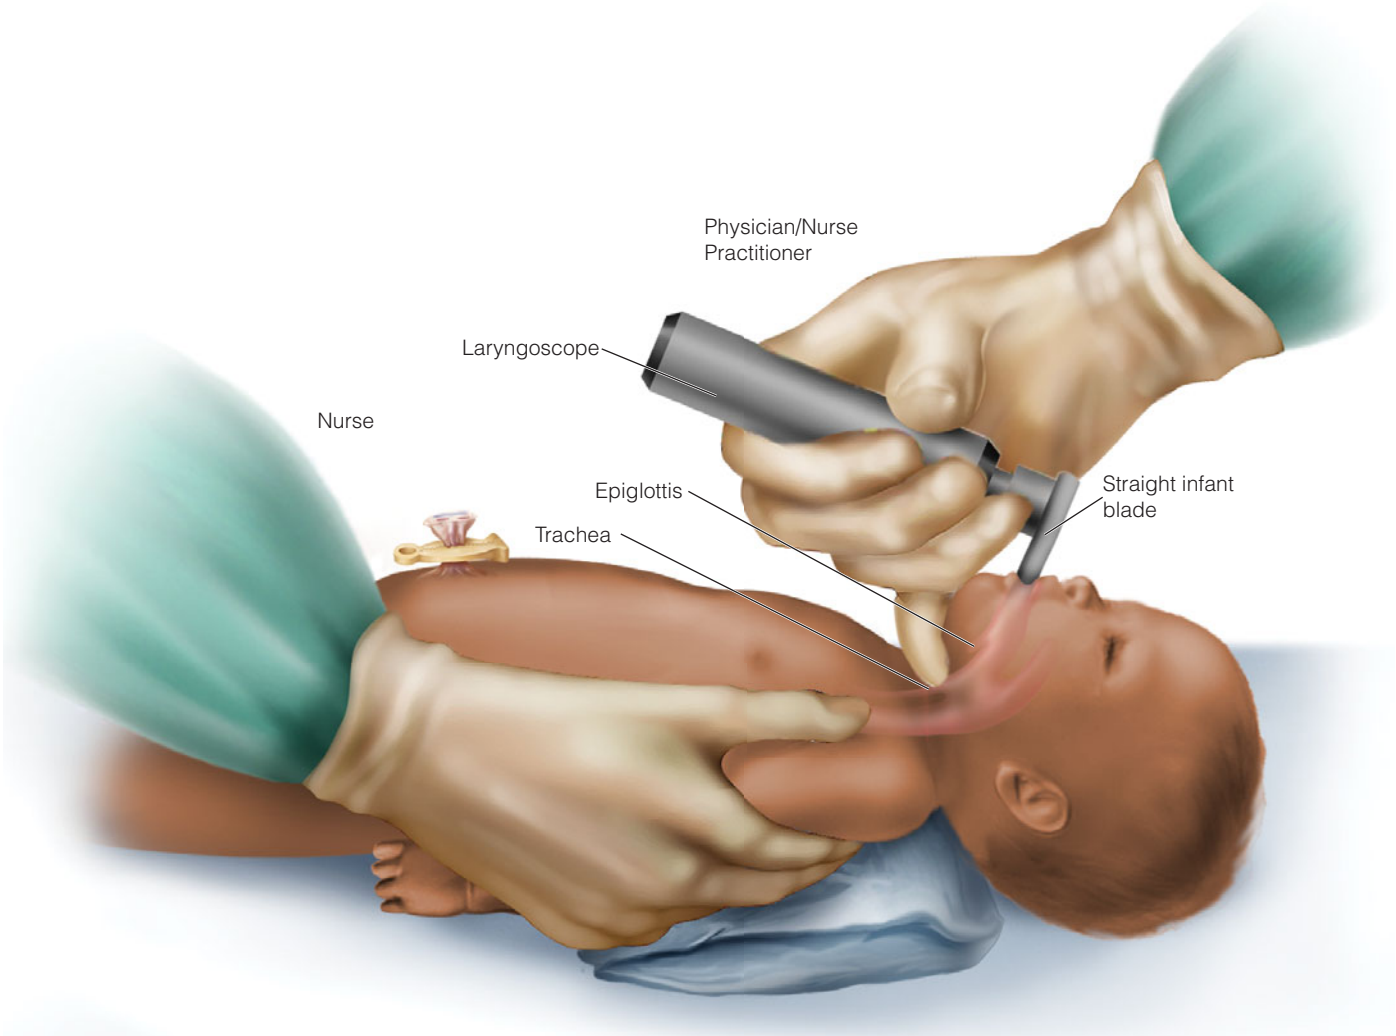

Figure 34-2 ■ Endotracheal intubation is accomplished with the infant's head in the "sniffing" position. The clinician places the fifth finger under the chin to hold the tongue forward and inserts the laryngoscope blade. Once the blade is in position as shown, an endotracheal tube is inserted through the groove in the laryngoscope blade. The endotracheal tube is not seen in this illustration.

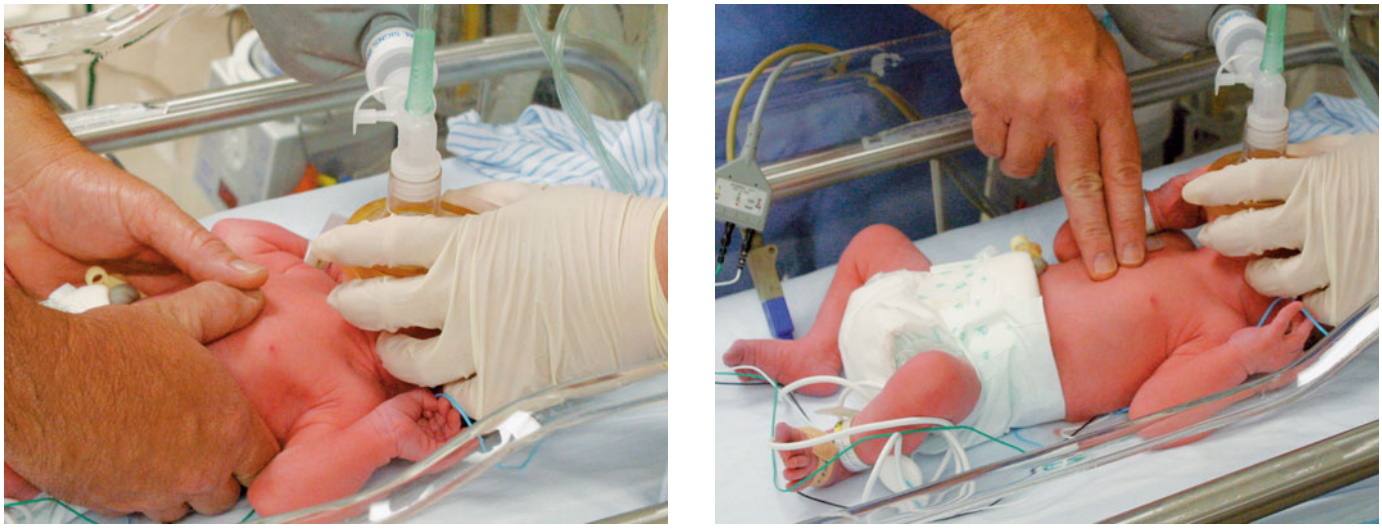
endotracheal route is associated with unreliable absorption and may not be effective at the lower dose (Gomella et al., 2009). *Sodium bicarbonate is rarely given in the birthing room.* Sodium bicarbonate is given only to correct metabolic acidosis that results from lactic acid buildup due to insufficient tissue oxygenation and only after effective ventilation is established. Dextrose (2 ml/kg) is given to prevent progression of hypoglycemia. A 10% dextrose in water IV solution ($D_{10}W$) is usually sufficient to prevent or treat hypoglycemia in the birthing area. Naloxone hydrochloride (0.1 mg/kg), a narcotic antagonist, is used to reverse known iatrogenic narcotic depression (Gomella et al., 2009). See Drug Guide: Naloxone Hydrochloride (Narcan).

If shock develops (e.g., low blood pressure [BP], pallor, or poor peripheral perfusion), the baby may be given a volume expander such as normal saline or Ringer's lactate in a dose of 10 ml/kg via umbilical vein route. If there is a known fetal hemorrhage or fetal anemia, whole blood (O Rh-negative crossmatched against the mother's blood) and packed red blood cells (RBCs) given over a 5- to 10-minute period can be used for volume expansion and treatment of hypovolemic shock. In some instances of prolonged resuscitation associated with shock and poor response to resuscitation, dopamine (starting at 5 mcg/kg/min) may be necessary.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Communication between the obstetric office or clinic and the birthing area nurse helps in the identification of newborns who may be in need of resuscitation. When the woman arrives in the birthing area, the nurse should have the prenatal/antepartal record and should note any contributory prenatal history factors and assess present fetal status. As labor progresses, nursing assessments include ongoing monitoring of fetal heartbeat and its response to contractions, assisting with fetal scalp blood sampling (if available), and observing for the presence of meconium in the amniotic fluid, when ruptured, to help identify possible fetal asphyxia. In addition, the



A B

Figure 34-3 ■ External cardiac massage. The lower third of the sternum is compressed with two fingertips or thumbs at a rate of 90 beats per minute. A. In the thumb method, the fingers support the infant's back, and both thumbs compress the sternum. B. In the two-finger method, the tips of two fingers of one hand compress the sternum, and the other hand or a firm surface supports the infant's back.

Source: George Dodson/Lightworks Studio/Pearson Education.

nurse should alert the resuscitation team and the practitioner responsible for the care of the newborn of any potential high-risk laboring women.

Nursing diagnoses that may apply to the newborn with asphyxia and the newborn's parents include the following:

- ***Ineffective Breathing Pattern*** related to lack of spontaneous respirations at birth secondary to in utero asphyxia
- ***Decreased Cardiac Output*** related to impaired oxygenation
- ***Compromised Family Coping*** related to baby's lack of spontaneous respirations at birth and fear of losing their newborn

DRUG GUIDE Naloxone Hydrochloride (Narcan)

OVERVIEW OF NEONATAL ACTION

Naloxone hydrochloride (Narcan) is used to reverse respiratory depression due to acute narcotic toxicity when the mother received a narcotic within 4 hours of delivery. It displaces morphine-like drugs from receptor sites on the neurons; therefore, the narcotics can no longer exert their depressive effects. It is essentially a pure opioid antagonist. Naloxone reverses iatrogenic narcotic-induced respiratory depression, analgesia, sedation, hypotension, and pupillary constriction.

ROUTE, DOSAGE, FREQUENCY

The dose is 0.1 mg/kg (0.25 ml/kg of 0.4 mg/ml preparation) concentration at birth, including premature infants. This drug is usually given through the umbilical vein (IV) or endotracheal tube (ET), although Naloxone can be given intramuscularly (delays onset of action) if adequate perfusion exists. For IV push, infuse over at least 1 minute; for ET administration, dilute in 1 to 2 millimeters of normal saline (NS).

Reversal of drug depression occurs within 1 to 2 minutes after IV administration and within 1 hour of intramuscular (IM) administration. The duration of action is variable (minutes to hours) and depends on the amount of the drug present and the rate of excretion. Duration of narcotic often exceeds that of the Naloxone. Dose may be repeated in 3 to 5 minutes. If initial reversal occurs, repeat dose as needed (Young & Mangum, 2010).

NEONATAL CONTRAINDICATIONS

Naloxone should not be administered to infants of narcotic-addicted mothers or those on methadone maintenance because it may precipitate acute withdrawal syndromes (increased HR and blood pressure (BP), vomiting, seizures, and tremors).

Respiratory depression may result from nonmorphine drugs, such as sedatives, hypnotics, anesthetics, or other nonnarcotic central nervous system (CNS) depressants.

NEONATAL SIDE EFFECTS

Excessive doses may result in irritability, increased crying, and possible prolongation of partial thromboplastin time (PTT).

Tachycardia may occur.

NURSING CONSIDERATIONS

- Monitor respirations—rate and depth—closely for improved respiratory effort.
- Assess for return of respiratory depression when Naloxone effects wear off and effects of longer-acting narcotics reappear.
- Assess continued respiratory depression after positive-pressure ventilation has restored normal HR and color.
- Have resuscitative equipment, O_2, and ventilatory equipment available.
- Note that Naloxone is incompatible with alkaline solutions such as sodium bicarbonate.
- Store at room temperature and protect from light.
- Compatible with heparin.

Nursing Plan and Implementation

Hospital-Based Nursing Care

Following identification of possible high-risk situations, the next step in effective resuscitation is assembling the necessary equipment and ensuring proper functioning.

Check and maintain equipment to ensure its reliability before an emergency arises. The equipment must be cleaned or replaced and restocked immediately after each use and rechecked before every birth. The nurse inspects all equipment—bag and mask, pressure manometer, oxygen and flow meter, laryngoscope bulb/battery, and suction machine—for damaged or nonfunctioning parts before a birth or when setting up an admission bed. A systematic check of the emergency cart and equipment is a routine responsibility of each shift. It is desirable to assemble equipment for pH and blood gas determination as well.

During resuscitation it is essential that the nurse keep the infant warm. The nurse dries the newborn quickly with pre-warmed towels or blankets and places a hat to prevent evaporative heat loss, then places the baby under a pre-warmed radiant warmer with servo control set at 36.5°C (97.7°F). The radiant warmer provides an overhead radiant heat source (a thermostatic mechanism that is secured to the infant's abdomen, over a solid organ like the liver, triggers the radiant warmer to turn on or off to maintain a constant temperature). An open bed is necessary for easy access to the newborn. Low-birth-weight (LBW) infants can be placed on a warm chemical mattress to help minimize their heat loss (Reynolds, Pilcher, Ring, et al., 2009).

Training and knowledge about resuscitation are vital to personnel in the birth setting for both normal and high-risk births. Neonatal Resuscitation Program (NRP) certification is renewed every 2 years for personnel working with newborns. Resuscitation is at least a two-person effort, and the nurse should call for additional support as needed. One member must have the skill to perform airway management and ventilation. The resuscitative efforts are recorded on the newborn's chart so that all members of the healthcare team will have access to this information.

Parent Teaching

The new cardiopulmonary resuscitation (CPR) guidelines favor family members being present during resuscitation in the birthing room and in the NICU, but the procedure may be particularly distressing for the parents. If the need for resuscitation is anticipated, the parents should be assured that a team will be present at the birth to care specifically for their newborn. Nurses should advise the parents that a support person will be available for them also. As soon as the infant's condition has been stabilized, a member of the interdisciplinary team needs to discuss the baby's condition with the parents. The parents may have many fears about the reasons for resuscitation and the condition of their baby following the resuscitation.

Evaluation

Expected outcomes of nursing care include the following:

- The newborn requiring resuscitation is promptly identified, and intervention is started early.
- The newborn's metabolic and physiologic processes are stabilized, and recovery proceeds without complications.
- The parents can verbalize the reason for resuscitation and what was done to resuscitate their newborn.
- The parents can verbalize their fears about the resuscitation process and potential implications for their baby's future.

Care of the Newborn with Respiratory Distress

One of the severest conditions to which the newborn may fall victim is respiratory distress—an inappropriate respiratory adaptation to extrauterine life. The nurse caring for a baby with respiratory distress needs to understand the normal pulmonary and circulatory physiology (see "Respiratory Adaptations" in chapter 29 ∞), the pathophysiology of the disease process, clinical manifestations, and supportive and corrective therapies. Only with this knowledge can the nurse make appropriate observations concerning responses to therapy and development of complications. Unlike the verbalizing adult patient, the newborn communicates needs only by exhibiting behaviors or physiologic parameters that must be interpreted by the neonatal intensive care unit (NICU) nurse. The neonatal nurse interprets this behavior as clues about the individual baby's condition. In this section, we discuss respiratory distress syndrome, transient tachypnea of the newborn, meconium aspiration syndrome, and persistent pulmonary hypertension.

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS), also referred to as *hyaline membrane disease (HMD),* is the result of a primary absence, deficiency, or alteration in the production of pulmonary surfactant, a substance produced in the lungs that keeps lungs from collapsing on expiration (Peterson, 2009). Respiratory distress syndrome affects almost 50% of the premature infants born at less than 30 weeks gestation, and the preterm delivery rate in the United States is 12% to 13% (Ramanathan, 2009). The syndrome occurs more frequently in premature Caucasian infants than in infants of African or Hispanic descent and almost twice as often in males as in females.

All the factors precipitating the pathologic changes of RDS have not been determined, but the main factors associated with its development are as follows:

1. ***Prematurity.*** All preterm newborns—whether average for gestational age (AGA), small for gestational age (SGA), or large for gestational age (LGA)—and especially infants of diabetic mothers (IDM) are at risk for RDS. The incidence of RDS increases with the degree of prematurity, with most deaths occurring in newborns weighing less than 1500 g. The maternal and fetal factors resulting in preterm labor and birth, complications of pregnancy, indications for cesarean birth, and familial tendency are all associated with RDS.
2. ***Surfactant deficiency disease.*** Normal pulmonary adaptation requires adequate surfactant, a lipoprotein that coats the inner surface of the alveoli. Surfactant provides alveolar stability by decreasing the alveoli's surface tension and

tendency for collapse. Surfactant is produced by type II alveolar cells starting at about 24 weeks' gestation. In the normal or mature newborn lung, it is continuously synthesized, oxidized during breathing, and replenished. Adequate surfactant levels lead to better lung compliance and permit breathing with less work. RDS is due to alterations in surfactant quantity, composition, function, or production.

CLINICAL TIP

An alveolus can be thought of as a small balloon filled with water and no air. When the balloon is emptied, the water droplets that remain inside the balloon increase the surface tension. As a result, the sides of the balloon stick together. The increased surface tension makes reinflation very difficult and requires an increased amount of energy.

Development of RDS indicates a failure to synthesize adequate surfactant, which is required to maintain alveolar stability (see "Factors Opposing the First Breath" in chapter 29 ∞). Upon expiration, the instability increases atelectasis, which causes hypoxia and acidosis because of the lack of gas exchange (Peterson, 2009). These conditions further inhibit surfactant production and cause pulmonary vasoconstriction. The resulting lung instability causes the biochemical problems of hypoxemia (decreased PO_2), hypercarbia (increased PCO_2), and acidemia (decreased pH), which further increases pulmonary vasoconstriction and hypoperfusion; alveolar endothelial and epithelial damage; and subsequent protein-rich interstitial and alveolar edema (Nash & Smith, 2008). The cycle of events of RDS leading to eventual respiratory failure is diagrammed in Figure 34-4 ■.

Because of these pathophysiologic conditions, the newborn must expend increasing amounts of energy to reopen the collapsed alveoli with every breath, so that each breath becomes more difficult than the last. The progressive expiratory atelectasis upsets the physiologic homeostasis of the pulmonary and cardiovascular systems and prevents adequate gas exchange. Breathing becomes progressively harder as lung compliance decreases, which makes it more difficult for the newborn to inflate the lungs and breathe.

The physiologic alterations of RDS produce the following complications:

1. ***Hypoxia.*** As a result of hypoxia, the pulmonary vasculature constricts, pulmonary vascular resistance increases, and pulmonary blood flow is reduced. Increased pulmonary vascular resistance may precipitate a return to fetal circulation as the ductus arteriosus opens and blood flow is shunted around the lungs in a right-to-left blood flow. This shunting increases the hypoxia and further decreases pulmonary perfusion. Hypoxia also causes impairment or absence of metabolic response to cold; reversion to anaerobic metabolism, resulting in lactate accumulation (acidosis); and impaired cardiac output, which decreases perfusion to vital organs.
2. ***Respiratory acidosis.*** Increased PCO_2 and decreased pH are results of alveolar hypoventilation. A persistent rise in PCO_2 is a poor prognostic sign of pulmonary function and adequacy because increased PCO_2 and decreased pH are results of alveolar hypoventilation.
3. ***Metabolic acidosis.*** Because cells lack oxygen, the newborn begins an anaerobic pathway of metabolism, with an increase

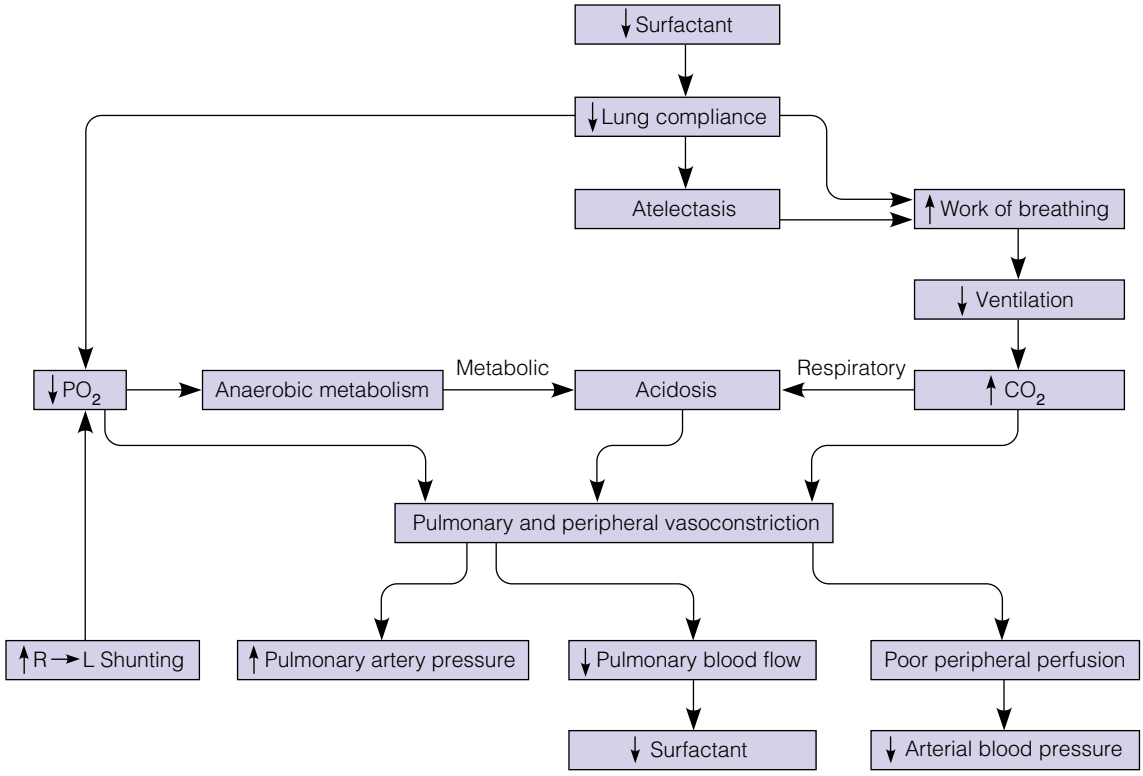


Figure 34-4 ■ Cycle of events of RDS leading to eventual respiratory failure.

in lactate levels and a resulting base deficit (loss of bicarbonate). As the lactate levels increase, the pH decreases in an attempt to maintain acid–base homeostasis (Askin, 2009).

The classic radiologic picture of RDS is diffuse bilateral reticulogranular (ground glass appearance) density, with portions of the air-filled tracheobronchial tree (air bronchogram) outlined by the opaque ("white-out") lungs with widespread atelectasis, potentially obliterating the heart borders (Figure 34-5 ■). Opacification of the lungs on x-ray image may be due to massive atelectasis, diffuse alveolar infiltrate, or pulmonary edema (Cloherty et al., 2008; Gomella et al., 2009). The progression of x-ray findings parallels the pattern of resolution, which usually occurs in 7 to 10 days, and the time of surfactant reappearance, unless surfactant replacement therapy has been used (Blackburn, 2007). Echocardiography is a valuable tool in diagnosing vascular shunts that shunt blood either away from, right to left reverting to a fetal pattern, or toward the lungs.

Clinical Therapy

The primary goal of prenatal management is to prevent preterm birth through aggressive treatment of preterm labor and administration of steroids to enhance fetal lung development if birth is imminent (see chapter 20 ∞). Antenatal steroids reduce the incidence and severity of RDS and improve survivability of the 24 to 34 weeks' gestation and extremely low-birth-weight newborn (less than 1250 grams) (Cloherty et al., 2008; Gomella et al., 2009).

Postnatal surfactant replacement therapy is available for infants to decrease the severity of RDS in low-birth-weight newborns. Surfactant replacement therapy is delivered through an endotracheal tube and may be given either in the birthing room or the nursery, as indicated by the severity of RDS. Repeat doses are often required. The most frequently reported response to treatment is rapidly improved oxygenation and decreased need for ventilatory support, sometimes occurring quite quickly after the dose is administered.

Supportive medical management consists of ventilatory therapy, blood gas monitoring, pulse oximetry monitoring, correction of acid–base imbalance, environmental temperature regulation, adequate nutrition, and protection from infection. Ventilatory therapy is directed toward preventing hypoventilation and hypoxia. Mild cases of RDS may require only increased humidified oxygen concentrations. Use of continuous positive airway pressure (CPAP) may be required in moderately afflicted infants. Babies with severe cases of RDS require mechanical ventilatory assistance from a respirator (Figure 34-6 ■).

High-frequency ventilation (HFV) can be tried when conventional ventilator therapy is not successful, and it sometimes can be the primary mode of ventilation to minimize lung injury in very small and/or sick infants (Gomella et al., 2009). In some institutions, morphine or fentanyl is used for its analgesic and sedative effects. Sedation may be indicated for infants most likely to have air leak respiratory problems. Use of pancuronium for muscle relaxation or paralysis in infants with RDS is controversial.

CLINICAL TIP

In babies with respiratory distress syndrome (RDS) who are on ventilators, increased urination/diuresis (determined by weighing diapers) may be an early clue that the baby's condition is improving (usually in the second to fourth day). As fluid moves out of the lungs into the bloodstream, alveoli open, and kidney perfusion increases; this results in increased voiding. At this point, the nurse must monitor chest expansion closely. If chest expansion is increasing, pulmonary compliance is improving and ventilator settings may have to be decreased, sometimes quite soon after surfactant dosing. Too high a ventilator setting may "blow the lungs," resulting in pneumothorax. If diuresis does not occur it is a sign that bronchopulmonary dysplasia (BPD), also called *chronic lung disease of prematurity (CLD)* may be developing.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Characteristics of RDS the nurse should look for are increasing cyanosis, tachypnea (greater than 60 respirations per minute), grunting respirations, nasal flaring, significant retractions, and apnea. Table 34-1 reviews clinical findings associated with respiratory distress in general. The Silverman-Andersen index (Figure 34-7 ■) may be helpful in evaluating the signs of respiratory distress and can be done in the birthing area.

Based on clinical parameters, the neonatal nurse implements therapeutic approaches to maintain physiologic homeostasis and provides supportive care to the newborn with RDS. See Nursing Care Plan: For the Newborn with Respiratory Distress Syndrome on pages 950 to 952.

Nursing interventions and criteria for instituting mechanical ventilatory assistance are done per institutional protocol. Noninvasive oxygen monitoring provides real-time information that is particularly useful in infants showing frequent swings in PaO_2 and oxygen saturation. These methods (pulse oximetry, transcutaneous oxygen monitor) can also reduce the frequency of blood gas sampling. Methods of noninvasive oxygen monitoring and nursing interventions are described in Table 34-2. (The nursing care of infants on ventilators or with umbilical artery catheters is not discussed here. These infants have severe respiratory distress and are cared for in NICUs by nurses with advanced knowledge and training.) Ventilatory assistance with high-frequency ventilators has shown positive results. The parents of a baby born having respiratory distress will need a very supportive environment (Figure 34-8 ■).

Figure 34-8 ■ This baby born at 36 weeks' gestational age had severe RDS. He has ongoing oxygen needs provided by a nasal cannula but still can be held by his proud big brother.

TABLE 34-1 Clinical Assessments Associated with Respiratory Distress

CLINICAL PICTURE	SIGNIFICANCE
Skin Color	
Pallor or mottling (pale or splotchy)	These represent poor peripheral circulation due to systemic hypotension and vasoconstriction and pooling of independent areas (usually in conjunction with severe hypoxia).
Cyanosis (bluish tint)	Depending on hemoglobin concentration, peripheral circulation, intensity and quality of viewing light, and acuity of observer's color vision, this is frankly visible in advanced hypoxia. Central cyanosis is most easily detected by examination of mucous membranes and tongue.
Jaundice (yellow discoloration of skin and mucous membranes due to presence of unconjugated [indirect] bilirubin)	Metabolic alterations (acidosis, hypercarbia, asphyxia) of respiratory distress mean the newborn is predisposed to having bilirubin dissociate from albumin-binding sites and be deposited in the skin and central nervous system.
Edema (presents as slick, shiny taut skin)	This is characteristic of preterm infants because their total protein concentration is low, with a decrease in colloidal osmotic pressure and transudation of fluid. Edema of hands and feet is frequently seen within first 24 hours and resolved by fifth day in infants with severe respiratory distress syndrome (RDS).
Respiratory System	
Tachypnea (normal respiratory rate 30–60/minute, elevated respiratory rate 60+/minute)	Increased respiratory rate is the most frequent and easily detectable sign of respiratory distress after birth. This compensatory mechanism attempts to increase respiratory dead space to maintain alveolar ventilation and gas exchange in the face of an increase in mechanical resistance. As a decompensatory mechanism, it increases workload and energy output by increasing respiratory rate, which causes increased metabolic demand for oxygen and thus increases alveolar ventilation on an already overstressed system. Shallow, rapid respirations increase dead space ventilation, thus decreasing alveolar ventilation.
Apnea (episode of nonbreathing for more than 20 seconds); periodic breathing, a common "normal" occurrence in preterm infants, is defined as apnea of 5–10 seconds alternating with 10–15 seconds of ventilation that is sometimes quite rapid	This poor prognostic sign indicates cardiorespiratory disease, central nervous system (CNS) disease, metabolic alterations, intracranial hemorrhage, sepsis, or immaturity. Physiologic alterations include decreased oxygen saturation, respiratory acidosis, and bradycardia.
Chest	Inspection of the thoracic cage includes shape, size, and symmetry of movement. Respiratory movements should be symmetric and diaphragmatic; asymmetry reflects pathology (pneumothorax, diaphragmatic hernia). Increased anteroposterior diameter indicates air trapping (meconium aspiration syndrome).
Labored respirations (Silverman-Andersen index in Figure 34-7 indicates severity of retractions, grunting, and nasal flaring, which are signs of labored respirations)	Indicates marked increase in the work of breathing.
Retractions (inward pulling of soft parts of the chest cage—suprasternal, substernal, intercostal, subcostal—at inspiration)	These reflect the significant increase in negative intrathoracic pressure necessary to inflate stiff, noncompliant lungs. Infants try to increase lung compliance by using accessory muscles. Lung expansion markedly decreases. Seesaw respirations are seen when the chest flattens with inspiration and the abdomen bulges. Retractions increase the work of breathing and oxygen need so that assisted ventilation may be necessary due to exhaustion.
Flaring nares (inspiratory dilation of nostrils)	This compensatory mechanism attempts to lessen the resistance of the narrow nasal passage.
Expiratory grunt (Valsalva maneuver in which the infant exhales against a closed glottis, thus producing an audible moan)	This increases transpulmonary pressure, which decreases or prevents atelectasis, thus improving oxygenation and alveolar ventilation. Intubation should not be tried unless the infant's condition is rapidly deteriorating, because it prevents this maneuver and allows the alveoli to collapse.
Rhythmic body movement with labored respirations (chin tug, head bobbing, retractions of anal area)	This is a result of using abdominal and other respiratory accessory muscles during prolonged forced respirations.
Auscultation of chest reveals decreased air exchange, with harsh breath sounds or fine inspiratory rales; rhonchi may be present	Decrease in breath sounds and distant quality may indicate interstitial or intrapleural air or fluid.
Cardiovascular System	
Continuous systolic murmur may be audible	Patent ductus arteriosus is common with hypoxia, pulmonary vasoconstriction, right-to-left shunting, and congestive heart failure.
Heart rate usually within normal limits (fixed heart rate may occur with a rate of 110–120/minute)	A fixed heart rate indicates a decrease in vagal control.
Point of maximal impulse usually located at fourth to fifth intercostal space, left sternal border	Displacement may reflect dextrocardia (heart in right side of chest), pneumothorax, or diaphragmatic hernia.
Hypothermia	This is inadequate functioning of metabolic processes that require oxygen to produce necessary body heat.
Muscle Tone	
Flaccid, hypotonic, unresponsive to stimuli	These may indicate deterioration in the newborn's condition and possible CNS damage due to hypoxia, acidemia, or hemorrhage.
Hypertonia and/or seizure activity	

TABLE 34-2 Oxygen Monitors

TYPE	FUNCTION AND RATIONALE	NURSING INTERVENTIONS
Pulse Oximetry—SpO_2		
Estimates beat-to-beat arterial oxygen saturation.	Calibration is automatic.	Understand and use oxyhemoglobin dissociation curve.
Microprocessor measures saturation by the absorption of red and infrared light as it passes through tissue.	Less dependent on perfusion than $TcPO_2$ and $TcPCO_2$; however, functions poorly if peripheral perfusion is decreased due to low cardiac output.	Monitor trends over time and correlate with arterial blood gases.
Changes in absorption related to blood pulsation through vessel determine saturation and pulse rate.	Much more rapid response time than $TcPO_2$—offers real-time readings. Can be located on extremity, digit, or palm of hand, leaving chest free; not affected by skin characteristics. Requires understanding of oxyhemoglobin dissociation curve. Pulse oximeter reading of 88% to 93% reflects a PaO_2 of 50–80 mm Hg (Gomella et al., 2009). Extreme sensitivity to movement; decreases if average of 7th or 14th beat is selected rather than beat to beat. Poor correlation with extreme hyperoxia.	Check disposable sensor at least every 8 hr. Use disposable cuffs (reusable cuffs allow too much ambient light to enter, and readings may be inaccurate).
Transcutaneous Oxygen Monitor–$TcPO_2$		
Measures oxygen diffusion across the skin. Clark electrode is heated to 43°C (preterm) or 44°C (term) to warm the skin beneath the electrode and promote diffusion of oxygen across the skin surface. PO_2 is measured when oxygen diffuses across the capillary membrane, skin, and electrode membrane (Gomella et al., 2009).	When transcutaneous monitors are properly calibrated and electrodes are appropriately positioned, they provide reliable, continuous, noninvasive measurements of PO_2, PCO_2, and oxygen saturation. Readings vary when skin perfusion is decreased. Reliable as trend monitor. Frequent calibration necessary to overcome mechanical drift. Following membrane change, machine must "warm up" 1 hour before initial calibration; otherwise, after turning it on, it must equilibrate for 30 minutes before calibration. When placed on infant, values will be low until skin is heated; approximately 15 minutes required to stabilize. Second-degree burns are rare but possible if electrodes remain in place too long. Decreased correlations noted with older infants (related to skin thickness), with infants with low cardiac output (decreased skin perfusion), and with hyperoxic infants. The adhesive that attaches the electrode may abrade the fragile skin of the preterm infant. May be used for both preductal and postductal monitoring of oxygenation for observations of shunting.	Use $TcPO_2$ to monitor trends of oxygenation with routine nursing care procedures. Clean electrode surface to remove electrolyte deposits; change solution and membrane once a week. Allow machine to stabilize before drawing arterial gases; note reading when gases are drawn and use values to correlate. Ensure airtight seal between skin surface and electrode; place electrodes on clean, dry skin on upper chest, abdomen, or inner aspect of thigh; avoid bony prominences. Change skin site and recalibrate at least every 4 hours; inspect skin for burns; if burns occur, use lowest temperature setting and change position of electrode more frequently. Adhesive disks may be cut to a smaller size, or skin prep may be used under the adhesive circle only; allow membrane to touch skin surface at center.

Transient Tachypnea of the Newborn

Some newborns, primarily LGA, term, and late preterm infants, may develop progressive respiratory distress that can resemble classic RDS. Other risk factors include maternal diabetes and asthma, male sex of the fetus, macrosomia (possibly related to maternal diabetes), and cesarean section delivery, especially elective without spontaneous labor (Guglani, Lakshminrusimha, & Ryan, 2008). Typically, supplemental oxygen of less than 40% will alleviate the hypoxia (Cloherty et al., 2008). They may have had intrauterine or intrapartal asphyxia due to maternal oversedation or poor uterine perfusion, maternal bleeding, prolapsed cord, or breech presentation. The newborn then fails to clear the airway of lung fluid, mucus, and other debris, or an excess of fluid in the lungs due to aspiration of amniotic or tracheal fluid (Gomella et al., 2009; Guglani et al., 2008). Transient tachypnea of the newborn (TTN), which occurs in 11 per 1000 live births (Nash & Smith, 2008), is also more prevalent in cesarean-birth newborns who have not had the thoracic squeeze that occurs during vaginal birth and removes some of the lung fluid (Blackburn, 2007).

Usually the newborn experiences little or no difficulty at the onset of breathing. However, shortly after birth, expiratory grunting, flaring of the nares, subcostal retractions, desaturation, and mild cyanosis may be noted in the newborn breathing room air. Air will become trapped and an increase in the anterior/posterior diameter of the chest will be observed. Tachypnea is usually present by 6 hours of age, with respiratory rates consistently greater than 60 breaths per minute (breaths/min), and reaching 80–100 breaths/min and higher (Guglani et al., 2008). Mild respiratory and metabolic acidosis may be present within the first 6 hours. These clinical signs usually improve within 12 to 24 hours. In mild TTN, the signs

NURSING CARE PLAN For the Newborn with Respiratory Distress Syndrome

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Risk for Ineffective Breathing Pattern related to immature lung development **Goal:** The infant will maintain an effective breathing pattern.	
■ Review maternal birth records, noting medications given to mother before birth and the infant's condition at birth such as Apgar scores and resuscitative measures.	■ Several drugs suppress respiratory function in the newborn.
■ Initiate cardiac and respiratory monitoring and calibrate these monitors every 8 hours or per unit protocol.	■ Close monitoring detects periodic apneic spells and allows for medical intervention if necessary.
■ Monitor infant's respiratory rate and rhythm, pulse, blood pressure, and activity.	■ Increases in respiratory rate and pulse and alteration in rhythm and blood pressure may indicate respiratory distress.
■ Assess skin color; note signs of cyanosis, duskiness, and pallor.	■ Any changes in the normal skin color may indicate a physiologic change occurring.
■ Clear infant's airway by suctioning PRN with bulb syringe.	■ Opens airway by clearing mucus and allows maximum respiratory effort.
■ Administer warmed, humidified oxygen by oxygen hood and monitor the oxygen concentrations every 30 minutes.	■ Prevents mucosal dryness and maintains an even level of oxygen administration.
■ Do not allow oxyhood to touch infant's face; maintain a stable oxygen concentration by increasing and decreasing oxygen by 5% to 10% increments.	■ Allowing oxyhood to touch infant's face may cause apnea by stimulating the facial nerve.
Collaborative: Obtain arterial blood gases (ABGs) per primary care provider/physician orders.	
a. Maintain constant O_2 concentration for 15–30 minutes before sample is obtained. b. Avoid stimulating infant for 15 minutes before obtaining sample. c. Avoid suctioning infant before obtaining sample. d. Obtain sample in heparinized tuberculin syringe and maintain the temperature of the sample. e. Assess the patency of the arterial line to prevent clot formation, then replace blood used to clear line. f. Flush line with 2 ml heparinized solution before restarting flow of IV fluids. g. Monitor transcutaneous pulse oximeter continuously or hourly and record. Rotate sensor site every 3–4 hours.	■ Obtaining ABGs is essential in managing an infant receiving oxygen. Suctioning may cause a discrepancy in ABG readings and should be avoided.
■ Assess infant's need for mechanical ventilation: apnea present, hypoxia (PaO_2 less than 50 mm Hg), hypercapnia ($PaCO_2$ greater than 60 mm Hg), respiratory acidosis (pH less than 7.2).	■ Mechanical ventilation improves oxygenation and ventilation, resulting in rise in PaO_2 and decrease in $PaCO_2$.
■ Administer mechanical ventilation per hospital protocol.	■ Continuous positive airway pressure (CPAP) or positive end-expiratory pressure (PEEP) can be administered by nasal prongs, nasopharyngeal or oral intubation.
EXPECTED OUTCOMES: The infant will maintain an effective breathing pattern as evidenced by respirations of 30–60 breaths/min, arterial blood gases are within normal range, infant is free of signs of retractions or nasal flaring, and blood pH is 7.35–7.45.	
2. Nursing Diagnosis: Ineffective Thermoregulation related to increased respiratory effort **Goal:** The infant will exhibit no signs of hypothermia.	
■ Review maternal prenatal and intrapartum records. Note any medications mother received during these times.	■ Medications such as Demerol and magnesium sulfate used by the mother during the prenatal or intrapartum periods significantly interfere with the infant's ability to retain heat.
■ Assess infant's temperature frequently. Place servo probe on infant's skin over a solid organ.	■ Hypothermia leads to pulmonary vasoconstriction because of the increase in oxygen consumption. Cold stress leads to increased oxygen needs; consequently, brown fat is used to maintain body temperature.
■ Observe for signs of increased oxygen consumption and metabolic acidosis.	■ Hypoxia and acidosis further depress surfactant production.

NURSING CARE PLAN For the Newborn with Respiratory Distress Syndrome continued

INTERVENTION	RATIONALE
■ Warm and humidify all inspired gases and record temperature of delivered gases.	■ Cold air/oxygen blown in face of newborn is stimulus for consumption of oxygen and glucose and increased metabolic rate.
■ Use radiant warmers or incubators with servo controls, and open cribs with appropriate clothing.	■ Maintains neutral thermal environment.
■ Note signs and symptoms of respiratory distress, including tachypnea, apnea, cyanosis, acrocyanosis, bradycardia, lethargy, weak cry, and hypotonia.	■ These signs can predispose the infant to metabolic acidosis.

EXPECTED OUTCOMES: The infant will not exhibit signs and symptoms of hypothermia as evidenced by temperature maintenance of 97.7°F–99.1°F and no signs and symptoms of respiratory distress.

3. Nursing Diagnosis: Imbalanced Nutrition: Less Than Body Requirements related to increased metabolic needs in the infant

Goal: Infant will gain weight in a normal curve.

■ Assess suck, swallow, gag, and cough reflexes.	■ Prevents feeding problems and assists in determining the best individualized method of feeding for infant.
■ Assess respiratory status of infant. If any problems are noted, notify physician.	■ In the presence of respiratory distress avoid oral fluids and initiate parenteral nutrition per physician's orders.
■ Monitor IV rates per infusion pump (starting at 80 ml/kg/day) as ordered by physician.	■ Allows for close monitoring of fluid intake.
■ Record hourly intake and output (I&O) and daily weights.	■ IV fluids are administered to replace sensible and insensible water loss, as well as evaporative water loss secondary to respiratory distress. Monitoring I&O will prevent circulatory system overload that can lead to pulmonary edema and cardiac problems.
■ Provide total parenteral nutrition (TPN) when indicated.	■ TPN is used as nutritional alternative if bowel sounds are not present and/or infant remains in acute distress.
■ Advance, based on tolerance, from IV to gastrointestinal (GI) feedings. Gavage or nipple feedings are used, and IV is used as supplement (discontinued when oral intake is sufficient).	■ If IV is discontinued before oral intake is established, baby will not receive adequate calories. ■ Formula or breast milk stimulate GI hormones necessary for a functional absorptive GI tract. ■ Avoid complications associated with nutrition by IV route only.
■ Provide adequate caloric intake: consider amount of intake, type of formula, route of administration, and need for supplementation of intake by other routes.	■ Calories are essential to prevent catabolism of body proteins and metabolic acidosis due to starvation or inadequate caloric intake.
■ Assess infusion site for signs and symptoms of infection including: erythema, edema, and drainage with a foul odor.	■ Appropriate intervention can be initiated when signs and symptoms of infection are detected early. Treatment may avoid infection and sepsis in the infant.

EXPECTED OUTCOMES: The newborn infant will maintain steady weight gain as evidenced by no more than 2%/day weight loss, tolerates oral feedings, and urine output of 1–3 ml/kg/hour.

4. Nursing Diagnosis: Risk for Deficient Fluid Volume related to increased insensible water losses

Goal: The infant will not exhibit signs of dehydration and will display appropriate weight gain.

■ Observe for weight fluctuations by obtaining daily weights.	■ Fluctuations in weight may indicate water imbalance or inadequate caloric intake.
■ Document cumulative balances of intake (IV fluid administration and feedings) and output (urine collection bags, weighing or counting diapers) hourly.	■ Balanced fluid intake and output suggest homeostasis.
■ Obtain urinalysis; monitor closely specific gravity and nitrites.	■ Specific gravity greater than 1.013 and nitrites present in the urine are indicative of not enough fluid intake.
■ Monitor vital signs including blood pressure, pulse, temperature, and mean arterial pressure (MAP).	■ A MAP of less than 20 mm Hg may indicate hypotension.

(continued)

NURSING CARE PLAN For the Newborn with Respiratory Distress Syndrome continued

INTERVENTION	RATIONALE
■ Assess patient for signs of dehydration (i.e., poor skin turgor, pale mucous membranes, and sunken anterior fontanelle).	■ Detecting signs and symptoms of dehydration early in the infant are important because early interventions are vital to prevent further damage.
■ Assess IV site for signs of infection (erythema and edema) and infiltration.	■ If signs and symptoms of infection are noted, intervention is necessary and IV site should be changed.
Collaborative: Obtain labs for hematocrit (Hct), serum calcium, serum magnesium, serum potassium, blood urea nitrogen (BUN), creatinine, and uric acid levels.	■ Determines necessity for TPN administration.
■ Administer fluids, blood products, and electrolytes as ordered by physician.	■ Replaces low nutrient stores and treats anemia if present.

EXPECTED OUTCOMES: The infant will be free of signs and symptoms of dehydration as evidenced by intake equaling output, urine specific gravity in normal range, and a weight gain of at least 20–30 grams/day.

can improve within 24 hours but may continue for 48 to 72 hours when more severe (Cloherty et al., 2008).

Clinical Therapy

Initial x-ray findings may be identical to those showing RDS within the first 3 hours. However, radiographs of infants with transient tachypnea usually reveal a generalized overexpansion of the lungs (hyperaeration of alveoli), which is identifiable principally by flattened contours of the diaphragm. Dense streaks (increased vascularity) radiate from the hilar region and represent engorgement of the lymphatic vessels, which clear alveolar fluid on initiation of air breathing. Within 48 hours the chest x-ray examination is generally normal with the exception of perihilar markings which may remain visible for 3 to 7 days (Gomella et al., 2009; Guglani et al., 2008).

Ambient oxygen concentrations of 30% to 50%, usually under an oxyhood, may be required to correct the hypoxemia (Figure 34-9 ■). Fluid and electrolyte requirements should be met with IV fluids during the acute phase of the disease. Oral feedings are contraindicated because of rapid respiratory rates and the subsequent risk of aspiration, intravenous fluids of $D_{10}W$ at 60–80 ml/kg/day is recommended for a maintenance fluid during the NPO period (Guglani et al., 2008). The duration of the clinical course of transient tachypnea is approximately 72 hours (Gomella et al., 2009).

When hypoxemia is severe and tachypnea continues, persistent pulmonary hypertension must be considered and treatment measures initiated. If pneumonia is suspected initially, antibiotics may be administered prophylactically.

NURSING CARE MANAGEMENT

For nursing actions, see the Nursing Care Plan: For the Newborn with Respiratory Distress Syndrome on pages 950 to 952.

CLINICAL JUDGMENT

Case Study: Baby Girl Linn

You are caring for baby girl Linn, who is a 39-week, AGA female born by repeat cesarean birth to a 34-year-old G3, now P3 mother. Baby Linn's Apgar scores were 7 at 1 minute and 9 at 5 minutes. At 2 hours of age, you note an elevated respiratory rate of 70 to 80 and mild cyanosis. The infant is now receiving 30% oxygen and has a respiratory rate of 100 to 120. The baby's clinical course, chest x-ray examination, and lab work are all consistent with transient tachypnea of the newborn. Her mother calls you to ask about her baby. She tells you that her last child was born at 30 weeks' gestation, had respiratory distress syndrome requiring ventilator support, and was hospitalized for 6 weeks. She asks you, "Is this the same respiratory distress?"

Critical Thinking

What will you tell Linn's mother?

See www.nursing.pearsonhighered.com for possible responses.

Care of the Newborn with Meconium Aspiration Syndrome

Because the body's physiologic response to asphyxia/hypoxia is increased intestinal peristalsis and relaxation of the anal sphincter, the presence of meconium in the amniotic fluid indicates that the fetus may be suffering from asphyxia, either in the immediate period during labor or perhaps some time in the recent past. Head or cord compression may illicit a vagal response in the fetus, thus causing passage of meconium in utero (Wiedemann, Saugstad, Barnes-Powell, et al., 2008). However, if the fetus is in a breech position, the presence of meconium in the amniotic fluid does not necessarily indicate asphyxia.

Approximately 8% to 20% of all live-born, late-preterm or term infants are born through meconium-stained amniotic fluid (MSAF). Of the newborns born through MSAF, 5% to 10% develop **meconium aspiration syndrome (MAS)** (Wiedemann et al., 2008). This fluid may be aspirated into the tracheobronchial tree by the fetus in utero or during the first few breaths taken by the newborn. This syndrome primarily affects term, small-for-gestational age (SGA), and postterm newborns and those who have experienced a long labor.

Presence of meconium in the lungs produces (Wiedemann et al., 2008):

- Mechanical obstruction of airways: ball-valve action (air is allowed in but not exhaled), so that alveoli overdistend, with oxygen and carbon dioxide trapping and hyperinflation, air leaks such as pneumothorax are common.
- Chemical pneumonitis leading to the possible development of secondary bacterial pneumonias.
- Inactivation of natural surfactant.
- Vasoconstriction of pulmonary vessels, allowing development of persistent pulmonary hypertension (PPHN).

Clinical Manifestations of MAS

Clinical manifestations of MAS include (1) fetal hypoxia in utero a few days or a few minutes before birth, indicated by a sudden increase in fetal activity followed by diminished activity, slowing of fetal heart rate (FHR) or weak and irregular heartbeat, loss of beat-to-beat variability, and meconium staining of amniotic fluid or particulate meconium; and (2) presence of signs of distress at birth, such as pallor, cyanosis, apnea, slow heartbeat, and low Apgar scores (below 6) at 1 and 5 minutes. Newborns with intrauterine asphyxia, meconium-stained newborns, or newborns who have aspirated particulate meconium often have respiratory depression at birth and require resuscitation to establish adequate respiratory effort.

After the initial resuscitation, the severity of clinical symptoms correlates with the extent of aspiration. Many infants require mechanical ventilation at birth because of immediate signs of distress (generalized cyanosis, tachypnea, and severe retractions). An overdistended, barrel-shaped chest with increased anteroposterior diameter is common. Auscultation reveals diminished air movement with prominent rales and rhonchi. Abdominal palpation may reveal a displaced liver caused by diaphragmatic depression resulting from the overexpansion of the lungs. Yellowish/pale green staining of the skin, nails, and umbilical cord is usually present, especially if the incident occurred some time before birth.

The MAS chest x-ray film reveals asymmetric, coarse, patchy, densities/infiltrates, with possible hyperinflation (9- to 11-rib expansion), atelectasis (collapse of part or all of a lung) which may predispose the newborn to air leak syndromes such as pneumothorax or pneumomediastinum (Wiedemann et al., 2008). Evidence of pulmonary air leak is frequently present. These infants have serious biochemical alterations, which include (1) extreme metabolic acidosis resulting from the cardiopulmonary shunting (bypassing the lungs) and hypoperfusion; (2) extreme respiratory acidosis due to shunting and alveolar hypoventilation; and (3) extreme hypoxia, even in 100% O_2 concentrations and with ventilatory assistance. The extreme hypoxia is also caused by the cardiopulmonary shunting and resultant failure to oxygenate and can lead to persistent pulmonary hypertension of the newborn (PPHN), discussed shortly.

Clinical Therapy

The combined efforts of the maternity and pediatric team are needed to prevent MAS. Previously, the most effective form of preventive management was intrapartum suctioning after the head of the newborn was delivered but the shoulders and chest were still in the birth canal. Current evidence does not support this practice, as routine intrapartum oropharyngeal and nasopharyngeal suctioning does not prevent or alter the course of MAS (AAP & ACOG, 2007; Carbine & Serwint, 2008; Wiedemann et al., 2008).

If the infant is vigorous even if there is meconium-stained amniotic fluid, no subsequent special resuscitation such as tracheal suctioning is indicated. Injury to the vocal cords is also more likely to occur during attempts to intubate a vigorous newborn.

If the infant has absent or depressed respirations, heart rate less than 100 beats per minute, or poor muscle tone, direct tracheal suctioning by specially trained personnel such as a neonatal nurse practitioner, an experienced neonatal intensive care unit (NICU) nurse trained in those skills, a respiratory therapist, or a nurse anesthetist is recommended. The glottis is visualized and the trachea suctioned to remove meconium or other aspirated material from beneath the glottis with use of a DeLee attached to low-pressure wall suction or a meconium aspirator to decrease the possibility of HIV transmission. When using mechanical suction, the suction pressure should be set so that negative pressure does not exceed 100 mm Hg. (This is also done with a cesarean birth.)

Further resuscitative efforts are undertaken as indicated, following the same principles of clinical therapy as for asphyxia (discussed earlier in this chapter). Resuscitated newborns should be immediately transferred to the nursery for closer observation. The infant should be maintained in a neutral thermal environment and tactile stimulation should be minimized. An umbilical arterial line may be used for direct monitoring of arterial blood pressures and blood sampling for pH and blood gases. An umbilical venous catheter may be placed for infusion of intravenous (IV) fluids, blood, or medications.

RESEARCH EVIDENCE IN PRACTICE

Prevention of Meconium Aspiration Syndrome

CLINICAL QUESTION

What is the most effective way to prevent meconium aspiration syndrome after birth?

RESEARCH EVIDENCE

Meconium aspiration syndrome (MAS) is a serious, life-threatening respiratory disorder. Meconium-stained amniotic fluid occurs in approximately 13% of live births and, of these, 5% to 10% subsequently develop MAS. This syndrome remains an important cause of admission for intensive care among term neonates. Traditionally, it was believed that the beginnings of MAS occurred after birth, when the baby took its first breaths and inhaled meconium. Preventive measures included suctioning the baby's upper airway after the head was delivered, and subsequent tracheal intubation and suctioning was standard care for all babies with meconium-stained amniotic fluid. Recent studies have focused on whether these procedures are necessary and result in better outcomes than using these procedures selectively.

Implicit in the traditional treatment is the belief that MAS is a postnatal condition, occurring after the baby takes its first breaths. This belief was tested by the knowledge that babies born via surgical birth also demonstrated MAS under certain conditions. Likewise, randomized trials demonstrated that the majority of babies who were born with meconium-stained amniotic fluid did not develop MAS.

Through randomized trials, systematic reviews, and convening expert panels, it has been determined that some babies are able to protect their airways, even in the presence of meconium-stained amniotic fluid. Other babies, such as the more compromised fetuses with hypoxia and acidosis that gasp in utero, may not protect their airways and, subsequently, develop the complications of meconium aspiration.

Although there is likely no benefit from upper airway suctioning, it is not associated with harm unless it delays handoff of the baby to the neonatal team. Tracheal intubation and suctioning, on the other hand, may carry risks for the baby. A treatment algorithm developed at Baylor University Medical Center provides guidelines for selectively applying upper airway and tracheal suctioning appropriately.

WHAT QUESTIONS REMAIN UNANSWERED?

Is meconium-stained amniotic fluid the cause of fetal distress or a result? Are there symptoms of MAS that are detectable in utero?

WHAT IS BEST PRACTICE?

Upper airway suctioning should be applied after the head—but before the shoulders—is delivered when meconium-stained amniotic fluid is present. Immediate handoff of the baby to the neonatal team should be followed by a second assessment. Vigorous babies need no additional treatment. Tracheal intubation and suctioning should be carried out in depressed newborns, defined as those with a heart rate of <100 beats/min, poor respiratory effort, and poor tone.

CRITICAL THINKING

Develop a checklist that can be used by the neonatal nurse to detect early signs of MAS after a birth with meconium-stained amniotic fluid.

Treatment usually involves delivery of high oxygen concentrations and high-pressure ventilation. Low positive end-expiratory pressures (PEEPs) (4–7 cm H_2O) are preferred to avoid air leaks such as pneumothorax. Unfortunately, high pressures may be needed to cause sufficient expiratory expansion of the obstructed terminal airways or to stabilize airways that are weakened by inflammation so that the most distal atelectatic (collapsed) alveoli are ventilated. Naturally occurring surfactant may be inactivated by the presence of meconium and the subsequent inflammatory response that occurs. Surfactant replacement therapy is most effective when given as a prophylactic measure. Providing exogenous surfactant possibly decreases the incidence of air leaks (Wiedemann et al., 2008). Systemic blood pressure and pulmonary blood flow must be maintained. Dopamine or dobutamine (volume expanders), or both, may be used to maintain systemic blood pressure.

Newborns with respiratory failure who are not responding to conventional ventilator therapy may require treatment with high-frequency ventilation and/or nitric oxide therapy or extracorporeal membrane oxygenation (ECMO) if baby is greater than 1.8 kg and 34 weeks estimated gestational age (EGA) (Gomella et al., 2009). Inhaled nitric oxide has proven successful for newborns with meconium aspiration, pneumonia, and PPHN who are not responding to traditional treatment modalities, and it avoids the need for ECMO.

Treatment also includes chest physiotherapy (chest percussion, vibration, and drainage) to remove the debris. Prophylactic antibiotics are frequently given. Continuous infusion of sodium bicarbonate to correct metabolic acidosis may be necessary for several days for severely ill newborns. Mortality in term and postterm infants is very high because the cycle of hypoxemia and acidemia is difficult to break.

Application: Meconium Aspiration Syndrome

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

During the intrapartum period, the nurse should observe for signs of fetal hypoxia and meconium staining of amniotic fluid. At birth the nurse assesses the newborn for signs of distress. During the ongoing assessment of the newborn, the nurse care-

fully observes for complications such as pulmonary air leaks; anoxic cerebral injury manifested by seizures/convulsions; myocardial injury evidenced by congestive heart failure or cardiomegaly; disseminated intravascular coagulation (DIC) resulting from hypoxic hepatic damage with depression of liver-dependent clotting factors; anoxic renal damage demonstrated by hematuria, oliguria, or anuria; fluid overload; sepsis secondary to bacterial pneumonia; and any signs of intestinal necrosis from ischemia, including gastrointestinal (GI) obstruction or hemorrhage.

Nursing diagnoses that may apply to the newborn with MAS and the infant's parents include the following:

- ***Impaired Gas Exchange*** related to aspiration of meconium and amniotic fluid during birth
- ***Imbalanced Nutrition: Less Than Body Requirements*** related to respiratory distress and increased energy requirements
- ***Compromised Family Coping*** related to life-threatening illness in a term newborn

Nursing Plan and Implementation

Hospital-Based Nursing Care

Initial interventions are aimed at early identification of meconium aspiration. When significant aspiration occurs, therapy is supportive with the primary goals of maintaining appropriate gas exchange and minimizing complications. Nursing interventions after resuscitation should include maintaining adequate oxygenation and ventilation, regulating temperature, performing glucose testing by glucometer to check for hypoglycemia, observing IV fluids, calculating necessary fluids (which may be restricted in the first 48 to 72 hours because of cerebral edema), providing caloric requirements possibly with total parenteral nutrition (TPN), and monitoring IV antibiotic therapy.

Evaluation

Expected outcomes of nursing care include the following:

- The newborn at risk of MAS is promptly identified, and early intervention is initiated.
- The newborn is free of respiratory distress and metabolic alterations.
- The parents verbalize their concerns about their baby's health problem and survival and understand the rationale behind management of their newborn.

Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension of the newborn (PPHN) is a serious disorder that may primarily affect on average 0.2% of live-born term and near-term newborns annually (Konduri & Kim, 2009; Rothstein, Paris, & Quizon, 2009). PPHN has also been called *persistent fetal circulation (PFC)* because the problems that occur are a result of right-to-left (R-L) shunting of blood away from the lungs and through the fetal ductus arteriosus and patent foramen ovale, consequently bypassing the lungs and the ability to be oxygenated, causing worsening hypoxemia and acidosis (Rothstein et al., 2009). The hypoxemia and acidosis are the most potent stimulants of pulmonary vasoconstriction and increased vascular resistance. Once this process has begun, it is self-perpetuating and difficult to interrupt. Clinical deterioration is rapid.

Clinical Therapy

Simultaneous preductal and postductal blood gases or pulse oximetry and/or transcutaneous monitoring can be used to demonstrate ductal shunting. A difference greater than 10% to 15% between preductal and postductal oxygen saturation is indicative of a right-to-left ductal shunt (Gomella et al., 2009). The hyperoxia-hyperventilation test is the most definitive test for PPHN. A positive indication of PPHN is when the PaO_2 increases more than 20 mm Hg or the pulse oximeter exhibits an increase greater than 10% with hyperoxia and hyperventilation (Konduri & Kim, 2009). Oxygen is a potent pulmonary vasodilator. The improved oxygenation can be noted clinically if the infant's mucous membranes turn pink. Echocardiography can show a prolonged ratio of right ventricular ejection period to right ventricular ejection time in infants with PPHN. The goal of therapeutic intervention is to lower the PVR and reverse the process of shunting. This can be accomplished with the use of nitric oxide, which is a selective pulmonary vasodilator, when other methods fail. Oxygenation, ventilation, volume expanders, and drug therapy such as Pavulon, Versed, vasopressors (dopamine or dobutamine) and afterload reducers (nitroprusside) are used until the PaO_2 can be consistently maintained at 60–90 mm Hg (Konduri & Kim 2009).

NURSING CARE MANAGEMENT

The nurse assesses for the onset of symptoms, which usually occur in the first 12 to 24 hours of life. Affected newborns exhibit signs of respiratory distress (grunting, nasal flaring, tachypnea), with increased anteroposterior diameter and cyanosis. They typically fail to respond to conventional methods of oxygenation and ventilation. Significant unexplained hypoxemia exists in the absence of congenital heart disease. The chest radiograph might show no evidence of pulmonary parenchymal disease (depending on the underlying disease). The hypoxemia and cyanosis associated with PPHN are characteristic of extreme changeability. Marked, rapid changes in PaO_2 and color are seen with agitation, stimulation, therapeutic intervention (suctioning), or rapid changes in ambient oxygen.

Infants with PPHN are critically ill and require experienced, highly skilled nurses to provide optimal care with minimal manipulation/stimulation. Any disturbance may cause agitation, which leads to hypoxemia. If a paralyzing agent is used, nursing care includes monitoring the newborn's response to artificial oxygenation and mechanical ventilation. The nurse ensures that the oxygen is delivered in correct amounts and route and records the percentage of oxygen flow. The ventilator settings are checked frequently and recorded per unit policy. The nurse carefully suctions the endotracheal tube only as necessary while assessing the effect of the procedure on the baby's oxygenation and perfusion. The amount and type of secretions are noted. The

nurse carefully assesses arterial blood gases and notifies the clinician if the results are out of the acceptable range. Oxygen monitoring is essential for identifying activities that may compromise the infant's status. (Nursing interventions required for noninvasive oxygen monitoring are discussed in Table 34-2.) Continuous monitoring of vital signs and blood pressure is required, and careful inspection of the skin during positioning is necessary to avoid pressure necrosis. Aggressive ventilation poses a potential risk for pneumothorax.

Many infants suffering PPHN are born at or near term at a time when parents least expect problems—especially life-threatening problems—to occur. The magnitude of the infant's illness and the rapid deterioration may be overwhelming to parents. Attachment becomes difficult when the infant responds poorly to touching (as seen by decreased PaO_2). Instead, the nurse can encourage parents to talk very softly to their infant because this will usually not compromise the baby's condition. The nurse should assess their level of understanding and assist them by providing information about their baby's condition and therapies in easily understandable terms. Continuity of nursing care is helpful because it will be less threatening for the parents to relate to a smaller group of nurses.

Care of the Newborn with Complications Due to Respiratory Therapy

Oxygen and mechanical ventilation, although required as therapeutic interventions to reduce hypoxia, hypercarbia, ischemia, and infarction to vital organs, may also have harmful effects. The concentrations of ambient oxygen administered to the newborn must be titrated according to oxygen tension within arterial blood to avoid development of retinopathy of prematurity or bronchopulmonary dysplasia/chronic lung disease.

Pulmonary Interstitial Emphysema

Pulmonary interstitial emphysema (PIE) is the accumulation of air in lung tissues occurring predominantly in very-low-birthweight (VLBW) neonates who are on mechanical ventilators (Miller & Carlo, 2008). It may be unilateral or bilateral. Air collections outside the lung are a function of lung compliance and use of increased pressures to ventilate. Overdistention of alveoli may progress to PIE when rupture occurs and air escapes and becomes trapped into the interstitial spaces. Air moves along perivascular spaces but not into the pleural space or mediastinum. As the air collections increase, blood vessels are constricted, and blood gas exchange is impaired; thus hypoxia and hypercarbia may develop. The air does not decrease on expiration. This condition is highly associated with subsequent bronchopulmonary dysplasia (BPD). It may also precede pneumothorax or pneumomediastinum (Gomella, et al., 2009; Miller & Carlo, 2008).

Pneumothorax

Pneumothorax, a common complication of respiratory therapy, is an accumulation of air in the thoracic cavity between the parietal and visceral pleura and precedes collapse of the lung (Posner & Needleman, 2008). Asymptomatic pneumothorax occurs in 1% to 2% of newborns. In addition, pulmonary air leaks occur in up to 15% to 30% of mechanically ventilated newborns; however, air leaks can be a consequence of injury due to the disease rather than the mechanical ventilation (Gomella et al., 2009).

Pneumothorax in the newborn causes several physiologic changes: collapse of the lung, compression of the heart and lungs, compromise of venous return to the right heart with mediastinal air, and development of tension in the pleural space. Symptoms of pneumothorax include a sudden, unexplained deterioration in the newborn's condition; decreased breath sounds; apnea; bradycardia; cyanosis; increased oxygen requirements; higher PCO_2; decrease in pH; mottled, asymmetric chest expansion; decreased arterial blood pressure; shock-like appearance; and a shift in the apical cardiac impulses to the side opposite the pneumothorax, often with muffled heart sounds.

Transillumination of the chest is used for rapid evaluation of pneumothorax. However, x-ray examination is the main method of diagnosing this complication (Figure 34-10 ■). Pneumothorax is a potentially life-threatening situation for the newborn

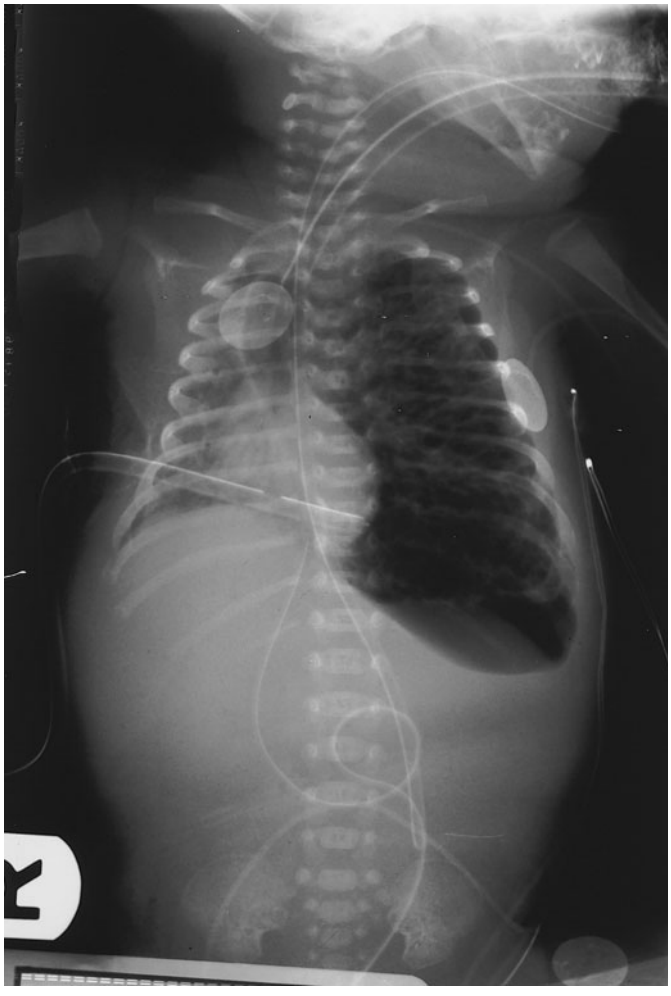

Figure 34-10 ■ Chest x-ray of a left-sided pneumothorax. A rupture of the alveoli sacs allows air to leak through the pleura, forming collections of air outside the lung (air shows on x-ray as dark area over lung).

Source: Courtesy of Carol Harrigan, RN, MSN, NNP-BC.

and may demand immediate removal of the accumulated air. Only skilled and specifically trained personnel should perform a thoracentesis. For complete resolution of the pneumothorax, a chest tube may be inserted (Posner & Needleman, 2008).

Bronchopulmonary Dysplasia/ Chronic Lung Disease

Bronchopulmonary dysplasia (BPD), also known as **chronic lung disease (CLD) of prematurity**, most commonly occurs in very compromised low-birth-weight (LBW) preterm infants who require oxygen therapy, which may cause oxidant injury, and assisted mechanical ventilation, causing volutrauma and barotrauma for the treatment of respiratory distress syndrome (RDS) or other medical condition (Geary, Caskey, Fonseca, et al., 2008). The incidence can reach up to 30% in infants born weighing less than 1 kg at birth (Geary et al., 2009). It has also been associated with neonatal pneumonia, meconium aspiration syndrome (MAS), persistent pulmonary hypertension (PPHN), congenital heart disease (patent ductus arteriosus), other congenital anomalies requiring high levels of oxygen and ventilatory support, and possibly low-grade or asymptomatic pulmonary infection with *Ureaplasma urealyticum* the microorganism frequently located in the amniotic fluid and pulmonary secretions after birth in the preterm newborn (Speer, 2009).

The definition of BPD is dependence on oxygen up to 28 days of age to maintain an oxygen saturation >89%. Mild BPD requires oxygen greater than or equal to 28 days but not at 36 weeks gestational age. Moderate BPD requires the use of oxygen greater than or equal to 28 days at 36 weeks gestational age with less than 30% oxygen required. Severe BPD requires supplemental oxygen greater than or equal to 30% at greater than or equal to 28 days and/or positive pressure support or mechanical ventilation at 36 weeks gestational age (Gomella et al., 2009). The process of BPD is one of continuous lung tissue injury and repair, delaying both lung and body growth.

Clinical Therapy

The goals of therapeutic intervention for the newborn with BPD are to provide adequate oxygenation and ventilation, prevent further lung damage, promote optimal nutrition, and give supportive care to ensure adequate rates of growth and development. Because of the chronic nature of BPD, therapeutic intervention must be individualized to meet the specific needs of the infant. Supplemental oxygen levels are adjusted to consistently keep O_2 saturations between 85% and 93%, depending on associated clinical problems such as poor growth, recurrent bradycardia, and pulmonary hypertension (Gomella et al., 2009). Diuretics and fluid restriction (120 ml/kg/day) are frequently used to control pulmonary fluid retention and to improve lung function; electrolyte supplements are necessary to offset the results of chronic diuretic therapy (Cloherty et al., 2008; Gomella et al., 2009). In addition, bronchodilators are indicated to decrease airway resistance and to control bronchospasm. The infant with chronic lung disease is often on long-term steroids. Serial echocardiography is used to monitor cardiac response to the chronic pulmonary disease.

NURSING CARE MANAGEMENT

Hospital-Based Nursing Care

The nurse observes carefully for any changes in the newborn's oxygenation, giving special attention to maintaining the prescribed oxygen concentration during all activities, especially during periods of stress, such as when the infant is crying; when blood is drawn; while starting an intravenous (IV) infusion; and during a lumbar puncture (LP), suctioning, chest physiotherapy (CPT), and feeding.

The nurse obtains blood gases based on the institution's chronic blood gas protocol—for example, every 3 days, 20 minutes after a permanent change in ambient oxygen concentration (FiO_2), or more frequently if the infant experiences increasing respiratory distress or increasing lethargy. Postural drainage, CPT, and vibration followed by suctioning are carried out with close attention to the baby's tolerance and should be coordinated with rest periods to avoid fatiguing the infant. The nurse maintains the infant's body temperature because hypothermia or hyperthermia will increase oxygen consumption and may increase oxygen requirements. Positioning on the abdomen helps the baby maintain higher transcutaneous oxygen saturation ($TcPO_2$) and improved ventilation.

Bronchodilators such as albuterol, diuretics, steroids, and electrolyte supplements may be used in the clinical management of the BPD infant (Gomella et al., 2009). Many of the side effects of these drugs, such as hypokalemia and mineral losses (fractures), can be avoided by giving the diuretics every other day.

Providing for adequate nutrition enhances formation of new alveoli and enlargement of the airway diameter. The more severely ill the baby, the higher the caloric need to meet the greater expenditure of energy for survival and healing. As soon as tolerated, a 24 kcal/oz formula for preterm infants is started, especially if the baby is on fluid restriction. More oxygen may be required during feeding, and the least energy-consuming feeding method should be used (Figure 34-11 ■). If the feeding schedule

Figure 34-11 ■ A baby with BPD requires oxygen at greater than 36 weeks' gestational age. She still needs to be fed through an NG tube, because she tires with nipple feeds.

Source: Courtesy of Lisa Smith-Pedersen, RN, MSN, NNP-BC.

is too stressful, smaller, more frequent feedings may be initiated (Cloherty et al., 2008; Gomella et al., 2009).

Infants with BPD frequently experience negative oral sensations due to suctioning and intubation. These can adversely affect their transition to nipple or spoon feeding and may require some type of feeding therapy to help them eat successfully. Positioning is often the key to adequate intake and decreasing gastroesophageal reflux (GER). In addition, most infants receive numerous, possibly unpalatable, medications with meals. Attempts must be made to include pleasurable activities such as cuddling at mealtime to develop positive associations with appropriate feeding behaviors.

Infants with BPD are very susceptible to infection, especially if they are on long-term steroids; therefore, it is important to discourage anyone with early signs of infectious disease from having contact with them. The infant's behavior and vital signs should be monitored for changes that might indicate early developing infection. Changes in color, quantity, or quality of pulmonary secretions are noted and reported. The frequency of CPT and suctioning may need to be increased.

Health Promotion Education

When the infant develops BPD and the family becomes aware of the implications of chronic illness and prolonged hospitalization, they may experience despair and find it difficult to cope with this added burden. The nurse can help the family cope by involving them in the plan of care and encouraging them to take an active role in their infant's daily activities. Their involvement will help dispel feelings of inadequacy and prepare them to perform the unique tasks necessary to meet their infant's needs.

Parents need to demonstrate their ability to provide all the care their child will require at home before leaving the hospital. This may include feeding, adjusting O_2 support, O_2 saturation monitoring, suctioning and airway management, CPT, bathing, and giving medications. They also need to know when to call the home health nurse who is providing care. Parents should be taught how to assess the infant's respiratory condition and understand the BPD baseline respiratory pattern (frequency of respiration, rhythm, degree of retractions, and color of skin and mucous membranes). Illness limits the tolerance level for activity, and parents must be taught to evaluate their infant's tolerance of activities and to recognize signs of distress due to poor oxygenation, inadequate ventilation, infection, fluid retention, and bronchospasm. The nurse should give special attention to formulating a program of early stimulation activities because psychomotor delays are frequently seen.

Care of the Newborn with Cold Stress

Cold stress is excessive heat loss resulting in the use of compensatory mechanisms (such as increased respirations and nonshivering thermogenesis/use of brown fat stores) to maintain core body temperature close to 37.0°C/98.6°F (Baumgart, 2008). Heat loss that results in cold stress occurs in the newborn through the mechanisms of evaporation, convection, conduction, and radiation. (See chapter 29 ∞ for a detailed discussion of thermoregulation.) Heat loss at birth that leads to cold stress can play a significant role in the severity of respiratory distress syndrome (RDS) and the ultimate outcome for the infant. Both preterm and small-for-gestational-age (SGA) newborns are at increased risk for cold stress because they have decreased adipose tissue, brown fat stores, and glycogen available for metabolism.

As discussed in chapter 29 ∞, the newborn's major source of heat production in nonshivering thermogenesis (NST) is brown fat metabolism. The ability of an infant to respond to cold stress by NST is impaired in the presence of several conditions:

- Hypoxemia (PO_2 less than 50 torr)
- Intracranial hemorrhage or any central nervous system (CNS) abnormality
- Hypoglycemia (blood glucose less than 40 mg/dl)

When these conditions occur, the infant's temperature should be monitored more closely and the neutral thermal environment conscientiously maintained. The nurse must recognize these conditions and treat them as soon as possible. The metabolic consequences of cold stress can be devastating and potentially fatal to an infant. Oxygen requirements increase; even before noting a change in temperature, glucose use increases; acids are released into the bloodstream; and surfactant production decreases (Blackburn, 2007). The effects are graphically depicted in Figure 34-12 ■.

NURSING CARE MANAGEMENT

The amount of heat lost by an infant depends to a large extent on the actions of the nurse or caregiver. Following the transfer of a neonatal intensive care unit (NICU) newborn from one bed to another, a transient, although not significant, decrease in temperature for up to 1 hour may be noted. Prevention is especially critical in the very-low-birth-weight (VLBW) infant. Placing the VLBW newborn in a polyethylene wrapping immediately following birth can decrease the postnatal fall in temperature that normally occurs. Using head coverings made of insulated fabrics, wool, polyolefin, or those lined with Gamgee can significantly decrease heat loss after childbirth (Blackburn, 2007). Convective, radiant, and evaporative heat loss can all be reduced. Swaddling and nesting maintain flexion, which reduces exposed surface area and thus convective and radiant losses. Both convective and evaporative heat loss can be reduced.

The nurse observes the baby for signs of cold stress. These include increased movements and respirations, decreased skin temperature and peripheral perfusion, development of hypoglycemia, and, possibly, development of metabolic acidosis.

Vasoconstriction is the initial response to cold stress; because it initially decreases skin temperature, monitor and assess skin temperature instead of rectal temperature. A decrease in rectal temperature means that the infant has long-standing cold stress. By monitoring skin temperature, possible decrease will become apparent before the infant's core temperature is affected.

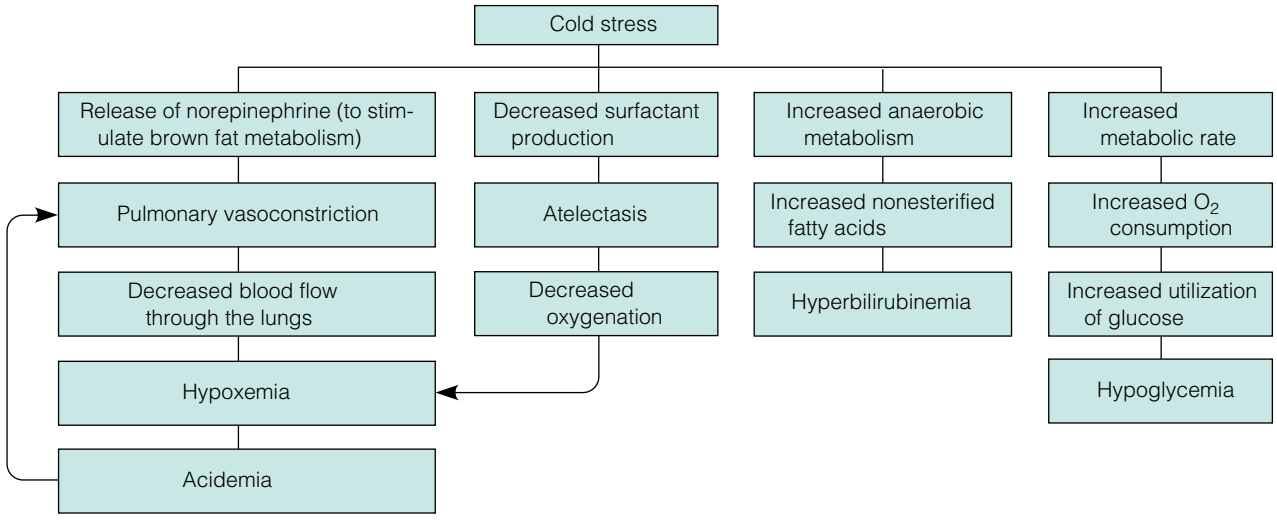

Figure 34-12 ■ Cold stress chain of events. The hypothermic, or cold-stressed, newborn attempts to compensate by conserving heat and increasing heat production. These physiologic compensatory mechanisms initiate a series of metabolic events that result in hypoxemia and altered surfactant production, metabolic acidosis, hypoglycemia, and hyperbilirubinemia.

If a decrease in skin temperature is noted, the nurse determines whether hypoglycemia is present. Hypoglycemia is a result of the metabolic effects of cold stress and is suggested by glucometer values below 40–50 mg/ml, tremors, irritability or lethargy, apnea, or seizure activity.

If hypothermia occurs, the following nursing interventions should be initiated (Gomella et al., 2009):

- Maintain a neutral thermal environment (NTE); adjust based on the gestational age and postnatal age.
- Warm the newborn slowly, because rapid temperature elevation may cause hypotension and apnea.
- Increase the air temperature in hourly increments of 1°C (33.8°F) until the infant's temperature is stable.
- Monitor skin temperature every 15 to 30 minutes to determine whether the newborn's temperature is increasing.
- Remove plastic wrap, caps, and heat shields while rewarming the infant so that cool air as well as warm air is not trapped.
- Warm IV fluids before infusion.
- Initiate efforts to block heat loss by evaporation, radiation, convection, and conduction. Maintain the newborn in NTE.

The nurse assesses the presence of anaerobic metabolism and initiates interventions for the resulting metabolic acidosis. Attempts to burn brown fat increase oxygen consumption, lactic acid levels, and metabolic acidosis. Hypoglycemia may be reversed by adequate glucose intake, as described in the following section.

Care of the Newborn with Hypoglycemia

Hypoglycemia, low blood sugar, can affect 3 to 29 out of 100 babies, both term and preterm (DePuy, Coassolo, Som, et al., 2009). An operational threshold for intervention in newborn hypoglycemia is a plasma glucose concentration of less than 40 mg/dl at any time in any newborn. It requires follow-up glucose measurement to document normal values (Cloherty et al., 2008). Within the first hours of life, normal asymptomatic newborns may have a transient glucose level in the 30s (mg/dl) that will increase either spontaneously or with feedings. Plasma glucose values less than 20 to 25 mg/dl should be treated with parenteral glucose $D_{10}W$, regardless of the age or gestation to raise plasma glucose to greater than 45 mg/dl. There is no absolute threshold that can be applied to all babies. Glucose concentrations must be looked at in conjunction with clinical manifestations.

Hypoglycemia is the most common metabolic disorder occurring in infants of diabetic mothers (IDM), small-for-gestational-age (SGA) infants, the smaller of twins, infants born to mothers with preeclampsia, male infants, and preterm average-for-gestational-age (AGA) infants. The pathophysiology of hypoglycemia differs for each classification (Gomella et al., 2009).

AGA preterm infants have not been in utero a sufficient time to store glycogen and fat. As a result, they have a decreased ability to carry out gluconeogenesis. This situation is further aggravated by increased use of glucose by the tissues (especially the brain and heart) during stress and illness (chilling, asphyxia, sepsis, and respiratory distress syndrome [RDS]).

Infants of White's classes A through C or type 1 diabetic mothers (women with diagnosed or gestational diabetes) have increased stores of glycogen and fat (see chapters 19 ∞ and 33 ∞). Circulating insulin and insulin responsiveness are also higher when compared with other newborns. Because the high glucose loads present in utero stop at birth, and the newborn continues to produce high levels of insulin from their pancreatic beta cells, the newborn experiences rapid and profound hypoglycemia (Gomella et al., 2009). Infants with recurrent episodes of hypoglycemia resulting from congenital hyperinsulinism showed that 50% have long-term neurologic deficits (Nash & Smith, 2008).

The SGA infant has used up glycogen and fat stores because of intrauterine malnutrition and has a blunted hepatic enzymatic response with which to produce and use glucose. Any

newborn stressed at birth from asphyxia or cold also quickly uses up available glucose stores and becomes hypoglycemic. Epidural anesthesia may alter maternal-fetal glucose homeostasis, resulting in hypoglycemia.

Clinical Therapy

The goal of medical management includes early identification of hypoglycemia through observation and screening of newborns at risk (Gomella et al., 2009; Nash & Smith, 2008). The baby may be asymptomatic, or any of the following may occur:

- Lethargy, apathy, and limpness
- Poor feeding, poor/inadequate sucking reflex, vomiting
- Hypothermia in low-birth-weight (LBW) infants
- Pallor, cyanosis
- Apnea, irregular respirations, respiratory distress, cyanosis, tachypnea
- Hypotonia, possible loss of swallowing reflex
- Tremors, jerkiness, seizure activity, irritability, eye rolling
- High-pitched cry
- Exaggerated Moro reflex
- Temperature instability

Aggressive treatment is recommended after a single low blood glucose value if the infant shows any of these symptoms. In at-risk infants, routine screening should be done frequently during the first hours of life and then whenever any of the noted clinical manifestations appears or at 1- to 4-hour intervals until the risk period has passed.

Hypoglycemia may also be defined as a *glucose oxidase reagent strip with reflectance meter* below 40 mg/dl, but only when corroborated with laboratory blood glucose (see Procedure 34-1: Performing a Heel Stick on a Newborn). Common bedside methods use whole blood, an enzymatic reagent strip, and a reflectance meter or color chart. Bedside glucose oxidase strip tests can screen for hypoglycemia, but laboratory determinations *must confirm* the results before a diagnosis of hypoglycemia can be made. Glucose reagent strips should not be used by themselves to screen and diagnose hypoglycemia because their results depend on the baby's hematocrit (they react to the glucose in the plasma, not the red blood cells [RBCs]), and there is a wide variance (5 to 15 mg/dl) when compared with laboratory determinations.

CLINICAL TIP

There is no significant evidence to support the use of heel warmers preceding a capillary heelstick of an infant and no evidence of an increased yield of blood with the use of heel warmers (National Association of Neonatal Nurses' Guidelines) (Folk, 2007).

Blood glucose sampling techniques can significantly affect the accuracy of the blood glucose value. It is important to note that whole blood glucose concentrations are 10% to 15% lower than plasma glucose concentration (Cloherty et al., 2008). The higher the hematocrit, the greater the difference is between whole blood and plasma values. Also, venous blood glucose concentrations are approximately 15% to 19% lower than arterial blood glucose concentrations because the tissues extract some glucose before the blood enters the venous system. Newer point-of-care techniques, such as using a glucose oxidase analyzer or an optical bedside glucose analyzer, are more reliable for bedside screening but must also be validated with laboratory chemical analysis.

CLINICAL TIP

Venous blood samples for the laboratory should be placed on ice and analyzed within 30 minutes of drawing to prevent the red blood cells (RBCs) from continuing to metabolize glucose and giving a falsely low reading.

Adequate caloric intake is important. Early breastfeeding or formula-feeding is one of the major preventive approaches. If early feeding or intravenous (IV) glucose is started to meet the recommended fluid and caloric needs, the blood glucose is likely to remain above the hypoglycemic level. During the first hours after birth, asymptomatic newborns may be given oral glucose contained in formula or breast milk (glucose water should not be used because it causes a rapid increase in glucose followed by an abrupt decrease), and then another plasma glucose measurement is obtained within 30 to 60 minutes after feeding.

IV infusions of a dextrose solution D_5W to $D_{10}W$ (5% to 10%) begun immediately after birth should prevent hypoglycemia. Plasma glucose levels are obtained when the parenteral infusion is started. However, in the very small AGA infant, infusions of 10% dextrose solution may cause hyperglycemia to develop, requiring an alteration in the glucose concentration. An IV glucose solution should be calculated based on body weight of the infant and fluid requirements and correlated with blood glucose tests to determine adequacy of the infusion treatment.

In more severe cases of hypoglycemia, corticosteroids may be administered. It is thought that steroids enhance gluconeogenesis from noncarbohydrate protein sources (Gomella et al., 2009).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The objective of nursing assessment is to identify newborns at risk and to screen symptomatic infants. For newborns diagnosed with hypoglycemia, assessment is ongoing with careful monitoring of glucose values. Glucose strips, urine dipsticks, and urine volume (monitor only if above 1 to 3 ml/kg/hr) are evaluated frequently for osmotic diuresis and glycosuria.

Nursing diagnoses that may apply to the newborn with hypoglycemia include the following:

- ***Imbalanced Nutrition: Less Than Body Requirements*** related to increased glucose use secondary to physiologic stress
- ***Ineffective Breathing Pattern*** related to tachypnea and apnea
- ***Acute Pain*** related to frequent heel sticks for glucose monitoring

PROCEDURE 34-1 Performing a Heel Stick on a Newborn

NURSING ACTION

Preparation

- Explain to parents what will be done.
- Select a clear, previously unpunctured site.

  Rationale: *The selection of a previously unpunctured site minimizes the risk of infection and excessive scar formation.*
- The infant's lateral heel is the site of choice because it precludes damaging the posterior tibial nerve and artery, plantar artery, and the important longitudinally oriented fat pad of the heel, which in later years could impede walking (Figure 34-13 ■). This is especially important for infants undergoing multiple heel stick procedures. Toes are acceptable sites if necessary.

Equipment and Supplies

Microlancet (do not use a needle)

Alcohol swabs

2 × 2 sterile gauze squares

Small bandage (may not use on premature infant with extremely sensitive skin, hold pressure until bleeding ceases)

Transfer pipette or capillary tubes

Glucose reagent strips or reflectance meters

Gloves

Procedure: Clean Gloves

1. Apply gloves.

   Rationale: *A needle may nick the periosteum. Gloves are used to implement standard precautions and prevent nosocomial infections.*
2. Warming the infant's heel for 5 to 10 seconds to facilitate blood flow is controversial. Check agency policy.

Performing the Heel Stick

1. Grasp the infant's lower leg and foot so as to impede venous return slightly. This will facilitate extraction of the blood sample (Figure 34-14 ■).
2. Clean the site by rubbing vigorously with 70% isopropyl alcohol swab.

   Rationale: *Friction produces local heat, which aids vasodilation.*
3. Blot the site dry completely with dry gauze square before lancing.

   Rationale: *Alcohol is irritating to injured tissue and it may also produce hemolysis, as well as causing a false low reading.*
4. With a quick, piercing motion, puncture the lateral heel with a microlancet. Be careful not to puncture too deeply. Optimal penetration is 4 mm.
5. Wipe the first drop of blood away with the gauze.

   Rationale: *The first drop may be contaminated by skin contact and the blood cells may have been traumatized during the stick. Blood glucose may be lowered by residual alcohol.*

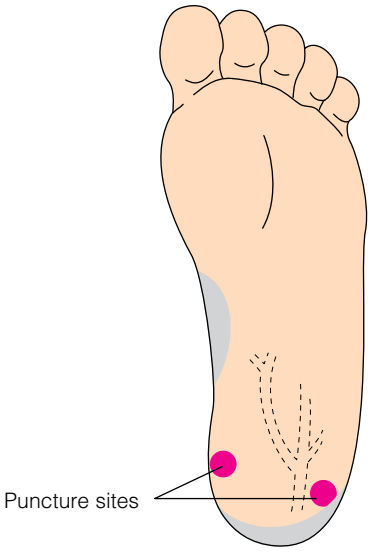

Figure 34-13 ■ Potential sites for heel sticks. Avoid shaded areas to prevent injury to arteries and nerves in the foot and the important longitudinally oriented fat pad of the heel, which in later years could impede walking.

Collecting the Blood Sample

1. Use transfer pipette to place drop of blood on glucose reflectance meter or directly onto the Glucometer test strip.
2. Use capillary tube for hematocrit testing.

Preventing Excessive Bleeding

1. Apply a folded gauze square to the puncture site and secure it firmly with a bandage, or hold pressure until bleeding stops.
2. Check the puncture site frequently for the first hour after sampling.

Figure 34-14 ■ Heel stick. With a quick, piercing motion, puncture the lateral heel with a microlancet. Be careful not to puncture too deeply.

Documentation

Record the findings on the infant's chart.

Nursing Plan and Implementation

The nurse should monitor all at-risk groups within 30 to 60 minutes after birth and before feedings or whenever there are abnormal signs (Nash & Smith, 2008). Monitor the IDM within 30 minutes of birth. Once an at-risk infant's blood sugar level is stable, glucose testing every 2 to 4 hours (or per agency protocol), or before feedings, adequately monitors glucose levels. See Procedure 34-1: Performing a Heel Stick on a Newborn on page 961.

The method of feeding greatly influences glucose and energy requirements; thus carefully calculating glucose requirements and attention to glucose monitoring is required during the transition from IV to oral feedings. Titration of IV glucose may be required until the infant is able to take adequate amounts of formula or breast milk to maintain a normal blood sugar level. Titrate by decreasing the concentration of parenteral glucose gradually to 5% (D_5W), then reducing the rate of infusion (mg/kg/min), and slowly discontinuing it over 4 to 6 hours. Enteral feeds are increased to maintain an adequate glucose and caloric intake and maintain normal blood glucose levels.

Complementary and Alternative Therapies

The newborn relies on the nurse's observational, assessment, and interventional skills for prompt, safe, and effective pain relief. It is vital that the nurse assist infants to cope with and recover from necessary painful clinical procedures. A variety of nonpharmacologic pain-prevention and relief techniques have been shown to be effective in reducing pain from minor procedures in newborns.

Any unnecessary stimuli (i.e., noise, visual, tactile, and vestibular) of the newborn should be avoided, if possible. Developmental care, which includes limiting environmental stimuli, lateral positioning, the use of supportive bedding, and attention to behavioral cues, assists the newborn to cope with painful procedures (Gardner, Enzman-Hines, & Dickey, 2011).

Containment with swaddling or facilitated tucking (holding the arms and legs in a flexed position) is effective in reducing excessive immature motor responses. Swaddling also may provide comfort through other senses, such as thermal, tactile, and proprioceptive senses. Breastfeeding and skin-to-skin contact with the mother during the painful procedure may help to relieve pain (Weissman, Aranovitch, Blazer, et al., 2009; Gardner et al., 2011).

Nonnutritive sucking (NNS) refers to the provision of a pacifier into the infant's mouth to promote sucking without the provision of breast milk or formula for nutrition. NNS is thought to produce analgesia through stimulation of orotactile and mechanoreceptors when the pacifier is placed into the infant's mouth. Allowing nonnutritive sucking with a pacifier aids in the reduction of procedural pain and stress. Unfortunately a rebound in distress occurs when the NNS pacifier is removed from the infant's mouth (Gardner et al., 2011).

A wide range of oral sucrose doses has been used for procedural pain relief (heel sticks, venipuncture, IM injections), but no optimal dose has been established (Gardner et al., 2011). The sweetness of the sucrose, a disaccharide, elevates the pain threshold through endogenous opioid release in the CNS and produces a calming effect (Gardner et al., 2011). A range of 0.05 to 0.5 ml of 24% sucrose is administered on the anterior part of the tongue via a syringe or nipple approximately 2 minutes before the procedure (Dilli, Kucuk, & Dallar, 2009). Some authors have suggested that multiple doses, such as giving a dose 2 minutes before and 1 to 2 minutes after a procedure, is more effective. It is important to be careful with repeated doses of sucrose, as the concern for hyperglycemia, necrotizing enterocolitis (NEC), and fluid overload may arise. Oral sucrose should be limited to infants greater than 34 weeks gestational age (Gomella et al., 2009). Also, repeated use of sucrose analgesia in preterm infants may affect their neurologic development and behavioral outcomes. Until further research is done, repeated doses of sucrose are not recommended (Gardner et al., 2011). Because oral sucrose reduces but does not eliminate pain, it should be used with other nonpharmacologic measures to enhance effectiveness.

PROFESSIONALISM IN PRACTICE

Litigious Medicolegal Issues in the NICU

Stokowski (2008) cited that the two most litigious medicolegal issues in the neonatal intensive care unit (NICU) are cases involving neonatal resuscitation and hyperbilirubinemia. Neonatal nurses, as do all nurses, have the professional obligation to stay current with all the standards of care in their clinical setting. Cases that involve neonatal resuscitation found some of the following deficiencies:

1. Delay in initiation of resuscitation
2. Miscommunication
3. Equipment unavailable
4. Perception of ineptness
5. Poor documentation—**Need to Chart!**

Some of the deficient areas that were evaluated during cases involving neonatal patients with a diagnosis of jaundice were the following:

1. Not performing baseline bilirubin evaluations (transcutaneous or serum) prior to discharge
2. Charting that is incomplete about jaundice **(if it is not charted, it was not done)**
3. Improper recognition of high-risk conditions predisposing the neonate to jaundice
4. Not following up on clinical assessment of jaundice with serum bilirubin levels
5. Not obtaining a serum bilirubin level if any concerning clinical symptoms are present
6. Incomplete follow-up with any neonate with jaundice

Nurses are considered both independent professionals and institution employees and are increasingly named as individual defendants. In addition, allegations against NICU nurses frequently include, for example: failure to monitor, failure to notify the primary caregiver of clinical changes, treatment delays, not possessing proper competence or knowledge, proper procedure not followed, failure to obtain informed consent, and improper delegation.

The two best recommendations to help prevent legal issues in the NICU environment are:

1. Know the current standards of care/practice and **follow** them.
2. The primary evidence that can be provided is the patient's chart.

Evaluation

Expected outcomes of nursing care include the following:

- The newborn at risk of hypoglycemia is promptly identified, and intervention is started early.
- The newborn's glucose level is stabilized; recovery proceeds without sequelae.

Care of the Newborn with Jaundice

The most common abnormal physical finding in newborns is jaundice (*icterus neonatorum*). Some degree of newborn jaundice, resulting from elevated unconjugated bilirubinemia, occurs in approximately 60% of healthy newborns and 80% of preterm infants (Bhutani and Johnson, 2009; Bradshaw, 2010). **Jaundice** is a yellowish coloration of the skin and sclera of the eyes that develops from the deposit of yellow pigment bilirubin in lipid/fat-containing tissues, as described in chapter 29 ∞. Fetal unconjugated bilirubin is normally cleared by the placenta in utero, so total bilirubin at birth is usually less than 3 mg/L unless an abnormal hemolytic process has been present. Postnatally, the infant must conjugate bilirubin (convert a lipid-soluble pigment into a water-soluble pigment) in the liver.

The rate and amount of conjugation of bilirubin depend on the rate of hemolysis, the bilirubin load, the maturity of the liver, and the presence of albumin-binding sites. See chapter 29 ∞ for discussion of conjugation of bilirubin. A normal, healthy, full-term infant's liver is usually mature enough and produces enough glucuronyl transferase that the total serum bilirubin concentration does not reach a pathologic level. The diagnosis of pathologic jaundice is given to newborns who exhibit jaundice within the first 24 hours of life, have a total serum bilirubin concentration increase of greater than 0.2 mg/dl/hour, surpass the 95th percentile on the nomogram for age in hours, or have persistent visible jaundice after 1 week of age in term infants or after 2 weeks in preterm infants.

Physiologic Jaundice

Physiologic or neonatal jaundice is a normal process that occurs during transition from intrauterine to extrauterine life and appears *after 24 hours of life*. It is typically due to the newborn's increased red cell mass, shorter red cell lifespan (90 days as compared with 120 days in the adult), slower uptake of bilirubin by the liver, lack of intestinal bacteria, and/or poorly established hydration from initial breastfeeding (Gomella et al., 2009). Total bilirubin levels peak around 96 to 120 hours of age, usually after discharge from the hospital (Bhutani & Johnson 2009).

Lab tests reveal a predominance of unconjugated bilirubin. The average level of unconjugated bilirubin in cord blood is approximately 2 mg/dl at birth. This level rises to an average of 5 to 6 mg/dl between the third and fifth days of life. The jaundice is usually not visible after 14 days. The pattern of physiologic jaundice differs between breastfed and formula-fed newborns (for further discussion of physiologic jaundice, see "Physiologic Jaundice" in chapter 29 ∞). Physiologic jaundice remains a common problem for the term newborn and may require treatment with phototherapy.

Pathophysiology of Hyperbilirubinemia

Serum albumin-binding sites are usually able to conjugate enough bilirubin to meet the demands of the normal newborn. However, certain conditions tend to decrease the number or quality of available binding sites. Fetal or neonatal asphyxia and neonatal drugs such as indomethacin decrease the binding affinity of bilirubin to albumin, because acidosis impairs the capacity of albumin to hold bilirubin. Hypothermia and hypoglycemia release free fatty acids (FFAs) that dislocate bilirubin from albumin. Maternal use of sulfa drugs and salicylates interferes with conjugation or with serum albumin-binding sites by competing with bilirubin for these sites. Finally, premature infants have less albumin available for binding with bilirubin. Neurotoxicity is possible because unconjugated bilirubin has a high affinity for extravascular tissue, such as fatty tissue (subcutaneous tissue) and cerebral tissue.

Bilirubin not bound to albumin is free to cross the blood-brain barrier, damage cells of the central nervous system (CNS), and produce **kernicterus** or **acute bilirubin encephalopathy (ABE)** (Moerschel, Cianciaruso, & Tracy, 2008). *Kernicterus* (meaning "yellow nucleus") usually refers to the deposition of unconjugated bilirubin in the basal ganglia of the brain and to permanent neurologic sequelae of untreated **hyperbilirubinemia** (elevation of bilirubin level). The incidence is 0.9 to 1.5 per 100,000 live births (Burke et al., 2009; Manning, Todd, Maxwell, et al., 2007).

The classic bilirubin encephalopathy of kernicterus most commonly found with Rh and ABO blood group incompatibility is less common today because of aggressive treatment with phototherapy and exchange transfusions. Kernicterus cases are reappearing as a result of early discharge and the increased incidence of dehydration (a result of discharge before mother's milk is established when breastfeeding). Unfortunately, current therapy cannot distinguish all infants who are at risk. It is recommended that *all* newborns be screened for their bilirubin level prior to leaving the hospital either using total serum bilirubin (TSB) or transcutaneous bilirubin (TcB) (Maisels et al., 2009).

Causes of Hyperbilirubinemia

A primary cause of pathologic hyperbilirubinemia is **hemolytic disease of the newborn**. All pregnant women who are Rh negative or who have blood type O (possible ABO incompatibility) should be asked about outcomes of any previous pregnancies, including abortions, and history of blood transfusion. Prenatal amniocentesis with spectrophotographic examination may be indicated in some cases. Cord blood from newborns is evaluated for bilirubin level, which normally does not exceed 5 mg/dl. Newborns of Rh-negative and O blood type mothers are carefully assessed for blood type status, appearance of jaundice, and levels of serum bilirubin.

Alloimmune hemolytic disease, also known as **erythroblastosis fetalis**, occurs when an Rh-negative mother is pregnant with an Rh-positive fetus and maternal antibodies cross the placenta. Maternal antibodies enter the fetal circulation, then attach to and destroy the fetal red blood cells (RBCs). The fetal system

responds by increasing RBC production. Jaundice, anemia, and compensatory erythropoiesis result. A marked increase in immature RBCs (erythroblasts) also occurs, hence the designation erythroblastosis fetalis. Because of the widespread use of Rh immune globulin (RhoGAM), the incidence of erythroblastosis fetalis has dropped dramatically.

Hydrops fetalis, the most severe form of erythroblastosis fetalis, occurs when maternal antibodies attach to the Rh site on the fetal RBCs, making them susceptible to destruction; severe anemia and multiple organ system failure result. Cardiomegaly with severe cardiac decompensation and hepatosplenomegaly occur. Severe generalized massive edema (anasarca) and generalized fluid effusion into the pleural cavity (hydrothorax), pericardial sac, and peritoneal cavity (ascites) develop. Jaundice is not present until the newborn period because the bilirubin pigments for the fetus are being excreted through the placenta into the maternal circulation. The hydropic hemolytic disease process is also characterized by hyperplasia of the adrenal cortex and pancreatic islets, which predisposes the infant to neonatal hypoglycemia similar to that of infants of diabetic mothers (IDMs). These infants also have increased bleeding tendencies due to associated thrombocytopenia and hypoxic damage to the capillaries. Hydrops is a frequent cause of intrauterine death among infants with Rh disease.

ABO incompatibility (the mother is blood type O and the baby is blood type A or B) may result in jaundice, although it rarely results in hemolytic disease severe enough to be clinically diagnosed and treated. Hepatosplenomegaly may be found occasionally in newborns with ABO incompatibility, but hydrops fetalis and stillbirth are rare.

During pregnancy, predisposing maternal conditions include hereditary spherocytosis, diabetes, intrauterine infections, gram-negative bacilli infections that stimulate production of maternal alloimmune antibodies, drug ingestion (such as sulfas, salicylates, novobiocin, and diazepam), and oxytocin administration. Early prenatal identification of the fetus at risk for Rh or ABO incompatibility allows prompt treatment. (See chapter 20 ∞ for discussion of in utero management of this condition.) Table 34-3 presents risk factors for development of severe hyperbilirubinemia.

TABLE 34-3 Risk Factors for Development of Severe Hyperbilirubinemia in Infants of 35 or More Weeks' Gestation (in Approximate Order of Importance)

Major Risk Factors

- Predischarge total serum bilirubin (TSB) or transcutaneous bilirubin (TcB) level in the high-risk or high intermediate zone
- Jaundice observed in the first 24 h after birth
- Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (e.g., glucose-6-phosphate dehydrogenase (G6PD) deficiency), elevated $ETCO_2$ (end-tidal carbon dioxide level)
- Gestational age 35–36 weeks (late preterm gestational age)
- Previous sibling received phototherapy
- Cephalhematoma/significant bruising
- Unrecognized hemolysis such as ABO blood type incompatibility or Rh incompatibility
- Infection
- Exclusive breastfeeding, particularly if nursing is not going well and excessive weight loss is experienced
- East Asian or Mediterranean descent*

Minor Risk Factors

- Predischarge TSB or TcB level in the high intermediate risk zone
- Gestational age 37–38 weeks
- Jaundice observed before discharge
- Previous sibling with jaundice
- Macrosomic infant of a diabetic mother
- Maternal age greater than or equal to 25 years
- Male gender

Decreased Risk (these factors are associated with decreased risk of significant jaundice, listed in order of decreasing importance)

- TSB or TcB level in the low-risk zone
- Gestational age greater than or equal to 41 weeks
- Exclusive bottle-feeding
- Black race*
- Discharge from hospital after 72 h

*Descent and race as defined by mother's description.

Pediatrics, 114*(1), 297–316 (Table 2, p. 301); Maisels, M. J., Bhutani, V. K., Bogen, D., Newman, T. B., Stark, A. R., & Watchko, J. F. (2009). Hyperbilirubinemia in the newborn infant ≥ 35 weeks' gestation: An update with clarifications,* Pediatrics, 124*(4), 1193–1198.*

DEVELOPING CULTURAL COMPETENCE

Ethnic Variations and Jaundice

Infants of East Asian descent (Japanese, Chinese, and Filipino ethnic groups) have a higher occurrence of hyperbilirubinemia than Caucasian infants. Infants with Asian fathers and Caucasian mothers have a higher incidence of jaundice than if both parents are Caucasian. Other ethnic groups at risk for increased bilirubinemia are Navajo, Eskimo, and Sioux Native American newborns; Greek newborns; Sephardic-Jewish newborns; and some Hispanic newborns.

The prognosis for a newborn with hyperbilirubinemia depends on the extent of the hemolytic process and the underlying cause. Severe hemolytic disease may result in fetal or early neonatal death from the effects of anemia—cardiac decompensation, edema, ascites, and hydrothorax. Hyperbilirubinemia may lead to kernicterus if not aggressively treated. The initial symptoms requiring acute intervention of an exchange transfusion are poor tone, lethargy, and/or feeding/sucking issues. Continuing worsening progression includes neurologic damage, which may cause death, cerebral palsy, cognitive impairment, or hearing loss, or, to a lesser degree, perceptual impairment, delayed speech development, hyperactivity, muscle incoordination, or learning difficulties (Okumura et al., 2009). Intravenous gamma globulin (IVIG) may be used with newborns suffering from isoimmune hemolytic disease, 0.5 to 1 gram per kg over 2 hours and repeat in 12 hours if required (Moerschel et al., 2008).

Clinical Therapy

The best treatment for hemolytic disease is prevention. Prenatal identification of the fetus at risk for Rh or ABO incompatibility will allow prompt treatment. See chapter 20 ∞ for discussion of in utero management of this condition.

Laboratory and Diagnostic Assessments

When one or more of the predisposing factors are present, or the appearance of early jaundice, the maternal and neonatal blood types should be tested in the laboratory for Rh or ABO incompatibility (Watchko, 2009). Other necessary laboratory evaluations include Coombs' test, serum bilirubin levels (direct and total), hemoglobin, reticulocyte percentage, white blood cell count, and positive smear for cellular morphology (Table 34-4).

Neonatal hyperbilirubinemia must be considered pathologic if any of the following criteria are met (Bhutani, Johnson, & Keren, 2004; Gomella et al., 2009):

1. Clinically evident jaundice appearing before 24 hours of life or if jaundice seems excessive for the newborn's age in hours
2. Serum bilirubin concentration rising by more than 0.2 mg/dl per hour
3. Total serum bilirubin concentrations exceeding the 95th percentile on the nomogram
4. Conjugated bilirubin concentrations greater than 2 mg/dl or more than 20% of the total serum bilirubin concentration
5. Clinical jaundice persisting for more than 2 weeks in a term newborn

Initial diagnostic procedures are aimed at differentiating jaundice resulting from increased bilirubin production, impaired conjugation or excretion, increased intestinal reabsorption, or a combination of these factors.

Transcutaneous bilirubin (TcB) measurements are a noninvasive method of assessing bilirubin levels and may be used for predischarge risk assessment. A TcB can be performed quickly and painlessly, and repeated measures are easily obtained. TcB can quantify the amount of bilirubin pigment in the infant's skin. Nurses need to measure bilirubin levels to confirm the presence, absence, or suspicion of jaundice. However, it is important to remember that total serum bilirubin levels remain the standard of care for confirmation or diagnosis of hyperbilirubinemia (Gomella et al., 2009).

CLINICAL TIP

Because of exposure to sunlight, sternal transcutaneous bilirubin (TcB) measurements may be more accurate than those taken on the forehead. The sternum, in a dressed infant, is less likely to be affected by the influence of ambient light (such as sunlight) on the skin.

Because of the shorter lifespan of RBCs in the newborn, a significant bilirubin load is produced. When bilirubin breaks down, carbon monoxide (CO) is released. This production of carbon monoxide is being investigated as a marker in the study of bilirubin production. Measuring end-tidal CO (ETCO) has been shown to provide results similar to laboratory measures of bilirubin; however, devices to measure CO are not widely available (Gomella et al., 2009).

TABLE 34-4 Laboratory Evaluation of the Jaundiced Infant of 35 or More Weeks' Gestation

INDICATIONS	ASSESSMENTS
Jaundice in first 24 h	Measure transcutaneous bilirubin (TcB) and/or total serum bilirubin (TSB).
Jaundice appears excessive for infant's age	Measure TcB and/or TSB.
Infant receiving phototherapy or TSB rising rapidly (i.e., crossing percentiles on the nomogram and unexplained by history and physical examination)	Blood type and Coombs' test, if not obtained with cord blood. Complete blood count and smear. Measure direct or conjugated bilirubin. It is an option to perform reticulocyte count, glucose-6-phosphate dehydrogenase (G6PD), and end-tidal carbon dioxide ($ETCO_2$), if available. Repeat TSB in 4–24 h depending on infant's age and TSB level.
TSB concentration approaching exchange levels or not responding to phototherapy	Perform reticulocyte count, G6PD albumin, $ETCO_2$, if available.
Elevated direct (or conjugated) bilirubin level	Do urinalysis and urine culture. Evaluate for sepsis if indicated by history and physical examination.
Jaundice present at or beyond age 3 weeks, or sick infant	Total and direct (or conjugated) bilirubin level. If direct bilirubin elevated, evaluate for causes of cholestasis. Check results of newborn thyroid and galactosemia screen, and evaluate infant for signs or symptoms of hypothyroidism.

Source: From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia. (2004). Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. Pediatrics, 114*(1), 297–316 (Table 1, p. 300).*

Essential laboratory evaluations are Coombs' test, serum bilirubin levels (direct and total), hemoglobin, reticulocyte percentage, white cell count, and positive smear for cellular morphology. The Coombs' test determines whether jaundice is due to Rh or ABO incompatibility. The indirect Coombs' test measures the amount of Rh-positive antibodies in the mother's blood. Rh-positive RBCs are added to the maternal blood sample. If the mother's serum contains antibodies, the Rh-positive RBCs will agglutinate (clump) when rabbit immune antiglobulin is added, which is a positive test result. The direct Coombs' test reveals the presence of antibody-coated (sensitized) Rh-positive RBCs in the newborn. Rabbit immune antiglobulin is added to the specimen of neonatal blood cells. If the neonatal RBCs agglutinate, they have been coated with maternal antibodies, a positive result.

If the hemolytic process is due to Rh sensitization, laboratory findings reveal the following: (1) an Rh-positive newborn with a positive Coombs' test; (2) increased erythropoiesis with many immature circulating RBCs (nucleated blastocysts); (3) anemia, in most cases; (4) elevated levels (5 mg/dl or more)

Infant Receiving Phototherapy

of bilirubin in cord blood; and (5) a reduction in albumin binding capacity. Maternal data may include an elevated anti-Rh titer and spectrophotometric evidence of fetal hemolytic process.

If the hemolytic process is due to ABO incompatibility, laboratory findings reveal an increase in reticulocytes. The resulting anemia is usually not significant during the newborn period and is rare later on. The direct Coombs' test may be negative or mildly positive, whereas the indirect Coombs' test may be strongly positive. Infants with a positive direct Coombs' test have increased incidence of jaundice with bilirubin levels in excess of 10 mg/dl. Increased numbers of spherocytes (spherical, plump, mature erythrocytes) are seen on a peripheral blood smear. Increased numbers of spherocytes are not seen on blood smears from Rh disease infants.

Clinical Therapy

Whatever the cause of hyperbilirubinemia, management of these infants is directed toward alleviating anemia, removing maternal antibodies and sensitized erythrocytes, increasing serum albumin levels, reducing serum bilirubin levels, and minimizing the consequences of hyperbilirubinemia. Early discharge of newborns from birthing centers has significantly influenced the diagnosis and management of neonatal jaundice, increasing the emphasis on outpatient and home care management.

Hemolytic disease may be treated with phototherapy, exchange transfusion, and drug therapy. When determining the appropriate management of hyperbilirubinemia due to hemolytic disease, the three variables that must be taken into account are the newborn's (1) serum bilirubin level, (2) birth weight, and (3) age in hours. If a newborn has hemolysis with an unconjugated bilirubin level of 14 mg/dl, weighs less than 2500 g (birth weight), and is 24 hours old or less, an exchange transfusion may be the best management. However, if that same newborn is over 24 hours old, which is past the time where an increase in bilirubin would result from pathologic causes, phototherapy may be the treatment of choice to prevent the possible complications of kernicterus.

Phototherapy

Phototherapy is the exposure of the newborn to high-intensity light. It may be used alone or in conjunction with exchange transfusion to reduce serum bilirubin levels. Exposure of the newborn to high-intensity light (a bank of fluorescent light bulbs or bulbs in the blue-light spectrum) decreases serum bilirubin levels in the skin by facilitating biliary excretion of unconjugated bilirubin. Phototherapy decreases serum bilirubin levels by changing bilirubin from the non–water-soluble (lipophilic) form to water-soluble by-products that can then be excreted via urine and bile. Photoisomerization occurs when the natural form of bilirubin is exposed to light at a certain wavelength and the bilirubin is converted to a less toxic form. The new isomer, photobilirubin, is created rapidly but is quite unstable. The photobilirubin is bound to albumin, transported to the liver, and incorporated into bile. If it is not quickly eliminated from the bowel, it can convert back to its original form and return to the bloodstream. In addition, the photodegradation products formed when light oxidizes bilirubin can be excreted in the urine.

Case Study: Newborn with Jaundice

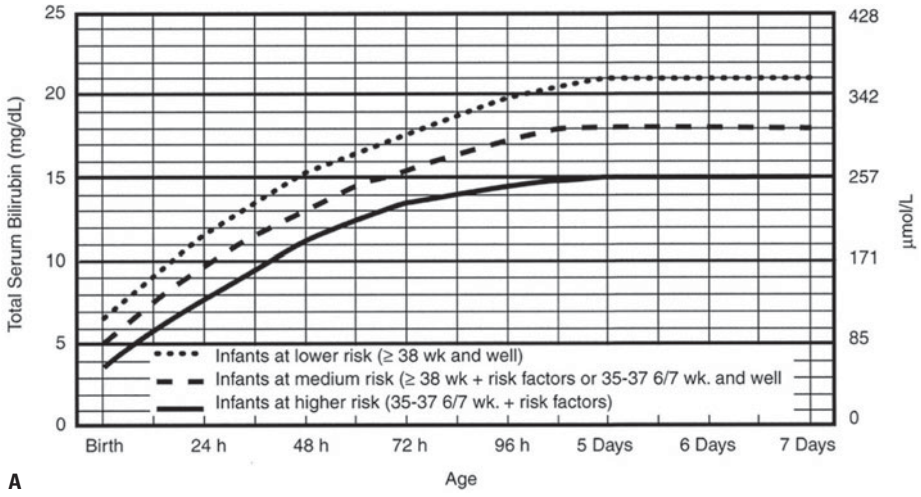
Phototherapy is an intervention that is used more for the prevention of hyperbilirubinemia to halt bilirubin levels from climbing dangerously high. The decision to start phototherapy is based on two factors: gestational age and age in hours. Phototherapy is the most effective in the first 24 to 48 hours of usage; frequently the light can be discontinued during or immediately after this time frame. Phototherapy does not alter the underlying cause of jaundice, and hemolysis may continue to produce anemia. Many researchers have recommended initiating phototherapy "prophylactically" in the first 24 hours of life in high-risk, very-low-birth-weight (VLBW), or severely bruised infants. Figure 34-15A ■ shows guidelines for the use of phototherapy. The risk of neonates requiring follow-up/intervention for their hyperbilirubinemia is evaluated by plotting their serum bilirubin level and age in hours on the chart shown in Figure 34-15B ■.

Phototherapy can be provided through halogen spotlights (although these are not widely used because of the risk of thermal burns), conventional banks of phototherapy lights, a fiberoptic blanket attached to a halogen light source around the trunk of the newborn, or a combination of these delivery methods. The bank of bilirubin lights utilize light in the blue spectrum. This is the most effective source available but can mask cyanosis and causes dizziness and nausea in the staff.

With the fiberoptic blanket, the light stays on at all times, and the newborn is accessible for care, feeding, and diaper changes; greater surface area is exposed and there are no thermoregulation issues. The eyes are not covered. Fluid and weight loss are not complications of this system. Furthermore, it makes the infant accessible to the parents and is less alarming to parents than standard phototherapy. Many institutions and pediatricians use fiberoptic blankets for home care. A combination of a fiberoptic light source in the mattress under the baby and a standard light source above may also be used. This is termed *intensive phototherapy.* Intensive phototherapy should reduce the total serum bilirubin (TSB) by 1 to 2 mg/dl within 4 to 8 hours. Levels should continue to decline when phototherapy covers a wider surface area. If a drop in bilirubin levels is not reached then an exchange transfusion should be considered. The nurse uses a photometer to measure and maintain desired irradiance levels. The nurse keeps track of the number of hours each lamp is used so that each can be replaced before its effectiveness is lost (Bradshaw, 2010). Neurotoxicity risk factors such as late prematurity, galactosemia, congenital spherocytosis, asphyxia, sepsis, acidosis, dehydration, albumin <3 mg/dl, G6PD deficiency, Crigler-Najjar syndrome, or isoimmune hemolytic disease are used in making decisions to initiate phototherapy or exchange transfusion (Maisels et al., 2009).

Exchange Transfusion

Exchange transfusion is the withdrawal and replacement of the newborn's blood with donor blood. It is used to treat anemia with RBCs that are not susceptible to maternal antibodies, remove sensitized RBCs that would be lysed soon, remove serum bilirubin, and provide bilirubin-free albumin and increase the binding sites for bilirubin. Concerns over doing an exchange transfusion are related to the use of blood products and associated potential for HIV infection and hepatitis. If the TSB is at or approaching the exchange level, the nurse should send blood



- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin < 3.0g/dL (if measured)
- For well infants 35–37 6/7 wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wks and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50mmol/L) below those shown but home phototherapy should not be used in any infant with risk factors.

Note: These guidelines are based on limited evidence and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy, which should be used when the TSB (total serum bilirubin) exceeds the line indicated for each category. Infants are designated as "higher risk" because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin.

Figure 34-15 ■ A. Guidelines for phototherapy in hospitalized infants of 35 or more weeks' gestation. B. When to follow up a predischarge bilirubin level on an hour-specific bilirubin nomogram.

for immediate type and cross-match. Blood for exchange transfusion is modified whole blood (red cells and plasma) cross-matched against the mother and compatible with the infant.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Assessment is aimed at identifying prenatal and perinatal factors that predispose to development of jaundice and identifying jaundice as soon as it is apparent. Significant hyperbilirubinemia in the neonatal population is often due to a multitude of causes including a genetic basis (Watchko et al., 2009). Clinically, ABO incompatibility presents as jaundice and occasionally as hepatosplenomegaly. Fetal hydrops or erythroblastosis fetalis is rare (see chapter 20 ∞). Hemolytic disease of the newborn is suspected if the placenta is enlarged, if the newborn is edematous with pleural and pericardial effusion plus ascites, if pallor or jaundice is noted during the first 24 to 36 hours, if hemolytic anemia is diagnosed, or if the spleen and liver are enlarged. The nurse carefully notes changes in behavior and observes for evidence of bleeding. If laboratory tests indicate elevated bilirubin levels, the nurse checks the newborn for jaundice about every 2 hours and records observations.

To check for jaundice in lighter skinned babies, the nurse should blanch the skin over a bony prominence (forehead, nose, or sternum) by pressing firmly with the thumb. After pressure is released, if jaundice is present, the area appears yellow before normal color returns. The nurse should check oral mucosa and the posterior portion of the hard palate and conjunctival sacs for yellow pigmentation in darker skinned babies. Jaundice progresses in a cephalocaudal direction from the face to the trunk and then to the lower extremities. The overall progression of

jaundice should be noted. Assessment in daylight gives the best results, because pink walls and surroundings may mask yellowish tints and yellow light makes differentiation of jaundice difficult. The time at onset of jaundice is recorded and reported. If jaundice appears, careful observation of the increase in depth of color and of the newborn's behavior is mandatory.

In addition to visual inspection, reflectance photometers that measure transcutaneous bilirubin (TcB) should be used to screen and monitor neonatal jaundice (Dalal, Mishra, Agarwal, et al., 2009). Most hospitals have developed a mandatory screening policy for all newborns before discharge using the TcB monitor, and it is recommended that this predischarge screening be done universally (Varvarigou et al., 2009). If the level comes back as high, a follow-up TSB will be performed. Another portable screening tool is the analysis for end-tidal carbon monoxide (ETCO). This analysis allows for rapid identification of newborns with significant hemolytic disease who may be at risk for the sequelae of unconjugated hyperbilirubinemia. Measurements in newborns using the TcB devices are within 2 to 3 mg/dl of the TSB and useful for TSB levels less than 15 mg/dl. When universal screening is performed, there is a reduction in severe hyperbilirubinemia but there is a significant increase in the use of phototherapy, sometimes at levels that are not necessary (Kuzniewicz, Escobar, & Newman, 2009; Newman, 2009).

Nursing diagnoses that may apply to a newborn with jaundice include the following:

- ***Risk for Deficient Fluid Volume*** related to increased insensible water loss and frequent loose stools
- ***Risk for Injury*** related to use of phototherapy
- ***Disturbed Sensory Perception*** related to neurologic damage secondary to kernicterus
- ***Risk for Impaired Parenting*** related to deficient knowledge of infant care and prolonged separation of infant and parents secondary to illness

Nursing Plan and Implementation

Hospital-Based Nursing Care

Hospital-based care is described in Nursing Care Plan: For the Newborn with Hyperbilirubinemia on pages 969–971. Phototherapy success is measured every 12 hours or daily by serum bilirubin levels (more frequently if there is hemolysis or a higher level before initiation of phototherapy). The nurse must turn off the lights while drawing blood for serum bilirubin levels. Because it is not known whether phototherapy injures the delicate eye structures, particularly the retina, the nurse applies eye patches over the newborn's closed eyes during exposure to banks of phototherapy lights (see Figure 34-16 ■ in Procedure 34-2: Infant Receiving Phototherapy on page 971). Conventional phototherapy is discontinued and the eye patches are removed at least once per shift to assess the eyes for the presence of conjunctivitis. Patches are also removed to allow eye contact during feeding (for social stimulation) or when parents are visiting (to promote parental attachment).

Most phototherapy units will provide this level of irradiance 45 to 50 cm below the lamps. The nurse can use a photometer to measure and maintain desired irradiance levels. Disadvantages of lights are that they create a difficult work environment and can distort an infant's color. The nurse must be careful about using ointments under bilirubin lights because they may cause burns.

Some parents may feel guilty about their baby's condition and think they have caused the problem. Under stress, parents may not be able to understand the physician's or nurse practitioner's first explanations. The nurse must expect that the parents will need explanations repeated and clarified and that they may need help voicing their questions and fears. Eye and tactile contact with the infant is encouraged. The nurse can coach parents when they visit with the baby. After the mother's discharge, parents are kept informed of their infant's condition and are encouraged to return to the hospital or to telephone at any time so that they can be fully involved in the care of their infant. The nurse should tell parents that they can expect a rebound of 1 to 2 mg/dl after discontinuation of phototherapy and that a follow-up bilirubin test may be done (Cloherty et al., 2008; Bradshaw, 2010).

While the mother is still hospitalized, some healthcare facilities may allow phototherapy to be carried out in the mother's room if the only problem is hyperbilirubinemia. The mother must be willing to keep the baby in the room for 24 hours a day; be able to take emergency action, such as for choking, if necessary; and complete instruction checklists. Some institutions require that parents sign a consent form. The nurse gives the instructions to the parents but also continues to monitor the infant's temperature, activity, intake & output (I&O), and positioning of eye patches (if conventional light banks are used) at regular intervals.

Community-Based Nursing Care

Some studies have shown that with early discharge of newborns and their mothers comes an increase in hospital readmission and elevated risk of pathologic hyperbilirubinemia. Home phototherapy use is recommended only if the bilirubin level is plotted on the nomogram and found to be in the "optional phototherapy" range. Any newborn with a level in the higher range should be hospitalized for continual phototherapy and serum bilirubin levels closely monitored on a regular schedule.

Jaundice and its phototherapy treatment can be very disturbing to parents and may generate feelings of guilt and fear. The parents' perception of and/or misconceptions about jaundice can affect parent-infant interactions. The nurse should explain the causes of jaundice and emphasize that it is usually a transient problem and one to which all infants must adapt after birth. Reassurance and support are vital especially for the breastfeeding mother, who may question her ability to adequately nourish her newborn.

It is essential that the impact of cultural beliefs be considered. Some Latina women believe that showing strong maternal emotions during pregnancy and breastfeeding can be detrimental. *Bilis* associated with anger may be blamed by some Latina women for jaundice. Cultural beliefs lead mothers to interpret illness within their cultural framework, especially when left without clear and understood explanations. Maternal reactions can be lessened by careful explanations to the mothers about the diagnosis, prognosis, duration, and management options for jaundice and about the possibility of its recurrence.

NURSING CARE PLAN For the Newborn with Hyperbilirubinemia

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Impaired Tissue Integrity related to predisposing factors associated with hyperbilirubinemia **Goal:** Babies at risk for jaundice and early signs of jaundice will be identified.	
■ Evaluate baby's history for predisposing factors for hyperbilirubinemia.	■ Early identification of risk factors enables the nurse to monitor babies for early signs of hyperbilirubinemia. Acidosis, hypoxia, and hypothermia increase the risk of hyperbilirubinemia at lower bilirubin levels.
■ Observe color of amniotic fluid at time of rupture of membranes.	■ Amber-colored amniotic fluid indicates hyperbilirubinemia.
■ Assess baby for developing jaundice in daylight if possible. 1. Observe sclera. 2. Observe skin color and assess by blanching. 3. Check oral mucosa, posterior portion of hard palate, and conjunctival sacs for yellow pigmentation in dark-skinned newborns.	■ Early detection is affected by nursery environment. Artificial lights (with pink tint) may mask beginning of jaundice. 1. Most visible sign of hyperbilirubinemia is jaundice noted in skin, sclera, or oral mucosa. Onset is first seen on face and then progresses down the trunk. 2. Blanching the skin leaves a yellow color to the skin immediately after pressure is released. 3. Underlying pigment of dark-skinned infants may normally appear yellow.
■ Report jaundice occurring within 24 hours of birth.	
EXPECTED OUTCOMES: Baby's jaundice is identified early.	
2. Nursing Diagnosis: Risk for Deficient Fluid Volume related to phototherapy **Goal:** The infant will not exhibit signs of dehydration and will display appropriate weight gain.	
■ Offer feedings every 2 to 3 hr.	■ Adequate hydration increases peristalsis and excretion of bilirubin.
■ Breastfeed on demand with no supplementation unless excessive weight loss or increasing total serum bilirubin (TSB) with adequate feeding.	
■ Provide 25% extra fluid intake.	■ Replace fluid losses due to watery stools, if under phototherapy.
■ Assess for dehydration: 1. Poor skin turgor 2. Depressed fontanelles 3. Sunken eyes 4. Decreased urine output 5. Weight loss 6. Changes in electrolytes	■ Phototherapy treatment may cause liquid stools and increased insensible water loss, which increases risk of dehydration.
■ Monitor intake and output (I&O).	
■ Weigh daily.	
■ Report signs of dehydration.	
■ Administer IV fluids: 1. Monitor flow rates. 2. Assess insertion sites for signs of infection.	■ Prevents fluid overload. ■ IV fluids may be used if baby is dehydrated or in presence of other complications. IV may be started if exchange transfusion is to be done.
EXPECTED OUTCOMES: Baby will have good skin turgor, clear amber urine output of 1–3 ml/kg/hr, six to eight wet diapers/day, and will maintain weight.	
3. Nursing Diagnosis: Risk for Injury related to use of phototherapy **Goal:** Baby will not have any corneal irritation/drainage, skin breakdown, or major fluctuations in temperature.	
■ Cover baby's eyes with eye patches while under phototherapy lights. Cover testes/penis in male infants.	■ Protects retina from damage due to high intensity light and testes from damage from heat.
■ Make certain that eyelids are closed before applying eye patches.	■ Prevents corneal abrasions.
■ Remove baby from under phototherapy and remove eye patches during feedings.	■ Provides visual stimulation and facilitates attachment behaviors.

(continued)

NURSING CARE PLAN For the Newborn with Hyperbilirubinemia continued

INTERVENTION	RATIONALE
■ Inspect eyes each shift for conjunctivitis, drainage, and corneal abrasions due to irritation from eye patches.	■ Prevents or facilitates prompt treatment of purulent conjunctivitis.
■ Administer thorough perianal cleansing with each stool or change of perianal protective covering.	■ Frequent stooling increases risk of skin breakdown. Prevents infection.
■ Provide minimal coverage—only of diaper area.	■ Provides maximal exposure. Shielded areas become more jaundiced, so maximum exposure is essential.
■ Avoid the use of oily applications on the skin.	■ Prevents superficial burns to skin.
■ Reposition baby every 2 hours.	■ Provides equal exposure of all skin areas and prevents pressure areas.
■ Observe for bronzing of skin.	■ Bronzing is related to use of phototherapy with increased direct bilirubin levels or liver damage; may last for 2 to 4 months.
■ Place Plexiglas shield between baby and light.	■ Hypothermia and hyperthermia are common complications of phototherapy.
■ Monitor baby's skin and core temperature frequently until temperature is stable.	■ Hypothermia results from exposure to lights, subsequent radiation, and convection losses.
■ Check axillary temperature with readings on servo-controlled unit on incubator.	■ Hyperthermia may result from the increased environmental heat.
■ Regulate incubator temperature as needed.	■ Additional heat from phototherapy lights frequently causes a rise in the baby's and incubator's temperatures. ■ Fluctuations in temperature may occur in response to radiation and convection.

EXPECTED OUTCOMES: Baby's eyes are protected, skin is intact, and baby maintains a stable temperature.

4. Nursing Diagnosis: Risk for Impaired Parenting related to deficient knowledge of infant care and prolonged separation of infant and parents secondary to illness

Goals: Parents will bond with infant and have realistic expectations about their infant. Parents are comfortable taking their infant home. They are able to demonstrate normal infant care and assessments of possible complications, and they know when to return for follow-up.

■ Encourage parents to provide tactile stimulation during feeding and diaper changes.	■ Newborn has normal needs for tactile stimulation. ■ Presence of equipment may discourage parents from interacting with newborn.
■ Encourage cuddling and eye contact during feedings.	■ Provides opportunity for parents to bond with their newborn.
■ Offer suggestions to comfort restless infant: ■ Nesting when beneath bili lights ■ Talking softly and singing quietly to infant ■ Taped music or tape recording of evening activities from home ■ Rhythmic patting of buttocks ■ Firm, nonstroking touch, assisting with control of extremities ■ Pacifier for nonnutritive sucking	■ Provides comfort and decreases sensory deprivation.
■ Encourage family/friend support of mother/parents (i.e., meals, rest, child care for siblings, allow expressions of concerns/feelings).	■ Decreases strain on mother/parents by assisting with other responsibilities and allows for additional time with newborn for bonding, care, etc.
■ Evaluate additional psychosocial needs.	■ Parents may not understand what is happening or why.
■ Discuss rationale for treatment and possible side effects of phototherapy with family (stool changes, increased fluid loss, possible temp instability, slight lethargy, rash, altered sleep-wake patterns).	■ Physician preference of treatment modalities may vary. Parents may not understand why their newborn is not receiving a treatment that another with the same condition is receiving.
■ Instruct family on infant's care while undergoing phototherapy: ■ Safety precautions—bili mask (to protect eyes), incubator door closed and latched, covering genitalia per policy. ■ Skin care, cord care, circumcision care as appropriate. ■ Lab draws, rationale I&O.	

NURSING CARE PLAN For the Newborn with Hyperbilirubinemia continued

INTERVENTION	RATIONALE
■ Encourage parent/significant other/sibling involvement in infant care as possible.	
■ Give explanation of equipment being used and changes in bilirubin levels. Allow parents an opportunity to ask questions; reinforce or clarify information as needed.	
■ Evaluate family's understanding of information.	
■ As necessary, review role of pumping breasts and offering formula for limited time.	■ The etiology of breast milk jaundice remains uncertain. The serum bilirubin levels begin to fall within 48 hr after discontinuation of breastfeeding. Opinion of physicians varies regarding the need for discontinuing breastfeeding.
■ Assist mother to pump her breasts to maintain milk supply.	■ If breastfeeding is temporarily discontinued, assess mother's knowledge of pumping her breasts in regular increments (q 2–3 hours), and provide information and support as needed.

EXPECTED OUTCOMES: The parent will demonstrate ability to perform basic infant care tasks as evidenced by exhibiting appropriate attachment behaviors (i.e., talking and holding infant, feeding infant, and caring for infant under home bili therapy).

Parents verbalize understanding of rationale and possible side effects from phototherapy; parents/family demonstrate safety precautions when caring for infant; parents getting meals, rest, and verbalize support given.

PROCEDURE 34-2 Infant Receiving Phototherapy

NURSING ACTION

Preparation

- Explain the purpose of phototherapy, the procedure itself (including the need to use eye patches), and possible side effects such as dehydration and skin breakdown from more frequent stooling.
- Note evidence of jaundice in the skin, sclera, and mucous membranes (in infants with darkly pigmented skin). Be sure that recent serum bilirubin levels are available.

Rationale: *The decision to use phototherapy is based on a careful assessment of the newborn's condition over a period of time. The most recent results before starting therapy serve as a baseline to evaluate the effectiveness of therapy.*

Equipment and Supplies

Bank of phototherapy lights

Eye patches

Small scale to weigh diapers

Procedure

1. Obtain vital signs including axillary temperature.

   Rationale: *Provides baseline data.*

2. Remove all of the infant's clothing except the diaper.

   Rationale: *Exposure of the newborn to high-intensity light (a bank of fluorescent light bulbs or bulbs in the blue-white spectrum) decreases serum bilirubin levels in the skin by aiding biliary excretion of unconjugated bilirubin. Because the tissue absorbs the light, best results are obtained when there is maximum skin surface exposure.*

3. Apply eye coverings (eye patches or a bili mask) to the infant according to agency policy. (See Figure 34-16.)

   Rationale: *Eye coverings are used because it is not known if phototherapy injures delicate eye structures, particularly the retina.*

Figure 34-16 ■ Infant receiving phototherapy. The phototherapy light is positioned over the incubator. Bilateral eye patches are always used during photo light therapy to protect the baby's eyes.

Source: Courtesy of Lisa Smith-Pedersen, RN, MSN, NNP-BC/Pearson Education.

(continued)

PROCEDURE 34-2 Infant Receiving Phototherapy continued

NURSING ACTION

4. Place the infant in an open crib or isolette (more commonly used in preterm infants and infants who are sicker) about 45 to 50 cm below the bank of phototherapy lights. Reposition every 2 hours.

   Rationale: *The isolette helps the infant maintain his or her temperature while undressed. Repositioning exposes different areas of skin to the lights, prevents the development of pressure areas on the skin, and varies the stimulation the infant receives.*

5. Monitor vital signs every 4 hours with axillary temperatures.

   Rationale: *Temperature assessment is indicated to detect hypothermia or hyperthermia. Deviation in pulse and respirations may indicate developing complications.*

6. Cluster care activities.

7. Discontinue phototherapy and remove eye patches at least every 2 to 3 hours when feeding the infant and when the parents visit.

   Rationale: *Care activities are clustered to help ensure that the newborn has maximum time under the lights. Eye patches are removed to assess for signs of complications such as excessive pressure, discharge, or conjunctivitis. Patches are also removed to provide some social stimulation and to promote parental attachment.*

8. Maintain adequate fluid intake. Evaluate need for IV fluids.

9. Monitor intake and output carefully. Weigh diapers before discarding. Record quantity and characteristics of each stool.

   Rationale: *Infants undergoing phototherapy treatment have increased water loss and loose stools as a result of bilirubin excretion. This increases their risk of dehydration.*

CLINICAL TIP

If the area of jaundice about the eyes begins to disappear, it is probable that the eye patches are allowing light to enter and better eye protection is needed.

10. Assess specific gravity with each voiding. Weigh newborn daily.

    Rationale: *Specific gravity provides one measure of urine concentration. Highly concentrated urine is associated with a dehydrated state. Weight loss is also a sign of developing dehydration in the newborn.*

11. Observe the infant for signs of perianal excoriation and institute therapy if it develops.

    Rationale: *Perianal excoriation may develop because of the irritating effect of diarrhea stools.*

12. Ensure that serum bilirubin levels are drawn regularly according to orders or agency policy. Turn the phototherapy lights off while the blood is drawn.

    Rationale: *Serum bilirubin levels provide the most accurate indication of the effectiveness of phototherapy. They are generally drawn every 12 hours but at least once daily. The phototherapy lights are turned off to ensure accurate serum bilirubin levels.*

13. Examine the newborn's skin regularly for signs of developing pressure areas, bronzing, maculopapular rash, and changes in degree of jaundice.

    Rationale: *Pressure areas may develop if the infant lies in one position for an extended period. A benign, transient bronze discoloration of the skin may occur with phototherapy when the infant has elevated direct serum bilirubin levels or liver disease. A maculopapular rash is another transient side effect of phototherapy that develops occasionally.*

14. Avoid using lotion or ointment on the exposed skin.

    Rationale: *Lotions and ointments on a newborn receiving phototherapy may cause skin burns.*

15. Provide parents with opportunities to hold the newborn and assist in the infant's care. Answer their questions accurately and keep them informed of developments or changes.

    Rationale: *A sick infant is a source of great anxiety for parents. Information helps them deal with their anxiety. Moreover, they have a right to be kept well informed of their baby's status so that they are able to make informed decisions as needed.*

16. May also provide phototherapy using lightweight, fiberoptic blankets ("bili blankets"). The baby is wrapped in the blanket, which is plugged into an outlet (Figure 34-17 ■).

    Rationale: *With fiberoptic blankets the newborn is readily accessible for care, feedings, and diaper changes. The baby does not get overheated, and fluid and weight loss are not complications of this system. The infant is accessible to the parents and the procedure seems less alarming to parents than standard phototherapy.*

Figure 34-17 ■ Newborn on fiberoptic "bili" mattress and under phototherapy lights. A combination of fiberoptic light source mattress and standard phototherapy light source may also be used.

Note: The color is distorted because of the reflection of the bililight mattress.
Source: George Dodson/Lightworks Studio/Pearson Education.

If the baby is to receive phototherapy at home, parents are taught to record the infant's temperature, weight, fluid I&O, stools, and feedings and to use the phototherapy equipment. In addition, if phototherapy lights are being used, parents must agree that the baby will be exposed to the lights for long periods of time; that they will hold the baby for only short periods for feedings, comforting, and cleansing of the perineal area; and that the room temperature will be regulated to minimize heat loss. Fiberoptic phototherapy blankets eliminate the need for eye patches, decrease heat loss because the baby is clothed, and provide more opportunities for interaction between the baby and parents. The best method of home phototherapy depends on the cause of the hyperbilirubinemia and the rate of progression of the jaundice. Ongoing monitoring of bilirubin levels is essential with home phototherapy and can be carried out in the home, in the follow-up clinic, or in the clinician's office.

CLINICAL JUDGMENT

Case Study: Baby Boy Martin

Baby boy Martin is a term male infant born by vaginal delivery with vacuum assist. His mother has blood type O positive, and Baby Martin has blood type A positive. The baby has a normal complete blood count (CBC) with a hematocrit of 60%. While performing a physical examination on Baby Martin on day 2 of life, the nurse notes that he has a large cephalhematoma, an enlarged liver on palpation (hepatomegaly), and is clinically jaundiced. The nurse suspects that Baby Martin has hyperbilirubinemia and discusses her findings with the neonatal nurse practitioner who orders a total bilirubin level be drawn. When resulted, the level is 16 mg/dl. The decision is made to start this infant on phototherapy treatment.

Critical Thinking

What risk factors and clinical findings does this infant have that predispose him to hyperbilirubinemia?

How would the nurse explain Baby Martin's hyperbilirubinemia and subsequent treatment and nursing care to his mother?

See www.nursing.pearsonhighered.com for possible responses.

Evaluation

Expected outcomes of nursing care include the following:

- The newborns at risk for development of hyperbilirubinemia are identified, and action is taken to minimize the potential impact of hyperbilirubinemia.
- The baby will not have any corneal irritation or drainage, skin breakdown, or major fluctuations in temperature.
- Parents understand the rationale for, goal of, and expected outcome of therapy.
- Parents verbalize their concerns about their baby's condition and identify how they can facilitate their baby's improvement.

Care of the Newborn with Anemia

Neonatal anemia is often difficult to recognize by clinical evaluation alone. The hemoglobin concentration in a full-term newborn is 19.3 ± 2.2 g/dl (Manco-Johnson, Rodden, & Hays, 2011), slightly higher than in premature infants, in whom the mean hemoglobin is 14 to 18 g/dl. Infants with hemoglobin values of less than 11 mg/dl (term) and 7 to 9 g/dl (preterm) are usually considered anemic (Gomella et al., 2009). The most common causes of neonatal anemia are blood loss (preterm babies in the neonatal intensive care unit (NICU) can have 15% to 30% total blood volume loss per week due to lab draws), hemolysis/erythrocyte destruction, and impaired red blood cell (RBC)/erythrocyte production (Widness, 2008).

Blood loss (hypovolemia) occurs in utero from placental bleeding (placenta previa or abruptio placentae). Intrapartal blood loss may be fetomaternal, fetofetal, or the result of umbilical cord bleeding. Birth trauma to abdominal organs (adrenal hemorrhage) or the cranium (subgaleal bleed) may produce significant blood loss, and cerebral bleeding may occur because of hypoxia.

Excessive hemolysis of red cells is usually a result of blood group incompatibilities but may be due to infections. The most common cause of impaired red cell production is a genetically transmitted deficiency in glucose-6-phosphate dehydrogenase (G6PD). Anemia and jaundice are the presenting signs (Gomella et al., 2009).

A condition known as **physiologic anemia of infancy** exists as a result of the normal gradual drop in hemoglobin for the first 8 to 10 weeks of life and corresponds with the decline in fetal hemoglobin (Widness, 2008). Theoretically, the bone marrow stops production of RBCs in response to higher oxygen levels that result from breathing changes after birth. When the amount of hemoglobin decreases, reaching a nadir of 10 to 12 g/dl in the term infant and reaching a nadir at 8 to 10 weeks and 7 to 8 g/dl in preterm infants at about 4 to 8 weeks of age, the bone marrow begins production of RBCs again, and the anemia disappears (Diehl-Jones & Askin, 2010).

Anemia in preterm newborns is seen earlier and is more severe than in term newborns, and increased production of red blood cells does not start until hemoglobin is 7 to 8 g/dl. The preterm baby's hemoglobin reaches a low sooner than does a term newborn's because a preterm infant's red blood cell survival time is shorter than that of a term newborn (Diehl-Jones & Askin, 2010). This difference is a result of several factors: the preterm infant's rapid growth rate, decreased iron stores, and an inadequate production of erythropoietin (EPO). Iatrogenic causes occur more in preterm infants as their condition requires more laboratory assessment (Diehl-Jones & Askin, 2010).

Clinical Therapy

Clinical management depends on the severity of the anemia, whether blood loss is acute or chronic, clinical manifestations, and whether it was anticipated based on the pregnancy history. The age at which anemia is first noted is also of diagnostic value. Clinically, light-skinned anemic infants are very pale when they do not have other symptoms of shock and usually have abnormally low RBC counts. In acute blood loss, symptoms of shock may be present, such as pallor, low arterial blood pressure, and a decreasing hematocrit value.

The initial laboratory workup should include determinations of hemoglobin, hematocrit, bilirubin levels (in hemolytic disease), reticulocyte count, examination of peripheral blood

smear, direct Coombs' test of infant's blood, and examination of maternal blood smear for fetal erythrocytes (Kleihauer-Betke test). Mild or chronic anemia in an infant may be treated adequately with iron supplements alone or with iron-fortified formulas. In severe cases of anemia, transfusions with O-negative or typed and cross-matched packed red cells are the preferred method of treatment.

Management of anemia of prematurity includes treating the causative factor (e.g., antibiotics/antivirals used for infection, steroid therapy for disorders of erythrocyte production) and supplemental iron. Blood transfusions (dedicated units of blood ideally from a single donor source) are kept to a minimum. Evidence supports use of recombinant human erythropoietin (rEPO) in only selected cases (Von Kohorn & Ehrenkranz, 2009)—for example, infants in whom it is desirable to maintain a relatively high hematocrit, such as infants with bronchopulmonary dysplasia.

NURSING CARE MANAGEMENT

The nurse assesses the newborn for symptoms of anemia (pallor). If the blood loss is acute, the baby may exhibit signs of shock (a capillary filling time greater than 3 seconds, decreased pulses, tachycardia, and low blood pressure [BP]). Signs of compromise include poor weight gain, tachycardia, tachypnea, and apneic episodes. The baby should be placed on constant cardiac and respiratory monitoring. The nurse promptly reports any symptoms indicating anemia or shock. Continued observations will be necessary to identify physiologic anemia as the preterm newborn grows. The nurse should try to prevent iron deficiency by limiting phlebotomy losses and recording it in tenths of a milliliter. The total blood removed is assessed and replaced by transfusion when necessary or by starting iron therapy at 2 weeks of postnatal age (Aher, Malwatkar, & Kadam, 2008; Diehl-Jones & Askin, 2010).

Care of the Newborn with Polycythemia

Polycythemia, a condition in which blood volume and hematocrit values are increased, is observed more commonly in intrauterine growth restricted (IUGR), late preterm infants; placental transfusion caused by delayed cord clamping or cord stripping; infants receiving maternal-fetal or twin-to-twin transfusions; babies who have been exposed to intrauterine hypoxia; and babies of mothers who smoke, suffer from asphyxia, or take propranolol during pregnancy. Other conditions that may present with polycythemia are chromosomal anomalies such as trisomy 21, 18, and 13 and births at altitudes over 5000 feet (Gomella et al., 2009). The incidence ranges from 1% to 5% in healthy term neonates, and the condition is uncommon in newborns less than 34 weeks' gestation (Diehl-Jones & Askin, 2010).

An infant is considered polycythemic when the central venous hematocrit value is greater than 65%. A potential complication of polycythemia is hyperviscosity, which results in impaired perfusion of the capillary vessels (Diehl-Jones & Askin, 2010).

Clinical Therapy

The goal of therapy is to reduce the central venous hematocrit to a range of 50% to 55% in symptomatic infants (Gomella et al., 2009). To decrease the red cell mass, the symptomatic infant receives a partial exchange transfusion in which blood is removed from the infant and replaced milliliter for milliliter with colloids such as fresh frozen plasma or 5% albumin or crystalloids such as isotonic saline (Diehl-Jones & Askin, 2010). The preference is to use crystalloids because of decreased promotion of infection, incidence of necrotizing enterocolitis (NEC), and their hypoallergenic properties. Supportive treatment of presenting symptoms is required until resolution, which usually occurs spontaneously following the partial exchange transfusion.

NURSING CARE MANAGEMENT

The nurse assesses, records, and reports symptoms of polycythemia. The nurse also does an initial screening of the newborn's hematocrit on admission to the nursery. The peak of term newborn's hematocrit will occur at 2 hours of age and begin to drop slowly by 12 to 18 hours. A capillary hematocrit may be done (see Procedure 34-1: Performing Heel Stick on a Newborn); however, peripheral free-flowing venous hematocrit samples are usually obtained from the antecubital fossa for confirmation.

Many infants are asymptomatic, but as symptoms develop, they are related to the increased blood volume, hyperviscosity (thickness) of the blood, and decreased deformability of red blood cells (RBCs), all of which result in poor perfusion of tissues. The infants have a characteristic plethoric (ruddy) appearance. The most common symptoms observed include the following:

- ***Cardiopulmonary:*** Tachycardia and congestive heart failure due to the increased blood volume.
- ***Respiratory:*** Respiratory distress with grunting, tachypnea, and cyanosis; increased oxygen need; or hemorrhage in respiratory system due to pulmonary venous congestion, edema, and hypoxemia.
- ***Gastrointestinal:*** Feeding intolerance, poor feeding, vomiting, or NEC.
- ***Hematologic:*** Hyperbilirubinemia caused by increased numbers of RBCs breaking down; thrombocytopenia; or elevated reticulocytes and nucleated RBCs.
- ***Renal:*** Renal vein thrombosis with decreased urine output, hematuria, or proteinuria due to thromboembolism; or renal tubular damage.
- ***Central nervous system:*** Jitteriness, irritability, decreased activity and tone, lethargy, stroke (rare), or seizures due to decreased perfusion of the brain, and increased vascular resistance secondary to sluggish blood flow which can result in neurologic or developmental problems.

The nurse observes closely for signs of distress or change in vital signs during the partial exchange. The nurse assesses carefully for potential complications resulting from the exchange such as transfusion overload (which can result in congestive heart failure), irregular cardiac rhythm, bacterial infection, hypovolemia (because of decreased plasma volume), and anemia. Parents need specific explanations about polycythemia and its treatment. The newborn needs to be reunited with the parents as soon after the exchange as the baby's status permits.

Care of the Newborn with Infection

Newborns up to 1 month of age are particularly susceptible to infection, referred to as **sepsis neonatorum**, caused by organisms that do not cause significant disease in older children. Once any infection occurs in the newborn, it can spread rapidly through the bloodstream, regardless of its primary site. The incidence of early onset sepsis (EOS) is 1 to 2 per 1000 live births (0.1% to 0.2%) with a 10 times higher incidence in very-low-birth-weight (VLBW) infants (birth weight <1500 grams) (Puopolo, 2008). The risk of mortality is 5% to 15% in this population. Neonatal sepsis is a blood infection that occurs in an infant younger than 90 days old. Early-onset sepsis is seen in the first week of life. Late-onset sepsis occurs between days 8 and 89.

Nosocomial infections, infections acquired while a baby is in the neonatal intensive care unit (NICU), range from 7% to 24% (Carey, Saiman, & Polin, 2008; Garland & Uhing, 2009). Methicillin-resistant staphylococcus aureus (MRSA) and Candida are two of the most common pathogens causing hospital acquired infections in the NICU population (Venkatesh, Adams, & Weisman, 2011). The general debilitation and underlying illness often associated with prematurity necessitates invasive procedures such as umbilical catheterization, intubation, resuscitation, ventilatory support, monitoring, and parenteral alimentation (especially lipid emulsions), and prior broad-spectrum antibiotic therapy. The incidence of infections caused by umbilical and central line presence in the NICU baby is 3.1 to 9.1 infections for every 1000 days of having the lines in place in the 1001 to 1500 and <1000 gram birth weight babies respectively (Bell, 2008; Curry, Honeycutt, Goins, et al., 2009).

However, even full-term infants are susceptible because their immunologic systems are immature. They lack the complex factors involved in effective phagocytosis and the ability to localize infection or to respond with a well-defined recognizable inflammatory response. In addition, newborns lack IgM immunoglobulin, which is necessary to protect against bacteria, because it does not cross the placenta (refer to chapter 29 ∞ for immunologic adaptations in the newborn period).

Most nosocomial infections in the NICU present as bacteremia/sepsis, urinary tract infections, meningitis, or pneumonia. Maternal antepartal infections such as rubella, toxoplasmosis, cytomegalic inclusion disease, and herpes may cause congenital infections and resulting disorders in the newborn. Intrapartal maternal infections, such as amnionitis and those resulting from premature rupture of membranes (PROM) and precipitous birth, are sources of neonatal infection. (See "Care of the Woman with Perinatal Infection Affecting the Fetus" in chapter 20 ∞ for more detailed information.) Passage through the birth canal and contact with microorganisms in the vaginal flora (β-hemolytic streptococci, herpes, *Listeria,* and gonococci) expose the infant to infection (Table 34-5). With infection anywhere in the fetus or newborn, the adjacent tissues or organs are very easily penetrated, and the blood-brain barrier is ineffective. Septicemia is more common in males, except for those infections caused by group B β-hemolytic streptococcus.

Gram-negative organisms (especially *E. coli, Enterobacter, Proteus, Pseudomonas*, and *Klebsiella*) and the gram-positive organism β-hemolytic streptococcus are the most common causative agents. *Pseudomonas* is a common fomite contaminant of ventilatory support and oxygen therapy equipment. Gram-positive bacteria, especially coagulase-negative staphylococci, are common pathogens in nosocomial bacteremias, pneumonias, and urinary tract infections. Other gram-positive bacteria frequently isolated are *Bacillus, Corynebacterium*, and *Staphylococcus aureus* (Puopolo, 2008).

Protection of the newborn from infections starts prenatally and continues throughout pregnancy and birth. Prenatal prevention should include maternal screening for sexually transmitted infection and monitoring of rubella titers in women who test negative. Intrapartally, sterile technique is essential. Viral cultures are the definitive tests but take time to get results. Visual exam of the lesions is often reported on the labor and birth record to identify a patient with herpes. Placenta and amniotic fluid cultures are obtained if amnionitis is suspected. Local eye treatment with an antibiotic ophthalmic ointment is given to all newborns to prevent damage from gonococcal (occurring 3 days following birth) and possibly chlamydial (occurring 7 to 10 days after birth) infections. Prophylactic antibiotic therapy, for asymptomatic women who test positive for Group B streptococcus (GBS) during the intrapartum period, helps prevent EOS (Venkatesh et al., 2011).

Clinical Therapy

Infants with a history of possible exposure to infection in utero (for example, PROM more than 24 hours before birth or questionable maternal history of infection, maternal fever/chorioamnionitis, or high-risk behavior [such as multiple sexual partners or illicit drug use]) should have cultures taken as soon after birth as possible. Cultures are obtained before antibiotic therapy is begun (Venkatesh et al., 2011).

1. Anaerobic and aerobic blood culture is taken from a peripheral site rather than an umbilical vessel because catheters have yielded false-positive results because of contamination. The skin is prepared by cleaning with a unit-specified antiseptic solution and allowed to dry; the specimen is obtained with a sterile needle/syringe. Correct sterile technique will lessen the likelihood of contamination.
2. Spinal fluid culture is done following a spinal tap/lumbar puncture if there are concerns about central nervous system

TABLE 34-5 Maternally Transmitted Newborn Infections

INFECTION	NURSING ASSESSMENT	NURSING PLAN AND IMPLEMENTATION
Group B Streptococcus 1%–2% colonized, with 1 in 10 developing disease. Early onset—usually within hours of birth or within first week. Late onset—1 week to 3 months (Nash & Smith, 2008).	Severe respiratory distress (grunting and cyanosis). May become apneic or demonstrate symptoms of shock. Meconium-stained amniotic fluid seen at birth.	Early assessment of clinical signs necessary. Assist with x-ray examination—shows aspiration pneumonia or respiratory distress syndrome. Immediately obtain blood, gastric aspirate, external ear canal, and nasopharynx cultures. Administer antibiotics, usually aqueous penicillin or ampicillin combined with gentamicin, as soon as cultures are obtained. Early assessment and intervention are essential to survival.
Congenital Syphilis Spirochetes cross placenta after 16th–18th week of gestation. The more recent the maternal infection the more likelihood of transmission. Most are asymptomatic at birth but develop symptoms within first 3 months of life.	Check perinatal history for positive maternal serology Assess infant for: Elevated cord serum IgM and FTA-ABS (fluorescent treponemal antibody absorbed) IgM Rhinitis (snuffles) Fissures on mouth corners and excoriated upper lip Red rash around mouth and anus Copper-colored rash over face, palms, and soles Irritability, generalized edema, particularly over joints; bone lesions; painful extremities, hepatosplenomegaly, jaundice, congenital cataracts, small for gestational age (SGA), and failure to thrive	Refer to evaluate for blindness, deafness, learning or behavioral problems. Initiate standard precautions until infants have been on antibiotics for at least 24 hours. Administer penicillin. Provide emotional support for parents because of their feelings about mode of transmission and potential long-term sequelae.
Gonorrhea Approximately 30%–35% of newborns born vaginally to infected mothers acquire the infection.	Assess for: Ophthalmia neonatorum (conjunctivitis) Purulent discharge and corneal ulcerations Neonatal sepsis with temperature instability, poor feeding response, and/or hypotonia, jaundice	Administer ophthalmic antibiotic ointment (see Drug Guide: Erythromycin [Ilotycin] Ophthalmic Ointment in chapter 31 ∞) or penicillin. If positive maternal test, single dose systemic antibiotic therapy (AAP & ACOG, 2007). Make a follow-up referral to evaluate any loss of vision.
Herpes Type 2 1 in 7500 births. Usually transmitted during vaginal birth; a few cases of in utero transmission have been reported.	Check perinatal history for active herpes genital lesions. Small cluster vesicular skin lesions over all the body about 6 to 9 days of life. Disseminated form—disseminated intravascular coagulation (DIC), pneumonia, hepatitis with jaundice, hepatosplenomegaly, and neurologic abnormalities. Without skin lesions, assess for fever or subnormal temperature, respiratory congestion, tachypnea, and tachycardia	Carry out careful hand washing and contact precautions (gown and glove isolation with linen precautions) (AAP & ACOG, 2007). Obtain throat, conjunctiva, cerebral spinal fluid (CSF), blood, urine, rectal, and lesion cultures to identify herpes virus type 2 antibodies in serum IgM fraction. Cultures positive in 24–48 hours. Administer intravenous acyclovir (Zovirax). Make a follow-up referral to evaluate potential sequelae of microcephaly, spasticity, seizures, deafness, or blindness. Encourage parental rooming-in and touching of their newborn. Show parents appropriate hand washing procedures and precautions to be used at home if mother's lesions are active.
Cytomegalovirus (CMV) Most common cause of congenital infection in the United States—approximately 1% of all newborns (AAP & ACOG, 2007). Transmission occurs in utero, during labor, or may happen postnatally through breast milk.	Congenital CMV disease, including intrauterine growth restriction, jaundice, hepatosplenomegaly, petechiae or purpura (blueberry muffin spots), thrombocytopenia, and pneumonia. Central nervous system (CNS) manifestations are very common and include lethargy and poor feeding, hypertonia or hypotonia, microcephaly, intracranial calcifications, chorioretinitis, and sensorineural deafness.	Diagnosis of congenital CMV infection is established by isolating virus from urine, saliva, or tissue obtained during the first 3 weeks of life. All infants in whom the diagnosis is suspected should have a viral culture performed; a CT scan of the brain is particularly important to document the extent of CNS involvement; eye exam and hearing test; close long-term follow-up evaluating for developmental effects.
Oral Candidal Infection (Thrush) Acquired during passage through birth canal	Assess newborn's buccal mucosa, tongue, gums, and inside the cheeks for white plaques (seen 5 to 7 days of age) Check diaper area for bright-red, well-demarcated eruptions Assess for thrush periodically when newborn is on long-term antibiotic therapy	Differentiate white plaque areas from milk curds by using cotton tip applicator (if it is thrush, removal of white areas causes raw, bleeding areas). Maintain cleanliness of hands, linen, clothing, diapers, and feeding apparatus. Instruct breastfeeding mothers on treating their nipples with nystatin. Administer nystatin swabbed on oral lesions 1 hour after feeding or nystatin instilled in baby's oral cavity and on mucosa. Swab skin lesions with topical nystatin.
Chlamydia Trachomatis Acquired during passage through birth canal.	Assess for perinatal history of preterm birth. Symptomatic newborns present with pneumonia. Chlamydial conjunctivitis presents with inflammation, yellow discharge, and eyelid swelling 5 to 14 days after birth. Assess for chronic follicular conjunctivitis (corneal neovascularization and conjunctival scarring).	Instillation of prophylactic ophthalmic erythromycin is controversial (AAP & ACOG, 2007). Treat chlamydial conjunctivitis or pneumonia with oral erythromycin for 14 days. Monitor for hypertropic pyloric stenosis. Initiate follow-up referral for eye complications and late development of pneumonia at 4 to 11 weeks postnatally.

(CNS) symptoms/pathology. The fluid can be analyzed for culture and gram stain as well as for viral presence (Pacatte, 2008).

3. The specimen for urine culture is best obtained by a suprapubic bladder aspiration or sterile catheterization.
4. Skin cultures are taken of any lesions or drainage from lesions or reddened areas.
5. Tracheal aspirate cultures, if intubated, may be obtained.

Other laboratory investigations include a complete blood count, C-reactive protein (CRP), chest x-ray examination, serology, and Gram stains of cerebrospinal fluid, urine, skin exudate, and umbilicus. White blood cell (WBC) count with differential may indicate the presence or absence of sepsis. A level of 30,000 to 40,000 mm^3 WBC may be normal in the first 24 hours of life, whereas low WBC (less than 5000 to 7500/mm^3) may be indicative of sepsis. A low neutrophil count and high band (immature white cells) count indicate that an infection is present. Stomach aspirate should be sent for culture and smear if a gonococcal infection or amnionitis is suspected. CRP, an acute-phase reactant protein synthesized in response to inflammation, may or may not be elevated initially. Other inflammatory responses may cause an elevation in the CRP, so it should not be used as the only indicator of infection (Hawk, 2008; Lott, 2010; Venkatesh et al., 2011). The CRP may be helpful in watching for improvement once antibiotic therapy is initiated.

Serum IgM levels are elevated (normal level less than 20 mg/dl) in response to transplacental infections. If available, counterimmunoelectrophoresis tests for specific bacterial antigens are performed. In the future, repetitive sequence-based polymerase chain reactions (rep-PCR) will be used to identify specific infectious organisms within hours instead of days (Lott, 2010). Evidence of congenital infections may be seen on skull x-rays or CT scans for cerebral calcifications (cytomegalovirus or toxoplasmosis), on bone x-rays (syphilis or cytomegalovirus), and in serum-specific IgM levels (rubella). Cytomegalovirus infection is best diagnosed by urine culture.

Because neonatal infection causes high mortality, therapy is instituted before results of the sepsis workup are obtained. A combination of two broad-spectrum antibiotics, such as ampicillin and gentamicin, is given in large doses until a culture with sensitivities results is obtained.

After the pathogen and its sensitivities are determined, appropriate specific antibiotic therapy is begun. Combinations of penicillin or ampicillin and kanamycin have been used in the past, but new kanamycin-resistant enterobacteria and penicillin-resistant staphylococcus necessitate increasing use of gentamicin. Rotating aminoglycosides has been suggested to prevent development of resistance. Use of cephalosporins and, in particular, cefotaxime has emerged as an alternative to aminoglycoside therapy in the treatment of neonatal infections. Duration of therapy varies from 7 to 14 days (Table 34-6). However, if cultures are negative and symptoms subside, antibiotics may be discontinued after 2 days/48 hours of negative blood cultures. A normal CRP at 48 hours also supports discontinuing antibiotics if blood cultures are negative. Supportive physiologic care may be required to maintain respiratory, hemodynamic, nutritional, and metabolic homeostasis.

Care Plan Activity: Infection in a Newborn

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Symptoms of infection are most often noticed by the nurse during daily care of the newborn. The infant may deteriorate rapidly in the first 12 to 24 hours after birth if *B*-hemolytic streptococcal infection is present, with signs and symptoms mimicking respiratory distress syndrome (RDS). In other cases, the onset of sepsis may be gradual, with more subtle signs and symptoms. The most common symptoms include the following:

- Subtle behavioral changes—the infant "isn't doing well" and is often lethargic or irritable (especially after first 24 hours), hypotonic, and hypotensive. Color changes may include pallor, duskiness, cyanosis, or a "shocky" appearance. Skin is cool and clammy.
- Temperature instability, manifested most commonly by hypothermia (recognized by a decrease in skin temperature) or, rarely in newborns, hyperthermia (elevation of skin temperature) necessitates a corresponding increase or decrease in incubator temperature to maintain a neutral thermal environment.
- Feeding intolerance is evidenced by a decrease in total intake, abdominal distention, vomiting, poor sucking, lack of interest in feeding, and diarrhea.
- Hyperbilirubinemia, petechial hemorrhages, hepatosplenomegaly.
- Tachycardia initially, followed by spells of apnea/bradycardia.

Signs and symptoms may suggest CNS disease (jitteriness, tremors, seizure activity). A differential diagnosis is necessary because of the similarity of symptoms to other more specific conditions.

Nursing diagnoses that may apply to the infant with suspected sepsis neonatorum and the family include the following:

- ***Risk for Infection*** related to newborn's immature immunologic system
- ***Deficient Fluid Volume*** related to feeding intolerance
- ***Compromised Family Coping*** related to present illness resulting in prolonged hospital stay for the newborn

Nursing Plan and Implementation

In the nursery, controlling the environment and preventing acquired infection are the responsibilities of the neonatal nurse. An infected newborn can be isolated effectively in an isolette and receive close observation. The nurse must promote strict hand washing technique for all who enter the nursery, including nursing colleagues, physicians, laboratory, x-ray, and respiratory therapists, and parents. Visits to the nursery area by unnecessary personnel should be discouraged. The nurse assists in the aseptic collection of specimens for laboratory tests. Scrupulous care of equipment—changing and cleaning incubators at least every 7 days, removing and sterilizing wet equipment every 24 hours, preventing cross-use of linen and other equipment, cleaning

TABLE 34-6 Neonatal Sepsis Antibiotic/Antiviral Therapy

DRUG	DOSE (MG/KG) TOTAL DAILY DOSE	SCHEDULE FOR DIVIDED DOSES	ROUTE	COMMENTS
Acyclovir (Zovirax)	20 mg/kg	Every 8 hours	IV	Length of treatment is 14 days for skin/eye/mouth (SEM) or 21 days for CNS and disseminated disease: *Herpes.*
Ampicillin	25–50 mg/kg/dose (100 mg/kg/dose if treating meningitis and severe Group B streptococcal sepsis)	Every 12 hours* Every 8 hours† Every 6 hours **	IM or IV	Effective against gram-positive microorganisms, *Listeria,* and most *Escherichia coli* strains. Higher doses indicated for meningitis. Used with aminoglycoside for synergy.
Cefotaxime	50 mg/kg/dose (25 mg/kg/dose Gonococcal infection)	Every 12 hours* Every 8 hours Every 6 hours **	IM or IV	Active against most major pathogens in infants; effective against aminoglycoside-resistant organisms; achieves cerebrospinal fluid (CSF) bactericidal activity; lack of ototoxicity and nephrotoxicity; wide therapeutic index (levels not required); resistant organisms can develop rapidly if used extensively; ineffective against *Pseudomonas, Listeria.*
Gentamicin	4–5 mg/kg/dose	Every 24–48 hours‡ ***	IM or IV	Effective against gram-negative rods and staphylococci; may be used instead of kanamycin against penicillin-resistant staphylococci and *E. coli* strains and *Pseudomonas aeruginosa.* May cause neurotoxicity, ototoxicity, and nephrotoxicity. Need to follow serum levels. Must never be given as IV push. Must be given over at least 30–60 minutes. In presence of oliguria or anuria, dose must be decreased or discontinued. In infants less than 1000 g or 29 weeks, lower dosage 2.5–3 mg/kg/day. Monitor serum levels before administration of second dose.
	4–5 mg/kg/dose (first week of life)	Every 24–48 hours		Peak 5–10 mcg/ml Trough 1–2 mcg/ml
Vancomycin	10–20 mg/kg 30 mg/kg/day	Every 12–24 hours*‡ Every 8 hours†	IV	Effective for methicillin-resistant strains (*Staphylococcus epidermidis*); must be administered by slow intravenous infusion to avoid prolonged cutaneous eruption. For smaller infants, less than 1200 g, less than 29 weeks, smaller dosages and longer intervals between doses. Nephrotoxic, especially in combination with aminoglycosides. Slow IV infusion over at least 60 minutes. Peak 25–40 mcg/ml Trough 5–10 mcg/ml

*Up to 7 days of age.
** ≥45 weeks postmenstrual age.
†Greater than 7 days of age.
‡Dependent on gestational age.
***Dependent on postnatal age.

sink-side equipment such as soap containers periodically, and taking special care with the open radiant warmers (access without prior hand washing is much more likely than with the closed incubator)—will prevent contamination.

Provision of Antibiotic Therapy

The nurse administers antibiotics as ordered by the nurse practitioner or physician. It is the nurse's responsibility to be knowledgeable about the following:

- The proper dose to be administered, based on the weight of the newborn and desired peak and trough levels
- The appropriate route of administration, because some antibiotics cannot be given intravenously
- Admixture incompatibilities. Some antibiotics precipitate in IV solutions when mixed with other antibiotics
- Side effects and toxicity

For term infants being treated for infections, neonatal home infusion of antibiotics should be considered as a viable alternative to continued hospitalization. The infusion of antibiotics at home by skilled registered nurses (RNs) facilitates parent-infant bonding while meeting the ongoing healthcare needs of the infant.

Provision of Supportive Care

In addition to antibiotic therapy, physiologic supportive care is essential in caring for a septic infant. The nurse should carry out the following:

- Observe for resolution of symptoms or development of other symptoms of sepsis.
- Maintain a neutral thermal environment with accurate regulation of humidity and oxygen administration.
- Provide respiratory support: Administer oxygen and observe and monitor respiratory effort.
- Provide cardiovascular support: Observe and monitor pulse and blood pressure; observe for hyperbilirubinemia, anemia, and hemorrhagic symptoms.
- Provide adequate calories, because oral feedings may be discontinued because of increased mucus, abdominal distention, vomiting, or aspiration.
- Provide fluids and electrolytes to maintain homeostasis. Monitor weight changes, urine output, and urine specific gravity.
- Observe for the development of hypoglycemia, hyperglycemia, acidosis, hyponatremia, and hypocalcemia.

Restricting parental visits has not been shown to have any effect on the rate of infection and may be harmful to the newborn's psychologic development. With instruction and guidance from the nurse, both parents should be allowed to handle the baby and participate in daily care. Support of the parents is crucial. They need to be informed of the newborn's prognosis as treatment continues and to be involved in care as much as possible. They also need to understand how infection is transmitted.

Evaluation

Expected outcomes of nursing care include the following:

- The risks for development of sepsis are identified early, and immediate action is taken to minimize the development of the illness.
- Appropriate use of aseptic technique protects the newborn from further exposure to illness.
- The baby's symptoms are relieved, and the infection is treated.
- The parents verbalize their concerns about their baby's illness and understand the rationale behind the management of their newborn.

Care of the Family with Birth of an At-Risk Newborn

The birth of a preterm or ill infant or an infant with a congenital anomaly is a serious crisis situation for a family. Throughout the pregnancy, both parents, together and separately, have felt excitement, experienced thoughts of acceptance, and pictured how their baby would look and act. Both parents have wished for a perfect baby and feared a damaged, unhealthy one. Each parent and family member must accept and adjust when the fantasized fears become reality.

Parental Responses

Family members have acute grief reactions to the loss of the idealized baby they have envisioned. In a preterm birth, the mother is denied the last few weeks of pregnancy that seem to prepare her psychologically for the stress of birth and the attachment process. Attachment at this time is fragile, and interruption of the process by separation can affect the future mother-child relationship. Parents express grief as shock and disbelief, denial of reality, anger toward self and others, guilt, blame, and concern for the future. Self-esteem and feelings of self-worth are jeopardized.

Feelings of guilt and failure often plague mothers of preterm newborns. They may ask themselves, "Why did labor start? What did I do (or not do)?" A woman may have guilt fantasies and wonder what she may have done to cause the early labor: Was it because I had sex with my husband [a week, 3 days, a day] ago?" "Was it because I carried three loads of laundry up from the basement?" "Am I being punished for something I did in the past—even in childhood?"

The period of waiting between suspicion and confirmation of abnormality or dysfunction is a very anxious one for parents because it is difficult, if not impossible, to begin attachment to the infant if the newborn's future is questionable. During the waiting period, parents need support and acknowledgment that this is an anxious time. They must be kept informed about tests and efforts to gather additional data, as well as efforts to improve their baby's outcome. It is helpful to tell both parents about the problem at the same time with the baby present. An honest discussion of the problem and anticipatory management at the earliest possible time by health professionals help the parents (1) maintain trust in the physician and nurse, (2) appreciate the reality of the situation by dispelling fantasy and misconception, (3) begin the grieving process, and (4) mobilize internal and external support.

Nurses need to be aware that anger is a universal response and that it is best directed outward because holding it in check requires great energy, which is diverted away from grieving and physical recovery from pregnancy and giving birth. Anger, aggression, hostility, and irritability may be exhibited and directed unjustifiably at the physician and/or nurse, at the food, at nursing care, or at hospital regulations and routines (Mounts, 2009). Parents rarely show anger with the baby and such responses can precipitate guilt feelings. Perceived maternal stress may be lessened if information is provided regarding preterm behavioral cues. This empowers the mother and allows her to better care for her child. Mothers of preterm babies who have to spend time in a neonatal intensive care unit (NICU) suffer from psychologic distress similar to post-traumatic stress disorder (PTSD). Nurses working with the mothers in the NICU setting have the opportunity to encourage maternal competence and confidence, both during and after hospitalization, by teaching interpretation of their child's behavioral cues, prompting maternal care of the baby while in the NICU, and facilitating expression of their feeling (for more detailed discussion of PTSD see chapter 39 ∞).

Although reactions and steps of attachment are altered by the birth of these infants, a healthy parent-child relationship can occur. Kaplan and Mason (1974) identified four psychologic tasks as essential for coping with the stress of an at-risk newborn and for providing a basis for the maternal-infant relationship:

1. Anticipatory grief as a psychologic preparation for possible loss of the child while still hoping for his or her survival.
2. Acknowledgment of maternal failure to produce a term or perfect newborn expressed as anticipatory grief and depression and lasting until the chances of survival seem secure.
3. Resumption of the process of relating to the infant, which was interrupted by the threat of nonsurvival. This task may be impaired by a continuous threat of death or abnormality, and the mother may be slow in her response of hope for the infant's survival.
4. Understanding of the special needs and growth patterns of the at-risk newborn, which are temporary and yield to normal patterns.

Solnit and Stark (1961) postulated that grief and mourning of the loss of the loved object—the idealized child—mark parental reactions to an infant with abnormalities. *Grief work,* the emotional reaction to significant loss, must occur before adequate attachment to the actual baby is possible. Parental detachment precedes parental attachment. The parents must first

grieve the loss of the wished-for perfect child, and then must adopt the imperfect child as the new love object.

Parental responses to an infant with health problems may also be viewed as a five-stage process (Klaus & Kennell, 1982):

1. *Shock* is felt at the reality of the birth of this baby. This stage may be characterized by forgetfulness, amnesia of the situation, and a feeling of desperation.
2. *Denial* is expressed as disbelief of the reality of the situation, characterized by a refusal to believe the child has a problem. This stage is exemplified by assertions such as, "It didn't really happen!" "There has been a mistake; it's someone else's baby."
3. *Depression* over the reality of the situation and a corresponding grief reaction follows acceptance of the situation. This stage is characterized by much crying and sadness. Anger may also occur at this stage. A projection of blame on others or on self and feelings of "why me?" are characteristic of this stage.
4. *Equilibrium and acceptance* are characteristic of a decrease in the emotional reactions of the parents. This stage is variable and may be prolonged because of the continuing threat to the infant's survival. Some parents experience chronic sorrow in relation to their child.
5. *Reorganization* of the family is necessary to deal with the child's problems. Mutual support of the parents facilitates this process, but the crisis of the situation may precipitate alienation between the mother and father.

Postpartum depression occurs in new mothers from 10% to 15% of the time, and rates can be as high as 28% to 70% in mothers with babies in the NICU. Maternal depression can have a negative impact on attachment with the newborn (Mounts, 2009). Fathers also may suffer from depression both before and after the births of their children, adding to the discord in the family unit and compounding the perceived stress experienced by the mothers.

Developmental Consequences

The baby who is born prematurely, is ill, or has a malformation or disorder is at risk for emotional, intellectual, and cognitive development delays. The risk is directly proportional to the seriousness of the problem and the length of treatment. The necessary physical separation of family and infant and the tremendous emotional and financial burdens adversely affect the parent-child relationship. The recent trend to involve the parents with the newborn early, repeatedly, and over protracted periods of time has done much to facilitate positive parent-child relationships.

The parents must have a clear picture of the reality of the disability and the types of developmental hurdles ahead. Unexpected behaviors and responses from the baby because of his or her problem or disorder can be upsetting and frightening. The demands of care for the child and disputes regarding management or behavior stress family relationships. The entire multidisciplinary team may need to pool their resources and expertise to help parents of children born with problems or disorders so that both parents and children can thrive.

Figure 34-18 ■ Mother of a 26 weeks' gestational age infant with respiratory distress syndrome on a ventilator is getting acquainted with her baby. Physical contact is vital to the bonding process and should be encouraged whenever possible.

Source: Courtesy of Lisa Smith-Pedersen, RN, MSN, NNP-BC.

Early and continued involvement may only mean opportunities to look at or stroke the baby (Figure 34-18 ■). Later, when the mother's and baby's conditions warrant it, the mother should participate in her baby's care (to the extent she is willing) and in planning for the future. This type of involvement facilitates early bonding, attachment, and emotional investment. The parents need a sense of personal success, self-worth, self-esteem, and confidence from the knowledge that they can cope with the situation.

A variety of behavioral patterns may occur. For example, one or more members of the family may make a scapegoat of the child. Another may become the youngster's champion to the exclusion of others. One or the other spouse may feel pushed aside or denied attention and thus may withdraw or leave the family unit. Parents or siblings may feel that their own needs (schooling, material goods, and freedom of movement) are being set aside while all assets (financial and other) go to support the one child's needs. Also there may be an increase in child abuse.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

A concurrent illness of the mother or other family members or other concurrent stress (lack of health insurance, loss of job, age of parents) may change the family response to the baby. Feelings of apprehension, guilt, failure, and grief that are verbally or nonverbally expressed are important aspects of the nursing history. These observations enable all professionals to be aware of the parental state, coping behaviors, and readiness for attachment, bonding, and caretaking. Appropriate nursing assessments during interviewing and relating to the family include the following:

1. ***Level of understanding.*** Observations concerning the family's ability to assimilate information given and to ask appropriate questions; the need for constant repetition of information.

2. ***Behavioral responses.*** Appropriateness of behavior in relation to information given; lack of response; flat affect.
3. ***Difficulties with communication.*** Deafness (reads lips only); blindness; dysphasia; understanding only a non-English language.
4. ***Paternal and maternal education level.*** Parents who are unable to read or write; parents with eighth-grade–level education; parents with a graduate-level degree or health-care background.

Documentation of such information, gathered through continuing contact and development of a therapeutic family relationship, lets all professionals understand and use the nursing history to provide continuous individualized care.

A record of visits, caretaking procedures, affect (in relating to the newborn), and telephone calls indicates the level or lack of parental attachment. Serial observations, rather than just isolated observations that cause concern, must be obtained. Grant (1978) developed a conceptual framework depicting adaptive and maladaptive responses to parenting of a preterm or less-than-perfect infant (Figure 34-19 ■).

If a pattern of distancing behaviors evolves, the nurse should institute appropriate intervention. Follow-up studies have found that a statistically significant number of preterm, sick, and congenitally defective infants suffer from failure to thrive, battering, or other disorders of parenting. Early detection and intervention may prevent these aberrations in parenting behaviors from leading to irreparable damage or death.

Nursing diagnoses that may apply to the family of a newborn at risk include the following:

- ***Complicated Grieving*** related to loss of idealized newborn
- ***Fear*** related to emotional involvement with an at-risk newborn
- ***Impaired Parenting*** related to impaired bonding secondary to feelings of inadequacy about caretaking activities

(This item omitted from WebBook edition)

Nursing Plan and Implementation

Hospital-Based Nursing Care

In their sensitive and vulnerable state, parents are acutely perceptive about others' responses and reactions (particularly nonverbal) to the child. Parents can be expected to identify with the responses of others. Therefore, it is imperative that medical and nursing staff be fully aware of the parents' feelings and come to terms with their own feelings so that they are comfortable and at ease with the baby and the grieving family.

Nurses may feel uncomfortable not knowing what to say to parents or may fear confronting their own feelings as well as those of the parents. Each nurse must work out personal reactions with instructors, peers, clergy, parents, or significant others. It is helpful to have a stockpile of therapeutic questions and statements to initiate meaningful dialog with parents. Opening statements can be as follows: "You must be wondering what could have caused this"; "Are you thinking that you (or someone else) may have done something?"; "How can I help?"; and, "Are you wondering how you are going to manage?" Avoid statements such as, "It could have been worse"; "It's God's will"; "You have other children"; "You are still young and can have more"; and "I understand how you feel." This child is important now.

Figure 34-20 ■ This 25 weeks' gestational age infant with respiratory distress syndrome may be frightening for her parents to see for the first time because of the technology that is attached to her.

Support of Parents in Initial Viewing of the Newborn

Before parents see their child, the nurse must prepare them for the visit. It is important to present a positive, realistic attitude regarding the infant. An overly negative, fatalistic attitude further alienates the parents from their infant and retards attachment behaviors. Instead of beginning to bond with their child, the parents will anticipate their loss and the process of grieving. Once started, this process is very difficult to reverse.

Before preparing parents for the first view of their infant, observe the baby. All infants exhibit strengths as well as deficiencies; prepare the parents to see both the deviations and the normal aspects of their infant. The nurse may say, "Your baby is small, about the length of my two hands. She weighs 2 lb 3 oz but is very active and cries when we disturb her. She is having some difficulty breathing but is breathing without assistance and in only 35% oxygen and room air is 21%."

Many NICUs have booklets for parents to read before entering the unit. Through explanations and pictures, the parents can be better prepared to deal with the feelings they may experience when they see their infant for the first time (Figure 34-20 ■). Describe the equipment being used for the at-risk newborn and its purpose before entering the unit.

Upon entering the unit, parents may be overwhelmed by the sounds of monitors, alarms, and respirators, as well as by the unfamiliar language and "foreign" atmosphere. Preparing the parents by having the same healthcare professional(s) accompany them to the unit can be reassuring. The primary nurse and physician caring for the newborn should be with the parents when they first visit the baby. Parental reactions vary, but there is usually an element of initial shock. Providing them with chairs and time to regain composure will assist the parents. Slow, complete, and simple explanations—first about the infant and then about the equipment—allay fear and anxiety.

Concern about the infant's physical appearance is common, yet may remain unvoiced. Parents may express such concerns as, "He looks so small and red—like a drowned rat." "Why do her genitals look so abnormal?" "Will that awful looking mouth [cleft lip and palate] ever be normal?" Such questions need to be anticipated by the nurse and addressed. Use of pictures, such as a photo of an infant after cleft lip repair, may be reassuring to doubting parents. Knowledge of the development of a "normal" preterm infant will allow the nurse to make reassuring statements such as "The baby's skin may look very red and transparent with lots of visible veins, but it is normal for her maturity. As she grows, subcutaneous fat will be laid down, and these superficial veins will begin to disappear."

The nursing staff set the tone of the NICU. Nurses foster the development of a safe, trusting environment by viewing the parents as essential caregivers, not as visitors or nuisances in the unit. It is important to provide parents privacy when needed and easy access to staff and facilities. An uncrowded and welcoming atmosphere lets parents know, "You are welcome here." However, even in crowded physical surroundings, the nurses can convey an attitude of openness and trust.

A trusting relationship is essential for collaborative efforts in caring for the infant. Use your responses therapeutically to relate to the parents on a one-to-one basis. Each individual has different needs, different ways of adapting to crisis, and different means of support. Professionals must use techniques that are real and spontaneous to them and avoid adopting words or actions that are foreign to them. Nurses must also gauge their interventions to match the parents' pace and needs.

Nurses show concern and support by planning time to spend with the parents, by being psychologically as well as physically present, by encouraging open discussion and grieving, by repetitious explanations (as necessary), by providing privacy as needed, and by encouraging contact with the newborn. Identi-

fying and clarifying feelings and fears decrease distortions in perception, thinking, and feeling. Nurses invest the baby with value in the eyes of the parents when they provide meticulous care to the newborn, talk and coo (especially in the face-to-face position) while holding or providing care to the newborn, and relate the newborn's activities ("He took a whole ounce of formula"; "She took hold of the blanket and just wouldn't let go"). Nurses should note the "normal" characteristics and capabilities of each newborn as well as the newborn's needs. The nurse should also learn the baby's name and refer to him or her by name. When the baby is physiologically stable and of an appropriate weight, allowing the baby to be dressed in clothes has been determined to aid the mother in perceiving the baby as a "person" or "actual baby" (Bosque & Haverman, 2009).

Facilitation of Attachment If Neonatal Transport Occurs

Transport to a regional referral center some distance from the parents' community may be necessary. It is essential that the mother see and touch her infant before the infant is transported. Bringing the mother to the nursery or taking the infant in a warmed transport incubator to the mother's bedside will allow her to see the infant before transportation to the center. When the infant reaches the referral center, a staff member should call the parents with information about the infant's condition during transport, safe arrival at the center, and present condition.

Support of parents, with explanations from the professional staff, is crucial. Occasionally, the mother may be unable to see the infant before transport, for example, if she is still under general anesthesia or experiencing postpartum complications such as shock, hemorrhage, or seizures. In these cases, take a photograph of the infant to give to the mother, and provide an explanation of the infant's condition and problems and a detailed description of the infant's characteristics. An additional photograph is also helpful for the father to share with siblings or the extended family. With the increased attention to improved fetal outcome, prenatal maternal transports, rather than neonatal transports, are occurring more frequently. This practice gives the mother of an at-risk infant the opportunity to visit and care for her infant during the early postpartal period.

Promotion of Touching and Parental Caretaking

Parents visiting a small or sick infant may need several visits to become comfortable and confident in their abilities to touch the infant without injuring her or him. Barriers such as incubators, incisions, monitor electrodes, and tubes may delay the mother's development of comfort in touching the newborn.

Klaus and Kennell (1982) found a significant difference in the amount of eye contact and touching behaviors of mothers of normal newborns and mothers of preterm infants. Whereas mothers of normal newborns progress within minutes to palm contact of the infant's trunk, the mother of a preterm infant is slower to progress from fingertip to palm contact and from the extremities to the trunk. The progression to palm contact with the infant's trunk may take several visits to the nursery.

Through use of support, reassurance, and encouragement, the nurse can facilitate the mother's positive feelings about her ability and her importance to her infant. Touching facilitates "getting to know" the infant and thus establishes a bond with the infant. Touching as well as seeing the infant helps the mother to realize the "normals" and potentials of her baby (Figure 34-21 ■).

Figure 34-21 ■ Mother of this 26 weeks' gestational age 600-g baby begins attachment through fingertip touch.

Source: Courtesy of Lisa Smith-Pedersen, RN, MSN, NNP-BC.

The nurse can also encourage parents to meet their newborn's need for stimulation. Stroking, rocking, cuddling, singing, and talking should be an integral part of the parents' caretaking responsibilities. Bonding can be facilitated by encouraging parents to visit and become involved in their baby's care (Figure 34-22 ■). When visiting is impossible, the parents should feel free to phone whenever they wish to receive information about their baby. A nurse's warm, receptive attitude provides support. Facilitate parenting by personalizing a baby to the parents, by referring to the infant by name, or relating personal behavioral characteristics. Statements such as, "Jenny loves her pacifier," help make the infant seem individual and unique.

Figure 34-22 ■ This mother of a 31 weeks' gestational age infant with respiratory distress syndrome is spending time with her newborn and meeting the baby's need for cuddling.

The variety of equipment needed for life support is hardly conducive to anxiety-free caretaking by the parents. However, even the sickest infant may be cared for, if only in a small way, by the parents. As a facilitator of parental caretaking, the nurse should promote the parents' success. Demonstration and explanation, followed by support of the parents in initial caretaking behaviors, positively reinforce this behavior. Changing the infant's diaper, giving their infant skin care or oral care, or helping the nurse turn the infant may at first be anxiety provoking for the parents, but they will become more comfortable and confident in caretaking and receive satisfaction from the baby's reactions and their ability "to do something." Complimenting the parents' competence in caretaking also increases their self-esteem, which has received recent "blows" of guilt and failure. It is vitally important that the parents never be given a task if there is any possibility they will not be able to accomplish it. Cues that the parents are ready to become involved with the child's care include their reference to the baby by name and their questioning as to amount of feeding taken, sleeping patterns, appearance today, and the like.

Often parents of high-risk infants have ambivalent feelings toward the nurse. These feelings may take the form of criticism of the care of the infant, manipulation of staff, or personal guilt. The nurse should accept this behavior but continue to remind the parents that it is okay and natural to feel disappointment, a sense of failure, helplessness, or anger about the birth. The overprotectiveness and over-optimism are defense mechanisms. To deny the negative feelings only entrenches them further, delays their resolution, and delays realistic planning. Instead of fostering (by silence) these inferiority feelings within mothers, nurses should recognize such feelings and intervene appropriately to enhance mother-infant attachment. The nurse needs to deal with ambivalent feelings that contribute to a competitive atmosphere. For example, the nurse should avoid making unfavorable comparisons between the baby's response to parental and nursing caretaking. Verbalizations that improve parental self-esteem are essential and easily shared. The nurse can point out that, in addition to physiologic use, breast milk is important because of the emotional investment of the mother. Pumping, storing, labeling, and delivering quantities of breast milk is time-consuming and a "labor of love" for mothers. Positive remarks regarding breast milk reinforce the maternal behavior of caretaking and providing for her infant: "Breast milk is something that only you can give your baby" or "You really have brought a lot of milk today" or "Even small amounts of milk are important, and look how rich it is."

If the infant begins to gain weight while being fed breast milk, it is important to point this correlation out to the mother. Parents should also be advised that initial weight loss with beginning nipple feedings is common because of the increased energy expended when the infant begins active rather than passive nutritional intake.

During quiet time it may help for the nurse to encourage the parents to talk about their hopes and fears and to facilitate their involvement in parent groups. Encourage parents to provide care for their infant even if the baby is very sick and likely to die. Detachment is easier after attachment because the parents are comforted by the knowledge that they did all they could for their child while he or she was alive.

Facilitation of Family Adjustment

During crisis, maintaining interpersonal relationships is difficult. Yet in a newborn intensive care area, the parents are expected to relate to many different care providers. It is important that parents have as few professionals as possible relaying information to them. A primary nurse should coordinate and provide continuity for parents. Care providers are individuals and thus will use different terms, inflections, and attitudes. These subtle differences are monumental to parents and only confuse, confound, and produce anxiety. The transfer of the baby from the NICU to a step-down unit or a "regular nursery" or transport back to the home hospital is very anxiety producing for the parents because they must now deal with new healthcare professionals. They may feel that their infant is not being cared for as proficiently because the nurses are not at the bedside as often as they were in the NICU. The nurse not only functions as a liaison between the parents and the wide variety of professionals interacting with the infant and parents, but also offers clarification, explanation, interpretation of information, and support to the parents.

The nurse encourages the parents to deal with the crisis with help from their support system. The support system attempts to meet the emotional needs and provide support for the family members in crisis and stress situations. Biologic kinship is not the only valid criterion for a support system; an emotional kinship is the most important factor. In our mobile society of isolated nuclear families, the support system may be a next-door neighbor, a best friend, or perhaps a schoolmate. The nurse must search out the significant others in the lives of the parents and help them understand the problems so that they can support the parents.

The impact of the crisis on the family is individual and varied. The nurse obtains information about the family's ability to adapt to the situation through the relationship with the family. To institute appropriate interventions, the nurse should view the birth of the infant (normal newborn, preterm infant, or infant with illness or congenital anomaly) as defined by the family. Because the family is a unit composed of individuals who must deal with the situation, it is important to encourage open intrafamily communication. The nurse should discourage the family from keeping secrets from one another, especially between spouses, because secrets undermine the trust of their relationship. Well-meaning rationales such as, "I want to protect her," "I don't want him to worry about it," and so on, can be destructive to open communication and to the basic element of a relationship—trust.

Open communication is especially important when the mother is hospitalized apart from the infant. The first person to visit the infant relays information regarding the infant's care and condition to the mother and family. In this situation, the mother has had minimal contact, if any, with her infant. Because of her anxiety and isolation, she may mistrust all those who provide information (the nurse, physician, father, or extended family) until she can see the infant for herself. This can put tremendous stress on the relationship between the mother and father. The parents (and family) should be given information together. This

practice helps overcome misunderstandings and misinterpretations and promotes mutual "working through" of problems.

The needs of siblings should not be overlooked. Siblings have been looking forward to the new baby, and they too suffer a degree of loss. Young children may react with hostility and older ones with shame at the birth of an infant with an anomaly. Both reactions make them feel guilty. Parents, preoccupied with working through their own feelings, often cannot give the other children the attention and support they need. Sometimes another child becomes the focus of family tension. Anxiety thus directed can take the form of finding fault or of overconcern. This is a form of denial; the parents cannot face the real worry—the infant at risk. After assessing the situation, the observant nurse could see to it that another family member or friend step in and give the needed support to the siblings of the affected baby.

The nurse must respect and facilitate the desires and needs of the individuals involved; differences are tolerable and should be able to exist side by side. The nurse can easily elicit the parents' feelings and the meaning of this experience to them by asking, "How are you doing?" The emphasis is on "you," and the interest must be sincere.

Parents from minority cultures must deal with language barriers and cultural differences that can make feelings of isolation and uncertainty more acute. Healthcare providers have the professional responsibility to be aware of cultural needs of all patients and to ensure that their needs are met. Feelings of isolation and uncertainty influence not only the parent's emotional responses to the ill newborn, but also their use of services and their interaction with health professionals. Hospital cultural interpreter programs can assist families with interactions with staff and provide translation during family meetings, multidisciplinary family conferences, and parent support groups (Lipson & Dibble, 2008).

Families with children in the NICU become friends and support one another. To encourage the development of these friendships and to provide support, many units have established parent groups. The core of the groups consists of parents who previously have had an infant in the intensive care unit. Most groups make contact with families within a day or two of the infant's admission to the unit, either through phone calls or visits to the hospital. Early one-on-one parent contacts are more effective than discussion groups in helping families work through their feelings. This personalized method gives the grieving parents an opportunity to share personal feelings about the pregnancy, labor, and birth and their "different from expected" infant with others who have experienced the same feelings and with whom they can identify.

Community-Based Nursing Care

Predischarge planning begins once the infant's condition becomes stable and indications suggest the newborn will survive. Discharge preparation and care conferences should involve a multidisciplinary team approach. The NICU nursing staff is the fulcrum for aiding in the transition of high-risk infants from the intensive care unit to the home. Effective open communication with the families during the entire discharge-planning phase of care empowers the families to assume the role of primary caregiver for their children.

Adequate predischarge teaching helps parents transform any feelings of inadequacy they may have into feelings of self-assurance and attachment. From the beginning the parents should be taught about their infant's special needs and growth patterns. This teaching and involvement are best facilitated by a nurse who is familiar with the infant and his or her family over a period of time and who has developed a comfortable and supportive relationship with them.

Cobedding of twins is often used in the NICU to provide comfort, decrease stress to the twins, and provide a form of developmentally supportive care. Cobedding is also a strategy to maximize the synchronization of sleep-wake cycles (Gardner & Goldson, 2011). Parents of multiples may desire cobedding at home to allow for clustering of care and to facilitate the parents' ability to spend time with both of their children (Figure 34-23 ■). If twins or other multiples experienced cobedding in the NICU, the nurse needs to discuss the advantages and disadvantages of continuing the practice at home. Currently, there is no evidence to establish cobedding of multiples outside the NICU as a safe or unsafe sleep practice (Gardner & Goldson, 2011). The high incidence of prematurity and low birth weight (LBW) in multiple-birth infants and the corresponding risks for sudden infant death syndrome (SIDS) should be considered. As with all families at discharge, parents of multiples should be taught SIDS risk-reduction practices. SIDS reduction practices include supine positioning, babies sleeping in parents' room, firm bedding surface, no loose coverings/items, and no barriers between infants (Bowers et al., 2008).

The nurse's responsibility is to provide home care instructions in an optimal environment for parental learning. Learning should take place over time, to avoid the necessity of bombarding the parents with instructions in the day or hour before discharge. Parents often enjoy doing minimal caretaking tasks with gradual expansion of their role. Many NICUs provide facilities for parents to room in with their infants for a few days before discharge. This

Figure 34-23 ■ Cobedding of twins facilitates delivery of care and parent interaction with healthcare members. These twins were born at 33 weeks' gestation and required oxygen and gavage feeding while in the NICU.

Source: Courtesy of Lisa Smith-Pedersen, RN, MSN, NNP-BC.

allows parents a degree of independence in the care of their infant with the security of nursing help nearby. This practice is particularly helpful for anxious parents, parents who have not had the opportunity to spend extended time with their infant, or parents who will be giving complex physical care at home, such as gastrostomy feeding and care (Collins, Makrides, & McPhee, 2008).

The families are able to interact with the staff while gradually transitioning to sole caretakers of their medically complex high-risk infant. When discharging a medically fragile infant to home, schedule a predischarge home visit by a public health nurse or home health agency. This predischarge visit evaluates the home for any possible issues that may complicate the parents' ability to care for their at-risk infant, especially if there are multiple monitoring equipment needs.

The basic elements of discharge and home care instruction are as follows:

1. Teach parents routine well-baby care, such as bathing, taking a temperature, preparing formula, and/or breastfeeding.
2. Help parents learn to do special procedures as needed by the newborn, such as gavage or gastrostomy feedings, tracheostomy or enterostomy care, medication administration, cardiopulmonary resuscitation (CPR), and operation of an apnea monitor or any required medical equipment. Before discharge, the parents should be as comfortable as possible with these tasks and should demonstrate independence. Written tools and instructions are useful for parents to refer to once they are home with the infant, but they should not replace actual predischarge participation in the infant's care.
3. Make sure that all applicable screening (metabolic, vision, hearing) tests, immunizations, and respiratory syncytial virus (RSV) prophylaxis are done before discharge and that all records are given to the primary care provider and parents.
4. Refer parents to community health and support organizations. The Visiting Nurses Association, public health nurses, or social services can assist the parents in the stressful transition from hospital to home by providing predischarge home visits and then the necessary home teaching and support. Some NICUs have their own parent support groups to help bridge the gap between hospital and home care. Parents can also find support from a variety of community support organizations, such as mothers of twins groups, March of Dimes Birth Defects Foundation, handicapped children services, and teen mother and child programs. Each community has numerous agencies capable of assisting the family in adapting emotionally, physically, and financially to the chronically ill infant. The nurse should be familiar with community resources and help the parents identify which agencies may benefit them.
5. Help parents recognize the growth and development needs of their infant. A developmental care program begun in the hospital can be continued at home, or parents may be referred to an infant development program in the community.
6. Arrange medical follow-up care before discharge. The infant will need to be followed up by a family pediatrician, a well-baby clinic, or a specialty clinic. The first appointment should be made before the infant is discharged from the hospital.

Figure 34-24 ■ Twins on the happy day of discharge, being held by staff in the NICU. This is what is so rewarding about working in the NICU: healthy babies going home to their families.

Source: Courtesy of Lisa Smith-Pedersen, RN, MSN, NNP-BC.

7. Evaluate the need for durable medical equipment for infant care (such as a respirator, oxygen, apnea monitor, feeding pump) in the home. Any extra equipment or supplies should be placed in the home before the infant's discharge.
8. Arrange for neonatal hospice for parents of the medically fragile infant, as needed.

According to a study by Sneath (2009) parents of NICU graduates do not feel adequately prepared for discharge from the NICU with their babies. Teaching that occurs with daily interaction of the NICU staff is not always perceived by the family as adequate, and the stress levels of the family while in the NICU can be a barrier to a learning environment.

Further evaluation after the infant has gone home is useful in determining whether the crisis has been resolved satisfactorily. The parents are usually given the intensive care nursery's telephone number to call for support and advice. The staff can follow up each family with visits or telephone calls at intervals for several weeks to assess and evaluate the infant's (and parents') progress (Figure 34-24 ■).

Evaluation

Expected outcomes of nursing care include the following:

- The parents are able to verbalize their feelings of grief and loss.
- The parents verbalize their concerns about their baby's health problems, care needs, and potential outcome.
- The parents are able to participate in their infant's care and show attachment behaviors.

Considerations for the Nurse Who Works with At-Risk Newborns

The birth of a baby with a problem is a traumatic event with the potential for either disruption or growth of the involved family. The neonatal intensive care unit (NICU) staff nurses may never

see the long-term results of the specialized, sensitive care they give to parents and their newborns. Their only immediate evidence of effective care may be the beginning of resolution of parental grief; discharge of a recovered, thriving infant to the care of happy parents; and the beginning of reintegration of family life.

Nurses cannot provide support unless they themselves are supported. Working in an emotional environment of "lots of living and lots of dying" takes its toll on staff. NICUs are among the most stressful areas in health care for patients, families, and nurses. Nurses bear most of the stress and largely determine the atmosphere of the NICU. The nurse's ability to cope with stress is the key to creating an emotionally healthy environment and a positive working atmosphere. The emotional needs and feelings of the staff must be recognized and dealt with to enable them to support the parents. An environment of openness to feelings and support in dealing with their own human needs and emotions is essential for the staff.

As caregivers, nurses may be unaware of their need to grieve for their own losses in the NICU. Working with babies for hours, days, weeks, and sometimes months can foster intimate attachments of the nurses with the baby and family. Nurses must also go through the grief work that parents experience, and they first have to be comfortable with their own feelings about death (Lisle-Porter & Podruchny, 2009). Techniques such as group meetings, individual support, and doing primary care nursing may assist in maintaining staff mental health. Reunions in some nurseries are beneficial for the families and healthcare professionals so they are able to see the children after discharge.

FOCUS YOUR STUDY

- The sick newborn—whether preterm, term, or postterm—must be managed within narrow physiologic parameters.
- These parameters (respiratory, cardiovascular, and thermal regulation) will maintain physiologic homeostasis and prevent introduction of iatrogenic stress to the already stressed infant.
- The nursing care of the newborn with special problems involves understanding normal physiology, the pathophysiology of the disease process, clinical manifestations, and supportive or corrective therapies. Only with this theoretic background can the nurse make appropriate observations concerning responses to therapy and development of complications.
- Asphyxia results in significant circulatory, respiratory, and biochemical changes in the newborn that make the successful transition to extrauterine life difficult. Asphyxia requires early identification and resuscitative management.
- Newborn conditions that commonly present with respiratory distress and require oxygen and ventilatory assistance are respiratory distress syndrome (RDS), transient tachypnea of the newborn, meconium aspiration syndrome (MAS), and persistent pulmonary hypertension of the newborn (PPHN).
- Management of respiratory problems can result in further respiratory compromising conditions such as pulmonary interstitial emphysema, pneumothorax, and bronchopulmonary dysplasia (BPD)/chronic lung disease (CLD).
- Cold stress sets up the chain of physiologic events of hypoglycemia, pulmonary vasoconstriction, hyperbilirubinemia, respiratory distress, and metabolic acidosis.
- Nurses are responsible for early detection and initiation of treatment for hypoglycemia.
- Differentiation between pathologic and physiologic jaundice is key to early and successful intervention.
- Anemia (decreased amount of red blood cell volume) or polycythemia (excess amount) place the newborn at risk for alterations in blood flow and the oxygen-carrying capacity of the blood.
- Nursing assessment of the septic newborn involves identifying very subtle clinical signs that are also seen in other clinical disease states.
- The nurse is the facilitator for interdisciplinary communication with the parents, identifying their understanding of their infant's care and their needs for emotional support.
- Parents of at-risk newborns need support from nurses and healthcare providers to understand the special needs of their baby and to feel comfortable in an overwhelming and often unfamiliar environment.

CRITICAL THINKING IN ACTION

Rebecca Prince, age 21, G2 now P2, gives birth to a 5 pound baby at 38 weeks' gestation by primary cesarean birth for nonreassuring fetal status. The infant's Apgars are 7 and 9 at 1 and 5 minutes. The infant is suctioned and given free-flow oxygen at birth, then is admitted to the newborn nursery for transitional care and does well. You are the nurse caring for baby Prince at 36 hours old. You review the newborn's record and note that the baby's blood type is A+ and his mother is O+. Rebecca wants to breastfeed. You are performing a shift assessment on baby Prince when you observe that the infant has a unilateral cephalhematoma and is lethargic. You blanch the skin over the sternum and observe a yellow discoloration of the skin. Lab tests reveal a serum bilirubin level of 12 mg/dl, hematocrit 55%, a mildly positive direct Coombs' test, and a positive indirect Coombs' test. Baby Prince is diagnosed with hyperbilirubinemia secondary to ABO incompatibility and cephalhematoma. You provide phototherapy by fiberoptic blanket around the trunk of the infant and take the baby to his mother's room.

1. How would you explain the purpose of phototherapy with the mother?
2. Plot the bilirubin on the hour specific nomogram to assess the zone.
3. Explain the follow-up laboratory testing required, and when it will be required.
4. Discuss the advantage of the fiberoptic blanket phototherapy for the newborn.
5. Describe the care the mother can give to the newborn.

Postpartum Family Adaptation and Nursing Assessment

CHAPTER 35

I had heard about the negatives—the fatigue, the loneliness, loss of self. But nobody told me about the wonderful parts: holding my baby close to me, seeing her first smile, watching her grow and become more responsive day by day. How can I describe the way I felt when she stroked my breast while nursing, or looked into my eyes or arched her eyebrows like an opera singer? This was the deepest connection I'd felt to anybody. Sometimes the intensity almost frightened me. For the first time I cared about somebody else more than myself, and I would do anything to nurture and protect her.

—The Boston Women's Health Collective, *The New Our Bodies, Ourselves*

LEARNING OUTCOMES

1. Delineate the basic physiologic changes that occur in the postpartum period as a woman's body returns to its prepregnant state.
2. Describe the psychologic adjustments that normally occur during the postpartum period.
3. Explain the impact of cultural influence upon the postpartum period.
4. Differentiate the physiologic and psychosocial components of a normal postpartum assessment.
5. Describe the normal characteristics and common concerns of the mother that are considered in a postpartum assessment.
6. Examine the physical and developmental tasks that the mother must accomplish during the postpartum period.
7. Identify the factors that influence the development of parent-infant attachment in the nursing assessment of early attachment.

Puerperium *992*
Reciprocity *1001*

The **puerperium**, or postpartum period, is the period during which the woman readjusts, physically and psychologically, from pregnancy and birth. It begins immediately after birth and continues for approximately 6 weeks or until the body has returned to a near nonpregnant state.

This chapter describes the physiologic and psychologic changes and adaptations that occur postpartally and the basic aspects of a thorough postpartum assessment.

Postpartum Physical Adaptations

Comprehensive nursing assessment is based on a sound understanding of the normal anatomic and physiologic processes of the puerperium. These processes involve the reproductive organs and other major body systems.

Reproductive System

Involution of the Uterus

The term **involution** is used to describe the rapid reduction in size of the uterus and its return to a condition similar to its nonpregnant state, although it remains slightly larger than it was before the first pregnancy. Specifically, the weight of the uterus decreases from 1000 g in the immediate postpartal period to 500 g at the end of the first week. It reaches 300 g by the end of the second week, finally terminating the involution process with a weight of 100 g or less (Cunningham et al., 2010).

Following separation of the placenta, the decidua of the uterus is irregular, jagged, and varied in thickness. The spongy layer of the decidua is cast off as lochia, and the basal layer of the decidua remains in the uterus to become differentiated into two layers within the first 48 to 72 hours after birth. The outermost layer becomes necrotic and is sloughed off in the lochia. The layer closest to the myometrium contains the fundi of the uterine endometrial glands, and these glands lay the foundation for the new endometrium. Except at the placental site, this process is completed in approximately 3 weeks. The placental site can take up to 6 weeks to completely heal (Cunningham et al., 2010). Bleeding from the larger uterine vessels of the placental site is controlled by compression of the retracted uterine muscle fibers. The clotted blood is gradually absorbed by the body. Some of these vessels are eventually obliterated and replaced by new vessels with smaller lumens.

Rather than forming a fibrous scar in the decidua, the placental site heals by a process of exfoliation. The placental site is undermined by the growth of the endometrial tissue, both from the margins of the site and from the fundi of the endometrial glands left in the basal layer of the site. The infarcted superficial tissue then becomes necrotic and is sloughed off (Cunningham et al., 2010). *Exfoliation* is one of the most important aspects of involution. If the healing of the placental site left a fibrous scar, the area available for further implantation would be limited, as would the number of possible pregnancies.

With the dramatic decrease in the levels of circulating estrogen and progesterone following placental separation, the uterine cells atrophy, and the hyperplasia of pregnancy begins to reverse. The process is one in which the *size* of the cells decreases markedly; the *number* of cells does not decrease. Proteolytic enzymes are released, and macrophages migrate to the uterus to promote autolysis (self-digestion). Protein material in the uterine wall is broken down and absorbed. Factors that enhance involution include an uncomplicated labor and birth, complete expulsion of the amniotic membranes and the placenta, breastfeeding, manual removal of the placenta during a cesarean birth, and early ambulation. Factors that slow uterine involution and the rationale for each factor are listed in Table 35-1.

TABLE 35-1 Factors That Retard Uterine Involution

FACTOR	RATIONALE
Prolonged labor	Muscles relax because of prolonged time of contraction during labor.
Anesthesia	Muscles relax.
Difficult birth	The uterus is manipulated excessively.
Grandmultiparity	Repeated distention of uterus during pregnancy and labor leads to muscle stretching, diminished tone, and muscle relaxation.
Full bladder	As the uterus is pushed up and usually to the right, pressure on it interferes with effective uterine contraction.
Incomplete expulsion of placenta or membranes	The presence of even small amounts of tissue interferes with ability of uterus to remain firmly contracted.
Infection	Inflammation interferes with uterine muscle's ability to contract effectively.
Overdistention of uterus	Overstretching of uterine muscles with conditions such as multiple gestation, hydramnios, or a very large baby may set the stage for slower uterine involution.

Changes in Fundal Position

Immediately following the expulsion of the placenta, the uterus contracts firmly to the size of a large grapefruit. The **fundus** (top portion of the uterus) is situated in the midline of the abdomen, one half to two thirds of the way between the symphysis pubis and the umbilicus (Figure 35-1 ■). The walls of the contracted uterus are in close proximity and the uterine blood vessels are firmly compressed by the myometrium. Within 6 to 12 hours after birth, the fundus of the uterus rises to the level of the umbilicus because of blood and clots that remain within the uterus and changes in support of the uterus by the ligaments. A fundus that is above the umbilicus and boggy (feels soft and spongy rather than firm and well contracted) is associated with excessive uterine bleeding. As blood collects and forms clots within the uterus, the fundus rises; firm contractions of the uterine muscle are interrupted, causing a **boggy uterus (uterine atony)**. When the fundus is higher than expected and is not in midline (usually deviated to the right), distention of the bladder should be suspected and the bladder should be emptied immediately and the uterus remeasured (Figure 35-2 ■). If the woman is unable to void, in-and-out catheterization of the bladder may be required. In the immediate postpartal period many women may not be aware of a full bladder. Because the uterine ligaments are still stretched, a full bladder can move the uterus. By the end of

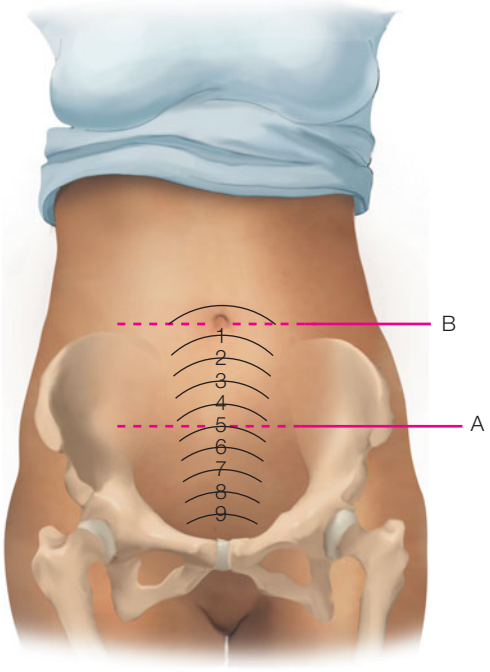

Figure 35-1 ■ Involution of the uterus. (A) Immediately after delivery of the placenta, the top of the fundus is in the midline and approximately two thirds to three fourths of the way between the symphysis pubis and the umbilicus (B). About 6 to 12 hours after birth, the fundus is at the level of (or one fingerbreadth below) the umbilicus. The height of the fundus then decreases about one fingerbreadth (approximately 1 cm) each day.

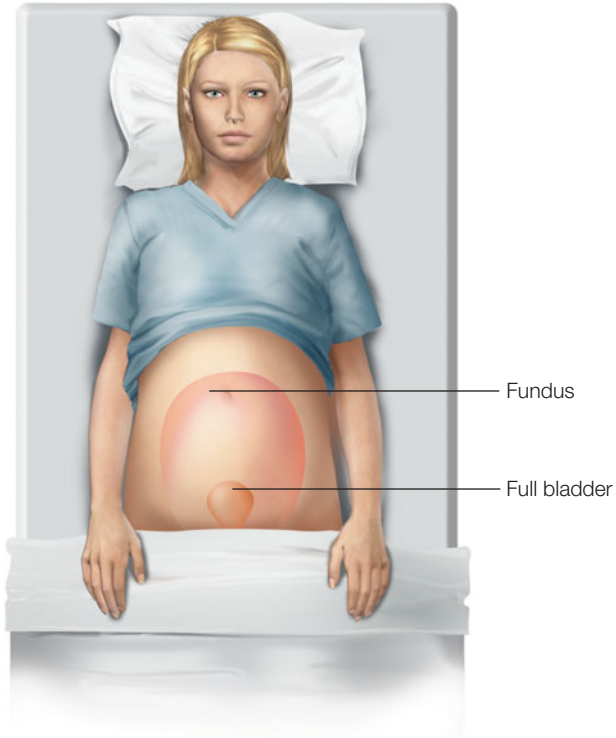

Figure 35-2 ■ The uterus becomes displaced and deviated to the right when the bladder is full.

the puerperium these ligaments have regained their nonpregnant length and tension.

After birth, the top of the fundus remains at the level of the umbilicus for about half a day. On the first postpartum day (first day following birth), the top of the fundus is located about 1 cm below the umbilicus. The top of the fundus descends approximately one fingerbreadth (width of index, second, or third finger), or 1 cm, per day until it descends into the pelvis on the 10th day.

If the mother is breastfeeding, the release of endogenous oxytocin from the posterior pituitary in response to suckling may hasten this process. Barring complications, such as infection or retained placental fragments, the uterus approaches its prepregnant size and location by 5 to 6 weeks. In women who had an oversized uterus during the pregnancy (hydramnios, birth of a large-for-gestational-age [LGA] infant, or multiple gestation), the time frame for immediate uterine involution process is lengthened. If intrauterine infection is present, in addition to the presence of foul-smelling lochia or vaginal discharge, the uterine fundus descends much more slowly. When infection is suspected, other clinical signs such as fever and tachycardia in addition to delay in involution must be assessed. Any slowing of descent is called *subinvolution* (for further discussion of subinvolution, see chapter 39 ∞).

Lochia

The uterus rids itself of the debris remaining after birth through a discharge called **lochia**, which is classified according to its appearance and contents. **Lochia rubra**, named for the Latin word for *red,* is dark red in color. It is present for the first 2 to 3 days postpartal and contains epithelial cells, erythrocytes, leukocytes, bacteria, shreds of the decidua, and, occasionally, fetal meconium, lanugo, and vernix caseosa. Clotting is often the result of pooling of blood in the upper portion of the vagina. A few small clots (no larger than a nickel) are common, particularly in the first few days after birth. However, lochia should not contain large (plum sized) clots; if it does, the cause should be investigated without delay. **Lochia serosa** is a pinkish color. It follows from about the 3rd to the 10th day. Lochia serosa is composed of serous exudate, shreds of degenerating decidua, erythrocytes, leukocytes, cervical mucus, and numerous microorganisms (Cunningham et al., 2010).

The red blood cell (RBC) component decreases gradually, and a creamy or yellowish discharge persists for an additional week or two. This final discharge, termed **lochia alba** from the Latin word for *white,* is composed primarily of leukocytes, decidual cells, epithelial cells, fat, cervical mucus, cholesterol crystals, and bacteria. Recent studies examining lochia patterns have found that the lochia rubra phase lasts longer than generally assumed and that it varies according to breastfeeding practice and parity (Blackburn, 2007). Variation in the duration of lochia discharge is not uncommon; however, the trend should be toward a lighter amount of flow and a lighter color of discharge. When the lochia stops, the cervix is considered closed, and chances of infection ascending from the vagina to the uterus decrease.

Like menstrual discharge, lochia has a musty, stale odor that is not offensive. Microorganisms are always present in the vaginal lochia, and by the second day following birth the uterus

is contaminated with the vaginal bacteria. Researchers speculate that infection does not develop because the organisms involved are relatively nonvirulent. In addition, by the time the bacteria reach the raw, exposed surface of the uterus, the process of granulation has begun, forming a protective barrier. Any foul smell to the lochia or used perineal pads suggests infection and the need for prompt additional assessment, such as white blood cell (WBC) count and differential and assessment for uterine tenderness and fever.

The total volume of lochia is approximately 225 ml, and the daily volume decreases gradually (Blackburn, 2007). Discharge is greater in the morning because of pooling in the vagina and uterus while the mother lies sleeping. The amount of lochia may also be increased by exertion or breastfeeding. Multiparous women usually have more lochia than first-time mothers. Women who undergo a cesarean birth typically have less lochia than women who give birth vaginally (Blackburn, 2007).

Evaluation of lochia is necessary not only to determine the presence of hemorrhage but also to assess uterine involution. The type, amount, and consistency of lochia determine the state of healing of the placental site, and a progressive color change from bright red at birth to dark red to pink to white or clear should be observed. Persistent discharge of lochia rubra or a return to lochia rubra indicates subinvolution or late postpartum hemorrhage (see chapter 39 ∞).

CLINICAL JUDGMENT

Case Study: Patty Clark

You have completed your assessment of Patty Clark, a 24-year-old, G2P2 woman who is 24 hours past childbirth. The fundus is just above the umbilicus and slightly to the right. Lochia rubra is present, and a pad is soaked every 2 hours.

Critical Thinking

What other information do you need in order to determine what to do next?

Why is this finding significant and what outcome would you anticipate?

See www.nursing.pearsonhighered.com for possible responses.

The nurse should exercise caution in evaluating bleeding immediately after birth. The continuous seepage of blood is more consistent with cervical or vaginal lacerations and may be effectively diagnosed when the bleeding is evaluated in conjunction with the consistency of the uterus. Lacerations should be suspected if the uterus is firm and of expected size and if no clots can be expressed.

Cervical Changes

Following birth, the cervix is spongy, flabby, and formless and may appear bruised. The lateral aspects of the external os are frequently lacerated during the birth process (Cunningham et al., 2010). The external os is markedly irregular and closes slowly. It admits two fingers for a few days following birth, but by the end of the first week it will admit only a fingertip.

The shape of the external os is permanently changed by the first childbearing. The characteristic dimplelike os of the nullipara changes to the lateral slit (fish-mouth) os of the multipara. After significant cervical laceration or several lacerations, the cervix may appear lopsided. Because of the slight change in the size of the cervix, a diaphragm or cervical cap will need to be refitted if the woman is using one of these methods of contraception.

Vaginal Changes

Following birth, the vagina appears edematous and gaping and may be bruised. Small superficial lacerations may be evident, and the rugae have been obliterated. The apparent bruising of the vagina is due to pelvic congestion and trauma and will quickly disappear. The hymen, torn and jagged, heals irregularly, leaving small tags called the *carunculae myrtiformes.*

The size of the vagina decreases and rugae begin to return within 3 weeks (Whitmer, 2011). This facilitates the gradual return to smaller, although not to nulliparous, dimensions. By 6 weeks, the nonlactating woman's vagina usually appears normal. The lactating woman is in a hypoestrogenic state because of ovarian suppression, and her vaginal mucosa may be pale and without rugae. This may lead to dyspareunia (painful intercourse), which may be reduced by the addition of a water-soluble personal lubricant. Tone and contractibility of the vaginal opening may be improved by perineal tightening exercises (Kegel exercises are discussed in chapter 16 ∞ and illustrated in Figure 16-13 ∞ on page 365), which may begin soon after birth. The labia majora and labia minora are looser in the woman who has borne a child than in the nullipara.

Perineal Changes

During the early postpartal period, the soft tissue in and around the perineum may appear edematous with some bruising. If an episiotomy or laceration is present, the edges should be approximated. Occasionally, ecchymosis occurs, and this may delay healing. Initial healing of the episiotomy or laceration occurs in 2 to 3 weeks after the birth, although complete healing may take up to 4 to 6 months (Blackburn, 2007). Perineal discomfort may be present during this time.

Recurrence of Ovulation and Menstruation

The return of menstruation and ovulation varies for each postpartal woman. Menstruation generally returns in nonbreastfeeding mothers between 6 and 10 weeks after birth; 50% of the first cycles are anovulatory (Cunningham et al., 2010). The return of ovulation is directly associated with a rise in the serum progesterone level. In nonlactating women the average time to first ovulation can occur within 5 to 11 weeks with a mean time of 7 weeks (Cunningham et al., 2010).

The return of menstruation and ovulation in breastfeeding mothers is usually prolonged and is associated with the length of time the woman breastfeeds and whether formula supplements are used. If a mother breastfeeds for less than 1 month, the return of menstruation and ovulation is similar to the nonbreastfeeding mother. In women who exclusively breastfeed, menstruation is usually delayed for at least 3 months. Sucking by the infant typically results in alterations in the gonadotropin-releasing hormone (GnRH) production, which is thought to be the cause of amenorrhea (Blackburn, 2007). Although exclusive breastfeeding helps to reduce the risk of pregnancy for the first 6 months after

Through the Eyes of a Nurse
Postpartum Bleeding and Perineal Changes

Family's Experience

Phone call to the birthing unit from a new mother: "I am still feeling some cramping and having vaginal bleeding at this point although it is easing up some. I am concerned because it had gotten lighter but now it seems to have picked up again. My vaginal area seems to feel better but sometimes it is still sensitive when I wipe after urination. Is this normal?"

Nurse's Response

"It is normal that the bleeding can increase when your activity level increases. At this point (after 3 to 4 days), the bleeding should be pink in color. You should not be having large clots, although a few small clots may occur. If your bleeding becomes heavy, more than 1 to 2 pads per hour, if there is a foul-smelling odor, if your abdomen becomes tender or painful, or if you have fever or chills, you would need to contact your healthcare provider immediately because those can be warning signs that need further assessing.

"Your uterus will continue to contract in the early postpartum period as a result of *involution*. This helps your uterus return to a prepregnant state and descend behind your pubic bone. You can take an anti-inflammatory medication as directed by your healthcare provider. You may notice that the cramping or afterbirth pains occur commonly with breastfeeding. This is also normal.

"The perineal area will continue to heal in the upcoming weeks. It is not unusual for the area to feel tender and to be sensitive. If the area becomes more painful, red, is warm to the touch, or appears to 'come open,' that could be a sign of an infection or a problem with the incision site. You would want to contact your healthcare provider if any of those things occur. The sutures that were placed after the birth will continue to heal and will dissolve over time. I would continue to use the topical agents you received in the birth setting and to use the sitz bath."

Nurse's Actions and Rationale

The nurse reviews the normal physiologic changes associated with the postpartum period. The signs and symptoms of bleeding and infection should be reviewed. The nurse explains the normal physical changes that occur, including involution of the uterus, cessation of lochia, healing of the laceration or episiotomy site, and breast changes related to lactation. Many women find it helpful if the nurse reviews the various changes that occur as the body returns to a prepregnant state.

delivery, it should be relied upon only temporarily and if it meets the observed criteria for lactational amenorrhea method (LAM). Furthermore, because ovulation precedes menstruation and women often supplement breastfeeding with bottles and pacifiers, breastfeeding is not considered a reliable means of contraception.

Abdomen

The uterine ligaments (notably the round and broad ligaments) are stretched and require the length of the puerperium to recover. The stretched abdominal wall appears loose and flabby, but it will respond to exercise within 2 to 3 months. In the grandmultipara, in the woman whose abdomen is overdistended, or in the woman whose muscle tone was poor before pregnancy, the abdomen may fail to regain good tone and will remain flabby. **Diastasis recti abdominis**, a separation of the rectus abdominis muscles, may occur with pregnancy, especially in women with poor abdominal muscle tone (Figure 35-3 ■). If diastasis occurs, part of the abdominal wall has no muscular support but is formed only by skin, subcutaneous fat, fascia, and peritoneum. This may be especially pronounced in women who have undergone a cesarean section, as the rectus abdominis muscles are manually separated to access the uterine muscle. Improvement depends on the physical condition of the mother, the total number of pregnancies, pregnancy spacing, and the type and amount of physical exercise. If rectus muscle tone is not regained, support may be inadequate during future pregnancies. This may result in a pendulous abdomen and increased maternal backache. Fortunately, diastasis usually responds well to exercise, and abdominal muscle tone can improve significantly.

The striae (stretch marks), which occurred as a result of stretching and rupture of the elastic fibers of the skin, take on different colors based on the mother's skin color. The striae of Caucasian mothers are red to purple at the time of birth and gradually fade to silver or white. The striae of mothers with darker skin are darker than the surrounding skin and remain darker. These marks gradually fade after a time but remain visible.

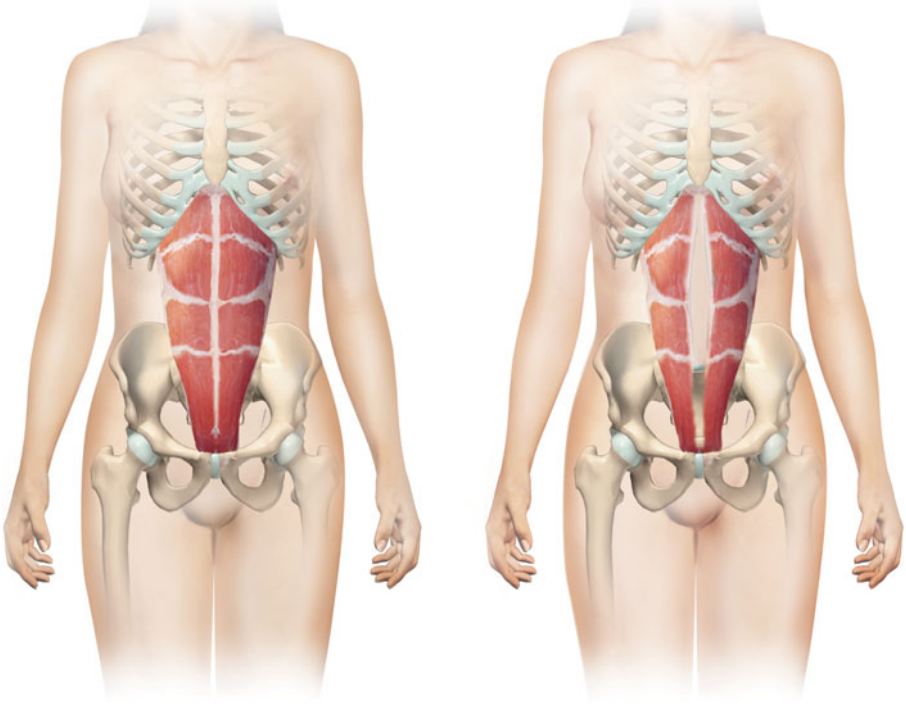
Lactation

During pregnancy, the breasts develop in preparation for lactation as a result of the influence of both estrogen and progesterone. After birth, the interplay of maternal hormones leads to the establishment of milk production (see chapter 32 ∞).

Gastrointestinal System

Hunger following birth is common, and the mother may enjoy a light meal. Frequently, she is quite thirsty and will drink large amounts of fluid. Drinking fluids helps replace fluid lost during labor, in the urine, and through perspiration.

The bowels tend to be sluggish after birth because of the lingering effects of progesterone, decreased abdominal muscle tone, and bowel evacuation associated with the labor and birth process. Women who have had an episiotomy, lacerations, or hemorrhoids may tend to delay elimination for fear of increasing their pain or in the belief that their stitches will be torn if they bear down. In resisting or delaying the bowel movement, the woman may cause increased constipation and more pain when elimination finally occurs.



Normal location of rectus muscles of the abdomen

Diastasis recti: separation of the rectus muscles

Figure 35-3 ■ Diastasis recti abdominis, a separation of the musculature, commonly occurs after pregnancy.

The woman with a cesarean birth may receive clear liquids shortly after surgery. Once bowel sounds are present, the diet is quickly advanced to solid food. In addition, the woman may experience some initial discomfort from flatulence, which is relieved by early ambulation and use of antiflatulent medications. Chamomile tea and peppermint tea may also be helpful in reducing discomfort from flatulence. It may take a few days for the bowel to regain its tone. The woman who has had a cesarean or a difficult birth may benefit from stool softeners.

Urinary Tract

The postpartal woman has an increased bladder capacity, swelling and bruising of the tissues around the urethra, decreased sensitivity to fluid pressure, and decreased sensation of bladder filling. Consequently, she is at risk for overdistention, incomplete emptying, and buildup of residual urine. Women who have had an anesthetic block have inhibited neural functioning of the bladder and are more susceptible to bladder distention, difficulty voiding, and bladder infections. In addition, immediate postpartal use of oxytocin to facilitate uterine contractions following expulsion of the placenta has an antidiuretic effect. Following cessation of the oxytocin the woman will experience rapid bladder filling (Cunningham et al., 2010).

Urinary output increases during the early postpartal period (first 12 to 24 hours) because of *puerperal diuresis*. The kidneys must eliminate an estimated 2000 to 3000 ml of extracellular fluid with a normal pregnancy, which causes rapid filling of the bladder. Thus adequate bladder elimination is an immediate concern. Women with preeclampsia, chronic hypertension, and diabetes experience even greater fluid retention, and postpartal diuresis is increased accordingly.

If stasis exists, chances increase for urinary tract infection because of bacteriuria and the presence of dilated ureters and renal pelves, which persist for about 6 weeks after birth. A full bladder may also increase the tendency of the uterus to relax by displacing the uterus and interfering with its contractility, leading to hemorrhage. In the absence of infection, the dilated ureters and renal pelves return to prepregnant size by the end of the sixth week.

Hematuria, resulting from bladder or urethral trauma, may occasionally occur after birth, but the presence of lochia may mask this sign. If hematuria occurs in the second or third postpartal week, there may be a bladder infection. Acetone may be present in the urine of women with diabetes or of women with prolonged labor and dehydration. Slight (1+) proteinuria may occur during the first week following birth. However, proteinuria may be associated with an infectious process (cystitis, pyelitis), so it should be evaluated further. A urine specimen contaminated with lochia may falsely indicate proteinuria, so any specimen should be obtained as a midstream or a catheterized specimen.

Vital Signs

During the postpartum period, with the exception of the first 24 hours, the woman should be afebrile. A maternal temperature of up to 38°C (100.4°F) may occur up to 24 hours after birth as a result of the exertion and dehydration of labor. An increase in temperature to between 37.8°C and 39°C may also occur during the first 24 hours after the mother's milk comes in (Cunningham et al., 2010). However, in women not meeting these criteria, infection must be considered in the presence of an increased temperature (see chapter 39 ∞).

Immediately following delivery, many women experience a transient rise in both systolic and diastolic blood pressure, which spontaneously returns to the prepregnancy baseline over the next few days (James, 2008). A decrease may indicate physiologic readjustment to decreased intrapelvic pressure, or it may be related to uterine hemorrhage. Orthostatic hypotension, as indicated by feelings of faintness or dizziness immediately after standing up, can develop in the first 48 hours as a result of abdominal engorgement that may occur after birth. A low or decreasing blood pressure may reflect hypovolemia secondary to hemorrhage, but it is a late sign. Blood pressure elevations may result from excessive use of oxytocin or vasopressor medications. Because preeclampsia can persist into or occur first in the postpartal period, routine evaluation of blood pressure is needed. If a woman complains of headache, hypertension must be ruled out before analgesics are administered.

Puerperal bradycardia with rates of 50 to 70 beats per minute (beats/min) commonly occurs during the first 6 to 10 days of the postpartal period. It may be related to decreased cardiac strain, the decreased blood volume following placental separation, contraction of the uterus, and increased stroke volume. A pulse rate greater than 100 beats/min may be indicative of hypovolemia, infection, fear, or pain and requires further assessment.

Blood Values

Blood values should return to the prepregnant state by the end of the postpartum period. Pregnancy-associated activation of coagulation factors may continue for variable amounts of time after birth. This condition, in conjunction with trauma, immobility, or sepsis, predisposes the woman to development of thromboembolism. The incidence of thromboembolism is reduced by early mobilization. Plasma fibrinogen is maintained at pregnancy levels for a week following childbirth, accounting for the higher sedimentation rate observed in the early postpartal period.

Nonpathologic leukocytosis often occurs during labor and in the immediate postpartal period, with WBC counts up to 25,000 to 30,000/mm^3 (Cunningham et al., 2010). WBC values typically return to normal levels by the end of the first postpartal week. Leukocytosis combined with the normal increase in erythrocyte sedimentation rate may obscure the diagnosis of acute infection at this time (Whitmer, 2011).

Hemoglobin and hematocrit levels may be difficult to interpret in the first 2 days after birth because of the changing blood volume. This loss in blood in the first 24 hours accounts for half of the RBC volume gained during the course of the pregnancy. Blood loss averages 200 to 500 ml with a vaginal birth and 1000 ml or more with a cesarean birth (Rhode, 2011). Lochia constitutes less than 25% of this blood loss (James, 2008). As extracellular fluid is excreted, hemoconcentration occurs, with a concomitant rise in hematocrit. A drop in values indicates an abnormal blood loss. The following is a convenient rule to remember: a 4–3 percentage-point drop in hematocrit equals a

blood loss of 500 ml (Whitmer, 2011). After 3 to 4 days, mobilization of interstitial fluid leads to a slight increase in plasma volume. This hemodilution leads to a decrease in hemoglobin, hematocrit, and plasma protein by the end of the first postpartal week. Decreases in plasma volume reach nonpregnant levels by 1 to 2 weeks postpartum (Whitmer, 2011).

Platelet levels typically fall as a result of placental separation. They then begin to increase by the third to fourth postpartum day, gradually returning to normal by the sixth postpartum week. Fibrinolytic activity typically returns to normal during the hours following the birth. The hemostatic system as a whole reaches its normal pregnant status by 3 to 4 weeks postpartal; however, the diameter of deep veins can take up to 6 weeks to return to prepregnant levels (Blackburn, 2007). This is why there is a prolonged risk of thromboembolism in the first 6 weeks following birth.

Cardiovascular Changes

The cardiovascular system undergoes dramatic changes during birth that can result in cardiovascular instability due to an increase in cardiac output. The cardiac output typically stabilizes and returns to pregnancy levels within an hour following birth (Whitmer, 2011). Maternal hypervolemia typically occurs immediately following birth because the maternal circulation has an increase in blood volume that no longer travels through the placenta. Maternal hypervolemia acts to protect the mother from excessive blood loss. Cardiac output declines by 30% in the first 2 weeks and reaches normal levels by 6 to 12 weeks (Blackburn, 2007). Diuresis in the first 2 to 5 days helps to decrease the extracellular fluid and results in a weight loss of 3 kg (James, 2008). Failure to diurese in the immediate postpartal period can lead to pulmonary edema and subsequent cardiac problems. This is seen more commonly in women with a history of preeclampsia or preexisting cardiac problems (Blackburn, 2007; James, 2008).

Neurologic Changes and Conditions

Neurologic problems and disorders can predispose women to higher rates of morbidity and mortality during pregnancy and in the postpartum period. Headaches are the most common neurologic symptoms encountered by postpartal women. Headaches can result from fluid shifts in the first week after birth, leakage of cerebrospinal fluid into the extradural space during spinal anesthesia, pregnancy-induced hypertension, or stress (Aminoff, 2009). It is estimated that up to 40% of postpartum women develop headaches within the first week following birth (James, 2008). There may be an increased incidence in headache if the woman had spinal or epidural anesthesia. Migraine headaches, although less frequent during pregnancy, tend to resume in the postpartal period. Women with epilepsy are nine times more likely to have a seizure during labor or in the first 24 hours after birth than during pregnancy (Samuels & Niebyl, 2007). The postpartum epileptic woman is more likely to be diagnosed with depression, and referral to a therapist or support group should be made (Rousseau, 2008). The physiologic changes of pregnancy that may have required increasing antiepileptic drug (AED) dosage are now removed, and retitration of the AEDs is required to prevent toxicity. Women with multiple sclerosis (MS) and Guillain-Barré syndrome are more likely to have symptoms in the postpartum period than during pregnancy (Samuels & Niebyl, 2007). Myasthenia gravis (autoimmune disease) affects the neuromuscular junctions. The increase in symptoms during pregnancy is variable; however, the first month of pregnancy and the first month of the postpartum period are the most critical (Kalayjian & Goodwin, 2007).

Weight Loss

An initial weight loss of 10 to 12 lb occurs as a result of the birth of infant, placenta, and amniotic fluid. Puerperal diuresis accounts for the loss of an additional 5 lb during the early puerperium. By the sixth to eighth week after birth, many women have returned to approximately prepregnant weight if they gained the average 25 to 30 lb. Women often express concern about the slow pace of their postpartal weight loss. Multiparas tend to have a more positive outlook than primiparas, probably because the multipara's previous experience has prepared her for the fact that the body does not immediately return to a prepregnant state.

Postpartum Chill

Frequently the mother experiences intense tremors that resemble shivering from a chill immediately after birth. Several theories have been offered to explain this shivering: the result of sudden release of pressure on the pelvic nerves after birth, a response to a fetus-to-mother transfusion that occurred during placental separation, a reaction to maternal adrenaline production during labor and birth, or a reaction to epidural anesthesia. If not followed by fever, this chill is of no clinical concern, but it is uncomfortable for the woman. The nurse can increase the woman's comfort by covering her with a warmed blanket and reassuring her that the shivering is a common, self-limiting situation. If she allows herself to go with the shaking, the shivering will last only a short time. Some women may also find a warm drink helpful. Chills and fever later in the puerperium indicate infection and require further evaluation.

Postpartum Diaphoresis

The elimination of excess fluid and waste products via the skin during the puerperium greatly increases perspiration. Diaphoretic (sweating) episodes frequently occur at night, and the woman may awaken drenched with perspiration. This perspiration is not significant clinically, but the mother should be protected from chilling.

Afterpains

Afterpains occur more commonly in multiparas than in primiparas and are caused by intermittent uterine contractions. Although the uterus of the primipara usually remains consistently contracted, the lost tone of the uterus of the multipara results in alternate contraction and relaxation. This phenomenon also occurs if the uterus has been markedly distended, as with multiple-gestation pregnancies or hydramnios, or if clots or placental fragments were retained. These afterpains may cause the mother

severe discomfort for 2 to 3 days following birth. The administration of oxytocic agents (intravenous infusion with Pitocin or oral administration of Methergine) stimulates uterine contraction and increases the discomfort of the afterpains. Because endogenous oxytocin is released when the infant suckles, breastfeeding also increases the severity of the afterpains. A warm water bottle placed against the low abdomen may reduce the discomfort of afterpains. In addition, the breastfeeding mother may find it helpful to take a mild analgesic agent approximately 1 hour before feeding her infant. The nurse can assure the mother that the prescribed analgesic agents are not harmful to the newborn and help improve the quality of the breastfeeding experience. An analgesic agent such as ibuprofen is also helpful at bedtime if the afterpains interfere with the mother's rest. See chapter 36 ∞ for a further discussion of analgesics for afterpains.

Postpartum Psychologic Adaptations

The postpartum period is a time of readjustment and adaptation for the entire childbearing family but especially for the mother. The woman experiences a variety of responses as she adjusts to a new family member, postpartal discomforts, changes in her body image, and the reality that she is no longer pregnant. One young mother described her responses well:

> "I feel like it's the day after Christmas. I'm relieved that everything went well and I have a fine baby, but I feel so let down. I had an image of what childbirth would be like, but everything was a little different. I figured that as soon as I gave birth, I would feel fine. Why didn't someone tell me I would still be sore? The pain didn't magically disappear! When I was pregnant, everyone treated me as though I was a little fragile. Now when people call or visit, all they talk about is the baby. I don't think I'm really jealous, but I do miss the attention. During this past day I've started to realize that my life will never, ever be the same again. I've always wanted to be a mother, but I'm not really sure how to do it. Isn't that strange?"

Taking In and Taking Hold Periods

Soon after birth during the *taking-in* period, the woman tends to be passive and somewhat dependent. The new mother follows suggestions, is hesitant about making decisions, and is still rather preoccupied with her needs (Rubin, 1984). She may have a great need to talk about her perceptions of her labor and birth. This helps her work through the process, sort out the reality from her fantasized experience, and clarify anything that she did not understand. Food and sleep are major needs.

After the taking-in period, which may end by the second day, the new mother may be observed to be ready to resume control of her body, her mothering, and her life in general. Rubin (1984) labeled this phase as *taking hold.* If she is breastfeeding, the mother may worry about her technique or the quality of her milk. If her baby spits up following feeding, she may view it as a personal failure. She may also feel demoralized by the fact that the nurse or an older family member handles her baby proficiently while she feels unsure and tentative. She requires assurance that she is doing well as a mother. Today's mothers seem to be more independent and adjust more rapidly, exhibiting behaviors of "taking in" and "taking hold" in shorter time periods than those previously identified.

Becoming a Mother

Maternal role attainment (MRA) is the process by which a woman learns mothering behaviors and becomes comfortable with her identity as a mother. The formation of a maternal identity indicates that the woman has attained the maternal role. This process occurs with each child a woman bears. As the mother grows to know this child and forms a relationship with her or him, the mother's maternal identity gradually and systematically evolves, and she "binds in" to the infant (Rubin, 1984). In most cases, maternal role attainment occurs within 3 to 10 months following birth. Social support, the woman's age and personality traits, the marital or partner relationship, the presence of underlying anxiety or depression, the woman's previous childcare skills, the temperament of her infant, the gestational age and health status of her infant, her birth experience, her own health status, her self-concept, and the family's socioeconomic status all influence the woman's success in attaining the maternal role (Hill & Aldag, 2007).

Mercer proposed replacing the term *maternal role attainment* (MRA) with the term **becoming a mother (BAM)**. She stated that BAM "more accurately encompasses the dynamic transformation and evolution of a woman's persona than does MRA, and the term MRA should be discontinued" (Mercer, 2004, p. 226). BAM more accurately reflects the transition process of becoming a mother that changes throughout the maternal-child relationship (see chapter 36 ∞ for further discussion).

PROFESSIONALISM IN PRACTICE

Enhancing Patient-Centered Care

Mercer (2006) emphasized the importance of individualized dialogue beteen the mother and the nurse, which involves: "a mutual identification by the mother and the nurse of the mother's needs and the available resources among the mother's family and friends, her community, and the larger society. With the mother's input about her preferences for available assistance. . . . Appropriate referrals may be made" (p. 650). Professional nurses who follow Mercer's recommendations enhance the process of a mother and engage in patient-centered care.

Postpartum Blues

The **postpartum blues** consist of a transient period of depression that occurs during the first few days of puerperium. Symptoms may include mood swings, anger, weepiness, anorexia, difficulty sleeping, and a feeling of letdown. This mood change frequently occurs while the woman is still hospitalized, but it may occur at home as well. Changing hormone levels are certainly a factor; an unsupportive environment and insecurity

Postpartum Depression Resources

also have been identified as potential causes. In addition, fatigue, discomfort, and overstimulation may play a part. The postpartum blues usually resolve naturally within 10 to 14 days, but if they persist or if symptoms worsen, the woman may need evaluation for postpartum depression (see chapter 39 ∞). Ideally a depression assessment should be completed each trimester to update a pregnant woman's risk status (Beck, 2008). If not done previously, the nurse assesses the woman for predisposing factors during labor and the postpartum stay. Several depression scales are available for assessing postpartum depression. The routine use of a screening tool, such as the Edinburgh Postnatal Depression Scale or Postpartum Depression Predictors Inventory-Revised, is a matter-of-fact approach that significantly increases the diagnosis (Beck, 2008).

Importance of Social Support

The psychologic outcomes of the postpartum period are far more positive when the parents have access to a support network. Women and their partners may find that family relationships become increasingly important, but the increased family interaction can be a source of stress. The attention that their infant receives from family members is a source of satisfaction to the new parents. In many cases, the ties to the woman's family become especially good. Fathers may report that their relationships with their in-laws become far more positive and supportive. However, the increased family interaction can be a source of stress, especially for the new mother, who often tends to have more contact with both families.

The new parents may also have increasing contact with other parents of small children although contact with coworkers declines. Of great concern are women and their partners who have no family or friends with whom to form a social network. Isolation at a time when the woman feels an increased need for support can result in tremendous stress and is often a contributing factor in situations of postpartum depression, child neglect, or abuse. New mother support groups are helpful for women who lack a social support system.

Postpartum doulas are professionals trained to help the new mother after the birth of the baby. As a "mother's helper," postpartum doula services are tailored to help the new mother feel as rested as possible and well-nourished, and to place her household in good order so that she can focus her energy on her new baby.

Case Study: Mother-Infant Bonding

DEVELOPING CULTURAL COMPETENCE

Middle East Initial Postpartum Experience

In many patriarchal countries in the Middle East, the new mother and her infant stay with the husband's family following the birth of the infant. Frequent visits from the woman's family are discouraged and may even be viewed as burdensome by the husband's family. Typically, only women visit the new mother during the postpartum period. For the birth of the first baby, the wife's parents are expected to purchase all of the supplies and clothing for the baby.

Development of Family Attachment

A mother's first interaction with her infant is influenced by many factors, including her family of origin, her relationships, the stability of her home environment, the communication patterns she has developed, and the degree of nurturing she received as a child. These factors have shaped the person she has become. The following personal characteristics are also important:

- ***Level of trust.*** What level of trust has this mother developed in response to her life experiences? What is her philosophy of childrearing? Will she be able to treat her infant as a unique individual with changing needs that should be met as much as possible?
- ***Level of self-esteem.*** How much does she value herself as a woman and as a mother? Does she feel generally able to cope with the adjustments of life?
- ***Capacity for enjoying herself.*** Is the mother able to find pleasure in everyday activities and human relationships?
- ***Adequacy of knowledge about childbearing and childrearing.*** What beliefs about the course of pregnancy, the capacities of newborns, previous experiences with infants or children, and the nature of her emotions may influence her behavior at first contact with her infant and later?
- ***Prevailing mood or usual feeling tone.*** Is the woman predominantly content, angry, depressed, or anxious? Is she sensitive to her own feelings and those of others? Will she be able to accept her own needs and to obtain support in meeting them?
- ***Reactions to the present pregnancy.*** Was the pregnancy planned? Did it go smoothly? Were there ongoing life events that enhanced her pregnancy or depleted her reserves of energy? How were other life roles changed because of her pregnancy and motherhood?

By the time of birth, each mother has developed an emotional orientation of some kind to the baby based on these factors.

Initial Attachment Behavior

After labor and birth, a new mother demonstrates a fairly regular pattern of maternal behaviors as she continues to familiarize herself with her newborn. In a progression of touching activities, the mother proceeds from fingertip exploration of the newborn's extremities toward palmar contact with larger body areas and finally to enfolding the infant with the whole hand and arms. The time taken to accomplish these steps varies from minutes to days. The mother also increases the proportion of time spent in the **en face** position (Figure 35-4 ■). She arranges herself or the newborn so that she has direct face-to-face and eye-to-eye contact. There is an intense interest in having the infant's eyes open. When the eyes are open, the mother characteristically greets the newborn and talks in high-pitched tones to him or her.

In most instances the mother relies heavily on her senses of sight, touch, and hearing in getting to know what her baby is really like. She also tends to respond verbally to any sounds emitted by the newborn, such as cries, coughs, sneezes, and grunts. The sense of smell may be involved as well.

Figure 35-4 ■ The mother has direct face-to-face and eye-to-eye contact in the en face position.

Source: Courtesy of Joanna Allen.

While interacting with her newborn, the mother may be experiencing shock, disbelief, and denial. She may state, "I can't believe she's finally here," or, "I felt he was a stranger." However, the mother may express feelings of connectedness between the newborn and the rest of the family, either in positive or in negative terms: "She's got your cute nose, Daddy," or "Oh, no! He looks just like my first one, and he was an impossible baby." A mother's facial expression or the frequency and content of her questions may demonstrate concerns about the infant's general condition or normality, especially if her pregnancy was complicated or if a previously born baby was not healthy.

During the first few days after her child's birth, the new mother applies herself to the task of getting to know her baby. This is termed the *acquaintance phase.* If the infant gives clear behavioral cues about needs, the infant's responses to mothering will be predictable, which will make the mother feel effective and competent. Other behaviors that make an infant more attractive to caretakers are smiling, grasping a finger, breastfeeding eagerly, cuddling, and being easy to console.

During this time the newborn is also becoming acquainted. Within a few days after birth, infants show signs of recognizing recurrent situations and responding to changes in routine. To the extent that their mother is their world, they are actively acquainting themselves with her.

During the *phase of mutual regulation,* mother and infant seek to deal with the degree of control to be exerted by each in their relationship. In this phase of adjustment, a balance is sought between the needs of the mother and the needs of the infant. The most important consideration is that each should obtain a good measure of enjoyment from the interaction. During the mutual adjustment phase, negative maternal feelings are likely to surface or intensify. Because "everyone knows that mothers love their babies," these negative feelings often go unexpressed and are allowed to build up. If they are expressed, the response of friends, relatives, or healthcare personnel is often to deny the feelings to the mother: "You don't mean that." Some negative feelings are normal in the first few days after birth, and the nurse should be supportive when the mother vocalizes these feelings.

When mutual regulation arrives at the point where both mother and infant primarily enjoy each other's company, reciprocity has been achieved. **Reciprocity** is an interactional cycle that occurs simultaneously between mother and infant. It involves mutual cuing behaviors, expectancy, rhythmicity, and synchrony. The mother develops a new relationship with an individual who has a unique character and evokes a response entirely different from the fantasy response of pregnancy. When reciprocity is synchronous, the interaction between mother and infant is mutually gratifying and is sought and initiated by both partners (Reyna & Pickler, 2009).

Promoting Attachment in Special Circumstances

Newborns who require immediate care in a special care or intensive care nursery are sometimes taken from their parents immediately after birth. The separation can interfere with the normal attachment process. Consider ways to unite the parents with their newborn as soon as possible. Take into account the health status of the mother, the visitation policy of the nursery, even fear the family may have of the environment in the intensive care nursery. Perhaps the nurse or family can take digital pictures or video clips of the baby and can show them to the mother as soon as possible to reassure her of the baby's status. Education, support, and creativity may be needed to unite the parent(s) with the newborn. If the infant is in an incubator and cannot be held, encourage the parents to stroke the infant's hand, foot, or cheek. Provide reassurances that this will not hurt their infant and is in fact beneficial.

PROFESSIONALISM IN PRACTICE

Promoting Skin-to-Skin Contact

Many hospital units remove infants from their mother following birth to allow convenient assessment and performance of procedures by hospital staff despite a preponderance of evidence that supports immediate skin-to-skin contact (SSC) between mother (or father) and the newborn. Nurses are the professionals most often at the patient's bedside; they have the power and an obligation to serve as leaders and change agents by promoting clinical practices that are supported by research evidence.

Father-Infant Interactions

In Western cultures, commitment to family-centered maternity care has fostered interest in understanding the feelings and experiences of the new father. Evidence suggests that the father has a strong attraction to his newborn and that the feelings he experiences are similar to the mother's feelings of attachment (Figure 35-5 ■). The characteristic sense of absorption, preoccupation, and interest in the infant demonstrated by fathers during early contact has been termed **engrossment**. Differences in involvement still exist among fathers in Western culture and may be influenced by factors other than culture (e.g., previous experience with paternal role or exposure to male/father role models).

Figure 35-5 ■ The father experiences strong feelings of attraction during engrossment.

Source: Courtesy of Christopher Allen.

DEVELOPING CULTURAL COMPETENCE

Muslim Paternal Attachment

In some cultures there may be little involvement of the father in newborn care. In Muslim culture, for example, emphasis on childrearing and infant care activities is on the mother and female relatives. Nurses need to be aware of cultural differences when evaluating a father's interaction with his newborn.

Siblings and Others

Infants are capable of maintaining a number of strong attachments without loss of quality. These attachments may include siblings, grandparents, aunts, and uncles. The social setting and personality of the individual seem to be significant factors in the development of multiple attachments. Birth centers are especially geared toward the inclusion of the family in the birth process. In the hospital setting, the advent of open visiting hours and rooming-in permits siblings and grandparents to participate in the attachment process.

Cultural Influences in the Postpartum Period

Whereas Western culture places primary emphasis on the events of birth, many other cultures place greater emphasis on the postpartum period. For women not of the dominant American culture, the new mother's primary culture, personal values, and level of acculturation can influence her beliefs about her postpartum care. Her expectations regarding food, fluids, rest, hygiene, medications, relief measures, support, and counsel—as well as other aspects of her life—will be influenced by the beliefs and values of her family and cultural group. Sometimes a new mother's wishes will differ from the expectations of the certified nurse-midwife (CNM) or physician or nurse. (See chapter 2 ∞ for an in-depth discussion.)

All nurses belong to their particular ethnoculture and also share in the culture of health care. As a part of the healthcare cultural group, nurses implement practices that support their general beliefs, such as offering food in the recovery period following birth, providing iced fluids, expecting the woman to ambulate as soon as possible, and assuming the woman will want to shower and perhaps wash her hair soon after birth. It is important for nurses to recognize that they are approaching their patient's care from their own perspective and that, to individualize care for each mother, they need to assess the woman's preferences, her level of acculturation and assimilation to Western culture, her linguistic abilities, and her educational level (Lauderdale, 2008). In addition, the nurse should have the mother exercise her choices when possible, and support those choices, with the help of cultural awareness and a sound knowledge base.

Although describing the practices of different cultural groups always involves some generalization, it is helpful for nurses to understand some of the possible differences in beliefs and practices. Women of European heritage may expect to eat a full meal and have a large amount of iced fluids following the birth, in the belief that the food restores energy and the fluids help replace fluid lost during the labor. She may want to ambulate shortly after the birth, shower, wash her hair, and put on a fresh gown. She may expect a relatively short stay in the hospital and may or may not be interested in educational classes. Women of the Islamic faith may have specific modesty requirements; the woman must be completely covered, with only her feet and hands exposed, and no man, other than the husband or a family member, may be alone with her (Lauderdale, 2008; Reitmanova & Gustafson, 2008).

Some cultures emphasize certain postpartal routines or rituals for mother and baby that are designed to restore the hot-cold balance of the body. Some women of Hispanic, African, and Asian cultures may avoid cold after birth. This prohibition includes cold air, wind, and all water (even if heated). On the other hand, some traditional Mexican women may avoid eating "hot" foods, such as pork, just after the birth of a baby (considered a "hot" experience). It is important to note that each individual or cultural group may define hot and cold conditions as well as hot and cold foods differently. The nurse should ask each woman what she can eat and what foods she thinks would be helpful for healing. The nurse may encourage family members to bring preferred food and drink for the mother. For more detailed discussion of the hot-cold balance concept, see "Cultural Influences Affecting the Family" in chapter 2 ∞.

In many cultures, the extended family plays an essential role during the puerperium. The grandmother is often the primary helper to the mother and newborn. She brings wisdom and experience, allowing the new mother time to rest as well as giving her ready access to someone who can help with problems and concerns as they arise. It is important to ensure access of all family members during the postpartal period. Visiting rules

may be waived to allow family members or authority figures access to the mother and newborn. These practices show respect and foster a blending of old and new behaviors to meet the goals of all concerned (Purnell & Paulanka, 2008). African American mothers model their mothering skills after their older female relatives. In addition, these same older female relatives usually provide child care as needed (Purnell & Paulanka, 2008). Jewish patients may also request a kosher diet. Some traditional Jewish couples avoid physical contact while the woman is experiencing any vaginal discharge; as a result, unfortunately, the man may be viewed as unsupportive by the staff during the postpartal period (Zauderer, 2009).

DEVELOPING CULTURAL COMPETENCE

Caring for the Orthodox Jewish Couple

The orthodox Jewish couple's beliefs and practices are strictly adhered to in their dress, communication, dietary practices, and activities of daily living in the postpartum time. The nurse should assist the woman in maintaining her modesty in her dress and keeping her hair covered at all times. For the first 7 days after delivery the woman will be given special treatment and will be cared for by family members. Resting after childbirth is considered crucial for the first 6 weeks. The woman will breastfeed her newborn. The baby will not be named nor will the newborn male be circumcised until a later date after discharge from the hospital. Their Sabbath is sacred and begins at sundown on Friday evening and ends after dark on Saturday. During this time neither the man nor the woman will use electricity, travel, or write. They will not tear or cut anything. So if the woman is in the hospital during the Sabbath, the nurse should be sensitive to the fact that any forms that may need to be signed will have to be signed before or after the Sabbath. The woman will need the nurse to adjust an electric bed, turn off/on lights, and tear pieces of toilet paper for her to use. The woman will not leave the hospital and travel home until after the Sabbath (Noble, Rom, Englehardt, et al., 2009).

TABLE 35-2 Postpartum High-Risk Factors

FACTOR	MATERNAL IMPLICATION
Preeclampsia	↑ Blood pressure ↑ CNS irritability → ↑ risk for seizure ↑ Need for bed rest → ↑ risk thrombophlebitis
Diabetes	Need for insulin regulation Episodes of hypoglycemia or hyperglycemia ↓ Healing
Cardiac disease	↑ Maternal exhaustion
Cesarean birth	↑ Healing needs ↑ Pain from incision ↑ Risk of infection ↑ Length of hospitalization
Overdistention of uterus (multiple gestation, hydramnios)	↑ Risk thrombophlebitis (cesarean section [C/S] risk) ↑ Risk of problems breastfeeding (C/S risk) ↑ Risk of hemorrhage ↑ Risk of anemia ↑ Stretching of abdominal muscles ↑ Incidence and severity of afterpains
Abruptio placentae, placenta previa	Hemorrhage → anemia ↓ Uterine contractility after birth→ ↑ infection risk
Precipitous labor (less than 3 hours)	↑ Risk of lacerations to birth canal → hemorrhage
Prolonged labor (greater than 24 hours)	Exhaustion ↑ Risk of hemorrhage Nutritional and fluid depletion ↑ Bladder atony and/or trauma
Difficult birth	Exhaustion ↑ Risk of perineal lacerations ↑ Risk of hematomas ↑ Risk of hemorrhage → anemia
Extended period of time in stirrups at birth	↑ Risk of thrombophlebitis
Retained placenta	↑ Risk of hemorrhage ↑ Risk of infection

Postpartum Nursing Assessment

Comprehensive care is based on a thorough assessment, with identification of individual needs or potential problems. (See Assessment Guide: Postpartum—First 24 Hours After Birth on pages 1005–1006.)

Risk Factors

Ongoing assessment and patient education during the puerperium are designed to meet the needs of the childbearing family and to detect and treat possible complications. Table 35-2 identifies factors that may place the new mother at risk during the postpartum period. The nurse uses this knowledge during the assessment and is particularly alert for possible complications that may occur in an individual because of identified risk factors.

Physical Assessment

There are several principles to remember in preparing for and completing an assessment of the postpartum woman:

- Select the time that will provide the most accurate data. Palpating the fundus when the woman has a full bladder, for example, may give false information about the progress of involution. Ask the woman to void before assessment.
- Consider the patient's need for possible pre-medication before any painful assessments such as fundal massage.
- Provide an explanation of the purposes of regular assessment to the woman.
- Ensure that the woman is relaxed before starting; perform the procedures as gently as possible to avoid unnecessary discomfort.
- Document and report the results according to hospital/unit policy.
- Take appropriate precautions to prevent exposure to body fluids.

The physical assessment is an excellent opportunity for patient teaching. For example, when assessing the breasts of a lactating woman, the nurse can discuss breast care, breast milk production, the let-down reflex, and breast self-examination. A new mother may be very receptive to instruction on postpartum abdominal tightening exercises when the nurse assesses the woman's fundal height and diastasis. The assessment also provides an excellent

TABLE 35-3 Common Postpartum Concerns

Several postpartum occurrences cause special concern for mothers. The nurse will frequently be asked about the following events:

SOURCE OF CONCERN	EXPLANATION
Gush of blood that sometimes occurs when she first arises	Because of normal pooling of blood in vagina when the woman lies down to rest or sleep. Gravity causes blood to flow out when she stands.
Passing clots	Blood pools at top of vagina and forms clots that are passed upon rising or sitting on the toilet.
Night sweats	Normal physiologic occurrence that results as body attempts to eliminate excess fluids that were present during pregnancy. May be aggravated by plastic mattress pad.
Afterpains	More common in multiparas. Caused by contraction and relaxation of uterus. Increased by oxytocin, breastfeeding. Relieved with mild analgesics and time.
"Large stomach" after birth and failure to lose all weight gained during pregnancy	The baby, amniotic fluid, and placenta account for only a portion of the weight gained during pregnancy. The remainder takes approximately 6 weeks to lose. Abdomen also appears large because of decreased muscle tone. Postpartal exercises will help.

time to provide information about the body's postpartum physical and anatomic changes as well as common postpartum concerns (Table 35-3).

Because the time the woman spends in the postpartum unit is limited, nurses should use every available opportunity for patient teaching regarding self-care. To assist nurses in recognizing these opportunities, examples of patient teaching during the assessment have been provided throughout the following discussion.

Vital Signs

The nurse may organize the physical assessment in a variety of ways. Many nurses choose to begin by assessing vital signs because the findings are more accurate when they are obtained with the woman at rest. In addition, establishing whether the vital signs are within the expected normal range will assist the nurse in determining other assessments that might be needed. For instance, if the temperature is elevated, the nurse considers the time since birth and begins to gather information to determine whether the woman is dehydrated or whether an infection is developing.

Temperature elevations (less than 38°C [100.4°F]) due to normal processes should last for only 24 hours. The nurse should evaluate any temperature elevation in light of other signs and symptoms and should carefully review the woman's history to identify other factors, such as premature rupture of membranes (PROM) or prolonged labor that might increase the incidence of infection in the genital tract.

Alterations in vital signs may indicate complications, so they are assessed at regular intervals. After an immediate, transient rise after birth, the blood pressure should remain stable. The pulse often shows a characteristic slowness that is no cause for alarm. Pulse rates return to prepregnant norms very quickly unless complications arise.

CLINICAL TIP

During the first few hours after birth, the woman may have some orthostatic hypotension. This will cause her to have a lower blood pressure reading in a sitting position. For the most accurate reading, measure her blood pressure with the woman in the same position each time, preferably lying on her back with her arm at her side. Because of the propensity for hypotension, the nurse should assist the mother the first few times she attempts to ambulate after delivery.

The nurse informs the woman of the results of the vital signs assessment, providing information regarding the normal changes in blood pressure and pulse. This may also be an opportunity to assess whether the mother knows how to take her own and her infant's temperatures, how to read a thermometer, and how to select a thermometer from the wide variety now available.

Auscultation of Lungs

The breath sounds should be clear. Women who have been treated for preterm labor or preeclampsia are especially at risk for pulmonary edema (see "Care of Woman with a Hypertensive Disorder" in chapter 20 ∞).

Breasts

Before examining the breasts, the nurse dons gloves and then assesses the fit and support of the woman's bra. The nurse provides information about how to select a bra. A properly fitting bra provides support to the breasts and helps maintain breast shape by limiting stretching of supporting ligaments and connective tissue. If the mother is breastfeeding, the straps of the bra should be cloth, not elastic (because cloth has less stretch and provides more support) and easily adjustable. The back should be wide and have at least three rows of hooks to adjust for fit. Traditional nursing bras have a fixed inner cup and a separate half-cup that can be unhooked for breastfeeding while continuing to support the breast. Purchasing a nursing bra one size too large during pregnancy will usually result in a good fit because the breasts increase in size with milk production.

The nurse asks the woman to remove her bra so the breasts can be examined. It is important to note the size and shape of the breasts and any abnormalities, reddened areas, or engorgement. The nurse also palpates the breasts lightly for softness, slight firmness associated with filling, or firmness associated with engorgement, warmth, or tenderness. The nipples are assessed for fissures, cracks, soreness, or inversion. The nurse teaches the woman the characteristics of the breast and explains how to recognize problems such as fissures or cracks in the nipples.

The nurse assesses the nonbreastfeeding mother for evidence of breast discomfort and provides relief measures if necessary. (See discussion of lactation suppression in the nonbreastfeeding mother in chapter 36 ∞.) Breast assessment findings for a nonbreastfeeding woman may be recorded as follows: "Breasts soft, filling, no evidence of nipple tenderness or cracking, nipples everted."

ASSESSMENT GUIDE Postpartum—First 24 Hours After Birth

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
VITAL SIGNS		
Blood Pressure (BP): Should remain consistent with baseline BP during pregnancy.	High BP (preeclampsia, essential hypertension, renal disease, anxiety).	Evaluate history of preexisting disorders and check for other signs of preeclampsia (edema, proteinuria).
	Drop in BP (may be normal; uterine hemorrhage).	Assess for other signs of hemorrhage (↑ pulse, cool clammy skin).
Pulse: 50–90 beats/min. May be bradycardia if 50–70 beats/min.	Tachycardia (difficult labor and birth, hemorrhage).	Evaluate for other signs of hemorrhage (↓ BP, cool clammy skin).
	Marked tachypnea (respiratory disease).	
Respirations: 16–24/minute.	Diminished respirations (long-acting epidural narcotics).	Assess for other signs of respiratory disease.
Temperature: 36.2°C to 38°C (97.1°F to 100.4°F)	After first 24 hours, temperature of 38°C (100.4°F) or above suggests infection.	Assess for other signs of infection: notify physician or certified nurse-midwife (CNM).
BREASTS		
General Appearance: Smooth, even pigmentation, changes of pregnancy still apparent: one may appear larger.	Reddened area (mastitis).	Assess further for signs of infection.
Palpation: Depending on postpartal day, may be soft, filling, full, or engorged.	Palpable mass (caked breast, mastitis).	Assess for other signs of infection: If blocked duct, consider heat, massage, position change for breastfeeding.
	Engorgement (venous stasis).	Assess for further signs.
	Tenderness, heat, edema (engorgement, caked breast, mastitis).	Report mastitis to physician or CNM.
Nipples: Supple, pigmented, intact; become erect when stimulated.	Fissures, cracks, soreness (problems with breastfeeding), not erectile with stimulation (inverted nipples).	Reassess technique: recommend appropriate interventions.
LUNGS		
Sounds: clear to bases bilaterally.	Diminished (fluid overload, asthma, pulmonary embolus, pulmonary edema)	Assess for other signs of respiratory distress.
ABDOMEN		
Musculature: Abdomen may be soft, have a "doughy" texture; rectus muscle intact.	Separation in musculature (diastasis recti abdominis).	Evaluate size of diastasis: teach appropriate exercises for decreasing the separation.
Fundus: Firm, midline; following expected process of involution.	Boggy (full bladder, uterine bleeding, deviation from midline).	Massage until firm; assess bladder and have woman void if needed; attempt to express clots when firm.
		If bogginess remains or recurs, report to physician or CNM.
May be tender when palpated.	Constant tenderness (infection).	Assess for evidence of endometritis.
Cesarean section incision dressing; dry and intact	Moderate to large amount of blood or serosanguineous drainage on dressing.	Assess for hemorrhage. Reinforce dressing and notify healthcare provider.
LOCHIA		
Scant to moderate amount, earthy odor; no clots.	Large amount, clots (hemorrhage).	Assess for firmness, express additional clots; begin peripad count.
	Foul-smelling lochia (infection).	Assess for other signs of infection; report to physician or CNM.
Normal Progression: First 1–3 days: rubra.	Failure to progress normally or return to rubra from serosa (subinvolution).	Report to physician or CNM.
Following rubra: Days 3–10: serosa (alba seldom seen in hospital).		
PERINEUM		
Slight edema and bruising in intact perineum.	Marked fullness, bruising, pain (vulvar hematoma).	Assess size; apply ice glove or ice pack, analgesic and anesthetic sprays; report to physician or CNM.
Episiotomy: No redness, edema, ecchymosis, or discharge, edges well approximated.	Redness, edema, ecchymosis, discharge, or gaping stitches (infection).	Encourage sitz baths; review perineal care, appropriate wiping techniques.
Hemorrhoids: None present; if present, should be small and nontender.	Full, tender, inflamed hemorrhoids.	Encourage sitz baths, side-lying position; Tucks pads, anesthetic ointments, manual replacement of hemorrhoids, stool softeners, increased fluid intake.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing action.

(continued)

ASSESSMENT GUIDE Postpartum—First 24 Hours After Birth continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
COSTOVERTEBRAL ANGLE (CVA) TENDERNESS		
None.	Present (kidney infection).	Assess for other symptoms of urinary tract infection (UTI): obtain clean-catch urine sample; report to physician or CNM.
LOWER EXTREMITIES		
No pain with palpation; negative Homans' sign.	Positive findings (thrombophlebitis).	Report to physician or CNM.
ELIMINATION		
Urinary Output: Voiding in sufficient quantities at least every 4–6 hours; bladder not palpable.	Inability to void (urinary retention). Urgency, frequency, dysuria (UTI).	Employ nursing interventions to promote voiding; if not successful, obtain order for catheterization. Report symptoms of UTI to physician or CNM.
Bowel Elimination: Should have normal bowel movement by second or third day after birth.	Inability to pass feces or hard, small amount of stool (constipation due to fear of pain from episiotomy, hemorrhoids, perineal trauma).	Encourage fluids, ambulation, roughage in diet; sitz baths to promote healing of perineum; obtain order for stool softener.
Cultural Assessment‡	**Variations to Consider**	**Nursing Responses to Data†**
Determine customs and practices regarding postpartum care. Ask the mother whether she would like fluids and ask what temperature she prefers. Ask the mother what foods or fluids she would like. Ask the mother whether she would prefer to be alone during breastfeeding.	Individual preference may include: • Room-temperature or warmed fluids rather than iced drinks. • Special foods or fluids to hasten healing after childbirth. • Some women may be hesitant to have someone with them when their breast is exposed.	Provide for specific request if possible. If woman is unable to provide specific information, the nurse may draw from general information regarding cultural variation. Mexican women may want food and fluids that restore hot-cold balance to the body. Women of European background may ask for iced fluids. Provide privacy as desired by mother.
PSYCHOLOGIC ADAPTATION		
During First 24 Hours: Passive; preoccupied with own needs; may talk about her labor and birth experience; may be talkative, elated, or very quiet.	Very quiet and passive; sleeps frequently (fatigue from long labor; feelings of disappointment about some aspect of the experience; may be following cultural expectation).	Provide opportunities for adequate rest; provide physical comfort measures; provide nutritious meals and snacks that are consistent with what the woman desires to eat and drink; provide opportunities to discuss birth experience in nonjudgmental atmosphere if the woman desires to do so.
Usually by 12 hours; beginning to assume responsibility; some women eager to learn; others easily feel overwhelmed.	Excessive weepiness, mood swings, pronounced irritability (postpartum blues; feelings of inadequacy); culturally prescribed behavior.	Explain postpartum blues; provide supportive atmosphere; determine support available for mother; consider referral for evidence of profound depression.
ATTACHMENT		
En face position; holds baby close; cuddles and soothes; calls by name; identifies characteristics of family members in infant; may be awkward in providing care. Initially may express disappointment over sex or appearance of infant but within 1–2 days demonstrates attachment behaviors.	Continued expressions of disappointment in sex, appearance of infant; refusal to care for infant; derogatory comments; lack of bonding behaviors (difficulty in attachment, following expectations of cultural/ethnic group).	Provide reinforcement and support for infant caretaking behaviors; maintain nonjudgmental approach and gather more information if caretaking behaviors are not evident.
PATIENT EDUCATION		
Demonstrates basic understanding of self-care activities and infant care needs; can identify signs of complications that should be reported.	Unable to demonstrate basic self-care and infant care activities (knowledge deficit; postpartum blues; following prescribed cultural behavior and will be cared for by grandmother or other family member).	Identify predominant learning style. Determine whether woman understands English and provide interpreter if needed; provide reinforcement of information through conversation and through written material (remember that some women and their families may not be able to understand written materials because of language difficulties or inability to read); provide information regarding infant care skills that are culturally consistent; give woman opportunity to express her feelings and demonstrate skills taught; consider social service home referral for women who have no family or other support, are unable to take in information about self-care and infant care, and demonstrate no caretaking activities.

‡These are only a few suggestions. It is not our intent to imply this is a comprehensive cultural assessment.

*Possible causes of alterations are identified in parentheses.

†This column provides guidelines for further assessment and initial nursing action.

CLINICAL TIP

An easy way to remember the components specific to the postpartum examination is to remember the term BUBBLEHE: B-breast, U-uterus, B-bladder, B-bowel, L-lochia, E-episiotomy/laceration, H-Homans'/hemorrhoids, and E-emotional.

Abdomen and Fundus

The woman should void before her abdomen is examined. This practice ensures that a full bladder is not causing displacement of the uterus or any uterine atony; if atony is present, other causes (such as uterine relaxation associated with a regional block, overstretched uterus, or distended bladder) must be investigated.

The nurse determines the relationship of the fundus to the umbilicus and also assesses the firmness of the fundus. The top of the fundus is measured in fingerbreadths above, below, or at the umbilicus. The nurse notes whether the fundus is in the midline or displaced to either side of the abdomen. If not midline, the uterus position should be located. The most common cause of displacement is a full bladder; thus this finding requires further assessment. If the fundus is in the midline but higher than expected, it is usually associated with clots within the uterus. The results of the assessment should then be recorded. (See Procedure 35-1: Assessing the Status of the Uterine Fundus After Vaginal or Cesarean Birth).

While completing the assessment, the nurse teaches the woman about fundal position and how to determine firmness. The mother can be taught to massage her fundus gently if it is not firm.

CLINICAL TIP

Assessing the status of the uterine fundus may be uncomfortable. In addition to explaining the importance of the assessment to the mother, you can show her how to perform frequent light massage of the fundus herself to promote uterine involution. She may be delighted to be able to feel the difference between where the fundus is now and where "the top of the uterus" was just prior to delivery. Involving her in her own care encourages her participation. In addition, having her massage her own uterus may lessen bleeding and reduce the need for more thorough massage.

A well-contracted uterus feels as firm as the uterus does during a strong labor contraction. If handled gently, the uterus should not be overly tender. Excessive pain in the uterus during postpartal examination should alert the nurse to possible uterine infection. If the uterus is not firm, the nurse should gently massage the fundus with the fingertips of the examining hand, and then assess the results. If the uterus becomes firm, the chart should read: "Uterus: boggy → firm with light massage." A good habit for the nurse to develop during the postpartal examination is to have the woman lie flat on her back with her head on a pillow and legs flexed. Then the nurse can release the perineal pad to observe the results of uterine massage based on the amount of expelled blood. Occasionally, oxytocic agents, such as an intravenous Pitocin infusion or methylergonovine maleate (Methergine), need to be administered postpartally to maintain uterine contraction and prevent or treat hemorrhage (see Drug Guide: Methylergonovine Maleate [Methergine] in chapter 36 ∞).

CLINICAL TIP

During postpartum assessment, a firm uterus typically feels like a grapefruit because the muscles are well contracted. If the uterus loses its ability to contract and begins to relax, it is called boggy. A boggy uterus feels softer, like a sponge, or may become so relaxed that you cannot feel it at all. If the uterus is boggy but you can still feel it, massage it until it becomes firm. If you cannot feel it at all, place the side of one hand just above the woman's symphysis pubis to provide stability. Then place the other hand at the level of the umbilicus. (The fundus may have risen to this level because it is relaxed and filling with blood.) Press deeply into the abdomen and massage in a circular motion. You will usually feel the uterus begin to firm up under your hand. If you do not, move your hand slightly lower on the abdomen, and repeat the process.

A boggy uterus that does not contract with light, gentle massage may need more vigorous massage. The nurse assesses the amount and character of any expelled blood obtained while massaging the fundus. When a woman has postpartal uterine atony (the uterus does not remain firm), the nurse should do the following:

1. Reevaluate for full bladder; if the bladder is full, have the woman void.
2. Question the woman on her bleeding history since the birth or last examination. How heavy does her flow seem? Has she passed any clots? How frequently has she changed pads? Were the pads saturated? Look at the discarded pads.
3. For the breastfeeding mother, put the newborn to the mother's breast for feeding to stimulate oxytocin production.
4. Assess maternal blood pressure and pulse to identify hypotension.
5. Reassess the fundus; if the fundus is still boggy, alert the certified nurse-midwife (CNM) or physician immediately, because further interventions, such as intravenous fluids and an oxytocic medication, are needed.

In the woman who has had a cesarean birth, the abdominal incision is exquisitely tender. The nurse should palpate the fundus with extreme care and inspect the abdominal incision for signs of healing, such as approximation (absence of separation between edges of incision), bleeding, and for any signs of infection, including drainage, edema, foul odor, or redness. It is important to document whether internal sutures, steri-strips, or staples are intact. During the assessment, the nurse teaches the woman about her incision. The nurse can also review characteristics of normal healing, incision care, and discuss signs of infection.

Lochia

Lochia is then assessed for character, amount, odor, and the presence of clots. The nurse must wear disposable gloves when assessing the perineum and lochia. Nurses may put on

PROCEDURE 35-1 Assessing the Status of the Uterine Fundus After Vaginal or Cesarean Birth

NURSING ACTION

Preparation

- Consider offering to pre-medicate 30–45 minutes before assessing the fundus, especially if the patient has had a cesarean section.

  Rationale: *The postoperative area will be very tender, and she may be very fearful of the potential pain.*

- Explain the procedure, the information it provides, and what it might feel like.
- Ask the woman to void.

  Rationale: *A full bladder can cause uterine atony.*

- Have the woman lie flat in bed with her head on a pillow. If the procedure is uncomfortable, she may find that it helps to flex her legs. Flexing the legs and providing support under them with folded pillows is especially helpful with post–cesarean section patients.

  Rationale: *The supine position prevents falsely high assessment of fundal height. Flexing the legs relaxes the abdominal muscles.*

Equipment and Supplies

- A clean perineal pad (see Procedure 35-2)

> **CLINICAL TIP**
> Gloves may be put on before assessing the abdomen and fundus or when you are ready to assess the perineum and lochia.

Procedure

1. Gently place one hand on the lower segment of the uterus. Using the side of the other hand, palpate the abdomen until you locate the top of the fundus.

   Rationale: *One hand stabilizes the uterus while the other hand locates the top of the fundus. (Support of the uterus prevents stretching of the ligaments that support the uterus.)*

2. Determine whether the fundus is firm. If it is, it will feel like a hard round object (similar to a grapefruit) in the abdomen. If it is not firm, massage the abdomen lightly until the fundus is firm.

   Rationale: *A firm fundus indicates that the uterine muscles are contracted and bleeding will not occur.*

3. Measure the top of the fundus in fingerbreadths above, below, or at the fundus. See Figure 35-6 ■.

   Rationale: *Fundal height gives information about the progress of involution.*

4. Determine the position of the fundus in relation to the midline of the body. If it is not in the midline, locate it and then evaluate the bladder for distention.

   Rationale: *The fundus may deviate from the midline when the bladder is full because the enlarged bladder pushes the uterus aside.*

5. If the bladder is distended, use nursing measures to help the woman void. If she is not able to void after a specified period of time, catheterization may be necessary.
6. Measure urine output for the next few hours until normal elimination is established.

   Rationale: *During the postpartum as diuresis occurs, the bladder may fill far more rapidly than normal, putting the woman at risk for uterine atony and hemorrhage. (Diminished tone of the uterus may cause loss of the urge to void.)*

7. Assess the lochia (see Procedure 35-2).
8. During the first few hours postpartum, if the fundus becomes boggy frequently or is located high above the umbilicus and the woman's bladder is empty, the uterine cavity may be filled with clots of blood. In this case, do the following:
   - Release the front of the perineal pad and lay it back so that you can see the perineum and the pad laying between the woman's legs.
   - *Massage* the uterine fundus until it is firm.
   - Keep one hand in position, stabilizing the lower portion of the uterus. With the hand you used to massage the fundus, put steady pressure on the top of the now-firm fundus and see if you are able to express any clots. (Watch the pad between her legs for clots to pass from the vagina.)

Figure 35-6 ■ Measuring the descent of the fundus for the woman having a vaginal birth. The fundus is located two fingerbreadths below the umbilicus. Always support the bottom of the uterus during any assessment of fundus.

PROCEDURE 35-1 Assessing the Status of the Uterine Fundus After Vaginal or Cesarean Birth continued

NURSING ACTION

Rationale: *If the woman's uterus is filled with blood, it acts as an irritant and the uterus will not remain contracted. When the muscle fibers relax, bleeding results, further aggravating the problem. Pushing on a uterus that is not firm is dangerous because it is possible to cause the uterus to invert, a true emergency.*

9. If measurement of the blood loss is needed, the perineal pads and Chux can be weighed. See Procedure 35-2.
10. Provide the woman with a clean perineal pad.
11. Record findings. Fundal height is recorded in fingerbreadths (e.g., "2 FB ↓ U" or "1 FB ↑ U"). If fundal massage was necessary, note that fact: "Uterus boggy → firm with light massage."
12. Communicate bogginess or heavy flow to primary provider.
13. If the patient is post–cesarean section, inspect the abdominal incision for signs of healing, such as approximation, bleeding, and for any signs of infection, including drainage, edema, foul odor, or redness. Observe whether internal sutures, steri-strips, or staples are intact. If dressing is in place over the incision, observe for the dressing to be clean, dry, and intact.

    Rationale: *If drainage is present on the dressing, mark the outline of the drainage and reevaluate 30 minutes later for further bleeding or drainage.*
14. Document findings according to hospital or unit policy.
15. Communicate active bleeding, increasing drainage, redness, foul odor, or incision edges not approximated to primary care provider.

RESEARCH EVIDENCE IN PRACTICE Assessing Risk of Postpartum Hemorrhage

CLINICAL QUESTION

What nursing assessments can identify risk factors and early signs of hemorrhage?

RESEARCH EVIDENCE

Postpartum hemorrhage is the leading cause of pregnancy-related death, causing more than 140,000 maternal deaths a year worldwide. Besides death, postpartum hemorrhage is a significant cause of pregnancy-related morbidity, and is the primary reason for postpartum hysterectomy.

The National Collaborating Center for Primary Care convened a group of obstetric experts to review research literature and develop guidelines for postnatal assessments. While these guidelines do not recommend routine postpartum palpation or measurement of the uterus, assessment of uterine involution and position should be undertaken in women with excessive vaginal blood loss, abdominal tenderness, or fever in the postpartum period. Excessive blood loss is defined as greater than 500 ml for a vaginal birth and more than 1000 ml for a cesarean birth.

Blood loss may be indicated by a mother's complaints of faintness, dizziness, palpitations, or "heart racing." Sudden or profuse blood loss, or blood loss accompanied by signs of shock, should be evaluated as an emergency condition. Diagnostic indications of postpartum hemorrhage include a hematocrit drop of greater than 10%, need for blood transfusion, and hemodynamic instability.

Multiple epidemiological and cross-sectional studies have identified risk factors for postpartum hemorrhage. These factors include labor related causes (induction of labor, precipitous or prolonged labor), uterine overdistention (multiple pregnancies or polyhydramnios), genital tract trauma due to instrument births or cesarean birth, retained placenta or clots, coagulation disorders, and placenta previa. Women who had a third stage of labor longer than 18 minutes had a higher risk of postpartum hemorrhage, and those women with a third stage longer than 30 minutes had a sixfold increase in risk of hemorrhage.

One study focused on risk factors associated with postpartum hysterectomy due to abnormal bleeding. These researchers found that multiparous women with a history of cesarean birth, or women with abnormal placental implantation, were at highest risk for surgical removal of the uterus after birth.

WHAT QUESTIONS REMAIN UNANSWERED?

Many normal vaginal births result in blood loss greater than 500 ml, which has led to questions as to whether this is an appropriate threshold for considering postpartum hemorrhage. What is an appropriate amount of blood loss to expect in a normal vaginal birth?

WHAT IS BEST PRACTICE?

Abdominal palpation of the uterus is not necessary as a routine postpartum assessment after a normal birth. New mothers should be assessed for signs of blood loss, including complaints of faintness, dizziness, or palpitations. Sudden or profuse blood loss, or persistent blood loss after birth, may indicate an emergency situation. Intensive assessment should be focused on women with risk factors for hemorrhage or postpartum hysterectomy.

CRITICAL THINKING

What maternal signs and symptoms should trigger an abdominal assessment for uterine involution and position?

the gloves before beginning the assessment, just before assessing the abdomen and fundus, or when they are ready to assess the perineum and lochia. During the first 1 to 3 days, the lochia should be rubra. A few small clots are normal and occur as a result of blood pooling in the vagina. However, the passage of numerous or large clots is abnormal, and the cause should be investigated immediately. After 2 to 3 days, the lochia becomes serosa.

Lochia should never exceed a moderate amount, such as that needed to partially saturate four to eight peri-pads daily, with an average of six. However, because this number is influenced by an individual woman's pad changing practices, as well as the absorbency of the pad, the nurse must consider the length of time the current pad has been in use, the parity, and the size of the baby and ask whether the amount is normal compared with her typical menstrual period, and whether any clots were passed before the examination, such as during voiding. If heavy bleeding is reported but not seen, the nurse asks the woman to put on a clean perineal pad and reassesses the discharge in 1 hour (see Procedure 35-2 and Figure 35-7 ■).

When a more accurate assessment of blood loss is needed, the perineal pads can be weighed, with 1 g considered equivalent to 1 ml blood.

Clots and heavy bleeding may be caused by uterine relaxation (atony), retained placental fragments, or, rarely, an unknown cervical laceration (seen as heavy bleeding but with firm fundus) that may require further assessment (Table 35-4). Because of the evacuation of the uterine cavity during cesarean birth, women with such surgery usually have less lochia after the first 24 hours than mothers who give birth vaginally. If the woman is at increased risk for bleeding or is actually experiencing heavy flow of lochia rubra, her blood pressure, pulse, and uterus need to be assessed frequently, and the physician may prescribe oxytocin (Pitocin) or methylergonovine maleate (Methergine). See Drug Guide: Methylergonovine Maleate (Methergine) in chapter 36 ∞.

CLINICAL TIP

The parity, length of time since delivery, method of delivery, size of baby/gestation (and other factors that could cause hyperextension of the uterus such as multiple gestation, polyhydramnios, large-for-gestational age, etc.), *must* be considered when deciding whether the amount and color of the lochia is appropriate.

The odor of the lochia is nonoffensive and never foul. If foul odor is present, so is an infection. When using narrative nursing notes, document the amount of lochia first, followed by character. For example:

- Lochia: moderate rubra
- Lochia: small rubra/serosa

Patient teaching that the nurse may address during assessment of the lochia can center on normal changes, effect of position changes on or what can be expected in the amount and color of the flow. Hygienic measures, such as wiping the perineum from front to back and washing her hands after toileting and changing pads, may be reviewed if appropriate. The nurse should approach the timing of teaching hygienic practices delicately, along with the content to be included. By establishing positive goals for the teaching—promoting comfort, enhancing tissue healing, and preventing infection—the nurse can avoid value-laden statements regarding personal beliefs about the need for cleanliness or control of body odor. The nurse should review with the mother the need to notify a healthcare professional if there is regression in the lochia flow pattern (i.e., color or amount).

Perineum

The perineum is inspected with the woman lying in Sims' position. The buttock is lifted to expose the perineum and anus.

If an episiotomy was performed or a laceration required suturing, the nurse assesses the wound. To evaluate the state of healing, the nurse inspects the wound for redness, edema, ecchymosis, discharge, and approximation. After 24 hours, some edema may still be present, but the skin edges should be approximated ("glued" together) so that gentle pressure does not separate them. Gentle palpation should elicit minimal tenderness, and there should be no hardened areas suggesting infection. Ecchymosis interferes with normal healing, as does infection. Foul odors associated with drainage indicate infection. Hematomas sometimes occur, although these are considered abnormal. The nurse next assesses whether hemorrhoids are present around the anus. If present, they are assessed for size, number, and pain or tenderness (see Procedure 35-3 and Figure 35-8 ■).

During the assessment, the nurse talks with the woman to determine the effectiveness of comfort measures that have been used. The nurse provides teaching about the episiotomy or perineal laceration. Some women do not thoroughly understand what an episiotomy is and where it is and may believe that the stitches must be removed, as with other types of surgery. Frequently, when women fear that the stitches must be removed manually, they are afraid to ask about them. While explaining the findings

TABLE 35-4 Changes in Lochia That Cause Concern

CHANGE	POSSIBLE PROBLEM	NURSING ACTION
Presence of clots	Inadequate uterine contractions that allow bleeding from vessels at the placental site.	Assess location and firmness of fundus. Assess voiding pattern. Record and report findings.
Persistent lochia rubra	Inadequate uterine contractions; retained placental fragments; infection; undetected cervical laceration.	Assess location and firmness of fundus. Assess activity pattern. Assess for signs of infection. Record and report findings.

PROCEDURE 35-2 Evaluating Lochia

NURSING ACTION

Preparation

- Explain why lochia occurs, why it is assessed, how it is assessed, and how it changes during the postpartum.
- Ask the woman to void.

  Rationale: *A full bladder can cause uterine atony and increase the amount of lochia.*
- Complete the assessment of uterine fundal height and firmness.

  Rationale: *In almost all cases, fundal height and firmness are evaluated with an assessment of lochia. This practice provides a more thorough assessment.*
- If she has not already done so for the fundal assessment, ask the woman to flex her legs. Then ask her to spread her legs apart. Use the bed sheet as a drape to preserve her modesty.

  Rationale: *This position allows you to see the perineum and the perineal pad more effectively.*

Equipment and Supplies

Note: *Gloves are put on before assessing the perineum and lochia.*

- Gloves
- Clean perineal pad

Procedure: Clean Gloves

1. Don gloves.
2. Lower the perineal pad and observe the amount of lochia on the pad. Because women's pad-changing practices vary, ask her about the length of time the current pad has been in use, whether the amount is normal, and whether any clots were passed before this examination, such as during voiding.

   Rationale: *During the first 1 to 3 days the woman's lochia should be rubra, which is dark red in color. A few small clots are normal and occur as a result of pooling of blood in the vagina when the woman is lying down. The passage of large clots is abnormal and the cause should be investigated immediately.*
3. If the woman reports heavy bleeding or clots, ask her to put on a clean perineal pad and then reassess the pad in 1 hour. Also ask her to call you before flushing any clots she passes into the toilet during voiding.
4. When the uterine fundus is firm and stabilized with the nondominant hand, press down on it with the dominant hand while watching to see if any clots are expelled. (See Procedure 35-1, step 8.)
5. Determine the amount of lochia, using the following guide (see Figure 35-7):
   - Heavy amount—Perineal pad has a stain larger than 6 inches in length within 1 hour; 30 to 80 ml lochia.
   - Moderate amount—Perineal pad has a stain less than 6 inches in length within 1 hour; 25 to 50 ml lochia.
   - Small (light) amount—Perineal pad has a stain less than 4 inches in length after 1 hour; 10 to 25 ml lochia.
   - Scant amount—Perineal pad has a stain less than 1 inch in length after 1 hour or lochia is only on tissue when the woman wipes.

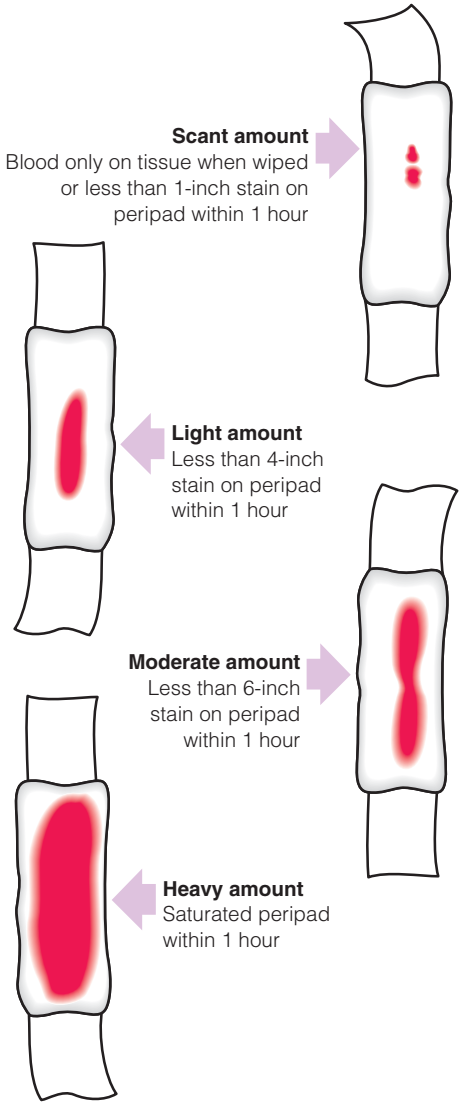

Figure 35-7 ■ Suggested guidelines for assessing lochia volume.

Source: Jacobson, H. A standard for assessing lochia volume. American Journal of Maternal/Child Nursing, 10, *174–175, May–June 1985. Copyright © Lippincott Williams & Wilkins. Reprinted with permission.*

   Rationale: *Lochia should never exceed a moderate amount such as four to eight partially saturated perineal pads daily. Using a consistent standard for measuring lochia improves the accuracy of the information charted and conveyed to others.*
6. In most cases, a woman is discharged while her lochia is still rubra. Provide her with information about lochia serosa and lochia alba.

   Rationale: *Accurate discharge information enables the woman to assess herself more accurately and enables her to judge better when to contact her caregiver.*
7. Document the findings according to hospital/unit policy. For example, "Uterus firm, 1 FB ↓ U, Lochia: moderate rubra, no clots passed."

PROCEDURE 35-3 Postpartum Perineal Assessment

NURSING ACTION

Preparation

- Explain the purpose and the procedure for assessing the perineum during the postpartum period.
- Complete the assessment of fundal height and lochia as described in Procedures 35-1 and 35-2.

  Rationale: *Typically, perineal assessment follows the fundal and lochial assessment.*
- At this point in a postpartum assessment, the woman is lying on her back with her knees flexed. Her perineal pad has already been lifted away from her perineum to permit inspection of the lochia. If an episiotomy was performed or if the birth was difficult, the woman may be using an ice pack on her perineum to reduce swelling. The ice pack would also have been removed for inspection of the lochia.
- Ask her to turn onto her side with her upper knee drawn forward and resting on the bed (Sims' position).

  Rationale: *When the woman is supine, even with her knees flexed, it is very difficult to expose the posterior portion of the perineum. Thus, Sims' position makes it easiest to inspect the perineum and anal area.*

Equipment and Supplies

Clean perineal pad, clean ice pack if desired or needed

Small light source such as a penlight may be necessary

Procedure: Clean Gloves

1. Use a systematic approach to assessment.

   Rationale: *A systematic approach helps ensure that you do not overlook a significant finding.*
2. In evaluating the perineum, begin by asking the woman's perceptions. How does she describe her discomfort? Does it seem excessive to her? Has it become worse since the birth? Does it seem more severe than you would expect?

   Rationale: *Information from the patient herself often helps identify developing problems.*

*(**Note:** Pain that seems disproportionately severe may indicate that the woman is developing a vulvar hematoma.)*

> **CLINICAL TIP**
>
> In evaluating the perineum, use the REEDA scale as a quick reminder of what to assess.
>
> Specifically:
>
> R = redness
> E = edema or swelling
> E = ecchymosis or bruising
> D = drainage
> A = approximation (how well the edges of an incision—the episiotomy—or a repaired laceration seem to be holding together)
>
> Be prepared to respond appropriately to findings.

3. After talking with the woman, assess the condition of the tissue. To allow for full visualization, it may be helpful to ask the woman to lift the knee of her upper leg to expose her perineum more fully. In some cases it may help to use the nondominant gloved hand to lift the buttocks and tissue. Note any swelling (edema) and bruising (ecchymosis).

   Rationale: *The tissue is often traumatized by the birth and mild bruising is not unusual. However, excessive bruising may indicate that a hematoma is developing.*
4. Evaluate the episiotomy, if there is one, or any repaired laceration for its state of healing. Is it reddened? Note the edges of the incision. Are they well approximated? Tell the woman that you are going to palpate the incision gently, then do so. Note any areas of hardness. Note whether the incision is warmer to the touch than the surrounding tissue.

   Rationale: *Gentle palpation should elicit minimal tenderness and there should be no redness, warmth, or areas of hardness, which suggest infection. Both bruising and infection interfere with normal healing. Typically, within 24 hours the edges of the incision should be "glued" together (well approximated).*
5. During the assessment be alert for odors. Typically the lochia has an earthy, but not unpleasant, smell that is easily identifiable.

   Rationale: *A foul odor associated with drainage often indicates infection.*
6. Finally, assess for hemorrhoids. To visualize the anal area, lift the upper buttocks to fully expose the anal area. (See Figure 35-8.) If hemorrhoids are present, note the size, number, and pain or tenderness.

Figure 35-8 ■ Intact perineum with hemorrhoids.

PROCEDURE 35-3 Postpartum Perineal Assessment continued

NURSING ACTION

Rationale: *Hemorrhoids often develop during pregnancy or labor and can cause considerable discomfort. If hemorrhoids are present, the woman may benefit from available comfort measures.*

7. During the assessment, talk to the woman about the effectiveness of comfort measures being used. Provide teaching about care of the episiotomy, hemorrhoids, and the like.

   Rationale: *Health teaching is an important part of nursing care. Many women have concerns about the episiotomy and may not know, for example, that the suture used is dissolvable. This is an excellent time to provide information about good healthcare practices for both the short and long term.*

8. Provide the woman with a clean perineal pad. Replenish the ice pack if necessary.

9. Document findings according to hospital or unit policy. For example: "Midline episiotomy; no edema, ecchymosis, or tenderness. Skin edges well approximated. Woman reports pain relief measures are controlling discomfort"; or "Perineal repair, is approximated, minimal edema, no ecchymosis or tenderness; ice pack to perineum relieves pain."

of the assessment, the nurse can provide information about the episiotomy, its location, and signs that are being assessed. In addition, the nurse can casually add that the sutures are special and will dissolve slowly over the next few weeks as the tissues heal. By the time the sutures are dissolved, the tissues are strong, and the incision edges will not separate. This is also an opportunity to teach comfort measures that may be used and reinforce the need to consult with the healthcare provider before using over-the-counter (OTC) medications or supplements if breastfeeding (see "Relief of Perineal Discomfort" in chapter 36 ∞).

Lysine, an essential amino acid, has been identified as a supplement that decreases the incidence of pain following an episiotomy. Lysine is available as a supplement. The recommended adult dosage is 12 mg/kg of body weight per day. It is present in dietary sources, including meat, cheese, fish, eggs, soybeans, and nuts.

An example of documentation of a perineal assessment might read: "Midline episiotomy; no edema, tenderness, or ecchymosis present. Skin edges are approximated"; or, if a perineal laceration repair, "Skin edges intact, no edema, tenderness or ecchymosis, pain meds helpful. Woman reports sitz bath and Tucks pads or pain relief measures are controlling discomfort."

Lower Extremities

Postpartal women are at increased risk for thrombophlebitis, thrombus formation, and inflammation involving a vein (see "Care of the Woman with Postpartum Thromboembolic Disease" in chapter 39 ∞). If thrombophlebitis occurs, the most likely site will be the woman's legs. Conditions that predispose a patient for thrombophlebitis are hypercoagulability, severe anemia, obesity, and traumatic delivery. To assess for thrombophlebitis, the nurse should have the woman stretch her legs out, with the knees slightly flexed and the legs relaxed. The nurse then grasps the foot and dorsiflexes it sharply. The second leg is assessed in the same way. No discomfort or pain should be present. If pain is elicited, the nurse notifies the CNM or physician that the woman has a positive Homans' sign (see Figure 35-9 ■). The pain is caused by inflammation of a vessel. The nurse also evaluates the legs for edema by comparing both legs, because usually only one leg is involved. Any areas of redness, tenderness, and increased skin temperature are also noted.

Figure 35-9 ■ Homans' sign: With the woman's knees flexed, the nurse dorsiflexes the foot. Pain in the foot or leg is a positive Homans' sign.

Source: Photographer, Elena Dorfman.

Some facilities have discontinued performing a Homans' sign in the nursing assessment, stating that it is not diagnostic and could lead to an embolus if the clot is dislodged during assessment. Although assessment of Homans' sign is not diagnostic, supporters advocate its use as a screening tool. There are no published reports of an embolus occurring as a result of performing a Homans' sign. In the event of a positive Homans' sign, diagnosis is made by compression or duplex ultrasonography. Low-dose heparin therapy is used in postpartal women who develop a deep vein thrombosis (Cunningham et al., 2010; James, 2008).

Early ambulation is an important aspect of preventing thrombophlebitis. Most women are able to get up shortly after birth or once they have fully recovered from the effects of the regional anesthetic agent, if one has been used. The mother's legs should be assessed for return of sensation following regional anesthesia. The cesarean birth patient requires passive range-of-motion exercises until she is ambulating more freely.

Patient teaching associated with assessment of the lower extremities focuses on the signs and symptoms of thrombophlebitis. In addition, the nurse may review self-care measures to promote circulation and prevent thrombophlebitis,

Care Plan Activity: Postpartum Patient Requesting Relief

such as leg exercises that may be performed in bed, dorsiflexion on an hourly basis while on bed rest, ambulation, avoiding pressure behind the knees, and avoiding crossing the legs.

Usually, the nurse records the results of the assessment on a flowsheet or a summary nursing note. If tenderness and warmth have been noted, they might be recorded as follows: "Tenderness, warmth, slight edema, and slight redness noted on posterior aspect of left calf—positive Homans'. Woman advised to avoid pressure to this area; lower leg elevated and moist heat applied per agency protocol. Call placed to Dr. Garcia to report findings."

Elimination

During the hours after birth, the nurse carefully monitors a new mother's bladder status. A boggy uterus, displaced uterus, or a palpable bladder are a sign of bladder distention and requires nursing intervention.

The postpartum woman can quickly show signs of bladder distention, possibly as soon as 1 to 2 hours after childbirth. This distention results because of normal postpartal diuresis. The nurse should assess the bladder for distention frequently until the woman is able to completely empty her bladder with each voiding. The nurse may employ techniques to facilitate voiding, such as helping the woman out of bed to void, pouring warm water on the vulva, running water in the sink, and encouraging the woman to relax and take deep breaths. The physician will order catheterization when the bladder is distended and the woman cannot void, when she is voiding small amounts (less than 100 ml) frequently, or when no voiding has occurred in 8 hours. Although many physicians or CNMs write orders stating that the woman can be catheterized in 8 hours if she has not voided, the nurse needs to assess the bladder and any voiding pattern frequently before the end of the 8-hour period. Some women may require catheterization sooner. The cesarean birth mother may have an indwelling catheter inserted prophylactically. The nurse should perform the same assessments in evaluating bladder emptying once the catheter is removed.

During the physical assessment, the nurse elicits information from the woman regarding the adequacy of her fluid intake, whether she feels she is emptying her bladder completely when she voids, and any signs of UTI she may be experiencing.

In the same way, the nurse obtains information about the new mother's intestinal elimination and any concerns she may have about it. Many mothers fear that the first bowel movement will be painful and possibly even damaging if an episiotomy has been performed. If a woman has a bowel movement during labor or delivery, bowel motility will normally return within 2 to 3 days after a vaginal childbirth. Stool softeners may be ordered to increase bulk and moisture in the fecal material and to allow more comfortable and complete evacuation. Constipation may cause pressure on sutures and increase discomfort and therefore should be prevented. Encouraging ambulation, forcing fluids (up to 2000 ml/day or more), and providing fresh fruits and roughage in the diet enhance bowel elimination and help the woman reestablish her normal bowel pattern.

During the assessment, the nurse may provide information regarding postpartal diuresis, explaining why the woman may be emptying her bladder so frequently. Information about the need for additional fluid intake, with suggestions of specific amounts, may be helpful. The woman should drink at least eight 8-oz glasses of water or juice in addition to other fluids. Breastfeeding mothers will have a higher requirement. The nurse discusses signs of retention and overflow voiding and reviews symptoms of urinary tract infection (UTI) with the mother at this time if it seems an appropriate moment for teaching. The nurse can also review methods of assisting bowel elimination and provide opportunities for the woman to ask questions.

Rest and Sleep Status

Physical fatigue often affects other adjustments and functions of the new mother. The mother requires energy to make the psychologic adjustments to a new infant and to assume new roles. Fatigue is often a highly significant factor in a new mother's apparent disinterest in her newborn. Frequently the woman is so tired from a long labor and birth that everything seems to be an effort.

To avoid inadvertently classifying a very tired mother as one with a potential attachment problem, the nurse should do a psychologic assessment on more than one occasion. After a nap the new mother is often far more receptive to her baby and her surroundings. As part of the postpartum assessment, the nurse evaluates the amount of rest the new mother is getting. If the woman reports difficulty sleeping at night, the nurse should try to determine the cause. If it is simply the strange environment, a warm drink, backrub, or mild sedative may prove helpful. Appropriate nursing measures are indicated if the woman is bothered by normal postpartal discomforts such as afterpains, diaphoresis, or episiotomy or hemorrhoidal pain. The impact of rooming-in on the mother's ability to rest should be assessed. See chapter 36 ∞ for more detailed discussion of comfort and pain relief measures.

A daily rest period should be encouraged, and hospital activities should be scheduled to allow time for napping. The nurse can also provide information about the fatigue a new mother experiences and strategies to promote rest and sleep at home, and the impact fatigue can have on a woman's emotions and sense of control.

DEVELOPING CULTURAL COMPETENCE

Rest, Seclusion, and Dietary Restraint in Non-Western Cultures

Rest, seclusion, and dietary restraint practices in many traditional non-Western cultures (African, traditional Mexican, Chinese, Japanese, South Asian groups) are designed to assist the woman and her baby during postpartum vulnerable periods. The period of postpartum vulnerability and seclusion varies between 7 and 40 days. In Ghana, new mothers are relieved from all chores, told to abstain from sex, and not allowed to leave the home (Holtz & Grisdale, 2008; Lauderdale, 2008). Decreased activity and seclusion practices are designed to lessen the influence of spirits or of spreading evil and misfortune. The time of seclusion coincides with the period of lochial flow or postpartum bleeding.

HEALTH PROMOTION EDUCATION: NUTRITION

Postpartum nutritional status is primarily determined based on information provided by the mother and on direct assessment. During pregnancy the daily recommended dietary allowances call for increases in calories, proteins, and most vitamins and minerals. After birth the nonbreastfeeding mother's dietary requirements return to prepregnancy levels, whereas the lactating mother's requirements increase.

Visiting mothers during mealtime provides an opportunity for unobtrusive nutritional assessment and counseling. The nonbreastfeeding mother should be advised about the need to reduce her caloric intake by about 300 kcal and to return to prepregnancy levels for other nutrients. The breastfeeding mother should increase her caloric intake by about 200 kcal over the pregnancy requirements, or a total of 500 kcal over the nonpregnant requirement. Basic discussion will usually prove helpful, followed by referral as needed. In all cases, the nurse should provide literature on nutrition so that the woman will have a source of information following discharge.

The nurse should inform the dietitian of any mother who is a vegetarian, has food allergies or lactose intolerance, or whose cultural or religious beliefs require specific foods. Appropriate meals can then be prepared for her. Many women, especially those who gained more than the recommended number of pounds, are interested in losing weight after birth. The dietitian can design weight reduction diets to meet nutritional needs and food preferences. The nurse may also refer women with unusual eating habits or numerous questions about good nutrition to the dietitian.

New mothers are also advised that it is common practice to prescribe iron supplements for 3 months after birth. Hemoglobin and hematocrit values are then checked at the postpartal visit to detect any anemia.

As a part of the nutritional assessment, the nurse can provide teaching about the nutritional needs of the woman during the postpartum period. See Table 35-5 as well as the discussion in chapter 18 ∞.

Psychologic Assessment

During the first several postpartum weeks, the new mother must accomplish certain physical and developmental tasks:

- Restoring physical condition
- Developing competence in caring for and meeting the needs of her infant
- Establishing a relationship with her new child
- Adapting to altered lifestyles and family structure resulting from the addition of a new member

TABLE 35-5 Daily Eating to Encourage Healthful Nutrition During the Postpartum Period

- 2–3 servings of milk, yogurt, and cheese group
- 2–3 servings of meat or protein group
- 3–5 servings of vegetable group
- 4 servings of whole grain
- 2–4 servings of fruit group
- 6–11 servings of bread, cereal, rice, and pasta group
- Fats, oils, and sweets sparingly

Adequate assessment of the mother's psychologic adjustment is an integral part of postpartal evaluation. This assessment focuses on the mother's general attitude, feelings of competence, available support systems, and caregiving skills. It also evaluates her fatigue level, sense of satisfaction, and ability to accomplish her developmental tasks.

Some new mothers have little or no experience with newborns and may feel totally overwhelmed. They may show these feelings by asking questions and reading all available material or by becoming passive and quiet because they simply cannot deal with their feelings of inadequacy. Unless a nurse questions the woman about her plans and previous experience in a supportive, nonjudgmental way, the nurse might conclude that the woman is uninterested, withdrawn, or depressed. Clues that may indicate a problem include excessive, continued fatigue; marked depression; excessive preoccupation with physical status or discomfort; evidence of low self-esteem; lack of support systems; marital or relationship problems; inability to care for or nurture the newborn; and current family crises (such as illness or unemployment). These characteristics frequently indicate a potential for maladaptive parenting, which may lead to child abuse or neglect (physical, emotional, intellectual) and cannot be ignored. Referrals to public health nurses or other available community resources may provide greatly needed assistance and alleviate potentially dangerous situations.

Assessment of Early Attachment

The nurse in any of the various postpartum settings should periodically observe and note the mother's progress toward attachment. The assessment should include both parents when possible; however, in this section, the behaviors focus primarily on the mother's attachment process. As discussed previously, research shows that fathers experience attachment feelings similar to those experienced by mothers. The following questions can be addressed in the course of nurse-patient interaction:

- Is the mother attracted to her newborn? To what extent does she seek face-to-face contact and eye contact? Has she progressed from fingertip touch to palmar contact to enfolding the infant close to her own body? Is attraction increasing or decreasing? If the mother does not exhibit increasing attraction, why not? Do the reasons lie primarily within her, in the baby, or in the environment?
- Is the mother inclined to nurture her infant? Is she progressing in her interactions with her infant?
- Does the mother act consistently? If not, is the source of unpredictability within her or her infant?
- Is her mothering consistently carried out? Does she seek information and evaluate it objectively? Does she develop solutions based on adequate knowledge of valid data? Does she evaluate the effectiveness of her maternal care and make appropriate adjustments?
- Is she sensitive to the newborn's needs as they arise? How quickly does she interpret her infant's behavior and react to cues? Does she seem happy and satisfied with the infant's

responses to her efforts? Is she pleased with feeding behaviors? How much of this ability and willingness to respond is related to the baby's nature, and how much to her own?
- Does she seem pleased with her baby's appearance and sex? Is she experiencing pleasure in interaction with her infant? What interferes with the enjoyment? Does she speak to the baby frequently and affectionately? Does she call him or her by name? Does she point out family traits or characteristics she sees in the newborn?
- Are there any cultural factors that might modify the mother's response? For instance, is it customary for the grandmother to assume most of the childcare responsibilities while the mother recovers from childbirth?

Once these questions are addressed and the facts are assembled, the nurse can combine the information with personal intuition and knowledge to answer three more unspoken questions: Is there a problem in attachment? What is the problem? What is its source? The nurse can then devise a creative approach to the problem as it presents itself in the context of a unique, developing mother-infant relationship.

Discharge Assessment and Follow-Up

The **Newborns' and Mothers' Health Protection Act (NMHPA)** of 1996 went into effect January 1, 1998. This law states that a woman who has given birth vaginally in a healthcare setting cannot be forcibly discharged within 48 hours of the time of birth for insurance reasons. A woman who had a cesarean birth is covered by her insurance until 96 hours following the time of giving birth. If a mother with an uncomplicated birth and her physician or caregiver mutually decide that discharge before this time frame is required, this can be accomplished. When this occurs it is recommended that the newborn be seen in a follow-up setting within 48 hours (American Academy of Pediatrics [AAP], 2004).

The final discharge assessment should include a physical examination and appropriate discharge teaching that includes both maternal and newborn care guidelines. The mother's laboratory values are examined. If the mother was nonimmune to rubella, a rubella vaccine is administered before discharge. Rh-negative mothers whose infants are Rh positive need RhoGAM before they go home. If either is given, the nurse documents this in the mother's chart. If referrals, such as to social service programs, support groups, a lactation consultant, or a pediatrician, are needed, they should be provided before the family leaves the facility.

Some obstetricians, certified nurse-midwives, and nurse practitioners see all postpartum women 1 to 2 weeks after birth in addition to the routine 6-week checkup. These visits provide opportunities for physical assessment as well as assessment of the mother's psychologic and informational needs and needs of the family. The routine physical assessment, which can be made rapidly, focuses on the woman's general appearance, breasts, reproductive tract, bladder and bowel elimination, and any specific problems or complaints. In addition, the nurse should talk with the mother about her diet, fatigue level, family adjustment, and psychologic status. The nurse explores any problems with child care and refers the mother to a pediatric nurse practitioner or pediatrician if needed. Available community resources, including public health department follow-up visits, are mentioned when appropriate. If not already discussed, teaching about family planning is appropriate at this time, and the nurse provides information regarding birth control methods. The quality of discharge teaching, specifically the relative difference in the amount of information needed and received and the skills of the nurses delivering the teaching, can help the mother feel ready for discharge from the hospital. Likewise, part of the quality of the teaching includes the nurse assessing the *readiness* to be discharged as a general guide for the teaching content, amount of reinforcement of the information, and evaluation of the understanding of the information (Weiss & Lokken, 2009).

Postdischarge care for the postpartum woman may be accomplished by home visits or follow-up phone calls, or both. The optimal time for a home visit or follow-up phone call is between 3 and 4 days after birth; this provides opportunities for further assessment of the mother and her infant and teaching. (See Assessment Guide: Postpartum—First Home Visit and Anticipated Progress at Six Weeks in chapter 37 ∞ on pages 1072–1074.) During this time period, infections, poor infant feeding, excessive weight loss, jaundice, and other problems become apparent (James, 2008). The follow-up phone call is often initiated by a nurse from the postpartum unit of the agency where the mother gave birth. It is made soon after discharge and is designed to provide assessment and, if necessary, care; to reinforce knowledge and provide additional teaching; and to make referrals if indicated. Alternatively, a follow-up phone call from a nurse from the physician or CNM's office can provide new mothers with a source of support and an opportunity to ask questions. Women who appear to be having adjustment problems should be scheduled for an appointment for further evaluation.

In ideal situations, a family approach involving the father, newborn, and other siblings permits a total evaluation and provides an opportunity for all family members to ask questions and express concerns. In addition, a family approach can sometimes enable the nurse to identify disturbed family patterns more readily and suggest, or even institute, therapeutic measures to prevent future problems of neglect or abuse.

FOCUS YOUR STUDY

- The uterus involutes rapidly, primarily through a reduction in cell size.
- Involution is assessed by measuring fundal height. The fundus is at the level of the umbilicus within a few hours after birth and should decrease by approximately one fingerbreadth per day.
- The placental site heals by a process of exfoliation, so no scar formation occurs.
- Lochia progresses from rubra to serosa to alba and is assessed in terms of type, quantity, and characteristics.
- The abdomen may have decreased muscle tone (flabby consistency) initially. The nurse should assess for diastasis recti abdominis, separation of the rectus abdominis muscles.
- Constipation may develop postpartum because of decreased tone in the abdominal muscles, limited diet, and denial of the urge to defecate because of fear of pain.
- Decreased bladder sensitivity, increased capacity, and postpartum diuresis may lead to problems with bladder elimination. Frequent assessment and prompt intervention are indicated. A fundus that is boggy but does not respond to massage, is higher than expected, or deviates to the side usually indicates a full bladder.
- Postpartum, a healthy woman should be normotensive and afebrile. Bradycardia is common.
- The white blood cell (WBC) count is often elevated postpartum. Activation of clotting factors predisposes the woman to thrombus formation.
- Psychologic adaptations of the postpartal woman are traditionally described as "taking-in" and "taking-hold."
- Postpartum "blues" is a common occurrence and ways to prevent and cope with it should be discussed not only with the mother but her significant other(s). Signs of postpartum depression should be discussed as well.
- In consideration of the patient's background, the nurse should recognize and respect cultural variations and individual preferences.
- Postpartum assessment should be completed in a systematic way, usually head to toe, and should include assessment of rest and sleep, nutrition, and attachment. The assessment provides opportunities for informal patient teaching.
- In the weeks following birth, the woman's physical condition returns to a nonpregnant state, and she gains competence in caregiving and confidence in herself as a parent.

CRITICAL THINKING IN ACTION

Source: George Dodson/Pearson Education.

Janet Burns, a 25-year-old G3 P3, is 2 hours past a low forceps vaginal birth with a right medial lateral episiotomy of a live 8 pound baby boy. You obtain vital signs of BP 118/70, T 98.8°F, P 76, R 14. You observe the fundus is +1 finger above the umbilicus and slightly to the right. Her episiotomy is slightly ecchymotic and well approximated without edema or discharge. Ice has been applied to the episiotomy for the last 20 minutes. Lochia rubra is present and a pad was saturated in 90 minutes. Janet has an intravenous of Ringer's lactate with 10 units of Pitocin infusing at 100 ml/hr in her lower left arm and is complaining of moderate abdominal cramping. Janet's baby is sleeping peacefully in the bassinet next to her bed. She tells you that she is very tired and requests some pain medication so she can sleep for a while.

1. What nursing assessment is of immediate concern?
2. Discuss care of her episiotomy and perineum.
3. What other self-care measures could you advise?
4. Discuss postpartal occurrences that may cause special concern for the mother.
5. Janet expressed concern about her episiotomy healing. What information can you offer?

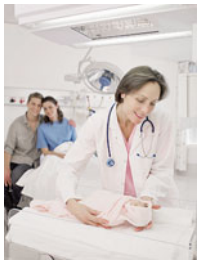
The Postpartum Family: Needs and Care

CHAPTER 36



Providing family-centered postpartum care is a challenge that requires creativity, patience, and a sincere desire to help families grow and thrive. Individual families come to the unit with a unique set of values, beliefs, life experiences, challenges, gifts, and expectations. The nurse needs to personalize care to meet their special needs in a manner that helps them to nurture one another and their newborn within the context of their family, their community, and the world. It has been helpful to remember that while it is simply another day of work for me, it is probably one of the most important days in the lives of my patients and their families. The care that I provide shapes their memories of this special time and may affect their health and family processes for many years to come.

LEARNING OUTCOMES

1. Delineate nursing responsibilities for patient teaching during the early postpartum period.
2. Discuss appropriate nursing interventions to promote maternal comfort and well-being.
3. Describe the nurse's role in promoting maternal rest and helping the mother to resume gradually an appropriate level of activity.
4. Identify patient teaching topics for promoting postpartum family wellness.
5. Compare the nursing needs of a woman who experienced a cesarean birth with the needs of a woman who gave birth vaginally.
6. Identify critical physiologic, psychosocial, and safety needs related to the care of obese and morbidly obese postpartum women.
7. Summarize the nursing needs of the childbearing adolescent during the postpartum period.
8. Describe possible approaches to sensitive, holistic nursing care for the woman who relinquishes her newborn.
9. Describe possible approaches to sensitive, holistic nursing care for the postpartum lesbian mother and her partner.
10. Delineate the nurse's responsibilities related to early postpartum discharge.

KEY TERMS

Bogginess *1027*
Couplet care *1039*
Family-centered care *1039*
Mother-baby care *1039*
Patient-controlled analgesia (PCA) *1044*
Relinquishing mother *1048*
Skin-to-skin contact (SSC) *1036*

Certain premises form the basis of effective nursing care during the postpartum period.

- The best postpartum care is family centered and disrupts the family unit as little as possible. This approach uses the family's resources to support an early and smooth adjustment to the newborn by all family members.
- Knowledge of the range of normal physiologic and psychologic adaptations occurring during the postpartum period allows the nurse to recognize alterations and initiate interventions early. Communicating information about postpartum adaptations to the family facilitates their adjustment to their situation.
- Nursing care is aimed at accomplishing specific goals that ultimately meet individual needs. These goals are formulated after careful assessment and consideration of factors that could influence the outcome of care.

Chapter 35 ∞ provides a thorough discussion of postpartum assessment. This chapter describes nursing care during the immediate postpartum period. Specific nursing responses to the mother's physical needs and the family's psychosociocultural needs are described at length and are summarized in the Clinical Pathway for the Postpartum Period on pages 1021–1023.

Nursing Care During the Early Postpartum Period

For most postpartum women, physical recovery proceeds smoothly and is considered a healthy process. Because of this perception, it is all too common for caregivers to think that the woman and her family have no "real" needs and thus no care plan is needed. Nothing can be further from the truth. Every member of the family has needs, although they may not be obvious, especially if they are educational or emotional.

Nursing Diagnosis

The postpartum family's needs, which should be identified during assessment, are the basis for developing nursing diagnoses. Once a nursing diagnosis is made and recorded, systematic action, as delineated in a nursing care plan or clinical pathway, can be used to meet the identified need.

Nursing schools and agencies frequently use NANDA International (Herdman, 2009) approved diagnoses. Examples of diagnoses with defining characteristics and related factors commonly found in postpartum patients include (Herdman, 2009):

- ***Impaired Urinary Elimination.*** Defining characteristics may include (a) dysuria, (b) hesitancy, or (c) retention. Related factors may include (a) anatomic obstruction (urethral swelling), (b) sensory motor impairment (spinal or epidural anesthesia), or (c) multiple causality.
- ***Impaired Skin Integrity.*** Defining characteristics may include (a) destruction of skin layers (abrasions) or (b) disruption of skin surface (lacerations). Related factors may include mechanical factors (tearing/shearing forces during delivery).
- ***Acute Pain.*** Defining characteristics may include (a) guarding behavior, (b) observed evidence of pain, (c) expressive behavior, (d) positioning to avoid pain, (e) protective gestures, or (f) verbal report of pain. Related factors may include (a) physical injuries sustained during labor and delivery (hematomas) or (b) physical changes of postpartum period (uterine contractions).
- ***Risk for Infection.*** Risk factors may include (a) inadequate primary defenses (surgical incision, lacerations, open cervix, etc.), (b) inadequate secondary defenses (decreased hemoglobin), (c) invasive procedures (history of cervical exams or instrumentation during labor and delivery), (d) history of premature rupture of amniotic membranes, or (e) history of prolonged rupture of amniotic membranes.
- ***Risk for Constipation.*** Risk factors may include (a) physiologic (decreased motility of gastrointestinal tract), (b) pharmacologic (opiates), or (c) mechanical (hemorrhoids).

Wellness diagnoses related to family coping, instructional needs, or infant nutrition are also used frequently. Examples of these diagnoses include the following (Herdman, 2009):

- ***Readiness for Enhanced Knowledge.*** Defining characteristics may include (a) expresses an interest in learning (about self- or newborn care), or (b) describes previous experiences pertaining to the topic.
- ***Readiness for Enhanced Coping.*** Defining characteristics may include (a) defines stressors (new family member) as manageable, (b) seeks knowledge of new strategies, or (c) seeks social support.
- ***Effective Breastfeeding.*** Defining characteristics may include but are not limited to (a) effective mother-infant communication patterns, (b) maternal verbalization of satisfaction with the breastfeeding process, (c) mother able to position infant at breast to promote a successful latching-on response, and (d) infant content after feeding. Related factors may include (a) basic breastfeeding knowledge, (b) infant gestational age >34 weeks, (c) maternal confidence, (d) normal breast structure, (e) normal infant oral structure, or (f) support source present.

After completing the assessment and diagnosis steps of the nursing process, the nurse identifies desired outcomes and selects nursing interventions that will promote these outcomes.

Nursing Plan and Implementation

Nursing care management is individualized to meet the needs of each postpartal woman, her newborn, and her family. The plan of care needs to consider the newborn's schedule of activities during the day, such as feeding times, because they frequently determine the mother's schedule. Flexibility is crucial because most breastfeeding infants feed on demand at frequent intervals.

An important component of nursing care is patient teaching, which is designed to help the woman and her family learn how to perform self-care and provide effective newborn care. Sophisticated, detailed forms and guidelines are often available to assist in health teaching. Such tools are a useful adjunct but cannot take the place of the nurse's patient-centered plan. As part of patient teaching, the nurse should discuss cultural beliefs, desired outcomes, and goals with the mother as soon as

CLINICAL PATHWAY For the Postpartum Period

Category	First 4 Hours	4–8 Hours Past Birth	8–24 Hours Past Birth
Referral	Report from labor nurse if not continuing in an LDR room	Lactation consultation as needed	Home nursing, social work, WIC referral if indicated; coordinate universal hearing and state-required newborn metabolic screening ■ ***Expected Outcomes*** Referrals made
Assessments	Postpartum assessments every 15 min × 4, every 30 min × 2, then every 4 h. Includes: • Fundus firm, midline, at or below umbilicus • Lochia rubra less than 2 pad/h; no free flow or passage of clots with massage • Bladder: voids large amounts of urine spontaneously; bladder not palpable following voiding • Incision or dressing clean, dry, and intact if CB • Foley draining if present • Perineum: sutures intact; no bulging or marked swelling; no c/o severe pain. Minimal bruising may be present. If hemorrhoids present, no tenseness or marked engorgement; less than 2 cm diameter • Breasts: soft, colostrum present Vital Signs: • BP WNL; usually between 90/50 and 140/90, consistent with baseline • Temperature: less than 38°C (100.4°F) • Pulse: bradycardia (50 to 70) normal, consistent with baseline • Respirations: 16–24/min; quiet, easy; lungs CTA Comfort level: pain less than 4 on scale of 1–10 Awake, alert, & LOS returning following initial recovery if had anesthesia	Continue postpartum assessment every 4 h Breast: evaluate nipple status; should be no evidence of cracks or bruising Observe feeding technique with newborn Vital signs assessment every 4 h; all WNL; report temperature greater than 38°C (100.4°F) Assess Homans' sign every 8 h Continue assessment of comfort level: pain less than 4 on 1–10 scale	Continue postpartum assessment every 4 h Breasts: nipples should remain free of cracks, fissures, bruising Newborn latches and breastfeeds successfully VS assessment every 4 h; all WNL; Lungs CTA; report temperature greater than 38°C (100.4°F) Continue assessment of comfort level D/C Foley PRN; Pt voids within 4 to 6 h after Foley D/C ■ ***Expected Outcomes*** VS WNL, voids QS, postpartum assessment WNL Incision healthy and intact if CB Comfort level: pain less than 4 on 1–10 scale Involution of uterus in process—fundus may migrate to 1 cm above umbilicus by 12 h; fundal height decreases 1 cm/day thereafter Lochia rubra < 1 pad/h by 24 h Demonstrates and verbalizes appropriate newborn feeding techniques
Teaching/ psychosocial	Explain postpartum assessments Assist with breastfeeding; discuss benefits and AAP recommendations if undecided Teach self-massage of fundus and expected findings; explain rationale for fundal massage Instruct to call for assistance first time OOB and PRN Demonstrate peri care, Surgigator, sitz bath PRN Explain comfort measures Begin newborn teaching: bulb suctioning, positioning, feeding, diaper change, cord care; needs for comfort, warmth, and touch; infant safety and security measures Orient to room if transferred from LDR room Teach TCDB if CB Provide information on early postpartal period Assess mother/infant attachment Encourage SSC between newborn and parent(s) Encourage mother to verbalize her birth story Encourage father to bond and provide newborn care	Discuss psychologic changes of postpartum period; facilitate transition through tasks of taking on maternal role Discuss peri care/hygiene Encourage use of supportive brassiere for all mothers Stress need for frequent rest periods Continue newborn teaching: newborn behavioral states, soothing/comforting techniques, swaddling Return demonstrations indicate woman's understanding Provide opportunities for questions; review and reinforce previous teaching Breastfeeding nipple care: air-drying, proper latch-on technique Formula-feeding breast care: supportive bra, cold compresses, no stimulation, analgesics Assess mother/infant attachment	Reinforce previous teaching, complete teaching evaluation Discuss involution; anticipated physical changes in first 2 weeks postpartum; postpartal exercises; need to limit visitors; baby blues; postpartum fatigue; postpartum depression Discuss postpartal nutrition; balanced diet Breastfeeding: • Increase calories by up to 500 kcal over nonpregnant state (200 kcal over pregnant intake) • Explain milk production, let-down reflex, use of supplements, sore nipples, breast pumping, and milk storage Formula-feeding: • Return to nonpregnant caloric intake • Explain formula preparation and storage Discuss birth control options, sexuality Discuss sibling rivalry and plan for supporting siblings at home Discuss circumcision care PRN Discuss pets; suggestions for improving acceptance of infant by pets Discuss fathering experience Emphasize car seat/vehicle safety, SIDS prevention, "never shake a baby" ■ ***Expected Outcomes*** Mother verbalizes teaching comprehension Positive bonding and emotional behaviors observed (both parents if present) Provides appropriate self- and infant care.

CLINICAL PATHWAY For the Postpartum Period continued

Category	First 4 Hours	4–8 Hours Past Birth	8–24 Hours Past Birth
Nursing care management and reports	Ice pack to perineum to decrease swelling and increase comfort Straight catheter PRN × 1 if distended or voiding small amounts Assess LOC, LOS, & lower extremity strength before ambulation If continues unable to void or voiding small amounts, insert Foley catheter and notify CNM or physician	Sitz baths PRN If woman Rh− and infant Rh+, RhoGAM workup; obtain consent; complete teaching Determine rubella status Obtain consent for rubella vaccine if indicated; explain purpose, procedure, implications of vaccine Obtain hematocrit	Continue sitz baths PRN May shower if ambulating without difficulty DC saline lock if present ■ ***Expected Outcomes*** Using sitz bath; voids QS; lab work WNL; performs ADL without sequelae
Activity	Assistance when OOB first time, then PRN SCDs until ambulating if CB Ambulates ad lib Rests comfortably between assessments	Encourage rest periods TCDB & SCDs until ambulating if CB Ambulates ad lib; may leave birthing unit after notifying staff of plan to ambulate off unit	Up ad lib ■ ***Expected Outcomes*** VB: Ambulates ad lib CB: OOB & ambulates by 24 h
Comfort	Institute comfort measures: • Perineal discomfort: peri care; sitz baths, topical analgesics • Hemorrhoids: sitz baths, topical analgesics, Tucks, side-lying or prone position • Afterpains: prone with small pillow under abdomen; warm shower or sitz baths; ambulation • Instruct on use of PCA pump PRN • Administer pain medication PRN	Continue with pain management techniques Offer alternative pain management options: distraction with music, television, visitors; massage; warmed blankets or towels to affected area; using breathing techniques when infant latches on to breast and/or during cramping until medication's action is felt	Continue with pain management techniques ■ ***Expected Outcomes*** Maintains comfort: Pain level less than 4 on 1–10 scale Verbalizes alternative pain management options
Nutrition & Hydration	Regular diet Fluid 2000 ml/day IV fluids if ordered	Continue diet and fluids	Continue diet and fluids ■ ***Expected Outcomes*** Skin turgor WNL Regular diet/fluids tolerated
Elimination	Voiding large amounts straw-colored urine	Voiding large quantities May have bowel movement	Same ■ ***Expected Outcomes*** Voiding QS; passing flatus or bowel movement
Medications	Pain medications as ordered Oxytocin IV infusion and/or Methergine po or IM if ordered Stool softener PRN Tucks pad PRN, perineal analgesic spray PRN, topical hemorrhoid cream PRN	Continue meds Lanolin to nipples PRN; assist with positioning and latch PRN Saline flush to saline lock (if present) every 8 h or as ordered May take own prenatal vitamins and iron—keep secure from siblings	Continue medications RhoGAM and/or rubella vaccine administered PRN ■ ***Expected Outcomes*** Vaccines administered if indicated; pain controlled Saline lock discontinued (site healthy)
Discharge planning/ home care	Evaluate knowledge of normal postpartum and newborn care Evaluate support systems	Discuss typical newborn schedule Plan for periods of rest Birth certificate paperwork completed Evaluate plans for transporting newborn; car seat available	Review discharge instruction sheet/checklist Describe postpartum warning signs and when to call CNM/physician Provide prescriptions Arrangements for baby pictures as per agency protocol Postpartum and newborn visits scheduled ■ ***Expected Outcomes*** Discharged home; mother verbalizes postpartum and newborn warning S/S, follow-up appointment times/dates Hearing and metabolic screens completed with follow-up scheduled if needed

CLINICAL PATHWAY For the Postpartum Period continued

Category	First 4 Hours	4–8 Hours Past Birth	8–24 Hours Past Birth
Family involvement	Identify available support persons Assess family perceptions of birth experience Parenting: demonstrates culturally expected early parenting behaviors	Involve support persons in care, teaching; answer questions Evidence of parental bonding behaviors present	Continue to involve support persons in teaching, involve siblings as appropriate Plans made for providing support to mother following discharge ***Expected Outcomes*** Evidence of parental bonding behavior Support persons verbalize understanding of woman's need for rest, good nutrition, fluids, and emotional support Support persons verbalize understanding of maternal/newborn follow up and S/S of complications requiring additional follow-up

Abbreviations: AAP, American Academy of Pediatrics; ADL, activities of daily living; BP, blood pressure; CB, cesarean birth; CNM, certified nurse-midwife; C/O, complaints of; CTA, clear to auscultation; D/C, discontinue; LDR, labor, delivery, and recovery; LOC, level of consciousness; LOS, level of sensation; OOB, out of bed; PCA, patient-controlled analgesia; PRN, as needed; PP, postpartum; QS, quantity sufficient; SCDs, sequential compression devices; SIDS, sudden infant death syndrome; S/S, signs and symptoms; SSC, skin-to-skin contact; TCDB, turn-cough and deep breathe; VB, vaginal birth; VS, vital signs; WIC, Women, Infants, & Children; WNL, within normal limits

possible after her arrival in the postpartum unit. Examples of these desired patient outcomes include the following:

- Mother and baby remain healthy, safe, and free of injury or complications.
- Mother verbalizes comfort.
- Mother tells birth story and verbalizes feelings and concerns regarding the event.
- Mother reviews educational resources for self- and infant care.
- Mother performs appropriate self- and infant care.
- Parent(s) and newborn demonstrate positive bonding behaviors.
- Parents practice principles of infant safety.
- Mother verbalizes understanding of and demonstrates successful breastfeeding and breast care; or mother describes accurate preparation of infant formula, demonstrates safe bottle-feeding techniques, and verbalizes understanding of lactation suppression care.
- Mother verbalizes sources of support to assist in newborn care and family responsibilities.
- Mother states plan for follow-up health care for self and infant.
- Mother identifies signs and symptoms of maternal or newborn complications and reasons to seek care before routine follow-up visits.

Additional outcomes for the cesarean birth mother include the following:

- Mother states in own words the reason for the cesarean birth and verbalizes feelings related to the event.
- Mother maintains desired comfort level (pain level less than 4 on 1 to 10 scale).
- Mother maintains mobility (up in chair within 12 hours; ambulates within 24).

In summary, all components of nursing care management are designed to achieve the desired outcomes identified for the woman and her family. If the mother is unable to meet these outcomes prior to discharge, the significant other or a family caregiver should verbalize and/or demonstrate understanding of outcomes related to maternal and infant health and safety.

Community-Based Nursing Care

Various services are available to meet the needs of the childbearing family during the immediate postpartum period and beyond. These services range from educational opportunities, such as classes on nutrition, breastfeeding, exercise, infant care and development, and parenting, to specific healthcare programs, such as well-baby checkups, immunization clinics, lactation centers, and family planning agencies. Services may be offered by the birthing unit, private caregivers, volunteer and charitable organizations, or publicly funded agencies. In all cases, the goal is consistent: to meet the health, safety, and psychosocial needs of the mother, the newborn, and the family.

Home health care is one of the most important forms of community-based nursing care offered to postpartum families. Home care visits and phone contacts (telephone follow-up) help ensure that families have the necessary skills and resources to care for an infant and to meet their own health needs. Because of its importance today in caring for childbearing families, home care is discussed in depth in chapter 37 ∞.

Health Promotion Education

Meeting the educational needs of the new mother and her family is one of the primary challenges facing the postpartum nurse. Each woman's educational needs vary according to age, background, culture, experience, and expectations. However, because the mother spends only a brief period of time in the postpartal area, identifying and addressing individual instructional needs can be difficult. Effective education provides the childbearing family with sufficient knowledge to meet many of their own health needs and to seek assistance if necessary.

The nurse assesses the learning needs of the new mother through observation, sensitivity to nonverbal clues, and tactfully phrased questions. For example, "What plans have you

made for handling things when you get home?" will elicit a more detailed response than, "Will someone be available to help you at home?" To assess learning needs, some agencies provide a patient handout listing the most frequently identified areas of concern for new mothers. The mother checks those that apply to her or writes in concerns not included. The nurse should plan and implement learning experiences in a logical, nonthreatening way based on knowledge of and respect for the family's cultural values and beliefs.

Timing and Methods of Teaching

Childbearing nursing units must provide education efficiently and effectively in today's healthcare environment, which is characterized by shortened postpartum stays. Assessment of learning needs and patient education should begin when the woman first accesses the healthcare system. Ideally, the woman completes a needs assessment during her pregnancy, which precedes or follows her to the inpatient unit and eventually becomes the discharge teaching tool (James, 2008).

Nursing units may offer a variety of educational options including structured group classes, individualized instruction, printed materials, videotapes, and educational television channels that are available at various times or around the clock to meet the needs of families. Women should have a pencil and paper to write down questions that arise when viewing resources independently. Afterward, nurses need to be available to clarify material or answer any questions about the content. Because more effective learning occurs when there is sensory involvement and active participation, videotapes (sight and hearing) are more helpful than lecture (hearing only). Demonstration, specifically sight, touch, hearing, and, possibly, smell and taste, is even more effective. Opportunities for continued learning through the use of printed materials, access to online educational materials, home visits, postpartum education and support groups, telephone advice lines, and outpatient nurse consultation need to be provided for all patients, especially those who are discharged within 24 to 48 hours following delivery.

Content of Teaching

Maternal learning needs scatter across a variety of topics and vary depending on the mother's age and whether she is a primipara or multipara. Therefore, it is essential that the teaching content be tailored to the individual mother and family. Kanotra et al. (2007) found that postpartum women commonly reported needs for (a) social support; (b) breastfeeding education, support, and assistance; (c) education related to newborn care; (d) education and support related to postpartum depression; (e) adequate length of stay; and (f) maternal insurance coverage following delivery. No list of educational needs is exhaustive, however, and the professional nurse bears the responsibility to assess the specific learning needs of each patient and her family when planning patient-centered care, education, and follow-up.

Teaching should not be limited to "how-to" activities. Anticipatory guidance is essential in assisting the family to cope with role changes, the realities of a new baby, and potential complications such as infant colic, and postpartum health issues. Small-group discussions provide a chance for the new parents to talk about fears and expectations. Questions may arise about sexuality, contraception, childcare, and even the grief associated with giving up the fantasized infant in order to accept the actual one.

Although childbearing is generally considered a natural and healthy experience, the incidence of complications and discomforts in the first year postpartum is common. Runquist (2007) found that both primiparas and multiparas "expressed surprise and distress over the length of the postpartum healing process" (p. 32). Women may experience fatigue, headaches, nausea, backaches, abdominal pain, vaginal pain, dyspareunia, constipation, hemorrhoids, urinary or bowel problems, breast soreness, and emotional disorders. A study that screened 1323 mostly low income, urban women for the problems mentioned above found that 69% experienced problems of minor to major severity within the first year after giving birth, while only 31% reported no problems. The most common problems cited were fatigue, headaches, and nausea, which were experienced by approximately half of the respondents. Backaches were the next most common complaint. Poor emotional health and functional limitations were associated with physical complications (Webb et al., 2008). A national study of 1573 women with a broad range of demographic backgrounds found that 79% of cesarean section patients experienced incisional pain, and approximately half of patients who delivered vaginally experienced perineal pain during the months after childbirth. Many women complained of physical exhaustion as well (Declercq, Cunningham, Johnson, et al., 2008). Therefore, it is important that nurses provide anticipatory guidance to patients regarding potential postpartum health issues and encourage them to seek follow-up care as needed.

Adolescent mothers, patients with cesarean delivery, and parents of newborns with congenital anomalies will have special concerns, as will patients with special needs related to their own physical, mental, or emotional health and abilities. Postpartum nurses need to ensure that special needs families have additional support in place from home care nurses, social workers, chaplains, and other professionals before discharge.

Table 36-1 is a form that identifies important topic areas to be included in postpartum patient teaching. Methods and validation can be checked off as they occur.

Evaluating Learning

Methods for evaluating learning vary according to the objectives and teaching methods. The nurse should validate the knowledge of self- and infant care through patient discussion and return demonstration. Follow-up is indicated if learning needs related to maternal and infant care and safety are not validated as met prior to discharge (James, 2008).

Evaluation of attitudinal or less concrete learning is more difficult. For example, a mother's ability to express her frustrations over an unanticipated cesarean birth or difficulties with breastfeeding as opposed to her desired and expected experience may be the nurse's only clues that learning has occurred. Follow-up phone calls and home visits after discharge may provide additional evaluative information and continue the helping process as the nurse assesses the family's current educational needs and begins planning accordingly.

TABLE 36-1 Areas to Include in Postpartum Teaching

KNOWLEDGE AND SKILLS TO BE TAUGHT	TEACHING METHOD			PATIENT VALIDATION	
	PRINTED MATERIALS	INDICATE VIDEO OR DEMO	VERBAL INSTRUCTION	VERBALIZES UNDERSTANDING	RETURN DEMONSTRATION
Care of the Mother					
Breast care					
Breastfeeding or lactation suppression					
Possible problems and care					
Involutional changes					
Position of fundus					
Afterpains					
Changes in lochia					
Signs of possible problems					
Bladder function					
Fluid needs					
Signs of possible problems					
Bowel function					
Normal patterns					
Dietary assistance					
Perineal care					
Expected healing changes in episiotomy/laceration					
Comfort measures (rinsing with warm water, use of icepacks, use of analgesic/anesthetic spray, sitz bath), home care					
Signs of possible problems					
Rest and activity					
Scheduling rest periods, postpartum fatigue					
Ambulation					
Watching for circulatory problems in legs					
Emotional changes					
Changes in mood, crying, anxiety; "baby blues," postpartum depression, psychosis					
Care of the Father/Partner					
Emotional changes					
Emotional changes and challenges that may occur					
Encouragement to seek support as needed					
Physiologic and psychologic changes that may occur in the mother and newborn					
Infant care concerns					
Possible supportive measures for the new family					
Care of the Baby					
Infant safety and security measures					
Observing the baby					
General appearance					
Five Senses					
Visual					
Hearing					
Touch					
Smell					
Taste					
Vital signs					
Normal parameters					
How to take a temperature

Promotion of Maternal Comfort and Well-Being

The nurse promotes and restores maternal physical well-being by assessing the patient on a regular basis and providing the requisite care. Although there is a lack of definitive research data indicating how often maternal status should be assessed, most institutions have assessment protocols for the focused postpartum assessment. At a minimum, blood pressure, pulse, the uterine fundus, the perineum, lochia, and urinary output or need to void are usually assessed at least every 15 minutes for the first hour following delivery of the placenta, every 30 minutes for the second hour, and then every 4 hours for 24 hours. Temperature is assessed at least every four hours (James, 2008).

The nurse performs nursing activities aimed at relieving specific discomforts, such as an edematous perineum or a distended bladder. In addition, medications may be needed to promote comfort, treat anemia, provide immunity to rubella, and prevent development of antibodies in the nonsensitized Rh-negative woman. Finally, the woman may be experiencing alterations in her emotional well-being. Interventions for these conditions are discussed in this section.

Monitoring Uterine Status

The nurse completes an assessment of the uterus as discussed in chapter 35 ∞. The nurse should follow institutional protocol regarding frequency of assessments and use professional judgment to decide when maternal status requires more frequent checks or additional assessments due to issues such as **bogginess** (softening of the uterus due to inadequate contraction of the muscle tissue), positioning out of midline, heavy lochial flow, or the presence of clots (Table 36-2).

The amount, consistency, color, and odor of the lochia are monitored on an ongoing basis. Increased bleeding is most often related to uterine atony and responds to fundal massage, expression of any clots, and emptying the bladder. Nipple stimulation can also be utilized to promote contraction of the uterus. Breastfeeding is an ideal and natural way to stimulate oxytocin release and contract a boggy uterus. Bleeding that does not respond readily requires additional evaluation to rule out complications such as retained placenta, lacerations, coagulation defects, or uterine inversion. Changes in lochia that need to be assessed further, documented, and reported to the physician or certified nurse-midwife (CNM) are presented in Table 35-4 ∞ on page 1010.

Occasionally a medication such as methylergonovine maleate (Methergine) is prescribed to promote uterine contractions. In some cases an intravenous (IV) infusion of oxytocin (Pitocin) may be necessary if the uterus does not remain firm and uterine bleeding is excessive. The nurse will need to ensure patent IV access in this case. See Drug Guide: Methylergonovine Maleate (Methergine) in this chapter and Drug Guide: Oxytocin (Pitocin) in chapter 28 ∞ on page 733. Uterine atony resistant to these drugs can require use of carboprost (Hemabate). See Table 39-1 ∞ on page 1118 regarding the use of uterine stimulants. A Cochrane review noted that research regarding the use of Misoprostyl for postpartum hemorrhage is under way, but additional trials are needed before it can be recommended as a first-line treatment (Mousa & Alfirevic, 2007).

TABLE 36-2 Key Facts to Remember About Monitoring Postpartum Uterine Status

Position of the Uterine Fundus Following Birth

Immediately after delivery of the placenta: The top of the fundus is in the midline about midway between the symphysis pubis and umbilicus.

Six to 12 hours after birth: The top of the fundus is in the midline and at the level of the umbilicus (may migrate to 1 cm above the umbilicus by the 12-hour point and then descend 1 cm/day).

One day after birth: The top of the fundus is in the midline and one fingerbreadth below the umbilicus.

Second day after birth and thereafter: The top of the fundus remains in the midline and descends about one fingerbreadth per day.

Normal Characteristics of Lochia

Lochia rubra is red and is present for the first 2 to 3 days.

Lochia serosa is pinkish red or brown and is present from day 3 to day 10.

Lochia alba is creamy white and is present from day 11 to day 14 (may last 3 to 6 weeks).

PROFESSIONALISM IN PRACTICE

Using Critical Thinking to Anticipate Postpartum Hemorrhage

The nurse uses critical thinking skills to anticipate a postpartum hemorrhage. The nurse needs to be particularly sensitive to a uterus that becomes boggy or to increases in lochial flow. The astute nurse will also be aware of risk factors, such as prolonged second stage, macrosomia, manual removal of placenta, the use of magnesium sulfate, cesarean during second stage, chorioamnionitis, or multiparity. The nurse will monitor closely, maintain intravenous access, have the patient's most recent vital signs in mind, and make certain that oxytocic drugs are readily available when caring for patients at increased risk for postpartum hemorrhage. Optimal communication between the nurse and other members of the healthcare team is essential to the prevention and treatment of this potentially life-threatening complication (Lu, Korst, Fridman, et al., 2009).

HEALTH PROMOTION EDUCATION

The nurse teaches the woman to assess her fundus for firmness and position and to massage the fundus gently to promote uterine contraction. In addition, the nurse instructs her to monitor the amount and color of the lochia. Being aware of normal involutional changes will help the woman identify problems. Discharge instructions should specify that women call their healthcare provider if their bleeding is saturating more than one standard-sized sanitary pad per hour. See Table 35-4 ∞ on page 1010 for changes in lochia that are causes for concern.

DRUG GUIDE Methylergonovine Maleate (Methergine)

OVERVIEW OF ACTION

Methylergonovine maleate (Methergine) is an oxytocic ergot alkaloid that stimulates uterine and vascular smooth muscle. It is used postpartally to stimulate the uterus to contract. Sustained contraction clamps off uterine blood vessels, decreases blood loss, and promotes involution. The drug has a vasoconstrictive effect on all blood vessels, especially the larger arteries. This may result in hypertension, particularly in a woman whose blood pressure is already elevated.

ROUTE, DOSAGE, AND FREQUENCY

Methergine has a rapid onset of action and may be given orally or intramuscularly.

Usual IM dose: 0.2 mg (200 mcg) following expulsion of the placenta. The dose may be repeated every 2–4 hours if necessary (up to 5 doses). Usual onset is 2–5 minutes.

Usual oral dose: 0.2 mg to 0.4 mg (200 mcg to 400 mcg) every 6–12 hours for 2–7 days. Usual onset is 5–10 minutes.

Not for IV use except in emergency—severe hypertension and vasoconstriction may result. Give no more than 0.2 mg (200 mcg)/minute IV. Do not mix with other drugs in syringe or IV line.

MATERNAL CONTRAINDICATIONS

Pregnancy, hypersensitivity. Use caution in hepatic or renal disease, cardiac disease, hypertension, preeclampsia, sepsis, and lactation (may decrease prolactin levels). Administration during the third stage of labor should occur only under immediate supervision of the obstetric provider.

MATERNAL SIDE EFFECTS

Hypertension, nausea, vomiting, headaches, and uterine cramping are common. Dizziness, tinnitus, palpitations, arrhythmias, diaphoresis, dyspnea, chest pain, and allergic reactions may be noted.

Rare and severe side effects include hypertension with seizures, encephalopathy, stroke, myocardial infarction, and pulmonary edema. Hypotension may occur in some women.

EFFECTS ON FETUS OR NEWBORN

Because Methergine has a long duration of action and can thus produce tetanic contractions, it **should never be used during pregnancy or before delivery of the fetus,** when a sustained uterine contraction could cause injury or death to the mother and/or fetus.

NURSING CONSIDERATIONS

- Monitor fundal height and consistency and the amount and character of the lochia.
- Notify provider if uterus remains boggy despite Methergine administration.
- Assess the blood pressure before and routinely throughout drug administration.
- Inform patient that Methergine may cause severe menstrual-like cramps.
- Observe for adverse effects or symptoms of ergot toxicity (ergotism) such as nausea and vomiting, headache, muscle pain, tingling of extremities, cold or numb fingers and toes, chest pain, and general weakness.
- Provide patient and family teaching regarding importance of not smoking during Methergine administration (nicotine from cigarettes constricts vessels and may lead to hypertension), signs of toxicity.
- Refrigeration of ampules is recommended, but it remains stable at room temperature for 60 days.

Sources: Aschenbrenner & Venable, 2009, pp. 1171–1172; Deglin & Valerand, 2009, pp. 806–807; McNulty, 2009, p. 264.

Relief of Perineal Discomfort

Many nursing interventions are available for relieving perineal discomfort. Before selecting a method, the nurse needs to have assessed the perineum to determine the degree of edema and other problems. It is also important to ask the woman whether there are special measures that she feels will be particularly effective and to offer her choices when possible. For instance, some cultures believe that the use of "cold" versus "hot" may alter the recovery or spirit of the new mother (see chapter 35 ∞). These beliefs will affect the choices made by the new mother. The nurse uses disposable gloves while applying all relief measures and washes hands before and after using the gloves. The nurse should be aware that severe perineal discomfort that does not respond to comfort measures may be indicative of a complication such as hematoma and warrants further investigation.

It is important to use good hygienic practices, such as moving from the front (area of the symphysis pubis) to the back (area around the anus) of the perineum. The nurse should follow this principle when placing ice packs and perineal pads and applying topical anesthetic agents or pain relief products. Avoiding contamination between the anal area and the urethral-vaginal area minimizes the risk of infection.

Case Study: Perineal Discomfort

CLINICAL TIP

You may be surprised by how quickly the postpartum woman shows signs of bladder distention, possibly as soon as 1 to 2 hours after childbirth. This is because of normal postpartal diuresis. You can help prevent overdistention by palpating the woman's bladder frequently and encouraging her to void. When urinating the first time after vaginal birth, some mothers may feel the urge to urinate but are unable to begin the flow of urine. Possible interventions include letting her hear running water by turning water on in the sink; running warm water in the sink and having her place one hand in the water; having her place one foot in a basin of warm water; squirting warm water over her perineum using a peri bottle; and placing a few drops of peppermint oil in the urine collection device ("hat"). Be sure to measure the first few voidings. The amount should be at least 150 ml. If she is still unable to void and catheterization becomes necessary, be prepared for difficulty in visualizing the urethra because of localized swelling and discomfort and tenderness in the area. If a patient requires more than one straight catheterization during the postpartum period, the provider may order a Foley for at least 8 to 12 hours to allow the swelling to subside.

PATIENT TEACHING Care of Episiotomy or Laceration

PATIENT GOALS At the completion of the teaching, the woman will be able to:

1. Identify the factors that promote and interfere with wound healing.
2. Summarize self-care activities to promote healing and increase personal comfort.
3. Demonstrate the correct procedure for peri care and taking a sitz bath.
4. Discuss the judicious use of prescribed analgesics or topical anesthetics as needed.

TEACHING PLAN

Content	Teaching Method
■ Describe the process of wound healing. Discuss the risk of contamination of the episiotomy/laceration by bacteria from the anal area.	Discussion helps women understand the importance of good wound care.
■ Explain techniques that are used to keep the episiotomy or laceration clean and promote healing such as: ■ Sitz bath ■ Use of peri bottle following each voiding or defecation ■ Pad change following each elimination and at regular intervals	Focus on open discussion. Demonstrate correct use of the peri bottle or sitz bath if necessary.
■ Describe comfort measures: ■ Ice pack or glove immediately following birth ■ Sitz bath ■ Judicious use of analgesics or topical anesthetics ■ Tightening buttocks before sitting	Focus on discussion and provide an opportunity for questions.
■ Identify signs of episiotomy or laceration infection. Advise the woman to contact her caregiver if infection develops.	Encourage discussion and provide printed handouts. Some of this content may also be covered during a small postpartum class.

Evaluation

At the end of the teaching session the woman will be able to verbalize the principles of wound healing and episiotomy or laceration care. She will also be able to demonstrate self-care measures such as peri care, ice packs, taking a sitz bath, and administration of topical anesthetics or analgesics.

Documentation

Documentation of patient teaching should include the teaching information discussed, the patient's verbalization of understanding, specific interventions or warning signs that were given, along with the patient's understanding of follow-up if needed in the future.

Perineal Care

Perineal care after each elimination (urination or defecation) cleanses the perineum and helps to promote comfort. Many agencies provide "peri bottles" that the woman can use to squirt warm tap water over her perineum following elimination. To cleanse her perineum, the woman may also use a Surgigator (peri bottle), moist antiseptic towelettes, or toilet paper in a blotting (patting) motion. She should be taught to start at the front (area just under the symphysis pubis) and proceed toward the back (area around the anus) to prevent contamination from the anal area. In addition, to prevent contamination, the perineal pad should be applied from front to back, placing the front portion against the perineum first. Perineal pads should be changed regularly to prevent infection.

TEACHING FOR SELF-CARE The nurse demonstrates how to cleanse the perineum and assists the woman as necessary, for example, by offering additional information regarding the use of perineal pads. Many women have never used a perineal pad or belt and will need instruction in using them during the postpartal period. (See Patient Teaching: Care of Episiotomy or Laceration.) Some women may prefer to use the pads designed for urinary incontinence. The pads are also highly absorbent and are usually self-adherent. Postpartum patients with genital piercings should be encouraged to exercise extra vigilance regarding perineal care to prevent infection (Young & Armstrong, 2008).

Ice Pack

If an episiotomy is performed at the time of birth or if a laceration occurs, an ice pack is generally applied to reduce edema and numb the tissues, which promotes comfort. Many agencies offer commercial ice packs or cold gel pads, which should be used according to the manufacturer's instructions. Before applying the ice pack the nurse should ask the woman for permission and consider cultural norms. A Cochrane review (East, Begg, Henshall, et al., 2007) noted that ice packs are commonly applied for 10 to 20 minutes, with no adverse effects. Optimal times and length of application have not been established, however. Use of ice packs may be continued for as long as necessary. Usually, they are needed during the first 24 hours postpartum.

TEACHING FOR SELF-CARE The nurse provides information about the purpose of the ice pack, anticipated effects, benefits, and possible problems.

PROCEDURE 36-1 Use of Sitz Baths, Ice Packs, and Perineal Hygiene

NURSING ACTION

Preparation

- Explain the importance and benefits of perineal care. These methods can be used for the woman who has had any type of perineal trauma such as an episiotomy, laceration, extension of the episiotomy, or edema from an extended period of pushing.

  Rationale: *Perineal care promotes healing, prevents infection, and relieves discomfort in the perineal area following a vaginal birth. It may be needed after a cesarean birth if the woman had perineal trauma before having to advance to a cesarean delivery.*

Equipment and Supplies

Peri bottle or squirt bottle

Chemical ice packs *or* exam glove filled with ice chips, tied at top, powder rinsed off and covered with clean cloth

Sitz bath as provided by the facility

Clean towel for drying perineum and one placed on floor around toilet to prevent slipping on wet floor

Rationale: *The woman may need only one of these procedures or she may need to use a combination of two or three. At the very least, the use of peri bottles should be encouraged after each urination or defecation.*

Procedure

Peri Bottle

1. Explain the purpose and use of the peri bottle as well as the benefits and possible problems. Its use can assist with keeping the area clean, provide comfort, prevent infection, and promote healing.
2. Demonstrate and assist the patient as needed to fill a small plastic peri bottle with warm water and reapply the cap. Have patient feel water to assure it is at a comfortably warm temperature. Open the top of the cap and gently squirt the warm water on the entire perineal, urethral, and anal area if able.

   Rationale: *The warm water will aid in increasing blood flow, which promotes healing, and will loosen dried blood that may be present, which aids in cleansing.*
3. Have the woman dry the perineal area with a clean towel, patting dry, beginning at the front (urethral area) and ending at the back (anal area). Apply new peri-pad, ice pack (if using), and underwear.

   Rationale: *Instruct the woman to perform this procedure and apply a new peri-pad after each urination and defecation.*

Ice Packs

1. Explain the purpose and use of the ice packs and expected results, as well as benefits and possible problems.

   Rationale: *Ice packs are generally used to reduce edema due to perineal trauma. Many women find the ice relieves the discomfort by providing temporary numbing of the area.*

   For edema, the ice packs will usually need to be used for 12–24 hours or until the mother no longer feels a need for it.
2. If chemical ice packs are used, activate the pack according to the manufacturer's instructions (written on plastic wrapper), which is usually to squeeze the middle tightly or to bend the ends toward the middle until a "pop" is heard or felt.
3. If chemical ice packs are not available, use an exam glove filled with ice chips and tied off the top of the glove like a balloon. Rinse any powder off the glove and wrap with a clean cloth. Do not apply the glove directly to the skin as it may cause a burn from the extreme cold.
4. The ice pack is to be placed directly on the perineal area, and larger, more absorbent peri-pads can be placed between the ice pack and underwear.
5. The ice pack can remain in place until the next time the woman uses the restroom or until it no longer feels cool to the touch.

   Rationale: *Document use of ice packs per agency guidelines. Report and document any adverse event related to the use of the ice packs.*

Sitz Baths

1. Explain the purpose and use of the sitz bath, anticipated effects, benefits, possible problems, and safety measures to prevent slipping or an injury from hot water. The sitz bath will last approximately 20 minutes.

   Rationale: *The nurse may compare the sitz bath to "sitting in a gentle whirlpool for 20 minutes."*
2. Raise the toilet seat on the toilet.
3. Insert large infusion bag or tube into the back of the sitz-bath basin, anchoring it to the bottom of the basin with the small opening at the end of the tubing facing upward, toward the ceiling.
4. Close the clamp on the tubing.
5. Fill the drainage bag with warm or cool water* up to the top line as indicated on the bag (have bag as full as possible without spilling when carried from the top).

   Rationale: **Warm water (102°F to 105°F or to touch) provides comfort, cleansing, and increases circulation which promotes healing and the prevention of infection. Cool water is effective in reducing edema and decreases pain. Offer both choices and allow the woman to choose which temperature she wants. If using cool water, add ice chips to the water if the woman desires a colder temperature.*
6. Place the basin in the toilet with the side marked "front" facing the front of the toilet.
7. Secure the drainage bag from a hook over the toilet or from the handle used to flush the toilet if it is a few feet higher than the toilet.
8. After placing towels on the floor around the toilet, assist the woman to sit directly on the basin edges as if it were the toilet seat.

   Rationale: *When the woman sits on the basin, excess water may overflow onto the floor around the toilet, thus the need for towels on the floor.*
9. Open the clamp on the tubing. The water will drain from the bag, into the basin, which already has water in it, thus

PROCEDURE 36-1 Use of Sitz Baths, Ice Packs, and Perineal Hygiene continued

NURSING ACTION

producing a gentle swirling movement of the water in the basin and on the perineal area. Water from the basin or bag will flow into the toilet through holes in the sides of the basin.

10. Once the sitz bath is complete, instruct the woman to close the clamp on the tubing, dry perineum with a clean towel, and apply new peri-pad.
11. Rinse the basin and place the tubing and bag inside and set it aside for the next use.
12. Take care to wipe up any spilled water from the floor to avoid slippage and injury.

Documentation

Document the use of the sitz bath as per agency documentation guidelines. Document and report any adverse events related to the use of the sitz bath.

Sitz Bath

The warmth of the water in the sitz bath provides comfort; decreases pain; and increases circulation to the tissues, which promotes healing and reduces the incidence of infection. Sitz baths may be used PRN. The nurse teaches the mother to fill the disposable sitz bath with water at a temperature (warm or cool) that is comfortable for her. The nurse instructs the woman to remain in the sitz bath for 20 minutes. It is important for the woman to have a clean towel to pat dry her perineum after the sitz bath and to have a clean perineal pad ready to apply. The woman should rinse the sitz bath with clean warm water after each use. See Procedure 36-1: Use of Sitz Baths, Ice Packs, and Perineal Hygiene.

RESEARCH EVIDENCE IN PRACTICE

Relieving Postpartum Perineal Pain

CLINICAL QUESTIONS

What are the determinants of postpartum perineal pain? How can it be alleviated?

RESEARCH EVIDENCE

Perineal pain affects nearly three quarters of women in the postnatal period. Pain may be a result of perineal bruising, spontaneous tears, surgical incision (episiotomy), or the use of instruments to assist the birth.

Several epidemiologic and cross-sectional studies have focused on the causes and risk factors associated with perineal pain. Primiparous women experience the highest rate of perineal pain. More significant perineal pain is associated with longer periods of active maternal pushing efforts. Ninety-seven percent of women with episiotomies and 100% of those with more severe tears report pain throughout the first week after birth. As one might expect, women with an intact perineum or first-degree tears had significantly less pain than women with second-, third-, or fourth-degree tears. Women with spontaneous first and even second-degree tears reported less pain than women with episiotomies.

The National Collaborating Center for Primary Care convened a group of obstetric experts to review research literature and provide expert advice on postnatal care. Women in the postnatal period should be asked if they have perineal pain, discomfort, stinging, burning, or offensive odor. If any of these symptoms are reported, the healthcare provider should assess the perineum for signs of inflammation and infection.

Women can be advised to use cold therapy in the form of crushed ice packs or gel pads as an effective method of pain relief for perineal pain. If additional analgesia is required, acetaminophen has been demonstrated to be an effective treatment for pain.

Most perineal pain lessens significantly within the first week after birth. Even women with more severe tears had near complete relief of pain within 6 weeks, and reported no pain at 3 months post-birth.

WHAT QUESTIONS REMAIN UNANSWERED?

Are any topical agents effective in lessening the severity of pain and enhancing healing?

WHAT IS BEST PRACTICE?

Women should be asked if they have postnatal perineal pain, stinging, burning, or offensive odor. The perineum should be assessed if there are concerns about infection or excessive inflammation. Cold therapy and acetaminophen can help reduce the painful symptoms. The mother can be counseled that substantial relief can be expected within a week, and symptoms should subside altogether in the first 2 months.

CRITICAL THINKING

Develop an educational plan for counseling the mother about perineal pain, its treatment, and expected course in the postnatal period.

TEACHING FOR SELF-CARE The nurse provides information about the purpose and use of the sitz bath, anticipated effects, benefits, possible problems, and safety measures to prevent injury from possible slipping or extreme water temperature. Home use of sitz baths may be recommended for the woman with an extensive episiotomy or laceration; the woman may use either the disposable sitz bath from the birthing unit or her clean bathtub. When using a bathtub, the woman should draw 4 to 6 inches of water, assess the temperature of the water, and soak in the water for 15 to 20 minutes. If other family members use the bathtub, it should be cleaned prior to her use. The use of a handheld showerhead to irrigate the perineum is another way to cleanse and soothe the traumatized tissue.

Topical Agents

Topical anesthetic agents may be used to relieve perineal discomfort. The woman is advised to apply the anesthetic agent after a sitz bath or perineal care. Anesthetic sprays, foams, ointments, or Tucks pads may be ordered for relief of both perineal and hemorrhoidal pain. It is important for the nurse to emphasize that the woman should wash her hands before and after using the topical treatments.

TEACHING FOR SELF-CARE The nurse provides information about the anesthetic spray or topical agent. The woman needs to understand the purpose, use, anticipated effects, benefits, and possible problems associated with the product. The nurse can combine an explanation with a demonstration of correct application. A return demonstration is a useful method of evaluating the woman's understanding. Directions for self-application should be provided in the woman's primary language and should include instructions to keep the product away from children. Some facilities post instructions with text and photos in postpartum patient restrooms.

PROFESSIONALISM IN PRACTICE

Managing Postpartum Perineal Trauma

The nurse should be aware that approaches to management of postpartum perineal trauma vary between facilities and regions of the country. It is important for baccalaureate-prepared nurses to be familiar with online databases such as the Cochrane Library, to periodically review current literature, and to participate in the development of unit policies and procedures that promote the use of interventions substantiated by research. Nurses who do this are engaged in the Quality and Safety Education in Nursing (QSEN) competency of evidence-based practice.

Relief of Hemorrhoidal Discomfort

Some mothers experience hemorrhoidal pain after giving birth. Relief measures include the use of sitz baths, topical anesthetics, cool packs, or witch hazel pads (Tucks) applied directly to the anal area. Short-term use of topical creams or rectal suppositories containing hydrocortisone is often helpful. Increasing fiber and fluids in the diet, exercising moderately, and using stool softeners as needed prevents straining (Staroselsky, Nava-Ocampo, Vohra, et al., 2008). Women who have had a fourth-degree laceration during birth should not use rectal suppositories.

HEALTH PROMOTION EDUCATION

The woman may find it helpful to maintain a side-lying position when possible or to tighten her buttocks when sitting down to reduce contact of the perineum with the seat and to avoid prolonged sitting. The mother is encouraged to continue a high-fiber diet, maintain adequate fluid intake, and begin moderate exercise such as walking. The nurse can reassure her that hemorrhoids usually disappear a few weeks after birth if the woman did not have them before her pregnancy.

Relief of Afterpains

Afterpains are the pain associated with intermittent uterine contractions that occur when the uterus contracts as it returns to its prepregnant state (see chapter 35 ∞). A primipara may not notice afterpains, because her uterus is able to maintain a contracted state. Multiparous women and those who have had an overdistended uterus (due to multiple gestation or hydramnios) frequently experience discomfort from afterpains as the uterus intermittently contracts more vigorously. Breastfeeding women are also more likely to experience afterpains than formula-feeding women because of the release of oxytocin when the infant suckles. The nurse can suggest the woman lie prone with a small pillow under the lower abdomen, explaining that the discomfort may be intensified for about 5 minutes but then will diminish greatly. The prone position applies pressure to the uterus and therefore stimulates contractions. When the uterus maintains a constant contraction, the afterpains cease. Additional nursing interventions include positioning, ambulation, or administration of an analgesic agent, such as ibuprofen or acetaminophen.

Prescription combination drugs such as Lortab or Vicodin (hydrocodone and acetaminophen) and Percocet (oxycodone and acetaminophen) are commonly used for postpartum discomfort, although in June 2009 an FDA advisory panel recommended taking these drugs off the market due to the risk of fatal liver damage when patients take multiple medications, including acetaminophen. While the FDA has not made a final decision, it is likely that narcotics and acetaminophen will be available separately, rather than in combination, in the future. The panel also recommended decreasing the maximum daily dosage of acetaminophen to below 4 grams and recommended that individual dosages of more than 650 mg be available by prescription only (Associated Press [AP], July 1, 2009).

The mother's description of the type and severity of her pain is usually the most reliable method of determining which analgesic agent will best promote the comfort she desires. Many women who are breastfeeding have concerns about the effects of medications on the infant. It is helpful to point out to concerned mothers that mild analgesics such as acetaminophen and ibuprofen pose little risk to their newborns when used judiciously in the short term to allow them the ability to bond and breastfeed in comfort. Short-term use of prescription narcotic agents may be necessary for pain that does not respond to ibuprofen or acetaminophen. Nurses can use references such as *Medications and Mothers Milk* (Hale, 2008) when advising breastfeeding mothers about use of analgesics.

TEACHING FOR SELF-CARE The nurse provides information about the cause of afterpains and methods to decrease discomfort. The nurse also explains any medications that are ordered, expected effect, benefits, possible side effects, and any special considerations such as the possibility of dizziness or sleepiness with particular medications. The nurse must inform patients who take acetaminophen about the risks of accidental overdose. Patients should be instructed to carefully read the labels of any drugs they take concurrently for the presence of acetaminophen.

Relief of Discomfort from Immobility and Muscle Strain

Discomfort may also be caused by immobility and muscle strain. The woman who pushed for a long time during labor may experience muscular aches. It is not unusual for women to experience joint pains and discomfort in both arms and legs, depending on the effort they exerted during the second stage of labor. Early ambulation is encouraged to help reduce the incidence of complications such as constipation and thrombophlebitis. It also helps promote a general feeling of well-being.

The nurse assists the woman the first few times she gets up during the postpartal period. Fatigue, effects of medications, loss of blood, and possibly even lack of food may cause feelings of dizziness or faintness when the woman stands up. Because this may be a problem during the woman's first shower, the nurse should remain in the room, check the woman frequently, and have a chair close by in case the woman becomes faint. Dizziness may be aggravated by standing still and by the warmth of the water, so it is best to wait until the woman has eaten and has shown stability when ambulating. The first shower should be brief. On many postpartum units, ammonia inhalants (referred to as "smelling salts") are available for use in case of fainting. The nurse instructs the woman in the use of the emergency call button in the bathroom prior to the first shower, so the new mother can call for assistance if she becomes faint.

TEACHING FOR SELF-CARE The nurse provides information about ambulation and the importance of monitoring any signs of dizziness or weakness. If she becomes dizzy, the woman should sit down and call for assistance.

Postpartum Diaphoresis

Postpartum diaphoresis (excessive perspiration) may cause discomfort for new mothers. The nurse can offer a fresh dry gown and bed linens to enhance comfort.

Some women may feel refreshed by a shower. It is important to consider cultural practices and realize that some women may prefer not to shower in the first few days following birth. For example, some Hispanic and Asian women prefer to delay showering. Nurses can offer these women a wet washcloth to increase maternal comfort. Because diaphoresis also may lead to increased thirst, the nurse can offer fluids as the woman desires. Again, cultural practices are important to consider. Women of western European background may prefer iced water; Asian women may prefer water at room temperature (see chapter 35 ∞). The nurse should ascertain the woman's wishes rather than operate solely from the nurse's own values or cultural belief system.

TEACHING FOR SELF-CARE The nurse provides information about the normal physiologic changes that cause diaphoresis and methods to increase comfort.

Suppression of Lactation in the Nonbreastfeeding Mother

Many women who do not breastfeed experience some degree of engorgement, accompanied by milk leakage and discomfort. Some women report relief from non-pharmacologic means of suppression such as wearing a support bra continuously for the first week except when showering, avoiding breast stimulation, applying cold packs, or applying cabbage leaves. Although binding the breasts was used in the past, it is no longer recommended. Signs of engorgement usually peak by day 4 and spontaneously resolve by the 10th day postpartum, regardless of treatment. Analgesics such as acetaminophen and ibuprofen can be used until the discomfort subsides. Drugs such as Bromocriptine are no longer used in the United States for lactation suppression due to concerns related to possible rare side effects such as myocardial infarction, cerebral angiopathy, and thromboembolism, although causal relationships between Bromocriptine and these events were not proven. According to a Cochrane review, there is a lack of adequate research regarding side effects of pharmacologic suppression, and "there is currently no evidence to show that nonpharmacologic approaches are more effective than no treatment." Further research is needed (Oladapo & Fawole, 2009, p. 14).

HEALTH PROMOTION EDUCATION

The mother is advised to avoid any stimulation of her breasts and nipples by her baby, herself, breast pumps, or her sexual partner until the sensation of fullness has passed (usually in 7 to 10 days). Such stimulation will increase milk production and delay the suppression process. Heat is avoided for the same reason, and the mother is encouraged to let shower water flow over her back rather than her breasts. The wearing of a 24-hour support bra, the use of analgesics as prescribed, and the use of cabbage leaves and/or cold compresses should be helpful during this period of time (American Academy of Pediatrics [AAP] & The American College of Obstetricians and Gynecologists [ACOG], 2007). Suppression takes only a few days in most cases, but small amounts of milk may be produced up to a month after birth.

Pharmacologic Interventions

Pharmacologic preparations, including pain medications, vaccinations, and Rh immune globulin, are frequently administered in the postpartum period. (See Table 36-3.)

Rubella Vaccine

Women who are not rubella immune as determined by lab studies should receive the rubella vaccine early in the postpartum period. It is administered before discharge, even if she is breastfeeding (AAP & ACOG, 2007; Centers for Disease Control and

TABLE 36-3 Essential Information for Common Postpartum Drugs

TYLENOL NO. 3 (300 mg acetaminophen and 30 mg codeine)

Drug Class: Nonopioid analgesic/opioid analgesic combination.

Dose/Route: Usual adult dose: 1–2 tablets PO every 4 hours PRN.

Indication: For relief of mild to moderate pain.

Adverse Effects: Respiratory depression, apnea, light-headedness, confusion, sedation, dizziness, nausea, vomiting, sweating, dry mouth, constipation, hypotension, facial flushing, suppression of cough reflex, ureteral spasm, urinary retention, pruritus, hepatotoxicity (overdose).

Nursing Implications: Determine whether woman is sensitive to acetaminophen or codeine; has history of impaired hepatic or renal function. Assess pain before and 1 hour after administration. Monitor bowel sounds, respirations, urine output.

Administer with food or milk to minimize gastrointestinal (GI) upset; warn patient that it may cause drowsiness—assistance with newborn care and ambulation may be necessary.

Patient Teaching: Inform patient about name of drug, expected action, and possible side effects; ask if she has any questions.

Nursing Diagnoses Related to Drug Therapy:

Readiness for Enhanced Self-Health Management information regarding drug therapy.

Risk for Injury related to side effects of drugs.

Constipation related to slowed gastrointestinal activity secondary to effects of medications.

PERCOCET 5/325 (325 mg acetaminophen and 5 mg oxycodone)

Drug Class: Nonopioid analgesic/opioid analgesic combination.

Dose/Route: 1–2 tablets PO every 4 hours PRN.

Indication: For moderate to severe pain. Can be used in aspirin-sensitive women.

Adverse Effects: Acetaminophen: Hepatotoxicity, headache, rash, and hypoglycemia.

Oxycodone: Respiratory depression, confusion, sedation, dizziness, blurred vision, apnea, circulatory depression, orthostatic hypotension, euphoria, facial flushing, sweating, constipation, dry mouth, nausea, vomiting, suppression of cough reflex, ureteral spasm, urinary retention.

Nursing Implications: Determine whether woman is sensitive to acetaminophen or codeine; has bronchial asthma; respiratory depression; convulsive disorder; adrenal insufficiency; renal, hepatic, or pulmonary disease.

Assess pain before and 1 hour after administration. Assess blood pressure, pulse, and respirations before and periodically during administration. Increase fluids and fiber, use stool softener to prevent constipation. Warn patient that it may cause sedation—assistance with newborn care and ambulation may be necessary.

Observe woman carefully for respiratory depression if given with barbiturates or sedative/hypnotics or after epidural morphine. Consider that after a cesarean birth, the woman may have depressed cough reflex, so teaching and encouragement to breathe deeply and cough are needed.

Monitor bowel sounds, and urine and bowel elimination.

Patient Teaching: Teaching should include name of drug, expected effect, possible adverse effects, whether the drug is secreted in the breast milk, encouragement to report any signs of adverse effects immediately.

Nursing Diagnoses Related to Drug Therapy:

Ineffective Breathing Pattern related to respiratory depression.

Constipation related to slowed gastrointestinal activity secondary to the effects of medications.

RUBELLA VIRUS VACCINE, LIVE MERUVAX® II (rubella virus vaccine live) or MMR® II (measles, mumps, and rubella virus vaccine live) may be used.

Dose/Route: Single-dose vial of 0.5 ml; inject subcutaneously in outer aspect of the upper arm.

Primary Indication: Stimulate active immunity against rubella virus in the postpartum woman who is susceptible to rubella, in order to protect future pregnancies.

Adverse Effects: Burning, pain, or stinging at the injection site; fever; arthritis/arthralgia; encephalitis; allergic reactions

Nursing Implications: Women who are allergic to neomycin, eggs, or gelatin, or who are immunosuppressed should not receive it. The manufacturer recommends delaying immunization for 3 months following blood transfusions. The immunization is contraindicated during pregnancy, and the patient should avoid pregnancy for 1 month following administration. Patient consent is obtained prior to immunization, and a record of administration is usually filed with the local health department. As with any immunization, epinephrine should be available in case of anaphylactic reaction.

Patient Teaching: Name of drug, expected effect, possible adverse effects, comfort measures to use if adverse effects occur; instruct woman to AVOID PREGNANCY FOR AT LEAST 4 WEEKS following vaccination. Provide information regarding contraceptives and their use.

Nursing Diagnoses Related to Drug Therapy:

Acute Pain Defining characteristics may include guarding, position, or verbal report of pain during or following subcutaneous administration of immunization.

Readiness for Enhanced Immunization Status

Defining characteristics may include expressed desire to receive the immunization, keep a record of the immunization, or learn about possible problems related to the immunization.

Rh_0 (D) IMMUNE GLOBULIN (Rh immune globulin specific for D antigen)

Standard intramuscular (IM) formulations include ***RhoGAM®*** or ***HyperRHO S/D Full Dose®***

Microdose intramuscular (IM) formulations include ***HyperRHO S/D Mini-Dose®***, ***MICRhoGAM®***, & ***Mini-Gamulin R®*** (IM formulations are not intended for IV administration).

Dose/Route: Postpartum administration: One vial (300 mcg) IM (deltoid) within 72 hours of birth. Additional vials may be necessary after significant fetal-maternal hemorrhage as indicated by lab results (Kleihauer-Betke test).

Antepartum administration: One standard vial (300 mcg) is given IM at 28 weeks in Rh-negative women. One standard vial (300 mcg) is given IM: (a) after trauma, (b) after amniocentesis, (c) following obstetric manipulation such as version, and (d) following the termination of any pregnancy at 13 weeks or beyond (includes spontaneous or elective abortion, ectopic, etc.).

Antepartum administration prior to 13 weeks gestation: One microdose vial (50 mcg) is given IM following the termination of any pregnancy prior to 13 weeks.

Additional formulations are available. ***WinRho SDF®*** and ***Rhophylac®*** are IV formulations, which may be given IM, but dose may differ from the information above. As always, refer to current manufacturers' recommendations for safe administration.

Indication: Prevention of sensitization in Rh_0 (D)-negative women by preventing production of anti-Rh_0 (D) antibodies following exposure to Rh_0 (D) positive blood. Mother must be Rh negative, not previously sensitized to Rh factor. Infant must be Rh positive, direct antiglobulin negative. Given during pregnancy to prevent erythroblastosis fetalis if fetus is Rh_0 (D) positive in current and/or future pregnancies. Given postpartum to protect future pregnancies.

Adverse Effects: Pain at injection site, anemia, fever. May decrease response to live virus vaccines such as rubella.

Nursing Implications: Contraindicated in patients with documented hypersensitivity to human immune globulins. Confirm criteria for administration are present. Review type and crossmatch of mother's and infant's blood and any other labs, as dosage and administration depend on results. Do not confuse IM and IV formulations. If using a pre-filled syringe, allow it to come to room temperature before IM administration. If the mother is Rh (D) negative, and there is any doubt regarding the infant's blood type or lab studies, the medication should be given. **Do not administer to newborn.**

TABLE 36-3 Essential Information for Common Postpartum Drugs continued

Patient Teaching: Name of drug, expected action, possible side effects; report soreness at injection site to nurse; woman should carry information regarding Rh status and dates of RhoGAM injections with her at all times; explain relevance of RhoGAM to subsequent pregnancies.

Nursing Diagnoses Related to Drug Therapy:

Acute Pain: Defining characteristics may include guarding, position, or verbal report of pain during or following intramuscular administration of immunization.

Readiness for Enhanced Immunization Status: Defining characteristics may include expressed desire to receive the immunization, keep a record of the immunization, or learn about possible problems related to the immunization.

MOTRIN, ADVIL (ibuprofen)

Drug Class: nonopioid analgesic; nonsteroidal anti-inflammatory agent.

Dose/Route: 400 to 800 mg orally 3–4 times/day (use as an over-the-counter analgesic not to exceed 1200 mg/day; up to 2400 mg/day may be prescribed for short-term postpartum use)

Indication: Mild to moderate pain.

Adverse Effects: Headache, dizziness, drowsiness, blurred vision, tinnitus, constipation, dyspepsia, nausea, vomiting, hematuria, renal failure, arrythmias, edema, rashes, prolonged bleeding time, blood dyscrasias. Life-threatening adverse effects may include anaphylaxis, GI bleeding, hepatitis, exfoliative dermatitis, Steven-Johnson Syndrome, and toxic epidermal necrolysis.

Nursing Implications: Patients with asthma, aspirin-induced allergy, and nasal polyps are at increased risk for hypersensitivity. Assess pain before and 1 to 2 hours after administration. May cause prolonged bleeding time, which may persist for less than 1 day after discontinuation. Co-administration with opioid analgesics may have additive effects and permit smaller doses. Administer with food, milk, or antacid to decrease GI upset. May cause drowsiness or dizziness—new mothers may require assistance with newborn care and ambulation.

Patient Teaching: Name of drug, expected action, possible side effects. Encourage patient to drink a full glass of water with medication and to remain upright for 15 to 30 minutes. Instruct not to take it on an empty stomach. Inform patient that dosages prescribed for short-term postpartal use are higher than what is recommended for general over-the-counter use of ibuprofen. Ensure that patient knows the trade names (Motrin, Advil, etc.) to avoid accidental overdose. Patient should consult with provider before taking other medications or herbal supplements concurrently.

Nursing Diagnosis Related to Drug Therapy:

Readiness for Enhanced Knowledge: Defining characteristics may include expressing an interest to learn about the medication and how to promote comfort.

Nausea: Defining characteristics may include gagging sensation, report of nausea, and aversion toward food related to ingestion of ibuprofen.

Sources: AAP & ACOG, 2007; Deglin & Vallerand, 2009; Herdman, 2009; Merck, 2008a, pp. 2061–2062; Merck, 2008b, pp. 2054–2056.

Prevention (CDC), 1998, updated 2007). Administering the injection just after childbirth is advantageous because the woman is definitely not pregnant and typically does not want another pregnancy within the near future.

TEACHING FOR SELF-CARE The nurse needs to ensure that the woman understands the purpose of the vaccine and that she must avoid becoming pregnant for at least 1 month. To ensure that the woman understands, an informed consent is usually signed before administration. Because avoiding pregnancy is so important, counseling regarding contraception is necessary.

PROFESSIONALISM IN PRACTICE

How to Address Differing Drug Recommendations

The nurse will find that sources sometimes vary regarding recommendations for various drugs. For example, some sources recommend delaying pregnancy for a minimum of one month following rubella immunization (AAP & ACOG, 2007; Deglin & Vallerand, 2009), but the manufacturer recommends delaying pregnancy for 3 months (Merck, 2008a, 2008b). Both the AAP & ACOG (2007) and Merck (2008a, 2008b) noted that the risk of congenital rubella syndrome from the vaccine is theoretical, and emphasized that cases have not occurred despite accidental administration during pregnancy. The professional nurse should discuss issues such as these with providers, be aware of professional organization recommendations, and read current literature in order to give accurate advice to patients.

Rh Immune Globulin (RhoGam)

All Rh-negative women with Rh-positive babies should receive Rh immune globulin (RhoGAM® or a similar formulation) within 72 hours after childbirth to prevent sensitization from a fetomaternal transfusion of Rh-positive fetal red blood cells (AAP & ACOG, 2007). See discussion of criteria in Procedure 20-2: Intramuscular Administration of Rh Immune Globulin [RhoGAM, HyperRHO, Rhophlac, WinRho-SDF] ∞ on page 482.

TEACHING FOR SELF-CARE The Rh-negative woman needs to understand the implications of her Rh-negative status in future pregnancies. (See chapter 20 ∞ for a detailed discussion.) The nurse provides opportunities for questions during teaching.

Support of Maternal Psychosocial Well-Being

The birth of a child, with the role changes and increased responsibilities it produces, is a time of emotional stress for the new mother. This stress is increased by the tremendous physiologic changes that occur as her body adjusts to a nonpregnant state. Nurses working in maternal-child care should read the works of Rubin (1984) and Mercer (1986, 2004, 2006), two key theorists who have researched and written about the process of developing a maternal identity over the past 40 years. Mercer recommended changing the previous terminology, *maternal role attainment (MRA),* to *becoming a mother (BAM)* in 2004. Their work also is discussed in chapter 35 ∞.

Mercer (2004) described becoming a mother (BAM) as a life-transforming process through which mothers establish maternal identity, including "(a) commitment, attachment, and preparation (pregnancy); (b) acquaintance, learning, and physical restoration (first 2 to 6 weeks following birth); (c) moving toward a new normal (2 weeks to 4 months); and (d) achievement of the

maternal identity (around 4 months)" (p. 231). Mercer (2006) also noted that this process "requires extensive psychological, social, and physical work" and that the second stage, which most women enter after childbirth, might be extended after a complicated pregnancy or birth (p. 649). Postpartum nurses must support the individual woman's process of becoming a mother. An extensive review of the literature by Mercer & Walker (2006) discovered that interactive nurse-patient relationships are necessary to support this transition. Although agencies may use audiovisual approaches to patient education in an era of short stays and cost containment, a portion of patient education and support needs to be offered through individualized patient-nurse interaction.

Immediately following the birth (the taking-in period), the mother may be dependent and inwardly focused on bodily concerns. Although the mother will benefit from rest at some point early in the postpartum period, there is a preponderance of evidence that immediate **skin-to-skin contact (SSC)** between mother and newborn has many positive effects for both (Bystrova et al., 2009; Dabrowski, 2007; Klaus, 2009; Moore, Anderson, & Bergman, 2007). SSC should be encouraged for all mothers and newborns unless complications prevent it. Mother and newborn can rest comfortably together under close nursing supervision, and immediate newborn care such as Apgar scoring and assessment of vital signs can be performed in this position (Romano & Lothian, 2008).

Many women are focused on their own needs during the immediate postpartum period. Once the woman's self-care needs have been met, her focus will shift to the care of her newborn and her ability as a parent (the taking-hold period). During this time the mother is usually receptive to teaching, and tactful instructions and demonstrations assist her in developing mothering skills. The nurse must carefully avoid "taking over" the infant. By functioning as an adviser and allowing the mother to perform the actual care, the nurse demonstrates confidence in the mother's skill and ability, which in turn increases the mother's self-confidence about her effectiveness as a parent. Mercer (2006) emphasized the importance of positive feedback from the nurse regarding the mother's interactions with and provision of care for her newborn. "Mothers need to hear from an expert that it takes time, and trial and error for both mother and infant to know what to expect of the other" (p. 650).

The mother may benefit from the opportunity to tell her birth story during the hours and days following birth. During the postpartal period, the mother must adjust to the loss of her fantasized child and accept the child she has borne. This may be more difficult if the child is not of the desired sex or has birth defects. Parents of newborns requiring special care due to congenital anomalies or prematurity will require extra attention and opportunities to share their concerns, fears, and disappointment.

The incidence of postpartum mood disorders is between 10% and 15% across cultures (AAP & ACOG, 2007). The mother is often discharged before the onset of mood disturbances and disorders associated with the postpartum period. However, an extensive review of the literature, including the research of Beck and Dennis, found that "maternal mood in the immediate postpartum period (or up to 2 weeks postpartum) is a significant predictor of postpartum depression" (McQueen, Montgomery, Lappan-Gracon, et al., 2008, p. 129). Therefore, the nurse needs to individually assess all postpartum patients for mood disorders and coordinate follow-up care for women who exhibit postpartum *blues* prior to discharge (AAP & ACOG, 2007; McQueen et al., 2008). Postpartum blues (also referred to as *baby blues*), postpartum depression, and postpartum psychosis are discussed in detail in chapter 39 ∞. See chapter 35 ∞ for assessment and screening tools for postpartum blues and postpartum depression.

HEALTH PROMOTION EDUCATION

The nurse should advise the mother that physical, psychologic, and hormonal factors all influence an individual's response to childbirth. It is often helpful to discuss normal adaptations in the postpartum period with both the mother and her intimate partner or another family member. This ensures that someone close to her will be aware of the normal patterns of psychologic responses in the early postpartum period. Normal responses include a brief period of irritability, mood swings, crying spells, and other mood-related symptoms associated with postpartum blues. Symptoms are relatively mild and self-limiting, usually resolving within 10 days. Women who experience severe symptoms or symptoms that extend beyond the second postpartum week should be advised to contact their physician or certified nurse-midwife. The nurse should advise families about symptoms of postpartum depression and emphasize the importance of seeking help should they occur.

Promotion of Maternal Nutrition, Rest, and Activity

Promotion of Nutrition

The mother may be hungry and thirsty immediately following delivery, particularly if she had limited oral intake during a prolonged labor. She should be allowed to eat and drink as desired, unless complications prevent it. All postpartum women should be encouraged to eat a healthy, well-balanced diet. A breastfeeding mother will require 500 kcal/day above that which is ordinarily recommended for a woman of her age. Nonbreastfeeding women may return to normal caloric requirements for their age. Many women continue prenatal vitamin and iron supplementation until the postpartum checkup, and breastfeeding mothers may continue supplementation throughout lactation. See chapter 18 ∞ for more information about maternal nutrition, and chapter 35 ∞ for information on nutritional assessment and guidance.

Relief of Fatigue

Following birth, some women feel exhausted and in need of rest. Other women are euphoric and full of psychic energy, ready to retell their experience of birth repeatedly. The nurse evaluates individual needs, always with the goal of providing opportunities for rest (see chapter 35 ∞ for information on assessing rest and sleep status). This may include limiting visitors and providing a comfortable place for the significant other to sleep.

Fatigue is a common occurrence, which should be expected to resolve over the first few postpartal weeks. Additive sleep deprivation related to pregnancy discomforts, labor and delivery, and caring for a newborn, especially if there are other young children in the home, contributes to the problem. Adequate rest is essential to a smooth postpartum transition. The nurse can encourage rest by organizing activities to avoid frequent interruptions for the woman. Ideally, one person close to the mother will be in the room to watch the newborn when the mother sleeps. If this is not possible, the newborn may return to the nursery for a period of time to ensure that the infant remains safe while the mother is sleeping soundly.

Postpartum fatigue can be severe and extended in some women, complicating the recovery process. Runquist (2007) found that "postpartum fatigue emerged as an overwhelmingly negative, distressing, subjective experience that changed every aspect of participants' lives" (p. 30). Severe or prolonged fatigue potentially interferes with the woman's process of becoming a mother, interferes with her ability to care for herself and her baby, slows her return to social and work obligations, and puts her at increased risk for postpartum depression. Conditions such as anemia, infection and inflammation, and thyroid dysfunction predispose to postpartum fatigue, and women diagnosed with or experiencing symptoms of these complications should receive additional assessment and follow-up (Corwin & Arbour, 2007).

Although most mothers feel fatigued, they tend to view themselves as healthy and well if they perceive pregnancy and birth as natural processes. Some cultures have distinct customs regarding rest and activity in the postpartum period. For example, Taiwanese women may follow a traditional recuperation strategy of *doing-the-month* (Ko, Yang, & Chiang, 2008, p. 182), which restricts activity and encourages bedrest for the first month postpartum. Nurses unfamiliar with certain cultural customs may find it stressful if they are expected to perform all maternal-infant care or if women are resistant to Western recommendations for ambulation and exercise following childbirth. Most cultural customs can be accommodated if they are not harmful. The nurse should inform the mother of the health benefits of early ambulation.

HEALTH PROMOTION EDUCATION

Nearly all new mothers experience some degree of fatigue or sleep deprivation during the postpartum period. Women who have had a cesarean birth are coping with both the constant demands of the baby and their own recovery needs. Some women feel self-induced pressure to take care of household chores while the infant is napping. Fatigue and worry about unaccomplished tasks can become continuous and cyclical. Runquist (2007) found that prior experience with newborns, practical support with such things as newborn care, multiple sources of information, and the ability to "let go" of worries about nonessential tasks limited the experience of postpartum fatigue (p. 32). Mothers should be counseled to sleep when the baby sleeps, to utilize family and friends for support, and to delegate or postpone unnecessary chores and activities. Additionally, they should be advised to contact their healthcare provider if they experience signs of infection, anemia, thyroid dysfunction, or unrelenting postpartum fatigue that persists beyond the initial postpartum period.

Resumption of Activity

Ambulation and activity may gradually increase after discharge. The new mother should avoid heavy lifting, excessive stair climbing, and strenuous activity. One or two daily naps are essential and are most easily achieved if the mother sleeps when her baby does.

By the second week at home, the new mother may begin some light housekeeping activities. Although it is customary to delay the return to work outside the home for 6 weeks, most women are physically able to resume practically all activities in 4 to 5 weeks when the lochial flow has stopped. Delaying the return to work until after the final postpartal examination will minimize the possibility of problems.

HEALTH PROMOTION EDUCATION

The nurse can provide the new mother with suggestions for resuming her normal level of activity. Women should be encouraged to limit the number of activities to prevent excessive fatigue, increase in lochia, and negative psychologic reactions, such as feeling overwhelmed. The nurse can encourage the new mother to avoid the temptation to catch up on housework during infant naps, but instead use the time to rest. If excessive fatigue or an increase in lochia occurs, the woman should increase rest periods and decrease extra activities.

Postpartum Exercises

The nurse should encourage the woman to begin simple exercises while in the birthing unit and continue them at home, advising her that increased lochia or pain means she should reevaluate her activity and make necessary reductions. Most agencies provide a booklet describing suggested postpartal activities. (Exercise routines vary for women undergoing tubal ligation following birth and for cesarean birth patients.) See Figure 36-1 ■ for a description of some commonly used exercises. The postpartal woman is more likely to have positive views of her own well-being and less fatigue if she continues to do stretching and/or her own programmed pattern of exercise.

HEALTH PROMOTION EDUCATION

The nurse should advise the woman to begin Kegel exercises immediately after birth. The nurse can explain that these exercises will assist in returning vaginal tone and preventing urinary leakage. If no complications exist, normal exercise can be initiated at 2 weeks after birth. Women should be advised to take short walks outside if the weather is appropriate. Abdominal exercises can be suggested to retone the abdominal muscles. A regular exercise program including vigorous activities such as running, weight lifting, or competitive sports can usually be initiated after her 6-week postpartum examination or when approved by her physician or certified nurse-midwife.

Retention of weight gained during pregnancy contributes to future obesity, placing the woman at increased risk for diabetes, heart disease, and hypertension. Although further research is

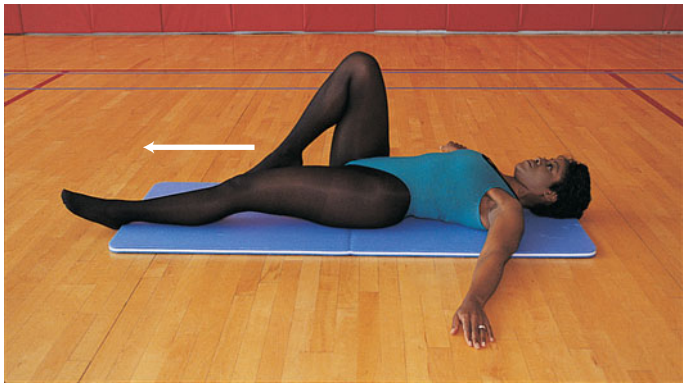
F

Figure 36-1 ■ Postpartum exercises. Begin with 5 repetitions two or three times daily, and gradually increase to 10 repetitions. First day: A. Abdominal breathing. Lying supine, inhale deeply, using the abdominal muscles. The abdomen should expand. Then exhale slowly through pursed lips, tightening the abdominal muscles. B. Pelvic rocking. Lying supine with arms at sides, knees bent, and feet flat, tighten abdomen and buttocks, and attempt to flatten back on floor. Hold for a count of 10; then arch the back, causing the pelvis to "rock." On the second day, add C. Chin to chest. Lying supine with legs straight, raise head and attempt to touch chin to chest. Slowly lower head. D. Arm raises. Lying supine, arms extended at a 90-degree angle from body, raise arms so that they are perpendicular and hands touch. Lower slowly. On fourth day, add E. Knee rolls. Lying supine with knees bent, feet flat, arms extended to the side, roll knees slowly to one side, keeping shoulders flat. Return to original position, and roll to opposite side. F. Buttocks lift. Lying supine, arms at sides, knees bent, feet flat, slowly raise the buttocks, and arch the back. Return slowly to starting position.

G



H

Figure 36-1 ■ Continued. On sixth day, add: G. Abdominal tighteners. Lying supine, knees bent, feet flat, slowly raise head toward knees. Arms should extend along either side of legs. Return slowly to original position. H. Knee to abdomen. Lying supine, arms at sides, bend one knee and thigh until foot touches buttocks. Straighten leg and lower it slowly. Repeat with other leg. After 2 to 3 weeks, more strenuous exercises, such as sit-ups and side leg raises, may be added as tolerated. Kegel exercises, begun antepartally, should be done many times daily during postpartum to restore vaginal and perineal tone.

needed, a Cochrane review found that diet alone or a combination of diet and exercise assisted women with weight loss following pregnancy. Although exercise without dietary changes did not contribute to postpartum weight loss in the studies reviewed, it did improve cardiovascular fitness. The authors recommended a combination of diet and exercise to promote heart health and preservation of lean body mass during weight loss (Amorim Adegboye, Linne, & Lourenco, 2007).

PROFESSIONALISM IN PRACTICE

Patient-Centered Care of Anemia

Professional nurses must be sensitive to risk factors for anemia, which contributes to postpartum fatigue. Nurses should pay particular attention to adolescent or low-income patients who may be at high risk for anemia. Education related to diet and iron supplementation is helpful, but the nurse should assess the patient's willingness and ability to comply with recommendations prior to discharge. Some patients stop use of iron supplements due to unpleasant side effects or inability to pay for them. Others lack the financial resources to procure healthy foods that are high in iron. Listening to the mother, providing individualized education, exploring options, and coordinating necessary resources and follow-up are professional nursing responsibilities that fulfill the Quality and Safety Education in Nursing (QSEN) competency of patient-centered care.

Promotion of Family Wellness and Shared Parenting

A satisfactory maternity experience may have a positive impact on the entire family. The new or expanding family who receives appropriate information and has adequate time to interact with its newest member in a supportive environment will feel more comfortable and secure at home.

In the past, newborns were typically separated from their parents immediately after birth. Today most facilities support **family-centered care**, which is focused on keeping the mother and baby together as much as the mother desires. **Mother-baby care**, or **couplet care** (care of both the mother and her baby), is an important part of the family-centered care approach, in which the infant remains at the mother's bedside and both are cared for by the same nurse. Couplet care allows the nurse to teach and role model and to integrate the entire family into the care of the woman and her infant. It also enables the mother to have time to bond with her baby and learn to care for him or her in a supportive environment.

A Cochrane review of 30 research studies involving 1925 mother-infant dyads found that skin-to-skin contact (SSC) immediately following birth helped to stabilize newborn temperature and cardiorespiratory status, promoted breastfeeding and maternal-infant attachment, and was associated with decreased infant crying (Moore et al., 2007). A study of 29 father-infant dyads found that the 15 infants offered SSC with their fathers following cesarean birth cried less and became drowsy sooner than those in the control group (Erlandsson, Dsilna, Fagerberg, et al., 2007). Therefore, the nurse should encourage immediate SSC following delivery of healthy term and late pre-term infants if stable. A warm blanket and hat should be placed over the infant, and these linens should be replaced if they become wet.

In a mother-baby unit, the newborn's crib is placed near the mother's bed, where she can see her baby easily. The crib should be a self-contained unit stocked with items the parents might require in providing care. A bulb syringe for suctioning the mouth or nares should always be accessible, and the mother and father or partner should be familiar with its use. The mother-baby unit is conducive to an on-demand feeding schedule for both breastfeeding and formula-feeding infants. It is essential that parents be oriented to the facility's infant security procedures and protocols to prevent infant abduction. This can be discussed in prenatal courses and upon admission to the birthing unit, and it will need to be reinforced when the infant begins rooming in.

Application: Clinical Pathway to Promote Family Wellness

Mothers are frequently very tired after birth, so the responsibility for providing total infant care could be overwhelming. The mother-baby policy must be flexible enough to permit the mother to return the baby to the nursery if she finds it necessary because of fatigue or physical discomfort. Many agencies have unlimited visiting hours for the father or significant others of the mother's choice. These opportunities to hold and care for the child promote paternal self-confidence and foster paternal attachment. Encouraging fathers or significant others to spend the night allows parents to share initial newborn care responsibilities while they still have the support of nursing staff if questions arise.

Although our culture idealistically and theoretically supports involved fathers, new fathers often lack role models, support, and resources. It is imperative that all teaching in the family-centered care unit be directed to both parents at times that are convenient for both and that fathers be encouraged to share their feelings and be actively involved in the childbearing experience. It is also helpful to provide anticipatory guidance for fathers regarding the feelings and situations they may experience, particularly if their baby is breastfed. Encouraging fathers to be involved in infant bathing, the bedtime routine, holding, cuddling, and playing will allow them to develop a relationship and reap the rewards they desire.

Reactions of Siblings

Sibling visitation helps meet the needs of both the siblings and their mother. A visit to the hospital reassures children that their mother is well and still loves them. It also provides an opportunity for the children to become familiar with the new baby. For the mother, the pangs of separation are lessened as she interacts with her children and introduces them to the newest family member.

Most agencies now recognize the importance of providing siblings with opportunities to see their mother and meet the infant during the early postpartal period (Figure 36-2 ■). Approaches to this issue vary from specified visiting hours for siblings to unlimited visiting privileges.

Figure 36-2 ■ The sister of this newborn becomes acquainted with the new family member.

HEALTH PROMOTION EDUCATION

Although the parents have prepared the child(ren) for the presence of a new brother or sister, the actual arrival of the infant requires some adjustments. Some children may be present for the birth and have an opportunity to spend time with their new sibling and their parents immediately following the birth. They may even remain throughout the woman's hospitalization, especially if it is brief, and all go home as a family.

For the mother who is returning home to small children, it is often helpful to have the father carry the new baby inside. This practice keeps the mother's arms free to immediately hug and hold her older children, reaffirming her love for them. Many mothers have found that bringing a doll home with them for an older child is helpful. The child cares for the doll alongside his or her parents, thereby identifying with the parent. This identification helps decrease anger and the need to regress to get attention.

Often older children enjoy working with the parents to care for the newborn. Involvement in care helps the older child develop a sense of closeness to the baby. It also helps the child learn acceptable behavior toward the newborn, feel a sense of accomplishment, and develop tenderness and caring. With constant supervision and assistance as necessary, even very young children can hold the baby or a bottle during feeding.

Regression is a common occurrence even when siblings have been well prepared. The nurse can provide anticipatory guidance so that parents are not surprised or upset if their previously toilet-trained child begins to have accidents or if an older sibling requests a bottle or the breast.

Regardless of age, an older sibling needs reassurance that he or she is still special to the parents, a truly loved and valued family member. Words of love and praise coupled with hugs and kisses are very important. So, too, is special parent-child time. Both parents should spend quality one-on-one time with each of their older children. This may require some careful planning, but its worth cannot be overestimated. It confirms the parents' love for the child and often helps the child accept the new baby.

The child, especially one of the opposite sex from the newborn, may raise queries about the appearance of the genitals as compared to his or her own. A simple explanation, such as, "That's what little girls (boys) look like," is often sufficient.

Resumption of Sexual Activity

Nursing interventions in the postpartal period acknowledge that each parent is also a sexual being. Couples were formerly discouraged from engaging in sexual intercourse until 6 weeks postpartum. Although the earliest time at which the couple can safely resume intercourse has not been demonstrated by research, the risks of hemorrhage and infection are minimal after 2 weeks postpartum (AAP & ACOG, 2007). Currently, the couple is advised to abstain from intercourse until the episiotomy is healed and the lochial flow has stopped (usually by the third to sixth week postpartum). During this period, couples can be encouraged to express their affection and love through kissing,

PATIENT TEACHING Resuming Sexual Activity After Childbirth

PATIENT GOALS At the completion of the teaching, the couple will be able to:

1. Discuss the changes in the woman's body that affect sexual activity.
2. Formulate alternative approaches to sexual activity based on an understanding of these changes.
3. Identify the length of time it is advisable to wait before resuming sexual activity.
4. Discuss information needed to make contraceptive choices.

TEACHING PLAN

Content	Teaching Method
■ Present information about changes that may affect sexual activity, including the following: ■ Tenderness of the vagina and perineum ■ Presence of lochia and the healing process ■ Dryness of the vagina ■ Breast tenderness/escape of milk during sex ■ Fatigue	Discussion is a logical approach. It may be useful to make a universal statement and link it with a question to determine a couple's initial level of knowledge. For example, "Many women experience vaginal dryness when they resume intercourse for the first several weeks after childbirth. Are you familiar with this change and the cause for it?" Use the information gained during this discussion to determine the depth to which to cover the material.
■ Discuss healing at the placental site and stress that the presence of lochia indicates that healing is not yet complete. Explain that vaginal dryness may pose a problem because of postpartal hormonal changes. Dryness may be prolonged if woman is breastfeeding, because of low estrogen levels. This can be managed by using a water-soluble lubricant. In most cases, coitus can resume at some point after 2 weeks, depending on the woman's comfort and desire (AAP & ACOG, 2007). Explain that escape of milk during sexual activity can be minimized by breastfeeding the baby immediately beforehand.	Provide printed information to clarify content and serve as a resource for the couple following discharge.
■ Discuss the importance of contraception during the early postpartal period. Provide information on the advantages and disadvantages of different methods, including special considerations for breastfeeding mothers. The woman's body needs adequate time to heal and recover from the stress of pregnancy and childbirth. Couples who are opposed to contraception may choose abstinence at this time.	Provide samples of different types of contraceptives. Provide literature on specific contraceptive methods.
■ Discuss the impact of fatigue and the new baby's schedule on the woman's feelings of desire. Refer the couple to a physician or certified nurse-midwife for additional information if needed.	Many couples are unprepared for the impact of fatigue and the baby's schedule on lovemaking. Information enables the couple to anticipate this impact.

Evaluation	Documentation
Determine the couple's learning by providing time for discussion and questions. If the couple indicates that they plan to use a particular contraceptive method, you may ask them about aspects of the method to ascertain that they have correct and complete information.	Documentation of patient teaching should include the teaching information discussed, the patient's verbalization of understanding, specific interventions or warning signs that were given, along with the patient's understanding of follow-up if needed in the future.

holding, and talking. Since postpartum women often experience vaginal dryness due to hormonal changes, some form of lubrication, such as K-Y jelly, may initially be necessary during intercourse. This may continue throughout the period of lactation in breastfeeding mothers because of lower estrogen levels. The female-superior or side-by-side positions for coitus may be preferable because they enable the woman to control the depth of penile penetration.

Breastfeeding couples should be forewarned that during orgasm, milk may spurt from the nipples because of the release of oxytocin. Some couples find this pleasurable or amusing; other couples choose to have the woman wear a bra during sexual activity. Breastfeeding the baby before lovemaking may reduce the chance of milk release.

Other factors may inhibit satisfactory sexual experience. The baby's crying may "spoil the mood," the woman's changed body may be unattractive to her or to her partner, and maternal sleep deprivation may interfere with a mutually satisfying experience. Couples may also be frustrated if there is decreased libido or other changes in the woman's physiologic response to sexual stimulation. These changes are due to hormonal changes and may persist for several months.

Maternal fatigue is often a significant factor limiting the resumption of sexual intercourse. Consequently, couples should

be encouraged to find a time for lovemaking when both are interested and awake. While interest and desire vary, most couples resume sexual activity within 3 months.

Anticipatory guidance during the prenatal and postnatal periods can forewarn the couple of these eventualities and of their temporary nature. See Patient Teaching: Resuming Sexual Activity After Childbirth on page 1041.

HEALTH PROMOTION EDUCATION

The nurse should discuss normal sexual changes that frequently occur in the postpartum period. A discussion that includes both partners can facilitate an open dialog between them and can provide an opportunity for questions and answers.

Contraception

Because many couples resume sexual activity before the postpartal examination, family-planning information should be made available before discharge. A couple's decision to use a contraceptive is often motivated by a desire to gain control over the number of children they will conceive or to determine the spacing of future children. In choosing a specific method, consistency of use outweighs the absolute reliability of a given method. The nurse must identify risk factors and contraindications of the various methods to help the couple select a contraceptive method that has practical application and is compatible with the couple's health and physical needs.

Often different methods of contraception are appropriate at different times in the couple's life. Thus they should have a clear understanding of all of the methods available to them so that they can make an appropriate choice. The currently available contraceptive methods are discussed in detail in chapter 5 ∞.

HEALTH PROMOTION EDUCATION

The nurse should discuss available contraceptive methods with both partners before discharge. Written information should also be provided for the couple to refer to at a later time. The nurse should stress the fact that pregnancy can occur before the first menstrual period returns and that contraception before that time is necessary to avoid pregnancy. The nurse should be frank and open with the couple, answering questions as needed.

Parent-Infant Attachment

Nursing interventions to enhance the quality of parent-infant attachment should be designed to promote feelings of well-being, comfort, and satisfaction. Table 36-4 describes parental attachment behaviors and those that require further assessment (see chapter 35 ∞ for ways to assess maternal-infant attachment). Following are some suggestions for ways of achieving this.

- Determine the childbearing and childrearing goals of the infant's mother and father, and incorporate them when planning nursing care for the family. This includes considering cultural preferences, and giving the parents choices about their labor and birth experience and their initial time with their new infant.
- Postpone eye prophylaxis for 1 hour after birth to facilitate eye contact between parents and their newborn (eye ointment further clouds the newborn's vision and makes eye contact difficult for the baby).
- Provide private time in the first hour after birth for the new family to become acquainted. Encourage SSC between mother (or father) and baby to promote breastfeeding and bonding.
- Arrange the healthcare setting so that the individual nurse-patient relationship can be developed and maintained. A primary nurse can develop rapport and assess the mother's strengths and needs.
- Encourage the mother to tell her birth story. Clarify information for the mother as necessary.
- Encourage the parents to involve the siblings in integrating the infant into the family by bringing them to the birthing center for sibling visits.
- Use anticipatory guidance from conception through the postpartal period to prepare the parents for expected problems of adjustment.

TABLE 36-4 Parent Attachment Behaviors

ASSESSMENT AREA	ATTACHMENT	BEHAVIOR REQUIRING ASSESSMENT AND INFORMATION
Caretaking	Talks with baby. Demonstrates and seeks eye-to-eye contact. Touches and holds baby "en face." Changes diapers when needed. Baby is clean. Clothing is appropriate for room temperature. Feeds baby as needed, and baby is gaining weight. Positions baby comfortably and checks on baby.	Does not refer or speak to baby. Completes activities without addressing the baby or looking at the baby. Lack of interaction. Does not recognize need for or demonstrate concern for baby's comfort or needs. Feeding occurs intermittently. Baby does not gain weight. Waits for baby to cry and then hesitates to respond.
Perception of the baby	Has knowledge of expected child development. Understands that the baby is dependent and cannot meet parent's needs. Accepts sex of child and characteristics.	Has unrealistic expectations of the baby's abilities and behaviors. Expects love and interaction from the baby. Believes that the baby will fulfill parent's needs. Is strongly distressed over sex of baby or feels that some aspect of the baby is unacceptable.
Support	Has friends who are available for support. Seems to be comfortable with being a parent. Has a realistic belief of parenting role.	Is alone or isolated. Is on edge, tense, anxious, and hesitant with the baby. Demonstrates difficulty incorporating parenting with own wants and needs.

Please note: These are a few of the behaviors that may be associated with attachment. It is vitally important for the nurse to observe the parents on more than one occasion and to take into consideration individual characteristics, values, beliefs, and customs.

- Include parents in any nursing intervention, planning, and evaluation. Give choices whenever possible.
- Initiate and support measures to alleviate fatigue in the parents.
- Help parents identify, understand, and accept both positive and negative feelings related to the birth, the newborn, and the overall parenting experience.
- Support and assist parents in determining the personality and unique needs of their infant.

Whenever possible and culturally acceptable, the mother and father should be allowed to care for their baby. This practice gives them a chance to learn their newborn's normal patterns and develop confidence in caring for him or her. It also allows them to spend more uninterrupted time with their infant in the first days of life. Early discharge may be advantageous if mother and baby are doing well, help is available for the mother at home, and the family and certified nurse-midwife or physician agree.

The nurse may observe beginnings of parent-newborn attachment in the first few hours after birth, and when continuing assessments during home visits after discharge. As the nurse assesses attachment, it is important to remember that cultural values, beliefs, and practices will direct child care activities and self-care practices. For example, traditionally religious-observant Jewish families may not name their newborns until the eighth day following birth at the circumcision ceremony known as the *brit* or *bris milah* (Noble, Rom, Newsome-Wicks, et al., 2009). Nurses should respect cultural norms and incorporate them into the care of the newborn whenever possible. Chapter 35 ∞ discusses this and other cultural practices in the postpartum period.

HEALTH PROMOTION EDUCATION

Some parents, especially first-time parents, may feel awkward in their new role. It is helpful for the nurse to advise parents that they may experience feelings of uncertainty as they grow into the parental role and alter their family processes to accommodate the new family member. The nurse should also provide reassurance and advise new parents of normal infant behavior and activity. The nurse assesses attachment before discharge. If the nurse identifies a possible alteration in attachment, the parents can be referred to a new parent support group, parenting classes, or counseling to assist them with their transition into their new roles. The nurse can explain that new attachments are being formed, and like all new relationships, both the infant and the parents are discovering each other. The nurse should discuss possible risk factors of altered attachment such as inability or lack of desire to care for the infant.

Nursing Care Following Cesarean Birth

Approximately 31.1% of women delivered by cesarean section in the United States in 2006; this represented a 50% increase since 1996 (Menacker & Martin, 2009). Nurses need to be adept at addressing the special needs of this growing population of patients. After a cesarean birth, the new mother has postpartal needs similar to those of women who gave birth vaginally. Because she has undergone major abdominal surgery, however, the woman also has nursing care needs similar to those of other surgical patients.

Care Plan Activity: Postpartum Care Following Cesarean Birth

Promotion of Maternal Physical Well-Being After Cesarean Birth

Care of the patient following cesarean delivery is similar to the care of patients who deliver vaginally, but also includes consideration of the postoperative condition. Nursing interventions will focus on promotion of maternal comfort, promotion of maternal and newborn safety, and prevention of postoperative complications. The nurse will monitor neurologic and neuromuscular status closely until effects of anesthesia have worn off. Routine postpartum assessments will include inspection of the dressing or incision for intactness and signs of complications or infection, as well as increased attention to lung sounds, gastrointestinal status, and genitourinary status.

Immobility after the use of narcotic and sedative agents and alterations in the immune response of postoperative patients increase the chances of pulmonary infection. For this reason, the woman is encouraged to cough and breathe deeply and to use incentive spirometry every 2 to 4 hours while awake for the first few days following cesarean birth.

Immobility increases the risk of abdominal distention and discomfort, deep vein thrombosis, and pulmonary embolism. The patient may wear sequential compression devices (SCDs) until she is ambulating. Within the first 12 hours postoperatively, unless medically contraindicated, the woman should be assisted to dangle her legs on the side of the bed. Once she is awake, alert, and has complete sensation and strength in her lower extremities, the woman should be assisted out of bed. Ambulation should begin no later than 24 hours postoperatively and should be encouraged at least two to three times a day.

The nurse continues to assess the woman's pain level and provide relief measures as needed. Sources of pain include incisional pain, gas pain, referred shoulder pain, periodic uterine contractions (afterpains), and pain associated with voiding, defecation, or constipation.

Nursing interventions are oriented toward preventing or alleviating pain or helping the woman cope with pain. The nurse should undertake the following measures:

- Administer analgesic medications as needed and ordered, especially during the first 24 to 72 hours. Their use will relieve the woman's pain and enable her to be more mobile and active.
- Promote comfort through proper positioning, backrubs, oral care, and the reduction of noxious stimuli, such as noise and unpleasant odors.
- Encourage the presence of the significant other and the newborn. This may provide distraction from the painful sensations and help reduce the woman's fear and anxiety. The presence of a significant other provides a watchful presence over the newborn, allowing the baby to stay in the room with the mother while she may not be alert or comfortable enough to be responsible for the newborn if left alone.
- Encourage the use of breathing, relaxation, and distraction techniques (for example, stimulation of cutaneous tissue) taught in childbirth preparation class.

- Instruct the woman to splint her incision with a pillow when changing positions, coughing, deep breathing, or sneezing.
- Encourage adequate rest periods. This may include limiting excessive visitors and phone calls.
- Encourage early ambulation to prevent abdominal distention that can occur with excess accumulation of gas in the intestines.
- Allow the woman to begin judiciously consuming food and fluids as desired when awake and alert. Although many institutions still withhold oral intake until bowel sounds return, a Cochrane review found no evidence to support this practice. Women experience fewer gastrointestinal complications and discomforts following cesarean when allowed to advance their own diet (Mangesi & Hofmeyr, 2005).

Neuraxial analgesia administered just after the cesarean birth is an effective method of pain relief for most women in the first 24 hours following birth (see Drug Guide: Postpartum Neuraxial Morphine).

The physician may prescribe **patient-controlled analgesia (PCA)**. With this approach, the woman is given a bolus of analgesia, often morphine, at the beginning of therapy. Using a special intravenous (IV) pump system, the woman presses a button to self-administer small doses of the medication as needed. For safety, the pump is preset with a time lockout so that the pump cannot deliver another dose until a specified time has elapsed. Women using PCA feel less anxious and have a greater sense of control with less dependence on the nursing staff. The frequent smaller doses help the woman experience rapid pain relief without grogginess and also eliminate the discomfort of injections. As with any drug therapy, the nurse will monitor the patient for side effects and intervene as necessary.

If general anesthesia was used, abdominal distention from the accumulation of gas in the intestines may produce discomfort for the woman during the first postpartum days. Additional measures to prevent or minimize gas pains include leg exercises, abdominal tightening, avoiding carbonated or very hot or cold beverages, and avoiding the use of straws. The woman may find it helpful to lie prone or on her left side. Lying on the left side allows gas to rise from the descending colon to the sigmoid colon so that it can be expelled more readily. Other women report that a rocking chair helps them obtain relief. Medical interventions for gas pain include the use of antiflatulents (such as Mylicon), suppositories, and enemas.

The nurse can minimize discomfort and promote satisfaction as the mother assumes the activities of her new role. Instruction and assistance in assuming comfortable positions when holding or breastfeeding the infant will do much to increase the mother's sense of competence and comfort. Sitting in a chair or tailor fashion in bed, leaning slightly forward with the infant propped on a pillow in her lap, will prevent irritation to the incision. Use of the football hold and side-lying positions may be most comfortable for breastfeeding during the initial postoperative course.

By the first or second day after the cesarean birth, the mother is usually receptive to learning how to care for herself and her infant. Demonstration of proper body mechanics in getting out of bed without the use of a side rail and ways of caring for the infant that prevent strain and torsion on the incision are also indicated. The nurse needs to place special emphasis on home management, encouraging the woman to let others assume responsibility for housekeeping and cooking. Fatigue not only prolongs recovery but also interferes with breastfeeding and mother-infant interaction.

The woman usually does extremely well postoperatively. If neuraxial anesthesia was used, the side effects of general anesthesia are absent. Even after general anesthesia, however, most women are ambulating by the day after the surgery. Usually the woman can shower by the first or second postpartal day, which seems to provide a mental as well as physical lift. The incision can be covered with plastic if the dressing is still in place. If staples have been used, the incision is sometimes left open to the air, and showering is permitted without covering it. Most women are discharged on the second or third postoperative day.

Women with cesarean births have several special needs following discharge: increased need for rest and sleep; incisional care; assistance with household chores, infant care, and self-care; and relief of pain and discomfort. Nurses need to address these areas during hospitalization and discharge planning. Perhaps one of the most important considerations for cesarean birth mothers is the need to plan for additional assistance at home to enable the new mother to rest and heal.

HEALTH PROMOTION EDUCATION

The nurse can assist the woman in identifying interventions to relieve discomfort or pain. The woman should be encouraged to take pain medication regularly, engage in frequent rest periods, avoid prolonged activity, and observe for signs of "overdoing it" (such as discomfort and fatigue). The nurse should advise the woman that recovery after a surgical procedure involves healing time and that fatigue and soreness are common symptoms of too much activity too quickly. The nurse can assist the family in identifying resources for assisting the new mother at home, such as assistance from friends and family, cleaning services, or food delivery services.

Promotion of Parent-Infant Interaction After Cesarean Birth

Many factors associated with cesarean birth may hinder successful and frequent maternal-infant interaction. These include the physical condition of the mother and newborn and maternal reactions to stress, anesthesia, and medications. The mother and her infant may be separated after birth because of hospital routines, prematurity, or neonatal complications. A healthy infant born by an uncomplicated cesarean birth is no more fragile than an infant born vaginally. Many agencies are beginning to provide time for the family together in the operating room if the mother's and infant's conditions permit. As noted earlier in the chapter, if skin-to-skin contact (SSC) with the mother is not possible immediately following cesarean delivery of a healthy newborn, the nurses should offer SSC with the father.

Signs of depression, anger, or withdrawal in the mother following cesarean birth may indicate a grief response to the loss

DRUG GUIDE Postpartum Neuraxial Morphine

OVERVIEW OF OBSTETRIC ACTION

Neuraxial administration (epidural or intrathecal) of morphine is used to provide relief of pain associated with cesarean births, extensive episiotomies, or third- and fourth-degree lacerations. Morphine binds to opiate receptors in the central nervous system, thereby altering both the perception of and emotional response to pain. Women experience little or no discomfort or pain during recovery and for up to 24 hours following epidural or intrathecal administration of morphine. This may be extended to 48 hours with the use of EREM (Depodur™), a sustained-release formulation. There is no motor or sympathetic block. Onset of analgesia is slower than with fentanyl, but duration is longer.

ROUTE, DOSAGE, AND FREQUENCY

Morphine (preservative-free formulation) is administered intrathecally or epidurally by the anesthesia provider. Dosages up to 200 µg intrathecal morphine, 5 mg epidural morphine, or 10 mg epidural EREM may be given. Larger doses increase the side effects without extending the length of analgesia. According to Carvalho (2008), "intrathecal doses of morphine >100 µg to 200 µg and epidural doses > 2 to 4 mg are unnecessary" for cesarean delivery (p. 958). If a subsequent dose is required, the anesthesia provider, not the nurse, administers it.

MATERNAL CONTRAINDICATIONS

Allergy/hypersensitivity to morphine.

MATERNAL SIDE EFFECTS

Most common: confusion, sedation, constipation, hypotension, pruritus, urinary retention, nausea, and vomiting.

Early-onset respiratory depression (30 to 90 minutes after administration) and late-onset respiratory depression (6 to 18 hours after administration) are rare in young, healthy obstetric patients, but can result in irreversible neurologic injury or death. Women who are obese, concurrently receiving magnesium sulfate, or who have obstructive sleep apnea are at increased risk for respiratory depression. Respiratory depression is managed by administration of Naloxone (Narcan), mask ventilation, and endotracheal intubation with mechanical ventilation if necessary.

NURSING CONSIDERATIONS

- Obtain history: sensitivity (allergy) to morphine.
- Assess vital signs, orientation, level of consciousness, motor function, sensation, reflexes, skin color, breath sounds, depth and rate of respirations, catheter insertion site, and ability to void (unless Foley in place). Notify anesthesia provider of abnormal assessments or complications.
- Monitor and evaluate analgesic effect. Ask patient about comfort level and notify anesthesia provider of inadequate pain relief.
- Check catheter (if still present) to ensure it is intact and not leaking.
- Assess for pruritus (scratching and rubbing, especially around face and neck).
- Administer comfort measures for narcotic-induced pruritus, such as lotion, backrubs, cool or warm packs, or diversional activities. Administer prescribed medications prn.
- If allergic reaction (urticaria, edema, or respiratory difficulties) occurs, administer naloxone or diphenhydramine per provider standing order. Have drugs immediately available.
- Provide comfort measures for nausea or vomiting, such as frequent oral hygiene or gradual increase of activity; administer prescribed prn medications as needed.
- Assess level of consciousness, lower extremity sensation and strength, postural blood pressure, and heart rate before ambulation.
- Assist patient with her first ambulation and then prn.
- Provide assistance and supervision with newborn care.
- According to guidelines approved by the American Society of Anesthesiologists in 2007, respiratory status should be assessed at least hourly for the first 12 hours and at least every other hour for the second 12 hours (12 to 24 hours) following a single administration of neuraxial morphine. Respiratory status should be assessed for 48 hours following administration of EREM. Patients receiving continuous morphine should be assessed for the duration of administration. Pulse oximetry and apnea monitors are sometimes employed as adjuncts to assessment, but they cannot take the place of a thorough nursing assessment. Pulse oximetry is not sensitive to hypercarbia, and neither tool is sensitive to hypoventilation (Carvalho, 2008).
- Assess bladder for distention if unable to void. Assist patient to void. Catheterization may be necessary if unresolved.
- Inform patient that headaches related to epidurals are uncommon, but occasionally occur 2 to 5 days after administration. Bed rest in a quiet dark room, caffeine, and hydration may help. Call anesthesia provider as needed. Blood patch can be administered by anesthesia if unresolved.

of the fantasized vaginal birth experience. Fathers as well as mothers may experience feelings of "missing out," guilt that the surgery was the result of something they did "wrong," and even jealousy toward another couple who had a vaginal birth. The couple may also feel guilty that they are considering their personal needs and not simply the welfare of the infant.

Newborn Safety Following Cesarean Birth

One of the primary concerns regarding the nursing care of the couplet is the promotion of safety. Mothers who have experienced cesareans, particularly unanticipated ones that follow lengthy labors, may be fatigued, sleep deprived, and under the influence of medications that alter their level of consciousness. Vigilant attention must be paid to the mother's level of consciousness and ability to stay awake when holding her infant, providing care, and breastfeeding. Some mothers will require constant support and observation to complete these activities safely, particularly if the father is sleep deprived as well. Nursing units should have risk management guidelines in place to assist nurses in their assessment and support of these vulnerable patients.

CLINICAL TIP

A thorough nursing assessment of respiratory status includes rate, depth, and regularity of respirations; lung sounds; level of consciousness; and color of skin and mucous membranes. The nurse should be sensitive to subtle changes in level of consciousness, including mild anxiety or agitation, which may be early signs of hypoxia. Changes in the mental status of postpartum patients, however, require astute assessment and critical thinking skills on the part of the nurse in order to differentiate physiologic etiologies from possible postpartum psychosis.

The nurse can support the parents in a variety of ways. Initially, nurses must work through their own feelings about cesarean birth. The nurse who considers a vaginal birth "normal" and refers to it as such implies that a cesarean birth is "abnormal," rather than simply an alternative method. Thus language and terminology, though seemingly insignificant, can convey to the couple negative messages about their cesarean birth experience.

The nurse should offer positive support to the couple. They may need the opportunity to tell their story repeatedly to work through their feelings. The nurse can provide factual information about their situation and support the couple's effective coping behaviors. The nurse should provide the parents with choices by allowing them to participate in decision making about the options available to them.

The presence of the father or significant other during the birth process positively influences the woman's perception of the birth event. His or her presence not only reduces the woman's fears but also enhances her sense of control and enables the couple to share feelings and respond to one another with touch and eye contact. Later they have the opportunity to relive the experience and fill in any gaps or missing pieces. This is especially valuable if the mother has had general anesthesia. The father or significant other can take pictures, hold the baby, and foster the discovery process by directing the mother's attention to details about her newborn.

The perception of and reactions to a cesarean birth experience depend on how the woman defines that experience. Her reality is what she perceives it to be. If the woman's attitude is more positive than negative, successful resolution of subsequent stressful events is more likely. Because the definition of events is transitory in nature, the possibility of change and growth is present. Often the mothering role is perceived as an extension of the childbearing role, and inability to fulfill expected childbearing behavior (vaginal birth) might lead to parental feelings of failure and frustration. The nurse can help families alter their negative definitions of cesarean birth and encourage positive perceptions.

HEALTH PROMOTION EDUCATION

The nurse should advise the mother that she is able to hold, cuddle, lift, and feed her infant despite her surgical incision. The nurse can assist the woman in finding positions that are comfortable for holding and feeding the baby. Upon discharge, the woman should be encouraged to care for the infant and to allow family members or friends to assist with other household duties.

Nursing Care of the Obese Postpartum Patient

Obesity is increasing in the United States, and the postpartum nurse will care for a growing number of obese and morbidly obese patients. The obese patient has needs similar to all postpartum patients, but she needs special attention to prevent injury, respiratory complications, thromboembolic disease, and infection, for which she is at high risk.

The nurse should carefully assess the woman for airway obstruction and hypoxia, particularly if she received opioids. Ambulation should be encouraged as soon as possible to prevent pneumonia. The use of sequential compression devices (SCDs) and early ambulation are essential to the prevention of deep vein thrombosis, especially if the patient had a cesarean birth. If mechanical vacuum devices are used to facilitate drainage from her incision following a cesarean birth, the patient should be educated about them. The mother should demonstrate how to visualize, clean, and completely dry her incision prior to discharge. The use of a mirror may be helpful. She needs to recognize and report signs of infection or dehiscence of her surgical incision or episiotomy repair promptly.

The obese patient has special safety concerns. The nurse needs to utilize adequate personnel and appropriate assistive devices to maintain safety for both the patient and staff members during position changes, transport, and ambulation. Additionally, the new mother may need extra supervision and assistance when breastfeeding her baby to ensure newborn safety.

In addition to the health and safety risks, obese women sometimes experience prejudice and humiliation when in the healthcare setting. The nurse needs to be sensitive to special needs in order to promote the woman's dignity. Advance communication and coordination that ensures the woman will have the correct-sized bed, blood pressure cuff, transport equipment, gown, and assistive equipment for ambulation is essential to efficient, compassionate, and respectful patient-centered nursing care (Mahlmeister, 2007).

TEACHING FOR SELF-CARE The nurse should advise the mother to ambulate as early as possible to avoid medical complications. The mother is taught symptoms of infection and should report these symptoms immediately to her healthcare provider.

Nursing Care of the Postpartum Adolescent

The postpartum nurse will provide care for adolescent mothers, some of whom are very young. Following a 14-year decline, the birthrate for teenage women increased in 2006 to 41.9 births per 1000 females ages 15 to 19, resulting in a total of 435,436 births to women in this age group; in 2008 the rate for this age group was 41.5 births per 1000. The birthrate in females ages 10 to 14 continued to decline to a rate of 0.6 births per 1000 women (Martin et al., 2009). The transition to motherhood can be stressful for adult women. Teen mothers have fewer life experiences, and fewer social, educational, and financial resources to help with the transition than do older mothers. Their newborns are also more likely to suf-

fer from low birth weight, preterm birth, and death in infancy than those born to adult women (Martin et al., 2009). Additional teaching, support, referrals, and follow-up may be required, particularly if the young woman has delivered a baby with special concerns due to prematurity or low birth weight.

Adolescent mothers have the same basic physical care needs as older mothers. They usually recover without difficulty, as they are young and healthy. Some adolescents, however, may not have a working knowledge of their own anatomy and physiology or the related terminology, and they may require special assistance with postpartum hygiene and care. Some may never have had a gynecologic exam prior to pregnancy, and they may feel embarrassed by the experience of being examined by a variety of healthcare professionals. A hospital filled with healthcare workers may be intimidating to them as well. The nurse should be sensitive to the patient's needs and ensure that she understands the reason for assessments, demonstrates appropriate self- and newborn care, and feels comfortable to ask questions. The nurse should offer detailed teaching on contraception, as the young woman may have no prior experience with it and may not feel comfortable requesting this information.

The nurse-patient relationship is extremely important when working with an adolescent mother. The nurse should maintain a respectful, nonjudgmental attitude and listen to the patient to learn of individual needs. The nurse must also assess the development and cognitive level of the adolescent in order to communicate effectively and to provide patient-centered care for the young woman (King-Jones, 2008). Peterson, Sword, Charles, et al. (2007) discovered that adolescent mothers valued nursing care that was "friendly, patient, respectful, and understanding of the mothers' individual needs" (p. 204). The young women appreciated nurses who anticipated their needs, respected them as mothers, and talked to them in the same manner used when working with older mothers. They perceived encounters during which the nurse appeared rushed, too serious, judgmental, or not to understand their needs as unsatisfactory. Nurse-patient relationships that made them feel "at ease" (p. 210) and encouraged their participation were highly valued.

Working with the adolescent mother and her family requires sensitivity on the nurse's part. Adolescent mothers still trying to meet their own educational goals rely on the support of their husband or boyfriend, their own parents, teachers, childcare providers, and school nurses. They need support people to talk to, ask questions of, assist with childcare, provide financial support, and offer unconditional support to them and their children. Although each situation is different, adolescent mothers most often rely on their husbands or boyfriends and their own mothers to help with raising their children (Brosh, Weigel, & Evans, 2007). The nurse should work with the family whenever possible to promote healthy and positive interactions during the postpartal period.

The nurse has many opportunities for teaching adolescent parents about their newborn in the postpartum unit, and serves as a role model for new parents when responding to and caring for the newborn. The father, if he is involved, should be included as much as possible. Although the grandmother or another family member may plan to assist with or provide much of the newborn care in some cases, the nurse should always ensure that the adolescent mother has the knowledge and demonstrates the skills to provide care for her newborn before discharge. The young mother appreciates positive feedback about her newborn and her developing maternal responses. This praise and encouragement will increase her confidence and self-esteem.

A newborn physical examination performed at the bedside gives the parent(s) immediate feedback about the newborn's health and demonstrates methods of handling an infant. The nurse can teach as the examination progresses, giving the new mother information about the fontanelles, cradle cap, shampooing the newborn's hair, and so on. The nurse might also use this time to teach the young parent(s) about infant stimulation techniques. Because adolescents tend to concentrate their interactions in the physical domain, they need to comprehend the importance of verbal, visual, and auditory stimulation for newborns as well.

Performing an examination at the bedside also gives the adolescent permission to explore her baby, which she may have been hesitant to do. A Brazelton neonatal assessment (see chapter 30 ∞) will help the mother understand the newborn's response to stimuli, a key factor in the adolescent's response to the individuality of her newborn once she goes home. Parents who have some idea of what to expect from their infants will be less frustrated with the newborn's behavior.

Group classes for adolescent mothers should include infant care skills, information about growth and development, infant feeding, well-baby care, and danger signals in the ill newborn. If classes are offered in the hospital during the postpartum stay, the adolescent mother and father should be strongly encouraged to attend and participate. The nurse can correct misconceptions and unrealistic expectations about growth and development.

During the postpartum period, the adolescent may have special needs, depending on her level of maturity, support systems, and cultural background. Brosh, Weigel, & Evans (2007) found that adolescent mothers reported difficulty accessing services to which they were entitled from some public and community agencies. The nurse should inform teenage mothers of available options and assist them to begin navigating service agencies prior to discharge whenever possible.

Ideally, teenage mothers should visit adolescent clinics where mother and baby are assessed for several years after birth. School systems' classes for young mothers help adolescents finish school and learn how to parent at the same time. Support groups and programs should address the issues discussed above and meet at a time and place that is welcoming and allows the mother and father to attend together. Although the teen mother may already attend or have a plan to attend a local program accessed during the prenatal period, the postpartum nurse should be aware of local programs and support groups offered through schools and healthcare organizations and make referrals as needed.

In the event that a woman decides to keep an unwanted child, the nurse should be aware of the potential for parenting problems. Families with unwanted children are more prone to crisis than others, although in many cases parents grow to love their child after attachment occurs. The nurse should be ready to initiate crisis management strategies or make appropriate referrals as the need arises. Assessment and follow-up by social workers should be coordinated before discharge.

Nursing Care of the Woman Who Relinquishes Her Infant

A **relinquishing mother** is one who chooses an adoption plan for her newborn. It is difficult to determine how many mothers pursue this option each year, as information regarding the characteristics of children adopted independently or through private agencies is not always available (National Center for State Courts, 2009). It was estimated that more than 52,000 women in the United States pursued an adoption plan at the beginning of the 21st century (Kobokovich, as cited in Smith, 2008).

The reasons for relinquishment vary. Although relinquishing mothers were traditionally young and single, 38.5% of births in 2006 were to unmarried women (Martin et al., 2009). Single parenthood is no longer stigmatized to the extent it was in the past, although some single mothers still pursue adoption for their newborns. Some relinquishing mothers are living in poverty or simply unable to care for another child, whereas others do not have the desire or emotional maturity to be mothers. The decision not to parent the newborn may also involve complicated psychosocial issues such as rape, incest, conception outside the woman's current intimate relationship, domestic violence, or the threat of abandonment by her intimate partner or family if the mother keeps the child. The reasons are personal and complex, and the mother may or may not choose to share her decision process with the nurse. The nurse can support the mother by encouraging her to share her feelings, by listening actively, and by simply being there for her.

There are multiple avenues through which adoption occurs, including private independent agreements, private agencies, and public agencies. Adoptions may be considered open, semi-open, or closed. In an identified adoption, the birthparents select the adoptive parents (Smith, 2008). If a relationship already exists, both sets of parents may be present for the delivery and throughout the immediate postpartum period. The nurse may work with the birthmother, the birthfather, the parents planning to adopt the child, social workers, adoption agency personnel, or attorneys when caring for the relinquishing mother and her newborn. This is a potential source of anxiety for the nurse, particularly if controversies occur between the parties or if situations with which the nurse is unfamiliar arise. Birthing units should have policies and resources available to guide the care of relinquishing mothers, and nurses should consult with social workers or other support personnel if they are uncertain how to proceed in given situations.

The nurse's primary responsibility is to provide compassionate patient-centered care that supports the birthmother's adoption plan and promotes a positive experience for her (Smith, 2008). The nurse should make certain that the plan is understood and communicated to other staff members. If no support person is present, the nurse acts as the primary support person and ensures that the woman has a clear understanding of all that occurs. Following delivery, the woman should be given the choice to remain on a childbearing unit or to move to a different inpatient unit. The amount of contact she chooses to have with her newborn should be respected. When the birthfather and/or prospective adoptive parents are present, the nurse will need to take cues from the birthmother as to how to best provide support for all. Nurses should have a familiarity with the rights of birthfathers within their state and provide support to the father whenever possible as well.

Respectful communication that involves choosing words thoughtfully and accurately is important when caring for women who choose adoption for their newborns. The National Council for Adoption (2008) recommended use of the phrases "choosing an adoption plan" or "finding a family to parent your child" rather than terms such as "giving away," "giving up your child," or "putting your child up for adoption."

Finally, the nurse needs to acknowledge the significance of the birthmother's experience. Aloi (2009) noted, "The birthmother experience has been unheard and unacknowledged by the healthcare delivery system and by society, as well, even though the effects are lifelong and profound" (p. 27). It is essential that the nurse acknowledges the woman's loss and supports her decision. Although a thorough discussion of grief and loss is beyond the scope of this section, perinatal nurses should be aware that relinquishing mothers are at risk for *disenfranchised grief*, in which they are unable to proceed through the grieving process and come to resolution with the loss (Robinson, as cited in Aloi, 2009, p. 28). The nurse can support the relinquishing mother by acknowledging her relationship with the newborn, validating her loss, offering her the opportunity to hold and spend time with the baby to create memories, and giving her time to say goodbye (Aloi, 2009).

The woman should be referred to a support group following discharge, as participation is helpful for many women. Charitable and religious organizations that assist birthmothers with the experience of adoption often provide support to these mothers throughout the prenatal and postpartum experience. If she is not already connected in this way, the mother may benefit from a referral to an organization, a therapist, or clergy member if she desires additional support beyond what she expects to receive from family and friends. For additional information, see chapter 38 regarding nursing care of parents experiencing grief and loss.

PROFESSIONALISM IN PRACTICE

Patient-Centered Care of the Relinquishing Mother

A relinquishing mother who receives only physical care, while providers fail to acknowledge or address her emotional needs, is denied her right to quality, patient-centered nursing care. It is essential for nurses to use active listening, provide nonjudgmental support, show concern and compassion, and personalize care for the relinquishing mother. When the mother is admitted to the birthing unit, the staff should be informed about her decision to relinquish the infant. Any special requests regarding the birth should be respected, and the woman should be encouraged to express her emotions. Birthfathers are often forgotten in this process, and they should be included and supported whenever possible and acceptable to the birthmother. This demonstrates the Quality and Safety Education in Nursing (QSEN) competency of patient-centered care.

Nursing Care of the Lesbian Mother

Although the literature regarding gay and lesbian families is growing, much of it is focused on options for conception, challenges experienced by gay parents, and legal issues. There has been little published about the labor, delivery, and postpartum experiences of lesbian mothers. A qualitative study of lesbian couples in Norway discovered that they were generally happy with the perinatal care they received. They felt somewhat vulnerable in their visibility as lesbian parents, and they took responsibility to be open about their sexuality without being overly assertive when first meeting their healthcare provider(s). The women noted that most providers became more confident while interacting with them over time. When faced with rude or uncaring behaviors, the women sometimes thought it may be related to their sexuality, but acknowledged that perhaps the provider behaved in that way to everyone. The women appreciated healthcare professionals who were warm, respectful, and accepting (Spidsberg, 2007). The women's desire to be treated as any other mothers, with acknowledgment of their intimate relationships, echoed the findings of Wilton and Kaufmann (2001) in the United Kingdom. A review of the literature did not find similar recent studies in the United States, and further research is needed to meet the needs of these mothers.

The nurse should maintain an attitude that is respectful, caring, and open to sexual diversity when working with all patients. Providing quality patient-centered care for any postpartum woman involves acknowledging, welcoming, and involving her intimate partner in care and decision-making. If the nurse has not cared for a postpartum lesbian mother before, it may be helpful to admit this to the patient and to ask her for guidance regarding any special needs or requests that she or her partner may have. The nurse should be aware that standardized postpartum instructions, particularly those related to intercourse and contraception, might need to be individualized and amended.

Nursing Care of the Developmentally Disabled Postpartum Mother

The postpartum time period is one of great growth in the maternal mothering role. New mothers are faced with various challenges and different learning opportunities. Women with developmental or intellectual disabilities are at particular risk during this time period. Material should be presented to them in an easy-to-understand format. Peer mentors are often helpful role models for these women. Teaching should be performed at a level that is achievable for the individual woman. A needs assessment should be performed to determine what needs the mother and new family may have. Community and private resources should be available to make the transition to the postpartum period as flawless as possible.

PROFESSIONALISM IN PRACTICE

Caring for a Complex Patient Population

Nursing students will work with a variety of patients in the postpartum setting, including women at the far ends of the childbearing age spectrum; women across the socioeconomic spectrum; women who abuse substances; women who have experienced a variety of assistive reproductive techniques; women who will return to prison after childbirth; women with a history of trauma, domestic violence, or abuse; and women who are homeless or otherwise disenfranchised. This responsibility may initially be overwhelming to students, particularly as they worry about the future of the woman and/or her newborn. It may also be difficult for students to imagine a professional lifetime of caring for such a complex patient population. Post-conference conversations with faculty members, peers, and staff nurses, if possible, are the appropriate time to discuss such concerns. There are no easy answers, but it is helpful to view problematic issues within the context of guiding principles such as the American Nurses Association (ANA) (2005) Code of Ethics for Nurses, the Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN) (2009) Standards for Professional Nursing Practice in the Care of Women and Newborns, and the mission of the university, hospital, or nursing school.

Nursing Care of the Mother with a History of Sexual Abuse

Women who have been previously sexually abused tend to have more anxiety and stress related to hospital procedures, interactions with unfamiliar staff, and being touched in general. The postpartum woman who has a history of sexual abuse may have difficulty establishing trust and may feel uncomfortable when private information or demonstrations are being performed. The nurse should treat the woman with respect by providing draping whenever possible. Speaking to the woman in private protects her fragile emotions from being observed by others. Support groups may offer the mother with a history of sexual abuse a safe haven to share her experiences and the impact it has on her mothering.

Discharge Information

Healthy postpartum women and newborns are frequently discharged within 24 to 48 hours of delivery, before many of their important healthcare and educational needs have been addressed. These include establishing breastfeeding, ruling out infections, supporting infant-family bonding, and patient teaching. Home health services are increasingly being recognized as a cost-effective means of meeting the postbirth needs of mothers and newborns. Home care of the postpartum family is the subject of chapter 37 ∞.

CLINICAL JUDGMENT

Case Study: Dana Sullivan

You walk into her room and find Dana Sullivan, a 29-year-old G2P2, crying 48 hours after a repeat cesarean birth. She states "I'm not ready to go home. With my first baby they made me go home after 2 days. Can they make me go home so early again?"

Critical Thinking

What therapeutic nursing questions would you ask Dana to assess her reluctance to go home?

See www.nursing.pearsonhighered.com for possible responses.

Ideally, preparation for discharge begins the moment a woman initially enters the healthcare system for prenatal care. Nursing efforts should be directed toward assessing the couple's knowledge, expectations, and beliefs, and then providing anticipatory guidance and teaching accordingly (see Table 36-1). Because teaching is one of the primary responsibilities of the postpartum nurse, many agencies have elaborate teaching programs and classes. Before the actual discharge, however, the nurse should spend private time with the woman (or couple) to determine whether they have any last-minute questions (Figure 36-3 ■). In general, discharge teaching should include at least the following:

Application: Discharge Planning

1. The woman should contact her caregiver if she develops any of the signs of possible complications:
   a. Sudden, persistent, or spiking fever (greater than 100.4°F) or chills
   b. Change in the character of the lochia—foul smell, return to bright red bleeding, excessive amount (more than one pad per hour after 24 hours)
   c. Evidence of mastitis, such as breast tenderness, reddened areas, malaise, fever, chills
   d. Evidence of thrombophlebitis, such as calf pain, tenderness, redness, or pain with walking
   e. Evidence of urinary tract infection, such as urgency, frequency, burning on urination
   f. Evidence of infection in an incision (either episiotomy or cesarean), such as redness, edema, pain or discomfort, discharge, or lack of approximation
   g. Continued mood changes or signs of postpartum depression, inability to care for self or baby, feelings of self-harm, or anxiety
   h. Severe pelvic pain or abdominal tenderness
2. The woman should review the literature she has received that explains recommended postpartum exercises, the need for adequate rest, the need to avoid overexertion initially, and the recommendation to abstain from sexual intercourse until lochia has ceased. The woman may take a shower and may continue sitz baths at home if she desires.
3. The woman should be given the phone numbers of the postpartum unit, lactation consultant, and nursery, and should be encouraged to call if she has any questions.
4. The woman should receive information on local agencies or support groups, such as La Leche League and Mothers of Twins, which might be of particular assistance to her.
5. Both breastfeeding and formula-feeding mothers should receive information geared to their specific nutritional needs. They should also be told to continue their vitamin and iron supplements until their postpartal examination.
6. The woman should have a scheduled appointment for her postpartal examination and for her infant's first well-baby examination before they are discharged.
7. The mother should clearly understand the correct procedure for obtaining copies of her infant's birth certificate.
8. The new parents should be able to provide home care for their infant and should know when to anticipate that the cord will fall off, when the infant will need his or her immunizations, and so on. They should also be comfortable feeding and handling the baby and should be aware of basic safety considerations, including the need to use a car seat whenever the infant is in a car, sudden infant death syndrome (SIDS) prevention, and prevention of shaken baby injuries. These topics are covered in chapter 37 ∞.
9. The parents should be aware of signs and symptoms in the infant that indicate possible problems and whom they should contact about them.

Figure 36-3 ■ The nurse provides discharge instructions to the mother and father before discharge.

The nurse can use this final period to reassure the couple of their ability to be successful parents, stressing the infant's need to feel loved and secure. The nurse can also urge parents to talk to each other and work together to solve any problems that may arise.

The nurse addresses follow-up visits when appropriate. If not already discussed, teaching about family planning is appropriate at this time, and the nurse can provide information regarding contraception.

In ideal situations, a family approach involving the father or significant other, infant, and possibly other siblings would permit a total evaluation and provide an opportunity for all family members to ask questions and express concerns. In addition, a family approach can enable the nurse to identify disturbed fam-

ily patterns more readily and initiate interventions to prevent future problems of neglect or abuse.

Evaluation of the Postpartum Family

Anticipated outcomes of comprehensive nursing care of the postpartum family include the following:

- The mother and infant remain healthy, safe, and free of injury or complications.
- The mother verbalizes comfort and uses self-comfort measures as appropriate.
- The mother verbalizes feelings and concerns related to the birth event and her newborn.
- The mother performs appropriate self-care measures.
- The new parents demonstrate safe and effective care of their baby.
- The parents and newborn display positive bonding behaviors.
- The mother-infant dyad demonstrates successful breastfeeding (or parents describe safe formula preparation and demonstrate safe bottle-feeding). Mothers describe breast care as appropriate.
- The mother is rested and verbalizes understanding of the importance of gradual return to activities.
- The mother identifies sources of support to assist with newborn care and family responsibilities.
- The mother states plan for follow-up health care for herself and her infant.
- The mother identifies signs and symptoms of maternal-newborn complications and reasons to seek care before routine follow-up visits.
- The cesarean birth mother states in her own words the reason for the cesarean birth and verbalizes feelings.
- The cesarean birth mother verbalizes comfort and maintains mobility.
- The obese patient remains free of injury or complications.
- The adolescent mother has been supported physically and emotionally.
- The woman relinquishing her newborn verbalizes the rationale for her decision and demonstrates acceptance of her decision.
- All women and their significant others have been supported with regards to their cultures (may include special considerations related to age, sexual preference, ethnic background), their abilities, and their histories.
- In summary, all components of nursing care are designed to achieve the desired outcomes identified for the woman and her family.

FOCUS YOUR STUDY

- Effective parent learning requires precise timing of teaching, as well as choice of a teaching method that is effective for the family, such as videotapes, return-demonstration, and so on. Content on self-care, infant care, and anticipatory guidance is important.
- Postpartum discomfort may be due to a variety of factors, including an edematous perineum, an episiotomy or extension, engorged hemorrhoids, hematoma formation, afterpains, immobility, diaphoresis, sore nipples, or engorged breasts. Various self-care approaches are helpful in promoting comfort. Cultural values are incorporated in providing care to the new family.
- Lactation occurs in response to breast stimulation. Nursing support is essential to effective breastfeeding.
- A variety of techniques may be helpful to relieve discomfort during suppression of lactation if breastfeeding is not planned.
- The first day or two following birth are marked by maternal behaviors that are more dependent and oriented to the woman's comfort. Thereafter the woman becomes more independent and ready to assume responsibility.
- The new mother requires opportunities to discuss her childbirth experience with an empathetic listener.
- Maternal rest is promoted by advising the woman to take frequent rest periods, nap when the baby is napping, avoid unnecessary activities, and use her social support system. Ambulation and activity should be resumed gradually.

- Rooming-in provides the childbearing family with opportunities to interact with their newborn during the first hours and days of life. This enables the family to develop some confidence and skill in a "safe" environment.
- Sexual intercourse may resume once the episiotomy has healed and lochia has stopped. Couples should be forewarned of possible changes; for example, the vagina may be "dry," fatigue may inhibit the level of desire, or the woman's breasts may leak milk during orgasm.
- Following cesarean birth, a woman has the nursing care needs of a surgical patient in addition to her needs as a postpartum patient. She may also require assistance in working through her feelings if the cesarean birth was unexpected.
- Following vaginal or cesarean birth, obese and morbidly obese women are at high risk for injury and complications. These new mothers have special physiologic, safety, and psychosocial needs.
- Postpartum, the nurse evaluates the adolescent mother in terms of her level of maturity, available support systems, cultural background, and existing knowledge and then plans care accordingly.
- The mother who decides to relinquish her baby needs emotional support and validation of her loss. She should be able to decide whether to see and hold her baby and should have any special requests regarding the birth honored.
- The lesbian mother and her intimate partner value the same treatment as other couples. Nurses should acknowledge, accept, and involve the partner in care and decision-making.
- Before discharge, the nurse should give the couple any information necessary for the woman to provide appropriate self-care. They should have a beginning skill in caring for their newborn and should be familiar with warning signs of possible complications for mother or baby. Printed information is valuable for reference, as couples will have questions after they return home.
- Because of the trend toward early discharge, follow-up care is more important than ever. Many approaches are used, especially home visits.

CRITICAL THINKING IN ACTION

Wendy Calahan, a 31-year-old G3, P2, gave birth to an 8.5 pound baby boy by primary cesarean birth for failure to progress. The baby's Apgar scores were 9 and 9 at 1 and 5 minutes. The baby was admitted to the newborn nursery for transitional observation. Wendy was transferred to the postpartum unit, where you assume her care. You introduce yourself and orient her to the room, call bell, and safety measures. You perform an initial assessment, with all findings within normal limits. Wendy tells you she is very tired and would like to rest while her baby is in the nursery. Her husband and family have left the hospital after spending time with her in the recovery room but will return later. She admits she is disappointed that she could not give birth vaginally even though she pushed for 2 hours. She says, "This baby was just too big."

1. How would you discuss with Wendy the need for frequent assessments after birth?
2. Explain "maternity or baby blues."
3. Explore activities to minimize maternity blues.
4. Discuss concerns of a woman experiencing her second pregnancy.
5. Discuss behaviors that inhibit paternal attachment.

CHAPTER 37

Home Care of the Postpartum Family

Working as a home-care nurse with an early discharge program is the most fulfilling job I have ever had. It is an honor and a privilege to be allowed into the home to share this special time with childbearing families. When I offer breastfeeding support, help new parents to access the resources they need, or recognize a problem and ensure timely follow-up, I know that I am making a difference in their lives. The appreciation expressed by the families and the health-care providers I serve is a gift that I receive.

LEARNING OUTCOMES

1. Explain the history of the controversy surrounding length of stay (LOS).
2. Discuss the components of postpartum home care.
3. Identify the main purposes of home visits during the postpartum period.
4. Summarize actions the nurse should take to ensure personal safety during a home visit.
5. Delineate aspects of fostering a caring relationship in the home.
6. Describe assessment, care of the newborn, and reinforcement of parent teaching in the home.
7. Discuss maternal and family assessment and anticipated progress after birth.
8. Describe appropriate nursing interventions for women who are experiencing breastfeeding difficulties.
9. Identify postpartum resources that are available to new families.

KEY TERMS

Active alert state *1068*
Bed sharing *1066*
Cosleeping *1066*
Crying state *1068*
Deep sleep *1068*
Drowsy awake state *1068*
Late preterm infant *1059*
Light sleep *1068*
Postpartum home care *1055*
Quiet alert state *1068*
Room sharing *1065*
Shaken baby syndrome (SBS) *1069*
Sudden infant death syndrome (SIDS) *1065*
Weaning *1080*

Home care is an essential component of perinatal nursing care, particularly as caregivers struggle to find an appropriate balance between providing quality patient care and managing escalating healthcare costs. The hospital length of stay (LOS) following childbirth proved controversial during the last years of the 20th century. Consumers often requested early discharge as an alternative to home delivery in the 1980s. The average LOS decreased further during the early 1990s in an effort to contain healthcare costs, with third-party payers reimbursing only a 24-hour stay following an uncomplicated vaginal delivery. Professional organizations questioned the safety of this trend during the mid-1990s, and Congress responded with the Newborns' and Mothers' Health Protection Act (NMHPA) of 1996 (Bernstein et al., 2007).

Role of Length of Stay and Professional Guidelines and Recommendations in Postpartum Home Care

The Newborns' and Mothers' Health Protection Act (NMHPA) was signed into law in 1997 and took effect in January 1998. Although the bill does not prohibit earlier discharge, it provides for a guaranteed minimum stay of up to 48 hours following an uncomplicated vaginal birth and 96 hours following an uncomplicated cesarean birth at the discretion of the new mother and her healthcare provider (American Academy of Pediatrics [AAP] & the American College of Obstetricians and Gynecologists [ACOG], 2007; Bernstein et al., 2007; Evans, Garthwaite, & Wei, 2008). Despite numerous studies, findings are inconclusive as to whether a shortened length of stay (LOS) is harmful or beneficial to childbearing families.

An analysis of maternal and infant data from approximately 3 million births in California suggested that early discharge was not hazardous following routine pregnancy, but that newborns at highest risk of readmission benefited from laws that guaranteed a minimum LOS (Evans et al., 2008). Another large California study found that after the AAP Subcommittee on Hyperbilirubinemia mandated increased surveillance and follow-up regarding hyperbilirubinemia in 1994, readmissions increased and peaked in 1998. Readmissions decreased following the 1998 legislation regarding length of stay, suggesting again that increased LOS benefited high-risk infants. The authors noted, however, that demonstrating cause and effect is difficult, as many complex issues affect newborn readmission rates (Burgos, Schmitt, Stevenson, et al., 2008).

Optimal timing of discharge needs to be determined by considering the medical, social, and financial factors in each case. Bernstein et al. (2007) found that mothers and physicians do not always agree on readiness for discharge, and they emphasized that the decision regarding LOS needs to be made jointly. The AAP and ACOG (2007) developed guidelines for LOS and follow-up care for mothers and newborns. Newborns discharged prior to 48 hours of age should be examined by a healthcare professional "competent in newborn assessment," (p. 230) within 48 hours of discharge. A qualified nurse can accomplish the visit in a clinical setting or in the home, provided that the results are reported to the physician that day. Suggested discharge criteria and recommendations for follow-up after early discharge are found in Table 37-1.

The American Academy of Pediatrics (AAP) & The American College of Obstetricians and Gynecologists (ACOG) (2007) also recommended provision of adequate screening and follow-up for hyperbilirubinemia, depending on the infant's risk status. Therefore, infants who are discharged at 48 hours or older may require follow-up as well. The assessment is ideally accomplished between 72 and 96 hours, during the time of highest risk for hyperbilirubinemia. The visit(s) should include assessment of the weight and percent change since birth, adequacy of intake, voiding and stooling patterns, and the presence or absence of jaundice. The health professional uses clinical judgment to determine the need for a bilirubin test.

Considerations for the Home Visit

In planning a home visit, the nurse should clearly understand the purpose of the visit and identify the maximum amount of content to be addressed. Other important considerations include ways of creating and fostering relationships with families, techniques for preplanning and executing the visit while maintaining safety, documenting the visit, and ensuring telephone follow-up.

The postpartum home visit differs from community health visits in that only one or two visits are typically planned, and long-term follow-up by the nurse is not anticipated. Although the postpartum home visit is comprehensive, it is specifically focused on a postpartum family's needs and care.

Because of the established guidelines for discharge of the mother and baby (refer to Table 37-1), the nurse can logically expect to find certain levels of health and wellness. However, because the status of the mother and newborn can change, the nurse should stay alert for deviations from the norm.

Purpose and Timing of the Home Visit

Home care for the postpartum family focuses on assessment, teaching, and counseling. The visit frequently occurs on the third to sixth day postpartum, depending on when the couplet was discharged. This time frame encompasses the potential peak times for newborn jaundice and maximal weight loss, and it meets the recommendations set forth by the AAP Subcommittee on Hyperbilirubinemia (2004). Additionally, by this time the milk should be coming in, and breastfeeding is either going well or problems are becoming apparent. Parents frequently have new and different questions, having spent a couple of days and nights caring independently for their newborn since discharge.

Postpartum home care provides opportunities for expanding information and reinforcing self- and infant-care techniques initially presented in the birth setting. The home setting provides an opportunity for the nurse and family to interact in a more relaxed environment, one in which the family has control of the setting. It also provides an invaluable opportunity for the nurse to assess home safety in the setting where the family will grow together. In some instances, a

TABLE 37-1 Minimal Criteria for Discharge of Newborns Prior to 48 Hours of Age

1. Antepartum, intrapartum, and postpartum course for both the mother and the newborn is uncomplicated
2. Vaginal delivery
3. Singleton birth at 38 to 42 weeks' gestation, with birth weight appropriate for gestational age according to appropriate intrauterine growth curves
4. Newborn's vital signs are normal and stable for 12 hours before discharge
   - Respiratory rate less than 60/min
   - Heart rate 100 to 160/min
   - Axillary temperature of 36.5°C to 37.4°C (97.7°F to 99.3°F) in an open crib with appropriate clothing
5. Newborn has urinated and passed at least one spontaneous stool
6. Newborn has completed at least two successful feedings
   - Documentation has been made regarding the newborn's ability to coordinate sucking, swallowing, and breathing while feeding
   - If breastfeeding, a knowledgeable caregiver has observed and documented latch, swallowing, and infant satiety
7. Physical exam reveals no abnormalities requiring continued hospital stay
8. No evidence of excessive bleeding from the circumcision site for the previous 2 hours
9. Clinical significance of any jaundice has been determined and appropriate management and follow-up is in place
10. Mother's knowledge, ability, and confidence to care for the newborn are documented to include teaching of the following:
    - Condition of the newborn
    - Appropriate newborn output (urine and stools)
    - Care of the cord, skin, and genitals as well as temperature assessment and measurement
    - Maternal knowledge of signs of illness and common problems, particularly jaundice
    - Instruction in newborn safety to include car seat use and positioning for sleep
11. Family or other support persons and healthcare providers are available to the couplet during the first few days following discharge
12. Instructions given to follow in the event of a complication or emergency
13. Lab data have been reviewed to include maternal syphilis, hepatitis B virus surface antigen, and HIV; umbilical cord or newborn blood type and direct Coombs' if indicated
14. Required screening tests have been accomplished; if a test was performed before 24 hours of milk feeding, a plan for repeat must be in place in accordance with local or state policy
15. Initial hepatitis B vaccine has been administered or an appointment made for its administration
16. Hearing screening has been completed per hospital protocol
17. A physician-directed source of continuing medical care for both mother and baby has been identified; appropriate follow-up within 48 hours by a person qualified to assess the newborn is scheduled
18. Family, environmental, and social risk factors have been assessed. If risk factors are present, the discharge should be delayed until resolved or a plan is in place to safeguard the infant. Factors may include but not be limited to untreated parental substance use, positive maternal or infant toxicology results, history of child abuse or neglect, mental illness in a parent who is in the home, lack of social support, no fixed home, history of domestic violence, adolescent mother—especially with other risk factors, and barriers to follow-up (lack of access to telephone, transportation issues, non–English speaking parents).

Recommended follow-up for infants with a shortened hospital stay of less than 48 hours should include the following within 48 hours of discharge:

- Weigh the infant
- Assess the newborn's general health, hydration, and degree of jaundice; identify any new problems
- Review feeding pattern and technique; observe breastfeeding for adequate position, latch on, and swallowing
- Assess historical evidence of stool and urine patterns for adequacy
- Assess quality of mother-newborn interaction and details of newborn behavior
- Reinforce maternal or family education in neonatal care, particularly feeding and sleep position
- Review results of laboratory tests performed at discharge
- Perform screening tests as required by the state and others as clinically indicated
- Identify a plan for healthcare maintenance, including a method for obtaining emergency services, preventive care and immunizations, periodic evaluations and physical examinations, and necessary screening

home provides unique challenges in assessing and enhancing the woman's self-care and infant care, and the nurse has many opportunities to exercise critical thinking and develop creative options with the family.

Fostering a Caring Relationship with the Family

Although the nurse in the birthing center strives to enhance family autonomy and control, the inherent atmosphere of the institutional environment may cause the new mother and family to feel disempowered. It is important for the professional nurse to recognize that the parameters of the home visit are different in many ways from those of the hospital or birthing center environment. In the home, the family has control of their environment and the nurse is an invited visitor. The nurse can rely on the same characteristics of a caring relationship that have been integral to hospital-based practice—regard for patients, genuineness, empathy, and establishment of trust and rapport—but the relationship may take on new elements as the nurse moves into the home setting for the first time (Table 37-2).

Planning the Home Visit

Before the home visit, the nurse prepares by identifying the purpose of the visit and gathering anticipated materials and equipment. Communication with the primary healthcare provider(s) and a thorough review of inpatient records gives the nurse an understanding of current needs and any special concerns for each individual mother-baby couplet. A personal contact while the woman is still in the birth setting or a previsit telephone call is used to arrange the appointment with the woman and her family. During the previsit contact it is important for the nurse to identify clearly the purpose and goals of the visit, to let the patient know approximately how long the visit will take, and to begin establishing a rapport.

Maintaining Safety

In the past, nurses were viewed as a mainstay of communities and could move in most settings without fear or concern for safety. However, in current times some communities are not safe for visiting nurses. Risks noted by home-care nurses include isolated locations, illegal drugs, threatening animals,

TABLE 37-2 Fostering a Caring Relationship

DEMONSTRATED GOAL	APPROACHES TO ACHIEVE GOAL
Regard	Introduce yourself to the family. Call the family members by their surnames until you have been invited to use the given or a less formal name. Ask to be introduced to other members of the family who are present. Allow the mother or spokesperson to assume this role. Use active listening. Maintain objectiveness. Ask permission before sitting.
Genuineness	Mean what you say. Make sure that your verbal and nonverbal messages are congruent. Be nonjudgmental. Don't make assumptions about individuals or settings. Always strive to demonstrate caring behaviors. Be prepared for the visit, honestly answer questions and provide information, and be truthful. If you don't know the answer to a question, tell the patient you will find the information and report back.
Empathy	Listen to the mother and family without judgment, trying to view events and circumstances from their point of view. Be attentive to what the birthing experience means to them so that you will understand their concerns from their perspective. Remember, empathy denotes understanding, not sympathy.
Trust and Rapport	Do what you say you will do. Be prepared for the visit and be on time. Notify the family if you are running late because of patient care. Follow up on any areas that are needed.

gangs, vandalism, inadequate lighting, guns, verbal abuse, robberies, inappropriate sexual comments, adverse weather and road conditions, dilapidated or pest-infested buildings, unsanitary conditions, and violent lifestyles (Anderson, 2008). Thus it is important for the nurse to follow some basic safety rules when conducting a home visit. Specifically, the nurse should:

- Confirm the address, and ask for directions during the previsit contact.
- Trace out the route to the patient's home on a map or the Internet before leaving for the visit, and take the map along; use a GPS device if available.
- Provide a daily schedule of visits, including patient addresses and phone numbers, to supervisors.
- Notify an instructor or supervisor when leaving for a visit and check in as soon as the visit is completed.
- Carry a cellular phone with the battery charged at all times.
- Carry a hard copy of agency and emergency phone numbers that are also programmed into the cellular phone.
- Carry a phone card or enough change to make a call from a pay phone in case of poor cellular transmission in some locations.
- Ensure that the vehicle used for visits is well maintained and has sufficient fuel.
- Pay close attention to traffic conditions and exercise care and caution while driving.
- Exercise caution when using a cellular phone while driving (first pull over to a safe place and stop, use a hands-free device, etc.).
- Wear a name tag and carry identification.
- Carry a flashlight, particularly for night visits.
- Carry food and water for personal use.
- Avoid wearing expensive jewelry.
- Before starting out (or before arriving at the home) lock personal belongings in the trunk of the car, out of sight.
- Call patients when on the way to confirm that they are home and that they are expecting the nurse.
- Identify other individuals present in the home at the start of the visit.
- Pay attention to the body language of all present during the visit.
- Request that threatening or sexually inappropriate behavior stop immediately.
- Be aware of personal body language and how it might be interpreted (for example, avoid crossing arms or shoving hands in pockets; remain calm and convey a sense of respect at all times).
- Leave the home immediately if a weapon is visible and the patient or a family member refuses requests to put it away.
- Ask patients to keep threatening pets secured in a different area of the home during the visit.
- Request that patients and family members avoid the use of illegal substances during the visit.
- If a situation arises that feels unsafe or if the previous requests are not honored, terminate the visit.
- Always have car keys in hand before returning to the vehicle.
- Lock the doors and drive away upon return to the vehicle at the completion of visits—do not sit in the vehicle to chart.
- Inform the supervisor immediately of any threatening situation, assault, or injury.
- Notify authorities if a crime has been committed.

It may be helpful to drive around neighborhoods known to be unsafe before making an initial visit to identify potential cues to violence and to determine whether extra security is necessary. If the visit is in an area that seems very unsafe, it may be wise for two nurses to go together or for the nurse to be accompanied by a security officer. Nurses should avoid entering areas where violence is in progress. In such cases, they should return to the car and contact the appropriate authorities by calling 911. If violence erupts while in the home and the nurse is unable to safely exit, the nurse should stay in a secure room with the door locked, if possible, and call 911.

Home care agencies are required to have violence protection programs as mandated by the Occupational Safety and Health Administration (OSHA) in 1996. This includes having policies in place and providing safety education for new employees and at least annually for all. Agencies in high-risk areas often contract with security and escort services to protect personnel in the community. Agencies should also have code phrases to use and a set plan for all to follow if a nurse calls to report being in an unsafe situation. Incidents should be tracked and reported to authorities. Patients should be informed that they are required to provide a safe environment and may face termination of services otherwise. Agencies may face ethical dilemmas involving the refusal or termination of services to patients in homes deemed to be too risky for nurses. In that case, the physician should be notified and other options considered for the patient (Anderson, 2008).

Figure 37-1 ■ Nurse arriving for a home visit.
Source: George Dodson/Pearson Education.

Nurses will want to ask questions about and review the violence protection plan of a home care agency to ensure that their safety will be protected to the extent possible before accepting employment. Nurses may also wish to enroll in further personal safety training independently. Anderson (2008) provides additional recommendations and resources that will be helpful to prospective home-care nurses.

Because postpartum home care frequently involves only one visit, it may be helpful to discuss safety expectations during the previsit telephone contact. Home-care nurses should be familiar with their agency policies and notify supervisors if safety issues requiring agency support are present.

Most people are more comfortable in familiar settings and have some hesitation when entering other residential areas. It is important for nurses to be aware of their surroundings and the people who are nearby. First home visits may feel uncomfortable because they are unfamiliar, but comfort increases with experience (Figure 37-1 ■).

Carrying Out the Home Visit

When the door is answered, the nurse should introduce herself or himself and confirm that the location is correct. The nurse may tactfully request to be introduced to others present if this information is not offered. If a place to sit is not indicated, the nurse may inquire, "Where is the best place to sit so that we can talk for a while?" In some homes, the mother or family may offer refreshments, and this may be an important aspect of welcoming a visitor. In this case, it is beneficial to the relationship to accept the refreshment graciously. Other culturally appropriate customs should be respected in the home setting whenever possible.

Many agencies have developed a uniform assessment tool to be used during postpartum home visits. This ensures that the nurse completes a physical assessment of both the mother and the newborn; assesses infant feeding and weight; evaluates maternal psychosocial adjustment, parental bonding, parenting behaviors, family adaptation, and coping skills; and determines environmental strengths and risk factors. Based on these assessments the nurse may do any of the following:

- Provide direct physical care.
- Carry out patient and family teaching.
- Consult with the physician, midwife, or a specialist, such as a lactation consultant.
- Refer the woman or family to appropriate community agencies.
- Schedule additional home visits or telephone follow-up.

Because home-care nursing is practiced geographically independent of the healthcare facility, the nurse needs to have excellent assessment skills and be adept at noticing variations from the norm. Critical thinking and problem-solving skills are necessary. Effective communication with the families and the appropriate healthcare providers is essential in the coordination of required treatment and follow-up.

The remainder of the chapter focuses on specific aspects of newborn and maternal care that are assessed, addressed, and evaluated during the home visit.

Home Care: The Newborn

When the family provides care for their newborn, the nurse can instill confidence by giving them positive feedback. If the family encounters problems, the nurse can suggest alternatives and serve as a role model. Each newborn has variations in normal physiologic responses and in growth and development patterns. Parents need to learn to interpret these changes in their child. To help parents care for their newborn at home, some physicians encourage prenatal pediatric visits to establish contact before the birth. Public health nurses have long been involved as guides in newborn care and parent education. Some birthing units are now expanding their primary care functions to the new family to include one home visit by a nurse who cared for the family in the birthing unit. The birthing unit nursery staff may also make themselves available as a 24-hour telephone resource for the new family who needs additional support and consultation during the first few days at home with their newborn. Routine well-baby visits should be scheduled with the clinic, pediatric nurse practitioner, or physician.

The family should have been taught all necessary caregiving methods before discharge. However, the home-care nurse may use a checklist to determine that the family clearly understands the material. If not, the nurse should complete per-

tinent teaching. Parents are frequently overwhelmed, sensory overloaded, and exhausted during their short hospital stay and will require a review of initial teaching.

Parents often have questions regarding infant care, feeding, and signs of illness. Therefore, the home-care nurse will want to address those issues. The nurse also needs to review with the couple all areas for understanding and to answer any questions they may have, making sure that they have the phone number and address of, and any specific instructions from, their healthcare providers. Having the nursery phone number is also reassuring to a new family. The nurse encourages them to call with questions.

Physical Assessment of the Newborn at Home

In the home, a newborn physical exam is performed to assess general appearance and vital signs as well as the skin and the respiratory, cardiovascular, gastrointestinal, genitourinary, musculoskeletal, and neurologic body systems. The infant's behavioral state and the parent-infant interaction should be assessed as well. An exam of the infant's fontanelles, eyes, ears, mouth, nose, neck, color, evidence of jaundice, umbilical cord, circumcision if done, reflexes, hydration, nutritional status and feeding history, elimination of urine and stool, activity, sleep-wake cycles, weight, and percentage of change from birth weight should be documented under the appropriate body systems. See chapter 30 ∞ for a complete, step-by-step newborn assessment.

The home visit is the time to ensure that the appropriate screening exams as required by the state have been accomplished and to obtain the blood for screening if still needed. If the newborn did not pass a universal hearing screen before discharge, the nurse should ensure that the parents have a plan to accomplish the required screening or audiology follow-up. The nurse will also assess and reinforce knowledge related to infant care as detailed in the following sections.

Assessment of Late Preterm Infants

Late preterm infants are those infants born between 34 and 36 6/7 gestational weeks. Late preterm infants typically weigh 4 1/2 to 6 pounds and are at greater risk for a variety of complications due to immaturity of their compensatory mechanisms (March of Dimes, 2010). Because of a greater risk for complications, these infants should receive a home health visit within 24 to 48 hours of discharge (Engle, Tomashek, Wallman, et al., 2007). Late preterm births account for 70% of all premature births (Engle et al., 2007). Late preterm infants have higher infant morbidity and mortality rates than term infants. These infants have more respiratory complications and may have more feeding issues. Some may require a feeding tube before regular feedings can be established. The home health nurse needs to assess the frequency and duration of breast feedings. If the infant is formula fed, the amount of formula being ingested and the frequency of feedings should be recorded because dehydration is often a cause of rehospitalization of these infants. Infants who are breastfed and those that are firstborn are at greatest risk for readmission in the neonatal period (Engle et al., 2007).

Assessment of output, adequate weight gain, and hydration status is imperative. Follow-up visits are indicated to assess ongoing weight-gain patterns. Parent education should include the signs of dehydration, adequate feeding parameters, and expected urinary/stool output, and the symptoms of jaundice should be reviewed at the home visit.

These infants are also more likely to develop hyperbilirubinemia. Some infants may be undergoing home phototherapy. In these cases, the nurse assesses the infant's color, collects a blood sample if indicated, and ensures that phototherapy equipment is being properly used. Some late preterm infants are placed on iron supplements due to anemia, and the nurse should ask the family if the supplement is being given as ordered. The nurse should provide education on the need and use of such supplements. Since late preterm infants are also more likely to acquire infections, the nurse instructs the care provider to use good hand washing techniques and to avoid exposure of the infant to individuals with infections or illnesses. Taking the baby out in large crowded places should also be avoided. Sepsis occurs more commonly in late preterm infants.

Although later preterm infants may be similar in size and appearance to term infants, they require ongoing assessment and care from the family and the health care team. Close observation and intervention can help prevent readmission to the hospital and long-term complications. Since these infants are more prone to behavioral and developmental problems than term infants, healthcare providers should be advised of their premature status at birth (March of Dimes, 2010).

Positioning and Handling of the Newborn

The nurse demonstrates methods of positioning and handling the newborn as needed. When the newborn is out of the crib, one of the following holds can be used (Figure 37-2 ■). The cradle hold is frequently used during feeding. It provides a sense of warmth and closeness, permits eye contact, frees one of the adult's hands, and provides security because the cradling protects the newborn's body. Extra security is provided by gripping the thigh with the hand while the arm supports the newborn's body. The upright position provides security and a sense of closeness and is ideal for burping. One hand should support the neck and shoulders while the other hand holds the buttocks or is placed between the newborn's legs. The newborn may also be held upright in a cloth sling carrier that gently holds the baby against the mother's or father's chest and frees the hands for other tasks. The football hold frees one of the caregiver's hands and permits eye contact. This hold is ideal for shampooing, carrying, or breastfeeding. It frees the caregiver to talk on the telephone, answer the door, or do the myriad tasks that await attention at this busy time.

Skin-to-skin contact (SSC) immediately following delivery has been found to be beneficial to breastfeeding and to have positive effects on the mother-infant relationship over the first year of life (Bystrova et al., 2009; Dabrowski, 2007; Moore, Anderson, & Bergman, 2007; Romano & Lothian, 2008). Klaus (2009) noted that the benefits of skin-to-skin contact and carrying the infant against the chest continue during the first weeks of the newborn's life. Therefore, the nurse can encourage both parents to continue this practice at home, particularly if they had limited opportunities to do so while in the hospital.

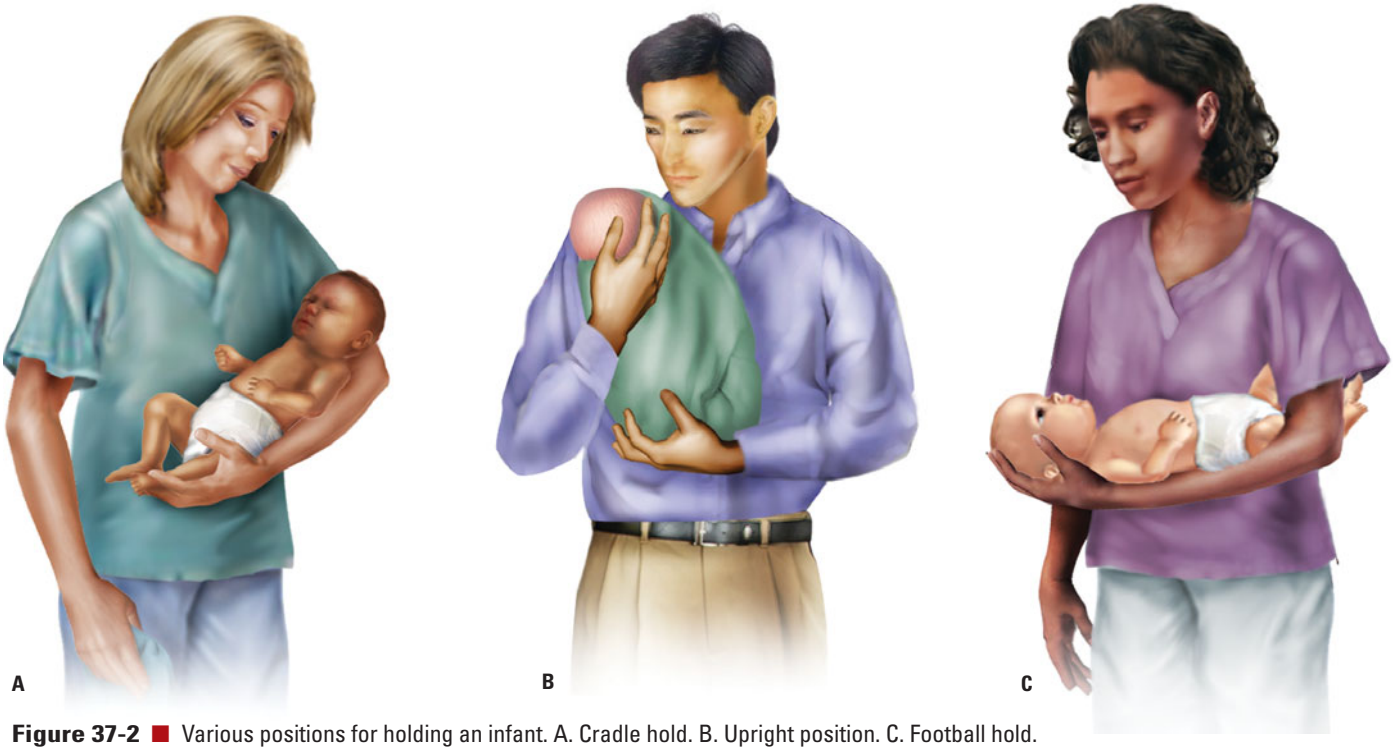

Figure 37-2 ■ Various positions for holding an infant. A. Cradle hold. B. Upright position. C. Football hold.

Skin Care and Bathing

The skin maintains temperature and serves as a barrier between the newborn and the environment. It is also a potential portal of entry for environmental toxins and infectious agents. Keeping the skin healthy and intact is essential to the newborn's health. The requirements of infant skin care include frequent assessment, effective cleansing, effective moisturizing, and maintenance of an effective barrier against external irritants. The following section provides information from the Association of Women's Health, Obstetric, and Newborn Nurses (AWHONN) Neonatal Skin Care Evidence-Based Clinical Practice Guideline (AWHONN, 2007a).

An actual bath demonstration is the best way for the nurse to provide information to parents. Because excess bathing and use of soap removes natural skin oils and dries out the newborn's sensitive skin, bathing should be done only two to three times per week. A mild, nonmedicated skin cleanser may be used as needed. Cleansing agents with a neutral pH (5.5 to 7.0) that are preservative-free are recommended. Because cleansers can be drying to the skin, they need not be used at every bath or in excess. Antimicrobial soaps should be avoided, as they may disturb the infant's normal skin colonization (AWHONN, 2007a).

Sponge baths have traditionally been recommended for the first 2 weeks or until the umbilical cord completely falls off and the umbilicus has healed. However, immersion bathing, in which the parents place the newborn's entire body except for the head and neck into a tub, is better tolerated by some infants, is more pleasurable for some newborns and parents, and results in less heat loss. This practice has been found to be safe prior to cord separation and has not been demonstrated to be associated with more cord infections (AWHONN, 2007a). Therefore, the nurse can reassure parents that either method is safe and that they can choose the method most comfortable for them and their newborn. The parents should take care to keep the room warm and free of drafts while using either method.

Many birthing units and agencies provide videos for parents to watch before bathing their baby for the first time, as a home visit does not usually allow time for a nurse demonstration and a parent return demonstration of a bath. See Patient Teaching: Newborn Bathing.

Supplies can be kept in a plastic bag or container for convenience (Table 37-3). At home, the family may want to use a small plastic dishpan, a clean kitchen or bathroom sink, or a large bowl as the baby's tub. Commercial plastic baby tubs are not necessary, but some parents prefer to purchase them.

Before starting, if no one else is at home, the parent may want to silence phones and place a sign on the door to avoid being disturbed. Having someone home during the first few baths is helpful, because that person can retrieve forgotten items, attend to interruptions, and provide moral support. It is important to have supplies gathered before beginning, as the caregiver will not be able to turn away or break hand contact with the newborn once he or she is positioned for the bath.

Sponge Bath

After the supplies are gathered, the tub (or any of the containers mentioned) is filled with approximately 5 inches of water

TABLE 37-3 Bath Supplies

Washcloths (2)	Shampoo
Towels (2)	Petrolatum product if indicated
Blankets (2)	Diapers
Unperfumed mild skin cleanser	Clean clothes

PATIENT TEACHING Newborn Bathing

Patient Goals

At the completion of the teaching, the family will be able to:

1. Identify safety concerns related to sponge and tub baths for newborns.
2. List appropriate supplies for bathing.
3. Demonstrate proper bathing procedures for both sponge and tub baths.
4. Discuss the use of appropriate skin care agents for newborn use.

TEACHING PLAN

Teaching Method	Content
Clarify information related to sponge bathing and tub bathing for safe newborn bathing. Explain that the proper environment is needed for newborn safety and comfort.	Describe the proper environment (including safety factors) for sponge and tub bathing for newborns.
Encourage the mother to assemble supplies before beginning the newborn bath to avoid cold exposure, and ensure that proper supplies are being used.	Identify proper bathing supplies that are needed for both sponge and tub baths.
Demonstrate proper technique and encourage the family to ask questions as they arise. Help instill confidence in new parents.	Demonstrate sponge bathing. Discuss and demonstrate tub bathing using an infant model.
Clarify the need for appropriate cleansing agents for newborns.	Explain the need for neutral pH, fragrance-free, and dye-free cleansing products for newborn use.

Evaluation

At the end of the teaching session the woman and family will be able to verbalize the principles of proper bathing for the newborn. They will be able to demonstrate the proper techniques to ensure safety during both sponge and tub baths.

Documentation

Document the information that was given, the type of teaching method used, indicate if the patient performed a bath, if it was demonstrated, or if verbal or written directions were given. Verbalization of understanding and clarification of any information should be documented. Safety issues and instructions should also be documented.

that is warm to the touch. Some parents carefully test the water temperature against their forearm. Others may also choose to purchase a thermometer to help them determine when the bath water is comfortable and safe to use. Water should be 38°C to <40°C (100°F to <104°F) (AWHONN, 2007a). Soap should not be added to the water.

The newborn is placed on a flat protected surface, such as a counter or in a bassinet adjacent to the container of water for a sponge bath. The newborn should be wrapped in a blanket, with a T-shirt and diaper on, to keep him or her warm and secure. Parents should be reminded never to leave an infant unattended on an elevated surface or near any amount of water. Parents should be encouraged to keep one hand on their infant at all times and to keep their eyes on their infant at all times while positioned for a bath.

To start the sponge bath, the adult wraps the dampened washcloth around the index finger once. Each eye is gently wiped from inner to outer canthus. This direction prevents the potential for clogging the tear duct at the inner canthus, where the eye naturally drains. A different portion of the washcloth is used for each eye to prevent cross-contamination. Some eye swelling and drainage may be present the first few days after birth as a result of the eye prophylaxis.

The bath giver washes the ears next by wrapping the washcloth once around an index finger and gently cleaning the external ear and behind the ear. Cotton swabs (Q-tips®) are never used in the ear canal, because it is possible to put a swab too far into the ear and damage the eardrum. In addition, a swab may push any discharge farther down into the ear canal.

The caregiver rinses out the washcloth and then wipes the remainder of the baby's face with the warm, dampened soap-free washcloth. Many babies start to cry at this point. The face should be washed every day, and the mouth and chin should be wiped off after each feeding.

The neck is washed carefully but thoroughly with the washcloth. A mild soap may now be used. Formula or breast milk and lint collect in the skin folds of the neck, so it may be helpful to sit the newborn up, supporting the neck and shoulders with one hand while washing the neck with the other hand.

When sponge-bathing, the bath giver will want to bathe the upper and lower body separately to minimize heat loss. Once the face and neck are clean and dry, the bath giver unwraps the blanket, removes the T-shirt, and wets the chest, back, and arms with the washcloth. The bath giver may then lather his or her hands with a mild infant skin cleanser and wash the baby's chest, back, and arms. Soap is rinsed off with the wet washcloth, and the upper part of the body is dried with a towel or blanket. The newborn's upper body is then wrapped with a clean, dry blanket to prevent heat loss.

Next the bath giver unwraps the newborn's legs, wets them with the washcloth, and lathers, rinses, and dries them well. If the newborn has dry skin, a small amount of an emollient such

as petrolatum may be used. Products without preservatives, perfumes, or dyes are recommended. Baby oil is not recommended because it clogs skin pores. Families need to be aware that baby powder should be avoided, as it can cause serious respiratory problems if the baby inhales it. The genital area is cleansed after each wet or dirty diaper. Females are washed from the front of the genital area toward the rectum to avoid fecal contamination of the urethra and the bladder. Newborn females often have a thick, white mucous discharge or a slight bloody discharge from the vaginal area. This discharge is normal for the first 1 to 2 weeks after birth. The mucus may come off if wiped gently after diaper changes but should not be intentionally scrubbed off.

Parents of uncircumcised males should cleanse the penis daily. Even minimal retraction of the foreskin is not advised (see in-depth discussion of care of uncircumcised male babies in chapter 31 ∞). Males who have been circumcised also need their penises cleansed daily. A very wet washcloth is squeezed above the baby's penis, allowing clear water to run over the circumcision site. The area is gently patted or fanned dry. Soap is not used around the penis for the first 3 to 4 days following circumcision, as it can be irritating to the tissues. A small amount of an emollient such as petrolatum, or petrolatum-impregnated gauze strips may be applied during each diaper change for the first 24 to 48 hours. Emollients promote comfort and healing and prevent adherence of the diaper to the site. It is important to avoid using ointments if a Plastibell is in place, because ointments may cause the Plastibell ring to slip off the penis too early. The Plastibell usually falls off within 5 to 8 days. If it does not, the family needs to call the healthcare provider.

The newborn should be wrapped in a terry cloth bath towel or bath blanket and gently patted dry at the end of the bath to promote skin integrity and prevent heat loss. It is particularly important that the cord be thoroughly dried if it has become wet during the bath.

The last step in bathing is washing the hair (although some prefer to do this step first). The newborn is swaddled in a dry blanket, leaving only the head exposed, and held in the football hold with the head tilted slightly downward. A cup or cupped hand may be used to pour warm water over the newborn's head, taking care to avoid the eyes and ear canals. Parents should avoid placing the infant's head directly under running water, as changes in water temperature could cause burns or discomfort. The hair is moistened and lathered with a small amount of shampoo. A very soft brush may be used to massage the shampoo over the entire head, including the fontanelles, which families often call the "soft spots." The hair is then rinsed and toweled dry. Oils or lotions are not used on the newborn's head unless prescribed by a healthcare provider.

Tub Baths

When tub-bathing, the bath can be completed efficiently with the newborn's trunk and lower extremities underwater. The newborn's face, eyes, ears, and neck can be washed and dried as described above before undressing him or her for the tub bath. A large, clean kitchen or bathroom sink, plastic container, or commercial infant tub that allows the baby to be immersed to the neck may be used as the infant's tub. A washcloth can be placed in the bottom of the container to prevent slippage. The infant should be held securely at all times (Figure 37-3 ■). Commercial infant tubs often support the infant's head and neck. If desired by the parents and if time allows, the nurse can demonstrate how to securely support the infant while giving an immersion bath.

Figure 37-3 ■ When bathing the newborn, the caregiver must support the head. Wet babies are very slippery.

Because wet newborns are slippery, some parents pull a cotton sock (with holes cut out for the fingers) over the supporting arm to provide a "nonskid" surface. The newborn's body is washed with a soapy washcloth or hand. To wash the back, the bath giver places the noncradling hand on the newborn's chest with the thumb under the newborn's arm closest to the adult. Gently tipping the newborn forward onto the supporting hand frees the cradling arm to wash the back. After the bath, the newborn is lifted out of the tub in the cradle position, dried well, and wrapped in a dry blanket. If the cord has not fallen off, it should be thoroughly dried before re-covering with clothing. The hair is then washed in the same way as for a sponge bath.

Once the bath is complete, the parents can double-blanket the newborn in clean dry blankets and a hat for approximately 10 minutes. Once the infant is totally dry, they may dress the baby and apply a clean, dry hat and blanket. The nurse must educate parents that infants and young children can drown even in small amounts of water. It is paramount that adults not allow the infant to be immersed above the neck and that they keep the infant safe by maintaining hand, arm, and eye contact with the infant at all times during the tub bath.

Cord Care

The parents should be instructed to allow the cord to dry naturally. They should be taught to:

- Wash their hands before and after handling the cord.
- Keep the cord clean and dry.

- Keep the cord exposed to air or covered only loosely by clean clothes.
- Keep the diaper folded below the cord to prevent contamination.
- Clean the cord if it becomes soiled with urine or stool.
- Dry the cord thoroughly after each cleansing.

Although some healthcare facilities still apply topical agents such as alcohol or triple dye to the cord, these have not been found to speed separation or to decrease infection. The use of such agents is potentially injurious and is not supported by research or recommended for routine use in developed countries (AWHONN, 2007a). Research continues on best practices related to umbilical cord care, however, and home-care nurses should review the literature frequently.

The nurse should teach the parents to inspect the cord during each diaper change and bath. Parents can be reassured that the stump may smell earthy as it necroses and that it might have a small amount of "cloudy mucoid material" (AWHONN, 2007a) at the stump. The parents should consult their healthcare provider immediately if they notice drainage from the stump or at the point of attachment, if the cord or drainage smells foul, or if they notice redness, swelling, or other discoloration of the surrounding skin. This could indicate omphalitis (infection of the umbilical cord stump) or necrotizing fasciitis (soft tissue infection), potentially fatal complications. Signs of systemic infection such as fever, inability to maintain temperature, poor feeding, or lethargy should always be reported. Parents should also notify the provider if the cord doesn't fall off within 2 weeks, or if the area fails to heal within 2 or 3 days of separation (AWHONN, 2007a).

Nail Care

During the first days of life, the nails may adhere to the skin of the fingers, and cutting is contraindicated. Within a week the nails separate from the skin and frequently break off. If the nails are long or if the newborn is scratching his or her face, the nails may be gently filed using a newborn file. This is most easily done while the infant is asleep. Newborn socks or mittens may be used to cover the newborn's hands and prevent facial scratching.

Dressing the Newborn

Newborns need to wear a T-shirt, diaper (diaper cover if using cloth diapers), and a sleeper. At home, the temperature determines the amount of clothing the newborn wears. Families who maintain their home at 60°F to 65°F should dress the infant more warmly than those who maintain a temperature of 70°F or higher.

Newborns should wear a head covering outdoors to protect their sensitive ears from drafts and to prevent heat loss. Parents can wrap a blanket around the baby, leaving one corner free to place over the head for added protection while outdoors or in crowds. The nurse must advise families about the ease with which a newborn's skin can burn when exposed to the sun. To prevent sunburn, the newborn should remain shaded, wear a light layer of clothing, or be protected with sunscreen specifically formulated for infants. Many healthcare professionals, however, recommend avoiding sunscreen until the infant is at least 6 months old.

Diaper shapes vary and are subject to personal preference. Prefolded and disposable diapers are usually rectangular. Cloth diapers may also be triangular or kite-folded. Extra material is placed in front for males and toward the back for females to increase absorbency.

Baby clothing should be laundered separately with a mild soap or detergent. Diapers are generally presoaked before washing. All clothing should be rinsed twice to remove soap and residue and to decrease the possibility of rash. Some newborns may not tolerate clothing treated with fabric softeners added to the washer or dryer.

Temperature Assessment, Fever, and Illness

As the nurse prepares to teach parents about taking their baby's temperature, it is important to provide opportunities for discussion and demonstration. Families often need a review of how to take their infant's temperature and when to call their primary healthcare provider.

CLINICAL TIP

Dressing a newborn baby with a T-shirt may be quite a challenge. The T-shirt is first pulled over the baby's head. The next challenge is getting the arms in the sleeves, because the newborn grasps at the fabric of the T-shirt as you try to pull it over the hands and arms. It helps to put your hand through the right sleeve of the T-shirt and hold the baby's right hand. Then pull the sleeve over your hand. Repeat the same movements for the left sleeve.

Parents need to take the newborn's temperature only when signs of illness are present. Axillary temperatures are used to determine temperature stability and readiness for discharge in healthy newborns, and a newborn axillary temperature of 36.5°C to 37.4°C (97.7°F to 99.3°F) is considered normal (AAP & ACOG, 2007). Although the axillary temperature doesn't correlate closely with the rectal temperature, this method is convenient, easy for parents to employ, and poses low risk to the newborn.

The rectal method is considered the gold standard for measuring temperatures of febrile infants, as rectal temperature is closer to the true core temperature found in the pulmonary artery and the bladder, but it carries the risk of rectal trauma, which can result in rare but life-threatening perforation, hemorrhage, or necrotizing fasciitis (Christensen, Pysher, & Christensen, 2007; De Curtis, Calzolari, Marciano, et al., 2008; Hutton et al., 2009). Some parents are comfortable taking rectal temperatures, whereas others prefer using the axillary method.

Parents may ask the home-care nurse for information about how to measure their baby's temperature if he or she seems sick. Tympanic thermometer measurements have not been found to be accurate in young infants, so they are not recommended. Although the infrared skin thermometer used on the forehead shows promise, further research is needed (De Curtis et al., 2008; Hutton et al., 2009). Some parents use skin palpation to determine temperature. This is not a reliable way to measure fevers in young infants, yet a study demonstrated that parents were usually able to determine the absence of a fever by using palpation (Katz-Sidlow, Rowberry, & Ho, 2009).

In the absence of one best answer, the nurse can recommend that parents purchase a new thermometer that is designed to measure infant temperature. It is helpful for nurses to periodically check thermometer availability at local retailers and review current academic and manufacturers' literature. The parents may also want to discuss their choice of temperature measurement location and type of thermometer with their primary healthcare provider.

The nurse should ensure that parents do not plan to use a mercury thermometer. Breakage of mercury thermometers has caused symptomatic mercury poisoning in children and adults, and improper disposal contributes to environmental contamination (Agency for Toxic Substances and Disease Registry [ATSDR], 2009; U.S. Environmental Protection Agency [EPA], 2009). Mercury thermometers should not be used or kept in homes and should be disposed of at a hazardous waste collection site. Digital thermometers provide a safe alternative. The nurse should ask parents if they are aware of the hazards of mercury thermometers during the safety assessment and inform parents of local programs or hazardous waste facilities where the thermometers may be turned in. Parents can contact their local health department or review Web sites for the EPA or Centers for Disease Control (CDC) if they need additional information.

Parents should use the same thermometer and measurement site during the course of one illness in order to more accurately monitor trends in the infant's temperature. The parents should inform the pediatric healthcare provider of the temperature, the site, and the type of thermometer used. Most healthcare providers will verify an axillary temperature with a rectal measurement when evaluating an infant for fever.

Traditionally, a rectal temperature of 38°C (100.4°F) has been considered a fever. Because newborns under 90 days of age, and particularly those under 30 days of age, are at high risk for serious bacterial infections, the nurse should tell parents to see their healthcare provider if their newborn has a rectal temperature of 100.4°F or greater or an axillary temperature of 99.4°F or greater. It will be important for the parents to document the measured temperature, time of measurement, and the method used. Parents can expect that their baby will receive a febrile workup if less than 3 months of age and will be admitted for a workup and observation if less than 1 month of age (Berkowitz, 2007).

Parents need to be informed that newborns with systemic infection may not be febrile but may exhibit more subtle manifestations such as temperature instability, poor feeding, abdominal distention, inability to tolerate feedings, apnea, or alterations in behavior such as irritability or lethargy. A baby who is feeding poorly or just not acting right, even in the absence of a fever, may be exhibiting signs of potentially serious infection. Therefore, parents of young infants should call their primary care provider immediately for any signs of illness and/or fever, rather than treating the infant at home.

Parents of older babies will want to discuss the management of colds, flu, teething, constipation, diarrhea, and other common ailments with their clinician before they occur. Although fevers in otherwise healthy older babies do not necessarily require treatment with antipyretics, their healthcare providers can make recommendations regarding over-the-counter analgesics and antipyretic medications, such as acetaminophen or ibuprofen, to increase comfort as necessary.

Aspirin is not recommended, as it was noted to be associated with Reye's syndrome in children with varicella or influenza. The use of ibuprofen or acetaminophen is not contraindicated in infants, but the nurse should instruct parents not to give any medications to a child under 2 years of age without first discussing it with their healthcare provider (Turkoski, 2007). As noted previously, infants under 3 months of age should see a provider for any measured fever or other signs of illness.

The home-care nurse should caution the parents not to administer any over-the-counter (OTC) cough or cold medications to their baby. Use of such OTC antihistamine and decongestant preparations has not been adequately researched in young children, package instructions have been misinterpreted by parents, and administration has been associated with adverse reactions and death in some cases. Therefore, the parents should talk with their healthcare provider regarding the management of coughs and colds. Additionally, parents should never give young children any medication designed for adult use, and parents should not give more than one medication concurrently to their child unless prescribed by their provider (Lokker et al., 2009; Ryan, Brewer, & Small, 2008; U.S. Food and Drug Administration [FDA], 2008a, 2008b).

Stools and Urine

The appearance and frequency of a newborn's stools can cause concern for parents. The nurse prepares them by discussing and showing pictures of meconium stools and transitional stools and by describing the difference between breast milk and formula stools. Although each baby develops his or her own stooling patterns, parents can get an idea of what to expect (see Figure 29-13 ∞ on page 774).

- Babies can be expected to have at least one meconium stool on the first day of life and at least two during the second 24 hours. Three to four stools can be expected each day by 3 to 5 days of age, and three to six stools per day on days 5 through 7 and thereafter (AAP & ACOG, 2007). Stools progress from meconium on the first 2 days to transitional (greenish-brown) stools, to mushy yellow and seedy. Once breastfeeding is well established, usually by 1 month of age, individual babies vary in their stooling patterns. Constipation is unlikely to occur in newborns receiving only breast milk. Infrequent stooling in the first few weeks may indicate inadequate milk intake.
- Formula-fed babies may have only 1 or 2 stools a day; their stools are more formed and may be darker yellow or brown in color

The nurse can show parents pictures of a constipated stool (small, pelletlike) and diarrhea (watery, loose, green). Families should understand that a green color is common in transitional stools so that they do not mistake transitional stools for diarrhea during the first week of a newborn's life.

Babies normally void (urinate) at least once in the first 24 hours and at least twice in the second 24 hours. At least three to five daily voids can be expected on days 3 through 5 and four to six daily voids on days 5 through 7 (AAP & ACOG, 2007).

By the fifth day of life and thereafter, the newborn can be expected to have five or more wet diapers per day. Fewer may indicate that the newborn needs more fluids. Frequency of voiding is easy to assess with cloth diapers. Parents who use superabsorbent single-use disposable diapers may have difficulty determining voiding patterns because the surface of the diaper feels dry. The liquid pools inside the filling of the diaper. Parents can pull the top layer off to check whether the filling is saturated. Although pink or orange uric acid crystals may be found in the diaper during the first few days of life, the presence of crystals beyond the third or fourth day may indicate inadequate hydration.

Diaper Area Care

The diaper area should be cleansed and well dried with each diaper change. Frequent diaper changes minimize contact between the skin and urine or stool, and decrease the risk of diaper dermatitis (DD)—often referred to by parents as diaper rash. It is also helpful to allow the infant to spend short periods of time air-drying with the diaper off in order to prevent maceration and irritation. Minimal soap is required when cleaning the diaper area, and scrubbing should be avoided. If the parents use commercial diaper wipes, they should be alcohol-free. If an emollient with petrolatum is routinely used as a barrier to protect the skin in the diaper area, the parents do not need to scrub all of it off with each diaper change. The urine and feces should be removed from the barrier, and an additional layer of the barrier can be applied once the area is clean and dry (Friedlander, Eichenfield, Leyden, et al., 2009).

Even with proper care many babies experience some type of diaper rash. This can take the form of a contact dermatitis, otherwise known as irritant diaper dermatitis (IDD), a localized, nonimmunologic reaction to the friction, occlusion, moisture, urine, feces, and chemicals in the diaper environment. Moisturizers such as petrolatum provide protection from wetness and promote healing of mildly irritated skin. If diaper rash occurs, the parents should also apply a protective skin barrier containing zinc oxide to prevent further injury. A thin layer of petrolatum can be placed on top of the zinc oxide layer to prevent the diaper from sticking. Fecal material and urine should be removed with each diaper change, but the skin barrier should be maintained if possible and reapplied as necessary.

A variety of commercial newborn care barrier products are available, which contain either petrolatum or zinc oxide. Some products also contain lanolin, which protects the skin but may be allergenic to some infants. The nurse can recommend a commercial product or tell the parents to choose one with petrolatum and another with zinc oxide. Parents should read labels and avoid over-the-counter ointments containing corticosteroids, as their use can be hazardous to newborns (AWHONN, 2007a; Friedlander et al., 2009).

Commercial disposable diapers have improved greatly over the years to keep newborns dry. This generally decreases the incidence of DD, but some newborns may develop an allergic response to fragrances, dyes, or rubber in diapers (Friedlander et al., 2009). Therefore, parents may want to try switching brands of diapers if the DD persists. If the family uses cloth diapers, a different mild detergent, more thorough rinsing, and hanging them in the sun to dry may alleviate the problem.

When the rash is severe or persists beyond 2 to 3 days despite the treatment above, the parents should contact their healthcare provider. DD is frequently complicated by *Candida albicans,* particularly in infants who have recently had diarrhea, oral thrush, or antibiotic exposure. If this is the case, the provider can prescribe Vusion, a topical agent including miconazole, zinc oxide, and petrolatum, which was approved by the FDA for the treatment of DD complicated by *C. albicans* in 2006 (Aschenbrenner & Venable, 2009; Friedlander et al., 2009). Persistent DD should receive further evaluation to rule out rare metabolic, nutritional, or cutaneous disorders; or malignancies (Friedlander et al., 2009).

Sleeping

When, where, and for how long their baby sleeps are common concerns of parents. The following sections address SIDS prevention, crib safety, cosleeping, and the proper positioning of a baby for sleep. The newborn's sleep-wake states are then described.

Sudden Infant Death Syndrome (SIDS) Prevention

Sudden infant death syndrome (SIDS) is defined as "the sudden unexpected death of an infant less than 1 year of age, with onset of the fatal episode apparently occurring during sleep, that remains unexplained after a thorough investigation, including performance of a complete autopsy and review of the circumstances of death and the clinical history" (Krous et al., as cited by Mitchell, 2009, p. 215).

The causes of SIDS are multifactorial and not fully understood. An extensive review of the literature from the past several decades noted that "thermal stress, rebreathing of expired gases, and infection seem the most viable hypotheses for the mechanisms of SIDS" at this point in time (Mitchell, 2009, p. 216). SIDS occurring during prone positioning appears to have a thermal component. As discussed later in this chapter, babies should sleep on their backs as recommended by the AAP and should not be overheated by the use of heavy clothing or blankets during sleep (Omojokun & Moon, 2008).

The AAP published a number of additional recommendations to prevent SIDS in 2005, which will be discussed in the following paragraphs. The AAP recommended a standard sleep surface such as a firm crib mattress that is covered only with a sheet. The infant should sleep in a separate crib or a bassinet next to the parent's bed, a practice which is known as *room sharing* without *bed sharing* (Fu, Colson, Corwin, et al., 2008, p. 503). **Room sharing** is when the infant sleeps in the same room in close proximity to the parents. Soft crib materials and makeshift bedding composed of pillows, comforters, sheepskin, quilts, or similar items should not be used. Infant toys, stuffed animals, and loose blankets and sheets should be removed from the crib as well. If a lightweight blanket is used, it should be secured by tucking it under the mattress. The blanket should not come higher than chest level on a sleeping infant to ensure it does not cover the infant's face. Parents may be advised to instead use sleep clothing or sleep sacks to reduce the

danger from unsecured blankets. Nurses should educate parents about the need to maintain proper temperature for the infant, because overheating is also a risk factor for SIDS (Mitchell, 2009; National Institute of Child Health and Human Development [NICHD], 2008; Omojokun & Moon, 2008).

Although a number of positioning devices have been marketed to decrease the risk of SIDS, their efficacy and safety has not been demonstrated, and they are not recommended. Some children require home monitoring for health reasons, but monitors are not recommended for the purpose of SIDS reduction (Omojokun & Moon, 2008).

"After prone sleeping position, maternal smoking is the next major modifiable risk factor for SIDS" (Mitchell, 2009, p. 217). Numerous studies have shown that women who smoke while pregnant have a much greater incidence of having a baby die of SIDS than do nonsmokers. Smoking should be avoided in the home and around children to minimize SIDS risk as well as the numerous additional risks of secondhand smoke. Adequate ventilation in and around the crib should be provided.

The AAP also recommends giving infants a pacifier when napping or sleeping, because the use of pacifiers has decreased the incidence of SIDS. Parents should be advised that the pacifier does not need to be reinserted once it falls out after the infant has fallen asleep. The pacifier should not be coated with sweet substances or sugar, and it should be cleaned and replaced frequently. Infants who do not wish to use a pacifier should not be forced to do so. The incidence of SIDS is very low in the first month of life, so introduction of the pacifier can be delayed until 1 month of age in breastfeeding infants to prevent issues with lactation (Damato, 2007).

These recommendations are for healthy infants, and parents should follow them unless otherwise directed by their healthcare provider in response to a particular medical condition. Nurses have the opportunity to assess for risk factors in the home environment and to educate families, particularly patients in groups at high risk for SIDS. Parents can be encouraged to attend infant cardiopulmonary resuscitation (CPR) classes, especially if there is a family history of SIDS, prematurity, or another health problem.

Families often ask nurses additional questions about SIDS, such as whether immunizations are a risk factor. The nurse can reassure the parents that the incidence of SIDS is less in fully immunized infants, and that they can follow current immunization recommendations with confidence (Vennemann, Hoffgen, Bajanowski, et al., 2007). Parents can find additional information at the National Institute of Child Health and Human Development (NICHD) and National Institutes of Health (NIH) Web sites.

The SIDS rate in African Americans continues to remain higher than that in other races. African American mothers have higher rates of bed sharing and are less likely to place their infants on the back to sleep than are other mothers. Cultural values and socioeconomic status may play a role in compliance. Nurses need to reinforce recommendations for placing babies on their backs to sleep, room sharing without bed sharing, and avoidance of smoking. Home-care nurses should inform parents of free crib distribution programs if available, and nurses should work with local agencies and charitable organizations to make approved cribs accessible to low-income families as needed (Bruckner, 2008; Fu, et al., 2008). Research regarding possible genetic links for SIDS in the African American population is ongoing (Cummings, et al., 2009). The NICHD provides a SIDS prevention pamphlet targeted for African American families, which can be downloaded from their Web site.

Crib Safety

During the home visit, the nurse discusses with the family their newborn's sleeping arrangements, and observes the crib, bassinet, cradle, mat, or other devices. If possible, the nurse should observe the infant while sleeping to ensure all safety precautions are being followed.

Parents will want to make certain that their infant's crib meets all federal safety standards as set by the Consumer Product Safety Commission and ASTM (formerly the American Society for Testing and Materials). The crib headboard and footboard should be solid, with no large designs cut out of the wood, as the infant's head could become entrapped in them. Crib slats should be no more than 2 inches apart. If the crib is older and painted, ensure that the paint is not lead-based. If there is any doubt, the crib should not be used unless it is stripped and painted with new lead-free enamel. It is important for parents to be aware that safety regulations today are different from those in years past and that there are safety issues associated with the use of an old crib.

Mattresses should fit snugly to prevent entrapment and suffocation and should always be lowered to a level at which the infant cannot fall out (Forsythe, Maher, Kirchick et al., 2007). Parents should always leave the side rails up when the baby is in the crib, even if they are in the room. Although the Consumer Product Safety Commission issues guidelines for crib safety, safety standards have not been changed since 1982, although changes are expected to be made in late 2010 (Michon, 2010). Parents should inspect the crib regularly to determine whether it is in safe working order, with no splinters, sharp edges, or loose parts. Parents can go to the Consumer Product Safety Commission Web site to check for information about infant products and to sign up for e-mail notifications of updates and recalls.

Cosleeping

The nurse should be aware that the topic of maternal infant cosleeping, which has been the norm in many cultures for centuries, has become a source of debate in the United States and Canada in recent years. The term has a variety of meanings and is sometimes used interchangeably with bed sharing. According to McKenna, Thoman, & Anders (as cited by the Academy of Breastfeeding Medicine Protocol Committee [ABM], 2008), **cosleeping** refers to an infant sleeping "in close social and/or physical contact with a caregiver (usually the mother)" (p. 38). Cosleeping may include sharing any surface, such as a bed, mat, futon, or floor. Bed sharing has been implicated in cases of SIDS and is not recommended by the AAP. **Bed sharing** (mother and infant sharing the same bed) is just one form of cosleeping, however, as cosleeping may also include the infant sleeping on a separate piece of furniture in close proximity to the parent (ABM, 2008).

RESEARCH EVIDENCE IN PRACTICE

Bedsharing with an Infant

CLINICAL QUESTION

What are the risks associated with sharing a bed with an infant?

RESEARCH EVIDENCE

Bed sharing with an infant remains a controversial topic. Yet, in one longitudinal study, more than a third of mothers reported frequent bed sharing with their infants, and two thirds reported sometimes sharing their beds with their babies. Mothers who breastfeed are twice as likely to bring their babies to bed with them.

Concerns have been raised about the association of bed sharing, sudden infant death syndrome (SIDS), and infant suffocation. Indeed, in one study, 13% of parents reported that they rolled onto or partly onto their infants while bed sharing. Still, these proposed associations with serious infant outcomes have not been confirmed by carefully controlled studies. Nine large-scale case-control studies focused on the relationship between bed sharing and SIDS. Three found no increased risk for SIDS. Six of the studies reported an increased incidence of SIDS in bed sharing with smoking mothers, but it was not possible to discriminate the effects of smoking from those of bed sharing. The risk of infant suffocation was increased for infants less than 11 weeks of age, but there was no statistical association between suffocation and bed sharing with infants older than 3 months.

In some cultures, bed sharing is commonplace and accepted. Hispanics, African Americans, and Asian/Pacific Islanders all bed share at higher rates than Caucasian women. Some women bed share due to economic limitations. Single mothers and mothers with an annual income of less than $30,000 were nearly twice as likely to bed share as their more economically advantaged counterparts.

One key issue is the finding that maternal sleep is hampered when bed sharing with an infant. Mothers report sleeping more lightly and feeling less rested when their infants share their beds.

WHAT QUESTIONS REMAIN UNANSWERED?

Are there long-term psychologic or physical effects from extensive bed sharing during infancy?

WHAT IS BEST PRACTICE?

Smoking mothers should be counseled to avoid sleeping with their infants at any age. Nonsmoking mothers, however, should not be pressured to abstain from bed sharing with their older infants (3 months or older). Mothers should be counseled that their own sleep will be enhanced if the infant sleeps in a separate bed, but that the risk of SIDS and suffocation are not increased with bed sharing of older infants.

CRITICAL THINKING

Under what conditions should a mother be counseled not to bed share at all?

Lahr, M., Rosenberg, K., & Lapidus, J. 2005. Bedsharing and maternal smoking in a population-based survey of new mothers. *Pediatrics, 116*(4), e530–e542.

Lahr, M., Rosenberg, K., & Lapidus, J. 2007. Maternal infant bedsharing: Risk factors for bedsharing in a population-based survey of new mothers and implications for SIDS risk reduction. *Maternal and Child Health Journal, 11*(3), 277–286.

The ABM (2008) has urged continued research, rather than an across-the-board policy against bed sharing, because sleeping in close proximity increases the frequency and duration of breastfeeding throughout the night. The organization noted that many of the cases of SIDS that occurred during bed sharing involved parents who smoked, were overtired, or under the influence of substances; involved the infant sleeping prone; or involved unsafe surfaces such as couches or waterbeds. The ABM suggested that cosleeping on a firm mattress on the floor might decrease risks related to entrapment and suffocation. Infant beds that attach to the side of the adult bed are available, but have not been researched for safety and efficacy.

Ateah and Hamelin (2008) surveyed 293 mothers of young infants. Despite the fact that 89% of them knew of the risks associated with bed sharing, 72% of the women reported sleeping with their infants at one point or another, in many cases during and/or following a nighttime breastfeeding. Thirteen percent of these women reported a close call, in which they or the father rolled onto their infant or the infant became covered by linens, particularly when the parents were very tired. The researchers published the following clinical implications of bed sharing based on their findings: (a) nurses should promote the practice of infant supine sleep in an approved crib in the parent's room, (b) cosleeping in a crib next to the parent's bed offers convenience to breastfeeding mothers without the risks of bed sharing, (c) recommendations for safe bed sharing cannot be provided, as issues such as maternal exhaustion and infant overheating are not within the parent's control, (d) parents should be informed about the risks of bed sharing as well as the recommendations of the AAP and the Canadian Pediatric Society, and (e) increased public education is needed regarding the benefits of cosleeping by room sharing without bed sharing (p. 280).

As the research continues, the AAP recommendations and those offered by Ateah and Hamelin (2008), which were published in *JOGNN: The Journal of Obstetric, Gynecologic, and Neonatal Nursing,* provide excellent guidance for home-care nurses when educating parents on SIDS prevention and safe infant sleep practices.

PROFESSIONALISM IN PRACTICE

Educating Parents About Bed Sharing

Parents will sometimes inform nurses that they intend to sleep with their infants in the bed for ease of breastfeeding or for personal reasons despite recommendations. It is important for nurses to realize that parents will make their own decisions regarding parenting, yet parent education remains a nursing responsibility. Nurses must make parents aware of AAP recommendations for supine sleep and room sharing without bed sharing, so the parents can make informed decisions regarding their newborn's safety within the context of current research, their culture, and personal beliefs.

Figure 37-4 ■ Infants should be placed on their backs when sleeping.

Proper Positioning

Newborns and infants should always be placed in the supine position to sleep, as recommended by the AAP since 1992 (Figure 37-4 ∞). Deaths related to SIDS have dramatically decreased since the initiation of "Back to Sleep" campaigns around the globe. However, an increase in the number of children with cranial asymmetry, particularly unilateral flattening of the occiput, has been noted since the campaign began. Some parents resist supine positioning due to concerns about flattening their baby's head (Hutchison, Stewart, & Mitchell, 2007).

Parents should therefore be counseled within the newborn's first 2 to 4 weeks of life to place their infant in the prone position to allow "tummy time" while the infant is awake and under their direct observation (Omojokun & Moon, 2008). This position will promote upper shoulder girdle strength and will help to prevent the development of flat areas on the occiput.

Parents can also be taught to alternate their infant's head position from right to left each night when placing the newborn supine for sleep. Periodically changing the infant's orientation to outside activity such as the bedroom door will encourage the infant to use more than one head position to sleep and rest. This can be accomplished by placing the infant at alternate ends of the crib or bassinet. The home-care nurse can demonstrate these positions for the parents, reinforce the importance of supine sleep in relation to SIDS prevention, and give parents other ideas for carrying and positioning, such as the use of front packs, backpacks, and slings. Parents should read and follow all product information provided by the manufacturer.

Some parents may resist supine positioning due to fears about aspiration. The nurse can encourage parents to hold their infants upright for 10 to 15 minutes following feedings. Additionally, the parents can be reassured that infant deaths related to aspiration have decreased since "Back to Sleep" was initiated (Hutchison, Stewart, & Mitchell, 2007).

Many mothers return to the workforce during the first year of their newborn's life, so the nurse should remind parents to educate caregivers and family members who will care for the newborn in their absence about the importance of supine sleep positioning and insist that it is practiced with their child.

Sleep-Wake States

The newborn demonstrates several different sleep-wake states after the initial periods of reactivity. It is not uncommon for a newborn to sleep almost continuously for the first 2 to 3 days following birth, awakening only for feedings every 3 to 4 hours. Some newborns bypass this stage of deep sleep and require only 12 to 16 hours of sleep. The parents need to know that this is normal.

Sleep states include deep sleep and light sleep. During **deep sleep** the infant will be nearly still except for occasional startles, twitches, and sucking. The infant will arouse to intense stimuli, and care and feeding at this time will be frustrating. **Light sleep** makes up the highest proportion of newborn sleep and usually precedes awakening. It is characterized by some body movements, rapid eye movements (REM), and brief fussing or crying. The infant may arouse, remain in light sleep, or return to deep sleep in response to stimuli. Infants are not usually ready to feed in this state.

Awake states include drowsy awake, quiet alert, active alert, and crying states. During the **drowsy awake state**, infants open and close their eyes, but the eyes appear glazed and the face is often still. They may return to sleep or awaken further in response to stimuli. The **quiet alert state** (also called *wide awake state*) is characterized by a brightening of the eyes and face. Infants are most attentive to their environment in this state and provide positive feedback to caregivers. This is an optimal state during which to initiate breast feeds (Koehn & Riordan, 2010). The **active alert state** (also called *active awake state*) brings about an increase in facial and body movement, with periods of fussiness occurring. The infant in this state has increased sensitivity to disturbing stimuli, and intervention to console the infant at this point is beneficial. The **crying state** is evidenced by increased motor activity, grimaces, eyes tightly closed or open, and extreme responsiveness to stimuli. Infants may be able to console themselves, or they may require consoling from a caregiver.

For newborns, crying is a spontaneous response to unpleasant stimuli, and their only means of expressing their needs vocally. After 2 or 3 days, newborns settle into individual patterns and families learn to distinguish different tones and qualities of their newborn's cry. The amount of crying is also highly individual. Some newborns cry as little as 15 to 30 minutes in 24 hours, or as long as 2 or more hours. When crying continues after causes such as discomfort and hunger are eliminated, the newborn may be comforted by swaddling, rocking, or other reassuring activities. There is some indication that newborns who are held more tend to be calmer and cry less when not being held. Some parents may be afraid that holding will "spoil" the newborn, and need reassurance that this is not the case. On the contrary, picking babies up when they cry teaches them that adults are responsive to them. This helps build a sense of trust

in humankind. Of course, the nurse documents and assesses any crying, and provides teaching and referrals as necessary. See Table 37-4 for the characteristics and caregiving implication of each state.

> "It was so exciting to go home with our new baby. That first day went quite well, and Joe and I felt that we were on our way as new parents. Our son had been fed and diapered a number of times, and it was now time for bed. When we snuggled him in his bassinet, he lay quietly and didn't cry. Then we looked at each other and at the same time said, "What if we don't hear him in the middle of the night?" We went on to bed but with much trepidation. Our baby's first cry in the night woke us immediately. We both sat up and simultaneously said, "There he is!"
>
> After a few weeks, we could laugh at the anxiety we had during those first few days. I'm sure all new parents must have had similar experiences."

Injury Prevention

Accidental injuries were the fifth leading cause of death in infants under 1 year of age in the United States in 2004 and the sixth leading cause of death in this age group in 2005 (Mathews & MacDorman, 2008). The top five most common fatal injuries in infants under 1 year of age in 2005 included unintentional suffocation, motor vehicle accidents, unspecified homicide, classifiable homicide, and drowning. The top five most common nonfatal accidental injuries in infants under 1 year of age who were treated in U.S. emergency departments in 2006 were falls, strikes, bites or stings, foreign bodies, and fires/burns (National Center for Injury Prevention and Control, Centers for Disease Control & Prevention, n.d. [page updated 15 July 09]). It is helpful to keep these causes of injury in mind when counseling new parents regarding safety in the home.

During the home visit, the nurse can share information regarding common injuries and accidents that occur in infants as well as how to prevent them from occurring. The parents should have been instructed on car seat safety before leaving the birthing unit, and the nurse can confirm this. It is essential that the parents understand never to leave a baby unattended on any elevated surface, near water, or near pets or other children who may unintentionally harm them.

If time allows, the nurse observes the environment and identifies future changes that need to be made to childproof the home. Safety related to electrical outlets, appliances, and sources of danger in kitchens and bathrooms will need to be addressed as the infant becomes mobile. Poisonous substances and medications should be secured. It is important for nurses to be aware of the impact they can have on the safety of families through home visits.

Shaken Baby Syndrome

Shaken baby syndrome (SBS) is a traumatic brain injury that results from violent shaking, with or without contact between the infant's head and an exterior surface. Swelling and bleeding are the result, and the infant may sustain permanent neurologic damage. SBS results in death in approximately 20% of cases (Lewin, 2008; Mraz, 2009). The AAP has made a number of recommendations to address and prevent shaken baby injuries, including home visitation programs and any other child abuse prevention efforts that prove efficacious. The Shaken Baby Syndrome Prevention Act of 2007 was introduced in the U.S. 110th legislative session, but did not pass. However, a number of states have passed legislative preventive programs (Govtrack, n.d.; National Conference of State Legislatures, 2009). A variety of educational preventive programs have been introduced by nurses to educate parents and communities regarding the risks of SBS (Goulet, et al., 2009; Smith & deGuehery, 2008).

Risks for SBS include infants who are inconsolable, fragile, premature, special needs, and/or male. Parental risk factors include male caregiver; less educated, young, substance-abusing, poorly supported, or single parent; history of domestic violence; depression; unrealistic expectations; or the belief that the infant is intentionally manipulative (Carbaugh, as cited by Lewin, 2008). Home visits provide an excellent opportunity to educate parents regarding safety and injury prevention, shaken baby injuries, and the hazards of abuse and neglect. Nurses need to directly inform parents to never shake a baby. Home visits are also the ideal time to provide appropriate resources and referrals to local preventive educational and support programs. Home-care nurses can access parent information from sources such as the Web site of the National Center on Shaken Baby Syndrome.

Infant Colic as a Parental Stressor

Infant colic is manifested by persistent, unexplained, inconsolable crying, that can continue for several hours each day, often occurring in the evening. It is a source of great distress and anxiety to new parents, as the colicky infant does not respond to usual methods of soothing. Colic can emerge by 2 to 3 weeks of age, and it can continue until the infant is 4 to 6 months of age. The etiology is unknown, but is believed by many to be gastrointestinal in nature (Cohen-Silver & Ratnapalan, 2009; Jarvis, 2008). Research investigating the differences in the microorganisms found in the gastrointestinal tracts of colicky versus non-colicky infants is ongoing and shows promise (Mentula, Tuure, Koskenala, et al., 2008; Savino et al., 2008).

Interventions including dietary modifications in the infant and/or the breastfeeding mother; administration of pharmacologic agents such as simethicone and anticholinergics; administration of herbal preparations, sucrose, and probiotics; infant massage; vibration of the infant; carrying; changes in the amount and type of infant stimulation; and parental support have been used and researched. Definitive treatment guidelines have not been developed, however (Arikan, Alp, Gözüm, et al., 2008; Cohen-Silver & Ratnapalan, 2009).

Catherine, Ko, and Barr (2008) found 51 articles in 11 parenting magazines popular in Canada and the United States that addressed crying, colic, soothing, or SBS over a 5-year period. The articles presented contradictory advice regarding the etiology and treatment of colic, perhaps reflecting the current state of

TABLE 37-4 Infant Sleep and Awake States*

INFANT STATES	PHYSICAL CHARACTERISTICS	BODY ACTIVITY	EYE MOVEMENTS	FACIAL MOVEMENTS	BREATHING PATTERN	RESPONSES	CAREGIVER IMPLICATIONS
Sleep States							
Quiet sleep (also known as deep sleep)	Anabolic, restorative sleep, increased cell mitosis and replication, lowered oxygen consumption, release of growth hormone.	Typically still, may occasionally startle or twitch.	None.	None or may have occasional sucking movements.	Slow and regular.	Only intense or disturbing stimuli will arouse infant, threshold to stimuli is high.	Difficult to arouse for feedings. Teach parents to time feedings when infant is in a more responsive state. Infant may arouse slightly if an attempt is made to awaken but typically returns to the quiet sleep state.
Active sleep (also light sleep or known as rapid eye movement [REM] state)	Processing and recording information. Often linked to learning. Is the highest proportion of sleep and precedes awakening.	Some body movements.	REM, eyelids flutter beneath closed eyelids.	May smile or make fussing or crying noises.	Irregular.	More responsive to internal stimuli (hunger) and external stimuli (such as being picked up by caregiver). When stimulated may arouse, return to quiet sleep, or remain in active sleep.	Inexperienced care providers may attempt to feed when infant makes normal crying sounds.
Awake States							
Drowsy awake	May return to sleep or awaken further.	Smooth movements with variable activity level. May experience mild startles intermittently.	Eyes may open and close. May appear heavy-lidded, or eyes may appear like slits.	May have no facial movements and appear still, or may have some facial movements.	Irregular.	Usually reacts to stimuli but may be slowed. May change to other states such as quiet alert, active alert, or crying.	To stimulate infant, provide verbal, sight, or oral stimulation. If left alone, infant may return to a sleep state.
Quiet alert (also called *wide awake*)	Attentive to environment, focuses attention on stimuli.	Minimal.	Eyes bright and wide.	Attentive appearance.	Regular.	Most attentive, focuses attention on stimuli.	In the first hours after birth, may experience intense alertness before going into a long sleeping period. This state increases in intensity as the infant becomes older. Providing stimuli will help maintain an active alert state or a drowsy awake or quiet alert state. Infant provides pleasure and positive feedback to care providers. Good time to feed infant.
Active alert (also called *active awake*)	Infant's eyes are open, not as bright as in quiet alert. More body activity than in a quiet alert state.	Smooth movements may be interspersed with mild startles from time to time.	Eyes open with a glazed, dull appearance.	May be still with or without facial movements.	Irregular.	Reacts to stimuli with delayed responses to stimuli, or may change to quiet alert or crying state.	Infant may be fussy and become sensitive to stimuli, may become more and more active and start crying. If fatigue or caregiver interventions disturb this state, infant may return to a drowsy awake or sleep state.
Crying	Communication tool, response to unpleasant stimuli from environment or internal stimuli. Characterized by intense crying for more than 15 seconds.	Increased motor activity, skin color changes to darkened appearance, red, or ruddy.	Eyes may be tightly closed or open.	Grimaces.	More irregular than in other states.	Very responsive to internal or external unpleasant stimuli.	Indicates that the infant's limits have been reached. May be able to console himself or herself and return to an alert or sleep state, or may need intervention from caregiver.

* A *state* is a group of characteristic behaviors and physiologic changes that occur together in a regular pattern.

knowledge about colic. Conflicting information leads to uncertainty and frustration among parents. The authors also expressed concern that very few of the articles mentioned the increased risks of child abuse and SBS related to incessant crying.

It is important for nurses to provide new parents with anticipatory guidance regarding the symptoms of infant colic and the strain that it can cause in family relationships. Parents will want to see their infant's healthcare provider to rule out other causes for prolonged crying, such as urinary tract infection (Freedman, Al-Harthy, & Thull-Freedman, 2009). If no physiologic etiology is found, the parents should be supported and educated regarding the risks of child abuse. Nurses must remind parents to simply lay the baby down safely in his or her crib and take a break if they become frustrated with the crying. Parents should be encouraged to seek support from healthcare providers as well as support from family and friends if colic occurs. It is also important to reassure parents that the condition does resolve in time and that newborns go on to develop normally. Home-care nurses should be aware of local support groups and/or hotlines for colic and share these resources with all new parents.

Newborn Screening and Immunization Program

Before the newborn and mother are discharged from the hospital, the nurse informs parents about the normal screening tests for newborns and tells them when to return for further tests if needed. The home-care nurse ensures that the blood specimens have been obtained and may obtain a specimen as necessary.

Newborn screening tests detect disorders that cause intellectual disability (mental retardation), physical handicaps, or death if left undiscovered. Disorders that can usually be detected from a drop of blood obtained by a heel stick on the second or third day of life include galactosemia, congenital adrenal hyperplasia, congenital hypothyroidism, phenylketonuria (PKU), and sickle cell anemia. Parents should be instructed that a second blood specimen will often be required from the newborn after 7 to 14 days. Nurses should clarify that an abnormal test result is not diagnostic. More definitive tests must be performed to verify the results. It is important to follow protocols that incorporate state laws about newborn testing, as the required screening and protocols vary between states. See chapter 33 ∞ for more information regarding newborn screening.

The nurse should ensure that the family has information regarding the current childhood immunization schedule and has plans to begin or continue immunizations. The nurse should be familiar with current recommendations and should share information about immunizations with the family as necessary.

Home Care: The Mother and Family

Home care of the mother and family involves performing an assessment of the mother and family as well as discussing breastfeeding concerns.

Assessment of the Mother and Family at Home

During the home visit, the nurse will continue the ongoing postpartum assessment that started prior to discharge. The initial goal is to assess the woman's perceptions of her current circumstances, her recovery from childbirth, her adjustment and that of her partner to parenthood, the newborn's condition, family-newborn bonding, and any problems or concerns the woman may have. The nurse asks specifically about the following areas:

- Progression of lochia (color, amount of flow, presence of foul odor or clots)
- Fever or malaise
- Dysuria or difficulty voiding
- Pain in the pelvis or perineum
- Painful, reddened hot spots or shooting pains in the breasts during or between feedings
- Areas of redness, edema, tenderness, or warmth in the legs

The nurse also talks with the mother about her diet, fatigue level, ability to rest and sleep, pain management, signs of postpartal complications, activity level, sexuality issues, self-care ability, social support system, and any pertinent cultural or religious practices related to postpartum or newborn care. Before performing the physical assessment, the nurse ensures privacy. The physical assessment focuses on maternal physical adaptation, which is assessed by evaluating vital signs, heart and lungs, breasts, abdominal musculature, bowel and bladder elimination patterns, fundal height and location, the perineum, lochia, edema, extremities, and laboratory values.

The psychologic assessment focuses on attachment, adjustment to the parental role, maternal emotions, sibling adjustment, and educational needs. When appropriate, the nurse mentions available community resources, including the public health department, which can be used for follow-up visits. In ideal situations, a family approach involving the presence of the father and any siblings provides an opportunity to observe family interactions and opportunities for all family members to ask questions and express concerns. In addition, this approach may bring to the surface any questionable family interaction pattern, such as one suggestive of abuse or neglect; the nurse can consider further referral if needed. See Assessment Guide: Postpartum—First Home Visit and Anticipated Progress at Six Weeks.

During the home visit, the nurse continues to provide teaching to the mother and her family and describes self-care measures as needed. The nurse also reviews the signs of developing illness with the woman and her partner. If signs of potential complications are present, the nurse completes a more in-depth evaluation and determines whether it is necessary for the woman to see her primary care provider. If information about family-planning options has not been addressed previously, the nurse provides it at this time and answers any questions the woman or her partner may have about methods of birth control and their sexual relationship.

Postpartum Fatigue

Postpartum fatigue is a major concern that may trouble new mothers for as long as 19 months postpartum. It is characterized

ASSESSMENT GUIDE Postpartum—First Home Visit and Anticipated Progress at Six Weeks

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
VITAL SIGNS		
Blood Pressure: Return to normal prepregnant level.	Elevated blood pressure (anxiety, essential hypertension, renal disease), preeclampsia (can occur postpartum).	Review history, evaluate normal baseline; refer to physician/certified nurse midwife (CNM) if necessary.
Pulse: 60–90 beats/min (or prepregnant normal rate).	Increased pulse rate, tachycardia, chest pain (excitement, anxiety, blood loss, cardiac disorders).	Count pulse for full minute, note irregularities; marked tachycardia or beat irregularities require additional assessment and possible physician/CNM referral.
Respirations: 12–24/min.	Marked tachypnea or abnormal patterns (respiratory or cardiac disorders).	Evaluate for respiratory disease or cardiac complications; refer to physician/CNM if necessary.
Temperature: 36.6°C–37.6°C (98°F–99.6°F).	Increased temperature (infection or engorgement).	Assess for signs and symptoms of infection or disease state.
WEIGHT		
2 days: Possible weight loss of 12–20+ lb.	Minimal weight loss (fluid retention, preeclampsia).	Evaluate for fluid retention, edema, deep tendon reflexes, and blood pressure elevation.
6 weeks: Returning to normal prepregnant weight.	Retained weight (excessive caloric intake).	Determine amount of daily exercise. Provide dietary teaching. Refer to dietitian if necessary for additional dietary counseling.
	Extreme weight loss (excessive dieting, inadequate caloric intake).	Discuss appropriate diets, refer to dietitian for additional counseling if necessary; reinforce need for up to 500 additional kcal/day when breastfeeding.
BREASTS		
Nonbreastfeeding: 2 days: May have mild tenderness; small amount of milk may be expressed.	Some engorgement (incomplete suppression of lactation).	Engorgement may be seen in nonbreastfeeding mothers. Advise patient to wear a supportive, well-fitted bra, avoid very warm showers, avoid pumping or any stimulation of breasts, use ice packs for comfort, evaluate for signs and symptoms of mastitis.
6 weeks: Soft, with no tenderness; return to prepregnant size.	Redness; hardened area, marked tenderness (mastitis). Palpable mass (tumor).	Counsel about nipple care. Observe infant feeding. Evaluate patient condition, evidence of fever; refer to physician/CNM for initiation of antibiotic therapy, if indicated. A breastfeeding mother should examine her breasts monthly, after feeding, when breasts are empty; if palpable mass is felt, refer to physician for further evaluation.
Breastfeeding: Full, with prominent nipples; lactation established.	Cracked, fissured nipples (improper latch). Redness, marked tenderness, hardened area (mastitis or abscess). Palpable mass (plugged milk duct, tumor).	For breast engorgement accompanied by erythema, instruct the mother to: 1. Keep breast empty by frequent feeding. 2. Rest when possible with breasts elevated. 3. Take prescribed pain relief med. 4. Drink adequate fluids. If symptoms persist for more than 24 hours, or if accompanied by fever greater than 100.4°F, or flu-like symptoms, redness, instruct her to call her physician/CNM.
ABDOMINAL MUSCULATURE		
2 days: Improved firmness, although "bread dough" consistency is not unusual, especially in multipara. Striae pink and obvious.	Marked relaxation of muscles.	Evaluate exercise level; provide information on appropriate exercise program.
Cesarean incision healing.	Drainage, redness, tenderness, pain, edema (infection).	Evaluate for infection; refer to physician/CNM if necessary.
6 weeks: Muscle tone continues to improve; striae may be beginning to fade, may not achieve a silvery appearance for several more weeks; linea nigra fading.		
ELIMINATION PATTERN		
Urinary Tract: Return to prepregnant urinary elimination routine.	Urinary incontinence, especially when lifting, coughing, laughing, and so on (urethral/perineal trauma, hormonal influences, cystocele).	Assess for cystocele; instruct in appropriate muscle tightening exercises; refer to physician/CNM.
	Pain or burning when voiding, urgency and/or frequency, pus or white blood cells (WBC) in urine, pathogenic organisms in culture (stinging may be due to lacerations or episiotomy; urinary tract infection).	Evaluate for urinary tract infection; obtain clean-catch urine; refer to physician/CNM for treatment if indicated.
	*Possible causes of alterations are placed in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

ASSESSMENT GUIDE Postpartum—First Home Visit and Anticipated Progress at Six Weeks continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
ELIMINATION PATTERN (continued)		
Routine urinalysis within normal limits (proteinuria disappeared).	Sugar or ketone in urine—may be some lactose present in urine of breastfeeding mothers (diabetes).	Evaluate diet; assess for signs and symptoms of diabetes; refer to physician/CNM.
Bowel Habits: 2 days: May be some discomfort with defecation, especially if patient had severe hemorrhoids or third- or fourth-degree extension.	Severe constipation or pain when defecating (trauma or hemorrhoids).	Discuss dietary patterns; encourage fluid, adequate roughage. Continue use of stool softener if necessary to prevent pain associated with straining; continue sitz baths, periods of rest for severe hemorrhoids; assess healing of episiotomy and/or lacerations; severe constipation may require administration of laxatives, stool softeners, and an enema if not contraindicated (check with physician/CNM).
6 weeks: Return to normal prepregnancy bowel elimination.	Marked constipation (inadequate fluid and/or fiber intake).	See previously discussed interventions.
	Fecal incontinence or constipation (rectocele).	Assess for evidence of rectocele; instruct in muscle tightening exercises; refer to physician/CNM.
REPRODUCTIVE TRACT		
Lochia: 2 days: Lochia rubra or lochia serosa, scant amounts, fleshy odor.	Excessive amounts and/or large clots (nonfirm uterus), foul odor (infection), passing tissue (possible retained placenta).	Assess for evidence of infection and/or failure of the uterus to descend and decrease in size; refer to physician/CNM.
6 weeks: No lochia, or return to normal menstruation pattern.	See above.	See above.
Fundus and Perineum: 2 days: Fundus is at least two fingerbreadths below the umbilicus; uterine muscles still somewhat lax; introitus of vagina lacks tone—gapes when intra-abdominal pressure is increased by coughing or straining.	Uterus not decreasing in size appropriately or extremely tender (infection).	Assess fundus for firmness and/or signs of infection; refer to physician/CNM if indicated.
Episiotomy and/or lacerations healing; no signs of infection; may have some bruising and tenderness.	Evidence of redness, severe pain, poor tissue approximation in episiotomy and/or laceration (wound infection).	Continue perineal hygiene care; refer to physician or CNM as necessary.
6 weeks: Uterus almost returned to prepregnant size with almost completely restored muscle tone.	Continued flow of lochia, failure to decrease appropriately in size (subinvolution).	Assess for evidence of subinvolution and/or infection; refer to physician or CNM for further evaluation and treatment if necessary.
HEMOGLOBIN AND HEMATOCRIT LEVELS		
6 weeks: Hemoglobin (Hb) 12 g/dl; Hematocrit (Hct) 37% ± 5%	Hb less than 12 g/dl; Hct less than 32% (anemia).	Assess nutritional status, assess for signs or symptoms of anemia, begin (or continue) supplemental iron; for marked anemia (Hb less than or equal to 9 g/dl) additional assessment and/or physician/CNM referral may be necessary.
ATTACHMENT		
Bonding process demonstrated by soothing, cuddling, and talking to infant; appropriate feeding techniques; eye-to-eye contact; touching; calling infant by name.	Failure to bond demonstrated by lack of behaviors associated with bonding process; calling infant by nickname that promotes ridicule; inadequate infant weight gain; infant is dirty; hygienic measures are not being maintained; severe diaper rash; failure to obtain adequate supplies to provide infant care (malattachment).	Provide counseling; talk with the woman about her feelings regarding the infant; provide support for the caretaking activities that are being performed; refer to public health nurse or social worker for continued home visits; refer if abuse or neglect is suspected.
Parent interacts with infant and provides activities soothing, caretaking activities.	Parent is unable to respond to infant needs (inability to recognize needs, inadequate education and support, fear, family stress).	Provide support for caretaking activities observed; provide information regarding caretaking activities, such as responding to infant cry; methods of wrapping infant; methods of soothing the infant such as swaddling, rocking, increasing stimuli by singing to the infant or decreasing stimuli by putting infant to rest in quiet room; methods of holding the infant; differences in the cry. Identify support system such as friends, neighbors; provide information regarding community resources and support groups; reinforce "Never shake a baby."
	*Possible causes of alterations are placed in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

(continued)

ASSESSMENT GUIDE Postpartum—First Home Visit and Anticipated Progress at Six Weeks continued

Physical Assessment/Normal Findings	Alterations and Possible Causes*	Nursing Responses to Data†
ATTACHMENT (continued)		
Parents express feelings of comfort and success with the parent role.	Evidence of stress and anxiety (difficulty moving into or dealing with the parent role).	Provide support and encouragement; provide information regarding progression into parent role and assist parents in talking through their feelings; refer to community resources and support groups.
Woman is in the informal or personal stage of maternal role attainment.	Woman is still greatly influenced by others, has not developed an image or style of her own (woman remains in the anticipatory stage).	Provide role modeling for the woman in working through problem solving with the infant; provide encouragement as she thinks through decisions and develops her sense of problem solving; encourage her to make decisions regarding infant care; provide positive reinforcement.
ADJUSTMENT TO PARENTAL ROLE		
Parents are coping with new roles in terms of division of labor, financial status, communication, readjustment of sexual relations, and adjusting to new daily tasks.	Inability to adjust to new roles (immaturity, extremes of maternal age, inadequate education and preparation, ineffective communication patterns, inadequate support, current family crisis).	Provide counseling, provide anticipatory guidance, refer to parent groups.
EDUCATION		
Mother understands self-care measures.	Inadequate knowledge of self-care (inadequate education).	Provide education and counseling.
Parents are knowledgeable regarding infant care.	Inadequate knowledge of infant care (inadequate education).	
Siblings are adjusting to new baby.	Excessive sibling rivalry.	
Parents have a method of contraception.	Birth control method not chosen.	
	*Possible causes of alterations are placed in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

Breastfeeding Issues

by feelings of exhaustion and decreased capacity for physical and mental work. Chapter 36 ∞ includes an extensive discussion on postpartum fatigue, including risk factors, complications, and management.

The home-care nurse should inform mothers that fatigue may be a significant problem, which can increase the risk of postpartum depression. The nurse can emphasize the benefits of good nutrition and periods of uninterrupted sleep. The mother should be encouraged to ask family and friends for assistance with responsibilities, limit visitors, and use an answering machine or voicemail to allow for more rest. The nurse can also reinforce the need for continued use of prescribed prenatal vitamins and iron, particularly if the patient is breastfeeding.

PROFESSIONALISM IN PRACTICE

Privacy During Postpartum Home-Care Visit

Childbearing women should be asked and informed about postpartum depression at every health care encounter, and the home visit is no exception. It is helpful for the nurse to include other family members in this discussion, so everyone is aware of the symptoms. However, the patient may share things with the nurse in private that she would not share in front of others, so it is important that the nurse request at least a few minutes alone with her. Asking others to leave briefly during the perineal exam is one option for the nurse. The private interaction also allows the nurse to screen the patient regarding domestic violence, which often escalates during the childbearing period.

Breastfeeding Concerns Following Discharge

AWHONN supported the *Healthy People 2010* goals related to breastfeeding and encouraged the national goals to be expanded even further. AWHONN (2007b) "supports an exclusive breastfeeding initiation rate of 90%, a 75% 6-month breastfeeding rate and a 50% 1-year breastfeeding goal by 2025" (para 3). The recommendations are based on benefits to mothers and babies, which have been demonstrated by research.

Breastfed infants have decreased risks of infections. Breastfeeding as an infant is also associated with lower rates of SIDS, insulin dependent diabetes, allergies, asthma, lymphoma, ulcerative colitis, and adult-onset hypertension. Breastfeeding benefits maternal-infant attachment, maternal self esteem, and uterine involution. Finally, mothers who breastfeed have decreased risk for subsequent osteoporosis, ovarian cancer, premenopausal breast cancer, and rheumatoid arthritis (AWHONN, 2007b).

The benefits of breastfeeding result in cost savings for parents, insurers, and employers. Therefore, it has a high economic as well as health value for society. However, most mothers are discharged before breastfeeding is well established, and many require anticipatory guidance and support in order to continue once they go home. The U.S. Breastfeeding Committee (2009) proposed that breastfeeding support is important to health care reform, as it has the potential to save $14 billion per year in the United States.

Avery, Zimmerman, Underwood, et al. (2009) found that women who accept breastfeeding as a learned skill and demonstrate a confident commitment to the process, continue to breast-

feed. Because many mothers discontinue breastfeeding as a result of problems and concerns early on, the home visit is the ideal time to promote continuation of breastfeeding. The home-care nurse has the opportunity and privilege to not only reinforce initial breastfeeding teaching and answer questions, but also to observe an episode of breastfeeding in the home environment where it will continue until weaning. Guidance and support can be individualized according to the mother's specific needs and living situation. There are numerous books and references available to assist nurses in the care of breastfeeding couplets.

The AAP recommends that all breastfeeding newborns be seen by a pediatrician or other knowledgeable healthcare professional at 3 to 5 days of age to assess weight and to have a physical exam to include assessment of jaundice and hydration, maternal breastfeeding status, infant elimination, and formal observation of a breastfeeding session (AAP & ACOG, 2007). A home visit a few days after discharge meets these requirements and can identify at-risk infants before they lose excessive weight and at a time when intervention can correct most breastfeeding problems before they become complicated by insufficient milk. The home health nurse can assess the infant and the breastfeeding process, provide appropriate education to promote breastfeeding, and initiate referrals to a lactation consultant or primary healthcare provider as needed. Additionally, the nurse can provide individualized support and encouragement as desired by the patient.

Breastfeeding Assessment

The nurse should observe a feeding episode, if possible, to assess for correct position, maternal and infant feeding cues, latch on, position, let-down, sucking pattern, nipple condition, infant response, and maternal response. The nurse can assess the parents' ability to identify infant feeding cues such as rooting, hand-to-mouth movements, sucking, opening of mouth in response to stimulation, and infant transition from sleep to drowsy awake to quiet alert states. Various tools are available to assess the breastfeeding session, including the LATCH Scoring Table (Figure 32-15 ∞ on page 874). Assessment of the mother's ability to perceive infant satiety cues such as a gradual decrease in sucking, pulling away and releasing the nipple, relaxation, sleep, contentment, and a small amount of milk visible in the mouth can be accomplished at this time as well (AWHONN, 2007c).

Concerns Related to the Breastfeeding Infant

According to AAP criteria, the infant's weight should remain within 10% of his or her birth weight, and the infant should feed at least 8 to 10 times per day by the fourth day of life. The infant should have at least three voids and at least three stools per 24 hours by the third day of life. Infants with a weight loss of more than 7% that continues beyond 72 hours of life or inadequate output require more extensive evaluation of breastfeeding to correct potential problems. In this case the nurse should notify the primary healthcare provider (AAP & ACOG, 2007; AWHONN, 2007c).

The nurse can assist the couplet experiencing a 7% to 9% infant weight loss with techniques to increase milk production and promote better milk transfer. The nurse will provide assistance with breastfeeding techniques as needed, encourage breastfeeding every 2 hours for the next 24 hours, and then recheck the newborn's weight the next day. If breastfeeding technique is correct and the milk is just starting to come in, the newborn generally begins gaining weight back within hours. The newborn's primary healthcare provider should be notified regarding a weight loss of more than 9% regardless of when it occurs. Lactation problems beyond the expertise of the nurse always require a lactation consultant and/or provider referral.

Newborns frequently require assistance in awakening to feed at least 8 times a day during the first week of life. The quiet alert state is ideal for latch on, and parents should be taught to recognize this state as well as the presence of early feeding cues. The quiet alert baby has bright eyes and is responsive to stimuli. Early feeding cues include sucking motions, bringing the hands to the mouth, rooting, extending the tongue, turning the head to the side, and whimpering (Koehn & Riordan, 2010). Techniques that are helpful in arousing a sleepy baby to the quiet alert state include undressing the baby, changing the diaper, lightly touching, speaking, turning on lights, placing the baby skin-to-skin on the mother's chest, and gently rocking the baby. Overaroused newborns who are crying or who exhibit closed down behaviors such as tightly closed eyes and uncoordinated movements of extremities require calming techniques to bring them to a quiet alert state. Changing the diaper, comforting, holding, swaddling, gently rocking, and talking softly will assist the newborn to return to the quiet alert state so the breast can be offered (Koehn & Riordan, 2010; Riordan & Hoover, 2010).

Many mothers have concerns related to their breast milk supply. The nurse can educate and reassure the mother regarding the signs of adequate transfer. The baby should feed at least 8 to 12 times in 24 hours for a total of at least 140 minutes of active suckling per day during the first 2 weeks. Audible swallowing should be heard. The mother's nipple should be moist, and mother and baby should be satisfied at the end of feedings. The baby's lips and mucous membranes should look moist. The baby should pass at least three to five loose yellow stools per day by day 4 or 5, and five or more per day by 1 week of age. The baby should have at least six diapers that are saturated with clear urine each day by 1 week of age. Additionally, the baby should return to birth weight by the 2-week well-baby visit (Riordan & Hoover, 2010; Smith & Riordan, 2010). The satiated baby will be content at the end of feedings with arms extended and relaxed. A small amount of milk may be visible at the side of the mouth. If all of the previous criteria are met, the nurse can feel confident in telling the mom that the baby is "getting enough" and that exclusive breastfeeding is the ideal diet for the baby until 6 months of age.

Recommendations at this point would be to continue nursing on demand, at least every 3 hours, and to expect the baby to demand more frequent feedings during growth spurts. The mother can allow the baby who is actively sucking and swallowing to nurse for as long as desired on the first side and then for as long as the baby desires on the second side to encourage consumption of the high-fat hind milk. The mother will need to take the newborn in for periodic weight checks, well-baby exams, and immunizations as directed by the infant's provider. As recommended by the AAP, the parents will want to talk with their provider about vitamin D supplementation within the first 2 months, fluoride supplementation at six months, and adding additional foods that contain iron or an iron supplement at 6 months (AAP & ACOG. 2007).

The home-care nurse will occasionally discover a breastfed baby with a weight loss of up to 7% in a normal newborn. Infants experiencing breastfeeding difficulties whose weight loss is greater than 7% may need supplementation. A call to the pediatrician from the patient's home is warranted to discuss the issue. An infant with a weight loss of more than 9% will almost always need supplementation. Because it is important to begin rehydrating the newborn as soon as possible, the home-care nurse may need to help a patient who has planned only to feed from the breast to formulate an interim contingency plan. The nurse can assist her with pumping or hand expressing.

Some mothers may prefer to feed their breast milk to the baby using a syringe, finger, or cup, rather than a bottle. Additional research needs to be done to make recommendations regarding these approaches, however (AWHONN, 2007c). Therefore, only nurses who are experienced with breastfeeding support and lactation consultants should assist mothers with these alternatives.

Expressed breast milk is the ideal intervention. However, if the mother does not have enough breast milk, the nurse will find it necessary to assist the mother with preparation of formula until her supply is adequate and the baby is rehydrated. Therefore, it is important that the home-care nurse be familiar with infant formulas and preparation. The use of infant formula is discussed later in this chapter.

Concerns Related to Maternal Breastfeeding Difficulties and Formula-Feeding

In addition to problems with milk transfer and concerns about milk supply, many new mothers have breastfeeding difficulties, including leaking, nipple soreness, cracked nipples, breast engorgement, and plugged ducts. The nurse can assess for these complications at the home visit and provide interventions to decrease maternal discomfort.

NIPPLE SORENESS Mothers should be counseled to expect sensations of massaging and stretching as the infant elongates the nipple during nursing. This may be uncomfortable when the infant initially latches for feedings, but the discomfort should decrease after the first few seconds of nursing. Nipple soreness is a common complaint and frequent reason for early discontinuation of breastfeeding. The nipples may exhibit erythema, edema, abrasions, fissures, cracks, bruises, blisters, and bleeding. This early transient discomfort is usually due to mechanical trauma, and it peaks between the third and sixth days. Poor latch and/or suck are the primary causes of mechanical trauma, and a change in nipple shape at the end of a feeding is a common indicator. Therefore, observation of feeding, assistance with proper positioning and latching technique, and observation of the shape of the nipple at the end of the feeding are essential to the prevention and treatment of soreness (AWHONN, 2007c; Dennis, Allen, McCormick, et al., 2008; Smith & Riordan, 2010).

The baby's position at the breast is a critical factor in nipple soreness. The mother's hand should be off the areola, and the baby should be tummy to tummy and facing the mother's chest, with ear, shoulder, and hip aligned. The nose is near or just touching the breast, and the lips should be flanged out. The gums are on the areola, and the tongue is over the bottom gum and cupping the nipple. (See Figures 32-11 through 32-14 on pages 872–873.) Because the area of greatest stress to the nipple is in line with the newborn's chin and nose, encouraging the mother to rotate positions when feeding the infant may decrease nipple soreness. Changing positions alters the focus of greatest stress and promotes more complete breast emptying. Although some mothers are initially hesitant to try the side-lying position, this is frequently a helpful position to use when difficulty in latching is encountered. Nipple soreness due to mechanical trauma is frequently related to the infant's sucking pattern or to anatomical variations of the newborn's oral cavity or the mother's nipples. Nipple characteristics such as their size, shape, and ability to elongate may affect comfort during sucking. The size and shape of the infant's oral cavity may also affect the sucking pattern and comfort. A short or tight newborn lingual frenulum (ankyloglossia or tongue-tie) can cause discomfort as well (AWHONN, 2007c; Smith & Riordan, 2010).

An observation of the feeding should assess the baby's oral cavity for anatomical concerns as well as the ability to open the mouth wide enough to attain a deep latch. When latched, the lips should be flanged out, and the newborn should cover as much of the areola as possible. Turning the lips under can cause pain and inadequate transfer of milk. The mother can be taught to observe this and to apply gentle upward pressure on the newborn's upper lip and gentle downward pressure on the infant's chin to correct the position as needed. To prevent trauma, the mother should also be taught to gently insert her finger between the infant's gums to break the latch before removing the baby from the breast.

While nursing, the baby can be expected to suck rapidly at the beginning and more slowly toward the end of a feeding. Sucking should be quiet, with swallowing heard every two to three sucks. The baby's cheeks should be full and rounded. Movement should be seen at the jawline. Dimpling at the cheek may be indicative of a poor or shallow latch or an unusual movement of the tongue. The presence of clicking, smacking, or slurping may indicate an improper seal or suck, and the infant should be re-latched. Persistent clicking may be heard if the infant has ankyloglossia (tongue-tie) (Smith & Riordan, 2010).

Finally, the mother's nipple will be elongated at the end of a feeding, but it should be the same shape as at the beginning. Nipples that are angled, creased, or distorted at the end of feedings indicate anatomical variations or latch problems. Intervention is required if distorted nipples are painful (Smith & Riordan, 2010).

The nurse can instruct the mother in a number of measures to promote comfort and healing and to prevent skin breakdown. Washing the breasts with warm water and avoiding drying soaps is recommended. Simply keeping the nipples clean and dry is adequate for many mothers. Alternatively, warm water compresses can be applied followed by air-drying (Figure 37-5 ■). Gently massaging or pumping the breast before feedings stimulates let-down and flow and may be helpful in decreasing initial latch-on pain related to vigorous nursing. The mother can also apply an ice compress to the nipples just before feeding to decrease sensation (Smith & Riordan, 2010).

Lanolin is sold over the counter and offered to mothers by many healthcare providers for the treatment of sore nipples. However, the practice guidelines developed by AWHONN (2007c) noted that additional research is needed before hydrogel dressing, paraf-

Care Plan Activity: Breastfeeding Pain

Figure 37-5 ■ Air-drying the nipples can help prevent cracking and fissures.

fin, lanolin, sprays, or antibiotic creams can be recommended. Smith & Riordan (2010) emphasized that ointments should not be applied to infected nipples, with the exception of currently prescribed antifungal or antibiotic preparations. Although application of expressed breast milk was recommended in the past, this may actually spread organisms into wounded nipples (Smith and Riordan, 2010). Dennis et al. (2008) noted that it is unclear which intervention(s) are best, and developed a protocol to conduct a Cochrane review regarding interventions for nipple pain.

If a woman finds that her bra or clothing rubs against her nipples and adds to her discomfort, she may find it helpful to use breast shells between feedings. It is not helpful to limit nursing time at the breast. This may actually increase discomfort related to engorgement and have a negative effect on milk production and infant nutrition. For severe cases, in which the mother is unable to tolerate breastfeeding, the mother will need to pump or hand-express the breast milk until the nipple condition improves (Smith & Riordan, 2010).

The most important factor in decreasing pain is educating the mother about proper latch-on techniques. Anticipatory guidance and informing patients that many mothers experience nipple discomfort on days 3 through 6 and that the discomfort usually improves markedly by the end of the first week should be helpful in encouraging new mothers to continue breastfeeding, knowing that an end to the discomfort is in sight (AWHONN, 2007c).

The home-care nurse can make recommendations for interventions for patients with sore nipples. It is essential that the nurse read the product literature and current research on products recommended by the providers and lactation consultants in the local area. Additionally, the nurse should remind the mother that small amounts of any product applied to her nipples will be ingested by her newborn. Therefore, she will want to consult her primary care provider or a lactation consultant before applying commercial products.

The nurse should talk with a lactation consultant or provider if the patient's discomfort is severe enough to require temporary use of a thin silicone nipple shield and/or pumping rather than nursing. Nipple shields should be used only under close monitoring, as they can potentially affect milk transfer and have a negative impact on the infant. Nipple pain that does not resolve after a few days may indicate infection or other problems and should be referred to a provider so the appropriate therapy can be prescribed.

FLAT OR INVERTED NIPPLES Many women with flat or inverted nipples have the fear that they will be unable to breastfeed. This is not usually the case. Pregnancy and previous breastfeeding often lessen the inversion to the point that it is not an issue with subsequent babies. Breastfeeding mothers with flat or inverted nipples may experience difficulties after discharge if breastfeeding was not successfully established before leaving the hospital. Frequently, positioning the infant well back on the areola will be enough to promote the suckling that stretches and elongates the nipple during feedings. Exercising the nipple before latching loosens the tissue and helps to separate adhesions that cause retraction or inversion. The nurse can teach the mother to stimulate and shape the nipple just before feeding. A cold pack will evert a flat nipple. Inverted nipples that can be everted can be shaped by the mother by placing her thumb 1 1/2 to 2 inches behind the nipple and pulling back into her chest. As noted previously, use of the side-lying position is helpful (Smith & Riordan, 2010; Riordan & Wambach, 2010).

The nurse can also recommend use of a pump to evert the nipple just before latch on. Experienced nurses may feel comfortable assisting mothers to use a thin silicone nipple shield during the initial latch. The shield can be removed once the baby has suckled enough to elongate the nipple. Inverted nipples that are not easily everted by the measures above should be referred to a lactation consultant.

BREAST ENGORGEMENT A distinction exists between breast fullness and engorgement. All lactating women experience a transitional fullness at first, initially because of venous congestion and later because of accumulating milk. However, this fullness generally lasts only 24 hours, the breasts remain soft enough for the newborn to suckle, and there is no pain. Severely engorged breasts are hard, painful, and warm, and may appear taut and shiny. Engorgement can be accompanied by a fever up to 101°F. Engorgement may occur as a result of infrequent feedings, delayed initiation of feedings, use of supplements, time-limited feedings, and too quickly removing the baby from the first side to ensure feeding from both breasts at each feeding (Riordan & Hoover, 2010).

Treatments employed for engorgement may include warm compresses or showers for a short time just before nursing, cold compresses or frozen bags of vegetables applied to breasts after feedings, cabbage compresses, breast massage and milk expression, ultrasound, anti-inflammatory medications, and pumping.

Many women anecdotally express increased comfort with the use of cold compresses, frozen vegetable bags, and the judicious use of cabbage leaves, but anti-inflammatory medications are the only treatments demonstrated by research to be effective (Riordan & Hoover, 2010). A Cochrane review is planned to determine which interventions are most effective for treating engorgement (Mangesi & Muzonzini, 2008).

Although unrelieved engorgement and stasis are not necessarily associated with mastitis, they do lead to involution and decreased milk synthesis. Frequent feedings for a minimum of approximately 160 minutes of nursing every 24 hours are essential to the treatment of engorgement. Although pumping is sometimes discouraged in this situation for fear that it will increase milk production, it is necessary to pump if the infant is unable to nurse to empty the breasts (Riordan & Hoover, 2010; Smith & Riordan, 2010). A technique described as *areolar compression* by Riordan and Hoover and *reverse pressure softening* by Cotterman (2004) is recommended before pumping or attempting to latch if severe breast and alveolar edema is present. It will be helpful for homecare nurses working with breastfeeding mothers to review these references and to work with a lactation consultant to learn this technique as well as to learn more about the use of commercial breast pumps and manual expression of breast milk. See Nursing Care Plan: For the Woman with Engorgement on page 1079.

PLUGGED DUCTS Some mothers experience plugging of one or more ducts. Manifested as an area of tenderness, redness, and heat, or a palpable lump in an otherwise well woman, plugging may be relieved by the use of massage and frequent feedings. The nurse can encourage the mother to massage her breasts from her chest wall forward to the nipple while standing in a warm shower or following the application of moist heat to the breast. The mother should then breastfeed her infant, starting on the affected breast to promote drainage. Frequent breastfeeding and the use of a variety of positions to ensure complete emptying help to prevent and to resolve the problem. The nurse should also encourage the patient to wear a comfortable bra and loose, nonrestrictive clothing (Riordan & Wambach, 2010).

CLINICAL JUDGMENT

Case Study: Ann Nyembe

Ann Nyembe calls you from home in tears on her third postpartum day. She states breastfeeding was going well in the hospital but now her breasts are swollen, hard, and very painful, and her baby is refusing to suckle. Ann expresses some disappointment that "the breastfeeding didn't work" because she truly believes that breastfeeding is best for babies, and she enjoyed her breastfeeding experience in the hospital, especially breastfeeding the baby immediately after birth. But she also states she has been crying all day and can no longer tolerate her painful breasts. In addition, she says the baby "seems happier" with the bottle.

Critical Thinking

What actions can the nurse recommend to Ann to increase the likelihood she will continue breastfeeding and to decrease her discomfort?

See www.nursing.pearsonhighered.com for possible responses.

MASTITIS Plugged ducts and milk stasis increase the risk for *mastitis*, an inflammatory condition of the breast. Stress and fatigue, cracked nipples, and an abundant milk supply are associated with mastitis as well. Symptoms of mastitis include fever (greater than 100.4°F); a hot, red, tender area on the breast; and flulike symptoms. Treatment of mastitis includes continued breastfeeding, application of moist heat, increased fluids, rest, analgesics, and antibiotics as prescribed if necessary (Riordan & Wambach, 2010). For more information about mastitis see chapter 39 ∞ and Figure 39-2 ∞ on page 1132.

A Cochrane review found a lack of research regarding antibiotic treatment for mastitis and urged further studies (Jahanfar, Ng, & Teng, 2009). As with nipple pain and engorgement, a Cochrane review is planned to determine the risks and benefits of the various interventions currently used to prevent mastitis (Crepinsek, Crowe, Michener, et al., 2008).

EFFECT OF MEDICATIONS AND ALCOHOL Analgesics are appropriate as directed by a primary healthcare provider. Avoidance of breastfeeding while the drug levels are peaking in maternal plasma minimizes the amount received by the infant. The peak concentration varies from drug to drug, and it may be difficult to time this during the first week of breastfeeding. Nursing ideally occurs frequently, and the mother may require analgesics to nurse comfortably. Non-narcotic analgesics can be administered approximately 30 minutes prior to nursing if the mother suffers afterpains when nursing (AWHONN, 2007c).

Hale (2010) pointed out that the nonsteroidal anti-inflammatory drug (NSAID) ibuprofen is cleared for infant use and that its levels in milk are generally subclinical. Because most drugs do pass into the breast milk, the mother will want to check with her provider before taking medications. The nurse can use the references listed in Table 37-5 to check recommendations regarding use of specific drugs during lactation.

Alcohol passes into the breast milk. Therefore, it is not recommended for breastfeeding women. Mothers who do occasionally drink while lactating should be advised to consume the alcohol with a meal and after breastfeeding rather than shortly before a breastfeeding in order to minimize the amount the infant receives (Bronner, 2010).

NURSING CARE PLAN For the Woman with Engorgement

INTERVENTION	RATIONALE
1. Nursing diagnosis: Acute Pain related to increased breast fullness secondary to increased blood supply to breast tissue causing swelling of tissue around milk ducts **Goal:** Patient will remain free of breast fullness and pain.	
■ Instruct patient to nurse frequently.	■ Engorgement may be a result of infrequent or missed feedings. Frequent feedings will prevent the breast from becoming increasingly full which in turn decreases pain caused by engorgement. The newborn should be offered the breast at least eight to ten times in a 24-hour period.
■ Instruct patient to nurse at least 10 to 15 minutes on each breast per feeding.	■ Hind milk may be brought forward when the newborn is able to suckle for 10 to 15 minutes per breast. This will allow the breast ducts to empty with each feeding.
■ Assist patient to pre-express milk onto nipple or baby's lips.	■ Engorgement may be the result of newborns who are too sleepy to suck at each feeding or not eager to nurse vigorously. Expressing some milk onto the nipple may entice the newborn to nurse more aggressively.
■ Initiate pumping or manually express milk at the beginning of the feeding.	■ Engorgement may be the result of the breast not emptying at each feeding. Pumping or manually expressing the breast will allow the breast to empty. Pumping or hand expressing the milk at the beginning of each feeding will help soften the breast so the newborn can latch on to the nipple and facilitate letdown.
■ Instruct patient to pump, hand express, or massage to empty breast when feedings are missed.	■ If patient develops a feeling of fullness in the breast, or the newborn has missed a feeding, then pumping or hand expressing the milk will help keep the milk ducts empty. When the milk ducts become backed up, milk production can be inhibited, eventually decreasing the milk supply. Pumping during engorgement should not affect the milk supply.
■ Administer analgesics before nursing.	■ Acetaminophen and ibuprofen alone or in combination with codeine may be administered just before nursing to relieve pain and discomfort. The medication will reach the milk within 30 minutes.
■ Apply warm and/or cold compresses before nursing.	■ Warm compresses may be applied before nursing to stimulate letdown or soften the breast. This will allow the newborn to grasp the areola. A proper latch on will help prevent plugged ducts and assist in emptying the breast to reduce breast fullness and pain associated with engorgement. Relaxing in the shower with warm water running over the breast may have the same effect. Cold compresses may also be used to help reduce pain.
■ Apply fresh cabbage leaves to the breast between feedings.	■ Placing fresh cabbage leaves inside the bra is a home remedy that may relieve edema associated with engorgement, thereby reducing pain. Relief may be experienced within 30 minutes. Prolonged application of cabbage leaves may reduce the milk supply.
EXPECTED OUTCOMES:	There will be no evidence of swelling found in breast tissue. The woman's pain will have decreased, and her breast tissue will be soft and without tenderness.

BREASTFEEDING AND THE WORKING MOTHER Many mothers return to work while still breastfeeding. The home-care nurse can help the woman to explore options and solve problems related to breastfeeding in the workplace to promote continuation. The earlier the breastfeeding mother returns to work, the more often she will need to pump her breasts to express the breast milk. Recommendations for mothers who are using a breast pump can be found in Table 32-5 ∞ on page 876. Because milk production follows the principle of supply and demand, if breasts are not pumped, the milk supply will decrease. The nurse can review pumping and storage of breast milk with the mother, as the mother will want to begin pumping at least a week or two before returning to work. The mother will also want to introduce her baby to expressed milk from a

Application: Maintaining Lactation After Returning to Work

bottle or cup prior to her return. An electric pump and double collection system is optimal for the working mother (see Figure 32-20 ∞ on page 878). Working mothers can obtain printed materials on pumping, storage, working while breastfeeding, and related issues from lactation consultants and breastfeeding support groups, such as La Leche League (Lawrence & Lawrence, 2008; Rojjanasrirat & Wambach, 2010).

The nurse can suggest methods of maintaining breast milk supply such as relaxation, stress reduction, proper nutrition, adequate fluid intake, and frequent nursing during the evenings, in the mornings, and on days off. The nurse and patient can explore options such as pumping at work, visiting the infant or having the infant brought to work during the mother's lunch, and having the child care provider give expressed breast milk or formula (Rojjanasrirat & Wambach, 2010).

Use of the side-lying position is less fatiguing and may allow the mother to relax when she does have the opportunity to breastfeed her baby before and after work. Night breastfeeding presents a dilemma. It may help a working mother maintain her milk supply, but it may also contribute to fatigue. Depending on the rigidity and demands of the mother's work schedule, the nurse can explore options with the mother to promote the continuation of breastfeeding as much as possible during the first year of life.

PROFESSIONALISM IN PRACTICE

Workplace Issues Related to Breastfeeding

Mills (2009) and Stewart-Glenn (2008) found that maternal employment continues to be a barrier to long-term breastfeeding. Many employers are uninformed regarding the benefits of breastfeeding and do not view breastfeeding as a workplace issue. Many working mothers, particularly lower-income employees, are not aware of their options to continue breastfeeding after they return to work. Little research has been done on workplace issues related to breastfeeding. The professional nurse can advocate for patients by informing and encouraging them to discuss breastfeeding with their employers. Nurses can engage in public education campaigns related to the benefits of breastfeeding in the workplace, such as less absenteeism related to infant illness. Nurses also need to conduct research that investigates the effects of corporate lactation support programs and work cultures that are supportive of breastfeeding. Finally, as recommended by Thulier and Mercer (2009), nurses should contact their legislators and work to promote legislation that protects and supports breastfeeding mother-infant dyads.

WEANING **Weaning** is a process that begins with the introduction of sources of nutrition other than breast milk and ends when the child no longer breastfeeds and receives all nutrition from other sources. Ideally, the decision to wean is based on the child's nutritional needs, psychologic needs, and developmental milestones (Lawrence & Lawrence, 2008). However, the decision to *wean* the baby from the breast may be made for a variety of reasons, including family or cultural pressures, changes in the home situation, work schedules, pressure from the woman's partner, or a personal opinion about when weaning should occur.

Although the Centers for Disease Control and Prevention (CDC) reported that 77% of infants born in 2005 and 2006 were initially breastfed, many women wean their infants prior to 6 months of age. The home-care nurse will likely visit the mother early in the postpartum period, and it is important to provide anticipatory guidance and support to the mother in order to extend breastfeeding for as long as possible to benefit mother and baby. Many women wean their infants earlier than originally planned, because they don't believe they are adequately nourishing and satisfying their baby with the breast (Gatti, 2008; Li, Fien, Chen, et al., 2008; Thulier & Mercer, 2009). Therefore, education regarding how to establish and maintain sufficient milk supply and how to respond to infant growth spurts is essential. The woman should also receive contact information for support groups and lactation consultants in her local area.

Although some women need to wean abruptly due to medical or logistical reasons, a gradual approach is physically and emotionally comfortable for many mothers and their babies. The mother may wish to start by substituting one or two breast feedings with other sources of nutrition and cup feedings each day. Eventually, the mother may want to breastfeed only once or twice a day prior to stopping entirely.

If a baby initiates weaning during the first year of life and the mother wishes to continue breastfeeding, she can often work through this with the help of a lactation consultant. The infant who is weaned before 12 months should receive iron-fortified newborn formula rather than cow's milk (AAP & ACOG, 2007).

Nurses should inform mothers that lactation consultants will help them with weaning issues in addition to providing support for establishing and continuing lactation. The nurse can also share resources with breastfeeding mothers (see Table 37-5).

CULTURAL CONSIDERATIONS RELATED TO BREASTFEEDING Cultures vary tremendously in their initiation of breastfeeding, support persons important to the continuation of breastfeeding, and weaning practices. Despite increases in breastfeeding in the United States, minority women still breastfeed at lower rates than white women. Many immigrants breastfeed less than family members from their native countries after moving to the United States. African American women, in particular, breastfeed at low rates (Thulier & Mercer, 2009; Wambach & Riordan, 2010). Lack of family support decreases the likelihood that the woman will continue breastfeeding once she goes home, so it is important to find out the important support persons for breastfeeding in each cultural context.

Although cultural considerations related to each group are beyond the scope of this chapter, it is important for the home-care nurse to individualize care for all women by incorporating their cultural beliefs and practices related to breastfeeding. Thulier and Mercer (2009) recommended the use of peer counselor programs to support women who are breastfeeding. The authors also noted the need for research that explores ethnic influences on breastfeeding and investigates interventions designed to promote breastfeeding in minority populations.

For further discussion regarding cultural influences on infant feeding practices, see chapter 2 ∞ of this text. Another excellent reference is the chapter, "The Cultural Context of Breastfeeding," in *Breastfeeding and Human Lactation* by Riordan & Wambach (2010).

BREASTFEEDING REFERRALS AND SOCIAL SUPPORT

Support from the woman's family and social contacts is very important with regard to the initiation and continuation of breastfeeding, as is support from healthcare professionals. Providers of care need to be educated about breastfeeding physiology and resources in order to educate and support patients. Family members require information and education from professionals in order to support breastfeeding women as well (Clifford & McIntyre, 2008; Thulier & Mercer, 2009). Women who participate in local support groups can learn over time and observe role models to enhance their breastfeeding experience. The home-care nurse should be familiar with local lay support groups and encourage breastfeeding mothers to contact them.

FORMULA-FEEDING

The AAP recommends that parents use a commercially prepared, iron-fortified infant formula until 1 year of age if the baby is not breastfed (AAP & ACOG, 2007). Some mothers need or choose to feed their infants formula because of their own health status or personal preference. If the mother does not have a health history that precludes her from breastfeeding, it may be helpful to explore the reasons for her decision. Some mothers have chosen formula because of lack of education about the benefits of breastfeeding, misconceptions about breastfeeding, or lack of support. If that is the case and the mother desires help with breastfeeding, lactation can still be established at this time with proper support. If the mother needs or chooses to use formula, it is important for the nurse to support her choice and provide information related to safe formula feeding.

Most human milk substitutes in this country are available in ready-to-feed, liquid concentrate, and powder forms. Many parents reconstitute the powder, as it is the most economical formulation. Chronic overconcentration can result in hypernatremic dehydration, whereas underconcentration can result in water intoxication and undernourishment. Therefore, it is important to emphasize the importance of mixing the formula exactly as the package directs. Product storage recommendations should be followed, expiration dates should be honored, and parents should date and time the bottles when prepared. Families must use uncontaminated water and employ safe-handling practices during preparation of formula as well.

According to the EPA, between 15% and 20% of U.S. households rely on private wells for the water they use and consume. Private wells are not publicly inspected and regulated, as are municipal water supplies, so the individual family is responsible for testing its water and maintaining its well. Water can be contaminated with microorganisms and with chemicals such as nitrates and pesticides, which are not necessarily removed by filtering or boiling. Infants and children are highly susceptible to waterborne illness. Therefore, the nurse should make certain that families who use private wells are aware that they need to purchase bottled water to reconstitute infant formula until their well water has been tested for safety. Information on safe use of well water can be obtained from sources such as the CDC, the U.S. Environmental Protection Agency (EPA), the U.S. Food and Drug Administration (FDA), the Department of Agriculture, and local public health departments (Rogan, Brady, and the Committee on Environmental Health, and the Committee on Infectious Diseases, 2009). Descriptions of the various types of bottled water and the Web sites and telephone contact numbers for well water resources in every state are found in Rogan et al. (2009).

The World Health Organization (WHO) published new guidelines regarding the preparation of powdered formula in 2007, due to concerns regarding *Enterobacter sakazakii* and *Salmonella enterica*. Guidelines include sterilizing bottles and nipples between uses and boiling the water used to reconstitute the powder. The water should be mixed with the powder when it is still 70°C (158°F) or warmer. Ideally, the formula will be consumed within 2 hours of preparation, but individually prepared bottles that have not been touched can be stored in a refrigerator at 5°C (41°F) or less for a maximum of 24 hours (WHO, 2007).

A large study of women in the United States evaluated mothers' use of four important safe handling practices for infant formula: (a) hand washing before preparation, (b) washing bottles and nipples thoroughly between uses, (c) discarding formula left at room temperature for >2 hours, and (d) never heating formula in microwave ovens. More than half of the women reported that they did not always wash their hands prior to preparation, and a significant number reported not following one or more of the other practices as well. More than 70% of women reported not receiving any information regarding formula preparation from a healthcare provider by the time they were 5 months postpartum (Labiner-Wolfe, Fein, & Shealy, 2008).

Home-care nurses should be aware that there are significant education gaps regarding the safe preparation and storage of infant formula. The home visit is an excellent time to assess the parents' understanding and to inspect the area where the formula will be prepared and stored. The WHO (2007) developed pamphlets describing safe formula preparation, which offer explicit instructions for healthcare workers and for infant caregivers in multiple languages. The pamphlets can be downloaded from the WHO Web site.

CLINICAL JUDGMENT

Case Study: Carla Humphrey

During a home visit, you notice that the new mother, Carla Humphrey, has many bottles and nipples laying at the bottom of the dish drainer. You ask her how she has cleaned them, and she says she usually rinses them at the end of each evening.

You note that the family is in a rural area, and confirm with Mrs. Humphrey that they use well water. You decide to research the current recommendation further, and find that the WHO (2007) recommends sterilizing bottles and nipples between uses, and the FDA (2007, updated 2009) advocates sterilizing bottles and nipples prior to the first use only and then washing with hot water or in the dishwasher between uses if a clean source of tap water is available.

Critical Thinking

What is your best recommendation for sterilizing the bottles and nipples?

See www.nursing.pearsonhighered.com for possible responses.

Other Types of Follow-Up Care

Other types of follow-up care may include return home visits, telephone follow-up, and postpartum classes or support groups.

Return Visits

If the mother and family and physician or certified nurse-midwife have chosen discharge earlier than 48 hours after vaginal birth, the mother may, in some states, request a total of three visits. In such cases, the nurse would schedule the first visit about 24 hours after discharge and then space out the other two visits over the next week. In other instances, the nurse may schedule additional home visits based on the findings of the first home visit and the follow-up phone call.

Telephone Follow-Up

Case Study: Follow-Up with the Patient at Home

The postpartum home-care nurse usually makes a follow-up phone call a few days after the home visit. During the call, the nurse may provide additional information, address questions or areas of confusion, and make referrals.

Some families may be offered or may request a telephone follow-up at the time of discharge. A mutually agreeable time is set for the call, typically within 3 days of discharge, or earlier if desired. Calls typically last about 20 minutes and are preplanned and goal directed.

To perform an effective telephone assessment, the nurse must be able to listen skillfully, use open-ended questions, and wait for answers. The nurse projects a warm, caring attitude so that the mother feels comfortable talking to a faceless caller. When assessment reveals signs of an initial or recurring postpartum complication, the nurse refers the woman to her primary care provider for further evaluation.

The plan of care developed and implemented during a telephone conversation is limited to supportive counseling, teaching, and referral. The new mother may have many questions, especially about newborn care, and is generally at a high level of learning readiness. The nurse can answer the woman's questions and use the questions as a "stepping stone" for further teaching. Many communities have established 24-hour advice lines for new parents to call when they have questions or need support. In areas where help lines are not available, parents may be directed to call the birthing center. If birthing center nurses field parent phone calls, they should follow established protocols regarding the advice to be given and the documentation required. In either case, the home-care nurse provides the number so that it is readily accessible for the family.

Postpartum Classes and Support Groups

Postpartum classes are becoming more common as caregivers recognize the continuing needs of the childbearing family. In many instances, classes are prepared to meet the specific needs of a variety of families so that, for example, single mothers and adolescent mothers can attend class with peers. A series of structured classes may focus on topics such as parenting, postpartal exercise, or nutrition, or there may be loosely structured group sessions that address mothers' concerns as they arise. Such classes offer chances for the new mother to socialize, share her concerns, and receive encouragement. Because babysitting arrangements may be difficult or expensive, it is desirable to provide child care for siblings.

Some cities offer breastfeeding or new-parent support groups through birthing centers or hospitals or as a community effort. Once again, the support group provides an opportunity for parents to interact with one another and to share information and experiences.

Many parents look to Internet resources for additional information on parenting and newborn care. Internet sites can be devised by anyone, so the quality, currency, usefulness, and accuracy of the information may vary. Nurses have an opportunity to assist parents in evaluating the reliability of the information they find. Parents can be encouraged to view Web sites affiliated with government organizations, universities, or healthcare organizations, as such sites are usually credible.

PROFESSIONALISM IN PRACTICE

Reporting Unsanitary Conditions in the Home

As healthcare professionals, nurses are required to report infant neglect or abuse. When practicing in private homes, the nurse will be exposed to a wide range of home management practices with regards to aesthetics and sanitation. For example, the nurse will need to distinguish a home that is simply messy from a home that is unsanitary. It is important to develop rapport with the parents and to provide education as needed when sanitation issues are present. In certain cases, a follow-up visit is warranted. In cases of extreme filth or severe pest infestations, the nurse will need to use critical thinking skills to determine whether the most vulnerable patient—the infant—is at risk for injury. If that is the case, the nurse should notify the appropriate authorities and follow the home care agency plan for such contingencies. If in doubt, the nurse should call upon resource persons and supervisors for assistance.

FOCUS YOUR STUDY

- The Newborns' and Mothers' Health Protection Act took effect in January 1998, and provides for a guaranteed minimum stay of up to 48 hours following an uncomplicated vaginal birth and 96 hours following an uncomplicated cesarean birth. The AAP recommends that all infants discharged before 48 hours be examined within 48 hours after discharge, and, ideally, that all newborns be seen at the 3- to 5-day point for weight, hydration, intake and output, and jaundice screening. Home care nursing meets this requirement.
- The overall goal of postpartum home visits is to enhance opportunities for smooth transition of the new family. The home visit provides opportunities for assessment, teaching, breastfeeding support, and fostering a caring relationship with new families.
- In planning the home visit, the nurse needs to take precautions to maintain safety, such as carrying a cellular phone, notifying supervisors of location of visit, keeping personal belongings out of sight, assessing the neighborhood and home for signs of danger, and, if present, terminating the visit.
- Physical assessment of the newborn during a home visit includes assessments of vital signs, weight, overall color including jaundice, assessment of body systems, intake/output, hydration, umbilical cord and circumcision, newborn nutrition, newborn safety, parent education, and attachment.
- Teaching goals during home visits include reinforcing daily newborn care, including demonstrations of positioning and handling, sponge and tub bathing, nail care, and dressing; discussing temperature assessment and signs of illness; assisting with newborn feeding; discussing expected newborn output; discussing newborn behavioral states; promoting safe and appropriate newborn sleeping, including SIDS prevention; promoting crib safety; encouraging childproofing of the home environment; discussing prevention of unintentional injuries and abuse; and encouraging newborn screening and immunization.
- The physician or pediatric nurse practitioner should be notified if there is evidence of redness around the newborn's umbilicus, if there is bright red bleeding or puslike drainage near the cord stump, or if the umbilical site remains unhealed.
- A primary risk factor for sudden infant death syndrome (SIDS) is sleeping in the prone position. Guidelines that came out in 2005 discourage cosleeping, smoking in pregnancy, and smoking after birth. Further recommendations include placement of the infant crib in close proximity to the parents' bed and the use of pacifiers as measures to further prevent SIDS.
- State-mandated screening is performed on all newborns in the first 1 to 3 days. States vary regarding the conditions for which they screen.
- Universal hearing screening is performed on all newborns. Newborns who do not pass the screening should receive diagnostic testing by age 3 months and interventions by age 6 months as necessary.
- Signs of illness in mothers include pain or burning with urination, passage of clots or placental tissue, excessive pelvic or perineal pain, chest pain, difficulty breathing, excessive or foul-smelling lochia, failure of fundus to descend at the anticipated rate, temperature of 100.4°F or above, elevation of blood pressure, tenderness, redness, or pain in the legs or breasts, and feelings consistent with postpartum depression.
- Difficulties with breastfeeding include sore, cracked, flat, or inverted nipples; breast engorgement; plugged ducts; and mastitis.
- Breastfeeding mothers require information on effects of alcohol and various medications on breast milk; pumping; weaning; and breastfeeding referrals and social support.
- Return visits, telephone follow-up, classes, and support groups can provide valuable information and support to new mothers and their families.

CRITICAL THINKING IN ACTION

Jane Benne, age 23, G1 gave birth by cesarean for cephalopelvic disproportion to a healthy 7 pound 1 ounce baby boy 5 days ago. You are making a home visit 2 days after Jane was discharged from the hospital to her two-story home. When you arrive the baby is sleeping in a bassinet in Jane's bedroom on the second level. Jane has been trying to breastfeed and complains to you of sore nipples and swollen breasts. She is also having problems getting the baby to latch on and says that she has been supplementing her baby's feedings with a bottle because she is afraid her baby is not getting enough milk from her breasts alone. She also mentions that the baby seems more satisfied after she gives the bottle and seems to sleep longer. You ask her how she has been feeling, and she tells you that she is very tired and upset about her body not making enough milk to feed her child. You assess Jane's breasts and find them to be full and firm, but the nipples are cracked and blistered.

1. What is your focus in the home postpartum visit?
2. What counseling can you give Jane regarding her sore nipples?
3. What suggestion do you give Jane regarding supplemental bottle-feedings?
4. Explain your assessment of Jane's abdominal incision and provide suggestions for healing.
5. How would you discuss the baby's voiding patterns to ensure adequate hydration?

CHAPTER 38

Grief and Loss in the Childbearing Family

"You have a beautiful baby," the ultrasound technician said quietly. She was studying the flickering images on her screen, staring intently at the shadows of the tiny heart. I think she had already seen that our baby was going to die.

—Amy Kuebelbeck

(Excerpt from *Waiting with Gabriel: A Story of Cherishing a Baby's Brief Life* by Amy Kuebelbeck (Loyola Press, 2003). Reprinted with permission of Loyola Press. To order copies call 1-800-621-1008 or go to www.loyolapress.com.)

LEARNING OUTCOMES

1. Discuss perinatal loss including etiology, diagnosis, and the nurse's role in facilitating the family's mourning process.
2. Describe the physical, cognitive, emotional, behavioral, and spiritual responses experienced by parents during grieving associated with perinatal loss.
3. Delineate the personal, societal, and cultural issues that may complicate responses to perinatal loss.
4. Identify nursing diagnoses and interventions to meet the special needs of parents and their families related to perinatal loss and grief.
5. Differentiate between helpful and nonhelpful responses in caring for families experiencing perinatal loss.

KEY TERMS

Attachment theory *1090*
Bereavement *1089*
Caring theory *1100*
Disenfranchised grief *1090*

Mourning *1090*
Perinatal hospice *1108*
Perinatal loss *1087*
Religion *1093*
Responding model *1100*
Spirituality *1093*

Perinatal loss is the death of a fetus or infant from the time of conception through the end of the newborn period 28 days after birth. This chapter discusses grief and loss in the childbearing family and the nurse's role in facilitating the family's mourning process. Although the primary focus is stillbirth, care of the family experiencing the death of an infant in the newborn period is inclusive. Causes and clinical aspects of spontaneous abortion (miscarriage) in the antepartum period are discussed in chapter 15 ∞, and chapter 27 ∞ discusses labor-related complications that can lead to fetal demise; this section discusses causes and clinical aspects of intrauterine fetal death (IUFD) after 20 weeks' gestation, often referred to as *stillbirth* or *fetal demise.*

Perinatal loss is a tragic event for the couple experiencing it and the family who loves them. Compounding the tragedy are many misconceptions surrounding perinatal loss, a lack of grief education afforded healthcare personnel, and clinical interventions that are out of step with current research. One of the biggest misconceptions about perinatal loss is that it is not as relevant as other losses because of the lack of interaction with the infant. In reality, this could not be further from the truth. Studies have shown that about 90% of couples believe that the loss of their infant was the worst thing that ever happened to them, and more than 80% believe that the death caused a significant decrease in their ability to function for a time (Swanson, Connor, Jolley, et al., 2007). Additionally, the grief for parents is lifelong and nonlinear, often described as the grief that never goes away (Arnold & Gemma, 2008, Cacciatore & Bushfield, 2007).

With regard to education, studies assessing the comfort level of nurses assisting families experiencing perinatal loss clearly demonstrate that many nurses are uncomfortable with death and dying and that more education is needed and, indeed, greatly desired (Chan et al., 2008; Kain, 2007; Kendall & Guo, 2008; Roehrs, Masterson, Alles, et al., 2008; Rogers, Babgi, & Gomez, 2008). The level of comfort, or lack thereof, observed in the study was mostly dependent upon the nature of thinking on a more hopeful level, length of experience in nursing, and palliative care education, with palliative care education making the most significant difference (Feudtner et al., 2007).

Lastly, concerning research and practice, in recent years there has been a paradigm shift in the field of grief and bereavement regarding the components of a "normal" mourning process as well as when, where, and how much intervention is warranted. Much of what has become the traditional standard of care for bereaved individuals has come into question as new research sheds light on the inefficacy of predetermined early and intense intervention. This chapter focuses on providing frameworks for understanding grief and loss, guidelines for effectively responding to a grieving family, and specific nursing interventions for the family experiencing perinatal loss in the clinical setting.

Common Causes of Perinatal Loss

The National Center for Health Statistics' most recent compilation of fetal mortality statistics occurred in 2005, and for the first time in decades, there was a slight reverse to the trend of declining fetal mortality rates from 2003 to 2005. In the United States, the incidence of fetal death after 20 weeks stands at 6.2 per 1000 total births, accounting for 60% of all perinatal deaths (fetal and neonatal) (MacDorman & Kirmeyer, 2009). Stillbirth currently occurs in 1 in 160 deliveries in the United States, (American College of Obstetricians and Gynecologists [ACOG], 2009) and more than 80% of stillbirths occur before term, with approximately half occurring before 28 weeks' gestation (MacDorman & Kirmeyer, 2009).

Antepartal fetal deaths, although infrequent, account for about half of all perinatal mortality in the United States (Druzin, Smith.,Gabbe, et al., 2007). Approximately 25,000 fetal deaths occur annually (ACOG, 2009). The *perinatal mortality rate (PMR)* is defined by the National Center for Health Statistics as late fetal deaths (over 28 gestational weeks) plus the first 6 days of life. It is estimated that 70% to 90% of stillbirths occur before the onset of labor, with more than 50% occurring between 20 and 28 weeks' gestation (Druzin et al., 2007). The cause may be unknown, or it may result from any of a number of physiologic maladaptations including asphyxia; congenital malformations; superimposed pregnancy complications including preeclampsia or eclampsia, diabetes, systemic lupus erythematosus, renal disease, thyroid disorders, cholestasis of pregnancy, abruptio placentae, placenta previa, diabetes, renal disease, cord accidents, fetal growth restriction, and alloimmunization (ACOG, 2009).

Perinatal loss can also occur due to infections such as human parvovirus B19, syphilis, streptococcal infection, and *Listeria* (ACOG, 2009). Perinatal loss is increased in women with multiple gestations and among women who smoke, have lower education attainment levels, advanced maternal age, and those who are obese (ACOG, 2009). Women who have had other pregnancies affected by stillbirth or growth restriction are at greater risk for having a stillborn infant (ACOG, 2009). Perinatal loss associated with birth defects can occur as a result of congenital anomalies or may occur if the fetus is exposed to teratogens late in the pregnancy.

Although the cause is often unknown, several risk factors elevate the chances of stillbirth, including maternal race or ethnicity, age, multiple gestation, and number of previous pregnancies (with nulliparas at highest risk). Most disturbing is the continuing disparity in race and ethnicity. African American women have fetal mortality rates 2.3 times higher than that of Caucasian American women, with Native Americans at 29% and Hispanic Americans at 14% higher respectively (MacDorman & Kirmeyer, 2009). In the United States, black women have higher rates of stillbirth, nearly double that of either white or Hispanic women (ACOG, 2009). Some recent studies have been undertaken to try to determine the cause of the unacceptably higher number of African American women experiencing infant mortality, but further studies are needed (Barnes, 2008).

Twin pregnancies demonstrated a mortality rate 2.7 times higher than singleton pregnancies, and triplets or higher were at 4.6 times the singleton rate. Fetal mortality rates were highest with decreasing maternal age; women under the age of 15 had 2.2 times the rate of stillbirth than that of women from 25 to 29 years of age. Additionally, women of advanced maternal age (greater than 35 years of age) also showed increased risk; in fact, advanced maternal age appeared to be

an independent risk factor even when concurrent medical conditions were factored out (MacDorman & Kirmeyer, 2009). Obesity is one of the most common modifiable risk factors, in which the risk appears to increase with gestational age and is a major cause of stillbirth related to placental dysfunction (ACOG, 2009).

Perinatal loss in industrialized countries has declined in recent years as early diagnosis of congenital anomalies and advances in genetic testing techniques have increased the use of elective termination. Surprisingly, other reproductive advances have increased the incidence of fetal death. Pregnancies conceived by in vitro fertilization had higher rates of pregnancy loss, pregnancy complications (placenta abruption, fetal loss after 24 weeks' gestation, gestational hypertension, placenta previa, and cesarean births) (Gibbs, Karlan, Haney, et al., 2008). Conversely, fetal death occurs more frequently in monochorionic twins, which generally are conceived naturally. Most twins conceived via assisted reproductive technology are dichorionic placentation (Fletcher, Zach, Pramanik, et al., 2009). In addition, certain genetic testing procedures such as amniocentesis and chorionic villus sampling (CVS) can actually cause fetal loss.

In industrialized countries, infection plays a significant role in fetal deaths, accounting for 10% to 20% of all fetal demises; however, rates are believed to be much higher in developing countries (Reddy et al., 2009). Infection can be a causal factor in stillbirth by various means:

1. Causing severe maternal illness
2. Infecting the placenta and preventing oxygen and nutrients from crossing to the fetus
3. Infecting the fetus and causing a congenital deformity that is incompatible with life
4. Infecting the fetus and damaging a vital organ such as the brain or heart
5. Precipitating preterm labor, with the fetus dying in labor.

Ascending bacterial organisms include *Escherichia coli,* group B streptococci, and *Ureaplasma urealyticum.* These infections can occur before or after the membranes have ruptured, resulting in fetal demise. Prevalent viral causes of fetal demise include parvovirus and coxsackievirus. *Toxoplasma gondii, Listeria monocytogenes,* and the organisms that cause leptospirosis, Q fever, and Lyme disease have also been identified as causative factors for stillbirth, but the prevalence is unknown. Untreated syphilis is associated with a high stillbirth rate, as is malaria infection when contracted for the first time by the mother during the pregnancy (Reddy et al., 2009). These infections carry a much higher morbidity and mortality rate in developing countries.

Certain maternal conditions can also be associated with higher rates of fetal death. Past maternal exposure to some bacterial and viral antigens can produce an autoimmune response that can result in fetal death. Women with acquired and immune thrombophilia have higher rates of miscarriage and fetal demise than those without hematologic alterations (ACOG, 2009).

Maternal medical conditions contributing to the incidence of stillbirth include (Reddy et al., 2009):

- Hypertensive disorders
- Diabetes mellitus
- Thyroid, renal, or liver disease
- Connective tissue disease (such as systemic lupus erythematosus [SLE])
- Cholestasis

Other maladaptations that can cause stillbirth are:

- Antiphospholipid syndrome
- Heritable thrombophilias
- Red cell and/or platelet alloimmunization
- Congenital anomaly and malformations
- Chromosomal abnormalities including confined placental mosaicism
- Fetomaternal hemorrhage
- Fetal growth restriction
- Placental abnormalities including vasa previa and placental abruption
- Umbilical cord pathology including velamentous insertion, prolapse, occlusion, and entanglement
- Multifetal gestation including twin–twin transfusion syndrome/twin reverses arterial perfusion
- Amniotic band sequence
- Central nervous system lesions

Maternal Physiologic Implications

Prolonged retention of the dead fetus may lead to the development of disseminated intravascular coagulation (DIC), also called consumption coagulopathy, in the mother. After the release of thromboplastin from the degenerating fetal tissues into the maternal bloodstream, the extrinsic clotting system is activated, triggering the formation of multiple tiny blood clots. Fibrinogen and factors V and VII are subsequently depleted, and the woman begins to display symptoms of DIC. Fibrinogen levels begin a linear descent 3 to 4 weeks after the death of the fetus and continue to decrease in the absence of appropriate medical intervention.

Besides DIC, other adverse outcomes can also occur if the onset of labor and subsequent birth are delayed. Women with prolonged retention of a dead fetus are more prone to infection. A resulting infection can cause endometritis or sepsis. The longer the pregnancy continues, the higher the incidence of maternal infection.

Although immediate induction is routinely performed, there may be situations in which induction is delayed, such as maternal refusal or the presence of a multiple gestation.

In cases of multiple gestations, fibrinogen, prothrombin time (PT), partial thromboplastin time (PTT), and platelet count are obtained. If these values are normal, no further monitoring is required. DIC rarely occurs in cases of multiple gestations where the remaining fetus(es) are allowed to grow and mature; however, there is a risk of multicystic encephalomalacia in monochorionic twins.

Clinical Therapy

Many women first report an absence of fetal activity, although some women may fail to recognize this change in fetal activity. Diagnosis of intrauterine fetal death (IUFD) is confirmed by

visualization of the fetal heart with absence of heart action on ultrasound. Some practitioners routinely have a second ultrasound performed or have a second practitioner verify the absence of cardiac activity before making the diagnosis. When a fetal demise occurs, maternal estriol levels fall. Without medical intervention, most women have spontaneous labor within 2 weeks of fetal death. The once common practice of waiting for the onset of labor has largely been abandoned in recent years because the risks of complications increase with delaying the birth. It is estimated that 60% of fetal deaths have no known cause. In 25% to 60% of all fetal deaths, the cause remains unknown even after an autopsy (Lindsey, 2010). The specific cause is more difficult to identify if the time since the death is prolonged. Prompt birth increases the ability to identify the cause of death.

In modern practice, most women with a diagnosed fetal demise are given the option of waiting a few days or scheduling an induction procedure immediately. Most women will elect for an induction within a day or two of the final diagnosis. One study determined that women who waited more than 24 hours experienced more prolonged anxiety compared with women who underwent induction within 6 hours of diagnosis (Lindsey, 2010).

The mode of induction is dependent upon the gestational age of the fetus and the readiness of the cervix. Women with an unfavorable cervix may be given vaginal prostaglandin agents, misoprostol, or laminaria tents. Women whose gestations are less than 16 gestational weeks may have a laminaria tent inserted into the cervix before a dilatation and extraction procedure. *Laminaria tents* are made from the stems of brown seaweed which are cut, shaped, dried, sterilized, and packaged in specific sizes. Laminaria tents work by drawing water out of the cervical tissue, allowing the cervix to soften and dilate. They are commonly used to dilate the cervix in preterm gestations when induction is warranted. They may be placed before surgical procedures or inductions of labor.

Women less than 28 weeks' gestation are typically given misoprostol 200 to 400 mg vaginally every 4 to 12 hours until spontaneous labor occurs (ACOG, 2009). Women who are term and have not had a previous cesarean birth or other uterine scar may undergo an induction of labor. Women with an unfavorable cervix may be given cervical ripening agents, such as vaginal prostaglandin agents or misoprostol. Induction with high-dose Pitocin regimen can be performed following the same protocol as any other term induction of labor (ACOG, 2009).

In women who have had a previous low transverse incision cesarean birth over 28 gestational weeks, cervical ripening and transcervical Foley catheter are recommended. Misoprostol 400 micrograms every 6 hours has been given to women between 24 to 28 weeks with a previous uterine incision (ACOG, 2009). Management of women with a previous classical incision or uterine surgery is limited and the method of birth should be individualized.

Postbirth Evaluation

Identifying the causative factor of fetal loss assists many families in progressing through the mourning process. Information obtained from a postmortem examination or postmortem studies can provide vital information related to the cause of the fetal death, the possibility for reoccurrence, and closure for the couple. The types of studies and tests performed depend on the parents' past history, medical history, and the couple's preferences for the depth of testing desired. Chromosome studies should be considered if the couple has a history of other second- or third-trimester losses or if either parent has a suspected balanced translocation or mosaic chromosomal pattern (ACOG, 2009).

If an intra-amniotic infection is the suspected cause, cultures of both the placenta and the fetus should be obtained. If specific infections are being considered, both IgM and IgG antibodies should be drawn to determine if an acute infectious process has occurred.

All stillborn infants should have a careful visual inspection at the time of birth for obvious defects or abnormalities. The placenta and membranes should also be closely examined and the placenta should be sent to pathology for further testing. The umbilical cord should be inspected for true knots, a velamentous insertion, lack of Wharton's jelly, or a short cord to determine if a cord accident was the cause. If a specific cause is suspected, blood tests and x-rays can be performed (Lindsey, 2010). An autopsy is the best mechanism to determine the cause of death; however, in the event that the parents decline an autopsy, magnetic resonance imaging (MRI) can also provide detailed information (Lindsey, 2010).

Most practitioners perform a complete blood count (CBC) and antibody screen upon admission. Because diabetes is a causative factor, a random or postpartum glucose level can be obtained to rule out this cause. Additional maternal factors can also be evaluated. Additional tests that may be performed are listed in Table 38-1.

The Experience of Loss

Application: Grief

The term **bereavement** comes from a root term meaning to be "deprived of something" or to be left "desolate or alone." To be bereaved simply means to have suffered the *event of loss* (Corr, Nabe, & Corr, 2009). **Grief** is an individual's *reaction to the loss,* including physical symptoms, thoughts, feelings, functional limitations, and spiritual responses. Grief reactions may

TABLE 38-1 Tests to Determine Cause of Fetal Loss

FETAL TESTING	MATERNAL TESTING
• Fetal blood tests and x-rays	• Diabetes testing
• Autopsy or magnetic resonance imaging (MRI)	• Complete blood count (CBC) with platelet count
• Placental studies	• Kleihauer-Betke test
• Chromosomal studies (if indicated)	• Abnormal antibody testing (lupus anticoagulant, anticardiolipin antibodies)
	• Thyroid stimulating hormone (TSH) levels
	• Infectious disease testing (rubella, syphilis, malaria, toxoplasmosis, cytomegalovirus)
	• Hereditary thrombophilia testing
	• Toxicology testing

be immediate or delayed, heightened or stunted, and highly variable. Though often used interchangeably, **mourning** is the *process* by which individuals incorporate the experience into their lives. Mourning is influenced by many factors, including personality, gender, family dynamics, and social, religious, and cultural norms (DeSpelder & Strickland, 2005). Mourning may be manifested by certain behaviors and rituals, such as weeping or visiting a gravesite, which help the person experience, accept, and adjust to the loss. The unanticipated loss of an expected child can be devastating and traumatic for parents. Though most people eventually regain a sense of purpose and adjust well, some suffer long-lasting and destructive consequences. "Studies suggest that 15% to 25% of women who experience perinatal loss have enduring adjustment problems and many seek professional help to guide them through this difficult time" (Bennett, Litz, Lee, et al., 2005, p. 180). Bennett et al. suggest that there is nothing in a person's background to prepare him or her for the abrupt transition from a joyous event to the sorrow of perinatal loss. Perinatal loss is also unique in that the parents have not had experiences with the child that was to be, and attachment is based mostly upon hopes and dreams for the future relationship (Callister, 2006).

Society typically does not offer the kind of support for perinatal loss that is offered for other, more recognized losses. This places perinatal loss in the category of disenfranchised grief. **Disenfranchised grief**, as defined by Kenneth Doka (2002), is grief that is not supported by the usual societal customs. Perinatal loss is sometimes referred to as a "silent loss" because of this phenomenon of disenfranchising grief. People are uncomfortable discussing the loss with the parents and often pull away when their support is most needed. "The loss of a child and all the child has to offer, compounded with the societal attitude discounting the loss and the potential withdrawal of social support, may leave the bereaved parents feeling distraught and alone at a time that was supposed to be full of happiness" (Bennett, et al., 2005, p. 181). Parents struggle to come to terms with the devastation of the loss and are often confused and bewildered as to how to make that happen. The nurse caring for a family experiencing perinatal loss can take positive steps to help facilitate the family's mourning process and help them begin their journey to recovery.

Frameworks for Understanding Perinatal Loss

There have been a plethora of models and theories postulated over the years attempting to explain patterns of grief and loss, and there is no consensus for which models should serve as the cornerstones of theory and teaching. There has been some very enlightening research in the last decade, however, that is presenting a vastly different perspective of bereavement than previously offered. Surprisingly, research into the grieving process in the past decade has not successfully replicated data supporting the stage model of grieving made famous by Elisabeth Kubler-Ross (Maciejewski, Zhang, & Block, 2007). For instance, in natural deaths, whether expected or unexpected, acceptance and sense making were the predominant emotions throughout the first 24 months, rather than the previous stage model where the acceptance stage followed the depression stage close to the end of the first year (Neimeyer, 2009). Current evidence-based research supports the belief that the grieving process is entirely variable, and dependent upon many factors, such as the type of death, age of the deceased, and age of the griever. It is nonlinear and more easily understood when simply thought of as a process that encompasses the need of the griever to remain connected to the deceased, while simultaneously finding a way to exist in a changed world without the deceased (Currier, Holland, & Neimeyer, 2006; Neimeyer, 2009). For a mother who loses a baby, this might be phrased as "Am I still a mother? Who am I now?" The *intensity* to which the grief will be experienced is best understood from the aspect of the level of attachment the grieving person had to the deceased and usually entails finding personal meaning in the loss for successful integration into the grieving person's life. Several models explain these concepts.

Worth noting is the **dual process model**, a view of grief encompassing two competing spheres: loss and restoration. The loss orientation is concerned with the individual's need to confront the reality of the loss, and the restoration orientation seeks to regain balance and temper the pain of grief. Both spheres of orientation are important; some people may gravitate more toward the loss side and some more toward the restoration side. The dual process model can be helpful as the griever comes to understand that they have the choice to consciously shift between spheres, allowing grief in the safer moments, while recognizing the necessity of change (Neimeyer, 2009).

With respect to perinatal loss specifically, there are two theories that may provide the best framework for the nurse seeking to understand and assess the grieving family in his or her care. **Attachment theory**, first developed by John Bowlby (1969) and revisited by Brier (2009) and Shaver and Tancredy (2001), begins with the basic premise that human beings are biologically predisposed to bond with emotionally significant persons in their lives. The grief response as seen through the lens of attachment theory is a state of separation anxiety brought on by the disruption in the attachment bond. The intensity of the grief response displayed by parents experiencing perinatal loss can be assessed to some extent by determining the level of attachment to the anticipated infant. For mothers, nine events are important to the formation of attachment to her baby (Bennett, et al., 2005; Klaus & Kennell, 1976):

1. Planning the pregnancy
2. Confirming the pregnancy
3. Accepting the pregnancy
4. Feeling fetal movement
5. Accepting the fetus as an individual
6. Giving birth
7. Seeing the baby
8. Touching the baby
9. Giving care to the baby

Helpful questions to assess the first five levels of attachment could include topics such as naming of the baby, future plans,

TABLE 38-2 Psychologic Process of Becoming a Parent

- Feelings of procreativity or generativity
- A sense of continuity through the generations
- Responses to quickening and bodily changes
- Fears and expectations about the coming baby
- The impact of this exciting process on expectant parents' relationship at home
- Changes that the baby will bring to their careers and to their lives in general
- Attachment to real and idealized aspects of the infant
- Self-esteem building

nursery preparations, and personal stories of the pregnancy. Additionally, there are psychologic processes related to becoming a parent that can help to identify those parents who have a strong level of attachment. These are noted in Table 38-2.

Several researchers and theorists have demonstrated the need for continuing bonds as a means to remain connected to the deceased infant (Arnold & Gemma, 2008; Boelen, Stroebe, Schut, et al., 2006; Boerner & Heckhausen, 2003; Talbot, 2002). Therefore, the goal of recovery, as related to attachment theory, is for the grieving parent to find a way to maintain the bond with the deceased infant while at the same time acknowledging that the infant is not physically present for future interactions.

The second theory centers on a search for meaning and is probably the most prevalent theme for bereaved parents. Robert Neimeyer (2005, 2009) proposes that meaning reconstruction is one of the most important aspects of the grieving process for bereaved individuals. Simply put, **meaning reconstruction** focuses on redefining ourselves and our interactions with the world after a significant loss. There is no question that the unexpected loss of a baby can precipitate a crisis of meaning for the parents. Are they still parents? How do they readapt to the world without their child in it? A large percentage of parents (61%) are troubled by the question, "Why me?" and 70% to 85% find themselves searching for meaning early in the loss. Evidence supporting the conceptualization of parental bereavement as a crisis of meaning is plentiful (Attig, 2004; Cacciatore & Bushfield, 2007; Neimeyer, 2009; Wheeler, 2001). However, it has also been suggested that some individuals do not seek meaning; that of those who do, less than half are able to find it; and that even when they do, the tendency is to continue searching (Currier, Holland, & Neimeyer, 2006). Other studies showed that a significant factor of influence is the particular meaning construct the person places on the loss. People who tend to find positive constructs within the loss fare better than those who tend toward negative constructs (Gamino & Sewell, 2004). Neimeyer concluded, partly in response to the Davis study, that when parents are struggling with meaning making, it is important to facilitate the process; but if they are not, the caregiver should not initiate the process. The goal of recovery, as related to meaning reconstruction, is a positive change in self-identity by assigning the loss a meaning, thereby allowing the individual to assimilate the loss into her or his world.

Once there is an understanding of the frameworks for the mourning process, or the rationale behind the grief, common manifestations of grief can be explored. It is important to note that for purposes of this discussion, only the possible early responses are identified, as these are the ones the nurse is most likely to encounter in the clinical care setting. Initial grief reactions can include shock, numbness, denial, protest, disorientation, guilt, and confusion. In the initial grief reaction, there is a protective brain mechanism at work that activates to prevent us from taking in too much damaging information at one time and going into "meltdown." For a couple experiencing perinatal loss, this might manifest itself in *denial* of the impending or actual death of the fetus or infant. Even when the initial healthcare provider suspects fetal demise, the couple is hoping that a second opinion may be different. Some couples may not be convinced of the death until they see and hold the dead infant after birth. The couple may move rapidly from shock, confusion, and denial into very intense emotions. *Anger,* resulting from feelings of loss, loneliness, and, perhaps, guilt, is a common reaction, as is despair and an intense longing for the event not to have occurred. Anger may be projected at significant others and/or healthcare team members. The mother may attempt to identify a specific event that caused the death and may blame herself for the death. As the couple and their families begin to confront the pain of their loss, many normal manifestations of grief may be present. The nurse should be familiar with these normal reactions, so that abnormal or complicated reactions can be identified when present. See Table 38-3.

Special Issues for Consideration

Many factors will influence a couple's response to perinatal loss, including individual factors such as age, gender, and personality type. A teenage couple is going to react very differently than a couple in their 30s, men and women tend to respond differently, and emotional personalities will display differently than stoic personalities. Family dynamics will greatly factor into the grief response. Is the family chaotic in nature? Is there a family leader? Do they have open communication or closed and guarded interactions? Do they deny the reality of the event and pretend it isn't happening? Answers to these questions can greatly assist the nurse who is caring for the family. Culture and religious beliefs also influence the couple's reaction in a negative or positive manner. Socioeconomic status will play a role, in that for some people, grief is a luxury. If the grieving parent(s) are more concerned with children at home, or putting food on the table, their grief will most likely be delayed to a time when they have the resources to deal with it. Finally, there are special circumstances that will influence the grief response. Early pregnancy loss has a special form of grief attached, fetal reduction and multifetal pregnancy loss entail separate and distinct issues, and grief from infertility is a largely ignored segment of the grieving population. Each of these components bears further discussion.

TABLE 38-3 Normal Physical, Cognitive, Emotional, Behavioral, and Spiritual Early Responses to Loss

PHYSICAL	COGNITIVE	EMOTIONAL	BEHAVIORAL	SPIRITUAL
Physical signs and symptoms of shock	Denial, disbelief	Sadness	Withdrawal	Blaming God
Palpitations	Confusion	Anger/rage	Dependence	Hostility toward God
Shortness of breath	Sense of unreality	Guilt/self-reproach	Fear of being alone	Lack of meaning or direction
Difficulty sleeping	Disorientation	Anxiety	Memorializing the loss	Wishing to join the deceased
Nausea/vomiting	Time confusion	Numbness	Disorientation	Isolation
Loss of appetite	Vigilance or obliviousness	Flat affect	Sleep and appetite disturbances	Feelings of betrayal
Dry mouth	Focused or detached	Indifference	Absent-minded behavior	Hopelessness
Feeling of emptiness in the pit of the stomach	Poor concentration	Withdrawn or explosive	Dreams of the deceased	Destruction or strengthening of beliefs
Weakness/lethargy	Preoccupation	Repetitive storytelling	Crying/sighing	Feelings of being punished
Tightness in throat	Sense of presence	Loneliness	Restlessness	Acceptance as "Divine Will"
Sighing	Hallucinations of the deceased infant	Yearning/nostalgia	Avoidant behaviors	Assigning of deceased infant as "angel" in heaven
Fatigue			Treasuring of mementos	
Oversensitivity to light and sound				
"Aching" arms

Individual and Family Issues

Age

Age plays a major role in grief reactions. Couples in their 30s may feel that they are running out of time for childbearing; however, they are most likely to have living children at the time of the loss, which may eventually soften the blow somewhat. Couples in their 20s may be experiencing their first significant death, yet often have the sense that they still have time to have another child. With regard to age, however, adolescent parents probably pose the greatest challenge to nursing interventions.

The birthrate for females aged 15 to 19 rose 3% to 41.9 births per 1000 in 2006, the first increase since 1991 (Martin et al., 2009). When adolescents become pregnant, 70% have mixed feelings or do not want to be pregnant and only 41% view themselves as pregnant with a "baby" (Wheeler, 1997). The adolescent who attaches meaning to her pregnancy has the highest rate of grief reaction and life impact. Wheeler's landmark study (1997) showed that grief responses of adolescents were also affected by age of the adolescent, the gestational age at the time of the loss, and the length of time since the loss. Those who were 16 years and younger reported more physical and emotional responses to the loss than did the older adolescents, and those whose losses occurred after 14 weeks' gestation reported more sensitivity to the lack of social support afforded them following the loss.

Though adolescents have a mature concept of death, it is often clouded by their sense of invulnerability, an "It can't happen to me" mentality (Corr et al., 2009). Adolescents rely heavily on peer support and have a natural mistrust of authority figures, which can make assisting them more difficult. It is important to remember that adolescents are already experiencing major life changes, and the death of an infant can have a profound impact on their development. For many adolescents, a pregnancy loss may be the first time they are experiencing the psychologic impact of grief, and normal adolescent growth and development must be taken into consideration when assessing the impact of grief responses (Wheeler & Austin, 2000). Nursing care of the adolescent parent experiencing perinatal loss requires patience and understanding on the part of the nurse. Adolescent parents should be treated with respect and offered the same consideration as adult grievers. They should not be forced into any particular mode of response, but allowed to dictate their own needs within the experience. Gentle and honest guidance are often all that are needed to ensure a healthy nurse-patient interaction.

Family Dynamic

Family dynamics and the presence or lack of cohesion will greatly factor into a couple's grief response. Families who are chaotic and have poor interfamily communication skills are often fractured and of little support to the couple experiencing the loss. Families who demonstrate strong familial ties and open group interaction tend to fare better in the long run. The most difficult family dynamic to assess and assist is the "lie and deny" family. This family deals with bad news and loss events as though they have not occurred. If they do not talk about it, it did not happen. Because a necessary component for the beginning of a healthy mourning process is to accept the reality of the death, the nurse is placed in the tenuous position of mediator between medical personnel and the family members, who do not want to hear anything negative. It is important to discern the possible causes for denial before proceeding. Denial is a normal and necessary process in the beginning of the mourning process, and the family may just need more time to assimilate the difficult information. Persistent denial, however, can be addressed by a gentle review of the facts of the situation with an emphasis on past tense verbiage when discussing the infant.

Gender Issues

Historically, most of the research regarding grief and bereavement has been done on women. As a result, many stereotypes developed regarding how men and women cope with loss. Hallmark research by Martin and Doka (2000) identified a new model for the two major coping styles and reveals a more effective means of supporting the griever. The model identified the two dominant styles of coping as "intuitive" and "instrumental." People with **intuitive styles of coping** generally feel their way through loss and prefer care with an emphasis on emotional and psychosocial support. People with **instrumental styles of coping** generally use more cognitive skills to navigate loss and value care that includes an emphasis on problem solving (Corr et al., 2009). It is important for the nurse to be aware that although gender *influences* mourning, it does not *determine* the experience for the bereaved.

For intuitive grievers, the nurse may initiate discussion of thoughts and feelings concerning the loss. Mobilization of support from nonjudgmental family and friends is generally appreciated, and providing resource materials that include support groups and the opportunity for networking is usually welcome. The nurse should share with intuitive grievers that enlisting the support of others with whom they can talk rather than relying solely on their spouses is favorable for both partners. The nurse should also share that spouses are commonly unable to be emotionally available to each other following loss. The nurse should normalize the lack of emotional accessibility and provide reassurance that the relationship is not doomed to fail because of the death of an infant.

For the instrumental griever, the nurse should specifically address that a parent who seems detached and unaffected by the loss is not uncaring. It is more common for men to fall into this category, as they frequently experience pregnancy through the mother and, when traditionally trained, believe they are not supposed to be emotional but be strong for their partners (Worden, 2009). The parent who is an instrumental griever may not mention the infant, talk about the loss, or view pictures. He or she may resist when the partner shows emotion or attempts to engage him or her in conversation regarding the loss. Instrumental grievers tend to be more active as well as more vocal in assigning blame and commonly use explosive emotion to obtain desired results. Contrary to traditional thought, instrumental grievers' response to loss is not unhealthy, yet they are often criticized for their behavior. Because of their perceived strength, they rarely receive validation and support from others. In supporting instrumental mourners, the nurse should keep in mind that they value acceptance, acknowledgment of their pain, information regarding the loss, what to expect in the aftermath, and tasks that are connected to the loss.

The nurse should inform bereaved couples that both styles of grieving are acceptable and should be honored. Intuitive grievers (most often women) should understand that instrumental grievers may not show emotion or wish to talk about the loss, but are mourning in their own way. Instrumental grievers (most often men) should understand that intuitive grievers will need to talk about the event and help to provide avenues for that outlet. The nurse can instill a measure of hope by reassuring parents that although they may feel as if they cannot bear the pain of the loss, it will not always remain so intense.

Other Features of Bereaved Individuals

In addition to age, family traits, and gender issues, Parkes and Weiss (1983) identified overall features of bereaved individuals that place them at increased risk for pathologic or complicated grief reactions. These features include insecurity, anxiety, or low self-esteem; previous psychiatric history; excessive anger and guilt; a physical disability or illness; previous unresolved losses; inability to express emotion; and concurrent problems of living. Parkes and Weiss also identified features of bereaved individuals' circumstances that will put them at risk; these include an unsupportive or unavailable family, lack of social/religious or other supports, and low socioeconomic status.

Societal Issues

Spirituality

In times of crisis, spirituality brings comfort and strength to some people, and for some it is the single most important factor in quality of life. For others, a life crisis may precipitate a spiritual crisis and catalyze a complete redefining of the belief system, though the new belief system is often stronger than the one previously ascribed to (Frantz, Farrell, & Trolley, 2005).

Religion and spirituality are not one in the same. **Spirituality** is defined as the human search for meaning and connectedness to life, others, God, the universe, and transcendence. **Religion** is defined as structured efforts conducted in a systematic approach to attain holiness (Balk, 2004). Religious practices are based upon the level of a person's assimilation into the particular religion and are too varied and numerous to define for standards of care. With regard to specific religious practices, it is prudent for the nurse simply to ask the family how they can best be assisted in meeting their religious needs.

One study identified six themes affecting the spiritual needs of bereaved parents: honest exchange of information, empathy and presence, continuing bonds, spiritual rites, attachment with others, and grief support (Meert, Thurston, & Briller, 2005). The nurse can facilitate the spiritual needs of the couple by providing an atmosphere of acceptance regarding spiritual rites and encouraging the couple's use of spiritual writings, prayers, and observances. Questions that solicit the spiritual viewpoint of the couple regarding the loss can allow release of parental distress concerning spiritual matters. It is important for the nurse not to answer rhetorical questions, but allow the parents to process their own thoughts and feelings concerning meaning, purpose, and significance of the life and death of their infant. It is also important for the nurse to distinguish between his or her own personal beliefs and those of the parents. Some healthcare professionals get defensive and critical when the spiritual needs of the parents conflict with their own spiritual viewpoint. Recognition of personal limitations is healthy and providing care is not exclusive to direct delivery. The nurse acts as a family advocate by offering to contact the couple's clergyperson, spiritual advisor, or the hospital chaplain. Research

CLINICAL TIP

It is vitally important to respect the family's religious beliefs and not interject our own preferences into the situation. Baptizing an infant whose parents have not requested such is a violation of their rights and disrespecting of their wishes. Allow the parents to dictate all spiritual aspects of their infant's care.

DEVELOPING CULTURAL COMPETENCE

Cultural Responses to Perinatal Loss

There is much information a nurse can learn about a particular culture's response to perinatal loss and grieving. While knowledge of specific beliefs and rituals is helpful when caring for a family from an unfamiliar culture, it is *most* important that the nurse simply remains open, curious, nonjudgmental, and unassuming. There are underlying threads that weave together the relevant factors affecting grief response, yet no two people will grieve alike and even knowledge of a person's cultural and religious background does not offer the nurse a guaranteed blueprint to follow. This is particularly true where culture is concerned. Not only are there many country of origin and regional differences, but the extent of assimilation into American culture will factor in as well. Therefore, to say that all Hispanic Americans will respond to the death of an infant alike because they are all Hispanic Americans would be akin to saying that all Protestants will worship alike because they are Protestant. One only has to consider the vast number of Protestant denominations with varying and often conflicting viewpoints to realize that such a generalization is useless to the nurse assisting grieving parents and families. Perinatal loss is unique in cultural awareness because one can never be sure to what extent culture, religious beliefs, or other factors will dominate the response to such an unexpected and unnatural event as the death of a baby. Even people who have assimilated into American culture will often revert in times of crisis and death.

confirms that providing effective spiritual care to a parent during loss and bereavement is valuable in facilitating healthy parental mourning (Meert et al., 2005).

Remembering that while the family is the most reliable source of information about its own beliefs and how to best assist it, there *are* some commonalities within culture groups that the nurse should be aware of in anticipation of meeting the parents' and family's needs (Table 38-4). The way many cultures experience grieving and death rituals is often heavily influenced by their religious beliefs, and therefore addressed in the table as well.

CLINICAL TIP

A basic rule of thumb for cultural issues is to remember that curiosity is okay; avoidance is not. If you are not sure what the family needs, simply ask them how you can help to accommodate their wishes. Families appreciate an honest and caring attitude.

PROFESSIONALISM IN PRACTICE

Instituting Culturally Competent Care

There are ways that a nurse can provide culturally competent care in such a challenging situation. A good place to start is with a formal or informal cultural awareness questionnaire similar to ones used for general nursing care. Questions pertaining to death, dying, and perinatal losses should provide answers for the following:

- What the families beliefs are about what happens after death
- How the family views the death of an infant, in particular
- How the dying infant should be cared for as he or she approaches death, including who should be present and any ceremonies that should be performed at the moments before and after death
- How the body should be handled after death, including how the body should be cleansed and dressed, who should handle the body, and whether the body should be buried or cremated
- Whether grief should be expressed quietly and privately, or loudly and publicly, such as with public crying, keening, or wailing
- Whether there are different expectations on how a man should grieve versus a woman, or for children versus adults; what the family considers the role for each member in coping with the death
- What ceremonies and rituals should be performed and who should participate, such as children, community members, and friends

(Adapted from Cancer.Net. (2009). Understanding grief within a cultural context. From http://www.cancer.net/patient/Coping/Grief+and+Bereavement/Grief+Among+Cultures; Clements, P. T., Vigil, G. J., Manno, M. S., Henry, G. C. Wilks, J., Das, S., et al. (2003). Cultural perspectives of death, grief, and bereavement. *Journal of Psychosocial Nursing, 41,* 18–26.)

Specific Circumstance

Infertility

Infertility is not an episode, but an ongoing struggle for those who are caught in its grasp. The focus of treatment for infertility is a correct diagnosis, appropriate treatment, and successful live birth, yet infertility brings with it grief and loss issues that affect all realms of the couple's life. Not only are the medical and physical components extremely challenging, but the loss issues of infertility go largely unrecognized by the usual support systems, placing it within the disenfranchised grief category. In the early phase, the patients are trying to assimilate the diagnosis of infertility and what the diagnosis actually means for them. Then they are faced with a gamut of decisions and difficulties such as:

- Treatment available (method that is best for them; when to begin; repercussion of choices; risk involved)
- Waiting (menstrual cycles; pregnancy; failed pregnancy; surgery; hormone treatments; in vitro fertilization)
- Psychologic roller coaster (spiritual impact; the strain on finances and primary, secondary, familial, and workplace relationships)
- When to discontinue treatment.

TABLE 38-4 Common Cultural Practices: Grief, Bereavement, and Perinatal Loss

CULTURE	FAMILY HIERARCHY & REACTION TO MEDICAL COMMUNITY	COMMON BELIEFS AND EXPRESSIONS OF GRIEF	CARE AND HANDLING OF THE BODY: RELIGIOUS & CULTURAL RITUALS
		Before & After Death	*Before & After Death*
African American	Matriarchal; family decision making. Family, religion, and community play a large role in grief recovery; considered collectivists. May distrust majority healthcare system; common to rely on internal resources. Healthcare providers should work to build trust and respect family dynamics.	Vary widely because of diversity in religious beliefs, countries of origin, and geographical regions. Some will cry or wail while others will appear stoic, especially if mistrustful of healthcare providers. Many hold strong religious beliefs; will turn to clergy for assistance. Prayer for healing or comfort around the bedside is a common occurrence for Christians. May be averse to withdrawal of life support.	Will generally want pictures and mementos; naming of the infant is important for family heritage. Death is often called "home going" or "passing on," especially by Christians. May desire pre- or post-death baptism. Common to wait for extended family to arrive for funeral services. Most likely to prefer burial to cremation. May have elaborate caskets and/or services as a way of showing respect and giving the infant a final tribute. Tend to view life as a continuous circle, and therefore many have a steadfast belief of being reunited with their infant.
Old Order Amish	Patriarchal; strong family and community ties. Decisions dictated by religious beliefs; made by both parents, but father will usually relay. Will accept life-supporting medical technology. Most have eighth-grade education, so information should be provided appropriately. Will consent to legal dictates.	Children are a gift from God. Many losses occur due to advanced maternal age and consanguinity. The loss is profound, but viewed as God's will. Very private in grief; will keep to themselves for comfort. Rare for them to share with outsiders, known as the "English."	Do not believe in infant baptism. Family and friends will usually want to wash the body for burial in a white gown. Photos are not permitted (for the living or dead). May not accept mementos as community prepares casket and burial clothes, but offer should be made as less conservative families may accept. Bracelet may be accepted as legal identification. May want to transport body home and burial will be at a designated facility or on the family farm as laws permit.
Asian American	Generally patriarchal, but strong community influence. In the more traditional families, older members are highly respected and should be included. Generally avoid confrontation and more traditional may avoid eye contact. Touching is impolite. Saying "no" directly may be considered rude, so healthcare provider should ask open-ended questions.	Community oriented. May believe that bad *karma* causes illness and death. May believe the number "4" is associated with death. Death of an infant is intensely mourned. Initial grief is acceptable and there may be crying and/or wailing at times. Death is not a usual topic for discussion and overt expressions of prolonged grief may be viewed as mental illness and therefore may alternately be expressed as somatic complaints (safer to be body related than mind related).	Usually a blend of Western and Eastern grieving and death ritual practices. The body should be handled with much care and always with respect. Family members may wear white clothing or headbands to mark mourning. Common to have an elaborate funeral ritual for the soul's passing.
European American	Family hierarchy is dependent upon faith values; Christian families tend toward patriarchy, while secular families tend toward companion marriage with equal decision making. Comfortable with technology and generally utilize to fullest extent possible. More likely to question authority and expect answers from healthcare providers.	Expressions of grief span the spectrum of responses; most often dictated by religious beliefs, geographical regions within the United States, and country of origin. Crying is acceptable; intense grief reactions are dependent upon previous factors noted. Usually no set mourning period and most likely to mourn longer than support is offered.	May or may not wish to bathe infant personally. May or may not wish to view and/or hold the infant. May or may not desire pictures. The nurse should inquire about all, but not place pressure for any. Naming of the baby and use of the name by healthcare providers is important. Burial or cremation preference may be determined by faith practices, financial status, or personal preference. May desire funeral services; infant areas in cemeteries are acceptable, especially to Catholics, who view infants as sinless. Baptism may or may not be desired and should not be done unless the parents request such. Pictures and mementos are usually appreciated.
Hinduism (addressed separately, although Indian Americans are included in the Asian American minority group)	Patriarchal, though family oriented; needs of all over individual emphasized. Husband or eldest male will usually communicate decisions.	Combination of culture, philosophy, and religion. Believe in *karma* and reincarnation; seek to transcend birth and death by good deeds (karma), which ultimately frees the soul.	The body should be bathed, oils applied, and dressed in new clothes. Cremation should take place before the next sunrise in order to release the soul from the body. Eldest male member begins the cremation by physically pushing the button or flipping the switch (or, in older traditions, lighting the funeral pyre).

(continued)

TABLE 38-4 Common Cultural Practices: Grief, Bereavement, and Perinatal Loss continued

CULTURE	FAMILY HIERARCHY & REACTION TO MEDICAL COMMUNITY	COMMON BELIEFS AND EXPRESSIONS OF GRIEF	CARE AND HANDLING OF THE BODY: RELIGIOUS & CULTURAL RITUALS
		Before & After Death	*Before & After Death*
Hispanic & Latino American	Patriarchal; family decision making. Male to female, older to younger concept of *respeto* (respect) in social order. Applies to healthcare providers and mutual respect is expected. More trusting of individual practitioners than system; expect warmth, caring and attention. More traditional will expect handshake and formal use of last name upon introduction (Senor y Senora). Generally view human touch as respect from healthcare professionals.	View loss as God's will. Tend to rely on faith and prayer as tools for coping. Outward expression is encouraged, especially crying among women. Men tend toward stoicism for the family. Both may experience depressive symptoms. Support comes from family and friends. Extended family will usually travel for services. Support is found in family, friends, church, and community. Tend not to look toward medical community for support.	Baptism and naming are usually desired. Generally prefer burial to cremation. Pictures and other mementos are important, as they tend to utilize them for honoring the infant in the home. Country of origin will determine particular rituals involved in grief and death. Catholicism predominates. Prefer open casket ceremonies. May wear traditional dark funeral clothing for an undefined mourning period. Continuing bonds with the deceased are important (hence, the "Day of the Dead" in Mexico). Belief of a fine line between the living and dead. Rituals include the lighting of candles, prayers for the dead, and shrines for honoring them.
Jewish	Traditionally patriarchal; modern Jews tend toward companion marriage with equal decision making.	For observant Jews, having children is commanded by God and considered a great blessing. Loss of an infant is profound and support may be sought from the family's rabbi. Some will tend toward stoicism while others will openly grieve. Believe the soul begins the journey from the body immediately; this is why it is important to bury the body as soon as possible. The parents may not want to view the body as they tend to want to remember the deceased as alive rather than dead.	Perinatal loss is a somewhat controversial topic in Judaism today. Traditionally, neonates (infants under 30 days of age) were not named or provided traditional bereavement practices such as sitting shiva. In recent times, the customs have changed and many will observe full mourning and burial rituals for a perinatal loss. Adherence to traditional Jewish tradition will entail body washing by a special group of people who ritually wash and dress the body in linen shrouds. Naming the infant will depend upon whether the family adheres to the old traditions, as will sitting shiva. The infant may be named at the burial and given a name associated with comfort. Pictures of the dead are not permitted and autopsy not acceptable unless there is benefit to the living. Burial should take place within 24 hours and cremation is forbidden. Bodies should be whole if possible. Burial is sometimes in an infant section, but always in a Jewish cemetery and usually in a wood coffin with no metal to delay decomposition. Prefer monetary donations to charities in lieu of flowers as the withering and dying of the flowers is considered a painful reminder of the loss.
Muslim	Patriarchal, but decision making is shared. Information should be provided to both parents, even though the father may relay all decisions. Autopsy is usually forbidden unless for major concerns or demanded by law.	Death is considered a part of life. Children are a gift from Allah and are returned to Allah if they die, as they are considered sinless. The death of a fetus or infant is not minimized, but regarded as just as significant as that of an adult. Crying and solemn expressions of grief are permitted as long as control is maintained. Excessive grieving is considered not accepting of the will of Allah. The funeral is followed by three formal days of mourning (and 40 days of unofficial mourning), but for infants less than 4 months gestation, the fetus may only be wrapped and buried.	If the child is born alive, but death is imminent, the father may whisper the phrase "There is no God but Allah" in the infant's ear, securing the infant's call to worship. Naming is essential as the mother and infant will be bound together in paradise. Parents may desire to perform a ritual washing of the body, usually by the same sex parent. Conversely, they may not wish to see or hold the baby, as the viewing of bodies unnecessarily is discouraged. The legs should be straightened and sometimes the parents may request that the body face the right and face Mecca. Pictures are not usually desired, but should be offered. Locks of hair should not be removed; the body should be left intact and wrapped in a plain white shroud. Cremation is forbidden.
Native American	Patriarchal, though parents will make decisions together.	Navajo, the second largest Native American population, have traditional customs followed upon death. Tend to be stoic, and grieve privately. Death is viewed as a transitional step on the journey to the next world and the mourners must follow strict burial and bereavement rituals to ensure a successful journey.	Rituals must be completed within 4 days of death. The body is washed and painted for the journey. They do not speak of the dead after the fourth day because it is believed that it will impair the journey of the deceased. After a time, any discussion of the deceased is believed to bring ill health to the surviving family, and therefore support following the loss can be a challenge.

In supporting the patient dealing with infertility, the nurse should assess where the woman is in the process and respond accordingly. The nurse should be compassionate, give accurate and honest information, validate the many losses incurred, and support whatever decisions the couple makes regarding the continuation of treatment or decision to stop treatment. The nurse should not avoid the couple, offer pat answers or reasons for the infertility or the outcome, or relay unsolicited stories of others' successes or failures. For couples finally experiencing a pregnancy following infertility treatment, there may be heightened anxiety for which additional reassurances will need to be offered.

Early Pregnancy Loss

Early pregnancy loss, whether by ectopic or molar pregnancy, blighted ovum, or spontaneous abortion, is devastating for many couples. As attachment is based on the level of emotional bonding, it is necessary for the nurse to assess the situation in order to respond to actual patient needs and validate the loss for those who view the event as the death of their baby. Compounding early pregnancy loss is the extraordinary guilt the couple typically harbors, especially the mother. Mothers will often blame themselves, whether by commission or omission, particularly in cultures where a woman's status is dominated by themes of motherhood and childrearing. The nurse should reassure the couple that they did not do anything to precipitate the loss, and provide support materials specific to the type of loss incurred and what to expect in the immediate aftermath.

Assessment of future pregnancies will need to be dealt with gently, as some couples have no desire to try again. Healthcare professionals sometimes find it easier and more comfortable to refocus on something other than the loss; however, that tends to minimize the loss event and isolate the griever. Even if the parents are expressing an interest in trying again, it is important not to focus exclusively on the future pregnancy, but to provide opportunities to address the current loss. The nurse should prepare the couple for the fact that family members and friends will often underestimate the impact of the loss and may offer well-meaning, though often harmful, remarks or platitudes in an attempt to ease emotional pain. This is a common reaction in early pregnancy loss, as they may have not known about the pregnancy or feel as if the couple "didn't know the baby." The nurse should reassure the parents that they have a right to their feelings, thoughts, emotions, and reactions to the loss. An early pregnancy remembrance box (a remembrance journal, sachet pillow, and a baby ring) provides a sensitive and caring way to give parents something to take with them that contains memories of their baby (Figure 38-1 ■).

Figure 38-1 ■ Early pregnancy remembrance box.

Multifetal Pregnancy Loss

In 2006, the U.S. live twin birth rate was 32.1 per 1000, and the high-order multiple-birth rate was 153.3 per 100,000 births, a decline since the 2002 statistics. One of every eight twins, and one of every three triplets are born very premature (less than 32 weeks gestation) and thus death during infancy is much more common in twins and multiples at 29.8 per 1000 and 59.6 per 1000 births, respectively (Martin et al., 2009). Multifetal pregnancy loss (MPL) may occur by spontaneous abortion, elective termination for unwanted pregnancy, selective reduction for fetal malformation, or selective reduction in high-risk multiple pregnancy to provide a greater chance of survival for remaining embryos. The loss of an infant in a multiple pregnancy may also occur by intrauterine demise, twin-to-twin transfusion syndrome, complications of monoamniotic twinning, placental problems, adverse intrapartum events, delayed interval delivery, postoperative complications, and the effects of prematurity. Parents whose multiples die have an increased risk of prolonged or delayed grief (Pector, 2004).

Many aspects of multifetal pregnancy loss have historically been overlooked by healthcare professionals (Keefe-Cooperman, 2004–2005; Kersting et al., 2005; Pector, 2004). Some of the predominant issues affecting parents are the following:

- Traumatic impact of diagnoses of malformation or birth defects
- Options and impact of difficult decisions
- Sudden death of an infant, fear and anxiety for surviving infants
- Prospect of infertility because of previous abortions
- Last attempt at in vitro fertilization (IVF) or such fertility intervention, guilt
- Cohabitation of mourning and joy, and resurgence of the body's remembering on special days and holidays

In supporting bereaved parents caring for surviving infant(s) in the loss of a multiple, the nurse should resist the urge to suggest the parents refocus on the positive aspect of having surviving siblings. Statements inferring that the death was meant to be, the death allowed the other infant(s) to live, or the child who died would have had a compromised quality of life should never be made. The nurse should understand that the couple might have difficulty mourning their loss as they attempt to balance emotions of joy and sadness while caring for the surviving infant(s). Parents will often imagine what the deceased infant might have looked like, what kind of personality the infant might have developed, and what the relationship

with siblings might have been. They may harbor feelings of guilt if they feel relief for not having to care for numerous infants. The nurse should support parents by addressing these distinctive concerns and prepare them for the unique issues related to multifetal loss before they leave the hospital.

When creating visual memories for bereaved parents, an effort should be made to take pictures of the multiples together. The nurse should ask parents how they prefer to address surviving infants, for example, twins, triplets, quadruplets, and so forth. Additionally, the nurse should ask the couple whether they wish to delay funeral services until the mother is able to attend the ceremony. If the couple desires a delay, the nurse should contact appropriate disciplines to arrange for the delay in disposition of fetal remains (Pector, 2004). The nurse should prepare the mother for the likelihood of her body missing and remembering the baby immediately after delivery, while caring for surviving infant(s), and surrounding special days, milestones, and holidays. Finally, the nurse should be aware of the risk for complicated bereavement and refer the couple for appropriate support via resource materials (Keefe-Cooperman, 2004–2005).

Maternal Death

Maternal death is defined by the World Health Organization as "the death of a woman while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and the site of the pregnancy, from any cause related to or aggravated by the pregnancy or its management, but not from accidental or incidental causes (2007)." The most common causes of maternal death are hemorrhage, hypertensive disorders, embolism, infection, and pre-existing chronic conditions, such as diabetes and cardiovascular disease. Obesity is also becoming a significant factor in maternal deaths because of the medical conditions that result (The Joint Commission, 2010). In 2006, the national maternal mortality rate was 13.2 deaths per 100,000 live births (Heron, et al., 2009). A recent number of reports indicate that maternal mortality may be rising in the United States, although there has been a change in the classification system that may have resulted in the identification of more deaths as pregnancy-related (Hoyert, 2007). The numbers of maternal deaths are certainly not decreasing, however, and the death of even one mother on a perinatal unit can be a devastating experience for all involved.

For the husband or father of the child, the death of his partner is shocking (even if she had previous medical problems) and traumatic, somewhat akin to the proverbial knock on the door when there has been an unexpected accident. There is an even deeper shock presenting here, in that the death is surrounding an expectedly joyous event, a birth. The initial shock of maternal death experienced by the husband or father is traumatic and powerful. The grieving process is complicated by a number of factors (such as possibly caring for the newborn infant while grieving his partner) and too comprehensive a topic for this venue. What is important for nurses caring for the father and/or other family members is to recognize that initial grief reactions may be extremely intense. As long as no one is violating the fundamental principles of grief reaction (not hurting themselves, others, or personal property), the father and family should be fully supported through this initial time with all support available to them and the facility in which the nurse is practicing. Interactions should be brief and direct, such as offering tissues, and straightforward condolences (e.g., "I'm so sorry this is happening to you"). As with all losses, it is important to resist offering explanations or platitudes. There are no adequate explanations, and platitudes are not helpful and in most cases prove harmful.

For the staff, a maternal death on the perinatal unit can be traumatic as well. When a death occurs on any unit, there are individual as well as group reactions to the event. The individual nurses involved may experience feelings of shock, sadness, anger, guilt, and other grief-associated reactions. The unit as a whole may experience feelings of inadequacy, anger, guilt, confusion, and depression. For the nurses directly involved, the father and family must still be cared for, and for everyone on the unit, nursing care continues. It is important for management in these situations to step in and provide an opportunity for the staff to express their feelings in a safe environment. Intervention for the staff could include professional debriefing or, where professional assistance is not available, simply calling a staff meeting to allow the nurses to work through some of the emotions while supporting one another (Dietz, 2009). The most important thing for the nurse to remember is to take care of his or her own grief reactions and allow time for personal healing. Focusing on the positive aspects of the situation where they exist (such as personal kindness shown to the mother before the death, or to the family in the aftermath) is an important step in the healing process as well as reflecting objectively on those things out of one's personal control (the mother's underlying medical issues or unforeseen complications). The idea, as with the loss of an infant, is to eventually memorialize the event with a balanced perspective, recognizing where personal effectiveness as well as limitations exist and learning to live with them, both personally and professionally.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The Clinical Setting

Cessation of fetal movement reported by the mother to the nurse is frequently the first indication of fetal death. It is followed by a gradual decrease in the signs and symptoms of pregnancy. Fetal heart tones are absent, and fetal movement is no longer palpable. Once fetal demise is established, the nurse assesses the family members' ability to adapt to their loss. Open communication among the mother, her partner, and the healthcare team members contributes to a realistic understanding of the medical condition and its associated treatments. The nurse may discuss prior experiences the family has had with loss and what they feel were their perceived coping abilities at that time. Identifying the family's social supports and resources is also important.

Perinatal loss may also occur in the intrapartum period as a result of an intrapartum complication, such as an unresolved shoulder dystocia, prolapsed umbilical cord, abruptio placentae, or other complication. In such emergent situations, healthcare team members often focus on the physical needs of the mother and an attempt to save the fetus's life. Commonly, it is not until the infant is delivered that the family is advised a perinatal death has occurred. Thus, the parents are faced with the sudden and completely unanticipated death of their infant. The most common response is protest or disbelief.

Although the physician or certified nurse-midwife (CNM) informs the family of the death, the nurse continues one-on-one care with the family, providing both physical and emotional support throughout this crucial period. The nurse assists the family in the mourning process and explores their immediate wishes for viewing and holding their deceased

Nursing diagnoses that may apply include the following:

- ***Grieving*** related to the imminent loss of a child
- ***Powerlessness*** related to lack of control in current situational crisis
- ***Compromised Family Coping*** related to death of a child/unresolved feelings regarding perinatal loss
- ***Interrupted Family Processes*** related to fetal demise
- ***Hopelessness*** related to sudden, unexpected fetal loss
- ***Risk for Spiritual Distress*** related to intense suffering secondary to unexpected fetal loss

Nursing Plan and Implementation

Most facilities have an established protocol to follow in the event of perinatal death. It typically provides a holistic focus for family-centered nursing care. It is important that the entire healthcare team be notified so multidisciplinary care can be initiated. When fetal death has been confirmed before admission, the entire staff on the unit is informed so they can avoid making inappropriate remarks. Many facilities have a symbol, such as a card with a leaf or a cluster of flowers, which is placed on the mother's door so that all of the staff is aware of the loss (Figure 38-2 ■). This is something that should be discussed with the family before placement, as some may view the symbol as an identification of them as "damaged." As is stated throughout the chapter, it is important to allow the family to dictate their own experience.

Avoiding the Use of Clichés

> "There were the inevitable platitudes about God "needing another angel" or God "taking" Gabriel from us for a reason. I can't imagine those concepts being a comfort to anybody. What kind of sadistic God would breathe life into a baby only to snuff it out? After millennia of infant deaths, you'd think God would have plenty. If God needed more babies in heaven, God could simply will some into existence . . . I would be bitter for the rest of my life—and probably beyond—if I thought a higher power had targeted my baby to die."
>
> —Amy Kuebelbeck*

Inappropriate remarks are a hallmark of uninformed interactions, even though the intent behind them is honorable. The nurse should become familiar with statements that are helpful in facilitating the family's mourning process. Although grieving people often say that it is easier to forgive less-than-helpful remarks than to forgive those who do not reach out to them at all, the use of clichés can be harmful. The nurse can facilitate a healthy mourning process for the family by using active listening techniques and avoiding the use of clichés. Sitting in silence with a family is often the most helpful form of intervention available. For a list of helpful versus unhelpful statements with rationales, see Table 38-5.

Facilitating the Family's Mourning Process

As mentioned at the opening of this chapter, there has been a recent paradigm shift in the field of grief and bereavement with regard to what constitutes a "normal" mourning process, as well as when and where early intervention is warranted. The standard of care has been centered on the notion that early and intense grief responses should be encouraged and even elicited for healing to begin. The relevant research, however, determined that many people are naturally resilient and will recover in their own time, without the benefit of assistance (Balk, 2004; Bonnano, 2008; Lang, Goulet, & Amsel, 2003; Miller, 2003). For instance, stoic responses, when exhibited because of familial or cultural traits, are not always counterproductive and may not need intervention in order for the person to begin the path to recovery. Furthermore, not only is early intervention not always necessary, it can even be harmful in some instances (Bonnano, 2008; Brier, 2009; Murray, Terry, Vance, et al., 2000). Although the research confirms that traumatic grief is usually best assisted by early intervention, perinatal loss does not *always* fall into this category, which leads to the current quandary: When is early intervention warranted and effective? The debate continues, but for the nurse caring for a family experiencing perinatal loss, avoiding the trap of "cookie cutter" responses is not difficult if simple, caring guidelines are followed rather than rigid rules. The nurse should keep two goals

TABLE 38-5 Unhelpful Versus Helpful Interactions with Grieving Families

UNHELPFUL	HELPFUL	RATIONALE
You're young; you can try again. At least you have your other children.	I am sure you'll miss [Sara] and no one will ever take her place in your heart.	Saying that they can try again diminishes their current pain. Saying that no one can ever take the deceased infant's place validates the loss as real and the infant as unique.
At least you didn't know him or her yet.	I'm sure you had many hopes and dreams for the future.	Never start a sentence with the words "at least." It diminishes whatever follows. Speaking of future plans validates the loss of the hoped-for child and the dreams that will never be.
It's a blessing in disguise.	I don't know why this terrible thing has happened to you. I just want you to know that I care and want to help you through it.	Statements like, "It's a blessing in disguise" are often said when there are deformities involved. There is no adequate explanation for the family as to why this tragedy has befallen them and none should be offered. Instead, reassurance that they will not be alone should be given.
God needed another angel in heaven.	I'm so sorry this is happening to you. You are a good person and this is a terrible thing to have to go through. I'm here to listen if you would like to talk about it.	The family may make this statement as an indication of their belief system, and that is perfectly acceptable. It is not acceptable, however, for the nurse to impose her or his own belief system upon the family. It is much more effective to address the issue at hand (they are in pain) and reassure them of your caring presence.

in mind when assisting grieving parents and families. The first is to help the family navigate the medical/hospital system and the second is to facilitate the family's mourning process by allowing them to dictate their own experience.

CLINICAL TIP

Allowing families to meet their own needs in grief offers them the best path to learning to live with their loss; trying to force them into doing things the way that you think is best for them serves your own needs, not theirs, and can prove harmful.

The Caring Theory

The classic caring model developed by Swanson (1991), has sustained the test of time; it is as relevant today as when it was originally developed. Perhaps because of its lack of rigidity and concentration wholly on the overall *attitude* of the caregiver, it can best serve as a solid foundation for good nursing practice related to bereavement care. The **caring theory** consists of five attributes of the caregiver: (1) knowing, (2) being with, (3) doing for, (4) enabling, and (5) maintaining belief.

Knowing is defined as attempting to understand the event as it has meaning in the life of the parents. A thorough nursing assessment will facilitate the nurses' understanding of the significance of the loss to the parents. Nurses who operate from a level of knowing are perceived as sensitive, knowledgeable, and appropriate. Nurses who do not are often perceived as distant, cold, and uncaring. *Being with,* or being emotionally present, is the nurse's ability to reach beyond professionalism and give of herself or himself as a human being. *Doing for* is a restating of the golden rule. It means that the nurse does for the parents as she or he would have things done for her or him in the same situation. This does not mean detail by detail, as every family is unique in their needs; rather, this is an overall, treat-them-as-you-would-your-own-family type of behavior. *Enabling* means facilitation of the parents' passage through life transitions and unfamiliar events. Enabling encompasses all of the interventions listed throughout the text regarding perinatal loss and places the caregiver in the role of facilitator. Finally, *maintaining belief* is defined as believing in the parents' capacity to get through the event and face a future with meaning. The nurse who ascribes to this model of care well serves the needs of bereaved parents by compassionately helping them in the midst of their pain and imprinting positive memories to sustain them.

The Art of Responding

Employing the caring theory of behavior, the nurse can then look to the responding model as a set of guidelines for successful interactions with grieving families. Keeping in mind the uniqueness of each situation, the **responding model** is offered to give the nurse an overall set of guidelines for effectively interacting with families experiencing perinatal loss (see Table 38-6). The specific elements of the model are addressed throughout the rest of the chapter and within the nursing care plan.

Preparing the Family for the Birth and Death

Upon arrival to the facility, the couple with a known or suspected fetal demise should immediately be placed in a private room. When possible, the woman should be in a room that is farthest away from other laboring women. Care should be taken not to

leave the couple in the waiting room with other expectant parents or visitors waiting for news from other women in labor. The nurse should sit down for a moment, offer an introduction, and acknowledge the loss in the event of a known demise or impending death. A simple statement such as "My name is Brenda and I'll be your nurse today; I'm so sorry; this must be so hard for you. I'd like to help you through it," will go a long way toward establishing a relationship of trust between the nurse and the parents.

The couple should be allowed to remain together as much as they wish. The nurse provides privacy as needed and maintains a supportive environment. The couple should be given complete information about what to expect and what will happen. Questions should be encouraged and answered (Figure 38-3 ■). The nurse stays with the couple so they do not feel alone and isolated; however, cues that the couple wants to be alone should be assessed continuously. Some couples may want outside support, such as family members or friends, to be present during the labor. The nurse facilitates the couple's wishes.

When possible, the same nurse should provide care for the couple so that a therapeutic relationship can be established. As the relationship develops, the nurse provides solace by listening to the couple without offering explanations. The nurse also provides ongoing opportunities for the couple to ask questions. It is not uncommon for the family to ask the same questions repeatedly. This is part of the initial process. Clear explanations and straightforward answers should be provided and the parents treated equally in giving of information. The nurse also arranges for other members of the multidisciplinary team to interact with the family. The team should take great care to avoid inflicting further trauma on the couple by

PERINATAL COMFORT CARE PROGRAM
PLANNING FOR OUR BABY'S BIRTH A PARENT'S REVIEW LIST

♥ Let your doctor and Labor/Delivery staff know the name of your baby.
♥ Your baby's condition may be different at time of birth than expected right now. Your doctor may need to make immediate medical decisions at the time of your baby's birth in order to give your baby the best chance for a quality life. Some of your plans may not be possible in this situation. Please talk about this with your doctor before your baby's birth.

displaying conflicting words and behavior, such as using a falsely cheerful tone of voice while their body language clearly indicates sorrow (Trulsson & Radestad, 2004). The nurse offers to contact the hospital chaplain or another cleric for them, and a social worker should be involved. The nurse typically coordinates members of the multidisciplinary team so that a comprehensive plan of care can be initiated.

The nurse explains details of the plan of care (Figure 38-4 ■) and allows the family to ask questions and make decisions for their labor and birth preferences. The availability of anesthesia and analgesia should be reviewed. The woman typically can have pain medication whenever she desires. The nurse facilitates the participation of the woman and her partner in the labor and birth process.

It is important to remember that, in contrast to a typical birth experience, the birth of a terminal or stillborn infant marks both the beginning and the end. For this reason, it is imperative that the couple and family have all wishes and preferences respected. The family may be overwhelmed and may have difficulty making decisions in this period. The nurse can strengthen the couples' ability to cope by providing a warm atmosphere of acceptance. The nurse must assist the couple in exploring their feelings and help them to make decisions about who will be present and what rituals will occur during and following the birth. Examples of birth preferences include the following:

- Use of music, dimmed lighting, or other environmental preferences
- Laboring or birthing in a specific position
- Having the infant placed on the mother's chest immediately after birth

- Allowing the father to cut the umbilical cord
- Including other family members or friends present at the birth

Sometimes couples worry that others may view their preferences as "strange" or "wrong." Reassure the family that it is their experience and that there are no right or wrong feelings or wishes.

The couple may have waves of overwhelming grief, disbelief, or sadness. Encourage them to experience the grief that they feel, but do not force the issue. It is not uncommon for one partner to attempt to put on a "brave front," feeling that, by showing grief, he or she will make the other partner feel worse. It is also not uncommon for partners to have intense feelings that they feel unable to share. Encourage partners to express their emotions freely to the extent they are able. Help them understand that they may each experience different feelings.

> "At last, we are holding our beautiful baby. Swaddled in his hospital blanket decorated with pastel teddy bears and hot-air balloons, he is crying with some effort, his eyes squeezed tightly closed. He has the plump newborn cheeks his sisters had and a hint of downy dark hair. He is a little pale, and his fingernails are faintly blue. He is beautiful. We are overwhelmed with pride and love—and concern—for the newest member of our family."
>
> —Amy Kuebelbeck*

Supporting the Family in Decision Making

It is important to remember that the family will need guidance *throughout* the process. The couple should be offered simple choices all along the way to help them retain as much control over their situation as possible. If the infant is born alive, but suffering from a complication that is incompatible with life, the nurse should make every effort to allow the parents as much time as possible with the infant. In addition, the extended family should be allowed as much access as is comfortable for the parents.

> "I kiss Gabriel's forehead. It is cool . . . I kiss him again and whisper to him, "Don't leave yet." I tell him (Mark) that the nurse seemed concerned about Gabriel's heart rate. She comes back and listens with her stethoscope again. "Six," she said. Six? We don't understand. Her face close to mine, she says gently, "Your baby is dying." No! Not yet! The words scream through my mind, but nothing comes out except a sob."
>
> —Amy Kuebelbeck*

Advocates of seeing the stillborn infant believe that viewing assists in dispelling denial and enables the couple to progress to the next step in the mourning process. In recent years, this has become a topic of controversy in the field of death and dying. A study by Hughes and colleagues in 2002 concluded that adverse outcomes such as higher anxiety levels were reported in higher numbers in mothers who held the infant than in mothers who only saw the infant or did not see or hold the infant (Turton, 2008). One potential explanation for this aberrant finding is the possibility that if nurses who are uncomfortable with death and dying are rigidly following standard bereavement checklists rather than recognizing the uniqueness of each situation, the mother and father may be forced into uncomfortable situations they are not properly prepared for. Another proposed explanation is that when the parents view and hold the infant, further bonding occurs, which leads to a more intense grief reaction. Even more recently, Turton (2008) found an increase in posttraumatic stress disorder among women who held their dead infant. Ironically, though the women wanted to hold and see the infant, the trauma appears to be related to the vivid imagery that is implanted during holding and see the dead infant. It should be noted, however, that numerous other studies did not find an increase in anxiety and instead found that most women who held their infant did not regret it, while many who did not had subsequent feelings of regret (Cacciatore, Radestad, & Froen, 2008; Flenady & Wilson, 2008; Radestad & Christofferson, 2008; Radestad, Saflund, Wredling, et al., 2009). Until more conclusive studies are reported, the nurse should offer the couple the opportunity to see and hold the infant, assess possible motivations behind negative responses (such as a fear of the unknown), and reassure the couple that *any decision they make for themselves is the right one.* Careful listening on the part of the nurse should allow the parent(s) to make clear their wishes. Additionally, the nurse should not allow pressure from others to be put upon the couple to either see and hold or not see and hold their stillborn infant. If they choose to see their stillborn infant, prepare the couple for what they will see by saying "she is going to feel cold," "he is going to be blue," or other appropriate statements. If the parents have shared with you the name they had chosen for their baby, use that name in discussing the baby; for example, "Jessie's face is bruised." If the couple is hesitant to view the infant out of a fear of what the infant will look like, offering a Polaroid picture will sometimes help to allay their fears. With the development of digital bereavement photography, it is becoming easier for nurses to offer the family quality photos of their infant. Most facilities have a digital camera and printer for such use. There are also Web sites where parents can obtain digital photography or have photographs enhanced, edited, or have effects added, such as selective coloring (McCartney, 2007).

CLINICAL TIP

A picture that appears distressing in color may be comforting in black-and-white. A close-up of the infant's hand or foot lying in the parent's hand may provide a loving memory. Use your creativity in taking bereavement pictures.

Postmortem Care

Properly preparing the infant for viewing and holding is an essential step in the process. Stillborn infants are often misshapen, and the skin can be discolored or in a state of maceration. **Maceration** is the process of tissue breakdown, which begins from the moment an undelivered infant dies. It is characterized by sloughing of the skin, which can help determine the interval between death and delivery of the infant; that is, the more sloughing, the greater length of time between the demise and delivery (Pauli, 2005). When bathing the infant for viewing, care should be taken to cause as little additional disruption to the skin as possible. A gloved hand is preferable to a washcloth for these infants. After bathing, the infant should be placed in a suitable-sized gown and then wrapped in a blanket. A hat can be applied to cover birth defects. This allows the parents an opportunity to view the infant before seeing the birth defect. Many parents will eventually remove the covering to inspect the infant; however, applying a covering allows them time to adjust to the appearance at their own pace. In cases of extreme maceration, the parents should be fully informed of the condition of the skin, so that they can decide for themselves if they want to see, hold, and/or fully uncover the infant. Couples will often look to assisting medical and nursing personnel for the "correct" attitude toward their stillborn infant. The nurse should carefully monitor personal reactions and display acceptance of the choices the parents make. For step-by-step postmortem care instructions, see Table 38-7.

In a compromised or dying infant, bathing should be done quickly, so that the infant can be returned to the parents as soon as possible. Some parents may wish to participate in the bath

Rights of Parents When a Baby Dies—Choices or Mandates?

TABLE 38-7 Postmortem Care

Document Time of Death per Physician
Gather Supplies per Hospital Protocol

Appropriate forms.

Bathing—2 basins, absorbent pads, diapers, clothing, washcloths, hat.

Memory kit—memory card with foot or handprint area, memory box.

Morgue kit—identification tags, pads for wrapping, paperwork.

Remove Tubes and Wires When Applicable

Cap and leave all indwelling tubes and catheters if autopsy is to be performed. Plug endotracheal tube (E.T.) with cotton ball and tape over opening to hold in place and prevent seepage.

Bathe and Dress Fetus/Infant

Offer parents opportunity to assist with bathing and dressing infant as appropriate (if infant is stillborn, skin maceration may be traumatic for parents).

With gloved hands, place infant in lukewarm basin of water.

Rinse if skin breakdown is present; if skin integrity is intact, rub gently with washcloth. Soap is optional; based also on integrity of skin.

Place fetus/infant in second basin of lukewarm water to rinse.

Gently pat dry. Do not use scented (especially baby products) lotions or powders.

If seepage present from nasal cavity, place petroleum jelly in nostrils.

Diaper and dress fetus/infant in outfit provided either by parents, hospital, or volunteer organization. Consider the use of a hat, particularly where deformity is present.

Take Pictures

Cover imperfections and deformities when applicable.

Use mementos in pictures when available.

Use soft, yet vibrant, colors in background or consider black and white photos.

Place fetus/infant in a flattering and comforting position (different for every infant).

Offer parents opportunity to participate in picture taking, but do not force the issue.

If Desired by Parents, Wrap in Warm Blanket and Present Infant for Holding

Prepare parents before holding fetus/infant by telling them what they will see, feel, and smell.

Offer a picture before holding.

Model normal nurturing behavior for parents.

Offer time alone with infant and check back frequently within previously specified time frame.

After Holding, Remove Clothing for Weight and Measurements, Footprints, Handprints, Memory Card, and Lock of Hair (When Applicable)

Prepare Fetus/Infant for Pathology/Morgue/Family Transport According to Hospital Protocol

For morgue care:

Complete all hospital paperwork.

Place infant in supine position on top of folded diapers and pad to maintain body position and prevent disfigurement.

Use neck and body rolls to help with alignment.

Wrap infant according to hospital protocol.

Take Memory Box and Bereavement Information to Parents

Memory box should include pictures, ID bracelet, memory card, other personal items, and bereavement clothes.

Bereavement information should include pamphlets on grief and loss as well as local and national resources for support and information.

Document the Events Leading Up to and Following the Death Including

Time and pronouncement of death with physician's name.

Placement of tubes and catheters.

Postmortem care.

Comfort measures and bereavement care provided to family.

Preparation and transport to morgue.

process or complete it themselves. Some parents will hold their infant for a short time before returning him or her to the nurse, whereas others will wish to spend a great deal of time with their infant. The nurse allows the infant to remain with the parents for as long as they desire.

CLINICAL JUDGMENT

Case Study: Lu Chen

Lu Chen, a 23-year-old G1 female of Asian heritage was admitted to the hospital 1 week ago for premature rupture of membranes and preterm labor. By dates, the fetus is 21 weeks gestation and nonviable at this point in time. Lu has been on strict bedrest and a medication regimen to halt her labor, but has developed a fever and nonreassuring fetal heart tones (FHT) and has been brought over to the labor and delivery unit for monitoring with the likelihood of imminent delivery. You have been assigned as Lu's nurse for your shift. In report, you are told that Lu is quiet and withdrawn. She answers questions with "yes" or "no," and does not elaborate. Her mother is in the room with her, but does not speak English. Lu is listed as married, but the father is not present. You are aware that the obstetrician has spoken with Lu regarding the impending delivery and the baby's incompatibility with life at the current gestational age. You do not know how much Lu understands of what she has been told and you are unsure what role, if any, her culture will play in her reaction to the loss of her baby.

The decision is made to stop the medications and let the labor progress. When you ask Lu if she would like you to call her husband to be with her, she says that he is overseas on business and cannot make it back in time. She says that her mother will be with her and that she will be fine.

The delivery takes place and you clean and pat dry the infant, and prepare for holding. You ask Lu if she would like to hold her baby, and she shakes her head no, not making eye contact. You are concerned that she may regret not holding her baby or taking pictures.

Critical Thinking

What might you say to Lu in order to assist her in emotionally preparing for the delivery of her infant?

What questions could you ask Lu that a culturally sensitive plan of care may have answered?

See www.nursing.pearsonhighered.com for possible responses.

Supporting Siblings and Extended Family Members

Some couples may want other family members, friends, or their other children to be with them in their experience, and possibly view and hold the infant. The nurse acts as an advocate to ensure that the family's wishes are respected. Siblings will respond according to their age and maturity level. Children younger than seven may not recognize that the death is permanent, whereas older children may respond with concern for the parents' well-being. It is normal for them to slightly regress in social and cognitive behaviors when under stress. Children should be included as much as desired by the parents and told the truth in a simple, honest, and age-appropriate manner, avoiding the use of euphemisms when describing death and the aftermath. A **euphemism** is a substituted word or expression with a more pleasant association than the one that, although more direct, is considered to be harsher (Corr et al., 2009). Children will need reassurance of two things: that they are still going to be taken care of and that nothing they did caused the event to happen. In facilities in which child life specialists are present, their help can be elicited to assist the family in preparing the children for the death and provide an outlet for the children during the event.

Extended family members, especially grandparents, are "doubly" grieving as they suffer through the pain their children are experiencing and the loss of their grandchild. They will have varied reactions, from the extreme of attempting to completely control the process for their child to a display of total passivity. Most reactions fall somewhere in the middle of the continuum. The nurse can help to validate the grandparents' grief by acknowledging the difficulty of their position and extending her support to them as well as to the parents. Even grandparents who are blaming, questioning, or demanding can be made a part of the team when approached in a nondefensive, nonjudgmental, and aid-enlisting manner.

Family support has been shown to be a major comfort to couples in families in which there is open communication and honest interaction. Less intense grief over time has been reported in families who are able to express their emotions with one another as compared with more stoic families. The nurse should provide every opportunity for family cohesion throughout the process, encouraging as much participation and interaction as desired by the couple.

Actualizing the Loss: Providing Memories

In a fetal demise, the nurse should remember that mementos are some of the few memories the parents have to provide them comfort after the death of their baby. Every effort should be made to offer as many quality mementos as possible, such as pictures and hand- or footprint molds and cards (Figure 38-5 ■). Most facilities prepare a remembrance box or package for the family to take home (Figure 38-6 ■). This typically consists of a photograph taken of the infant or the family, a card with the baby's footprints, a crib card, identification band, a lock of hair, and, possibly, a blanket or clothing worn by the infant. In the event that the couple decline the package, it is common for the hospital to retain these items for a specific period of time in case they change their minds.

> "Our night nurse, Cindy, encouraged us to take Gabriel's footprints before we went to sleep. She tenderly made several prints of his feet and his hands, and she helped us mix the plaster of Paris that we had brought along for a permanent imprint of his feet. While Mark held him, she carefully snipped a tiny lock of almost-black hair from the back of Gabriel's head.
>
> . . . So in the dim fluorescent light, I rearranged the pillows on my bed to make a place for him . . . My arm draped over his chest, my cheek touching his cool forehead, I fell asleep with my son for one last time."
>
> —Amy Kuebelbeck*

Providing Discharge Care

The family usually has three options open to them for disposition of the fetus or infant's body. The first is a traditional burial. Many funeral homes offer reduced fees for infant burial services. The family should contact the funeral home directly to make arrangements. Some families may wish to bury their infant on private land. This is state, county, and locally dictated and it is up to the family to ascertain any restrictive ordinances as to transportation and burial. Hospitals with comprehensive bereavement programs in place usually have access to this information. The second option is cremation at a funeral home. Families will need to decide what to do with the cremains. The third option, and not one generally recommended, is hospital disposition. **Hospital disposition** at most facilities is incineration at regular intervals, usually with other body parts, and the family does not have the option to obtain the ashes. Some institutions, especially private and/or religiously affiliated facilities, offer mass burial options for hospital disposition, but not many.

In the last decade or so, a few programs have been initiated that offer more individualized burial options for infants designated for hospital disposition. These programs are usually a coordinated effort between facilities within a specific area and one of the local funeral homes and cemeteries that serve their community. The program is usually offered at little or no charge to the family. Whatever option the family decides upon, the nurse should support their decision and assist them in any way possible to achieve their goal for disposition and/or funeral services.

After the birth, the couple can be given the option of an early discharge (as early as 6 to 8 hours after the birth). Facility protocol will dictate where mothers are transferred after a perinatal loss. Some hospitals have the woman remain on the labor and delivery unit, whereas others will give the mother the option of choosing a postpartum room or one on a medical unit. If the mother is transferred to a postpartum unit, care is given to put her in a room far away from other rooms and the newborn nursery. Again, it is imperative that all staff members, as well as student nurses, housekeeping, dietary, and the like be notified of the mother's status (refer to Figure 38-2).

Discharge focuses on the physical considerations and adaptation of the mother and emotional considerations of the couple. Postpartum directions for follow-up care should be provided. Written materials should be provided and a phone number for questions can be given. The woman should also be given information on her milk coming in and interventions to follow to decrease the discomfort associated with engorgement.

Additional information should be given on the mourning process (Figure 38-7 ■). The nurse can prepare the couple to return home by stressing that others may not know what to say, and that even loved ones may make inappropriate comments because they do not know how to respond to grief and loss. This can prepare the couple for the reactions of others. If there are siblings, each will usually progress through age-appropriate grieving. Provide the parents with information about normal grief reactions, both psychologic and physiologic. The couple should be given information regarding depression as a normal part of grieving. Couples may feel empty and lost and may experience physical symptoms such as sleep disturbances, weight loss or gain, listlessness, fatigue, hyperactivity, inability to concentrate, and a lack of motivation. The onset of the symptoms of depression often coincides with the time when other people have moved on and withdrawn support for the couple, making it harder for them to cope. The couple should be informed that depression following perinatal loss is normal and unless debilitating or prolonged need not be medicated or treated and will subside in time. If depression is prolonged, outside help should be sought. Additionally, as the mourning process ensues, families should be encouraged to implement cultural, religious, or social customs that will assist them in their grief. The nurse should advise the family that certain upcoming milestones, such as holidays, future birthdays, baby showers, Mother's Day, Father's Day, and other social events may trigger their grief. The family can better cope with these events if they are adequately prepared. Finally, the couple should be advised not to make any major life change decisions in the first year following the death, whenever possible. Making major life changes compounds grief reactions by adding other losses (such as moving away from the familiar) on top of the loss of infant, often resulting in complicated mourning.

When caring for a family suffering from a perinatal loss, it is important to remember that the nurse experiences many of the same grief reactions as the parents of a stillborn infant. It is important to have colleagues and family members available for counseling and support.

Following discharge, some families may need closure of the intrapartum event to continue their mourning process. A consultation can be scheduled with the practitioner who cared for them during the pregnancy and birth. Families may also wish to read the results of tests performed during the intrapartum period and the autopsy report. The couple should be provided with a copy of the medical record and encouraged to ask questions, express their feelings, and ask for clarification.

Families are routinely referred for counseling services after a perinatal loss has occurred. A counselor who specializes in perinatal issues can provide expertise and assist the couple in their grieving. Partners should be allowed to verbalize fears and

concerns about future pregnancies. When appropriate, referrals to genetic counselors, religious support persons, and social service agencies also should be provided.

Besides referral information, the parents should receive scheduled follow-up phone calls to assess the family's functioning and their progress with grief work, *if* they indicated the desire for follow-up contact. During these follow-up phone calls, pertinent information can be given and additional resources can be identified.

Perinatal Loss Resources

Referring the Family to Community Services

Although most facilities have an established protocol for families experiencing perinatal loss, programs that are more comprehensive are being established in communities to provide a systematic intervention program to assist these families. Community support groups that focus on perinatal loss can provide an important support network and resources. Specialized groups, such as those focused on early pregnancy loss, stillbirth, and perinatal loss associated with specific congenital anomalies, allow families the opportunity to interact with peers who have lost infants under similar circumstances. The nurse provides the group name, contact person (if possible), and phone number. Bereavement resources can be offered that provide a list of relevant articles and books on death, dying, and grieving the loss of an infant. Information should be provided on supportive organizations such as Share Pregnancy and Infant Loss Support, RTS Bereavement Services, Centering Corporation, and Compassionate Friends.

Internet technology has allowed large numbers of individuals to share resources and information and participate in online support groups. Internet resources can be effective for all families and may be the only resources available for families in rural underserved areas. A study by Capitulo (2004) found that online perinatal loss support groups were "cultures," in that they had distinct beliefs, behaviors, norms, and attitudes that set a pattern of behavior for members of the online community. They were very helpful in allowing mothers to interact with other mothers in similar circumstances.

Perinatal Hospice

Specialized hospice programs are another community resource that assists grieving families. **Perinatal hospice** offers a compassionate, structured program providing a context in which parents can find meaning in the intimate experience of the life and death of their child. In perinatal hospice programs, parents whose fetus has a known lethal congenital anomaly, are given the opportunity to explore options, such as elective termination or waiting for the onset of spontaneous labor or a medically indicated induced labor. For families wishing to continue their pregnancies, the program typically assigns a multidisciplinary team that provides compassionate care, ongoing counseling, referral to support groups, and spiritual guidance (Munson & Leuthner, 2007). Perinatal hospice programs have sprung up in over 40 hospitals in the country, sometimes by request of genetic clinicians who, having given parents devastating news, found themselves with nowhere to refer the parents for assistance (Roush, Sullivan, Cooper, et al., 2007). These programs offer parents much needed support and guidance through the entire process of the pregnancy, birth, discharge, and/or death of the fetus or infant.

Application: Pregnancy After Miscarriage

According to Suzanne Engelder, of the St. Joseph Perinatal Comfort Care program in Orange, California:

> "Regarding the future of perinatal hospice. . . . There has been tremendous growth over the past 4 years. More and more hospitals are looking at providing this special care. I think what is unique about our program (and a few others across the country) is that we are a collaborative program between hospice (outpatient) and hospital (inpatient). Most perinatal hospice care is being provided in the NICU setting and it really is more palliative care in the NICU versus hospice care which focuses on care and support before the birth/death to prepare and educate parents/families. What I would like to see is more hospitals collaborating with hospices to provide care before and after. Another issue is reimbursement. Currently this is a non-reimbursable service. When adult hospice first came to the U.S. in the 1970s, it was run by volunteers and there was no reimbursement for it. In 1983, Medicare made it a benefit. My hope is that perinatal hospice will follow the same path—that insurance companies will see the benefit for the patient and family and be willing to pay for the care. The care provided on the front end saves resources at the time of birth/death and the back end (bereavement)."

The strength and success of these programs are a testament to the progress that has been made in bereavement care in the last decade. The challenge ahead is to move these programs into more awareness and ensure that healthcare providers are offered education to assist them in recognition of the need for these services.

Care of the Couple Who Has Experienced Loss in a Previous Pregnancy

A couple who has had a previous perinatal loss typically enters a subsequent pregnancy with conflicting feelings and may experience ambivalence, fear, and anxiety (Callister, 2006; Côté-Arsenault & Donato, 2007; DeBackere, Hill, & Kavanaugh, 2008). Many times, their experience is relived when another pregnancy occurs. Some couples conceive soon after a loss, whereas others wait years. Some couples enter a subsequent pregnancy with grief work largely completed, whereas others are still experiencing unresolved grief.

The nurse caring for a couple who has had a previous loss needs to be kind, compassionate, and patient. Couples need specific information and clear explanations of all prenatal information. Referrals to a genetic counselor should be made when appropriate (Barr, 2006). Some couples may wish to have a consultation with a perinatologist. If unresolved grief issues are present or the family experiences extreme anxiety, counseling may be beneficial.

Interventions to decrease anxiety can help the couple tremendously. At the first visit, an early ultrasound can be performed to verify the presence of the fetal heartbeat. In early pregnancy, women may be fearful when first-trimester pregnancy symptoms begin to resolve. It may be helpful for these women to come in for weekly visits for a period of time sim-

RESEARCH EVIDENCE IN PRACTICE

Pregnancy After a Perinatal Loss

CLINICAL QUESTION

How can families be supported through a subsequent pregnancy after a perinatal loss?

RESEARCH EVIDENCE

One of the most difficult situations in obstetric nursing is helping a family deal with the death of a fetus or baby. The grief process can be severe and enduring. Although one might believe a subsequent pregnancy would alleviate feelings of loss, research shows that these feelings do not disappear when the family becomes pregnant again. Indeed, some research shows that the grief from the previous perinatal loss may extend and impact the subsequent pregnancy. Parents may question whether they will be capable of having a normal pregnancy and carrying a baby to term.

Several studies have focused on the impact of a perinatal loss on subsequent pregnancies. One integrative review summarized the findings from multiple quantitative and qualitative studies. Responses to a subsequent pregnancy included anxiety that was present for both parents, but was higher for women than their partners. The timing of the most severe anxiety was linked to the timing of the fetal loss. In one study, anxiety decreased as the pregnancy advanced.

Depressive symptoms were commonly reported in women who were pregnant but had experienced a previous perinatal loss. These symptoms were higher for women than for men. As a contrast with anxiety, depressive symptoms worsened as the pregnancy progressed and appear to be greater for women who conceive less than a year after their perinatal loss.

Studies did not reveal a clear relationship between perinatal loss and attachment to the subsequent fetus. Findings were conflicting in that some showed decreased prenatal attachments, while other, more controlled, studies reported that prenatal attachment may be delayed to the third trimester but not absent by the time of birth.

The themes from these studies show parents who are trying to balance being hopeful while worried about a subsequent perinatal loss. These are complex emotions that parents may not be willing to share openly with a healthcare provider. Nursing interventions that were found to be helpful were conducting an evaluation of emotional health, encouraging parents to talk and voice their concerns, tailoring childbirth education for expectant parents who have had a previous loss, and encouraging early attachment behaviors.

WHAT QUESTIONS REMAIN UNANSWERED?

More study is needed to determine the effect of perinatal loss on subsequent fetal and infant attachment. How can the nurse encourage fetal and infant attachment when a previous perinatal loss has occurred?

WHAT IS BEST PRACTICE?

Parents with a history of perinatal loss should be encouraged to talk about their losses and voice their concerns. Prenatal education should be modified for these parents to address grief, manage anxiety, and facilitate communication with healthcare providers. Mothers in particular should be assessed for signs of anxiety and depression throughout the pregnancy.

CRITICAL THINKING

How can traditional prenatal education be adapted for parents with a previous perinatal loss?

References

ply to hear the fetal heartbeat. This intervention may continue to be helpful until the woman begins to feel fetal movement. Throughout the pregnancy, the office or clinic nurse can play a key role by providing reassurance and answering questions that the woman may have.

Women with a previous loss typically receive additional antepartum testing throughout the pregnancy. Ultrasounds can be used to provide reassurance and assess fetal growth and development, placental functioning, and cord variations. Nonstress testing and biophysical profiles can be performed weekly after 32 weeks to ensure fetal well-being. Fetal kick counts should be initiated at 28 weeks and continue until the birth occurs. Women with a previous loss should be delivered at their expected date of birth or when the pregnancy is at term and should not go over their due date, because placental functioning can decline in postdate pregnancies.

Evaluation

Caring for a family experiencing perinatal loss is a challenging, yet rewarding, opportunity for the nurse who offers his or her humanity, concern, and acceptance. There is nothing quite like helping a family through one of the most difficult events of their lives. The reward is often greater for the giver than for those who are receiving, because the important life lessons learned and the sense of accomplishment achieved when reaching out to others in need is rarely rivaled. Nurses should remember to process their own grief reactions so that they remain healthy responders for the next family in need.

Expected outcomes of nursing care for the family experiencing perinatal loss include the following:

- Family members feel free to express their feelings about the death of their baby if they desire to do so.
- Family members participate in decision making regarding preferences for the labor, birth, and the immediate postpartum period.
- Family members participate in the decision of whether to see their baby and other decisions about the baby.
- The family has resources available for continued support.
- Family members know the community resources available and have names and phone numbers to use if they choose.

Nursing care of a family experiencing perinatal loss is further described in the following Nursing Care Plan.

Case Study: Family with Perinatal Loss

NURSING CARE PLAN For a Family Experiencing Perinatal Loss

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Compromised Family Coping related to perinatal loss as evidenced by crying/sadness, irritability/anger, guilt responses, and/or fear **Goal:** The patient will verbalize thoughts and feelings associated with the loss, and understand the factual events surrounding the loss. The patient begins to form a trust relationship with the nurse and freely asks for and accepts support provided by nursing staff.	
■ Normalize the experience by assuring parents that there is no right or wrong way to express grief.	■ Grief reactions encompass a broad spectrum of thoughts and emotions. Providing a nonjudgmental, supportive environment validates the grief response, thereby establishing a trust relationship, which helps to facilitate a healthy mourning process.
■ Crying. Offer tissues while allowing free expression of emotion.	■ Crying is a normal reaction to the loss event and offering tissues is a tangible form of acceptance.
■ Anger. Avoid defensiveness, state the obvious, and enlist the parent's assistance in exploring possible sources of, and solutions to, their anger.	■ Anger as a part of the grief response usually stems from frustration at the circumstances and should not be taken personally. Allowing for the free expression of anger, as well as remaining neutral in responses, will help to defuse the situation. Utilizing a team approach will assist the patient in viewing hospital personnel as partners in care, rather than adversaries.
■ Guilt responses. Reframe the event in a reality-based forum, reassuring the parents that they did nothing to precipitate the loss.	■ Guilt is a predominant feature of grief following loss, especially in parents experiencing the death of an infant. Reality testing, a companion of factual information versus the parents' perceptions of culpability, assists them in coming to the conclusion that they did the best they could in the circumstance.
■ Fear. Provide honest, simple explanations of what to expect before, during, and after the loss event.	■ Families can cope with extreme situations when they are properly informed in an honest and forthright manner. Maintaining a close presence while providing factual information will help alleviate feelings of fear and isolation. Offering simple choices allows patients to maintain a semblance of control over their circumstances.
EXPECTED OUTCOMES:	The patient and family acknowledge the loss as evidenced by verbalizing an understanding of the factual events surrounding the loss and openly expressing thoughts and feelings regarding the loss in a safe and constructive manner. The patient and family begin to form a trust relationship as evidenced by freely asking for and accepting support provided by nursing staff, and relating to the nurse in an environment of acceptance.
2. Nursing Diagnosis: Interrupted Family Processes related to sudden, unexpected crisis of perinatal loss **Goal:** The patient and family are able to maintain family cohesion necessary for returning to homeostasis.	
■ Gather information regarding the family and the surrounding loss event before initial interaction.	■ Effective intervention requires an extensive knowledge of the situation at hand. Failure to gather essential facts can precipitate a negative interaction with the family, leading to a breakdown in communication.
■ Determine the extent of the family's knowledge regarding the situation before initial interaction.	■ Effective crisis intervention always begins with the point of the family's knowledge and bridges from what they know to what you need them to know. Presenting the facts in an orderly fashion with increasing detail will help the family process difficult information.
■ Assess the family's internal resources necessary for maintaining family cohesion by active listening and asking open-ended questions regarding normal coping styles.	■ Asking open-ended questions will help to identify the family's resources for coping. Identifying the family's internal resources allows the nurse to utilize the family's unique strengths and normal coping mechanisms in dealing with crisis and loss. This will help them regain equilibrium as a family unit.

NURSING CARE PLAN For a Family Experiencing Perinatal Loss continued

INTERVENTION	RATIONALE
■ Mobilize family and hospital support systems.	■ The family support system is preferable because of the comfort factor associated with familiarity and the consistency of long-term support. The hospital support system is supplementary to the family support system and can provide additional resources and support for individual family members, thereby strengthening the family unit.

EXPECTED OUTCOMES: The patient and family maintain the cohesion necessary for returning to homeostasis as evidenced by openly interacting, supporting, and communicating needs within the family and using family, hospital, and community support systems as needed.

FOCUS YOUR STUDY

- Perinatal loss poses a major nursing challenge to provide support and care for the parents.
- Perinatal loss is a tragic and often traumatic event in the life of most families experiencing it.
- Fetal death after 20 weeks accounts for 60% of all fetal deaths per year, with 50% of those deaths occurring before 28 weeks' gestation.
- Bereavement is the *event* of the loss, grief is the *reaction* to that loss, and mourning is the *process* by which we incorporate the loss into our lives with individual, cultural, religious, and social norms.
- Up to 25% of women will need professional help to facilitate their mourning process following the death of their infant.
- Attachment theory with regard to perinatal loss is based upon the premise that human beings are biologically predisposed to bond with emotionally significant persons in their lives and the grief response is a state of separation anxiety brought on by the disruption in the attachment bond.
- For mothers, there are nine events that are important to the formation of attachment to her infant. They are (1) planning the pregnancy, (2) confirming the pregnancy, (3) accepting the pregnancy, (4) feeling fetal movement, (5) accepting the fetus as an individual, (6) giving birth, (7) seeing the baby, (8) touching the baby, and (9) giving care to the baby.
- Meaning reconstruction focuses on redefining ourselves and how we interact with the world after a significant loss. The goal of recovery, as related to meaning reconstruction, is a positive change in self-identity by assigning the loss a meaning, thereby allowing the individual to assimilate the loss into her or his world.
- There are many normal physical, cognitive, emotional, behavioral, and spiritual early responses to loss. The recognition of normal responses helps to identify the presence of abnormal or exaggerated responses.
- Many factors will influence a couple's response to perinatal loss, including individual and family personality traits, as well as social, cultural, and religious customs.
- Cessation of fetal movement reported by the mother to the nurse is frequently the first indication of fetal death. The nurse continues one-on-one care with the family, providing both physical and emotional support throughout this crucial period.
- The nurse can facilitate a healthy mourning process for the family by using active listening techniques and avoiding the use of clichés. Sitting in silence with a family is often the most helpful form of intervention available.
- Traditionally, it was believed that early and intense grieving was necessary for healing, but recent studies show that many people are naturally resilient and will not necessarily grieve initially or intensely.
- The caring theory places the emphasis of care on the attitude adopted by the nurse toward the grieving family as paramount to successful intervention and includes knowing, doing for, enabling, and maintaining belief.

- The responding model describes 10 behaviors and actions necessary for effective interaction with the grieving family and includes recognition of the loss, emotional availability, spiritual and cultural accommodation, physical presence, open communication, normalization of grief reactions, decision-making assistance, interdisciplinary involvement, nonjudgmental attitude, and genuine caring.
- Upon arrival to the facility, the nurse should make introductions, acknowledge the loss, and establish the beginnings of a trust relationship with the family.
- The nurse functions as advocate for the family in organizing interdisciplinary involvement, maintaining continuity of care, offering the opportunity for open communication, and ensuring that the family's wishes regarding their loss experience are honored.
- Couples experiencing perinatal loss should be offered the opportunity to participate in postmortem care and to view, hold, and name their baby. In the event a couple declines the opportunity, the nurse should assess for fear of the unknown as a motivating factor and take steps to alleviate that fear. The couple should never be coerced into viewing and holding their infant if they choose not to, and the nurse should display a nonjudgmental, accepting attitude regardless of the decision made by the couple.
- Siblings and extended family members should be included in the plan of care to whatever extent the couple wishes. Children should be given information in an honest and age-appropriate manner, and grandparents should be recognized for the "double" grief they are experiencing through the pain of their child and death of their grandchild.
- Mementos are important links for the family to their deceased infant. A memory box should be offered with as many personal items of the infant as possible. Hand- and/or footprint cards are especially desired items.
- Follow-up care should include bereavement materials and community support information as well as a telephone call to assess the family's well-being and provide any further desired information.
- Couples experiencing pregnancy following a loss can be expected to have higher levels of fear and anxiety and will need to be treated with care and concern. Information may need to be repeated and details of time lines provided to raise the comfort level of the couple.

CRITICAL THINKING IN ACTION

Marguerite, a 25-year-old married woman, is admitted for delivery of a stillborn baby girl. Through tears, Marguerite shares that she has named the baby, Alicia, after her grandmother. She has already decorated the nursery with the many gifts she received at her baby shower. Marguerite apologizes for "crying so much" and frequently expresses a fear that her husband, John, may blame her for Alicia's death because she worked until the time of the final ultrasound. She wonders aloud if he would be right. She communicates a desire to see and hold Alicia, but is very fearful of how the baby will look and whether people will think that she is morbid for wanting to hold a dead baby. Marguerite apologizes again for crying and shares that she does not know who else to talk to because no one seems to understand what she is going through.

1. What should the nurse helping families through the crisis of perinatal loss know about grief in general?
2. What should the nurse know about the unique nature of perinatal loss?
3. What types of nursing behaviors will facilitate the family's mourning process?

See www.nursing.pearsonhighered.com for possible responses.

CHAPTER 39

The Postpartum Family at Risk

We are surviving. Just. Why don't they give the Croix de Guerre to people who can go without more than 2 hours total daily sleep for 5 weeks? I thought babies ate at 6–10–2–6–10–2—mine does. He also eats at 5–7–9–11 and 4–8–12. I am getting rather used to going around with my breasts hanging out. They are either drying from the last feed or getting ready for the next one. But the love—I never knew, never imagined that I would love him like this. This incredible feeling of boundless, endless love—a wish to protect his innocence from ever being hurt or wounded or scratched. And that awful, horrible, mad feeling in the first week that you'll never be able to keep anything so precious and so vulnerable alive.

—The Boston Women's Health Collective, *The New Our Bodies, Ourselves*

LEARNING OUTCOMES

1. Identify the causes of and appropriate nursing interventions for early and late hemorrhage during the postpartum period.
2. Develop a nursing care plan that reflects knowledge of etiology, pathophysiology, current clinical therapy, nursing and preventive management for the woman experiencing postpartum hemorrhage, reproductive tract infection, urinary tract infection, lactation mastitis, thromboembolic disease, or a postpartum psychiatric disorder.
3. Explain how to evaluate the mother's knowledge of health promotion measures.
4. Delineate signs of complications to be reported to the primary care provider and measures that can be taken to prevent recurrence of complications.
5. Identify ways to provide continuity of nursing care for women with postpartum complications in the community setting.

KEY TERMS

Adjustment reaction with depressed mood *1141*
Early (primary) postpartum hemorrhage *1115*
Late (secondary) postpartum hemorrhage *1115*
Mastitis *1131*
Pelvic cellulitis (parametritis) *1126*
Peritonitis *1124*
Postpartum blues *1141*
Postpartum depression (PPD) *1141*
Postpartum endometritis (metritis) *1125*
Postpartum major mood disorder *1141*
Postpartum psychosis *1143*
Post-traumatic stress disorder (PTSD) *1142*
Puerperal infection *1124*
Puerperal morbidity *1124*
Subinvolution *1120*
Thrombophlebitis *1134*
Uterine atony *1116*

The postpartum period is typically envisioned as a smooth, uneventful time, somewhat anticlimactic, that follows the anticipation of pregnancy and the excitement and work of labor and birth. Often it is, despite the challenges of new parenthood and integration of a new person into the family. Short maternity hospitalization—1.5 days after vaginal childbirth and 2.5 days following cesarean childbirth—may wrongly reinforce the notion that the postpartum recovery is speedy and uncomplicated. Early postpartum discharge challenges the nurse to impart anticipatory information about normal postpartum recovery and self-care for the new mother and care of the newborn. Other issues that make identification difficult include at risk families, limited resources (including transportation), attitudes toward the pregnancy and adolescent pregnancies, and overall access to care. It is equally important for the nurse to be aware of physical or emotional complications that may develop during the postpartum period, and to teach the family the signs of such complications; findings to report to the physician or certified nurse-midwife (CNM); and preventive measures, if available.

Written instructions to supplement any discussion will be of great value to the family in the early weeks at home with a newborn, when life can be chaotic and verbal instructions may be forgotten. The family should have telephone numbers for postpartum follow-up services and other resources for getting answers to questions. By communicating an attitude of willingness to answer questions and to listen to concerns, the nurse enhances the family's comfort in making calls later for what they might otherwise perceive as "too trivial to bother someone about."

When a telephone follow-up or an examination at the home visit, where available, provides evidence of a developing complication, the nurse shares these findings or impressions with the woman, and they mutually plan an appropriate next step. In the case of telephone follow-up, the nurse usually counsels the woman to notify her physician or CNM, and is prepared to schedule an appointment immediately if risk assessment indicates. The nurse who identifies a complication at the home visit will need to communicate the clinical findings to the physician or CNM and document them and any interventions for the permanent record. See chapter 37 ∞ for a more detailed discussion of home care for the postpartum family.

Complications, by their very nature, suggest the need for immediate collaborative management and are inherently stressful. Postpartum complications sometimes necessitate readmission of the woman to the hospital, thereby disrupting the family and adding concerns not only about her health but the way in which infant care will be managed. The most common complications of the postpartum period are hemorrhage, infection, thromboembolic disease, and postpartum psychiatric disorders. These are the major focus of this chapter.

Care of the Woman with Postpartum Hemorrhage

Hemorrhage in the postpartum period is described as either early (immediate or primary) or late (delayed or secondary) postpartum hemorrhage. **Early (primary) postpartum hemorrhage** occurs in the first 24 hours after childbirth and is the more common of the two. **Late (secondary) postpartum hemorrhage** occurs from 24 hours to 6 weeks after birth. Classifying hemorrhage as early or late can be helpful in considering the cause; issues of uterine tone and reproductive tract trauma are more common causes of early hemorrhage while retained placental tissue is more likely associated with later problems. Postpartum hemorrhage (PPH) continues to be a cause of significant maternal mortality and morbidity and accounts for approximately one sixth of maternal deaths attributable to pregnancy in the United States (Poggi, 2007). Worldwide, it is estimated that 140,000 women die from postpartum hemorrhage, about one every four minutes (Oyelese & Ananth, 2010).

The traditional definition of postpartum hemorrhage has been a blood loss of greater than 500 ml following childbirth. This definition is being questioned, because careful quantification indicates that the average blood loss in a normal vaginal birth is actually greater than 500 ml, the average blood loss after cesarean childbirth exceeds 1000 ml, and the average blood loss is more than 1500 ml during repeat cesarean birth (Oyelese & Ananth, 2010). Clinical estimates tend to underestimate actual blood loss by up to 50%. Regardless of clinical experience, healthcare providers tended to overestimate low volumes of loss and significantly underestimate excessive blood loss.

Clinical estimation of blood loss at childbirth may be difficult because blood mixes with amniotic fluid and is obscured as it oozes onto sterile drapes or is sponged away. As the amount of blood loss increases, as in the case of hemorrhage, estimates are likely to be even less accurate than those associated with normal childbirth. Moreover, postpartum hemorrhage may occur intra-abdominally, into the broad ligament, or into hematomas arising from genital tract trauma, wherein the blood loss is concealed. Given the increased blood volume of pregnancy, the clinical signs of hemorrhage—such as decreased blood pressure (BP), increasing pulse, widening pulse pressure, thirst, restlessness, and decreasing urinary output—do not appear until as much as 1800 ml to 2100 ml of blood has been lost, shortly before the woman becomes hemodynamically unstable (Gilstrap & Yeomans, 2008).

To meet the standard of care in cases of postpartum hemorrhage, systems are needed in every obstetrical setting that enable nurses to respond quickly to implement certain actions independently based on evidence-based protocols (Simpson, 2010). In some settings with significant numbers of childbirths, rapid response teams have been initiated for obstetric (OB) emergencies such as postpartum hemorrhage, similar to a call for coding someone experiencing a cardiac arrest. To minimize the "cry wolf" phenomenon, such measures require training and an attitude that these are "our" (the hospital's) patients (Catanzarite, Almyrde, & Bombard, 2007).

Early (Primary) Postpartum Hemorrhage

At term, blood volume and cardiac output have increased so that 20% of cardiac output, or 600–800 ml per minute, perfuses the pregnant uterus, supporting the developing fetus. When the

placenta separates from the uterine wall, the many uterine vessels that have carried blood to and from the placenta are severed abruptly. The normal mechanism for hemostasis after expulsion of the placenta is contraction of the interlacing uterine muscles to occlude the open sinuses that previously brought blood into the placenta. Absence of prompt and sustained uterine contraction (uterine atony) can cause significant blood loss. Other causes of hemorrhage include laceration of the genital tract; episiotomy; retained placental fragments; vulvar, vaginal, or subperitoneal hematomas; uterine inversion; uterine rupture; problems of placental implantation; and coagulation disorders.

Uterine Atony

Uterine atony (relaxation of the uterus) is a common cause of early postpartum hemorrhage. As many as 1 in every 20 new mothers will experience some degree of uterine atony. Although uterine atony can occur after any childbirth, its contributing factors include the following (Cunningham et al., 2010):

- Overdistention of the uterus due to multiple gestation, polyhydramnios, or a large infant (macrosomia)
- Dysfunctional or prolonged labor, which indicates that the uterus is contracting abnormally
- Oxytocin augmentation or induction of labor
- Grandmultiparity, because stretched uterine musculature contracts less vigorously
- Use of anesthesia (especially halothane) or other drugs such as magnesium sulfate, calcium channel blockers such as nifedipine, or tocolytics like terbutaline (Brethine), any of which cause the uterus to relax
- Prolonged third stage of labor—more than 30 minutes
- Preeclampsia
- Asian or Hispanic heritage
- Operative birth (includes vacuum extraction or forceps-assisted births)
- Retained placental fragments
- Placenta previa

Hemorrhage from uterine atony may be slow and steady or sudden and massive. The blood may escape vaginally or collect in the uterus, evident as large clots. The uterine cavity may distend with up to 1000 ml or more of blood, while the perineal pad and linen protectors remain suspiciously dry. A treacherous feature of postpartum hemorrhage is that maternal vital signs may not change until significant blood loss has occurred because of the increased blood volume associated with pregnancy. Women with preeclampsia are an exception to this finding because they do not have the normal hypervolemia of pregnancy and cannot tolerate even normal postchildbirth blood loss (Gilstrap & Yeomans, 2008). Any anemia should be treated prior to labor. The nurse will assess the woman's beliefs about blood transfusion and document those findings in the record that follows her throughout her childbirth stay. Knowing whether or not the woman will willingly accept transfusions, if needed, is important to decision making about managing hemorrhage, although the woman will be questioned again about transfusion if such treatment seems warranted.

Ideally, postpartum hemorrhage is prevented, beginning with adequate prenatal care, good nutrition, avoidance of traumatic procedures, risk assessment, early recognition, and management of complications as they arise. Review of maternal records for risk factors will help nurses to plan assessment timelines to maximize early identification and management of excessive bleeding. *It is critical to remember that a woman with no identifiable risk factors may hemorrhage after childbirth as well.* The woman and her partner, sometimes other family members, are excited about the birth and wish to celebrate or to have some private time engaging with the newborn when he or she is appropriately warm and ready for an early visit. But postpartum women must be assessed at frequent intervals, especially in the initial hours after delivery of the placenta when most deaths from hemorrhage occur.

There is some evidence that active management of the third stage of labor through administration of an oxytocic after delivery, controlled traction on the umbilical cord, and uterine massage after birth could prevent half of the cases of postpartum hemorrhage (Oyelese & Ananth, 2010). Any woman at risk should be typed and cross-matched for blood transfusion. After expulsion of the placenta, the fundus is palpated to ensure that it is firmly contracted. If it is not firm, fundal massage is performed until the uterus contracts. Fundal massage is uncomfortable for the woman who has not received regional anesthesia; she will need an explanation for why this uncomfortable procedure is necessary and support as massage is initiated. A reminder to use the same breathing patterns for control of discomfort as she used in labor can serve in this situation as well. Clinical guidelines schedule vital signs and assessment of fundal contractility and lochia at regular intervals (see chapter 35 ∞ and chapter 36 ∞).

Clinical Therapy

If bleeding is excessive, venous access with large bore catheters (18 gauge), sometimes using two concurrent access sites, will be established and crystalloid solutions such as normal saline or Lactated Ringer's are begun to replace blood volume. When excessive bleeding continues despite external uterine massage, the obstetrician may elect to do a bimanual massage (Figure 39-1A ■). Bimanual massage compresses the body of the uterus from below while the abdominal hand massages the fundus from above.

If uterine massage is not effective, uterine stimulants (uterotonic agents) will be administered at a rapid infusion rate to contract the atonic musculature. Oxytocin, ergotamine, and prostaglandin are most often used. Misoprostol, best known for its use in labor induction and medical abortion, is being used to prevent and treat uterine atony after attempts to control bleeding with oxytocics. Table 39-1 summarizes critical nursing information about the use of uterine stimulants to control bleeding.

MANAGEMENT BY SELECTIVE ARTERIAL EMBOLIZATION

For the woman who had a vaginal delivery and unsuccessful tamponade effort to control postpartum bleeding, the next step is arterial embolization.The woman must be hemodynamically stable as the procedure itself takes approximately 30 minutes.

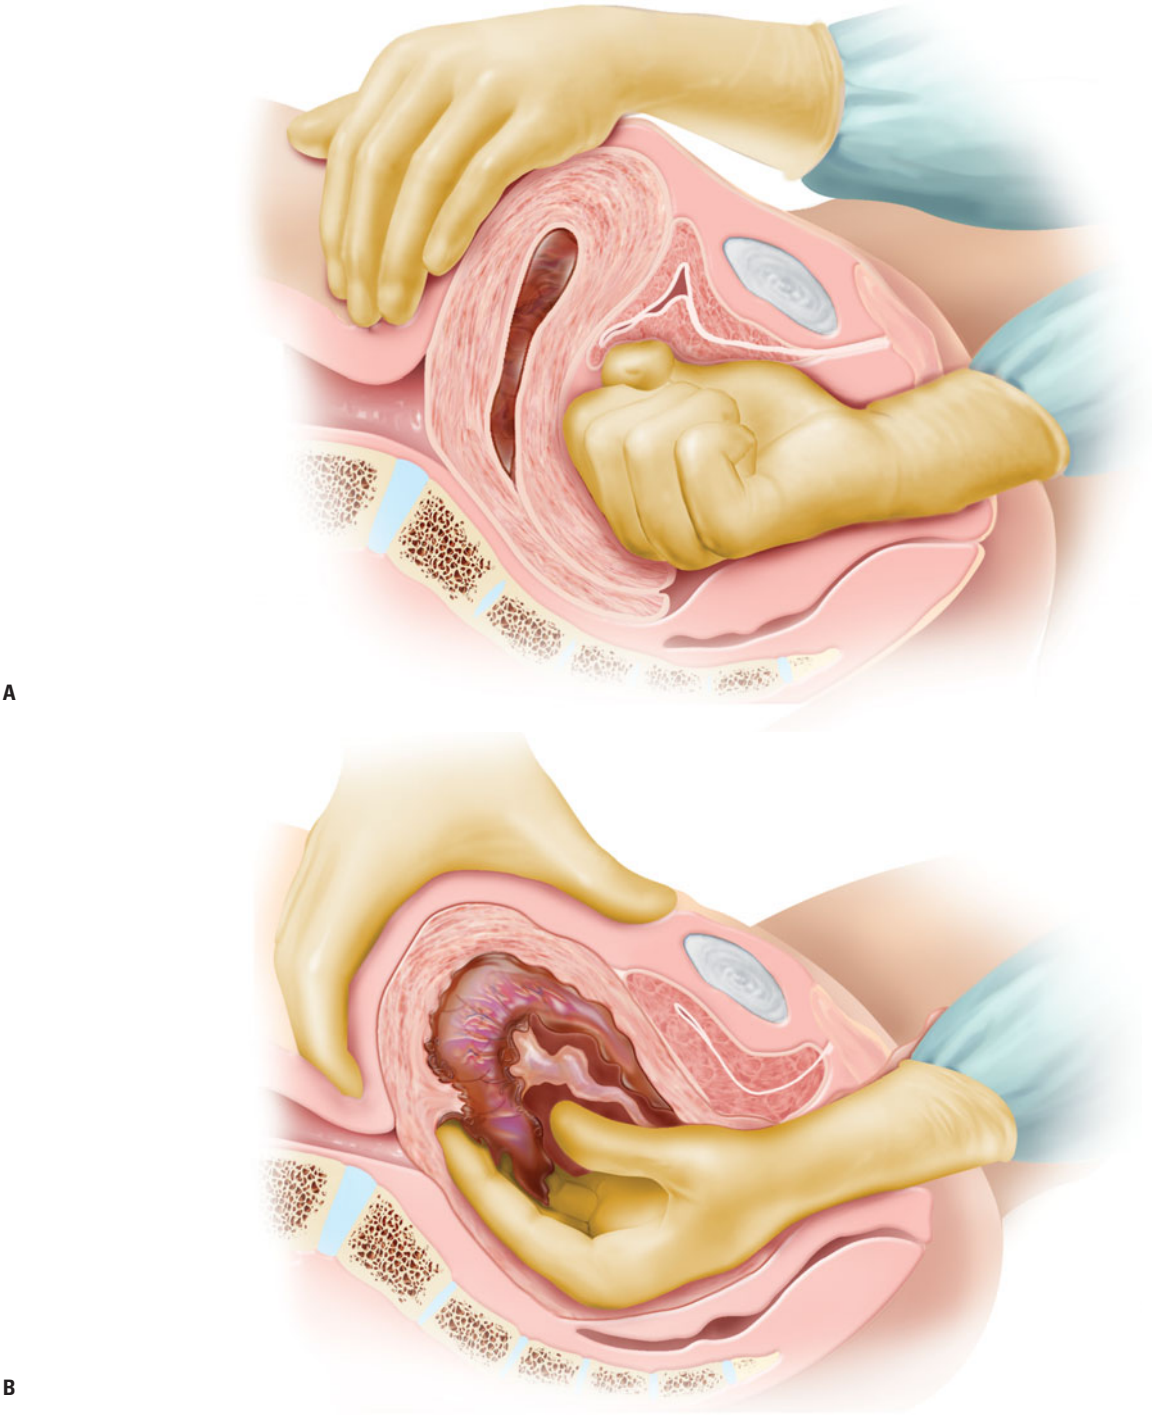

Figure 39-1 ■ A. Manual compression of the uterus and massage with the abdominal hand usually will effectively control hemorrhage from uterine atony. B. Manual removal of placenta. The fingers are alternately abducted, adducted, and advanced until the placenta is completely detached. Both procedures are performed only by the medical clinician.

Source: Adapted from Cunningham, F. G., MacDonald, P. C., & Gant, N. F. (Eds.). (1989). Williams obstetrics *(18th ed., pp. 417–418). Norwalk, CT: Appleton & Lange.*

A percutaneous catheter is inserted to embolize bleeding vessels using Gelfoam, glue, coils, or polyvinyl alcohol. Arterial embolization also can be used for bleeding that continues after hysterectomy or as an alternative to hysterectomy when the woman wishes to preserve fertility. Regular menstrual cycles follow and women have had successful subsequent pregnancies (Fiori et al., 2009).

SURGICAL MANAGEMENT OF POSTPARTUM HEMORRHAGE Surgical management depends on the clinical situation, institution, available personnel, and available equipment. Packing the uterine cavity tightly with 4-inch-wide sterile gauze provides time for blood and fluid replacement prior to laparotomy and time to provide prophylactic antibiotics. In some settings, the gauze is presoaked with 5000 units of thrombin diluted in 5 ml

TABLE 39-1 Uterine Stimulants Used to Prevent and Manage Uterine Atony

DRUG	DOSING INFORMATION	CONTRAINDICATIONS	EXPECTED EFFECTS	SIDE EFFECTS
Oxytocin (Pitocin, Syntocinon)	IV use: 10–40 units in 500–1000 crystalloid fluid at 50 milliunits/min administration rate. Onset: immediate. Duration: 1 hr. **IV bolus administration not recommended.** IM use: 10 units. Onset: 3–5 min. Duration: 2–3 hr.	None for use in postpartum hemorrhage. Avoid undiluted rapid IV infusion, which causes hypotension.	Rhythmic uterine contractions that help to prevent or reverse postpartum hemorrhage caused by uterine atony.	Uterine hyperstimulation, mild transient hypertension, water intoxication rare in postpartum use.
Methylergonovine maleate (Methergine)	IM use: 0.2 mg every 2–4 hr. Onset: 2–5 min. Duration: 3 hr (for 5 dose maximum). PO use: 0.2 mg every 4 hr (for 6 doses). Onset: 7 to 15 min. Duration: 3 hr (for 1 week). **IV administration not recommended—can cause dangerous hypertension and stroke.**	Women with labile or high blood pressure or known sensitivity to drug, cardiac disease, and Raynaud's disease. Use with caution during lactation.	Sustained uterine contractions that help to prevent or reverse postpartum hemorrhage caused by uterine atony; management of postpartal subinvolution.	Hypertension, dizziness, headache, flushing/hot flashes, tinnitus, nausea and vomiting, palpitations, chest pain. Overdose or hypersensitivity is recognized by seizures; tingling and numbness of fingers and toes.
Prostaglandin (PGF_{2a}, Carboprost tromethamine [Hemabate], Prostin/15M)	IM use: 0.25 mg repeated every 15–90 min, up to 8 doses max. Physician may elect to administer by direct intramyometrial injection.	Women with active cardiovascular, renal, liver disease, or asthma or with known hypersensitivity to drug.	Control of refractory cases of postpartum hemorrhage caused by uterine atony; generally used after failed attempts at control of hemorrhage with oxytocic agents.	Nausea, vomiting, diarrhea, headache, flushing, bradycardia, bronchospasm, wheezing, cough, chills, fever.
Dinoprostone Prostin E_2	Vaginal or rectal suppository 20 microgram every 2 hours. Stored in frozen form—must be thawed to room temperature.	Avoid if woman is hypotensive, or has asthma or acute inflammatory disease.	Stimulate uterine contractions	Fever is common and occurs within 15 to 45 min of insertion; bleeding, abdominal cramps, N/V.
Misoprostol (Cytotec)	800–1000 microgram rectally. Rapid effects, contractions within minutes.	History of allergies to prostaglandins.	Used to prevent and treat uterine atony after failed attempts to control bleeding with oxytocics.	Diarrhea, abdominal pain, headache

Implications for Nursing Management of the Postpartum Woman Receiving Uterine Stimulants

- Assess fundus for evidence of contraction and amount of uterine bleeding at least every 10–15 min for 1–2 hr after administration, then every 30–60 min until stable.
  Note: More frequent assessments are determined by the woman's condition or by orders of the physician or certified nurse-midwife (CNM).
- Weigh peripads or Chux dressing for objective estimate of blood loss.
- Monitor pulse and blood pressure every 15 min for at least 1 hr after administration, then every 30–60 min until stable. Often the early sign is a slightly increased heart rate. Assess blood loss by hematocrit and hemoglobin levels.
  Note: Remember that the physiologic changes of pregnancy increased the blood volume by 40% and the RBC volume by 30%. The woman will not show signs of severe hypovolemia until she has lost about 1/3 of her volume—1800 ml.
- Apply pulse oximeter and administer oxygen according to agency protocol.
- Note expected duration of action of drug being administered, and take care to recheck fundus at that time for adequate tone.
- When the drug is ineffective, the fundus remains atonic (boggy or uncontracted), and bleeding continues, massage the fundus. If massage fails to cause sustained contraction, consider the status of the urinary bladder. If uterine tone is not restored after the bladder is empty and fundal massage has been performed, notify the physician or CNM immediately.
- Monitor woman for signs of known side effects of the drug; report to physician or certified nurse-midwife if side effects occur.
  - Continuous electrocardiogram (EKG) monitoring may be indicated for hypotension, continuous bleeding, tachycardia, or shock.
  - Elevate the legs to a 20- to 30-degree angle to increase venous return.
- Remind the woman and her support person that uterine cramping is an expected result of these drugs and that medication is available for discomfort. Administer analgesic medications as needed for pain relief. Provide nonpharmacologic comfort measures. If analgesic medication ordered is insufficient for pain relief, notify the physician or CNM.
- Provide information to woman and family regarding importance of not smoking during Methergine administration (nicotine from cigarettes leads to constricted vessels and may lead to hypertension) and signs of toxicity.

When Prostaglandin Is Used

- Check temperature every 1–2 hr and/or after any chill. Administer antipyretic medication as ordered for prostaglandin-induced fever.
- Auscultate breath sounds frequently for signs of adverse respiratory effects.
- Assess for nausea, vomiting, and diarrhea. Administer antiemetic and antidiarrheal medications as ordered. (In some settings, women are premedicated with these drugs.)

of normal saline (Gilstrap & Yeomans, 2008). As uterine packing is no longer a favored way for providing uterine tamponade, some clinicians now use one or two Foley catheters or Sengstaken-Blakemore tubes with isotonic saline to provide pressure against the uterine walls. The tubes have open tips, which permit any continuous drainage from the uterus to be visualized even as pressure tamponade is controlling the bleeding. In addition, an SOS Bakri Balloon Tamponade made of silicone, which limits clot adhesion, can be inserted transvaginally past the cervical os with ultrasound guidance and can detect ongoing bleeding..

For non–life-threatening levels of hemorrhage, the uterine artery or internal iliac (hypogastric) artery may be surgically ligated to control bleeding, especially when excessive bleeding occurs during cesarean childbirth. In most cases regular menstrual cycles resume and successful pregnancy can be expected in the future. Several kinds of uterine compression suturing procedures are being investigated such as the B-Lynch compression (brace suture) procedure. When tied, the suture creates uterine compression to control bleeding associated with uterine atony and averting hysterectomy (Cunningham, 2010).

Peripartum hysterectomy provides definitive surgical treatment of uterine bleeding related to uterine atony and placenta accreta (Gilstrap & Yeoman, 2008). Because it ends childbearing for the woman, it is often considered a procedure of last resort. The new mother may experience emotional distress related to loss of fertility and need opportunities to discuss those feelings candidly with a caring professional.

Lacerations of the Genital Tract

Early postpartum hemorrhage also may be associated with lacerations of the perineum, vagina, or cervix. Several factors predispose women to higher risk of reproductive tract lacerations:

- Nulliparity
- Epidural anesthesia
- Precipitous childbirth (less than 3 hours)
- Macrosomia
- Forceps- or vacuum-assisted birth
- Use of oxytocin

Genital tract lacerations should be suspected when bright red vaginal bleeding persists in the presence of a firmly contracted uterus. The nurse who suspects a laceration should notify the clinician so that the laceration can be immediately sutured to control hemorrhage and repair the integrity of the reproductive tract (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 2007). The woman is moved to a delivery or surgical area for access to special lighting to facilitate treatment.

Episiotomies can be an underappreciated source of postpartal blood loss because of slow, steady bleeding, especially if it was done early in the birth process. The risk for bleeding is increased with mediolateral episiotomies. To fully assess the episiotomy site, the nurse must position the woman on her side.

Retained Placental Fragments

Retained placental fragments can be a cause of early postpartum hemorrhage; however, they generally are the most common cause of late hemorrhage. Retention of fragments is usually attributable to partial separation of the placenta during massage of the fundus before spontaneous placental separation, so this practice should be avoided.

Following birth, the placenta should always be inspected for intactness and evidence of missing fragments or cotyledons on the maternal side and for vessels that traverse to the edge of the placenta outward along the membranes of the fetal side. The latter finding may indicate succenturiate placenta and a retained lobe. Uterine exploration by the physician may be required at that time to remove missing fragments (see Figure 39-1B ■). This cause should be immediately suspected if bleeding persists and no lacerations are noted. Sonography may be used to diagnose retained placental fragments. Curettage, formerly a standard treatment, is now thought by some to traumatize the implantation site, thereby increasing bleeding and the potential for uterine adhesions. It may be necessitated by the degree of hemorrhage, however (Cunningham et al., 2010).

Vulvar, Vaginal, and Pelvic Hematomas

Hematomas occur as a result of injury to a blood vessel from birth trauma, often without noticeable trauma to the superficial tissue, or from inadequate hemostasis at the site of repair of an incision or laceration. The soft tissue in the area offers little resistance, and hematomas containing 250 to 500 ml of blood may develop rapidly. Hematomas may be vulvar (involving branches of the pudendal artery), vaginal (especially in the area of the ischial spines), vulvovaginal, or subperitoneal. The latter are rare but most dangerous because of the large amount of blood loss that can occur without clinical symptoms until the woman becomes hemodynamically unstable. Subperitoneal hematomas involve the uterine artery branches or vessels in the broad ligaments and require laparotomy for surgical correction.

Risk factors for hematomas include the following: preeclampsia, use of pudendal anesthesia, first full-term birth, precipitous labor, prolonged second stage of labor, macrosomia, forceps- or vacuum-assisted births, and history of vulvar varicosities. Hematomas less than 3 cm in size and nonexpanding are managed expectantly with ice packs and analgesia. Heat may be used after 24 hours to facilitate absorption of the blood within the hematoma. Small hematomas usually resolve over several days. For larger hematomas and those that expand, surgical management is usually required: The hematoma is evacuated using incision and drainage (I&D) (Gilstrap & Yeomans, 2008). The bleeding vessel is ligated, and the wound closed, with or without vaginal packing. A temporary indwelling urinary catheter may be necessary because voiding may be impossible with packing in place. Frequent assessment of the perineum of the woman under the effects of regional anesthesia is important since her pain sensation is disrupted. Once the effects of anesthesia have subsided, vaginal and vulvar hematomas are generally associated with perineal pain, often intense and sometimes disproportionate to the objective findings observed. The hematoma site is an ideal medium for proliferation of flora normally present in the genital tract. Consequently, broad-spectrum antibiotics are usually ordered prophylactically to prevent infection or abscess.

Uterine Inversion

Uterine inversion, a prolapse of the uterine fundus to or through the cervix so that the uterus is, in effect, turned inside out after birth, is a rare (the incidence is 1 in 2000 or more) but life-threatening cause of associated postpartal hemorrhage (Gilstrap & Yeomans, 2008). Although not always preventable, uterine inversion is often associated with these factors: fundal implantation or abnormal adherence of the placenta, weakness of the uterine musculature or other uterine abnormalities, protracted labor, uterine relaxation secondary to anesthesia or drugs such as magnesium sulfate, and excess traction on the umbilical cord or vigorous manual removal of the placenta. Most cases of uterine inversion are managed by immediate repositioning of the uterus within the pelvis by the physician.

Uterine Rupture

Spontaneous rupture of the uterus is rare in the United States but continues to be seen in developing countries where emergency surgery for obstructed labors may be less immediately accessible. The woman with a ruptured uterus will have acute, severe abdominal pain, with minimal to diffuse external bleeding. Concealed hemorrhage may occur in the abdominal cavity or broad ligaments, undetected until the woman becomes symptomatic from hypovolemic shock. Risk factors for uterine rupture include prior uterine surgery, including cesarean birth; fetal malpresentation; grandmultiparity; operative vaginal birth; and oxytocic induction of labor. With uterine rupture, immediate surgery is required with fluid and blood replacement as needed.

Coagulation Disorders (Coagulopathies)

Coagulopathies should be suspected when postpartal bleeding persists with no identifiable cause. A consumptive coagulopathy such as disseminated intravascular coagulation (DIC) may occur during pregnancy as a result of preeclampsia, amniotic fluid embolism, sepsis, abruptio placentae, or prolonged intrauterine fetal demise syndrome (Roberts & Funai, 2009). (See chapter 20 ∞.)

Late (Secondary) Postpartum Hemorrhage

Although early postpartum hemorrhage most often occurs within hours of birth, delayed hemorrhage occurs most often within 1 to 2 weeks after childbirth, most frequently as a result of **subinvolution** (failure to return to normal size) of the placental site or retention of placental tissue. Blood loss at this time may be excessive but rarely poses the same risk as that from immediate postpartum hemorrhage. Late postpartum hemorrhage is much less common but can be extremely stressful for the woman and her family who are at home by this time.

The site of placental implantation is always the last area of the uterus to regenerate after childbirth. In the case of subinvolution, adjacent endometrium and the decidua basalis fail to regenerate to cover the placental site. Deficiency of immunologic factors has been implicated as a cause. Faulty implantation in the less vascular lower uterine segment, retention of placental tissue, or infection may contribute to subinvolution. With subinvolution, the postpartum fundal height is greater than expected. In addition, lochia often fails to progress from rubra to serosa to alba normally. Lochia rubra that persists longer than 2 weeks postpartum is highly suggestive of subinvolution (Poggi, 2007). Some women report scant brown lochia or irregular heavy bleeding. Leukorrhea, backache, and foul-smelling lochia may occur if infection is a cause. There may be a history of heavy early postpartal bleeding or difficulty in expulsion of the placenta during the third stage of labor. When portions of the placenta have been retained in the uterus, bleeding continues because normal uterine contraction that constricts the bleeding site is prohibited. Presence of placental tissue within the uterus can be confirmed by pelvic ultrasonography.

Subinvolution is most commonly diagnosed during the routine postpartum examination at 4 to 6 weeks after childbirth. The woman may relate a history of irregular or excessive bleeding or describe the symptoms listed previously. An enlarged, softer-than-normal uterus, palpated bimanually, is an objective indication of subinvolution. Treatment includes oral administration of methylergonovine maleate (Methergine) 0.2 mg every 3 to 4 hours for 24 to 48 hours (see Table 39-1). When uterine infection is present, antibiotics also are administered. The woman is reevaluated in 2 weeks. If retained placenta is suspected or other treatment is ineffective, curettage may be indicated (Poggi, 2007).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Careful and ongoing assessment of the woman during labor and birth and evaluation of her prenatal history will help identify factors that put her at risk for postpartum hemorrhage. However, it is critical to remember that postpartum hemorrhage may occur without any risk factors, so that all women must be monitored. Regular and frequent assessment of fundal height and evidence of uterine tone or contractility will alert the nurse to the possible development or recurrence of hemorrhage. Monitoring the bladder for evidence of increasing distention, with immediate intervention can sometimes help to prevent excessive bleeding that occurs when a full bladder displaces the uterus and interferes with contractility. Assessment for bleeding can be done visually, by pad counts, or by weighing the perineal pads or other items that have absorbed blood.

For all complaints of perineal pain, the nurse should examine the perineal area for signs of hematomas: ecchymosis, edema, tenseness of tissue overlying the hematoma, a fluctuant mass bulging at the introitus, and extreme tenderness to palpation. Estimating the size on first assessment of the perineum enables the nurse to better identify increases in size and the potential blood loss. The nurse notifies the physician or certified nurse-midwife (CNM) if a hematoma is suspected. The nurse can decrease the risk of vulvar or vaginal hematoma by applying an ice pack to the woman's perineum during the first

Care Plan Activity: Postpartum Perineal Pain

hour after birth and intermittently thereafter for the next 8 to12 hours. If a small hematoma develops despite preventive measures, a sitz bath after the first 12 hours will aid fluid absorption once bleeding has stopped and will promote comfort, as will the judicious use of analgesic agents (see chapter 36 ∞). Close monitoring of the woman who has had excessive bleeding is important during sitz baths to ensure safety.

In cases of excess bleeding, nurses should be alert for signs of impending hypovolemic shock. Frequent noninvasive monitoring should continue: heart rate, blood pressure, auscultation of heart sounds and breath sounds, oxygen saturation, skin turgor, color, temperature, color and moisture of mucous membranes, capillary refill, level of consciousness, and urinary output, possible with Foley catheter/urometer and electrocardiogram (ECG) readings. Throughout the bleeding episode, assessment of color and amount of blood loss will be ongoing with pad counts or weighing to estimate loss. The nurse will note the odor of the drainage to enable early diagnosis of infection. The nurse will anticipate the addition of invasive monitoring for a more objective evaluation of status: central venous pressure (CVP) monitoring via a peripheral line and/or Swan-Ganz central line insertion for pulmonary artery wedge pressure monitoring, and arterial blood gases to ascertain acidosis and hypoxia. In some settings, the woman needing invasive hemodynamic monitoring may be transported to an intensive care unit.

Nursing diagnoses that may apply when a woman experiences postpartum hemorrhage include the following:

- ***Deficient Fluid Volume*** related to blood loss secondary to uterine atony, lacerations, hematomas, retained placental fragments, or coagulopathies
- ***Risk for Ineffective Peripheral Tissue Perfusion*** related to hypovolemia
- ***Risk for bleeding*** related to lack of information about signs of delayed postpartum hemorrhage
- ***Risk for Impaired Parenting*** related to separation from newborn, urgency of personal health status, and fatigue
- ***Risk for Infection*** related to surgical procedures, invasive procedures, anemia, and blood transfusions

Nursing Plan and Implementation

If the nurse detects a soft, boggy uterus, it is massaged until firm. If the uterus is not contracting well and appears larger than anticipated, the nurse may express clots during fundal massage. Once clots are removed, the uterus tends to contract more effectively. Overly aggressive massage should be avoided so as not to injure the vessels in the broad ligaments or cause reactive relaxation of the musculature.

If the woman seems to have a slow, steady, free flow of blood, the nurse begins weighing the perineal pads (1 ml = 1 g) and monitors the woman's vital signs at least every 15 minutes, more frequently if indicated (James, 2008). If the fundus is displaced upward or to one side because of a full bladder, the nurse encourages the woman to empty her bladder—or catheterizes her if she is unable to void—to allow for efficient uterine contractions.

CLINICAL TIP

A boggy uterus indicates that the uterus is not well contracted. This results in increased uterine bleeding which may remain in the uterus and form clots or may result in increased flow. To assess the amount of blood loss, you must first massage the uterus until it is firm and then express clots. Even though the woman may have a firm uterus, significant bleeding can occur from causes other than uterine atony. To accurately determine the amount of blood loss, it is not sufficient to assess only the peri-pad. You should also ask the woman to turn on her side so you can assess underneath her for pooling of blood.

When there are risk factors for postpartum hemorrhage or frequent fundal massage has been necessary to sustain uterine contractions, the nurse should maintain the vascular access (the IV line) initiated during labor in case additional fluid or blood becomes necessary. Sometimes physicians and CNMs write orders that specify "discontinue IV after present bottle." The astute postpartum nurse will assess the consistency of the fundus and the presence of normal versus excessive lochia before discontinuing the infusion. If the assessments are not reassuring, the nurse continues the IV and notifies the physician or CNM.

The nurse reviews these findings when available, compares them to the admission baseline, and notifies the physician or CNM if the hematocrit has decreased by 10 percentage points or more. In cases where there is risk of postpartum hemorrhage and blood has been cross-matched earlier, the nurse checks that blood is available in the blood bank. During bleeding episodes, it is important to appreciate that hemoglobin and hematocrit levels will not reflect the volume lost until after equilibration in 6–24 hours (Smith, 2008).

As the woman's blood volume becomes depleted, positioning her with her legs elevated to 30 degrees facilitates venous return and promotes oxygenation. Unlike the Trendelenberg position used in the past for those in shock, this position does not impede breathing or cardiac function and promotes cerebral circulation. Supplemental oxygen may be necessary to keep peripheral tissues oxygenated when blood is shunted to protect vital organs like the brain and kidneys.

Keeping the woman as comfortable as possible with perineal care and frequent changes of disposable pads is important. Frequent position changes will aid in comfort but cannot be allowed to compromise venous return or oxygenation. She will be kept NPO in case surgery is needed, so oral care is important for comfort. There are many interruptions when the patient is experiencing a complication, so the nurse will need to seek opportunities to promote rest whenever possible. Any intervention to help with maternal infant bonding in the interval of separation is of great value to the woman—photographs or videotapes of the newborn, direct reports from the nursery staff, and brief visits to the room if her condition allows. The father also can be encouraged to visit the newborn and bring information to the mother.

If assessment reveals that the woman's condition is deteriorating, the nurse anticipates that more intensive monitoring will be necessary. At times, this will translate to preparing the woman and her family for a transfer to an intensive care setting, helping them to understand the justification for this change, and

reassuring them about the continued level of quality care, despite leaving a now familiar environment. If the woman will remain on the obstetrical unit, the nurse will anticipate and request necessary resources and personnel to ensure the patient's safety and well-being. In urgent situations, such as escalating postpartum bleeding, it is easy for the woman and her family to feel as if they are the center of attention but not to understand what is happening—only that something is going "badly wrong." The need to provide them with ongoing information about her status and each procedure and its rationale in understandable terms is a critical dimension of quality nursing care. A calm competent approach by the nurse goes a long way to calming the woman and her family, as does offering them opportunities to verbalize their feelings and ask questions or seek clarification.

Clearly, the care of the woman experiencing postpartum hemorrhage depends on good nursing assessment and prompt reporting of nonreassuring findings to the physician. Direct treatment methods, however, require the collaboration of a physician and in some cases, radiography or surgical staff. The nurse becomes an important liaison between these departments, keeping the necessary individuals apprised of the woman's status. For example, if additional transfusions of whole blood or blood products are anticipated, it may be the nurse who keeps the hospital laboratory informed to facilitate timely response. Care may well include the preprocedural preparation of the woman for surgery or for procedures such as arterial embolization performed by a radiologist.

The nurse may assume a prominent role in preparing the woman for insertion of CVP or Swan Ganz catheters and in the administration of crystalloid fluids (normal saline and Lactated Ringer's solution) or of blood and blood products. With rapid attempts to replace depleted blood volume, the nurse must carefully monitor the woman for evidence of fluid overload. When blood products are transfused, watching for transfusion reactions and responding promptly according to hospital procedures becomes a nursing role. Typically, volume is replaced initially with rapid administration of crystalloid solutions, in a 3 ml solution per 1 ml of estimated blood lost ratio (Diepenbrock, 2008). Normal saline must be hung prior to administration of blood since dextrose causes hemolysis and Lactated Ringer's causes agglutination of cells. Once it is evident that fluid replacement alone is not adquate, red blood cells (RBCs) are often transfused to replace depleted oxygen-carrying red cells. If platelets decrease significantly, fresh frozen plasma may be added. Frequent laboratory testing of hemoglobin, hematocrit, platelets, and a coagulation panel are monitored. Table 39-2 provides basic information about blood products used with women experiencing PPH.

When blood loss is significant and vital signs become unstable, crystalloid and colloid fluid replacement can no longer compensate for the loss and transfusion of blood products becomes necessary (see Table 39-2). Initially, colloid and crystalloid solutions are administered to replace lost intravascular volume. Second, RBCs are given to restore oxygen carrying capacity, and then clotting factors and platelets are given to restore physiologic hemostasis (Burtelow et al., 2007). Whole blood is not used routinely; rather the specific components being depleted are replaced without the addition of unnecessary volume of whole blood (Diepenbrock, 2008). Women who require blood products may be concerned about the associated risks. They should receive assurance that follow-up care will monitor for untoward consequences of blood replacement. Adherence to strict clinical protocols while accessing blood products from the lab and administering blood products is imperative to maximize patient safety. More immediately evident transfusion reactions range from a nonhemolytic and self-limited febrile response to life-threatening hemolytic reactions with blood group incompatibility, often because of error. Nurses assess for any type of transfusion reaction and notify the physician immediately. In the case of the hemolytic reaction, the uninfused blood will be returned to the lab for reevaluation (Diepenbrock, 2008).

The nurse evaluates the woman for signs of anemia, such as fatigue, pallor, headache, thirst, and orthostatic changes in pulse or BP, and reviews the results of all hematocrit determinations. All medical interventions, IV infusions, blood transfusions, oxygen therapy, and medications such as uterine stimulants are monitored as necessary and evaluated for effectiveness. Urinary output should be monitored to determine adequacy of fluid replacement and renal perfusion, with amounts less than 30 ml per hour reported to the physician (James, 2008). Good hand washing using Standard Precautions throughout the hospitalization and emphasizing proper hand washing for home care, is important to minimize risk of postpartum infection.

TABLE 39-2 Blood Products for Managing Postpartum Hemorrhage (PPH)

BLOOD PRODUCT	USE IN PPH	VOLUME/UNIT	INFUSION INFORMATION
Cryoprecipitate	Corrects deficiencies of factor VIII, XIII, von Willebrand factor + fibrinogen.	40 ml	Increases fibrinogen levels 10 mg/dl/ per unit transfused.
Fresh Frozen Plasma	Contains increased Factor V, VIII, and fibrinogen, and antithrombin III	200–250 ml	Thawed for use. Must use within 24 hours of thaw. Infuse with blood filter or component filter. May give at 200 ml/hour unless flluid overload.
Packed Red Blood Cells	Contains RBCs, WBCs, and plasma Increases oxygen carrying capacity of blood without adding volume—used for acute blood loss.	250 ml	Filter required for administration. Infusion rate <4 hours/unit. Expected to increase hemoglobin by 1 gram/dl and hematrocit by 3% per unit transfused.
Platelets	Controls or prevents blood loss associated with deficiency in platelets and for prophylactic use for those with platelet counts <10,000.	50–70 ml (taken from 1 unit of blood)	Give within 4 hours of preparation. Use component filter for administration. Increases platelets by 5000–10,000^3 per unit transfused.

Source: Data from Diepenbrock, N. H. (2008). Quick reference to critical care. *Philadelphia, PA: Lippincott Williams & Wilkins.*

The nurse also helps the woman plan activities so that adequate rest is possible.The woman who is experiencing anemia and fatigue may need assistance with self-care and progressive ambulation for several days. When she is able to be out of bed to shower, use of a shower chair permits independence while providing a measure of safety should the woman experience weakness or dizziness. The emergency call light should be easily accessible whenever nurses have left the bedside, even temporarily.

Once her condition has stabilized somewhat, the mother may find it difficult to care for her baby because of the fatigue associated with blood loss. The mother may require additional assistance in caring for her infant. If she has IV lines in place, even carrying the newborn may be awkward. For the mother who feels compelled to do as much as possible, the nurse may also need to "give permission" to the mother to return her infant to the nursery so she can have adequate periods of uninterrupted rest.

If the father of the child is involved in the birth experience, he can support the mother's recovery by helping to meet her physical needs while encouraging her to rest. The mother is likely to feel less concern over her limited opportunities for newborn care if she can witness the father's interactions with and care for the newborn. The couple may wish for arrangements to be made for the father to stay in the hospital room, sleeping on a cot and eating with the mother so that limited rooming-in with the newborn is still an option. In that way, even if the mother is too fatigued to care for the infant, she can enjoy the infant's presence and initiate bonding. The extent to which the father becomes involved with the care of the mother and baby must be carefully balanced with his need to be rested for the extra responsibilities he will assume when his partner and newborn child are discharged from the hospital.

CLINICAL JUDGMENT

Case Study: Betsy Lambert

Betsy Lambert is a primigravida who had a spontaneous vaginal delivery at 0941 today. An overview of her history reveals the following:

23 years old, married, G 1 P0 on admission to Labor Unit. Pregnancy normal. Rh positive. No drug allergies. Labs on admission to L&D normal with exception of Hemoglobin 11 grams and Hematocrit 33%. Labor: 13 hours. Estimated Blood Loss: 450 ml. Delivered female (7 lb 7 oz) spontaneously after epidural anesthesia. APGAR 9/10. Newborn exam was within normal limits and routine newborn orders were implemented. Day shift reports firm fundus, voided 210 ml around 1100, vital signs stable. Baby visited and breastfed briefly with help from lactation nurse. Ate lunch and had Tylenol #3 at 1300 for perineal pain. Has been sleeping for long intervals.

You find Mrs. Lambert still dozing but awaken her for exam and note the following: B/P 112/20, HR 116, R 16, T 100. Breasts—soft, nontender, wearing support bra. Uterus—fundus firm and 2 cm below umbilicus slightly left of midline. Bladder—possibly slightly distended but she feels no urge to void. Lochia—the two perineal pads and blue absorbent underpads are covered with bright red blood. Perineum—covered with blood, as are thighs. Some of the blood has dried on the skin. Slight edema noted—midline episiotomy intact. Ice pack in place but ice melted. Homans' sign—negative. Emotional status—reports her husband went home to rest and will be back at dinnertime. Talks with excitement about first attempt to nurse baby. Asks for something cold to drink. The patient cannot remember when she was last checked for bleeding. You don gloves and wash her perineum gently and her thighs and change all her pads so you can better assess her degree of bleeding. An IV is in place with 10 units of Pitocin (100 ml is left in the IV bag).

You return, as promised, in 15 minutes to reevaluate her lochia and find that her perineal pads are again covered in blood.

Critical Thinking

Based on your assessments and Mrs. Lambert's lab findings, what actions will you take first?

If one of your anticipated actions is to inform the obstetrician, what specific information will you report and what management should you anticipate initially?

What follow-up care will you anticipate performing during the remainder of your shift?

See www.nursing.pearsonhighered.com for possible responses.

Health Promotion Education

The woman and her family or other support persons should receive clear, preferably written, explanations of the normal postpartum course, including progressive changes in the lochia and fundus and signs of abnormal bleeding. Instructions for the prevention of bleeding should include fundal massage, ways to assess the fundal height and consistency, and inspection of the episiotomy and lacerations, if present. The woman should receive instruction in perineal care (see chapter 36 ∞). The woman and her family are advised to contact their caregiver if any of the signs of postpartum hemorrhage occur (Table 39-3). If iron supplementation is ordered, instructions for proper dosage should be provided to enhance absorption and avoid constipation and nausea.

Community-Based Nursing Care

For most postpartum women, routine discharge instructions include advice such as:

> "You take care of the baby, and let someone else care for you, the family, and the household."

TABLE 39-3 Signs of Postpartum Hemorrhage

Excessive or bright red bleeding (saturation of more than one pad per hour)
A boggy fundus that does not respond to massage
Abnormal clots
High temperature
Any unusual pelvic discomfort or backache
Persistent bleeding in the presence of a firmly contracted uterus
Rise in the level of the fundus of the uterus
Increased pulse or decreased BP
Hematoma formation or bulging/shiny skin in the perineal area
Decreased level of consciousness

Because of her fatigue and weakened condition, the woman who experienced postpartum hemorrhage may be unable even to care for her newborn unassisted. The caregivers at home need clear, concise explanations of her condition and needs for recovery. For example, all should understand the woman's need to rest and to be given extra time to rest after any necessary activity. They should also be told that anemia is associated with postpartum depression so that they can be vigilant for and promtly report any change in the woman's affect. To ensure her safety, the woman should be advised to rise slowly to minimize the likelihood of orthostatic hypotension. Until she regains strength, the mother should be seated when holding the newborn.

The person who assumes responsibility for grocery shopping and meal preparation will need advice about the importance of including foods high in iron in the daily menus. Having the woman indicate her preferences from a list of such foods will promote cooperation with the diet. The nurse also explains the rationale for continuing medications containing iron and reminds the woman that vitamin C–containing fluids maximize absorption of iron, and tea or milk products prevent absorption.

The woman should continue to count perineal pads for several days so she can recognize any recurring problem with excessive blood loss (hypovolemia). Invasive procedures, her debilitated condition, and anemia associated with hemorrhage increase the woman's risk of puerperal infection. She and her caregivers should use good hand washing technique and minimize exposure to infection in the home. They should be given a list of signs of infection and should understand the importance of alerting her healthcare provider immediately should signs occur.

In addition to meeting the woman's physical needs, the nurse will assess the couple's coping strategies and resources for dealing with the impending crisis. Providing realistic information, offering to call those in their support network, and exploring effective coping strategies can be of immeasurable value as they try to maintain a sense of balance in this difficult situation. A sense of emergency often exists in the event of late postpartum hemorrhage. Because it commonly occurs 1 to 2 weeks after birth, the couple is generally at home, involved in the day-to-day activities demanded by their new roles, when the unexpected, excessive bleeding begins. Quick decisions about child care arrangements must often be made so that the mother can return to the hospital. Both mother and father are likely to be alarmed by the excessive bleeding and concerned about her prognosis. There will be additional worries about separation from the newborn, especially when the mother is breastfeeding. The father may find himself torn between the needs of the mother and those of the newborn and any other children. Ideally, arrangements can be made to minimize separation of the family members.

Evaluation

Expected outcomes of nursing care include:

- Signs of postpartum hemorrhage are detected quickly and managed effectively.
- Maternal-infant attachment is maintained successfully.
- The woman is able to identify abnormal changes that might occur following discharge and understands the importance of notifying her caregiver if they develop.

Care of the Woman with a Reproductive Tract Infection or Wound Infection

Puerperal infection is an infection of the reproductive tract associated with childbirth that occurs at any time up to 6 weeks postpartum. The most common postpartum infection is endometritis (metritis), which is infection limited to the uterine lining. The cause of postpartum fever is presumed to be endometritis until proven otherwise. However, infection can spread by way of the lymphatic and circulatory systems to become a progressive disease resulting in parametrial cellulitis and **peritonitis** (infection involving the peritoneal cavity). Other causes of postpartum fever should be considered: respiratory complications such as atelectasis or pneumonia, acute pyelonephritis, thrombophlebitis, or breast engorgement, which rarely lasts more than 24 hours (Duff, Sweet, & Edwards, 2009). Careful assessment of all postpartum women with elevated temperatures is clearly essential to ensure early and accurate diagnosis and treatment. Moreover, preventive measures to prevent respiratory infection, urinary tract infection (UTI), and thrombophlebitis are crucial components of postpartum nursing care. The woman's prognosis is directly related to the stage of the disease at the time of diagnosis, the causative organism, the appropriateness of treatment, and the state of her health and immune system. The death rate from postpartum infection is low in the United States, but "infection continues to account for 7% of maternal deaths after live birth in the United States and is the fourth leading cause of death following delivery" (Duff et al., 2009, p. 749).

The standard definition of **puerperal morbidity** established by the Joint Committee on Maternal Welfare is "a temperature of 38°C (100.4°F) or higher, with the temperature occurring on any 2 of the first 10 days postpartum, exclusive of the first 24 hours, and when taken by mouth by a standard technique at least four times a day." During today's short obstetric hospital stays, the temperature is measured every 6 hours in most settings, consistent with the definition for puerperal morbidity. However, serious infections can occur in the first 24 hours or may cause only persistent low-grade temperatures.

The vagina and cervix of approximately 70% of all healthy pregnant women contain pathogenic bacteria that, alone or in combination, are sufficiently virulent to cause extensive infections. Although the uterus is considered a sterile cavity before rupture of the fetal membranes, bacterial contamination of amniotic fluid with the membranes still intact at term is more common than previously believed and may contribute to premature labor. Following rupture of the membranes and during labor, contamination of the uterine cavity by vaginal or cervical bacteria can easily occur. Other factors also must be present for infection to occur, such as the change to an alkaline pH

postpartally that favors growth of aerobes. Uterine infections are relatively uncommon following uncomplicated vaginal births but they continue to be a major source of morbidity for women who give birth by cesarean.

Routine antibiotic prophylaxis for cesarean childbirth in conjunction with aseptic technique, fewer traumatic operative births, a better understanding of labor dystocia, improved surgical intervention, and a population that is generally at less risk from malnutrition and chronic debilitative disease have contributed to a reduction in overal postpartal morbidity and mortality.

Because shortened inpatient stays are the norm in maternity care, women will likely be discharged following childbirth before clinical signs of puerperal infection are evident. According to Gorgas (2008), 94% of postpartal infections manifest after hospital discharge and many of the women present to the emergency room. Consequently, birthing center nurses are challenged to analyze the woman's history and clinical course for risk assessment and to recognize the sometimes early subtle signs of infection so that discharge may be delayed as needed. Before discharge, the nurse advises the woman about preventive measures, including scrupulous hand washing, and signs of infection. Nurses should educate the patient and her family about the risk of infection and how to recognize and respond appropriately, should it occur. Community and home care nurses, where available, review the prenatal and birth record for continuity of risk assessment, conduct physical assessment for objective findings of infection, collect specimens as ordered for diagnosing infection, and collaborate with the primary caregiver in managing infection.

Postpartum Uterine Infection

Postpartum uterine infection is known as *metritis* and *endometritis*. Because the infection involves the decidual lining of the uterus, the myometrium, and parametrial tissue, some authorities are proposing the terminology *metritis with parametrial cellulitis* (Cunningham et al., 2010).

Risk factors for postpartum uterine infection include the following:

- Cesarean birth is the single most significant risk (10 times greater than in vaginal births) (James, 2008). If a cesarean occurs after an extended labor with ruptured membranes, the incidence of infection can be as high as 35% without antibiotic prophylaxis and 15% with prophylactic coverage (Duff et al., 2009).
- Prolonged premature rupture of the amniotic membranes (PPROM)
- Prolonged labor preceding cesarean birth
- Multiple vaginal examinations during labor
- Compromised health status (low socioeconomic status, anemia, obesity, smoking, use of illicit drugs or alcohol, poor nutritional state)
- Use of fetal scalp electrode or intrauterine pressure catheter for internal monitoring during labor
- Obstetric trauma—episiotomy, laceration of perineum, vagina, or cervix
- Chorioamnionitis—infection of placenta, chorion, and amnion
- Pre-existing bacterial vaginosis or *Chlamydia trachomatis* infection
- Instrument-assisted childbirth—vacuum or forceps
- Manual removal of the placenta or uterine exploration after delivery
- Retained placental fragments
- Urinary catheters and intravenous lines in place (Smith, 2008)
- Lapses in aseptic technique by surgical staff
- Diabetes mellitus (four times more common than in non–diabetic mothers) (Davies & Gibbs, 2008)
- Immunocompromised status

Postpartum Endometritis

Postpartum endometritis (metritis), an inflammation of the endometrium portion of the uterine lining, may occur postpartally in 1% to 3% of women who give birth vaginally and ranges from 5% to 15% of those who give birth by cesarean (Duff et al., 2009).

Postpartum infection from vaginal delivery primarily affects the placental implantation site, the decidua, and adjacent myometrium. Bacteria that colonize the cervix and vagina gain access to the amniotic fluid during labor and postpartum and begin to invade devitalized tissue (the lower uterine segment, lacerations, and incisions). The same pathogenesis, polymicrobial proliferation and tissue invasion, is associated with cesarean delivery, but surgical trauma, additional devitalization of tissue, blood and serum accumulation, and foreign bodies (sutures, staples) provide additional favorable anerobic bacterial conditions. For highly indigent populations, the risk remains high (Duff et al., 2009). Both aerobic and anaerobic organisms cause endometritis, which is often polymicrobial. See Table 39-4 for a list of common causative organisms.

Clinical findings of metritis in the initial 24 to 36 hours postpartum tend to be related to group B streptococcus (GBS). Late-onset postpartum endometritis/metritis is most commonly associated with genital mycoplasmas and *Chlamydia trachomatis.* These microbes have a longer replication time and latency period than other bacteria and are not consistently eradicated by antibiotics used for early postpartal infections.

In mild cases of metritis, the woman generally has vaginal discharge that is bloody, foul smelling, and either scant or profuse. In more severe cases, she also has uterine tenderness;

TABLE 39-4 Common Causative Organisms in Endometritis

AEROBES	ANAEROBES
• Group A, B, D streptococcus	• *Peptostreptococcus*
• Enterococcus	• *Clostridium* species
• *Staphylococcus* species	• *Bacteroides* species
• *Escherichia coli*	• *Chlamydia trachomatis*
• *Klebsiella pneumoniae*	• Genital mycoplasma
• *Proteus mirabilis*

Resnik (Eds.), Maternal-fetal medicine: Principles and practice *(6th ed., pp. 739–796). Philadelphia: Saunders; James, D. C. (2008). Postpartum care. In K. R. Simpson & P. A. Creehan,* AWHONN's perinatal nursing *(3rd ed., pp. 473–526). Philadelphia: Lippincott Williams & Wilkins.*

sawtooth temperature spikes, usually between 38.3°C (101°F) and 40°C (104°F) on two separate assessments at least 6 hours apart; tachycardia that parallels temperature increase; and chills. Purulent and foul-smelling lochia is cited as a classic sign of endometritis (Smith, 2008).

Broad spectrum antibiotics are used for treatment. Ampicillin is often added for the nonallergic woman when high fevers begin within the first 24 to 48 hours after delivery, since early spikes are generally associated with enteroccocal infection. Women generally improve within 2 days of initiating antibiotics. If fever continues at 48 hours after antibiotic therapy, an additional workup is necessary to check for refractory pelvic infection (Cunningham et al., 2010). Antibiotics are continued until the woman has been afebrile for a minimum of 24 hours and the clinical exam is benign; then antibiotics may be discontinued.

Pelvic Cellulitis (Parametritis)

Pelvic cellulitis (parametritis) is infection that has ascended to involve the connective tissue of the broad ligament or, in more severe forms, the connective tissue of all the pelvic structures. The infection generally ascends upward in the pelvis by way of the lymphatic vessels in the uterine wall but may also occur if pathogenic organisms invade a cervical laceration that extends upward into the connective tissue of the broad ligament—a direct pathway into the pelvis. This level of infection should be suspected in those whose fever persists when another source cannot be identified.

A pelvic abscess may form and is most commonly found in the uterine ligaments, the cul-de-sac of Douglas, and the subdiaphragmatic space. Parametritis may be a secondary result of pelvic thrombophlebitis. This condition occurs when a clot, usually in the right ovarian vein, becomes infected, and the wall of the vein breaks down from necrosis, spilling the infection into the connective tissues of the pelvis (Cunningham et al., 2010).

A woman suffering from parametritis may demonstrate a variety of symptoms, including marked high temperature (38.9°C to 40°C or 102°F to 104°F), chills, malaise, lethargy, abdominal pain, subinvolution of the uterus, tachycardia, and local and referred rebound tenderness. If peritonitis develops, the woman will be acutely ill with severe pain; marked anxiety; high fever; rapid, shallow respirations; pronounced tachycardia; excessive thirst; abdominal distention; nausea; and vomiting.

Postpartum Wound Infections

Given the degree of bacterial contamination that occurs with normal vaginal birth, it is surprising that more women do not have infections of the episiotomy or repaired lacerations of the perineum, vagina, or vulva. Good aseptic technique is the likely rationale. When perineal wound infection does occur, it is recognized by the classic signs: redness, warmth, edema, purulent drainage, and, later, gaping of the previously approximated wound. Local pain may be severe.

After cesarean delivery, wound infection is most often associated with concurrent endometritis. The wound is typically red, indurated, tender at the margins, and draining purulent exudate. Some women have cellulitis without actual purulent drainage. Clinical exam is usually sufficient for diagnosis but culture of the exudate should be routinely done since methicillin-resistant *Staphylococcus aureus* (MRSA) infections are possible (Duff et al., 2009).

Clinical Therapy

The infection site and causative organism(s) are diagnosed by careful history and complete physical examination, blood tests, aerobic and anaerobic endometrial cultures (although this may be of limited value, because multiple organisms are usually present), and urinalysis to rule out urinary tract infection (UTI). Blood cultures are positive in up to 25% of febrile women but do not reflect accurately the severity of the infection (Smith, 2008).

Localized wound infection is treated with broad-spectrum antibiotics, sitz baths, and analgesics as necessary for pain relief (chapter 36 ∞). Wounds with evidence of pus or serosanguineous effusion or an infected stitch site are opened and drained completely. Once the incision and drainage (I&D) of the wound is complete, it may be packed with saline dampened gauze and repacked 2 to 3 times daily, and covered with clean gauze using aseptic technique. This allows removal of necrotic debris when packing is removed. When the infection is resolved and there is evidence of healthy granulation tissue, secondary closure is considered. Antibiotics with coverage against *Staphyloccus aureus* should be given. Nafcillin, 2 grams IV every 6 hours is a common choice. For allergy to β-lactam antibiotics, an appropriate alternative is vancomycin 1 gram IV every 12 hours. Antibiotics are typically continued until the wound base is clean and any signs of cellulitis have resolved.

The incidence of metritis has been reduced by prophylactic administration of antibiotics to women undergoing cesarean childbirth. Metritis, once diagnosed, is treated by the administration of parenteral broad spectrum antibiotics (Duff et al., 2009; James, 2008). Common standard treatment regimens consist of clindamycin for gram-positive and anaerobic coverage in combination with an aminoglycoside, typically gentamicin, and for gram negative coverage or ampicillin and sulbactan every 6 hours (Cunningham et al., 2010). The route and dosage are determined by the severity of the infection. Careful monitoring is also necessary to prevent the development of a more serious infection. Parametritis and peritonitis are treated with aggressive IV therapy. Broad-spectrum antibiotics effective against the most common causative organisms are chosen initially until the results of culture and sensitivity reports are available. If multiple organisms are present, the approach to antibiotic therapy is continued unless no improvement is observed; then the antibiotic is changed. With appropriate antibiotic coverage, improvement should occur within a few days. Antibiotics are generally continued until the woman is afebrile for 24 to 48 hours (James, 2008). Follow-up with oral antibiotics is not necessary (Cunningham et al., 2010).

An abscess is frequently manifested by the development of a palpable mass and may be confirmed with ultrasound. An abscess usually requires incision and drainage to avoid rupture into the peritoneal cavity and the possible development of peritonitis. After drainage of the abscess, the area may be packed with iodoform gauze to promote drainage and facilitate healing (Duff et al., 2009). Approximately 90% of women with postpartum infection respond quickly to antibiotic therapy or

drainage of abscesses and are associated with complete recovery and no long-term sequelae (Smith, 2008).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse should inspect the woman's perineum or abdominal wound site every 8 to 12 hours for signs of early infection. The REEDA scale helps the nurse remember to consider *r*edness, *e*dema, *e*cchymosis, *d*ischarge, and *a*pproximation of either the perineal or surgical wound. Any degree of induration (hardening) should be immediately reported to the clinician.

Fever, malaise, abdominal pain, foul-smelling lochia, larger than expected uterus, tachycardia, and other signs of infection should be noted and reported immediately so that treatment can begin. The white blood cell (WBC) count, a usual objective measure of infection, cannot be used reliably because of the normal increase in WBCs during the postpartum period; a postpartum WBC count of 14,000 to 16,000/mm^3 is not an unusual finding. An increase in WBC level of more than 30% in a 6-hour period, however, is indicative of infection.

Nursing diagnoses that may apply to the woman with a puerperal infection include the following:

- ***Risk for Injury*** related to the spread of infection
- ***Acute Pain*** related to the presence of infection
- ***Deficient Knowledge*** related to lack of information about condition and its treatment
- ***Risk for Impaired Parenting*** related to delayed parent-infant attachment secondary to woman's pain and other symptoms of infection as well as possible separation of the newborn from the mother

Nursing Plan and Implementation

Hospital-Based Nursing Care

Careful attention to Standard Precautions, aseptic technique, and good hand washing during labor, birth, and postpartum is essential to minimze the risk of puerperal infection.

The nurse caring for a woman during the postpartum period is responsible for teaching the woman self-care measures that are helpful in preventing infection. The woman should understand the importance of good perineal care, hygiene practices to prevent contamination of the perineum (such as wiping from front to back, changing perineal pads after voiding), and thorough hand washing. Once edema and perineal pain are under control, the nurse can also encourage sitz baths, which are cleansing and promote healing (see chapter 36 ∞). Adequate fluid intake coupled with a diet high in protein and vitamin C, which are necessary to promote wound healing, also helps prevent infection (James, 2008). If the woman has a draining wound or purulent lochia, it is especially important that those in contact with soiled items and linens practice good hand washing. Clear, concise instructions about wound care and how to discard soiled dressings appropriately must be provided to safeguard the woman and her caregivers. Assuming a semi-Fowler's position will facilitate drainage of purulent discharge.

If the woman is seriously ill, ongoing assessment of urine specific gravity and intake and output is necessary. The nurse also carefully administers antibiotics as ordered and regulates the IV fluids rate. Ongoing assessment of the woman's condition is vital to detect subtle changes in her health status. The nurse also recognizes the woman's comfort needs related to hygiene, positioning, oral care, and pain relief.

Promoting maternal-infant attachment can be difficult with the acutely ill woman. The nurse may provide pictures of the infant and keep the mother informed of the infant's well-being. Mementos, such as a footprint, a note written by the father "from the baby," or a videotape of the baby can be comforting to the mother during their separation. If she feels up to it, the new mother will also benefit from brief visits with her newborn.

The woman who wishes to breastfeed when her condition allows can maintain lactation by assistance with pumping her breasts regularly. Understanding that the opportunity to breastfeed is simply delayed, not eliminated by the infectious process may serve as helpful reassurance. The partner of a seriously ill woman will be concerned about her condition and torn about spending time with her or with their newborn. Because maternal-infant bonding may be compromised, father-newborn bonding can be especially important. See Nursing Care Plan: For the Woman with a Puerperal Infection on pages 1128–1129 for specific nursing care measures.

Community-Based Nursing Care

The woman with a puerperal infection needs assistance when she is discharged from the hospital. If the family cannot provide this home assistance, a referral to home care services is needed. Home care services should be contacted as soon as puerperal infection is diagnosed so that the nurse can meet with the woman for a family and home assessment and development of a home care plan.

The family needs instruction in the care of a newborn, including feeding, bathing, cord care, immunizations, and significant observations that should be reported. A well-baby appointment should be scheduled. The woman who has maintained lactation by pumping and discarding her milk may need assistance with early breastfeeding. Breastfeeding mothers receiving antibiotics should be instructed to inspect the infant's mouth for signs of thrush and to report the finding to their physician.

The mother should be instructed regarding activity, rest, medications, diet, and signs and symptoms of complications, and she should be scheduled for a return medical visit. She needs to know the importance of taking the entire course of prescribed antibiotics even though she may begin to feel better before the bottle is empty. She also needs to be informed about the importance of pelvic rest; that is, she should not use tampons or douches nor have intercourse until she has been examined by the physician and told it is safe to resume those activities.

Evaluation

Expected outcomes of nursing care include the following:

- The infection is quickly assessed, and treatment is instituted successfully without further complications.

NURSING CARE PLAN For the Woman with a Puerperal Infection

INTERVENTION	RATIONALE
1. Nursing Diagnosis: Risk for Infection related to traumatized tissues **Goal:** The woman will be free of complications associated with infection.	
■ Encourage the woman, staff, and family members to adhere to a strict hand washing policy.	■ Hand washing kills bacteria and prevents cross-contamination.
■ Review the woman's prenatal, intrapartal, and postpartal records for underlying problems that could contribute to poor wound healing or increased risk for spread of infection.	■ Identifying underlying problems gives the caregiver an opportunity to initiate preventive measures that will promote healthy wound healing and stop the spread of infection.
■ Monitor blood pressure, pulse, respiration, and temperature.	■ Obtain baseline data; signs and symptoms of septic shock produce a decrease in blood pressure and an increase in respirations. Temperature increase of 38°C/100.4°F or greater on any 2 days after the first 24 hours indicates infection.
■ Instruct the woman on proper perineal care including wiping perineum from front to back after voiding, washing the perineum after voiding and defecating, and changing peri-pads frequently, always followed by hand washing.	■ Proper perineal care techniques enhance good hygiene and assist in removing urine and fecal contaminants from perineum. Changing peri-pads frequently decreases skin contact with a moist medium that favors bacteria growth.
■ Encourage a well-balanced diet with adequate protein, calories, and vitamin C. ■ Continue prenatal vitamins and iron as ordered	■ Protein and vitamin C are essential nutrients for tissue healing and repair.
■ Encourage the woman to consume 2000 ml of fluid a day.	■ Maintains hydration and increases circulating volume. Dilutes organisms which are eliminated with voiding.
■ Encourage use of the sitz bath, Surgigator, or the perineal light two to four times a day for at least 10–15 minutes.	■ Moist or dry heat to the perineum increases localized blood flow, promotes healing, and provides comfort.
■ Encourage early ambulation.	■ Enhances circulation and drainage of lochia.
■ Assess and report signs and symptoms of infection in perineum including: redness, erythema, edema, discharge, approximation of wound edges (REEDA), and pain.	■ Identifying signs and symptoms of infection early allows for prompt treatment and healing.
Collaborative: Obtain lab work as ordered by the physician including culture and sensitivity, complete blood count (CBC) with differential, and white blood cell (WBC) count.	■ Identifies abnormal lab values for early intervention. In addition, identifies infection and its causative organism for appropriate antibiotic treatment.
■ Administer antibiotic therapy as ordered by the physician.	■ Fights infection and helps prevent ascension of organisms into further tissue.
■ Encourage semi-Fowler's position at intervals.	■ Uses gravity to assist drainage of infected material.
■ Promote wound drainage by assisting physician in opening the wound if necessary. Also, if the wound is greater than 2–3 cm, pack with iodoform gauze.	■ Iodoform gauze is used to maintain patency of wound opening. This promotes drainage and prevents abscesses from developing.
■ Report signs and symptoms of severe infections: foul-smelling lochia, uterine subinvolution, uterine tenderness, severe lower abdominal pain, elevated temperature, elevated WBC count, general malaise, chills, lethargy, tachycardia, nausea and vomiting, and abdominal rigidity.	■ Reporting signs and symptoms of severe infections early allows for initiation of appropriate therapy by the physician and prevents further spread of the invading pathogen.
EXPECTED OUTCOME:	The woman will be free of complications associated with infection as evidenced by practicing behaviors that prevent the spread of infection and promote timely wound healing.
2. Nursing Diagnosis: Acute Pain related to the infection process **Goal:** The woman will be free of pain or have a level of relief that is acceptable.	
■ Assess pain location and intensity; have the woman describe on a scale from 1 (mild) to 10 (severe). Assess nonverbal signs of pain, including facial grimacing and agitation.	■ Assesses the need for pain management and evaluates interventions already implemented.
■ Teach the woman to request or take analgesic before pain is severe.	■ Allows timing of medication for effective relief. The effects of IV analgesia are almost immediate; the effects of intramuscular (IM) analgesics occur in 20–30 min, while those of oral medications are 30–45 min.

NURSING CARE PLAN For the Woman with a Puerperal Infection continued

INTERVENTION	RATIONALE
■ Encourage the woman to discuss anxiety and fears.	■ Reduces anxiety/fear and may decrease the woman's perception of pain.
■ Encourage frequent rest periods and decrease disturbing environmental stimuli.	■ Frequent rest periods will conserve woman's energy. Excessive environmental stimuli may increase woman's pain perception.
■ Promote relaxation by encouraging diversional activities and the use of exercises including radio/television, reading, guided imagery, deep breathing techniques, massage, visualization, and meditation.	■ Promotes relaxation and refocuses woman's attention away from the intensity of pain.
Collaborative: Administer analgesics as ordered by the physician, evaluating the response to the analgesic and any adverse effects in a timely manner.	■ Relieves pain and interrupts the pain, fear, tension cycle to facilitate relaxation.

EXPECTED OUTCOME: Woman is free of pain or has an acceptable level of pain as evidenced by verbalization of pain relief and the exhibition of a relaxed demeanor.

3. Nursing Diagnosis: Risk For Impaired Parenting/Attachment related to pain secondary to maternal infection and/or separation from infant to minimize exposure
Goal: Mother will have no problems bonding with infant and assuming responsibility for the care of the infant with assistance and later independently

■ Provide quality time for mother and infant contact.	■ Aids in the bonding process.
■ Encourage the partner or family members to give the woman videos and pictures of the infant if the mother's condition requires separation from the infant.	■ Promotes bonding and gives the mother reassurance that the infant is being cared for.
■ Encourage the partner and family members to become involved with the care of the infant and verbalize interaction to the mother.	■ Allows the mother to feel as though she is involved in the care of the infant.
■ Encourage the mother to feed (breast or bottle) infant if her condition is stable. If the mother is unable to breastfeed, encourage and assist her in pumping her breasts to maintain milk production.	■ Hands-on participation in the infant's care gives mother a positive outlook.
■ Assess maternal support systems.	■ As the mother is recovering, she will need assistance in household organization and personal care.
Collaborative: Offer referrals to home health services, doula services, lactation services, and/or support groups.	■ Ensures the woman's well-being, and identifies problems that may require intervention

EXPECTED OUTCOME: Mother will bond with the infant as evidenced by exhibiting appropriate attachment behaviors when interacting with infant, providing care to self and infant, and verbalization of understanding of the parenting role.

- The woman understands the nature of the infection and the purpose of therapy; she carries out any ongoing antibiotic therapy necessary after discharge.
- Maternal-infant attachment is maintained.

Care of the Woman with a Urinary Tract Infection

The postpartum woman is at increased risk of developing urinary tract problems because of the normal postpartum diuresis, increased bladder capacity, decreased bladder sensitivity from stretching or trauma, bacterial shedding with urinary stasis, and possible inhibited neural control of the bladder following the use of general or regional anesthesia and contamination from catheterization. It is important that the mother empty her bladder completely with each voiding.

Overdistention of the Bladder

Overdistention occurs postpartally when the woman is unable to empty her bladder, usually because of trauma or the effects of anesthesia. Women who have not sufficiently recovered from the effects of anesthesia cannot void spontaneously, and catheterization is necessary. After the effects of anesthesia have worn off, if the woman cannot void, postpartal urinary retention is highly indicative of a urinary tract infection (UTI). Other risk factors for urinary retention after childbirth include

nulliparity, instrumental delivery, and prolonged first and second stages of labor, episiotomy, lacerations, and nulliparity (Cunningham et al., 2010).

CLINICAL TIP

Postpartum urinary retention is often defined as "the absence of spontaneous urination within 6 hours of a vaginal delivery or within 6 hours after removal of an indwelling catheter post-Cesarean delivery." The astute nurse will watch the woman's bladder for signs of retention—not the clock! As urinary retention promotes uterine atony and a subsequent increase in bleeding and also contributes to the possibility of UTI, timely intervention is crucial.

Clinical Therapy

Overdistention in the early postpartum period is often managed by draining the bladder with a straight catheter as a one-time measure. If the overdistention recurs or is diagnosed later in the postpartum period, an indwelling catheter may be ordered for 24 hours. An alternate urinary retention protocol involves bladder ultrasound scans with intervention based on the amount of urine volume. For example, if the volume is greater than 200 ml, the bladder is drained and the catheter is left in for another day, whereas if the volume is 200 ml or less, the catheter is removed and the bladder rechecked after 4 hours (Cunningham et al., 2010).

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The overdistended bladder appears as a large mass, reaching sometimes to the umbilicus and displacing the uterine fundus upward and to one side. There is increased vaginal bleeding, the fundus is boggy, and the woman may complain of cramping as the uterus attempts to contract. Some women also experience backache and restlessness. Nursing diagnoses that may apply when a woman has difficulties due to overdistention include the following:

- ***Risk for Infection*** related to urinary stasis secondary to overdistention of the bladder
- ***Urinary Retention*** related to decreased bladder sensitivity and normal postpartum diuresis

Nursing Plan and Implementation

Diligent monitoring of the bladder during the recovery period and preventive health measures greatly reduce the chance for overdistention of the bladder. Encouraging the mother to void spontaneously and helping her use the toilet, if possible, or the bedpan if she has received conductive anesthesia, prevents overdistention in most cases. The nurse assists the woman to a normal position for voiding (i.e., sitting with the legs and feet lower than the trunk) and provides privacy to encourage voiding. The woman should be medicated for whatever pain she may be having before attempting to void because pain may cause a reflex spasm of the urethra. Perineal ice packs applied after birth will minimize any edema, which may interfere with voiding. Pouring warm water over the perineum or having the woman void in a sitz bath may also be effective. Some women note that hearing running water nearby, blowing bubbles through a straw into a glass of water, or voiding onto a bedpan into which a few drops of tincture of peppermint have been added helps stimulate voiding.

If catheterization becomes necessary, careful, meticulous, aseptic technique should be employed during catheter insertion. The vagina and vulva are traumatized to some degree by vaginal birth, and edema is common. This edema may obscure the urinary meatus; therefore, the nurse needs to be extremely careful in cleansing the vulva and inserting the catheter. It is imperative to discard a catheter that has inadvertently been introduced into the vagina and thus contaminated. Because catheterization is an uncomfortable procedure as a result of the postpartal trauma and edema of the tissue, the nurse should be careful and gentle not only in inserting the catheter but also in handling and cleaning the perineal area.

If the amount of urine drained from the bladder reaches 900 to 1000 ml, the catheter should be clamped and taped firmly to the woman's leg. The nurse should carefully document the procedure, including taking the woman's vital signs before and after the procedure and noting her responses. After an hour, the catheter may be unclamped and placed on gravity drainage. This technique protects the bladder and avoids rapid intra-abdominal decompression. When the indwelling catheter is removed, a urine specimen is often sent to the laboratory. The tip of the catheter may also be removed and sent for culture.

Evaluation

Expected outcomes of nursing care include the following:

- The woman voids adequately to meet the demands of the increased fluid shifts during the postpartum period.
- The woman does not develop infection due to stasis of urine.
- The woman actively incorporates self-care measures to decrease bladder overdistention.

Cystitis (Lower Urinary Tract Infection)

Retention of residual urine, bacteria introduced at the time of catheterization, and a bladder traumatized by childbirth combine to provide an excellent environment for the development of cystitis (lower urinary tract infection). *Escherichia coli* has been demonstrated to be the causative agent in most cases of postpartum cystitis and pyelonephritis (upper urinary tract infection). *Klebsiella pneumoniae* and *Proteus* species are significant pathogens, especially in women with a history of recurrent UTIs (Duff et al., 2009). In most cases, the infection ascends the urinary tract from the urethra to the bladder. If cystitis is not treated, the infection can spread to the kidneys (pyelonephritis) because vesicoureteral reflux (backward flow of urine) forces contaminated urine into the renal pelvis.

Clinical Therapy

When cystitis is suspected, a clean-catch, midstream urine sample is obtained for microscopic examination, culture, and sensi-

tivity tests. The specimen may require collection by the nurse with the woman on a bedpan because few postpartal women can collect a true midstream, clean-catch specimen without contaminating the specimen with lochia. A catheterized specimen is avoided when possible because of the increased risk of infection. When the bacterial concentration is greater than 100,000 colonies of the same organism per milliliter of fresh urine, infection is generally present. Counts between 10,000 and 100,000 may also suggest infection, particularly if clinical symptoms are noted.

In the clinical setting, antibiotic therapy is often begun before culture and sensitivity reports are available. Frequently used antibiotics include a preparation of trimethoprim-sulfamethoxazole–double strength (Bactrim DS, Septra DS), one of the short-acting sulfonamides, nitrofurantoin (Macrodantin), or, in the case of sulfa allergy, ampicillin or amoxicillin-clavulanic acid. The antibiotic is changed later if indicated by the results of the sensitivity report. Antispasmodic or urinary analgesic agents, such as phenazopyridine hydrochloride (Pyridium), may be given to relieve discomfort.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Assessment for urinary distention and developing UTI is a component of postpartum assessment, performed at least daily during hospitalization and more often with risk factors. Intake and output of urine is commonly measured for 24 hours after vaginal delivery and an additional 24 hours after the indwelling catheter is removed from women with cesarean deliveries. Women should be encouraged to void every 2 to 4 hours to prevent urinary stasis and to report any sensations of incomplete emptying of the bladder or dysuria.

Acute cystitis usually causes symptoms of frequency, dysuria, urgency, hesitancy and dribbling, nocturia, and suprapubic pain. Gross hematuria may be noted but high fever and systemic symptoms are not expected.

When a UTI progresses to pyelonephritis, systemic symptons usually occur, and the woman becomes acutely ill. Symptoms include high fever, chills, flank pain (unilateral or bilateral), nausea, and vomiting, in addition to the signs of lower UTI. Costovertebral angle (CVA) tenderness may be noted on exam but is not required for diagnosis. Clean-catch urine specimens show large numbers of white blood cells and are positive for infection (Smith, 2008).

Nursing diagnoses that may apply if a woman develops a UTI postpartally include the following:

- ***Acute Pain*** with voiding related to dysuria secondary to infection
- ***Ineffective Self Health Management*** related to need for information about self-care measures to prevent UTI

Nursing Plan and Implementation

Screening for asymptomatic bacteriuria in pregnancy should be routine. Frequent emptying of the bladder during labor and postpartum should be encouraged to prevent overdistention and trauma to the bladder. Catheterization technique and nursing actions to prevent overdistention (previously discussed) also apply. If symptoms of UTI occur, they should be reported to the physician or certified nurse-midwife (CNM). A clean-catch-midstream specimen for culture and sensitivity may be ordered. A 10- to 14-day course of antibiotics to treat UTI is typically started while culture results are pending. Changes in the regimen can be made once culture results are consulted, if necessary. The woman with pyelonephritis must understand the importance of follow-up care after discharge to prevent recurrence or further complications.

Health Promotion Education

All postpartum women should be taught the signs and symptoms of cystitis and pyelonephritis as symptoms are more likely to be noted later in the postpartum interval.

The nurse should advise the postpartum woman to continue good perineal hygiene following discharge, to maintain a good fluid intake (at least 8 to 10 8-oz glasses daily) especially of water, and to empty her bladder whenever she feels the urge to void, but at least every 2 to 4 hours while awake. Once sexual intercourse is resumed, the new mother should void before (to prevent bladder trauma) and following intercourse (to wash contaminants from the vicinity of the urinary meatus). Wearing cotton-crotch underwear to facilitate air circulation also reduces the risk of UTI. Acidification of the urine is thought to aid in preventing and managing UTI. The nurse thus advises the woman to avoid carbonated beverages, coffee, citrus fruits, tomatoes, and chocolate, which increase alkalinity of urine, and to drink cranberry, plum, apricot, and prune juices and take vitamin C, which increase the acidity of urine (Mengel & Schwiebert, 2009).

Evaluation

Expected outcomes of nursing care include:

- The woman identifies the signs of UTI and her condition is treated successfully.
- The woman uses self-care measures to prevent the recurrence of UTI as part of her personal hygiene routine.
- The woman continues with any long-term therapy or follow-up as appropriate for the diagnosis.
- Maternal-infant attachment is maintained; the woman is able to care for her newborn effectively.

Care of the Woman with Postpartum Mastitis

Mastitis is a unilateral inflammation of the interlobular connective tissue in the breast that occurs primarily in lactating women. (Chapter 37 ∞ discusses the breastfeeding difficulties of the woman with mastitis.) Inflammation can occur at any time during breastfeeding but onset is usually between 2 to 8 weeks postpartum or any other time that nursing frequency decreases. It ranges in severity from local inflammation to abscess and septicemia. The incidence of sporadic mastitis is 5%

to 10% of breastfeeding mothers and less than 1% in nonlactating mothers (Duff et al., 2009).

The usual causative organisms are *Staphylococcus aureus, Haemophilus parainfluenzae, H. influenzae, E. coli,* and *Streptococcus* species. Clinical features include fever; chills; headache; flulike muscle aches and malaise because of myalgia; and a warm, reddened, painful area of the breast, often wedge-shaped because of septal distribution of connective tissue (Figure 39-2 ■). The infection usually begins when bacteria invade the breast tissue after it has been traumatized in some way (see the factors commonly associated with mastitis in Table 39-5). Milk serves as a favorable medium for the invasive bacteria to multiply; thus, milk stasis is another risk factor. The most common source of the causative organism is the infant's nose and throat, although other sources include the hands of the mother or hospital staff and the woman's circulating blood. Infants of women with mastitis generally remain well unless the causative organism is *Candida albicans.*

When *Candida albicans* is the causative organism of mastitis, entering the breast through a small fissure or abrasion on the nipple, the baby will often have thrush, a candidal infection of the mouth. There may be a history of a recent course of antibiotics in the woman. Signs include late-onset nipple pain, followed by shooting pain between feedings, often radiating to the chest wall (Lawrence & Lawrence, 2009). Eventually, the skin of the affected breast may become pink, flaking, and pruritic. Women may notice a yeasty odor to their milk. Unless the mother and her newborn are treated for *Candida,* recolonization will occur when breastfeeding is resumed.

Figure 39-2 ■ Mastitis. Erythema and swelling are present in the upper outer quadrant of the breast. Axillary lymph nodes are often enlarged and tender. The segmental anatomy of the breast accounts for the demarcated, often V-shaped wedge of inflammation.

TABLE 39-5 Factors Affecting Development of Postpartum Mastitis

Milk Stasis
- Failure to change infant position to allow emptying of all lobes
- Failure to alternate breasts at feedings
- Poor suck
- Poor let-down

Actions That Promote Access/Multiplication of Bacteria
- Poor hand washing technique
- Improper breast hygiene
- Failure to air-dry breasts after breastfeeding
- Use of plastic-lined breast pads that trap moisture against nipple

Breast/Nipple Trauma
- Incorrect positioning for breastfeeding
- Poor latch on
- Failure to rotate position on nipple
- Incorrect or aggressive pumping technique
- Cracked nipples

Obstruction of Ducts
- Restrictive clothing
- Constricting bra
- Underwire bra

Change in Number of Feedings/Failure to Empty Breasts
- Attempted weaning
- Missed feeding
- Prolonged sleeping of infant, including sleeping through the night
- Favoring side of nipple soreness

Lowered Maternal Defenses
- Fatigue
- Stress
- Poor diet

Clinical Therapy

Clinical diagnosis is possible in most cases, although culture and sensitivity testing of breast milk may be done. If a culture of the breast milk is ordered either for initial diagnosis or with recurrence or failed treatment of mastitis, it is more reliable with a midstream-type collection process. The nipple is washed first; then the first 3 ml of breast milk are manually expressed and discarded, after which the actual specimen is collected. A leukocyte count greater than 1 million/ml and a bacterial count greater than 10,000 colonies/ml are diagnostic (Newton, 2007).

Treatment of mastitis involves bed rest for at least 24 hours; increased fluid intake (at least 2 to 2.5 L/day); a supportive bra; frequent breastfeeding; local application of warm, moist heat or ice packs; and analgesics that are compatible with breastfeeding (James, 2008). Nonsteroidal anti-inflammatory agents are recommended to treat both fever and inflammation. Some clinicians question the worth of milk culture because it is not ductal tissue that is infected, and recommend antibiotic coverage empirically based on the most common etiologic organisms, for example, a course of 7- to 10-day antibiotics, depending on response, usually a penicillinase-resistant penicillin, such as dicloxacillin

500 mg every 6 hours or a cephalosporin, such as cephalexin 500 mg every 6 hours (Duff et al., 2009). Both drugs have similar safety profiles and are relatively inexpensive. The woman should continue to breastfeed; in fact, regular drainage of both breasts actually helps by preventing milk stasis and abscess formation, and there is virtually no risk to the newborn. If there has been no change in symptomatology in 48 hours, modification of the antibiotic therapy will be considered—perhaps changing to ampicillin/clavulanate (Augmentin) in the nonallergic patient. There have been reported cases of methicillin-resistant *staph aureus* (Academy of Breastfeeding Medicine (ABM), 2008).

Candidal infections can be especially stubborn. Initial treatment generally involves antifungal creams or ointments once or twice daily. Oral Diflucan is excreted in breast milk but is not considered toxic to the infant and can be used if other agents fail. Women should be instructed to cleanse their nipples with warm water and allow air-drying before application of the antifungal medication. For the woman who prefers to avoid medication, an alternative treatment is cleansing of the nipples with a solution of 1 tablespoon of vinegar in 1 cup of water or 1 teaspoon of baking soda in 1 cup of water, followed by air-drying.

Ten percent of cases will progress to abscess formation if mastitis remains untreated, treatment fails, or the infant is abruptly weaned (Cunningham et al., 2010). Abscess is more common when there is a lag of 24 hours or more between onset of symptoms and care seeking. Abscesses are associated with exquisite tenderness of the breast and an undurated area with possible fluctuation. Breast abscess may require incision and drainage, and intravenous (IV) antibiotics; analgesics and antipyretics are commonly ordered. Community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) is likely to cause abscess formation (Cunningham et al., 2010).

Improved outcome, a decreased duration of symptoms, and decreased incidence of a breast abscess result if the breasts continue to be emptied by either breastfeeding or pumping. Thus, continued breastfeeding is recommended in the process of mastitis. The plan of care should include contacting the woman within 24 hours of initiation of treatment to ensure that symptoms are subsiding.

PROBIOTICS AND OTHER COMPLEMENTARY THERAPIES FOR MASTITIS

Probiotics are a category of dietary supplements consisting of beneficial microorganisms (*pro* means "for" and *biotic* means "life" versus *antibiotic,* which literally means "against life"). Probiotics compete with disease-causing microorganisms in the gastrointestinal tract. When antibiotics are taken, they kill many of the beneficial bacteria that exist naturally in the digestive tract. Supplementing with probiotics after a course of antibiotics is frequently prescribed by nutritionists and complementary practitioners. Commonly used probiotics include *Lactobacillus acidophilus* and *Bifidobacterium bifidum;* there are other species of *Lactobacillus* and *Bifidobacterium* that have been shown to be effective in such conditions as diarrhea and vaginal infections. *Bifidobacterium* also competes against *Candida albicans.* Probiotics can be taken in the form of powder, capsules, and suppositories, or in fermented milk products such as yogurt or *kefir.*

Other complementary therapies used for mastitis include belladonna, acupuncture, oxytocin nasal spray to improve milk ejection, a traditional Chinese herb known as extracts of *Fructus gleditsiae,* and application of cabbage leaves over the affected area to relieve engorgement. (See chapter 37 ∞ for more details.)

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Daily assessment of breast consistency, skin color, surface temperature, nipple condition, and presence of pain is essential to detect early signs of problems that may predispose to mastitis. The mother should be observed breastfeeding her baby to ensure use of proper technique for positioning, latch on, and disengagement of the infant from the nipple. Consultation with a lactation specialist can be of great value, especially for first-time mothers. During the breast assessment while the breastfeeding woman is still hospitalized, the nurse is advised to teach her about the potential for mastitis, risk factors, preventive measures, recognition of symptoms, and the need to notify the physician promptly if symptoms occur.

If an infection has developed, the nurse should assess for contributing factors such as cracked nipples, poor hygiene, engorgement, supplemental feedings, change in routine or infant feeding pattern, abrupt weaning, or lack of proper breast support so that these factors may be corrected as part of the treatment plan. Nursing diagnoses that may apply to the woman with mastitis include the following:

- ***Risk for trauma*** related to lack of information about appropriate breastfeeding practices
- ***Ineffective Breastfeeding*** related to pain secondary to development of mastitis

Nursing Plan and Implementation

Preventing mastitis is far simpler than treating it. Ideally, mothers should be instructed in proper breastfeeding technique prenatally. The nurse should help the mother breastfeed soon after birth and should review correct technique. Comanagement of breastfeeding between the nurse and a certified lactation specialist is often possible. All women, even those not breastfeeding, are encouraged to wear a good supportive bra at all times to avoid milk stasis, especially in the lower lobes.

Meticulous hand washing by the breastfeeding mother and all personnel is the primary measure for preventing epidemic nursery infections and subsequent maternal mastitis. Prompt attention to mothers who have blocked milk ducts eliminates stagnant milk as a growth medium for bacteria or the development of cracks and fissures, a common portal for bacterial entry. If the mother finds that one area of her breast feels distended, she can rotate the position of her infant for breastfeeding, manually express milk remaining in the breast after feeding (usually only necessary if the infant is not sucking well), or massage the caked area toward the nipple as the infant nurses. Mothers who have developed mastitis can apply

warm, moist compresses to the affected area before breastfeeding. The nurse encourages the mother to breastfeed frequently, starting with the unaffected breast until let-down occurs in the affected breast, then encourages feeding from the affected breast until it is emptied completely (James, 2008). After nursing, the mother can leave a small amount of milk on each nipple to prevent cracking and allow nipples to air dry and apply cold packs to reduce pain and edema (ABM, 2008). Early identification of and intervention for sore nipples are also essential, as is prompt assessment of the breastfeeding mother's breasts when thrush is discovered in her newborn's mouth. For a detailed discussion of breastfeeding, see "Breastfeeding Concerns Following Discharge" in chapter 37 ∞.

Health Promotion Education

The woman should be aware of the importance of regular, complete emptying of the breasts to prevent engorgement and stasis. She should also understand the role of let-down in successful breastfeeding, correct positioning of the infant on the nipple, proper latch on, and the principles of supply and demand. If the mother is taking antibiotics, she needs to understand the importance of completing the full course of antibiotics, even if the infection seems to clear quickly. Infants tolerate the small amount of antibiotics in breast milk without difficulty. Postpartum women need to be advised that mastitis may recur. Breastfeeding mothers who will be returning to work outside the home need information on how to do so successfully. Because mastitis tends to develop following discharge, it is important to include information about signs and symptoms in the discharge teaching and printed materials (Table 39-6). All flulike symptoms should be considered a sign of mastitis until proven otherwise. If symptoms develop, the woman should contact her caregiver immediately, because prompt treatment helps to avoid abscess formation.

Community-Based Nursing Care

Because symptoms seldom occur before the second to fourth week postpartum, birthing unit nurses often are not fully aware of how uncomfortable and acutely ill the woman can be. The home care nurse who suspects mastitis on the basis of assessment findings refers the woman to the physician. The nurse may be asked to obtain a sample of breast milk to be cultured for the causative organism.

If the mother feels too ill to breastfeed or develops an abscess that prevents breastfeeding, the home care nurse can help the mother obtain an appropriate breast pump to help her maintain lactation and can provide opportunities for demonstration and return demonstration of pumping. The nurse can assist the mother to deal with her feelings about temporarily being unable to breastfeed. Referral to a lactation consultant or to La Leche League can be invaluable to the woman's physical and emotional adjustment to mastitis.

Evaluation

Expected outcomes of nursing care include the following:

- The woman is aware of the signs and symptoms of mastitis.
- The woman reports her signs and symptoms of mastitis early, and it is treated successfully.
- The woman can continue breastfeeding if she chooses.
- The woman understands self-care measures she can use to prevent recurrence of mastitis.

Care of the Woman with Postpartum Thromboembolic Disease

Thromboembolic disease may occur during pregnancy, but it is generally considered a postpartum complication. *Venous thrombosis* refers to formation of a blood clot (thrombus formation) at an area of impeded blood flow in a superficial or deep vein. When the thrombus is formed in response to inflammation in the vein wall, it is termed **thrombophlebitis**. Pulmonary embolism, a rare but life-threatening condition, occurs when thrombi formed in the deep leg veins are carried to the pulmonary artery, obstructing pulmonary blood flow to one or both lungs. These vascular occlusive processes—venous thrombosis, thrombophlebitis, septic pelvic thrombophlebitis, and pulmonary embolism—are known as thromboembolic diseases (Mengel & Schwiebert, 2009).

Three major causes of thromboembolic disease, often referred to as *Virchow's Triad*, are hypercoagulability of blood, venous stasis, and injury to the epithelium of the blood vessel. Changes in the woman's coagulation system in pregnancy contribute to hypercoagulability, and compression of the common iliac vein by the gravid uterus leads to venous stasis. These factors increase the risk of this phenomenon appropriately 2 to 6 times in pregnant and postpartum women (Poggi, 2007). Super-

TABLE 39-6 Comparison of Findings of Engorgement, Plugged Duct, and Mastitis

CHARACTERISTICS	ENGORGEMENT	PLUGGED DUCT	MASTITIS
Onset	Gradual, immediately postpartum	Gradual, after feedings	Sudden, after 10 days
Site	Bilateral	Unilateral	Usually unilateral
Swelling and heat	Generalized	May shift, little or no heat	Localized, red, hot, and swollen
Pain	Generalized	Mild but localized	Intense but localized
Body temperature	Less than 38.4°C (101.1°F)	Less than 38.4°C (101.1°F)	Greater than 38.4°C (101.1°F)
Systemic symptoms	Feels well	Feels well	Flulike symptoms

ficial vein thrombophlebitis complicates the general childbearing period for 1 in 500 to 750 women. Deep vein thrombosis (DVT), which is more serious, occurs most commonly in postpartum women between postpartum days 10 to 20.

Risk factors associated with increased risk of thromboembolic disease include the following:

- Cesarean birth
- Immobility (prolonged)
- Obesity
- Cigarette smoking
- Previous thromboembolic disease or strong family history
- Trauma to extremity (can include injury from incorrect positioning or prolonged interval in stirrups during labor)
- Varicose veins
- Diabetes mellitus
- Advanced maternal age
- Multiparity
- Anemia
- Malignancy
- Inherited coagulation pathway deficiency
- Protein C & S deficiency

Factors contributing directly to the development of postpartum thromboembolic disease include (1) increased amounts of certain blood clotting factors; (2) postpartum thrombocytosis (increased quantity of circulating platelets and their increased adhesiveness); (3) release of thromboplastin substances from the tissue of the decidua, placenta, and fetal membranes; and (4) increased amounts of fibrinolysis inhibitors. These same factors protect childbearing women from exsanguinating from blood loss at delivery. Because women are at risk for thromboembolic disease during the childbearing period, attention should be given to measures that might prevent this complication (Table 39-7).

Women with inherited thrombophilias are at significantly greater risk of thromboembolism than women without these conditions. In these conditions, several regulatory proteins that act as inhibitors in the coagulation cascade are deficient, exacerbating hypercoagulability and contributing to recurrent venous thromboembolism. Most are transmitted by autosomal-dominant inheritance and affect predominantly Caucasian European populations, rarely those with Asian or African ethnic backgrounds. A personal or family history of thrombosis at any age is not uncommon, nor is a history of adverse pregnancy outcomes, such as severe pregnancy-induced hypertension, placental abruption, intrauterine growth retardation, or fetal loss after 20 weeks (Cunningham et al., 2010). Women with thrombophilias may require therapeutic levels of low-molecular-weight or unfractionated heparin throughout pregnancy and continued heparin therapy, followed by warfarin sodium (Coumadin) for at least 6 weeks postpartum.

Superficial Vein Disease

Superficial thrombophlebitis is far more common in postpartum women than during pregnancy. Often the clot involves the saphenous veins. This disorder is more common in women with pre-existing varices (enlarged veins), although it is not limited to that group. Superficial vein disease (SVD) may also occur as a sequelae to IV catheterization. Symptoms—tenderness in a portion of the vein, local heat and redness, normal temperature or low-grade fever, and, occasionally, slight elevation of the pulse—usually become apparent about the third or fourth postpartum day. A tender palpable cord may be noted along a portion of the vein. Treatment involves application of local heat, elevation of the affected limb, bed rest and analgesic agents, and the use of elastic compression support hose. Anticoagulants are usually not necessary unless complications develop. Pulmonary embolism is extremely rare. If improvement is not evident or deep vein involvement is suspected, appropriate diagnostic measures are taken and serve as a basis for treatment decisions (Mengel & Schwiebert, 2009).

Deep Vein Thrombosis

Deep vein thrombosis (DVT) or thrombophlebitis is more frequently seen in women with a history of thrombosis. Obstetric complications such as polyhydramnios, preeclampsia, and operative birth are associated with an increased incidence. After a clinical diagnosis of DVT, a woman's risk in a subsequent pregnancy increases.

TABLE 39-7 Measures to Decrease Risk of Thromboembolic Disease in Childbearing Women

ANTEPARTUM MEASURES	INTRAPARTUM MEASURES	POSTPARTUM MEASURES
Advise woman to avoid sedentary lifestyle and to exercise as much as possible (walking is ideal).	Encourage ambulation unless contraindicated in early labor.	Encourage early ambulation.
Recommend plenty of fluids to avoid dehydration.	Later, encourage leg exercises.	For women on bed rest, advise or assist with turning and leg exercises every 2 hours (woman may be encouraged to rotate ankles and to "write baby's name in air with toes").
Advise to quit smoking.	Do not gatch bed or use pillows under knees.	Encourage fluids to avoid dehydration.
Teach to avoid prolonged standing or sitting in one position or sitting with legs crossed.	Pad stirrups.	Advise no smoking.
Encourage elevation of legs when sitting.	Ensure correct positioning in stirrups that minimizes pressure on the popliteal area.	Use antiembolism stockings with those at risk. Pneumatic compression stockings may be ordered after cesarean birth until ambulation occurs.
Teach to avoid tight knee-high hose or other constrictive garments.	Limit time in stirrups as much as possible. After cesarean birth, initiate leg and foot exercises as soon as possible (in recovery).	Advise against prolonged sitting and crossing legs. Avoid knee gatch in hospital bed.
Encourage to take frequent breaks during long car trips to walk around, thereby preventing prolonged venous stasis.	Use antiembolism stockings for women at risk of deep vein thrombosis (DVT).	Encourage elevation of legs while sitting.

Clinical manifestations may include edema of the ankle and leg and an initial low-grade fever often followed by high temperature and chills. Other findings include tenderness or pain, a palpable cord, changes in limb color, and difference in limb circumference of more than 2 cm (0.8 in.). Depending on the vein involved, the woman may complain of pain in the popliteal and lateral tibial areas (popliteal vein), entire lower leg and foot (anterior and posterior tibial veins), inguinal tenderness (femoral vein), or pain in the lower abdomen (iliofemoral vein). Homans' sign (refer to chapter 35 ∞ and Figure 35-9 ∞) may or may not be positive. A positive Homans' sign is a specific finding but has a low sensitivity for helping diagnose DVT (Smith, 2008). Most DVTs occur in the left leg. Because of reflex arterial spasm, sometimes the limb is pale and cool to the touch—the so-called *milk leg* or *phlegmasia alba dolens*—and the dorsalis pedis pulse may be diminished or difficult to palpate.

CLINICAL JUDGMENT

Case Study: Wanda Sugiyama

Wanda Sugiyama, G1P1, had a cesarean birth after a prolonged labor and failure to progress. As she is walking in the hallway with her husband, you notice that Wanda is limping slightly, and you comment on that observation. Wanda responds that she is having pain in her right lower leg. She says, "Maybe I pulled a muscle during labor."

Critical Thinking

What would you do?

See www.nursing.pearsonhighered.com for possible responses.

Pulmonary Embolism

Pulmonary embolism (PE) occurs when a thrombus from a lower extremity or the pelvis lodges in the pulmonary vascular bed and restricts circulation to the corresponding area of the lung vasculature. The embolus may be microscopic in size or may be massive enough to occlude the branches of the pulmonary artery (McCaffery & Blum, 2009). Pulmonary embolism is a particularly catastrophic event with a high mortality rate; most fatalities occur within 30 to 60 minutes; however, early recognition and prompt action can decrease the mortality rate significantly and treatment of DVT can often prevent this complication. Although the incidence of DVT in pregnancy is now believed to be almost comparable with that of postpartum DVT, PE develops most commonly in postpartum women. The most common risk factors are proximal DVT and recurrent thromboembolic disease. Diagnosis may be difficult because the most common clinical findings include nonspecific signs and symptoms such as dyspnea, pleuritic chest pain, cough with or without hemoptysis, cyanosis, tachypnea and tachycardia, panic, syncope, or sudden hypotension. Physical assessment will also reveal diaphoresis, friction rub, changes in the heart sounds, and electrocardiogram (ECG) may document a right axis shift (Turrentine, 2008). The nurse who recognizes the clinical findings of this clinical emergency, especially in a woman at risk, should alert the woman's physician immediately, as time can be critical. Elevating the head of the woman's bed may facilitate ease of breathing; oxygen by facemask at 8 to10 L per minute is initiated. Narcotics may be ordered for pain and to decrease anxiety, thereby decreasing the respiratory effort. Several imaging tests are available to assist in diagnosing pulmonary embolism; the choices depend on availability, the woman's condition, and the element of time (McCaffery & Blum, 2009). The woman with pulmonary embolism will be transferred to an intensive care setting where cardiovascular and respiratory status are monitored closely.

Clinical Therapy

Treatment involves the immediate IV administration of either standard unfractionated heparin or low molecular weight heparin (LMWH) using an infusion pump to permit continuous, accurate infusion to stabilize the clot. An example of a possible regimen is a subcutaneous injection of Enoxaparin 1 mg/kg twice daily. Heparin therapy is continued until the international normalized ratio (INR) with oral warfarin is achieved at 2.0–3.0. An advantage of LMWH is a safe profile and dosing not reliant on monitoring the activated partial thromboplastin time (aPTT) at a laboratory. In some cases thrombolytics (streptokinase or urokinase) or an embolectomy may be used. Maintenance with warfarin sodium (Coumadin) is started at 1 to 5 days. An initial dose of 5 to 10 mg/daily PO is titrated based on the prothrombin time (PT) with the INR target rate cited above (Cunningham et al., 2010). Strict bed rest and elevation of the affected leg are required, and analgesics are given as necessary to relieve discomfort. If fever is present, the woman may also be given an antibiotic (Smith, 2008). In most cases thrombectomy (surgical removal of the clot) is not necessary.

Once the symptoms have subsided (usually in several days), the woman may begin walking while wearing elastic support stockings. The woman will continue on warfarin sodium (Coumadin) for 3 to 6 months and for 12 months after recurrence (McCaffery & Blum, 2009). While taking warfarin sodium (Coumadin), prothrombin times are assessed periodically to maintain correct dosage levels. Periodic assessment for signs of bleeding is essential, including those for hematuria and fecal occult blood. In those who cannot be given anticoagulants, a vena cava filtering device may be considered (Smith, 2008). To prevent recurrence in subsequent pregnancies, prophylactic treatment will be considered.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

The nurse carefully assesses the woman's history for factors predisposing to development of thrombosis or thrombophlebitis. In addition, as part of regular postpartum assessment, the nurse is alert to any patient complaints of pain in the leg, inguinal area, or lower abdomen, because such pain may indicate DVT. The nurse also assesses the woman's legs for evidence of edema, temperature change, or pain with palpation.

Nursing diagnoses that may apply to a postpartal woman with thromboembolic disease include the following:

- ***Ineffective Peripheral Tissue Perfusion*** related to obstructed venous return

- ***Acute Pain*** related to tissue hypoxia and edema secondary to vascular obstruction
- ***Risk for Impaired Parenting*** related to decreased maternal-infant interaction secondary to bed rest and intravenous lines
- ***Interrupted Family Processes*** related to illness of family member
- ***Deficient Knowledge*** related to self-care after discharge on anticoagulant therapy

Nursing Plan and Implementation

Women with varicosities should be evaluated for the need for support hose during labor and postpartum. Adequate fluid intake is necessary during labor to avoid dehydration. Because trauma is often a factor in the development of thrombophlebitis, the nurse avoids keeping the woman's legs elevated in stirrups for prolonged periods. If stirrups are used, they should be comfortably padded and adjusted to provide correct support and prevent pressure on popliteal vessels. Early ambulation is encouraged following birth, and the use of the knee gatch on the bed should be avoided. Women confined to bed following a cesarean birth are encouraged to perform regular leg exercises to promote venous return.

Once the diagnosis of DVT is made, the nurse maintains the heparin therapy, provides for appropriate comfort measures, and monitors the woman closely for signs of PE. The nurse also assesses for evidence of bleeding related to heparin and keeps the antagonist for heparin, protamine sulfate, readily available.

The nurse instructs the woman to avoid prolonged standing or sitting, because these positions contribute to venous stasis. She is also instructed to avoid crossing her legs because of the pressure it causes. The nurse also advises her to take frequent breaks, such as when taking car trips and while working if she sits most of the day. Walking is acceptable because it promotes venous return. The woman is reminded to identify her history of thrombosis or thrombophlebitis to her physician during subsequent pregnancies so that preventive measures may be instituted early. Recurrence is not uncommon (Turrentine, 2008).

Health Promotion Education

Women discharged on warfarin sodium (Coumadin) should be taught about the drug and safety factors associated with its use. Women need to be educated about foods high in vitamin K (a nutrient that lessens warfarin's effectiveness) and the need to strive for consistent daily intake so that accurate dosage of the drug can be achieved. When the dietary intake of these foods, such as cauliflower, soybean and canola oil, mayonnaise, broccoli, green and black tea, peppers, spinach, collard greens, and others increases significantly, the drug's anticoagulant effect can be lessened; when intake decreases significantly, there is a risk of bleeding. Thus consistency of intake is important. Favorites from these foods can be consumed in moderation and others avoided daily. Cranberry juice increases the effects of the drug and, if desired, should be consumed in moderation and with consistency. Binge alcohol use inhibits warfarin metabolism; an occasional alcoholic beverage does not affect coagulation adversely. Several herbals affect the efficacy of warfarin sodium; for example, garlic, ginger, and ginkgo prolong PT and should be avoided. Many multivitamins contain vitamin K; women on warfarin sodium (Coumadin) may take them but, again, should do so consistently. Vitamin C doses up to 500 mg per day and vitamin E doses up to 400 international units per day are considered safe; higher doses can affect coagulation.

While taking anticoagulants, the woman will be asked to undergo frequent coagulant tests to guide dosing. Point-of-care testing is now available to decrease the inconvenience of going into a laboratory environment for testing. Home self-testing involves a single capillary finger stick (Coaguchek, ProTime, Avocet) to test thromboplastin-mediated clotting expressed as prothrombin time (PT) or international normalized ratio (INR). The risk of bleeding increases significantly when the INR is 3 or greater (Lockwood, 2009). Bleeding should be reported if it fails to stop within 10 minutes. The nurse encourages the woman to carry a MedicAlert card or to wear a bracelet in case of emergency, to inform all healthcare providers (including dentists) that she is taking anticoagulants, and to have vitamin K available in case of bleeding.

While on anticoagulants, women should be cautious about using sharp objects such as knives or razor blades to avoid injury. Risky behaviors that could contribute to falls should be avoided. Wearing protective gloves during gardening or heavy housework and always wearing shoes can keep hands and feet safe from injury. For any severe bleeding episode, the woman should seek emergency care where IV vitamin K may be administered and fresh frozen plasma may be used to return her to an appropriate INR level.

Women who are discharged on warfarin must understand the purpose of the medication and be alert to signs of hemorrhage, such as bleeding gums, epistaxis, petechiae or ecchymosis, or evidence of blood in the urine or stool. Because careful monitoring is important, the woman should clearly understand the need to keep scheduled appointments for PT assessment. Certain medications, such as aspirin and other nonsteroidal anti-inflammatory drugs, increase anticoagulant activity, so they should be avoided. In fact, while she is taking warfarin sodium (Coumadin) the woman should check for possible medication interaction before taking *any* other medication. See the Nursing Care Plan: The Woman with Thromboembolic Disease for specific nursing care measures.

Community-Based Nursing Care

Because the mother with postpartum thromboembolic disease will depend on others for much of her initial home care, it is helpful for the father to be involved in preparations for discharge. The nurse should provide ample opportunities to answer questions and clarify instructions, verbally and in writing. The nurse will evaluate the extent to which both mother and father have understood instructions regarding the plan of care. It is especially important before discharge to assess the couple's plans to ensure bed rest for the mother if ordered. They might explore ways for her to maintain bed rest and still spend quality time with her newborn and any other children. For example, young children can sit on the bed for storytelling or play quiet games, and the newborn's crib can be placed adjacent to the mother's bed.

NURSING CARE PLAN The Woman with Thromboembolic Disease

INTERVENTION	RATIONALE
1. Nursing diagnosis: Ineffective Peripheral Tissue Perfusion related to interruption of venous blood flow secondary to complications of labor and birth **Goal:** The woman's presenting signs and symptoms are relieved.	
■ Assess, record, and report signs of thrombophlebitis.	■ Early detection of developing thrombophlebitis permits prompt treatment. As the thrombus increases in size, signs of obstruction also increase. Assessment provides baseline data that may be used to monitor success of treatment.
■ Assess leg for edema, peripheral pulse, temperature, color, and tenderness every 8 hours. Initially note presence of palpable cord.	■ Edema/swelling, diminished or absent peripheral pulse, pallor, cool skin temperature, and tenderness are symptoms of deep vein thrombosis (DVT) and indicate dysfunction of peripheral circulation in the lower extremities. Measure circumference of lower leg to monitor for swelling. Peripheral pulses in both legs should be palpated for pulse rate and pulse strength to allow for comparison. A lower extremity cool to the touch may be due to reflex arterial spasm.
■ Assess Homans' sign every 8 hours (see Figure 35-9 ∞ on page 1013).	■ Normally there is no pain or discomfort associated with this procedure. Pain is caused by inflammation of the vessel. If pain is elicited the nurse documents the response as a positive Homans' sign and reports findings to the physician. Some women with thrombophlebitis never have a positive Homans' sign.
■ Maintain bed rest during the acute phase.	■ Bed rest is ordered to decrease the possibility that a portion of the clot will dislodge and result in pulmonary embolism.
■ Provide warm, moist soaks as ordered.	■ Warmth promotes blood flow to affected area.
■ Maintain limb in elevated position.	■ Elevation of affected limb promotes venous return and helps decrease edema.
■ Add a footboard to the bed and encourage use.	■ Flexion and extension of legs against a footboard activates the calf muscle pump and promotes venous reurn.
■ Initiate progressive ambulation following the acute phase and provide properly fitting compression stockings before ambulation. These should be properly measured.	■ Elastic compression stockings or "TEDs" help prevent pooling of venous blood in lower extremities. Stockings should be carefully measured according to guidelines to ensure proper pressure gradient and avoid "garter-like" roll at top. ■ Woman may begin to ambulate within a few days when symptoms subside.
Collaborative: Administer unfractionated heparin as ordered, by continuous intravenous drip, heparin lock, or subcutaneously, or administer low molecular weight heparin (LMWH) subcutaneously as ordered including: 1. Monitor IV or heparin lock site (if in use) for patency, signs of infiltration, or signs of infection. 2. Obtain international normalized ratio (INR) and partial thromboplastin time (PTT) per physician order and review before administering heparin. 3. Observe for signs of anticoagulant overdose with resultant bleeding including: a. Hematuria b. Epistaxis c. Ecchymosis or petechiae d. Bleeding gums e. Nose bleeds f. Bruising disproportionate to injury g. Cuts, scratches, injection, or venipuncture sites that bleed excessively	■ Heparin does not dissolve blood clot but is administered to prevent further clotting and improve tissue perfusion. It is safe for breastfeeding mothers because heparin is not excreted in breast milk.
4. Provide protamine sulfate, per physician order, to combat bleeding problems related to heparin overdose.	■ Protamine sulfate is a heparin antagonist, given intravenously, which is almost immediately effective in counteracting bleeding complications caused by heparin overdose.

NURSING CARE PLAN The Woman with Thromboembolic Disease continued

INTERVENTION	RATIONALE
5. Monitor and report any signs of pulmonary embolism.	■ Pulmonary embolism is a major complication of DVT/thrombophlebitis.
6. Initiate or support any emergency treatment.	■ Signs and symptoms may occur suddenly and require immediate emergency treatment; prognosis is related to size and location of embolism.
7. Obtain prothrombin time (PT) and review before beginning warfarin. Repeat periodically per physician order.	■ PT is the test most commonly used to monitor the blood of women receiving warfarin.

EXPECTED OUTCOME: Woman will have increased venous return from lower leg as evidenced by decreased edema in lower leg, negative Homans' sign, and no pain or tenderness in lower leg.

2. Nursing Diagnosis: Acute Pain related to tissue hypoxia and edema secondary to vascular obstruction
Goal: Woman will obtain relief of pain or experience level of pain that is acceptable.

■ Administer analgesics per physician order. Notify physician if pain is not relieved.	■ Analgesics act to relieve pain and enable the woman to rest. Aspirin or ibuprofen products are contraindicated because they inhibit platelet adhesiveness. Acetaminophen may be ordered by the physician.
■ Observe or report disruptive effects of pain on emotions and behavior.	■ Once pain decreases, woman is more likely to ambulate, which will help increase venous return and decrease edema.
■ Provide supportive nursing comfort measures such as backrubs, provision of quiet time for sleep, diversional activities, or imagery.	

EXPECTED OUTCOME: Woman will have reduction in pain as evidenced by a pain level less than 5 at all times.

3. Nursing Diagnosis: Risk for Impaired Parenting related to decreased maternal-infant interaction secondary to bed rest and IVs
Goal: Woman will demonstrate evidence of positive physical and social interaction with newborn.

■ Maintain mother-infant attachment when mother is on bed rest: 1. Provide frequent contacts for mother and infant; modified rooming-in if possible by having the crib placed close to the mother's bed and nurse checks often to help mother lift or move infant. 2. Encourage mother to continue feeding infant.	■ Maternal-infant attachment is enhanced by frequent contact and opportunities to interact.

EXPECTED OUTCOME: Woman will develop attachment bonds as evidenced by physical interactions: good eye contact, touching the baby, holding baby close, attempting to comfort baby, and kissing baby and social interactions: calling baby by name, making positive comments about baby, asking questions about baby, asking questions about baby care, and talking to baby.

4. Nursing Diagnosis: Interrupted Family Processes related to illness of family member
Goal: Woman and her family will cope effectively with her illness.

■ Encourage woman to express her concerns to her partner. Assist couple in planning ways to manage while woman is hospitalized and after her discharge.	■ Illness of any family member impacts the entire family. This is especially true when the family situation is such that the mother is the primary nurturer and she is absent. Family members attempt to continue their own roles while also assuming the tasks of the missing mother. This can result in crisis.
■ Encourage partner or support person to bring other children to the hospital to visit mother and meet new sibling. ■ Encourage partner or support person to bring in family pictures and notes from other children. Encourage phone calls. ■ Contact social services if indicated to obtain additional assistance for family if needed.	

EXPECTED OUTCOMES: Woman expresses assurance that her family misses her but is coping effectively as evidenced by:
- Family visits woman frequently.
- Woman and family verbalize plan for division of family tasks while the woman is hospitalized, and understanding of potential needs of woman once released from hospital.

(continued)

NURSING CARE PLAN The Woman with Thromboembolic Disease continued

INTERVENTION	RATIONALE
5. Nursing Diagnosis: Risk for Bleeding related to lack of information about DVT/thrombophlebitis, its treatment, preventive measures, and the medication, warfarin sodium (Coumadin). **Goal:** Woman will understand her condition, its treatment, safety during treatment, and long-term implications.	
■ Provide information (both verbal and written supplements) about the woman's condition, its treatment regimen, the importance of compliance, and safety factors. Provide contact information that the woman can access 24/7.	■ Such discussion is essential to help the woman understand the condition, her medication, and its implications. She must have a clear understanding to be able to provide effective self-care.
■ Discuss ways of avoiding circulatory stasis such as avoiding prolonged standing, sitting, crossing legs, and wearing restrictive clothing.	■ Prolonged sitting, standing, and crossing legs should be avoided, as these activities decrease venous return.
■ Discuss safety precautions necessary while taking LMWH and warfarin sodium (Coumadin) (extra care with knives, razors, and other sharp objects; care around animals in the home that may scratch or bite; wear MedicAlert bracelet identifying that she is on anticoagulant therapy, avoiding being barefoot).	■ Anticoagulation places woman at risk of excessive bleeding and requires increased attention to safety issues that typically do not pose a significant risk. During warfarin sodium therapy, the international normalized ratio (INR) levels are monitored regularly to minimize risks.
■ Advise use of soft toothbruth and to avoid aggressive brushing.	
■ Advise to routinely inspect her body for evidence of bleeding.	
■ Advise to wear seatbelt in car.	
■ Advise to monitor menstrual flow, as it may be increased.	
■ Teach importance of compliance with warfarin sodium therapy and interactions of vitamin K with warfarin sodium, and check for interactions when starting new medications.	■ Warfarin sodium interacts with numerous medications that either increase or decrease its effectiveness.
■ Teach woman and partner to advise all healthcare providers, including dentists, that she is taking anticoagulants.	
■ If LMWH is being used at home, teach proper sterile technique for self-injection and safe disposal of syringes.	■ INR levels are monitored initially to facilitate dosage decisions. Once consistent effects are obtained, LMWH may be used without laboratory monitoring. With warfarin therapy, INR results will be monitored and dosage managed on the basis of lab results.
■ Teach importance of consistent level of vitamin K intake while on warfarin sodium and foods high in vitamin K to facilitate planning.	■ Vitamin K interacts with warfarin sodium. A consistent (balanced) intake of foods with vitamin K minimizes the problem of interaction.
■ Explain necessary follow-up testing ordered to maintain target INR.	■ Knowing details of anticipated follow-up care facilitates planning for home and child management issues.

EXPECTED OUTCOMES: Woman has health promotion knowledge as evidenced by:

- Woman verbalizes understanding of ways to avoid circulatory stasis, need to wear supportive stockings, medications dosage and side effects, and the importance of a balanced diet.
- Woman verbalizes understanding of signs and symptoms of bleeding that need to be reported to healthcare provider.

The father may be assuming multiple roles in the circumstances—household manager, parent, worker, and caregiver. Fatigue is inevitable. There may be financial concerns as a result of prolonged health care or his extended time away from work to care for the family. Many concerns will not surface until the couple returns home and fully comprehends the reality of their situation. For that reason it is valuable to provide them with an accessible resource and to plan telephone or home visit follow-up care. Signs of postpartum thrombophlebitis may not occur until after discharge from the birthing unit. Consequently, all couples must be taught about the signs and symptoms and to appreciate the importance of reporting them immediately and of not massaging the affected leg. If signs and symptoms occur after discharge, a short readmission might be required. Every effort is made in that case to allow mother, father, and newborn to remain together.

After DVT, some women continue to have leg pain, edema, and dermatitis of the affected extremity for prolonged periods

caused by a residual venous abnormality and can significantly affect one's quality of life. Continuing use of compression stockings for a minimum of 1 year after diagnosis will help to prevent the complication of DVT (McCaffery & Blum, 2009).

Evaluation

Expected outcomes of nursing care include:

- The woman seeks treatment for her thrombophlebitis early and is managed successfully without further complications.
- At discharge, the woman is able to explain the purpose, dosage regimen, and necessary precautions associated with any prescribed medications, such as anticoagulants.
- The woman can discuss self-care measures and ongoing therapies (such as the use of compression stockings) that are indicated.
- The woman has bonded successfully with her newborn and is able to care for the baby effectively.

Care of the Woman with a Postpartum Psychiatric Disorder

The relationship of affective disorders to childbirth is reflected in the fact that the rate of admission to a psychiatric hospital is greater during the year after childbirth than at any other time in a woman's life.

Types of Postpartum Psychiatric Disorders

Many types of psychiatric problems may occur in the postpartum. The *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 2000) has added a postpartum-onset specifier to the mood disorder diagnostic category of psychiatric disorders. It is proposed that postpartum psychiatric disorders be considered one diagnosable syndrome with three subclasses: (1) adjustment reaction with depressed mood, (2) postpartum major mood disorder, and (3) postpartum psychosis. The incidence, etiology, symptoms, treatment, and prognosis vary with each subclass, but the subclasses appear on a continuum from mild to severe.

Adjustment Reaction with Depressed Mood

Adjustment reaction with depressed mood is commonly known as **postpartum blues**, or as *maternal* or *baby blues*. It occurs in as many as 50% to 75% of mothers and is characterized by mild depression interspersed with happier feelings (Beck, 2008b). This adjustment reaction does not consistently affect the woman's ablity to function. Postpartum blues typically begin within 3 to 5 days after the baby's birth and are self-limiting, lasting from a few hours to 1 to 14 days. The depression is more severe in primiparas than in multiparas and seems related to the rapid alteration of estrogen, progesterone, and prolactin levels after birth, challenges of new motherhood, fatigue, and life-style adjustments. New mothers experiencing postpartum blues commonly report feeling overwhelmed, unable to cope, fatigued, anxious, irritable, and oversensitive. A key feature is episodic tearfulness and rapid mood shifts often without an identifiable reason. Not uncommonly, when asked why she is crying, this woman responds that she does not know. Cunningham et al. (2010) identifies several factors that contribute to the "blues":

- Emotional letdown that follows labor and childbirth
- Physical discomfort typical in the early postpartum
- Fatigue
- Anxiety about caring for the newborn after discharge
- Depression during pregnancy or previous depression unrelated to pregnancy
- Severe PMS (premenstrual syndrome)

Validating the existence of this phenomenon, labeling it as a real but normal adjustment reaction, and providing reassurance can offer a measure of relief. Assistance with self and infant care, rest, good nutrition, information, and family support aids recovery. Helping the new mother anticipate a transient emotional letdown after discharge is important guidance from the nurse, as is talking with her about her view of "the perfect mother." Trying to achieve that image can contribute to fatigue and exacerbate the letdown feeling. The partner should be encouraged to watch for and report signs that the new mother is not returning to a more normal mood but is instead slipping into a deeper depression or that happier times are no longer interspersed with the blues.

Postpartum Major Mood Disorder

Postpartum major mood disorder, also known as **postpartum depression (PPD)** has an overall prevalence rate of about 4.5% to 28% of postpartum women across multiple studies (Doucet, Dennis, Letourneau, et al., 2009).

Many of the symptoms of this major depression are indistinguishable from serious depression at other times in life: sadness, frequent crying, insomnia or excessive sleeping, appetite change, difficulty concentrating and making decisions, feelings of worthlessness, obsessive thoughts of inadequacy as a person and parent, lack of interest in activities that are usually associated with pleasure (including sexual relations), and lack of concern about personal appearance. Persistent anxiety further contributes to the woman's feeling of being out of control. Irritability and hostility toward others, including the newborn, may be evident. Women participating in Beck's qualitative research on postpartum depression described a sense of living their daily life in a sort of fog, from which they believed they would never emerge. Once they improved, they often grieved over the time lost with their newborns while in this "fog." The duration of symptoms varies but as many as half continue to be symptomatic at 6 months or longer. Delayed treatment of major depression is associated with a longer duration.

Risk factors for postpartum depression include the following:

- Primiparity
- Ambivalence about maintaining the pregnancy
- Occurrence of postpartum blues
- History of postpartum depression or bipolar illness (recurrence rates are ≥20%)
- Lack of social support
- Lack of a stable and supportive relationship with parents (especially her father, as a child) or partner

- The woman's dissatisfaction with herself, including body image problems and eating disorders
- Poverty
- Depression during pregnancy
- Complications of delivery
- Loss of newborn
- Age (adolescence increases risk)
- Domestic violence

Although it may occur at any time during the first year postpartum, the greatest risk occurs within the first 4 weeks after childbirth. Surprisingly, it is not always associated with depression during pregnancy. Postpartum depression is considered to have a multifactorial cause. When depressive symptoms occur, physical causes, such as thyroid disease, anemia, or drug abuse, are ruled out through clinical and laboratory exams.

Because postpartum depression is complicated to detect when providers wait for the woman to self report or the family to become concerned enough to seek help, routine screening by those providers in contact with this population is imperative. For women considered to be at high risk, telephone follow-up after delivery or an earlier clinic appointment than 6 weeks may be helpful. Nurses in the pediatrician's office assisting with well-child visits have an excellent opportunity to screen women for PPD (Sheeder, Kabin, & Stafford, 2009). Community health nurses who are seeing other members of the family or parish nurses who know new mothers in their congregation can observe for evidence of depression. The Beck Depression Inventory or the Edinburg Postnatal Depression Scale (EPDS) are useful and validated for screening for postpartum depression. For the EPDS, a score of greater than 12 is indicative of depression.

The woman's safety, and that of her child(ren), is a priority. Inquiring about suicidal ideas and assessment for thoughts and feelings toward the infant, hallucinations and delusions, and impulsiveness that might put the infant and siblings at risk is critical. Women with postpartum depression are at risk for suicide, most prominently as they enter or exit the deeply depressed state. In a deep depression, the woman is unlikely to be able to plan and carry out suicide. For that reason, signs of improvement in depression should be celebrated with some caution, and continued observation is necessary. Whereas the woman with postpartum psychosis may attempt suicide because of illogical thought processes, delusions, and hallucinations, the woman with major depression attempts suicide because her suffering is so great that dying seems a more favorable option than continuing to live in such pain. She may also attempt suicide to save her newborn from some perceived or real threat—including the threat that she herself might cause harm. The risk of suicide is greater in those who have attempted suicide previously, have a specific plan, and can access the means or weapon identified within the plan. The more specific the plan, the greater is the probability of an attempt.

The woman and her family need information about the illness and its expected course, including the risk of recurrence, as well as comprehensive information about the treatment plan. They need opprtunities to clarify misconceptions about mental illness and to have answers to questions. Referral to local or online support groups may be helpful.

The expected outcomes for mild to moderate depression treated with antidepressants and psychotherapy are good; recurrence rates are increased after each episode of depression. The serotonin reuptake inhibitors (SSRIs) are used most often. Their most frequently occurring side effects include headache, nausea, diarrhea, sleep disruption, anxiety, and sexual dysfunction (Gjerdingen, Katon, & Rich, 2008). The second-line antidepressant drugs are the tricyclics. They cause dry mouth, constipation, orthostatic hypotension, and weight gain. Monoamine oxidase inhibitors (MAOIs) are rarely used in the treatment of PPD because these drugs have a high profile of interacting with other medications. Women typically continue antidepressants for 1 year after symptoms abate.

All current antidepressant agents are excreted into breast milk. Zoloft, Lustral, Paxil, Seroxat, and Deroxat are considered first-line agents. Because of its prolonged half-life, fluoxetine (Prozac) is not recommended for nursing mothers. Physicians will wish to educate their breastfeeding postpartum patients who need antidepressants about the different alternatives and help them to balance the risks and benefits with the safety profiles. The final decision about continuing to breastfeed and to take antidepressants is the informed woman's. To help in making the decision, she and her significant other need to be helped to consider how she will respond without pharmacologic therapy and how unmedicated depression will affect the maternal-infant relationship and the infant's well-being and development. An invaluable online resource for prescribers with current information on drug safety and toxic effects during pregnancy and lactation is the LacMed Database.

Electroconvulsive therapy (ECT) is used for quicker treatment of those who have severe depression or mania, are unresponsive to other treatment, or are at high risk of suicide. Antidepressants may take 2 to 3 weeks to become effective. ECT results often become noticeable within 1 week (Townsend, 2009).

Post-Traumatic Stress Disorder

Many women envision their own labor and delivery unfolding in a particular way and may experience angst if their labor reality fails to match their expectations. Labor and birth that go awry, including those associated with complications, may cause **post-traumatic stress disorder (PTSD)** (also called *post-traumatic stress syndrome (PTSS),* which the APA's *Diagnostic and Statistical Manual of Mental Disorders*—DSM-IV (2000, p. 463) describes as "exposure to an extreme traumatic event involving direct personal experience of an event that involves actual or threatened death or serious injury . . . a person's response to the event must involve intense fear, helplessness, or horror." These extreme traumatic situations are typically ones outside the realm of usual human experience—situations that would be distressing for anyone.

At particular risk for PTSD are women who are especially anxious or fearful about childbirth, have low coping capacity, and/or prior psychiatric histories (Tham, Christensson, & Ryding, 2007). For the woman, the facts of the labor and birth have become distorted, perhaps because of pain or change in consciousness related to medications she received. Perhaps she underwent an emergency cesarean delivery or her baby had a

serious physical anomaly. Perhaps her labor coach could not make the trip to the hospital in time for the birth or she experienced a postpartum hemorrhage. Her perceptions of what occurred and the actions of those involved frequently are far different from the reality, perhaps even seeming delusional.

Clinical features of PTSD include feeling numb, seeming dazed and unaware of her environment, intrusive thoughts and flashbacks to the threatening event, difficulty thinking, difficulty sleeping, irritability, and avoidance of others and reminders of the traumatic event. Tachycardia, hyperventilation, and nausea may occur (Stone, 2009). These signs and symptoms may not be evident until after the woman has left the birth setting. Distress associated with the original traumatic event can recur at anniversaries, and some women are hesitant to consider future pregnancies because of this birth trauma (Beck, 2008a).

Based on her qualitative research and the work of others related to traumatic birth experiences, Beck (2008a, p. 8) suggests the following implications for nursing care: (1) Whenever possible, intervene to prevent traumatic birth experiences; (2) provide technically competent, concerned care for the woman and family; (3) assess for anxiety and fears on admission to labor and provide information to dispel myths; (4) debrief the woman and family after a stressful traumatic childbirth experience ; and (5) visit the woman during her hospitalization to assess for evidence of signs of early trauma. Women should be asked to tell their birth story, to compare and contrast the actual experience with their birth plan or prior visions of the special day, and to tell what went well for them and what part, if any, of the experience was unexpected, troublesome, disappointing, or distressing.

Nurses who work in childbirth settings should appreciate that a woman they are admitting at any point in time may have previously had a traumatic birth. That woman will need sensitive caregivers who provide additional support and information and follow the birth plan to the extent possible. Support for new parents and helpful information is available online from the Trauma and Birth Stress (TABS) charitable trust located in New Zealand.

Postpartum Psychosis

Postpartum psychosis, which has an incidence of 1 to 2/1000, usually becomes evident within the first 1 to 4 weeks after childbirth (Sit, Rothschild, & Wisner, 2006). Although relatively rare, this disorder gains considerable national attention in the media and is considered an emergency, given the risk of infanticide or suicide, especially in teens. Symptoms include agitation, hyperactivity, insomnia, mood lability, confusion, irrational thinking and behaviors, difficulty remembering or concentrating, and poor judgment, as well as delusions and hallucinations, which tend to be related to the infant. Clinical features progress rapidly and include the following (Parry, 2007):

- Sleep disturbances—the woman is unable to sleep, even when her infant is sleeping
- Depersonalization—seeming unaware of or distant from the immediate environment and individuals within it
- Confusion; irrational or disorganized thinking; bizarre behaviors; delusions; hallucinations
- Psychomotor disturbances—stupor or agitated state sometimes with rapid and incoherent speech

Risk factors include (1) previous puerperal psychosis; (2) history of bipolar (manic-depressive) disorder; (3) prenatal stressors, such as lack of social support, lack of a partner, and low socioeconomic status; (4) obsessive personality; and (5) a family history of a mood disorder. There is some question among experts that postpartum psychosis represents a variant of bipolar disorder timed to coincide with the hormonal changes after childbirth, since the majority meet the criteria for a mood disorder and about half of women experience manic behavior (Sit et al., 2006).

The psychotic woman experiences delusions and/or visual, auditory, or tactile hallucinations. In some women, these symptoms support her perceptions that the infant should not be allowed to live or that she should commit suicide. For example, she may believe that her newborn is evil, some form of "changeling," and will harm her or others, or she may believe that her newborn would be "better off dead" than living in such an evil world. She may contemplate suicide because she believes that her child would be better off without a mother than with her as such a "terrible, crazy mother." Illogical thinking or evidence of bonding difficulties may serve as cues to infanticide and suicide risk; however, this assessment is often challenging because of periods of lucidity seen in some psychotic women. Nurses in various clinical settings who come in contact with this woman may note that the child has been neglected or the woman is practicing unsafe behaviors because of the woman's cognitive impairment. For example, a pediatric nurse noticed that one of her women placed the newborn across the room at the edge of the narrow exam table while she paced back and forth across the room, muttering to herself, appearing not to notice the baby. This same woman came to her appointment during heavy snow with both her infant and herself underdressed for warmth.

Provisions for safety of the woman and infant are paramount. This woman needs immediate referral to psychiatric care, usually requiring admission to an inpatient psychiatric hospital. Continued assessment of her symptomatology, safety, and functional capacity is a major nursing role in the setting. An initial history, physical examination, and lab work will help to rule out an organic cause of acute psychosis. If the woman has a fever, a urine culture should be performed, and if drug use is suspected, a urinary drug screen is ordered. A CT or MRI may be ordered if the neurologic exam increases concern about a stroke (Sit et al., 2006).

Treatment for postpartum psychosis is directed at the specific type of psychotic symptoms displayed, and may include antidepressants and a mood stabilizer such as lithium, valproic acid, or carbamazepine, combined with antipsychotics. Electroconvulsive therapy (ECT) is another treatment option if rapid stabilization is required. Psychotherapy and social support are part of the management plan as well.

A dilemma exists for breastfeeding women for whom lithium or psychotropic medication is being considered. Since infants have immature hepatic and renal systems and a more permeable blood-brain barrier, they may be vulnerable to side effects, especially when younger than 2 months of age, premature, or exposed to these medications in utero. With the exception of lithium (which is contraindicated with breastfeeding), the amount of psychotropic drugs excreted into breast milk appears

to be modest and not to compromise growth and development (Eberhard-Gran, Eskild, & Opjordsmoen, 2006). Parents of an infant need to be educated to consider these factors in making a decision about the use of psychotropic medications: (1) severity of symptoms and their effect on the infant if medications are not used; (2) benefits of breastfeeding to the baby; (3) potential risks to the baby if psychotropics are used; and (4) preferences of the woman. If psychotropics are prescribed, the lowest dose possible of monotherapy should be used and the infant should be monitored carefully by a pediatrician for difficulty being aroused from sleep, rigidity, tremors, irritability, poor hydration, and poor feeding with failure to gain weight (Sit et al., 2006).

Clinical Therapy

Women with a history of postpartum psychosis or depression or other risk factors should be referred to a mental health professional for counseling and biweekly visits between the second and sixth week postpartum for evaluation. Treatment for postpartum depression includes the following:

- Antidepression medications, usually the selective serotonin reuptake inhibitors. The woman and her partner should be reminded that antidepressants may take several weeks to have an effect.
- Individual or group psychotherapy and cognitive behavioral therapy. These are common treatment measures for both disorders; however, specific therapies used may vary. Cognitive behavioral therapy (CBT)—time limited, problem-focused therapy intended to reduce emotional distress by modifying maladaptive beliefs, assumptions, attitudes, and behaviors. With help, depressed women examine the factors that contribute to depression and attempt to better understand them in an effort to change what is dysfunctional. Interpersonal psychotherapy (IPT)—Depression generally has an interpersonal component, in that it affects one's roles and relationships. Role transitions, conflicts, disputes, loss, and grief are often explored. The first few sessions involve assessment of interpersonal issues that will be the therapy's focus. Maintenance therapy with a psychiatrist, psychologist, or social worker once monthly often follows the short-term phase.
- Psychoeducation (family therapy)—educating the woman and her family about her mental illness and the treatment regime and helpful ways of coping—will be part of the treatment plan.
- Practical assistance with child care and other demands of daily life.

Outpatient treatment may continue after discharge from the hospital. With a support group of postpartum women and their partners, a couple may feel consolation that they are not alone in their experience. Moreover, the support group provides a forum for gaining information about postpartum depression, learning stress-reduction measures, and experiencing renewed self-esteem and support. The most effective support groups provide for safe child care to facilitate attendance. If a support group is not available locally, the woman and her family may be encouraged to contact Depression After Delivery (DAD), or Postpartum Support International, a national Web-based support network. The Mills Depression and Anxiety Symptom-Feeling Checklist focuses on symptoms and feelings the postpartum woman has experienced over the previous 2-week interval. The woman is advised to contact her healthcare provider immediately if she marks the symptoms and feelings highlighted in red—those that relate to harm to herself or the infant. The checklist is not intended to be used for diagnosis but to help the woman put her feelings into context.

NURSING CARE MANAGEMENT

Nursing Assessment and Diagnosis

Assessment for factors predisposing a woman to postpartum depression or psychosis should begin prenatally. Questions designed to detect problems can be included as part of the routine prenatal history interview or questionnaire. Women with a personal or family history of psychiatric disease, particularly postpartum depression or psychosis, need prenatal instructions on the signs and symptoms of depression and may need additional emotional support. Ideally the assessment should be completed each trimester to update a pregnant woman's risk status (Beck, 2002). If the assessment has not been done previously, the nurse assesses the woman for predisposing factors during her labor and postpartum stay. Answers to open-ended questions can be telling: What has been your greatest surprise about motherhood? Your greatest disappointment? Biggest concern? Biggest challenge? Or how does being a mother compare to what you had envisioned?

New mothers and their families expect a challenging adjustment period after bringing home a new baby; they may not realize that their experiences are outside the norm. There is general anticipation that motherhood will be a happy occasion; a woman may not be able to admit her unhappiness out of shame or embarassment that she is somehow different as a mother. The woman might be concerned that telling someone, even a professional, about her symptoms makes her sound "crazy" and that her baby might be taken away (Doucet et al., 2009). One woman reported that she wanted help and sensed she needed it, but did not know which doctor to call. "I had only been home for 3 weeks and my postpartum clinic visit was 3 weeks away when I started feeling so desperate. Should I call my OB? The pediatrician had seen the baby in the hospital nursery but we hadn't visited him yet and, besides, I'm not his patient—I'm an adult. My family doctor doesn't see pregnancy-related problems, so who do I call?"

Several depression scales are available for assessing postpartum depression. The routine use of a screening tool in a matter-of-fact approach significantly increases the diagnosis because the woman does not feel singled out. The Edinburgh Postnatal Depression Scale (Table 39-8) is likely the most widely used screening tool for postpartum depression in large populations of women. Mothers who score above 12 on the Edinburgh Postnatal Depression Scale are likely to be suffering from postpartum depression. Beck's (2002) revised Postpartum Depression Predictors Inventory (PDPI-Revised) tool is a practical and simple screening checklist for use during routine care with all postpartal women to identify those who might be experiencing postpar-

TABLE 39-8 Edinburgh Postnatal Depression Scale

In the past 7 days:

1. I have been able to laugh and see the funny side of things.
As much as I always could
Not quite so much now
Definitely not so much now
Not at all

2. I have looked forward with enjoyment of things.
As much as I ever did
Rather less than I used to
Definitely less than I used to
Hardly at all

***3. I have blamed myself unnecessarily when things went wrong.**
Yes, most of the time
Yes, some of the time
Not very often
No, never

4. I have been anxious or worried for no good reason.
No, not at all
Hardly ever
Yes, sometimes
Yes, very often

***5. I have felt scared or panicky for no very good reason.**
Yes, quite a lot
Yes, sometimes
No, not much
No, not at all

***6. Things have been getting on top of me.**
Yes, most of the time I haven't been able to cope at all
Yes, sometimes I haven't been coping as well as usual
No, I have been coping quite well
No, I have been coping as well as ever

***7. I have been so unhappy that I have had difficulty sleeping.**
Yes, most of the time
Yes, sometimes
Not very often
No, not at all

***8. I have felt sad or miserable.**
Yes, most of the time
Yes, quite often
Not very often
No, not at all

***9. I have been so unhappy that I have been crying.**
Yes, most of the time
Yes, quite often
Only occasionally
No, never

***10. The thought of harming myself has occurred to me.**
Yes, quite often
Sometimes
Hardly ever
Never

Note: Response categories are scored 0, 1, 2, and 3 according to increased severity of the symptoms. Items marked with an asterisk* are reverse scored (3, 2, 1, 0). The total score is calculated by adding together the scores for each of the 10 items. A score above the threshold of 12–13 out of 30 indicates with 86% sensitivity that the woman is suffering from postpartum depression.

British Journal of Psychiatry, 150, *782–786. Users may reproduce the scale without further permission provided they respect copyright by quoting the names of the authors, the title, and the source of the paper in all reproduced copies.*

tum depression so that early management might be initiated (Table 39-9). No matter what approach the nurse uses to assess for postpartum depression, enabling the woman's voice to be heard about her feelings of maternal role transition and how she is adjusting in this vulnerable time is of inestimable value. Listening to her story provides a critical emic (insider's) view of her circumstances as opposed to an etic (outsider's) view.

In providing daily care, the nurse observes the woman for objective signs of depression—anxiety, irritability, poor concentration, forgetfulness, sleeping difficulties, appetite change, fatigue, and tearfulness—and listens for statements indicating feelings of failure and self-accusation. Severity and duration of symptoms should be noted. Behavior and verbalization that are bizarre or seem to indicate a potential for violence against herself or others, including the infant, are reported as soon as possible for further evaluation. The nurse needs to be aware that many normal physiologic changes of the puerperium are similar to symptoms of depression (lack of sexual interest, indecisiveness, appetite change, sleep disturbance, and fatigue). It is essential that observations be as specific and as objective as possible and that they be carefully documented.

Beck and Indman (2005) found that anxiety was a prominent feature of illness for some women and suggested that women be assessed for their level of anxiety, particularly regarding infant care. Because of the strong association of interrupted sleep and postpartum depression and the finding that severe fatigue was an excellent predictor of postpartum depression (Corwin, Brownstead, Barton, et al., 2005), assessing fatigue level at 2 weeks postpartum by telephone may be helpful in predicting depression risk early. Restorative sleep improves one's ability to cope and make decisions, thereby producing a sense of better self-control.

A central challenge for nursing is identifying women at risk of suicide. Like others with psychologic disorders, the postpartum woman is likely ambivalent about suicide, and may be "rescuable" if suicide ideation is assessed and timely action follows. Assessment of suicide risk reflects the standard of care; contrary to myth, asking a depressed woman about suicidal thoughts does not increase her risk, but it may save her life. Introducing the issue of suicide can be as simple as saying something like, "I'm concerned about the amount of emotional pain you're feeling, and I'm wondering whether you've ever thought of hurting yourself." Ambivalence about suicide is likely to make the woman answer candidly. A suicide prevention contract may be established with the woman to exact an agreement that she will seek help immediately if she begins to consider self-harm. For example, the nurse might say, "Promise me that should you begin to feel as if you are going to hurt yourself, you will telephone me or the hotline immediately—that you will not act without talking to someone." Because of the hope this offers, the woman is likely to respond by seeking help; she does not want to renege on a promise she made to a nurse who has shown such caring for her.

If a woman admits that she has thought of hurting herself, assessment of the risk that she will follow through is imperative. The mnemonic **SAL** is useful for risk assessment: Is there a **S**pecific plan with a designated time? Is there an **A**ccessible weapon or other means? How **L**ethal is the method identified

RESEARCH EVIDENCE IN PRACTICE

Screening for Postpartum Depression

CLINICAL QUESTION

What is the most appropriate method to screen for postpartum depression?

RESEARCH EVIDENCE

Postpartum depression (PPD) occurs in approximately 10% to 20% of mothers and is the most common serious postpartum disorder. PPD can occur at any time in the first year after birth, but usually starts within the first 4 weeks. It can be a debilitating disease that affects the whole family, and may have long-term effects on the child. Despite the potential for negative consequences, rates of diagnosis and treatment are low because of lack of recognition by healthcare providers or an underestimation of its impact.

Symptoms of PPD are severe and may be long-lasting, requiring treatment. However, these symptoms may be subtle and are often confused with other medical or psychologic conditions. Use of a sensitive, valid screening tool can help identify mothers who are exhibiting a range of symptoms that represent PPD.

The most thoroughly researched and recognized screening tool for PPD is the Edinburgh Postnatal Depression Scale (EPDS). This screening tool is a self-report that is quick, easy, and takes only 5 minutes or less. It consists of 10 questions with 4 possible responses, and yields a summary score that can be interpreted to determine the presence of PPD. An equally valid tool is the Postpartum Depression Screening Scale (PDSS) that is more sensitive than the EPDS but requires responses to 35 items. Both screening tools have been administered via the Internet, which was found to be an effective way to solicit participation. The relative anonymity of the Internet screening process actually resulted in a higher level of participation than in-person administration, with larger numbers of ethnic minority women responding via the Internet.

There are no antenatal or prenatal tools that adequately predict postpartum depression. Therefore, all women should be screened before they are discharged from the hospital and screening should continue throughout the first year after birth.

WHAT QUESTIONS REMAIN UNANSWERED?

Is Internet administration of PPD screening tools comparable to in-person completion in terms of accurate diagnosis of postpartum depression?

WHAT IS BEST PRACTICE?

Screening for postpartum depression should be done in the first postpartum follow-up after birth. Of the screening tools available, the EPDS is the quickest and easiest to use, and the PDSS is the most sensitive. Administering the screening tool in person or via the Internet are both effective in identifying women who have PPD.

CRITICAL THINKING

What are ways that the nurse can encourage mothers to complete screening tools for depression during the postpartum period?

in the plan? A specific plan that identifies a highly lethal method that is immediately accessible is evidence of very high risk of suicide. Immediate intervention is critical; emergency psychiatric hospitalization is likely necessary. Those considered a threat to themselves or others may be admitted to involuntary hospitalization for a minimum of 48 hours until further evaluation is complete.

Family members of the depressed woman should also be alert to signals that she may be intent on self-harm; they must be advised that threats should always be taken seriously. Clues to suicide that might be noted by family are comments such as "I don't deserve to live," "Life is no longer worth living," or "You won't have to worry about me for long." Someone who is considering suicide may also telephone or write family or friends to say good-bye or give away prized possessions. Family members should be told to be especially vigilant for suicide when the woman seems to be feeling better.

Possible nursing diagnoses that may apply to a woman with a postpartum psychiatric disorder include the following:

- ***Ineffective Coping*** related to postpartum depression
- ***Risk for Impaired Parenting*** related to postpartum mental illness
- ***Self-Directed Violence*** against self (suicide), newborn, and other children related to depression.

Nursing Plan and Implementation

Nurses working in antepartum settings or teaching childbirth classes play indispensable roles in helping prospective parents appreciate the lifestyle changes and role demands associated with parenthood. Offering realistic information and anticipatory guidance and debunking myths about the perfect mother or perfect newborn may help prevent postpartum depression. Social support teaching guides are available for nurses to help postpartum women explore their needs for postpartum support.

The nurse should alert the mother, partner, and other family members to the possibility of postpartum blues in the early days after birth and reassure them of the short-term nature of the condition. Symptoms of postpartum depression should be described and the mother encouraged to call her healthcare provider if symptoms become severe, if they fail to subside quickly, or if at any time she feels she is unable to function. Encouraging the mother to plan how she will manage at home and providing concrete suggestions on how to cope will aid in her adjustment to motherhood. Table 39-10 provides suggestions for the mother that serve as primary prevention for postpartum depression.

Information, emotional support, and assistance in providing or obtaining care for the infant may be needed. The nurse can

TABLE 39-10 Primary Prevention Strategies for Postpartum Depression

1. Celebrate childbirth but appreciate that it is a life-changing transition that can be stressful—at times it can seem overwhelming. Share your feelings with each other and/or others.
2. Consider keeping a journal where you write down feelings. Not only is it emotionally cathartic, it provides a great memory book.
3. Appreciate that you do not have to know everything to be a good parent—it is okay to seek advice during this transition.
4. Connect to others who are parents—use them as a support and information network.
5. Set a daily schedule and follow it even if you do not feel like it. Structuring activity helps counteract inertia that comes with feeling sad or unsettled.
6. Prioritize daily tasks. Decide what must be done and what can wait. Try to get one major thing done every day. Remember, you do not always have to look like a magazine fashion model.
7. Remember that you do not have to entertain or care for everyone who drops by. Doing something for someone else, however, often tends to make you feel better.
8. If someone volunteers to help you with tasks or baby care, take them up on it. While your volunteer is in action, do something pleasurable or get some rest.
9. Maintain outside interests. Plan some time every day—even if it's just 15 minutes—to do something exclusively for "you" that is pleasurable.
10. Eat a healthful diet. Limit alcohol. Quit smoking. Get some exercise. (All of these can positively affect the immune system.)
11. Get as much sleep as possible. Rest whenever you can, such as when the baby is napping. If you have other young children, bring them onto your bed to read or play quietly while you lie down.
12. Limit major changes (moves, job changes, etc.) the first year insofar as possible.
13. Spend time with others.
14. If things get overwhelming, and you feel yourself slipping into depression, reach out to someone for help.
15. Attend a postpartum support group if one is available. Consider also an international program.

Source: Data from Postpartum Support International (PSI).

assist family members by identifying community resources and making referrals to public health nursing services and social services. Postpartum follow-up is especially important, as well as visits from a psychiatric home-health nurse.

Community-Based Nursing Care

Home visits, especially for early discharge families, are invaluable in fostering positive adjustments for the new family constellation. Telephone follow-up at 2 to 3 weeks postpartum to ask whether the mother is experiencing difficulties is also helpful. Monitoring for signs of depression or performing brief screening at well-child follow-ups also can be valuable for early identification and timely intervention.

In all women, the presence of three symptoms on 1 day or one symptom for 3 days may signal serious postpartum depression and requires immediate referral to a mental health professional. Immediate referral should also be made if rejection of the infant or threatened or actual aggression against the infant has occurred. In such cases, the newborn is never left unattended with the mother. Depression does appear to interfere with optimal mothering; there is less interaction between mother and child, more mood and cognitive development problems, and more visits to the doctor in these children (Beck, 2002). A diagnosis of postpartum depression or other psychiatric disorder will pose major problems for the family, especially the father. The symptoms of these disorders are difficult to witness and may be harder to understand than physical problems such as hemorrhage or infection. The father may feel hurt by his partner's hostility and may worry that she is becoming insane, or be baffled by her mood swings and lack of concern about herself, the newborn, or household responsibilities. He may be troubled by their lack of intimacy or deteriorating communication. Certainly, he has cause for concern about how the newborn and any other children are being affected. There may be very real practical matters to handle—running the household; managing the children, including the totally dependent newborn; and caring for the mother—added to his usual routines and work responsibilities. It is not surprising that even in the most supportive families, relationships may suffer in response to these circumstances. It is often a family member who in desperation makes contact with the healthcare agency. This is especially difficult when the mother is reluctant to admit she is suffering emotional difficulty or is too ill to recognize her own needs. The integration of the newborn into the family and care of the newborn and other children can be further compromised by co-occurrent postpartum depression in fathers. With both parents having depressive symptomatology, the infant and other children are further at risk.

Evaluation

Expected outcomes of nursing care include the following:

- The woman's signs of depression are identified and she receives therapy quickly.
- The newborn is cared for effectively by the father or another support person until the mother is able to provide care.
- The mother and newborn will remain safe.
- The newborn is integrated into the family.

Postpartum Support

FOCUS YOUR STUDY

- Nursing assessment and intervention play a large role in preventing postpartum complications.
- The main causes of early postpartum hemorrhage are uterine atony, lacerations of the vagina and cervix, and retained placental fragments. Late postpartum hemorrhage most often originates from retained placental fragments and, though not usually as catastrophic as early hemorrhage, may require readmission.
- The most common postpartum infection is metritis, which is limited to the uterine cavity.
- A postpartum woman is at increased risk for developing urinary tract problems because of normal postpartum diuresis, increased bladder capacity, decreased bladder sensitivity from stretching or trauma, and possibly inhibited neural control of the bladder following the use of anesthetic agents.
- Mastitis is an inflammation of the breast often caused by *Staphylococcus aureus, Escherichia coli,* and *Streptococcus* species. Mastitis is seen primarily in breastfeeding women. Symptoms seldom occur before the second to fourth postpartal week. Continuation of breastfeeding is recommended as part of the treatment plan.
- Thromboembolic disease originating in the veins of the leg, thigh, or pelvis may occur antepartally or postpartally and carries with it the potential for creating a life-threatening pulmonary embolus.
- Although many different types of psychiatric problems may be encountered in the postpartum period, postpartum blues is the most common. Postpartum blues episodes occur frequently in the week after birth, are associated with hormonal fluctuations, and are typically transient.
- Risk factors for postpartum depression should be screened for during each trimester of pregnancy and during the immediate postpartum period. Nurses should be alert to the risk of suicide and infanticide in cases of severe postpartum depression or psychosis.
- Telephone calls and home visits are effective measures for extending comprehensive care into the home setting of the postpartum family at risk. Support groups in which child care is available also can be an invaluable community service by professional nurses.

CRITICAL THINKING IN ACTION

Betty Jones, a 32-year-old G4 P2012, is admitted to the postpartum unit after a precipitous birth of a preterm (35 weeks' gestation) 4-pound baby girl followed by a postpartum tubal ligation. Betty's vital signs and postpartum assessment are within normal limits. She has an abdominal dressing that is dry and intact and she is able to void. Her IV with 10 units of Pitocin is infusing well in her lower left arm. She admits to 3 on a pain scale of 10. Betty admits to active use of crack cocaine throughout her pregnancy, and smoked it most recently 5 hours before she gave birth. She is HIV positive with a CD_4 count of 726 cells/mm^3 and was treated with zidovudine during the pregnancy, labor, and birth. She also has a history of genital herpes and had been treated for chlamydia during the pregnancy. Her infant has been admitted to the special care nursery because of her preterm status. Betty anticipates her baby will be taken into foster care when discharged from the nursery. Wishing to establish as much of a relationship with her infant as possible before that happens, she asks if she can breastfeed the baby while she is in the hospital.

1. What is your response to Betty's request to breastfeed her infant?
2. Over the course of the first postpartum day, Betty appears lethargic and spends most of her time sleeping. After her evening visitors leave, you observe that she is highly energetic and excitable. Would urine testing be useful to help determine if Betty has used cocaine this evening?
3. Discuss supportive nursing care for infants born of HIV-positive mothers.
4. Betty wishes for an early discharge from the hospital. What physical criteria must be met before leaving the hospital?
5. Discuss when she should contact her physician/CNM after her discharge.

APPENDIX A: Common Abbreviations in Maternal-Newborn and Women's Health Nursing

ABE	Acute bilirubin encephalopathy
AC	Abdominal circumference
accel	Acceleration of fetal heart rate
AFAFP	Amniotic fluid alpha-fetoprotein
AFI	Amniotic fluid index
AFP	Alpha-fetoprotein
AFV	Amniotic fluid volume
AGA	Average for gestational age
AI	Amnioinfusion
AMOL	Active management of labor
AOP	Apnea of prematurity *or* Anemia of prematurity
ARBD	Alcohol-related birth defects
ARBOW	Artificial rupture of bag of waters
ARND	Alcohol related neurodevelopmental disorder
AROM	Artificial rupture of membranes
ART	Artificial reproductive technology
BAM	Becoming a mother
BAT	Brown adipose tissue (brown fat)
BBOW	Bulging bag of water
BBT	Basal body temperature
β-hCG	Beta-human chorionic gonadotropin
BL	Baseline (fetal heart rate baseline)
BOW	Bag of waters
BPD	Biparietal diameter *or* Bronchopulmonary dysplasia
BPP	Biophysical profile
BRB	Bright red bleeding *or* Breakthrough bleeding
BR CA	Breast cancer
BSE	Breast self-examination
BSST	Breast self-stimulation test
BV	Bacterial vaginosis
CC	Chest circumference or Cord compression
CD	Cycle day
CEI	Continuous epidural infusion
C–H	Crown-to-heel length
CID	Cytomegalic inclusion disease
CLD	Chronic lung disease
CMV	Cytomegalovirus
CNM	Certified nurse-midwife
CNS	Clinical nurse specialist
COCs	Combined oral contraceptives
CPAP	Continuous positive airway pressure
CPD	Cephalopelvic disproportion *or* Citrate-phosphate-dextrose
CRL	Crown-rump length
CRNP	Certified registered nurse practitioner
C/S	Cesarean section (or C-section)
CST	Contraction stress test
CVS	Chorionic villus sampling
D&C	Dilatation and curettage
D&E	Dilatation and evacuation
decels	Deceleration of fetal heart rate
DFMR	Daily fetal movement response
dil	Dilatation
DPNB	Dorsal penile nerve block
DRI	Dietary reference intake
DTR	Deep tendon reflexes
DUB	Dysfunctional uterine bleeding
EAB	Elective abortion
EASI	Extra-amniotic saline infusion
ECMO	Extracorporeal membrane oxygenator
ECV	External cephalic version
EDB	Estimated date of birth
EDC	Estimated date of confinement
EDD	Estimated date of delivery
EFM	Electronic fetal monitoring
EFW	Estimated fetal weight
EIA	Enzyme immunoassay
ELF	Elective low forceps
ELISA	Enzyme-linked immunosorbent assay
EOS	Early onset sepsis
EP	Ectopic pregnancy
epis	Episiotomy
EPT	Expedited partner therapy
ERCS	Elective repeat cesarean section
FAB	Fertility awareness-based methods
FAD	Fetal activity diary
FAS	Fetal alcohol syndrome
FASD	Fetal alcohol spectrum disorder
FBM	Fetal breathing movements
FBS	Fetal blood sample *or* Fasting blood sugar test
FCC	Family-centered care
FECG	Fetal electrocardiogram
fFN	Fetal fibronectin
FGM	Female genital mutilation
FHR	Fetal heart rate

FHT	Fetal heart tones
Fhx	Family history
FISH	Fluorescence in situ hybridization
FL	Femur length
FMC	Fetal movement count
FMH	Fetal-maternal hemorrhage
FMR	Fetal movement record
FPG	Fasting plasma glucose test
FSE	Fetal scalp electrode
FSH	Follicle-stimulating hormone
FSHRH	Follicle-stimulating hormone-releasing hormone
$FSPO_2$	Fetal arterial oxygen saturation
G or grav	Gravida
GDM	Gestational diabetes mellitus
GIFT	Gamete intrafallopian transfer
GnRF	Gonadotropin-releasing factor
GnRH	Gonadotropin-releasing hormone
GTD	Gestational trophoblastic disease
GTPAL	Gravida, term, preterm, abortion, living children; a system of recording maternity history
HA	Head-abdominal ratio or headache
HAI	Hemagglutination-inhibition test
HC	Head compression
hCG	Human chorionic gonadotropin
hCS	Human chorionic somatomammotropin (same as hPL)
hMG	Human menopausal gonadotropin
hPL	Human placental lactogen
HPTs	Home pregnancy tests
HPV	Human papilloma virus
HT	Hormone therapy
HRT	Hormone replacement therapy
HSV	Herpes simplex virus
IAP	Intrapartum antimicrobial prophylaxis
ICSI	Intracytoplasmic sperm injection
IDM	Infant of a diabetic mother
IPV	Intimate partner violence
ISAM	Infant of a substance-abusing mother
IUD	Intrauterine device
IUFD	Intrauterine fetal death
IUGR	Intrauterine growth restriction
IUI	Intrauterine insemination
IUPC	Intrauterine pressure catheter
IUS	Intrauterine system
IVF	In vitro fertilization
LADA	Left-acromion-dorsal-anterior
LADP	Left-acromion-dorsal-posterior
LBC	Lamellar body count
LBW	Low birth weight
LDRP	Labor, delivery, recovery, and postpartum
LGA	Large for gestational age
LH	Luteinizing hormone
LHRH	Luteinizing hormone-releasing hormone
LMA	Left-mentum-anterior
LML	Left mediolateral (episiotomy)
LMP	Last menstrual period *or* Left-mentum-posterior
LMT	Left-mentum-transverse
LOA	Left-occiput-anterior
LOF	Low outlet forceps
LOP	Left-occiput-posterior
LOS	Length of stay
LOT	Left-occiput-transverse
L/S	Lecithin/sphingomyelin ratio
LSA	Left-sacrum-anterior
LSP	Left-sacrum-posterior
LST	Left-sacrum-transverse
MAS	Meconium aspiration syndrome
mec	Meconium
MEN	Minimal enteral nutrition
MLE	Midline episiotomy
MSAF	Meconium-stained amniotic fluid
MSAFP	Maternal serum alpha-fetoprotein
multip	Multipara
NAS	Neonatal abstinence syndrome
NEC	Necrotizing enterocolitis
NFP	Natural family planning
NNS	Nonnutritive sucking
NP	Nurse practitioner
NSCST	Nipple stimulation contraction stress test
NST	Nonstress test or Nonshivering thermogenesis
NSVD	Normal sterile vaginal delivery
NT	Nuchal translucency
NTD	Neural tube defects
NTE	Neutral thermal environment
NVP	Nausea and vomiting of pregnancy
OA	Occiput anterior
OCPs	Oral contraceptive pills
OCT	Oxytocin challenge test
OF	Occipitofrontal diameter of fetal head
OFC	Occipitofrontal circumference
OGTT	Oral glucose tolerance test
OM	Occipitomental (diameter)
OP	Occiput posterior

p	Para
PABC	Pregnancy-associated breast cancer
Pap smear	Papanicolaou smear
PAPP-A	Pregnancy-associated plasma protein A
PCEA	Patient-controlled epidural analgesia
PCOS	Polycystic ovarian syndrome
PDA	Patent ductus arteriosus
PG	Phosphatidylglycerol *or* Prostaglandin
PGS	Preimplantation genetic screening
PID	Pelvic inflammatory disease
Pit	Pitocin
PKU	Phenylketonuria
PMR	Perinatal mortality rate
PMS	Premenstrual syndrome
PNV	Prenatal vitamins
PPHN	Persistent pulmonary hypertension
primip	Primipara
PROM	Premature rupture of membranes
PSI	Prostaglandin synthesis inhibitor
PTB	Preterm birth
PTL	Preterm labor
PUBS	Percutaneous umbilical blood sampling
RADA	Right-acromion-dorsal-anterior
RADP	Right-acromion-dorsal-posterior
RDS	Respiratory distress syndrome
REM	Rapid eye movements
RIA	Radioimmunoassay
RLF	Retrolental fibroplasia
RMA	Right-mentum-anterior
RMP	Right-mentum-posterior
RMT	Right-mentum-transverse
ROA	Right-occiput-anterior
ROM	Rupture of membranes
ROP	Right-occiput-posterior *or* Retinopathy of prematurity
ROT	Right-occiput-transverse
RPL	Recurrent pregnancy loss
RRA	Radioreceptor assay
RSA	Right-sacrum-anterior
RSP	Right-sacrum-posterior
RST	Right-sacrum-transverse
SAB	Spontaneous abortion
SBS	Shaken baby syndrome
SET	Surrogate embryo transfer
SGA	Small for gestational age
SIDS	Sudden infant death syndrome
SMB	Submentobregmatic diameter
SOB	Suboccipitobregmatic diameter *or* Shortness of breath
SPA	Sperm penetration assay
SRBOW	Spontaneous rupture of bag of waters
SRMC	Single-room maternity care
SROM	Spontaneous rupture of membranes
STI	Sexually transmitted infection
STS	Serologic test for syphilis
SVE	Sterile vaginal exam
TAB	Therapeutic abortion
TcB	Transcutaneous bilirubin
TCM	Transcutaneous monitoring
TDI or THI	Therapeutic donor insemination (*H* designates mate is donor)
TET	Tubal embryo transfer
TOL	Trial of labor
TOLAC	Trial of labor after cesarean
TORCH	Toxoplasmosis, rubella, cytomegalovirus, herpesvirus hominis type 2
TSS	Toxic shock syndrome
ū	Umbilicus
UA	Uterine activity
UAC	Umbilical artery catheter
UAU	Uterine activity units
UC	Uterine contraction
UNHS	Universal newborn hearing screening
UPI	Uteroplacental insufficiency
US	Ultrasound
VBAC	Vaginal birth after cesarean
VDRL	Venereal Disease Research Laboratories
VIP	Voluntary interruption of pregnancy
VLBW	Very low birth weight
VVC	Vulvovaginal *candidiasis*
WIC	Supplemental food program for women, infants, and children
ZIFT	Zygote intrafallopian transfer

APPENDIX B: Conversions and Equivalents

TEMPERATURE CONVERSION

(Fahrenheit temperature − 32) × 5/9 = Centigrade temperature
(Centigrade temperature × 9/5) + 32 = Fahrenheit temperature

SELECTED CONVERSION TO METRIC MEASURES

Known Value	Multiply by	To Find
inches	2.54	centimeters
ounces	28	grams
pounds	454	grams
pounds	0.45	kilograms

SELECTED CONVERSION FROM METRIC MEASURES

Known Value	Multiply by	To Find
centimeters	0.4	inches
grams	0.035	ounces
grams	0.0022	pounds
kilograms	2.2	pounds

CONVERSION OF POUNDS AND OUNCES TO GRAMS

Pounds	Ounces 0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15
0	—	28	57	85	113	142	170	198	227	255	283	312	340	369	397	425

APPENDIX C: Spanish Translations of English Phrases*

This appendix includes phrases you might find helpful in working with families during pregnancy, labor, and birth, and after the birth. There are many ways to phrase questions. We have chosen some statements we consider essential and have tried to phrase them in a straightforward way. The phrases are designed to help you in situations in which translation is not possible at the moment.

This list begins with introductory statements, which are presented in a logical conversational flow. The remaining phrases are arranged according to the phases of pregnancy and birth during which they are most applicable.

Essential Introductory Phrases	**Frases Introductoras Esenciales**
Hello	Hola
I am a nurse.	Soy enferera (enfermero).†
I am a student nurse.	Soy estudiante de enfermería.
My name is _____.	Mi nombre es _____.
What is your name?	Me llamo _____.
	¿Cuál es su nombre?
	¿Cómo se llama?
What name should I call you?	¿Cómo quiere que la llamemos?
	¿Cómo quiere ser llamada?
Thank you	Gracias
Please	Por favor
Is someone here with you?	¿Hay alquien aquí con usted?
Does he (she) speak English?	¿Habla él (ella) inglés?
Goodbye	Adiós.
Phrases for the Antepartum Period	**Frases para el Periodo Prenatal**
Are you taking any medications now?	¿Está tomando algunas medicinas ahora?
Show me the medicine bottles please.	Por favor, muéstreme los frascos.
Have you ever had trouble with your blood pressure?	¿Ha tenido problemas alguna vez con la presión arterial?
When was the first day of your last period?	¿Cuál fue el primer día de su última regla?
	¿Cuál fue el primer día de su última menstruación?
Have you had any spotting or bleeding since your last period?	¿Ha sangrado o ha tenido manchas de sangre desde su última regla?
Have you been on birth control pills?	¿Ha estado tomando píldoras anticonceptivas?
When did you stop taking them?	¿Cuándo dejó de tomarlas?
Do you have an intrauterine device (IUD)?	¿Usa un aparato intrauterino?
How many times have you been pregnant?	¿Cuántas veces ha estado usted embarazada?
Are you having any problems with your pregnancy?	¿Tiene problemas con su embarazo?
Is there anything that is worrying you?	¿Hay algo o alguna cosa que la preocupe?
I would like to take your blood pressure.	Quisiera tomarle la presió arterial.
I would like to take your pulse.	Quisiera tomarle el pulso.
I would like to take your temperature.	Quisiera tomarle la temperatura.
I would like to listen to your heart and lungs.	Quisiera escucharle el corazon y los pulmones.
I would like to check your uterus.	Quisiera examinarle el útero.
Please urinate in this cup and leave it in the bathroom.	Puede orinar en este vaso y dejarlo en el baño.
Please stand up.	Por favor, levántese.
Please sit down.	Por favor, siéntese.
Please lie down.	Por favor, acuéstese.
Phrases Related to Client Safety	**Frases Relacionadas con la Seguridad del Cliente**
I would like to talk to you alone.	Quisiera hablar a solas con usted.

*Prepared by Elizabeth Medina, PhD. Associate Professor of Spanish, Regis University, Denver, Colorado.
†In Spanish, nouns that end in *a* indicate female gender; nouns that end in *o* indicate male gender.

Are you safe at home?	¿Sufre de peligros en casa?
Are you afraid of your partner?	¿Le tiene miedo a su compañero?
During your pregnancy has your partner hit, slapped, kicked, or punched you?	Durante su embarazo, ¿la ha golpeado? ¿la ha abofeteado? ¿la ha pateado? o ¿le ha dado puñetazos?
How many times?	¿Cuántas veces?
Do you have someone for support?	¿Cuénta con alguien que la pueda ayudar?
Questions the Mother or Father May Ask	**Posibles Preguntas que Madres o Padres Hacen**
How big is my baby?	¿De qué tamaño es el (la) bebé?
How much does the baby weigh now?	¿Cuánto pesa el bebé ahora?
When will I feel my baby move?	¿Cuándo lo (la) voy a sentir moverse?
Phrases for the Intrapartum Period	**Frases Durante el Parto**
Note: Review the essential introductory phrases for beginning a conversation.	*Nota:* Repase las frases introductoras para comenzar una conversación.
Are you having labor pains?	¿Tiene dolores de parto?
Are you having contractions?	¿Tiene contracciones?
Are you having pain?	¿Tiene dolores?
Do you need medicine for pain?	¿Necesita medicina para el dolor?
Do you need to urinate?	¿Necesita orinar?
This is a bedpan to urinate in.	Aquí tiene el bacín (la chata) (el pato) para orinar.
Can I help you to the bathroom?	¿La ayudo a ir al baño?
Do you need to have a bowel movement?	¿Necesita mover el vientre (obrar)? Necesita "Hacer caca"—coloquial
Has your bag of water broken?	¿Se le ha roto la bolsa de agua(s)?
Have you had any bright-red bleeding during your pregnancy?	¿Ha tenido algún sangramiento de color rojo durante su embarazo?
How many births have you had?	¿Cuántos niños le han nacido?
I need to do a vaginal examination.	Necesito hacerle un examen vaginal.
I will help you.	La voy a ayudar.
I will stay with you.	Me quedaré con usted.
Please pant. I will show you how.	Por favor, jadee. Le voy a mostrar cómo.
Do not push now.	No puje ahora.
Push now.	Puje ahora.
Stop pushing.	Pare de pujar. No puje más.
The doctor needs to do a cesarean birth.	El doctor le va a hacer una operación cesárea.
This is medicine for your pain. You will feel better soon.	Esta medicina es para el dolor. Va a sentirse mejor pronto.
When is your baby supposed to be born?	¿Cuando está supuesto a nacer el bebé?
January	enero
February	febrero
March	marzo
April	abril
May	mayo
June	junio
July	julio
August	agosto
September	septiembre
October	octubre
November	noviembre
December	diciembre

What is your doctor's name?	¿Cuál es el nombre de su doctor?
What is your midwife's name?	¿Cuál is el nombre de su comadrona (partera)?
Your baby is having some trouble now.	El bebé está pasando por algunos problemas. El bebé está sufriendo algunas dificultades.
I need to put this oxygen mask on you. It will help your baby. It may smell funny, but it is OK.	Le voy a poner esta máscara de oxígeno. Va a ayudar al bebé. Huele extraño, pero no hay problemas.
Please turn on your left side.	Por favor voltéese al lado izquierdo.
Please turn on your right side.	Por favor voltéese al lado derecho.
Your baby is OK.	El bebé está bien.
Phrases for the Postpartum Period and the Newborn Area	**Frases para el Periodo Despues del Parto y el Area del Recien Nacido**
Note: Review the essential introductory phrases for beginning a conversation.	*Nota:* Repase las frases introductoras para comenzar una conversación.
Are you hungry?	¿Tiene hambre?
Are you thirsty?	¿Tiene sed?
Are you cold?	¿Tiene frío?
Are you tired?	¿Está cansada?
I am going to put antibiotic ointment in the baby's eyes.	Le voy a poner al bebé un ungüento antibiótico alrededor de los ojos.
It will help protect your baby from some infections.	Lo (la) va a proteger contra algunos infecciones.
I am going to take some blood from your baby's foot to check the blood sugar and hematocrit.	Le voy a sacar sangre del pie al bebé para determinar el azúcar del la sangre ye el hematocrítico.
If your baby begins to spit up, please turn him (her) on his (her) side.	Si el bebé comienza a vomitar, colóquelo (colóquela) de costado.
It may help to position your baby like this.	Lo (la) ayudará—si lo coloca así. Lo (la) ayudaría—si lo colocara así.
I would like to suggest that you clean your nipples this way before you breastfeed your baby.	Es bueno que se lave los pezones de esta manera antes de darle el pecho al bebé.
It is better that you clean your baby's cord this way.	Es mejor para el bebé que le lave el ombligo de esta manera.
It is better that you bathe your baby this way.	Es mejor que lo (la) bañe de esta manera.
It is better that you clean your baby's penis this way.	Es mejor que le limpie el pene así.
I would like to suggest that you fold the diaper this way.	Le sugiero que doble el pañal así.
I would like to suggest that you fasten the diaper this way.	Le sugiero que asegure el pañal así.
Take the baby's temperature this way.	Tómele la temperature así.
I need to check (your breasts, your uterus, your flow, your stitches, your legs and feet).	Necesito examinarle (los pechos, el útero, el flujo, los puntos, las pierns y los pies).
I need to feel your uterus.	Necesito examinarle el útero.
I need to massage your uterus.	Necesito darle un masaje en la región del útero.
Place your baby on its side.	Coloque al bebé de costado.
Place the baby's used diapers here.	Coloque aquí los pañales usados.
Please rub your uterus every half hour to keep it firm. I will show you how.	Necesita darse un masaje en la región del útero cada media hora para mantenerlo firme. Le voy a mostrar cómo.
Would you like to see your baby now?	¿Quiere ver a su bebé ahora?
Would you like me to help you feed your baby?	¿Quiere que le ayude a alimentarlo (la)?
Your baby needs a car seat to go home in.	El (la) bebé necesita un asiento para bebé en el automóvil.
Special Neonatal Needs	**Necesidades del Recien Nacido**
We are giving your baby oxygen.	Le vamos a dar oxígeno al (a la) bebé.
Your baby is having problems breathing.	El (la) bebé tiene problemas al respirar.
Your baby needs extra help.	El (la) bebé necesita ayuda especial.
Your baby needs to go to a special care nursery.	El (la) bebé necesita ir a la sala de cuidados especiales para bebés.

APPENDIX D: Guidelines for Working with Deaf Patients and Interpreters

1. First, remember that it requires trust on the part of the patient to allow nonsigning caregivers and an interpreter into her life.
2. It is important to use a registered interpreter. Medical interpreters are registered with the Registry of Interpreters for the Deaf. Although family members and friends may offer to interpret, it is best to use registered medical interpreters because they are required to translate the patients' and nurses' words exactly and accurately without adding in any other opinion.
3. Greet the patient and family with a handshake and body posture that indicates welcome. You may point to your name tag and use the American Sign Language (ASL) alphabet cards to spell out your name. The patient may wish to select cards to indicate her name. It is especially important as you work together to make the effort to provide a greeting as you would with speaking patients; greetings help develop rapport.
4. Once the interpreter is present, continue to look at the patient and speak directly to her. There will be a temptation to look at the interpreter, and it will help to remember that you are speaking to the patient.
5. Avoid phrasing your words as if you are talking to the interpreter (e.g., "Can you tell her . . . ?"). Instead, phrase your questions as you do with speaking patients (e.g., "I'm going to ask you some questions now.").
6. Depend on the deaf patient to ask questions.
7. Look at the patient's face for signs of difficulty in understanding. Deaf patients have a behavior of "gesturing" that involves shaking their heads as if to indicate "yes" even when they do not understand. If the patient is nodding "yes," ask her to repeat the directions you have just given.
8. Be as direct as possible. Keep to what you want to know or what you want to convey. Speak in short sentences, using nontechnical words. Avoid colloquial or slang words. Be sure to explain what you want to do before you do it. For instance, tell her you want to start an IV and explain the equipment. Then, with her permission, start the IV.
9. Be aware that deaf patients may have difficulty understanding when to take medications. It will be helpful to associate taking medications or completing some treatment or activity with meals. (For instance, while showing her the two capsules she is to take when she goes home, tell her to take the two capsules at breakfast and another two capsules at bedtime.) Avoid saying, "Take two capsules at 8:00 a.m., 2:00 p.m., and 12:00 a.m."
10. The difference in interpreting time may also affect obtaining a history. It is best to begin with a specific event in the past and work forward.

What to Do Until the Interpreter Arrives

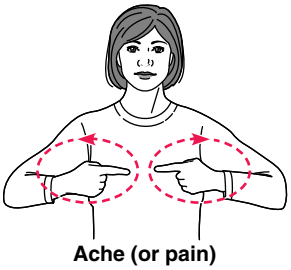
1. Role-play as much as possible.
2. Demonstrate what you want the patient to do or what you want to do.
3. Be resourceful.
4. Remember that some deaf patients can read lips. Some may read written language, but use care in assuming the patient understands.

What to Do to Prepare for Working with a Deaf Patient

1. Contact local agencies that work with deaf patients to see what resources are available. Ask about classes in ASL. Being able to use some basic signs will be very helpful while waiting for an interpreter to arrive.
2. Read to learn more about the deaf culture. Contact your local agency or the National Information Center on Deafness, Silver Springs, Maryland, to get suggestions on books you might read.
3. Investigate your health facility. What is available to assist you? Look for videos used for teaching in the maternal-child unit and note if they have captions. Remember that many deaf patients do not read written language, so it will be important to review the content of the video with an interpreter present.

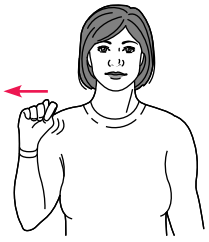
Prepared with the kind assistance of Mr. Gerald Dement, Interpreter Coordinator, Pikes Peak Center on Deafness, Colorado Springs, Colorado.

Appendix E: Sign Language for Healthcare Professionals

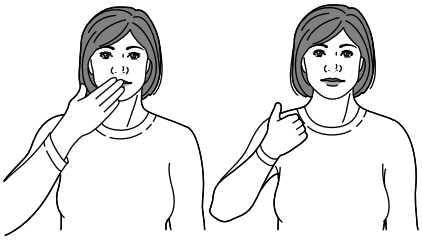


Ache (or pain)

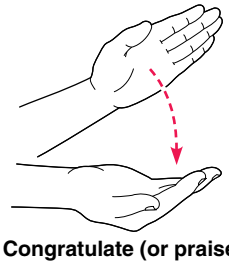
Allergic*



Bathroom

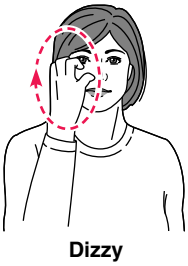


Better

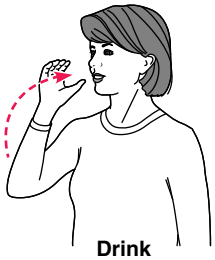


Congratulate (or praise)

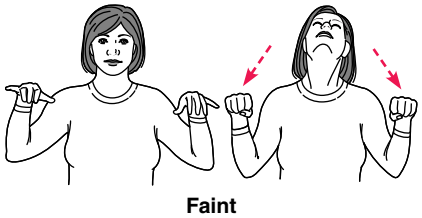
Constipate*



Dizzy

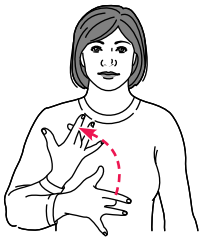


Drink



Faint

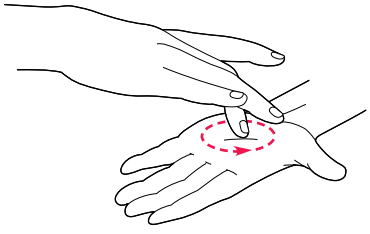
*Indicates signs that are in manually signed English. Those without an asterisk are in American Sign Language.



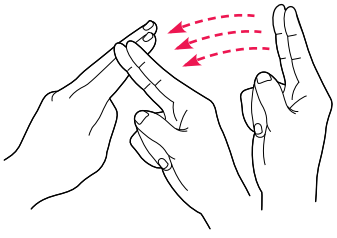
Feel

Headache

Lie down

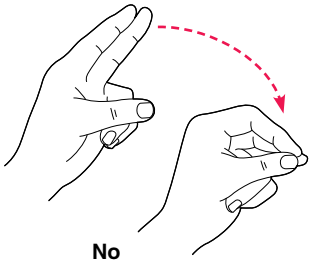


Medicine



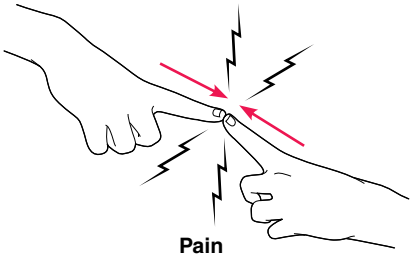
Name

Nauseous



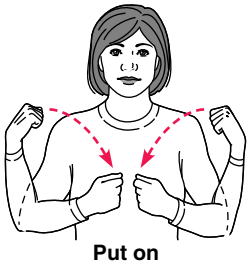
No

Nurse



Pain

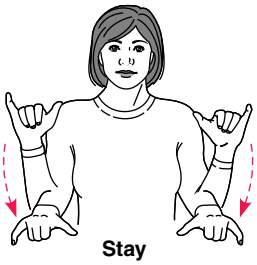
Please



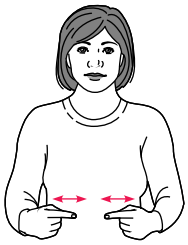
Put on

Sick

*Indicates signs that are in manually signed English. Those without an asterisk are in American Sign Language.



Stay

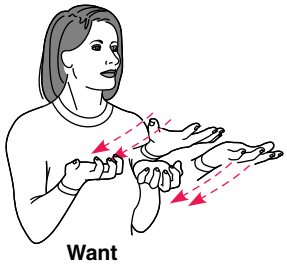


Stomachache*

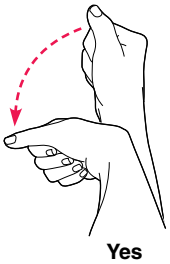
Thank you (or good)

Thirsty

Vomit



Want



Yes

*Indicates signs that are in manually signed English. Those without an asterisk are in American Sign Language.

APPENDIX F: Actions and Effects of Selected Drugs During Breastfeeding*

Anticoagulants

Coumarin derivatives (warfarin, dicumarol): Relatively safe to use; only small amount in breast milk; check PTT

Heparin and derivatives (Lovenox): Does not cross into breast milk; check PTT

Anticonvulsants

Phenytoin (Dilantin), phenobarbital: Generally considered safe; if high doses of phenobarbital are ingested, may cause drowsiness; short-acting phenobarbiturates (secobarbital) preferred, because they appear in lower concentration in milk

Magnesium sulfate: Lactogenesis may be delayed

Antidepressants

SSRI class:

Fluoxetine (Prozac), fluvoxamine: Effect on newborn unknown but may be of concern

Tricyclic antidepressants (Doxepin): Sedation, potential respiratory arrest in infant

Antihistamines

Diphenhydramine (Benadryl), Claritin, Allegra: May cause decreased milk supply; infant may become drowsy or irritable

Clemastine (Tavist): Counterindicated

Antihypertensives

β adrenergic blockers:

Atenolol, acebutolol: Cyanosis, bradycardia, hypotension

Tenormin: Hypotension, bradycardia

Antimetabolites/Antineoplastics

Unknown, probably long-term anti-DNA effect on the infant; potentially very toxic

Antimicrobials

Aminoglycosides: May cause ototoxicity or nephrotoxicity if given for more than 2 weeks

Ampicillin: Skin rash, candidiasis; diarrhea

Azithromycin: No risk to newborn

Chloramphenicol (rarely used): Possible bone marrow suppression; too low a dose for Gray syndrome; refusal of breast

Erythromycin: Accumulates in breast milk, idiopathic hypertrophic pyloric stenosis

Methacycline: Possible inhibition of bone growth; may cause discoloration of the teeth; use should be avoided

Metronidazole (Flagyl): Possible neurologic disorders or blood dyscrasias; delay breastfeeding for 12 hours after dose

Penicillin: Possible allergic response; candidiasis

Quinolones (synthetic antibiotics): Can cause arthropathies

Sulfonamides: May cause hyperbilirubinemia; use contraindicated until infant over 1 week old

Tetracycline: Long-term use and large doses should be avoided; may cause tooth staining or inhibition of bone growth

Antithyroids

Thiouracil: Contraindicated during lactation; may cause goiter or agranulocytosis

Propylthiouracil: Safe; monitor infant thyroid function

Barbiturates

Phenothiazines: May produce sedation

Bronchodilators

Aminophylline: May cause insomnia or irritability in the infant

Leukotriene inhibitors (Zyflo, Accolate): Potential tumorigenicity

Caffeine

Excessive consumption may cause jitteriness or wakefulness

Cardiovascular

Amiodarone: Transient bradycardia, IUGR; contains iodine—potential for thyroid gland problems

Clonidine (Catapres): May reduce milk volume

Methyldopa: May increase milk volume; monitor for hypotension for 48 hours after birth

Propranolol (Inderal): May cause hypoglycemia; possibility of other blocking effects, especially if infant has renal or liver dysfunction

Quinidine: May cause arrhythmias in infant

Reserpine (Serpasil): Nasal stuffiness, lethargy, or diarrhea in infant

Corticosteroids

Adrenal suppression may occur with long-term administration of doses greater than 20 mg/day

Diuretics

Furosemide (Lasix): Not excreted in breast milk

Thiazide diuretics (Esidrix, HydroDIURIL Oretic): Safe but can cause dehydration, reduce milk production

Heavy Metals

Gold: Potentially toxic; gold salts—compatible with breastfeeding

Lead: Excreted in breast milk; high maternal levels can affect neuropsychologic development

Mercury: Excreted in the milk and hazardous to infant

Hormones

Androgens: Suppress lactation

Thyroid hormones: May mask hypothyroidism

Laxatives

Peri-Colace, Dulcolax: Relatively safe

Milk of magnesia, Metamucil: Relatively safe

Narcotic Analgesics

Codeine: Accumulation may lead to neonatal depression

Meperidine: Avoid use. May lead to neonatal depression

Morphine: Long-term use may cause newborn addiction

Nonnarcotic Analgesics, NSAIDS

Acetaminophen (Tylenol): Relatively safe for short-term analgesia

Ibuprofen (Motrin): Safe

Propoxyphene (Darvon): May cause sleepiness and poor breastfeeding in infant

Salicylates (aspirin): Safe after first week of life; monitor PTT

Oral Contraceptives

Combined estrogen/progestin pills: Significantly decrease milk supply; may alter milk composition; may cause gynecomastia in male infants

Progestin only (DMPA, Norplant): Safe if started after lactation is established

Radioactive Materials for Testing

Gallium citrate (67G): Insignificant amount excreted in breast milk; no breastfeeding for 2 weeks

Iodine: Contraindicated; may affect infant's thyroid gland

^{125}I: Discontinue breastfeeding for 24 hours

^{131}I: Breastfeeding should be discontinued until excretion is no longer significant; may be resumed after 10 days

*Based on data from Riordan, J., & Auerbach, K. J. (2010). *Breastfeeding and human lactation* (4th ed., pp. 147–196). Boston: Jones & Bartlett; Briggs, G. G., Freeman, R. K., & Yaffe, S. J. (2008). *Drugs in pregnancy and lactation* (8th ed.). Baltimore: Williams & Wilkins; Hale, T. (2010). *Medications and mothers' milk* (14th ed.). Amarillo, TX: Pharmasoft Publishing; Committee on Drugs, American Academy of Pediatrics. (2001). The transfer of drugs and other chemicals into human milk. *Pediatrics, 108*(3), 776.

Technetium-99m: Discontinue breastfeeding for 24 hours (half-life = 6 hours)

Sedatives/Tranquilizers

Diazepam (Valium): May accumulate to high levels; may increase neonatal jaundice; may cause lethargy, weight loss, and poor suck

Lithium: Contraindicated; may cause neonatal flaccidity, hypotonia, affect thyroid and cardiac arrhythmia

Smoking Cessation

Nicotine patch (Nicoderm, Nicotrol): Irritability, abnormal sleep patterns, poor feeding

Bupropion (Zyban, Wellbutrin): No effect on breastfeeding

Substance Abuse

Alcohol: Potential motor developmental delay; mild sedative effect

Amphetamines: Controversial; may cause irritability, poor sleeping pattern

Cocaine, crack: Extreme irritability, tachycardia, vomiting, apnea

Marijuana: Drowsiness

Heroin: Tremors, restlessness, vomiting, poor feeding

Nicotine (smoking): Shock, vomiting, diarrhea, decreased milk production

GLOSSARY

Abdominal effleurage Gentle stroking used in massage.

Abortion Loss of pregnancy before the fetus is viable outside the uterus; miscarriage.

Abruptio placentae (ab-rŭp'shē-ō pla-sen'tē) Partial or total premature separation of a normally implanted placenta.

Abstinence Refraining voluntarily, especially from indulgence in food, alcoholic beverages, or sexual intercourse.

Acceleration Periodic increase in the baseline fetal heart rate.

Acculturation The process by which people adapt to a new cultural norm.

Acme Peak or highest point; time of greatest intensity (of a uterine contraction).

Acquaintance and date rape Rape in which the assailant is someone with whom the victim has had previous nonviolent interaction (acquaintance rape) or which occurs between a dating couple. Date rape is a form of acquaintance rape.

Acquired immunodeficiency syndrome (AIDS) An immunologic disorder caused by infection with the human immunodeficiency virus (HIV) and characterized by increasing susceptibility to opportunistic infections and rare cancers.

Acrocyanosis Cyanosis of the extremities.

Acrosomal reaction Breakdown of the hyaluronic acid in the corona radiata by enzymes from the heads of sperm; allows one spermatozoon to penetrate the ovum zona pellucida.

Active acquired immunity Formation of antibodies by the pregnant woman in response to illness or immunization.

Active alert state Alert state marked by an increase in facial and body movement, with periods of fussiness occurring. The infant in this state has increased sensitivity to disturbing stimuli. Also called *active awake*.

Active management of labor (AMOL) Medical protocol for augmentation of labor that includes (1) a strict criterion for labor admission, (2) early amniotomy, (3) high-dose oxytocin infusion for inefficient labor contractions, and (4) a commitment to provision of continuous nursing care.

Acupressure Therapy using pressure from the fingers and thumbs to stimulate pressure points.

Acupuncture Therapy using very fine (hairlike) stainless steel needles to stimulate specific acupuncture points depending on the client's medical assessment and condition.

Acute bilirubin encephalopathy (ABE) See *Kernicterus*.

Adequate intake (AI) A value cited for a nutrient when there are not sufficient data to calculate an estimated average requirement.

Adjustment reaction with depressed mood A maternal adjustment reaction occurring in the first few postpartum days, characterized by mild depression, tearfulness, anxiety, headache, and irritability. Also called *postpartum blues*.

Adnexa Adjoining or accessory parts of a structure, such as the uterine adnexa: the ovaries and fallopian tubes.

Adolescence Period of human development initiated by puberty and ending with the attainment of young adulthood.

Afterpains Cramplike pains due to contractions of the uterus that occur after childbirth. They are more common in multiparas, tend to be most severe during breastfeeding, and last 2 to 3 days.

Alpha-fetoprotein (AFP) A fetal protein produced in the yolk sac for the first 6 weeks of gestation and then by the fetal liver.

Alternative therapy Any procedure or approach that is used in place of conventional medicine.

Alveolar surface tension The contracting force between alveoli.

Alveoli Small units of the breast tissue in which milk is synthesized by the alveolar secretory epithelium.

Amenorrhea Suppression or absence of menstruation.

Amniocentesis Removal of amniotic fluid by insertion of a needle into the amniotic sac; amniotic fluid is used to assess fetal health or maturity.

Amnioinfusion (AI) Procedure used to infuse a sterile fluid (such as normal saline) through an intrauterine catheter into the uterus in an attempt to increase the fluid around the umbilical cord to decrease or prevent cord compression during labor contractions; also used to dilute thick meconium-stained amniotic fluid.

Amnion The inner of the two membranes that form the sac containing the fetus and the amniotic fluid.

Amniotic fluid The liquid surrounding the fetus in utero. It absorbs shocks, permits fetal movement, and prevents heat loss.

Amniotic fluid embolism An obstetric emergency that occurs when a bolus of amniotic fluid, fetal cells, hair, or other debris enters the maternal circulation and then the maternal lungs; the cause is unknown but has a 60% to 80% mortality rate.

Amniotic fluid index (AFI) A method of reporting fluid volume. The AFI is calculated by dividing the maternal abdomen into four quadrants with the umbilicus as the reference point. Then the deepest vertical pocket is measured. These measurements are summed to calculate the AFI.

Amniotomy (am-nē-ot'ō-mē) The artificial rupturing of the amniotic membrane.

Ampulla The outer two-thirds of the fallopian tube; fertilization of the ovum by a spermatozoon usually occurs here.

Anaphylactoid syndrome of pregnancy See *Amniotic fluid embolism*.

Androgen Substance producing male characteristics, such as the male hormone testosterone.

Android pelvis Male-type pelvis.

Antepartum Time between conception and the onset of labor; usually used to describe the period during which a woman is pregnant.

Anterior fontanelle Diamond-shaped area between the two frontal and two parietal bones just above the newborn's forehead.

Anthropoid pelvis Pelvis in which the anteroposterior diameter is equal to or greater than the transverse diameter.

Apgar score A scoring system used to evaluate newborns at 1 minute and 5 minutes after birth. The total score is achieved by assessing five signs: heart rate, respiratory effort, muscle tone, reflex irritability, and color. Each of the signs is assigned a score of 0, 1, or 2. The highest possible score is 10.

Apnea A condition that occurs when respirations cease for more than 20 seconds, with generalized cyanosis.

Areola Pigmented ring surrounding the nipple of the breast.

Aromatherapy The use of certain essential oils, derived from plants, whose odor or aroma is believed to have a therapeutic effect.

Artificial rupture of membranes (AROM) Use of a device such as an amnihook or allis forceps to rupture the amniotic membranes.

Assimilation Phenomenon in which a minority group completely changes its cultural identity to become part of the majority culture.

Assisted reproductive technology (ART) Term used to describe the highly technologic approaches used to produce pregnancy.

Attachment Enduring bonds or relationship of affection between persons.

Attachment theory A framework for understanding perinatal loss that begins with the basic premise that human beings are biologically predisposed to bond with emotionally significant persons in their lives.

Autosome A chromosome that is not a sex chromosome.

Ayurveda The classical system of Hindu medicine. The term *ayurveda* means the knowledge of how to live a vital, healthful life.

Babinski reflex Reflex found normally in infants under 6 months of age in which the great toe dorsiflexes when the sole of the foot is stimulated.

Bacterial vaginosis (BV) A bacterial infection of the vagina, formerly called *Gardnerella vaginalis* or *Hemophilus vaginalis,* characterized by a foul-smelling, grayish vaginal discharge that exhibits a characteristic fishy odor when 10% potassium hydroxide (KOH) is added. Microscopic examination of a vaginal wet prep reveals the presence of "clue cells" (vaginal epithelial cells coated with gram-negative organisms).

Bag of waters (BOW) The membrane containing the amniotic fluid and the fetus.

Ballottement (bal-ot-maw') A technique of palpation to detect or examine a floating object in the body. In obstetrics, the fetus, when pushed, floats away and then returns to touch the examiner's fingers.

Barlow maneuver A test designed to detect subluxation or dislocation of the hip. A dysplastic joint will be felt to be dislocated as the femur leaves the acetabulum.

Barr body Deeply staining chromatin mass located against the inner surface of the cell nucleus. It is found only in normal females. Also called *sex chromatin.*

Basal body temperature (BBT) The lowest waking temperature.

Baseline fetal heart rate (BL FHR) The average fetal heart rate observed during a 10-minute period of monitoring.

Baseline variability (BL VAR) Changes in the fetal heart rate that result from the interplay between the sympathetic and the parasympathetic nervous systems.

Battledore placenta Placenta in which the umbilical cord is inserted on the periphery rather than centrally.

Becoming a mother (BAM) See *Maternal role attainment.*

Bed sharing An infant sleeping in close social and/or physical contact with a committed caregiver (usually the mother). Also called *cosleeping.*

Bereavement To have suffered the *event* of loss.

Beta human chorionic gonadotropin (beta hCG) A product of the trophoblast or placenta that is detected through serum testing and is a very accurate marker of the presence of pregnancy and placental health.

Bilirubin encephalopathy See *Kernicterus.*

Biofeedback The use of monitoring devices to help individuals learn to control their autonomic responses.

Biophysical profile (BPP) Assessment of five variables in the fetus that help to evaluate fetal risk: breathing movement, body movement, tone, amniotic fluid volume, and fetal heart rate reactivity.

Birth center A setting for labor and birth that emphasizes a family-centered approach rather than obstetric technology and treatment.

Birth defects Structural abnormalities present at birth.

Birth plan A written document prepared by the expectant parents that is used to identify available options in the birth setting and aspects of the childbearing experience that are most important to them.

Birthing room A room for labor and birth with a relaxed atmosphere.

Birth rate Number of live births per 1000 population.

Bishop score A prelabor scoring system to assist in predicting whether an induction of labor may be successful. The total score is achieved by assessing five components: cervical dilatation, cervical effacement, cervical consistency, cervical position, and fetal station. Each of the components is assigned a score of 0 to 3, and the highest possible score is 13.

Blastocyst The inner solid mass of cells within the morula.

Bloody show Pink-tinged mucus secretions resulting from rupture of small capillaries as the cervix effaces and dilates.

Body stalk Future umbilical cord; structure that attaches the embryo to the yolk sac and contains blood vessels that extend into the chorionic villi.

Bogginess The softening of the uterus due to inadequate contraction of the muscle tissue.

Boggy uterus (uterine atony) A term used to describe the uterine fundus when it is not firmly contracted after the birth of the baby and in the early postpartum period; excessive bleeding occurs from the placental site, and maternal hemorrhage may occur.

Bonding Process of parent-infant attachment occurring at or soon after birth.

Brachial palsy Partial or complete paralysis of portions of the arm resulting from trauma to the brachial plexus during a difficult birth.

Brachial plexus injury Injury due to improper or excessive traction applied to the fetal head during birth that results in damage to the network of nerves that send signals from the spine to the shoulder, arm, and hand.

Braxton Hicks contractions Intermittent painless contractions of the uterus that may occur every 10 to 20 minutes. They occur more frequently toward the end of pregnancy and are sometimes mistaken for true labor signs.

Brazelton's neonatal behavioral assessment A brief examination used to identify the infant's behavioral states and responses.

Breasts Mammary glands.

Breast self-examination (BSE) A manual examination conducted monthly by a woman to evaluate her own breasts for signs of masses, changes, nipple discharge, or evidence of abnormalities.

Breech presentation A birth in which the buttocks and/or feet are presented instead of the head.

Broad ligament The ligament extending from the lateral margins of the uterus to the pelvic wall; keeps the uterus centrally placed and provides stability within the pelvic cavity.

Bronchopulmonary dysplasia (BPD)/chronic lung disease (CLD) of prematurity Chronic pulmonary disease of multifactorial etiology characterized initially by alveolar and bronchial necrosis, which results in bronchial metaplasia and interstitial fibrosis. Appears in x-ray films as generalized small, radiolucent cysts within the lungs.

Brown adipose tissue (BAT) Fat deposits in newborns that provide greater heat-generating activity than ordinary fat. Found around the kidneys, adrenals, and neck; between the scapulas; and behind the sternum. Also called *brown fat.*

Calorie (cal) Amount of heat required to raise the temperature of 1 kg of water 1 degree centigrade.

Capacitation Removal of the plasma membrane overlying the spermatozoa's acrosomal area with the loss of seminal plasma proteins and the glycoprotein coat. If the glycoprotein coat is not removed, the sperm will not be able to penetrate the ovum.

Caput succedaneum (kap'ut suk-s''ĕ-dáne-um) Swelling or edema occurring in or under the fetal scalp during labor.

Cardinal ligaments The chief uterine supports, suspending the uterus from the side walls of the true pelvis.

Cardinal movements The positional changes of the fetus as it moves through the birth canal during labor and birth. The positional changes are descent, flexion, internal rotation, extension, restitution, and external rotation. Also called *mechanisms of labor.*

Cardiopulmonary adaptation Adaptation of the newborn's cardiovascular and respiratory systems to life outside the womb.

Caring theory Consists of five attributes of the caregiver: (1) knowing, (2) being with, (3) doing for, (4) enabling, and (5) maintaining belief.

Centering Group prenatal care.

Cephalhematoma (sef′ăl-hé-mă-tōmă) Subcutaneous swelling containing blood found on the head of an infant several days after birth; it usually disappears within a few weeks to 2 months.

Cephalic presentation Birth in which the fetal head is presenting against the cervix.

Cephalopelvic disproportion (CPD) A condition in which the fetal head is of such a shape or size, or in such a position, that it cannot pass through the maternal pelvis.

Cerclage Surgical procedure in which a stitch is placed in the cervix to prevent a spontaneous abortion or premature birth.

Certified nurse-midwife (CNM) An RN who has received special training and education in the care of the family during childbearing and the prenatal, labor and birth, and postpartal periods. After a period of formal education, the nurse-midwife takes a certification test to become a CNM.

Certified registered nurse (RNC) A registered nurse who has shown expertise in a specific field by passing a national certification examination.

Cervical dilatation Process in which the cervical os and the cervical canal widen from less than 1 cm to approximately 10 cm, allowing birth of the fetus.

Cervical funneling A cone-shaped indentation in the cervical os which is common in cases of cervical incompetence.

Cervical insufficiency Painless dilatation of the cervix without contractions because of a structural or functional defect of the cervix. Also called *incompetent cervix.*

Cervical ripening Softening of the cervix; occurs normally as a physiologic process before labor or is stimulated to occur through the process of induction of labor.

Cervix The "neck" between the external os and the body of the uterus. The lower end of the cervix extends into the vagina.

Cesarean birth Birth of fetus accomplished by performing a surgical incision through the maternal abdomen and uterus.

Chadwick's sign Violet bluish color of the vaginal mucous membrane caused by increased vascularity; visible from about the fourth week of pregnancy.

Chemical conjunctivitis Irritation of the mucous membrane lining of the eyelid; may be due to instillation of silver nitrate ophthalmic drops.

Child abuse Nonaccidental physical or threatened harm, including mental or emotional injury, sexual abuse, and sexual exploitation.

Child neglect Failure by parents or other custodians to meet the medical, emotional, physical, or supervisory needs of a child.

Childbearing decisions The decisions parents face about their childbirth preferences and experiences.

Chiropractic The third largest independent health profession found in the United States. Uses spinal manipulation to address abnormal nerve transmission (subluxation) caused by misalignment of the spine.

Chlamydial infection Caused by *Chlamydia trachomatis,* this infection is the most common bacterial sexually transmitted infection in the United States.

Chloasma (klō-az′mă) **(melasma gravidarum)** Brownish pigmentation over the bridge of the nose and the cheeks during pregnancy and in some women who are taking oral contraceptives. Also called *mask of pregnancy.*

Chorioamnionitis (kō′rē-ō-am′nē-ō-nī′tis) An inflammation of the amniotic membranes stimulated by organisms in the amniotic fluid, which then becomes infiltrated with polymorphonuclear leukocytes.

Chorion The fetal membrane closest to the intrauterine wall that gives rise to the placenta and continues as the outer membrane surrounding the amnion.

Chorionic villus sampling (CVS) Procedure in which a specimen of the chorionic villi is obtained from the edge of the developing placenta at about 8 weeks' gestation. The sample can be used for chromosomal, enzyme, and DNA tests.

Chromosomes The threadlike structures within the nucleus of a cell that carry the genes.

Circumcision Surgical removal of the prepuce (foreskin) of the penis.

Circumvallate (ser-kŭm-val′āt) **placenta** A placenta with a thick, white fibrous ring around the edge.

Civil unions Legally recognized partnerships that involve rights and responsibilities comparable with those enjoyed by married couples. Often used by same-sex couples.

Cleavage Rapid mitotic division of the zygote; cells produced are called *blastomeres.*

Climacteric The period of time that marks the cessation of a woman's reproductive function; the "change of life," or menopause.

Clinical nurse specialist (CNS) A nurse possessing a master's degree and specialized knowledge and competence in a specific clinical area.

Clitoris Female organ homologous to the male penis; a small oval body of erectile tissue situated at the anterior junction of the vulva.

Coitus interruptus Method of contraception in which the male withdraws his penis from the vagina before ejaculation.

Cold stress Excessive heat loss resulting in compensatory mechanisms (increased respirations and nonshivering thermogenesis) to maintain core body temperature.

Colostrum (kō-los′trŭm) Secretion from the breast before the onset of true lactation; contains mainly serum and white blood corpuscles. It has a high protein content, provides some immune properties, and cleanses the newborn's intestinal tract of mucus and meconium.

Colposcopy The use of an instrument inserted into the vagina to examine the cervical and vaginal tissues by means of a magnifying lens.

Combined oral contraceptives (COCs) Commonly called birth control pills or "the pill," COCs are a form of contraception that uses a combination of a synthetic estrogen and a progestin.

Comparable worth The standard that the same wages should be paid for different types of work that require comparable skills, responsibility, education, and experience.

Complementary and alternative medicine (CAM) A group of diverse medical and healthcare systems, practices, and products that are not generally considered part of conventional medicine.

Complementary therapy Any procedure or product that is used together with conventional medical treatment.

Conception Union of male sperm and female ovum; fertilization.

Condoms Rubber sheaths that cover men's penises to prevent conception or disease.

Conduction Loss of heat to a cooler surface by direct skin contact.

Condylomata acuminata Known also as genital or venereal warts, they are a common sexually transmitted infection caused by the human papilloma virus (HPV).

Condylomata lata Wartlike growth of skin, usually seen on the external genitals or anus. There are two types, a pointed variety and a broad, flat form usually found with syphilis.

Conjugate Important diameter of the pelvis, measured from the center of the promontory of the sacrum to the back of the symphysis pubis. The diagonal conjugate is measured and the true conjugate is estimated.

Conjugate vera The true conjugate, which extends from the middle of the sacral promontory to the middle of the pubic crest.

Contraception The prevention of conception or impregnation.

Contraction Tightening and shortening of the uterine muscles during labor, causing effacement and dilatation of the cervix; contributes to the downward and outward descent of the fetus.

Contraction stress test (CST) A method of assessing the reaction of the fetus to the stress of uterine contractions. This test may be utilized when contractions are occurring spontaneously or when contractions are artificially induced by oxytocin challenge test (OCT) or breast self-stimulation test (BSST).

Convection Loss of heat from the warm body surface to cooler air currents.

Coombs' (kōōmz) **test** A test for antiglobulins in the red cells. The indirect test determines the presence of Rh-positive antibodies in maternal blood; the direct test determines the presence of maternal Rh-positive antibodies in fetal cord blood.

Cordocentesis Also called percutaneous umbilical blood sampling (PUBS), a technique used to obtain pure fetal blood from the umbilical cord while the fetus is in utero, which is used for diagnosis of hemophilias, hemoglobinopathies, fetal infections, chromosome abnormalities, nonimmune hydrops, and isoimmune hemolytic disorders, as well as assessment of fetal hemoglobin and hematocrit for calculation of transfusion requirements in the second and third trimesters.

Cornua The elongated portions of the uterus where the fallopian tubes open.

Corpus The upper two thirds of the uterus.

Corpus luteum A small yellow body that develops within a ruptured ovarian follicle; it secretes progesterone in the second half of the menstrual cycle and atrophies about 3 days before the beginning of menstrual flow. If pregnancy occurs, the corpus luteum continues to produce progesterone until the placenta takes over this function.

Cosleeping An infant sleeping in close social and/or physical contact with a committed caregiver (usually the mother).

Cotyledon (kot-i-lē'don) One of the rounded portions into which the placenta's uterine surface is divided, consisting of a mass of villi, fetal vessels, and an intervillous space.

Couplet care A family-centered approach for maternal-child nursing where both the mother and her baby are cared for by the same nurse, with the baby remaining at the mother's bedside. Also called mother-baby care.

Couvade (kū-vahd') In some cultures, the male's observance of certain rituals and taboos to signify the transition to fatherhood.

Crack A form of freebase cocaine that is smoked.

Crisis intervention Actions taken by the nurse to help the client deal with an impending, potentially overwhelming crisis; regain his or her equilibrium; grow from the experience; and improve coping skills.

Critical thinking Intellectual processes that include separating fact from opinion, identifying prejudices and stereotypes that may influence interpretation of information, exploring differing ideas and views, and arriving at conclusions or insights.

Crowning Appearance of the presenting fetal part at the vaginal orifice during labor.

Crying state A state in the infant sleep-awake cycle in which the infant exhibits increased motor activity, grimaces, eyes that are tightly closed or open, and extreme responsiveness to stimuli.

Cultural beliefs Those beliefs that reflect the predominating values, attitudes, and practices accepted by a population, community, or ethnic group.

Cultural competency Referring to the skills and knowledge necessary to appreciate, understand, and work with individuals from different cultures.

Culture The beliefs, values, attitudes, and practices that are accepted by a population, community, or an individual.

Cycle of violence A theory that postulates that battering takes place in a cyclic fashion through three phases: the tension-building phase, the acute battering incident, and the tranquil phase (honeymoon period).

Cystocele The downward displacement of the bladder, which appears as a bulge in the anterior vaginal wall.

Deceleration Periodic decrease in the baseline fetal heart rate.

Decidua (dē-sid'yū-ă) Endometrium or mucous membrane lining of the uterus in pregnancy that is shed after childbirth.

Decidua basalis The part of the decidua that unites with the chorion to form the placenta. It is shed in lochial discharge after childbirth.

Decidua capsularis The part of the decidua surrounding the chorionic sac.

Decidua vera (parietalis) Nonplacental decidua lining the uterus.

Decrement Decrease or stage of decline, as of a contraction.

Deep sleep State of sleep in which the infant will be nearly still except for occasional startles, twitches, and sucking.

Depo-Provera A long-acting, injectable progestin contraceptive.

Descriptive statistics Statistics that describe or summarize a set of data.

Diagonal conjugate Distance from the lower posterior border of the symphysis pubis to the sacral promontory; may be obtained by manual measurement.

Diaphragm A flexible disk that covers the cervix to prevent pregnancy.

Diastasis (dī-as'tă-sis) **recti** (rek'ti) **abdominis** Separation of the recti abdominis muscles along the median line. In women, it is seen with repeated childbirths or multiple gestations. In the newborn, it is usually caused by incomplete development.

Dietary reference intakes (DRIs) Specific allowances for pregnant and lactating women, DRIs are subdivided into the recommended dietary allowance (RDA) and adequate intake (AI).

Dilation and curettage (D&C) Stretching of the cervical canal to permit passage of a curette, which is used to scrape the endometrium to empty the uterine contents or to obtain tissue for examination.

Dilatation of the cervix Expansion of the external os from an opening a few millimeters in size to an opening large enough to allow the passage of the infant.

Diploid number of chromosomes Containing a set of maternal and a set of paternal chromosomes; in humans, the diploid number of chromosomes is 46.

Disability Impairment in one or more of five function categories: cognition, communication, motor abilities, social abilities, or patterns of interactions.

Disassociation relaxation A pattern of active relaxation in which the woman learns to tighten one area of the body and then relax other areas simultaneously. This relaxation pattern is very effective for some women during labor.

Disenfranchised grief Grief that is not supported by the usual societal customs.

Domestic partnership A mechanism by which public and private employers can provide insurance coverage and pension-rights benefits to the partners of gay and lesbian employees.

Domestic violence Defined as the collective methods used to exert power and control by one individual over another in an adult intimate relationship. Forms of abuse typically fall into three categories: psychologic abuse, physical abuse, and sexual abuse.

Doula A supportive companion who accompanies a laboring woman to provide emotional, physical, and informational support and acts as an advocate for the woman and her family.

Down syndrome An abnormality resulting from the presence of an extra chromosome number 21 (trisomy 21); characteristics include mental retardation and altered physical appearance. Formerly called ***mongolism.***

Drowsy awake state A state in the infant sleep-wake cycle that occurs between light sleep and the quiet alert state. It is marked by infants opening and closing their eyes, but the eyes appear glazed and the face is often still. They may return to sleep or awaken further in response to stimuli.

Drug-exposed infant The newborn of an alcoholic or drug-addicted woman.

Dual process model A view of grief encompassing two competing facets: loss and restoration. The loss orientation is concerned with the individual's need to confront the reality of the loss, and the restoration orientation seeks to regain balance and temper the pain of grief.

Dubowitz tool A clinical gestational age assessment tool.

Ductus arteriosus A communication channel between the main pulmonary artery and the aorta of the fetus. It is obliterated after birth by rising PO_2 and changes in intravascular pressure in the presence of normal pulmonary functioning. It normally becomes a ligament after birth but sometimes remains patent (patent ductus arteriosus, a treatable condition).

Ductus venosus A fetal blood vessel that carries oxygenated blood between the umbilical vein and the inferior vena cava, bypassing the liver; it becomes a ligament after birth.

Duncan's mechanism Occurs when the maternal surface of the placenta rather than the shiny fetal surface presents upon birth.

Duration The time length of each contraction, measured from the beginning of the increment to the completion of the decrement.

Dysfunctional uterine bleeding (DUB) A condition characterized by anovulatory cycles with abnormal uterine bleeding that does not have a demonstrable organic cause.

Dysmenorrhea Painful menstruation.

Dyspareunia Painful intercourse.

Dystocia (dis-tō'sē-ă) Difficult labor due to mechanical factors produced by the fetus or the maternal pelvis or due to inadequate uterine or other muscular activity.

Early adolescence A term referring to adolescents who are age 14 and under.

Early decelerations Periodic change in fetal heart rate pattern caused by head compression; deceleration has a uniform appearance and early onset in relation to maternal contraction.

Early (primary) postpartum hemorrhage See *Postpartum hemorrhage.*

Eclampsia (ek-lamp'sē-ă) A major complication of pregnancy. Its cause is unknown; it occurs more often in the primigravida and is accompanied by elevated blood pressure, albuminuria, oliguria, tonic and clonic convulsions, and coma. It may occur during pregnancy (usually after the 20th week of gestation) or within 48 hours after childbirth.

Ectoderm Outer layer of cells in the developing embryo that gives rise to the skin, nails, and hair.

Ectopic pregnancy Implantation of the fertilized ovum outside the uterine cavity; common sites are the abdomen, fallopian tubes, and ovaries. Also called *oocyesis.*

Effacement Thinning and shortening of the cervix that occurs late in pregnancy or during labor.

Effleurage (e-fler-ahz') A light stroking movement of the fingertips over the abdominal area during labor; used to provide distraction during labor contractions.

Ejaculation Expulsion of the seminal fluids from the penis.

Elder abuse Any deliberate action or lack of action that causes harm to an elderly person.

Electronic fetal monitoring (EFM) A method of placing a fetal monitor on the fetus in order to obtain a continuous tracing of the FHR, which allows many characteristics of the fetal heart rate to be observed and evaluated.

Emancipated minors Minors who are legally considered to have assumed the rights of an adult. An adolescent may be considered emancipated if he or she is self-supporting and living away from home, married, pregnant, a parent, or in the military.

Embryo The early stage of development of the young of any organism. In humans the embryonic period is from about 2 to 8 weeks' gestation and is characterized by cellular differentiation and predominantly hyperplastic growth.

Embryonic membranes The amnion and chorion.

Endoderm The inner layer of cells in the developing embryo that give rise to internal organs such as the intestines.

Endometrial biopsy (EMB) Procedure providing information about the effects of progesterone produced by the corpus luteum after ovulation and endometrial receptivity.

Endometriosis Ectopic endometrium located outside the uterus in the pelvic cavity. Symptoms may include pelvic pain or pressure, dysmenorrhea, dispareunia, abnormal bleeding from the uterus or rectum, and sterility.

Endometritis (metritis) Infection of the endometrium.

Endometrium (en'dō-mē'trē-ŭm) The mucous membrane that lines the inner surface of the uterus.

En face An assumed position in which one person looks at another and maintains his or her face in the same vertical plane as that of the other.

Engagement The entrance of the fetal presenting part into the superior pelvic strait and the beginning of the descent through the pelvic canal.

Engorgement Vascular congestion or distention. In obstetrics, the swelling of breast tissue brought about by an increase in blood and lymph supply to the breast, preceding true lactation.

Engrossment Characteristic sense of absorption, preoccupation, and interest in the infant demonstrated by fathers during early contact with their infants.

Environmental toxins Chemical compounds found in air, food, and water, whose bioaccumulation can lead to adverse health effects.

Epidural block Regional anesthesia effective through the first and second stages of labor.

Episiotomy (ĕ-piz-ē-ot'o-mē) Incision of the perineum to facilitate birth and to avoid laceration of the perineum.

Epstein's (ep'stīnz) **pearls** Small, white blebs found along the gum margins and at the junction of the hard and soft palates; commonly seen in the newborn as a normal manifestation.

Erb-Duchenne paralysis (Erb's palsy) Paralysis of the arm and chest wall as a result of a birth injury to the brachial plexus or a subsequent injury to the fifth and sixth cervical nerves.

Erythema toxicum Innocuous pink papular rash of unknown cause with superimposed vesicles; it appears within 24 to 48 hours after birth and resolves spontaneously within a few days.

Erythroblastosis fetalis Hemolytic disease of the newborn characterized by anemia, jaundice, enlargement of the liver and spleen, and generalized edema. Caused by isoimmunization due to Rh incompatibility or ABO incompatibility.

Essure Method of permanent sterilization that requires no surgical incision. Under hysteroscopy, a stainless steel micro-insert is placed into each proximal section of the fallopian tube.

Estimated date of birth (EDB) During a pregnancy, the approximate date when childbirth will occur; the "due date."

Estrogens The hormones estradiol and estrone, produced by the ovary.

Ethnicity A social identity that is associated with shared beliefs, behaviors, and patterns.

Ethnocentrism An individual's belief that the values and practices of his or her own culture are the best ones.

Euphemism A substituted word or expression with a more pleasant association than the one which, although more direct, is considered to be harsher.

Evaporation Loss of heat incurred when water on the skin surface is converted to a vapor.

Evidence-based practice An approach to problem solving and decision making based on the consideration of data from research, statistical analysis, quality measures, risk management measurements, and other sources of reliable information.

Exchange transfusion The replacement of 70% to 80% of circulating blood by withdrawing the recipient's blood and injecting a donor's blood in equal amounts, for the purpose of preventing the accumulation of bilirubin or other by-products of hemolysis in the blood.

External cephalic version (ECV) Procedure involving external manipulation of the maternal abdomen to change the presentation of the fetus from breech to cephalic.

External os The opening between the cervix and the vagina.

Fallopian tubes Tubes that extend from the lateral angle of the uterus and terminate near the ovary; they serve as a passageway for the ovum from the ovary to the uterus and for the spermatozoa from the uterus toward the ovary. Also called *oviducts* and *uterine tubes.*

False labor Contractions of the uterus, regular or irregular, that may be strong enough to be interpreted as true labor but that do not dilate the cervix.

False pelvis The portion of the pelvis above the linea terminalis; its primary function is to support the weight of the enlarged pregnant uterus.

Family Two or more persons who are joined together by bonds of sharing and emotional closeness and who identify themselves as being part of a family.

Family assessment The process by which a nurse collects data regarding a family's current level of functioning, support systems, sociocultural influences, home and work environment, type of family, family structure, and needs.

Family-centered care An approach to health care based on the concept that a hospital can provide professional services to mothers, fathers, and infants in a homelike environment that would enhance the integrity of the family unit.

Family development The changes that families experience over time, including changes in relationships, communication patterns, roles, and interactions.

Family planning Actions an individual or a couple take to avoid a pregnancy, to space future pregnancies for a specific reason, or to gain control over the number of children conceived.

Family power The individual who has either the potential or actual ability to change the behavior of other family members.

Family roles The specific roles of individuals within a family unit. Examples of roles include breadwinner, homemaker, mother, father, social planner, and family peacemaker.

Family values A system of ideas, attitudes, and beliefs about the worth of an entity or a concept that consciously or unconsciously bind together the members of the family in a common culture.

Fecundability The ability to become pregnant.

Female condom A thin, disposable polyurethane sheath with a flexible ring at each end that is placed inside the vagina and serves to prevent sperm from entering the cervix, thus preventing conception.

Female genital mutilation (FGM) Also known as *female genital cutting, female circumcision,* and *genital circumcision,* the practice of removing all or parts of a girl's or woman's genitalia for cultural reasons.

Female reproductive cycle (FRC) The monthly rhythmic changes in sexually mature women.

Feminization of later life Worldwide trend for women to comprise a majority of the elderly population.

Feminization of poverty Term used to describe the fact that, in the United States, women comprise a majority of the adult poor.

Fern ing capacity Formation of a palm-leaf pattern by the crystallization of cervical mucus as it dries at mid-menstrual cycle. The formation can be helpful in determining time of ovulation. Observed via microscopic examination of a thin layer of cervical mucus on a glass slide. This pattern is also observed when amniotic fluid is allowed to air dry on a slide and is a useful and quick test to determine whether amniotic membranes have ruptured.

Fertility awareness-based (FAB) methods Also known as natural family planning, fertility awareness-based methods are founded on an understanding of the changes that occur throughout a woman's ovulatory cycle. All these methods require periods of abstinence and recording of certain events throughout the cycle; cooperation of the partner is important.

Fertilization Impregnation of an ovum by a spermatozoon; conception.

Fetal acoustic stimulation test (FAST) A fetal assessment test that uses sound from a speaker, bell, or artificial larynx to stimulate acceleration of the fetal heart; may be used in conjunction with the nonstress test.

Fetal alcohol spectrum disorder (FASD) An umbrella term that includes all categories of prenatal alcohol exposure, including fetal alcohol syndrome (FAS); it is not meant to be used as a clinical diagnosis.

Fetal alcohol syndrome (FAS) Syndrome caused by maternal alcohol ingestion and characterized by microcephaly, intrauterine growth restriction, short palpebral fissures, and maxillary hypoplasia.

Fetal attitude Relationship of the fetal parts to one another. Normal fetal attitude is one of moderate flexion of the arms onto the chest and flexion of the legs onto the abdomen.

Fetal blood sampling Blood sample drawn from the fetal scalp (or from the fetus in breech position) to evaluate the acid–base status of the fetus.

Fetal bradycardia A fetal heart rate less than 120 beats per minute during a 10-minute period of continuous monitoring.

Fetal breathing movements (FBM) Intrauterine practice respiratory movements that begin around the 17th to 20th week of gestation.

Fetal death Death of the developing fetus after 20 weeks' gestation. Also called *fetal demise.*

Fetal fibronectin (fFN) A glycoprotein that is produced by the trophoblast and fetal tissues whose presence between 20 and 34 weeks' gestation is a strong predictor of preterm birth associated with preterm spontaneous rupture of membranes.

Fetal heart rate (FHR) The number of times the fetal heart beats per minute; normal range is 120 to 160.

Fetal lie Relationship of the cephalocaudal axis (spinal column) of the fetus to the cephalocaudal axis (spinal column) of the woman. The fetus may be in a longitudinal or transverse lie.

Fetal movement record (FMR) A method for tracking fetal activity taught to pregnant women.

Fetal position Relationship of the landmark on the presenting fetal part to the front, sides, or back of the maternal pelvis.

Fetal presentation The fetal body part that enters the maternal pelvis first. The three possible presentations are cephalic, shoulder, and breech.

Fetal tachycardia A fetal heart rate of 160 beats per minute or more during a 10-minute period of continuous monitoring.

Fetoscope An adaptation of a stethoscope that facilitates auscultation of the fetal heart rate.

Fetus The child in utero from about the seventh to ninth week of gestation until birth.

Fibrocystic breast changes Benign breast changes characterized by bilateral, cyclic breast pain and breast nodularities that may be unilateral or bilateral, and often in the upper outer quadrants of the breasts.

Fibrocystic breast disease Benign breast disorder characterized by a thickening of normal breast tissue and the formation of cysts.

Fimbria Any structure resembling a fringe; the fringelike extremity of the fallopian tubes.

Folic acid An important vitamin directly related to the outcome of pregnancy and to maternal and fetal health.

Follicle-stimulating hormone (FSH) Hormone produced by the anterior pituitary during the first half of the menstrual cycle, stimulating development of the graafian follicle.

Fontanelle (fon'tă-nel') In the fetus, an unossified space, or soft spot, consisting of a strong band of connective tissue lying between the cranial bones of the skull.

Foramen ovale Special opening between the atria of the fetal heart. Normally, the opening closes shortly after birth; if it remains open, it can be repaired surgically.

Forceps Obstetric instrument occasionally used to aid in childbirth.

Forceps-assisted birth A birth in which a set of instruments, known as forceps, are applied to the presenting part of the fetus to provide traction or to enable the fetal head to be rotated to an occiput-anterior position. Forceps-assisted birth is also known as *instrumental delivery, operative delivery,* or *operative vaginal delivery.*

Forceps marks Reddened areas over the cheeks and jaws caused by the application of forceps. The red areas usually disappear within 1 to 2 days.

Foremilk Breast milk obtained at the beginning of the breastfeeding episode.

Frequency The time between the beginning of one contraction and the beginning of the next contraction.

Functional residual capacity (FRC) The amount of air remaining in the lungs at the end of a normal expiration.

Fundus The upper portion of the uterus between the fallopian tubes.

Galactorrhea Nipple discharge.

Gamete (gam′ēt) Female or male germ cell; contains a haploid number of chromosomes.

Gamete intrafallopian transfer (GIFT) Retrieval of oocytes by laparoscopy; immediately combining oocytes with washed, motile sperm in a catheter; and placement of the gametes into the fimbriated end of the fallopian tube.

Gametogenesis The process by which germ cells are produced.

General anesthesia A state of induced unconsciousness that may be achieved through intravenous injection, inhalation of anesthetic agents, or a combination of both methods.

Genotype The genetic composition of an individual.

Gestation (jes-tā′shŭn) Period of intrauterine development from conception through birth; pregnancy.

Gestational age The number of complete weeks of fetal development, calculated from the first day of the last normal menstrual cycle.

Gestational age assessment tools Systems used to evaluate the newborn's external physical characteristics and neurologic and/or neuromuscular development to accurately determine gestational age. These replace or supplement the traditional calculation from the woman's last menstrual period.

Gestational diabetes mellitus (GDM) A form of diabetes of variable severity with onset or first recognition during pregnancy.

Gestational trophoblastic disease (GTD) Disorder classified into two types: benign (hydatidiform mole) and malignant.

Gonadotropin-releasing hormone (GnRH) A hormone secreted by the hypothalamus that stimulates the anterior pituitary to secrete FSH and LH.

Gonadotropins Hormones that stimulate the gonads (ovaries in women or testes in men).

Gonorrhea A sexually transmitted infection caused by the bacterium *Neisseria gonorrhoeae.*

Goodell's sign Softening of the cervix that occurs during the second month of pregnancy.

Graafian follicle The ovarian cyst containing the ripe ovum; it secretes estrogens.

Grasping reflex Normal newborn reflex elicited by stimulating the palm with a finger or object, resulting in newborn firmly holding on to the finger or object.

Gravida (grav′i-dă) A pregnant woman.

Grief An individual's *reaction* to loss, including physical symptoms, thoughts, feelings, functional limitations, and spiritual responses.

Grief work The inner process of working through or managing the bereavement.

Guided imagery A state of intense, focused concentration used to create compelling mental images. It is sometimes considered a form of hypnosis.

Gynecoid pelvis Typical female pelvis in which the inlet is round instead of oval.

Habituation (ha-bit-chū-ā′shŭn) Infant's ability to diminish innate responses to specific repeated stimuli.

Haploid number of chromosomes Half the diploid number of chromosomes. In humans there are 23 chromosomes, the haploid number, in each germ cell.

Harlequin sign A rare color change that occurs between the longitudinal halves of the newborn's body, such that the dependent half is noticeably pinker than the superior half when the newborn is placed on one side; it is of no pathologic significance.

Hatha yoga The physical branch of yoga; in the United States, it is commonly practiced for wellness, illness prevention, and healing.

Hegar's sign A softening of the lower uterine segment found upon palpation in the second or third month of pregnancy.

HELLP syndrome A cluster of changes including ***h***emolysis, ***e***levated ***l***iver enzymes, and ***l***ow ***p***latelet count; sometimes associated with severe preeclampsia.

Hemolytic disease of the newborn *Hyperbilirubinemia* secondary to Rh incompatibility.

Herpes genitalis A lifelong, recurrent sexually transmitted infection caused by the herpes simplex virus (HSV).

Heterozygous A genotypic situation in which two different alleles occur at a given locus on a pair of homologous chromosomes.

Hindmilk Breast milk released after initial let-down reflex; high in fat content.

Homeopathy Term derived from the Greek word *homos,* meaning "the same," and describing a healing system that uses as remedies minute dilutions of substances that, if ingested in larger amounts, would produce effects *similar* to the symptoms of the disorder being treated.

Homozygous A genotypic situation in which two similar genes occur at a given locus on homologous chromosomes.

Hormone therapy (HT) Administration of hormones, usually estrogen and a progestin, to alleviate the symptoms of menopause.

Hospital disposition The incineration at regular intervals of a dead fetus or infant's body, usually with other body parts.

Human chorionic gonadotropin (hCG) A hormone produced by the chorionic villi and found in the urine of pregnant women. Also called *prolan.*

Human immunodeficiency virus (HIV) A virus that causes a progressive disease that ultimately results in the development of *acquired immunodeficiency syndrome (AIDS).*

Human placental lactogen (hPL) A hormone synthesized by the syncytiotrophoblast that functions as an insulin antagonist and promotes lipolysis to increase the amounts of circulating free fatty acids available for maternal metabolic use.

Hydatidiform (hī-da-tid′i-form) **mole** Degenerative process in chorionic villi, giving rise to multiple cysts and rapid growth of the uterus, with hemorrhage.

Hydramnios (hī-dram′nē-os) An excess of amniotic fluid, leading to overdistention of the uterus. Frequently seen in diabetic pregnant women, even if there is no coexisting fetal anomaly. Also called *polyhydramnios.*

Hydrops fetalis See *Erythroblastosis fetalis.*

Hydrotherapy Type of therapy that makes use of hot or cold moisture in any form. Hydrotherapy is used to relax muscles, promote rest, decrease pain, reduce swelling, promote healing, cleanse wounds and burns, reduce fever, lessen cramps, and improve well-being.

Hyperbilirubinemia (hī-per-bil′i-rū-bi-nē′mē-ă) Excessive amount of bilirubin in the blood; indicative of hemolytic processes due to blood incompatibility, intrauterine infection, septicemia, neonatal renal infection, and other disorders.

Hyperemesis gravidarum Excessive vomiting during pregnancy, leading to dehydration and starvation.

Hyperventilation Rapid breathing that occurs over a prolonged period of time resulting in an imbalance of oxygen and carbon dioxide that can result in tingling or numbness in the tip of nose, lips, fingers, or toes; dizziness; spots before the eyes; or spasms of the hands or feet (carpal-pedal spasms).

Hypnosis Whether guided by a trained hypnotherapist or self-induced, a state of great mental and physical relaxation during which a person is very open to suggestions.

Hypoglycemia Abnormally low level of sugar in the blood.

Hysterectomy Surgical removal of the uterus.

Hysterosalpingography (HSG) Testing by instillation of radiopaque substance into the uterine cavity to visualize the uterus and fallopian tubes.

Hysteroscopy Use of a special endoscope to examine the uterus.

Implanon (subdermal implant) A single-capsule implant inserted subdermally in the woman's upper underarm; it is impregnated with etonogestrel, a progestin, which prevents ovulation, and is effective as a contraceptive method for 3 years.

Inborn error of metabolism A hereditary deficiency of a specific enzyme needed for normal metabolism of specific chemicals.

Incompetent cervix See *Cervical insufficiency.*

Increment Increase or addition; to build up, as of a contraction.

Induction of labor The process of causing or initiating labor by use of medication or surgical rupture of membranes.

Infant A child under 1 year of age.

Infant mortality rate Number of deaths of infants under 1 year of age per 1000 live births in a given population per year.

Infant of diabetic mother (IDM) At-risk infant born to a woman previously diagnosed as diabetic or who develops symptoms of diabetes during pregnancy.

Infant of substance-abusing mother (ISAM) Formerly called infant of an addicted mother, an infant born to a mother who abuses or is addicted to drugs or alcohol.

Inferential statistics Statistics that allow an investigator to draw conclusions about what is happening between two or more variables in a population and to suggest or refute causal relationships between them.

Infertility Diminished ability to conceive.

Informed consent A legal concept that protects a person's rights to autonomy and self-determination by specifying that no action may be taken without that person's prior understanding and freely given consent.

Infundibulopelvic ligament Ligament that suspends and supports the ovaries.

Instrumental style of coping A style of coping by which persons generally use more cognitive skills to navigate loss and value care that includes an emphasis on problem solving.

Integrative medicine An approach that combines mainstream medical therapies with complementary therapies for which there is some high-quality scientific evidence of safety and effectiveness.

Intellectual disability The most common type of developmental disability; formerly called *mental retardation.*

Intensity The strength of a uterine contraction during acme.

Internal os An inside mouth or opening; the opening between the cervix and the uterus.

Internal version Procedure used for the vaginal birth of a second twin. The obstetrician inserts a hand into the uterus, grasps the feet of the fetus, and changes the fetus from a transverse to a breech presentation. Also called *podalic version.*

Intrapartum The time from the onset of true labor until the birth of the infant and expulsion of the placenta.

Intrauterine device (IUD) Small metal or plastic form that is placed in the uterus to prevent implantation of a fertilized ovum.

Intrauterine fetal surgery Surgery performed on a fetus to correct anatomic lesions that are not compatible with life if left untreated.

Intrauterine growth restriction (IUGR) Fetal undergrowth due to any etiology, such as intrauterine infection, deficient nutrient supply, or congenital malformation. A term used to describe fetuses falling below the 10th percentile in ultrasonic estimation of weight at a given gestational age.

Intrauterine pressure catheter (IUPC) A catheter that can be placed through the cervix into the uterus to measure uterine pressure during labor. Some types of catheters may be inserted for the purpose of infusing warmed saline to add additional intrauterine fluid when oligohydramnios is present.

Introitus Opening or entrance into a cavity or canal such as the vagina.

Intuitive style of coping A style of coping by which persons generally feel their way through loss and prefer care with an emphasis on emotional and psychosocial support.

In vitro fertilization (IVF) Procedure during which oocytes are removed from the ovary, mixed with spermatozoa, fertilized, and incubated in a glass petri dish; then up to four viable embryos are placed in the woman's uterus.

Involution Rolling or turning inward; the reduction in size of the uterus following childbirth.

Ischial spines Prominences that arise near the junction of the ilium and ischium and jut into the pelvic cavity; used as a reference point during labor to evaluate the descent of the fetal head into the birth canal.

Isthmus The straight, narrow part of the fallopian tube with a thick muscular wall and an opening (lumen) 2 to 3 mm in diameter; the site of tubal ligation. Also, a constriction in the uterus that is located above the cervix and below the corpus.

Jaundice Yellow pigmentation of body tissues caused by the presence of bile pigments. See also *Physiologic jaundice.*

Karyotype The set of chromosomes arranged in a standard order.

Kegel exercises Perineal muscle tightening that strengthens the pubococcygeus muscle and increases its tone.

Kernicterus (ker-nik'ter-ŭs) An encephalopathy caused by deposition of unconjugated bilirubin in brain cells; may result in impaired brain function or death.

Kilocalorie (kcal) Equivalent to 1000 calories, it is the unit used to express the energy value of food.

Klinefelter syndrome A chromosomal abnormality caused by the presence of an extra X chromosome in the male. Characteristics include tall stature; sparse pubic and facial hair; gynecomastia; small, firm testes; and absence of spermatogenesis.

Labor The process by which the fetus is expelled from the maternal uterus. Also called *childbirth, confinement,* or *parturition.*

Labor augmentation The stimulation of uterine contractions when spontaneous contractions have failed to result in progressive cervical dilation or descent of the fetus.

Labor induction The stimulation of uterine contractions before the spontaneous onset of labor, with or without ruptured fetal membranes, for the purpose of accomplishing birth.

Labor support The emotional, physical, and informational support of the woman during childbirth.

Lactase deficiency (lactose intolerance) A condition characterized by difficulty digesting milk and dairy products. Results from an inadequate amount of the enzyme lactase, which breaks down the milk sugar lactose into smaller digestible substances.

Lactation The process of producing and supplying breast milk.

Lacto-ovovegetarians Vegetarians who include milk, dairy products, and eggs in their diets and occasionally fish, poultry, and liver.

Lactose intolerance A condition in which an individual has difficulty digesting milk and milk products.

Lactovegetarians Vegetarians who include dairy products but no eggs in their diets.

La Leche League International (LLLI) Organization that provides information on and assistance with breastfeeding.

Lamaze method A method of childbirth preparation.

Lanugo (lă-nū′gō) Fine, downy hair found on all body parts of the fetus, with the exception of the palms of the hands and the soles of the feet, after 20 weeks' gestation.

Laparoscopy Procedure that enables direct visualization of pelvic organs.

Large for gestational age (LGA) Excessive growth of a fetus in relation to the gestational time period.

Last menstrual period (LMP) The last normal menstrual period experienced by the woman before pregnancy; sometimes used to calculate the infant's gestational age.

Late adolescence A term referring to adolescents who are ages 18 to 19 years.

Late decelerations Symmetrical decrease in fetal heart rate beginning at or after the peak of the contraction and returning to baseline only after the contraction has ended, indicating possible uteroplacental insufficiency and potential that the fetus is not receiving adequate oxygenation.

Late preterm infant An infant born between 34 and 37 weeks of gestation.

Late (secondary) postpartum hemorrhage See *Postpartum hemorrhage.*

Lecithin/sphingomyelin (les′i-thin sfing′gō-mī′ĕ-lin) **(L/S) ratio** Lecithin and sphingomyelin are phospholipid components of surfactant; their ratio changes during gestation. When the L/S ratio reaches 2:1, the fetal lungs are thought to be mature and the fetus will have a low risk of respiratory distress syndrome (RDS) if born at that time.

Leiomyoma A benign tumor of the uterus, composed primarily of smooth muscle and connective tissue. Also referred to as a *myoma* or a *fibroid.*

Leopold's maneuvers A series of four maneuvers designed to provide a systematic approach whereby the examiner may determine fetal presentation and position.

Let-down reflex Pattern of stimulation, hormone release, and resulting muscle contraction that forces milk into the lactiferous ducts, making it available to the infant. Also called *milk ejection reflex.*

Leukorrhea Mucous discharge from the vagina or cervical canal that may be normal or pathologic, as in the presence of infection.

Lightening Moving of the fetus and uterus downward into the pelvic cavity.

Light sleep State that makes up the highest proportion of newborn sleep and precedes awakening; characterized by some body movements, rapid eye movements (REM), and brief fussing or crying.

Linea nigra (lin′ē-ă ni′gră) The line of darker pigmentation extending from the umbilicus to the pubis noted in some women during the later months of pregnancy.

Local anesthesia Injection of an anesthetic agent into the subcutaneous tissue in a fanlike pattern.

Lochia (lō′kē-ă) Maternal discharge of blood, mucus, and tissue from the uterus; may last for several weeks after birth.

Lochia alba White vaginal discharge that follows lochia serosa and that lasts from about the 10th to the 21st day after birth.

Lochia rubra Red, blood-tinged vaginal discharge that occurs following birth and lasts 2 to 4 days.

Lochia serosa Pink, serous, and blood-tinged vaginal discharge that follows lochia rubra and lasts until the 7th to 10th day after birth.

Lung compliance The ease with which the lung is able to fill with air.

Luteinizing hormone (LH) Anterior pituitary hormone responsible for stimulating ovulation and for development of the corpus luteum.

Maceration The process of tissue breakdown that begins from the moment of death.

Macrosomia (mak-rō-sō′mē-ă) A condition seen in newborns of large body size and high birth weight (more than 4000 to 4500 g [8 lb, 13 oz to 9 lb, 14 oz]), such as those born of prediabetic and diabetic mothers.

Malposition An abnormal position of the fetus in the birth canal.

Malpresentation A presentation of the fetus into the birth canal that is not "normal"—that is, brow, face, shoulder, or breech presentation.

Mammogram A soft-tissue radiograph of the breast without the injection of a contrast medium.

Massage therapy Manipulation of the soft tissues of the body to reduce stress and tension, increase circulation, diminish pain, and promote a sense of well-being.

Mastitis Inflammation of the breast.

Maternal mortality rate The number of maternal deaths from any cause during the pregnancy cycle per 100,000 live births.

Maternal role attainment (MRA) Process by which a woman learns mothering behaviors and becomes comfortable with her identity as a mother.

Maternal serum alpha-fetoprotein (MSAFP) Screening test performed between 16 and 22 gestational weeks that utilizes the multiple markers (the "triple screen") of alpha-fetoprotein (AFP), human chorionic growth hormone (hCG), and urine estriol (uE3) to screen pregnancies for neural tube defect, Down syndrome, and trisomy 18.

Mature milk Breast milk that contains 10% solids for energy and growth.

McDonald's sign A probable sign of pregnancy characterized by an ease in flexing the body of the uterus against the cervix.

Meaning reconstruction A framework for understanding perinatal loss that focuses on redefining ourselves and how we interact with the world after a significant loss. The goal of recovery, as related to meaning reconstruction, is a positive change in self-identity by assigning the loss a meaning, thereby allowing the individual to assimilate the loss into her or his world.

Meconium Dark green or black material present in the large intestine of a full-term infant; the first stools passed by the newborn.

Meconium aspiration syndrome (MAS) Respiratory disease of term, postterm, and SGA newborns caused by inhalation of meconium or meconium-stained amniotic fluid into the lungs; characterized by mild to severe respiratory distress, hyperexpansion of the chest, hyperinflated alveoli, and secondary atelectasis.

Meiosis The process of cell division that occurs in the maturation of sperm and ova that decreases their number of chromosomes by one half.

Melasma gravidarum See *Chloasma.*

Menarche (me-nar′kē) Beginning of menstrual and reproductive function in the female.

Mendelian inheritance A major category of inheritance whereby a trait is determined by a pair of genes on homologous chromosomes. Also called *single gene inheritance.*

Menopause The permanent cessation of menses.

Menorrhagia Excessive or profuse menstrual flow.

Menstrual cycle Cyclic buildup of the uterine lining, ovulation, and sloughing of the lining occurring approximately every 28 days in nonpregnant females.

Mentum The chin.

Mesoderm The intermediate layer of germ cells in the embryo that gives rise to connective tissue, bone marrow, muscles, blood, lymphoid tissue, and epithelial tissue.

Metrorrhagia Abnormal uterine bleeding occurring at irregular intervals.

Middle adolescence A term referring to adolescents who are ages 15 to 17 years.

Milia (mil′ē-ă) Tiny white papules appearing on the face of a newborn as a result of unopened sebaceous glands; they disappear spontaneously within a few weeks.

Milk/plasma ratio The comparison of the concentration of substances in the breast milk and the maternal blood serum.

Miscarriage See *Spontaneous abortion.*

Mitosis Process of cell division whereby both daughter cells have the same number and pattern of chromosomes as the original cell.

Molding Shaping of the fetal head by overlapping of the cranial bones to facilitate movement through the birth canal during labor.

Mongolian blue spots Macular areas of bluish black or gray-blue pigmentation found on the dorsal area and the buttocks of newborns.

Moniliasis Yeastlike fungal infection caused by *Candida albicans.*

Monosomies A genetic condition that occurs when a normal gamete unites with a gamete that is missing a chromosome.

Mons pubis (monz pu'bis) Mound of subcutaneous fatty tissue covering the anterior portion of the symphysis pubis.

Morning sickness A term that refers to the nausea and vomiting that a woman may experience in early pregnancy. This lay term is sometimes used because these symptoms frequently occur in the early part of the day and disappear within a few hours.

Moro reflex Flexion of the newborn's thighs and knees accompanied by fingers that fan, then clench, as the arms are simultaneously thrown out and then brought together, as though embracing something. This reflex can be elicited by startling the newborn with a sudden noise or movement. Also called the *startle reflex.*

Morula Developmental stage of the fertilized ovum in which there is a solid mass of cells.

Mosaicism Condition of an individual who has at least two cell lines with differing karyotypes.

Mother-baby care Also called *couplet care,* a family-centered care approach in which the infant remains at the mother's bedside and both are cared for by the same nurse.

Mottling (mot'ling) Discoloration of the skin in irregular areas; may be seen with chilling, poor perfusion, or hypoxia.

Mourning The process by which individuals incorporate the loss experience into their lives, it is influenced by many factors including personality, gender, family dynamics, and social, religious, and cultural norms.

Mucous plug A collection of thick mucus that blocks the cervical canal during pregnancy. Also called *operculum.*

Multigravida (mŭl-tē-grav'i-dă) Woman who has been pregnant more than once.

Multipara (mŭl-tip'ă-ră) Woman who has had more than one pregnancy in which the fetus was viable.

Multiple gestation More than one fetus in the uterus at the same time.

Music therapy Form of sound therapy using one or more musical instruments and improvisations or musical compositions. *Sound therapy* is based on the premise that when the body is exposed to the correct sound frequency (including some very low and very high frequencies that humans cannot normally hear) the body restores itself.

Myometrium Uterine muscular structure.

Nägele's rule A method of determining the estimated date of birth (EDB): after obtaining the first day of the last menstrual period, subtract 3 months and add 7 days.

Naturopathy A healing system that employs various natural means of preventing and treating human disease, such as foods, herbs, rest, etc. Also called *natural medicine.*

Neonatal morbidity The number of potential cases per year of a disease, illness, or complication occurring in the neonatal period.

Neonatal mortality risk The chance of death within the newborn period.

Neonatal transition The first few hours of life, in which the newborn stabilizes his or her respiratory and circulatory functions.

Neonatology The specialty that focuses on the management of at-risk conditions of the newborn.

Neutral thermal environment (NTE) An environment that provides for minimal heat loss or expenditure.

Nevus (nē'vŭs) **flammeus** (flaem'iŭs) Large port-wine stain.

Nevus vasculosus "Strawberry mark": raised, clearly delineated, dark-red, rough-surfaced birthmark commonly found in the head region.

New Ballard score (NBS) A postnatal gestational age assessment tool, it is a refinement of a previous Ballard score tool with added criteria for more accurate assessment of the gestational age of newborns between 20 and 28 weeks' gestation and less than 1500 g.

Newborn Infant from birth through the first 28 days of life.

Newborn screening tests Tests that detect inborn errors of metabolism that, if left untreated, cause mental retardation and physical handicaps.

Newborns' and Mothers' Health Protection Act (NMHPA) Legislation which states that women who have given birth vaginally cannot be forcibly discharged from the hospital within 48 hours of the time of birth for insurance reasons. Cesarean birth mothers are covered by their insurance for 96 hours following the time of birth.

Nidation Implantation of a fertilized ovum in the endometrium.

Nipple A protrusion about 0.5 to 1.3 cm in diameter in the center of each mature breast.

Nonmendelian (multifactorial) inheritance The occurrence of congenital disorders that result from an interaction of multiple genetic and environmental factors.

Nonstress test (NST) An assessment method by which the reaction (or response) of the fetal heart rate to fetal movement is evaluated.

Nuchal cord Term used to describe the umbilical cord when it is wrapped around the neck of the fetus.

Nuchal folds The accumulation of fluid between the posterior cervical spine and the overlying skin in the fetal neck identified during an ultrasound examination.

Nuchal translucency testing A combination of an ultrasound and maternal serum test that is used to screen fetuses between 11 weeks and 1 day and 13 weeks and 6 days to determine if a fetus is at risk for a chromosomal disorder, such as Down syndrome (trisomy 21) and trisomy 18.

Nulligravida (nŭl-i-grav'i-dă) A woman who has never been pregnant.

Nullipara A woman who has not given birth to a viable fetus.

Nurse practitioner A professional nurse who has received specialized education in either a master's degree program or a continuing education program and thus can function in an expanded role.

Nurse researcher A professional nurse who has an advanced doctoral degree, typically a Doctor of Philosophy (PhD), and assumes a leadership role in generating new research.

Nursing advocacy An approach to patient care in which the nurse educates and supports the patient and protects his or her rights.

Obstetric conjugate Distance from the middle of the sacral promontory to an area approximately 1 cm below the pubic crest.

Oligohydramnios (ol'i-gō-hī-dram'nē-os) Decreased amount of amniotic fluid, which may indicate a fetal urinary tract defect.

Oocyte Early primitive ovum before it has completely developed.

Oogenesis Process during fetal life whereby the ovary produces oogonia, cells that become primitive ovarian eggs.

Ophthalmia (of-thal'mē-ă) **neonatorum** Purulent infection of the eyes or conjunctiva of the newborn, usually caused by gonococci.

Oral contraceptives Birth control pills that work by inhibiting the release of an ovum and by maintaining a type of mucus that is hostile to sperm.

Orientation Infant's ability to respond to auditory and visual stimuli in the environment.

Ortolani maneuver A manual procedure performed to rule out the possibility of developmental dysplastic hip.

Osteoporosis A condition most common in postmenopausal women that is characterized by decreased bone strength related to diminished bone density and bone quality. It is thought to be associated with lowered estrogen and androgen levels. Osteoporosis puts an individual at increased risk for fractures of the hip, forearm, and vertebrae.

Ovarian ligaments Ligaments that anchor the lower pole of the ovary to the cornua of the uterus.

Ovary Female sex gland in which the ova are formed and in which estrogen and progesterone are produced. Normally there are two ovaries, located in the lower abdomen on each side of the uterus.

Ovulation Normal process of discharging a mature ovum from an ovary approximately 14 days before the onset of menses.

Oxytocin Hormone normally produced by the posterior pituitary, responsible for stimulation of uterine contractions and the release of milk into the lactiferous ducts.

Oxytocin challenge test (OCT) See *Contraction stress test.*

Palpation The technique of assessing a uterine contraction by touch.

Pap smear Procedure to detect the presence of cancer of the uterus by microscopic examination of cells gently scraped from the cervix.

Para (par′ă) A woman who has borne offspring who reached the age of viability.

Parametritis Inflammation of the parametrial layer of the uterus.

Parent-newborn attachment Close affectional ties that develop between parent and child. See *Attachment.*

Passive acquired immunity Transfer of antibodies (IgG) from the mother to the fetus in utero.

Patient-controlled analgesia (PCA) A method of pain control where anesthesia, usually morphine or meperidine, is initially administered by the anesthesiologist and subsequent doses are self-administered by pushing a button controlled by a special IV pump system.

Pedigree Graphic representation of a family tree.

Pelvic cavity Bony portion of the birth passages; a curved canal with a longer posterior than anterior wall.

Pelvic cellulitis (parametritis) Infection involving the connective tissue of the broad ligament or, in severe cases, the connective tissue of all the pelvic structures.

Pelvic diaphragm Part of the pelvic floor composed of deep fascia and the levator ani and the coccygeal muscles.

Pelvic floor Muscles and tissue that act as a buttress to the pelvic outlet.

Pelvic inflammatory disease (PID) An infection of the fallopian tubes that may or may not be accompanied by a pelvic abscess; may cause infertility secondary to tubal damage.

Pelvic inlet Upper border of the true pelvis.

Pelvic outlet Lower border of the true pelvis.

Pelvic tilt Exercise designed to reduce back strain and strengthen abdominal muscle tone. Also called *pelvic rocking.*

Penis The male organ of copulation and reproduction.

Percutaneous umbilical blood sampling (PUBS) See *Cordocentesis.*

Perimenopause A term referring to the period of time before menopause during which the woman moves from normal ovulatory cycles to cessation of menses.

Perimetrium The outermost layer of the corpus of the uterus. Also known as the *serosal layer.*

Perinatal hospice A compassionate, structured program that provides a context in which parents can find meaning in the intimate experience of the life and death of their child.

Perinatal loss Death of a fetus or infant from the time of conception through the end of the newborn period 28 days after birth.

Perinatal mortality rate The number of neonatal and fetal deaths per 1000 live births.

Perineal (per′i-nē-ăl) **body** Wedge-shaped mass of fibromuscular tissue found between the lower part of the vagina and the anal canal.

Perineal prep An aseptic cleansing of the woman's vulvar and perineal area before she gives birth.

Perineum (per′i-nē′ŭm) The area of tissue between the anus and scrotum in a man or between the anus and vagina in a woman.

Periodic breathing Sporadic episodes of apnea, not associated with cyanosis, that last for about 10 seconds and commonly occur in preterm infants.

Periods of reactivity Predictable patterns of newborn behavior during the first several hours after birth.

Peritonitis Infection involving the peritoneal cavity.

Persistent occiput posterior (OP) position Malposition of the fetus in which the fetal occiput is posterior in the maternal pelvis.

Persistent pulmonary hypertension of the newborn (PPHN) Respiratory disease resulting from right-to-left shunting of blood away from the lungs and through the ductus arteriosus and patent foramen ovale.

Phenotype The whole physical, biochemical, and physiologic makeup of an individual as determined both genetically and environmentally.

Phenylketonuria (PKU) (fen′il-kē′tō-nū′rē-ă) A common metabolic disease caused by an inborn error in the metabolism of the amino acid phenylalanine.

Phosphatidylglycerol (PG) (fos-fă-tī′dĭl-glis′er-ol) A phospholipid present in fetal surfactant after about 35 weeks' gestation.

Phototherapy The treatment of jaundice by exposure to light.

Physiologic anemia of infancy A harmless condition in which the hemoglobin level drops in the first 6 to 12 weeks after birth, then reverts to normal levels.

Physiologic anemia of pregnancy Apparent anemia that results because during pregnancy the plasma volume increases more than the erythrocytes increase.

Physiologic jaundice A harmless condition caused by the normal reduction of red blood cells, occurring 48 or more hours after birth, peaking at the 5th to 7th days, and disappearing between the 7th and 10th days.

Pica The eating of substances not ordinarily considered edible or to have nutritive value.

Placenta (plă-sen′tă) Specialized disk-shaped organ that connects the fetus to the uterine wall for gas and nutrient exchange. Also called *afterbirth.*

Placenta accreta Partial or complete absence of the decidua basalis and abnormal adherence of the placenta to the uterine wall.

Placenta increta A high-risk condition that occurs when the placenta attaches to the uterine wall and invades or attaches itself within the myometrium.

Placenta percreta A high-risk condition that occurs when the placenta penetrates the myometrium, sometimes attaching to peritoneal structures within the abdominal cavity, where the removal of the uterus (hysterectomy) is sometimes necessary.

Placenta previa Abnormal implantation of the placenta in the lower uterine segment. Classification of type is based on proximity to the cervical os: *total*—completely covers the os; *partial*—covers a portion of the os; *marginal*—is in close proximity to the os.

Placental delivery Placenta and membranes expelled after the birth of the infant, during the third stage of labor.

Platypelloid pelvis An unusually wide pelvis, having a flattened oval transverse shape and a shortened anteroposterior diameter.

Podalic version Type of version used to turn a second twin during a vaginal birth. See *Internal version.*

Polar body A small cell resulting from the meiotic division of the mature oocyte.

Polycystic ovarian syndrome (PCOS) The most common endocrine disorder affecting women of reproductive age, marked by menstrual dysfunction, androgen excess, obesity, hyperinsulinemia, and infertility.

Polycythemia An abnormal increase in the number of total red blood cells in the body's circulation.

Polydactyly (pol-ē-dak'ti-lē) A developmental anomaly characterized by more than five digits on the hands or feet.

Polypharmacy The act of taking multiple drugs to treat symptoms, when the etiology of the symptoms is actually a side effect from one or more prescribed medications.

Positive signs of pregnancy Indications that confirm the presence of pregnancy.

Postcoital emergency contraception (EC) A form of combined hormonal contraception that is used when a woman is worried about pregnancy because of unprotected intercourse, rape, or possible contraceptive failure (e.g., broken condom, slipped diaphragm, missed oral contraceptives, or too long a time between Depo-Provera injections).

Postcoital test (PCT) An examination that evaluates the cervical mucus, sperm motility, sperm-mucus interaction, and the sperm's ability to negotiate the cervical mucus barrier. Also called *Sims-Huhner test*.

Postconception age periods Period of time in embryonic/fetal development calculated from the time of fertilization of the ovum (about 266 days [38 weeks] or 9 1/2 calendar months). Also called *fertilization age*.

Postmature newborn See *Postterm newborn.*

Postmaturity See *Postterm newborn.*

Postpartum After childbirth.

Postpartum blues See *Adjustment reaction with depressed mood*.

Postpartum depression Severe depression that occurs within the first year after giving birth with increased incidence at about the fourth week postpartum, just before resumption of menses, and upon weaning.

Postpartum endometritis (metritis) A reproductive tract infection limited to the uterus and associated with childbirth that occurs at any time up to 6 weeks postpartum.

Postpartum hemorrhage A loss of blood of greater than 500 ml following birth. The hemorrhage is classified as *early* if it occurs within the first 24 hours and *late* if it occurs after the first 24 hours.

Postpartum home care Home visits for postpartum families occurring in the home setting. This provides opportunities for expanding information and reinforcing self- and infant care techniques initially presented in the birth setting.

Postpartum major mood disorder See *Postpartum depression*.

Postpartum psychosis Psychosis occurring within the first 3 months after birth.

Postterm labor Labor that occurs after 42 weeks' gestation.

Postterm newborn Any infant born after 42 weeks' gestation.

Postterm pregnancy Pregnancy that lasts beyond 42 weeks' gestation.

Post-traumatic stress disorder (PTSD) Intense psychologic distress resulting from a traumatic event and evidenced by recurrent, intrusive thoughts; flashbacks, persistent avoidance of stimuli associated with the trauma; a generalized feeling of "numbness"; and persistent signs of arousal.

Post-traumatic stress syndrome (PTSS) See *Post-traumatic stress disorder (PTSD).*

Precipitous birth (1) Unduly rapid progression of labor. (2) A birth in which no physician is in attendance.

Precipitous labor Labor lasting less than 3 hours.

Preeclampsia (prē-ē-klamp'sē-ă) Toxemia of pregnancy, characterized by hypertension, albuminuria, and edema. See also *Eclampsia.*

Premature infant See *Preterm infant.*

Premature rupture of membranes (PROM) See *Rupture of membranes (ROM).*

Premenstrual dysphoric disorder (PMDD) A disorder associated with the luteal phase of the menstrual cycle (2 weeks before onset of menses) in which a woman experiences five or more affective (emotional) or somatic (physical) symptoms, which are relieved with menstruation and have occurred during most cycles during the previous year.

Premenstrual syndrome (PMS) Cluster of symptoms experienced by some women, typically occurring from a few days up to 2 weeks before the onset of menses.

Prenatal education Programs offered to expectant families, adolescents, women, or partners to provide education regarding the pregnancy, labor, and birth experience.

Presentation The fetal body part that enters the maternal pelvis first. The three possible presentations are cephalic, shoulder, and breech.

Presenting part The fetal part present in or on the cervical os.

Presumptive signs of pregnancy Symptoms that suggest but do not confirm pregnancy, such as cessation of menses, quickening, Chadwick's sign, and morning sickness.

Preterm infant Any infant born before 38 weeks' gestation.

Preterm labor Labor occurring between 20 and 38 weeks of pregnancy. Also called *premature labor.*

Primigravida (prī-mi-grav'i-dă) A woman who is pregnant for the first time.

Primipara (prī-mip'ă-ră) A woman who has given birth to her first child (past the point of viability), whether or not that child is living or was alive at birth.

Probable signs of pregnancy Manifestations that strongly suggest the likelihood of pregnancy, such as a positive pregnancy test, enlarging abdomen, and positive Goodell's, Hegar's, and Braxton Hicks signs.

Professional nurse A person who has graduated from an accredited basic program in nursing, has successfully completed the nursing licensure examination (NCLEX), and is currently licensed as a registered nurse (RN).

Progesterone A hormone produced by the corpus luteum, adrenal cortex, and placenta whose function is to stimulate proliferation of the endometrium to facilitate growth of the embryo.

Progressive relaxation A relaxation technique that involves relaxing first one portion of the body and then another portion, until total body relaxation is achieved; may be used during labor.

Prolactin A hormone secreted by the anterior pituitary that stimulates and sustains lactation in mammals.

Prolapsed umbilical cord Umbilical cord that becomes trapped in the vagina before the fetus is born.

Prolonged decelerations Decelerations in which the FHR decreases from the baseline for 2 to 10 minutes.

Prolonged labor Labor lasting more than 24 hours.

Prostaglandins (PGs) Complex lipid compounds synthesized by many cells in the body.

Pseudomenstruation Blood-tinged mucus from the vagina in the newborn female infant; caused by withdrawal of maternal hormones that were present during pregnancy.

Psychologic disorders Abnormal mental or emotional conditions characterized by alterations in thinking, mood, or behavior.

Ptyalism Excessive salivation.

Puberty The developmental period between childhood and the attainment of adult sexual characteristics and functioning.

Pubic Pertaining to the pubes or pubis.

Pubis Pertaining to the pubes or pubic area.

Pudendal (pyū-den′dăl) **block** Injection of an anesthetizing agent at the pudendal nerve to produce numbness of the external genitals and the lower one third of the vagina to facilitate childbirth and permit episiotomy if necessary.

Puerperal infection Infection of the reproductive tract associated with childbirth and occurring any time up to 6 weeks postpartum.

Puerperal morbidity A maternal temperature of 38°C (100.4°F) or higher on any 2 of the first 10 postpartal days, excluding the first 24 hours. The temperature is to be taken by mouth at least four times per day.

Puerperium (pyū-er-pēr′ē-ŭm) The period after completion of the third stage of labor until involution of the uterus is complete, usually 6 weeks.

Quickening The first fetal movements felt by the pregnant woman, usually between 16 and 18 weeks' gestation.

Quiet alert state Alert state characterized by a brightening of the eyes and face. Infants are most attentive to their environment in this state and provide positive feedback to caregivers. Also called *wide awake state*.

Radiation Heat loss incurred when heat transfers to cooler surfaces and objects not in direct contact with the body.

Rape Sexual activity, often intercourse, against the will of the victim.

Rape trauma syndrome A term that refers to a variety of symptoms, clustered in phases, that a rape survivor experiences following an assault.

Reciprocity An interactional cycle that occurs simultaneously between mother and infant. It involves mutual cuing behaviors, expectancy, rhythmicity, and synchrony.

Recommended dietary allowances (RDA) Government recommended allowances of various vitamins, minerals, and other nutrients.

Recurrent pregnancy loss (RPL) Three or more consecutive pregnancy losses before 24 weeks gestation.

Reflexology Form of massage involving the application of pressure to designated points or reflexes on the client's feet, hands, or ears using the thumb and fingers.

Regional analgesia The temporary and reversible loss of sensation produced by injecting an anesthetic agent (called a local anesthetic) into an area that will bring the agent into direct contact with nervous tissue.

Regional anesthesia Injection of local anesthetic agents so that they come into direct contact with nervous tissue.

Reiki Tibetan-Japanese hand-mediated therapy designed to promote healing, reduce stress, and encourage relaxation. During Reiki sessions, practitioners place their hands on or above specific problem areas and transfer energy from themselves to their clients in order to restore the balance of the client's energy fields.

Relaxin A water-soluble protein secreted by the corpus luteum that causes relaxation of the symphysis and cervical dilatation.

Religion An institutionalized system that shares a common set of beliefs and practices.

Relinquishing mothers Those mothers who choose to give their infants up for adoption.

Respiratory distress syndrome (RDS) Respiratory disease of the newborn characterized by interference with ventilation at the alveolar level, thought to be caused by the presence of fibrinoid deposits lining the alveolar ducts. Formerly called *hyaline membrane disease*.

Responding model A set of guidelines for successful interactions with grieving families.

Retained placenta Retention of the placenta beyond 30 minutes after birth.

Retinopathy (ret-i-nop′ă-thē) **of prematurity (ROP)** Formation of fibrotic tissue behind the lens; associated with retinal detachment and arrested eye growth, seen with hypoxemia in preterm infants.

Rh factor Antigens present on the surface of blood cells that make the blood cell incompatible with blood cells that do not have the antigen.

Rh immune globulin An anti-Rh *(D)* gamma globulin given after birth to an Rh-negative mother of an Rh-positive fetus or child. Prevents the development of permanent active immunity to the Rh antigen.

Rhythm method The timing of sexual intercourse to avoid the fertile time associated with ovulation.

Risk factors Any findings that suggest the pregnancy may have a negative outcome, for either the woman or her unborn child.

Roles Patterns of behavior normatively defined and expected of an occupant of a given social position.

Room sharing An arrangement in whichthe infant sleeps in the same room in close proximity to the parents, but in his or her own bed.

Rooting reflex An infant's tendency to turn the head and open the lips to suck when one side of the mouth or cheek is touched.

Round ligaments Ligaments that arise from the side of the uterus near the fallopian tube insertion to help the broad ligament keep the uterus in place.

Rugae (rū′gē) Transverse ridges of mucous membranes lining the vagina that allow the vagina to stretch during the descent of the fetal head.

Rupture of membranes (ROM) Rupture may be PROM (premature), SROM (spontaneous), or AROM (artificial). Some clinicians may use the abbreviation RBOW (rupture of bag of waters).

Sacral promontory A projection into the pelvic cavity on the anterior upper portion of the sacrum; serves as an obstetric guide in determining pelvic measurements.

Salpingitis Infection of the fallopian tubes.

Scalp stimulation A test used during labor to assess fetal well-being by pressing a fingertip on the fetal scalp. A fetus not under excessive stress will respond to the digital stimulation with heart rate accelerations.

Scarf sign The position of the elbow when the hand of a supine infant is drawn across to the other shoulder until it meets resistance.

Schultze's mechanism Expulsion of the placenta with the shiny, or fetal, surface presenting first.

Secondary infertility Condition in which couples are unable to conceive after one or more successful pregnancies.

Self-quieting ability Infant's ability to use personal resources to quiet and console himself or herself.

Semen Thick whitish fluid ejaculated by the male during orgasm and containing the spermatozoa and their nutrients.

Sepsis neonatorum Infections experienced by a newborn during the first month of life.

Sex chromosomes The X and Y chromosomes, which are responsible for sex determination.

Sexual assault A broad term that refers to a variety of types of unwanted sexual touching or penetration without consent, from unwanted sexual contact or touching of an intimate part of another person to forced anal, oral, or genital penetration.

Sexually transmitted infection (STI) Refers to infections ordinarily transmitted by direct sexual contact with an infected individual. Also called *sexually transmitted disease*.

Shaken baby syndrome (SBS) A traumatic brain injury that results from violent shaking, with or without contact between the infant's head and an exterior surface.

Simian line A single palmar crease frequently found in children with Down syndrome.

Sims-Huhner test See *Postcoital test (PCT).*

Situational contraceptives Contraceptive methods that involve no prior preparation (e.g., abstinence or coitus interruptus).

Skin turgor Elasticity of skin; provides information on hydration status.

Skin-to-skin contact Physical contact between the mother and baby whereby the naked baby is placed prone on the mother's chest during the first 24 hours.

Small for gestational age (SGA) Inadequate weight or growth for gestational age; birth weight below the 10th percentile.

Spermatogenesis The process by which mature spermatozoa are formed, during which the number of chromosomes is halved.

Spermatozoa Mature sperm cells of the male animal, produced by the testes.

Spermicides A variety of creams, foams, jellies, and suppositories that, when inserted into the vagina before intercourse, destroy sperm or neutralize any vaginal secretions and thereby immobilize sperm.

Spinal block Injection of a local anesthetic agent directly into the spinal fluid in the spinal canal to provide anesthesia for vaginal and cesarean births.

Spinnbarkheit The elasticity of the cervical mucus that is present at ovulation.

Spirituality A belief in a transcendent power pertaining to the spirit or soul.

Spontaneous abortion Abortion that occurs naturally. Also called *miscarriage.*

Spontaneous rupture of membranes (SROM) The breaking of the "water" or membranes marked by the expulsion of amniotic fluid from the vagina.

Station Relationship of the presenting fetal part to an imaginary line drawn between the pelvic ischial spines.

Sterilization An inclusive term that refers to surgical procedures that permanently prevent pregnancy. In the male, sterilization is achieved through a procedure called a vasectomy. In the female, sterilization is done by tubal ligation.

Stillbirth The birth of a dead infant.

Striae (strī′ă) Stretch marks; shiny purplish lines that appear on the abdomen, breasts, thighs, and buttocks of pregnant women as a result of stretching the skin.

Subconjunctival hemorrhage (sŭb′kon-jŭnk-tī′văl hem′ŏ-rij) Hemorrhage on the sclera of a newborn's eye, usually caused by changes in vascular tension during birth.

Subfertility A couple who has difficulty conceiving because both partners have reduced fertility.

Subinvolution (sŭb-in-vō-lū′shŭn) Failure of a part to return to its normal size after functional enlargement, such as failure of the uterus to return to normal size after pregnancy.

Sucking reflex Normal newborn reflex elicited by inserting a finger or nipple in the newborn's mouth, resulting in forceful, rhythmic sucking.

Sudden infant death syndrome (SIDS) The sudden death of an infant; the primary cause of infant death beyond the neonatal period in the United States.

Supine hypotensive syndrome (vena caval syndrome, aortocaval compression) A condition that can develop during pregnancy when the enlarging uterus puts pressure on the vena cava when the woman is supine. This pressure interferes with returning blood flow and produces a marked decrease in blood pressure with accompanying dizziness, pallor, and clamminess, which can be corrected by having the woman lie on her left side.

Surfactant (ser-fak′tănt) A substance composed of phospholipid, which stabilizes and lowers the surface tension of the alveoli during extrauterine respiratory exhalation, allowing a certain amount of air to remain in the alveoli during expiration.

Suture Fibrous connection of opposed joint surfaces, as in the skull.

Symphysis pubis Fibrocartilaginous joint between the pelvic bones in the midline.

Syndactyly (sin-dak′ti-lē) Malformation of the fingers or toes in which there may be webbing or complete fusion of two or more digits.

Syphilis A chronic, sexually transmitted infection caused by the spirochete *Treponema pallidum.*

Taboos Behaviors or objects that are avoided by individuals or groups.

Telangiectatic nevi (tel-an′jē-ek-tat′ik nē′vī) **(stork bites)** Small clusters of pink-red spots appearing on the nape of the neck and around the eyes of infants; localized areas of capillary dilatation.

Teratogens Nongenetic factors that can produce malformations of the fetus.

Term The normal duration of pregnancy.

Testes The male gonads, in which sperm and testosterone are produced.

Testosterone The male hormone; responsible for the development of secondary male characteristics.

Therapeutic abortion Medically induced termination of pregnancy when a malformed fetus is suspected or when the woman's health is in jeopardy.

Therapeutic insemination Procedure to produce a pregnancy in which sperm obtained from a woman's husband or from a donor is deposited in the woman's vagina.

Therapeutic touch Complementary therapy grounded in the belief that people are a system of energy with a self-healing potential. The therapeutic touch practitioner, often a nurse, unites his or her energy field with that of the client, directing it in a specific way to promote well-being and healing.

Thermogenesis The newborn's physiologic mechanisms that increase heat production.

Thrombophlebitis Inflammation of a vein wall, resulting in thrombus.

Thrush A fungal infection of the oral mucous membranes caused by *Candida albicans.* Most often seen in infants; characterized by white plaques in the mouth.

Tocolysis Use of medications to arrest preterm labor.

Tonic neck reflex Postural reflex seen in the newborn. When the supine infant's head is turned to one side, the arm and leg on that side extend while the extremities on the opposite side flex. Also called the *fencing position.*

TORCH An acronym used to describe a group of infections that represent potentially severe problems during pregnancy. *TO,* toxoplasmosis; *R,* rubella; *C,* cytomegalovirus; *H,* herpesvirus.

Total serum bilirubin Sum of conjugated (direct) and unconjugated (indirect) bilirubin.

Touch relaxation A relaxation technique that involves relaxing an area of one's body as another person provides a "touch" cue to that specific area. Touch relaxation is very effective during labor contractions.

Toxic shock syndrome (TSS) Infection caused by *Staphylococcus aureus,* found primarily in women of reproductive age.

Traditional Chinese medicine (TCM) System of medicine developed more than 3000 years ago in China that seeks to ensure the balance of energy, which is called *chi* or *qi* (pronounced "chee").

Chi is thought to maintain health and vitality and enable the body to carry out its physiologic functions.

Transitional milk Breast milk produced from the end of colostrum production until about 2 weeks postpartum.

Transvaginal ultrasound A follicular monitoring test that is used in women undergoing induction cycles, for timing ovulation for insemination and intercourse, for retrieving oocytes for in vitro fertilization, and for monitoring early pregnancy.

Transverse diameter The largest diameter of the pelvic inlet; helps determine the shape of the inlet.

Transverse lie A lie in which the fetus is positioned crosswise in the uterus.

Trichomonas vaginalis A parasitic protozoan that may cause inflammation of the vagina, characterized by itching and burning of vulvar tissue and by white, frothy discharge.

Trichomoniasis A sexually transmitted infection caused by *Trichomonas vaginalis,* a microscopic motile protozoan that thrives in an alkaline environment.

Trimester Three months, or one third of the gestational time for pregnancy.

Trisomy The presence of three homologous chromosomes rather than the normal two.

Trophoblast The outer layer of the blastoderm that will eventually establish the nutrient relationship with the uterine endometrium.

True pelvis The portion that lies below the linea terminalis, made up of the inlet, cavity, and outlet.

Trunk incurvation (Galant reflex) Reflex resulting from the stroking of the spine that causes the pelvis to turn to the stimulated side.

Tubal embryo transfer (TET) Procedure in which eggs are retrieved and incubated with the man's sperm then transferred back into the women's body at the embryo stage.

Tubal ligation Sterilization of a woman accomplished by transecting or occluding the fallopian tubes.

Turner syndrome A number of anomalies that occur when a woman has only one X chromosome. Characteristics include short stature; little sexual differentiation; webbing of the neck, with a low posterior hairline; and congenital cardiac anomalies.

Ultrasound High-frequency sound waves that may be directed, through the use of a transducer, into the maternal abdomen. The ultrasonic sound waves reflected by the underlying structures of varying densities allow identification of various maternal and fetal tissues, bones, and fluids.

Umbilical cord (ŭm-bil'i-kăl kōrd) The structure connecting the placenta to the umbilicus of the fetus and through which nutrients from the woman are exchanged for wastes from the fetus.

Urinary tract infection (UTI) Significant *bacteriuria* in the presence of symptoms.

Uterine atony Relaxation of uterine muscle tone following birth.

Uterine inversion Prolapse of the uterine fundus through the cervix into the vagina; may occur just before or during expulsion of the placenta; associated with massive hemorrhage, requiring emergency treatment.

Uterine rupture A nonsurgical disruption of the uterine cavity.

Uterosacral ligaments Ligaments that provide support for the uterus and cervix at the level of the ischial spines.

Uterus The hollow muscular organ in which the fertilized ovum is implanted and in which the developing fetus is nourished until birth.

Vacuum extraction An obstetric procedure used to assist in the birth of a fetus by applying suction to the fetal head with a soft suction cup attached to a suction bottle (pump) by tubing and placing the device against the occiput of the fetal head.

Vagina The musculomembranous tube or passageway located between the external genitals and the uterus of a woman.

Vaginal birth after cesarean (VBAC) Practice of permitting a trial of labor and possible vaginal birth for women following a previous cesarean birth for nonrecurring causes such as fetal distress or placenta previa.

Variability Baseline fluctuations of two cycles per minute or greater in the FHR and classified by the visually quantified amplitude of peak-to-trough in beats per minute.

Variable deceleration Periodic change in fetal heart rate caused by umbilical cord compression; decelerations vary in onset, occurrence, and waveform.

Vasa previa Condition occurring when the fetal vessels course through membranes and are present at the cervical os. Although this is a rare cause of antepartum bleeding, it has a high rate of fetal death.

Vasectomy Surgical removal of a portion of the vas deferens (ductus deferens) to produce infertility.

Vegan A "pure" vegetarian; one who consumes no food from animal sources.

Vena caval syndrome Symptoms of dizziness, pallor, and clamminess that result from lowered blood pressure when a pregnant woman lies supine and the enlarged uterus presses on the vena cava. Also known as supine hypotensive syndrome.

Vernix caseosa (ver'niks kā'sē-ō-să) A protective, cheeselike, whitish substance made up of sebum and desquamated epithelial cells that is present on the fetal skin.

Version Turning of the fetus in utero.

Vertex The top or crown of the head.

Viability The potential for the pregnancy to result in a live birth.

Vibroacoustic stimulation (VAS) Application of device delivering 90 dB of sound and vibration for 1 to 3 seconds to the mother's abdomen to stimulate movement in the fetus, thereby accelerating the fetal heart rate. (Also called *FAST* for *fetal acoustic stimulation test* or *VST* for *vibroacoustic stimulation test*.)

Vicarious trauma A condition that can occur as a result of working with people who are trauma victims. Also called *secondary trauma effect.*

Visualization Complementary therapy in which a person goes into a relaxed state and focuses on or "visualizes" soothing or positive scenes such as a beach or a mountain glade. Visualization helps reduce stress and encourage relaxation.

Vulva The external structure of the female genitals, lying below the mons veneris.

Vulvovaginal candidiasis (VVC) A genital infection most often caused by *Candida albicans.* Also called *moniliasis* or *yeast infection.*

Weaning The process of discontinuing breastfeeding and accustoming an infant to another feeding method.

Wharton's (hwar'tunz) **jelly** Yellow-white gelatinous material surrounding the vessels of the umbilical cord.

Zona pellucida Transparent inner layer surrounding an ovum.

Zygote A fertilized egg.

Zygote intrafallopian transfer (ZIFT) Retrieval of oocytes under ultrasound guidance, followed by in vitro fertilization and laparoscopic replacement of fertilized eggs into the fimbriated end of the fallopian tube.

INDEX

Page numbers followed by f indicate figures and those followed by t indicate tables or special features. The titles of special features (e.g., Focus Your Study, Critical Thinking in Action, Research Evidence in Practice, Developing Cultural Competence) are also capitalized.

Success in the Classroom, Clinical, and on NCLEX®

nursing.pearsonhighered.com

CLASSROOM

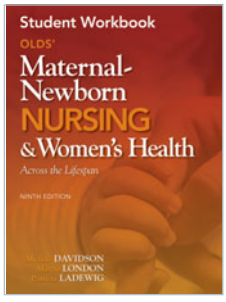
Online Student Resource Center

- Includes NCLEX®-style review questions with comprehensive rationales, case studies, animations and videos, and more

mynursinglab™

- Test yourself on key concepts and skills from every chapter
- Track your progress through the course and use a personalized study plan to achieve success
- Includes select set of *Real Nursing Skill* videos
- Available with *Pearson's Interactive e-Text*
  - Integrated media and website links
  - Full search capability and note-taking functionality
  - Customizable organization

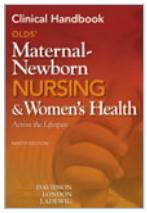
Student Workbook



- Companion workbook to help you succeed in maternal-newborn nursing
- Includes case studies, review questions, labeling exercises, critical thinking challenges, and more

CLINICAL

Clinical Handbook

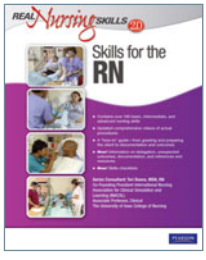


- Portable, quick reference to maternal-newborn nursing
- Chapters on antepartum, intrapartum, postpartum, newborn, and at-risk patients
- Includes home care of the postpartum family
- Features procedures and drug guides to enhance safe practice

my nursing app™

- Your complete mobile solution
- Visit **www.mynursingapp.com** for free trials and available titles

Real Nursing Skills



- Video demonstrations of over 200 clinical nursing skills
- Each skill includes Purpose, Preparation, Procedure, Post-Procedure, Expected and Unexpected Outcomes, Documentation and References and Resources

NCLEX®

- Concentrated review of core content
- Thousands of practice questions with comprehensive rationales

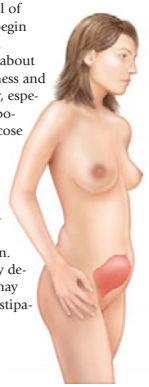
MATERNAL-FETAL DEVELOPMENT

	0 CONCEPTION	1 4 WEEKS	2 8 WEEKS	3 12 WEEKS	4 16 WEEKS
FETAL DEVELOPMENT	The sperm fertilizes the ovum, which then divides and burrows into the uterus. 	From the embryonic disk (ectoderm, entoderm, mesoderm), the first body segments appear that will eventually become the spine, brain, and spinal cord. Heart, blood circulation, and digestive tract take shape. Embryo is less than a quarter-inch long.	Development is rapid; heart begins to pump blood; limb buds are well developed. Facial features and major divisions of the brain are discernible. Ears develop from skin folds; tiny bones and muscles are formed beneath the thin skin.	Embryo becomes a fetus, its beating heart discernible by ultrasound. Assumes a more human shape as lower body develops. At week 12, first movements begin. Sex is determinable. Kidneys produce urine.	Musculoskeletal system has matured; nervous system begins to exert control. Blood vessels rapidly develop. Fetal hands can grasp; legs kick actively. All organs begin to mature and grow. Fetus weighs about 7 oz (½ lb). FHT discernible with Doppler. Pancreas produces insulin.
MATERNAL CHANGES		Mother misses first period; breasts become tender, may enlarge. Chronic fatigue and urinary frequency begin, may persist for three or more months. hCG in urine and serum 9 days after conception.	Morning sickness, may persist to 12 weeks. Uterus changes from pear to globular shape. Hegar's, Goodell's and Piskacek's signs appear. Cervix flexes; leukorrhea increases. Surprise and ambivalence about pregnancy may occur. No noticeable weight gain.	Chadwick's sign appears. Uterus rises above pelvic brim by 12 weeks. Braxton Hicks contractions may begin and continue throughout pregnancy. Potential for urinary tract infection (UTI) increases and exists throughout pregnancy. Weight gain of about 2 ½ to 4 lb during first trimester. Placenta now fully functioning and producing hormones.	Fundus halfway between symphysis and umbilicus. Woman gains slightly less than 1 lb per wk for remainder of pregnancy. May feel more energetic. BPD measurement on ultrasound. Vaginal secretions increase. Itching, irritation, malodor suggest infection. Woman may begin wearing maternity clothes. Pressure on bladder lessens and urinary frequency decreases.
CLIENT TEACHING/ ANTICIPATORY GUIDANCE		Supportive bra may ease discomfort. Increased rest and relaxation necessary now and throughout pregnancy. Increase fluids during the day; decrease fluid intake only at night to help prevent nocturia; sleep on side to decrease pressure on bladder. Avoid using any medications unless prescribed. Avoid use of social drugs; check with caregiver before using any OTC preparations.	Eat dry crackers before arising; try frequent small, dry, low-fat meals with fluids taken between meals. Avoid use of hot tubs, saunas, and steam rooms throughout pregnancy. Discuss attitudes toward pregnancy. Discuss value of early pregnancy classes that focus on what to expect during pregnancy. Provide information about childbirth preparation classes.	Adequate fluid intake and frequent voiding (every 2 hr while awake) help prevent UTI. Also helpful to void following intercourse. Wipe from front to rear. Discuss nutrition and appropriate weight gain. Stress value of regular physical exercise, especially non-weightbearing activities or walking. Discuss possible effects of pregnancy on sexual relationship.	Daily shower or bath and thorough drying of vulva helpful; avoid douching during pregnancy. Consult caregiver if infection suspected; use only prescribed medications. Review danger signs of pregnancy. Discuss infant feeding options; provide information on the value of breastfeeding. Provide information about clothing, shoes.

5 — 20 WEEKS

Vernix protects the body; fine hair (lanugo) covers the body and keeps the oil on the skin. Eyebrows, eyelashes, and head hair develop. Fetus develops a regular schedule of sleeping, sucking, and kicking.

Fundus reaches level of umbilicus. Breasts begin secreting colostrum. Amniotic sac holds about 400mL fluid. Faintness and dizziness may occur, especially with sudden position changes. Varicose veins may begin to develop. Woman experiences fetal movement, and pregnancy may suddenly seem more "real." Areola darken. Nasal stuffiness may develop. Leg cramps may begin to occur. Constipation may develop.



Sit with feet elevated when possible; rise slowly and carefully. Avoid pressure on lower thighs. Support stockings may be helpful. Cool-air vaporizer may help. Eat foods containing fiber, such as raw fruits, vegetables, cereals with bran; drink liquids and exercise frequently. Discuss breast care. Discuss dorsiflexion of foot to relieve cramps; heat to affected muscle.

6 — 24 WEEKS

Skeleton develops rapidly as bone-forming cells increase activity. Respiratory movements begin. Fetus weighs about 1 lb, 10 oz.

Fundus above umbilicus. Backache and leg cramps may begin. Skin changes can include striae gravidarum, chloasma, linea nigra, acne, redness on palms of hands and soles of feet. Nosebleeds can occur. May experience abdominal itching as uterus enlarges; will continue until end of pregnancy.

Assure woman that skin changes generally subside soon after birth. Discuss specific exercises such as pelvic tilt to help strengthen back and abdominal muscles, and stress importance of good body mechanics. Reiterate importance of avoiding medications, caffeine, alcohol, and smoking. Woman may choose to apply petroleum jelly in nostrils to relieve nosebleeds. Cool vaporizer may also help. Lanolin-based cream can relieve itching. Mild soap can remove excess oil associated with acne.

7 — 28 WEEKS

Fetus can breathe, swallow, regulate temperature. Surfactant forms in lungs. Eyes begin to open and close. Baby is ⅔ the size it will be at birth.

Fundus halfway between umbilicus and xiphoid process. May develop hemorrhoids. Thoracic breathing replaces abdominal breathing. Fetal outline palpable. May be tired of pregnancy and eager for the mothering role. Heartburn may begin to occur. May begin taking childbirth preparation classes with partner or support person.

Avoid constipation; use sitz baths, gentle reinsertion of hemorrhoids with a fingertip as necessary. Topical anesthetic agents may offer relief of hemorrhoids. Stool softeners may be prescribed by caregiver. Elevate legs and assume sidelying position when resting. Eat small, more frequent meals; avoid fatty foods, lying down after eating. Maalox or Mylanta may be helpful; Avoid sodium bicarbonate. Discuss expectations about labor and delivery, caring for an infant.

8 — 32 WEEKS

Brown fat deposits are developing beneath the skin to insulate the baby following birth. Baby has grown to about 15–17 in. Begins storing iron, calcium, and phosphorus.

Fundus reaches xiphoid process; breasts full and tender. Urinary frequency may return. Swollen ankles and sleeping problems may develop. Dyspnea may develop.

Wear well-fitting supportive bra. Elevate legs once or twice daily for an hour or so. Sleep on left side if possible. Use naturally occurring diuretics such as 2 tbsp lemon juice in 1 cup water or a generous serving of watermelon if available. Avoid most diuretics unless specifically prescribed. Maintain proper posture; use extra pillows at night for severe dyspnea. Following culture and personal preference, may begin preparing nursery now. Review signs of labor. Discuss plans for other children (if any), transportation to agency.

9 — 38 WEEKS

The entire uterus is occupied by the baby, thus restricting its activity. Maternal antibodies are transferred to the baby. This provides immunity for about 6 months until the infant's own immune system can take over.

The fetus descends deeper into the mother's pelvis (lightening). The placenta is nearly 4 times as thick as it was 20 weeks ago, weighing nearly 20 oz. Mother is eager for birth, may have final burst of energy. Backaches, urinary frequency increase. Braxton Hicks contractions intensify as cervix and lower uterine segment prepare for labor. Couple may tour labor and delivery area.

Continue pelvic tilt exercises. Wear low-heeled shoes or flats. Avoid heavy lifting. Sleep on side to relieve bladder pressure. Urinate frequently. Avoid all analgesics except acetominophen. Pack suitcase for delivery.

Discuss postpartum period including decisions such as circumcision, rooming-in. Discuss common postpartum discomforts; mention postpartum blues. Discuss family planning methods, infant care. Stress need for adequate rest post-partally. Provide support, especially if baby is overdue.

Prentice Hall Health
Upper Saddle River, New Jersey 07458

A Day in the Life of a Nurse-Midwife

TO ME, PREGNANCY IS A WONDERFUL, normal experience—part of the cycle of life. That's why I love the fact that I can participate in all aspects of it, from pregnancy through birth and into the postpartal period. My practice enables me to ensure that a family's childbirth experience incorporates their personal beliefs and meets their expectations as much as possible. Come along with me for a day.

Cherrene has come for contraceptive information. I find it helpful to use models and examples during the discussion.

Dianne and her family come together for every appointment. We all enjoy listening to the fetal heartbeat.

Gretchen's pregnancy is progressing well. She asks what her baby looks like now. I like to use a visual device as I talk with her about her baby's development.

I measure the height of the fundus to determine if the baby is growing as expected. Gretchen and I talk about the impact of her nutrition, exercise, and healthy lifestyle habits on her baby and the outcome of her pregnancy.

Darnell and Ayisha are expecting their first baby. Ayisha calls to tell me her labor has begun, and I meet with them at the birth center. After the electronic fetal monitor is applied, we talk about the fetal heart tracing. I want to be sure they understand the monitor and have the opportunity to ask questions.

During the active phase of Ayisha's labor, Darnell lovingly provides comfort and support.

I do an exam to see how labor is progressing and my findings with them.

It's time to push. Ayisha wants to stand and is comfortable on the bed. Darnell stands behind h provides support. I continue to talk with them an vide encouragement. After an hour of pushing Kinshasha is born.

While I'm at the birth center, I check in on Alisa and Richard. Their baby, Lydia Rose, was born 6 hours ago. Alisa has asked for help with breastfeeding. Baby Lydia is a sleepy little one and needs encouragement to latch on and begin feeding.

Alisa is fascinated with baby Lydia's tiny fingers and toes. I love being with parents as they explore their baby. Each new baby is such a wonder . . . such a miracle.

After baby Lydia has finished nursing, I do a physical assessment. I prefer to do an assessment in the room with the parents. It is such a wonderful opportunity for them to learn about their baby.

Now my attention turns to Alisa. As part of my assessment, I check the position and tone of her fundus. All is well. I head home after a busy, but rewarding, day.

Photographer: Jenny Thomas

place pillow under right hip to displace uterus and avoid venal caval syndrome ♦ Encourage sexual activities enjoyed by both partners as long as they are generally not contraindicated medically ♦ To avoid introducing *Escherichia coli* into the vagina, the couple should *not* go from anal to vaginal penetration without thoroughly washing the penis ♦ Encourage the exploration of other methods of expressing affection such as hugging, cuddling, and stroking each other to increase feelings of closeness ♦ Suggest masturbation, either privately or as a shared experience, to provide release ♦ Woman's orgasmic contractions from masturbation may be unusually intense in later pregnancy ♦ Encourage openly expressing feelings, preferences, and concerns to partner

Contraindications to Sexual Intercourse

Ruptured membranes ♦ Presence of bleeding ♦ Woman with history of preterm labor due to release of oxytocin with orgasm (breast stimulation also triggers the release of oxytocin and should therefore be avoided)

Copyright © by Prentice Hall Nursing

Combined Oral Contraceptives and Other Methods

Combination birth control pills (8% failure) have rare but serious medical complications and may have annoying side effects ♦ Spermicides such as jellies, creams, foam, film, and vaginal suppositories (29% failure) minimally effective if used alone ♦ Operative sterilization (vasectomy [0.15% failure] and tubal ligation [0.5% failure]) theoretically reversible, but 30%–85% reversible in men and 40%–75% reversible in women

Correct Procedure for Using Method

Identify supplies or equipment needed ♦ Provide details of how method is used ♦ Discuss what to do if unusual circumstances arise (missed pill, missed AM temperature, second episode of intercourse with diaphragm)

Warning Signs Requiring Immediate Action

For combined oral contraceptive pill users: shortness of breath or chest pain; severe headaches; severe abdominal pain; visual disturbances such as double vision, reduced visual fields, blindness; severe leg pain or swelling ♦ For IUD users: severe or persistent abdominal pain, late or missed periods, fever, chills, noticeable or foul discharge, spotting, bleeding, heavy periods, clots *Note:* Failure rates are percentages of women experiencing an unintended pregnancy with first year of typical use. Failure rates are much lower for perfect use of a method.

Source: Hatcher, R. A., et al. (2004). *Contraceptive technology* (18th ed.). New York: Ardent Media.

Copyright © by Prentice Hall Nursing

If a Warning Sign Develops

Call caregiver immediately ♦ Note any specific information about the sign: how long it has been present, any related signs or symptoms, any other important information

Copyright © by Prentice Hall Nursing

1 c green leafy vegetables) ♦ **Meat, poultry, fish, dry beans, eggs, nuts** normally 2–3 servings daily; increase to 3–4 servings during pregnancy (1 serving = 2 oz cooked lean meat, poultry, or fish; 2 eggs; ⁄. c cottage cheese; 1 c cooked legumes [kidney, lima, garbanzo, or soy beans, or split peas]; 6 oz tofu; 2 oz nuts or seeds; 4 tablespoons peanut butter)

Additional Considerations

Consider calories in making choices (not all nutritionally equivalent foods have same number of calories) ♦ Eat foods with low nutrient value (sometimes called empty calories) sparingly (cakes, doughnuts, potato chips, butter, mayonnaise) ♦ Combine foods to enhance nutrition (eg, 1 c spaghetti with a 2-oz meatball and 1/4 c tomato sauce = 1 serving of meat, 1 1/3 servings of grain, and 1/2 serving of vegetable) ♦ Drink adequate amount of fluids daily, preferably 8–10 8-oz glasses of water or other fluid ♦ Do not eat swordfish, shark, tilefish, or king mackeral because these fish contain high levels of mercury, which may be toxic to the fetal brain ♦ Eat up to 12 oz/week of other fish and shellfish (canned light tuna, shrimp, salmon, catfish, pollock ♦ Avoid soft cheeses such as feta, brick and blue-veined cheeses unless label states they were made with pasteurized milk.

Copyright © by Prentice Hall Nursing

While Being Monitored

If the woman remains in bed, it is best if she lies on her left side ♦ The right side may also be used ♦ Monitoring can be done while the woman is sitting up in a chair or rocker ♦ Monitoring may continue while the woman ambulates if a telemetry unit is used

Normal Findings with Electric Fetal Monitoring

Normal fetal heart rate baseline between 110 and 160 beats per minute ♦ Variability is present, and average ♦ Accelerations of FHR occur with fetal movement ♦ Early decelerations may be present (indicate pressure of fetal head on the cervix) ♦ Absence of late and/or variable decelerations

Indications of Possible Nonreassuring Fetal Stress

Sustained fetal heart rate baseline below 110 beats/min (bradycardia) or above 160 beats/min (tachycardia) ♦ Decreased variability ♦ Development of periodic decelerations (late or variable) ♦ Meconium-stained amniotic fluid ♦ Signs of nonreassuring fetal status not always clear

Interventions That May Be Used When There Is Possible Nonreassuring Fetal Status

As a result of changes in the FHR pattern, the maternal position may be changed from one side to the other, oxygen administered by face mask ♦ An IV may be started, or, if one is in place, the rate may be increased ♦ Blood pressure is checked more frequently to identify hypotension pitocin should be discontinued.

Copyright © by Prentice Hall Nursing

AWHONN standards) during labor (monitor the woman's vital signs, the uterine contraction pattern, and the fetal heart rate) ♦ Explain assessments and the results (prior to vaginal examinations, explain what will be done and validate the woman's discomfort during the examination) ♦ Assist the woman in pushing when the first stage is completed and the woman has a natural urge to push

Essential Points

Remember that the woman (couple) has the right to determine what happens, and the nurse acts as an advocate when needed ♦ The nurse should be prepared to act as an advocate for analgesia and anesthesia if the woman requests it, regardless of her social status ♦ The nurse should be available to the couple during labor and birth and supportive ♦ Request privacy during the labor and birth if desired

Copyright © by Prentice Hall Nursing

before and cool down after exercising ♦ Wear supportive shoes and supportive bra ♦ Stop exercising if the following signs and symptoms develop: extreme fatigue, dizziness or faintness, sudden sharp pain, difficulty in breathing, nausea and vomiting, pain, vaginal bleeding, excessive muscle soreness; contact caregiver if symptoms persist

Basic Body Conditioning Exercises

Pelvic tilt to reduce back strain and strengthen abdominal muscles (may be done standing, on hands and knees, or lying down) ♦ Exercises to strengthen abdominal tone: abdominal muscle tightening, partial sit-ups (knees must be flexed and feet flat on the floor) ♦ Kegel exercises to improve perineal muscle tone ♦ Tailor sitting to prepare inner thigh muscles for birth

Copyright © by Prentice Hall Nursing

Teaching in the Home

The home provides an excellent setting because the family members are in their own territory and may feel more in control of the visit; the nurse is a visitor ♦ During the introduction, observe family relationships and communication style. Who is the greeter? Who makes the decisions? Who asks the questions and how is information shared? Who is the primary caretaker of the infant? How are siblings incorporated into care of the new baby? ♦ During the assessment of the mother and newborn, continue to provide information regarding findings of each assessment and encourage mother to ask questions ♦ Ask for return demonstrations when appropriate and maintain a supportive environment in which they may occur ♦ Make referrals to appropriate healthcare professionals or agencies as needed ♦ Carry a listing of resources in your community so information can be easily shared ♦ Assist the family in problem solving and locating special resources or in meeting healthcare needs ♦ Act as an advocate for healthcare that meets the needs of the mother, child, and new family

Copyright © by Prentice Hall Nursing

tag that identifies you as a professional nurse ♦ Do not wear expensive jewelry ♦ Always carry enough change so that you can make a phone call from a pay phone if necessary or phone card ♦ Carry needed phone numbers with you in an easily accessible place ♦ If you are very uncomfortable with the location of the home or have concerns for your safety, pay attention to your feelings and leave; contact the family immediately and arrange another appointment at a time when another nurse can accompany you ♦ It is important to follow your intuition

Copyright © by Prentice Hall Nursing

(excessive salivation): use astringent mouthwash; suck on hard candy ♦ *Heartburn:* eat small, more frequent meals; take low-sodium antacids; avoid overeating, fatty and fried foods, lying down after eating, and sodium bicarbonate ♦ *Ankle edema:* elevate legs frequently; dorsiflex feet when standing; avoid tight garters or constricting bands ♦ *Varicose veins:* elevate legs; wear support hose; do not cross legs, wear tight garters, or stand for long periods ♦ *Hemorrhoids:* gently reinsert into rectum as necessary; avoid constipation; use ice packs, topical ointments, anesthetic agents, warm soaks, or sitz baths ♦ *Constipation:* increase fluid intake; eat high-fiber diet; get regular exercise; develop regular bowel habits; use stool softeners as recommended by caregiver ♦ *Backache:* perform good body mechanics; do pelvic-tilt exercise; avoid uncomfortable working heights, high-heel shoes, heavy lifting, and fatigue ♦ *Leg cramps:* dorsiflex foot to stretch affected muscle; apply heat to affected muscle; evaluate diet ♦ *Faintness:* arise slowly from resting position; avoid prolonged standing in warm or stuffy environments ♦ *Dyspnea* (shortness of breath): maintain proper posture when sitting and standing; sleep propped up on pillows if dyspnea occurs at night ♦ *Flatulence:* avoid gas-forming foods; chew food thoroughly; get regular daily exercise; maintain normal bowel habits ♦ *Carpal tunnel syndrome:* avoid aggravating hand movements; use splint as prescribed; elevate affected arm

Copyright © by Prentice Hall Nursing

Third Pattern

Breathe rapidly and shallowly with periodic forced exhalations ♦ Draw lips back to the teeth and make a "Hee" sound during exhalation ♦ Then purse lips and exhale, making a "Hoo" sound ♦ Begin with a pattern of 4 breaths (Hee, Hee, Hee, Hoo) and, as contractions become more intense, change pattern to 3 breaths (Hee, Hee, Hoo), then 2 breaths (Hee, Hoo)

Pushing Breaths

Begin with a cleansing breath ♦ Breathe in 2 additional breaths and, holding them, push down on the perineum ♦ Visualize pushing down through the vagina ♦ Exhale during the pushing effort or hold breath, whichever is more comfortable

Copyright © by Prentice Hall Nursing

TEACHING INITIAL POSTPARTUM CARE

Checking the Uterine Fundus

Determine location of the fundus (normally at umbilicus or one finger breadth above within hours of birth; descends at rate of about one finger breadth per day for first 10–14 days) ♦ Assess position and consistency (affected by distention of bladder, presence of infection, breastfeeding, ambulation, and retention of products of conception) ♦ Gently massage the fundus to alleviate atonic (boggy) uterus ♦ Report recurrence of bogginess to the caregiver immediately

How to Apply Perineal Pads

Apply from front to back ♦ Change after voiding or whenever they are soiled

Caring for the Perineum

Use perineal spray, rinse bottle, or cleansing pads and pat dry with toilet paper ♦ Always clean from front (at the symphysis pubis) to back (around the anus) ♦ May apply witch hazel pads or analgesia sprays

(continued)

TEACHING RESUMPTION OF SEXUAL ACTIVITY AFTER BIRTH

When to Resume Sexual Activity

Couples advised to abstain from intercourse until the episiotomy is healed and the lochial flow has stopped (usually by end of 3rd week). Many practitions advise women to wait for 6 weeks.

The Woman May Experience

Some vaginal dryness for the first few weeks ♦ Difficulty feeling excitement because of fatigue associated with newborn care (moreover, her partner may be unaware of the extreme fatigue she may be experiencing because of the demands of newborn care and her recovery from childbirth) ♦ Awkwardness if there is a leakage of breast milk during sexual activity ♦ Vaginal tenderness ♦ Fear of pain during intercourse ♦ Fear of another pregnancy

(continued)

TEACHING NEWBORN BATHING

Bath Supplies

Basin for water ♦ Washcloths, towels ♦ Receiving blankets (to rest baby on and dry baby off with) ♦ Hair brush ♦ Mild, unperfumed soap ♦ Diaper ♦ Cotton balls (optional) ♦ Ointment ♦ Alcohol pads/rubbing alcohol (controversial) ♦ Warm water supply

Bathing the Baby

Start at the baby's head while baby is still clothed ♦ Using a wet washcloth (no soap), wipe one eyelid from inner to outer corner ♦ Change the spot on the washcloth to clean the other eye ♦ Wash external ears using index finger in washcloth ♦ Wash rest of face and, using soap now, progress to neck creases ♦ Dry off each area after washing it to decrease heat loss ♦ Remove baby's shirt and wash chest, arms, and hands (use soapy hands instead of washcloth if desired) ♦ Wash trunk and back (hold baby off table, supporting baby while doing the back) ♦ Keep a circumcised baby off his abdomen if possible and wash with warm water only ♦ Keep baby's upper body warm by wrapping in towel or blanket before washing legs and feet ♦ Wash genitalia (wash girls front to back; do not retract foreskin of uncircumcised boys) ♦ Wash hair: put a little water and shampoo on hair; use

(continued)

TEACHING POSTPARTUM COMFORT MEASURES

Relief of Breast Discomfort

Wear supportive, well-fitting bra ♦ Apply ice packs for 20 minutes, 4 times a day ♦ If not breastfeeding avoid breast stimulation

Relief of Uterine Cramping (Afterpains)

Lie on abdomen, with a small pillow placed under it to apply pressure ♦ Apply heat ♦ Walk (obtain assistance for first ambulation) ♦ Take analgesic medication (if breastfeeding, take mild analgesic about 1 hour before breastfeeding)

Relief of Episiotomy Discomfort

Apply ice packs to the perineum during the first few hours after birth ♦ Take 20-minute sitz baths 3–4 times a day ♦ Use perineal analgesic/anesthetics sprays ♦ Keep perineum clean and free from dried discharge ♦ Use gentle spray of warm water on perineum after voiding to provide cleansing; then pat dry, front to back ♦ Take analgesic medication

(continued)

TEACHING INFANT DISCHARGE CARE

Immediate Safety Measures for the Newborn

Watch for excessive mucus: use bulb syringe to remove secretions ♦ Keep newborn on his or her back in crib or in someone's arms ♦ Avoid leaving newborn unattended in parent's room ♦ Always check that ID bands or sensor is in place when transporting newborn.

Voiding and Stool Characteristics and Patterns

At least 6–10 wet diapers per day after first few days of life ♦ Urine straw to amber color without foul smell ♦ Normal progression of stool changes: (1) meconium (thick, tarry, dark green); (2) transitional stools (thin, brown to green); (3a) breastfed infant: yellow gold, soft or mushy stools; (3b) formula-fed infant: pale yellow, formed and pasty stools ♦ Only 1–2 stools a day for formula-fed baby ♦ 6–10 small, loose yellow stools per day or only one stool every few days after breastfeeding is well established (after about 1 month)

Umbilical Cord Care

Clean cord and skin around base with a cotton swab or cotton ball ♦ Clean 2–3 times a day or with each diaper change ♦ Do not give tub baths until cord falls off in 7–14 days ♦ Fold diaper below umbilical cord to let the cord air-dry ♦ Check each day for any odor, oozing

(continued)

TEACHING TECHNIQUES FOR WAKING AND QUIETING NEWBORNS

Using Waking Techniques

When getting ready for feeding ♦ During feeding if baby is sleepy or goes to sleep ♦ To alter baby's feeding schedule

Techniques for Waking Baby

Loosen clothing, change diaper ♦ Hand express milk onto baby's lips ♦ Talk with baby while making eye contact ♦ Hold baby in upright position (sitting or standing) ♦ Have baby do sit-ups (gently and rhythmically bend baby back and forth while grasping baby under his or her knees and supporting baby's head and back with your other hand) ♦ Play patty-cake with baby ♦ Stimulate rooting reflex (brush one cheek with hand or nipple) ♦ Increase skin contact (gently rub hands and feet)

Use Quieting Techniques

In first months after birth ♦ With a baby who is easily stimulated and excited ♦ To calm an excited baby before feeding ♦ With an overly hungry or overeager baby

(continued)

TEACHING POSTPARTUM WARNING SIGNS

Warning Signs: Possible Causes

Alterations in pattern of lochia (increased amount, change from lochia alba to serosa or from lochia serosa to rubra, and/or presence of clots): possible uterine infection or uterine relaxation ♦ *Development of foul-smelling lochia:* uterine infection ♦ *Maternal temperature elevation above 38C (100.4F):* infection ♦ *Constant uterine tenderness:* infection ♦ *Failure of fundus to descend as expected:* uterine infection or subinvolution ♦ *Continued or increased discomfort in the episiotomy site* (separation of the suture line, development of swelling, increased tenderness, or presence of whitish or gray-green discharge at the site of episiotomy): infection or incomplete approximation of sutures ♦ *Tenderness, swelling, and warmth in any area of the legs:* thrombophlebitis ♦ *Swelling, warmth, and tenderness in any area of the breast:* clogged milk ducts or mastitis

If a Warning Sign Develops

Call caregiver immediately ♦ Note specific information about the sign: length of time it has been present, related problems, or activities, and specific characteristics of the problem

TEACHING BREASTFEEDING

Basics of Milk Production

Milk produced according to demand ♦ Milk stored in ducts under areola ♦ Adequate maternal fluid intake required ♦ Milk supply established by frequent breastfeeding (every 1 1/2 to 3 hours) ♦ Let-down reflex: flow of milk initiated by newborn's sucking, presence, or cry; by mother's thoughts; or during maternal orgasm

Positioning Baby at the Breast

Turn baby's entire body toward mother, with mouth adjacent to nipple and the ear; shoulder and hip are in direct alignment ♦ Mother should assume a comfortable position with arms supported ♦ Direct nipple straight into baby's mouth so that during sucking, jaw compresses ducts directly beneath areola ♦ Lightly brush infant's mouth with breast to stimulate rooting reflex (but avoid touching both cheeks)

(continued)

TEACHING SIGNS OF POSSIBLE ILLNESS DURING NEWBORN PERIOD

Possible Warning Signs

Temperature above 38C (100.4F) axillary and below 36.6C (97.8F) axillary ♦ Continued rise in temperature ♦ More than one episode of forceful vomiting or frequent vomiting (over a 6 hour period) ♦ Refusal of two feedings in a row ♦ Lethargy (listlessness), difficulty in waking ♦ Inconsolable infant (quieting techniques are not effective) or continuous high-pitched cry ♦ Cyanosis (bluish discoloration of skin) with or without a feeding ♦ Absence of breathing longer than 20 seconds ♦ Reddened umbilical cord ♦ Abdominal distention, crying when trying to pass stools, or absence of stools after stool pattern is established ♦ Two consecutive green watery or black, loose stools or increased frequency of stooling ♦ No wet diapers for 18–24 hours or less than 6 wet diapers per day after 4 days of age ♦ Increasing jaundice of the skin and jaundice over abdomen and extremities ♦ Pustules, rashes, or blisters other than normal newborn rashes ♦ Development of eye drainage

If a Warning Sign Develops

Call caregiver ♦ Be prepared to tell caregiver length of time since onset, related activities or problems, specific characteristics of problem, and baby's temperature *(continued)*

POSTPARTUM DISCHARGE TEACHING

Review Important Self-Care Measures

Care of breasts ♦ Expected positional changes in the uterus, and continued comfort measures for uterine cramping (afterpains) ♦ Care of the episiotomy and hemorrhoids if present ♦ Expected changes in lochia ♦ Need for adequate nutrition and fluid intake ♦ Measures to promote bowel elimination ♦ Strategies to promote rest and relaxation ♦ Postpartum exercises ♦ Resumption of sexual activity ♦ Warning signs of possible problems

Review Important Infant Care Measures

Information and support regarding feeding techniques ♦ Bathing and diaper changes ♦ Umbilical cord care ♦ Care of the uncircumcised and circumcised penis ♦ Recognizing normal characteristics of the newborn ♦ Maintaining safety ♦ Soothing techniques ♦ Recognizing illness or problems in the newborn

TEACHING NEWBORN FORMULA-FEEDING

Types of Formula

Ready-to-feed: use directly from the can ♦ Concentrate: dilute with water before feeding ♦ Powder: add water and mix well for proper concentration

Amount of Formula

Start with 3 oz in each bottle (since a newborn usually takes 1–3 oz every 2 1/2 to 4 hours) ♦ Expect increases in baby's appetite with demand feeding (as baby needs more he or she will start finishing each bottle) ♦ Do not feed the baby a partially used bottle after 1 hour at room temperature ♦ Prepare a fresh bottle for each feeding: do not add new formula to old ♦ Refrigerate bottles made in advance ♦ Do not feed the baby an opened, refrigerated can of concentrated or ready-to-feed formula after 48 hours ♦ Travel with water and formula separated—carry the premeasured water bottles and bottles with premeasured amounts of powdered formula, or carry premeasured commercially prepared formula packets

Temperature of Formula

Mother can try a bottle directly from the refrigerator, but most babies prefer warm formula, close in temperature to breast milk ♦ Warm bottle under hot tap water, in bottle warmer, or in pan of heated water ♦ Always test temperature of formula by sprinkling a few drops on wrist ♦ BE VERY CAREFUL if using a microwave oven to warm formula,

(continued)

COMMUNICATING WITH A CLIENT WHO SPEAKS SPANISH

Tips

♦ In Spanish, nouns and adjectives that end in *a* indicate female gender, whereas nouns and adjectives that end in *o* indicate male gender ♦ Most often, the stress in Spanish words is placed on the second-to-last syllable
♦ *ay* is pronounced like the word *eye* ♦ *ll* is pronounced *y* ♦ *cu* is pronounced *qu* ♦ *qu* is pronounced *k* ♦ *h* is silent ♦ *v* is pronounced *b* ♦ *j* is pronounced *h* ♦ *z* is pronounced *s*

Helpful Words and Phrases

Hello	Hola
I am a student nurse.	Soy estudiante de enfermería.
My name is _____ .	Mi nombre es _____ .
What is your name?	¿Cómo se llama?
Please	Por favor
Thank you	Gracias
Is there anything worrying you?	¿Hay algo o alguna cosa que la preocupe?
Are you having pain?	¿Tiene dolores?

(continued)

Beginning Ambulation

Call for assistance the first time ♦ Anticipate some dizziness

Changes in the Lochia

Lochia dark red (lochia rubra) for first 1–3 days (similar to menstrual flow) ♦ Lochia pinkish brown or serous (lochia serosa) after 2–3 days ♦ Moderate flow (use of 4–8 perineal pads per day) and small clots normal ♦ *Signs of possible problems:* increase in amount, change from serosa back to rubra, presence of larger clots, change in odor

Copyright © by Prentice Hall Nursing

Copyright © by Prentice Hall Nursing

Procedure for Feeding

Avoid arbitrary time limits (since let-down reflex may take up to 3 minutes) ♦ Allow baby to suckle at first breast until breast is emptied ♦ Insert finger in baby's mouth near nipple to break suction ♦ Burp baby before changing breast ♦ Burp baby again at completion of feeding ♦ To prevent skin breakdown wash nipple with warm water and dry thoroughly

Helpful Hints

Be certain baby is well awake before attempting feeding ♦ Alternate breast at which baby begins feeding (use safety pin as reminder) ♦ Lift breast slightly or press lightly on breast above nares if mother's large breast occludes infant's nares ♦ Rotate baby's position at breast to avoid undue trauma to nipples and improve emptying of ducts ♦ Avoid supplementary formula feedings until lactation is established ♦ Check with caregiver before taking any medication while breastfeeding (because medications may cross into breast milk)

Copyright © by Prentice Hall Nursing

The Partner May Experience

Fear of the postpartum partner being uncomfortable during sexual activity, particularly intercourse ♦ Disruption of the sexual pattern the couple had established ♦ Fear of partner becoming pregnant again ♦ Reduced interest in sex because of fatigue associated with newborn care

Contraceptive Considerations

Determine the couple's desires regarding contraceptive information ♦ If needed and desired, present factual information regarding different types of contraceptives ♦ Inform couple that 40% of *nonlactating* mothers resume menstruation by the 6th week after birth, and 45% of *lactating* mothers resume menstruation by the 12th week after birth ♦ Breastfeeding does not provide adequate protection against pregnancy

Copyright © by Prentice Hall Nursing

How to Obtain Baby's Temperature

Properly place thermometer to ensure greatest accuracy ♦ Never leave baby unattended, no matter which method is used ♦ After taking baby's temperature, find and note the temperature ♦ *Rectal temperatures are not recommended*

Taking Axillary Temperature

Place tip of the thermometer underneath baby's armpit ♦ Hold outer aspect of baby's arm next to his or her body ♦ Hold thermometer securely in place for 3–4 minutes

Helpful temperature ranges (Centigrade and Fahrenheit values)

Temperatures: 36.5C (97.7F), 37.0C (98.6F), 37.8C (100.0F), 38.3C (101.0F), 38.9C (102.0F), 39.4C (103.0F), or 40.0C (104.0F)

Copyright © by Prentice Hall Nursing

hairbrush to work it in; rinse, dry, and brush hair ♦ Brush during shampooing once a week and brush dry hair daily to help prevent cradle cap

General Considerations

Bathe baby in warm, draft-free room ♦ Collect all supplies before starting the bath so baby is never left unattended ♦ Use only tepid water (warm to inner wrists) ♦ Test water each time before putting baby in ♦ Bathe baby every day in warm, humid weather; give full body bath twice a week in dry weather ♦ Keep one hand on baby at all times during bath, cradling baby's head and back with arm while securely holding on to thigh ♦ Ointments are better than lotions for dry, cracked hands and feet ♦ Lotion or talc-free powder may be used, but controversy exists over their use (do not let baby inhale powder) ♦ Do not immerse baby in bath water until umbilical cord falls off ♦ Choose a convenient bath time that allows parents and baby to enjoy the experience ♦ Baths may be useful in soothing a fussy baby

Copyright © by Prentice Hall Nursing

Relief of Hemorrhoidal Discomfort

Take 20-minute sitz baths 3–4 times a day ♦ Apply anesthetic ointments or witch hazel pads ♦ Maintain side-lying or prone position when in bed ♦ Avoid prolonged sitting ♦ Maintain adequate fluid intake ♦ Take stool softener if needed to avoid constipation

Copyright © by Prentice Hall Nursing

because milk is superheated and plastic bottle bags may burst; use "defrost" setting on microwave oven and carefully check temperature of formula before feeding

Positioning the Baby for Feeding

Hold baby close, establishing eye contact as in breastfeeding ♦ Hold baby's bottom or foot firmly, keeping his or her back straight to aid digestion and provide a sense of security ♦ Quiet baby before feeding ♦ Alternate the side baby is fed from to give baby two-sided stimulation ♦ Avoid feeding while baby is on his or her back ♦ Do not prop the bottle

Procedure for Feeding

Nipple hole should allow only drops of milk to flow ♦ Keep nipple full with milk to decrease air ingestion

How to Burp a Baby

Position baby so his or her head rests on mother's shoulder or face down on lap, or sit baby on lap with baby's chin and chest supported ♦ Gently pat or stroke baby's back ♦ Burp baby halfway through feeding and at end of feeding ♦ Learn baby's preferred burping position and whether baby is a slow or quick burper ♦ Regurgitation of small amounts of formula is common ♦ Have burp cloth available

Copyright © by Prentice Hall Nursing

of greenish-yellow material, or reddened areas ♦ Expect tenderness around the cord and darkening and shriveling of cord ♦ A small drop of blood may be present when cord falls off ♦ Never pull on cord or attempt to loosen it ♦ If cultural custom demands binding of the abdomen, a sanitary method such as the use of a clean piece of gauze can be recommended.

Circumcision Care

Squeeze warm water over circumcision with each diaper change ♦ Rinse area off with warm water and pat dry ♦ Apply small amount of petroleum ointment (unless a Plastibell is in place) with each diaper change ♦ Fasten diaper loosely over penis ♦ Since the glans is sensitive, avoid placing baby on his stomach ♦ Check for any foul-smelling drainage, bleeding, swelling or cessation of urination at least once a day ♦ Let Plastibell fall off by itself (about 8 days after circumcision); ♦ Plastibell should not be pulled off, after 8 days have parents consult their health care provider. Light, sticky, yellow film or granulation tissue (part of healing process) may form over head of penis

Uncircumcision Care

Clean uncircumcised penis with water during diaper changes and with bath ♦ Do not force foreskin back over the penis; foreskin will retract normally over time (may take 3–5 years)

Copyright © by Prentice Hall Nursing

How many births have you had?	¿Cuantos niños le han nacido?
I will help you.	La voy a ayudar.
I need to examine your [breasts, uterus, flow, stitches, legs, feet, baby].	Necesito examinarle [los pechos, el útero, el flujo, los puntos, las piernas, los pies, su bebé].
I would like to take your [blood pressure, pulse, temperature].	Quisiera tomarle [la presió arterial, el pulso, la temperatura].
Are you taking any medications now?	¿Está tomando algunas medicinas ahora?
Please pant. I will show you how.	Por favor, jade. Le voy a mostrar cómo.
Do not push now.	No puje ahora.
Push now.	Puje ahora.
Stop pushing.	Pare de pujar.
	No puje mád.
Please turn on your left side.	Por favor voltéese al lado izquierdo.
Your baby is OK.	El bebé está bien.

Copyright © by Prentice Hall Nursing

Techniques for Quieting Baby

Check for soiled diaper ♦ Swaddle or bundle baby (bring arms and legs into midline, which increases sense of security) ♦ Hold swaddled baby upright against mid-chest supporting the buttock and the back of baby's head. ♦ Use slow, calming movements with baby ♦ Softly talk, sing, or hum to baby ♦ Baby can hear heartbeat, feel warmth, and hear parent's softly spoken words or calming sounds.

Copyright © by Prentice Hall Nursing

TEACHING ABOUT METHODS OF CONTRACEPTION

Factors to Consider in Choosing a Method of Contraception

Effectiveness ♦ Safety ♦ Age and future childbearing plans ♦ Contraindications in health history ♦ Religious or moral factors ♦ Personal preferences, biases ♦ Lifestyle: frequency of intercourse, number of partners, cost factors, access to medical care ♦ Partner's support and willingness to participate. If no method used, 85% chance of pregnancy

Fertility Awareness or Natural Family-Planning Methods

Include basal body temperature (BBT), calendar (rhythm), cervical mucus (ovulation or Billings), and symptothermal methods ♦ Require periodic abstinence ♦ Generally require no artificial devices or substances ♦ Readily reversible ♦ 25% failure rate

Mechanical Contraceptives

Include male condom (15% typical use failure rate), female condom (21% failure), diaphragm (16% failure), cervical cap (nulliparous → 16% failure), intrauterine device (IUD) (less than 2% failure) ♦ Condoms available over the counter ♦ All barrier methods readily reversible and generally free of side effects in appropriate clients ♦ Women who have had a child may accept an IUD more easily but women who have never given birth are candidates if their uterus is deep enough

(continued)

TEACHING DIETARY CHANGES RECOMMENDED DURING PREGNANCY

General Information

Desired weight gain during pregnancy for woman of normal prepregnant weight is 25–35 pounds (not really "eating for two") ♦ Increased caloric intake of 300 kcal/day sufficient during pregnancy (usually includes 1–2 additional servings of milk and 1 additional serving of meat or a protein alternative) ♦ MyPyramid may be used for planning a nutritionally balanced diet.

Specifics

Dairy normally 2–3 servings daily; increase to 4 servings during pregnancy (1 serving = 1 cup [c] milk or yogurt, 1.5 ounces [oz] hard cheese, 2 c cottage cheese, 1 c pudding made from milk) ♦ **Bread, cereal, rice, & pasta group** 6–11 servings daily (1 serving = 1 slice of bread, 1/2 hamburger roll, 1 oz dry cereal, 1 tortilla, 1/2 c pasta, rice, or grits) ♦ **Fruits** 2–4 servings including at least 1 good source of vitamin C (1 serving = 1 medium size piece of fruit or 1/2 cup juice) ♦ **Vegetables** 3–5 servings vegetables such as tomatoes may also serve as a good source of vitamin C (1 serving = 1/2 cup cooked vegetables, 1 c raw vegetables,

TEACHING NURSING CARE DURING LABOR

During Admission the Birthing Room Nurse Will

Welcome the laboring woman and her partner/support person(s) ♦ Obtain a brief history: include questions regarding woman's physical and psychologic safety and history of domestic violence; provide privacy (just the woman and the nurse for this section of the history) ♦ Assess maternal vital signs, contraction status, membrane status, and fetal heart rate ♦ Perform a vaginal examination if no bleeding is present (provides information about cervical dilatation and effacement; status of amniotic membranes; fetal position, presentation, and station) ♦ Explain findings and answer questions ♦ Orient woman to environment ♦ Establish rapport

During Ongoing Care the Birthing Room Nurse Will

Stay with the woman to provide comfort and reassurance ♦ Be available to assist the woman (couple) with breathing techniques and relaxation ♦ Provide comfort measures such as backrubs, lotion rubs, effleurage, distraction, visualization, music, use of focal point, Therapeutic Touch, coaching, encouragement, perineal care, showers, whirlpool tubs, ambulation, positioning ♦ Provide encouragement and support for the partner/support person ♦ Assess the woman and her fetus on an ongoing basis (according to

(continued)

TEACHING HOME CARE OF THE POSTPARTAL FAMILY

When possible the nurse prepares for the home visit by establishing contact and a beginning relationship with the family while they are still in the birthing center or hospital setting ♦ Purposes of the home visit are to assess maternal, neonatal, and family status, to provide teaching, and to make referrals as needed

Fostering a Caring Relationship with the Family

Introduce yourself to the family ♦ Address family members by their surnames until invited to use the given name ♦ Ask to be introduced to other family members ♦ Ask for permission before sitting ♦ Be genuine; make sure your verbal and nonverbal messages are congruent; do not make assumptions; demonstrate caring behaviors; answer questions honestly and thoroughly; provide opportunity for family members to ask further questions for clarification; provide opportunity for return demonstration if needed ♦ Demonstrate empathy; listen to the family without judgment; be attentive; listen to the family's perspective ♦ Establish trust; do what you say you will do; be on time; be prepared for the visit; provide any follow-up as needed; provide information about community resources

TEACHING ABOUT COMMON DISCOMFORTS OF PREGNANCY

General Information about Common Discomforts

Caused by hormonal changes, especially elevated levels of human chorionic gonadotropin (hCG), estrogen, and progesterone, and/or anatomic changes such as enlarged uterus or engorged breasts ♦ Not all discomforts experienced by all women ♦ Generally not health threatening

Self-Care Measures for Relief of Common Discomforts

Nausea and vomiting: eat crackers or dry toast before arising; avoid causative foods and odors; eat small, frequent meals and dry foods with fluids between meals; avoid greasy or highly seasoned foods ♦ *Urinary frequency:* void when urge experienced; increase fluid intake during day ♦ *Breast tenderness:* wear well-fitting, supportive bra ♦ *Increased vaginal discharge:* bathe regularly; avoid douching, nylon underpants, and panty hose; wear cotton underwear; use powder to maintain dryness (light layer; avoid caking) ♦ *Nasal stuffiness and epistaxis* (nosebleed): avoid use of medicated nasal sprays and decongestants; use cool-air vaporizer (may be unresponsive to treatment) or normal saline sprays ♦ *Ptyalism*

(continued)

TEACHING BREATHING TECHNIQUES FOR LABOR

Essentials of the Lamaze Method

Involves three patterns of chest breathing ♦ One pattern is maintained until no longer effective, then woman moves to the next pattern ♦ Breathing with each contraction begins and ends with a cleansing breath (inhale through nose and exhale through pursed lips)

First Pattern

Begin with a cleansing breath ♦ Inhale slowly through nose, lift chest up and out during inhalation ♦ Exhale through pursed lips ♦ Maintain breathing rate of 6–9 breaths per minute (2 breaths every 15 seconds) ♦ End with a cleansing breath

Second Pattern

Begin with a cleansing breath, then push out a short breath at the end of this inhalation ♦ Inhale and exhale through mouth at a rate of about 4 breaths every 5 seconds ♦ Keep jaw relaxed and mouth slightly open ♦ End with a cleansing breath

(continued)

TEACHING ABOUT SEXUAL ACTIVITY DURING PREGNANCY

During Pregnancy the Woman May Experience

Sexual desire may change or may remain unchanged ♦ *First trimester:* possible decreased sexual desire due to discomforts such as breast tenderness, nausea, fatigue ♦ *Second trimester:* woman tends to feel at her best; sexual desire may increase ♦ *Third trimester:* possible decreased sexual desire due to discomfort and fatigue ♦ More intense orgasms followed by cramping possible in last weeks of pregnancy

During Pregnancy the Partner May Experience

Sexual desire may change or may remain unchanged ♦ Possible changed desire due to feelings about partner's changing appearance, beliefs about sexual activity with a pregnant woman, concern about hurting the woman or fetus, personal view of pregnancy as erotic or not, response to the notion of partner as a mother

Sexual Activities

Suggest positions such as side lying, female superior, or vaginal rear entry for more comfortable intercourse in later pregnancy ♦ If male superior position is used, woman should

TEACHING WARNING SIGNS DURING PREGNANCY

Warning Signs: Possible Causes

Sudden gush of fluid from vagina: possible premature rupture of membranes (PROM) ♦ *Vaginal bleeding:* placenta previa or abruptio placentae, cervical lesion, bloody show ♦ *Abdominal pain:* PROM, abruptio placentae, preeclampsia ♦ *Fever at least 101F (38.3C):* infection ♦ *Dizziness, blurred vision, double vision, spots before eyes:* high blood pressure, preeclampsia ♦ *Persistent vomiting:* hyperemesis gravidarum ♦ *Severe headache:* hypertension, preeclampsia ♦ *Edema of hands, face, legs, feet:* preeclampsia ♦ *Muscular irritability, convulsions:* preeclampsia, eclampsia ♦ *Epigastric pain:* preeclampsia, ischemia in major abdominal vessels ♦ *Oliguria* (decreased urination): renal impairment, decreased fluid intake ♦ *Dysuria* (painful urination): urinary tract infection ♦ *Decrease or absence of fetal movement:* maternal medication, obesity, fetal death

(continued)

TEACHING ABOUT FETAL HEART RATE MONITORING

Purpose of Fetal Monitor During Labor and Birth

Provides a useful continuous assessment of numerous characteristics of the fetal heart rate ♦ May indicate the development of nonreassuring fetal status

Types of Fetal Heart Rate Monitoring

Auscultation using special equipment such as a fetoscope (performed intermittently) ♦ Intermittent monitoring by a handheld Doppler ultrasound device ♦ Continuous monitoring by electronic fetal monitor (EFM); the EFM may also be used intermittently, either externally or internally

What to Expect from the Electronic Fetal Monitor

The uterine contraction pattern and the fetal heart rate will be recorded continuously on special graph paper ♦ The nurse and physician or certified nurse-midwife will evaluate the tracing periodically ♦ A light on the front of the monitor will blink with each beat of the fetal heart ♦ A sound dial can be adjusted so that a beep is heard with each fetal heartbeat ♦ The actual count of the fetal heart rate at each moment is displayed on a digital screen ♦ At any moment, the fetal heartbeat is recorded on the graph paper, is heard as a beep, and is seen as a blink of light and on the digital display

TEACHING ABOUT EXERCISE DURING PREGNANCY

Value of Regular Exercise During Pregnancy

Improves maternal fitness and muscle tone ♦ Relieves stress, improves sleep ♦ Helps control weight gain ♦ Promotes more rapid recovery following birth ♦ Promotes sense of well-being ♦ May help prevent certain complications

Choosing the Best Exercise

In general, continue any exercise at which woman is proficient ♦ Avoid learning new, strenuous sports ♦ Avoid high-risk activities or sports that require good balance and coordination ♦ Walking is excellent exercise choice. Non-weight-bearing activities (swimming, cycling) may be more comfortable as pregnancy progresses ♦ When in doubt, contact caregiver

Basic Guidelines for Exercise During Pregnancy

Exercise regularly, most days of the week if possible ♦ Avoid exercising while lying supine ♦ Decrease intensity of exercise as pregnancy progresses and stop when fatigued ♦ Avoid high-risk activities or activities that require good balance and coordination ♦ Avoid prolonged overheating ♦ If woman is unable to talk or feels unable to breathe, exercise is too intense ♦ Warm up

(continued)

TEACHING SAFETY CONSIDERATIONS DURING HOME VISITS

Currently, communities are quite complex, and the safety of the nurse may be a concern

Follow Basic Safety Rules

Be aware of your personal body carriage: carry yourself with a sense of determination that demonstrates that you know where you are going and are in charge of yourself (stand straight, shoulders square; appear sure of yourself; look forward); have a determined, steady stance and gait; avoid appearing hesitant, confused, or lost ♦ Establish contact with the family prior to the visit; clearly identify the address and specific characteristics and identifying factors that will enable you to find the family's home ♦ Ask the family for directions ♦ Carry a map and trace out the route on the map prior to the visit ♦ Be sure to take the map along and leave it out of sight from passing cars; if you need to look at the map, do so unobtrusively to avoid drawing attention to yourself (remember, you want to appear as if you are in charge) ♦ Prior to your visit, notify someone of where you are going and when you expect to return ♦ Prior to your visit, remove personal items from the interior of your car and lock them in your trunk ♦ Carry a fully charged cell phone ♦ Wear a name
